The comparison arm of the bridge consisted of a parallel combination of a General Radio (GR) Type 1424-A Standard Polystyrene Decade Capacitor,  $1 \mu F$  per step, and a GR Type 1412-BC Decade Capacitor representing  $C_d'$ , a GR Type 1432-J Decade Resistor serving as  $R_p'$ , and a GR Type 1432-K Decade Resistor making up  $R_e'$ . This gave a range of  $\sim 50$  pF to  $11.111100 \mu F$  in 100 pF steps and a Vernier dial with 1 pF divisions, nominal accuracy  $\pm 0.25\%$  for the  $1 \mu F$  steps,  $\pm 1.0\%$  for steps  $< 1 \mu F$  (at 1 kHz), for the capacity, a range for  $R_p'$  of 1-11,110 ohms in 1 ohm steps, nominal accuracy  $\pm 0.025\%$  for settings above 100 ohms/step, and a range of 0.1-1111 ohms, same accuracy, for  $R_e'$ . Current pulses were supplied to the bridge by a GR Type 1398-A Pulse Generator. No attempt was made to minimize induction and this necessitated the use of rather long pulses of 100  $\mu sec$  duration. A repetition rate of 10 pulses/sec was found satisfactory. The pulses were dropped through two ( $R_d$  and  $R_d'$ ) GR Type 500-M resistors, 5 kohm  $\pm 0.025\%$ . Pulse current was approximately 10 ma. The difference signal was observed on a Tektronix Type RM35A oscilloscope with a Tektronix Type 1A7 plug-

in unit. The scope was normally operated at 500  $\mu v/cm$  and 10  $\mu sec/cm$ .

The bridge was tested using for  $C_d$  commercial capacitors, nominal 2.0, 1.0, 0.33, 0.25, and 0.1  $\mu F$ , for  $R_p$  resistors (carbon type) nominal 47, 330, 1k, 10k, 110k, 1M, and 10 Mohms, for  $R_e$  resistors (carbon type) nominal 27, 150, and 910 ohms, in various combinations. The components were measured on a GR Type 1608-A Impedance Bridge of 1 kHz to 0.1%. Values of  $R_p > 100$  k-ohm could not be measured on the pulsed bridge with any kind of accuracy. The decade box serving as  $R_p'$  was then replaced by a resistor equal in nominal value to  $R_p$  and no further attempt was made to balance the bridge for  $R_p$ . For each combination  $C_d - R_p - R_e$  the bridge was balanced for  $C_d$  20 times. Results for two capacitors are given in Table I. The balance was checked for  $R_p < 100$  k-ohm and  $R_e$  periodically, precision generally being within a few per cent. Representative values are included in Table I.

It is seen that generally the agreement between the  $C_d$  value obtained on the pulsed bridge and that measured on the 1608-A is within  $< 1\%$ , often around 0.2%, and this is well within the accuracy of the capacitors used in the pulsed bridge. The internal consistency of the pulsed bridge is excellent, the standard deviation being usually  $< 1$  p.p.t., often 0.1 p.p.t.

While working with the pulsed bridge some interaction was observed between  $C_d$  and  $R_p$ . At a given  $C_d$ , the smaller  $R_p$ , the more difficult it becomes to obtain a precise balance for  $C_d$  (see Table I). Evidently, the time constant  $R_p C_d$  becomes too small to achieve the condition  $t \ll R_p C_d$  (Eq. [5] and [8]) within the times accessible to the equipment used ( $R_p$  also appears as a factor in Eq. [2]). Also, the bridge loses precision rapidly for  $C_d > 3 \mu F$ . This limitation could possibly be removed by using larger pulse currents, but this was not tried.

### Application

The pulsed bridge was used to measure the capacity of a gold electrode in 1M HClO<sub>4</sub> in the range 0.0 to +1.4v vs. a saturated calomel electrode (SCE). This system is (nearly) ideally polarizable over the lower part of this potential region, faradaic processes are absent, and measurements at low frequencies (5 kHz) should be satisfactory. At the more anodic potentials adsorbed "oxygen" and/or an oxide film is formed. Nevertheless, the pulsed bridge in its present form gives results in substantial agreement with fast single pulse measurements (see below).

The gold electrode was made from gold wire (Engelhard Industries, Fine Gold) by melting the tip of the wire to a bead using a hydrogen flame. The bead, ap-

proximately 0.075 cm<sup>2</sup> in apparent area, was mounted in a Teflon holder, washed in hot chromic acid cleaning solution, degreased with acetone, and thoroughly rinsed with triple distilled water. The latter was distilled once from alkaline permanganate in Pyrex and twice more in a quartz still. Solutions, 1M HClO<sub>4</sub>, were made up from B and A reagent grade 70% HClO<sub>4</sub> and triple distilled water. They were treated for a minimum of 12 hr with activated charcoal purified according to Barker. Helium was passed through for at least 2 hr prior to, and during, a run. The all Pyrex cell was of conventional design. It contained a large area platinum wire gauze electrode concentric to the gold test electrode, and two SCE's, each separated from the main compartment by a closed stopcock.

The gold electrode was polarized with a Sensitive Research Instrument Corporation Type PV potentiometer through one of the SCE's. Potentials were measured with respect to the other SCE (connected to the test electrode through a Haber-Luggin Capillary) with a Keithley Type 660 Differential Voltmeter. They are reported with respect to SCE. The pulsed bridge was connected to the test electrode and the grounded platinum wire gauze. The pulse generator was protected from the polarizing circuit with a 1N270 diode. The comparison arm of the bridge was not isolated from the polarizing circuit. This arm provides an external connection for the cell Au/1M HClO<sub>4</sub>/Pt through  $R_d$ ,  $R_d'$ ,  $R_p'$ , and  $R_e'$ . Thus, special care is necessary during current-potential measurements. (They were not made in this study.) All connections were removed from the cell during open circuit rest periods. A schematic circuit diagram is shown in Fig. 3.

Before each experiment, the test electrode was treated briefly and alternately in situ at -0.3 and +1.4v, always ending with -0.3v. Capacities were then measured as a function of potential in 100 mv steps, starting at 0.0v. The bridge could be balanced in all cases to  $\pm 0.01 \mu\text{F}$  or to  $\pm 0.3$  to 1% ( $\pm 0.13 \mu\text{F}$ /apparent cm<sup>2</sup>). The potential was changed every 10 min, this being sufficient time for the capacity to reach a steady state. Spot checks showed no change in capacity after 10 min for up to 2 hr. After 1.4v had been reached, the electrical equipment was disconnected and the cell left at open circuit overnight. The capacity determinations were repeated the next day.

The results of three such experiments, i.e., six determinations, are shown in Table II together with the standard deviation for each potential. Reproducibility is acceptable, the average standard deviation being  $\pm 6\%$ . The reproducibility within an experiment (two

subsequent determinations > 12 hr apart, same bead, same solution) can be much better. The three experiments had individual average deviations (not shown) of  $\pm 2.4$ ,  $\pm 3.8$ , and  $\pm 6.2\%$ .

Between -0.3 and -0.1v the capacity decreases from > 10  $\mu\text{F}$  at -0.3v for a bead 0.075 cm<sup>2</sup> in apparent area. This large capacity is not found in a (short) single pulse measurement (11, 12). The pulsed bridge in its present form uses 100  $\mu\text{sec}$  pulses. In an a-c measurement this would correspond to a base frequency of 5 kHz. In the region of beginning hydrogen evolution (< -0.2v) a faradaic impedance is expected for such a measuring frequency (2) and its influence is indeed observed with the pulsed bridge.

Comparison of the data in Table II with those obtained previously with a single pulse method (11) shows that the previous capacity minimum at 0.9-1.0v is shifted to 0.6v, the previous maximum at 1.2-1.3v to 0.8-0.9v. This seems to be due to a difference in pre-treatment, the previous (planar) electrodes having been etched in aqua regia, the present ones (beads) melted in a hydrogen flame. Beads etched in aqua regia showed a capacity minimum at 0.8v and a maximum at 1.0v in better agreement with previous data (the maximum is less pronounced).

It is thus evident that the pulsed bridge gives results in substantial agreement with, and of higher precision than, a single pulse capacity measurement.

## The Growth of Aluminum Oxide Films on Copper-Aluminum Alloys

S. R. J. Saunders and M. J. Pryor

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

Pure aluminum oxidizes at temperatures above 300°C to form thin films of "amorphous"  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> by parabolic kinetics (1). Despite the fact that at 450°C and above roughly cylindrical crystals of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> nucleate and grow at the amorphous oxide-metal interface they do not affect the continued growth of the amorphous film. The temperature sensitivity of the parabolic growth of amorphous aluminum oxide films is high, and recent work suggests a value of around 54 kcal/mole for the activation energy.

Habraken *et al.* (2) recently reported a low activation energy of from 8-12 kcal/mole for the growth of complex oxide films including an aluminum oxide layer on a copper-7% Al alloy and on a copper-5% Al-5% Sn alloy. Since the over-all oxidation process of the copper-aluminum alloys is likely controlled by the film of aluminum oxide such a wide divergence of activation energy is puzzling. Accordingly, in the present work we have studied the growth kinetics of aluminum oxide films formed upon a copper 3% aluminum, 2% silicon alloy. Kinetics of growth of the aluminum oxide film have been studied independently of the presence of overlaying oxides of copper so as to permit a more ready comparison of the activation energies for the formation of alumina on copper-aluminum alloys with that of the formation of similar films on pure aluminum.

The copper-aluminum-silicon alloy specimens were polished in a solution of equal parts of concentrated nitric, sulfuric, and acetic acids, washed in water and methanol. They were heated for varying periods of up to 30 min at 450°, 600°, and 740°C. A uniform layer of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> is formed at temperatures above 300°C. This layer is overlaid by films of CuO and Cu<sub>2</sub>O. The maximum temperature (740°C) was low enough to prevent the formation of cupric aluminate. The soluble copper oxides were removed by dissolution in 2% (vol) sulfuric acid at room temperature. Separate studies showed that the underlying  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> resists attack by this acid for prolonged periods. Weight loss permitted determination of the quantities of copper oxides removed. The residual films were identified as  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> by reflection electron diffraction. The thickness and electrical properties of the aluminum oxide films were measured using a capacitance-loss technique described by one of the authors in earlier publications (3, 4).

The results of aluminum oxide thickness determinations as a function of time and temperature are shown in Fig. 1. The formation of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> obeys simple parabolic kinetics to periods of up to 30 min. An activation energy of 19.1 kcal is obtained from an Arrhenius plot of these data (Fig. 2); this value is approximately one-third of the activation energy obtained previously for the parabolic oxidation of aluminum which is also depicted in the same figure. Table I shows the relative amounts of copper and aluminum oxides formed in a fixed time at the three temperatures. It may be seen that the proportion of copper oxides decreases as the temperature increases. Therefore the over-all oxidation process of the Cu-3% Al-2% Si alloy has a lower temperature sensitivity and

a lower activation energy than that measured for the formation of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> alone on the copper alloy. This is consistent with the observations of Habraken for somewhat similar copper alloys.

It is of interest to consider why the temperature sensitivity of the parabolic formation of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> on the Cu-3% Al-2% Si alloy should be so much lower than that of the formation of a structurally similar film on pure aluminum. A significant clue is provided by a plot of parallel a-c resistance at 1000 cps *vs.* thickness of the thermal oxide films formed both on pure aluminum (1) and on the copper-aluminum-silicon alloys (Fig. 3). It is clear from Fig. 3 that very thin aluminum oxide films on the copper alloy have lower resistivity than those on pure aluminum, whereas the reverse is true at higher thicknesses.

The foregoing data can be rationalized on the basis of a change in composition, defect structure, and ionic resistance of the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> film formed on the copper alloy. Because the aluminum oxide film must be permeable not only to the outward diffusion of aluminum but also copper ions it must surely contain a certain number of this latter species. Since at higher temperatures and longer times than those reported in this work, cupric aluminate will also form as an oxidation product, the amount of copper ions retained in the aluminum oxide films will increase with increasing temperature at constant time. This factor will produce much more variability in the defect structure and conductivity of the aluminum oxide films formed on the copper alloy than that which occurs when the substrate is pure aluminum.

There must be a strong tendency for the copper ions present in the aluminum oxide to associate with the substantial proportion of cation vacancies that exist in stoichiometric  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>. These cation vacancies should represent the preferred paths for the outward

Fig. 1. Relationship between oxide thickness and the square root of time for the growth of aluminum oxide on copper 3% aluminum, 2% silicon at 450°, 600°, and 740°C.

Fig. 2. Arrhenius plot of the logarithm of the rate constant for the formation of aluminum oxide on aluminum and copper, 3% aluminum, 2% silicon vs. the reciprocal of the temperature.

diffusion of both aluminum and copper ions. As more copper ions are introduced into the  $\gamma$ - $\text{Al}_2\text{O}_3$  structure by raising the oxidation temperature the number of diffusion paths must simultaneously decrease. This must in turn result in a reduced temperature sensitivity for the formation of the copper-doped aluminum oxide film. The fact that cation vacancies are preferred sites of diffusion for both aluminum and copper ions also results in a reduction of the proportion of copper oxides formed with increasing temperature, thereby making the activation energy for the total oxidation process even less than that for the formation of the copper-doped aluminum oxide itself.

The above interpretation is directly supported by calculation of the value of  $A$  the exponential constant in the Arrhenius equation (below) using the activation energies derived from Fig. 2.

$$R = Ae^{-Q/RT}$$

where  $R$  is the rate constant and the remaining symbols are conventional. Although many different interpretations of the significance of the value of  $A$  exist for heterogeneous reactions most emphasis has been placed on interpretations relating  $A$  to the number of active sites. Three values of  $A$  were calculated from Fig. 2, two for the formation of  $\gamma$ - $\text{Al}_2\text{O}_3$  on aluminum (above and below  $525^\circ\text{C}$ ) and one for the formation of copper doped  $\gamma$ - $\text{Al}_2\text{O}_3$  on the copper-aluminum-silicon alloy. These are given below in Table II.

The very low values of  $A$  for the formation of copper doped  $\gamma$ - $\text{Al}_2\text{O}_3$  on the copper alloy compared

	$2.26 \times 10^{-2} \text{ g}^2 \text{ cm}^{-4} \text{ sec}^{-1}$	(above $525^\circ\text{C}$ )
$\gamma$ - $\text{Al}_2\text{O}_3$ on copper alloy	$1.20 \times 10^{-9} \text{ g}^2 \text{ cm}^{-4} \text{ sec}^{-1}$	

Fig. 3. Relationship between the a-c resistance and the thickness of thermally formed aluminum oxide on aluminum and copper, 3% aluminum and 2% silicon.

with either value for the formation of  $\gamma$ - $\text{Al}_2\text{O}_3$  on aluminum strongly suggests a considerable reduction in the number of cation vacancies as diffusion paths in the former structure, i.e., consistent with the defect structure-temperature relationship described earlier.

The variation of defect structure of the  $\gamma$ - $\text{Al}_2\text{O}_3$  film formed on the copper-aluminum-silicon alloy in which more copper ions fill cation vacancies in the  $\gamma$ - $\text{Al}_2\text{O}_3$  as the temperature is raised appears to account for the observed kinetics (Fig. 1) as well as for their reduced temperature dependence (Fig. 2). However, the a-c resistance vs. thickness curves (Fig. 3) deserve brief amplification. The measurement of a-c resistance at 1 kc is generally acknowledged to sense both electronic and ionic relaxation effects. At high thickness (high temperature) the resistivity of copper-doped  $\gamma$ - $\text{Al}_2\text{O}_3$  is around two times higher than that of  $\gamma$ - $\text{Al}_2\text{O}_3$  formed on aluminum. This appears to be primarily an ionic resistance effect due to filling of the cation vacancies by copper ions. However, at low thicknesses (and temperature) a reversal in resistivity is observed despite the fact the  $\gamma$ - $\text{Al}_2\text{O}_3$  formed on the copper alloy must contain some (but a smaller number) of copper ions. However, as copper ions occupy the cation vacancies additional electrons must be added to the structure for electrical neutrality. Accordingly, at low thicknesses and modest copper substitution the primary effect is the enhancement of a n-type structure showing higher electronic conductivity. As substitution is increased (by increasing temperature) the electronic conductivity must continue to rise, but the reduction of the number of cation sites becomes so pronounced so as to overwhelm electronic effects and thereby limit growth rate.

## Pulsed Electrolysis of Wet Hydrogen Fluoride

J. A. Donohue and A. Zletz

Research and Development Department, American Oil Company, Whiting, Indiana

Although preparative electrolyses are usually carried out at a constant applied potential, recent work has shown that a pulsed potential can be used to advantage in varying the types of products formed (1) and in improving the operation of fuel cells (2). Our studies of the production of oxygen difluoride by electrolysis of wet hydrogen fluoride with a nickel/nickel fluoride anode likewise showed that periodic interruption of the voltage is advantageous (3). We have now improved our experimental and analytical techniques and have observed how the yields are affected by the water and potassium fluoride concentrations of the electrolyte as well as by the applied voltage. Our results reemphasize the importance of voltage interruption in maximizing oxygen difluoride and reducing ozone and oxygen, the other major products at the anode. In addition, we have found that continuous electrolysis of wet hydrogen fluoride is a potentially good method for producing ozone.

Although much work has been done on the preparation of ozone by electrolysis of aqueous acids (4), it has been reported that only sulfuric and perchloric acids give reasonable yields, and only platinum and its alloys are suitable anode materials (5). With respect to aqueous hydrogen fluoride, some investigators suggest that only small amounts of ozone are produced (6-8), and one claims that none is formed (9).

Of necessity, comments on the mechanism of any electrolysis in hydrogen fluoride have been pessimistic (10) or highly speculative (11), mainly because product analyses have been incomplete or the results have not been reproducible. Since our results largely avoid such obstacles, they provide a less speculative basis for predicting mechanism.

### Experimental

With the exception of some recent improvements, the electrolysis cell and analytical equipment (g.c. for determination of the gaseous products and infrared for water in the electrolyte) have already been described (3,12). The infrared cells are now made by flattening and polishing Kel-F tubing. These did not fog in wet hydrogen fluoride so the usual absorbance *vs.* concentration calibration can now be used. Modifications in the electrolysis cell include the introduction of the helium flush gas through a Kel-F gas dispersion disk below the electrodes to ensure better mixing of the electrolyte and removal of the product gases. Also, the anodes are smaller, ranging from 2.5 to 7.5 cm<sup>2</sup>. Both electrodes were untreated 20 gauge nickel sheet with about ¼ in. spacing between cathodes and the anode. A satisfactory Hg/Hg<sub>2</sub>F<sub>2</sub> reference electrode was not developed until late in this work and was used here only for the study of the anode voltage. Details of its construction will be given later (13).

Except during interruption, the applied voltage is constant during an entire run. Changing the voltage during a run will generally result in changing, non-reproducible yields. The applied voltage is adjusted manually at the power supply to maintain a pre-

determined value, which is displayed on a vacuum-tube voltmeter attached to the electrodes. Voltage decrease during interruption was not controlled, but cell potential generally fell to about 2.8v. However, no effect on product yields was noted when the voltage decrease was deliberately adjusted to within  $\pm 1v$  of the usual decrease, i.e., from 1.8 to 3.8v.

The electrolyte was prepared from Matheson anhydrous hydrogen fluoride (99.9%), reagent grade potassium fluoride, and distilled water. Its initial water concentration was 0.1-0.2 m/o (mole per cent) as determined by Karl Fischer titration. The same electrolyte was used in many experiments, since expended hydrogen fluoride and water were replaced. The electrolyte temperature was generally not controlled and usually warmed slightly above bath temperature (0°C) due to iR heating and circulation to infrared cell. This was acceptable at 1.0 m/o KF since temperature studies showed little effect on yield between 0° and 12°C. However, at higher KF concentrations there were appreciable yield variation at higher temperatures. Thus in this case the electrolyte temperature was held constant.

Runs generally were carried out for 4 to 5 hr at selected voltages, electrolyte concentrations, and interruption schedules. Gaseous products were analyzed at 10- to 20-min intervals. The electrolyte was analyzed for water before and after a run, and water was added during a run to maintain the desired concentration.

Two variables associated with interruption are frequency and duration. Frequency was not studied extensively, but preliminary results showed that one interruption every 2 min allowed optimum oxygen difluoride yields and stable current densities. Duration was ordinarily 1 sec, but sometimes was increased to prevent a drop in oxygen difluoride yields when other variables were changed.

### Results and Discussion

Figure 1 compares typical continuous and interrupted runs. Since there is always an induction period of about 2 hr, during which yields and current density change rapidly, comparisons among runs are best made with yields measured during the 4th hr (180-240 min). In a typical continuous run, oxygen difluoride yields pass through a maximum while ozone and oxygen yields continue to increase. However, these yields are not reproducible. By contrast, after the induction period, the interrupted runs show higher oxygen difluoride and lower ozone and oxygen yields, all of which are constant. As shown by the shaded areas in Fig. 1, interrupted runs are reproducible despite considerable variation in current density.

These product distributions doubtless reflect different reactions occurring at the anode-electrolyte interface. As continuous electrolysis gives changing product distributions, it presumably causes a continuously changing anode interface. Conversely, as properly timed pulsed electrolysis leads to stable product distributions, a steady state must develop at the interface. This particular steady state also results in greater fluorination of the substrate, water. Thus we predict that pulsed electrolysis of other

substrates in hydrogen fluoride should lead to improved yields of fluorine compounds.

To improve our understanding of the interruption technique and reactions at the interface we made studies of the reaction parameters. Some phenomena that occur at very low water concentrations are illustrated in Fig. 2. In a continuous run started at 0.1 m/o water, the yields of oxygen and oxygen difluoride are both less than 5%; with a dry electrolyte the rest of the current presumably goes to form fluorine or corrosion products (3). When the water concentration is increased at 2 hr to 0.26 m/o but voltage is not interrupted, oxygen yield jumps to 22%, oxygen difluoride increased to only 9-10%, and no ozone is yet detected. But a shift at 4 hr to interrupted operation at this same water concentration causes the oxygen difluoride yield to jump to 45%; ozone definitely becomes a product, and oxygen yield decreases slightly.

We postulate that the products formed at 2-4 hr primarily result from fluorine reacting chemically with the water and so preventing it from reaching the anode. This reaction produces only small amounts of oxygen difluoride and little, if any, ozone (14). Under such conditions, interruption is necessary to permit water to react at the anode interface. Then, since water has a lower oxidation potential (15), it is electrochemically decomposed before fluoride ion (fluorine precursor), and so leads to a sequence of reactions that produce ozone and higher oxygen difluoride yields.

At higher water concentrations, interruptions have a different function. If the only function were to allow water to reach the anode, shorter interruptions suffice at higher water concentrations. But as Fig. 3 shows, the opposite is true, longer interruptions are required to maintain oxygen difluoride yields. Since the decrease in oxygen difluoride at shorter interruptions is balanced by an increase in ozone, the decomposition products of water apparently are reacting with each other to form ozone rather than with some fluorine species to form oxygen difluoride. Consequently, interruption must also prevent a buildup of the decomposition products of water at the anode.

As shown in Fig. 3, during continuous electrolysis the 4th-hr ozone yield exceeds 30%, which is comparable to the best reported for electrolysis of other

Fig. 1. Continuous vs. interrupted operation at constant cell potential.

Fig. 2. Interruption effect

Fig. 3. Effect of interruption length

aqueous acids on platinum anodes (5) and much greater than previous (6-9) aqueous hydrogen fluoride yields. Despite the erratic yields, continuous operation may therefore have some potential for ozone synthesis.

In our experiments to date no combination of water concentration or interruption schedule produced oxygen difluoride yields exceeding 45%. Thus, while decomposition of water is the initial electrochemical reaction, oxygen difluoride yields also appeared to be limited by the availability of some reactive fluorine species. The possible fluorine species here include fluoride ion, fluorine atom, free fluorine molecules, hydrogen fluoride, and the nickel fluoride anode. The data in Fig. 2 exclude free fluorine as an important species, and the concentration of the solvent, hydrogen fluoride, is so high that its availability should not be limiting.

Fig. 4. Effect of KF concentration on yield

Figure 4 shows the results of increasing the concentration of the fluoride ion to determine whether it was the limiting species. However, the oxygen difluoride yield dropped with oxygen now showing a compensating increase. At the highest potassium fluoride concentration 4th-hr yields are not even constant (the range is denoted by the T marks). Increasing the interruption to 5 sec improves the oxygen difluoride yield, but only to 30%, while current density decreases. While this evidence does not exclude fluoride ion from some participation, it is certain that the availability of fluoride ion is not limiting oxygen difluoride yields and probable that fluoride ion is not a major source of fluorine in oxygen difluoride.

If fluorine atom is the limiting species, its concentration should be increased at higher voltages. But in Fig. 5 the oxygen difluoride yield shows no change over a 0.6v range of anode potential. At higher potentials (5.4v) the 4th-hr oxygen difluoride yield was less than 40% and decreased with time. Thus it is improbable that any electrochemical intermediate from fluoride ion discharge, as fluorine atom, is an important source. Since ozone yield does increase at higher potential, this indicates that it is more closely related to the initial electrochemical reaction than is oxygen difluoride.

Thus we believe that the remaining possibility, the nickel fluoride anode, is the source of fluorine and we propose the following sequence as a plausible outline of the mechanism. First

We favor oxygen atom as the decomposition product of water because ozone, which usually requires oxygen atoms for its formation, and oxygen difluoride appear to have a common intermediate (see Fig. 3). Next, the oxygen atoms react with the nickel fluoride anode

However, the resulting anode material, possibly an oxyfluoride, must be very unstable in hydrogen flu-

Fig. 5. Voltage effects

oride and, consequently, it reacts to regenerate nickel fluoride

During continuous electrolysis at high water levels, the oxyfluoride layers build up and so cause a drop in oxygen difluoride yield. Interruption permits reaction [3] to remove such layers and restore the oxygen difluoride yield. Also such oxyfluoride layers can explain the apparent 45% limit on oxygen difluoride yields if the oxygen atoms in it are not available for oxygen difluoride but can only go to oxygen or ozone.

## The Nickel/Nickel Fluoride Anode in Wet Hydrogen Fluoride The Conductive Nature of the Nickel Fluoride Film

J. A. Donohue, A. Zletz, and R. J. Flannery\*

Research and Development Department, American Oil Company, Whiting, Indiana

From our studies of the electrolysis of wet hydrogen fluoride with a nickel/nickel fluoride anode, we have tentatively concluded that oxygen difluoride, a principal product, is formed by a reaction involving fluorine derived from the anode (1). But to test this conclusion, we need a clearer understanding of the electrochemistry of the nickel/nickel fluoride system. In the presence of fluorine at high temperatures, nickel forms a nickel fluoride coating that limits further attack; the mechanism is well understood (2). Apparently, such coatings also catalyze reactions of fluorine (3). However, much less is known about the nickel fluoride formed in wet hydrogen fluoride or its behavior during electrolysis.

Appreciable amounts of nickel fluoride are lost from the anodes in fluorine cells (4), in the electrolytic drying of hydrogen fluoride (5), and often in the electrochemical fluorination of organic compounds (6). Conversely, in wet hydrogen fluoride, the nickel fluoride undergoes passivation so that losses are minimized (7, 8). The passivation is not due to water decreasing the solubility of nickel fluoride (8, 9), and the mechanism has yet to be identified.

To learn more about the effects of electrolysis on nickel fluoride, we obtained potential decay curves and measured the weight losses of nickel/nickel fluoride anodes that had been exposed to known pretreatments and electrolysis conditions in wet hydrogen fluoride. We also examined replicas of the anode surfaces with an electron microscope.

### Experimental

Most of our equipment and procedures have been described (1, 7). Consequently, only new developments and details specific to this work are discussed here. These include addition of a reference electrode to the electrolysis cell, as shown in Fig. 1, and an electrical system for automatic potentiostatic control of electrolysis, as shown in Fig. 2.

Weight loss and electron microscope studies were carried out with preweighed anodes that had been exposed to known conditions of electrolysis during previous experiments (1, 7). After these experiments, the anodes were removed from the cell, rinsed with hydrogen fluoride to remove potassium fluoride, dried at reduced pressure, and weighed. An equivalent weight of 29.4g ( $\text{Ni}^{+2}$ )/faraday was assumed, and weight loss was calculated as a percentage of the current passed during electrolysis. For the electron microscope studies, carbon replicas of the anode surfaces were obtained by a standard technique (10). The replicas were dried, "shadowed" at a low angle with gold-platinum, and observed on an RCA type EMU electron microscope.

The mercury/mercurous fluoride reference electrode (11) is an order of magnitude more stable than other alternatives for use in anhydrous hydrogen fluoride

(12), and we found it remains stable even when water and dissolved electrolysis products are present. However, because mercury decomposes ozone (13a) and oxygen difluoride (14), we avoided yield losses by placing the reference electrode outside the main cell (Fig. 1). Otherwise, the construction differs from the former design (12) only in that a porous plug and a valve were added to restrict diffusion. Except the nickel wire contact, all parts in contact with the electrolyte are of Teflon. Mercurous fluoride for the electrode was prepared from mercurous nitrate by Henne's method (15); the mercury was reagent grade, used as received. The reference was used at 0°C.

Rather than placing the opening of the salt bridge close to the anode, where bubbles could block the opening and cause a high resistance in the reference circuit, it was necessary to position the opening beside the sparger, approximately 1 in. from the anode. Because this distance was much greater than the 1/4-in. separation between the anode and the cathode, the IR drop in the electrolyte was included in the potentials measured during electrolysis.

For the potential decay studies, the upper limit of the potentiostat current prevented the use of anodes any larger than 2.5 cm<sup>2</sup> in area. Moreover, a break-in period was required in which the voltage was slowly increased so that the current would not exceed that limit. Otherwise, operation of the electrolysis cell was not appreciably different from previous work (1). First, the electrolyte (hydrogen fluoride containing 1 m/o (mole per cent) potassium fluoride and 0.75 m/o water) was pre-electrolyzed with an auxiliary anode until clear and colorless. Next, the test anode was placed in the cell for the break-in period, during which the nickel fluoride coating appeared to build up to some optimum thickness (8) and then stopped growing. (This coating also appeared to be thinner

and more adherent than those produced without the gradual increase in voltage). Finally, the ohmic polarization ( $\eta_R$ ) was measured as a function of current density by potential decay techniques.

As diagrammed in Fig. 2, pulsed electrolysis was obtained from the potentiostat using an a-c timer, relay  $R_1$ , and control voltages set by CV 1 and CV 2. CV 2 allowed control of the voltage during pulsing, but was set to simulate previous uncontrolled work (1, 7). Since  $\eta_R$  decays rapidly ( $<1$  msec), it was recorded during the regular pulses; but the potentiostatic control had to be broken or only the potentiostat response was found. Thus, when a decay curve was to be obtained, a relay  $R-2$  was used to disconnect the potentiostat and allow normal decay during the pulse. Also, because the a.c. of the timer produced noise on the oscilloscope, the relays and scope trigger were operated manually on d-c current to observe decays. When the potential decay was observed for more than 1 sec, the regular electrolysis pulses were not long enough, and only one decay could be obtained per electrolysis run. To prevent rapid decay, the anode connection to the potentiostat was also broken. An electrometer and recorder were used to observe the longer decay processes.

### Results and Discussion

Our anode weight loss data are summarized in Table I. Of the principal electrolysis conditions studied, water concentration appears the most significant in producing a stable (passivated) anode. Appreciable weight losses were noted only when water concentration was less than 0.2 m/o. And contrary to our previous report (7), pulsed operation did not prevent such losses.

Changes in anodic voltage between 4.6 and 5.4v caused only negligible losses. However, at higher voltage (6.0v), at least a 2% loss has been observed (8) regardless of the water concentration. Thus, complete passivation apparently is maintained only if the anode voltage is less than 5.4v. Our experience suggests that about 5.0v anodic (6.2 for total cell voltage) is optimum for our system, but this may not hold for substrates other than water.

On the basis of our early yield data (7) at more than 0.2 m/o water, passivation was assumed (8) to persist after water was reacted away. However, recent yield data (1) at less than 0.1 m/o water now show low current efficiency for water-based products. Therefore, some small traces of water probably persist so long as there is any passivation.

Figure 3 compares electron micrographs of (A) a replica of one of our "passivated" anodes and (B) a nickel fluoride coating produced from the high-temperature reaction of nickel with fluorine. The latter coating, although polycrystalline, is hard without any cracks and is probably only one crystal layer thick (16). In contrast, the replicas of the anode has black areas caused by an adherent, soft, spongy nickel fluoride, whose presence was confirmed by electron diffraction analysis. The irregularly shaped lines in the remainder of the replica may indicate small pores or single crystal boundaries. From these observations we assume that the passivated nickel fluoride is soft, amorphous, or microcrystalline, and probably porous. However, it is unlikely that the porosity extends to the nickel support because the electrolyte would then be able to attack the nickel and probably cause further weight losses. Unfortunately, photomicroscopy was not very useful because the nickel fluoride was too soft to be polished, but a film thickness of 1-5 $\mu$  was found.

Our electrochemical measurements are summarized in Fig. 4 and 5. The ohmic polarization ( $\eta_R$ ) measured as a function of current density was found to obey Ohm's law, as shown in Fig. 4, and similar linear plots were obtained during the induction period of the electrolysis where current density changes with time at constant voltage. These results negate our earlier assumption (7) because, if ohmic resistance is constant, it cannot account for these changes in current density.

The very small value of  $\eta_R$  is significant; the 0.3-0.4v is only 5% of the total cell voltage ( $\sim 6.2$ v) at

Fig. 3. Electron micrographs of nickel fluoride surfaces. A, nickel fluoride by electrolysis in wet HF; B, nickel fluoride from Ni and F<sub>2</sub> at high temperature.

Fig. 4. Ohmic polarization

Fig. 5. Potential decay with intermittent short

normal operating conditions. Since  $\eta_R$  includes the IR drop in the electrolyte, which is estimated to be at least a few tenths of a volt, little if any ohmic polarization can be attributed to nickel fluoride. By contrast, the nickel anodes in a dry fluorine cell show very high ohmic polarization (17). Thus, the passivating substrate water also dramatically reduces the ohmic polarization of nickel fluoride. These phenomena may be related, at least on the basis of one theory (18) which holds that passivation occurs when a coating becomes electronically conducting. This prevents ion transport through the film, i.e., film growth.

As shown in Fig. 5, an indication of how conductivity may develop was obtained from additional potential decay studies. When the anode voltage was allowed to decay on open circuit, it fell rapidly ( $<1$  sec) to a stable potential plateau ( $E_p$ ) 2.5-3.0v more anodic than the rest potential of nickel/nickel fluoride. When an anode at  $E_p$  was grounded, the voltage decayed rapidly toward the expected rest potential. Then it recovered toward  $E_p$  when returned to open circuit if the grounded period was not long. Thus, we conclude that the anode is in an oxidized state as an electrode in a battery. Further, by analogy with the nickel oxide battery electrode (19), we assume that the accumulation of higher valent nickel ( $Ni^{+3}$  or  $Ni^{+4}$ ) species is the cause.

By integrating the current during grounding over the time to reach the expected rest potential, we were able to estimate the concentration of higher valent nickel species in the coating. As Table II shows,

Table II. Coulometry of  $E_p$ 

Total charge passed during electrolysis, coulombs	Charge in $NiF_3$ recovered on grounding, coulombs	% of Charge recovered
0.06	0.00062	0.97
0.78	0.0024	0.31
7.7	0.006	0.09

the charge in the coating decreases from 1 to 0.1% of the total charge as the total charge is increased. This percentage should be low since up to 90% of the total charge is accounted for as volatile products (1,7) of the electrolysis.

The concentration of higher valent nickel that would account for this charge in the coating was calculated to be from 0.1 to 1.0%. Semiconductors of good conductivity are obtained from nickel oxide doped with lithium oxide in this same concentration range. The conductivity of doped nickel oxide is thought to arise from higher valent nickel caused by the presence of the lithium cations in the host oxide (20). Therefore, we predict similar processes will be possible in anodic nickel fluoride.

That  $E_p$  is indeed a nickel fluoride bulk rather than a surface effect is shown by the fact that hydrogen bubbled over an anode at  $E_p$  will not cause a change in potential. Also, adsorption of soluble electrolysis products does not affect the potential of a resting anode during electrolysis on a different anode. Therefore, the products are not responsible for maintaining  $E_p$ .

We conclude that water passivates the nickel/nickel fluoride anode by making the nickel fluoride conducting, probably by stabilizing the formation of higher valent nickel species. This proposal is supported by the observation that water is required to stabilize the high valent nickel species in nickel oxide (13b). However, the water-dependent phase changes of nickel fluoride (9) and the amorphous or microcrystalline nature of anodic nickel fluoride should also affect conductivity.

We believe these studies have indicated the conditions required to produce a passivated nickel/nickel fluoride anode and hence should permit further progress toward identifying the mechanisms in the formation of oxygen difluoride and other products during the electrolysis of hydrogen fluoride. However, any electrochemical approach will require a better understanding of conductivity in nickel fluoride. Such an understanding should lead to anodes with permanently high conductivity, possibly even from metals that generally have nonconducting films (12), and also to improved electrolysis of the more difficult substrates such as ammonia (12) or hydrocarbons (6).

## Kinetics of the Reaction between Lithium Hydride and Liquid Ammonia at $-78^{\circ}\text{C}$

Irving Warshawsky

*Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio*

Although the quantitative reaction between an alkali hydride and liquid ammonia to form the corresponding alkali amide and hydrogen has been known for many years (1), neither the reaction rate nor the mechanism has been reported. The purpose of this study is to elucidate the kinetics of the reaction between lithium hydride and liquid ammonia at  $-78^{\circ}\text{C}$ .

Experimental procedures were similar to those employed in previous work (2). A small amount of powdered, reagent grade lithium hydride was introduced into an ampoule on the vacuum line, and the system was evacuated for several days at  $<10^{-6}$  mm Hg. Next, liquid ammonia, which had been dried over sodium, was distilled into the ampoule containing the hydride and cooled to liquid nitrogen temperature. The volume of liquid ammonia was 3.00 cc at  $-78^{\circ}\text{C}$  in every case.

The rate of the reaction,  $\text{LiH}_{(s)} + \text{NH}_{3(l)} \xrightarrow{-78^{\circ}\text{C}}$

$\text{LiNH}_{2(s)} + \text{H}_{2(g)}$  was followed by measuring the pressure of hydrogen evolved. At convenient time intervals, pressure readings were taken by means of a calibrated McLeod gauge. In the range of interest, the error in reading the McLeod gauge was estimated to be less than 3%. During a pressure measurement, the dry ice-acetone bath (used to hold the ampoule at  $-78^{\circ}\text{C}$ ) was replaced with a liquid nitrogen bath, usually for about 1 hr, with the rest of the system ( $1.741$ ) at room temperature. The hydrogen was then pumped out of the system, and the liquid nitrogen bath replaced once more by the dry ice-acetone bath. This manipulation introduced an error of approximately 4 min in the time span between pressure measurements, causing an error of 3% in the worst cases.

The data are plotted as  $\log P_{\text{H}_2}$  vs.  $\log t$  in Fig. 1. For convenience, the region prior to the break in the slope of the curve is called region A, and that following, region B. In region A, the equation  $P=Ct^n$  may be used to represent the data, where  $P$  is the pressure of hydrogen evolved in microns of mercury,  $t$ , the time in hours, and  $n$  and  $C$  constants. In region B, there is a large increase in the rate of reaction which takes place after approximately 5% of the hydride has reacted. The constants were determined by a least square fit of the experimental points. The data for region A is summarized in Table I. It is apparent that the reaction rate is effectively parabolic, i.e.,  $n=0.5$ .

Assuming a linear relationship between surface area and weight of lithium hydride, Table I shows that the expected proportionality between the rate constant  $C$  and the amount of lithium hydride is lacking. This

may be attributed partly to data variation and partly to a surface area variation. For instance, the presence of impurities at the surface, such as hydroxide, might cause a variation in the surface area from run to run. However, the inherent difficulty of reproducing the same surface area from run to run for a given amount of material has been noted in kinetic studies of the oxidation of copper (3) and uranium dioxide (4), respectively.

In tarnishing reactions, it is customary to assume that parabolic kinetics are due to a rate-determining step which is diffusion-controlled. Further, the assumption is made that the diffusion process takes place in a nonporous film which separates the reactants (5, 6). If a similar set of assumptions is made here for region A, where  $n$  is approximately 0.5, it may be envisaged that the highly insoluble reaction product, lithium amide (7), forms a nonporous film which separates the reactants, lithium hydride and liquid ammonia, and which increases in thickness as the reaction proceeds.

One may speculate that once the reaction is underway, its continuation necessitates a chemisorption process in which ammonia dissociates at the lithium amide-liquid ammonia interface into a proton and an amide ion. Thus, given a source of protons and also given a sink for their removal at the lithium hydride-lithium amide interface (via the reaction with hydride ions), conditions are created favoring the transport of protons through the amide film. As a con-

Fig. 1.

Table I. Constants of the kinetic equation

Run	Moles of LiH initially present $\times 10^4$	$n$	$C$
1	4.50	$0.54 \pm 0.04$	$11.6 \pm 0.5$
2	1.52	$0.41 \pm 0.01$	$10.5 \pm 0.2$
3	4.55	$0.49 \pm 0.01$	$12.2 \pm 0.2$

sequence, a charge imbalance created by hydrogen formation favors the migration of lithium ions from the lithium hydride-lithium amide interface to the lithium amide-liquid ammonia interface, leading to the formation of lithium amide at the latter interface. A transport process must also be assumed for the passage of hydrogen molecules through the amide film, leading to hydrogen evolution. Further, it may be suggested that the continued growth of the amide film may, at some critical film thickness, lead to the film breaking away (8), causing an increase in the rate of reaction by exposing new hydride surface to the liquid ammonia. Film breakaway may possibly

account for the abrupt change in the kinetic behavior in going from A to region B.

Manuscript received July 1, 1968.

## Electrochemical Painting of Titanium

Roberto Piontelli\* and Pietro Pedferri

*Institute of Chemical Physics, Electrochemistry and Metallurgy, Polytechnic of Milan, Milan, Italy*

The large variety of titanium oxides, obtainable by electrochemical passivation of the metal in various conditions, is well known. Furthermore, a wide range of modifications of the surface oxide may be obtained by operating with alternating or pulsating current, with various baths and working conditions. These modifications correspond as a rule to those obtainable with d.c., as far as the appearance and probably the composition and structure are concerned.

With applied voltages of 50 Hz, the substitution of the natural oxide by colored passivating layers requires that the current density exceed a roughly critical value, which, however, depends also on bath composition, temperature, and initial surface conditions. By plunging titanium or some of its alloys in a liquid already containing a counter electrode, an alternating voltage<sup>1</sup> being applied between them, the modifications of the metal surface region which comes into contact with the liquid depend on the instantaneous sign and value of the applied voltage. The influence of this value appears to be nearly discontinuous.

We may obtain, therefore, a succession of typical stripes, whose number on a given area is proportional to the product of the frequency (Hz) of the alternating current and the time (sec) required for the immersion of this area in the liquid. These stripes (see Fig. 1) are due to the alternation along the metal surface of regions in which the formed layers are different in color, thickness, electrical conductivity, porosity, adhesion, and resistance to chemical or electrochemical attack. Previous observations on oxide films formed on tantalum with alternating potential are due to Vermilyea (1).

\* Electrochemical Society Active Member.

<sup>1</sup> Of course, connecting the cell with a source of symmetric a.c., also, as a rule, has the result that the effective circulating current is strongly deformed due to the sudden changes of internal equivalent resistance, involving corresponding abrupt voltage changes.

In the case of titanium the appearance is largely influenced by the following factors: initial surface conditions, bath composition, characteristics of the electrical supply, temperature, etc.

As typical conditions under which these effects may be observed we may quote the following:

- aqueous solution of HCl 18% (by weight); room temperature; applied voltage: symmetric a.c. at 50 Hz and 5000/8000 amp/m<sup>2</sup>;
- ibid.*, the cell being supplied by both a source of a.c. (50 Hz;  $E_{eff} = 7v$ ) and one of d.c. (anodic voltage  $E_d = 8v$ , so that the titanium for most of the time is the anode);
- ibid.*, with  $E_{eff} = 7v$ ;  $E_d = 10.5v$ ;
- aqueous solution of NaOH 400 g/l; room temperature; applied voltage: symmetric a.c. at 50 Hz and 5000/10,000 amp/m<sup>2</sup>.

To obtain the effects above, the specimens may be utilized either with that surface condition which obtains following an exposure of many days to the atmosphere (at room temperature), or that derived from HF pickling, followed by boiling (for 15 min or more) in aerated water.

Those regions of the surface eventually wet at the moment of immersion become coated by a more conducting layer in a basic bath and by a less conducting layer in an acid bath.

Especially suggestive effects may be obtained when the electrolytic solution comes in contact with the metal surface by partially displacing a nonconducting liquid (Fig. 2).

The form of the figures then depends on the following circumstances:

- the conditions of the relative motion of the titanium surface (dry or on the other hand wetted with a nonconducting liquid) with respect to the electrolytic solution;

Fig. 1. Stripes obtained by vertical immersion of a Ti plate in aqueous HCl solution (18% by weight), at room temperature: (a) with alternating voltage; (b) and (c) with alternating voltage superimposed on d-c. voltage. Magnification 1X.

2. the inclination of the titanium surface with respect to the free surface of the liquid;
3. the boundary conditions;
4. the presence of obstacles;
5. the properties of the liquid phases (viscosity, surface tension and also their mixing-or reaction rate);
6. properties of the surface (microgeometry);
7. relationships between the surface and liquids (wettability, adhesion, and so on).

As possible applications of the results above one may consider the possibilities:

1. of fixing on the titanium surface, at definite time intervals, a line, which defines where the metal encounters an electrolytic solution, the frequency of this reproduction being coincident with the one of the applied a.c.;
2. of making conducting or insulating regions on a surface previously wetted with an electrolytic solution or with water, thus allowing selective metallizing of the surface by electroplating, following previously assigned drawings;
3. of fixing in the form of "isochronous lines" the three-phase boundary line formed by a foreign liquid

Fig. 2. Oxide film patterns formed at room temperature on titanium plates plunged horizontally into aqueous HCl solution (18% by weight) with alternating voltage superimposed on a d-c anodic voltage. The unique effects are obtained by partial displacement of previously applied wetting films of the following non-conducting liquids: (a) chloroform; (b) and (d) benzene; (c) and (e) acetic anhydride; (f) acetone; (a) (c) (d) figures formed on the upper face of the plate; (b) (e) (f) figures formed on the lower face. Magnification 0.5X.

coming into contact with an electrolytic solution on a titanium surface;

4. by differentiation from this map, the field of the advancement speed of the boundary line may also be deduced.

The details of the experimental work carried out in this laboratory on this matter are given in papers in print (2).

Manuscript submitted Feb. 23, 1968; revised manuscript received April 3, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## ABSTRACT

Single p-type, GaAs crystals of high purity, Zn doped, were used to determine whether or not the inverse octahedral {111} faces show potential differences and various rates of anodic dissolution. The Ga{111}, As{111}, {110}, and {100} faces, were polished, etched, and etch-polished with concentrated  $\text{H}_2\text{SO}_4 + \text{H}_2\text{O}_2$ , and immersed in 1N KOH. The Ga{111} faces were found to be the most noble with respect to rest and anodic dissolution potentials. The potential difference between the inverse {111} faces was as large as 0.14v for the rest and 0.123v for the dissolution potentials. The 4 anodic polarization curves gave nearly parallel Tafel lines, with a slope of  $66.0 \pm 1 \text{ mv}/\log i$ , up to current densities of  $0.5 \text{ ma}/\text{cm}^2$ . The rate of anodic dissolution of the As{111} faces was 69 X as high as the inverse Ga{111}. The activation energies of dissolution of all 4 faces were equal within experimental limits:  $16.7 \pm 0.7 \text{ kcal mole}^{-1}$ . It is concluded that the slow step in the dissolution of GaAs is a one electron discharge with subsequent steps leading to the formation of  $\text{Ga}(\text{OH})_3$  to provide a protective coating not readily soluble in KOH. From this point of view all observed phenomena can be explained in a qualitative manner.

Crystals without a symmetry center are polar; the polarity shows up through differences in chemical and physical behavior of the inverse planes of the respective crystals. The cubic III-V semiconductor compounds of diamond-type structure belong to this class, of which the best known are GaAs and InSb. Their polarity is displayed by the behavior of the inverse octahedral planes III{111} and V{111}, e.g., GaAs by Ga{111} and As{111}.

Reaction of III-V semiconductors in various media, with or without applied current have been studied by Gatos *et al.* (1), Pleskov (2), Gerischer (3, 4), Harvey (5), Brummer (6), Arthur (7), and others (8). They found that the various crystal planes react differently in aqueous media, such that the III{111} and V{111} inverse planes can be distinguished by the formation of specific etch patterns (1, 3, 8). The distinction can also be made from etching rates (1) from the inclination of etch tunnels produced by an anodic current on the GaAs octahedral planes (the tunnels run perpendicularly to As{111} and at an angle of  $20^\circ$  to Ga{111}) (8), and from LEED patterns (9). Furthermore, the two inverse planes exhibit different activation energies of oxygen desorption (as  $\text{Ga}_2\text{O}$ ):  $54 \pm 4$  from the Ga{111} and  $42 \pm 4$  kcal/mole from the As<111> face. Since there is little transfer of charges over the valence bridges (9, 10-13), the Ga atoms on the III{111} side retain their 3-valence electrons, while the As atoms on the inverse side retain 5. All this suggests that the two planes should also develop potential differences in electrolytes.

However, in this respect there are major disagreements. Gatos *et al.* reported that group III{111} planes exhibit more noble electrode potentials than group V{111} surfaces: for instance InSb inverse octahedral planes show a potential difference of 75 and more mv (1). Harvey (5) does not insist on a difference, but examination of his data (Fig. 2-3) reveals that the anodic potentials on Ga{111} are more noble than on As{111} at least up to current densities of  $50 \text{ ma}\cdot\text{cm}^{-2}$ . Conversely, Gerischer finds no difference either in dissolution rates or in the current density-potential curves.

Evidently the measurements have not been made under strictly identical conditions. The intention of the present investigation was, therefore, to use high-purity

GaAs crystals and to try to get an answer regarding the potentials exhibited in 1N KOH by the inverse 111-faces of GaAs, and also by the 110 and 100 planes.

## Materials and Preparation of the Electrodes

The single GaAs crystals were obtained from the Monsanto Company (St. Louis, Missouri), grown by the gradient-freeze technique. They were of the p-type containing Zn (<0.5 ppm) as a dopant. The impurity level was less than 1 ppm. The carrier concentration was  $\sim 1.6 \times 10^{16} \text{ cm}^{-3}$ , mobility  $\sim 250 \text{ cm}^2 \cdot \text{volt}^{-1} \cdot \text{sec}^{-1}$ , resistivity  $\sim 2 \text{ ohm}\cdot\text{cm}$ , and etch pit density  $\sim 800 \text{ cm}^{-2}$ . The disks (14-18 mm in diameter, 2-3 mm thick), were cut from the single crystal rod with a wire-blade slicer using a SiC slurry.

The orientation was determined from Laue back reflection patterns and the respective surface planes were adjusted within  $\pm 0.5^\circ$  of the desired orientation by successive grinding of the disks at a certain angle on fine SiC paper wetted with water and rechecking of the new direction with the Laue technique.

The damaged surface layer was removed from each crystal wafer by chemical etching for about 5 min with an aqueous mixture of 1HF (conc.): 1 $\text{H}_2\text{O}_2$  (30%): 2 $\text{H}_2\text{O}$  (by volume). After this operation the polarity of the {111} planes could be determined by comparing the etch patterns with those published in the literature (1, 3, 8).

Scratches, if present, were removed mechanically by polishing on cotton cloth with SiC slurry (600 mesh). Then a chemical polisher 3 $\text{H}_2\text{SO}_4$  (conc.): 1 $\text{H}_2\text{O}_2$  (30%) was used, which removed all remaining surface irregularities. The polisher has a high viscosity, provides a slow etch rate, and is not as sensitive to concentration changes as is CP4 etchant (mixture of HF,  $\text{HNO}_3$ , and  $\text{CH}_3\text{COOH}$ ). After this treatment the wafers were immediately transferred into dilute HF to prevent precipitation of a surface film, traces of which could be completely removed by dipping the samples into an aqueous solution of EDTA. Finally the wafers were rinsed in water and dried with alcohol. The whole procedure was repeated before any new series of potential measurements. The wafers then had a mirrorlike appearance (Fig. 1). To insure good electrical contact, one side of the wafer (less suited for potential measurements) was vacuum sputtered with Ag at room temperature, so that the impurity

\* Electrochemical Society Active Member.

Fig. 1. GaAs wafer in a Teflon holder (electrode)

level of the wafer could not be affected by the very slowly diffusing Ag. The contact with the circuit was achieved by Pt foil pressed to the wafer in a Teflon electrode holder (Fig. 1). A section through the holder is shown in Fig. 2. Teflon does not dissolve in the electrolyte (1N KOH) and repels water. The pressure of the screw cap against the wafer was equalized by the use of an O-ring below the Pt foil. Several runs were made on the same sample at current densities below  $0.5 \text{ ma} \cdot \text{cm}^{-2}$  where no surface disintegration of the electrode occurred (8). The potential determining anodic reactions are represented by Eq. [1] and [2]. As the exchange current could only be very small, it was not considered.

Then the electrode was placed in the cell and the potential measurements were made of the GaAs electrode against a 1N calomel reference in a  $\text{N}_2$  atmosphere at constant temperatures. Temperatures of  $4^\circ$  and  $21^\circ\text{C}$  were selected for the measurements of activation energies. The exposed GaAs surface was between  $1.2$  and  $1.4 \text{ cm}^2$ . The electrolyte was vigorously agitated employing a special stirrer and by bubbling  $\text{N}_2$  through the electrolyte. The influence of stirring rate on the potentials was not determined.

The d-c power was supplied and the potential controlled by an Anatrol potentiostat. Both power and potential were recorded on a 2-channel recorder on calibrated strip charts.

The chemicals used were all of reagent grade, and the nitrogen was prepurified. The electrolyte (1N aqueous KOH, 1600 ml) was pre-electrolyzed prior to each run using two Pt electrodes at  $180 \text{ ma}$  ( $\sim 60 \text{ ma/cm}^2$ ) over a period of 8 hr. Only traces of Pt could pass into solution and these would not affect the anodic dissolution of GaAs.

Fig. 3. Anodic dissolution potentials  $E'_H$  of GaAs vs. log of current density  $i$  of the planes Ga{111}, As{111}, {110}, and {100}. Hydrogen scale;  $4^\circ\text{C}$ .

### Results

Plots of anodic potential vs. the log of current density were linear for all the planes investigated (Ga{111}, As{111}, {110} and {100}). All had nearly the same slope, as shown by Fig. 3. The potential measurements for the various planes were highly reproducible. Rest potentials were not as reproducible:  $-402 \pm 40 \text{ mv}$  was obtained for As{111} and  $-262 \pm 40 \text{ mv}$  for Ga{111}. The  $\Delta E'/\Delta \log i$  values for the four planes in the sequence listed above are: 66.7, 65.6, 67.4, and  $64.8 \text{ mv}/\log i$ . They, therefore agree with the values of previous measurements, which usually were between 70 to  $95 \text{ mv}$  at room temperature (3). In acidic solutions (1N  $\text{H}_2\text{SO}_4$ ) they are lower, e.g.,  $62 \text{ mv}$  (5).

The fact that the slope  $\text{mv}/\log i$  on all 4 faces is the same within the limits of error, indicates that the rate-determining step is the same for all the planes subjected to anodic dissolution. The average value of  $66.1 \text{ mv}$  also suggests that a one-electron charge transfer is involved in the rate-determining step, similarly as for Ge (14, 15).

The activation energies (apparent) were calculated from the Arrhenius equation from the rates of dissolution (current density) at two temperatures ( $4^\circ$  and  $\sim 21^\circ\text{C}$ ), with all other factors remaining unchanged. The values are given in Table I.

Although the measurements were made with two or three GaAs crystals and the planes were etched-polished before each run, the activation energies differ only within the limits of error and, thus, are equal for all crystallographic planes. This result again suggests that the mechanism of dissolution (rds) must be the same on all the crystal faces.

However, Fig. 3 shows that appreciable differences in dissolution potentials do exist. While those exhibited by the As{111} and {110} planes may agree within the limits of error, the largest differences are found between Ga{111} and As{111}, ranging up to

Table I. Activation energies (apparent) of dissolution of various planes of GaAs in 1N KOH at temperatures of  $4.0^\circ$  and  $\sim 21^\circ\text{C}$  in  $\text{kcal mole}^{-1}$

{100}	15.6, 16.8, 17.3	16.7	0.8
		Average 16.7	$\pm 0.7$

\* Excluded.

0.123v, which is in good agreement with 0.14v, the difference between the rest potentials. The III{111} plane exhibits thereby a more noble dissolution potential than the V{111} plane in agreement with the statements of Gatos *et al.* (1). The potentials of the {100} plane lie in between those of the {111} planes.

It is also apparent from Fig. 3, that the reaction rates on As{111} are highest. For instance, at an anodic potential of -250 mv (hydrogen scale) the rate of reaction on As{111} is about 69 times faster than on Ga{111}, since the current densities developed (16) are  $1.1 \times 10^{-1}$  and  $1.6 \times 10^{-3}$  ma, respectively.

### Discussion

The first important question to be answered is: why are there differences in the rest and dissolution potentials on various faces of the single GaAs crystal, especially between the inverse {111} planes? GaAs, contrary to Ge (14, 15), has a noncentrosymmetric lattice. On etching such a crystal more Ga atoms will be present on one {111} plane whereas on the inverse side more As atoms will be present. This behavior is a consequence of the differential number of valence electrons (3 and 5) of the Ga and As atoms involved. While the bulk of the GaAs structure is, of course, neutral with no charge transfer across the four tetrahedral valence bridges (9-13), a difference in polarity should manifest itself on the outer planes, especially on the inverse {111}, where predominantly either Ga or As atoms are present. This situation causes a considerable difference in the chemical behavior and in the strength of bonding of the surface atoms. In fact, Arthur (7), has shown from O-desorption measurements that the gas is covering both inverse {111} planes; however, the binding state on the Ga{111} is stronger than on the inverse As side. Thus, Ga atoms are the active adsorption centers for O and the latter can be removed from the planes only as Ga<sub>2</sub>O (7). There was also evidence for an additional, weaker binding state on As{111} (7). Consequently, the sticking probability of O on clean As{111} faces is greater although the bonding is weaker than on Ga{111} faces, which agrees qualitatively with the LEED measurements (9).

However, oxygen may affect the potential of an anode in two or three ways. Taking, as an example, a metal in which O can be dissolved (formation of a solid solution) the free energy of the metal becomes less negative and its potential more noble (17). The same is also achieved by the development of oxides on the surface, presumably because of a mixed potential (18) formation and/or because of a reduction of the effective surface area. The more adherent and less permeable the oxide layer, the more noble is the potential of the metal. Passivation may eventually occur. Removal of the oxide layer must then result in activation of the metal. This behavior was confirmed by Beck and Gerischer, measuring rest potentials of semiconducting Ge in 0.1N NaOH in the presence of air or N<sub>2</sub>: in air the potential was considerably more noble (by 393 and more mv) than in N<sub>2</sub> (14). The reversibility of the change from a more noble potential to a less noble and *vice versa* indicated that the oxygen adsorbed on centrosymmetric Ge was rather loosely bound.

It is not known that GaAs dissolves O; therefore, only surface oxides are of importance with respect to surface charges. Since GaAs is noncentrosymmetric, the largest difference in surface arrangement of the Ga and As atoms occurs on the inverse {111} faces. Hence, the adsorption ability of O or of other species of ions such as OH<sup>-</sup> (in the electrolyte) by the two faces is not equal. Furthermore, the strength of bonding is influenced by the atomic species. According to Arthur (7) the bonding of O is stronger on Ga{111}, and it should exhibit a more noble potential than the inverse face in aqueous electrolytes. Such a behavior was actually observed not only in air but also in

a N<sub>2</sub>-atmosphere. In our study a difference of 0.14v for the rest potentials (3.23 kcal) between the two inverse faces was obtained. Therefore, different adsorption products must have been formed on the inverse faces. Figure 4 shows a 110-plane, perpendicular to both 111-planes of the GaAs lattice. On anodic dissolution both atomic species go into solution as trivalent ions (3, 5)

the 3e being absorbed by the cathode of the d-c source. The reaction of the Ga and As ions with OH<sup>-</sup> of the KOH-solution results in colloidal Ga(OH)<sub>3</sub> and soluble As(OH)<sub>3</sub> or HAsO<sub>2</sub> (+ H<sub>2</sub>O), which is quickly neutralized by the basic solution to form KAsO<sub>2</sub>. However, since the dissolution of Ga(OH)<sub>3</sub>

is slower and the rate decreases with aging of the colloidal hydroxide, the white hydroxide will be adsorbed by the Ga{111} face. The OH<sup>-</sup> might also react directly with the Ga surface atoms, since the Ga bonds are saturated by the bulk of the crystal and the positive charge of the Ga<sup>3+</sup> is on the {111} surface. Ga(OH)<sub>3</sub> adsorption is suggested by the fine, very thin white films observed on GaAs crystals especially on the {110} faces after 3 to 4 hr of anodic dissolution at higher current densities (~ 1 ma·cm<sup>-2</sup>). The adherence of the oxide is surely not equal on all the GaAs planes. It is expected that it will be strongest on Ga{111}, although the layer may be thinner than on the {110} face. Thus, even in a neutral gas atmosphere there is a protective layer on Ga{111} (less developed on As{111}) causing a potential difference between the two, the former being more positive. It is impossible at this time to give other than a qualitative characterization of the surface layers. Nevertheless, the layers explain the decreased rate of anodic dissolution of Ga{111} (Fig. 3).

The inverse side is attacked faster because of easy dissolution of As(OH)<sub>3</sub> in KOH. However, the closely adjacent layer of Ga-atoms (Fig. 4) dissolves also, as the Ga(OH)<sub>3</sub> formed, evidently cannot adhere to the next As row of atoms and, hence slowly dissolves in KOH according to Eq. [2] (formation of gallates). The next As-Ga layer is then attacked in the same way, starting from the dissolving Ga atoms and continuing at higher current densities into the depth of the crystal frequently along etch tunnels perpendicular to the As{111} plane (8). Thus the Ga and As atoms have to go into solution in pairs in accord with the premise of Gerischer (3).

Fig. 4. GaAs{110}-face being in the plane of the page. Both {111}-faces are normal to it. P, primary etch tunnels. The chemical bonds, symbolized by heavy lines, lie in the {110} plane. The arrows represent the direction of the etch tunnels lying in the same plane as the heavy lines (8).

Fig. 5. Various rates of dissolution of Ga atoms on inverse {111} faces.

The Ga{111}-face is partially protected by the slowly dissolving  $\text{Ga}(\text{OH})_3$  film. Where the latter disappears (reaction [2]) the adjacent As atom also dissolves readily. However, this atom is in the {110} plane at an angle of  $20^\circ$  to the Ga{111}. Therefore, at higher current densities this direction may be that of the etch tunnels (Fig. 4) continuing from Ga to As into the depth of the crystal, which actually was observed (8). Consequently, different etch patterns should be produced on the inverse {111}-planes, in agreement with the photomicrographs (8). The dissolution rates on other crystallographic planes must lie between those found for Ga{111} and As{111} (Fig. 3).

The slope of all the  $\text{mv}/\log i$  lines is the same (Fig. 3) and there is no difference in the activation energies (Table I). The conclusion is, therefore, that the rate-determining step must be the same on all the crystallographic planes. The Ga atoms are those which, because of the reasons mentioned, will remain on any of the dissolving GaAs planes, although starting from the As{111} they will dissolve faster than from the Ga{111} side. Therefore, the dissolution of the complex  $\text{Ga-Ga}(\text{OH})_3$  which represents the  $\text{Ga}(\text{OH})_3$  adsorbed by Ga atoms, should be involved in the over-all mechanism. Depending on where the Ga atoms are in the planes (on faces, corners, or edges of the steps developed during dissolution) and how they are followed by As atoms (Fig. 5), different rates of dissolution on various planes will be developed, although the rate-determining reaction will be the same. The value of the dissolution potential appears then to be dependent on the extent of surface coverage and solubility of the  $\text{Ga}(\text{OH})_3$ .

Therefore, it is expected, that every III-V semiconductor will behave differently during etching and anodic dissolution, depending on the chemical behavior of the atoms in the respective electrolytes.

## Structural Changes During the Anodizing and Sealing of Anodic Aluminas: Intermediate and Far Infrared Analysis

G. A. Dorsey, Jr.

Department of Metallurgical Research, Kaiser Aluminum & Chemical Corporation, Spokane, Washington

#### ABSTRACT

The longer wavelength far infrared absorptions of anodic coatings are attributed to  $\text{Al-O-Al}$  or  $\text{Al-O}^{\cdot}\text{Al}$  linkages.

Absorption band shifts are found to coincide with changes in anodizing conditions, and these shifts appear to be caused by changes in alumina cross-linking. The effects of anodizing time and current density are examined, as are the effects of sealing; the latter also influencing alumina cross-linking. Apparently, during the formation of these films, there is a relatively short period during which an appreciable quantity of barrier layer converts into the form of the porous layer. Sealing yields a similar conversion.

The intermediate infrared region of from 4000 to  $\sim 400$  wavenumbers has been widely used for the examination of aluminas. For example, Frederickson (1) characterized the stretch and bend modes for a

number of mineralogical aluminas while Fichter (2) did some earlier work with anodic aluminas. Our own work (3), again with mineralogical aluminas, was used to derive the following correlation chart for the infrared absorptions of hydrous and anhydrous aluminas.

Alumina bond type	Infrared absorption frequency range (wavenumbers)	Interpretation
AlO $\leftrightarrow$ H (stretch)	3660-2940 $\text{cm}^{-1}$	Bands in this region indicate the presence of water; either free, adsorbed, or combined as hydroxide.
Al $\leftrightarrow$ O (stretch)	1696-1345 $\text{cm}^{-1}$	Monohydrate and anhydrous aluminas may show varying amounts of double bond character. The presence of this bond type indicates a potentially adsorptive or reactive material.
Al $\leftrightarrow$ OH (bend)	1162-900 $\text{cm}^{-1}$	Aluminum hydroxides are indicated by an absorption in this region. Monohydrates are characterized by a band near 1070 $\text{cm}^{-1}$ while trihydrates show bands near, or below, 1025 $\text{cm}^{-1}$ .
Al $\leftrightarrow$ OAl (stretch)	Below 900 $\text{cm}^{-1}$	Bands in this region indicate a high degree of cross-linking; intense bands in this region are often associated with an absence of Al=O bonds. As the degree of cross-linking, i.e., polymer weight, increases, the bond absorption frequency will shift to progressively lower values.

It was also found that the IR absorption of the anodic barrier layer could always be distinguished from IR absorptions due to other structural features within the same film, e.g., absorptions due to the porous layer (4). Deuteration experiments indicated that the anodic barrier layer, from aqueous electrolytes, appeared to be a cyclic trihydrate which underwent certain structural changes during the course of film formation (5). But it was difficult to correlate these changes with those occurring in the porous layer portion of these films. The most reliable indicator for the various anodic porous layers would be the Al—O— $\overset{\text{H}}{\text{H}}$

Al (or Al—O $\rightarrow$ Al) linkage (5). However, IR absorptions of this bond type begin only near the lower wave number limit of the instrument then available to us. Further, the band placement of this linkage shifts rapidly, for progressively thicker films, into the still longer wavelength (lower wavenumber) region of the far infrared.

The far infrared region is a comparatively new one for commercially available instrumentation, and aluminas have not been thoroughly explored with it. Kolesova (6) examined alpha alumina (corundum), alpha trihydrate (gibbsite), and sodium aluminate in the KBr region down to  $\sim 400$  wavenumbers as did Marshall (7), again for alpha alumina. This and our own work, however, indicate that the far infrared spectrum of aluminas is indeed useful in their analysis, often providing the only pertinent IR data that can be used to differentiate between various anhydrous alumina phases.

Alumina absorption in the far infrared appears to be due to Al—O—Al and Al—O $\rightarrow$ Al stretch modes. These occur below 900  $\text{cm}^{-1}$  and are especially pertinent for the investigation of alumina properties relating to cross-linking (polymer weight). Two aluminas of the same type might be expected to have different chemical properties if one were high in polymer weight while the other had a lower, less highly cross-linked, mass. So too, might the properties of various anodic aluminas vary as a function of porous layer cross-linking. Earlier work (5) has shown that the anodic barrier layer, by itself, produces no absorption in the far IR region and does not interfere with porous-layer measurements.

### Experimental

**Anodic aluminas.**—Cleaned alloy KS32 aluminum sheets (alloy 1100 clad with 1100) were used as the

substrate material for the samples prepared. A 1.7M (15 w/o [weight per cent]) sulfuric acid electrolyte was employed, with lead cathodes, at 25°C. Anodizing current densities of 1.3 and 2.6 amp/dm<sup>2</sup> were used with various anodizing times that ranged from 1 to 30 min.

After anodizing, the panels were cut in half and one half of each was sealed in pH 5.5 boiling distilled water while the other half was left unsealed.

**Infrared analysis.**—The samples were examined over the 4000-600  $\text{cm}^{-1}$  range of the Beckman IR-7, as before (3), using a reflectance attachment set at 45° angle of incidence. The far IR data were obtained using a Beckman IR-11 over the 600-35  $\text{cm}^{-1}$  range, but with the reflectance attachment set at 20° angle of incidence. This lower angle was necessary to avoid ATR effects that appear to originate at the barrier-porous interface, when higher reflectance angles are employed in the far IR region. With both instruments, double beam spectra were obtained *vs.* a front-surfaced aluminized mirror which was mounted the same as the sample.

Quantitative determinations were made using a weight method of graphical integration, while band center measurements were made using ordinate scale expansion.

The far IR data were further treated to include the effects of polymer weight (molecular mass) on the placement of an absorption band (wavenumber at maximum absorbance). An alumina with a high mass (highly cross-linked) would have absorption bands at longer wavelengths (lower wavenumbers) than an identical alumina with a lower mass (3). Taking this into account, an empirical relationship was used to differentiate between the same amounts of aluminas of different polymer weights. This relationship can be expressed as:

$$\text{Amount of cross-linking} = \frac{A_{\text{Al-O-Al}}}{\frac{\nu_{\text{Al-O-Al}}}{900}}$$

where:  $A_{\text{Al-O-Al}}$  is band absorbance,  $\nu_{\text{Al-O-Al}}$  is wavenumber of band peak, and 900 is the upper limit for Al—O—Al or Al—O $\rightarrow$ Al stretch vibrations.

### Results and Discussion

**Anodizing mechanisms.**—Figure 1 shows the effects of anodizing time, current density, and sealing on the amount of porous-layer cross-linking. Note that the level portion of each curve, which is established shortly after anodizing begins, breaks suddenly upward. The break occurs after about 10 min anodizing time, for the 1.3 amp/dm<sup>2</sup> coating, and 5 min anodizing time for the 2.6 amp/dm<sup>2</sup> film. Since the number of cou-

Fig. 1. Amount of porous-layer cross linking

lombs applied during anodizing (at either 1.3 or 2.6 amp/dm<sup>2</sup>) is increasing at a constant rate, the anodic alumina may be forming first one structure and then another. Clearly, the rapid growth of the porous layer accounts for much of this alumina, after the first 14 min of 1.3 amp/dm<sup>2</sup> anodizing (after 7 min of 2.6 amp/dm<sup>2</sup> anodizing). Prior to that, the apparently lower growth rate of the porous layer would imply an alumina distribution between this and other structures. After 20 min at 1.3 amp/dm<sup>2</sup> (10 min at 2.6 amp/dm<sup>2</sup>) the amount of porous-layer cross-linking again changes: it ceases to increase as rapidly, implying another such structural redistribution.

Intermediate range IR data indicated that the amount of incorporated sulfate (1325 cm<sup>-1</sup> band) showed the same trend as did the porous-layer cross-linking. This is reasonable, since the incorporated sulfate content of the porous layer is essentially constant: ~13 w/o. Thus, the apparent changes in porous layer growth rate cannot be accounted for by assuming new sulfate structures. And the amount of structural Al = O remained small and fairly constant, with respect to anodizing time, disappearing almost entirely during sealing. Since the amount of porous layer Al = O did not change during anodizing, this would imply that the apparent changes in porous layer growth rate were due to structural features apart from the porous layer, rather than due to a structural redistribution within that layer. Changes within the barrier layer itself should therefore be examined (Fig. 2).

The amount of barrier layer, identified as primary phase barrier layer, from its band position (5), remains relatively constant for the first 5 min at 1.3 amp/dm<sup>2</sup> anodizing. During this same period, the amount of porous layer increases. Next, the amount of barrier layer increases rapidly with further anodizing time, while the amount of porous-layer cross-linking levels off. But a key feature, here, is an apparent occurrence that took place after the first 10 min of 1.3 amp/dm<sup>2</sup> anodizing, or after the first 5 min of 2.6 amp/dm<sup>2</sup> anodizing. The amount of barrier layer decreases rapidly at this point, while the amount of porous layer increases. Further, as indicated by the band position of the barrier-layer absorption (Fig. 3), it appears that the primary phase barrier layer has been transformed into the secondary phase barrier layer (5).

Based on these data, something resembling the following processes might have taken place:

1. The bare aluminum is oxidized, and the oxidized metal distributes itself between the primary-phase barrier and porous-layer structures.

2. Later, after about 5 min anodizing at 1.3 amp/dm<sup>2</sup>, the oxidized aluminum stays largely in the form of the primary phase barrier layer (925 wavenumber band). Further oxidation of the metal substrate appears to lead mainly to the formation of more primary phase barrier layer.

Newly oxidized aluminum could be expected, under the driving force of the impressed voltage, to capture an oxygen (hydroxide ion) from the layer above it and thus enter the barrier-layer structure. A net

Fig. 2. Amount of barrier layer

Fig. 3. Barrier layer data also showing band position (sealing did not produce a detectable change in band positions).

transfer of oxygen might then be accomplished if the surface portion of the barrier layer, now oxygen deficient, replenishes its oxygen (hydroxide) from the aqueous electrolyte.

3. Still later, after about 10 min anodizing at 1.3 amp/dm<sup>2</sup>, the already oxidized aluminum in the primary phase barrier structure is apparently transformed into the secondary phase barrier-layer structure (975-1000 wavenumber band). This transformation might be expected to occur at the outer surface of the barrier layer, perhaps due to the dissolving action of the electrolyte, here, due to the sulfate anion.

Note that the linkages in the primary and secondary phase barrier layers are represented as being somewhat different. The primary phase barrier layer may be strongly hydrogen bonded (viz., Al—O—H···O—Al bonds) whereas the secondary phase barrier layer may be composed of a mixture of hydrogen bonds and mu-

hydroxy linkages (viz., Al—O···Al).

4. Simultaneous with the transformation of primary-to-secondary phase barrier layers, there seems to be an additional transformation of the secondary phase into the porous layer structure. The rate of primary-to-secondary transformation apparently is somewhat

greater than the secondary-to-porous transformation. Therefore, while a portion of the barrier layer still remains, an appreciable amount of barrier layer appears to be in the form of the secondary phase.

Aluminum ions, created at the metal surface, migrate through the primary phase structure, being drawn out by the impressed voltage. Perhaps now, however, the new oxide layer forms at the primary-secondary barrier interface or somewhere within the secondary phase. The lower-polymer-weight secondary barrier phase would probably be a more open structure and therefore somewhat permeable to the electrolyte. This could mean that, while the coating thickness is continuously increasing, the voltage required to maintain a fixed current density would be relatively constant. The decreased voltage drop across the primary phase (due to the formation of less primary phase) might be offset by the combined (but lower) resistance of the secondary barrier phase and porous layer.

(Note that porous layer oxide is "dead" oxide. There is no migration of metal ions or hydroxide in the porous layer.)

Much work has been done [ref. (8) through (13)] to determine the nature of the migrating species during anodizing. The general conclusion is that both aluminum and oxygen (as in the hydroxide ion) are the migrating species during the early stages of anodizing (which fits with our model previously described) with anion transport predominating.

**Sealing mechanisms.**—Note (Fig. 2) that sealing appears to have decreased the amount of barrier layer. This finding is in keeping with the earlier observations of Hunter and Fowle (14) who noted that sealing lowered the electrical resistance of the anodic coating. Their observation regarding the barrier layer was based on the fair assumption that most of the resistance of the coating is across the barrier layer.

The effect of sealing is also apparent in Fig. 1, showing porous layer cross-linking. Sealing uniformly increased the amount of cross-linking. Furthermore, we know that sealing improves the protectiveness of anodic oxide films. After sealing, the films are more resistant to chemical attack.

Since sealing decreased the amount of barrier layer but increased that of the porous layer, we are led to speculate that at least one important effect of sealing lies in a structural change at the interface between the barrier and porous layers. The upper portion of the barrier layer (secondary phase) may be transformed into the porous layer structure and thereby

cause an increase in the amount of porous layer cross-linking. Perhaps this is accomplished by a structural incorporation joining the individual alumina fibrils of the porous layer at their base. Schematically, this might be represented as follows.

Conventionally, the effects of sealing are measured by observations regarding the changed nature of the porous layer surface (dye rejection, etc.). Certainly, the outer surface of the porous layer is changed, structurally hydrated, by the sealing process. However, it may be that a more important change is that which has taken place at the barrier layer-porous layer interface.

# Effluent Gas Detection and Infrared Data for Anodic Alumina Films

G. A. Dorsey, Jr.

Kaiser Aluminum & Chemical Corporation, Department of Metallurgical Research, Spokane, Washington

## ABSTRACT

A simple technique is described for the measurement of volatile components evolved from thin films during baking. This technique is applied to measurements of water liberated from anodic alumina barrier-layer coatings, prepared in boric acid and ammonium tartrate electrolytes, and from the composite films produced in sulfuric acid electrolytes. When correlated with infrared data, these measurements appear to strengthen some earlier speculations regarding anodic oxide structures and transformations.

The infrared analysis of hydrate structures is frequently accompanied by thermogravimetric data, so that sample weight changes may be correlated with structural changes. Many papers have dealt with aluminum oxides using these techniques. But while infrared has been used in the analysis of anodic alumina films, similar thermogravimetric or related data have not been available.

Since infrared data led us to propose that hydroxide structures are produced during barrier-layer formation in aqueous electrolytes (1), we sought to re-examine this interpretation using thermal analysis. Unfortunately, a thermobalance is not suited to the measurement of the small quantities of water that might be evolved from these thin films. The anodic films cannot be isolated from aluminum substrates without jeopardizing the integrity of their water contents; for example, boiling methanol-iodine solution is commonly used to isolate these films. Weighing error generally precludes good thermogravimetric data when these films remain on their comparatively massive substrates.

Therefore, a new technique was developed for the thermal analysis of these thin films.

## Experimental

**Effluent gas detection (EGD) apparatus.**—A gas chromatograph, if one is available, will provide all the necessary instrumentation needed for these measurements. We used a Varian Aerograph Model 1525B, although any instrument should prove satisfactory if the column oven is large and accessible. Lacking a gas chromatograph, the necessary elements are: (a) an oven which can be heated to  $\sim 400^\circ\text{C}$ , or above, at a rate of  $\sim 15^\circ\text{C}/\text{min}$ , (b) a dual gas flow controller, and a regulated supply of helium, (c) a thermal conductivity detector (TC cell) with associated power supply, wheatstone bridge, and separate constant temperature oven, (d) a strip chart recorder, preferably equipped with a Disc Integrator (Disc Instruments, Inc.), and (e) associated tube fittings and stainless steel columns (diagram a).

The analysis is begun by stabilizing the TC oven to some preselected temperature, usually about  $30^\circ\text{C}$  above the maximum temperature to be reached by the column oven. The sample is then loaded into a short length of stainless tubing ( $\frac{3}{8}$ -in. OD), and this is joined to the gas inlet and outlet (TC side) fittings of the main sample column. Helium flow is then adjusted

to  $\sim 65$  ml/min through reference and sample columns, via a bubble flowmeter temporarily attached at the TC gas outlet. After allowing a few minutes to purge all air from the system, the TC bridge circuit may be turned on and adjusted (it should always be turned off before breaking connections at the end of a run, and when the system has not been thoroughly purged with helium). Starting at room temperature, the column oven heating is begun while the sample temperature is monitored with a thermocouple attached to the sample tube. As heating begins to liberate volatile components from the sample, the recorder tracing will be deflected in accordance with the quantity of gas liberated (Fig. 1), which may be recorded as a function of sample temperature. Once calibrated, the area under the deflection curve provides a direct measure of the quantity of volatile components liberated. The components themselves may be identified either by foreknowledge of the sample or by trapping the components, as they emerge in the TC outlet gas stream, for identification by other techniques.

We used a somewhat different arrangement for thin film analysis. Instead of tubing to contain the sample, a stainless steel cell was employed (diagram b). The

cell cavity easily contained 600 to 800  $\text{cm}^2$  of anodized foil, or thin sheet, so that the quantity of volatiles evolved (in this case, water) were relatively large. The O-ring and aluminum gasket combination provided a leaktight assembly throughout the baking cycle.

Fig. 1. Calibration curve for effluent gas detection method using copper sulfate pentahydrate (AR grade standard).

Key words: anodic aluminas, hydration, gas chromatograph, IR.

The heating rate of the cell, along with that of the column oven, is shown in Fig. 2. A calibration curve, for water, is shown in Fig. 1. The response, in counts  $\times 10^3$ , shown in Fig. 1 was taken from the readout of a Disc Integrator mounted on the recorder.

The effluent from some of the anodized samples (400-v boric acid films and 15-min sulfuric acid coatings) was trapped in nujol at the TC outlet and subsequently identified, by IR, as water. No detectable water was found in a similar trapping of carrier gas during a blank run.

**Anodized samples.**—Cleaned alloy 1199 aluminum foil was used as the substrate material for the samples. The following electrolytes were employed, prepared with distilled water: 0.2M ammonium tartrate at pH 5.5, 2.0M boric acid, and 0.3M sulfuric acid. The barrier-layer electrolytes (tartrate and borate) were operated at 90°C, with a current density of 0.32 amp/dm<sup>2</sup>, to the desired final voltage, after which the current was allowed to decay to  $\sim 0.02$  amp/dm<sup>2</sup>. The sulfuric acid-anodized films were prepared at 30°C, with a current density of 1.08 amp/dm<sup>2</sup>, and with the various anodizing times indicated in the Results section. None of these samples was sealed.

The coatings were rinsed thoroughly after anodizing and were dried at room temperature and humidity before proceeding further. Surprisingly, long periods of storage time before analysis (up to 60 hr) produced no measurable effects in the EGD data, when compared with duplicate films analyzed within 1 hr of preparation.

**Infrared analysis.**—The sulfuric acid-anodized samples were examined over the 4000-to-600 cm<sup>-1</sup> range of a Beckman IR-7 instrument operated in double-beam mode. As before (1), 45° specular reflectance attachments were used. The IR data were obtained both before and after the EGD bake.

The amount of barrier layer present was taken from the absorbance of the 900-to-1000 cm<sup>-1</sup> band. The amount of porous layer was based on the absorbance of the 1325 cm<sup>-1</sup> Al=O band (2); actually, this is probably an Al=O  $\leftarrow$  S band associated with structurally incorporated sulfate. We did not use far infrared here since, for thin films, this 1325 cm<sup>-1</sup> band provides as reliable a measure of porous layer quantity as does the far infrared Al—O—Al stretch. This may be seen by comparing the data shown in Fig. 6 with those given in ref. (3).

## Results and Discussion

Figure 3 shows Effluent Gas Detection (EGD) data obtained for barrier-layer oxides formed at various voltages (100 through 400v) for which the 14Å/v relationship should apply. Note the linear correspondence between the forming voltage and the micrograms of water evolved per square centimeter of sample area. Note, also, that these data were independent of the type of barrier-layer electrolyte employed: boric acid

Fig. 2. Heating rate of effluent gas detection cell in gas chromatograph oven.

Fig. 3. Micrograms water (per cm<sup>2</sup>) evolved from boric-acid-anodized barrier-layer films plotted vs. forming voltage (350°C maximum cell temperature).

or ammonium tartrate. However, these data were obtained by heating only up to  $\sim 350^\circ\text{C}$ . Two partially resolved water peaks were thus obtained, near 120° and 170°C, but there are indications (Fig. 4) that another, probably larger, water liberation peak lies above 400°C. Since we are now unable to work in this upper temperature range, total hydrate contents could not be determined. However, even these limited data have proven useful.

Figure 5 shows similar EGD data obtained for unsealed films prepared in the 0.3M sulfuric acid electrolyte. Although most of these films contained porous layers as well as barrier layers, the EGD data (water liberation temperatures) for these films were not materially different from those obtained with the pure barrier-layer films formed in boric acid or ammonium tartrate. Furthermore, there was no detectable hydrate in the porous-layer portion of these unsealed films (the absence of 3400, 1640, or 1020 cm<sup>-1</sup> absorption bands in the IR data indicated that there was no physically adsorbed or structural hydroxide). These two observations allow us to propose that at least some of the effluent water came from the barrier-layer portion of these films.

Infrared data (Fig. 6) for these same films show that some correlation exists between the EGD data and the amount of barrier layer present. The quantity of effluent water was linear with respect to the amount of barrier layer (IR absorbance) for the first 4 min of

Fig. 4. Typical EGD curves of sulfuric-acid-anodized films. Recorder response vs. cell temperature.

Fig. 5. Micrograms water (per cm<sup>2</sup>) evolved from films formed in 0.3M sulfuric acid at 1.08 amp/dm<sup>2</sup> and 30°C plotted vs. anodizing time.

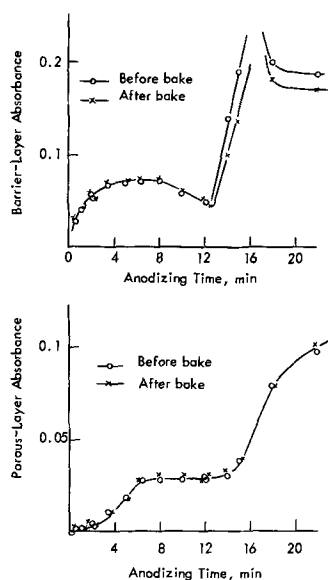

Fig. 6. Infrared data showing effect of baking on amounts of barrier and porous layers formed in sulfuric acid electrolyte.

anodizing time. But, from 4 to 14 min, the amount of effluent water increased while the amount of barrier layer remained relatively constant. However, there was an apparent change taking place within the barrier layer during this same period. The placement of the barrier-layer IR band center (Fig. 7) shifted from 920 to 980  $\text{cm}^{-1}$ ; this suggests a decrease in polymer weight of the barrier layer as anodizing progressed from 4 to 14 min.

We reported such a change earlier and termed it a transformation from primary to secondary barrier phases. It would probably be accompanied by an increase in the percentage of water released from the barrier layer at these temperatures. When heated to  $\sim 350^\circ\text{C}$ , the less polymerized secondary barrier phase might be expected to release proportionally more of its structural water than the more highly polymerized primary barrier phase. For these same films, there was also a minor confirming trend in the EGD peak placement: the major liberation temperature shifted from  $170^\circ\text{C}$ , for thin films, to  $\sim 150^\circ\text{C}$  for the thick films (see Fig. 4).

Infrared data for these films were obtained both before and after the EGD bake. But the IR data obtained after baking are subject to question. We found that baking to  $\sim 350^\circ\text{C}$  rendered these films highly reactive toward readsorption of water. After being baked under helium and cooled to room temperature, the purge was broken for 5 min. The purge was then resumed, and the EGD run was repeated. Most of the samples thus

Fig. 7. Infrared data showing placement of barrier-layer absorption band center plotted as a function of anodizing time in sulfuric acid electrolyte.

treated regained 30-50% of their original water during this brief interruption of purge, and apparently regained their original structure: liberation peaks were again observed at  $120^\circ$  and  $170^\circ\text{C}$ , not at  $80^\circ$ -to- $100^\circ\text{C}$  as is the case for nonstructural water. When repetitive determinations were made with similar samples, but without interrupting the purge, no further water liberation took place once the sample had been baked to equilibrium at  $350^\circ\text{C}$ .

Since the IR analysis re-exposed each sample, after EGD bake, to atmospheric humidity, we should not expect too much difference in the IR spectra of these films before and after baking. Indeed, there was very little difference (Fig. 6). The amount of barrier layer was unaltered by baking, but only for those films prepared by anodizing for less than 14 min in sulfuric acid. After 14 min of anodizing, there was a noticeable decrease in the amount of barrier layer present after baking. This would seem to indicate that the secondary barrier phase, discussed earlier (1), was less subject to rehydration than the primary barrier phase which predominates in the first few minutes of anodizing. Baking did not appear to alter the amount of porous layer in any of these same films.

# Preparation and Luminescence of Selected $\text{Eu}^{3+}$ -Activated Rare Earth-Oxygen-Sulfur Compounds

James W. Haynes and Jesse J. Brown, Jr.\*<sup>1</sup>

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

## ABSTRACT

The hydrated sulfate, sulfate, oxysulfate, and oxysulfide compounds of yttrium, lanthanum, gadolinium, and lutetium were prepared using precipitation techniques and controlled atmosphere high temperature heat treatments. The temperature stability range in air for each compound was investigated by DTA and TGA methods. X-ray diffraction powder data are presented for the fourteen compounds isolated. The only compounds that showed significant  $\text{Eu}^{3+}$ -activated luminescence were the oxysulfates and oxysulfides.  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ , the most efficient phosphor examined, is as bright as  $\text{YVO}_4:\text{Eu}$  and distinctly more "red." Luminescence data are presented and discussed.

The luminescence of  $\text{Eu}^{3+}$ -activated rare earth compounds has been a subject of considerable interest for a number of years, primarily, because of the use of certain of these materials in the preparation of color television screens. Recent interest throughout the industry has involved compounds arising from rare earth-oxygen-sulfur combinations.

In the present investigation the preparation, characterization, and luminescence of fourteen  $\text{Eu}^{3+}$ -activated rare earth sulfate, oxysulfate, and oxysulfide compounds are described. Of the rare earth elements, those which have been found to be most useful as host lattice cations for impurity activation are the ones with  $4f^0$ ,  $4f^7$ , or  $4f^{14}$  electronic configurations. These are lanthanum, gadolinium, and lutetium; yttrium, because of its close similarity to lanthanum, was also studied.

### Related Literature

Wendlandt and co-workers (1-3) investigated the thermal decomposition of the rare earth sulfates using differential thermal analysis (DTA) and thermogravimetric analysis (TGA) techniques. The hydrated sulfates, mainly octa-hydrates, were crystallized from solutions at room temperature. The thermal decomposition in air was found to follow the scheme: rare earth hydrated sulfate,  $\text{R}_2(\text{SO}_4)_3 \cdot x\text{H}_2\text{O} \xrightarrow{\text{I}}$  anhydrous rare earth sulfate,  $\text{R}_2(\text{SO}_4)_2 \xrightarrow{\text{II}}$  rare earth oxysulfate,  $\text{R}_2\text{O}_2\text{SO}_4 \xrightarrow{\text{III}}$  rare earth sesquioxide,  $\text{R}_2\text{O}_3$ .

The temperature ranges over which each of these reactions take place for the yttrium, lanthanum, gadolinium, and lutetium compounds are summarized in Table I.

The stable rare earth oxysulfide compounds,  $\text{R}_2\text{O}_2\text{S}$ , have been prepared by several methods. Eastman *et al.* (4) and others (5, 6) have prepared  $\text{Ce}_2\text{O}_2\text{S}$  by passing sulfur vapor or  $\text{H}_2\text{S}$  over  $\text{CeO}_2$  at  $1200^\circ$  and  $1300^\circ\text{C}$ . Surgutskii and Serebrennikov (7) prepared most of the rare earth oxysulfides by heating the appropriate anhydrous rare earth sulfate in a CO atmosphere above  $600^\circ\text{C}$ . Pitha, Smith, and Ward (8) prepared  $\text{La}_2\text{O}_2\text{S}$  by heating  $\text{La}_2(\text{SO}_4)_3$  to form  $\text{La}_2\text{O}_2\text{SO}_4$ , followed by reduction in a hydrogen atmosphere. It was also found that  $\text{La}_2\text{O}_2\text{S}$  was an ultraviolet excited phosphor when activated by lead-indium or lead-europium ions.

### Chemicals and Equipment

High purity, 99.99+%, rare earth oxides were used as starting materials. Semiquantitative spectrographic analyses of each oxide were obtained to assure that other rare earth impurities were not present above trace levels.

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Department of Metals and Ceramic Engineering, Virginia Polytechnic Institute, Blacksburg, Virginia 24061.

High-temperature heat treatments in air were carried out in an electrical resistance heated box furnace. Controlled atmosphere ( $\text{H}_2$ ,  $\text{H}_2\text{S}$ , and/or  $\text{N}_2$ ) heat treatments were performed in electrical resistance heated fused silica tube furnaces. Samples were normally heated in fused silica containers.

A Norelco x-ray diffractometer employing  $\text{CuK}\alpha$  radiation, operating at 40 kv and 15 ma was used and a goniometer scanning rate of  $1^\circ\text{-}2\theta/\text{min}$  was used.

Differential thermal analysis (DTA) data were obtained using a Model 12BC2 apparatus manufactured by Robert L. Stone Company, Austin, Texas. Thermogravimetric analysis (TGA) data were obtained using a Stanton Thermobalance, distributed by the Burrell Corporation, Pittsburgh, Pennsylvania. Both DTA and TGA data were normally obtained using a heating rate of  $10^\circ\text{C}/\text{min}$ .

All fluorescence excitation and emission spectra and peak height measurements were obtained with a Perkin-Elmer spectrofluorimeter as previously described (9). Cathodoluminescent spectra were obtained using a demountable cathode ray tube operating at 12 kv anode potential and 6  $\mu\text{amp}$  beam current over a standard scan TV raster of 1 in.<sup>2</sup> area. Brightnesses under these conditions were measured with an eye-corrected Weston foot-lambert meter.

## Experimental Results

**Preparation and identification of compounds.**—All compounds isolated in this study were routinely identified by x-ray diffraction powder methods. Since most of these data are not readily available in the literature, they are listed here in Table II.

**Hydrated sulfate compounds.**—Yttrium, lanthanum, gadolinium, and lutetium hydrated sulfates were prepared by precipitation techniques. The respective rare earth oxide was dissolved in concentrated nitric acid and the solution was diluted by addition of an equal volume of water, then a solution of sulfuric acid (enough to give approximately 10% excess sulfate ion over that required to form the stoichiometric rare earth sulfate) was added slowly. The solution was allowed to cool to room temperature and the rare earth hydrated sulfate was precipitated by adding a 200% (by volume) excess of methanol. After digesting for

were examined by DTA and TGA methods. Although these results are in part repetitious of a previous study by Wendlandt *et al.* (1-3) their relevance to the luminescence results discussed in a later section justifies their appearance here (Fig. 1 and Table III). Because of variations in heating rates and purity of starting materials, small variations are expected and observed between the reaction temperatures observed in this investigation and those by Wendlandt *et al.* In addition, Wendlandt and co-workers found 9 waters of hydration for the lanthanum sulfate compound whereas the present study indicated only 6. This discrepancy may originate from the different methods of preparation employed.

Anhydrous rare earth sulfate compounds suitable for x-ray diffraction studies were prepared by igniting the hydrates at 600°C for 4 hr.

*Oxysulfate compounds.*—In view of the DTA and TGA data, decomposition of the rare earth sulfate compounds occurs in two steps: first, two molecular-equivalents of SO<sub>3</sub> are expelled, and then at a higher temperature, the final SO<sub>3</sub> is released. The temperature range separating these two steps was found to vary a great deal depending on the rare earth cation involved. The oxysulfate phases of yttrium and lutetium are either unstable or stable over such a limited temperature range that it was impossible to prepare them in the pure state. The oxysulfate compounds of lanthanum and gadolinium were prepared by heating the corresponding sulfate at 1100°C for several hours. La<sub>2</sub>O<sub>2</sub>SO<sub>4</sub> is stable from 1025° to 1275°C and Gd<sub>2</sub>O<sub>2</sub>SO<sub>4</sub> from 990° to 1125°C. The weight loss data contained in Table III along with x-ray diffraction data were used to identify the formation of these compounds.

*Oxysulfide compounds.*—The oxysulfide compounds of yttrium, lanthanum, and gadolinium were successfully prepared by heating the respective oxysulfate compounds at 1000°C for 2 hr in an inert atmosphere which contained a few per cent by volume of H<sub>2</sub> and H<sub>2</sub>S.

Identification of the oxysulfide compounds was carried out by observing the weight loss resulting from the decomposition of the oxysulfide compound to the sesquioxide as shown in Fig. 2 and Table IV. On heating the oxysulfide compounds in air they initially gain weight in the range of 500°-600°C. This results from the oxidation to the oxysulfate compound which, on further heating, decomposes to the oxide. Since these two reactions occur simultaneously for the yttrium and lutetium compounds it was necessary to follow the net weight loss instead of the stepwise weight change.

Several other methods were used successfully to prepare the oxysulfide compounds. Gassing the oxide with a H<sub>2</sub>S-N<sub>2</sub> mixture at high temperatures was found to be successful for preparing oxysulfide phosphors. This was the method used to prepare Y<sub>2</sub>O<sub>2</sub>S:Eu, the most efficient phosphor found in this investigation. The optimum conditions for the preparation of this phosphor consisted of a 1½ hr heat treatment at 1200°C in a 72% N<sub>2</sub>-28% H<sub>2</sub>S gas mixture (by volume). Although pure Y<sub>2</sub>O<sub>2</sub>S could be prepared over a wide

Fig. 1. TGA and DTA curves of the hydrated sulfates of yttrium, lanthanum, gadolinium, and lutetium.

range of temperatures, times, and atmospheres, the above conditions provided the brightest phosphor. Although some interdependence exists between these three variables, it was generally observed that below 800°C and at H<sub>2</sub>S concentrations below 10% incomplete reaction occurred. Above 38%, at all temperatures examined, a dark brown colored product developed on the exposed areas of the sample. Presumably this material was Y<sub>2</sub>S<sub>3</sub>.

Another method of preparation involved blending of rare earth oxide with excess (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and heat treating the mixture between 600° and 900°C for 2 hr in an H<sub>2</sub> atmosphere. Several per cent H<sub>2</sub>S gas (by volume) added to the atmosphere insured the formation of the appropriate rare earth oxysulfide compound.

**Luminescence studies.**—All of the stable yttrium, lanthanum, gadolinium, and lutetium sulfate, oxysulfate, and oxysulfide compounds previously described were activated by co-precipitating Eu<sup>3+</sup> in the starting material and systematically examined for photo- and cathodoluminescence. The extent of examination varied from phosphor to phosphor depending on the promise each showed after preliminary experiments.

1. Sulfate compounds—The hydrous and anhydrous rare earth sulfate compounds are poor host matrices for Eu<sup>3+</sup>-activated luminescence. Both La<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>·Eu and Gd<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>·Eu showed weak red luminescence when prepared by igniting the hydrates at 600°C for 6 hr. The remainder of the rare earth sulfates were inert.

2. Oxysulfate compounds—La<sub>2</sub>O<sub>2</sub>SO<sub>4</sub> and Gd<sub>2</sub>O<sub>2</sub>SO<sub>4</sub>, the only oxysulfate compounds examined that were stable in air, provided mediocre red-emitting Eu<sup>3+</sup>-activated phosphors. Figure 3 shows the excitation and emission spectra for these two preparations. The most intense emission for both phosphors is approximately one third as intense as that of the commercial phosphor YVO<sub>4</sub>:Eu under 253.7 nm excitation. Neither phosphor displayed significant luminescence under cathode-ray excitation.

3. Oxysulfide compounds—Of the three groups of rare earth-oxygen-sulfur compounds investigated the oxysulfides consistently provided the most efficient Eu<sup>3+</sup>-activated luminescence. Three of these phosphors, Y<sub>2</sub>O<sub>2</sub>S:Eu, La<sub>2</sub>O<sub>2</sub>S:Eu, and Gd<sub>2</sub>O<sub>2</sub>S:Eu were examined in depth and the experimental data are included in Table V.

Lu<sub>2</sub>O<sub>2</sub>S:Eu was only briefly studied because of the high cost of lutetium.

The excitation and emission spectral energy distribution of the four rare earth oxysulfide phosphors are shown in Fig. 4. All of these preparations contained 5.0 m/o (mole per cent) Eu<sub>2</sub>O<sub>2</sub>S in crystalline solution with the host matrix. For all practical purposes the cathodoluminescent spectra are identical with those obtained using ultraviolet excitation.

As is the case with most families of rare earth compounds, the crystal structures of the oxysulfides are sufficiently similar to one another that only minor variations exist in the luminescent spectra. The major

Fig. 2. TGA and DTA curves of the oxysulfide compounds of yttrium, lanthanum, gadolinium, and lutetium.

emission of all four phosphors arises from  ${}^5D_0 \rightarrow {}^7F_2$  transition of the  $\text{Eu}^{3+}$  ion. Less intense emissions arising from  ${}^5D_0 \rightarrow {}^7F_1$ ,  ${}^5D_0 \rightarrow {}^7F_4$ , and other transitions are also evident.

The excitation spectra of all four  $(\text{RE})_2\text{O}_2\text{S}:\text{Eu}$  phosphors show two broad bands which vary in relative intensity depending on the chemical composition of the host matrix.

A. Yttrium oxysulfide—The effect of activator concentration on cathodoluminescent brightness and color (chromaticity coordinates  $x$  and  $y$ ) is shown in Fig. 5. The brightness initially shows a rapid increase, reaching a maximum near 0.5 m/o  $\text{Eu}^{3+}$ . Between 0.5 and 4.0%  $\text{Eu}^{3+}$  the brightness decreases rapidly to a plateau (it should be noted that the brightness decrease in this region is partly due to the decrease in  $x$  chromaticity coordinate and partly to concentration quenching). The plateau extends from approximately 4 to 7 m/o  $\text{Eu}^{3+}$  and is followed by another region of rapidly decreasing brightness. As indicated by the two top curves in Fig. 5, the emission color of  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$  changes rapidly below 4 m/o Eu. At low activator concentrations (below 4 m/o) the emission is distinctly more orange and the total eye-corrected light output high. At high activator concentrations (above 4 m/o) the emission color is more red and does not change appreciably with activator concentration. In order to more fully understand the peculiar shape of the activator quenching curve of  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ , the entire series of samples were examined carefully using a programmed slit spectrofluorimeter (9).

Figure 7 shows the marked difference in the emission spectrum of a sample containing 5 m/o  $\text{Eu}_2\text{O}_3\text{S}$  (top curve) compared with a sample containing 0.5

m/o activator. Numerous low wavelength emission lines become prevalent at low activator concentrations. Careful intensity measurements of each emission line, or in some cases, groups of lines, as activator concentration varied, resulted in the two curves shown in Fig. 6. All emissions occurring below about 600 nm followed curve A. The intensity of the "red"  ${}^5D_0 \rightarrow {}^7F_1$  emissions varies with activator concentration as shown by curve B of Fig. 6. This is a typical activator concentration vs. brightness curve for  $\text{Eu}^{3+}$ -activated phosphors.

By making the most reasonable energy level term assignment from analogy to the work of Brecher *et al.* (10), the groups of observed emissions were identified as shown in Fig. 7. The intensities of all of the transitions arising from  ${}^5D_1$  or  ${}^5D_2$  excited energy levels varied with europium concentration according to curve A in Fig. 6; those originating from  ${}^5D_0$  levels followed curve B.

B. Lanthanum oxysulfide— $\text{La}_2\text{O}_2\text{S}:\text{Eu}$  was prepared in a similar manner to that of  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ . The optimum conditions for phosphor preparation were found to be a heat treatment at  $1260^\circ\text{C}$  for  $1\frac{1}{2}$  hr using a 90%  $\text{N}_2$ -10%  $\text{H}_2\text{S}$  (by volume) atmosphere. The lanthanum compound is much more sensitive to the atmosphere composition; formation of a dark skin, presumably  $\text{La}_2\text{S}_3$ , occurred at  $\text{H}_2\text{S}$  concentrations as low as 20%.

The effect of activator concentration on the cathodoluminescent brightness and color of  $\text{La}_2\text{O}_2\text{S}:\text{Eu}$  are shown in Fig. 8. The effect of low activator levels is very similar to that noted for  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$  as evidenced

by the top two curves in Fig. 8. The brightness curve for  $\text{La}_2\text{O}_2\text{S}:\text{Eu}$  apparently changes slope similar to  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$  in the 5–10 m/o  $\text{Eu}^{3+}$  region. ( $\text{La}_2\text{O}_2\text{S}:\text{Eu}$  was not investigated in as much detail over this activator range as was  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ ; consequently, this portion of the curve in Fig. 8 is shown by a dashed line to indicate this uncertainty.) The lanthanum compound could not be prepared nearly as bright or as "red" as the analogous yttrium compound.

C. Gadolinium oxysulfide— $\text{Gd}_2\text{O}_2\text{S}:\text{Eu}$  was found to parallel  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$  and  $\text{La}_2\text{O}_2\text{S}:\text{Eu}$  in brightness, color, and variation of luminescent properties with activator concentration (Fig. 9).  $\text{Gd}_2\text{O}_2\text{S}:\text{Eu}$ , optimized for brightness at constant europium concentration, was prepared by firing at  $1260^{\circ}\text{C}$  for  $1\frac{1}{2}$  hr in a 90%  $\text{N}_2$ -10%  $\text{H}_2\text{S}$  (by volume) atmosphere.

D. Lutetium oxysulfide—Only one sample of  $\text{Lu}_2\text{O}_2\text{S}:\text{Eu}$  was prepared because of the difficulty and high cost involved in obtaining a pure lutetium compound to use as a starting material. From qualitative visual examinations of a sample prepared at  $1200^{\circ}\text{C}$  for  $1\frac{1}{2}$  hr in a 90%  $\text{N}_2$ -10%  $\text{H}_2\text{S}$  atmosphere, it appears that this phosphor is as bright as  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$  and equally "red."

## Discussion of Results

Throughout this investigation it was noted that the behaviors of the yttrium compounds more nearly approximate those of the compounds of the heavy rare earth elements, viz., gadolinium and lutetium, than the corresponding light rare earth compounds.

From the x-ray powder data, within a given family, apparent isostructural relationships exist between the yttrium, gadolinium, and lutetium compounds. The d-spacings for the yttrium compounds typically lie intermediate between those of the corresponding gadolinium and lutetium compounds. Lanthanum oxysulfide is apparently isostructural with the yttrium, gadolinium, and lutetium analogues, while the hydrated sulfate, sulfate, and oxysulfate show distinctly different x-ray reflections, indicating significant structural differences.

The DTA and TGA data also reflect this over-all trend. For example, the temperature stability range of the oxysulfate compounds is largest for lanthanum and decreases in the order gadolinium, yttrium, lutetium. It is interesting to note the differences between the excitation and emission spectra of the oxysulfate (Fig. 3) and oxysulfide (Fig. 4) phosphors.

Fig. 4. Excitation and emission spectra of the  $\text{Eu}^{3+}$ -activated oxysulfide compounds of yttrium, lanthanum, gadolinium, and lutetium.

Fig. 5. Effect of activator concentration on cathodoluminescence brightness and chromaticity coordinates for  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ .

The single excitation band of the oxysulfate phosphors can be assumed to arise from some type of  $(\text{RE})^{3+}-\text{O}^{2-}$  absorption. Presumably absorptions involving the  $(\text{SO}_4)^{2-}$  ions lie outside the energy range examined. On the other hand, the oxysulfide compounds show two distinct excitation bands. This implies  $(\text{RE})^{3+}-\text{S}^{2-}$  as well as  $(\text{RE})^{3+}-\text{O}^{2-}$  absorptions.

There are also marked differences between the emission spectra of the oxysulfate and oxysulfide compounds, most notably in the relative intensities of the

Fig. 6. Illustration of two types of activator concentration-brightness curves observed for  $\text{Eu}^{3+}$  emissions in  $\text{Y}_2\text{O}_2\text{S}:\text{Eu}$ .

Fig. 7. Photoluminescence emission spectra of  $(\text{Y}_{0.95}, \text{Eu}_{0.05})_2\text{O}_2\text{S}$  and  $(\text{Y}_{0.995}, \text{Eu}_{0.005})_2\text{O}_2\text{S}$ .

Fig. 8. Effect of activator concentration on cathodoluminescence brightness and chromaticity coordinates for  $\text{La}_2\text{O}_2\text{S}:\text{Eu}$ .

emission lines. These variations may result from structural differences which affect the activator site symmetry. For example, a strict center of symmetry makes the  ${}^5\text{D}_0-{}^7\text{F}_2$  transition forbidden. This may be the case with the oxysulfate phosphors.

On the other hand, Blasse *et al.* (11, 12) have noticed drastic changes in the relative intensities of various  $\text{Eu}^{3+}$  transitions resulting from chemical changes in the first coordination sphere of the activator ion. The substitution of S for  $(\text{SO}_4)^{2-}$  as we go from the oxysulfate to the oxysulfide matrix probably introduces severe changes in the neighborhood of the  $\text{Eu}^{3+}$  activator in addition to structural changes. Undoubtedly,

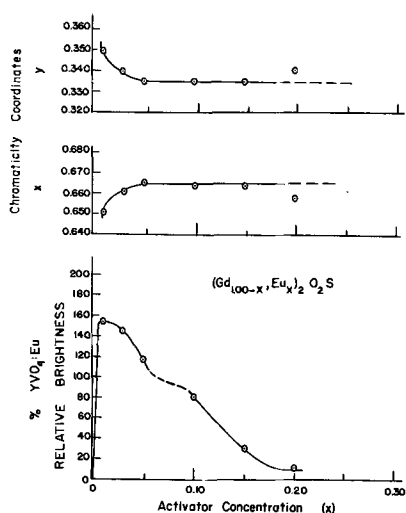

Fig. 9. Effect of activator concentration on cathodoluminescence brightness and chromaticity coordinates for  $Gd_2O_2S:Eu$ .

both the site symmetry and the chemical constitution of the ligands are responsible to varying degrees for these different emission spectra.

### Summary

Four families of Y, La, Gd, and Lu oxygen-sulfur compounds were studied and characterized. These families are  $R_2(SO_4)_3 \cdot n H_2O$ ,  $R_2(SO_4)_3$ ,  $R_2O_2(SO_4)$ , and  $R_2O_2S$ .

A. The rare earth hydrated sulfates were prepared by precipitation. In air these compounds begin decomposing to the anhydrous sulfates upon heating above  $100^\circ C$ . They do not provide efficient phosphors when activated by  $Eu^{3+}$ .

B. The rare earth sulfate compounds are stable in air up to near  $900^\circ C$  where they begin to decompose to the oxysulfate or the oxide. These compounds do not provide good  $Eu^{3+}$ -activated phosphors.

C. Only the oxysulfate compounds of lanthanum and gadolinium were found to be stable in air. They both exist over a relatively narrow temperature range, and at high temperatures decompose to the oxide. Yttrium and lutetium sulfates apparently decompose directly to the oxide without a stable intermediate oxysulfate phase. When activated by  $Eu^{3+}$ , both lanthanum and gadolinium oxysulfate exhibit the characteristic red  $Eu^{3+}$  luminescence. This emission is about 30% as bright as that of  $YVO_4:Eu$  under 253.7 nm excitation.

Both compounds are nearly inert when excited by cathode rays.

D. Heating the rare earth oxide, sulfate, or oxysulfate in a  $N_2-H_2S-H_2$  atmosphere at  $900^\circ-1100^\circ C$  will form the oxysulfide compound. The required temperature and atmosphere varies depending on the starting compound. All of the oxysulfide compounds are efficient  $Eu^{3+}$ -activated phosphors. The color and brightness of each compound is dependent on activator concentration. Low activator levels introduce low wavelength emission lines which become quenched as the activator level increases. The oxysulfide of yttrium is the most efficient phosphor with an emission which is characteristically more saturated and brighter than that of  $YVO_4:Eu$ .

### Acknowledgments

Messrs. O. Bullock, J. Looney, and J. Cook assisted with the sample preparation. Cathodoluminescent measurements were made by Mr. W. Persun. Numerous discussions with Mr. D. T. Palumbo and Dr. S. Z. Toma are greatly appreciated.

Manuscript submitted Jan. 10, 1968; revised manuscript received June 3, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Photoluminescent Efficiency of Phosphors with Electronic Transitions in Localized Centers

G. Blasse and A. Brill

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

## ABSTRACT

No general theory exists that can predict the efficiency of phosphors with electronic transitions in localized centers. In this paper a survey and discussion are given of the correlation between fluorescent properties and chemical properties, like composition and structure. Points of discussion are (a) choice of the activator together with concentration quenching and critical concentration for this phenomenon, (b) influence of the host lattice on the photoluminescence efficiency for direct excitation of the activator, and (c) energy transfer between fluorescent centers. These considerations are illustrated by a large number of experimental examples.

In this paper we shall restrict ourselves to luminescence involving electronic transitions in simple, localized centers. Chemically this means that we shall deal mainly with the so-called oxygen-dominated phosphors. At the moment no general theory exists that can predict whether a phosphor of this type is efficient or not (1).

In our research of the last three years we have tried to contribute to the solution of this problem by studying the fluorescent properties as a function of crystal structure and chemical composition. Such an approach has been very successful in the case of other physical properties, for example, the magnetic and electrical properties of transition metal oxides. We have indeed found a number of correlations between structure and composition on the one hand and fluorescent properties on the other hand, part of which could be explained. In this paper we will survey and discuss the observed correlations.

In the group of phosphors under consideration two types of phosphors can be distinguished: (a) those in which the exciting radiation is absorbed by the luminescent center consisting of an activator and its immediate surroundings and where this absorption is followed by emission from the same center (called A); (b) those in which the absorption takes place outside the luminescent center. The absorbing center may be a host-lattice group or an intentionally added ion (usually called sensitizer, S). We shall not make a distinction between these two types of centers and will denote both centers (or sensitizers) by S. The absorption can be followed by energy transfer from S to S and finally from S to A. Emission can occur also from S itself.

In  $\text{Sb}^{3+}$ - and  $\text{Mn}^{2+}$ -coactivated calciumhalophosphate with blue  $\text{Sb}^{3+}$  and yellow  $\text{Mn}^{2+}$  emission the  $\text{Sb}^{3+}$  ion acts as a sensitizer (S) for  $\text{Mn}^{2+}$  (A). Simultaneously  $\text{Sb}^{3+}$  plays the role of activator for the blue emission. A given ion can play different roles in different host lattices: in  $\text{EuAl}_3\text{B}_4\text{O}_{12}$ -Cr, for example,  $\text{Eu}^{3+} = \text{S}$  (and  $\text{Cr}^{3+} = \text{A}$ ), but in  $\text{YVO}_4$ -Eu, on the other hand  $\text{Eu}^{3+} = \text{A}$  (and vanadate = S).

In later sections we shall first deal with the choice of the activator: which elements in which valency state can be used to give efficient phosphors? In this connection concentration quenching will also be dealt with. A second problem that will be treated is why the efficiency of the fluorescence of a certain activator varies strongly with the host lattice for the case that the exciting radiation is absorbed by the activator centers (phosphors of type a). Later sections discuss energy transfer between centers. This determines the efficiency of phosphors of the type b. The influence of the surroundings on the position of the energy levels of the fluorescent centers is considered later. This is

especially important for the efficiency of the energy transfer.

## Choice of the Activator

The question "which elements give efficient fluorescence?" is the first problem one encounters when one tries to predict the efficiency of phosphors. Recently we have given an empirical criterion to answer this question (2). It is based on the well-known assumption that it is necessary for efficient fluorescence from an isolated center that the configuration coordinate curve of the excited state is situated within the curve of the ground state (see Fig. 1A). Seitz (3) stated that no fluorescence can be expected if the equilibrium distance of the configuration coordinate curve of the fluorescent state is outside the curve of the ground state (Fig. 1C). Dexter *et al.* (4) have shown that even under less extreme conditions the excitation energy can be lost by radiationless transitions, *viz.*, if the system passes the intersection of the extrapolated curves of the fluorescent and the ground state after the excitation process (see Fig. 1B). If this is not the case, efficient fluorescence may be expected. This fluorescence will be quenched at higher temperature (Seitz-Mott).

It is immediately clear from Fig. 1 that the difference between the values of the equilibrium distance of the ground and excited state ( $\Delta r$ ) must play an important role. Unfortunately no values of  $\Delta r$  are known in the literature. It is possible, however, to obtain a rough measure of  $\Delta r$  from the set of radii corresponding to the principal maximum in the radial wave functions for atoms and ions given by Waber and Cromer (5). The difference between the sum of these radii for the ground and excited state of the constituents of the fluorescent center is considered as a measure of  $\Delta r$ .

Fig. 1. Configuration coordinate diagram of the ground state and the fluorescent state (schematically). A, Excitation results in efficient fluorescence, the intersection of the two states being high above the excited vibrational levels of the excited state. B, Excitation results in inefficient fluorescence, since the excitation energy can be lost radiationlessly via the intersection of the two states. C, Excitation does not result in fluorescence, since all the excitation energy returns radiationlessly to the ground state.

Table I. Excitation transitions of some fluorescent centers in oxides and the orbital radii (Å) involved

Ion	Excitation transition <sup>a</sup>	Largest outer orbital radius connected with			Difference ( $\Delta r$ )	
		The ground state		The excited state		
Nb <sup>5+</sup>	2p <sub>0<sup>2</sup></sub> → 4d	4p (Nb)	0.59	4d (Nb)	0.75	0.16
W <sup>6+</sup>	2p <sub>0<sup>2</sup></sub> → 5d	5p (W)	0.58	5d (W)	0.75	0.17
Sn <sup>4+</sup>	4d → 5s, 5p	4d (Sn)	0.46	5s (Sn)	1.03 <sup>b</sup>	0.57
Sb <sup>5+</sup>	4d → 5s, 5p	4d (Sb)	0.44	5s (Sb)	0.97 <sup>b</sup>	0.53
Sn <sup>2+</sup>	5s → 5p	5s (Sn)	1.03	5p (Sn)	1.24	0.21
Sb <sup>3+</sup>	5s → 5p	5s (Sb)	0.97	5p (Sb)	1.16	0.19
Pb <sup>2+</sup>	6s → 6p	6s (Pb)	1.01	6p (Pb)	1.21	0.20
Ce <sup>3+</sup>	4f → 5d	5p (Ce)	0.82	5d (Ce)	~1.07	0.25
Eu <sup>2+</sup>	4f → 5d	5p (Eu)	0.74	5d (Eu)	~0.98	0.24
Eu <sup>3+</sup>	2p <sub>0<sup>2</sup></sub> → 4f	5p (Eu)	0.74	5p (Eu)	0.74	0
Mn <sup>2+</sup> , Mn <sup>4+</sup>	3d → 3d	3d (Mn)	0.39	3d (Mn)	0.39	0

<sup>a</sup> See e.g., ref. (36). Orbitals with subscripts relate to the O<sup>2-</sup> ions, orbitals without subscript to the metal ions.

<sup>b</sup> Values for the orbital radius of 5p are even larger than those for 5s.

The agreement is good for those cases where a comparison is possible between these values and the values used in configuration coordinate diagrams derived from experimental results (2). Table I gives some values of  $\Delta r$  derived from the Waber and Cromer radii. Consider, for example, the Sb<sup>5+</sup> ion. The excitation and fluorescence transition is 4d → 5s (or 5p). The outer orbital of the ground state is 4d (maximum at 0.44Å) and of the excited state 5s (maximum at 0.97Å). Their difference (~0.5Å) is considered as a measure of  $\Delta r$ . For further details the reader is referred to the original paper.

It seems to be a necessary, but not a sufficient, condition for efficient fluorescence that  $\Delta r$  is about 0.3Å or less. This is the case for the higher-charged transition metal ions without d-electrons (like V<sup>5+</sup>, W<sup>6+</sup>), the ions with ns<sup>2</sup>-configuration (Sn<sup>2+</sup>, Pb<sup>2+</sup>, etc), the rare earths ions and also for manganese and chromium. For the latter two elements the orbitals involved are the same for the ground and excited state, so that  $\Delta r$  is zero in first approximation. By applying this criterion it is possible to select possible fluorescent centers from the periodic table. This selection coincides with the selection that could be made before from experience:  $\Delta r = 0$  for manganese and trivalent europium, which elements give efficient temperature-persistent phosphors when used as activators in various materials. CaWO<sub>4</sub> and MgWO<sub>4</sub> are well-known efficient phosphors, while materials activated with Sn<sup>2+</sup>, Ce<sup>3+</sup>, and Pb<sup>2+</sup> can also show high efficiencies. For these activators  $\Delta r$  is 0.2Å.

Even if we have successfully selected the activator, efficient emission is not guaranteed on excitation in the activator, because in practice we are not dealing with isolated centers. In many cases there are restrictions on the concentration of the activator. Usually the quantum efficiency at room temperature decreases with increasing concentration. This phenomenon is known as concentration quenching. The amount of activator for which it starts is usually called the critical concentration. This concentration is very low in the case of uranium fluorescence in oxides (~0.1%). Usually it is somewhat higher, 1-5%, for example, for Bi<sup>3+</sup>. In other cases, however, no concentration quenching is observed at all (CaWO<sub>4</sub>, CaNb<sub>2</sub>O<sub>6</sub>). In Table II the critical concentration is given for a number of systems together with the Stokes shift of the fluorescence. Note that in first approximation the critical concentration increases, if the Stokes shift increases (6). The rare earth ions with line emissions are not considered here, since it is difficult to define the Stokes shift of their fluorescence. Since concentration quenching strongly depends on the probability of energy transfer between the fluorescent centers, the discussion of the relation given in Table II is deferred to the section on Phosphors with Very High Sensitizer Concentration.

Table II. Critical concentration ( $x_{crit.}$ ) and Stokes shift of the fluorescence of some systems

Composition	$x_{crit.}$	Stokes shift, 10 <sup>3</sup> cm <sup>-1</sup>
Li <sub>3+1/4x</sub> Nb <sub>1-5/4x</sub> U <sup>0+x</sup> O <sub>4</sub>	~0.001	1
Y <sub>1-x</sub> Bi <sub>x</sub> Al <sub>3</sub> B <sub>4</sub> O <sub>12</sub>	~0.005	2
Y <sub>1-x</sub> Bi <sub>x</sub> OCl	0.05	5
Sr <sub>3-3x</sub> Eu <sup>2+3x</sup> MgSi <sub>2</sub> O <sub>8</sub>	0.01	1.5
Y <sub>3-3x</sub> Ce <sup>3+3x</sup> Al <sub>3</sub> O <sub>12</sub>	0.04	4
Mg <sub>3</sub> Sn <sub>1-x</sub> Ti <sub>x</sub> O <sub>4</sub>	0.05	8
YP <sub>1-x</sub> V <sub>x</sub> O <sub>4</sub>	0.25	12

CaNb <sub>2</sub> O <sub>6</sub>	a	17
CaWO <sub>4</sub>	a	17

<sup>a</sup> No concentration quenching.

Nevertheless we may remark here that concentration quenching also plays a role in the group of transition metal ions without d electrons (Ti<sup>4+</sup>, V<sup>5+</sup>, Nb<sup>5+</sup>, W<sup>6+</sup>, etc.), a fact which has been overlooked up till now [see e.g., (7)]. Usually the absence of fluorescence at room temperature in compounds of the transition metal ions without d-electrons is ascribed to thermal quenching (i.e., a low activation energy). Undoubtedly this is the case for molybdates, because the isolated molybdate group does not fluoresce efficiently at room temperature. However, in the case of the vanadate or titanate group, concentration (and not thermal) quenching explains the absence of fluorescence at room temperature in the majority of the compounds of these groups (6).

#### Influence of the Host Lattice

If we have selected an efficient fluorescent center, a second and even more difficult problem arises, namely, the choice of the host lattice. In this section we restrict ourselves to those cases in which only the activator itself is directly excited, i.e. transfer through the host lattice and from the host lattice to the activator does not play a role (phosphors of type a). It is well known that a given center fluoresces efficiently only in a restricted number of host lattices. We recall two examples of fluorescent centers, viz., Eu<sup>3+</sup> and the niobate group. At room temperature Y<sub>2</sub>O<sub>3</sub>-Eu has a maximum quantum efficiency  $q = 75\%$  in the uv region, YAl<sub>3</sub>B<sub>4</sub>O<sub>12</sub>-Eu has  $q = 35\%$  and LaAlO<sub>3</sub>-Eu has  $q = 10\%$  [excitation is always in the Eu<sup>3+</sup>-center only (8)]. The compounds Li<sub>3</sub>NbO<sub>4</sub> and CaNb<sub>2</sub>O<sub>6</sub> fluoresce efficiently at room temperature, but LiNbO<sub>3</sub> and SrNb<sub>2</sub>O<sub>6</sub> do not do so (9, 10).

A relation between the efficiency of phosphors of this type and their chemical properties has been found. In his paper on the fluorescence of niobates Wachtel (9) puts forward a possible relation between the position of the absorption edge and the quenching temperature of the fluorescence of the niobates. We have shown that this relation holds not only for niobates, but also for other compounds.

In the case of the fluorescence of the octahedral niobate center (2, 10) it was found that, if the position of the first absorption band moves to longer wavelengths, the quenching temperature of the fluorescence decreases (see Table III). It is possible to account for the dependence of the position of the absorption band on the host lattice. The absorption (and emission)

Table III. Some data on fluorescent niobates

Compound	Absorption edge, cm <sup>-1</sup>	Quenching temperature, °K	Anion potential <sup>a</sup>
Li <sub>3</sub> NbO <sub>4</sub>	41,600	500	2-1/3
MgNb <sub>2</sub> O <sub>6</sub>	37,000	350	2-1/6
LiZnNbO <sub>4</sub>	36,800	350	2-1/9
LiNbO <sub>3</sub>	35,100	200	2

Nb <sub>2</sub> O <sub>5</sub>	27,000	<100	—

<sup>a</sup> See text.

transition involves a charge-transfer process in which an electron is transferred from the  $O^{2-}$  ions to the central  $Nb^{5+}$  ion. The higher the potential field from the cations at the  $O^{2-}$  site is, the more energy is needed for the electron transfer, so that the absorption band will be at shorter wavelengths. A qualitative measure of this potential field is given by using Pauling's electrostatic valence rule (11): if the sum of the electrostatic bond strengths from cation to anion is larger than 2, the potential field at the anion site is relatively large. This value gives indeed a rough measure of the quenching temperature.

The relations between the position of the absorption edge and the quenching temperature of the fluorescence could be accounted for even quantitatively by assuming that the  $NbO_6$  octahedron can be considered as a more or less isolated group (2). Configuration coordinate curves with a fixed shape and a fixed difference between the equilibrium distances were used. Only the vertical energy shift between the two curves is assumed to vary (Fig. 2). The relation can already be inferred from this figure on visual inspection. For excitation into curve 1 the excitation energy can be dissipated radiationlessly via the intersection point P. If the excited state moves to higher energies, this does not happen any more for the curves above curve 2. The higher the curve of the excited state, the higher the activation energy  $E_A$ .

It can be shown that a relation of this type exists also for centers with similar electron configuration as the niobates (titanates, molybdates, tungstates). A strict requirement is that the central metal ion is in six-coordination (Table IV). If, however, ions of this type are in four-coordination, the relation is no longer valid (Table IV). There is a tendency toward higher quenching temperatures, if the bonding between the tetrahedral groups becomes stronger. To illustrate this for the tetrahedral tungstate group:  $CaWO_4$  has a higher quenching temperature than  $SrWO_4$  and  $BaWO_4$ ,  $Li_2WO_4$  higher than  $Na_2WO_4$ . More examples are given in ref. (10).

It is remarkable that a relation between the position of the absorption band and the quenching temperature of the fluorescence (and therefore also the quantum efficiency at room temperature) has also

Fig. 2. Illustration of the relation between the position of the absorption (excitation) band and the quenching temperature of the fluorescence. The shape of the excited curve and the difference between the equilibrium distance of the ground and excited state remains fixed.

Table IV. Absorption edge and quenching temperature of the fluorescence of tungstates

Compound	Fluorescent center	Absorption edge, $cm^{-1}$	Quenching temperature, $^{\circ}K$
$\beta$ - $MgWO_4$	$WO_6$	34,200	475
$Ca_2WO_6$	$WO_6$	33,200	300
$Y_2WO_6$	$WO_6$	32,300	240
$Ba_3Gd_3WO_9$	$WO_6$	30,800	100
$CaWO_4$	$WO_4$	40,600	450
$Li_2WO_4$	$WO_4$	35,700	300
$BaWO_4$	$WO_4$	42,500	<100
$Na_2WO_4$	$WO_4$	45,400	<100

been observed for two centers completely different from the niobate group, viz., the  $Eu^{3+}$  center in oxides [in this case the charge-transfer absorption of the center is considered and not the  $4f - 4f$  absorptions (8, 12)] and the  $UO_6$  center (especially in the rocksalt lattice) (13). It seems probable that the explanation in these cases is similar to that for the octahedral niobate fluorescence. The quenching temperature and efficiency of the fluorescence of  $Ce^{3+}$  in oxides, however, can again be related to the size and charge of the cations of the host lattice (14). The fluorescence of  $Bi^{3+}$  was also investigated, but no apparent correlation between efficiency and other properties could be detected (15).

No doubt much more work has still to be done in order to obtain a better understanding of the dependence of the fluorescence efficiency on the host lattice.

#### General Discussion of Energy Transfer

Due to the work of Förster (16) and especially Dexter (17) the process of energy transfer in solids is nowadays reasonably well understood. This section reviews the theory briefly.

Neglecting energy transfer by movement of charge carriers, there remain two different mechanisms for energy transfer from a sensitizer S to an activator A, viz. (i) radiative transfer by emission by S and reabsorption by A, and (ii) nonradiative transfer associated with resonance between absorber (S) and emitter (A).

The probability of radiative transfer depends on how efficiently the A fluorescence is excited by the S emission. It requires a significant overlap of the emission region of S and the absorption region of A and an appreciable intensity of absorption of A. Especially in view of the latter requirement, radiative transfer does not often occur in inorganic systems.

Only two types of nonradiative transfer seem to be of importance, namely, those by electric multipole interactions and those by exchange interaction. The probability of nonradiative energy transfer by electric multipole-multipole interaction ( $P_{SA}^m$ ) is proportional to the reciprocal of the radiative decay time of S ( $\tau_S$ ), the absorption band area of A ( $Q_A$ ), the energy overlap between the emission band of S and the absorption band of A ( $E_{SA}$ ) and the reciprocal of a certain power of the distance between S and A ( $R_{SA}$ ), so that

$$P_{SA}^m \sim \frac{Q_A \cdot E_{SA}}{\tau_S \cdot R_{SA}^n} = g_{SA} \cdot E_{SA} \quad [1]$$

Here  $n = 6$  for electric dipole-dipole interaction and  $n = 8$  for electric dipole-quadrupole interaction. If  $P_{SA} \tau_S = 1$  (i.e., the transfer probability equals the probability of radiative decay), Eq. [1] can be solved for the critical distance  $R_0$ .

In the case of transfer by exchange the probability of nonradiative energy transfer ( $P_{SA}^e$ ) is proportional to  $E_{SA}$  and a function of the wave function overlap of the S and A electrons involved in the exchange interaction ( $f_{SA}$ )

$$P_{SA}^e \sim f_{SA} \cdot E_{SA} \quad [2]$$

$P_{SA}^m$  therefore depends on the optical strength of the transitions involved, whereas  $P_{SA}^e$  does not. Trans-

fer by exchange is restricted to nearest neighbors. Transfer by multipole interactions can be of importance even over distances of 20-30 Å.

From [1] and [2] we see that the probabilities of transfer  $P_{SA}$  for the two processes are determined by two factors, one which they have in common, viz., the energy overlap ( $E_{SA}$ ) and the other indicating the strength of the interaction between S and A (the functions  $f$  or  $g$ ).

In the next sections we shall deal first with phosphors that are excited in the host lattice (this is equivalent with a very high sensitizer concentration). Usually energy travels through the lattice and is finally transferred to the activator (next section). Afterward we shall discuss phosphors with a low sensitizer concentration. Here the sensitizer is an intentionally added foreign ion. We may stress, however, that there is no principal difference in the physical treatment of these two types of sensitized phosphors. The activator concentration of sensitized phosphors is always assumed to be low.

#### Phosphors with Very High Sensitizer Concentration (i.e., Host Lattice Excitation)

For high S and low A concentration one of the two following conditions must be fulfilled to have efficient A fluorescence on excitation into S. (a) The SA transfer takes place over large distances (of the order of magnitude of the separation between the activators in the crystal). Transfer through the host lattice (SS transfer) is not needed in that case. This situation is, however, not often realized in inorganic materials. (b) The SA transfer occurs only over short distances, and excitation of S has to be followed by several SS transfers (transfer through the host lattice) before finally the SA transfer occurs, resulting in the characteristic A fluorescence.

*Transfer through lattice plays no role.*—Let us first consider case (a) or long-distance transfer from S to A. Transfer by exchange interaction can be ruled out here, since transfer of this type is restricted to distances of a few angstrom units. Transfer can take place by multipole interaction which can be efficient for the case of overlapping reasonably allowed electric-dipole transitions. However, radiative transfer can also be expected in such a case. Two examples, where long-distance transfer from S to A occurs, may be mentioned, viz.,  $\text{Li}_3\text{NbO}_4\text{-Cr}$  (S = niobate group; A =  $\text{Cr}^{3+}$ ) and  $\text{EuAl}_3\text{B}_4\text{O}_{12}\text{-Cr}$  (S =  $\text{Eu}^{3+}$ , A =  $\text{Cr}^{3+}$ ).

The niobate emission of  $\text{Li}_3\text{NbO}_4$  (peaking at 370 nm) is quenched by very small amounts of  $\text{Cr}^{3+}$  ions (18). The addition of  $\text{Cr}^{3+}$  to  $\text{Li}_3\text{NbO}_4$  causes a strong absorption band at about 380 nm which is due to a charge-transfer process in the chromium-niobate center. This means that the emission is completely overlapped by this absorption (Fig. 3). Because the optical strength of both bands is strong, nonradiative

Fig. 3. Diffuse reflection spectra of  $\text{Li}_3\text{NbO}_4$  and  $\text{Li}_3\text{NbO}_4\text{-Cr}$  and spectral energy distribution of the emission of  $\text{Li}_3\text{NbO}_4$  (254 nm excitation). For the emission the relative radiant power per constant wavelength interval (I) is plotted in arbitrary units. Note the large overlap of the emission of  $\text{Li}_3\text{NbO}_4$  and the extra absorption of  $\text{Li}_3\text{NbO}_4\text{-Cr}$ .

Fig. 4. Diffuse reflection spectrum (broken line) and spectral energy distribution of the emission of  $\text{EuAl}_3\text{B}_4\text{O}_{12}\text{-Cr}$  (254 nm excitation). Note the large overlap of the  ${}^5\text{D}_0\text{-}{}^7\text{F}_1$  and  ${}^5\text{D}_0\text{-}{}^7\text{F}_2$  emission of the  $\text{Eu}^{3+}$  ion and the  ${}^4\text{A}_2 \rightarrow {}^4\text{T}_2$  absorption of  $\text{Cr}^{3+}$  in the region around 600 nm.

as well as radiative transfer from niobate to  $\text{Cr}^{3+}$  occurs followed by  $\text{Cr}^{3+}$  emission (in the infrared). The same phenomenon occurs for  $\text{CaWO}_4\text{-Cr}$  (18).

The efficient red  $\text{Eu}^{3+}$  emission of  $\text{EuAl}_3\text{B}_4\text{O}_{12}$  is quenched by small amounts of  $\text{Cr}^{3+}$  ions (substituted for  $\text{Al}^{3+}$ ) (19). The exciting energy (e.g., 254 nm radiation) is absorbed mainly by the  $\text{Eu}^{3+}$  centers, but the emission consists, for the greater part, of a broad band and narrow line emission characteristic for  $\text{Cr}^{3+}$ . Since the SS transfer (from  $\text{Eu}^{3+}$  to  $\text{Eu}^{3+}$ ) can be neglected, no energy overlap being present, SA transfer (from  $\text{Eu}^{3+}$  to  $\text{Cr}^{3+}$ ) must be very efficient. Indeed the  $\text{Eu}^{3+}$  emission (mainly at 615 nm) overlaps the  $\text{Cr}^{3+}$  absorption in this compound ( ${}^4\text{A}_2 \rightarrow {}^4\text{T}_2$  absorption band at 590 nm) very well (Fig. 4). The critical distance for this transfer was experimentally determined as 14 Å and estimated theoretically at 17 Å. This is in fact a large distance for energy transfer in inorganic materials. The average Cr-Cr distance is of the same order of magnitude.

*Transfer through lattice plays an important role.*—Usually SA transfer occurs only over short distances. This means that SS transfer must also be involved in order to obtain efficient fluorescence from A. For efficient SS transfer it is necessary that the emission of S overlaps the absorption of S (energy overlap) and that there is a certain interaction between the S centers (either by exchange or by electric multipole interaction).

Although there is no difference in principle in the treatment of transfer through the lattice (SS transfer) and transfer from the lattice to the activator (SA transfer), in practice differences occur due to the fact that in SS transfer we are dealing with identical centers and in SA transfer with different centers. Consider, for example, transfer from a host lattice group (usually a broad band emitter) to a trivalent rare earth ion (usually a weak narrow band absorber). Nearly always the energy overlap condition is fulfilled due to the fact that the broad band emission extends over such a broad spectral region that it overlaps always one or more narrow absorption bands of the rare earth ion. Here the strength of the interaction is often the dominating factor which determines the transfer probability.

We will now illustrate these considerations of energy transfer by some examples. These examples have been selected in such a way that only one or two of the factors influencing the energy transfer processes are varied, whereas the other factors remain constant.

*Concentration quenching (energy overlap condition varied).*—It is possible to obtain information on the efficiency of the transfer through the lattice (SS transfer) from a study of concentration quenching. In this section it will be shown that the efficiency of this transfer is mainly determined by the energy overlap condition ( $E_{SS}$ ). The critical concentration for concentration quenching can be related to the efficiency of the SS transfer.

To explain concentration quenching at room temperature it was assumed by Dexter and Schulman (20) that the main factor in this process is the presence of particular quenching centers ("energy sinks") in the crystal lattice (e.g., imperfections, surface states, or impurities). The absorbed excitation energy is lost radiationlessly at these sinks during the migration through the lattice, so that the critical concentration depends on the probability of the transfer through the lattice: suppose the probability of this transfer is low, then the energy cannot escape to a quenching center and the quantum efficiency is high even at high concentrations (as a matter of fact, thermal quenching can still occur because this is a property of the isolated center). On the other hand, if the probability of the transfer is high, the excitation energy can be lost at an energy sink even for low center concentrations.

This condition for concentration quenching is illustrated by Table II. The energy overlap can be roughly estimated from the Stokes shift of the fluorescence, although of course the width of the bands also plays a role, broad bands having a larger overlap than narrow bands. From Table II we see: (A) The absence of concentration quenching in  $\text{CaWO}_4$  and  $\text{CaNb}_2\text{O}_6$ , where every host lattice group is a center, agrees with the large Stokes shift of the emission. This implies that the overlap of the emission and absorption bands is small. This holds in general for tungstates and niobates (see Fig. 5a). (B) In the system  $\text{YP}_{1-x}\text{V}_x\text{O}_4$  concentration quenching of the vanadate emission occurs for  $x > 0.25$ . The Stokes shift is smaller and  $E_{SS}$  therefore larger than for tungstates and niobates (Fig. 5b). The fluorescence of  $\text{YVO}_4$  is concentration-quenched at room temperature. We have to decrease the concentration of the vanadate groups by nonabsorbing phosphate groups to obtain efficient vanadate emission at room temperature. This means that the average distance between the vanadate groups increases, so that the interaction strength between these groups decreases. Consequently the probability for the vanadate-vanadate transfer becomes lower (see General Discussion of Energy Transfer). (C) Well-known fluorescent centers like  $\text{Bi}^{3+}$ ,  $\text{Ce}^{3+}$ , and  $\text{Eu}^{2+}$  show concentration quenching at still lower concentrations. Due to the smaller Stokes shift of the emission the energy overlap is larger (Fig. 5c). (D) For one and the same activator the Stokes shift may be different. The smaller the Stokes shift, the larger the energy overlap, the higher the transfer probability and the lower the critical concentration for concentration quenching.

This consideration does not take into account the variation of the factors  $f$  and  $g$  in the interaction between the centers. Obviously these factors are not dominating the variation of the transfer probability, although they will explain deviations from the correlation between critical concentration and Stokes shift. For ions like  $\text{Ce}^{3+}$ ,  $\text{Bi}^{3+}$ , or  $\text{Eu}^{2+}$ , for example, the emission and absorption transitions are practically allowed electric dipole transitions, so that the electric dipole-dipole interaction must be strong. For tungstates and niobates, however, this interaction is weaker. It is usually assumed that the interaction in this case is of the exchange type (17).

In general, however, the critical concentration of concentration quenching can be used as a measure of the probability of transfer through the lattice. This transfer probability increases in the sequence: tungstates (or niobates), vanadates,  $\text{Ce}^{3+}$  (or  $\text{Bi}^{3+}$ ,  $\text{Eu}^{2+}$ ). Since energy overlap clearly plays a dominant role in transfer through the host lattice, host lattice emission is only to be expected, if the Stokes shift is large. *Tungstate-molybdate systems (energy overlap conditions varied).*—Also in this example only the energy overlap will be varied. It is a well-known phenomenon that the fluorescence of tungstates at room temperature is quenched by partial replacement of tungsten by

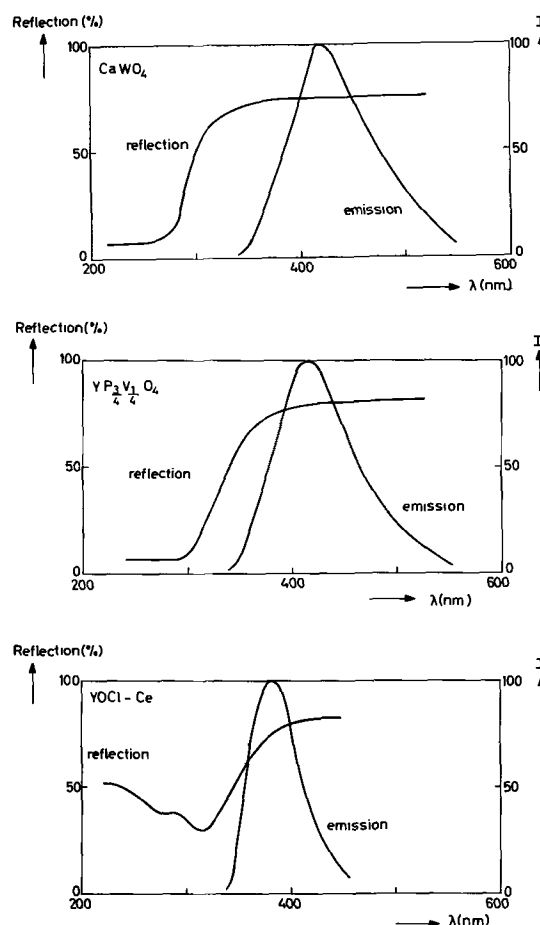

Fig. 5. Diffuse reflection spectra and spectral energy distribution of the emission (254 nm excitation) of a,  $\text{CaWO}_4$ ; b,  $\text{YP}_{0.75}\text{V}_{0.25}\text{O}_4$ ; c,  $\text{YOC1-Ce}$ . The three figures are on the same scale. Note the increase of the overlap of emission and absorption in the sequence a, b, c.

molybdenum (7, 21). At low temperatures mainly molybdenum emission is observed, if the tungstate group is excited. We investigated this phenomenon for the system  $\text{Y}_2\text{W}_{1-x}\text{Mo}_x\text{O}_6$  (22). The probability of energy transfer in this case varies in good approximation only with the energy overlap, since the interaction between tungstate groups and between molybdate groups mutually and between the tungstate and the molybdate group will not be strongly different. The shape of the bands involved being roughly equal, the difference between the position of the absorption edge and the emission band gives a good measure of the energy overlap. For the system  $\text{Y}_2\text{W}_{1-x}\text{Mo}_x\text{O}_6$  these values are given in Table V (compare also Fig. 6). Judging from these values the transfer probability should decrease in the sequence  $\text{WO}_4 \rightarrow \text{MoO}_4$ ,  $\text{WO}_4 \rightarrow \text{WO}_4$ ,  $\text{MoO}_4 \rightarrow \text{MoO}_4$ ,  $\text{MoO}_4 \rightarrow \text{WO}_4$ . An inspection of Fig. 6 even indicates that the two latter transfers have a negligible probability. This explains the experimental results mentioned above. If a tungstate group is excited, the excitation energy will travel through the lattice until a molybdate group is reached,

Table V. Position of the emission band and absorption edge ( $\text{cm}^{-1}$ ) of the molybdate and tungstate group in  $\text{Y}_2\text{W}_{1-x}\text{Mo}_x\text{O}_6$ , in relation to the transfer probability between these groups

Transfer from	Transfer to	Emission band	Absorption edge	Difference
Mo	Mo	14,300	28,600	14,300
W	W	21,300	32,300	11,000
W	Mo	21,300	28,600	7,300
Mo	W	14,300	32,300	18,000

Fig. 6. Diffuse reflection spectra and spectral energy distribution of the emission of the tungstate and molybdate group in  $Y_2WO_6$ -Mo. The molybdate emission is excited by 365 nm, the tungstate emission of undoped  $Y_2WO_6$  by 254 nm. Note the decrease of the overlap of the emission and absorption bands in the sequence  $WO_4 \rightarrow MoO_4$ ,  $WO_4 \rightarrow WO_3$ ,  $MoO_4 \rightarrow MoO_4$ ,  $MoO_4 \rightarrow WO_4$ . The latter two have even a negligible overlap.

to which the excitation energy is transferred. It must be kept in mind that the molybdate emission is thermally quenched at room temperature.

An exception to this behavior is formed by  $Y_2SiW_{1-x}Mo_xO_8$  (23). At liquid nitrogen temperature this compound gives mainly tungstate emission, if the tungstate group is excited, and molybdate emission, if the molybdate group is excited. The positions of the emission and absorption bands in this system are similar to those given in Table V. The reason that no energy transfer occurs in this system must therefore be a vanishing interaction between the centers.  $Y_2SiWO_8$  has the same crystal structure as  $CaWO_4$ , but the  $Si^{4+}$  and  $W^{6+}$  ions occupy the tungstate sites of scheelite ( $CaWO_4$ ) in an ordered way, so that the distance between the tungstate groups in  $Y_2SiWO_8$  is indeed larger than in  $CaWO_4$ . Consequently the interaction strength will be less.

**$Eu^{3+}$ -activated  $Ln_2WO_6$  ( $P_{SS}$  constant,  $P_{SA}$  varied).**—In this section we will deal with systems where  $P_{SS}$  (transfer through the lattice) is constant and where  $P_{SA}$  (lattice to activator transfer) varies. Moreover the energy overlap term  $E_{SA}$  remains constant, so that only the interaction term  $f_{SA}$  is varied. It is an intriguing problem to explain why  $Y_2WO_6$ -Eu is an efficient red phosphor, whereas  $Gd_2WO_6$ -Eu has a medium efficiency (22, 24). First the efficiency of SS transfer should be considered.

Energy can be transferred through the host lattice in both cases, albeit the efficiency of this transfer will not be very high (see above). Since it has been shown that the efficiency of the  $Eu^{3+}$  emission of these tungstates for excitation into the narrow 4f levels of the activator itself is near to 100% (25), the difference between the efficiencies of the  $Eu^{3+}$  emission of  $Y_2WO_6$ -Eu and  $Gd_2WO_6$ -Eu for excitation of the tungstate groups must be ascribed to a difference in the SA (tungstate- $Eu^{3+}$ ) transfer probability. Since the energy overlap condition is fulfilled (the tungstate emission overlaps some  $Eu^{3+}$  levels), this difference must be due to the strength of the interaction. In view of the analogy between both compounds, electric multipole-multipole interaction can be excluded, since that would not depend so strongly on the crystal structure. Estimations indicate in fact that for this case transfer by exchange interaction has an order of magnitude higher probability than transfer by electric multipole interactions (22).

A necessary condition for exchange interaction is that the wavefunctions of the centers involved overlap each other. Therefore this type of energy transfer is comparable to the magnetic interaction between paramagnetic ions in insulators, the so-called superexchange (26). Superexchange is known to be strongly dependent on the angle between the paramagnetic ions and the intermediary oxygen ions. In the ferrites,

for example, the  $Fe^{3+}-O^{2-}-Fe^{3+}$  angle is about  $135^\circ$  giving rise to strong interaction, whereas in  $ZnFe_2O_4$  with  $Fe^{3+}-O^{2-}-Fe^{3+}$  angle  $90^\circ$  the interaction is very weak. In  $Ba_2GdNbO_6$  magnetic superexchange in the configuration  $Gd-O-Nb-O-Gd$  proves a certain 4f electron density on the intermediary niobate group (27). Also in  $GdPO_4$  magnetic interactions between  $Gd^{3+}$  ions using the phosphate group as an intermediary play a role (28). The latter compounds bring us back to rare earth activated oxides. Energy transfer from a tungstate group to  $Eu^{3+}$  by exchange interaction is possible, if also here the 4f electrons of the  $Eu^{3+}$  ion have a certain density at the tungstate group. This means that the angle  $W-O-Eu$  in  $Y_2WO_6$ -Eu and  $Gd_2WO_6$ -Eu ( $Eu^{3+}$  replaces  $Y^{3+}$  and  $Gd^{3+}$ , respectively) will determine the transfer efficiency. For  $Y_2WO_6$  this angle is about  $180^\circ$ ; for  $Gd_2WO_6$  it is about  $90^\circ$ . This then must be the explanation why the SA transfer is much more efficient in  $Y_2WO_6$ -Eu than in  $Gd_2WO_6$ -Eu. For low  $Eu^{3+}$  concentrations (say less than 1%) the efficiency of the  $Eu^{3+}$  emission on excitation into the tungstate group of  $Y_2WO_6$ -Eu is low. This must be ascribed to the relatively low probability of SS transfer (see also below).

The hypothesis that the transfer from lattice to rare earth ion is determined by the angle between the rare earth ion, the oxygen ion, and the cation at the center of the uv absorbing group has been confirmed for many other phosphors (6), e.g.,  $Y_6WO_{12}$ -Eu (low efficiency, angle  $100^\circ$ ),  $YVO_4$ -Eu (high efficiency, angle  $170^\circ$ ) and  $Gd_2Ti_2O_7$ -Eu (low efficiency, angle  $100^\circ$ ).

**The system  $YP_{1-x}V_xO_4$ -Eu ( $P_{SS}$  varied,  $P_{SA}$  constant).**—In the section on concentration quenching it was shown that in the system  $YP_{1-x}V_xO_4$  the probability of vanadate-vanadate transfer decreases by diluting the vanadate groups by nonabsorbing phosphate groups. In the system  $YP_{1-x}V_xO_4$ -Eu,  $P_{SS}$  varies with  $x$  (because the interaction depends on the distance) and  $P_{SA}$  is in first approximation constant. This is the reverse of the situation in the preceding section, where  $P_{SA}$  was varied and  $P_{SS}$  remained constant.

$YVO_4$ -Eu is known to be a very efficient phosphor even for very low  $Eu^{3+}$  concentrations (29). The host lattice emission of  $YVO_4$  is quenched for the greater part at room temperature (30). In the system  $YP_{1-x}V_xO_4$ , however, efficient vanadate fluorescence is observed, which shows concentration quenching for  $x > 0.25$  (6, 31). In this connection it is conspicuous that in the system  $YP_{1-x}V_xO_4$ - $Eu^{3+}$  the quantum efficiency of the  $Eu^{3+}$  emission remains constant in the region  $0.2 < x \leq 1$ , but decreases strongly for lower vanadium content (32). All these facts can be explained from the foregoing.

The low efficiency of the fluorescence of  $YVO_4$  at room temperature is due to concentration quenching. We conclude therefore that  $YVO_4$  is a compound in which the efficiency for transfer through the host lattice is high. This explains, on the one hand, the concentration quenching in this system (efficient transport of excitation energy to killer sites). On the other hand, it explains also the high efficiency of rare earth activated vanadates even for low activator concentration (efficient transport of excitation energy to the activator), because also the conditions for an efficient SA transfer are satisfied: the vanadate emission overlaps some rare earth absorption levels and the  $Y-O-V$  angle is  $\sim 170^\circ$ .

By diluting the vanadium concentration with phosphorus the efficiency of SS transfer will decrease due to the increasing vanadium-vanadium distance. This explains why at a certain critical vanadium concentration the effect of concentration quenching disappears (*viz.*, 25% vanadium). For this concentration the efficiency of SS transfer becomes so low that the excitation energy cannot travel through the lattice over large distances. This means also that we can no longer expect that all of the exciting quanta reach the  $Eu^{3+}$  ions. It is indeed a fact that the concentration region

in the system  $\text{YP}_{1-x}\text{V}_x\text{O}_4\text{-Eu}$  where the  $\text{Eu}^{3+}$  quantum efficiency decreases is the same region in the unactivated system where concentration quenching is absent.

The present considerations are summarized in Table VI. We conclude that the agreement between prediction and experiment is good, albeit qualitative.

*Rare earth activated  $\text{YNbO}_4$  (a quantitative calculation).*—Finally we will treat one special case in a more quantitative way. We will show that the quantum efficiency of the red  $\text{Eu}^{3+}$  emission and the blue niobate emission of  $\text{YNbO}_4\text{-Eu}$  can be calculated, if one assumes that the transfer through the host lattice is restricted on the average to one niobate-niobate step.

In  $\text{YNbO}_4$  the energy transfer through the lattice cannot be efficient due to the poor overlap of the emission and absorption band (see Fig. 7). It is therefore interesting to see how high the efficiencies of rare earth activated  $\text{YNbO}_4$  phosphors are. In Fig. 8 we have plotted the quantum efficiency of the niobate emission and the quantum efficiency of the  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  emission for  $\text{YNbO}_4\text{-Eu}$  and  $\text{YNbO}_4\text{-Tb}$  (32). Note that even for high rare earth concentrations (15%) the niobate emission is not completely quenched. A complication arises from the fact that for such high activator concentrations the occurrence of concentration quenching of the rare earth emission

Fig. 7. Diffuse reflection spectrum and spectral energy distribution of the emission of  $\text{YNbO}_4$  (254 nm excitation).

Fig. 8. Quantum efficiency of the niobate, europium, and terbium emission of phosphors  $\text{Y}_{1-x}\text{Eu}_x\text{NbO}_4$  and  $\text{Y}_{1-x}\text{Tb}_x\text{NbO}_4$  (250-270 nm excitation).

cannot be excluded. The sum of the niobate and rare earth quantum efficiency remains roughly constant for  $\text{YNbO}_4\text{-Eu}$ , but decreases for  $\text{YNbO}_4\text{-Tb}$ . It is therefore concluded that in  $\text{YNbO}_4\text{-Eu}$  the SS transfer is not very efficient, whereas the SA transfer is reasonably efficient. This agrees with the arguments given above, because the energy overlap in the case of the SS transfer is poor (Fig. 7) and the Nb-O-Y angle (of importance for SA transfer) is roughly  $130^\circ$ .

We tried to carry out a more quantitative calculation based on this simple model. Let us assume that the probability of SS transfer in the case of  $\text{YNbO}_4\text{-Eu}$  is 0% and that of SA transfer from the  $\text{NbO}_4$  group to an  $\text{Eu}^{3+}$  ion on the nearest Y-sites is 100% and that of transfer to all other  $\text{Eu}^{3+}$  ions 0%. Each  $\text{NbO}_4$  group has eight nearest Y sites. This means that, if a quantum is absorbed by a niobate group, the probability of niobate emission is  $(1-x)^8$  and the probability of europium emission  $1 - (1-x)^8$ . Here  $x$  is the  $\text{Eu}^{3+}$  concentration as defined by the formula of the sample  $\text{Y}_{1-x}\text{Eu}_x\text{NbO}_4$ . Another possibility is to assume that the SS transfer is not completely negligible and that on the average the excited niobate group transfers its energy to one of the four nearest niobate groups. If the restrictions on the SA transfer remain the same as above, the absorbed excitation quantum can then be transferred to 22 Y-sites (either directly or after one niobate-niobate transfer). The probability of niobate emission is now  $(1-x)^{22}$ . Loss of excitation energy by nonradiative transitions is neglected. For  $\text{Eu}^{3+}$  this has been proved to be correct by excitation into the narrow  $\text{Eu}^{3+}$  levels (25), and for the niobate group this is a good approximation, since the quenching range of the niobate fluorescence is in the region  $400^\circ\text{-}500^\circ\text{K}$  (33).

Table VII compares the results for these two models with the experimental results. To make the comparison easier the experimental quantum efficiencies are corrected in such a way that their sum is taken as 100%. It is seen that the model without SS transfer is too simple. The decrease of the efficiency of the niobate emission with increasing  $\text{Eu}^{3+}$  concentration is not rapid enough. The model which allows for one-step SS transfer gives surprisingly good agreement with the experimental results. For  $x = 0.15$  the theoretical

<sup>b</sup> No SS transfer.

<sup>c</sup> Not more than one SS transfer step allowed.

$\text{Eu}^{3+}$  efficiency is too high. This may be ascribed to concentration quenching.

Although we may conclude that our ideas on transfer from host lattice to rare earth ion are always valid for  $\text{Eu}^{3+}$ ,  $\text{Sm}^{3+}$ ,  $\text{Dy}^{3+}$  (and probably for other ions, but this has not been studied), the results for  $\text{YNbO}_4\text{-Tb}$  cannot be accounted for in such a simple way (34). In  $\text{YNbO}_4\text{-Tb}$  the niobate fluorescence is quenched in a similar way as in  $\text{YNbO}_4\text{-Eu}$ , but the efficiency of the  $\text{Tb}^{3+}$  emission is always very low. This is even more pronounced in, e.g.,  $\text{YVO}_4\text{-Tb}$  and  $\text{Y}_2\text{WO}_6\text{-Tb}$  which do not emit any  $\text{Tb}^{3+}$  fluorescence on host lattice excitation. We have shown that, if the absorption edge of the host lattice moves to shorter wavelengths, the  $\text{Tb}^{3+}$  output becomes higher:  $\text{YNbO}_4\text{-Tb}^{3+}$  shows at least some emission and  $\text{YPO}_4\text{-Tb}^{3+}$  is rather efficient (see Table VIII). Elsewhere we have given a possible explanation for this phenomenon (34, 35): in the case of exchange-regulated energy transfer from S to A the state  $\text{S}^+ + \text{A}^-$  (or  $\text{S}^- + \text{A}^+$ ) must have a much higher energy than the state S (excited) + A. If this is not the case, there is no reason why simultaneously the excited electron should be transferred from S to A and another electron back from A to S. There is no doubt that, e.g., in  $\text{YVO}_4\text{-Tb}$ , the energy of the excited state  $\text{Tb}^{3+}\text{-O}^{2-}\text{-V}^{5+}$  is near to that of the state  $\text{Tb}^{4+}\text{-O}^{2-}\text{-V}^{4+}$  in view of the low fourth ionization potential of terbium (in the ground state the configuration must be  $\text{Tb}^{3+}\text{-O}^{2-}\text{-V}^{5+}$  in view of the white body color of the sample).

#### Low Sensitizer Concentration

The example of  $\text{YP}_{1-x}\text{V}_x\text{O}_4\text{-Eu}$  in the preceding section shows that there is no essential difference between the case of high S concentration (host lattice excitation) and low S concentration (usually called sensitizer excitation). Well-known examples of sensitizers are  $\text{Sb}^{3+}$  (calcium halophosphates!),  $\text{Ce}^{3+}$ , and  $\text{Bi}^{3+}$ . The SS transfer between these ions is expected to be very efficient, since the energy overlap is large and the interaction strong (see above). The critical concentration for concentration quenching is therefore always low (Table II). These sensitizers cannot be used in high concentrations, because then the SS transfer probability would be much larger than the SA transfer probability, so that the energy travels "easily" through the lattice from S to S until a killer site is reached. We illustrate our considerations with some examples taken from a study on transfer from  $\text{Ce}^{3+}$ ,  $\text{Bi}^{3+}$ , and  $\text{Sb}^{3+}$  to  $\text{Sm}^{3+}$ ,  $\text{Eu}^{3+}$ ,  $\text{Tb}^{3+}$ , and  $\text{Dy}^{3+}$  in nonabsorbing yttrium compounds (35).

First we consider phosphors  $\text{YOCl} : \text{Bi}^{3+}$ ,  $\text{Ln}^{3+}$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Tb}, \text{Dy}$ ). The sensitizer  $\text{S} (= \text{Bi}^{3+})$  is the same for all cases, but the activator  $\text{Ln}^{3+}$  is varied, i.e.,  $P_{SS}$  is constant, but  $P_{SA}$  is varied. The efficiency of the  $\text{Ln}^{3+}$  emission for excitation into  $\text{Bi}^{3+}$  decreases in the sequence  $\text{Eu}^{3+}$ ,  $\text{Sm}^{3+}$  and  $\text{Dy}^{3+}$ ,  $\text{Tb}^{3+}$ . This must be ascribed to a variation of the SA transfer probability, since the SS transfer probability is equal for the four cases. It can be shown that the energy overlap of the S emission and A absorption is roughly equal for the four  $\text{Ln}^{3+}$  ions. Therefore the variation of the total transfer efficiency must be ascribed to a

variation of the interaction strength between S and A. For electric multipole interaction the SA transfer probability is expected to increase in the sequence  $\text{Tb}^{3+}$ ,  $\text{Eu}^{3+}$ ,  $\text{Dy}^{3+}$ ,  $\text{Sm}^{3+}$ , because the oscillator strength of the absorption bands in the region of the  $\text{Bi}^{3+}$  emission increases in this sequence. This does not agree with the experimental results. For exchange interaction the SA transfer probability is expected to increase in the sequence  $\text{Tb}^{3+}$ ,  $\text{Dy}^{3+}$ ,  $\text{Sm}^{3+}$ ,  $\text{Eu}^{3+}$ , because the energy necessary to promote an electron from  $\text{O}^{2-}$  to the 4f orbitals of the rare earth ion decreases in this series, i.e., the wave function admixture increases. This again proves that energy transfer from a sensitizer to a rare earth ion occurs generally by exchange interaction.

Now we will compare the efficiency of the  $\text{Eu}^{3+}$ -fluorescence of  $\text{YOCl-Bi}$ ,  $\text{Eu}$  and  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$ ,  $\text{Eu}$  for excitation into the  $\text{Bi}^{3+}$  absorption band. Here the same S and A ions are introduced in different host lattices to study the influence of the host lattice on  $P_{SS}$  and  $P_{SA}$ . Figure 9 shows that the SS transfer probability is much higher in the borate than in the oxychloride due to the larger energy overlap. This is one reason why  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$ ,  $\text{Eu}$  shows a much higher total transfer efficiency from  $\text{Bi}^{3+}$  to  $\text{Eu}^{3+}$  than  $\text{YOCl-Bi}$ ,  $\text{Eu}$ . There is still another reason. The SA transfer in the oxychloride is exchange-regulated (see above) and therefore of medium efficiency. In  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$ ,  $\text{Eu}$ , however, the  $\text{Bi}^{3+}$  emission band overlaps the  $\text{Eu}^{3+}$  charge-transfer band. Both bands have a high oscillator strength, so that efficient transfer by electric multipole interaction can be expected (Fig. 10). This is the second reason why  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$ ,  $\text{Eu}$  has a higher transfer efficiency than  $\text{YOCl-Bi}$ ,  $\text{Eu}$ . This example illustrates how the choice of the host lattice can influence energy transfer efficiencies, because the energy levels are also influenced.

It is remarkable that energy transfer from  $\text{Ce}^{3+}$  to  $\text{Eu}^{3+}$  is absent in many lattices, for example in  $\text{YOCl-Ce}$ ,  $\text{Eu}$ . The interaction between  $\text{Ce}^{3+}$  and  $\text{Eu}^{3+}$  in this case is expected to be of the exchange type, since the broad  $\text{Ce}^{3+}$  emission overlaps several narrow  $\text{Eu}^{3+}$  absorption levels. This absence of energy transfer can

Fig. 9. Excitation spectra (Exc) and spectral energy distribution of the emission (Em) of  $\text{YOCl-Bi}$  and  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$  (254 nm excitation). Note the larger overlap of the two spectra in the case of  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Bi}$ .

Fig. 10. Excitation spectrum of the emission of  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Eu}$  and spectral energy distribution of the emission of  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Eu}$  (254 nm excitation).

also be ascribed to the fact that the state  $Ce^{4+} + Eu^{2+}$  will not have a much higher energy than that of the state  $Ce^{3+}$  (excited) +  $Eu^{3+}$ , so that the probability of exchange-regulated transfer is decreased. As a matter of fact this is not true for  $Ce^{3+}$ ,  $Tb^{3+}$  and  $Ce^{3+}$ ,  $Dy^{3+}$  for which cases energy transfer was observed. In  $LaOCl-Ce, Eu$ , however, the emission of  $Ce^{3+}$  overlaps the charge transfer absorption band of  $Eu^{3+}$  giving rise to strong electric multipole interaction. Indeed transfer from  $Ce^{3+}$  to  $Eu^{3+}$  was observed for this case. The energy overlap for SS transfer is roughly equal for both oxychlorides.

#### Position of Energy Levels

From the previous section on energy transfer it follows that it is important to know how the position of absorption and emission bands is influenced by the host lattice. As a matter of fact this also influences the emission color of the phosphor and its absorption strength at certain wavelengths, important for the use of the phosphors in fluorescent lamps and in phosphor-coated high-pressure mercury vapor discharge lamps. Jørgensen (36) has done much work on the dependence of the position of absorption bands on the surroundings of the absorbing center. In our work we have in general followed his approach. The shift of the charge-transfer absorption band of  $Eu^{3+}$  in oxides was related to the potential field at the site of the  $O^{2-}$  anions (see above). The same can be done for the absorption (and emission) bands of niobates with  $NbO_6$  octahedra. The case of  $Ce^{3+}$  and  $Tb^{3+}$  is more complicated than that of  $Eu^{3+}$ . The shift of the broad band absorption and emission of  $Ce^{3+}$ -activated oxides will be given as an example (14).

The  $Ce^{3+}$  ion has  $4f^1$  configuration. The lowest excited state is the 5d level which is split by the crystal field. The position of the lowest absorption and emission level of the  $Ce^{3+}$  ion in solids is therefore determined by the energy difference  $4f - 5d$  in the solid and by crystal field effects. The energy difference between the 4f and 5d level is strongly influenced by the surroundings: it amounts to  $51,000\text{ cm}^{-1}$  for the free ion,  $48,000\text{ cm}^{-1}$  in fluorides and about  $33,000\text{ cm}^{-1}$  in oxides [nephelauxetic effect (36)]. The influence of crystal-field splitting is shown in Fig. 11, where the energy levels of  $Ce^{3+}$  in  $YAl_3B_4O_{12}$  (trigonal prismatic surroundings) and in  $Y_3Al_5O_{12}$  (distorted cubic surroundings) are given. The emission of the former is situated in the ultraviolet, that of the latter consists of a band in the green and a weaker band in the ultraviolet. Note the exceptional case of  $Y_3Al_5O_{12}-Ce$ : there is also emission from the next to the lowest

Fig. 11. Crystal field effects on the excited 5d level of  $Ce^{3+}$  in solids: a, center of gravity of the 5d level of  $Ce^{3+}$  in  $YAl_3B_4O_{12}$  (the free ion level is at  $51,000\text{ cm}^{-1}$ ); b, crystal field components of the 5d level of  $Ce^{3+}$  in  $YAl_3B_4O_{12}$  (trigonal prismatic coordination); c, center of gravity of the 5d levels of  $Ce^{3+}$  in  $Y_3Al_5O_{12}$ ; d, cubic crystal field components of the 5d level of  $Ce^{3+}$  in  $Y_3Al_5O_{12}$  (lower-symmetrical splittings neglected); e, crystal field components of the 5d level of  $Ce^{3+}$  in  $Y_3Al_5O_{12}$  (distorted cubic coordination). Emission has been observed from the two lower levels.

level; the emission from the lowest level is at extremely long wavelengths (usually  $Ce^{3+}$  emits in the ultraviolet or blue). How important the large crystal field splitting is, becomes clear by replacing  $Al^{3+}$  in  $Y_3Al_5O_{12}-Ce$  by  $Ga^{3+}$ . The crystal field splitting becomes smaller and the absorption and emission shift to the ultraviolet ( $Y_3Al_5O_{12}-Ce$  has a yellow body color, whereas  $Y_3Ga_5O_{12}-Ce$  is nearly white).

#### Acknowledgment

The authors express their sincere thanks to Dr. H. A. Klasens for his interest and constructive criticism during this work.

Manuscript received May 7, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 28.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Alkaline Earth Halophosphate Phosphors Activated by Divalent Europium

F. C. Palilla\* and B. E. O'Reilly

The Bayside Laboratory, research center of  
General Telephone & Electronics Laboratories Incorporated, Bayside, New York

## ABSTRACT

A new class of phosphors is described based on alkaline earth halophosphates possessing spodosite and apatite structures as host matrices for lanthanide ion activators. The materials are presented in terms of the formulations used for their synthesis; these formulations have pronounced effects on efficiency and spectral properties of the final compositions. Divalent europium is the principal activator considered.

The alkaline earth halophosphates were discovered as efficient ultraviolet stimulable luminescent materials in 1942 by McKeag and Ranby (1). Their adoption by the lighting industry in England and the United States for use in fluorescent lamps immediately established them as an important class of compounds (2-5). Since then, these halophosphates have been the subject of intensive theoretical and experimental investigations. An extensive literature has accumulated over the past twenty years which has recently been surveyed, in part, by Johnson (6).

$\text{Ca}_5(\text{PO}_4)_3(\text{Cl}, \text{F}) : \text{Sb}^{3+}, \text{Mn}^{2+}$  remains the principal fluorescent lamp phosphor, but no really useful cathode-ray halophosphate phosphor has been reported previously. This paper describes the preparation of alkaline earth halophosphates activated by divalent europium and the high luminescent response of these materials to both uv and cathode-ray excitation.

Divalent europium, as an activator, has been extensively studied, particularly in fluorite structures. The use of  $\text{Eu}^{2+}$  in such structures was the subject of a recent review by Feofilov (7). Freed and Katcoff (8) and Butement (9) have reported on the fluorescence spectrum of  $\text{Eu}^{2+}$  in the  $\text{EuCl}_2\text{-SrCl}_2$  system, and Reinfeld and Glasner (10) have extended the studies to alkali halide crystals. The structureless emission bands observed are attributed to  $4f \leftarrow 5d$  transitions. This result is confirmed by the sensitivity of the emission to the crystalline environment, as described by Jenkins and McKeag (11) in silicates and by McClure and Kiss (12) in several cubic crystals. More recent work by Palilla *et al.* on alkaline earth aluminates supports this view (13).

Most of the reported investigations utilizing divalent europium as an activator have been concerned with the emission under ultraviolet excitation. Nazarova (14) reported on the blue-violet cathodoluminescence of strontium meta-, pyro-, and orthophosphates activated with  $\text{Eu}^{2+}$ , and Levshin *et al.* (15) described in detail the cathode-ray response of  $\text{Sr}_3(\text{PO}_4)_2 : \text{Eu}$  as a function of excitation conditions.

This paper describes an investigation of the ultraviolet and cathode-ray-excited fluorescence from  $\text{Eu}^{2+}$  in alkaline earth halophosphates as a function of preparation conditions and formulation. In particular, it discusses single, binary and ternary alkaline earth halophosphates, activated by  $\text{Eu}^{2+}$ , which possess both spodosite and apatite structures.

## Experimental

The alkaline earth halophosphates were formulated according to  $w\text{M}_{3(1-x)}(\text{PO}_4)_2 \cdot y\text{M}'_{(1-x)}\text{Cl}_2 : \text{Eu}_x^{2+}$  or, approximately  $w\text{M}_3(\text{PO}_4)_2 \cdot y\text{M}'\text{Cl}_2 : \text{Eu}^{2+}$  where M and M' are Ca, Ba, Sr or combinations of the three, the ratio of  $y$  to  $w$  varied between 1 and 3. The source of the  $\text{M}_{3(1-x)}(\text{PO}_4)_2$  component can be the corre-

sponding orthophosphate itself, the salt  $\text{MHPO}_4$ , or appropriate mixtures of  $\text{MCO}_3 + (\text{NH}_4)_2\text{HPO}_4$ . The activator concentration  $x$  can be between 0.0025 and 0.10 gram-atom per gram atom of the host cation (M + M'). The starting ingredients were mixed and then fired in a molybdenum crucible at temperatures above  $1000^\circ\text{C}$ . The firings were generally performed under a reducing  $\text{H}_2$  atmosphere for several hours. No beneficial effects were observed when the  $\text{Cl}^-$  was completely or partially replaced by other halogens.

The procedures for the measurements of cathodoluminescent response, spectra and CIE color coordinates have been described by Avella *et al.* (16). Measurements of selected phosphors were also performed in 5-in. monochrome cathode-ray tubes fabricated by conventional techniques. To evaluate their potential commercial utility, the phosphors were incorporated in 40-w and 15-w fluorescent lamps fabricated by the usual production procedures.

The spodosite and apatite halophosphates are generally represented by the formulas  $\text{M}_2\text{PO}_4\text{X}$  and  $\text{M}_{10}(\text{PO}_4)_6\text{X}_2$  or  $\text{M}_5(\text{PO}_4)_3\text{X}$  where M = one or more alkaline earth elements and X is a halide other than  $\text{I}^-$ . These formulas can also be written as  $\text{M}_3(\text{PO}_4)_2 \cdot \text{MX}_2$  and  $3\text{M}_3(\text{PO}_4)_2 \cdot \text{MX}_2$ , respectively, corresponding to  $y/w$  ratios of 1/1 and 1/3. The conventional syntheses involve formulations close to the stoichiometric requirements. However, in order to emphasize the significant effect on fluorescence properties of the use of excess halide in the preparations, which corresponds to an initial  $y/w$  ratio of 1/3, the materials described herein will be discussed and presented in terms of their formulation. These formulations are such that the amount of alkaline earth halide used is in excess of that required for the formation of the spodosite or apatite composition, *e.g.*,  $y/w \cong 1$ . The excess halide is subsequently removed by water washing after the reaction at elevated temperatures is completed. Of the compounds so formed, the spodosite compound is obtained only in the case where M and M' = Ca and the preparation temperature is about  $1000^\circ\text{C}$ . In all other cases, *i.e.*, where M or M' is predominantly Ba or Sr, an apatite structure is obtained corresponding to the composition  $3(\text{M}, \text{M}')_3(\text{PO}_4)_2 \cdot (\text{M}, \text{M}')\text{X}_2$ .

## Results and Discussion

In the preparation of the alkaline earth halophosphates, no difficulties were experienced in the incorporation of divalent europium as activator. The substitution of  $\text{Eu}^{2+}$  (ionic radius 1.12Å) for  $\text{Ca}^{2+}$  (0.99Å) and  $\text{Sr}^{2+}$  (1.13Å) is facilitated by the similarity in ionic radii. Indeed, europium shows a tendency to assume the divalent state during substitution for  $\text{Ca}^{2+}$  or  $\text{Sr}^{2+}$  even when the syntheses are performed in air instead of  $\text{H}_2$ . The divalent state of europium is indicated by the band character of the emissions observed and by the absence of narrow emission lines in the

\* Electrochemical Society Active Member.

red spectral region typical of trivalent europium. In the preparation of the  $\text{Ba}^{2+}$  (1.35Å) compounds, divalent europium easily substitutes for this cation despite the large difference in ionic radii when the synthesis is performed in a  $\text{H}_2$  atmosphere. When synthesized in air, the Ba compounds contain both divalent and trivalent europium. This suggests that when the ionic radii are not nearly equal, there is competition between the valence which europium would normally prefer to assume in air and the valence which leads to easy substitution because no charge compensation is required. Attempts were made to prepare the Mg analogs, but the smaller ionic size of  $\text{Mg}^{2+}$  (0.65Å) prevents effective  $\text{Eu}^{2+}$  incorporation. Only when  $\text{Mg}^{2+}$  is part of a binary and ternary system can the  $\text{Eu}^{2+}$  be accommodated by the host matrix.

The alkaline earth phosphates, prepared as above, provide a series of phosphors with predominant emissions in the blue to green spectral regions. In general, when M and M' are the same cation, a narrow-band, symmetrical spectral energy distribution is obtained under cathode-ray excitation with peaks at 454 nm for the Ca compound, 446 nm for the Sr compound, and 447 nm for the Ba compound. These are shown in Fig. 1 together with the spectral distribution from  $\text{ZnS:Ag}$  for comparisons. The bandwidths of these unary  $\text{M} = \text{M}'$  compounds are narrow relative to that of  $\text{ZnS:Ag}$ . Some binary and ternary compounds, instead, yield an unsymmetrical spectrum skewed toward the longer wavelength region. This is especially pronounced for the compound formulated as  $\text{Sr}_3(\text{PO}_4)_2 \cdot 2\text{BaCl}_2:\text{Eu}$  (Fig. 1). The ternary formulation  $\text{Ba}_3(\text{PO}_4)_2 \cdot 2(\text{Ca}_{0.335}\text{Sr}_{0.665})\text{Cl}_2:\text{Eu}$  (Fig. 1) demonstrates a pronounced emission shift to longer wavelengths which sometimes occurs with cationic mixing. The consequences of unsymmetrical distributions and the effects of bandwidths on the color coordinates of the spectral emissions is discussed later.

$\text{Sr}_3(\text{PO}_4)_2 \cdot 2\text{SrCl}_2:\text{Eu}$  was used to illustrate the effect of activator concentration in the alkaline earth halophosphates. Table I presents the cathode-ray response and color coordinates of members of this system as functions of  $\text{Eu}^{2+}$  concentration. Maximum response is obtained with 0.02 gram atom of  $\text{Eu}^{2+}$  per gram atom of  $\text{M} + \text{M}'$ . With increasing  $\text{Eu}^{2+}$  concentration, the x coordinate is essentially unaffected, but the changes in y coordinate indicate a gradual but slight shift in spectral peak position toward longer wavelengths.

To examine the effect of the excess alkaline earth chloride used in the synthesis, several series of phosphors were formulated in which the ratio of  $\text{MCl}_2$  to  $\text{M}_3(\text{PO}_4)_2$  ranged from 1 to 3. The relative cathode-ray and uv performances of representative systems are tabulated in Table II. For cathodoluminescence evaluation, the samples in groups (a) and (b) have been compared with the commercially available, silver-activated zinc sulfide. Under short-uv excitation (2537Å) the samples listed in group (a) are fairly saturated blue-emitting phosphors and have been compared with the standard short uv responsive tin-activated strontium pyrophosphate ( $\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn}$ ). The phosphors of group (b) have broad emissions extending into the green region of the visible spectrum and therefore have been compared with the efficient green-emitting phosphor manganese-activated zinc silicate. The calcium halophosphate samples in group (a) best exemplify the effect of the phosphate-to-halide ratio on  $\text{Eu}^{2+}$  emission intensity. The 1:1 ratio yields an inefficient material which, according to its x-ray spectrum, consists of two major phases,  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCl}_2$  and  $\beta\text{-Ca}_3(\text{PO}_4)_2$ . The 2:1 and 3:1 formulations both yield  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCl}_2$  as the only phase. The products from these formulations are significantly more efficient than the product from the 1:1 formulation. It appears that once the stoichiometric requirements for formation of the apatite structure are satisfied, any additional halide serves to enhance fluxing and leads to more perfect and larger crystallite sizes. Figure 2 presents photomicrographs of the crystallites obtained in the calcium halophosphate series. The effect of excess  $\text{CaCl}_2$  on the particle size is clearly demonstrated.

A series of divalent europium-activated halophosphates were synthesized to examine changes in emission character, under cathode-ray excitation, brought about by cationic mixing. In this series, the phosphors are the result of the formulation  $\text{M}_3(\text{PO}_4)_2 \cdot 2\text{M}'\text{Cl}_2:\text{Eu}(0.02)$  where M is either strontium, calcium, or barium and where M' can be the same as M or a combination of any two alkaline earths. It was found that the most saturated emissions are obtained when M' is identical with M and when Ba is not a major component of either M or M'. When M' represents Ba or a cationic combination that includes Ba, desaturation of the blue emission color takes place. These findings are

Table II. Effect of excess halide on performance characteristics

Composition	Relative luminosity	
	Cathode-ray excitation	Ultraviolet excitation
(a)	( $\text{ZnS:Ag} = 100$ )	( $\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn} = 100$ )

Fig. 2. Crystallite size vs. ratio of phosphate to halide used in formulation.

presented in graphic form in Fig. 3 to 5 in terms of the computed C.I.E. color coordinates of the emissions.

Thus, the formulations which contain Ba as part of a binary or ternary system appear less satisfactory as replacements for ZnS:Ag in television applications than those formulations which do not contain Ba. Although the desaturation which occurs with Ba is accompanied by an increase in luminosity, the requirement for increased efficiency as desaturation proceeds, in order to maintain color balance with the red and green primaries, increases at a faster rate than the luminosity increase (17). In addition, the loss in color gamut obtainable in combination with the red and green primaries is relatively great.

The saturated emissions from the unary compounds ( $M = M'$ ) and from the Ca-Sr binaries are acceptable. These compounds all have color coordinates close to those of the ZnS:Ag primary ( $x = 0.145, y = 0.052$ ). Indeed, the strontium unary compound has a lower  $y$  ( $x = 0.152, y = 0.032$ ) so that the output from this more saturated emission need only be about 70% of that of the sulfide to perform as well in color balancing; in addition, its use would result in an increase of about 11% in color area when combined with the currently used green and red primaries (18).

These latter materials now yield 30% or more of the levels of efficiency attainable in conventional shadow mask tubes, and for this reason the emission intensities are compared in this paper with ZnS:Ag under cathode-ray excitation at low current densities.<sup>1</sup> However, with increasing current densities, the efficiency of these materials remains unchanged, while the efficiency of ZnS:Ag decreases drastically.

Figure 3 presents the chromaticity data obtained for the strontium halophosphate group of phosphors. It may be noted, particularly in 3a and 3b, that the  $x$  coordinate remains relatively constant while the  $y$  coordinate changes as a function of composition. Figure

<sup>1</sup> The results reported herein were taken at 10 kv and at about  $0.5 \mu\text{a}/\text{cm}^2$ .

Fig. 3. Color coordinates from  $\text{Sr}_3(\text{PO}_4)_2 \cdot X \cdot \text{Eu}(0.02)$  where (a) (top)  $X = 2(\text{Ca}_{1-z}\text{Sr}_z)\text{Cl}_2$ , (b) (center)  $X = 2(\text{Ba}_{1-z}\text{Sr}_z)\text{Cl}_2$ , and (c) (bottom)  $X = 2(\text{Ba}_{1-z}\text{Ca}_z)\text{Cl}_2$ .

4 presents the corresponding data for the calcium analogs. This figure shows that in the phosphor group  $\text{Ca}_3(\text{PO}_4)_2 \cdot M'\text{Cl}_2 \cdot \text{Eu}(0.02)$ , the compositions where  $M'$  corresponds to a single alkaline earth halide have  $y$  coordinates which bracket those of compositions where the alkaline earth halide is mixed. This was generally true with the strontium compounds with one exception (Fig. 3c). Here again the unary compound ( $M = M'$ ) yields the most saturated phosphor of the group. In Fig. 5, the data for the barium analogs are presented. In contrast to the calcium and strontium series, the barium analogs give color coordinates which are unpredictable functions of cationic formulation. The only similarity to the previous series remains the greater saturation of the emission when  $M$  and  $M'$  are the same, in this case Ba. A possible explanation for this behavior, and for the one exception noted in Fig. 3c, may lie in the nature of the formation of the various apatites. The  $M_3(\text{PO}_4)_2$  component of the formulations described herein represents the larger part of the resulting phosphor  $(M, M')_5(\text{PO}_4)_3\text{Cl} \cdot \text{Eu}$ . Nonetheless, complex reactions are undoubtedly taking place during the formation of the final product from the halide and phosphate ingredients. These involve the ease of formation of the calcium, strontium, and barium apatites, the source of these cations, the variable effects on cell

Fig. 4. Color coordinates from  $\text{Ca}_3(\text{PO}_4)_2 \cdot X:\text{Eu}(0.02)$  where (a) (top)  $X = 2(\text{Ca}_{1-z}\text{Sr}_z)\text{Cl}_2$ , (b) (center)  $X = 2(\text{Ba}_{1-z}\text{Sr}_z)\text{Cl}_2$ , and (c) (bottom)  $X = 2(\text{Ba}_{1-z}\text{Ca}_z)\text{Cl}_2$ .

dimensions with cationic species (19), and the degree to which each cation can accommodate the  $\text{Eu}^{2+}$ .

In order to clarify some of these factors, additional series of materials were prepared in which the amount of alkaline earth cation available from the halide component was equal to that available from the phosphate component of the formulation. In this way, it was found analytically that, in the formation of the final composition, preferential incorporation of the alkaline earth cation increased in the order barium, strontium and calcium. In these series, the ratio of  $\text{M}_3(\text{PO}_4)_2$  to  $\text{M}'\text{Cl}_2$  was 1/3. The europium concentration was formulated at 0.02 gram atom per gram atom of alkaline earth.<sup>2</sup> The cathode-ray brightness and color coordinates from these products follow the general trends which had been observed with the 1/2 formulations. Table III presents the formulations and the ratio of alkaline earth constituents analytically found in the final compositions.

From the  $\text{Ba}_3(\text{PO}_4)_2 \cdot \text{M}'\text{Cl}_2$  series it becomes obvious that, when the halide does not contain  $\text{BaCl}_2$ , the barium from the phosphate component is preferentially displaced by calcium and/or strontium. Even where  $\text{BaCl}_2$  is a constituent of the halide component, calcium and/or strontium are again incorporated into the final product to greater extent than the barium.

<sup>2</sup> The  $\text{Eu}^{2+}$  concentrations in the final products were found to reflect differences in the equilibrium distribution between the halophosphate formed and the excess halide subsequently removed. The final  $\text{Eu}^{2+}$  concentration in the unary Sr compounds was close to 0.02 indicating a 1:1 distribution while the  $\text{Eu}^{2+}$  concentrations in the unary Ca and Ba compounds were close to 0.01 and 0.03, respectively. The binary and ternary compositions contained intermediate concentrations. These variations in final  $\text{Eu}^{2+}$  concentrations would have little effect on emission efficiencies and colors (see Table I).

Fig. 5. Color coordinates from  $\text{Ba}_3(\text{PO}_4)_2 \cdot X:\text{Eu}(0.02)$  where (a) (top)  $X = 2(\text{Ba}_{1-z}\text{Sr}_z)\text{Cl}_2$ , (b) (center)  $X = 2(\text{Ca}_{1-z}\text{Sr}_z)\text{Cl}_2$ , (c) (bottom)  $X = 2(\text{Ba}_{1-z}\text{Ca}_z)\text{Cl}_2$ .

In the  $\text{M}_3(\text{PO}_4)_2 \cdot \text{M}'\text{Cl}_2$  series in which  $\text{M} = \text{Ca}$  or  $\text{Sr}$ , where the entire halide is  $\text{BaCl}_2$ , an additional two moles of the barium are not incorporated with the three moles of calcium or strontium from the phosphate component to give a final composition of  $(\text{M}_3\text{Ba}_2)(\text{PO}_4)_3\text{Cl}$ , where  $\text{M} = \text{Ca}$  or  $\text{Sr}$ . Instead, a smaller proportion of the  $\text{BaCl}_2$  component is utilized

Fig. 6. Color coordinates from  $\text{Sr}_3(\text{PO}_4)_2 \cdot X \cdot \text{Eu}(0.02)$  where  $X = 3(\text{Sr}_{1-z}\text{Mg}_z)\text{Cl}_2$ .

to yield a final product in which the Ca (or Sr) to Ba ratio is greater than 3/2.

To a lesser extent, calcium is more easily accommodated in the final product than is strontium. Therefore, from the formulations  $\text{Sr}_3(\text{PO}_4)_2 \cdot 3\text{CaCl}_2$  and  $\text{Ca}_3(\text{PO}_4)_2 \cdot 3\text{SrCl}_2$ , products result which are close to  $(\text{Ca}_3\text{Sr}_2)(\text{PO}_4)_3\text{Cl}$ . Also, in those series in which  $\text{Ca}_3(\text{PO}_4)_2$  or  $\text{Sr}_3(\text{PO}_4)_2$  are reacted with both  $\text{CaCl}_2$  and  $\text{SrCl}_2$  as the halides, the calcium is preferentially utilized in the formation of the final product.

A detailed examination of all these complex interactions is beyond the scope of this paper. The results are included here to illustrate the various effects on emission characteristics. In general, while the effects on emission colors are reasonably predictable when only calcium and strontium are involved, the predictability is considerably reduced when barium is a constituent of a binary or ternary combination.

It has been mentioned previously that the formulation in which M and M' are both Mg results in an inefficient luminescent product. However, Mg may be a constituent in a binary or ternary system. A series of compounds formulated according to  $\text{Sr}_3(\text{PO}_4)_2 \cdot M'\text{Cl}_2 \cdot \text{Eu}(0.02)$  was prepared in which Mg was a constituent of the halide component. The chromaticity relationships among the products so obtained are given in Fig. 6. The behavior here resembles that of the Ca-Sr binary systems.

Selected members of the described families of phosphors were prepared with rare earth ions other than  $\text{Eu}^{2+}$  as activators. It was found that holmium did not yield noticeable luminescence, and thulium, erbium, samarium, gadolinium, and praseodymium were inefficient. However, the luminescence from dysprosium, ytterbium, cerium, and terbium under cathode-ray excitation was found to be within a useful range. The dysprosium and terbium emissions are typical of the trivalent species and yield line emissions in the yellow and green spectral regions, respectively. The emission from  $\text{Ce}^{3+}$  consists of two broad emissions in the blue and uv spectral regions. Ytterbium yields a band emission in the yellow spectral region which is attributable to its divalent state. The ytterbium is particularly interesting because the transitions probably involve valence electrons and therefore its emission, like that of  $\text{Eu}^{2+}$ , should also be sensitive to structural changes. Table IV summarizes the relative brightness and emission colors from  $\text{Sr}_3(\text{PO}_4)_2 \cdot 2\text{CaCl}_2$  formulations activated by the more effective rare earth ions.

Table IV. Emission properties of rare earth ions in the Sr-Ca binary

$\text{Sr}_{2.97}(\text{PO}_4)_2 \cdot 2\text{Ca}_{0.99}\text{Cl}_2 \cdot \text{A}_{0.01}$	Relative luminosity	Color
A		
$\text{Eu}^{2+}$	100.0	Blue
$\text{Dy}^{3+}$	97.0	Off-white
$\text{Yb}^{2+}$	33.0	Yellow
$\text{Ce}^{3+}$	11.0	Blue*
$\text{Tb}^{3+}$	33.0	Green

\*  $\text{Ce}^{3+}$  also exhibits a broad emission in the uv region.

It had been mentioned earlier that from formulations where  $M = M' = \text{Ca}^{2+}$ , a chlorospodiosite structure results when the synthesis is carried out at about  $1000^\circ\text{C}$ . The product here corresponds to  $\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCl}_2 \cdot \text{Eu}$ . The emission of this compound is slightly more saturated than that of the chlorapatite  $3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{CaCl}_2 \cdot \text{Eu}$ . The calculated color coordinates for the former are  $x = 0.147$ ,  $y = 0.046$ , and  $x = 0.144$ ,  $y = 0.053$  for the latter. The efficiencies are, however, comparable.

So far this paper has been concerned principally with the performance of these phosphors under cathode-ray excitation. The materials also respond efficiently to ultraviolet excitation. Figure 7 presents the excitation spectra of the phosphors whose emission curves are given in Fig. 1. The excitation curves are all characterized by a peak at 375 nm, attributable to effective absorption by  $\text{Eu}^{2+}$ . However, the curves are also unusually broad, indicating appreciable response throughout the entire uv region. Consequently, the utility of these materials in light applications is suggested. Figure 8 presents the excitation spectra of the spodiosite composition and, for comparison, a commercial halophosphate.

Several of the phosphors were tested in 15w fluorescent lamps and compared with a standard commercial phosphor  $\text{Sr}_2\text{P}_2\text{O}_7 \cdot \text{Sn}$  used for blue color correction. The comparison is presented in Table V. The Ba-Sr

Fig. 8. Excitation spectra of calcium chlorospodiosite activated by divalent europium, and comparison with commercial  $(\text{Ca,Cd})(\text{PO}_4)_3(\text{F,Cl})\text{:Sb,Mn}$  for the Sb (465 nm) and Mn (574 nm) emissions.

Table V. Lamp performance of some alkaline earth halophosphates activated by  $\text{Eu}^{2+}$ 

Composition	Brightness in lumens			
	Initial	100 hr	500 hr	1700 hr
$\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn}$ (Standard)	1477	1361	1300	1240
$\text{Ba}_{2.97}(\text{PO}_4)_2 \cdot 2\text{Sr}_{0.99}\text{Cl}_2:\text{Eu}^{2+0.01}$	1510	1461	1404	1290
$\text{Sr}_{2.94}(\text{PO}_4)_2 \cdot 2\text{Sr}_{0.9}\text{Cl}_2:\text{Eu}^{2+0.02}$	499	478	472	449
$\text{Sr}_{2.91}(\text{PO}_4)_2 \cdot 2\text{Ca}_{0.97}\text{Cl}_2:\text{Eu}^{2+0.03}$	915	878	869	830

binary is equivalent in emission color to that from  $\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn}$  and its lumen output compares favorably with that from  $\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn}$ . The unary Sr compounds and the Ca-Sr binary are less bright than  $\text{Sr}_2\text{P}_2\text{O}_7:\text{Sn}$ , but are more saturated in color. The same considerations apply here as in color television with regard to combining light of various colors to give a derived color. Therefore, a more saturated blue need not be as efficient as a less saturated blue to effect proper color balance. For this reason the  $\text{Sr}_{2.91}(\text{PO}_4)_2 \cdot 2\text{Ca}_{0.97}\text{Cl}_2:\text{Eu}^{2+0.03}$  sample of Table V, in effect, would probably be more useful than the Ba-Sr sample listed. The three phosphors listed in Table V show exceptional maintenance characteristics (rate of decrease of emission intensity with operational lifetime).

#### Acknowledgments

The authors wish to thank D. Bracco for his encouragement in this work, G. Gashurov for helpful discussions on structural details, C. Wiggins for the spectral data, W. Shelby for chemical analyses, and K. Butler of Sylvania Lighting Products Division for lamp evaluations. The authors also appreciate the critical review of this manuscript by S. Natansohn, F. Avella, and R. Amster.

Manuscript submitted April 19, 1968; revised manuscript received June 12, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Crystal Growth and Electrical Properties of Potassium-Strontium and Potassium-Lead Niobates Containing Lanthanum

D. F. O'Kane, G. Burns, B. A. Scott, and E. A. Giess

IBM Watson Research Center, Yorktown Heights, New York

#### ABSTRACT

Crystal growth conditions are described for compositions from the  $\text{KNbO}_3\text{-SrNb}_2\text{O}_6\text{-LaNb}_3\text{O}_9$  and  $\text{KNbO}_3\text{-PbNb}_2\text{O}_6\text{-LaNb}_3\text{O}_9$  ternary systems. Typical compositions examined were the tetragonal tungsten bronze structures of  $(\text{KNbO}_3)_{45}(\text{SrNb}_2\text{O}_6)_{55}$  containing 3, 6, 9, and 18 w/o (weight per cent)  $\text{LaNb}_3\text{O}_9$ ,  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$  with 3 w/o  $\text{LaNb}_3\text{O}_9$ , and  $(\text{KPb}_2\text{Nb}_5\text{O}_{15})_x\text{-}(\text{K}_2\text{LaNb}_5\text{O}_{15})_{1-x}$  where  $x = 0.4$  and  $0.6$ . The dielectric constant has been determined as a function of temperature for each composition.

We were interested in examining one method of altering the temperature dependence of the dielectric constant,  $\epsilon$ , of ferroelectric compositions with high dielectric and electrooptic constants. The dielectric constant is directly proportional to the electrooptic coefficient,  $r$  (1-3). Therefore, by broadening the peak in the  $\epsilon$  vs. temperature curve, it should be possible to raise  $r$  and also reduce the temperature sensitivity of  $r$ .

It has been reported that  $\text{La}_2\text{O}_3$  caused a lowering of the Curie temperature and a broadening of the peak in the  $\epsilon$  vs. temperature curve for ceramic compositions from the  $\text{Pb}_x\text{Ba}_{1-x}\text{Nb}_2\text{O}_6$  system (4). We studied the effect of lanthanum on the dielectric properties of the

tungsten bronze structures from the binary systems of  $\text{KNbO}_3\text{-SrNb}_2\text{O}_6$  and  $\text{KNbO}_3\text{-PbNb}_2\text{O}_6$ . Compositions from these binary systems were selected on the basis of their high room temperature dielectric constants and the large electrooptic coefficient reported for the composition  $\text{KSr}_2\text{Nb}_5\text{O}_{15}$  (5) from the  $\text{KNbO}_3\text{-SrNb}_2\text{O}_6$  binary system. The space group of  $\text{KSr}_2\text{Nb}_5\text{O}_{15}$  is probably  $\text{C}^{2}_{4v}\text{-P4bm}$  (6).

Lanthanum has an ionic radius larger than other rare earths and close to the radii of potassium, strontium, and lead. The niobate form was selected since  $\text{LaNb}_3\text{O}_9$  has a tetragonal structure (7) and could be expected in low concentrations to form a solid solution with

$\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$  compositions and  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$ . The composition  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  was also used for the La addition since it has a tetragonal bronze structure (8) and also could be expected to form a solid solution with  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$ .

Figures 1 and 2 show the ternary diagrams which are composed of the binary systems:  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$ ,  $\text{KNbO}_3$ - $\text{LaNb}_3\text{O}_9$ ;  $\text{SrNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$ ; and  $\text{KNbO}_3$ - $\text{PbNb}_2\text{O}_6$ . The phase diagram for the  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$  system has been reported (6) to have a single-phase tetragonal bronze-type structure between 25 and 65 m/o (mole per cent)  $\text{KNbO}_3$ . The maximum melting composition occurs near 33%  $\text{KNbO}_3$ . In the  $\text{KNbO}_3$ - $\text{LaNb}_3\text{O}_9$  system, the composition  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  has been reported (8) to be a tetragonal tungsten bronze-type structure. No other data are available. In the  $\text{SrNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$  system there are no data. The  $\text{KNbO}_3$ - $\text{PbNb}_2\text{O}_6$  system has been examined (9);  $\text{KNbO}_3$  is soluble in  $\text{PbNb}_2\text{O}_6$  up to at least 50 m/o. The orthorhombic tungsten bronze  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$  is contained in this region of solid solution.

### Experimental Procedures

The starting materials used were  $\text{PbO}$ ,  $\text{K}_2\text{CO}_3$ ,  $\text{SrCO}_3$ ,  $\text{Nb}_2\text{O}_5$  from the Johnson-Matthey Company, Grade I, with 10 ppm impurities, except for  $\text{Nb}_2\text{O}_5$  which contained less than 0.03 w/o Ta and  $\text{La}_2\text{O}_3$  (Linsay chemical, 99.997%). Differential thermal analysis was used to establish the freezing points of the various compositions. Two-gram powder samples of the various compositions were prepared by annealing about  $200^\circ\text{C}$  below the melting point. The reacted powders were loaded in platinum capsules containing a thermocouple well in the bottom. The sample and

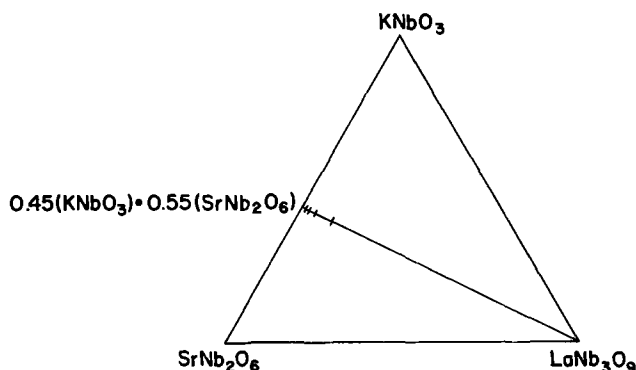

Fig. 1.  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$  ternary system. Crystals were grown at the compositions indicated.

Fig. 2.  $\text{KNbO}_3$ - $\text{PbNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$  ternary system. Crystals were grown at compositions indicated by  $x$ .

alumina reference material were heated and cooled at  $5^\circ\text{C}/\text{min}$ .

Each composition was prepared by heating stoichiometric quantities of the starting materials to  $1350$ - $1500^\circ\text{C}$  in a 100 cc platinum crucible. A Czochralski type crystal puller, Fig. 3, was used to obtain single crystals. A 23 kw RF generator supplied power to melt the charge in the platinum crucible. The output from the Pt-Pt, 10% Rh thermocouple under the platinum crucible was filtered to remove the RF pick-up before entering a L&N C.A.T. controller. Oxygen was passed into the system at 0.3 l/min to avoid reduction of the crystals and the resulting discoloration. Crystal growth was started with a seed crystal mounted on a shaft. Pull rates were approximately 10 mm/hr. The system was usually cooled at  $5^\circ\text{C}/\text{hr}$  to  $300^\circ\text{C}$  below the melting point and then at  $15^\circ\text{C}/\text{hr}$  to room temperature by moving the set-point potentiometer of the controller with a synchronous motor and gear train. In many cases, crystals were obtained from the frozen melt in addition to the pulled material. Crystals containing  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$  had a tendency to grow along the  $c$ -axis in the crystal puller. During the growth of these compositions, the crystals were very sensitive to small changes in the melt temperature and to the temperature gradient above the melt surface. Compositions containing lead were the most volatile above their melting points. However, vapor loss was not a serious problem.

Crystal growth of  $0.45 \text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6$  is more difficult than  $\text{KSr}_2\text{Nb}_5\text{O}_{15}$  which is to be expected since the phase diagram shows a larger difference in the melt and solid compositions at  $0.45 \text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6$ . Slower growth rates are required to maintain equilibrium conditions.  $\text{KSr}_2\text{Nb}_5\text{O}_{15}$  would have been a better choice for the  $\text{LaNb}_3\text{O}_9$  doping since it is closer to the maximum melting point in the  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$  diagram and the melt composition is almost the same composition as the crystals pulled from the melt. However, this information was not known when the  $\text{LaNb}_3\text{O}_9$  doping was started. Single crystals of  $0.45 \text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6$  containing 3, 6, 9, and 18 w/o  $\text{LaNb}_3\text{O}_9$  for x-ray and dielectric measurements were grown by slowly cooling 400g melts of each composition in a platinum crucible.

Single crystals of  $x \text{KPb}_2\text{Nb}_5\text{O}_{15} \cdot (1-x) \text{K}_2\text{LaNb}_5\text{O}_{15}$ , where  $x = 0.4, 0.6$ , were grown after x-ray analyses indicated that the tetragonal tungsten bronze structure of  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  is retained when  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$  is added in concentrations up to 60 m/o. The composition  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$  with 3 w/o  $\text{LaNb}_3\text{O}_9$  was one of the easiest single crystals to grow from the melt. However,

Fig. 3. Crystal puller.

Table I. Freezing points of some ternary compositions

Compositions	Temp. °C
(KNbO <sub>3</sub> ) <sub>45</sub> (SrNb <sub>2</sub> O <sub>6</sub> ) <sub>55</sub>	1460
(KNbO <sub>3</sub> ) <sub>45</sub> (SrNb <sub>2</sub> O <sub>6</sub> ) <sub>55</sub> with 18 w/o LaNb <sub>3</sub> O <sub>9</sub>	1480
KPb <sub>2</sub> Nb <sub>5</sub> O <sub>15</sub>	1325
(KPb <sub>2</sub> Nb <sub>5</sub> O <sub>15</sub> ) <sub>60</sub> (K <sub>2</sub> LaNb <sub>5</sub> O <sub>15</sub> ) <sub>40</sub>	1405
(KPb <sub>2</sub> Nb <sub>5</sub> O <sub>15</sub> ) <sub>40</sub> (K <sub>2</sub> LaNb <sub>5</sub> O <sub>15</sub> ) <sub>60</sub>	1432
K <sub>2</sub> LaNb <sub>5</sub> O <sub>15</sub>	1441

the material had a tendency to crack during cooling and lead oxide was lost from the melt during growth.

The KNbO<sub>3</sub>-SrNb<sub>2</sub>O<sub>6</sub> compositions were easily poled by applying an electric field of 20,000 v/cm along the c-axis at room temperature. Hysteresis loops can be observed even at room temperature. The crystals containing KPb<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub> had an electric field of 20,000 v/cm applied along the a-axis while slowly cooling through the ferroelectric transition temperature. Hysteresis loops were not observed for these compositions.

The small signal dielectric constants were measured on poled, oriented, single crystals at 10<sup>4</sup> Hz. The temperature was measured continuously from room temperature to a point above the Curie temperature with various applied electric fields.

### Results

The crystal compositions investigated, (KNbO<sub>3</sub>)<sub>45</sub>-(SrNb<sub>2</sub>O<sub>6</sub>)<sub>55</sub> with 3, 6, 9, and 18 w/o LaNb<sub>3</sub>O<sub>9</sub>, KPb<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub> with 3 w/o LaNb<sub>3</sub>O<sub>9</sub>, and  $x$  KPb<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub> · (1 -  $x$ ) K<sub>2</sub>LaNb<sub>5</sub>O<sub>15</sub>, where  $x = 0.4$  and  $0.6$ , are shown as they appear in the respective ternary systems in Fig. 1 and 2. Single crystals of each of these compositions were obtained either by pulling or by slowly cooling a 400g melt. The compositions containing lead were more easily pulled in single crystalline form although they often cracked near 500°C during the slow cooling cycle. Freezing point data are contained in Table I.

Attempts to grow single crystals of K<sub>2</sub>LaNb<sub>5</sub>O<sub>15</sub> (mp 1441°C) were not successful; two liquid phases were present. On freezing, two phases were found with tetragonal bronze structures. The predominant phase had lattice parameters of  $a_0 = 12.58\text{Å}$  and  $c_0 = 3.930\text{Å}$  and the small amount of second phase (< 5%) had  $a_0 = 12.59\text{Å}$  and  $c_0 = 3.985\text{Å}$ . These data are different from the values of  $a_0 = 17.70\text{Å}$  and  $c_0 = 7.82\text{Å}$  reported for a ceramic sample by Krainik (8), who used a different unit cell which is equivalent to  $a_0 = 12.52\text{Å}$  and  $c_0 = 3.91\text{Å}$ . The two cells differ by factors of  $\sqrt{2}$  in the  $a_0$  direction and 2 in the  $c_0$  direction. Chemical analyses showed that the predominant phase corresponded closely to the starting composition. The second phase had approximately 0.1 w/o La and  $12.4 \pm 0.4$  w/o K. This suggested that the second phase may be from the K<sub>2</sub>O-Nb<sub>2</sub>O<sub>5</sub> phase diagram. Assuming this to be the case, 12.4 w/o K corresponds to (K<sub>2</sub>O)<sub>33</sub>(Nb<sub>2</sub>O<sub>5</sub>)<sub>67</sub> or K<sub>2</sub>Nb<sub>4</sub>O<sub>11</sub>. The phase diagram reported by Reisman (10) shows compounds at 25, 40, and 50 m/o K<sub>2</sub>O. The 25 and 40 m/o compositions would con-

tain 8.77 and 15.86 w/o K, respectively. The analytical result for the second phase is midway between these two values. The structure of the (K<sub>2</sub>O)<sub>40</sub>(Nb<sub>2</sub>O<sub>5</sub>)<sub>60</sub> is tetragonal bronze type (11) with  $a_0 = 12.525\text{Å}$  and  $c_0 = 3.763\text{Å}$ . However, there are significant differences between this structure and the second phase material in the x-ray patterns. It is not known what effect small concentrations of La (about 0.1 w/o) have on K<sub>2</sub>O-Nb<sub>2</sub>O<sub>5</sub> compositions.

The effects of the LaNb<sub>3</sub>O<sub>9</sub> addition on the lattice parameters of 0.45 KNbO<sub>3</sub> · 0.55 SrNb<sub>2</sub>O<sub>6</sub> are shown in Table II. The  $c_0$  parameter is lowered from 3.941Å to 3.919Å by 9 w/o LaNb<sub>3</sub>O<sub>9</sub>. No change is observed between the 9 and 18 w/o LaNb<sub>3</sub>O<sub>9</sub>.

The structural effects of the LaNb<sub>3</sub>O<sub>9</sub> can be examined by considering the cation sites available in 0.45 KNbO<sub>3</sub> · 0.55 SrNb<sub>2</sub>O<sub>6</sub>. There are 10 possible cation (A<sup>+</sup>, A<sup>2+</sup>) sites available in the tungsten bronze-type structure. These are: two  $\alpha$  sites which have 12 oxygen ions coordinating the site; four  $\beta$  sites with 15 oxygen ions; and four  $\gamma$  sites with 9 oxygen ions. Giess *et al.* (6) have discussed the atomic distributions in compositions from the KNbO<sub>3</sub>-SrNb<sub>2</sub>O<sub>6</sub> system. In the 0.45 KNbO<sub>3</sub> · 0.55 SrNb<sub>2</sub>O<sub>6</sub> composition, the  $\alpha$  and  $\beta$  sites probably are filled along with 0.45 of the four  $\gamma$  sites. As LaNb<sub>3</sub>O<sub>9</sub> is added to the structure, the  $\gamma$  sites probably become vacant at a concentration of 15.1 w/o or 8.26 m/o.

Giess *et al.* (6) have reported on the lattice parameters for  $x$  KNbO<sub>3</sub> · (1 -  $x$ ) SrNb<sub>2</sub>O<sub>6</sub> between  $x = 0.65$  and  $0.25$ . The  $c_0$  parameter decreases from 3.952 to 3.936Å as the SrNb<sub>2</sub>O<sub>6</sub> concentration is increased. The largest observed value of  $c_0$  (3.952Å) occurs at  $x = 0.65$  and may correspond to completely filled  $\alpha$  and  $\beta$  sites and to 1.4 of the four  $\gamma$  sites being filled. At  $x = 0.33$ , KSr<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub>, the  $\gamma$  sites are thought to be empty; further decreases in  $x$  could cause an emptying of the  $\alpha$  or  $\beta$  sites. This decrease in the  $c_0$  parameter with the reduction in the number of occupied  $\gamma$  sites may be similar to that obtained by LaNb<sub>3</sub>O<sub>9</sub> additions to 0.45 KNbO<sub>3</sub> · 0.55 SrNb<sub>2</sub>O<sub>6</sub>.

A large electrooptic coefficient is usually associated with a large dielectric constant (1-3). This is true for KSr<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub> [0.33 KNbO<sub>3</sub> · 0.67 SrNb<sub>2</sub>O<sub>6</sub>] which has an electrooptic coefficient of  $r_{11} = 1.3 \times 10^{-8}$  cm/v and a half-wave voltage of 500v (5) while the dielectric constant on poled single crystals is 430 at room temperature.

Dielectric measurements on compositions from the single phase region (25 to 65 m/o KNbO<sub>3</sub>) of the KNbO<sub>3</sub>-SrNb<sub>2</sub>O<sub>6</sub> system show no significant variation in ferroelectric transition temperature or dielectric constant (5). A room temperature dielectric constant,  $\epsilon_{RT}$ , of 430 and a peak dielectric constant,  $\epsilon_p$ , of 14,000 at the ferroelectric transition temperature,  $T_0$ , of 156°C are typical of both KSr<sub>2</sub>Nb<sub>5</sub>O<sub>15</sub> and 0.45 KNbO<sub>3</sub> · 0.55 SrNb<sub>2</sub>O<sub>6</sub>.

Addition of 3, 6, and 9 w/o LaNb<sub>3</sub>O<sub>9</sub> causes a progressive increase in  $\epsilon_{RT}$  to 5300 and a decline in  $\epsilon_p$  to 5740. The  $\epsilon$  vs.  $T$  data taken along the c-axis for the 3 and 9 w/o LaNb<sub>3</sub>O<sub>9</sub> crystals are shown in Fig. 4 and 5.

Fig. 4. Dielectric constant vs. temperature as a function of applied electric field for 0.45  $\text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6 + 3 \text{ w/o LaNb}_3\text{O}_9$  single crystal.

Fig. 5. Dielectric constant vs. temperature as a function of applied electric field for 0.45  $\text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6 + 9 \text{ w/o LaNb}_3\text{O}_9$  single crystal.

Also,  $T_0$  is reduced to 37°C. Further addition of  $\text{LaNb}_3\text{O}_9$  lowers both  $\epsilon_{RT}$  and  $\epsilon_p$ , and  $T_0$  is below room temperature (9°C) for the crystal containing 18 w/o  $\text{LaNb}_3\text{O}_9$  (Table III).

The addition of 3 w/o  $\text{LaNb}_3\text{O}_9$  to  $\text{KPb}_2\text{Nb}_5\text{O}_{15}$  lowered  $T_0$  from 449° to 416°C; however, no broadening was observed in the  $\epsilon$  vs.  $T$  curves. The room temperature dielectric constant was increased from 332 to 442 by the  $\text{LaNb}_3\text{O}_9$  addition. Data on ceramic samples from the  $x \text{KPb}_2\text{Nb}_5\text{O}_{15} \cdot (1-x) \text{LaNb}_3\text{O}_9$  system show a reduction in  $T_0$  to 203°C when  $x = 0.6$ , and an increase in  $\epsilon_{RT}$  and a decrease in  $\epsilon_p$ . A ceramic sample of  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  had values of  $T_0 = -120^\circ\text{C}$ ,  $\epsilon_{RT} = 500$ , and  $\epsilon_p = 1400$ . Polarization vs. electric field measurements along the  $c$ -axis showed no hysteresis loops in single crystals of the main phase in frozen melts of  $\text{K}_2\text{LaNb}_5\text{O}_{15}$ .

The effect of  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  additions to  $\text{KSr}_2\text{Nb}_5\text{O}_{15}$  was examined with ceramic samples. The  $T_0$  was lowered from 156° to 141°C by the addition of 20 m/o  $\text{K}_2\text{LaNb}_5\text{O}_{15}$ , and  $\epsilon_{RT}$  increased while  $\epsilon_p$  decreased. The

$(\text{KPb}_2\text{Nb}_5\text{O}_{15})_{60}(\text{K}_2\text{LaNb}_5\text{O}_{15})_{40}$	1,630	1,700	—

use of low concentration of  $\text{LaNb}_3\text{O}_9$  rather than  $\text{K}_2\text{LaNb}_5\text{O}_{15}$  proved to be more effective in changing the  $T_0$  of compositions from the  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$  system.

### Summary

Single crystals were grown from compositions contained in the ternary systems of  $\text{KNbO}_3$ - $\text{SrNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$  and  $\text{KNbO}_3$ - $\text{PbNb}_2\text{O}_6$ - $\text{LaNb}_3\text{O}_9$ . Crystals from the former system were the more difficult to grow.

$\text{K}_2\text{LaNb}_5\text{O}_{15}$  was found to contain less than 5% of a second phase. This second phase had a composition close to  $\text{K}_2\text{Nb}_4\text{O}_{11}$  with approximately 0.1 w/o La.

The addition of  $\text{LaNb}_3\text{O}_9$  to 0.45  $\text{KNbO}_3 \cdot 0.55 \text{SrNb}_2\text{O}_6$  caused an increase in the number of vacant cation sites in the tetragonal tungsten bronze structure and a lowering of the lattice parameter,  $c_0$ . Also, the  $\text{LaNb}_3\text{O}_9$  results in higher  $\epsilon_{RT}$  and lower  $\epsilon_p$  and  $T_0$ . The ferroelectric transition also becomes less sharp.

# Measurement of Epitaxial Doping Density vs. Depth

D. R. Decker

Bell Telephone Laboratories, Inc., Reading, Pennsylvania

## ABSTRACT

The determination of doping density *vs.* depth from capacitance-voltage measurements on diffused diodes in epitaxial material is derived for the general case. These calculations extend the useful range of the capacitance-voltage technique and allow profiling of epitaxial doping in depth through the use of deep-diffusion test diodes. Experimental comparison of the deep-diffusion and shallow-diffusion characterization techniques shows that the deep-diffusion technique extends the depth capability of capacitance-voltage measurements with accuracy comparable to the shallow-junction measurements (5-15%).

The use of epitaxial material for microwave devices requires a more complete characterization on this type of material than has been common in the past. Especially needed is a simple technique for determining the distribution of the doping impurity within the epitaxial film. This need arises for several types of devices operated under reverse bias, where the exact nature of the impurity profiles determines such device characteristics as capacitance and series resistance as functions of voltage, the reverse recovery and transition times, and the avalanche breakdown voltage (1, 2).

The profile that will be measured by any capacitance technique based on a diffused junction is a combination of the profiles produced by both the growth of the film and the diffusion of impurities into it. The advantage of the shallow junction is that it can generally be made abrupt with a very high concentration on the diffused side. Hence, the effects of the diffusion profile can be ignored. However, it is often desirable to be able to calculate impurity profiles from capacitance voltage measurements of diodes with junctions that are relatively deep compared to this approximation. For a deep-diffusion technique to work the diffusion profile must be known and subtracted from the measurement. The error involved in the uncorrected impurity density is to first order proportional to the ratio of the unknown density to the density of diffused impurities at the edge of the depletion layer. Thus, it is desirable to include corrections for the diffused impurities if it is not certain that their density is at least 10 or 20 times that of the unknown impurities.

A technique is described which gives the information needed for device design and is also compatible with standard epitaxial material evaluation techniques. The accuracy of the technique is comparable to the accuracy of present techniques for measuring the surface doping density of epitaxial layers, and the technique allows doping density measurements to be extended in depth through the use of deep-junction diffused diodes.

### Discussion of the Shallow-Junction, Capacitance-Voltage, Doping Density Measuring Technique

One standard technique for measuring epitaxial film doping density involves the fabrication of shallow-junction, diffused, mesa diodes (3, 4). The shallow diffusion is used so that the asymmetrical-junction capacitance-voltage law is a good approximation to the reverse biased junction behavior. This gives the following relationship (see Appendix I) between the film doping density and the diode capacitance  $C$ , diode area  $A$ , and bias voltage  $V$

$$N = \frac{C^3}{q\epsilon A^2 \left( \frac{dC}{dV} \right)} \quad [1]$$

The measurement involves an accurate determination of  $A$  and measurement of capacitance at two slightly different reverse bias voltages. The capaci-

tance is taken as the average of the two readings and is also used to calculate the depletion-layer width using the following formula

$$w = \frac{\epsilon A}{C} \quad [2]$$

The depth at which the doping density is thus determined is to a good approximation

$$d = x_j + w = x_j + \frac{\epsilon A}{C} \quad [3]$$

where  $x_j$  is the depth of the metallurgical junction.

The doping density of an epitaxial layer can be profiled in depth using a shallow-diffusion and making the differential capacitance measurements at many reverse bias voltages up to the breakdown voltage of the test diode.

This technique has the following two disadvantages:

1. Differential capacitance measurements made at large reverse bias voltages are subject to substantial measurement error due to the decrease of the change in capacitance,  $dC$ , with voltage (see section on accuracy).

2. The depth at which the test diode breaks down by avalanching may be shallower than the depth of interest, thus preventing further measurement.

The second limitation listed above is the most serious since it precludes obtaining the necessary information by use of the shallow-diffusion technique. The maximum measurement depth for this technique may be calculated from shallow-junction avalanche-breakdown curves. Devices whose characteristics are dependent on the impurity profile in the region inaccessible to the shallow-junction measurement should be characterized by a technique with greater depth capability.

### Evaluation of Doping Density in Depth by Combining a Deep Diffusion with the Differential Capacitance Technique

For an arbitrary impurity profile on each side of a p-n junction the relationship between doping densities, capacitance, and voltage is as follows (see Appendix I and Fig. 1)

$$\frac{1}{N_A(x_1)} + \frac{1}{N_D(x_2)} = \frac{1}{N_T(w)} \quad [4]$$

where  $N_S$  = surface concentration of the diffusant;  $N_0$  = substrate doping level;  $N_A(x_1)$  and  $N_D(x_2)$  are the net impurity densities at the edges of the depletion layer;  $x_e$  = epitaxial layer thickness;  $x_1$  = p-type edge of depletion region;  $x_2$  = n-type edge of depletion region;  $w = x_2 - x_1 = \epsilon A/C$  = width of depletion region.

$$N_T = \frac{C^3}{q\epsilon A^2 \frac{dC}{dV}}$$

(the effective doping density as determined from the C-V relationship) [5]

Fig. 1. Depletion layer spreading vs. bias

Also

$$N_D(x_2) = \frac{N_A(x_1)N_T(w)}{N_A(x_1) - N_T(w)} \quad [6]$$

The quantity  $N_T$ , which is a function of capacitance and voltage and has the units of impurity density ( $\text{cm}^{-3}$ ), has been defined for mathematical convenience. However, it will be seen that  $N_T$  is closely related to the individual impurity densities  $N_A$  and  $N_D$ , thus substantiating the concept of  $N_T$  being an effective impurity density.

It is seen that [6] reduces to [1] for the case that  $N_A(x_1) \gg N_D(x_2)$ . Therefore we can compare the true value given by [6] with the value that would be obtained using the asymmetrical-junction approximation.

$$N_D(x_2) = \frac{N_T(w)}{\left[1 - \frac{N_T(w)}{N_A(x_1)}\right]} > N_T(w)$$

also  $x_2 = x_1 + w < x_j + w$  since  $x_1 < x_j$ . Therefore, application of the asymmetrical-junction approximation to the general case leads to the erroneous result that the calculated impurity density is less than the actual density and that the calculated depth of the measurement is greater than the actual depth of measurement. The error in impurity density and the error in depth are both in such a direction as to shift the calculated distribution to lower densities and to greater depths than are actually measured. It is necessary to calculate the actual depth  $x_2$  and to correct the doping density according to Eq. [6] in order to obtain an accurate interpretation of the measurement.

The exact calculation of doping density and depth using the C-V technique with a deep junction requires determination of  $x_1$ ,  $x_2$ ,  $N_A(x_1)$  as functions of  $w$ . With the knowledge of  $x_1(w)$ ,  $x_2(w)$ , and  $N_A(x_1)$  it is simply a matter of substitution in Eq. [6] to find the desired impurity profile. However, the relationship between the depletion layer edges,  $x_1$  and  $x_2$ , and the total width,  $w$ , depends on the total integrated space charge through the charge conservation equation.

$$\int_{x_1}^{x_j} d\xi N_A(\xi) = \int_{x_j}^{x_2} d\xi N_D(\xi) \quad [7]$$

Therefore, an accurate knowledge of  $N_A(x)$  is necessary for an accurate determination of  $x_1(w)$  and  $x_2(w)$ . The relationship between  $x_1(w)$  and the measured quantities  $C$  and  $V$  is derived in Appendix II and yields the following result

$$\int_{x_1}^{x_j} d\xi N_A(\xi) = \int_0^w d\eta N_T(\eta) \quad [8]$$

This relation equates the total charge in one side of the depletion layer to the integral of the effective charge density,  $N_T(w)$ , from zero depletion layer width to the width  $w$  corresponding to  $x_1$ . Obviously, the right-hand side of Eq. [8] is also equal to the in-

tegrated donor density from Eq. [7], and this equality would be used if an unknown acceptor concentration was to be determined, e.g., a diffusion profile.

The right-hand side of Eq. [8] can be determined by a piecewise integration of the measured values of  $N_T$  vs. total depletion layer width. Since the integrals include the part of the depletion region that is swept at zero applied bias, it is necessary to make some approximation for the contribution of this region to the integral (this is analogous to calculating the built-in voltage of the junction). The approximation used in this work is that of an ideal graded junction for this region since the net compensated impurity density very near the metallurgical junction will closely approximate this distribution. Any error involved in this approximation will have a negligible effect on the doping density calculation for points moderately far removed from this area since the net impurity charge near the junction is quite small in comparison to the total depletion layer charge. Equation [8] is rather difficult to solve for  $x_1$ ; however, solution by computer is straightforward. Therefore, for a particular value of  $w$  it is possible to determine  $x_1$  from Eq. [8], to substitute  $x_1$  and  $w$  in Eq. [6] to find  $N_D$ , and finally to add  $x_1$  and  $w$  to obtain  $x_2$ .

#### Discussion of Accuracy

The accuracy involved in the calculation of  $N_T$  and  $N_A$  from capacitance-voltage data involves rather lengthy calculation which will be omitted here. The applicable results which are useful are

$$SN_T = \sqrt{9\left(\frac{\Delta C}{C}\right)^2 + 2\left(\frac{SC}{C_2 - C_1}\right)^2 + 4\left(\frac{\Delta A}{A}\right)^2} \quad [9]$$

and

$$SN_A = \frac{1}{2} \sqrt{\left(\frac{\Delta C}{C}\right)^2 + \frac{1}{2}\left(\frac{SC}{C}\right)^2 + \left(\frac{\Delta A}{A}\right)^2} \quad [10]$$

where  $SN_T$  and  $SN_A$  are the standard deviations from the actual values of these quantities,  $\Delta C$  is the capacitance calibration error (fixed),  $SC$  is the standard deviation of the repeatability of the capacitance measurement,  $C_1$  and  $C_2$  are the two values of capacitance chosen for calculating  $dC/dV$ ,  $C$  is the average value of  $C_1$  and  $C_2$ , and  $\Delta A$  is the error in measuring the junction area.

Equation [10] gives only the error in  $N_A$  that results from the measurement and calculation, not including the error inherent in assuming a specific profile for the diffused impurities. Typical values calculated for  $SN_T$  and  $SN_A$ , respectively, are 10-15% and  $< 1\%$ . Therefore, the error in  $N_A$  resulting from calculation is much smaller than the error in  $N_T$ , and any significant error in  $N_A$  is a result of deviations from the assumed diffusion profile.

The accuracy of calculation of  $N_D$  for the deep-diffused junction can now be discussed. Equation [6] can be rewritten as follows

$$N_D(x_2) = \left[1 + \frac{N_T(w)}{N_A(x_1) - N_T(w)}\right] N_T(w) = (1 + \alpha) N_T(w)$$

$$\text{with } \alpha = \frac{N_T(w)}{N_A(x_1) - N_T(w)} = \frac{N_D(x_2)}{N_A(x_1)} \quad [11]$$

Equation [4] can be used to derive the relationship between errors in  $N_A(x_1)$ ,  $N_T(w)$ , and the calculated values of  $N_D(x_2)$ . The normalized differential error is given by the following expression

$$\delta N_D = \frac{dN_D}{N_D} = N_D \left( \frac{dN_T}{N_T^2} - \frac{dN_A}{N_A^2} \right) \quad [12]$$

The normalized error is not independent of concentration. Equation [12] may be rewritten entirely in terms of  $N_A(x_1)$  and  $N_T(w)$  and their normalized

errors as follows

$$\delta N_D = \frac{N_A \delta N_T - N_T \delta N_A}{N_A - N_T} \quad [13]$$

From Eq. [13], it may be seen that for  $N_A \gg N_T$  the error in  $N_D$  is determined by the error in  $N_T$ . This is in accord with the asymmetrical-junction case.

It has been shown that the error in  $N_A(x_1)$  resulting from measurement errors is typically much less than the error in  $N_T$  (see Eq. [9] and [10]). Therefore, the error in  $N_A(x_1)$  is almost entirely the result of the inaccuracy inherent in the assumption of a specific profile for the diffused impurities. This error is not correlated with the error in  $N_T$ . Therefore, it is convenient to rewrite Eq. [13] in the following form

$$\delta N_D = (1 + \alpha) \delta N_T - \alpha \delta N_A \quad [14]$$

From Eq. [14], it is seen that the per cent error in  $N_D$  increases as the factor  $\alpha$  increases. From Eq. [11],  $\alpha$  is equal to the ratio of  $N_D(x_2)$  to  $N_A(x_1)$ . For the diffused junctions considered here  $N_A(x_1)$  remains greater than  $N_D(x_2)$ , and  $\alpha$  remains less than 1. Only if the impurity profile on the unknown side of the junction is steeper than the profile on the known side of the junction will  $\alpha$  be greater than 1. Therefore, for most cases, the error in  $N_D$  will be between 1 and 2 times the error in  $N_T$ . The statistical error in  $N_D$  can be written as follows, assuming that  $\delta N_T$  and  $\delta N_A$  are not correlated

$$SN_D = (1 + \alpha) \sqrt{\delta N_T^2 + \left(\frac{\alpha}{1 + \alpha}\right)^2 \delta N_A^2} \quad [15]$$

Equation [15] has been written so as to emphasize the major dependency of the error on  $\delta N_T$  (for  $\alpha < 1$ ).

**Experimental**

Figures 2 through 8 show plots of donor density vs. depth for diffused mesa diodes on epitaxial silicon slices as determined by three different methods. Shown for each slice on the same plot are:

1. The plot of concentration vs. depth using a shallow-diffused junction and the asymmetrical-junction approximation. These plots are extended as deep as

Fig. 2. Donor density vs. depth, slice 1283-3. ■  $x_j = 0.7\mu$  plot of  $N_T$ ; ●  $x_j = 5.2\mu$  plot of  $N_T$ ; ▲  $x_j = 5.2\mu$  plot of  $N_D$ . These symbols apply to Fig. 2 to 8.

Fig. 3. Donor density vs. depth, slice 1283-4

the breakdown voltage of the test diode will permit.

2. A plot of concentration *vs.* depth for a deep-diffused junction ( $5.2\mu$ ) calculated from the asymmetrical-junction approximation. (This is actually a plot of  $N_T$  *vs.*  $x_j + w$ ).

3. A plot of concentration *vs.* depth for a deep-diffused junction using the same *C-V* data as in 2 above but calculating  $N_D$  and  $x_2$  using the method described.

#### Discussion of Experimental Results

The first aspect of the experimental results that merits discussion is the shallow-junction-generated profile, its accuracy and range of usefulness. It will be noted that all the concentration data points have a variation ranging from  $\pm 0\%$  to  $\pm$  about 15% (with the exclusion of the reading made at the highest bias voltage) from a smooth curve that could be drawn through the points. The typical variation is about  $\pm 8-10\%$  substantiating the error calculations previously discussed. Also noted is a tendency for the last point (highest bias voltage) to be quite out of line with the other points generally indicating a much lower doping density. This effect is mostly attributable to the small value of  $dC/dV$  in this range causing a large error in the measurement of  $dC$ . (Several other factors such as high leakage conductance or changes of depletion layer geometry with bias may cause measurement errors at large bias voltages. These effects must be minimized as much as possible to obtain good data in this region.) Therefore, the asymmetrical-junction technique is typically  $\pm 10\%$  accurate with the exclusion of the last data point.

The extension of the shallow-junction measurements is seen to give readings as deep as  $4.7$  to  $7.8\mu$  depending on the specific doping profile being measured. However, there is in general no guarantee of how deep the measurement can be extended. Nevertheless, the extended shallow-junction measurements are useful for resistivities greater than 1 ohm-cm and layer thicknesses less than  $7\mu$ . However, a deeper measurement is required to be able to predict junction characteristics such as capacitance *vs.* bias or series resistance or breakdown voltage for thicker or more heavily doped layers.

Turning our attention to the deep-diffused-measurement portion of Fig. 2 to 8 several features may be mentioned:

1. Smooth curves drawn through the deep-diffused asymmetrical-junction-calculated points and the shallow-diffused asymmetrical-junction-calculated points do not line up within the limits of accuracy discussed. In most cases, the deep-diffused points give lower values of doping density.

2. Excepting Fig. 3 and 4 the corrected deep-diffusion points line up acceptably well with the results of the shallow-junction points. Since the deep junction and shallow-junction are on different diodes there is a possibility of the curves being shifted up or down due to a difference in the error of measurement of the area on the two test units.

3. The corrected points always give larger values of doping density than the values of  $N_T$ . However, when the background doping density is low the correction is small (*e.g.*, Fig. 6 and 7).

4. The deep-diffused points exhibit about the same degree of fluctuation as do the shallow-diffused points, and in one case (Fig. 7), have the same tendency for deviation of the deepest point.

5. The uncorrected points always indicate a deeper measurement than the corrected points. In Fig. 6 this is so exaggerated that the last uncorrected measurement indicates a density of  $9 \times 10^{15}/\text{cm}^3$  only  $0.2\mu$  from the substrate interface. The substrate doping is greater than  $10^{19}/\text{cm}^3$ .

The details discussed above indicate that the corrected, deep-diffused measurement gives values that line up with and extend the range of the shallow-

diffused measurements. The error of this type of measurement is seen to be comparable to the error of the shallow-junction technique under the conditions considered.

Some mention of the correction for out-diffusion from the substrate should be made here. For the substrate doping levels (As,  $3 \times 10^{19}/\text{cm}^3$ ) and diffusion times and temperatures involved here, the distance of out-diffusion to a level of  $1 \times 10^{15}/\text{cm}^3$  additional donor atoms, amounts to less than  $1.5\mu$  assuming a step distribution at the interface initially. Since the initial profile is not a step distribution, but is probably close to that of a complementary error function, the resultant shift from the initial distribution is less than  $1.5\mu$ . The initial distribution may be estimated by assuming that both distributions are complementary error function and calculating the movement corresponding to the diffusion time and then subtracting this from the measured values to obtain the initial distribution. However, in many instances it is not necessary, or even desirable to find the initial distribution since the impurity distribution of the test diode will be close to that of the device to be made from the material under evaluation.

#### Conclusion

The general capacitance-voltage relationships for arbitrary impurity profiles on either side of a p-n junction have been discussed with their application to the measurement of unknown impurity profiles in mind. A technique of measurement using deep-diffused junctions has been described which allows measurement of epitaxial layer doping density in depth. The deep-diffusion technique allows measurement of impurity concentration without the necessity of any prior assumption of an asymmetrical junction.

The doping density profiles of a number of slices have been calculated for both shallow-diffused junctions and deep-diffused junctions using both the asymmetrical-junction approximation and a general calculation technique. These profiles exhibit the erroneous results obtained for deep diffusions using the asymmetrical-junction calculation. The fluctuations of the points and the error of measurement have been discussed for the curves exhibited. The correction for out-diffusion, if it is desirable to make such a correction, has been outlined.

The error of measurement of the effective doping profile,  $N_T$ , has been discussed and it has been shown that for a typical epitaxial measurement ( $0 < \alpha < 1$ ) using the technique outlined here the error is mostly determined by this error in  $N_T$  (according to Eq. [15]). It has been shown that a major source of error in  $N_T$  is the measurement of  $dC$ . Therefore, the accuracy of either technique can be improved significantly by the use of a capacitance bridge with better than  $\pm 0.1\%$  accuracy.

This measurement technique is very useful in the characterization of epitaxial material for devices that require thick epitaxial layers or where the low resistivity limits the depth of measurement. The technique is especially useful for devices whose operation is dependent on the exact shape of the doping profile throughout the entire active region, *e.g.*, varactor diodes, "punch-through" diodes, and IMPATT devices.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

#### APPENDIX I

##### The Diode Capacitance-Voltage Law

Assuming that the charge due to free carriers within the depletion layer is negligible, the following equations govern the variation of depletion layer capacitance with voltage (refer to Fig. 1 for nomenclature).

$N_A$  and  $N_D$  are net acceptor concentration and net donor concentration, respectively.

$$\frac{d^2V}{dx^2} = -\frac{q[-N_A(x) + N_D(x)]}{\epsilon} \quad (\text{Poisson's equation}) \quad [\text{A1}]$$

$$\int_{x_1}^{x_2} [N_A(x) - N_D(x)] dx = 0 \quad (\text{charge conservation}) \quad [\text{A2}]$$

$$C = \frac{\epsilon A}{x_2 - x_1} \quad [\text{A3}]$$

Taking the derivative of [A2] with respect to  $x_1$  or  $x_2$  yields:

$$N_D(x_2) dx_2 = -N_A(x_1) dx_1 \quad [\text{A4}]$$

In order to find how the variation of capacitance with voltage is affected by the impurity concentrations at the edges of the depletion layer, consider the following derivative:

$$\frac{dC}{dV} = \frac{-C^2}{\epsilon A} \left[ \frac{1}{dV/dx_2} - \frac{1}{dV/dx_1} \right] \quad [\text{A5}]$$

We can now calculate  $dV/dx_2$  and  $dV/dx_1$  from the integral formula for  $V(x_1, x_2)$  which is obtained by a double integration of Eq. [A1]. The result of this differentiation using Leibnitz's rule (5), is the following two equations.

$$dV/dx_2 = q/\epsilon(x_2 - x_1) N_D(x_2) \quad [\text{A6}]$$

$$dV/dx_1 = -q/\epsilon(x_2 - x_1) N_A(x_1) \quad [\text{A7}]$$

Substitution of  $dV/dx_2$  and  $dV/dx_1$  into the formula for  $dC/dV$  yields the final result.

$$\frac{1}{N_A(x_1)} + \frac{1}{N_D(x_2)} + \frac{1}{\frac{C^3}{q\epsilon A^2 (dC/dV)}} = 0 \quad [\text{A8}]$$

It is convenient to write Eq. [A8] in the form

$$\frac{1}{N_A(x_1)} + \frac{1}{N_D(x_2)} = \frac{1}{N_T(w)} \quad [\text{A9}]$$

$$\text{with } N_T(w) \equiv \frac{C^3}{q\epsilon A^2 (dC/dV)}$$

(this reverses the voltage convention) [A10]

In this form it is readily apparent that for an abrupt-junction ( $N_A(x_1) \gg N_D(x_2)$ )

$$N_T(w) = \frac{N_A(x_1) N_D(x_2)}{N_A(x_1) + N_D(x_2)} \approx N_D(x_2) \quad [\text{A11}]$$

This is the approximation normally used in calculating doping density from C-V measurements on shallow-junction diodes.

#### APPENDIX II

##### Calculation of $N_D(x_2)$ and $x_2(w)$ from C-V Measurements

The relationships that will be used in the calculation are

$$N_D(x_2) = \frac{N_A(x_1) N_T(w)}{N_A(x_1) - N_T(w)} \quad [\text{B1}]$$

$$\int_{x_1}^{x_j} dy N_A(y) = \int_{x_j}^{x_2} dz N_D(z) \quad [\text{B2}]$$

The first step in the solution of the problem is to find  $x_1$  as a function of the depletion layer width  $w$ . This can be accomplished by noting that Eq. [A4] is true for all values of  $z$  inside the integral of Eq. [B2]. Therefore, Eq. [B2] can be rewritten in terms of  $\eta$  and  $N_T(\eta)$  instead of  $dz$  and  $N_D(z)$  as follows

$$dz = \frac{dz}{d\eta} d\eta = \frac{dz}{dz - dy} d\eta$$

but, from Eq. [A4]

$$dy = \frac{-N_D(z)}{N_A(y)} dz$$

therefore,

$$dz = \frac{dz d\eta}{dz + \frac{N_D(z)}{N_A(y)} dz} = \frac{N_A(y)}{N_A(y) + N_D(z)} d\eta$$

this can also be written

$$dz = \frac{N_T(\eta)}{N_D(z)} d\eta$$

Therefore, Eq. [B2] becomes

$$\int_{x_1}^{x_j} dy N_A(y) = \int_0^w d\eta N_T(\eta) \quad [\text{B3}]$$

This is the basic equation that is needed, since it relates the unknown  $x_1$  to the known functions  $N_A$  and  $N_T$  and the measured variable  $w$ . When  $x_1$  is found,  $N_A(x_1)$  is obtained by direct substitution, and  $N_D(x_2)$  is calculated using Eq. [B1]. It should be noted that  $N_T(w)$  must be integrated, and, therefore, a range of C-V measurements must be made up to the bias voltage required to obtain the desired measurement depth.

It is easily shown from Eq. [5] that the following identity is true (since  $dw = \epsilon A dC/C^2$ )

$$dw N_T(w) = \frac{CdV}{qA} \quad [\text{B4}]$$

Equation [B4] may be understood as stating a relationship between the applied charge increment per unit area and the depletion layer widening. Substitution of [B4] into [B3] yields the physical insight that the charge stored in one side of the depletion layer at any voltage equals the integral of the charge transferred during charging of the reverse bias junction capacitance.

## Optical and Electrical Properties of SiC Films Prepared in a Microwave Discharge

O. A. Weinreich and A. Ribner

*The Bayside Laboratory, research center of  
General Telephone & Electronics Laboratories, Bayside, New York*

Microwave induced chemical reactions have been investigated increasingly in recent years (1). Relatively few reports, however, describe formation of films in microwave discharges. With this technique, films may be obtained at low temperatures by direct reaction of the plasma with the substrate, or by deposition of the products formed by the reaction of gaseous compounds in the discharge tube. Examples of the first kind are oxidation of silicon and gallium arsenide in an oxygen plasma. Oxidation in this case occurs at unexpectedly low temperatures (300°C for the oxidation of Si and 70°C for the oxidation of GaAs) (2, 3).

It has recently been reported that oxide films have been formed from the gas phase in a microwave plasma (4). These films were formed by the decomposition of gaseous organometallic compounds. In our Laboratory, films of several refractories have been formed from gaseous components by microwave induced reactions at low temperature. For example, we have prepared boron nitride from diborane and nitrogen, boron carbide from diborane and methane, silicon nitride from silane and nitrogen, and silicon carbide from silane and methane. This note describes the formation of the silicon carbide films and presents the results of a brief investigation of their optical and electrical properties.

### Equipment for Film Preparation

The experimental arrangement used in the preparation of the silicon carbide films is shown in Fig. 1. The microwave generator (MG) consists of a magnetron capable of delivering power up to 1 kw at a frequency of 2.54 GHz. Tuning is accomplished by a standard impedance transformer (E-H tuner T). The power toward the discharge tube is measured as the difference between forward and reflected power using the directional coupler (D<sub>1</sub>), attenuators A<sub>1</sub> and A<sub>2</sub> and power meters P<sub>f</sub> and P<sub>r</sub>. The microwave power is partly absorbed and partly transmitted by the discharge tube (DT), inserted into the wave guide (W) parallel to the E field. The transmitted power is measured using a second directional coupler (D<sub>2</sub>), attenuator (A<sub>3</sub>), and power meter P<sub>tr</sub>. The transmitted power is absorbed by a matched load (L). At the early stage of this investigation absolute power measurements were not made because the discharge tubes were initially placed in an open-ended tapered wave guide. With this arrangement transmitted power could not be determined. However, specific samples, the properties of which are described below, were prepared using the set up shown in Fig. 1, and for these the absorbed power in the discharge is given. Generally speaking, one advantage of film preparation in microwave discharges lies in the practicability of measuring and controlling the power absorbed in the discharge by applying standard microwave techniques.

The substrates are polished disks of either 14 ohm-cm p-type silicon or fused quartz. They are placed

on the silicon sample holder (SH) which can be moved vertically in the discharge tube and rotated during deposition by using a rotary Seal (RS). The temperature of the sample holder is measured with thermocouple (TC). Quartz discharge tubes of 0.5-1 in. in diameter were used. Before the gas mixture is admitted, the system is evacuated with a diffusion pump until the pressure measured by the ion gauge (IG) near the sample is in the 10<sup>-6</sup> Torr range. The gas is then admitted through the leak valve (LV) and the pumping speed is adjusted such that a pressure of 2 Torr is read with gauge (G).

### Film Preparation

Films were prepared in the equipment described above from a gas mixture of 90 m/o (mole per cent) He, 5 m/o SiH<sub>4</sub>, and 5 m/o CH<sub>4</sub> at a total pressure of 2 Torr. Flow rates varied from 5 to 20 Torr-liters/min. The substrates were heated by the plasma discharge itself without the use of external sources. A temperature range from 40° to 400°C was covered by varying the absorbed microwave density from a few tenths to about 4 w/cm<sup>2</sup>.

The location of the substrate in the plasma turned out to be an important factor in determining the deposition rate and the nature of the film. Slight variations in substrate position was sufficient to mask any effect of flow rates in the range investigated. Growth rates were varied from 50 to 500 Å/min by varying the position of the substrate in the plasma. Generally, growth rates were higher when the sample was outside the glow region. A dependence of the growth rate upon position in the plasma was also observed by Ligenza for the oxidation of Si in oxygen (2). When the sample was in the glow region, the growth was greatest in the center and usually a ring pattern of interference colors was obtained. This is believed to be related to the distribution of the electric field in the wave guide. Films formed outside the glow region were more uniform in thickness. The growth rates of the films were estimated during deposition from the interference colors. Color charts for SiO<sub>2</sub> on Si were used (5). Since equal colors indicate equal optical paths, the observed color gives the SiC film

Fig. 1. Schematic representation of experimental equipment

thickness

$$d(\text{SiC}) = \frac{n(\text{SiO}_2)}{n(\text{SiC})} \cdot d(\text{SiO}_2)$$

where  $d$  is the thickness and  $n$  the refractive index. At substrate temperatures up to about 400°C the films obtained had a glassy structure, and therefore electron diffraction could not be used for identification. However, the following experimental results strongly indicate that the deposited films are SiC:

1. An intense absorption peak at 12.6 $\mu$  coincides with the fundamental lattice absorption reported by Spitzer and co-workers (6) for crystalline SiC films prepared by a reaction of Si with CH<sub>4</sub> at 1300°C. Figure 2 shows the infrared spectrum of one of the glassy films together with the absorption curve of Spitzer and co-workers.

2. The bandgap of the glassy SiC films on quartz substrates obtained from the short wavelength cut off of the transmission spectrum in the visible region was found to be 2.5 eV. This value falls between the values reported for  $\beta$  SiC (2.2 eV) and  $\alpha$  SiC (2.86 eV) (7).

3. The deposited films are inert with respect to acids such as HF, HNO<sub>3</sub>, HF-HNO<sub>3</sub> mixtures, etc. This is the chemical behavior to be expected from SiC.

#### Electrical and Optical Properties

To determine the refractive index, the films were deposited on quartz substrates with a step, and the Abeles Brewster angle method was used (3). Values for  $n$  varied from 1.8 to 2.3 depending on the position of the sample in the plasma. The bulk refractive index of SiC is 2.6 (8). Films with low values of  $n$  were always obtained when the sample was placed at the edge of the glow region or further away where no glow was observed. When the samples were placed near the waveguide in the region of glow, films with higher  $n$  values were formed, although in a less reproducible manner. It was found that the temperature of the sample was not responsible for change of the refractive index in the range from 40° to 400°C.

Breakdown strength measurements of the films made at 60 Hz gave an average value of 3 x 10<sup>8</sup> v/cm. These measurements were made with SiC films on 14 ohm-cm silicon wafers 17 mm in diameter and 20 mils thick. The back side was gold plated, and 16-mil diameter Al dots were evaporated onto the SiC film.

Samples having high resistivity, breakdown strength, and refractive index were obtained with a power absorbed by the plasma of 3 w/cm<sup>2</sup>, flow rates of 5 Torr liters/min, and sample temperatures of 380°C during deposition. An I-V curve for a typical sample is shown in Fig. 3. The d-c voltage is applied between the gold-

Fig. 2. Infrared transmission of SiC. Curve I, film prepared in microwave plasma; curve II, polycrystalline SiC reported by Spitzer and co-workers.

Fig. 3. Current-voltage characteristic of SiC film

plated side of the Si disk and the aluminum dots as described for the breakdown measurements. When  $\log I$  is plotted against  $\sqrt{V}$ , straight lines are obtained regardless of polarity. This field-dependent conductivity may be due to Schottky emission or the Poole-Frenkel mechanism (9), both of which predict  $\log I$  to be proportional to  $\sqrt{V}$ . Further work is needed to determine the actual conduction mechanism. The thickness of the SiC film of this particular sample was 1600Å and uniform in the center over a circular region of about 6 mm in diameter. The resistivity of this SiC film was of the order of 10<sup>13</sup> ohm-cm at a field strength of 5 x 10<sup>5</sup> v/cm and about 10<sup>11</sup> ohm-cm at 4 x 10<sup>6</sup> v/cm. The relatively high resistivity at low field strength may be due to submicroscopic grain structure rather than high purity. It has been reported in the literature that the resistivity of SiC increased 7 orders of magnitude when the compound was changed from bulk to granular form (10). The relative permittivity at 1 kHz was 3.9.

Since the SiC layers have reasonably high resistivity and breakdown values, the films were evaluated for use as dielectrics for insulated-gate field-effect devices. Measurement of capacitance at 1 kHz as a function of d-c bias yielded an interface charge density as low as 5 x 10<sup>11</sup>, at the flat-band point, lower than for silicon nitride. At fields up to 1.3 x 10<sup>6</sup> v/cm room temperature instabilities were negligible, i.e., less than  $\pm 0.2$ v. However, the slopes of the C(V) curves were only 35% of the theoretical maximum, indicating a relatively high density of fast surface states. This slope is comparable to that obtained for pyrolytically grown glassy silicon nitride films.

#### Summary and Conclusion

The feasibility of preparing refractory films at low temperatures from gaseous compounds in microwave plasmas has been demonstrated. Some properties of SiC films obtained by this method are disclosed. Many questions concerning film formation in microwave discharges such as influence of gas mixture, pressure, temperature and power, await further work to be answered.

#### Acknowledgment

The authors wish to express their thanks to C. F. Tufts for taking and evaluating the electron diffraction patterns and to E. Goldman for analyzing the C(V) curves. They also wish to thank R. Summergrad for reading the manuscript and for his many helpful suggestions.

## Direct Nitridation of Silicon Substrates

R. G. Frieser\*<sup>1</sup>

Sprague Electric Company, North Adams, Massachusetts

Thin, continuous films of silicon nitride have been of considerable interest in the last few years because of their dielectric properties and their considerable inertness toward chemicals. Bulk silicon nitride, of course, has been a commonly available material for quite some time. It is manufactured by standard metallurgical techniques, based on reacting finely divided silicon powder with nitrogen at elevated temperatures (1). This fact appears to bear out the simple statement found in many current textbooks, namely, that silicon nitride can be produced by the direct combination of the elements at temperatures above 1300°C (2-5). This statement, although correct as far as it goes, ignores the great importance which the role of physical subdivision of the silicon plays in this reaction.

Oxide films of varying thickness can easily be formed either by direct oxidation of silicon surfaces, large surfaces as well as powders, or by a chemical vapor deposition process. Direct oxidation yields the more uniform oxide.

With respect to nitrides, excellent results in this laboratory as well as in others have been obtained by CVD reaction of a silicon hydride or halide with ammonia. Since more uniform and more desirable properties are obtained for the oxide by direct oxidation, direct nitridation of silicon surfaces has been attempted. Although the free energy of formation of silicon nitride becomes less negative as the reaction temperature increases, at ~ 1300°C  $\Delta F$  is still about 45 kcal/mole. It appears therefore reasonable that direct nitridation should be feasible. Indeed, Knopp and Stickler reported thin, noncontinuous films of silicon nitride when heating silicon wafers in argon containing small percentages of oxygen and nitrogen (6). In their work, no efforts were made to remove the native film of oxide on the silicon surfaces prior to reaction with nitrogen. On the other hand, Gregor (7) states that: "Silicon nitride films cannot be grown on a silicon substrate by thermal nitridation either in nitrogen or anhydrous ammonia."

In our laboratory, early attempts by Sprague and by Saxena (8) led to the conclusion that direct nitridation is possible, but very hard to control. These experiments were made at 1250°C employing low nitrogen flow rates (1 l/min). Film formation rates were very slow (~ 500 Å/16 hr) and their refractive index varies from 2.0 to 2.4.

A more comprehensive look at direct nitridation seemed warranted in order to reconcile the different claims in the literature and to investigate whether film qualities achieved by chemical vapor deposition could be approached. Such a film grown directly

would also permit the study of the electrical properties without the interference of an underlying oxide film.

The experiments described here were performed in a commercial (Pittsburgh Material and Chemical Company) upright, 8-slice epitaxial rotating reactor. The substrates were silica sol-polished silicon wafers oriented in the <111> or <100> plane, having resistivities of 1.0, 4.0, and 10 ohm-cm, both p- and n-type. The substrates were placed in the reactor without any pretreatment. After a 2-min H<sub>2</sub> flush at room temperature, the substrates were heated in H<sub>2</sub> at 1250°C for 10 min and then HCl etched (10% HCl in 24 l/min H<sub>2</sub>) at 1250°C for 5 min. This treatment removed oxides and silicon by removing ~ a 25μ layer from the top surface. At this stage the surface did not exhibit any surface structure. After a 2-min H<sub>2</sub> flush and as soon as the substrate reached the requisite temperature, nitrogen was introduced in the reactor directly from the plant lines (containing no more than 1-2 ppm of H<sub>2</sub>O) for direct nitridation of silicon surfaces. Holding the above conditions constant, the following parameters were varied: the nitrogen flow rate (10-30 l/min), the deposition time (1 min-2 hr) and the deposition temperature (1150°-1375°C). The effect on the film properties of uv illumination during growth was also examined.

Under these conditions, the following results were observed:

1. Films were neither uniform nor continuous. The growth pattern was a function of the reactor geometry. Final films were approximately concentric with and covered only the central portion of the substrate. Increasing either the growth time (up to 2 hr), growth temperature, or N<sub>2</sub> flow rate, only increased the diameter of the growth area. Inspection of the grown films under the microscope showed that the films were highly faulted and faceted. Furthermore, the density of the nucleation was not uniform but greatest at the central portion. No obvious reason other than reactor geometry seemed to be apparent. It was noted, too, that these films showed either isolated growth or domains growing into each other (Fig. 1). Even after 6 hr of growth, individual nucleation sites could still be distinguished under a microscope, showing crystalline-looking structures which had not fused. No further increase in the diameter of the grown film was noted after 2 hr (up to 6 hr) of reaction time. Nor did these 6-hr films appear to be more continuous or thicker than the 2-hr films.
2. The films did not appear to be attacked by either concentrated (48%) HF or by a solution of 5 parts (48%) HF plus 95 parts HNO<sub>3</sub>.

<sup>1</sup> Present address: IBM Corporation, East Fishkill Facility, Hopewell Junction, New York 12533.

Fig. 1. Photomicrograph of the surface of a nitrided silicon wafer. Magnification ca. 330X.

3. Infrared transmission spectroscopy showed sharp absorption peaks at 11.0, 12.2, and 21.3 $\mu$ ; this is indicative of  $\text{Si}_3\text{N}_4$  (Fig. 2). No absorption was noted at 9, 13, or 23 $\mu$ ; this could be interpreted as an absence of Si-O bonds. Comparison of absorption peak heights of several runs indicated little change in the film thickness as a function of deposition time. A film of 1725 $\text{\AA}$  had a refractive index of 2.44 as determined by the ellipsometric technique. This higher value may be due to a high silicon content; it was not further investigated. Film thickness measurements were very difficult to make because of the unevenness of the films and were attempted only on a few samples.
4. The physical appearance of the films was dark, but transparent with some interference colors. Reflection electron diffraction studies indicated that the films were polycrystalline (Fig. 3). The d-spacings (Table I) calculated from these films matched those of alpha and beta  $\text{Si}_3\text{N}_4$ . This would indicate that the films are a mixture of both forms. Since the beta-form is the usual high-temperature form, some rearrangement on cooling may have occurred. These results differ in this respect from data published recently (9).
5. The n-type substrates used in this experiment showed consistently more extensive growth

Fig. 2. Infrared transmission curve of a nitrided silicon under from 5 to 40 $\mu$ .

Fig. 3. Reflection electron diffraction picture of Cu nitrided silicon wafer. Magnification ca. 2X.

- (larger diameter) spots than p-type silicon, with all other parameters being equal. No effect of substrate orientation, (111) vs. (100), was noted.
6. No growth at all was obtained at 1150°C, and very little at 1250°C.
7. "Best" results were obtained at 1375°C with a  $\text{N}_2$  flow of 10 l/min. Decreasing the flow rate decreased the total growth area. Larger flow rates resulted in films which were too uneven for electrical measurements.
8. Omission of the HCl etch in situ did change the appearance, although not the character of the films. The Si wafers used in this experiment did not exhibit any surface structure. The extent of growth was about the same, the films if anything were thinner and not continuous, but in place of the "circular" growth about the nucleation sites, nucleation followed the crystallographic 110 directions in the (111) plane, reflecting the triangular pattern of that plane. This may indicate that the flow pattern of the HCl etch determined nucleation pattern of the substrates and therefore, the observed growth pattern.
9. Illumination of the substrates with a mercury vapor lamp during film growth possibly increased the size of the growth area slightly but not significantly. This experiment was performed for one reason; an orientation effect of uv illumination on the silicon surface was noted during low-temperature deposition of silicon on silicon (10).
10. An attempt was made to characterize electrically a 1725 $\text{\AA}$  thick film. Extremely low breakdowns frustrated this attempt.
11. The addition of  $\text{H}_2$  to the  $\text{N}_2$  decreased the size of the deposition area, with all other parameters being equal.

This work indicates that the growth of silicon nitride by direct nitridation is self-limiting. One has to assume that diffusion of N or Si through the nitride film is so slow at the deposition temperatures investigated that it is practically nonexistent. Similar results were obtained by Clark (12) of our laboratory. Using a glow discharge to produce atomic nitrogen, he found it impossible to diffuse nitrogen into Si to any extent at 1200°C, but in all cases formed a thin silicon nitride layer, which effectively stopped any nitrogen diffusion. It appears then that silicon nitride can be produced from the elements as stated in the literature, in a practical sense, only if silicon is present as a powder. Thus, if useful silicon nitride films are the objective one appears to be limited to chemical vapor deposition techniques.

## Brief Communications

### Deposition of New Binary Oxide Thin Films by the Pyrolytic Decomposition of Trimethylsiloxy-Aluminum-Isopropoxide ( $\text{Me}_3\text{SiO})_n\text{Al}(\text{O}^i\text{Pr})_{3-n}$ )

Yasuaki Nakaido and Satoshi Toyoshima

Department of Applied Chemistry, Faculty of Technology, Gunma University, Kiryu-shi, Japan

Thin films of metal oxide have previously been obtained by the pyrolytic decomposition of metal alkoxides in the vapor phase (1-5). Mixtures of two different kinds of alkoxides have also been used (6). The present paper describes the deposition of binary metal oxide films by the vapor phase pyrolysis of trimethylsiloxy-aluminum-diisopropoxide at temperatures in the range 300°-800°C with nitrogen gas as carrier. By using a compound in which the Al-O-Si bonds already exist, binary oxide films were obtained, a considerable proportion of the initial Al-O-Si bonds not being broken.

The starting material  $\text{Me}_3\text{SiOAl}(\text{O}^i\text{Pr})_2$  (7) was prepared by the method of transesterification between trimethylacetoxysilane and aluminum triisopropoxide in 1:1 molar ratio in cyclohexane solution. The apparatus consisted of an evaporator vessel, a resistance furnace 30 cm in length and a quartz reactor tube 3 cm in diameter. (111) silicon slices to be coated were placed on a quartz substrate holder. The reactor had a uniform hot zone about 20 cm long. A 360 l/hr flow of nitrogen was introduced to purge the reactor before the power was turned on. When the substrate reached

the operating temperature, 20 l/hr of nitrogen were passed through the sample in an evaporator at 150°C, and the sample gas was introduced into the reactor and pyrolyzed for a set period.

The thickness of the films was measured by interferometry. The films attained a maximum thickness of 4 $\mu$  without cracking.

The relation between the deposition rate and furnace temperature is shown in Fig. 1. Up to 600°C increasing furnace temperature decreased the rate of deposition; above 600°C increasing furnace temperature increased the rate.

The films were clear, almost transparent, and hard. No crystalline state was detected in the x-ray photographs of films deposited up to 500°C, but the films deposited at 600°, 700°, and 800°C gave distinct Debye-Scherrer rings. The lattice spacings of the oxide films are given in Table I, in which the spacings are compared with those of Kyanite (triclinic crystal of  $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ ). Crystal phases of  $\text{Al}_2\text{O}_3$  or  $\text{SiO}_2$  alone were not detected. Analysis of films deposited at 800°C are Al, 33.9%, Si, 16.7%; calculated values for  $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$  are : Al, 33.3%, Si, 17.3%.

## Crystallographic Character of the $\text{Sr}_{2-x}\text{Mg}_x\text{P}_2\text{O}_7$ System

Crispin Calvo

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

Single crystals in the  $\text{Sr}_2\text{P}_2\text{O}_7$ - $\text{Mg}_2\text{P}_2\text{O}_7$  system have been prepared in conjunction with crystallographic (1) and electron spin resonance (2) studies of  $\alpha\text{Ca}_2\text{P}_2\text{O}_7$  and  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$ . The structures of these compounds, although closely related, are nevertheless not the same.  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$  is orthorhombic with space group  $\text{Pbnm}$  (2) and lattice parameters  $a = 13.1054\text{\AA}$ ,  $b = 8.9104\text{\AA}$ ,  $c = 5.4035\text{\AA}$  (3), while  $\alpha\text{Ca}_2\text{P}_2\text{O}_7$  has the monoclinic space group  $\text{P2}_1/\text{n}$  and lattice parameters  $a = 12.66\text{\AA}$ ,  $b = 8.542\text{\AA}$ ,  $c = 5.315\text{\AA}$ ,  $\beta = 90.3^\circ$  (1). The cations are coordinated to eight oxygen ions in the former compound and to seven in the latter one, but beyond this the structural differences are small. Since the space group of  $\alpha\text{Ca}_2\text{P}_2\text{O}_7$  is a subgroup of that of  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$  and their difference transforms as one irreducible representation of the space group of the  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$ , it appears possible that a reversible transformation relates the two structures (2). Further, the EPR data (2) were consistent with preferred solubility of  $\text{Mn}^{2+}$  in only one cation site. In an attempt to resolve the site of preferred solubility for  $\text{Mn}^{2+}$ ,  $\text{SrMnP}_2\text{O}_7$  was prepared. When this phase was found to be triclinic, emphasis was then directed toward the  $\text{Sr}_2\text{P}_2\text{O}_7$ - $\text{Mg}_2\text{P}_2\text{O}_7$  system.  $\text{SrMgP}_2\text{O}_7$  was prepared and found to have the  $\alpha\text{Ca}_2\text{P}_2\text{O}_7$  structure. The results of a study of the single crystal diffraction patterns are reported here. These results suggested that the transformation from the  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$  to the  $\alpha\text{Ca}_2\text{P}_2\text{O}_7$  should be found as the composition is varied in the  $\text{Sr}_2\text{P}_2\text{O}_7$ - $\text{Mg}_2\text{P}_2\text{O}_7$  system.

In contrast to these results, Hoffman (4) reported no solid solution in the  $\text{Sr}_2\text{P}_2\text{O}_7$  and  $\text{SrMg}_2\text{P}_2\text{O}_7$  sys-

tem. Wanamaker and ter Vrugt (5) suggested a similarity between the powder pattern of  $\text{SrMgP}_2\text{O}_7$  and  $\text{BaMgP}_2\text{O}_7$ . However, the latter has the same triclinic structure as  $\text{SrMnP}_2\text{O}_7$ .

#### Experiments

$\text{Sr}_{2-x}\text{Mg}_x\text{P}_2\text{O}_7$  single crystals were prepared having compositions specified by  $x = 1/16, 1/8, 1/4, 1/2$ , and 1. Strontium nitrate and magnesium acetate were dissolved in distilled water and mixed with an aqueous solution of  $(\text{NH}_4)_2\text{HPO}_4$ . The precipitate was washed several times with distilled water, dried, and heated to 800°C. The sample was then transferred to a Vycor container, melted, and cooled slowly across its melting temperature. The sample's temperature was quenched to room temperature from about 1000°C to prevent the  $\alpha$  to  $\beta$  transformation.

Single crystals were examined at room temperature to determine unit cell sizes and symmetry. In addition, the density of  $\text{SrMgP}_2\text{O}_7$  was measured and used together with the accurately determined lattice parameters to check the composition. These lattice parameters were determined from films calibrated with reflections from a synthetic rutile ( $\text{TiO}_2$ ) sample whose lattice parameters were taken as  $a = 4.9529(5)\text{\AA}$  and  $c = 2.9591(3)\text{\AA}$  (6). These crystal data are recorded in Table I.

The intensity of about 500 reflections was estimated in order to establish the site of preferred occupancy for the  $\text{Sr}^{2+}$  ion. The intensity of the reflections of the type  $hnl$   $n = 0, 1, 2$  and  $mkl$   $m = 0, 1$  were estimated visually;  $\text{MoK}\alpha$  radiation was used to record the former data and  $\text{CuK}\alpha$  the latter. The data were corrected for Lorentz, polarization, and absorption effects.

Key words: pyrophosphate  $\text{SrMg}$ , phase transition, structure.

Table I. Crystal data for SrMgP<sub>2</sub>O<sub>7</sub>

$a$	= 12.59 (10) Å
$b$	= 8.293 (8) Å
$c$	= 5.260 (5) Å
$\beta$	= 91.0 (2)°
Extinctions:	hOl h + 1 odd OkO k odd
Density exp.	3.41 g/cm <sup>3</sup>
calc.	3.46 g/cm <sup>3</sup>

These data were compared to calculate intensity based on various fractional occupancy of Sr and Mg in the available cation sites. The final atomic parameters obtained in the refinement of the structure of  $\alpha$ -Ca<sub>2</sub>P<sub>2</sub>O<sub>7</sub> (1) were used as trial input parameters.

#### Results and Discussion

The Sr<sup>2+</sup> ion preferentially dissolves into cation site 1. This was anticipated on crystallographic grounds since this site cannot easily distort to accommodate a small cation. This cation site is bonded to oxygen atoms from opposite ends of the anion and therefore for the new environment to collapse about a small cation the P-O-P angle must change substantially from the value of 130.7° found in  $\alpha$ -Sr<sub>2</sub>P<sub>2</sub>O<sub>7</sub>. Since the anion has an eclipsed configuration and the shared oxygen atoms are on the trans side of the molecule, a smaller cation would demand a decrease in the P-O-P

angle of the anion. This angle, however, is already near the lowest value reported for a pyrophosphate.

It appears that at room temperature a phase boundary separating the  $\alpha$ -Sr<sub>2</sub>P<sub>2</sub>O<sub>7</sub>-like phase and  $\alpha$ -Ca<sub>2</sub>P<sub>2</sub>O<sub>7</sub>-like phase occurs at a composition of about 10 m/o (mole per cent). Mg<sub>2</sub>P<sub>2</sub>O<sub>7</sub> in Sr<sub>2</sub>P<sub>2</sub>O<sub>7</sub>. The space group of Sr<sub>15/8</sub>Mg<sub>1/8</sub>P<sub>2</sub>O<sub>7</sub> is the orthorhombic Pnbn while that of Sr<sub>7/4</sub>Mg<sub>1/4</sub>P<sub>2</sub>O<sub>7</sub> is the monoclinic P2<sub>1</sub>/n. These results suggest a continuous solid solution when the samples are prepared from the melt. This possible phase boundary is under investigation.

## Relation Between Solid-State Cohesion of Metal Fluorides and the Electrochemical Behavior of Metals in Hydrogen Fluoride

Ashok K. Vijh\*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

Hackerman, Snavely, and Fiel (1) have recently reported some investigations on the anodic behavior of 23 materials in 0.01M NaF solutions made in high-purity anhydrous hydrogen fluoride (AHF). They classified the dissolution (anodic and/or on open circuit) tendency of these materials as follows:

**Class I: rapid corrosion.**—antimony; bismuth; cadmium; molybdenum; silver; zirconium diboride; thallium; tungsten; carbon (pyrolytic); tantalum.

**Class II: low corrosion.**—aluminum; chromium; cobalt; Hastelloy-F; iron; magnesium; titanium; zinc; zirconium.

**Class III: passive.**—Monel; platinum; nickel.

Hackerman *et al.* also attempted to relate the three types of aforementioned behavior of these materials to some of their fundamental properties, *e.g.*, solubility of the respective metal fluorides and Pilling-Bedworth ratios. Such correlations, however, were demonstrated not to exist.

Here, an attempt has been made to correlate the anodic behavior of these materials in AHF with those fundamental properties which of their fluorides characterize their general stability in the solid state, *e.g.*, melting points (and hence lattice energies and percentage ionic character) (2), heats of formation per equivalent ( $\Delta H_f/eq$ ), heats of atomization per equivalent ( $\Delta H_a/eq$ ), and a large variety of other properties which are derived from these quantities (2-4).

In the discussions to follow, only 20 elemental substances will be considered since relevant data, it is

believed, are not available for the three nonelemental substances, *i.e.*, Hastelloy-F, ZrB<sub>2</sub>, and Monel, which were also studied by Hackerman *et al.*

In Fig. 1, the fluorides of these substances have been arranged in order of their melting points. The data shown refer to the fluorides for which melting points are readily available in the Handbook (5); these, presumably are, in general, the stablest fluorides of the corresponding metals. It is clear that the higher the melting point (and hence the higher the lattice energy) (2) of a metal fluoride, the lower is the corrosion tendency of the corresponding metal in AHF. The classification into three classes on the basis of melting points coincides with the three types of corrosion behavior reported by Hackerman *et al.*; the only exception is CdF<sub>2</sub>.

In Fig. 2, two classifications have been attempted. In the first classification these materials have been arranged in order of the  $-\Delta H_f/eq$  values for the corresponding fluorides. The three groups may again be delineated except for a slight "buffer" region in which some metals of class I and II overlap. The data were calculated from the values of heats of formation per mole for the corresponding fluorides as obtained from ref. (5) and (6). It may be noted that the higher (exothermic) the  $\Delta H_f/eq$  for a metal fluoride, the lower the tendency for the corresponding metal to corrode in AHF.

In the second classification in Fig. 2, these materials have been arranged in order of the  $\Delta H_a/eq$  of the corresponding fluorides. Heats of atomization per mole for a metal fluoride MF may be obtained by algebraic addition of heat of formation per mole for MF, heat

\* Electrochemical Society Active Member.

Fig. 1. Twenty metal fluorides arranged in order of their melting points; (s) and (d) mean sublimes and decomposes, respectively; no data available for  $\text{NiF}_2$ ; I, II, and III refer to the classification of Hackerman *et al.* on anodization behavior in AHF of the corresponding metals, in ref. (1).

of sublimation per mole for Metal M, and half the heat of dissociation per mole of  $\text{F}_2$  (4, 7). To obtain  $\Delta H_f/\text{eq}$  from  $\Delta H_f/\text{mole}$  is, of course, quite straightforward; e.g.,  $\Delta H_f/\text{eq}$  for  $\text{AlF}_3$  is  $(1/3) \times \Delta H_f/\text{mole}$ . The thermodynamic data used in the computation of  $\Delta H_f/\text{eq}$  have been obtained from ref. (5) and (6). It may be mentioned that it is immaterial as to which particular fluoride of a given metal may be used in the foregoing computations, since the values used are in per equivalent (and hence "normalized") and not in per mole. Taking several fluorides of a given metal gives the values of  $\Delta H_f/\text{mole}$  and  $\Delta H_a/\text{mole}$ , which are quite different; however  $\Delta H_f/\text{eq}$  or  $\Delta H_a/\text{eq}$  values for various fluorides of a given metal are approximately the same. Another rather obvious point may also be emphasized here; the only valid procedure in the types of arguments presented here is to use values of various quantities as per equivalent, *i.e.*, neither as per mole, nor as per atom but as per atom equivalent (2,4).

From the preceding discussion, it is clear that lower corrosion tendency of materials in AHF is observed in cases which tend to have fluorides with: (a) high melting point and hence high lattice energies and percentage ionic character (2); (b) high (exothermic)  $\Delta H_f/\text{eq}$ ; (c) high  $\Delta H_a/\text{eq}$ .

On dissolution, bonds between constituents of an ionic crystal are broken and a collapse of the lattice occurs (3). An increase in the energy needed to breakdown the lattice, *i.e.*, lattice energy (*cf.* melting point) would increase the tendency of the lattice to resist corrosion, either on open circuit or for a given value of the field at lattice-electrolyte interface. This conclusion is clearly supported by Fig. 1 here.

Again with increasing lattice energy (*cf.* Fig. 1) and increasing heat of formation (Fig. 2), heats of hydration, solution, fusion, and evaporation increase; also increase bond energies, the heats of activation for formation of ionic vacancies, band gaps, dielectric strength (*i.e.*, ability to sustain high fields), activation energies for the creation of dislocations and other physical "faults," specific heats and a variety of other

Fig. 2. (left) Eighteen substances arranged in order of  $-\Delta H_f/\text{eq}$  of their respective fluorides; I, II, and III refer to the classification of Hackerman *et al.* (1); slight "buffer" zone where classes I and II overlap has been shown by the dotted line; data for  $\text{PtF}_4$  and  $\text{TaF}_5$  not available. (right) Seventeen substances arranged in order of  $\Delta H_a/\text{eq}$  of their respective fluorides; relevant data not available for the case of Bi, Pt, and Ta; I, II, and III correspond to the classification of Hackerman *et al.* (1); two exceptions (Zn, Cu) may be noted.

related properties (3,4). In short, higher lattice energies (*cf.* Fig. 1) and heats of formation (Fig. 2) increase the magnitude of those properties which signify the general stability, in the solid state, of materials (3,4); hence, probably, the lower corrosion tendencies in Fig. 1 and 2 with increasing melting points and  $\Delta H_f/\text{eq}$ , respectively.

The heat of atomization emphasizes the covalent aspects of the bonding in these materials (fluorides), since almost all ionic crystals are at least partially covalent. If the spin correlation stabilization energies, which are usually small, are ignored, heat of atomization per equivalent is approximately equal to the average bond energy [not bond dissociation energy for a particular bond (8)]. Hence higher bond energies in metal fluorides indicate relatively high resistance to corrosion of the corresponding metals in AHF.

From the preceding discussion, it may be concluded that, roughly, in the case of those metals which do not corrode relatively readily in AHF (either open circuit or on anodization), the corresponding fluorides are held together rather strongly in the solid state. It is important, however, to qualify this statement by adding that in a given specific case of anodization of a metal in AHF (or in any solution, for that matter), electrochemical factors and the associated overpotentials at the metal-electrolyte (or metal-fluoride-electrolyte) interface may indeed be of paramount importance in the determination of the anodic behavior. It may also be remarked that the type of approaches outlined here yield only approximate trends and not exact predictions of anodization behavior of metals.

A tacit assumption involved in the foregoing arguments is that the corrosion of a metal proceeds via formation of a fluoride film on the metal. From our knowledge of the corrosion behavior of metals in general (9), it seems that this assumption is entirely valid in a great majority of cases (9). Irrespective of

the mechanism of corrosion, the relation between solid-state cohesion of metal fluorides and the anodization behavior of the corresponding metals in AHF (Fig. 1 and 2) is still quite persuasive.

Manuscript received July 12, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Galvanic Monitoring of Battery Gases

P. A. Hersch\*

Gould-National Batteries, Inc., Minneapolis, Minnesota

## ABSTRACT

The rates of evolution of oxygen and hydrogen from a battery can be transduced continuously to an electric current for recording. A stream of nitrogen carries the evolved gases into a self-attenuating system with a galvanic-coulometric cell selectively activated by oxygen. Oxygen from the battery is monitored directly; hydrogen by a difference method invoking continuous combustion. The method may be used for studying charge acceptance, formation efficiency and, omitting attenuation, for determining self-discharge, corrosion rate, and other battery-related data.

In nearly all aqueous electrochemical systems the imposition of sufficiently extreme potentials or currents results in the evolution of oxygen at the anode and of hydrogen at the cathode. The same two gases are also products in the spontaneous decomposition of oxidizers and in the self-discharge of battery fuels. Measuring the rate of gassing along with the electrochemical and other variables is thus often desirable when studying electrodes and their depolarizers. The rate of gassing is of special interest in mixed processes such as occur at secondary battery electrodes towards the end of charging, when not all the electricity supplied is accepted for storage and coulombs are used up in the evolution of battery gases.

Simple collection methods for the gases and subsequent analysis with Orsats and gas chromatographs have been employed variously. Figure 1 shows a volumetric system combining an oil drop displacement flowmeter for low gassing rates with a two-stage soap bubble flowmeter for medium and fast rates. The travel time of the drop or soap bubble between a start and a finish mark gives the total rate of gassing. A one-quarter turn of the four-way stopcock permits a reversal of the drop movement. Although this primitive apparatus does not separate oxygen from hydrogen it nevertheless provides useful information. The gassing pattern of a battery on constant current charging and overcharging may be compared with the theoretical pattern of Fig. 2. A plot of gassing rate (ml gas/amp min) vs. charge (amp-hr) displays, ideally, a first plateau at a gassing rate of either 3.73 ml O<sub>2</sub>/amp min or 7.45 ml H<sub>2</sub>/amp min (at 20°C, 1 atm), according to whether the anode or the cathode is first in reaching saturation with charge. Following this, there is a second plateau at 11.2 ml gas/amp min when both electrodes are saturated. The distance on the abscissa between the onset of the two steps represents the excess ampere hour-capacity of the one electrode over the other. Similarly shaped curves appear on overdischarge. Failure in reaching the plateau and distortion of the theoretical pattern indicate the occurrence of gas recombination or reabsorption, frequently when the rate of charge is low.

The objective of this present work was primarily the continuous, separate monitoring of oxygen and hydrogen evolved singly or simultaneously in a battery, by a technique that expresses at any instant the individual rates of evolution of the two gases, in terms of an electrical quantity. To this end, a stream of nitrogen is sent through the head space of the battery, carrying the evolved gases to a measuring system. Specific detectors could be used, based on paramagnetism for oxygen and on thermal conductivity for hydrogen, but the more recently perfected galvanic method (1), based on electroabsorption of gases, is more genuinely fitted to the purpose of monitoring

\* Electrochemical Society Active Member.

Key words: batteries, charge acceptance, coulometry of gases, galvanic monitoring, gases, gassing, hydrogen, oxygen, rate of evolution.

Fig. 2. Gassing behavior of a battery with surplus negative capacity

electroevolved gases; it is also simpler, selective and far more sensitive.

## Principle

In the case of oxygen measurement a stream of nitrogen carries the evolved oxygen into a galvanic system that absorbs it and thereby reproduces that part of the charging current that gives rise to the oxygen.

The oxygen sensor is essentially a primary battery with a base metal anode and an inert, partially gas-exposed, oxygen-absorbing cathode. Such cells have been proposed as analyzers since about 1930. The older cells were of limited use because they transduced only a small and variable portion of the oxygen delivered to them into electricity. Stability was poor

and linearity of response uncertain. Recent developments, borrowing from fuel cell technology, overcome these limitations, and an output close to the theoretical maximum for complete conversion of oxygen to hydroxyl ion is attained.

For monitoring the hydrogen, an analogous cell may be applicable, employing a partly gas-exposed, hydrogen-absorbing anode, as used in fuel cells, and a solid oxidizer cathode. A hydrogen sensor based on the system gas/Pt/HCl + KCl/Hg<sub>2</sub>Cl<sub>2</sub>, with the same geometry as one of the earlier galvanic sensors for oxygen, has been described (2). The system gas/Pt/H<sub>2</sub>SO<sub>4</sub>/Cu<sup>II</sup> is also practicable. However, the output of cells with platinum anodes in response to hydrogen is variable and sensitive to poisons, in contrast to the oxygen sensors based on silver or graphite cathodes. Moreover, while most oxygen-reducing cathodes are indifferent to hydrogen, the hydrogen-oxidizing anodes of platinum are not at all indifferent to oxygen. They tend to combine the two gases locally, giving a measurable galvanic response only to the excess of one gas over the other. With a cell of this kind one must remove all oxygen by a selective absorbent before hydrogen can be determined.

The procedure followed in this work, while also requiring a selective absorbent for oxygen, avoids a separate sensor for hydrogen. The nitrogen stream, stripped of all oxygen in the absorber, receives a constant proportion of oxygen in a microelectrolyzer, then passes a catalyst bed where all the hydrogen burns up, consuming part of the added oxygen. The oxygen left over is carried to the oxygen sensor. Hydrogen is thus signalled in coulometric terms by the extent to which a base line, representing the oxygen generated in the microelectrolyzer, is depressed as a result of the combustion. Oxygen absorber, microelectrolyzer, and catalyst form the "combustion segment" of the apparatus. The segment is bypassed when oxygen, not hydrogen, is of interest.

A uniquely suitable selective absorbent for oxygen is a bed of granular manganous oxide, made from the dioxide by reduction with hydrogen at about 400°C (3). The lower oxide removes all traces of oxygen at room temperature without absorbing hydrogen or catalyzing the hydrogen/oxygen reaction. The absorbent is self-indicating, changing from pale green to brown, with a sharp boundary between the virgin and used-up zones. Most popular absorbents for oxygen are based on copper. Among these, the "BTS catalyst" has been especially developed for action at room temperature (4). However, this material cannot be recommended for the present purpose since it retains and releases some hydrogen.

The galvanic sensor operates properly only on traces of oxygen. In order to measure the large rates of evolution of battery gases, very drastic dilution is essential. This has been achieved reliably by a special continuous sampling technique that needs no auxiliary diluent gas and does not delay response.

### Apparatus

**Sampling system.**—The carrier gas stream, prepurified tank nitrogen, adjusted to a flow rate  $F = 100$  ml/min, passes through a rotameter and along a wet paper wick to pick up moisture (Fig. 3). The wick is fed with water saturated with NaCl. At  $P_1$  the gas stream splits into two branches. The partial stream  $f$ , routed through a MnO absorber and flow restrictor  $R_2$ , flows to the analysis portion of the train. The other partial stream,  $F - f$ , traverses the head space of the battery under test and the head space of a calibrating electrolyzer, receiving  $\phi$  ml/min of electrode gases from either the battery or the calibrator. Nearly all of the mixture  $F - f + \phi$  discharges through  $R_1$  into the atmosphere. A minute portion  $\alpha(F - f + \phi)$  only flows through  $R_3$ , joining  $f$  at  $P_2$ . Thus, only the aliquot  $\alpha\phi$  of the battery gases reaches the analysis portion of the train.

The three flow restrictors are best made from stainless steel syringe needle tubing and are seated in silicone rubber plugs. The relationship  $R_1 < R_2 \ll R_3$  should hold. Typically,  $R_2$  is a 10 cm long, 22 gauge capillary (internal diameter  $D_2 = 0.394$  mm). Upon passing 50 ml N<sub>2</sub>/min through this capillary, a pressure head of about 26 cm H<sub>2</sub>O is established. When choosing appropriate lengths ( $L$ , cm) and gauge numbers (internal diameter  $D$ , mm) for the restrictors, one may use the formula

$$R = 0.00123 L D^{-4} \text{ cm H}_2\text{O}/(\text{ml N}_2/\text{min}) \text{ at } 20^\circ\text{C} \quad [1]$$

This approximation is derived from Poiseuille's law and applies to the present situation, where the pressure drop across the restrictors is small compared with the pressures at their entrance and exit.

Restrictor  $R_3$  may be of the same gauge and length as  $R_2$  but rendered far more restrictive by inserting a stainless steel wire into the bore.

The attenuation factor  $\alpha$  is largely determined by the ratio of flow resistances  $R_1 : R_3$ , and the splitting ratio  $f : (F + \phi)$  by the ratio  $R_1 : R_2$ . More precisely, the relationships are

$$\alpha = \frac{R_1}{R_3} \cdot \frac{1}{1 + \frac{r}{R_2} + \frac{R_1 + r}{R_3}} \quad [2]$$

$$\frac{f}{F + \phi} = \frac{R_1}{R_2} \cdot \frac{1}{1 + \frac{R_1 + r}{R_2} + \frac{R_1 + r}{R_3}} \quad [3]$$

where  $r$  is the flow resistance of the analytical part of the train.

These two equations may be derived by equating (a) the pressure drops (= flow rate flow resistance) along the path  $P_1$ -battery-electrolyzer- $R_3$ - $P_2$  with the pressure drop along  $P_1$ -MnO- $R_2$ - $P_2$  and (b) the pressure drop along  $P_1$ -battery-electrolyzer- $R_1$ -atmosphere with that along  $P_1$ -MnO- $R_2$ -analysis parts-atmosphere. The pressure drops in the battery and electrolyzer head spaces may be assumed to be zero and that within the MnO bed considered part of  $R_2$ .

**Calibrating electrolyzer.**—This, a "dummy battery" that accepts no charge, serves to determine the over-all attenuation factors ( $\alpha\eta$  for O<sub>2</sub>,  $\epsilon\alpha\eta$  for H<sub>2</sub>; see Table I), the combustion efficiency ( $\epsilon$ ), and, from time to time, the constancy of these factors. The electrolyzer (Fig. 3, lower right) is made from a 100 ml measuring cylinder and employs Ni-wire electrodes in aqueous KOH

Fig. 3. Sampling system and calibrating electrolyzer

Fig. 4. Segment for hydrogen measurement

(5N). A wad of glass wool prevents liquid spray from reaching the restrictor  $R_3$ .

**Combustion segment.**—The segment (Fig. 4) follows in series to the sampling system and is bridged by a four-way stopcock permitting insertion or exclusion of the three components: MnO tube, microelectrolyzer, and catalyst.

The MnO tube is of the same type as the one in the sampling system.

The microelectrolyzer evolving  $O_2$  must not evolve any  $H_2$ . Its cathode is a Ni-screen carrying  $Cd(OH)_2$ , and the cathodic process is  $Cd^{++} \rightarrow Cd$ . The screen is a portion of the negative of a Ni/Cd battery in its discharged or partly discharged state and is formed into a scroll. A useful size is 5 x 6 cm, with up to about 1 amp-hr "worth" of  $Cd^{II}$ . The electrode is rejuvenable *in situ* by reverse current, resulting in reoxidation  $Cd \rightarrow Cd^{++}$ . The electrolyte is aqueous KOH (5N). The anode is the barely immersed tip of a thin Ni-wire carried as an extension by a thicker Ni-wire. The anode area is thus kept to a minimum and oxygen bubbles can grow to a small size only. The bubbles, barely visible, emerge in quick succession, ensuring a noise-free base line.

The microelectrolyzer is energized by a 12v battery in series with a milliamperemeter, a limiting resistor, variable resistors for coarse and fine adjustment, and an interrupter switch. A shunting switch, when closed, permits setting the current; it should also be closed when the combustion segment is bypassed for measurement of  $O_2$  evolution.

The combustion catalyst is 0.5 w/o Pt/ $Al_2O_3$  (about 40  $\frac{1}{8}$ -in. cylindrical pellets, from Engelhard Industries, Inc., Newark, New Jersey). The catalyst works at room temperature, despite the high dilution of the  $O_2$  and  $H_2$  it combines, and despite the brevity of contact time, 1-2 sec. If calibration as scheduled in Table I shows incomplete efficiency ( $\epsilon < 1$ ) the catalyst should be reconditioned by taking it to about 70°C, using heating tape, while passing  $N_2$  carrying some 5 ma "worth" of  $H_2$  generated in the microelectrolyzer with reverse current. After about 5 min the  $H_2$  generation is discontinued, but warming in the  $N_2$  stream

continued for another 5 min. Thereafter, an efficiency check at room temperature should show  $\epsilon \approx 1$ .

**Oxygen sensor.**—The principle and construction of the coulometric sensor have been described and illustrated elsewhere (1). The preferred embodiment is a sandwich structure: gas-exposed porous silver or graphite cathode/porous plastic sheet imbibed with 5N KOH/ negative from a Ni/Cd battery, in its virgin or charged state, as anode. The volume of electrolyte applied must be substantially smaller than the aggregate pore volume of the porous materials so that much of the cathode remains unflooded. A double sandwich structure is recommended, with a central stainless steel blade carrying one set of the three layers on either face. The two external (cathode) layers may each be 15 cm long and 20 mm wide. The housing may be a glass or stainless steel tube 18 cm long and with a 25 mm internal diameter.

This cell should be connected in series with a load resistor not greater than 100 ohm (preferably 10 ohm or less); the current, in terms of the potential difference across the resistor, is followed by a millivolt recorder. Its response to a step change of  $O_2$ -concentration (e.g.,  $O_2$  from the microelectrolyzer) should be 90% complete within 1 min. A high internal or load resistance would stretch the response time.

The element, once wet with electrolyte, must not be exposed to air, except for brief periods. Otherwise the cell may dry out and anode capacity will be wasted. Shorting in air may drain as much as 200-500 ma. When isolated from air and gas flow while on circuit electrically, the cell consumes all  $O_2$  from its gas space and the current decays to a few microamperes or less, except if there are leaks or unpurged pockets of air. After the initial assembly or after extended exposure of the cell to air or to  $O_2$ -rich gas the decay to low background takes 1-2 hr; after only brief ingress of oxygen, a few minutes. When nitrogen flows through the cell, coming from a manganous oxide column, through ducts connected end to end with a few Tygon sleeves, a residual current  $i_0$  below 10  $\mu a$  is attainable, but a higher one may be tolerated. The residual current does not fluctuate and drifts very little.

The volume and concentration of the KOH solution tends to adjust itself to the relative humidity of the gas stream. Moderate changes of relative humidity do not affect the performance.

The service life of the element is limited only by the amount of accessible metallic cadmium in the two anode strips. Two strips of common commercial negative material 15 cm long and 20 mm wide contain an amount of Cd equivalent to 2 amp-hr. Even discounting nonaccessible Cd and the Cd oxidized before use, the material should last for several weeks of continuous operation at levels of output on the order of 1-2 ma. Spent anodes may be "recharged." This may be done *in situ* if the cathode is of graphite. If it is of silver, the element should be submerged in 5N KOH solution and a third electrode, of a material more inert than silver, should be used as anode during the charging process. A nickel wire helix, surrounding the electrode bundle, serves the purpose.

The response to  $X$  volumes  $O_2$  per million volumes of gas in a stream of  $F$  ml/min (measured at  $\theta^\circ C$  and  $P$  Torr) conforms to the equation

$$i - i_0 = 0.268 \eta F X \cdot \left[ 1 - \frac{\theta - 20}{293} - \frac{760 - P}{760} \right] \mu a \quad [4]$$

where  $i_0$  is the residual current, with  $X = 0$ . The factor 0.268 derives from Faraday's law. The coulometric yield  $\eta$  should be within a few per cent of unity, at least when  $F \leq 100$  ml/min and the drain  $i < 2$  ma. The yield may be determined by passing  $j$  ma through the microelectrolyzer, which is done anyway when establishing the  $O_2$  supply for  $H_2$  measure-

Table I. Summary of Procedure

	Battery charge current input, ma	Macro-electrolyzer input, ma	Combustion segment	Micro-electrolyzer input, ma	O <sub>2</sub> sensor output, ma	Calculated ratios
<i>Determination of:</i>						
Background $i_0$	0	0	in or out	0	$i_0 = 0.02$	
Over-all attenuation factor for O <sub>2</sub> , $\alpha\eta$	0	$I_c = 2000$	out	0	$i_c = 1.21$	$\alpha\eta = (i_c - i_0)/I_c = 0.595 \cdot 10^{-3}$
Anodic gassing ratio $\rho$ at time $t$	$I = 2000$	0	out	0	$i(t) = 0.32$	$\rho(t) = \frac{i - i_0}{\alpha\eta I} = 0.15$
Base line $i_1$	0	0	in	$j = 2.00$	$i_1 = 1.94$	$\eta = (i_1 - i_0)/j = 0.96$
Over-all attenuation factor for H <sub>2</sub> , $\epsilon\alpha'\eta$	0	$I_c' = 2000$	in	$j = 2.00$	$i_c' = 0.78$	$\epsilon\alpha'\eta = (i_1 - i_c')/I_c' = 0.58 \cdot 10^{-3}$
Check on catalyst efficiency, $\epsilon$						$\epsilon \approx \frac{i_1 - i_c'}{i_c - i_0} \cdot \frac{I_c}{I_c'} = 0.97$
Cathodic gassing ratio $\rho'$ at time $t$	$I = 2000$	0	in	$j = 2.00$	$i'(t) = 1.30$	$\rho'(t) = \frac{i_1 - i'}{\epsilon\alpha'\eta I} = 0.55$

ment. One obtains, then,  $\eta = (i - i_0)/j$ , independently of  $F$ . Another check is to pass prepurified, but still O<sub>2</sub>-carrying, nitrogen from a tank, measuring  $i - i_0$  at two different flow rates. In this check, since  $X$  is constant,  $i - i_0$  should change in proportion to the change in  $F$ . (Transients, always occurring when the flow rate changes, should be ignored.)

### Procedure

Table I lists generally and by way of a numerical example the steps necessary to establish the oxygen flux  $\rho I$ , or the hydrogen flux,  $\rho' I$ , that results from a charging current  $I$ . The "gassing ratios,"  $\rho$  and  $\rho'$ , rise from zero and approach unity as a sigmoid function of charging time. Where there is recombination or reabsorption of gas,  $\rho$  and  $\rho'$  stay below unity and represent less than the proportion of current rejected by the battery electrodes. It is desirable for a battery to produce a steep slope of the two sigmoid curves.

Figure 5 reproduces a recording of the oxygen evolution rate from an 8 amp-hr Planté cell charged at  $I = 2$  amp. The terminal voltage was plotted manually. The steep rise of the voltage coincided with the beginning of oxygen evolution. However, the plateau of voltage was reached at a time when the gassing rate was still rising. The recorder trace is jagged because of the erratic release of the oxygen bubbles. The order of hold-up time of the major bubbles may be judged from the width of the small indentations of the curve. The over-all attenuation factor was  $\alpha\eta = 5.0 \cdot 10^{-4}$ . The gassing ratio  $\rho$  approached the value 1.0, showing absence of recombination and reabsorption of oxygen.

Figure 6 shows the recording of the hydrogen evolution rate during another charging of the same

battery, at the same current. Owing to excess negative capacity, gassing set in later than in the case of oxygen, at a time when the voltage was already on its way up. The voltage plateau was again reached earlier than the gassing plateau. The over-all attenuation factor was  $\epsilon\alpha'\eta = 5.0 \cdot 10^{-4}$ , the same as  $\alpha\eta$  in the run of Fig. 5. (This is not generally the case, since  $\epsilon$  may be less than unity, and  $\alpha'$  less than  $\alpha$ .) The gassing ratio  $\rho'$  approached 1.0, again showing that no gas has recombined or been reabsorbed.

Curves from sealed batteries, which for the purpose of measurement of gassing rates have to be unsealed, do not in general represent the events as they occur under service conditions when recombination and reabsorption take place. Flushing the head space of such batteries interferes with these processes. Accessories to the present system are being considered for the examination of sealed batteries through intermittent withdrawal or by means of a continuous bleed of gas from the head space, to be transferred to a carrier gas that does not sweep through the battery case.

*Simultaneous recording of O<sub>2</sub> and H<sub>2</sub> from a battery.*—The gas stream issuing from the sampling stream may be split to feed two analyzing branches, one, without catalyst, for O<sub>2</sub>, the other, with catalyst, for H<sub>2</sub>. It seems more practical to alternate instead between the two modes, jumping from the rising sigmoid curve for O<sub>2</sub> to the declining one for H<sub>2</sub>, and back following each curve for an interval of, say, 10 min before each change. The combustion segment and the microelectrolyzer current must be switched in and out at the same moment. It is also possible to design a routing system in which the combustion segment, instead of being bypassed, is made to succeed the

Fig. 5. Charge of positive

Fig. 6. Charge of negative

sensor in the  $O_2$  mode, but precedes it in the  $H_2$  mode. In this case the microelectrolyzer may be left in operation continuously.

**Transients.**—A step-change of charging current from  $I$  to  $I^*$  causes a transient excursion of the recorder trace before a new sensor output,  $i^*$ , is reached. This transient has nothing to do with the battery itself. Following a step in the total gassing rate, from  $\phi = 3.73 (\rho + 2\rho') I$  to  $\phi^* = 3.73 (\rho + 2\rho') I^*$  ml/min, the gas flow into the sensor changes immediately, but carrier gas with the changed oxygen concentration reaches the sensor only after a time interval. This interval depends on the volume of the ducts between the electrolytic source of oxygen and the sensor. Ignoring  $i_0$ , the transition of  $i$  is from  $\alpha\eta\rho I$  through  $\alpha\eta\rho IZ$  to  $\alpha\eta\rho I^*$ , with  $Z = (F - f + \phi^*) / (F - f + \phi)$ . There is no transient when the step is from  $I = 0$  to  $I^* > 0$ , but there is one when switching from  $I > 0$  to  $I^* = 0$ . Because  $Z$  is a function of both  $\rho$  and  $\rho'$ , the amplitude of the excursion of the oxygen trace is affected by the rate of evolution of both oxygen and hydrogen.

The hydrogen trace  $i'$  goes even through a double transient, depending on the duct volumes between the microelectrolyzer and the sensor and that between the source of electrolytic hydrogen and the microelectrolyzer. A sudden rise of  $I$  to  $I^*$  causes first a sharp rise of  $i'$ , then a mild fall, followed by a further fall. A step-down of charging current causes the opposite moves. The changes in output  $i'$  are from  $i_1 - \epsilon\alpha'\eta\rho'I$  through  $(i_1 - \epsilon\alpha'\eta\rho'I)Z$  through  $i_1 - \epsilon\alpha'\eta\rho'IZ$  to  $i_1 - \epsilon\alpha'\eta\rho'I^*$ .

**Related applications.**—The gradual decline of charge acceptance of a battery may be determined during formation, the battery's first cycle.

The galvanic technique may be used to advantage in determining slow evolution rates of hydrogen from self-discharging negatives of secondary, or anodes of primary, cells. The accidental or deliberate release of gases from incompletely sealed batteries may be measured. The loss of oxygen from silver oxide cathodes or the catalytic evolution of hydrogen from hydrazine anodes may be studied.

When the gas evolves very slowly, the attenuation system and the large electrolyzer should be omitted, while retaining the humidifier and combustion segment with its microelectrolyzer. The combustion efficiency ( $\epsilon$ ) can then be determined by placing two nickel wire electrodes in the microelectrolyzer, in addition to the submerged Cd/Cd<sup>II</sup> electrode. Using two electrolytic circuits, with the Cd/Cd<sup>II</sup> electrode in common, an oxygen flux  $j$  is produced at one nickel wire and a hydrogen flux  $j'$  at the other. First, with

$j' = 0$ , one obtains an oxygen base line  $i_1 = i_0 + \eta j$ ; then, injecting hydrogen, with  $0 < j' < j$ , one obtains a depressed level  $i' = i_1 - \epsilon\eta j'$ ; hence

$$\eta = \frac{i_1 - i_0}{j}; \quad \epsilon = \frac{i_1' - i_1}{i_1 - i_0} \cdot \frac{j}{j'}$$

The formulas for charge acceptance are still valid, but with  $\alpha = 1$  and the "input" current  $I$  representing the rate of the spurious spontaneous gassing under observation. Where the gas evolution stems from local galvanic action,  $I$  is the invisible action current, rendered visible. The method supersedes the writer's earlier galvanic procedure for measuring rates of metallic corrosion of the hydrogen evolution type (5).

The present technique may be applied in studies of gas evolution overvoltage and also of the thermal dissociation of oxides (PbO<sub>2</sub>, AgO, Ag<sub>2</sub>O, etc.) at temperatures too low for thermogravimetry to be applicable. The efficiency of oxygen/hydrogen combination catalysts under various conditions, and the effect of activating treatments given these catalysts, may be assessed using variants of the described procedures.

Applications for monitoring the fast or slow evolution of oxygen and hydrogen exist in chemical and biochemical systems. With appropriate catalysts, or with combustion at a sufficiently elevated temperature, the rates of emanation of most organic gases and vapors from liquid and solid systems could also be determined.

# The Electric Resistivity of AgO

Aladar Tvarusko\*<sup>1</sup>

Research Center, ESB, Inc., Yardley, Pennsylvania

## ABSTRACT

The electric resistivity,  $\rho$ , of powder AgO samples, made by the chemical oxidation of AgNO<sub>3</sub>, was measured *in situ* up to 10 kbar.  $\rho$  increased linearly with decreasing AgO content of the samples (>70%). 63 AgO samples of 98.4% mean AgO content had a mean  $\rho$  of 59.3 ohm cm at 2.1 kbar. When Mg, Ca, Cd, In, Si, Y, Pd, Ni, or Co was added (as compounds) during the preparation of AgO,  $\rho$  of the sample increased. The addition of Hg, Ge, Sn, Pb, As, Sb, or Bi had a beneficial effect on  $\rho$  of AgO samples. Pb increased the length of the higher voltage plateau of AgO-Zn cells during discharge whereas Hg had no influence.

Silver oxide is extensively used in packaged power sources because it yields cells of high voltage and capacity per unit weight or volume. The capacity and discharge rate of these cells is greatly influenced by the electric resistivity of the silver oxide.

Silver belongs to group IB of the Periodic Table and may have three oxidation states, I, II, and III. The common valence of silver is +1, and Ag<sub>2</sub>O is its corresponding oxide. Ag<sub>2</sub>O has a high electric resistivity (1, 2) and 10<sup>8</sup> ohm cm (3) and 7.10<sup>8</sup> ohm cm (at 4.3 kbar) (4) were measured. Fortin and Weichman (2) found a band gap of 1.5 eV for Ag<sub>2</sub>O.

The trivalent silver compounds are unstable unless stabilized by coordination with suitable species (5, 6); the existence of the corresponding oxide, Ag<sub>2</sub>O<sub>3</sub>, has not yet been proven conclusively.

The divalent silver oxide, commonly designated as AgO, was found to be a silver (I)—silver (III) oxide (5, 7) with a considerable covalent bond and with no divalent silver present. The AgO formula will be used to describe the aforementioned silver oxide in this work.

The resistivity of AgO is much lower than that of Ag<sub>2</sub>O and the following values were found for AgO: 10 ohm cm at 20°C (3), 14.3 ohm cm  $\pm$  15% at 20°C and 12.16 kbar (8), 0.012 ohm cm (9), 5000 ohm cm at 4.3 kbar (4). These values form three distinctly different groups.

Yoshizawa and Takehara (10) found that the presence of Pb, Sn, In, Ti, Au, and Cu in the silver electrode had a marked influence on its charge and discharge. They claim that the lattice defects in Ag<sub>2</sub>O or AgO increase due to the addition of metals of higher valency than Ag<sup>+</sup> or Ag<sup>2+</sup>, and therefore the electric conductivity will increase. This is to be expected because the conductivity,  $\sigma$ , of a material is given by the product of the charge carrier concentration,  $n$ , their charge,  $e$ , and their mobility,  $\mu$ , [*e.g.*, (11)].

$$\sigma = ne\mu = \rho^{-1} \quad [1]$$

Yoshizawa and Takehara, however, did not measure the resistivity,  $\rho$ . According to Cahan (12, 4) silver plumbate forms in an alkaline electrolyte when lead or a compound of it is added to the active material of a silver electrode; the resistivity of silver plumbate is said to be approx. 3 x 10<sup>-3</sup> ohm cm.

The resistivity of AgO is studied in this work. The investigated variables are: pressure, time, AgO content of AgO samples, coprecipitated impurities in AgO, and AgO content in physical mixtures of Ag<sub>2</sub>O — AgO and AgO — HgO.

## Experimental

The AgO samples were made by the chemical oxidation of aqueous AgNO<sub>3</sub> solution in alkaline medium

by K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> as described by Hammer and Kleinberg (13). "Baker Analyzed" reagents of the J. T. Baker Chemical Company were used for the synthesis. The AgO sample was dried in a vacuum oven at 60°  $\pm$  1°C for 16 hr and subsequently stored in an amber glass bottle with a ground joint. The sample was exposed to the ambient as little as possible. The active oxygen content of the various AgO samples was determined iodometrically and is expressed as AgO content. Commercially available battery-grade Ag<sub>2</sub>O (Ames Chemical Work, Inc., Glens Falls, New York) and reagent-grade red HgO (Merck and Company) were used. The various reagent-grade additives were incorporated into AgO during its preparation. The metal nitrate salt was added to the aqueous AgNO<sub>3</sub> solution before its addition to the alkaline K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> reaction medium. Some of the impurities had to be added to AgNO<sub>3</sub> solutions as anions or mixed with alkaline K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> medium before the AgNO<sub>3</sub> addition.

The electric resistivity of the powder sample was measured under pressure (*in situ*) in the measuring cell by a Keithley Milliohmmer, Model 503 (for samples of R < 1 kohm) or a Keithley Electrometer, Model 610 (for R > 1 kohm). The output of the aforementioned instruments was recorded on a recorder of adequate rise time and variable strip chart speed.

A Carver Laboratory Press, Model B was used for the compression of the sample. The measuring cell consisted of a flat Stellite base plate and rod which fitted a steel-jacketed insulating cylinder. The insulating material (Black XX-79 molded rod of The Budd Polychem Division, Newark, Delaware) had 5-6 x 10<sup>9</sup> ohm surface resistance (between ½ in. electrodes at ¼ in. basic). The steel-jacketed cylinder was firmly and flatly held to the base plate by a contoured steel plate, placed over its top, with the help of two strong embedded steel rods and wing nuts. Two similar measuring cells were used: (a) 5.0 cm<sup>2</sup> pellet area, used up to 2.1 kbar; the thickness of the pellet was measured, after its careful removal from the cell, by a micrometer caliper; (b) 1.0 cm<sup>2</sup> active area, used up to 10.6 kbar; the thickness of the sample during compression was measured *in situ* by an indicating micrometer caliper; naturally, the solidly attached resting arms for the caliper shoes were electrically insulated from the Stellite base plate and rod by polyethylene screws and spacers. The electric leads of the measuring instruments were connected to copper sheets (1 x 2 x 0.3 cm), firmly screwed to the base plate and rod, respectively.

At least two separate measurements were made on each dried sample (5000 and 2000g for up to 2.1 and 10.6 kbar pressures, respectively) at an ambient temperature of 25°  $\pm$  2°C. The sample was evenly distributed in the assembled, clean, and dry measuring cell, and the rod was slowly lowered into the cylinder. The assembled cell was placed into the press between two insulating layers consisting of Bakelite and pressed

mica sheets. The pressure on the sample was first slowly raised and after selecting the proper resistance range on the instrument, rapidly ( $\sim 5$  sec) increased to the maximum pressure, unless otherwise mentioned. The resistance of the empty measuring cell was around 1m ohm and was neglected because it was less than 0.1% of the smallest measured resistance value.

### Results and Discussion

$\rho$  as a function of pressure and time.—In order to measure the resistivity of silver oxides, the powder samples had to be compacted. Figure 1 shows  $\log \rho$  of two AgO samples as a function of pressure. The resistivity of both samples decreased very rapidly at lower pressures as the AgO powder was compressed into shiny, brittle pellets. The apparent density of AgO samples at 2.1 kbar was calculated from the linear plot of sample weight and pellet thickness to be around 70% of that given in the literature. Thus, it can be safely assumed that the initial rapid decrease of  $\rho$  is due to the increased compaction of the sample. The initial decrease is reproducible in both measuring cells.

$\log \rho$  decreased linearly with pressure after its initial rapid decrease regardless of the AgO content of the sample.  $\rho$  should decrease with pressure because both  $\mu$  and  $n$  in Eq. [1] depend on pressure, in addition to temperature (14). The mobility increases to some degree with pressure, but the carrier production is the controlling factor in the resistivity of semiconductors. The carrier production is usually an activated process which is dominated by an exponential term containing the energy gap (14). An approximately linear decrease of the energy gap could possibly explain the aforementioned linear decrease of  $\log \rho$  with pressure.

Figure 1 shows that the resistivity of AgO samples increases with decreasing AgO content; this will be discussed later. The transition to the linear decrease of  $\log \rho$  shifts toward higher pressures with decreasing AgO content. Furthermore, the slope of the regression lines [fitted by the least square method (Fig. 1)] decreases with decreasing AgO content. The high resistivity of Ag<sub>2</sub>O, present in a sample of low AgO content, seems to be the controlling factor behind all these observations.

In order to compare the resistivity of AgO with the published values,  $\rho$  was extrapolated to the 12.16 kbar pressure of Neiding and Kazarnovskii (8) using the regression line equation (Fig. 1, 99.0%); the calculated 14.6 ohm cm compares very favorably with their 14.3 ohm cm  $\pm 15\%$ . Jones and Thirsk (9) obtained 0.012 ohm cm by extrapolation to  $1/P = 0$  pressure from a series of measurements up to 0.7 kbar. Replotting the  $\rho$  values of Fig. 1 (99.0% AgO) as a function  $1/P$ , the following regression lines were obtained: (a)  $\rho = 36.8 + 6.15 \times 10^4 1/P$  up to 2100 bar, coefficient of correlation,  $R = 0.998$ , and (b)  $\rho = 13.4 + 0.56 \times 10^4 1/P$  up to 10,600 bar,  $R = 0.998$ . The intercepts of these regres-

sion lines are approximately 3 orders of magnitude larger. The extrapolations to  $1/P = 0$ , i.e., extremely high pressures from measurements up to 700 bar, cannot be justified because of the possibility of a sharp discontinuity in the  $\rho - P$  curve at higher pressures (14).

It was observed that  $\rho$  of both silver oxides changed with time after a specified constant pressure was reached. The resistivity behavior of the two silver oxides was opposite and  $\rho$  of AgO increased whereas  $\rho$  of Ag<sub>2</sub>O decreased with time. The largest change occurred within the first minute of the measurement (10% increase for AgO and 3X decrease for Ag<sub>2</sub>O) and certain constant  $\rho$  values were approached asymptotically at the end of an hour long measurement (additional 10% increase for AgO and 1.8X decrease for Ag<sub>2</sub>O in 59 min). The time required to reach a constant  $\rho$  decreased with decreasing AgO content of AgO samples or AgO — Ag<sub>2</sub>O physical mixtures; the transition between the aforementioned opposite  $\rho$ -time behaviors occurred at 10 and 5% Ag<sub>2</sub>O contents ( $\rho$  remained constant right from the beginning). In view of the time dependence of  $\rho$ , the pressure was uniformly raised in approx. 5 sec to the final value. The  $\rho$  values reported here represent  $\rho$  right after the specified pressure was reached. The asymptotic value of  $\rho$  could be equally or perhaps more significant than the reproducible  $\rho$  values reported in this paper; the later ones were preferred because of the speed ( $< 1$  min vs. 1 hr) and ease of measurement (maintenance of constant pressure over long period is not required). No efforts were made to elucidate the time dependence of  $\rho$ , which may be due to several factors (e.g. development of contacts between some of the particles, temperature rise due to compression, carrier concentration and mobility changes, etc).

$\rho$  as a function of AgO content.—X-ray diffraction analysis revealed that AgO samples of inherently low AgO content contained only AgO and Ag<sub>2</sub>O. During the discharge of AgO in alkaline batteries Ag<sub>2</sub>O forms. In view of the high resistivity of Ag<sub>2</sub>O, the resistivity of AgO samples and the active materials of battery plates should be influenced by the amount of Ag<sub>2</sub>O present. It can be seen in Fig. 2 that resistivity of AgO samples increases with decreasing AgO content. The regression line represents 122 samples, and the coefficient of correlation is low ( $R = 0.859$ ). The large solid circles represent the resistivity of AgO — Ag<sub>2</sub>O physical mixtures prepared by the thorough mixing of AgO (98.2%) and commercially available battery-grade Ag<sub>2</sub>O (Ames Chemical Work, Inc.). The close agreement of  $\rho$  with the other data support the x-ray evidence that an AgO sample of inherently low AgO content is a physical mixture of AgO and Ag<sub>2</sub>O. Ball-milling did not influence the resistivity of the physical mixtures. The influence of the high resistivity of Ag<sub>2</sub>O

Fig. 1. Resistivity of AgO samples as a function of pressure

Fig. 2. Resistivity of chemically prepared AgO samples and physical mixtures of AgO — Ag<sub>2</sub>O as a function of AgO content.

on the resistivity of AgO — Ag<sub>2</sub>O physical mixtures became more apparent below 50% AgO and dominant below 20% AgO.

Table I shows the mean resistivity at 2.1 kbar and related statistical data of AgO samples at arbitrarily chosen AgO content levels. The majority of the usable ( $\geq 95.0\%$ ) AgO samples had an AgO content  $\geq 98.0\%$ . It can be seen that  $\bar{\rho}$  decreases with increasing mean AgO content according to  $\bar{\rho} = 435 - 3.819 (\text{AgO}\%)$  ( $R = 0.975$ ) which is similar to the regression line equation in Fig. 2. In view of the similarity of  $\rho$  values of Table I and Fig. 1 at 2.1 kbar (99.0% AgO) and resistivity behavior of AgO samples with pressure, it can be safely assumed that the  $\bar{\rho}$  values extrapolated to 12 kbar are comparable to the 14.3 ohm cm of Neiding and Kazarnovskii (8).

*Effect of inorganic additives.*—According to Yoshizawa and Takehara (10), the resistivity of AgO should decrease with the addition of metals of higher valency than I or II [this really should be I and III (5, 7)]. An investigation was undertaken to determine the effect of various impurities on the resistivity of chemically prepared AgO samples. Some elements are not suited for addition (inert gases, radioactive elements, etc), whereas salts of others were not available in commercial quantity, at the time, or have no effect (alkali metal ions are present during preparation). The investigated elements, in salt form, were added first at one concentration level, 1000 parts by weight per million parts of silver used for the preparation of AgO, i.e., 1000 ppm(Ag).

Results are presented in Tables II and III for the nontransition and transition elements, respectively. The transition elements in their broader definition (15) include also the coinage metals (Cu, Ag, Au) which have partly filled d or f shells in any of their commonly occurring oxidation states.

The AgO content should not decrease due to the addition of the aforementioned small amount of impurity unless the impurity is detrimental. The AgO contents of the samples with added nontransition elements vary slightly, but all are  $\geq 96.0\%$ . The samples made in the presence of transition elements have, in general,

slightly lower AgO contents. Low AgO contents ( $\sim 90\%$ ) were obtained in the presence of Zr and Ta, and Co and Ni drastically reduced the AgO content to 38%. This AgO content shows up in the high resistivity of the two, latter mentioned samples. The addition of Mg, Ca, Cd, In, Si, Y, and Pd resulted in AgO samples of higher resistivity whereas Hg, Ge, Sn, Pb, As, Sb, and Bi (mainly at larger concentrations) yielded samples of lower resistivity. The resistivity of AgO samples with group IV elements seems to decrease with increasing atomic number. It is interesting to note that all beneficial additives have a IV and V valence (in their oxidized state) with the exception of Hg. Tables II and III show that In and Cu increased the resistivity of chemically precipitated AgO samples in contradiction with Yoshizawa and Takehara (10); in the case of Pb and Sn, however, the results of the present study support their claim.

$\rho$  as a function of additive concentration.—In view of the aforesaid beneficial and detrimental effects of the additives, it was of interest to determine the effect of additive concentration. The quantity of NaOH and K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> was maintained constant (13) in these experiments, but the amount of AgNO<sub>3</sub> was decreased at higher additive concentrations to keep the reaction product to about 72g. Metal nitrates were preferentially added to the AgNO<sub>3</sub> solution, but Na<sub>2</sub>SnO<sub>3</sub>, GeO<sub>2</sub>, Na<sub>2</sub>SiO<sub>3</sub>, Na<sub>2</sub>HAsO<sub>4</sub>, Sb<sub>2</sub>O<sub>3</sub>, H<sub>2</sub>SeO<sub>3</sub>, and Na<sub>2</sub>TeO<sub>3</sub> were added to the alkaline K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> medium.

Figure 3 shows the resistivity of AgO as a function of additive concentration. This concentration represents the metal content used in the preparation of AgO and does not necessarily correspond to the added metal content of the sample. It can be seen that the resistivity of the samples varies over 7 orders of magnitude, and the  $\rho$ -concentration curves form three distinct groups.

Ni, Cd, Mg, Be, and Te detrimentally affected the resistivity. Ni and Co (Table III) were detrimental already at very small concentrations and samples of low AgO contents were obtained. This can be seen very clearly in Fig. 4 which shows the AgO content of the samples as a function of the additive concentration. V up to  $2 \times 10^5$  ppm(Ag) concentration, did not influence the resistivity and the AgO content of the samples. It is very likely that soluble meta-vanadates formed on the addition of V<sub>2</sub>O<sub>5</sub> to the alkaline persulfate which were subsequently washed out from the AgO precipitate. Cr and Mn [1000 ppm(Ag)] did not influence the aforementioned properties to any significant degree because they were oxidized to soluble chromate and permanganate, respectively, by the alkaline persulfate as judged by the yellowish and red-wine colored mother liquors obtained.

Cd, which was found to replace Ag<sup>++</sup> (16), increased  $\rho$  already at small concentrations without detrimentally

Fig. 3. Resistivity of AgO samples with additives which were intentionally added in various amounts during their preparation.

Fig. 4. AgO content of AgO samples as a function of additive concentration.

affecting the AgO content. At higher additive concentrations the AgO content of the samples, in general, decreased because the amount of silver nitrate used was decreased; the decrease of the AgO content is larger if the additive is detrimental (Fig. 4). Cadmium hydroxide was detected by x-ray diffraction in samples of higher Cd content.

The resistivity was slightly increased by the addition of Mg and Be in the  $10^3$  to  $10^4$  ppm(Ag) range; Be above this concentration increased  $\rho$  considerably. X-ray diffraction patterns of AgO samples with higher Be additions showed AgO present along with unidentified peaks.

The oxidation of  $\text{Ag}^+$  in the presence of  $\text{TeO}_2$  and NaOH by  $\text{K}_2\text{S}_2\text{O}_8$  yields a tellurate complex (5, 6, 15) with stabilized trivalent silver. The resistivity of samples with Te increased slowly up to  $10^5$  ppm(Ag) and rapidly above this concentration. X-ray diffraction patterns revealed the presence of AgO and a Te compound (not listed in ASTM file) in samples with  $10^4$  to  $2 \times 10^5$  ppm(Ag) Te added. Samples containing  $5 \times 10^5$  ppm(Ag) or more Te gave an x-ray diffraction pattern which had no AgO peaks and was different from the aforementioned pattern. No effort was made to identify these compounds.

AgO samples with 1000 ppm(Ag) Fe, Zr, Mo, Pr, Ge, As, or Sb have resistivities between 20 to 45 ohm cm. These additives form a transition between the detri-

mental and beneficial additives. Only As and Sb were studied as a function of concentration. In the case of As,  $\rho$  remained almost unchanged up to  $2 \times 10^5$  ppm(Ag) As concentration (52.1 ohm cm) and the AgO content decreased only to 95.3%. This and the obtained yields show that little or no As was incorporated into the AgO sample. When Sb or Bi were added, the product yield was greater than the anticipated yield for AgO. X-ray diffraction patterns showed AgO present as well as unidentified peaks in the aforementioned two series of samples. No values in the ASTM file corresponded to these peaks, and no attempt was made to identify these and other unknown compounds by analytical methods.

The resistivity of Sb-containing AgO samples changes little as a function of concentration. In contrast, the resistivity of samples with more than 1000 ppm(Ag) Bi, decreased rapidly to 0.148 ohm cm at  $2 \times 10^5$  ppm(Ag) in spite of a concomitant AgO content decrease.

Pb, Sn, and Hg markedly decreased the resistivity already at  $10^2$  ppm(Ag) concentration (Fig. 3). In the presence of Pb,  $\rho$  steadily decreased whereas  $\rho$  went through a minimum in the presence of Sn and Hg. Figure 5 shows  $\rho$  as a function of additive content which was determined by chemical analysis and is expressed in gram atomic weight (GAW) of elemental additive per gram atomic weight of silver present in the sample. The behavior of  $\rho$  is similar to that shown in Fig. 3. The comparison of the tin content of the AgO samples,  $c$ , with the amount of tin added during their preparation,  $c_a$ , however, revealed that much (82-92%) of tin added did not precipitate with the product; the  $c/c_a$  ratio decreased with increasing  $c_a$ . X-ray diffraction patterns of AgO samples containing tin at high concentrations showed the presence of  $\text{Ag}_2\text{O}$  which could account for the increase of  $\rho$ .

In view of the similarity of the structural dimensions of AgO ( $a_o = 5.85\text{\AA}$ ,  $b_o = 3.47\text{\AA}$ ,  $c_o = 5.49\text{\AA}$ ,  $\beta = 107^\circ 30'$ ) and HgO ( $a_o = 6.60\text{\AA}$ ,  $c_o = 3.52\text{\AA}$ ,  $b_o = 5.52\text{\AA}$ ,  $\beta = 90^\circ$ ), it is expected that  $\text{Hg}^{++}$  can replace some of the silver ions in the lattice, and influence the properties of the resulting AgO. The x-ray pattern of AgO was gradually distorted with increasing Hg content until it became identical with the HgO pattern at  $1.86 \times 10^6$  ppm(Ag) Hg indicating the replacement of Ag by Hg in the lattice.

The resistivities of physical mixtures of HgO and AgO (ball-milled) were also measured and are shown

Fig. 5. Resistivity of AgO samples as a function of their additive content.

Fig. 6. Resistivity of physical mixtures of AgO—HgO and AgO samples with coprecipitated Hg.

in Fig. 6. It can be clearly seen that  $\rho$  increased in the physical mixtures steadily with increasing HgO content due to the very high resistivity of HgO. In contrast, the resistivity of the coprecipitated oxides decreased to a minimum and then increased with increasing Hg content (expressed as HgO content in Fig. 6). This supports the x-ray evidence for the incorporation of Hg in the lattice.

The resistivity of AgO samples continuously decreased with increasing elemental Pb content (Fig. 5) in the investigated range in contrast to samples containing Sn and Hg. Seemingly, the low resistivity of PbO<sub>2</sub> [as low as  $4 \times 10^{-5}$  ohm cm (17)] and high resistivity of tin oxides [ $\cong 10^4$  ohm cm (3)] and HgO (Fig. 6) could explain the aforementioned behavior. The lowest measured resistivities correspond to samples for which Pb was added in a ratio of the silver plumbate formula, Ag<sub>5</sub>Pb<sub>2</sub>O<sub>6</sub>. This was hydrothermally synthesized by Byström and Evers (18) from a mixture of Ag<sub>2</sub>O and PbO<sub>2</sub>, and its chemical essay is shown in Table IV. It can be seen that the experimental values of Byström and Evers agree well with the calculated percentages. In our case (average of 3 samples), the Ag and Pb contents are slightly lower but the available oxygen is approximately 3X larger than the calculated values for Ag<sub>5</sub>Pb<sub>2</sub>O<sub>6</sub>. The latter implies that some of the silver atoms are present in higher than monovalent state; the Pb atoms are said to be in tetravalent state (18). The x-ray diffraction patterns of these AgO samples showed an increase of the pattern of Ag<sub>5</sub>Pb<sub>2</sub>O<sub>6</sub>. It is, however, possible that the samples with various Pb contents form a mixed oxide phase of varying composition.

Table IV. Chemical analyses of AgO samples with Pb added in the ratio of formula Ag<sub>5</sub>Pb<sub>2</sub>O<sub>6</sub>

Content, %	Calculated for Ag <sub>5</sub> Pb <sub>2</sub> O <sub>6</sub>	Experimental	
		Byström and Evers (18)	Present study
Ag	51.39	51.0 ± 0.5	50.4 ± 0.5
Pb	39.44	39.0 ± 0.5	37.5 ± 0.45
Available O (peroxide)	2.29	2.32 ± 0.02	6.50 ± 0.09

Table V. Influence of Hg, Pb, Sn, and Ge in binary mixtures on the resistivity of AgO samples

Hg	Elements added, ppm (Ag)		Ge	AgO content, %	$\rho$ , ohm cm
	Pb	Sn			
1000	—	—	—	97.5	9.12
500	500	—	—	98.0	5.58
500	—	500	—	98.2	7.87
500	—	—	500	97.5	10.7
—	1000	—	—	98.5	6.95
—	500	—	500	98.4	7.41

*Influence of additives in binary mixtures.*—It was of interest to see the influence of two jointly added beneficial additives on the resistivity of AgO samples. Table V shows the effect of Hg, Pb, Sn, and Ge in mixtures of equal weight ratios. When part of Hg was replaced by Pb or Sn,  $\rho$  decreased, but increased with Ge. When half of Pb was replaced by Hg,  $\rho$  slightly decreased, and the replacement by Sn or Ge had no effect or slightly increased the resistivity. Thus, it can be said that the nature of the additives and their concentration affect the resistivity of AgO samples regardless whether they are used alone or in mixtures.

*Discharge of AgO-Zn cells with additives.*—Cahan *et al.* (4, 12) showed that the addition of PbO to the AgO in the cathode mix enhances the discharge of AgO at its higher voltage plateau. Therefore, it was of interest to discharge these AgO samples in cells (Ray-O-Vac 675 size). Figure 7 shows the discharge voltage of cells with various amounts of Pb added to the AgO during its preparation; cells were discharged continuously at 770 ohms (ca. 2 ma). It can be seen that the length of the higher voltage plateau, *i.e.*, the capacity to 1.6v, increases and the lower voltage plateau, concomitantly decreases and eventually disappears with the increasing amount of Pb added. The cell capacity decreased when the amount of Pb is increased from  $5 \times 10^4$  to  $10^5$  ppm (Ag). The optimum Pb amount seems to be between  $10^4$  and  $5 \times 10^4$  ppm (Ag). In view of the resistivity decrease of AgO samples with Pb content (Fig. 5), it was of no surprise that the flash amperage of the cell increased about three times (0.12-0.42 amp) and the cell impedance (at 60 Hz) decreased (14.7-4.6 ohms) with increasing Pb content [up to  $10^5$  ppm (Ag)].

Figure 8 compares the discharge voltages of cells containing AgO with  $5 \times 10^4$  ppm (Ag) coprecipitated Pb and 5% admixed PbO, respectively. It is obvious that the cells with PbO are superior to those containing AgO with coprecipitated Pb. The flash amperage and the impedance (60 Hz) of cells with admixed PbO were superior (0.56 amp, 2.6 ohms) to those with coprecipitated Pb (0.33 amp, 4.5 ohms). The improvement seems to be caused by a surface coating of a Pb-Ag compound [likely silver plumbate (12)] formed slowly in contact with alkaline electrolyte.

Fig. 7. Discharge voltage of AgO—Zn cells (Ray-O-Vac 675 size, discharged continuously at 770 ohms, ca. 2 ma) with various amounts of Pb added to AgO during its preparation.

Fig. 8. Discharge voltage of AgO—Zn cells (Ray-O-Vac 675 size, discharged continuously at 770 ohms, ca. 2 ma) with AgO containing coprecipitated Pb, Hg, or admixed PbO.

It was shown earlier (Fig. 3, 5) that the resistivity of AgO samples containing Hg up to  $5 \times 10^4$  ppm(Ag) concentrations is only slightly higher than  $\rho$  of AgO samples with Pb. Figure 8 clearly shows that cells made with AgO containing  $5 \times 10^4$  ppm(Ag) Hg are inferior to cells with Pb added by either method and in any amount. This shows that the low resistivity of AgO samples alone is not sufficient to obtain a large capacity at the higher voltage plateau of AgO. No attempt was made to elucidate the cause of the aforementioned phenomena.

### Summary

The electric resistivity of powder AgO samples was measured *in situ* up to 10 kbar. The AgO samples were made by chemical oxidation of  $\text{AgNO}_3$  (13) in the absence or presence of intentionally added metal additives (as compounds). Log  $\rho$  was found to decrease linearly with pressure after its initial rapid decrease at lower pressures regardless of the AgO content of samples (Fig. 1). The resistivity of AgO samples increased linearly with decreasing AgO content (> 70%). 63 AgO samples of 98.4% mean AgO content had a mean resistivity of 59.3 ohm cm at 2.1 kbar.  $\rho$  is 14.6 ohm cm at 12 kbar which compares very favorably with 14.3 ohm cm  $\pm$  15% of Neiding and Kazarnovskii (8).

The AgO content of samples made in the presence of 1000 ppm(Ag) elemental additive (1000 ppm parts Ag) did not change noticeably with the exception of Zr, Ta (90%) and Co, Ni (38%). The addition of Mg, Ca, Cd, In, Si, Y, Pd, Ni, or Co yielded AgO samples of higher resistivity whereas the addition of Hg, Ge, Sn, Pb, As, Sb, or Bi (mainly at higher concentrations) gave samples of lower resistivity than the mean AgO resistivity. The resistivity of samples continuously decreased with increasing Pb and Bi concentration. In the presence of increasing Sn and Hg contents  $\rho$  first decreased, then went through a minimum and increased

rapidly. All the beneficial additives have four and five valence in their oxidized state with the exception of Hg. The nature of the additives and their concentration affect the resistivity of AgO samples regardless whether they are used alone or in mixture.

The continuous discharge of AgO samples in Ray-O-Vac 675 size cells at 770 ohms (ca. 2 ma) showed that the length of higher voltage plateau increased with increasing Pb content of the sample. Cells with admixed PbO were found to be superior to those with coprecipitated Pb. Cells with Hg were inferior to those with Pb in any amount.

### Acknowledgment

The author wishes to thank Dr. R. A. Schaefer for permission to publish this paper and Messrs. C. J. Venuto and H. Wilson for the x-ray and analytical data.

Manuscript submitted May 15, 1968; revised manuscript received ca. July 15, 1968. This paper was presented at the Montreal Meeting, Oct. 6-11, 1968, as Paper 371.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# The Active Iron Electrode

## II. Anion Adsorption and Its Effects on the Iron Dissolution and Hydrogen Evolution Reactions

Eugene J. Kelly\*

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

### ABSTRACT

The kinetics of adsorption/desorption of an anion inhibitor on zone-refined iron in the active state and the effects of the adsorbed inhibitor on the iron dissolution and hydrogen evolution reactions have been determined by means of quantitative analyses of "instantaneous," transient, and steady-state anodic and cathodic electrochemical polarization data. The mechanism proposed for iron dissolution in the inhibited system involves formation of an electrochemically active surface intermediate from the adsorbed anion and  $(\text{FeOH})_{\text{ad}}$ . On the other hand, the adsorbed anion accelerates the hydrogen evolution reaction, and this is attributed to a  $\psi$ -effect, i.e., to a double-layer effect and to a simultaneous diminution in the standard chemical free energy of activation for proton discharge. Of particular interest with regard to the hydrogen evolution reaction is the fact that, at constant solution composition,  $(\partial \log i_c / \partial E)_\theta = 1/S$ , where  $S$  is a constant the magnitude of which is a function of  $\theta$  and, consequently, the measurement of which enables the indirect evaluation of  $\theta$ .

A comparative study has been made of the electrochemical behavior of the active iron electrode in typical inhibiting and noninhibiting media. The purpose of the investigation was to examine the changes produced in the kinetics and mechanistics of a non-inhibited system as a result of specific adsorption of an anion inhibitor. Such information is not only essential to the understanding of corrosion inhibition, but is also relevant to the interpretation of kinetic data for other electrode processes involving adsorption.

The first paper in this series (1) reported on the iron dissolution and hydrogen evolution reactions for zone-refined iron in hydrogen-saturated, acidic sulfate solutions (hereafter referred to as the noninhibited system). It was shown that the steady-state iron dissolution reaction is characterized by an anodic Tafel slope of  $(2/3)(2.303 RT/F)$ , i.e., 40 mv/decade, and a first order dependency on the hydroxyl ion activity. These results were interpreted in terms of the following mechanism, which takes formal account

of the simultaneous coverage of the electrode surface by adsorbed water molecules, hydroxyl ions, and the surface intermediate,  $(\text{FeOH})_{\text{ad}}$ . The kinetic description of this mechanism is given by Eq. [6]-[9], in which

$$i_a/F = \bar{k}_3\theta_2 - \bar{k}_{-3}\theta_3 + \bar{k}_4\theta_3 \quad [6]$$

$$\beta d\theta_1/dt = \bar{k}_1(1 - \theta_T) - \bar{k}_{-1}\theta_1 - \bar{k}_2\theta_1 + \bar{k}_{-2}a_{(\text{H}^+)}\theta_2 \quad [7]$$

$$\beta d\theta_2/dt = \bar{k}_2\theta_1 - \bar{k}_{-2}a_{(\text{H}^+)}\theta_2 - \bar{k}_3\theta_2 + \bar{k}_{-3}\theta_3 \quad [8]$$

$$\beta d\theta_3/dt = \bar{k}_3\theta_2 - \bar{k}_{-3}\theta_3 - \bar{k}_4\theta_3 \quad [9]$$

$i_a$  is the net anodic current density,  $\bar{k}_j$  are electrochemical rate constants, and  $\theta_1$ ,  $\theta_2$ , and  $\theta_3$  represent the fractions of the total possible adsorption sites occupied by  $\text{Fe}(\text{H}_2\text{O})_{\text{ad}}$ ,  $\text{Fe}(\text{OH}^-)_{\text{ad}}$ , and  $(\text{FeOH})_{\text{ad}}$ , respectively, i.e.,

$$\begin{aligned} [\text{Fe}(\text{H}_2\text{O})_{\text{ad}}] &= \beta\theta_1, & [\text{Fe}(\text{OH}^-)_{\text{ad}}] &= \beta\theta_2, \\ [(\text{FeOH})_{\text{ad}}] &= \beta\theta_3 \end{aligned}$$

where the surface concentrations are expressed in mole/cm<sup>2</sup>, and  $\beta$  is a proportionality constant. The total fraction of sites occupied,  $\theta_T$ , is equal to  $(\theta_1 + \theta_2 + \theta_3)$ , and the other symbols have their conventional significance. It was shown that Eq. [6]-[9] reduce to the steady-state solution,

$$i_{a,\infty} = 2Fk_4 \frac{k_3k_2}{k_{-3}k_{-2}a_{(\text{H}^+)}} \left( \frac{k_1}{k_1 + k_{-1}} \right) \exp(3FE/2RT) \quad [10]$$

where  $E$  is the potential of the iron electrode relative to a reference electrode. Equation [10] fully describes the experimental results. The conditions leading to Eq. [10] are  $\bar{k}_{-3} \gg \bar{k}_4$ ,  $\bar{k}_{-2} a_{(\text{H}^+)} \gg \bar{k}_3/\bar{k}_{-3}$ , and  $\bar{k}_{-2} a_{(\text{H}^+)}$ ,  $(\bar{k}_1 + \bar{k}_{-1}) \gg \bar{k}_2 \{ \bar{k}_1 [1 + (\bar{k}_3/\bar{k}_{-3})] + \bar{k}_3\bar{k}_4/\bar{k}_{-3} \}$ . The latter condition means that  $1 \gg (\theta_2 + \theta_3)$  and, consequently, if  $\theta_T \approx 1$ , then  $\theta_1 \approx 1$ , i.e.,  $\bar{k}_1/(\bar{k}_1 + \bar{k}_{-1}) \approx 1$ .

The rate-determining step in the hydrogen evolution reaction on zone-refined iron in the noninhibited system has been shown to be slow proton discharge (1),  $\text{H}^+ + e^- \rightarrow \text{H}_{\text{ad}}$ , with a corresponding steady-state cathodic Tafel slope of  $-120$  mv/decade, i.e.,  $-2(2.303 RT/F)$ , and a first order dependency on the proton activity in solution, i.e.,

$$i_{c,\infty} = k_c a_{(\text{H}^+)} \exp(-FE/2RT) \quad [11]$$

where  $i_{c,\infty}$  is the absolute value of the steady-state current density corresponding to the hydrogen evolution reaction. Evidence favoring removal of  $\text{H}_{\text{ad}}$  via fast electrochemical desorption,  $\text{H}^+ + \text{H}_{\text{ad}} + e^- \rightarrow \text{H}_2$ , for zone-refined iron, and via catalytic desorption,  $2\text{H}_{\text{ad}} \rightarrow \text{H}_2$ , for Armco iron was discussed in detail.

The mechanisms described above serve as the experimental and mechanistic base for the analysis of the electrochemical behavior of the active iron electrode in an inhibited system. The present paper reports on the results obtained for the iron dissolution and hydrogen evolution reactions on zone-refined iron in hydrogen-saturated sodium benzoate solutions (hereafter referred to as the inhibited system). Transient and steady-state potentiostatic polarization data are analyzed and related to the adsorption/desorption kinetics and the potential-dependent steady-state adsorption isotherm for the benzoate anion; to the changes introduced into the iron dissolution mechanism, Eq. [1]-[5], as a result of the adsorbed inhibitor; and, of particular interest, to the double-

\* Electrochemical Society Active Member.  
<sup>1</sup> Operated by Union Carbide Corporation for the U. S. Atomic Energy Commission.

layer effect of the anion on the proton discharge reaction.

In many respects, the benzoate anion is an ideal anion for the studies described herein. It possesses no redox properties of its own under the conditions employed here. Its buffering action extends the current density region of activation control for the hydrogen evolution reaction, at a given pH, and enables the study of potentiostatic current/time transients over long periods of time without pH change. It may be obtained in a state of high purity and may easily be further purified by recrystallization. Its one relatively minor drawback arises from the relative insolubility of benzoic acid, coupled with an ionization constant of  $6.30 \times 10^{-5}$ . If one insists on excluding other ions as an inert electrolyte while maintaining a reasonably high ionic strength in order to suppress the potential drop in the diffuse part of the double layer, then these factors restrict the studies to the pH region in the vicinity of 5.0.

### Experimental

The experimental apparatus and techniques, as well as the composition of the zone-refined iron, have been described elsewhere in detail (1) and, therefore, only a brief resume is given here. In order to preclude contamination problems, the entire cell assembly was made of Pyrex glass and Teflon, and was so designed that essential operations, such as the addition of hydrogen-saturated pre-electrolyzed solutions, could be accomplished without opening the apparatus to the atmosphere. This latter feature was of particular importance in view of the extreme sensitivity of the iron/benzoate system to oxygen. Similarly, the pronounced effect of temperature variations on the inhibited system, in contrast to the noninhibited system, added significance to the maintenance of a constant solution temperature,  $25.00^\circ \pm 0.02^\circ\text{C}$ .

Sodium benzoate solutions were prepared from reagent grade materials, benzoic acid (recrystallized) and sodium hydroxide, and triply distilled water, and were pre-electrolyzed at an iron cathode. The saturated calomel electrode and the counter electrode were located in separate compartments from the test electrode, and a continuous stream of hydrogen was maintained throughout the assembly at all times. The hydrogen source was a Matheson generator which produces ultrapure gas via diffusion of electrolytically generated hydrogen through a palladium membrane. Additional stirring in the test compartment was achieved with a Teflon-coated magnetic stirrer.

Potentials were measured with a high impedance Beckman Research Model pH meter and recorded with a 10 mv Brown recorder. An O.R.N.L. Model Q-2003 Potentiostat was employed, the currents being measured via the potential drop across precision resistors.

### Results

In order to acquaint the reader with various aspects of a rather complex system, a Tafel diagram of typical data is shown in Fig. 1. If an electrode, initially in a steady state at the corrosion potential,  $E_{\text{corr}}$ , is subjected to "fast" anodic or cathodic polarization, the curves marked  $i_{a,1}$  and  $i_{c,1}$ , respectively, are obtained.<sup>2</sup> These anodic and cathodic curves exhibit Tafel behavior, the slopes of the Tafel lines being 59 and  $-88$  mv/decade, respectively. The extrapolated Tafel lines intersect at  $E_{\text{corr}}$  and, thereby, locate the corrosion current density,  $i_{\text{corr}}$ .

If the potential is held constant at some point along  $i_{c,1}$ , one observes a potentiostatic current/time transient,  $i_{c,t}$ , in which the current decreases from its initial value on  $i_{c,1}$  to a steady-state value on  $i_{c,\infty}$ . A subsequent fast cathodic polarization then yields a new Tafel line,  $i_{c,2}$ , having a more negative slope than  $i_{c,1}$ . In fact, at any point along  $i_{c,t}$ , a fast cathodic po-

larization yields a Tafel line having a slope lying between those of  $i_{c,1}$  and  $i_{c,2}$ . At sufficiently negative potentials,  $i_{c,\infty}$  approaches a limiting Tafel line,  $i_H$ , which has the same slope as that observed for proton discharge in the noninhibiting system, i.e.,  $-2$  ( $2.303 RT/F$ ) mv/decade. If an electrode is initially in a polarized steady state, for example, at the intersection of  $i_{c,3}$  and  $i_{c,\infty}$ , and the potential is changed to a less negative cathodic value, the initial current, lying along  $i_{c,3}$ , will be less than the steady-state current and, consequently, one observes a potentiostatic current/time transient in which the absolute value of the cathodic current increases with time.

If, at some point along  $i_{a,1}$ , the potential is fixed, an anodic current/time transient is observed, in which the current increases from its initial value to the steady-state value on  $i_{a,\infty}$ , as shown, for example, by the vertical line,  $i_{a,t}$ . A subsequent fast anodic polarization results in a new Tafel line,  $i_{a,2}$ , which is parallel to  $i_{a,1}$ , the Tafel slope being  $2.303 RT/F$  or 59 mv/decade. If the potential is then fixed at a less anodic value than that associated with  $i_{a,t}$ , the current decreases with time from its initial value on  $i_{a,2}$  to the steady-state value on  $i_{a,\infty}$ . It should be noted that the steady-state anodic polarization curve does not exhibit Tafel behavior. By the application of arbitrary time intervals, one may obviously generate the polarization hysteresis loops, both anodic and cathodic, so frequently mentioned in the corrosion literature. In the following sections, the system just described is treated in a quantitative fashion.

**Hydrogen evolution reaction.**—In the inhibited system illustrated in Fig. 1, the cathodic current density, at constant solution composition, is a function not of just the electrode potential, as in the case of the noninhibited sulfate system, but also of the surface activity of the adsorbed inhibitor, i.e.

$$\ln i_c = f(\eta, \theta) \quad [12]$$

where  $\eta$  is the electrode polarization relative to the steady-state corrosion potential at constant solution composition, and  $\theta$  represents the fraction of the electrode surface occupied by the adsorbed inhibitor. At sufficiently negative potentials, the benzoate anion is completely desorbed and, consequently,  $i_{c,\infty} = i_H$ , i.e.,  $i_H$  is the cathodic current density corresponding to  $\theta = 0$ . The total differential of  $\ln i_c$  is given by Eq. [13]

$$d \ln i_c = \left( \frac{\partial \ln i_c}{\partial \eta} \right)_\theta d\eta + \left( \frac{\partial \ln i_c}{\partial \theta} \right)_\theta d\theta \quad [13]$$

where, in the most general case, both  $(\partial \ln i_c / \partial \eta)_\theta$  and

Fig. 1. Polarization of iron in 0.10M ( $\text{C}_6\text{H}_5\text{COOH} + \text{C}_6\text{H}_5\text{COONa}$ ); pH = 5.00;  $T = 25^\circ\text{C}$ .

<sup>2</sup> "Fast" here meaning on the order of a few seconds, as determined by the response time of the recorder ( $\sim 3$  sec full scale). In the noninhibited system, true steady states are attained within this time interval.

$(\partial \ln i_c / \partial \theta)_\eta$  may be functions of both  $\eta$  and  $\theta$ . In the present case, however,  $(\partial \ln i_c / \partial \eta)_\theta$  is a constant, the magnitude of which is a function of  $\theta$  only, i.e.,

$$\left( \frac{\partial \ln i_c}{\partial \eta} \right)_\theta = \frac{2.303}{S} \quad [14]$$

where  $S$ , a function of  $\theta$  only, represents the slope of a cathodic Tafel line resulting from a "fast" polarization, for which  $\theta$  remains essentially constant. As illustrated by the sequence of Tafel lines,  $(i_{c,1}, i_{c,2}, \dots, i_H)$  in Fig. 1,  $S$  becomes increasingly negative as  $\theta$  decreases, and ultimately attains the value of  $-2$  ( $2.303 RT/F$ ), i.e.,  $-118.24$  mv/decade, when  $\theta = 0$ . As  $\theta$  increases to its maximum value,  $\theta_m$ ,  $S$  approaches a limiting value of  $-88$  mv/decade. In Fig. 2, a "fast" cathodic Tafel line obtained for an electrode initially in a steady state at  $E = -0.800$  v vs. SCE is shown for the purpose of demonstrating the precision with which values of  $S$  may be determined. Since  $\partial(\partial \ln i_c / \partial \eta)_\theta / \partial \theta$  must equal  $\partial(\partial \ln i_c / \partial \theta)_\eta / \partial \eta$ , the result expressed by Eq. [14] enables one to write Eq. [15]

$$\left( \frac{\partial \ln i_c}{\partial \theta} \right)_\eta = -\frac{2.303}{S^2} \left( \frac{dS}{d\theta} \right) \eta + h(\theta) \quad [15]$$

where  $h(\theta)$ , i.e.,  $(\partial \ln i_c / \partial \theta)_\eta=0$ , is a potential-independent term for which the dependency on  $\theta$  remains to be considered below. If the expressions for the partial derivatives given by Eq. [14] and [15] are substituted into Eq. [13] integration of the latter leads to Eq. [16]

$$i_c = i_{c,\eta=0} \exp(2.303 \eta / S) \quad [16]$$

where  $i_{c,\eta=0}$  is equal to  $i_{H,\eta=0} \exp[\int_0^\theta h(\theta) d\theta]$ . Since  $i_H = i_{H,\eta=0} \exp(-F\eta/2RT)$ , Eq. [16] may be divided by  $i_H$  to obtain Eq. [17]

$$\frac{i_c}{i_H} = \left( \frac{i_c}{i_H} \right)_{\eta=0} \exp[2.303 (S + 118.24) \eta / 118.24 S] \quad [17]$$

Let the functional dependencies of  $(i_c/i_H)_{\eta=0}$  and  $S$  on  $\theta$  be represented by Eq. [18] and [19], respectively,

$$(i_c/i_H)_{\eta=0} = \exp(a\theta/\theta_m) \quad [18]$$

and

$$S = -118.24/[1 + b(\theta/\theta_m)] \quad [19]$$

where  $a$  and  $b$  are constants, the latter of which is equal to  $0.34363$  since  $S = -88$  mv/decade when  $\theta = \theta_m$ . The significance of Eq. [18] and [19] will be

Fig. 2. "Fast" cathodic Tafel line for an electrode initially in a polarized steady state at  $E = -0.800$  v vs. SCE;  $0.10M$  ( $C_6H_5COOH + C_6H_5COONa$ );  $pH = 5.00$ ;  $T = 25^\circ C$ .

considered in the Discussion section, but it should be noted here that Eq. [18] identifies  $h(\theta)$  as a constant rather than as a function of  $\theta$ , i.e.,  $h(\theta) = a/\theta_m$ . If Eq. [19] is solved for  $\theta/\theta_m$  in terms of  $S$  and the results substituted into Eq. [18], the latter may be written in the form given by Eq. [20]

$$\log(i_c)_{\eta=0} = \log(i_H)_{\eta=0} - (S + 118.24) a/2.303 b S \quad [20]$$

However, according to Eq. [16]

$$\log(i_c)_{\eta=0} = \log i_c - \eta/S \quad [21]$$

and, therefore, one may subtract Eq. [21] from Eq. [20] to obtain Eq. [22]

$$\log i_c - (\eta/S) = \log(i_H)_{\eta=0} - (S + 118.24) a/2.303 b S \quad [22]$$

which shows that a plot of  $[\log i_c - (\eta/S)]$  vs.  $(S + 118.24)/S$  should result in a straight line having a slope of  $-(a/2.303 b)$ . Any set of corresponding  $i_c$ ,  $\eta$ , and  $S$  values may be used in testing Eq. [22]. For example, one might use values of  $S_x$  corresponding to points along the steady-state curve,  $i_{c,ss}$ , in Fig. 1. A test of data obtained in this manner is shown by the dashed curve in Fig. 3. Another convenient method is to determine the values of  $S$  corresponding to instantaneous values of  $i_c$  during a potentiostatic current/time transient by superimposing short potentiostatic pulses. Data obtained by this method are shown by the solid curve in Fig. 3. The linearity of the resulting curves provides confirmation of the validity of Eq. [22].

In view of the fact that  $S$  is a function of  $\theta$  only, one may determine the potential dependency of the steady-state coverage,  $\theta_{ss}$ , from the measured potential dependency of  $S_x$  and the relationship between  $S$  and  $\theta$ , i.e., Eq. [19]. In Fig. 4, measured values of  $S_x$  are plotted against  $\eta$ . If the steady-state coverage obeys a potential-dependent Langmuir type adsorption isotherm, i.e.,

$$(\theta_{ss}/\theta_m) = 1/[1 + K \exp(j\eta)] \quad [23]$$

then, according to Eq. [19]

$$S_x = -118.24/\{1 + 0.34363/[1 + K \exp(j\eta)]\} \quad [24]$$

This equation was used to calculate the solid curve shown in Fig. 4, where close agreement between the measured and calculated results is observed. The corresponding values of  $\theta_{ss}/\theta_m$  are plotted against  $\eta$  in Fig. 5. By means of Eq. [18] and [19], Eq. [17] may be written in terms of either  $\theta/\theta_m$  and  $\eta$  or  $S$  and  $\eta$ , i.e.,

$$i_c/i_H = \exp\{[a - (2.303 b\eta/118.24)](\theta/\theta_m)\} \quad [25]$$

or

Fig. 3. Test of Eq. [22]: dashed line --  $i_{c,ss}$ ,  $S_{st}$ , and  $\eta$  values taken from Fig. 4 and 6; solid line —  $i_t$ ,  $S_t$  and  $\eta$  values observed during potentiostatic current/time transient at  $\eta = -200$  mv.  $0.10M$  ( $C_6H_5COOH + C_6H_5COONa$ );  $pH = 5.00$ ;  $T = 25^\circ C$ .

Fig. 4. Effect of potential on  $S_w$ . Solid curve calculated by means of Eq. [24]. 0.10M ( $C_6H_5COOH + C_6H_5COONa$ ); pH = 5.00,  $T = 25^\circ C$ .

Fig. 5. Effect of potential on the steady-state coverage of the adsorbed inhibitor: curve calculated by means of Eq. [23], using the values of  $K$  and  $j$  corresponding to the solid curve of Fig. 4.

Fig. 6. Steady-state cathodic polarization curve for iron in 0.10M ( $C_6H_5COOH + C_6H_5COONa$ ); pH = 5.00,  $T = 25^\circ C$ . Solid curve calculated by means of either Eq. [25] with values of  $(\theta_w/\theta_m)$  and  $a$  taken from Fig. 5 and 3, respectively, or Eq. [26] with values of  $S$  and  $a$  taken from Fig. 4 and 3, respectively.

$$i_c/i_H = \exp \left\{ - \left[ \frac{a}{b} \right] - 2.303\eta/118.24 \right\} \left[ \frac{S + 118.24}{S} \right] \quad [26]$$

One may calculate the steady-state polarization curve using the values of  $\theta_w/\theta_m$  shown in Fig. 5 in Eq. [25], or by using the values of  $S_w$  shown in Fig. 4 in Eq. [26]. The results are shown in Fig. 6, where good

Fig. 7. Typical cathodic potentiostatic current/time transient. 0.10M ( $C_6H_5COOH + C_6H_5COONa$ ); pH = 4.88;  $T = 25^\circ C$ ; electrode apparent area = 1.346  $cm^2$ ;  $\eta = -210$  mv.

agreement between the experimental and calculated results is observed. Since the set of observed  $i_c$ ,  $\eta$ , and  $S$  values satisfies Eq. [26], it follows that it satisfies Eq. [22], and this is shown by the dashed curve in Fig. 3.

A typical potentiostatic current/time transient is shown in Fig. 7. The analysis of such a transient proceeds from Eq. [25], according to which one may write

$$\ln \left\{ \frac{\ln(i_c/i_{c,\infty})}{\ln(i_{c,0}/i_{c,\infty})} \right\} = \ln \left[ \frac{(\theta - \theta_\infty)}{(\theta_0 - \theta_\infty)} \right] \quad [27]$$

where the subscript zero refers to initial values, i.e., to values at  $t = 0$ . If the net rate at which the anion is adsorbed may be described by an equation of the form

$$(\partial\theta/\partial t)_\eta = \bar{k}_a a_{(Bz^-)} (\theta_m - \theta) - \bar{k}_d \theta \quad [28]$$

where  $a_{(Bz^-)}$  represents the constant solution activity of the benzoate anion, and  $\bar{k}_a$  and  $\bar{k}_d$  are potential dependent adsorption and desorption rate constants, respectively, then the relationship between  $\theta$  and  $t$ , obtained by integration of Eq. [28] under the potentiostatic condition, is given by Eq. [29]

$$\theta = \theta_\infty - (\theta_\infty - \theta_0) \exp \left[ - (\bar{k}_a a_{(Bz^-)} + \bar{k}_d) t \right] \quad [29]$$

The use of Eq. [29] in conjunction with Eq. [27] leads to the desired working equation

$$\log \log (i_c/i_{c,\infty})_\eta = - (\bar{k}_a a_{(Bz^-)} + \bar{k}_d) t / 2.303 + \log \log (i_{c,0}/i_{c,\infty}) \quad [30]$$

according to which a plot of  $\log \log (i_c/i_{c,\infty})$  vs.  $t$  should result in a straight line having a slope,  $\tau$ , equal to  $-(\bar{k}_a a_{(Bz^-)} + \bar{k}_d) / 2.303$ . As shown in Fig. 8, the transient depicted in Fig. 7 conforms to Eq. [30].

In the steady-state case,  $(\partial\theta/\partial t)_\eta = 0$ , Eq. [28] may be solved for  $\theta_\infty$

$$\theta_\infty/\theta_m = 1 / \left[ 1 + \frac{\bar{k}_d/\bar{k}_a a_{(Bz^-)}}{\exp(-\gamma F\eta/RT)} \right] \quad [31]$$

This expression for  $\theta_\infty$  is identical to that written earlier, Eq. [23], with  $(\bar{k}_d/\bar{k}_a a_{(Bz^-)}) = K$  and  $-\gamma F/RT = j$ . In writing Eq. [31], use was made of the identities,  $\bar{k}_a = k_a \exp(\epsilon\gamma F\eta/RT)$  and  $\bar{k}_d = k_d \exp[-(1-\epsilon)\gamma F\eta/RT]$ , where  $k_a$  and  $k_d$  are the chemical rate constants,  $\epsilon$  is the symmetry factor, and  $\gamma (< 1)$  may be regarded as the ratio of the Galvani potential difference between the initial and final states to the Galvani potential difference between the metal and the initial state (2). Since  $\tau$  is equal to  $-(\bar{k}_a a_{(Bz^-)} + \bar{k}_d) / 2.303$ ,  $|\tau|$  is a minimum when  $\bar{k}_a a_{(Bz^-)} / \bar{k}_d = (1-\epsilon)/\epsilon$ . It is apparent from Eq. [31] that if  $\epsilon = (1-\epsilon)$ , the minimum in  $|\tau|$ ,  $|\tau^*|$ , occurs at  $\theta_\infty/\theta_m = 1/2$  and, designating the corresponding polarization by  $\eta^*$ , one may write Eq. [32]

Fig. 8. Analysis of cathodic potentiostatic current/time transient. Test of Eq. [30] using the data shown in Fig. 7.

$$\tau/\tau^* = \cosh [\epsilon\gamma F(\eta - \eta^*)/RT] \quad [32]$$

which shows that  $\tau/\tau^*$  depends only on  $|\eta - \eta^*|$ . In Fig. 9, experimental values of  $\tau$  are plotted against  $\eta$ . The solid curve was calculated by means of Eq. [32], and a reasonable agreement between the experimental and calculated results is observed. In the calculation of the solid curve,  $\epsilon$  was assumed equal to 0.5, and the values of  $\eta^*$  and  $\gamma$  were taken from Fig. 5 via Eq. [31].

The order of the proton discharge reaction with respect to hydrogen ion activity was determined by measuring the cathodic current at various pH values while maintaining a constant potential sufficiently negative to eliminate interference from the anodic process. The electrode was initially in a steady state at the selected potential, and the pH was varied by the addition of deoxygenated NaOH solution. The results are shown in Fig. 10 and correspond to a reaction order,  $-(\partial \log i_c/\partial \text{pH})_{E,\theta}$ , equal to unity, just as in the noninhibited system.

**Iron dissolution reaction.**—From a diagnostic viewpoint, the most important observation relating to the dissolution of iron in the presence of the adsorbed inhibitor is expressed by Eq. [33]

$$(\partial \log i_a/\partial E)_{\theta,\text{pH}} = F/2.303 RT \quad [33]$$

which states that anodic polarization at constant pH and  $\theta$ , i.e., fast anodic polarization, results in a transitory Tafel line having a slope of 59 mv/decade. This result, described in connection with Fig. 1, is to be contrasted to that observed in the noninhibited system

Fig. 9. Effect of potential on  $\tau$ . Test of Eq. [32] with  $\gamma$  and  $\eta^*$  taken from Fig. 5 via Eq. [31].

Fig. 10. Determination of the orders of the anodic (solid circles) and cathodic (open circles) reactions with respect to proton activity in 0.10M ( $\text{C}_6\text{H}_5\text{COOH} + \text{C}_6\text{H}_5\text{COONa}$ ) at 25°C. Anodic and cathodic data obtained at  $E = -620$  mv vs. SCE and  $E = -850$  mv vs. SCE, respectively. Electrode area = 2.86  $\text{cm}^2$ .

Fig. 11. Typical anodic potentiostatic current/time transient. 0.10M ( $\text{C}_6\text{H}_5\text{COOH} + \text{C}_6\text{H}_5\text{COONa}$ ); pH = 4.87;  $T = 25^\circ\text{C}$ ; electrode apparent area = 1.346  $\text{cm}^2$ ;  $E = -630$  mv vs. SCE.

for which a comparable rate of polarization results in a true steady-state Tafel line having a slope of (2/3) ( $2.303 RT/F$ ). Tafel behavior is not exhibited by the steady-state polarization curve for the inhibited system.<sup>3</sup>

A typical anodic potentiostatic current/time transient is shown in Fig. 11. In Fig. 12, a plot of  $\log(i_{a,\infty} - i_a)$  vs.  $t$  is shown for this transient, and one may conclude that  $[\partial \log(i_{a,\infty} - i_a)/\partial t]_{\eta}$  is essentially constant. The significance of this result is examined in the Discussion section.

An evaluation of the order of the iron dissolution reaction with respect to the hydroxyl ion activity,  $(\partial \log i_a/\partial \text{pH})_{E,\theta}$ , was accomplished by the rapid addition of deoxygenated NaOH solution under potentiostatic conditions. The potential was sufficiently positive to eliminate interference from the hydrogen evolution reaction. The results are shown in Fig. 10. The straight line was drawn with a unit slope, i.e.,  $(\partial \log i_a/\partial \text{pH})_{E,\theta} = 1$ , corresponding to a first order dependency on the hydroxyl ion activity.

### Discussion

Adsorption of the benzoate ion is accompanied by marked changes in the kinetics and/or mechanistics of both the iron dissolution and hydrogen evolution reactions. As indicated by the results described in the preceding section, the effect of the adsorbed anion on

<sup>3</sup> Actually, the degree of reproducibility of the steady-state anodic curve precludes a statement regarding the sign of  $d^2 i_{a,\infty}/dE^2$ .

Fig. 12. Analysis of anodic potentiostatic current/time transient. Test of Eq. [71] using the data shown in Fig. 11.

the hydrogen evolution reaction is fundamentally different in character from that on the iron dissolution reaction and, consequently, in the following discussion, the two reactions are dealt with separately.

**Hydrogen evolution reaction.**—If absolute rate theory is applied in the usual fashion to the rate-determining proton discharge reaction, the resultant expression for the absolute value of the corresponding current density,  $i_c$ , is given by Eq. [34]

$$\ln i_c = \ln k - (\alpha F/RT)E - [(1 - \alpha)F/RT]\psi + \ln a_{(H^+)}, \quad [34]$$

where  $E$  is the previously defined potential,  $\psi$  is the Galvani potential difference between the pre-electrode plane and the bulk of solution,  $\alpha$  is the symmetry factor which, ideally, is equal to  $1/2$ , and  $a_{(H^+)}$  is the proton activity in the bulk of solution (2, 3). The differential of  $\ln i_c$ , at constant solution composition, is given by Eq. [35]

$$d \ln i_c = d \ln k - (\alpha F/RT)d\eta - [(1 - \alpha)F/RT]d\psi \quad [35]$$

Since  $\psi = f(\eta, \theta)$ ,  $d\psi$  is given by Eq. [36]

$$d\psi = (\partial\psi/\partial\eta)_{\theta} d\eta + (\partial\psi/\partial\theta)_{\eta} d\theta \quad [36]$$

which, when substituted into Eq. [35], leads to Eq. [37]

$$d \ln i_c = -[\alpha + (1 - \alpha)(\partial\psi/\partial\eta)_{\theta}](F/RT) d\eta + [(d \ln k/d\theta) - (1 - \alpha)(F/RT)(\partial\psi/\partial\theta)_{\eta}] d\theta \quad [37]$$

It should be noted that  $\alpha$  is regarded as being a true constant,  $\alpha = 1/2$ , independent of  $\theta$ , i.e., the symmetry of the activation barrier is retained in the presence of the adsorbed anion. On the other hand, although potential-independent,  $k$  is considered a function of  $\theta$  because  $k$  represents the quantity,  $k'(\kappa/\gamma^{\ddagger}) \exp(-\Delta\mu^{\ddagger,0}/RT)$ , where  $\kappa$  is the transmission coefficient,  $\gamma^{\ddagger}$  is the activity coefficient of the activated complex,  $k'$  is a constant, and  $\Delta\mu^{\ddagger,0}$  is the standard chemical free energy of activation. The quantity,  $\Delta\mu^{\ddagger,0}$ , in particular, must be regarded as a possible function of  $\theta$ .

According to Eq. [37],  $(\partial \ln i_c/\partial\eta)_{\theta}$  and  $(\partial \ln i_c/\partial\theta)_{\eta}$  are given by Eq. [38] and [39]

$$(\partial \ln i_c/\partial\eta)_{\theta} = -[\alpha + (1 - \alpha)(\partial\psi/\partial\eta)_{\theta}](F/RT) \quad [38]$$

and

$$(\partial \ln i_c/\partial\theta)_{\eta} = [(d \ln k/d\theta) - (1 - \alpha)(F/RT)(\partial\psi/\partial\theta)_{\eta}] \quad [39]$$

If one equates the values of  $(\partial \ln i_c/\partial\eta)_{\theta}$  given by Eq. [14] and [38], one obtains Eq. [40]

$$(\partial\psi/\partial\eta)_{\theta} = -[2.303 RT/(1 - \alpha)FS] - \alpha/(1 - \alpha) \quad [40]$$

which shows that  $(\partial\psi/\partial\eta)_{\theta}$  is a constant, the magnitude of which is a function of  $S$  and, therefore, of  $\theta$ . With  $\alpha = 1/2$ , Eq. [40] becomes

$$(\partial\psi/\partial\eta)_{\theta} = -(118.24 + S)/S \quad [41]$$

where, as usual,  $S$  is expressed in mv/decade. The explicit dependence of  $(\partial\psi/\partial\eta)_{\theta}$  on  $\theta$  is obtained from Eq. [19] and [41], and is given by Eq. [42]

$$(\partial\psi/\partial\eta)_{\theta} = b\theta/\theta_m \quad [42]$$

The significance of Eq. [40]-[42] will be discussed below. First, however, it should be observed that since  $\partial(\partial\psi/\partial\eta)_{\theta}/\partial\theta$  is equal to  $\partial(\partial\psi/\partial\theta)_{\eta}/\partial\eta$ , Eq. [42] enables one to write Eq. [43]

$$(\partial\psi/\partial\theta)_{\eta} = b\eta/\theta_m + g(\theta) \quad [43]$$

where  $g(\theta)$ , although independent of  $\eta$ , must for the moment be considered a possible function of  $\theta$ . If the value of  $(\partial\psi/\partial\theta)_{\eta}$  given by Eq. [43] is substituted into Eq. [39], one obtains Eq. [44]

$$(\partial \ln i_c/\partial\theta)_{\eta} = (d \ln k/d\theta) - (2.303 b\eta/118.24 \theta_m) - 2.303 g(\theta)/118.24 \quad [44]$$

On the basis of Eq. [16] and [19], one may write

$$(\partial \ln i_c/\partial\theta)_{\eta} = (\partial \ln i_c/\partial\theta)_{\eta=0} - 2.303 b\eta/118.24 \theta_m \quad [45]$$

which, when subtracted from Eq. [44], shows that

$$(\partial \ln i_c/\partial\theta)_{\eta=0} = (d \ln k/d\theta) - 2.303 g(\theta)/118.24 \quad [46]$$

However, according to Eq. [18],  $(\partial \ln i_c/\partial\theta)_{\eta=0}$  is a constant, i.e.,

$$(\partial \ln i_c/\partial\theta)_{\eta=0} = a/\theta_m \quad [47]$$

and, therefore, if  $d \ln k/d\theta$  is a constant, then  $g(\theta)$

must be a constant and *vice versa*. If  $\Delta\mu^{\ddagger,0}$  is a linear function of  $\theta$ , which is an entirely reasonable expectation, then  $d \ln k/d\theta$  should be a constant, provided  $(\kappa/\gamma^{\ddagger})$  is independent of  $\theta$ . If  $d \ln k/d\theta$  may be expressed by Eq. [48]

$$d \ln k/d\theta = A \quad [48]$$

where  $A$  is a constant, then, according to Eq. [46], [47], and [48],  $g(\theta)$  is given by Eq. [49]

$$g(\theta) = g = 118.24 \left( \frac{a}{\theta_m} - A \right) / 2.303 \quad [49]$$

and, therefore, Eq. [43] becomes simply

$$(\partial\psi/\partial\theta)_{\eta} = (b/\theta_m)\eta + g \quad [50]$$

i.e.,  $(\partial\psi/\partial\theta)_{\eta}$  is independent of  $\theta$ . To complete the analysis, the significance of the expressions obtained for  $(\partial\psi/\partial\theta)_{\eta}$  and  $(\partial\psi/\partial\eta)_{\theta}$  must now be examined.

One may divide  $\psi$  into two parts, i.e.,

$$\psi = \psi^i + \psi^o \quad [51]$$

where  $\psi^i$  is the Galvani potential difference between the pre-electrode plane and the outer Helmholtz plane, and  $\psi^o$  is the Galvani potential difference between the outer Helmholtz plane and the bulk of solution. In the absence of specifically adsorbed ions, one may identify  $\psi$  with  $\psi^o$  and, using conventional double-layer equations, interpret changes in the polarization data arising from changes in  $\psi^o$  (4). In the present case, however, Eq. [41] shows that  $(\partial\psi/\partial\eta)_{\theta}$  attains a maximum value of approximately  $1/3$ , corresponding to  $S = -88$  mv/decade, and the large value clearly identifies  $\psi$  with  $\psi^i$  rather than with  $\psi^o$ . The insignificant role of  $\psi^o$  in this system may be attributed to the use of a relatively high ionic strength, coupled with the fact that the potential region of in-

terest lies several hundred millivolts negative to the point of zero charge for iron (5). It should be noted that the observed value of  $S$  corresponding to  $\theta = 0$  is just that expected if, and only if,  $(\partial\psi^\circ/\partial\eta)_{\theta=0} = 0$ . One may conclude that specific adsorption of the anion is accompanied by a displacement of the pre-electrode plane from the outer Helmholtz plane toward the metal, the symmetry factor remaining equal to 1/2. If, in accordance with the concepts advanced by Grahame (6), one may regard the potential gradient in the inner region of the double-layer as essentially constant, then, identifying  $\psi^i$  with  $\psi$ , one may write Eq. [52]

$$\psi = (x/L) \Delta\phi \quad [52]$$

where  $\Delta\phi$  is the Galvani potential difference between the metal and the bulk of solution,  $x$  is the distance between the outer Helmholtz plane and the pre-electrode plane, and  $L$  is the distance from the outer Helmholtz plane to the electrode surface. The ratio,  $(x/L)$ , is a function of  $\theta$  only. Since  $(d\Delta\phi/d\eta) = 1$ , differentiation of Eq. [52] with respect to  $\eta$  leads to Eq. [53]

$$(\partial\psi/\partial\eta)_\theta = (x/L) \quad [53]$$

i.e.,  $(\partial\psi/\partial\eta)_\theta$  is a constant, the magnitude of which is a function of  $\theta$ . This is precisely the result expressed by Eq. [40] and [42] and, comparing Eq. [42] and [53], one finds that  $(x/L)$  may be related to  $\theta$  by Eq. [54]

$$(x/L) = b\theta/\theta_m \quad [54]$$

According to Eq. [54],  $d(x/L)/d\theta = b/\theta_m$  and, since  $(\partial\Delta\phi/\partial\theta)_\eta = 0$ , differentiation of Eq. [52] with respect to  $\theta$  results in Eq. [55]

$$(\partial\psi/\partial\theta)_\eta = (b/\theta_m) \Delta\phi \quad [55]$$

which, by means of the identity,  $\Delta\phi = \eta + \Delta E$ , where  $\Delta E$  is a constant equal to  $(E_{\text{corr}} - E_{\Delta\phi=0})$ , converts Eq. [55] into Eq. [56]

$$(\partial\psi/\partial\theta)_\eta = (b/\theta_m) \eta + (b/\theta_m) \Delta E \quad [56]$$

Again, this result is in accord with that expressed by Eq. [50] and, consequently, also serves to confirm Eq. [48]. Finally, at constant  $E$  and  $\theta$ ,  $\psi$  and  $k$  are constant and, therefore, according to Eq. [34],  $(\partial \log i_c/\partial \text{pH})_{E,\theta} = -1$ . This agrees with the results shown in Fig. 10.

**Iron dissolution reaction<sup>4</sup>.**—If the only effect of the adsorbed inhibitor on the iron dissolution reaction were to decrease the area available to the normal reaction scheme, Eq. [1]-[5], then  $(\partial \log i_a/\partial E)_\theta$  would retain the value observed for the noninhibited system, i.e.,  $(3/2)(F/2.303 RT)$ . However, as shown in Fig. 1 and expressed by Eq. [33],  $(\partial \log i_a/\partial E)_\theta$  is equal to  $(F/2.303 RT)$  and, consequently, one must conclude that the role of the adsorbed inhibitor cannot be adequately analyzed on the basis of a simple coverage concept alone. It is postulated that, once on the surface, the adsorbed benzoate anion interacts with the surface intermediate,  $(\text{FeOH})_{\text{ad}}$ , to form a surface complex,  $\{\text{I}^-\}_{\text{ad}}$ , as represented by Eq. [57]

where  $\text{Bz}^-$  represents the benzoate anion. The complex is oxidized according to the reactions represented by Eq. [58] and [59]

<sup>4</sup>The mechanism described here in detail, one involving a surface complex,  $\{\text{I}^-\}_{\text{ad}}$ , formed by  $(\text{FeOH})_{\text{ad}}$  and the inhibitor, was developed in a series of earlier publications (7,8). In particular, Eq. [65] may be found in ref. (7), and Eq. [57], [58], [59], [65], [69], and [71] in ref. (8). The mechanism, including the equations, was presented at the Buffalo Meeting of the Society, Oct. 10, 1965. With the preceding in mind, the author wishes to call to the attention of the reader two more recent articles (9, 10) by authors in attendance at the Buffalo presentation.

The latter reaction, Eq. [59], results in a desorption of the inhibitor, and is analogous to the "electrochemical" desorption of iodide from iron (11). This faradaic desorption of the inhibitor, together with the normal nonfaradaic adsorption/desorption reactions of the benzoate anion, determines the magnitude of  $\theta_R$ , i.e.,  $[\theta_4 + \lambda\theta_5/(\lambda + 1)]$ , where  $\theta_4$  and  $\theta_5$  are defined by the equations

$$[\text{Fe}_x(\text{Bz}^-)_{\text{ad}}] = \beta\theta_4/\lambda \quad \text{and} \quad [\{\text{I}^-\}_{\text{ad}}] = \beta\theta_5/(\lambda + 1)$$

in which the concentrations of the adsorbed benzoate anion and complex are expressed in moles/cm<sup>2</sup>, and  $\beta$  retains its earlier definition (see Eq. [6]-[9]). The symbol,  $\lambda$ , represents the number of H<sub>2</sub>O-type adsorption sites occupied by a benzoate anion. Studies relating to the adsorption of benzoate and other aromatics on mercury have shown that the aromatic ring is  $\pi$ -bonded to the metal, the plane of the ring being parallel to the metal surface (12), and one may assume this to be the case for iron.

During the short time interval required to establish the "fast" anodic Tafel lines defined by Eq. [33],  $\theta_R$  remains essentially constant while, for each potential, the system attains a pseudo steady-state corresponding to the fixed value of  $\theta_R$ . The kinetic description of the inhibited system, for constant  $\theta_R$ , is given by Eq. [60]-[64]

$$i_a/F = \bar{k}_3\theta_2 - \bar{k}_{-3}\theta_3 + \bar{k}_4\theta_3 + \bar{k}_{58}\theta_5 \quad [60]$$

$$\beta d\theta_1/dt = \bar{k}_1(1 - \theta_T) - \bar{k}_{-1}\theta_1 - \bar{k}_2\theta_1 + \bar{k}_{-2}a_{(\text{H}^+)}\theta_2 \quad [61]$$

$$\beta d\theta_2/dt = \bar{k}_2\theta_1 - \bar{k}_{-2}a_{(\text{H}^+)}\theta_2 - \bar{k}_3\theta_2 + \bar{k}_{-3}\theta_3 \quad [62]$$

$$\beta d\theta_3/dt = \bar{k}_3\theta_2 - \bar{k}_{-3}\theta_3 - \bar{k}_4\theta_3 - \bar{k}_{57}\theta_3\theta_4 + \bar{k}_{-57}\theta_5 \quad [63]$$

$$(\beta/\lambda) d\theta_4/dt = [-\beta/(\lambda + 1)] d\theta_5/dt \\ = -\bar{k}_{57}\theta_3\theta_4 + \bar{k}_{-57}\theta_5 + \bar{k}_{58}\theta_5 \quad [64]$$

where  $\theta_T$  is equal to  $\sum\theta_j$  ( $j = 1 \rightarrow 5$ ), and the other symbols retain their earlier definitions. It should be noted that if  $\theta_R = 0$ , this system of equations reduces to Eq. [6]-[9] and, consequently, describes the normal noninhibited system. The pseudosteady-state solution obtained from Eq. [60]-[64] by setting the coverage-time derivatives equal to zero, solving the resulting equations for  $\theta_j$ , and using the results to eliminate  $\theta_j$  from Eq. [60], is given by Eq. [65]

$$i_a/F = 2k_4 \frac{k_3k_2k_1(1 - \theta_R)}{k_{-3}k_{-2}a_{(\text{H}^+)}(k_1 + k_{-1})} \exp(3FE/2RT) \\ + 2k_{57} \frac{k_3k_2k_1\theta_R(1 - \theta_R)}{k_{-3}k_{-2}a_{(\text{H}^+)}(k_1 + k_{-1})} \exp(FE/RT) \quad [65]$$

In addition to the conditions imposed in the derivation of Eq. [10], the derivation of Eq. [65] requires only that  $\bar{k}_{58}/\bar{k}_{-57} \gg 1$ ,  $\bar{k}_{58}/\bar{k}_{57}\theta_3 \gg 1$ , and  $\bar{k}_{-3} + \bar{k}_4 + (\bar{k}_{57}\theta_4/\bar{k}_{-57}) \approx \bar{k}_{-3}$ . The latter two conditions correspond to  $\theta_3 \approx \bar{k}_3\theta_2/\bar{k}_{-3}$  and  $\theta_4/\theta_5 \gg 1$ , respectively. In Eq. [65],  $\theta_1 = k_1(1 - \theta_R)/(k_1 + k_{-1})$  and since, as in the noninhibited system,  $\theta_1 \gg (\theta_2 + \theta_3)$  and  $\theta_T \approx 1$ ,  $\theta_1 \approx (1 - \theta_R)$ , i.e.,  $k_1/(k_1 + k_{-1}) \approx 1$ , a fact which may be used to simplify Eq. [65]. For convenience sake, Eq. [65] may be written in an abbreviated form

$$i_a = i_{a,\theta_R=0}(1 - \theta_R) + i_a^* \quad [66]$$

where  $i_{a,\theta_R=0}(1 - \theta_R)$  and  $i_a^*$  represent the first and second expressions, respectively, on the right-hand side of Eq. [65]. If  $\theta_R = 0$ ,  $i_a^*$  vanishes and Eq. [66] reduces to Eq. [10], i.e.,  $i_{a,\theta_R=0}$  corresponds to the steady-state current density of the noninhibited system, and  $i_{a,\theta_R=0}(1 - \theta_R)$  corresponds to the same current density, reduced by the simple coverage factor,  $(1 - \theta_R)$ . According to Eq. [65], if one took into account only this simple coverage effect and omitted  $i_a^*$ , then, as previously mentioned, the slope of the fast ( $\theta_R = \text{constant}$ ) anodic Tafel lines would be

(3/2)(F/2.303 RT) instead of the observed slope of F/2.303 RT. The observed value results from the fact that, with  $\theta_R \approx 1$ ,  $i_a^* \gg i_{a,\theta_R=0} (1 - \theta_R)$ , i.e.,  $i_a \approx i_a^*$  and therefore, according to Eq. [65]

$$\left( \frac{\partial \log i_a}{\partial E} \right)_{\theta_R, pH} = \left( \frac{\partial \log i_a^*}{\partial E} \right)_{\theta_R, pH} = F/2.303 RT \quad [67]$$

which is in agreement with Eq. [33]. Again, according to Eq. [65], if  $i_a \approx i_a^*$ , then

$$\left( \frac{\partial \log i_a}{\partial pH} \right)_{\theta_R, E} = \left( \frac{\partial \log i_a^*}{\partial pH} \right)_{\theta_R, E} = 1 \quad [68]$$

Subject to the conditions imposed in the derivation of Eq. [65], the variation of  $\theta_R$  with time is given by Eq. [69]

$$(\beta/\lambda) (d\theta_R/dt) = \frac{\bar{k}_{ad} a_{(Bz^-)} (1 - \theta_R)}{-\bar{k}_{des} \theta_R - \bar{M} \theta_R (1 - \theta_R)} \quad [69]$$

where the first two expressions on the right side correspond to the nonfaradaic adsorption and desorption reactions, respectively, and the last term to the faradaic desorption process. The quantity,  $\bar{k}_{59} \bar{k}_{57} \bar{k}_{3} \bar{k}_{2} / \bar{k}_{58} \bar{k}_{-3} \bar{k}_{-2} a_{(H^+)}$ , is represented by  $\bar{M}$ . During the potentiostatic current/time transients,  $\theta_R$  remains nearly equal to unity and, therefore, although  $(1 - \theta_R)$  changes significantly,  $\theta_R$  may be considered virtually constant. Consequently, according to Eq. [65], since  $i_a \approx i_a^*$ , one may write Eq. [70]

$$i_a = \bar{\omega} (1 - \theta_R) \quad [70]$$

where  $\bar{\omega}$ , i.e.,  $2F (\bar{k}_{58} / \bar{k}_{59}) \bar{M} \theta_R$ , is regarded as being a constant. At constant potential and solution composition, integration of Eq. [69], followed by the substitution of  $i_a$  for  $\theta_R$  in accordance with Eq. [70], leads to Eq. [71]

$$\ln[(i_{a,x} - i_a)/(i_{a,\infty} - i_{a,0})] [(1 + P i_{a,0})/(1 + P i_a)] = -(\lambda/\beta) Q_x [\bar{k}_{des} + \bar{M} (1 - \theta_x)]^2 t \quad [71]$$

where  $P = \bar{M} (1 - \theta_x) / \bar{k}_{des} \bar{\omega}$  and  $Q_x = \bar{k}_{ad} a_{(Bz^-)} / \theta_x [\bar{k}_{des} + \bar{M} (1 - \theta_x)] = 1/(1 - \theta_x)$ . According to Fig. 12,  $[\partial \log (i_{a,x} - i_a)/\partial t]_\eta$  is virtually constant and, consequently,  $|\partial \ln (i_{a,x} - i_a)/\partial t|_\eta \gg |\partial \ln (1 + P i_a)/\partial t|_\eta$ , i.e.,  $2 + (1/P i_a) \gg i_{a,x}/i_a$ . This condition may also be expressed by the inequality,  $2 + [v_{des, nf, x} / v_{des, f, x} (1 - \theta)] \gg i_{a,x}/i_a$ , where  $v_{des, nf, x}$  and  $v_{des, f, x}$  represent the steady-state rates of the nonfaradaic and faradaic desorption processes, respectively. In view of the magnitudes attained by  $i_{a,x}/i_a$ , one may conclude that  $v_{des, nf, x} \gg v_{des, f, x} (1 - \theta)$ , a result which is true only because  $(1 - \theta) \ll 1$ . When an electrode, initially in a steady-state, is potentiostatically polarized at a more positive potential, the increase in  $i_a$  with time results from a decrease in  $\theta$ . If only the nonfaradaic adsorption/desorption reactions are considered, then, according to Eq. [31] or Fig. 5,  $\theta$  could only increase, not decrease, in such an experiment and, therefore, although  $v_{des, nf, x} \gg v_{des, f, x} (1 - \theta)$ ,  $v_{des, f, x}$  must be of sufficient magnitude to produce the decrease in  $\theta$ , i.e., to insure that  $d\theta_x/dE$  is negative. If  $d\theta/dt$  of Eq. [69] is set equal to zero and the result differentiated with respect to  $\eta$ , one finds that  $d\theta_x/dE$  is negative only if  $v_{des, f, x} (1 - \epsilon\gamma)/\gamma > v_{des, nf, x}$ . Since  $\epsilon\gamma \approx 1/3$ , the condition is entirely compatible with the previous condition,  $v_{des, nf, x} \gg v_{des, f, x} (1 - \theta)$ . It must be emphasized that  $d\theta_x/dE$  is negative in a potential region considerably negative to the point of zero charge for iron (5), i.e., negative to the potential at which one would expect maximum adsorption of the benzoate anion (the potential of maximum adsorption being positive to the potential of zero charge) if  $v_{des, f, x} = 0$ . Under proper conditions, at sufficiently positive potentials, complete faradaic desorption of the inhibitor occurs, and the system then obeys Eq. [10], the equation for

the noninhibited system. This has been observed in (0.01M benzoic acid + 0.10M Na<sub>2</sub>SO<sub>4</sub>) at pH values near 1. At higher pH values, one observes the "potentials of unpolarizability" previously described by Cartledge and Heusler (11).

In the preceding discussion, the anodic polarization data were interpreted on the basis of Eq. [66], with  $i_a \approx i_a^*$ , i.e.,  $i_a^* \gg i_{a,\theta_R=0} (1 - \theta_R)$ . This condition requires only that  $k_{57}\theta_R \gg \bar{k}_4$ . However, there is an alternative explanation which merits brief consideration. If to the reaction system represented by Eq. [1]-[5] there are added the reactions represented by Eq. [72] and [73]

reactions analogous to those represented by Eq. [57] and [58], then, proceeding as in the derivation of Eq. [10], one finds that, if  $k_{73}(k_{72}/k_{-72})\theta_1 \gg k_4$ , i.e., if the added reactions represent the principal mode by which  $(\text{FeOH})_{ad}$  is oxidized to  $(\text{FeOH})^+$ , then Eq. [10] is changed only to the extent of replacing  $k_4\theta_1$  by  $k_{73}(k_{72}/k_{-72})\theta_1^2$ . The effects of potential and pH on the steady-state current density remain unchanged and, as a result, provide no means of distinguishing between the two alternative representations of the noninhibited system. However, for the inhibited system,  $i_a^*$  remains unchanged and Eq. [66] must be replaced by Eq. [74]

$$i_a = i_{a,\theta_R=0} (1 - \theta_R)^2 + i_a^* \quad [74]$$

Consequently, in order that  $i_a \approx i_a^*$ , it is required only that  $k_{57}\theta_R \gg \bar{k}_{73}(k_{72}/k_{-72})(1 - \theta_R)$ , a condition which, since  $(1 - \theta_R) \ll 1$ , might appear to be more readily attainable than the previous condition,  $k_{57}\theta_R \gg \bar{k}_4$ .

### Summary

The complex electrochemical polarization behavior manifested by the active iron electrode in the presence of an adsorbed inhibitor has been analyzed in terms of the changes introduced into the mechanistic and kinetics of the iron dissolution and hydrogen evolution reactions in a noninhibited system as a consequence of the adsorbed inhibitor.

Specific adsorption of the inhibitor results in a reduction in the rate of the normal iron dissolution reaction via a simple coverage effect and, in addition, introduces a mechanistic change in which the adsorbed inhibitor interacts with the surface intermediate,  $(\text{FeOH})_{ad}$ , to form a surface complex. One mode of oxidation of the complex results in a faradaic desorption of the inhibitor and, as a consequence,  $(d\theta_x/dE)$  is negative in a potential region in which, in the absence of the faradaic or electrochemical desorption reaction, it would be positive. The proposed mechanism is consistent with the experimental observations:  $(\partial \log i_a/\partial E)_{\theta, pH} = F/2.303 RT$ ,  $(\partial \log i_a/\partial pH)_{E, \theta} = 1$ , and  $[\partial \log (i_{a,x} - i_a)/\partial t]_\eta = \text{constant}$ .

The adsorbed benzoate anion accelerates the rate of the proton discharge reaction and this has been shown to result from a  $\psi$ -effect, i.e., a double-layer effect, and a simultaneous diminution of the standard chemical free energy of activation for proton discharge. Of particular significance is the fact that, at constant solution composition,  $(\partial \log i_c/\partial E)_\theta = 1/S$ , where  $S$  is a constant the magnitude of which is a function of  $\theta$ , i.e., of the benzoate coverage. Using measured values of  $S_x$  together with the experimentally established relationship between  $S$  and  $\theta$ , it has been demonstrated that the steady-state coverage obeys a potential-dependent Langmuir adsorption equation. The variation of  $S$  with  $\theta$  was shown to result from the dependence of  $S$  on  $(\partial \psi/\partial \eta)_\theta$  which, in turn, was shown to be a linear function of  $\theta$ . The linear dependence of  $(\partial \psi/\partial \eta)_\theta$  on  $\theta$  was interpreted in terms of

the displacement of the pre-electrode plane from the outer Helmholtz plane toward the metal, the displacement being proportional to  $\theta$ . Similarly, on the basis of the experimental evaluation of  $(\partial \log i_c / \partial \theta)_\eta$  and the derived relationship between this variable and the variables,  $(\partial \psi / \partial \theta)_\eta$  and  $(d \ln k / d\theta)$ , it was established that the standard free energy of activation for proton discharge is a linear function of  $\theta$ , and that  $(\partial \psi / \partial \theta)_\eta$  is proportional to  $\eta$ . The hydrogen evolution reaction was shown to be first order in proton activity, i.e.,  $(\partial \log i_c / \partial \text{pH})_{E,\theta} = -1$ . In addition to the "instantaneous" and steady-state current/potential data, potentiostatic cathodic current/time transients were quantitatively analyzed on the basis of an appropriate potential-dependent adsorption/desorption rate equation and the established relationship between  $i_c$  and  $\theta$ .

The results of this investigation demonstrate the feasibility of analyzing the complex data characteristic of inhibited systems and provide further insight into the mechanisms of corrosion and corrosion inhibition.

## A Microstructural Study of the Reactivity of Cobalt Surfaces at Elevated Temperatures

R. Taggart, D. H. Polonis, and N. E. Dodds

*Division of Metallurgical Engineering, University of Washington, Seattle, Washington*

#### ABSTRACT

High-temperature metallographic techniques have been used to study the reactivity of cobalt surfaces at temperatures up to 1200°C and oxygen partial pressures in the range  $10^{-3}$  to  $10^{-7}$  Torr. The processes of thermal etching, faceting, and oxide particle formation can be controlled by adjusting the conditions of temperature and oxygen partial pressure. The faceting reaction is accompanied by sublimation and can be reversed in favor of either oxidation or thermal etching by changing the temperature and pressure. Oxide particles form with a density and morphology dependent on the orientation of the metal matrix. Dissolution of the particles on heating from 900°C has been attributed to the change in oxygen solubility in the cobalt matrix.

In the present work the formation of facets and oxide nuclei on cobalt surfaces has been investigated by means of direct observation of the microstructure during exposure to elevated temperatures under conditions of controlled oxygen partial pressure.

Previous investigations (1-10) of the oxidation of cobalt surfaces have revealed the formation of CoO layers at temperatures above 900°C and under oxygen pressures that varied between 0.005 and 1 atm. At temperatures below 900°C, the oxide  $\text{Co}_3\text{O}_4$  has also been reported, but it is unstable at higher temperatures and dissociates in favor of CoO.

Zettlemoyer *et al.* (11) and other investigators (1, 5, 12) have attributed the initial deviation from the parabolic rate law to adsorption, chemisorption, and phase boundary reactions. There has been an apparent disregard for the temperature dependence of oxygen solubility in cobalt and its potential effect on the very early stages of oxidation. Mathematical models to describe the initial oxidation process have been based on the concept of diffusion controlled thickening of

continuous oxide layers. Consideration has not been given in the case of cobalt to the discontinuous nature of the oxidation process as has been reported for copper and other metals (13, 14).

#### Experimental Methods

Polished and etched surfaces of 99.9% purity cobalt were examined at temperatures up to 1200°C in a Reichert hot stage metallograph. By means of a variable leak valve it was possible to control the oxygen partial pressure over the range  $10^{-3}$  to  $10^{-7}$  Torr, while the total pressure of oxygen and nitrogen in the chamber was in the range  $10^{-2}$  to  $10^{-6}$  Torr. The specimen temperature was determined by means of a chromel-alumel thermocouple spot welded on the polished surface.

#### Experimental Results

Three distinct microstructural processes have been identified during the exposure of cobalt surfaces to an oxidizing environment at temperatures above 500°C.

Fig. 1. Dependence of surface reactions on the temperature and pressure conditions.

The observations are summarized in Fig. 1 from which it can be deduced whether thermal etching, faceting, or oxidation should predominate, depending on the temperature and pressure conditions. Hot stage microscopy observations have shown that these stages may overlap and that the formation of oxide nuclei and thermal facets can be reversed. Although the available thermodynamic data for CoO suggests that this compound should be stable at the total pressures used in the present study, the oxide nuclei were observed to contract and, in some cases, to completely disappear at oxygen partial pressures below  $10^{-5}$  Torr.

*Thermal etching and faceting.*—Cobalt specimens that were heated for several hours above  $1000^{\circ}\text{C}$  in a vacuum of less than  $5 \times 10^{-6}$  Torr exhibited grain boundary grooving due to thermal etching, while at the same time all other features were eliminated from the grain surface. In accordance with the definition of a thermal facet by Moore (15), Fig. 2 shows the facets that developed on a cobalt surface after holding for several minutes at temperatures exceeding  $900^{\circ}\text{C}$  and pressures below  $10^{-5}$  Torr. The nucleation rate and the morphology of the facets varied with the orientation of the surface, the oxygen partial pressure, and the holding temperature. In general, the nucleation of facets occurred preferentially at oxide particle interfaces and at grain boundaries (see Fig. 3a and 3b). Figures 4a-4c illustrate the reversibility of facet formation at  $1000^{\circ}\text{C}$  when the oxygen

pressure was raised from  $8 \times 10^{-6}$  to  $1.2 \times 10^{-5}$  and then lowered to  $4.2 \times 10^{-6}$  Torr.

*Oxidation.*—The growth of discrete and discontinuous oxide particles characterized the initial stages of the oxidation of cobalt surfaces at  $900^{\circ}\text{C}$  and oxygen partial pressures of approximately  $2 \times 10^{-5}$  Torr. As shown in Fig. 5a-5c, the particles generally exhibited regular geometric shapes that were uniform within a given grain, suggesting an orientation relationship with the underlying matrix. During continued oxidation, the number of particles remained unchanged, but they eventually impinged to produce a uniform surface layer.

After oxide particles started to form on the surface, the reaction could be reversed by lowering the partial pressure or by raising the temperature. Figures 6a-6d show oxide reversion under constant temperature and varying pressure conditions. Dissolution of the oxide particles was followed by thermal faceting during prolonged holding at temperature. The facets developed preferentially at sites occupied by oxide particles resisting dissolution (see Fig. 3a) and, when oxidation conditions were restored, the facets were difficult to remove. The subsequent reoxidation of the surface resulted in particle formation at the pre-existing sites.

### Discussion of Results

*Thermal faceting.*—The observations of the present study point clearly to the heterogeneous nature of facet nucleation and its dependence on the oxidizing power of the atmosphere. Facet formation is favored at oxide particle interfaces, as shown in Fig. 3a and at grain boundaries, as shown in Fig. 3b. It is not

Fig. 4. Sequence of hot stage photomicrographs showing the growth and dissolution of thermal facets as a function of oxygen partial pressure at 1000°C. Optical micrograph. Fig. 4a, 3 min at  $1.2 \times 10^{-5}$  Torr. Magnification ca. 700X.

Fig. 4b. 8 min at  $1.2 \times 10^{-5}$  Torr

Fig. 4c. 22 min at  $4.2 \times 10^{-6}$  Torr

possible on the basis of the present work to define the relative contributions of surface diffusion and evaporation to the kinetics of facet formation on cobalt. However, it is apparent that oxygen assumes

Fig. 5. Oxide formation combined with facet dissolution at 1000°C and oxygen partial pressure of  $2 \times 10^{-5}$  Torr showing the dependence of oxide morphology on the substrate orientation. Optical micrograph. Fig. 5a, top; Fig. 5b, center; Fig. 5c, bottom. Magnification 700X.

an important role in controlling the evaporation process that is involved in faceting. The observations support a proposed model based on the selective adsorption of oxygen on low index planes while evaporation occurs from a particular set of high index planes (15). This argument is substantiated by the fact that the dissolution of facets on reducing the oxygen pressure,

or by raising the temperature, required an incubation period before any visible changes occurred. At  $4.2 \times 10^{-6}$  Torr, 20 min elapsed prior to any visible change in the facet structure, but as shown in Fig. 4c, the facets became diffuse after 22 min, whereas after 26 min it was observed that surface relief was almost completely eliminated. From a kinetic viewpoint, the

Fig. 6. Sequence of hot stage photomicrographs showing the growth and dissolution of oxide particles and the initiation of faceting. Fig. 6a. Oxidized at  $1000^\circ\text{C}$  and  $2 \times 10^{-5}$  Torr. Magnification ca. 315X.

Fig. 6b. Held at  $1100^\circ\text{C}$  for 8 min at  $10^{-5}$  Torr (oxide particles have dissolved and facets begin to form).

Fig. 6c. Re-oxidized at  $800^\circ\text{C}$  and  $4 \times 10^{-5}$  Torr

relative rates of metal evaporation and oxygen adsorption should determine for a given temperature whether thermal etching, faceting, or oxide formation will proceed on cobalt surfaces under a given set of oxygen partial pressure conditions. Thermal etching should occur when the evaporation rate exceeds the rate of oxygen adsorption, whereas faceting will be favored when these rates are approximately equal. When the oxygen pressure is sufficient for oxygen deposition to prevail, then the process of oxide formation should predominate.

In order to determine the time necessary for the adsorption of oxygen, it is essential to evaluate the rate of incidence of oxygen molecules on the surface for a particular set of temperature and pressure conditions. From kinetic theory (16) it may be deduced that  $N$ , the rate of incidence of gas molecules, of molecular weight  $M$  is given by

$$N = 3.513 \times 10^{22} (\text{Pmm}) (MT)^{-1/2} \text{ molecules/cm}^2\text{-sec} \quad [1]$$

For oxygen where the molecular weight is 32

$$N = 6.21 \times 10^{21} (\text{Pmm}) (T)^{-1/2} \quad [2]$$

On the basis of a value of  $3.64 \times 10^{-8}$  cm for the diameter of the oxygen molecule there are  $7.56 \times 10^{14}$  molecules/cm<sup>2</sup> for an adsorbed monolayer. The deposition time  $t$  for a monolayer of oxygen is then given by

$$t = \frac{7.56 \times 10^{14}}{N} \text{ sec/monolayer} \quad [3]$$

This relationship is plotted in Fig. 7 where it can be seen that the minimum time required for the

Fig. 7. Effect of temperature and oxygen partial pressure on the minimum time required for the formation of an oxygen monolayer.

formation of an adsorbed monolayer is strongly pressure dependent, but only slightly affected by temperature changes at constant pressure over the ranges of interest in the present work. The predominance of thermal etching at  $10^{-6}$  Torr can therefore be attributed to the relatively long incubation time necessary to establish the adsorbed monolayer that will inhibit the evaporation of cobalt atoms. On the other hand, at oxygen pressures of  $10^{-4}$  Torr an adsorbed layer can form almost instantaneously over the entire temperature range of the present experiments, resulting in conditions favoring oxide particle nucleation.

According to Fig. 7, raising the temperature of cobalt from  $900^{\circ}$  to  $1100^{\circ}\text{C}$  at  $10^{-5}$  Torr should not affect significantly the rate of impingement of oxygen molecules on the surface. Thermodynamic data for the compound CoO indicate that an existing oxide should continue to grow when the temperature is raised. The fact that the oxide particles disappear on heating under these conditions, requires an examination of the oxide stability in terms of the effect of temperature on the solubility of oxygen in the substrate.

*Kinetics of oxidation.*—For oxide thicknesses less than  $10,000\text{\AA}$  Reti reported (5) that the rate of oxidation is less than that predicted from the rate of cation vacancy diffusion through a homogeneous CoO layer. The results of the present research lend support to the contention of Reti (5) that the early stages of cobalt oxidation are controlled by the growth of small discrete nuclei of CoO. Rhead (17) assumes a concentration gradient at the edge of a radially growing cylinder of oxide and applies a surface diffusion coefficient in place of the bulk diffusivity in the diffusion equation. An important aspect of this analysis was the conclusion that the diffusion mechanism accounting for the growth of the particles may not be very different from either the surface diffusion of the metal or the surface transport of both metal and oxygen.

The observations of the oxidation of cobalt in the present study parallel the results of Lawless and Mitchell (18) who suggested that competition between the rate of the solution of oxygen in copper and the rate of formation of an oxide layer determined their rates for the nucleation and growth of oxide particles. The results of the present research suggest that Rhead's diffusion analysis is an oversimplification of the mechanism of oxidation as it occurs in cobalt. The incubation period observed during the initial stages of the oxidation of cobalt depends on both the temperature and the oxygen partial pressure and is a strong indication of the presence of a chemisorbed layer that exists when the underlying substrate of cobalt has satisfied local oxygen solubility requirements. The existence of such a stable layer is substantiated further by the fact that it was difficult to initiate the smoothing of an already faceted surface. When the partial pressure of the oxygen was reduced or when the temperature was raised, the localized oxidation reaction was reversed, and the oxide particles tended to disappear. This observation may be explained on the basis of the solubility of oxygen in the underlying cobalt metal (19) which increases up to  $800^{\circ}\text{C}$ , then decreases from  $800^{\circ}$ - $950^{\circ}\text{C}$ , and increases again at higher temperatures. Further evidence of the effect of oxygen solubility is provided by the fact that specimens oxidized at  $900^{\circ}\text{C}$  exhibited oxide particle dissolution when the temperature was raised to  $1100^{\circ}\text{C}$ . When the specimens were held for several minutes at the higher temperature, the oxide particles reappeared; this was taken as an indication that the solubility requirements had been satisfied and the necessary chemisorbed layer had been re-established.

The surface reactions under these conditions can therefore be attributed to the maintenance of a chemisorbed monolayer of oxygen established on a thin and highly defective layer of CoO. The thickness of this layer depends on the oxygen partial pressure

and the ambient temperature. Diffusion of oxygen from this thin film will establish an oxygen concentration gradient in the underlying cobalt matrix. Thus, the incubation period can be accounted for satisfactorily as the time during which the predominant reaction process is the solution of oxygen in the cobalt substrate. In accordance with the model proposed by Lawless and Mitchell for copper (18) the formation of cobalt oxide particles will occur when the process of cation diffusion through the thin film predominates over the diffusion of oxygen into the substrate. Under these conditions it is questionable to assume, as postulated by Rhead (17), that a surface diffusion coefficient will describe the transport process necessary to promote the radial growth of the particles. A more realistic model should consider cation diffusion through the stable chemisorbed layer that is maintained by a continuous reaction between oxygen and cobalt. In order to develop a meaningful quantitative description of the kinetics of particle growth, it is necessary to identify whether the surface transport of oxygen or the bulk diffusion of cations is rate controlling. In the oxidation experiments of the present study, the oxygen partial pressure is sufficient to provide a continuous supply of oxygen molecules to the surface. Under these conditions, the important unit processes leading to the migration of the oxide-metal interface and the radial growth of oxide particles should be the transport of cations through the thin surface layer followed by combination with the available adsorbed oxygen. The rate of radial growth will then be determined by the rate at which cobalt ions and oxygen can combine in the region immediately ahead of the oxide particle interface. It is obvious that a parabolic law cannot describe the kinetics of the oxide particle growth because layer thickening is not a significant factor until the radially growing particles impinge. The development of meaningful equations to describe particle growth is not possible unless the relative contributions of the separate diffusion processes are identified with certainty.

## Potentiostatic Current-Potential Measurements on Iron and Platinum Electrodes in High-Purity Closed Alkaline Systems

Clarence M. Shepherd\* and Sigmund Schuldiner\*

Naval Research Laboratory, Washington, D. C.

### ABSTRACT

Potentiostatic polarization curves were determined for Fe, Pt, and combinations of Fe and Pt electrodes in NaOH and LiOH solutions saturated with helium. With the high-purity, gas-tight system used, the level of reactable impurities was reduced to about  $10^{-6}$  ppm. Under these conditions the primary reactions are, depending on potential, the oxidation or reduction of  $\text{OH}^-$  and water. Iron does not significantly corrode or show a decrease in reaction rate with an increase in potential (passivate). Iron with its surface layer acts like an inert noble metal similar to platinum. Chloride ion causes extensive iron corrosion and completely changes the potentiostatic polarization behavior and does cause typical passive behavior. Under high-purity conditions, iron is an excellent catalyst for the hydrogen oxidation reaction; the presence of chloride ion, however, almost completely destroys the catalytic properties of Fe for this reaction. Unreactable and unremovable impurities such as carbonate, silicate, sulfate, etc., apparently do not have major effects on the polarization behavior of Fe. The major anion,  $\text{OH}^-$ , appears to dominate the inert anion effects.

Innumerable studies of the "passive" behavior of iron have been reported in the literature. Potentiostatic, steady-state investigations previously carried out on platinum electrodes, under conditions where the rates of the electrode reactions were very slow, have shown that under such conditions reactable impurities can play a dominant role (1). It therefore seemed reasonable that, in order to carry out meaningful electrochemical studies of the behavior of an iron electrode under conditions in which the electrode processes occurred at very slow rates, impurities which can react or otherwise affect reaction rates in a primary way would have to be minimized.

To carry out such an investigation the high-purity, gas-tight electrochemical system developed at this Laboratory (2) was used. In order to keep the iron electrode as inert as possible to corrosion, alkaline solutions were used.

A detailed explanation of the meaning of impurities should be made. By careful cleaning and aging of electrochemical cells and associated systems, the impurity level in solution can be kept low depending on the purity of the materials put into the cell. Further purification is possible by pre-electrolysis. Pre-electrolysis will remove species that deposit on an electrode which can then be removed from the cell. In addition, certain species, in particular organic materials, can be removed by electrochemical oxidation or reduction. If the electrochemical system is a tightly closed one, then a level of impurities which can be removed by electrochemical means can be reached and maintained which is limited by the rate of introduction of such impurities into the cell through leaks into the system or via materials (such as gases) which are introduced into the cell. Hence, the tighter the system, the more extensive the pre-electrolytic purification, and the better the purification of materials added during a run, then the lower the level of such impurities will be.

There always are, however, certain impurities which by our present technology are virtually impossible to remove below a certain level. For example, the elec-

trode material itself always contains impurities. At the present time it is virtually impossible to reduce these to a level much below 1 ppm. If the electrode is a solid, at room temperature, the rate of diffusion of such impurities from the bulk of the electrode to the surface may be slow enough so that during a run their rate of arrival will be insignificant. Also, under the proper conditions, such impurities may react and be removed as the run is being made. Depending on the net rate of the particular reaction being studied, the effect due to impurity reaction, may or may not be significant. In addition catalytic poisoning effects are possible.

Other possible sources of unremovable impurities in the electrolyte are the solvent, chemicals which compose the solute, and solution of species from the cell walls. The amounts of such unremovable species may be maintained at a low level, but their complete removal is not, as yet, possible. The best one can hope for is that such impurities have secondary effects only on the electrode processes under investigation. In short, one can with present techniques reduce the level of reactable impurities to very low quantities ( $10^{-12}$  to  $10^{-13}$  parts) and maintain these levels for long periods of time in a properly closed system (1, 2). Unremovable impurities should be maintained at as low a level as possible by careful purification and selection of materials and by adsorption on large areas of inert materials. It should always be kept in mind, however, that any such adsorbents, no matter how inert they are, also do contribute impurities to the system. The really important consideration concerning unremovable impurities is how they affect the electrode process being studied.

### Experimental

The high-purity closed electrochemical system and the experimental conditions were essentially the same as previously used (1, 2). Before each run, the cell was cleaned with hot concentrated nitric acid and rinsed by continually distilling triply distilled water into it for at least 24 hr; finally, about 100 ml of water

\* Electrochemical Society Active Member.

was distilled into the cell and cooled. The highest purity sodium hydroxide solutions (designated NaOH) were prepared by breaking in two a capsule of sodium metal (99.95% with < 55 ppm heavy metals, with the major unremovable impurities being potassium, iron, calcium, silicon, magnesium, and carbon, sealed under argon) and introducing the two halves into the cell under an atmosphere of purified helium. The two halves of the capsule were placed so the open ends were at the bottom of the cell. Thus as sodium metal dissolved, the hydrogen gas generated filled the capsule ends and regulated the introduction of water into the capsule. This allowed a rather slow solution of sodium metal.

Less pure sodium hydroxide solutions were prepared using a reagent grade sodium hydroxide (97.4%) pellets (designated NaOH pellets). The major unremovable impurities were  $\text{Na}_2\text{CO}_3$  (0.64%), NaCl (0.003%), and silicate (0.01%). Lithium hydroxide solutions were prepared using lithium metal from two sources (99.99 and 99.92%). The unremovable impurities were primarily potassium, sodium, chloride, calcium, silicon, aluminum, and iron.

The working electrodes were Fe wires (fabricated from 3 pass electron beam zone refined iron with less than 4 ppm metallic impurities, 20 mil diameter, geometric area about  $0.7 \text{ cm}^2$ ); a similar Fe wire with about 1 cm of 3 mil Pt wire spot welded to the Fe wire and wound around its tip (designated Fe  $\gg$  Pt electrode); and a Pt wire (99.99%, 20 mil diameter, geometric area =  $0.65 \text{ cm}^2$ ). Each of these electrodes were connected to Pt leads and sealed off in lead-free soft glass tubes. The counter electrode was a large Pt gauze electrode. The reference electrodes were in an arm off the main cell compartment and were a calibrated (*vs.* Pt/ $\text{H}_2$  in the same solution) miniature glass electrode and a Pd wire charged with hydrogen to a potential of about 50 mv positive to a hydrogen electrode in the same solution. This Pd-H wire electrode was used as the potentiostatic reference.

Each solution was pre-electrolyzed for several days in a helium saturated solution using a Pt pre-electrolysis cathode which was then removed from the cell. The purified helium flow was then replaced with a flow of hydrogen which was purified by passing through heated Pd-Ag tubes. The Pt wire, Pt gauze and Pd wire potentials were then determined against the glass electrode. After the Pt/ $\text{H}_2$  electrodes reached their equilibrium values and the Pd wire was 50 mv positive to the Pt/ $\text{H}_2$  potentials, an Fe wire (or Fe  $\gg$  Pt), cleaned in 1M  $\text{H}_2\text{SO}_4$  and rinsed with triply distilled water, was introduced into the cell under an anodic applied potential as the working electrode in the potentiostat circuit. The glass reference electrode continuously monitored the potential on the Fe working electrode via a Keithley 610B Electrometer. Current flow under potentiostatic conditions was determined with a Keithley 601 Electrometer and recorded.

A point was determined on the potentiostatic polarization curve by holding the working electrode at a constant potential [calculated and recorded in reference to the normal hydrogen electrode (NHE)] until a constant current was reached. The time required to reach steady state varied from minutes to days depending on the potential and potential sequence. The potential was then increased and the new steady-state current determined. This was continued until the potential was well into the oxygen generation region after which the potential was made less noble in similar constant current steps until the potential was well into the hydrogen generation region. Stepwise potential increases in the noble direction followed until a full potential cycle was achieved. The cycling continued until the current readings for consecutive cycles were consistent in value. These are the values given in the figures. It was found that several cycles over a period of several weeks were required before consistent polarization curves were attained. We believe that the inconsistencies in the initial cycles

were due to traces of reactable impurities (primarily organic) which were slowly removed by oxidation. The temperature was  $25^\circ \pm 2^\circ\text{C}$ , and the flow rate of gas was normally 40 ml/min.

### Characteristic Impurity Effects

During the pretreatment period when the potentiostatic current density *vs.* potential points varied considerably from cycle to cycle, certain characteristic behavior was observed which reflected decreases of reactable impurity levels in solution, from the electrode surfaces, and in the uppermost layers of the working electrode. In addition certain slow changes in the state of the working electrode surface undoubtedly occurred. We are not, as yet, in a position to specify, or even to speculate on, the species on the surface of the iron electrode and the changes which occur as the potential is varied. However, under the high-purity conditions which were maintained after the pretreatment purification, the surface states were consistently reproducible. The iron electrode itself underwent no visible change from the beginning to the end of a run (and some lasted for several months). The appearance of the iron did not indicate significant corrosion. Analysis of the solution at the end of a three month run gave about  $0.1 \mu\text{g}$  in the 50 ml of solution in the cell. Evidently the trace of iron which may come from the Fe electrode is so small that the anodic currents determined under potentiostatic conditions were primarily due to  $\text{OH}^-$  and water oxidation rather than to Fe oxidation.

Figure 1 represents typical current density changes with time due to a change in the working electrode potential. These show characteristic impurity behavior. Curve A, Fig. 1, typifies the smooth current *vs.* time behavior found after the pretreatment cycle purification. Curve B, is a synthesis which illustrates some of the abnormalities that may be caused by impurities found in a newly prepared electrolyte. Irregularities may occur such as those shown at point 1 or false trends such as those found in the neighborhood of point 2.

Oscillations similar to point 3 may occur and tend to extend over the full length of the curve. Over fairly long intervals their frequency and amplitude are roughly constant. Oscillations may occur from one every few seconds to one every few minutes and may be so large that they obscure the base curve and make it difficult or impossible to determine the final reading for the constant current value. Oscillations of this type have been induced in the pure Fe/NaOH system by the addition of small amounts of  $\text{O}_2$  or  $\text{Cl}^-$ .

Fig. 1. Typical current density changes with time following potential change: curve A, electrochemically purified system; curve B, types of abnormalities caused by impurities, No. 1-6 are explained in the text.

Impurities can cause sharp breaks in the current *vs.* time curve such as shown at points 4, 5, and 6 of curve B, Fig. 1. Such changes in current generally occur quite rapidly and then return fairly slowly to the normal rate. Impurities that are reactable can contribute to the net current and can either sharply increase or decrease its value depending on whether they are oxidized or reduced.

For the purest Fe/NaOH system, at anodic currents, the number of coulombs that are passed from the start of the current-time curve until constant current, are approximately constant and roughly equal to a fraction of a monolayer (2 electron reaction). This value is less for small potential steps and at potential settings which give relatively low current densities and appreciably higher for large potential steps and at potentials which give high current densities. In comparing curve B to A in Fig. 1, it can be seen that the presence of reactable impurities increases the current at any given time and increases the time required for the current to become constant. Hence, when reactable impurities are present, the total number of coulombs which flow can be much larger.

Another important characteristic of reactable impurities in solution is the stirring effect. The pure Fe/NaOH system under helium flow was essentially independent of stirring rate (40-1000 ml He/min) except at the lowest current densities ( $10^{-9}$  amp/cm<sup>2</sup>). Reactable impurities gave substantial current differences at the highest stirring rate. The direction of such a current change depended on whether the current at slow He flow was anodic or cathodic and whether the impurity was being oxidized or reduced. Each of the effects shown in Fig. 1, curve B, have been induced by addition of impurities, such as Cl<sup>-</sup> to a pure Fe/NaOH system.

Previous work (1) has shown that it is possible to estimate the amount of oxidizable or reducible impurities present in a purified system. This is done by introducing known trace amounts of hydrogen or oxygen to the helium flowing into the cell and observing the minimum amount required to change the steady-state current density at a sensitive (very low steady-state current density) set potential. Such measurements have been made for the systems investigated in this work, and it was shown that under the conditions which data were taken the minimum levels of oxygen or hydrogen to which the system was sensitive was approximately  $10^{-6}$  ppm.

In addition to reactable impurities, which have been reduced to insignificant values in this work, the question of the effects of unremovable impurities must be considered. In the system used, one immediately becomes concerned with the presence of such impurities which dissolve from the Pyrex glass cell. These would primarily consist of silicate, borate, aluminate, sulfate, phosphate, and chloride. Our first reaction was to avoid alkali-glass contact in the cell by use of a Teflon coating or use of a noble metal cell. However, on consideration of the total unremovable impurity problem it was soon realized that this would be an essentially useless complication. This is because similar amounts of the same impurities would remain in any cell. The level of such impurities is determined primarily by the unremovable impurities in the water, chemicals (Na, Li, NaOH) used to form the solution, the electrodes, and the impurities which come from the atmosphere (dust, etc.) which are virtually impossible to avoid in the assembly of any system. These impurities cannot be satisfactorily removed at the present time or even be reduced to levels which are significantly less than monolayer quantities.

In any case, the best we can do at present is to determine, as well as possible, if such unremovable impurities do affect the electrode reactions of interest in a primary way. Using 99.95% sodium metal, 97.4% NaOH pellets, 99.99 and 99.92% lithium metal in the preparation of solutions, we could compare data taken

with each solution after the pretreatment purification procedures on each. The amounts of unremovable impurities varied considerably from solution to solution, but in all cases there undoubtedly were sufficient amounts of any of these impurities to form multiple monolayers if they deposited on the electrode surfaces. The actual data showed some significant differences which will be discussed later, but the over-all current density *vs.* potential curve shapes and characteristics were fundamentally the same. It was felt that most of the unremovable impurities, such as, silicates, borates, phosphates, sulfates, etc., would have little effect since adsorption of hydroxide would predominate in potential regions where the net charge on the electrode was positive. This is verified by the work of Pryor and Cohen (3) who showed that nonoxidizing anions had corrosion inhibiting effects very similar to hydroxyl ion in the presence of air and that in the absence of air nonoxidizing anions do not inhibit iron corrosion. The most likely unremovable anion which may have important effects on electrode processes is chloride ion (and other halides) and most of the differences found for the varying purity of solutions used in this work can be reasonably laid primarily to the differences in chloride ion content. This was at the highest value for the sodium hydroxide pellets (0.003%), and this solution did give the widest variation in results from the purest solution studied. Work was done in which chloride additions (0.2%) did cause large differences in behavior and actual visual corrosion of the iron. This is reported below.

### Experimental Results

Figure 2 shows the potentiostatic polarization curves obtained in electrolyte prepared using 99.95% sodium metal which then underwent extensive pre-electrolysis. In all the figures, the symbol  $\Delta$  represents a steady-state current density made at a set potential that was higher than the potential of the previous reading (increasingly noble potential sequence). Conversely, the symbol  $\nabla$  indicates that the potential sequence was decreasingly noble.

Curve AEF (Fig. 2) represents the increasing potential sequence data found when the initial potential was negative to, or at  $-0.17$ v. The decreasing potential sequence starting at potentials positive to  $0.76$ v (point E) gave data on curve FCA. If, on the decreasing potential sequence FCA, the potential was taken to point B ( $0.04$ v) and then a sequence of more noble potentials were applied, curve BDF was obtained. If, on the increasing potential sequence, AEF, the most noble potential applied was  $0.76$ v (point E) and the potential was subsequently decreased, the data points fell on curve EDDBA.

In any segment where the arrow indicates the direction of change of the potential sequence, a reversal in potential gave a reading on that segment. For example; in a segment such as AE which shows what happens when the potential is increased stepwise from point A to point E, any decrease from a point in

Fig. 2. Fe potentiostatic polarization curves in 0.55M NaOH:  $\Delta$  increasing potential sequence;  $\nabla$  decreasing potential sequence; letters A-K are explained in the text.

AE which does not take the potential below point A, will give a reading which is still on the segment AE. This is indicated by  $\Delta$  and data points for each curve segment in Fig. 2.

At point A and above the currents are anodic, while at point G and below they are cathodic. As the potential is made more cathodic below point G, the readings followed curve GHJK. Making the potential more noble in the region JK gave data points which followed curve KJHG.

The results shown in Fig. 2 were obtained for 0.55M NaOH (13.4 pH). Runs were made also at 0.30 (13.2 pH), 0.13 (12.9 pH), and 0.067 (12.7 pH) M concentrations. Such variations in concentration had little effect on the data shown, except for the segment CF. In this potential region, a decrease in alkali concentration resulted in a linear segment parallel to CF with the current densities being generally smaller as the solution was more dilute. Similar results were found with LiOH and other NaOH solutions.

The experiments depicted in Fig. 2 were repeated in a 0.2M NaOH (13.1 pH) solution prepared from a different batch of high-purity sodium from the same supplier. The results are shown in Fig. 3 which includes data from Thomas and Nurse (5) taken in 0.1M NaOH. Figure 4 shows the results which were obtained from a 0.58M NaOH electrolyte prepared from a reagent grade NaOH (NaOH pellets).

A 0.85M LiOH solution was prepared from high-purity metallic lithium (99.92%). The potentiostatic polarization curve is shown in Fig. 5. When this solution was diluted to 0.34M LiOH, the change in this curve was negligible except in the linear  $b = 0.04$  region where the curve ran about 0.06v higher.

Fig. 3. Fe potentiostatic polarization curves in 0.2M NaOH. See Fig. 2 for meaning of symbols. Data from Thomas and Nurse (5),

Fig. 4. Fe potentiostatic polarization curves in 0.58M NaOH (pellets). See Fig. 2 for meaning of symbols.

Fig. 5. Fe potentiostatic polarization curves in 0.85M LiOH. See Fig. 2 for meaning of symbols.

A 0.28M LiOH solution was prepared from another pure lithium (99.99%) sample which contained about one fifth the amount of unreactable impurities as the lithium used in Fig. 5. The results were very similar. The current densities were slightly lower, the hysteresis loop was narrower, and the change-over from anodic to cathodic current occurred at about 0.55 instead of 0.64v.

### Discussion

There are a number of differences in the results shown in Fig. 2 to 5. Most of them are small and can probably be attributed to the presence of different unremovable impurity levels. The important fact here is that in every case in which the reactable impurities have been reduced to the very low levels represented by these data, the iron behaves as an inert or noble electrode. The current densities are very small and in the anodic region primarily represent the oxidation of  $\text{OH}^-$  and possibly  $\text{H}_2\text{O}$  to oxygen, whereas in the cathodic region, the primary reaction is the reduction of water to hydrogen. The electrodes showed no corrosion or etching either visibly or under low-power microscopic examination. The iron remained bright and shiny throughout the runs without any visible discoloration.

The electrolyte used in obtaining the data in Fig. 4 was prepared from reagent grade NaOH pellets and had by far the highest level of unremovable impurities. The sodium carbonate content was 65 ppm, which was at least one order of magnitude higher than that in the other Fe/NaOH systems. The data shown in Fig. 2 are believed to be for the purest system. In going from Fig. 2 to Fig. 3 and finally to Fig. 4, it can be seen that the anodic hysteresis loop becomes much narrower. In going from Fig. 2 to 4, it can be seen that the current density decreases slightly over the major part of the hysteresis loop and the change-over potential from anodic to cathodic current decreases. These differences may be related to the level of unremovable impurities.

It is interesting to note that the width of the hysteresis loop, shape of the curves, current densities, and change-over potential from anodic to cathodic current did not vary appreciably when the electrolyte used to obtain Fig. 2 was diluted in four steps from 0.55 to 0.067M NaOH or when the LiOH used for Fig. 3 was diluted from 0.85 to 0.34M. If the differences observed in Fig. 2-4 are caused by impurities, it is not the variations in level of impurity that is important but rather the type of impurity or possibly the ratio of impurity to  $\text{OH}^-$ .

In the case of LiOH the impurity differences in the two samples of metallic lithium used were not as great as for the sodium hydroxide solutions. For LiOH the narrower hysteresis loop was obtained with the solution made from the purer sample. The differences in  $\text{Li}^+$  and  $\text{Na}^+$  are not great enough to conclude that there is a cation effect. Here again the small differences in behavior are most likely due to the differences in specific unremovable species rather than the net amounts of the total amount of unremovable impurities.

The potentiostatic polarization curve for a platinum electrode in 0.2M NaOH is given in Fig. 6. Compared to the Fe electrode data (Fig. 2 to 5) the general electrode behavior for Pt and Fe in alkaline solution are quite similar. Both metals are essentially inert electrode materials on which  $\text{OH}^-$  and water can be either slowly oxidized to oxygen or reduced to hydrogen depending on the set potential. The anodic hysteresis effect found on platinum in acid solution (1) was attributed to the dermasorption of oxygen atoms at high positive potentials. Similarly it is believed that the hysteresis found on Pt (Fig. 6) in alkaline solution is due also to dermasorbed oxygen atoms. The anodic hysteresis found for Fe electrodes (Fig. 2 to 5) can be attributed to the formation of an iron oxidelike species in the uppermost layers of iron. There is certainly no formation of an extensive bulk iron oxide on the surface

Fig. 6. Pt potentiostatic polarization curves in 0.2M NaOH. See Fig. 2 for meaning of symbols.

although a thin film of iron oxide is undoubtedly present (6). The exact nature of the species on the iron surface, its interactions at the metal/solution interface, are not known and further work is required to clarify these very important points.

A question arises as to whether the platinum counter electrode does contribute Pt which contaminates the Fe electrodes investigated. It has been shown (4) that a pure Fe electrode operating under the conditions described in this paper is a far better catalyst for the hydrogen oxidation reaction than a Pt electrode. A small piece of Pt attached to an Fe wire electrode actually reduced the activity of the iron for the hydrogen oxidation reaction and gave a very different potentiostatic polarization relation (4). This demonstrated that the contamination of Fe with Pt did not occur in our system.

Potentiostatic current density vs. potential curves were determined for an Fe  $\gg$  Pt and an Fe = Pt (an Fe wire shorted outside the cell to an equal size Pt wire) electrode in helium-saturated 0.2M NaOH. The results are shown in Fig. 7 and 8. Comparing Fig. 7 and 8 with those for pure iron and platinum (Fig. 2 to 6) show a number of minor differences which indicate that the contamination of an Fe electrode with Pt would have slight effects only. The

Fig. 7. Fe  $\gg$  Pt potentiostatic polarization curves in 0.2M NaOH. See Fig. 2 for meaning of symbols.

Fig. 8. Fe = Pt potentiostatic polarization curves in 0.2M NaOH. See Fig. 2 for meaning of symbols.

important thing to note is that in each of these cases each electrode is inert and that no appreciable corrosion is taking place. (A small amount of a light brown corrosion product was found only for the Fe  $\gg$  Pt electrode at the juncture of the two metals.) Moreover in each of these cases the current densities have generally the same small values and the polarization curves have essentially the same shapes.

The major removable trace impurities whose presence may affect potentiostatic polarization curves are oxygen, hydrogen, organic species, and metals. The initial pre-electrolysis in the high-purity closed system used has reduced the level of metallic impurities to at least their level in the electrode material itself. In fact, such impurities at the electrode surface are probably much less than in the bulk of the electrode metal itself. The other impurities were removed by the repeated oxidation or reduction procedure used. The levels of these impurities (other than the amounts of hydrogen or oxygen generated at the applied potentials) were found to be less than  $10^{-6}$  ppm as calculated on the basis of the hydrogen oxidation or oxygen reduction currents required to change the residual current density at a potential near the change-over from net cathodic to net anodic reactions (1). Since the steady-state currents for many inert electrodes, such as iron, are so small in their inactive potential region, they can be completely eclipsed by the electrode reactions due to oxidizable or reducible trace impurities.

To study the effect of an impurity which is unremovable but still may alter electrode behavior, experiments were run in which chloride ion was deliberately added (as NaCl). Figure 9 shows the change in steady-state polarization behavior which the iron electrode underwent upon the addition of 0.2%  $\text{Cl}^-$  to 0.2M NaOH. The Fe electrode with this  $\text{Cl}^-$  addition was covered with a heavy dark brown corrosion film which formed during polarization. The open triangles represent anodic current, and the solid triangles represent cathodic currents. The leftmost broken line indicates the variation which occurred between cycles so that there is no clear hysteresis at potentials above 0.3v. For the decreasing potential sequence at potentials above 0.8v, the current density remains fairly constant, and the activation at  $-0.1$ v was not observed. Thus, there is a large hysteresis loop in which the current density for the increasing potential curve is more than an order of magnitude higher than it is for the decreasing potential curve.

As the potential decreased, the current went from anodic to cathodic at about  $-0.25$ v. When the potential was increased, the current went from cathodic to anodic at about  $-0.65$ v. This large difference in change-over potentials observed in the presence of  $\text{Cl}^-$  is in marked contrast to the purer systems (Fig.

Fig. 9. Effect of addition of 0.2% chloride ion on Fe potentiostatic polarization curves in 0.2M NaOH:  $\Delta$  anodic current, increasing potential;  $\nabla$  anodic current, decreasing potential;  $\blacktriangle$  cathodic current, increasing potential;  $\blacktriangledown$  cathodic current, decreasing potential.

2-5), where in any given system the change-over from anodic to cathodic currents and from cathodic to anodic occurred at essentially the same potential.

After the run the electrode remained at open circuit for about a week in the electrolyte while bubbling hydrogen through it. During this time the dark brown oxide film disappeared leaving a shiny but extensively pitted wire. The steady-state open-circuit potential in this hydrogen-saturated solution was  $-0.682\text{v}$ . In the absence of added chloride ion, the Fe wire electrode potential was at the equilibrium hydrogen potential of  $-0.78\text{v}$  (4).

On the increasing potential sequence shown in Fig. 9, the Fe electrode does undergo normal passive behavior, the potential of highest activity for iron corrosion being about  $-0.1\text{v}$ . An attempt was made to duplicate the results of Thomas and Nurse (5) shown in Fig. 3. Their data were taken 5 min after a change in potential. Using a similar technique of taking readings 5 min after a change in potential in the chloride containing NaOH, the results shown in Fig. 10 were obtained. Under these conditions passivity behavior similar to that found by Thomas and Nurse was observed.

It has been shown that the high-purity Fe/NaOH system very effectively oxidizes hydrogen (4). The potentiostatic polarization curve for this system is shown by the broken line in Fig. 11. The curve for the identical system to which 0.2%  $\text{Cl}^-$  was added is shown as a solid line. The variations of the increasing and decreasing potential data about this solid line are small, which is in sharp contrast to the large variations obtained in an inert helium atmosphere (Fig. 9). This indicates that the fraction of the current density in the  $\text{Cl}^-$  contaminated solution which represents corrosion is much less than the fraction that represents oxidation of hydrogen. In the high-purity system, the

current density is so high that it must be essentially all due to hydrogen oxidation.

Chloride contamination makes iron an extremely poor catalyst for the hydrogen oxidation reaction. First, the iron is no longer a reversible hydrogen electrode and even at very low current densities, the polarization potential required for hydrogen oxidation is over  $0.2\text{v}$  above the reversible hydrogen potential. Second, at comparable potentials the chloride-free NaOH oxidizes hydrogen about  $10^3$  times faster. In terms of fuel cell operation, which would be at low polarization potentials, the chloride-free system is infinitely better.

Another important consequence of the data shown in Fig. 11 is that the passivation (reversal of  $dE/d\log i$ ) of the hydrogen oxidation reaction which occurs in the pure NaOH at about  $-0.3\text{v}$  is essentially nonexistent in the chloride contaminated NaOH. This confirms the hypothesis (7) that passivation can be caused by a reduction in the active electrode area, but is primarily due to a poisoning of catalytically active sites which cause large changes in the heat of activation for the hydrogen oxidation reaction on the electrode surface. On an iron electrode in alkali solution, chloride ion and the resultant corrosion products induced by its presence so completely retard the hydrogen oxidation reaction that the catalytic properties of the electrode are virtually nonexistent and therefore further adsorption of anions at more noble potentials does not cause significant active area changes or passivation of the hydrogen oxidation reaction. In the chloride-free NaOH, the passivation of the hydrogen oxidation is rather small and is most likely primarily an effect of reduction in active electrode area due to anion adsorption (4).

## Conclusions

In the high-purity alkaline solutions used, iron does not significantly corrode or show passive behavior [defined (7) as a condition in which the net reaction rate decreases with an increase in potential] over a wide range of concentrations and potentials. Iron acts like an inert noble metal similar to platinum rather than as a "passivated" metal. Depending on potential the primary reactions are the oxidation or reduction of  $\text{OH}^-$  and water. This does not mean that the iron electrodes used do not have species other than iron atoms on their surfaces. The species on the surface of the iron have not been determined by us; however, Foley *et al.* (6) have found a  $\gamma\text{-Fe}_2\text{O}_3$ ,  $\text{Fe}_3\text{O}_4$  film on passive iron in alkaline solution. Hysteresis effects were observed on decreasing the potential sequence after high noble potentials were applied. This caused a reduction in  $\text{OH}^-$  oxidation rates which are likely caused by changes in the surface layers on the iron.

Iron in the high-purity, closed system is an excellent catalyst for the electrochemical oxidation of hydrogen, being appreciably superior to Pt (4). Chloride ion causes extensive iron corrosion, completely changes the potentiostatic polarization relation, and does show passive behavior. Chloride ion virtually destroys the catalytic properties of the Fe electrode for the hydrogen oxidation reaction.

The presence of reactable impurities was shown to change strongly the electrochemical behavior of iron in alkali solution. The high-purity, closed electrochemical system successfully eliminated the major effects of such impurities.

Even though there were some variations among the high-purity Fe-alkaline systems investigated, each system had approximately the same shape curves and the same low activity for both water oxidation or reduction except at extremes in anodic or cathodic potentials, respectively.

The variations in behavior for the various Fe/alkaline systems studied may be largely due to the unremovable impurities. Probably the most important of these would be halide ions. Such impurities as carbonate, silicate, sulfate, etc., which are unre-

movable may have caused minor differences in various runs. However, it is felt that the effects of the major anion,  $\text{OH}^-$ , would override those of other trace inert anions.

## Anodic Polarization of Austenitic Stainless Steels in Chloride Media

A. P. Bond\* and E. A. Lizlovs

Research Laboratory, Climax Molybdenum Company of Michigan, Ann Arbor, Michigan

### ABSTRACT

Potentiodynamic polarization experiments were performed in 0.1N hydrochloric acid and in 1N sodium chloride with austenitic alloys containing 18 to 20% Cr, 13 to 39% Ni, 0 to 5% Mo, and balance Fe. The pitting potentials varied consistently with alloy content and correlated well with the results of exposure tests in 0.33M ferric chloride. Increasing the molybdenum and nickel contents increased the resistance to pitting; however, decreasing the carbon and nitrogen contents also increased the resistance to pitting. Critical current densities for passivity decreased sharply at all nickel levels with increases in the molybdenum content.

One of the most important contributions of molybdenum alloying additions to stainless steels is the resulting increase in the resistance to pitting corrosion. Although this behavior has been known for a long time, very little quantitative information is available. Recent work on potentiodynamic determination of pitting potentials (1-6) suggests that this technique should be very useful in determining the relative pitting resistances of various alloys.

A study was undertaken to learn whether or not the concept of a pitting potential is valid and useful in characterizing the resistance to pitting corrosion of molybdenum-containing stainless steels. Once the utility of the technique was established the next step was to determine in detail how variations in molybdenum content affect the resistance of various stainless steels to pitting in environments containing chlorides. In achieving this goal, it seemed desirable to use stainless steels of widely differing nickel contents so that possible nickel-molybdenum interactions could be detected.

### Procedures

Two series of austenitic stainless steels, one containing about 13% nickel and the other 39% nickel, were induction-melted in an argon atmosphere and cast in air. Each series was prepared using the split heat technique. In this technique, the base composition is melted and part of the melt is cast into an ingot. To the balance of the melt, the required molybdenum addition is made and the next ingot is cast. This process is repeated until a series of the desired compositions is cast. By this procedure, the residual and impurity elements, which were intended to be in the range commonly present in commercial stainless steels, were held essentially constant within each series.

Three high-purity alloys were also prepared as separate heats by melting and casting in vacuum.

The compositions of all alloys produced for this investigation are shown in Table I.

The ingots were hot-forged and hot-rolled to a thickness of 0.76 cm and then cold-rolled to 0.38 cm. The 13% nickel steels were annealed at 1120°C for 1 hr and water-quenched. The 39% nickel steels and the high-purity alloys were annealed at 1150°C for 1 hr and water-quenched.

The electrodes for the potentiodynamic studies were mounted in acrylic plastic with a single exposed surface parallel to the rolling plane. Electrical contact was made by soft soldering a nickel wire to the back of the electrode. Soldering was accomplished quickly (about 5 sec) to minimize heat input, although no metallurgical changes would be expected even if the test surface of the electrode were heated to the melting point of the solder (190°C) for a few seconds. Contact between the solder or lead wire and the electrolyte

was excluded by the plastic and a glass tube. The exposed surface ( $0.5 \times 0.6$  cm) was polished using standard metallographic techniques, ending with the distilled water slurry of  $0.3\mu$  alumina. For the pitting potential measurements, the electrode was masked with electroplater's tape (Scotch 470) except for a circular area 0.3 cm in diameter.

The potentiodynamic scanning experiments were performed using standard equipment and techniques. The platinum auxiliary electrode was isolated from the test solution by means of a glass frit. The solutions used were argon-saturated 0.1N HCl and 1.0M NaCl. All potential measurements were made using a saturated calomel reference electrode. Work reported in the literature (3,4,6) indicates that pitting potentials measured on stainless steels are quite dependent on experimental procedure. To minimize the effects of the prior history of the electrodes, the potential scans were started with  $-0.7$ v in the active region. By scanning into the passive potential region, the passive film was formed *in situ* under reproducible conditions. Scanning rates in most tests were 600 mv/hr up to potentials of about 0.2-0.3v less noble than the expected pitting potential. At this potential, the scanning rate was decreased to 60 mv/hr. In a few tests, this procedure was varied to determine the effect of change in scanning rate on the observed pitting potential.

Exposure tests were performed in 0.33M  $\text{FeCl}_3$  dissolved in 0.01N HCl. This medium gave a chloride ion concentration equal to that in the 1.0M NaCl medium used in the polarization measurements. Test coupons,  $2.5 \times 3.8 \times 0.3$  cm, were suspended in the unstirred solution by means of a glass rod through a 0.64-cm hole in each specimen. In all experiments, the temperature was  $24^\circ \pm 1^\circ\text{C}$ .

## Results

**Measurements in 0.1N HCl.**—The initial anodic polarization measurements in 0.1N HCl disclosed that crevice corrosion occurred at the interface between the metal and the plastic mount. Masking the electrode surface with electroplaters tape usually eliminated this crevice corrosion. These effects are illustrated in Fig. 1. Microscopic examination of the electrodes after the runs depicted in Fig. 1 showed that neither electrode was pitted, confirming that the rise in current for the unmasked electrode starting at about 0.1v was due to crevice attack and the rise in current at potentials above 0.8 for the masked electrode was the start of the normal transpassive region.

Fig. 1. Polarization curves obtained on masked and unmasked electrodes for the 17.6% Cr-13.6% Ni-2.45% Mo austenitic stainless steel in argon-saturated 0.1N hydrochloric acid. The potential was scanned from negative toward positive. The arrows indicate the potential at which the scanning rate was decreased from 600 to 60 mv/hr.

Since crevice corrosion on the unmasked electrodes did not occur until potentials much more noble than the primary passivation potential were reached, unmasked electrodes were used to determine the critical current density and primary passivation potential. The unmasked electrodes also allowed more precise determination of electrode area than did the masked electrodes.

The critical current densities (maximum anodic current density reached in the active region) and primary passivation potentials (potential at which the critical current density is reached) measured are shown in Fig. 2 and 3 and Table II. Examination of the data for both series of austenitic alloys reveals that increases in molybdenum content decreased the critical current density for passivation. This behavior is especially evident in the steels containing 39% nickel and in the high-purity alloys because these alloys cover a wider range of molybdenum contents. Comparison of the data for the three series of alloys, at roughly the same molybdenum contents, shows that the critical currents are in the same range.

The changes in molybdenum content within the range studied in the 13.5% nickel alloys had no effect on the primary passivation potentials ( $E_{pp}$ ), which were close to  $-0.26$ v. No pronounced variation of passivation potential with molybdenum content was

found in the high-purity series. In the 39% nickel series, increasing molybdenum did shift  $E_{pp}$  slightly in the active direction. On the other hand, comparison of the 39% nickel series with the 13.5% nickel series suggests that increasing nickel content shifted  $E_{pp}$  in the noble direction.

Because of the interference of crevice corrosion at the interface between the metal and the plastic mount, these electrodes could not be used to obtain pitting potentials. Figure 4 shows a typical potentiodynamic scanning curve obtained on a masked electrode in 0.1N HCl for a metal susceptible to pitting corrosion. Note that the decrease in scanning rate at 0.1v leads to a sharp drop in the passive current measured. The pitting potential is taken as the potential at which the passive current rises sharply. Microscopic examination revealed that pits were visible after this sharp rise in current and were not present when the electrode was examined before the current rise. Crevice corrosion, in addition to the normal pitting corrosion, was frequently initiated under the tape mask after the onset of pitting. For this reason the magnitude of the corrosion current after the onset of pitting was not a reliable indicator of the degree of pitting corrosion. In a few tests, only crevice corrosion was observed, and no true pits appeared on the free electrode surface. The data from these tests were therefore rejected. No potential scan was continued more than 20 mv beyond the potential at which passivity broke down, even if the breakdown was due only to crevice corrosion.

Most alloys studied were quite resistant to pitting in 0.1N HCl (Table III). None of the high-purity alloys exhibited a pitting potential less noble than

Fig. 4. Polarization curve obtained for 17.6% Cr-13.6% Ni-1.99% Mo austenitic stainless steel in argon-saturated 0.1N hydrochloric acid. The scanning rate was 600 mv/hr from -0.3 to 0.1v; it was decreased to 60 mv/hr from 0.1v to the pitting potential.

<sup>b</sup> NP = no pitting up to 0.8v.

0.8v. Only the 39% nickel steel without molybdenum and the 13% nickel steel with 2% molybdenum displayed pitting potentials less noble than the transpassive range. Small increases in molybdenum content of the two susceptible alloys displaced the pitting potential beyond 0.8v. In addition, increasing the nickel content from 13.5 to 39% also increased the resistance to pitting corrosion.

*Measurements in 1M NaCl.*—An experimental program similar to that performed in 0.1N HCl was undertaken in 1.0M NaCl. The literature reports that increasing the chloride ion concentration increases the pitting susceptibility of stainless steels, but changing the pH from 1 to 7 does not affect pitting potentials (6). However, this increase in pH did suppress the critical current for passivity to such an extent that it could not be precisely measured on many of the steels tested. For this reason, the currents and potentials corresponding to the active-passive transition are not reported.

In contrast to the behavior observed in 0.1N HCl, in 1M NaCl many specimens showed current blips at potentials lower than those at which continuous pitting occurred. Microscopic examinations of electrodes on which momentary current increases had occurred showed some very small pits. Thus, these current blips appear to correspond to the initiation of a pit that then repassivates almost immediately. The pits thus formed are quite small and do not grow. A similar phenomenon has been described by Schwenk (2).

To check the significance of these current blips, some specimens were subjected to the usual potential scan until well-defined current pulses were obtained. At this point the scan was stopped, and the specimen was held at a constant potential while the current was recorded. The current pulses continued, becoming less frequent and smaller until they died away completely in a few hours. Holding electrodes at constant potentials, above those at which repassivating pits formed, for at least 24 hr did not cause a pit to propagate in any case. It is possible that these repassivating pits are associated with extremely small regions of considerable composition differences from the bulk composition and that after these regions are removed the pits are too small to propagate at the potential in question. Since this type of repassivating pit did not always occur on a given electrode and was never observed to lead to a propagating pit if the potential scan was stopped, the potential at which pits not only initiated, but continued to grow was taken as the most important pitting potential.

To determine the influence of scanning rate on these measurements, the 13.5% nickel steel containing 2.9% molybdenum was studied at various scanning rates in 1.0M NaCl. The results (Table IV) indicate that the pitting potentials tend to shift in the noble direction

Table IV. Pitting potentials obtained at various scanning rates on the 17.6% Cr-13.5% Ni-2.93% Mo alloy in 1.0M sodium chloride

Scanning rate, mv/hr	Repassivating pitting potential, v vs. SCE	Pitting potential, v vs. SCE
2000	0.29	0.43
600	0.32	0.47
600 from -0.7 to +0.3v then 60	0.29	0.525
600 from -0.7 to +0.3v then 20	0.31	0.495

as the scanning rate is decreased. The actual polarization curves obtained at the highest and lowest scanning rates (Fig. 5 and 6) indicate that scanning rate affects several aspects of the measurements. The higher scanning rate gives rise to a higher active anodic dissolution peak, which is shifted toward more noble potentials. As expected, the faster the scan, the higher the passive current. As the pitting potential is approached, the current blips corresponding to repassivating pits are much larger and more numerous at the faster scan. The potential at which the growth of stable pits begins is much more sharply defined at the lower scan rate and occurs at more noble potentials.

The results of the pitting potential measurements on the 13 and 39% nickel steels are shown in Fig. 7. The results obtained on the 13.5% nickel austenitic steels confirm that 1.0M NaCl is indeed a more severe pitting electrolyte than 0.1N HCl. It is also clear that increasing molybdenum content up to at least 3.5% improves pitting resistance of these alloys. However, at 3.9% molybdenum the pitting potential was tending toward lower values.

The anomalous behavior of the 3.9% molybdenum steel may be related to its microstructure. Delta ferrite is present in the alloys containing over 2.9% molybdenum, with the 3.9% molybdenum alloy containing an appreciable amount. It has been reported by others (7) that delta ferrite is detrimental to resistance to pitting corrosion. All the 39% nickel alloys were completely austenitic.

The results on the 39% nickel alloys were very similar to those obtained in 0.1N HCl, i.e., 1% molybdenum was sufficient to prevent stable pit growth at potentials below the transpassive region. Thus, even 1M NaCl is not a severe enough test medium to differentiate the behavior of the 1, 3, and 5% molybdenum alloys.

The behavior of the high-purity alloys in 1M NaCl was almost identical to that in 0.1N HCl. The molybdenum-free alloy showed a greater tendency toward pitting at potentials just below the onset of transpassivity (0.79v). The alloys containing 2.5 and 5% molybdenum were not pitted on scanning to 0.8v. Thus, the superior resistance of the high-purity alloys to pitting corrosion is even more evident in 1M NaCl than it was in 0.1N HCl.

The appearance of typical electrodes after exceeding the pitting potential is shown in Fig. 8.

Exposure tests in  $FeCl_3$ —Simple exposure tests were performed in 0.33M  $FeCl_3$  at pH 2. These results may be expected to be comparable with the pitting potential measurements in 1N NaCl despite the pH difference, since pH changes between 1 and 7 have little effect in NaCl solutions (6). The redox potential of this solution, as measured at a platinum electrode, was 0.540v vs. SCE. As can be seen from Table V, a rather sharp transition exists between compositions that undergo severe pitting corrosion and those that are highly resistant. These results agree quite well with the pitting potential data obtained in 1M NaCl, especially when account is taken of the fact that polarization effects would cause the potential at the local anodes of the corroding specimens to be somewhat less noble than that measured on the platinum electrode. It must be remembered that the pitting potential measurements were made on electrodes containing only the surface parallel to the rolling plane.

Fig. 5. Anodic polarization curves obtained on a masked electrode for the 17.6% Cr-13.6% Ni-2.93% Mo austenitic stainless steel in argon-saturated 1.0M sodium chloride. The scanning rate was 2000 mv/hr in the positive direction.

Fig. 6. Anodic polarization curves obtained on a masked electrode for the 17.6% Cr-13.6% Ni-2.93% Mo stainless steel in argon-saturated 1.0M sodium chloride. The scanning rate was 600 mv/hr up to 0.3v and thereafter, 20 mv/hr.

The appearance of typical electrodes after exceeding the pitting potential is shown in Fig. 8.

Fig. 7. Pitting potentials obtained from potentiodynamic polarization scans in argon-saturated 1.0M sodium chloride.

Fig. 8. Pits on representative electrodes after scanning beyond the pitting potential in argon-saturated 1M sodium chloride at 24°C, X100. (a) (top) 17.6% Cr-13.5% Ni-2.93% Mo stainless steel; (b) (bottom) 20% Cr-39% Ni stainless steel.

It is well-known that edges in stainless steels, *i.e.*, planes perpendicular to the rolling plane, are often more susceptible to pitting than is the rolling plane (2). Thus, the coupons that yielded only edge pitting in the exposure tests should be considered to correspond to no pitting up to a potential of about 0.5v in the controlled potential measurements.

### Discussion

These results show that the potentiodynamic scanning technique can give useful information about the relative pitting resistances of stainless steels. However, it is also clear that the details of experimental procedure must be carefully controlled. In particular, scanning rate was found to have a considerable influence on the results obtained. The avoidance of crevice corrosion was also found to be essential for obtaining any information on pitting potentials.

Table V. Results of exposure of austenitic steels to 0.33M ferric chloride at pH 2 for 3 days

Nominal Cr	Nominal composition, %		Weight loss in 3 days, mg/dm <sup>2</sup>	Remarks
	Ni	Mo		
17.6	13.5	1.99	703	General pitting
		2.45	828	General pitting
		2.93	173	Edge pitting
		3.37	77	One edge pit
		3.89	3	No visible attack
20	39	0.025	663	General pitting
		0.97	176	Pits at suspension hole
		3.03	40	Small edge pits
		4.85	8	No visible attack

The results of the effects of different scanning rates are at variance with results reported in the literature for molybdenum-free stainless steel (4,6). It has been reported that faster scans give more noble pitting potentials, but the opposite was found in this work on molybdenum-containing alloys. The observation made in the present studies can be rationalized by assuming that the passive film thickens with time, at a potential in the passive range. Thus the passive film would be thicker the slower the speed of scanning. As the film thickness increases, a larger fraction of the potential difference between metal and solution would be expected to occur within the film and thus not be available at the film-solution interface to assist in the entry of chloride ions into the film.

It has been found previously that for some stainless steel the passive film increases in stability, probably as a result of increasing thickness, as time at a given potential in the passive range increases (8). The effect was observed to be somewhat more pronounced for alloys with molybdenum than for those without molybdenum, perhaps indicating that passive film thickening is more important when molybdenum is present in the alloys. A similar effect was reported by Streicher (9), who found that passivation of type 316 after pickling and before undergoing a pitting test had a much larger beneficial effect than did a similar treatment of type 304. This reasoning is highly speculative, but may, at least in part, account for the contradiction between results from this work and those reported by others.

Even if absolute values of the pitting potential are open to question, it appears that relative pitting potentials provide useful information. In the two series of austenitic alloys investigated, increasing molybdenum content consistently increased the pitting potential except in the 13.5% nickel alloy of highest molybdenum content. Here the occurrence of ferrite as a second phase is promoted by higher molybdenum content and complicates the situation by introducing differences in composition, that is, the delta ferrite would be enriched in chromium and molybdenum and depleted in nickel (10). In all other steels, the beneficial effect of increasing molybdenum content on the pitting potential was clearly revealed even when the increments were as small as ½%. That these variations in pitting potential are significant was confirmed by the good correlation obtained with the results of exposure tests in FeCl<sub>3</sub>. Of course, since pitting potentials are dependent on test conditions and prior history of the specimen, agreement between pitting potentials and exposure results would only be expected when specimen treatment and exposure conditions were very similar in the two tests. Otherwise, only a relative correlation would be anticipated.

Pitting potential measurements clearly indicate the importance of minor constituents in these alloys. The high-purity alloys were much more resistant to pitting than were the alloys containing the usual levels of residual elements. The carbon and nitrogen contents are probably the most significant in this connection. Formation of chromium and molybdenum carbides and nitrides would deplete the matrix immediately surrounding the precipitates of chromium and molybdenum. Any depleted area would be more susceptible to pitting because of differences in composition; the discontinuities associated with an exposed particle of precipitate may also create favorable sites for initiation of pits. The work of Streicher (9) suggests that carbon is more effective than nitrogen in this regard. He found that large nitrogen additions reduced pitting. However, in some cases this was because the nitrogen addition produced a wholly austenitic steel and in no case did he study a steel with nitrogen as low as the high-purity steels considered in this work.

On the other hand, the high-purity alloys had about the same critical current densities for passivity as the impure steels of similar molybdenum content. It would be expected that small areas depleted in chromium

or molybdenum would make only a small contribution to the over-all current required to produce passivity.

The results of the critical current density and primary passivation potential determinations in 0.1N HCl agreed well with previous measurements in sulfuric acid on similar alloys, i.e., molybdenum decreases the critical current density required to produce passivity and to a lesser extent shifts the primary passivation potential to more active potentials (8). Nickel had little effect on critical current density, but did shift the primary passivation potential in the noble direction. Thus, molybdenum facilitates the attainment of the passive state for these alloys in 0.1N HCl, but nickel does not. These effects, however, are less significant than are the changes in pitting potential with alloy content as far as over-all corrosion behavior is concerned.

It should be kept in mind that even the most highly alloyed steels tested were not immune to crevice corrosion in chloride media even though their resistance to pitting was very high. Thus, crevice corrosion, although related to pitting, appears to be more difficult to avoid by means of alloy additions than is pitting.

### Conclusions

Potentiodynamic scanning in chloride electrolytes yields pitting potentials that vary consistently with alloy composition and that correlate well with exposure tests in FeCl<sub>3</sub> solution.

Resistance to pitting increases with increasing molybdenum content in 17.6% Cr—13.5% Ni or 20%

Cr—39% Ni austenitic stainless steels. Changes in molybdenum content as small as ½% have a significant effect on pitting potentials.

The pitting resistance of austenitic stainless steels increases when the nickel content is raised from 13.5 to 39%.

High-purity austenitic alloys are more resistant to pitting than are steels containing appreciable amounts of carbon and nitrogen.

## Polarographic and Coulometric Studies of Compounds Related to 1,8-Dinitronaphthalene

George M. LoPresti,<sup>1</sup> Suei-rong Huang, and Anthony A. Reidlinger\*

Chemistry Department, Long Island University,  
The Brooklyn Center, Zeckendorf Campus, Brooklyn, New York

### ABSTRACT

The polarographic reductions of 1,8-dinitronaphthalene, 5,6-dinitroacenaphthene, 3,4-dinitroacenaphthenequinone, and 4,5-dinitronaphthalic anhydride, were studied in buffered solutions at four different pH values. The relative wave heights of the multiple waves could be interpreted reasonably in terms of certain electron changes. A semi-empirical equation was derived to confirm certain electron changes in the polarographic reductions. These electron changes were also checked by coulometric measurements on electrolyses run at controlled potentials. Results indicated that in all but one instance there was agreement between the values for the electron changes obtained in the parallel analyses. The one exception was 3,4-dinitroacenaphthenequinone.

In general, the polarographic reduction of a polynitro aromatic compound proceeds in a stepwise manner, and the first step corresponds to a four-electron change. This has been interpreted as corresponding to the reduction of one of the nitro groups to an hydroxylamino group. In a study of the polarographic reductions of the ten dinitronaphthalenes (1), the 1,8-isomer was the only compound that did not exhibit this characteristic behavior. Instead it gave an initial wave that corresponded to either an eight or ten-electron change depending on the acidity of the solution. It was suggested that this might be due to the formation of the ring compound 1,8-naphthopyrazole.

Thus far large-scale electrolyses of 1,8-dinitronaphthalene at controlled potentials have not yielded a product identifiable as perinaphthopyrazole, but have instead yielded very high-melting, highly colored materials which appear to be polymeric.

Grimshaw and Rea (2) have recently reported that the electroreduction of 1-acetylnaphthalene did not yield the expected pinacol in base, but gave an unexpected product due to coupling in the 4-position.

In the present investigation several 4,5-disubstituted 1,8-dinitronaphthalenes were prepared, and their

polarographic behaviors determined in an attempt to elucidate the nature of the reduction process. Blocking the 4 and 5 positions would prevent coupling in these positions and might lead to the large-scale electrolytic preparation of the pyrazole ring system.<sup>2</sup>

### Experimental

**Nitro compounds.**—1,8-Dinitronaphthalene was prepared by the method of Hodgson and Walker (3), mp 172.0°–172.5° (lit. 172°). 5,6-Dinitroacenaphthene was prepared by the method of Sachs and Mosebach (4), mp 221°–224° (lit. 220°–224°). 3,4-Dinitroacenaphthenequinone was prepared by the method of Rowe and Davies (5), mp decomposes above 300° (lit. decomposes above 300°). 4,5-Dinitro-naphthalic anhydride was prepared by the oxidation of 5,6-dinitroacenaphthene, using the method of White and Elderfield (6), mp decomposes above 310° (lit. decomposes at 310°).

**Polarographic and coulometric procedure.**—The polarographic and constant-potential coulometric studies were carried out with the same equipment, in the same manner, and in the same buffers as described by Boyd *et al.* (7). A drop-time of mercury from the dropping electrode capillary was 4.0 sec, and the drop weight was 9.5 mg.

### Results

Polarographic data are given in Tables I and II.

#### Analysis of Data

The electrolytic reduction of an organic compound at the surface of a dropping mercury electrode is often an irreversible one. The chemical reaction can be written as

<sup>2</sup> Preliminary investigations have suggested that the product obtained from the coulometric analysis of 4,5-dinitroacenaphthene is the dihydro derivative of the pyrazole. However, because of the low solubility of the dinitro compound, complications arise in scaling-up the reaction. Reductions of the compound at lower acidities appear to be complicated by chemical reactions within the solutions. Similarly reductions of the other dinitro compounds are not simple. Work on the larger scale reductions is currently in progress and will be reported at a future date.

4,5-Dinitro-naphthalic-anhydride	2.1	-0.50	7.20	7
	6.4	-0.80	8.30	8

<sup>a</sup>  $E_r$  is the potential of the Cathode (vs. SCE) at which the reduction was carried out.

<sup>b</sup>  $n$  is the number of electrons involved in the reduction.

<sup>c</sup> Estimated to the nearest integral number of electrons from the wave heights of the polarographic curves.

<sup>d</sup> The difference between the coulometric  $n$  value and the polarographic  $n$  value is probably due to the fact that the macro reduction is complicated by reactions of nitro reduction intermediates with the carbonyl groups which are present.

where A is an organic compound, and B is the product. The rate constant  $k$  at a certain electrode potential  $E$ , and at 25°C, can be expressed as (8)

$$k = k_0 \exp(-2.303 \beta E n / 0.0591) \quad [2]$$

where  $E$  is the potential in volts referred to the normal hydrogen electrode;  $k_0$  is the value of  $k$  when  $E = 0$ ;  $n$  is the number of electrons transferred in Eq. [1]; and  $\beta$  is a parameter which is characteristic of the electrode reaction for given conditions of the electrolysis. The value of  $\beta$  ranges between 0 and 1 for many electrode reactions. The  $k$  value, according to the kinetic study of Eq. [1], depends on the height of energy barrier to be overcome by molecule, or ion A, and  $H^+$ . A schematic drawing of the reaction path is shown in Fig. 1. Therefore one can postulate a reaction

where  $M^+$  is the intermediate product at the height of potential energy-reaction path curve. The reaction rate  $k$  can also be expressed in another form

$$k = \frac{KT}{h} \cdot \left( \frac{f_{M^+}}{f_A \cdot f_{nH^+}} \right) \cdot \exp\left(\frac{-U}{RT}\right) \quad [4]$$

where  $K$  = Boltzmann's constant

$h$  = Plank's constant

$T$  = absolute temperature

$f$ 's = partition function for each component

$U$  = energy barrier to be overcome by reactants A and  $H^+$

Combining Eq. [2] and [4], one obtains

$$k_0 \exp(-2.303 \cdot \beta \cdot E n / 0.0591)$$

$$= \frac{KT}{h} \left( \frac{f_{M^+}}{f_A \cdot f_{nH^+}} \right) \exp\left(-\frac{U}{RT}\right) \quad [5]$$

Taking the natural logarithm on both sides of Eq. [5], rearranging and setting  $\beta$  equal to 1, gives

$$E = \alpha - 0.0591(pH) + \frac{1}{(n)23.06 \times 10^3} (\Delta E_0) \quad [6]$$

Fig. 1. Reaction path for the reaction  $A + nH^+ + ne^- \rightarrow B$

with

$$(H^+) \cong f_{H^+} \cdot \exp(-E_{H^+}^0/RT) \quad [7]$$

where

 $\alpha =$ 

$$\left\{ -\frac{0.0591}{(n)2.303} \ln \left[ \left( \frac{KT}{h} \right) \frac{f_{M^{\ddagger}}}{f_A} e^{-(nE_{H^+}^0/RT)} \right] + \frac{0.0591}{(n)2.303} \ln k_0 \right\} \quad [8]$$

$E_{H^+}^0 =$  ground state energy of  $H^+$  per mole and  $\Delta E_0 =$  difference in energy between reactant A and  $M^{\ddagger}$  per mole, and always is positive.

If the reactant A undergoes ring formation by the electrolytic reduction to form product B, then, as the first approximation, the following substitutions can be made;  $E$  is substituted by the half-wave potential,  $E_{1/2}$ , and  $\Delta E_0$  is replaced by the difference in resonance energies between molecules A and B,  $\Delta E_R$ . Equation [6] then yields

$$E_{1/2} = \alpha' - 0.0591 (pH) + \frac{1}{(n)23.06 \times 10^3} (\Delta E_R) \text{ volt} \quad [9]$$

where  $\alpha'$  is a constant related to  $\alpha$  but containing terms arising from the fact that an irreversible polarographic  $E_{1/2}$  depends on concentration polarization as well as the kinetics of electron transfer. The units for  $\Delta E_R$  are cal/mole. A similar attempt to relate half-wave potential to the resonance energy difference had been made by Hoijsink (9) and Evans (10).

For a particular set of values;  $E_{1/2}$ , pH, and  $\Delta E_R$ ,  $\alpha'$  can be evaluated. Similar aromatic compounds containing nitro groups yield a constant value for  $\alpha'$ . Furthermore, a particular aromatic compound, as previously mentioned, which can undergo several different polarographic reductions by the same intermediate path will also yield the same constant value for  $\alpha'$ .

### Discussion

The polarographic reductions of 1,8-dinitronaphthalene at the surface of dropping mercury electrode are assumed to be

Values of  $\alpha'$  for given sets of  $E_{1/2}$ ,  $n$ , pH, and  $\Delta E_R$  have been calculated and are listed in Table III.

Similarly, the polarographic reductions of 5,6-dinitroacenaphthene are proposed as follows

Table III. Polarographic reduction of 1,8-dinitronaphthalene<sup>a</sup>

$E_{1/2}$	$n$	pH	$\Delta E_R$	$\alpha'$	Type of reaction
-0.28	10	2.1	48.3	-0.365	[11]
-0.50	8	6.4	43.7	-0.359	[10]
-0.65	8	9.3	43.7	-0.337	[10]
-0.77	8	11.0	43.7	-0.357	[10]

<sup>a</sup> The values of  $E_{1/2}$  are in volts vs. saturated calomel electrode.  $n$  is the number of electrons involved in the reduction. The values of  $\Delta E_R$  are in kcal/mole. The resonance energy has been obtained from the molecular orbital calculations. The values of  $\alpha'$  are in volts.

Some values of  $\alpha'$  have been computed and listed in Table IV. The numerical values of  $\alpha'$  for the reduction of 5,6-dinitroacenaphthene are close to those of 1,8-dinitronaphthalene. This indicates that both compounds undergo the same types of reductions as shown in Eq. [10] through [15]. The average value for  $\alpha'$  is  $-0.36 \pm 0.02$ v. Substituting the average value for  $\alpha'$ , the half-wave potential for the reduction of 1,8-dinitronaphthalene and 5,6-dinitroacenaphthene can be expressed semiempirically by Eq. [9].

$$E_{1/2} = -0.36 - 0.0591 (pH) + \frac{\Delta E_R}{(n)23.06 \times 10^3} \quad [9']$$

Polarographic reductions of more complex aromatic compounds containing nitro groups, such as 3,4-dinitroacenaphthenequinone and 4,5-dinitronaphthalic anhydride, also lend themselves to the same analysis. The polarographic reductions are shown in the following equations

Using Eq. [9], values of  $\alpha'$  have been calculated for reactions [16] through [18] and are  $-0.32$ ,  $-0.29$ , and  $-0.31$ , respectively.

It may be seen from the preceding discussion that these calculated  $\alpha'$  values exhibit some deviations from a constant value of  $-0.36$ . Two possible explanations for this deviation are suggested. First, several different intermediate paths may exist for a given polarographic reduction. Second, any delocalization of  $\pi$  electrons in the  $O=C-C=O$  skeleton has not been

taken into account in the calculation of the resonance

Table IV. Polarographic reduction of 5,6-dinitroacenaphthene<sup>a</sup>

$E_{1/2}$	$n$	pH	$\Delta E_R$	$\alpha'$	Type of reaction
-0.26	10	2.1	48.3	-0.345	(14)
-0.48	10	6.4	48.3	-0.321	(14)
-0.70	8	9.3	43.7	-0.388	(13)
-0.79	8	11.0	43.7	-0.377	(13)
-0.52	12	2.1	0.000	-0.396	(15)

<sup>a</sup> See footnote a, Table III.

energy. Evans (10) has shown that this delocalization effect is small but not negligible.

The values obtained from the polarographic reductions of 4,5-dinitronaphthalic anhydride in nearly neutral solutions indicate that the reduction process is similar to that of the other compounds.

The  $\alpha'$  value for the reaction indicated in [19] is  $-0.33\text{v}$ . The reductions in acid are probably influenced by interaction of the anhydride with the acid while at higher pH values interaction of the anhydride with the nucleophiles present in solution is likely.

#### Acknowledgment

The authors wish to thank Dr. Stewart Karp for his many helpful and enlightening discussions.

## Thermodynamic Properties of Bismuth Trifluoride

Daniel Cubicciotti\*

Stanford Research Institute, Menlo Park, California

#### ABSTRACT

Thermodynamic properties were determined for bismuth trifluoride that had been dried by heating in a stream of hydrogen fluoride. The melting point was found to be  $649^\circ\text{C}$ . The thermodynamic functions of the gaseous molecule were calculated from estimates of the molecular geometry and vibration frequencies. Heat capacities were measured for the solid and liquid, and the heat (5.16 kcal) and entropy of fusion (5.6 eu) were obtained.

The vapor pressure over the solid was measured by a transpiration method. The vapor pressure of  $\text{BiF}_3$  over the solid is given by

$$\log p(\text{mm}) = -\frac{9753}{T} + 11.72$$

An equation for the vapor pressure over the liquid was derived and the boiling point calculated to be  $900^\circ\text{C}$ . The enthalpy of sublimation (48.1 kcal/mole) and the entropy of sublimation (46.6 eu) at  $298^\circ\text{K}$  were derived from the vapor pressures.

The enthalpy of formation of bismuth trifluoride ( $-215$  kcal/mole) was determined by solution calorimetry. The enthalpy of atomization of bismuth trifluoride gas (273 kcal/mole) was calculated from the enthalpy of formation. The derived bismuth-fluorine bond energy is compared with those of the other group VA halides.

There is little information in the literature about the properties of bismuth trifluoride ( $\text{BiF}_3$ ). It can be precipitated from aqueous solutions and is apparently stable in air at room temperature; however, at elevated temperatures it is hydrolyzed by moisture in the air with the formation of oxyfluorides and oxide. Even at  $200^\circ\text{--}300^\circ\text{C}$ , a sample in air will lose weight, presumably by hydrolysis. Therefore, a pure sample cannot readily be obtained by drying in air. This hydrolysis is probably the reason for some erroneous reports in the literature. [For example, a transition at  $220^\circ\text{C}$  has been reported (1), based on a change in x-ray structure after prolonged heating in air. Since no thermal arrests were observed by us when the solid was heated in a sealed platinum capsule, the structural change observed in air may have been due to the formation of oxyfluoride during heating. The melting point given in the literature (2) is about  $120^\circ\text{C}$  higher than the value reported below, and the difference may be as-

cribed to oxygen in the sample.] The crystal structure (3, 4) is like that of yttrium trifluoride, and therefore is more ionic than the other halides of bismuth. The melting and boiling points, as well as other properties reported below, are in keeping with its ionic nature.

#### Experimental Methods and Results

*Preparation and analysis.*—The bismuth trifluoride used in this work was made by precipitation from a solution of Baker and Adamson reagent-grade bismuth oxide in nitric acid with hydrofluoric acid in Teflon ware. Samples were analyzed for bismuth gravimetrically as bismuth phosphate by the method given by Hillebrand *et al.* (5) except that a prior treatment was made to remove fluorine from the solution. About 0.1g boric acid was added, and the sample was taken twice to dryness. Material that had been dried in air for several hours at  $200^\circ$  to  $300^\circ\text{C}$  gave analyses for bismuth from 78.7 to 78.9%. A batch heated in air at  $500^\circ\text{C}$  for several hours showed 85.4% Bi. The calcu-

\* Electrochemical Society Active Member.

lated value for BiF<sub>3</sub> is 78.57% Bi. Samples with higher bismuth content were presumed to contain oxygen as the oxide or oxyfluoride. (Theoretical for Bi<sub>2</sub>O<sub>3</sub> is 89.7% and for BiOF is 85.7% Bi.) Therefore, heating in air converts the sample to oxide, as already observed by Aurivillius (6).

As a means of purification from oxide, one sample was distilled in a platinum retort in a stream of nitrogen. The distillation proceeded at a reasonable rate above about 850°C. Analysis of the distillate showed 78.57 ± 0.05% Bi in good agreement with the theoretical percentage for BiF<sub>3</sub>. Since the distillation procedure was slow, another purification treatment was tried. A sample of air-dried BiF<sub>3</sub> was heated in a stream of dry hydrogen fluoride in a platinum container for about 2 hr at 500°C. Four analyses of the product gave 78.59 ± 0.05% bismuth. This material was used for all the studies reported below. It was a fine, grayish powder.

**Melting point.**—The melting point was determined by a cooling curve method. A 12g sample of BiF<sub>3</sub> was placed in a cp platinum tube (3/8 in. OD x 5 mil wall x 3 in. long) whose ends were crimped-closed and platinum-soldered. A Pt-10% Rh thermocouple was wired tightly to the outside of the middle of the tube. The thermocouple had been checked against an NBS calibrated couple as well as against the melting point of sodium chloride from a cooling curve in a similar platinum container. The thermocouple was within 0.3°C of standard tables (6) in the range of 600°-800°C and within 0.5°C of the melting point (7) of sodium chloride (800°C). The cooling curves showed a melting break at 649° ± 2°C. After several cooling curves had been run, the platinum container was found to be brittle. Analysis gave 78.74% Bi, indicating no serious change in the salt.

Von Wartenberg (2) reports a melting point of from 725° to 730°C observed on a sample in a platinum boat in a stream of hydrogen fluoride. Unfortunately, an analysis of the sample was not given. It is possible that the values are high because of oxide in the sample. It is also possible that the thermometer, which was not described, was in error because of attack by the hydrogen fluoride stream.

The results of Darnell and McCollum (8) on the melting point at high pressures, extrapolated to one atmosphere, indicate a value of about 760°C. However, these authors used a boron nitride container. We have found that when BiF<sub>3</sub> is melted in boron nitride in an atmosphere of N<sub>2</sub>, it turns black and corrodes the container. This corrosion is in accord with the fact that the reaction

has a zero enthalpy change at room temperature (9) and a large positive standard entropy change and therefore a negative standard free energy change at elevated temperatures.

**Thermodynamic functions for BiF<sub>3</sub> gas.**—The molecular geometry and vibration frequencies for BiF<sub>3</sub> have not been determined; however, sufficient information on related molecules is available so that the molecular constants can be estimated reliably enough for the purpose of calculating thermodynamic properties. The geometries of the molecules PF<sub>3</sub>, PCl<sub>3</sub>, AsF<sub>3</sub>, AsCl<sub>3</sub>, and BiCl<sub>3</sub> have been reported (10). These are all pyramidal molecules with halogen-M-halogen angles of about 100°; therefore, that angle was assumed to be 100° in the BiF<sub>3</sub> molecule as well. The internuclear distance was assumed to be 2.0Å, i.e., 0.48 smaller than that in BiCl<sub>3</sub> because the internuclear distance in AsF<sub>3</sub> is 0.45 smaller than in AsCl<sub>3</sub>. The vibration frequencies of this type of molecule have been reviewed by Manley and Williams (11). For the fundamental frequencies, the ratio of the value for AsF<sub>3</sub> to that for AsCl<sub>3</sub> is 1.75; therefore, for the present calculation the four fundamental vibration frequencies of BiF<sub>3</sub> were assumed to

be 1.75 times the values observed for BiCl<sub>3</sub>. The vibration frequencies used were: 505, 230, 425, and 175 cm<sup>-1</sup>, the last two being doubly degenerate. Electronic contributions to the entropy were assumed to be negligible. The thermodynamic functions calculated from these estimated molecular constants are given in Table I.

**Thermodynamic functions for the condensed phases.**—Enthalpy measurements above 298° to about 1000°K were measured in a drop calorimeter by the same method as described earlier (12, 13). The sample of about 10g of BiF<sub>3</sub> was placed in a platinum test tube and the end sealed by crimping and platinum soldering. Two different samples were used, and the results were in a good agreement. After the measurements were made, it was found that the platinum container was brittle and cracked open easily. Analysis of one of the BiF<sub>3</sub> samples which had been melted in the platinum container gave 78.74% Bi, indicating little change in the sample.

The observed data are given in Table II, expressed per mole of BiF<sub>3</sub> (266 g/mole). The data for the solid were fitted by a least squares method to a polynomial in powers of temperature ( $T$ ). The resultant analytical expression for the enthalpy increments ( $H_T - H_{298}$ ) is

$$(H_T - H_{298}) \pm 0.09 \text{ kcal/mole (solid BiF}_3) = \\ -6.72 + 2.499 \times 10^{-2}T - 1.192 \times 10^{-5}T^2 \\ + 1.438 \times 10^{-8}T^3. \quad [2]$$

The deviations of the experimentally observed points from this expression are also given in Table II. The standard deviation for all the points was ± 90 cal/mole. For the liquid, enthalpy increments were ob-

tained only over a 60° range, and since the results seemed linear in temperature, they were fitted to a linear expression by least squares. The result is

$$(H_T - H_{298}) \pm 0.07 \text{ kcal/mole (liquid BiF}_3) = -18.05 + 4.412 \times 10^{-2} T \quad [3]$$

The deviations of the experimental data from the equation are also given in Table II. The standard deviation was 70 cal/mole.

The enthalpy of fusion derived from the difference of the two analytical expressions at 922°K is  $5.16 \pm 0.15$  kcal/mole. This leads to an entropy of fusion of  $5.60 \pm 0.2$  entropy units. This value is substantially smaller than those of the other bismuth halides [BiCl<sub>3</sub>, 11.3 eu (14); BiBr<sub>3</sub>, 10.1 eu (15); BiI<sub>3</sub>, 13.7 eu (16)]. There is not much information on entropies of fusion available for comparison; however, for the calcium halides, the entropy of fusion (17) of the fluoride is substantially smaller than those of the chloride or bromide; barium fluoride (17) also has a substantially smaller entropy of fusion than its bromide or iodide. On the other hand, that of arsenious fluoride is about the same as its chloride or bromide. The melting points of these arsenious halides are below room temperature and indicate, together with their crystal structures (3), that they are molecular substances. The melting points and crystal structures of the bismuth halides indicate they are more ionic and should therefore behave more like the calcium and barium halides.

From the analytical expressions given above, enthalpy increments were calculated at even temperatures and at the melting point. Entropy increments were calculated from the derived heat capacity expressions and the heat of fusion. Free-energy function increments were also obtained. The results are compiled in Table III.

**Vapor pressures.**—The vapor pressure of BiF<sub>3</sub> was determined by the transpiration method with N<sub>2</sub> as carrier gas described in earlier reports from this laboratory (18). The cell and sample collectors were made of cp platinum. A first set of determinations was made on BiF<sub>3</sub> that had been heated in air to dry it. Analysis of that material showed 79.2% Bi, indicating that there was some oxide impurity. After it was apparent that BiF<sub>3</sub> was converted to an oxyfluoride during heating in air, a sample was prepared as described above by heating in a hydrogen fluoride stream.

Vapor pressures were measured for both samples over a temperature range for the solid. The data obtained for the two samples are shown in Fig. 1. The sample containing oxide shows a lower vapor pressure with a somewhat larger enthalpy of vaporization. If it is assumed that the vapor species are the same (BiF<sub>3</sub>) in both cases, the lower vapor pressures of the oxide-containing sample are in accord with a lower activity of BiF<sub>3</sub> and the larger enthalpy of vaporization implies that there is a (small) enthalpy solution of solid BiF<sub>3</sub> in the oxide-containing sample. The line drawn through the upper set of points represents the

Fig. 1. Vapor pressure of bismuth trifluoride: upper curve, "pure BiF<sub>3</sub>"; lower curve, BiF<sub>3</sub> containing oxide.

vapor pressure of the sample considered to be pure BiF<sub>3</sub>. The experimental results are given in Table IV. The equation for the line drawn through these points is

$$\log_{10} p (\text{mm, for solid BiF}_3) = -\frac{9,753}{T} + 11.72 \quad [4]$$

To obtain the best value for the enthalpy of sublimation, a sigma plot treatment of the data was made. The method used has been described earlier (19). The free-energy function increment data used were those given in Tables II and III. A least squares treatment of the experimental data for the sample of pure BiF<sub>3</sub> gave  $\Delta H^\circ$  (sublimation, 298°K) =  $48.1 \pm 0.6$  kcal/mole and  $\Delta S^\circ$  (sublimation, 298°K) =  $46.6 \pm 0.8$  eu.

An equation for the vapor pressure of the liquid can be derived from the enthalpy of sublimation; the vapor pressure at the melting point ( $1.8 \times 10^{-2}$  atm, as calculated from Eq. [4]) and the thermal data for the gas and the liquid are given in Tables I and III. The resulting equation for the vapor pressure over the liquid is

$$\log_{10} p \text{ atm} = \frac{-13,102}{T} - 12.3 \log T + 48.928 \quad [5]$$

The boiling point of the liquid calculated from Eq. [5] is  $1173^\circ \pm 10^\circ \text{K}$ .

A mass spectrometer examination was made of the vapors evolved from a sample of BiF<sub>3</sub>. A small platinum Knudsen cell was used to contain the sample. The geometry of the system was such that a part of the gas emitted by the cell drifted directly into the ionization

chamber of the mass spectrometer. The mass spectrometer was an Aero Vac Model 610-611 (Aero Vac Corporation, Troy, New York), which is a magnetic deflection type with an electron multiplier detector. The magnetic field applied during these experiments was great enough that mass numbers as large as 800 would be detectable. The ion fragments observed attributable to BiF<sub>3</sub> were BiF<sub>3</sub><sup>+</sup>, BiF<sub>2</sub><sup>+</sup>, BiF<sup>+</sup>, and Bi<sup>+</sup>, with relative intensities of approximately 2, 10, 1, and 5, respectively. No masses greater than 266 (BiF<sub>3</sub><sup>+</sup>) were observed. The vapors were examined over a range of cell temperatures from about 475° to 575°C. It was concluded that the only vapor species was BiF<sub>3</sub>, and no polymers were formed. Thus, the molecular weight of the gas observed in the transpiration experiments was taken to be 266.

The absolute entropy of gaseous BiF<sub>3</sub> at 298°K calculated from the estimated molecular constant data discussed above is 75.92 eu. Therefore, the absolute entropy of the solid at 298°K, obtained from the sublimation entropy, is 29.3 ± 1 eu. This is substantially in agreement with the value one would estimate by applying Latimer's rules (20), namely 28 eu. With this value for the absolute entropy for the solid, the free-energy functions and entropies can be evaluated as functions of temperature. These values are given in the last two columns of Table III.

**Enthalpy of Formation of BiF<sub>3</sub>.**—The enthalpy of formation of BiF<sub>3</sub> was determined by solution calorimetry in the same solvent used earlier in this laboratory (21, 22). The scheme of measurement involved determination of the individual enthalpies of solution of the following substances; BiF<sub>3</sub>, KF·2H<sub>2</sub>O (Baker and Adamson reagent grade) and KBr (Mallinckrodt, analytical reagent) plus the enthalpies of solution of Bi and Br<sub>2</sub> already reported. The results obtained and their standard error are given in the last column of Table V. The measurements were all made at solution temperatures of 295° ± 2°K. Because the precision of the results is only about 1%, it is presumed that they are the same as 298°K values within experimental error. Proper algebraic addition of the reactions and enthalpies of Table V results in the reaction

Table V. Enthalpies of Solution

Reaction	Sample weights, g	No. of determinations	ΔH <sub>298</sub> , kcal/mole
(Solvent = 200 cc 2N HBr + 2.0 cc Br <sub>2</sub> )			
BiF <sub>3</sub> (s) + solvent = Bi <sup>3+</sup> + 3F <sup>-</sup> (in solution)	0.5	4	- 3.90 ± 0.04
KF·2H <sub>2</sub> O + solvent = K <sup>+</sup> + F <sup>-</sup> + 2H <sub>2</sub> O (in solution)	0.5	4	+ 3.86 ± 0.04
KF·2H <sub>2</sub> O + solvent (containing 0.4g Bi <sub>2</sub> O <sub>3</sub> ) = K <sup>+</sup> + F <sup>-</sup> + 2H <sub>2</sub> O (in solution)	0.5	4	+ 3.88 ± 0.02
KBr + solvent = K <sup>+</sup> + Br <sup>-</sup> (in solution)	0.6	3	+ 4.63 ± 0.03
Bi(s) + 3/2 Br <sub>2</sub> (in solvent) = Bi <sup>3+</sup> + 3Br <sup>-</sup> (in solution)	}	[ref. (21) and (22)]	-72.6 ± 0.3
Br <sub>2</sub> (l) + solvent = Br <sub>2</sub> (in solution)			- 2.79 ± 0.02

with an enthalpy change of ΔH<sub>298</sub> = + 75.2 ± 0.6 kcal. This value can be combined with the following enthalpies of formation in kcal/mole given in Circular 500: KBr(s) (-93.73), H<sub>2</sub>O(-68.32), KF·2H<sub>2</sub>O (-277.0). The enthalpy of formation at 298°K of solid BiF<sub>3</sub> so derived is -215.1 kcal/mole. An uncertainty of about ±3 would give a reasonable estimate of the reliability of the result. This value is in essential agreement with the value of -212.0 ± 10 derived by Kubaschewski et al. (17) from the results of Jellinek (23).

## Discussion

**Bond energies.**—The information reported above can be used to evaluate the enthalpy of atomization of gaseous BiF<sub>3</sub>. This calculation is given in Table VI. The bond energy of a trihalide can be taken to be one third of the enthalpy of atomization of the gaseous trihalides at 298°K (26). The bond energies of most of the group VA trihalides can be evaluated from data now available. The values are given in Table VII.

There seems to be some regularities in the values, especially for the chlorides and bromides and iodides. The differences are about 2 to 3, - 1 to 2, and 5 to 7 for P - As, As - Sb, and Sb - Bi, respectively.

The bond energies of the fluorides from phosphorus to bismuth show a steady relatively large (26 kcal) drop as compared to the other halides which show a small drop (8-10 kcal) with a small alternation of values at antimony. This difference in the behavior of the fluorides from the other halides may be due to a smaller degree of binding of the d orbitals on the group V element with the lone pair electrons on fluorine as compared with the other halogens.

The ratio of the enthalpy of vaporization to the bond energy of a substance is a measure of the relative strengths of intermolecular and intramolecular binding. Small values of the ratio are indicative of small intermolecular energies compared to bond energies and arise from "molecular" substances, while large values are expected for "ionic" and "giant molecule" compounds. Values of this ratio for the group VA trihalides are given in Table VIII. There is a distinct trend in the values that increase with atomic weight

Table VI. Atomization enthalpy of BiF<sub>3</sub>

Reaction	ΔH <sub>298</sub> (kcal/mole)
Bi(s) + 3/2 F <sub>2</sub> (g) = BiF <sub>3</sub> (s)	-215.1 ± 3
Bi(s) = Bi(g)	49.5(24)
1/2 F <sub>2</sub> (g) = F(g)	18.9 ± 1(25)
BiF <sub>3</sub> (s) = BiF <sub>3</sub> (g)	48.1 ± 0.6
BiF <sub>3</sub> (g) = Bi(g) + 3 F(g)	273.2 ± 5

Table VII. Bond energies of group VA trihalides\*

	(1/3 enthalpy of atomization, in kcal at 298°K, of gaseous trihalide)				
	N	P	As	Sb	Bi
F	66.8	120.5	116.0	(107)**	91.1
Cl	(46)**	77.0	73.8	75	66.7
Br	—	62.8	61	62.9	55.9
I	—	(50)**	47.0**	47.6**	42.3

\* Enthalpies of formation of gaseous trihalides were taken from ref. (27), except values in parentheses, bismuth values, and for NF<sub>3</sub> from ref. (28) and PF<sub>3</sub> from ref. (29).

\*\* The enthalpy of formation of the solid or liquid was obtained from ref. (27), and the enthalpy of vaporization of sublimation was: for NCl<sub>3</sub>—estimated; for PI<sub>3</sub> and SbF<sub>3</sub>, ref. (30), AsI<sub>3</sub>, ref. (31), and SbI<sub>3</sub>, ref. (16) and (33). The enthalpies of atomization of the bismuth trihalides have been evaluated in ref. (32), (21), and (22), respectively, for the chloride, bromide, and iodide. The enthalpies of formation of all the monatomic gases except P were taken from ref. (27), the value for P from NBS Circular 500.

Note: The values in parentheses all involve an estimate in the enthalpy of sublimation and so have an uncertainty of about 2 kcal. The uncertainty in the other values is less than 1 kcal. The values for phosphorus compounds all include the enthalpy of formation of atomic P (75 kcal), which may be subject to revision.

Table VIII. Ratio of enthalpy of vaporization at the boiling point to bond energy (at 298°K) for group VA trihalides\*

	F	Cl	Br	I
P	(0.03)	0.09	0.15 <sup>1</sup>	0.21
As	0.061	0.068	0.12 <sup>1</sup>	0.22
Sb	---	0.14	0.23	0.36
Bi	0.34	0.26	0.34	0.43

\* Data from ref. (17), except PF<sub>3</sub> for which the enthalpy of vaporization was estimated from the boiling point (172°K), and the bismuth halides for which the enthalpies of vaporization were taken from earlier work in this laboratory.

of either the central atom or the halogen, with the exception of BiF<sub>3</sub>. To the left and above the dashed line in Table VIII, the compounds in the condensed states are molecular (3). The iodides all have layer lattices. The values of this ratio for the bismuth halides are relatively large and comparable to those found in the alkali halides. (Lithium halide values are: 0.38, 0.32, 0.35, and 0.49 for F, Cl, Br, and I; while sodium values are 0.47, 0.42, 0.44, and 0.53.) The ionic nature (3) of crystalline BiF<sub>3</sub> is in keeping with the relatively large value of this ratio, as well as other properties, including its crystal structure, lattice energy, and high melting point. In contrast, crystalline SbF<sub>3</sub> has a molecular structure. It would be valuable to have information on its vaporization properties to evaluate the energy ratio for comparison with bismuth fluoride.

**Electronegativity of bismuth.**—Allred (34) has considered the electronegativities of the elements as derived from thermochemical data as well as other methods. He points out that the value for bismuth has been based on only one measurement, namely, the enthalpy of formation of BiCl<sub>3</sub>. The enthalpies of formation of the other trihalides are now available and can be combined with Allred's values for the average electronegativities of the halogens [ref. (34), Table III] via Allred's Eq. 2 and 3 to yield electronegativities for bismuth of: 2.22, 2.02, 1.99, and 1.94 from the fluoride, chloride, bromide, and iodide, respectively. Corresponding values for antimony are 2.22, 2.01, 2.00, and 2.02. Values from the fluoride, chloride, and bromide for antimony are within 0.01 unit of the respective bismuth values.

Allred and Hensley (35) have considered the electronegativity differences for antimony and bismuth on several scales based on various properties and concluded that the value for bismuth should be larger than that for antimony. This conclusion seemed to be based mainly on NMR proton resonance of the protons on trimethyl bismuth and antimony in dilute solutions in 2,2 dimethyl propane. (However, the relatively large concentration effect that they observed with bismuth and antimony compared to nitrogen, phosphorus, and antimony implies that the chemical shift of the proton resonance depends on solution effects, and these effects may not be eliminated by extrapolation to infinite dilution.) Because the electronegativities of antimony and bismuth derived from the thermochemistry of their halides are now known to be the same, the NMR evidence indicating them to be different should be reexamined.

The equality of the thermochemical electronegativities of antimony and bismuth indicates that their bond energies with a given other element differ by the same amount from their bond energies in the elemental crystal. (Ideally, electronegativities are based on the single bond energies which are not known for these elements; therefore, the electronegativities are based on the bond energies in the crystalline elements.) The energies of the bonds of antimony and bismuth with another element are quite different, as indicated in Table VII. Not only do the bond energies of antimony and bismuth differ for a given halogen, but the difference for the fluoride is substantially larger than

for the other halides. The variation with halogen is compensated for by a difference in the enthalpies of sublimation, so that the electronegativities derived from enthalpies of formation of the solids do not show a variation.

### Acknowledgment

The author is indebted to Dr. H. Eding, who obtained the enthalpy increment data; to Mr. W. E. Robbins, who made many of the experimental measurements; and to Dr. Ward N. Hubbard of Argonne National Laboratory, for information on heats of formation.

This work was made possible by the support of the Research Division, U. S. Atomic Energy Commission, under Contract No. AT(04-3)-106.

Manuscript submitted April 29, 1968; revised manuscript received ca. July 8, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## EMF Measurements on Dilute Solutions of Tin in Mercury with a Structural Interpretation of the Calculated Activities

Guy R. B. Elliott\*

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

### ABSTRACT

Emf measurements with H-cells of the type

were made with high precision for compositions from 0.001 to 0.128 mole fraction of tin at 520° to 570°K. The results show a constant change of emf with temperature for any one composition, but the constants relating change of emf to change of temperature are different at different compositions. The interrelationships of the constants suggests a structural interpretation as follows: For the most dilute solutions, the tin atoms randomly occupy any atomic positions in the solution, and Henry's law is followed closely. As the concentration is increased (*e.g.*, above 0.01 mole fraction Sn for 525°K) the Sn loses a third of its entropy of mixing, quite possibly by moving into sheets within which the tin atom positions are two dimensionally random.

As a continuation of experimental tests of solution and thermodynamic theory (1-11) the system Hg-Sn with tin as the solute was measured by EMF using a technique similar to that used with tin as the solvent (5, 12).<sup>1</sup>

### Experimental Procedures

**Material purification.**—Water was removed from reagent grade SnCl<sub>2</sub> · 2H<sub>2</sub>O by fusion under rough vacuum. Three distillations under vacuum (0.01-0.1 μ beyond the cold trap), *in situ*, with each side arm plus tailings sealed off and removed after each step, served to purify the SnCl<sub>2</sub>. The first distillation removed oxides, the second (after boiling with tin) removed hydroxides and reactive halides, and the third was for safety. (In Fig. 1 the side arms are not drawn full size and the first arm has been removed.)

Reagent grade tin was melted under vacuum and washed by boiling with SnCl<sub>2</sub> to remove reactive materials, then cast into rods which were flamed to bring any trapped electrolyte to the surface. The cold Pyrex was broken off, and the tin was washed with water. These smooth and shining rods were cut up with clean diagonal cutters, examined by microscope for possible iron pickup (none found), weighed, and loaded into the argon-filled arms of the H-cell.

Triple distilled mercury, boiled under vacuum, was scavenged of oxide and electrochemically important impurities by boiling under an argon atmosphere with molten SnCl<sub>2</sub>. After cooling, the last SnCl<sub>2(s)</sub> scum was removed by pressure filtration through a glass frit. This mercury (container weighed before and after) was poured through a long funnel into the legs of the argon-filled H-cell.

Argon was cleaned by condensing it in an N<sub>2(l)</sub> cold trap, boiling it gently to flush out volatiles, then warming the trap gently by lowering the Dewar until

enough argon had vaporized. The tungsten electrodes were made clean and shiny by electrolysis (0-15 VAC) in concentrated NaOH, then water wash, and drying by touching a tissue. Each cell, used only once and clean from annealing, was outgassed and filled with argon before the chemicals were added.

**Furnace and measuring equipment.**—These have been described elsewhere (5). The only change was the use of a new proportional temperature controller designed by Rexroth and Pacheco of this laboratory (report in preparation).

Fig. 1. Stirred H cell. Tubes drawn oversize below standard taper joints. Evacuation holes are only into stirrers.

\* Electrochemical Society Active Member.

<sup>1</sup>In Ref. 5 an error in the Dundee plot in Fig. 4 should be corrected. At 0.094 mole fraction of gold, the point should have been plotted at 1.20 rather than 1.19 for the ordinate.

**Operation of the cell.**—With mercury in the cell legs and the system evacuated, the mercury was gently flamed to remove gases. Then  $\text{SnCl}_2$  was added by its final distillation. About  $\frac{1}{2}$  atm of argon was added (to prevent boiling of the mercury), and the cock was closed. The cell was placed in the hot furnace. After stirring, a piece of tin was added to each leg. The system was stirred intermittently and heated, normally, overnight.

When a cell could be stirred with almost negligible effect on the voltage and then it returned in a few minutes to the original voltage, the system was accepted as being at equilibrium. This condition was achieved in about an hour after adding tin if the stirring was frequent, but 2 hr or more elapsed between additions. For temperature changes at a single composition, some measurements were taken about  $\frac{1}{2}$  hr apart, but most were taken more slowly.

(Commercial models of the cell are available through Los Alamos Thermodynamic Equipment, Santa Fe, New Mexico.)

### Results

The results of measurements on three runs are listed in Table I. These are low-temperature data taken to emphasize the change of emf with composition. The results from run I, points 25-28, were established from extrapolation or interpolation of data at different temperatures. (See Uncertainty of the Results for the comparison of run I with runs II and III.)

Table II shows the temperature dependence of the emf at various compositions for run I and run IV. Two measurements at 0.003989 mole fraction tin in run I are not reported because they involved reversing the potentiometer leads, and their accuracy is questionable; rough constants for these measurements are indicated by question marks in later plots.

### Uncertainty of the Results

The precision is shown by Fig. 2-5. If, in Fig. 3, the scatter is ascribed to compositional error, point 25 is off the line by an amount equal to about 1% of the

tin mole fraction. The curve could be moved to apportion the error between it and points 33 and 34. That would raise the scatter at points 33 and 34 to about 0.4%, or more than shown by the other points. As discussed below there is reason to be somewhat dubious of the composition at point 25 from Run I.

**Composition.**—The materials added as weighed by TCX balance are probably not in error by 0.1%. One or more of the following compositional uncertainties would seem to be the source of the additional uncertainty. (A) As shown by Fig. 4, diffusion of tin from leg to leg through the electrolyte, or removal of mercury through the salt and to the vapor is trivial during a set of measurements at high temperatures or for long periods at 525°K. However, some error of this type may have occurred in runs I and IV on standing at high temperatures before the measurements at any composition were started. (B) Although the linearity of the data argues against an extensive trapping of  $\text{SnCl}_2$  in the solid tin, it might have occurred in a piece or two. (C) If the tin scrubbing did not destroy all the  $\text{Sn}(\text{OH})_2$ , or if the argon contained traces of oxygen, variable amounts from run to run would have destroyed different fractions of the first tin pieces added and especially the first compositions might be detectably wrong. (D) Although the indications are that the solubility of tin in  $\text{SnCl}_2$  is low (15, 16, also 5), the results are not definitive and the corrections might not really be trivial. (E) The differences in stability reported for mercury and tin chlorides (17) would not allow for a significant displacement reaction (18) of mercury with  $\text{SnCl}_2$ . Gross error in these reported stabilities seems unlikely. (F) It is very doubtful if correction is necessary for any compositional errors resulting from impurities in the small amount of tin or in the vaporized mercury. (G) To correct, if necessary, for the solubility of  $\text{SnCl}_2$  in the mercury, its solubility was estimated both at room temperature and at  $\sim 520^\circ\text{K}$  by the following procedure. Mercury, saturated with  $\text{SnCl}_2$  and cooled to just below the  $\text{SnCl}_2$  freezing point, was decanted from the solid and cooled. The barely visible traces

<sup>a</sup> Cell had had a preliminary heating with stirring for four days, then was cooled and later reheated.

<sup>b</sup> Cell had been taken out of furnace and returned to furnace on 7th day.

of  $\text{SnCl}_2$  which showed after cooling were dissolved in water and precipitated with  $\text{AgNO}_3$ . This gave the difference in solubility between 520°K and room temperature. The solubility of  $\text{SnCl}_2$  in mercury at room temperature was estimated by aqueous extraction of  $\text{SnCl}_2$  from mercury by vigorous shaking. The solubility of the  $\text{SnCl}_2$  in mercury at either temperature is <5 ppm.

**Emf.**—There was nothing erratic about the emf readings and nothing to indicate high resistance films, electrochemically active impurities, or irreversibility. The K-2 potentiometer was calibrated by A. N. Shopp of our laboratory. Allowing for the larger emf values and different potentiometer scales used, the precision is in line with earlier results (5). Also the grounded Faraday cages around the cell had already been tested and found adequate (5).

Probably associated with small temperature gradients top-to-bottom in the cell, stirring altered the voltage as much as 0.002 mv. This is consistent with anticipated thermocell effects [see ref. (12)] of 0.6 mv/°K plus a temperature gradient of around 0.003°K. Isopestic balance results indicate this uniformity of temperature is bettered by nesting copper cylinders under more ideal conditions. The long-term stability

of emf was acceptable, as in Fig. 4 the values before and after 15 days were about 0.012 mv (~0.05%) off the line.

Possible spurious emf values from thermocouple effects at the copper-tungsten room temperature junctions were tested by moving the connection clamps. No effect was observed. (The W leads were ~25 cm, i.e., longer than in Fig. 1.)

**Temperature.**—For the runs where temperature was varied, the effects of temperature gradients can best be evaluated from the scatter of the data. This scatter from linearity amounts to only a few microvolts: if ascribed to a discrepancy between the thermocouple temperature and the alloy temperature, it amounts to about 0.06°K for the average temperature error; if ascribed to thermocell effects caused by temperature gradients between the cell legs, as discussed in the previous section, the corresponding gradients would be about 0.01°K.

Experience with Pt/Pt-10%Rh thermocouples, as used in these experiments and in isopiestic balance experiments, has demonstrated that thermocouple strains after the thermocouple wires were checked would not change the absolute temperature as much as 0.7°K; furthermore, if such an error did exist, it has been shown that the error would appear essentially equally in all readings. The thermocouple hot junction was taped to the Pyrex just outside the active electrode-electrolyte interface.

Fig. 2. Deviations from Henry's law slopes for runs II and III. Other data from Haring and White (13) and Richards and Wilson (14). The logarithms listed have a negative characteristic and positive mantissa. These indicate the concentrations of the changed electrode; the reference electrode differences are eliminated by the reference constant.  $\epsilon$  in microvolts is plotted.

Fig. 4. Run IV data showing the effect of temperature for  $N_{\text{Sn}} = 0.01236$  vs.  $N_{\text{Sn}} = 0.07248$ .

Fig. 5. Data for run I showing the effect of temperature at various compositions. Equation form  $(\epsilon - \epsilon_0 + A) T = B$ .

**Checks of the over-all accuracy.**—The aqueous measurements (13, 14) may be compared with the molten salt measurements as in Fig. 2. Their close similarity of form is consistent with Kleppa's conclusion (19) that the heat of alloy mixing shows no trend with temperature. It suggests that all three groups of measurements are truly indicating the solution behavior.<sup>2</sup>

<sup>2</sup> Two other groups of emf measurements on Hg-Sn should be mentioned. Van Heteren (20) had results in general agreement with these, but his lack of precision and different reference electrodes make an exact comparison difficult. Petot-Ervas *et al.* (21) have also recently reported measurements on emf cells using electrodes of tin and tin in mercury. They used water, glycerine, and ZnCl<sub>2</sub>-LiCl-KCl eutectic as solvents for the SnCl<sub>2</sub>. There is satisfactory agreement among the various measurements except for somewhat anomalous temperature coefficients with the eutectic solvent.

The data relating emf to temperature may be checked against those from Kozin and Nigmatova (22) who used a glycerine solvent for the electrolyte up to 513°K. Although their paper was criticized for theoretical mistakes (23), the experimental results appear to be valid though not of high precision.

From the results shown in Fig. 5,  $d(\epsilon - \epsilon_0)/dT = 0.045645$  mv/°K at  $N_{\text{Sn}} = 0.05039$ , and  $0.008872$  mv/°K at  $N_{\text{Sn}} = 0.01399$ . The difference is  $0.03677 \pm 0.00018$  mv/°K. Kozin and Nigmatova find a difference of  $0.038 \pm 0.009$  mv/°K (corrected value because of a slightly different composition range). All of the uncertainties have been evaluated from the data;  $\pm 1.5$  mv has been used for Kozin and Nigmatova and  $\pm 0.005$  mv for this work, *i.e.*, slightly less than the maximum apparent scatter.

Similarly for the change of emf with composition using the results of run II,  $d(\epsilon - \epsilon_0) (1/T)/d \log N = 0.06042 \pm 0.00003$  mv per mole fraction unit in the range 0.056609 to 0.008918 mole fraction of tin. Kozin and Nigmatova show the value  $0.060 \pm 0.006$  for the range 0.05 to 0.01 mole fraction of tin.

## Discussion

*Emf vs. mole fraction.*—Because

$$\frac{\epsilon - \epsilon_0}{T} = - \frac{R}{nF} \ln \frac{\gamma N}{\gamma_0 N_0} \quad [1]$$

then for Henry's law ( $\gamma = \text{constant}$ )

$$\frac{\epsilon - \epsilon_0}{T} - \left( \frac{2.303 R}{2F} \right) \log N_0 = - \left( \frac{2.303 R}{2F} \right) \log N \quad [2]$$

and this gives the reference slopes on Fig. 2. Empirical constants (Table I) have been used to correct for the reference electrode potential differences.

Since the aqueous data in Fig. 2 were largely rejected in a comparative analysis (24), some comments should be made. The curvature shown by the measurements is not consistent with regular solution theory [ref. (24), p. 15] which apparently has been used [ref. (24), p. 785] to give a rather unsatisfactory description of the mercury vapor pressure data (25). [Other vapor pressure data (26) are in general agreement with, but are less precise than, those taken earlier (25).] Consistent with regular solution theory but not consistent with the data, two lines of different slope were used to represent the different sets of concordant aqueous emf results (Fig. 2, 13, 14) and a third intermediate line representing a third and much less precise group of data (20) was used to calculate dilute solution mercury activities [ref. (24), pp. 785, 789]. This treatment would now appear to have been in error. (Structural phenomena are discussed in the next section; Duhem integrations are then described.)

*Emf vs. temperature with interpretation.*—The constants applied in Fig. 5 are interrelated as shown in Fig. 6 and 7. In the region 0.01–0.08 mole fraction of tin, a single equation consistent with the relationships in Fig. 6 and 7 can be used to describe the data roughly, but not within their apparent precision. Using volts here,

$$\frac{\epsilon - \epsilon_0 - \alpha + 0.0916 N_{\text{Sn}}}{T} = \left( \frac{2}{3} \right) \frac{R}{nF} \ln \frac{N_{\text{Sn}}}{N_{\text{Sn}^0}} \quad [3]$$

with  $\alpha$  from  $0.0916 N_{\text{Sn}^0}$  of the reference electrode.

The constants from the temperature dependent relationships can be checked against the more precise run II as in Fig. 8. This plot shows that the relationship holds well here also to about 0.01 mole fraction where a change of behavior occurs and Eq. [2] fits the lower concentration data acceptably.

After considering a number of postulates, the following is the only one I have reached which seems to be consistent with the data.

Fig. 6. Variation with composition of the temperature dependent terms, A, in Fig. 5.

Fig. 7. Variation with log composition of the temperature independent terms, B, in Fig. 5.

The enthalpy changes for the cell reaction,  $-nFd[(\epsilon - \epsilon_0)/T]/d(1/T)$ , are indeed constant as observed less clearly by Kleppa calorimetrically (19). At about 0.1 mole fraction of tin, a deviation from the relationship (Fig. 6) occurs. It might be abrupt, although this is not clear either from the emf work or from the calorimetry. [Note that Kleppa's values from 0.1-0.4 mole fraction of tin in his Fig. 3 do all lie on a straight line of different slope from those for 0.02 to 0.1 mole fraction. Equations are given for other calorimetric measurements (27) but the data are not presented.] The linear enthalpy equation region suggests that these added tin atoms enter essentially equivalent sites, gradually changing the environment and bonding energy.

The 2/3 with the entropy term is unusual. Replacing  $n = 2$  by  $n = 3$  seems unacceptable: water (13, 14), glycerine (22), and pyridine (20) solvents, as well as the pure  $\text{SnCl}_2$  melt, produce comparable results so stray Sn(III) in the electrolyte and in contact with Sn(O) appears most unlikely; furthermore, using Sn(II) for melts of  $\text{SnCl}_{2(1)}$  (5) or with  $\text{SnCl}_2\text{-LiCl-KCl}$  (28) leads to Raoult's law behavior for solvent tin.

The only acceptable place for the 2/3 seems to be as  $(2/3) R \ln N_{\text{Sn}}$  or  $R \ln (N_{\text{Sn}})^{2/3}$  for the entropy of

Fig. 8. Temperature-composition equation applied to run II. Ordinate uses mv.

dilution, i.e., 2/3 the normal limiting value. The enthalpy linearity seems to rule out usual association, e.g., to  $\text{Sn}_2$  and  $\text{Sn}_3$ . Peculiar rotational or vibrational effects would not seem to lead to an almost exact 2/3 as shown by Fig. 7. Long chains of tin would apparently not give this behavior [see ref (29), p. 293]. Perhaps the metallic resonance and metallic bond strengths for the mercury solvent are less disturbed if the tin atoms arrange randomly in planes or sheets rather than randomly through the whole solution volume. [See a similar discussion regarding ordered solid defects (2b). Certainly the sheets cannot be large, since the alloy is fluid; a densely packed finely divided powder might provide a fair instantaneous analogy.] Fairly widely separated planes without significant edge effects would not contribute much randomness, and  $(2/3) R \ln N_{\text{Sn}}$  would be expected to be approximated closely. Then (for 523°K) at 0.01 mole fraction of tin (Fig. 8) the randomizing forces overcome the ordering forces, the whole solution becomes available to the solute, and Henry's law is either obeyed or approached closely. The data are not clear on how abruptly the change occurs.

*The Duhem integrations.*—In connection with the thermodynamic questions (1-11), the Duhem integration is very important. For the present experiments, a constant reference electrode composition was used on one side of the cell, and the changes of emf with changes of the other electrode composition may be used to calculate the changes in activity of the tin. Thus, even though the Henry's law constant cannot be obtained from the data, a Duhem integration can be carried out to predict the variation of the mercury activity with composition.

The required data are presented in Table I and Fig. 3. Either activity or activity coefficient can be used. (Arbitrary constants have been added to superimpose the runs.) From the activity coefficient equation

$$\int_{N_{20}}^{N_2} \frac{d \log \gamma_1}{dN_2} = - \int_{N_{20}}^{N_2} \frac{N_2}{N_1} \frac{d \log \gamma_2}{dN_2} \quad [4]$$

the area under the curve in Fig. 3 according to thermodynamic theory gives the change in the mercury activity coefficient with mole fraction. No extrapolation to infinite dilution is necessary to perform this integration: Knowing the mercury activity at any point fixes the activities all along the curve. However, for convenience, the short extrapolation to infinite dilution was performed in order to fix the mercury activity from its pure solvent value. The predicted mercury activities are plotted in Fig. 9, out to 0.09 mole fraction of tin for comparison with some vapor pressure measurement being carried out by Dr. D. R. Conant of our laboratory. Just where one chooses to switch from  $(2/3) R \ln N_{\text{Sn}}$  to  $R \ln N_{\text{Sn}}$  for the entropy

Fig. 9. Duhem integration of tin emf data at 525°K to predict the mercury activity-mole fraction relationships.

partial makes little difference to the value of the integral. Other errors in this extrapolation also may be expected to have only a very small effect on the shape of the curve in Fig. 9, e.g., if the mercury activity at the most dilute tin concentration measured were truly not at  $\sim 0.999$  but were even at  $\sim 0.900$ , the activity would drop only  $\sim 10\%$  less fast than is shown, since

$$(d \ln a_1/dN_1) = (1/a_1) (da_1/dN_1)$$

Likewise the uncertainty in the data leads to only a very small uncertainty in the Duhem integration—considering the reproducibility of the data, the fractional error in the area under the curve must necessarily be very small.

By extrapolating the temperature dependent equations to 595°K, a Duhem integration to 0.12752 mole fraction of tin can be carried out. This is shown in Fig. 10 along with the more precise earlier vapor pressure data (25). [The other vapor data (26) are comparable but less precise.]

The differences are systematic (each vapor pressure point represents several readings); the vapor pressure data lie some 10% closer to Raoult's law than the emf-Duhem prediction. Whether the differences are significant is not clear.

The published enthalpy data from solution calorimetry (19) are for a lower temperature. These agree approximately with the earlier emf data (22). Other enthalpy of mixing equations (no data, however) are given for 523°K (27). The present emf data offer no information on the total enthalpy of mixing, but only on its changes. The changes of slope in the  $\Delta \bar{H}_{Sn}$  for

Fig. 10. Duhem integration at 595°K using emf data extrapolated about 30°K. Vapor pressures from Hildebrand, Foster, and Beebe (25) at 595°K.

the present emf data (Fig. 6), and  $\Delta \bar{H}_{Sn}$  from calorimetry appear at about the same composition ( $\sim 0.1$  mole fraction of tin). However, the line used by Kleppa in his Fig. 3 to describe  $\Delta \bar{H}_{Sn}$  corresponds to a change of 560 cal/mole in  $\Delta \bar{H}_{Sn}$  in the range 0.01-0.1 mole fraction of tin. The Wittig and Scheidt equation value changes 241 cal/mole in this range. For the emf the value is 380 cal/mole. The published calorimetric data scatter enough, however, so that a thermodynamically consistent line could be used without forcing the data greatly; no measure of the equation uncertainty is given.

### Acknowledgments

This work is part of a program to measure both emf and vapor pressure for Hg-Sn solutions. The vapor pressure measurements are being carried out by Dr. D. R. Conant, and we have been in close contact during the course of the present work. The author has also had many valuable discussions with Dr. C. E. Holley regarding these problems.

This work was done under the auspices of the U. S. Atomic Energy Commission.

Manuscript submitted Nov. 10, 1967; revised manuscript received July 18, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Analysis and Application of the Thermoelectric Microprobe

J. S. Armijo

Stanford Research Institute, Menlo Park, California

### ABSTRACT

A microprobe technique has been developed and used for measuring thermoelectric profiles across Fe-Ni and Cu-Ni diffusion couples. Analysis of the technique permits calculation of the absolute thermoelectric power spectrum. Data are highly reproducible and are in good agreement with previous studies when probe loads of 3g or less are used. Resolution of the thermoelectric microprobe is found to compare favorably with the resolution of the electron microprobe.

The most widely used technique for studying the thermoelectric properties of alloy systems consists of preparing wire specimens of desired compositions, placing them in a temperature gradient, and measuring the thermal emf's produced by the alloys with respect to a reference metal.

The chief disadvantage of the technique is that one specimen must be prepared for each composition of interest. Consequently many specimens must be prepared and tested if the thermoelectric spectrum is to be studied in detail. Furthermore, absolute values of the measured thermoelectric properties can be incorrect if the alloys are not homogeneous. Another disadvantage is that the technique cannot be used for brittle phases which cannot be formed into wires.

A number of studies have been reported in which probe techniques have been used to make thermoelectric measurements on a microscale. In most of these studies (1-5) the experimental emphasis was on the use of thermoelectric effects to measure other physical properties. For example, probe techniques have been used extensively to measure the thicknesses of diffused p-n junctions in semiconductors. In these studies only the signs of the thermal emf's were of interest, since a change in sign during a probe traverse indicated a change from hole to electron conduction and thus defined the junction. The magnitudes of the thermal emf's produced in these studies were not reported and were not used to calculate thermoelectric properties. In 1959 Strug and Panchenko (6) described an improved thermoelectric probe that could be used to make measurements of the magnitudes of the thermal emf's generated at the contact point. This device consisted of a heated tungsten probe mounted on a microhardness testing machine. By using a fine enough tip, these authors found it possible to measure thermal emf differences between phases in alloys of a complex microstructure and between different compositions of binary alloys. The technique, however, was not analyzed in detail, and only qualitative values of thermoelectric properties were obtained.

A similar device was described by Westbrook, Seybolt, and Peat (7). These authors used the technique to detect evidence of solute segregation in NiGa and Pb bicrystals that were doped with oxygen and tin, respectively. In these experiments, pronounced ther-

moelectric minima were observed at grain boundaries. Efforts to calibrate the thermal emf with a series of specimens of homogeneous composition were unsuccessful. Further, the effects of experimental variables such as temperature and load on the probe were not determined. The technique therefore remained qualitative in nature.

The present studies were initiated with the objective of measuring quantitative thermoelectric spectra of Fe-Ni and Cu-Ni alloys with the thermoelectric microprobe.

### Experimental

The thermoelectric microprobe used in these studies was similar in design to those described previously (1-7). However, a number of significant changes were made in the design and operation of the probe to eliminate some of the problems encountered with the previous devices.

The probe itself was a tungsten rod approximately 6.5 cm in length and 0.6 mm in diameter. Efforts were made to maintain a high length to width ratio in order to maintain the cold junction at or very near room temperature. The probe tip was first roughly sharpened on a diamond grinding wheel, and then sealed into a close fitting alumina tube with epoxy cement. Uniform epoxy distribution was assured by submerging the assembled probe and insulator in the liquid epoxy and then evacuating all trapped gases. The probe was then removed from the bell jar and cleaned; the epoxy was allowed to harden for approximately 24 hr. The probe was then manually polished to a sharp point by using progressively finer diamond abrasives on standard metallographic polishing wheels. The electrolytic technique that Westbrook *et al.* (7) used to sharpen their probes was found to produce undesirably fragile probe tips. Probes made by mechanical polishing, however, were very strong, and did not lose their shape in normal experimental use.

The probe was then prepared for electrical connection by carefully abrading the end to remove surface contamination and expose a fresh metal surface. The probe was placed in a vacuum bell jar, masked where necessary, and coated with a thin layer of copper by vacuum deposition. The contact end was then covered

Fig. 1. Experimental arrangement showing microprobe, specimen, thermocouple, and specimen heating bath. Insert shows profile of mechanically polished probe tip.

with a thicker ( $\sim 0.1$  mm) copper layer by electropolating in a sulfuric acid-copper sulfate solution. With this procedure it was always possible to obtain a low contact resistance by normal soldering techniques. Efforts to copper plate directly to tungsten and efforts to solder directly to a thin vacuum-deposited copper were unsuccessful.

The probe was then mounted in a holder designed to fit a standard microhardness machine.<sup>1</sup> The design was such that the thermoelectric probe was located in the normal position of the diamond indenter. Consequently the normal precision of the microhardness machine with respect to position and load was maintained. The differences in weight between the thermoelectric microprobe and the diamond indenter were readily compensated for with normal load adjustments of the machine.

The placement of the probe in the microhardness machine is shown in Fig. 1. Also shown on the loading beam is a 2-g weight for load adjustment. Electrical connection to the probe was achieved by soldering a fine copper wire ( $\sim 0.025$  mm in diameter) to the copper-plated end. This connection provided good contact, and the effect of the wire on the motion of the loading mechanism was minimal.

Specimens studied in these experiments were binary diffusion couples of Fe-Ni and Cu-Ni. Specimens were prepared by clamping flat, polished pieces of high-purity materials (99.999 Cu, 99.95 Fe, 99.95 Ni) and annealing them in vacuum. The Fe-Ni couple was annealed at  $1300^{\circ}\text{C}$  for 4 hr and the Cu-Ni couple was annealed at  $1000^{\circ}\text{C}$  for 4 hr. Approximately 1 hr was required to cool the specimens to room temperature.

Electrical connection was made to each specimen by spot welding insulated wires of identical material, i.e., Fe to Fe, Cu to Cu, etc. Specimens were carefully mounted in epoxy cylinders to insure that the diffusion plane was normal to the surface. Metallographic polishing procedures were used to prepare the test surfaces.

For most measurements, only freshly polished (final vibratory polish with  $0.1\mu$  alumina slurry) specimens were used. Mounted specimens were placed in a standard holder that kept the plane of polish perpendicular to the probe axis. The holder was inserted

into a Plexiglas cylinder (see Fig. 1) and firmly wedged in place to avoid movement of the specimen during the experiment. The Plexiglas cylinder was then filled with silicone oil, and the oil was heated with electrically insulated, sheathed thermocouple wire. During each measurement, the oil temperature was measured with a fine Pt/Pt-13% Rh thermocouple or a calibrated thermometer. The procedure of heating the specimen rather than the probe was the most significant difference between these experiments and previous experiments (1-7). Heating of the specimen in the oil bath improved the thermal stability of the system and retarded the oxidation of the specimen during the experiment.

Heater current was supplied by a stabilized d-c power supply. Thermoelectric potential measurements were made with a high impedance electronic microvoltmeter which amplified the signal to a recording potentiometer. Manual measurement of thermal emf's also were made with a high precision potentiometer. Potentiometric measurements agreed within  $\pm 0.5\%$  with those obtained with the microvoltmeter-recorder arrangement. Therefore the microvoltmeter-recorder system was used throughout these measurements because of its speed and convenience.

The measurement procedures were closely followed in each test to minimize scatter. Freshly polished and mounted specimens were placed in the oil bath, and the bath was rapidly heated to the desired temperature. The heater current was then reset to a predetermined value which would hold the bath at the desired temperature. Approximately 2 hr were allowed for the bath temperature to reach a steady-state value. During this time the area of the specimen to be traversed was chosen and aligned with the indenter. Throughout each measurement, both the specimen and the probe tip were immersed  $\sim 7$  mm below the surface of the oil bath (the probe rested  $\sim 1$  mm above the specimen when not in contact).

When steady state had been reached, the probe was released and allowed to contact the specimen. After the thermal emf was recorded, the specimen temperature was recorded, and the specimen was moved for the next indentation. The specimen was removed from the solution after the electrical measurements were completed, and the location of each indentation was determined. Indentation positions were measured with respect to a reference interface for the Fe-Ni specimen and with respect to a line of Kirkendall porosity for the Cu-Ni specimen. These optical measurements (at magnifications of 500 to 750 times) were reproducible to  $\pm 2\mu$  with two different observers.

Several measurements of the thermoelectric spectra of the Fe-Ni and Cu-Ni diffusion couples were made. The effects of both temperature and load on the probe were evaluated for the Fe-Ni alloys only.

Chemical composition gradients in the specimens were determined by the use of an electron microprobe. Corrections for fluorescence and absorption were made by the use of internal standards.

## Results

In all measurements reported here, the oil temperature (as measured by the platinum/platinum-rhodium thermocouple) remained within  $\pm 0.25^{\circ}\text{C}$  of its reported value. The measured thermal emf was found to rise rapidly to its maximum value and remain constant within  $\pm 2\mu\text{v}$  during each measurement. The rise and stability of the specimen emf was almost identical to that of the thermocouple. This behavior was different from that observed by Westbrook *et al.* (7) who found a rapid initial rise in emf, then a slow steady rise to a value 15-20% higher than the initial value. This did not occur in the present studies, because the probe tip and the specimen surface were very nearly at the same temperature before contact.

The emf data and the indentation positions plotted together resulted in the thermoelectric spectrum at

<sup>1</sup> Wilson-Tukon Microhardness Tester Model MO.

the measurement temperature for each binary alloy system studied. The Fe-Ni spectrum was complex, while the Ni-Cu spectrum was simple. Results for these two systems will be described separately.

**Fe-Ni system.**—The thermoelectric spectrum for the Fe-Ni system was measured at various temperatures over the range 45°–80°C. The two measurements in Fig. 2 show that the thermoelectric spectrum of the Fe-Ni system is quite complex in this temperature range. The characteristics of this spectrum are as follows. First, there is a plateau on the pure Fe portion of the specimen, then a sharp peak (called peak I), followed by a minimum and then by a broad peak (peak II) and finally by a plateau on the pure Ni part of the specimen. These data were representative of the thermoelectric properties of small regions of the specimen. As Fig. 3 shows, the probe contact areas were small ellipses 1.5–2 $\mu$  wide and 3–4 $\mu$  long. Further metallographic examination of the specimen (Fig. 4) showed that the thermoelectric traverse had passed across a complex interface consisting of three zones. Zone I ( $\sim 8\mu$  wide) was a dark colored phase immediately adjacent to the iron. Zone II ( $\sim 10.5\mu$  wide) was a light gray phase adjacent to zone I. Between zones I and II and possibly within zone II there was evidence of an acicular phase. Zone III ( $\sim 170\mu$  wide) was a lighter color than zone II and extended from across the reference interface into the pure nickel part of the diffusion couple. On the basis of the measured composition profile and the Fe-Ni phase diagram (8), the various bands were identified as follows: zones I and II were, respectively, the Fe-rich and Ni-rich portions of the two phase ( $\alpha + \gamma$ ) field. The acicular structure in zone I is coarse martensite and the dark gray color of zone II is due to the presence of fine martensite. Zone III is simply iron-doped  $\gamma$ -Ni. Careful analysis of the data points from Fig. 2 and 3 showed that peak I occurred within the nickel-doped  $\alpha$ -iron, zones I and II. The minimum and peak II occurred entirely within zone III. Comparison of the thermoelectric profile with the composition profile (Fig. 2) shows that small composition changes were readily detected with the thermoelectric microprobe. The resolution of this instrument compares favorably with the resolution of the electron microprobe used for the composition profile measurement.

Fig. 2. Thermoelectric and composition profiles for Fe-Ni diffusion couple.

Fig. 3. Indentations produced by probe traverse across Fe-Ni diffusion couple using a 2-g load.

Fig. 4. Structural features of diffusion zone in the FeNi specimen

Changes in bath temperature resulted in changes in magnitude of the various thermal emfs (Fig. 2), but no change in the shapes of the curves. Increases in the load on the probe (Fig. 5) resulted in decreases in the thermal emfs of peaks I and II and an increase in the thermal emf of the minimum. Progressive shifts in the peak positions were also observed. As Fig. 5 shows, the shape of the thermoelectric spectrum could still be resolved even when the probe load was large. The effect of probe load on the apparent composition of the peaks and the minimum is shown in Fig. 6. Loads up to 3g produce no appreciable shift in composition, but

Fig. 5. Effect of probe load on thermoelectric profiles of Fe-Ni diffusion couple.

Fig. 6. Effect of probe load on measured composition of Fe-Ni diffusion couple.

further increases in load produce appreciable shifts. As will be shown later, loads from 1 to 3g yield essentially the same thermoelectric power spectrum for the Fe-Ni system; higher loads (10g or more) yield meaningless results.

**Cu-Ni system.**—The measured thermoelectric and composition profiles for the Cu-Ni specimen are shown in Fig. 7. As with the Fe-Ni data, the resolution of the thermoelectric microprobe was equivalent to the resolution of the electron microprobe. Small compositional changes ( $\sim 1\%$ ) were readily detected with the thermoelectric microprobe. Differences in the two thermoelectric profiles of Fig. 7 resulted from slightly different experimental conditions.

### Analysis and Discussion

It is evident that the high spatial and potential resolution of the thermoelectric microprobe makes it a useful tool for detailed qualitative studies of alloy systems. However, an analysis of the system is necessary before quantitative thermoelectric properties can be determined from the measured data. Consider the experimental arrangement shown in Fig. 8. Before the tungsten probe makes contact, the specimen surface is kept at a uniform temperature  $T_2$  by the hot oil bath. The cold ends of the tungsten probe and the electrical contact wire (in this example the contact wire is Fe) are at room temperature  $T_1$ . When the probe contacts the specimen, the local metal surface is cooled to a temperature  $T_3^x$  where  $x$  represents the metal com-

Fig. 7. Thermoelectric and composition profiles for Cu-Ni diffusion couple.

Fig. 8. Schematic of microprobe assembly

position of the contact point. The thermal emf produced when the probe makes contact on pure iron is given by

$$\Delta E_{Fe} = \int_{T_1}^{T_2} S_{Fe} dT + \int_{T_2}^{T_3^{Fe}} S_{Fe} dT + \int_{T_3^{Fe}}^{T_1} S_W dT \quad [1]$$

where  $\Delta E_{Fe}$  is thermal emf on the iron side of the diffusion couple, and  $S_{Fe}$ ,  $S_W$  are absolute thermoelectric powers of Fe and W, respectively. The thermal emf produced when the probe makes contact on pure nickel is

$$\Delta E_{Ni} = \int_{T_1}^{T_2} S_{Fe} dT + \int_{T_2}^{T_3^{Ni}} S_{Ni} dT + \int_{T_3^{Ni}}^{T_1} S_W dT \quad [2]$$

Substituting the identities

$$(T_1 - T_3^{Fe}) = (T_1 - T_2) + (T_2 - T_3^{Fe}) \quad [3]$$

$$(T_1 - T_3^{Ni}) = (T_1 - T_2) + (T_2 - T_3^{Ni}) \quad [4]$$

into Eq. [1] and [2] and subtracting [1] from [2] yields

$$\begin{aligned} (\Delta E_{Ni} - \Delta E_{Fe}) = & \int_{T_2}^{T_3^{Ni}} (S_{Ni} - S_W) dT \\ & - \int_{T_2}^{T_3^{Fe}} (S_{Fe} - S_W) dT \quad [5] \end{aligned}$$

Similarly, when the probe makes contact on an alloy of composition  $x$ ,

$$\begin{aligned} (\Delta E_x - \Delta E_{Fe}) = & \int_{T_2}^{T_3^x} (S_x - S_W) dT \\ & - \int_{T_2}^{T_3^{Fe}} (S_{Fe} - S_W) dT \quad [6] \end{aligned}$$

where  $S_x$  is the absolute thermoelectric power of an alloy of composition  $x$ .

During a given experiment, the values of  $\Delta E_{Fe}$ ,  $\Delta E_{Ni}$ ,  $\Delta E_x$ ,  $T_1$ , and  $T_2$  are measured. The values of  $T_3^{Fe}$  and  $T_3^{Ni}$  at the junction between the probe and the specimen can be calculated from Eq. [1] and [2] by using measured data and literature values of the thermoelectric powers of the pure elements. The values of  $T_3^x$  for alloys of intermediate composition, however, cannot readily be determined. Therefore, it is necessary to develop relations among  $T_3^{Fe}$ ,  $T_3^{Ni}$ , and  $T_3^x$ . A rigorous analytical determination of these relations will, in general, require the solution to a complex heat flow problem defined by the experimental conditions shown in Fig. 8. However, reasonable relations can be determined in the following manner. When the

probe contacts the metal surface it removes heat in proportion to the reciprocal of the thermal conductivity of the metal at the point of contact. Therefore the steady-state temperature gradient at the contact point can be written as

$$(T_2 - T_3^x) = \gamma/K_x \quad [7]$$

where  $K_x$  is the thermal conductivity of an alloy of composition  $x$ , and  $\gamma$  is a proportionality constant. The larger the value of  $K_x$ , the smaller will be the local temperature gradient. Assuming that the proportionality constant  $\gamma$  is the same for all alloy compositions,<sup>2</sup> one can write the relations required for the evaluations of Eq. [5] and [6]

$$(T_2 - T_3^{\text{Ni}})K_{\text{Ni}} = (T_2 - T_3^{\text{Fe}})K_{\text{Fe}} = (T_2 - T_3^x)K_x \quad [8]$$

The magnitude of the temperature gradient when the probe contacts the pure iron side of the couple can then be determined by substituting [8] into [5], which yields

$$(T_2 - T_3^{\text{Fe}}) = (\Delta E_{\text{Ni}} - \Delta E_{\text{Fe}}) / [(\bar{S}_{\text{Fe}} - \bar{S}_W) - \frac{K_{\text{Fe}}}{K_{\text{Ni}}} (\bar{S}_{\text{Ni}} - \bar{S}_W)] \quad [9]$$

where  $\bar{S}_{\text{Fe}}$ ,  $\bar{S}_{\text{Ni}}$ , and  $\bar{S}_W$  are the average thermoelectric powers of Fe, Ni, and W over the temperature range  $T_3^{\text{Fe}}$  to  $T_2$ .

Substituting [8] and [9] into [6] and simplifying yields the average thermoelectric power of the alloy of composition  $x$  over the temperature range  $(T_2 - T_3^x)$

$$\bar{S}_x = \bar{S}_W + \frac{K_x}{K_{\text{Fe}}} (\bar{S}_{\text{Fe}} - \bar{S}_W) \left( 1 - \frac{(\Delta E_x - \Delta E_{\text{Fe}})}{(\Delta E_{\text{Ni}} - \Delta E_{\text{Fe}})} \right) + \frac{K_x}{K_{\text{Ni}}} \left( \frac{\Delta E_x - \Delta E_{\text{Fe}}}{\Delta E_{\text{Ni}} - \Delta E_{\text{Fe}}} \right) (\bar{S}_{\text{Ni}} - \bar{S}_W) \quad [10]$$

It will be shown later that the temperature gradient at the tip of the probe is generally small enough ( $2^\circ$ - $5^\circ\text{C}$ ) that, for all practical purposes, Eq. [10] yields the value  $S_x$  rather than  $\bar{S}_x$  at temperature  $T_2$ . Equations analogous to [9] and [10] can be developed for the Ni-Cu system.

The thermoelectric power spectra were calculated for Fe-Ni and Cu-Ni alloys by using Eq. [10] and the thermal emf data of Fig. 2 and 6. Literature data (9, 10) were available for thermal conductivities of all elements and alloys at the temperature of interest. Literature values (11) of the thermoelectric powers of iron, nickel, copper, and tungsten with respect to various reference metals were converted to absolute thermoelectric powers (12, 13) by using values of the absolute thermoelectric power of platinum determined by Nystrom (14). Equations for the absolute thermoelectric powers used in this paper were

$$S_W = 4.4 + 0.38 \times 10^{-2}T$$

$$S_{\text{Ni}} = 13.52 - 8.38 \times 10^{-2}T + 5.7 \times 10^{-5}T^2$$

$$S_{\text{Fe}} = 19.46 - 6.00 \times 10^{-2}T - 26.75 \times 10^{-5}T^2$$

$$S_{\text{Cu}} = 5.57 - 1.81 \times 10^{-2}T$$

where  $T$  is given in  $^\circ\text{C}$  and  $S$  is in  $\mu\text{V}/^\circ\text{C}$ .

As Fig. 9 and 10 show, the thermoelectric power spectra of both the Fe-Ni and Cu-Ni specimens determined with the thermoelectric microprobe were in general agreement with data determined by conventional methods. The Fe-Ni data measured with the probe were in excellent agreement with Ingersoll's (15) data up to a composition of 35 a/o nickel. At

<sup>2</sup>It should be noted that  $\gamma$  will include a geometric term which will vary with the depth of penetration of the probe. For large differences in hardness of the materials studied,  $\gamma$  will not be the same and consequently will produce errors in measurement. The magnitude of error, however, cannot be estimated until the heat flow problem is solved.

Fig. 9. Thermoelectric power spectrum of Fe-Ni alloys

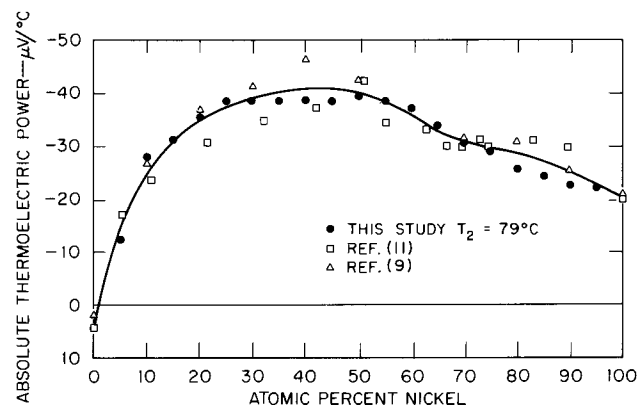

Fig. 10. Thermoelectric power spectrum of Cu-Ni alloys

higher nickel concentrations there were significant deviations. It should be noted that Ingersoll reported that the measured values of the thermoelectric powers in his study were dependent on the specimen dimensions. The only explanation for this effect would be inhomogeneity of the alloy. The agreement of the microprobe data with Rohn's (16) datum, and the absolute thermoelectric power of pure nickel suggest that Ingersoll's earlier data may not be correct at the higher nickel concentrations.

The effects of probe load and specimen temperature on the absolute thermoelectric powers of the characteristic emf maxima and minima of the Fe-Ni binary alloy system are listed in Table I and shown graphically in Fig. 11. As shown in Table I the temperature gradients calculated when the probe tip contacts the nickel side of the diffusion couple range from  $1.4^\circ$  to  $3.5^\circ\text{C}$ . In general, the gradient is lower for lower values of  $T_2$ . However, the temperature gradient can be varied at a given value of  $T_2$  by simply raising or lowering the oil bath level. This is what was done in run No. 3 of Table I. As Fig. 11 shows, the thermoelectric power spectrum of the Fe-Ni specimen is essentially independent of loads up to 3g. At higher loads, the thermoelectric powers are not correct. This loss of resolution at higher loads results from the increasing size of the probe contact area, and not from pressure effects on the thermal emf. Bridgman's (17) data on the effects of pressure gradients on the thermal emf indicate the maximum possible pressure-induced emf with the thermoelectric probe would be less than  $1 \mu\text{V}$ .

### Summary and Conclusions

The thermoelectric microprobe has been used for quantitative measurements of the absolute thermoelectric power spectra of Fe-Ni and Cu-Ni alloys. These spectra, measured from single Fe-Ni and Cu-Ni diffusion-couple specimens, were in good agreement with

Table I. Summary of measured thermoelectric properties of Fe-Ni alloys

7	25	79	3.5	50	-8.5	59	-10.0	70	-29.1

spectra determined by conventional techniques that require multiple specimens. In order to obtain quantitative thermoelectric properties from the measured emf data, one must know the composition and thermal conductivity profiles of the alloy system being studied, and the thermoelectric power of the pure elements in the system. Further, probe loads must be held below some low value (3g or less for the systems studied here) to obtain quantitative data. Use of higher load results in severe distortion of the measured thermoelectric power spectrum.

Because of its good spatial and potential resolution, the thermoelectric microprobe should be useful for diffusion studies, alloy phase analysis, grain boundary studies, and of course thermoelectric property measurements. In this latter application it is evident that

the probe technique would be particularly useful for rapid qualitative measurements of binary alloy systems and of brittle materials that are difficult to form into conventional wire specimens.

# A Chronocoulometric Study of the Adsorption of Anthraquinone Monosulfonate on Mercury

Fred C. Anson and Barry Epstein<sup>1</sup>

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California

## ABSTRACT

The quantity of anthraquinone monosulfonate (AQS) anions specifically adsorbed on mercury electrodes has been determined by chronocoulometry in fluoride, thiocyanate, nitrate, and p-toluene sulfonate electrolytes. In all electrolytes but fluoride competitive adsorption of AQS and the supporting electrolyte anion occurred. The adsorption produced very little change in the charge on the mercury or, therefore, on the amount of specifically adsorbed anions from the supporting electrolytes. The adsorbed anthraquinone monosulfonate anions produced large changes in the potential at the outer Helmholtz plane which were detected by the resulting changes in the rates of two irreversible electrode reactions.

The ability of the chronocoulometric technique to yield precise values for the surface concentrations of adsorbed reactants has been documented almost entirely with inorganic adsorbents (1-9). The present study was undertaken to test the technique with a simple organic redox couple and to examine the extent to which the composition of specifically adsorbed supporting electrolytes influences the adsorption of organic reactants.

Anthraquinone monosulfonate (AQS) was chosen for our experiments because Gill and Stonehill (10) and Furman and Stone (11) had established polarographically that the reduction of AQS in buffered aqueous solutions (*ca.* pH = 9) is a simple, reversible 2-electron reduction to give the monoprotonated quinol.

The semiquinone equilibrium constant is small in this pH range and no splitting of the wave is observed unless the pH is raised significantly or the dielectric constant of the solution is lowered. The polarographic  $E_{1/2}$  for AQS reduction has been reported as  $-0.55$  v. SCE (pH 8.69  $\rightarrow$  9.00) (10, 11) but no indication of adsorption in the form of pre- or postwaves has been reported.

In preliminary linear sweep voltametric experiments, the reduction peak for AQS was observed at  $-560$  mv vs. SCE (pH 8.9 buffer) as expected, but the peak current was unusually sharp and decayed much more rapidly than expected for typical diffusion controlled reactions. This behavior was strongly indicative of extensive adsorption (12, 13) so a quantitative chronocoulometric investigation was carried out.

The adsorption of aromatic compounds on mercury electrodes has been extensively investigated by electrocapillary experiments (14-18). The recent review by Frumkin (19) gives a full account of most earlier work. The general features which these previous studies have shown to characterize aromatic adsorption include: (i) substantial adsorption on both sides of the point of zero charge; (ii) flat orientation of the aromatic rings on the electrode surface which facilitates strong electronic interaction between the pi-electrons and the electrode surface so long as the latter bears a positive charge; (iii) increasing surface activity with increased number of aromatic rings; (iv) relatively small dependence of the adsorption on po-

tential (and therefore on charge), especially at positive charges on the electrode. Anthraquinone monosulfonate appears to follow this general pattern.

## Experimental

Double potential-step chronocoulometry (3, 20) was employed with the aid of the previously described digital data acquisition and analysis system (21). The electrode potential was stepped from various initial values,  $E_i$ , to  $-1400$  mv vs. SCE where drop time experiments with a dropping mercury electrode showed that no significant adsorption of the electrode reaction product occurred. A much less negative potential, *e.g.*,  $-800$  mv, would have sufficed to assure that the reaction remained diffusion controlled, but the appropriate double layer charging correction would have been more difficult to obtain because of extensive adsorption of the electrode reaction product. Positive feedback to the input of the potentiostat was employed to improve the potentiostatic compensation for solution resistance (22).

The electronic charge density of the mercury electrodes was determined as before (9) by measuring the charge flowing into dropping mercury electrodes (23). This procedure, in which the digital data acquisition and analysis system was again employed, gave a value for the electronic charge on the electrode,  $q^m$ , of  $-17.5 \pm 0.5$   $\mu\text{C}/\text{cm}^2$  in 0.5F NaNO<sub>3</sub>, 0.01F Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub> at  $-1400$  mv vs. SCE. This agrees excellently with Graham's value of  $-17.6$   $\mu\text{C}/\text{cm}^2$  for 0.5F NaF at the same potential (24). The electrode's charge at each of the initial potentials was similarly measured in the pure supporting electrolyte solutions. In the presence of the reactant, sodium anthraquinone sulfonate, the values of  $q^m$  at the initial potentials were usually determined from the known value at  $-1400$  mv and values of the change in double layer charge obtained from analysis of the double potential step chronocoulometric data (9, 20). In some cases, the resulting values of  $q^m$  at  $E_i$  were compared with values obtained by means of d.m.e. experiments conducted in the presence of reactant and excellent agreement was observed.

The hanging mercury drop electrode employed was the standard commercially available type (Brinkmann Instruments), but the two internal sealing gaskets were replaced by Neoprene or silicone rubber gaskets to produce better seals and eliminate occasional leakage of air into the electrode reservoir. To avoid the frequently encountered high resistance between the mercury drop and the electrical contact on the mercury reservoir housing the plastic chamber at the top of the capillary was partially filled with mercury and fitted with a platinum wire which al-

<sup>1</sup> Present address: Gulf General Atomic, La Jolla, California.

lowed good contact to be made with the plunger [cf. Wopschall and Shain (25)].

The capillary for the electrode was treated with a 10% HF solution for a few seconds then rinsed with water and dried prior to an application of "Desicote" (Beckman Instruments). This pretreatment improved the precision of the results apparently because it kept the mercury column from flexing during large potential excursions with consequent variations in the electrode area.

The sodium salt of anthraquinone-2-sulfonic acid was obtained commercially and recrystallized three times from water. According to Beilstein (26) the salt recrystallizes as the monohydrate. This was confirmed by drying the salt for 19 hr at 120°C which produced the loss of 1.00 moles of water per mole of salt. Confirmation of purity was also established by comparison of ultraviolet absorptivities with literature values (27). The agreement was within 1%. The recrystallized monohydrate salt was used to prepare all of the AQS solutions. Sample solutions were prepared by weighing solid AQS into a volumetric flask, adding an aliquot of concentrated supporting electrolyte solution and diluting to volume.

Sodium fluoride, sodium thiocyanate, and sodium-p-toluene sulfonate were recrystallized at least twice from water. Other chemicals were reagent grade and were used without further purification. Water was triply distilled, the second distillation coming from alkaline permanganate solution. All solutions were buffered at pH = 8.9 with 0.01F Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>.

Prepurified nitrogen gas for deaerating solutions, was repurified by passing it over copper turnings at 450°C and then through a cold trap at dry ice-acetone temperature. The solution was stirred for 30 sec after the creation of each new mercury drop electrode to assure the attainment of adsorption equilibrium.

### Results and Discussion

The primary data resulting from chronocoulometric experiments are the amounts of adsorbed reactant as a function of bulk reactant concentration, initial electrode potential, and supporting electrolyte composition. The simplest cases are those in which there is little or no specific adsorption of the ions comprising the supporting electrolyte. Sodium fluoride supporting electrolytes were employed for this purpose.

**Adsorption from fluoride electrolyte.**—Table I contains a typical set of data obtained with 0.5F NaF supporting electrolyte of pH 8.9 (0.01F Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>). (In this and the following tables the values of  $q^m$  are for the supporting electrolyte containing AQS at the specified concentrations.) The data are quite insensitive to the concentration of NaF or even of AQS down to 0.02 mF. The main points of interest are the virtual absence of any potential dependence of the adsorption

and the very small values of  $\Delta q^m$ , the changes in the charge on the electrode, produced by the adsorption. The coverage of the electrode by the AQS in this solution is quite substantial; geometrical calculation of the amount of AQS required to produce a monolayer of flatly adsorbed molecules leads to values ranging from  $1.5\text{--}2.1 \times 10^{-10}$  moles/cm<sup>2</sup> depending on the closeness of the two-dimensional packing. The virtual absence of a dependence on the AQS concentration in the data in Table I suggests that the electrode surface is essentially saturated with AQS in these fluoride solutions.

**Adsorption from thiocyanate electrolytes.**—Table II contains data obtained with sodium thiocyanate supporting electrolytes in order to examine the effect of strong anionic adsorption on the adsorption of AQS. The much smaller adsorption of the AQS and the much greater potential dependence of its adsorption are clearly evident. A remarkable feature is the very small changes in the electronic charge on the electrode produced by the adsorption of AQS. The strong adsorption of thiocyanate ions in the pure electrolyte makes the charge on the electrode much greater in thiocyanate than in fluoride solutions. The decrease (usually) in this charge produced by the adsorption of AQS is much smaller than the charge difference between pure fluoride and thiocyanate solutions which clearly shows that very little if any of the adsorbed thiocyanate is desorbed by the AQS adsorption. However, there certainly is a strong antagonistic interaction between the adsorbed thiocyanate and AQS as is evidenced in the large dependence of the AQS adsorption upon thiocyanate concentration and potential. The magnitude of the potential dependence of the adsorption of AQS in thiocyanate solutions seems too great to be attributable to direct interactions between the adsorbed AQS and the electrode because of the very much smaller potential dependence observed in fluoride solutions (Table I). It appears, therefore, that the chief effect of the adsorption of thiocyanate is to interfere with the compactness of the AQS layer by interposition. [Damaskin has explained the effect of halide ions on butanol adsorption in the same way (28).] For example, at -300 mv in 0.1F NaSCN solution 21.5  $\mu\text{C}/\text{cm}^2$  of thiocyanate is adsorbed (29). This corresponds to about 15% of the maximum possible (hexagonally closest packed) coverage with thiocyanate ions (30) and allows a separation of about 8Å between thiocyanate ions. Addition of 0.10 mF AQS leads to about one-half of the electrode's surface being covered with AQS molecules without appreciable loss of the adsorbed thiocyanate ions which are presumably scattered throughout the AQS layer.

An alternative possibility is that the thiocyanate ions are adsorbed "on top of" the adsorbed AQS. This

seems unlikely because one might then expect the adsorption of AQS to diminish the amount of adsorbed thiocyanate rather than *vice versa*, as observed.

Another possible explanation is that strong specific adsorption of anions "salts-out" the AQS from the electrode surface back into the bulk of the solution. This possibility has been discussed by Conway and Barradas in the case of aromatic amine adsorption (17).

*Adsorption from nitrate electrolytes.*—Table III contains extensive data obtained with sodium nitrate supporting electrolytes. The general features of the data are understandable on the basis of the data for fluoride and thiocyanate electrolytes. Nitrate ion is much less strongly adsorbed than thiocyanate so that the AQS adsorption shows smaller potential and nitrate concentration dependences than are observed in thiocyanate. Nevertheless, these dependences are clearly present in the nitrate electrolytes under conditions where they are absent in fluoride electrolyte. The charge changes produced by AQS adsorption in nitrate are also very small and indicate that little or none of the adsorbed nitrate is desorbed by the adsorption of AQS. This feature is somewhat more surprising with nitrate than it was for thiocyanate because of the generally weaker adsorption of nitrate. However, the nitrate coverages are much smaller and it may be that only a small perturbation of the adsorbed array of nitrate ions is produced by the adsorption of even a 0.7-0.8 monolayer of AQS.

At the highest concentration of AQS (0.5 mF) an anomaly appears in that the charge on the electrode appears to fall below the value in pure fluoride solutions even though comparable AQS adsorption in fluoride electrolyte has almost no effect on the electrode's charge. It seems likely that the values for  $q^m$  obtained in this experiment in nitrate media are erroneously small, possibly because at the highest concentration of AQS the product of the electrode reaction is not completely desorbed at -1400 mv and so depresses the measured double layer charge.

The data for nitrate show an apparent reversal in the dependence of the adsorption upon nitrate concentration. At low concentrations of AQS the adsorption decreases as the nitrate concentration increases presumably for the same reasons that were discussed in the case of thiocyanate electrolytes. At the highest concentration of AQS its adsorption appears to increase slightly with the nitrate concentration. This may be a reflection of a "salting out" of the organic compound from the solution as its ionic strength increases; the equilibrium solubility of AQS is only about 1.0 mF in 1F NaNO<sub>3</sub>.

*Mixed adsorption from p-toluene sulfonate electrolyte.*—The adsorption of p-toluene sulfonate anions (PTS) on mercury has been studied by Parry and Parsons (31). Higher concentrations of PTS are required to produce adsorption comparable to that displayed by AQS but in other respects these two aromatic sulfonates behave similarly. In particular, the adsorptions of both AQS and PTS show a very small potential dependence at positively charged electrodes. With high concentrations at negatively charged electrodes PTS adsorption displays a greater potential dependence which Parry and Parsons have attributed to a change from a flat orientation of the molecules on the electrode surface to a more perpendicular orientation.

Table IV contains data obtained with solutions containing both PTS (as supporting electrolyte) and AQS. A definite potential dependence of the AQS adsorption is apparent which contrasts with the behavior of either anion when present alone at the same concentrations. This behavior may result because the much more strongly adsorbing AQS forces the adsorbed PTS to convert to the perpendicular orientation at less negative potentials than are required in pure solutions of PTS.

*Effect of adsorbed AQS on electrode reactions.*—Having established that mercury electrodes in solutions of AQS are coated with almost a monolayer of adsorbed AQS it was of interest to investigate how other electrode reactions are affected by the adsorbed AQS. Two likely effects could be anticipated: The adsorbed organic compound might simply block off a major fraction of the electrode area thus decreasing the rate of other electrode reactions. In addition, a rather large double layer effect due to the adsorbed AQS seemed likely because it is an anion which is extensively adsorbed without much change in the electronic charge on the electrode (see Table I-III). This means that the potential at the outer Helmholtz

Table IV. Adsorption of AQS from p-toluene sulfonate (PTS) electrolyte

-300	7.2	0.56	+0.5
-400	4.7	0.61	+0.8

plane,  $\phi_2$ , must become much more negative when AQS is adsorbed.

To test these expectations, the reductions of  $\text{Co}(\text{NH}_3)_6^{+3}$  and  $\text{CrO}_4^{-2}$  were examined polarographically in a supporting electrolyte consisting of 0.1F  $\text{NaNO}_3$  and 0.01F  $\text{Na}_2\text{B}_4\text{O}_7$  (pH 8.9) in the absence and presence of 0.1 mF AQS. No evidence for any blocking of the electrode surface was observed and it seems likely that these electrode reactions are able to proceed via the flatly adsorbed AQS molecules about as well as on the uncoated mercury surface.

By contrast, the double layer effects observed were quite large. The half-wave potential for  $\text{Co}(\text{NH}_3)_6^{+3}$  reduction shifted from  $-0.24$  to  $-0.15\text{v}$  vs. SCE and that for  $\text{CrO}_4^{-2}$  reduction shifted from  $-0.31$  to  $< -0.55\text{v}$  vs. SCE upon addition of 0.1 mF AQS. Quantitative correlation with theoretical diffuse layer calculations of the changes in the  $\phi_2$ -potentials needed to account for the observed shifts in half-wave potentials, such as those recently employed in cadmium-iodide solutions (9), were not attempted in this case because of the time dependence of the amount of adsorbed AQS at the d.m.e. Nevertheless, the qualitative behavior is entirely in accord with the idea that AQS adsorption leads to a large change in the potential,  $\phi_2$ , at the outer Helmholtz plane. These results make it clear that the sulfonate group which carries the negative charge in the AQS molecule is not coordinated with a sodium or hydrogen ion in the adsorbed state, an interpretation which seemed possible on the basis of the very small changes in  $q^m$  which the adsorption of AQS produces.

To rule out the possibility that the observed behavior of AQS was, for some reason, atypical, the polarographic experiments with  $\text{Co}(\text{NH}_3)_6^{+3}$  and  $\text{CrO}_4^{-2}$  were repeated with 0.1M sodium p-toluene sulfonate as supporting electrolyte because Parry and Parsons (31) have shown that this organic anion is adsorbed to about the same extent in 0.1F solutions as is AQS in 0.1 mF solutions. The shifts in half-wave potentials were very similar to those in the case of AQS: for  $\text{Co}(\text{NH}_3)_6^{+3}$   $E_{1/2} = -0.17$ ; for  $\text{CrO}_4^{-2}$   $E_{1/2} = -0.48\text{v}$  vs. SCE.

It thus appears that the adsorptions of both AQS anions and p-toluene sulfonate anions affect other electrode reactions only indirectly by means of the changes in the  $\phi_2$ -potential produced by the anion adsorption. This behavior adds support to the assumption that the AQS molecules are adsorbed flatly on the electrode with the sulfonate group protruding no further than the compact layer.

# Anodic Oxidation Pathways of Carbazoles

## I. Carbazole and N-Substituted Derivatives

J. F. Ambrose and R. F. Nelson

*Department of Chemistry, Sacramento State College, Sacramento, California*

### ABSTRACT

Electrochemical and spectroscopic techniques have been employed in elucidating the anodic oxidation pathways of carbazole and several N-substituted derivatives. For carbazole and the N-alkyl or N-aryl derivatives, ring-ring coupling is the predominant decay pathway of the carbazole cations; the coupling rates are extremely rapid. N-N coupling is observed initially for carbazole, but in long-time electrolysis it is of little consequence. The oxidation products have been synthesized by chemical means and compared with the species formed electrochemically by matching of cyclic polarograms and visible absorption spectra. Molecular orbital calculations give a qualitative picture of active sites with regard to follow-up coupling reactions in the carbazole series. N-vinyl, N-acetyl, N-benzoyl, and N-nitroso carbazole were investigated briefly but found to be extremely complicated.

The area of anodic oxidations of heterocyclic molecules has received little attention in the past. A great deal of work on electrochemical reductions of these molecules is well documented (1); this makes the paucity of data on oxidations even more surprising. In contrast to electrochemical studies, a good deal of work on chemical oxidations of heterocyclics, in general, and carbazoles, in particular, has been published. It is not an uncommon situation when chemical and electrochemical oxidation pathways do not coincide, so the study of substituted carbazoles by electrochemical means was undertaken in order to compare these data with those from chemical oxidation studies. A number of differences and similarities were found and are reported herein.

Background material on the chemical oxidation work is extensive and merits mention. The first significant work was carried out independently by groups under Branch (2, 3) and Tucker (4). Branch and co-workers employed silver oxide as an oxidant and obtained two products, one of which was suspected as being 9,9'-dicarbazyl.<sup>1</sup> With permanganate in acetone, Tucker obtained a mixture of three products, designated A, B, and C. By synthesis of several possible dicarbazyls, the 3,3' (5), 9,9' (6), 1,1' (7) and 3,9' (8) isomers, it was determined that dicarbazyl A was in fact 9,9'-dicarbazyl. None of the other isomers could be identified as B or C. Subsequent work has shown that dicarbazyl B is really a tricarbazyl (9). Compound C had defied identification until just recently. It was, in fact, found to be several polymeric carbazole species whose structures were inferred from spectroscopic data (10).

Tucker also demonstrated that the oxidizing medium can affect the product distribution markedly; in an acetic acid/sulfuric acid mixture with dichromate present, only 3,3'-dicarbazyl was obtained (11). N-alkylated carbazoles also gave the respective 9,9'-dialkyl-3,3'-dicarbazyls (11). With the sulfuric acid absent, carbazole was oxidized to 9,9'-dicarbazyl (6). It is apparent from all these data that the coupling products formed depend markedly on solvent and ox-

idizing agents. A more definitive study along these lines has recently been published (12). It has been our experience that quite often electrochemical oxidations are somewhat more selective than their chemical counterparts, and it was hoped that this would be the case for the carbazoles. This hope was, in the main, confirmed. The formation of 3,3'-dicarbazyls is the predominant pathway by far; all others, with one notable exception, are undetectable.

Standard electrochemical and spectrophotometric techniques were employed to study the electrode processes and associated chemical reactions in these systems. These techniques have been amply reviewed, and it is assumed that the reader is familiar with them. The coupling rates are very rapid and radical stabilities are quite low, so the mechanisms could not be completely elucidated. However, a rather clear picture of the oxidation pathways of simple carbazoles has emerged; this, combined with further work now in progress on ring-substituted carbazoles, will hopefully yield a general interpretation of the electronic distribution and anodic oxidation pathways of these molecules.

### Experimental Section

The procedures for purification of solvent (acetonitrile, denoted hereafter as MeCN) and supporting electrolyte (tetraethylammonium perchlorate, TEAP), as well as the electrodes and cell employed, have been discussed elsewhere (13). The multipurpose electrochemical instrument used for cyclic voltammetry, chronoamperometry, and chronopotentiometry incorporates solid-state circuitry into the basic Booman-Deford design. Moseley 7035B X-Y and 7101B strip chart recorders were used in conjunction with this instrument.

For rotating disk voltammetry, an apparatus employing a synchronous motor and gears was employed. This afforded a range of rotation rates between 580 and 3000 rpm with an accuracy of better than 0.5%. Rotation rates were checked on each run with a Strobotac unit. The electrode was constructed according to the recipe of Marcoux and Adams (14).

Controlled potential electrolyses were carried out with a Wenking 61RH fast-rise potentiostat using a large platinum gauze as the working electrode and a carbon rod as the auxiliary. They were separated by a medium porosity frit in a cell designed for fairly rapid electrolysis. In experiments designed to obtain "n-values," the electrolysis time was typically 8-10 min. For large-scale work, the duration of electrolysis was in the neighborhood of 1 hr. In the n-value experiments, the amount of current passed was determined by taking the output of the potentiostat and

<sup>1</sup>The numbering system for the molecules discussed herein is shown below.

recording current *vs.* time on the strip-chart recorder. The number of coulombs passed was obtained by the area under the current-time curve. These results were reliable to  $\pm 3-4\%$ .

Visible absorption spectra were obtained with a custom-made optical cell (Precision Glass Products, Oreland, Pennsylvania) which was positioned within the cavity of a Cary Model 14 spectrometer. The cell has a thin quartz window with a platinum gauze fitting into it; the light beam of the spectrometer passes through this window, thus ensuring sufficient electrolysis in the light path. The cell operates in a three-electrode configuration in conjunction with the Wenking potentiostat. The auxiliary electrode was spatially removed (3 cm) from the working electrode to avoid mixing of electrolysis products. To insure that colored species were not formed at the auxiliary electrode, a saturated calomel electrode (SCE) was employed. The reference SCE was positioned as close to the gauze as possible, usually about 1-2 mm away.

Infrared spectra were recorded with a Perkin-Elmer 337 Grating infrared Spectrometer. Carbazoles and dicarbazyls show the usual bands for substituted ring compounds. Of particular diagnostic value are the out-of-plane bending bands. Carbazole, 9,9'-dicarbazyl and the N-substituted carbazoles all show the band due to ortho disubstitution at  $750\text{ cm}^{-1}$ . In addition, 3,3'-dicarbazyl and the N,N'-substituted-3,3'-dicarbazyls show bands due to 1:2:4 trisubstitution at 800 and  $880\text{ cm}^{-1}$ . N-phenylcarbazole and 9,9'-diphenyl-3,3'-dicarbazyl also gave a band due to monosubstitution at  $700\text{ cm}^{-1}$ . N-substituents all show the appropriate stretching bands. Products mentioned in the text were characterized by their infrared spectra according to these diagnostic bands.

Products from large-scale controlled potential electrolyses were isolated by stripping off the acetonitrile and extracting the residue with a nonpolar organic solvent to obtain the desired product or by extracting the TEAP with water, leaving the organic residue. The much higher solubilities of carbazoles over dicarbazyls in ethanol afforded separation of starting materials. In some cases, the dicarbazyl perchlorate salts precipitated out of solution during electrolysis. These were collected and washed with large volumes of benzene and ethanol.

Carbazole was obtained commercially from Aldrich and Southern Dyestuff and purified by sublimation followed by crystallization from boiling acetic acid, washing in water, and drying to give mp  $246^{\circ}-247^{\circ}$ .

9-Methylcarbazole was prepared by adding 0.12 mole of sodium metal to 0.10 mole of carbazole in 500 ml of toluene; the mixture was boiled for 15 min to remove water and refluxed for 48 hr. The resulting white precipitate was separated from the solvent and unreacted sodium and dissolved in 300 ml of dry acetone. Methyl iodide (0.20 mole) was added and the whole refluxed for 1 hr. The mixture was treated with a water-benzene solution and the benzene phase chromatographed on basic alumina. On addition of heptane to the eluent, 9-methylcarbazole was obtained in nearly quantitative yield. It was then chromatographed on alumina with benzene and recrystallized from benzene-ethanol, mp  $91^{\circ}$ .

9-Ethylcarbazole was obtained from Southern Dyestuff and purified by chromatographing with benzene on neutral alumina to give mp  $68^{\circ}-69^{\circ}$ .

9-Isopropylcarbazole (Eastman Chemical Company, mp  $118^{\circ}-119^{\circ}$ ), 9-phenylcarbazole (K & K Laboratories, mp  $94^{\circ}-95^{\circ}$ ) and 9-vinylcarbazole (K & K Laboratories, mp  $91^{\circ}-94^{\circ}$ ) were used directly without further purification.

9-Nitrocarbazole was prepared by the method of Eikhman *et al.* (15) to give mp  $81^{\circ}$ .

9-acetylcarbazole (mp  $78^{\circ}-79^{\circ}$ ) and 9-benzoylcarbazole (mp  $98^{\circ}-99^{\circ}$ ) were prepared by the method of Berlin (16).

9,9'-Dicarbazyl was synthesized by the method of Perkin and Tucker (4), mp  $226^{\circ}-227^{\circ}$ .

3,3'-Dicarbazyl was unambiguously synthesized by the method of Tucker (5) and purified by sublimation to give mp  $375^{\circ} \pm 3^{\circ}$  (measured by comparison with indicating liquid supplied by the Tempil Corporation). Sublimation was observed to take place above  $350^{\circ}$ .

9,9'-Dimethyl-3,3'-dicarbazyl (mp  $201^{\circ}-203^{\circ}$ ) and 9,9'-diethyl-3,3'-dicarbazyl (mp  $189^{\circ}-190^{\circ}$ ) were prepared by the method of Wieland (17).

## Results and Discussion

**Carbazole.**—The electrochemical oxidation of carbazole, the parent molecule, will be discussed first in some detail. The various N-substituted derivatives will then be mentioned. Table I summarizes the electrochemical data for the molecules studied. Data for the first oxidation process of 5,10-dihydro-5,10-dimethylphenazine (DMPZ) are included in order to compare the carbazole data with a reversible one-electron system (18). Electrochemical data are not tabulated for the nitroso, acetyl, benzoyl, and vinyl derivatives because of the poorly defined curves obtained. The data varied so badly that it was not felt justifiable to present them.

Carbazole is oxidized at a potential of *ca.*  $+1.2\text{v}$  *vs.* SCE, presumably to the cation radical which is quite unstable. Due to this high degree of instability, there is no direct electrochemical or spectroscopic evidence for the cation radical. A previous report had cited stabilization of the carbazole cation radical as carbazole $^{+\cdot}-\text{BF}_4^{-}$  (18), but recent work indicates that it was probably the dicarbazyl radical being observed (19). Also, electrochemical oxidation of carbazole in the presence of tetrabutylammonium  $\text{BF}_4$  showed the system to be totally irreversible (20). However, substituted carbazoles, where the nitrogen and the 3- and 6- ring positions are blocked with substituents, are electrochemically reversible (21). The electrochemical one-electron reversibility of a carbazole with the active coupling sites blocked with substituents infers similar behavior for carbazole itself. The characteristics of these systems are very much like those of triphenylamines (13), which are structurally similar to carbazole, so it is felt that the proposal of the cation radical as the initial intermediate is not unwarranted. This highly reactive cation radical then couples either with another cation radical or with a parent molecule to form, initially, two kinds of dicarbazyls. These coupling reactions involve the loss of two protons per dicarbazyl formed (or one proton per carbazole nucleus); it cannot be determined whether the protons are lost before or after coupling. Of the two dicarbazyls formed, the 3,3'

isomer is the predominant product. This species is more easily oxidized than carbazole, so at the applied potential the dicarbazyl undergoes two successive reversible one-electron redox steps to yield the quinoidal dication. This species is relatively unstable in the presence of carbazole and further slow follow-up reactions occur. Another dicarbazyl, the 9,9' isomer, is formed in small amounts and does not oxidize electrochemically until far anodic potentials, and its oxidation pathway is not known. The general reaction scheme is given below.

A fair amount of evidence is available for the proposed oxidation pathway. The oxidation of carbazole has all the characteristics of a classical ECE mechanism, where each electrochemical step involves one electron per parent molecule. The peak current for the primary oxidation wave is just about twice that of a reversible one-electron process, as seen in Table I by comparison with DMPZ. Had the primary oxidation been a two-electron process, the peak current would have been about 2.83 times that of DMPZ (22, 23). There is also a steady anodic shift of  $E_{p/2}$  with increasing scan rate (about 60 mv per 10-fold increase), indicative of an ECE system (22). A decrease in  $ip/v^{1/2}C$  with increasing  $v$  is not observed because in the carbazole system the coupling reaction is very rapid. Due to the fact that the coupling reactions are so rapid, and the primary oxidation wave is a mixture of ECE and EC processes, little could be ascertained regarding the kinetics of the system. Attempts were made to determine just an approximate coupling rate via potentiostatic and rotating disk measurements, but these experiments were uniformly unsuccessful. In both cases, at the upper limit of measurement available, the current for carbazole oxidation could not be diminished substantially below two electrons. The coupling reactions are indeed quite rapid; calculations from rotating disk polarograms at 3000 rpm, using a diffusion coefficient of  $2.0 \times 10^{-5}$  cm<sup>2</sup>/sec (that of DMPZ determined from linear scan voltammetry, chronoamperometry, chronopotentiometry, and rotating disk voltammetry), set a lower limit of  $k$  at  $3 \times 10^7$  l. moles<sup>-1</sup> sec<sup>-1</sup>.

Structures A, B, and C in the above scheme are the most important resonance forms for the carbazole radical cation. Electron densities represented by the squares of the atomic orbital coefficients ( $c^2$ ) from simple HMO theory show that the reactive sites are the 1, 3, 6, 8, and 9 positions. The 3, 6, and 9 positions should be readily available as coupling sites; the 1 and 8 carbons are somewhat sterically hindered

due to the rather rigid structure of carbazole. Therefore, the formation of 1,1'-dicarbazyl from resonance form C seems unlikely and in fact, has not been observed.

Figure 1 gives a qualitative picture of the carbazole system in MeCN. The initial oxidation wave at +1.2v vs. SCE is followed by another anodic peak at  $\pm 1.8$ v which appears to be due to a small amount of 9,9'-dicarbazyl. Figure 2 is a cyclic polarogram of an authentic sample of 9,9'-dicarbazyl; one sees that the far anodic wave matches up nicely with the second oxidation peak in the carbazole system. Figure 2 also shows a small wave at +1.45v which appears to be missing in the carbazole system. However, this is a relatively small peak and is probably just "buried" in the trailing portion of the primary oxidation wave of carbazole. In fact, if one enhances the current sensitivity so that the primary oxidation peak grinds off scale, and scans very slowly, this buried peak is seen clearly, although it is not as well defined as in Fig. 2.

The direction of scan is reversed at +2.0v, and on cycling back, cathodic peaks are observed in the region from +1.2 to +0.8v. These compare reasonably well with an authentic sample of 3,3'-dicarbazyl (Fig. 1B). The cathodic wave at +0.1v corresponds to reduction of protons released in the coupling reactions. On the second anodic-going scan, oxidation of the

Fig. 1A. Cyclic polarogram of  $2.0 \times 10^{-3}$ M carbazole in MeCN/0.1M TEAP; scan rate is 4.8 v/min on a Pt button electrode. B, Cyclic polarogram of saturated solution (approximately  $1 \times 10^{-4}$ M.) of 3,3'-dicarbazyl in MeCN/0.1M TEAP; scan rate is 4.8 v/min on a Pt button electrode. For both, abscissa is in volts vs. SCE.

Fig. 2. Cyclic polarogram of  $1.0 \times 10^{-3}$ M 9,9'-dicarbazyl in MeCN/0.1M TEAP; scan rate is 4.8 v/min on a Pt button electrode. Abscissa is volts vs. SCE.

3,3'-dicarbazyl is seen, but there is essentially no oxidation of 9,9'-dicarbazyl. From Fig. 2 it is seen that there is a similar type of behavior for the authentic 9,9'-dicarbazyl, but what actually occurs is not known at this time.

The cyclic polarogram of Fig. 1 shows the carbazole system as being relatively uncomplicated, *i.e.*, a straightforward ECE. However, chronoamperometric and chronopotentiometric data show that somewhat more than two electrons are consumed per carbazole molecule (Table I). The *n*-value determination also varies from 2.5-2.8, the larger value being at longer electrolysis time. Even in a 5-min electrolysis, though, one obtains about 2.5 electrons per carbazole and a steady-state current is obtained on the tail of the current-time curve. This all points to a slow follow-up reaction in the dicarbazyl system. The reaction is apparently between carbazole and dicarbazyl because an *n*-value of 1.92 was obtained for 3,3'-dicarbazyl. The absence of similar behavior in the *N*-substituted derivatives suggests that the unsubstituted nitrogens of the carbazole and/or dicarbazyl are involved. This would lead to products of the type characterized by Waters by chemical oxidation of carbazole (10).

The initial, but not continued, formation of 9,9'-dicarbazyl in the carbazole system appears to be contingent upon a low proton concentration in the area around the electrode. After a few seconds of electrolysis, a rather large number of protons accumulate in the vicinity of the electrode surface, and further formation of the 9,9'-dicarbazyl is inhibited. In fact, addition of  $H_2SO_4$  to a carbazole solution suppresses the 9,9'-dicarbazyl wave, and addition of pyridine (to act as a proton scavenger) enhances it considerably. These phenomena have also been observed in the chemical oxidation work (10, 11). Further studies are now being carried out to determine whether these acid-base effects are general for nonaqueous electrochemical oxidations.

Since peak assignments are by no means conclusive by themselves in studies of this type, another method of identification of products was deemed necessary. *In situ* electrolysis in a Cary spectrometer shows absorption maxima at about 380 and 760  $m\mu$  for both carbazole and 3,3'-dicarbazyl, as shown in Fig. 3. The shorter wavelength band probably corresponds to the dicarbazyl cation radical (by comparison with benzi-

Fig. 3. Visible absorption spectra obtained by *in situ* electrolysis in a Cary 14 spectrometer: A, background scan; B, saturated solution (approximately  $1 \times 10^{-4}M$ ) of 3,3'-dicarbazyl electrolyzed at  $+1.3v$ ; C,  $1.0 \times 10^{-3}M$  carbazole electrolyzed at  $+1.3v$ .

dines of similar structure (12) and spectra obtained by *in situ* electrolysis at the foot of the first oxidation wave of 3,3'-dicarbazyl) and the other band appears to be due to the 3,3'-dicarbazyl dication and/or a dicarbazyl perchlorate salt that forms, presumably from the highly conjugated dication.

The 9,9'-dicarbazyl could not be detected at all spectrophotometrically due to the fact that electrolysis of an authentic sample produces only a weak band with  $\lambda_{max} = 425\mu$ . In the carbazole system, this band would be smothered by the 3,3'-dicarbazyl cation peak, which exhibits an intense absorbance in the same region.

Electron paramagnetic resonance (epr) was also employed in order to determine that 3,3'-dicarbazyl was the principal electrolysis product. *In situ* electrolysis in the cavity of a Varian E-3 epr spectrometer of both carbazole and 3,3'-dicarbazyl resulted in identical single-line spectra of the same shape and width.

Controlled potential electrolysis of carbazole in MeCN produced only 3,3'-dicarbazyl and the perchlorate salt; infrared spectra of electrolysis products revealed no detectable amount of 9,9'-dicarbazyl or any other product. Interestingly, in the presence of pyridine, only 9,9'-dicarbazyl is formed.

*N*-substituted carbazoles.—A series of *N*-substituted carbazoles was also studied and found to behave in a similar manner to carbazole. *N*-ethyl and *N*-methyl carbazole were investigated in some detail; the *N*-isopropyl and *N*-phenyl derivatives appeared to follow the same reaction pathway. Figure 4 shows the cyclic polarogram for oxidation of *N*-ethylcarbazole. Here, formation of 9,9'-dicarbazyl cannot occur, so only the 9,9'-diethyl-3,3'-dicarbazyl is seen. The cyclic polarogram of an authentic sample of the dicarbazyl matches up nicely (polarogram B), as do the visible absorption spectra (Fig. 5). The formation of dicarbazyl is quantitative, as shown by reverse-current chronopotentiometry (RCC) with unequal current densities. If  $i_r = 0.414i_f$  and  $n_f$ , the number of electrons involved in the forward (oxidation here) process, is two while  $n_r$ , the *n*-value for the reverse process, is one, a ratio of  $\tau_f/\tau_r$  of 2.34 should be obtained (24). In fact, at a number of different current density ratios, a quotient of transition times between 2.3 and 2.4 was obtained for *N*-ethyl carbazole, as well as for the methyl, isopropyl, and phenyl analogs.

These *N*-substituted carbazoles form dicarbazyls that are extremely stable, so they are pure ECE systems. The stability of the dicarbazyls is attested to by the *n*-values in Table I; all are two electrons,

Fig. 4A. Cyclic polarogram of  $2.0 \times 10^{-3}M$  *N*-ethylcarbazole in MeCN/0.1M TEAP; scan rate is 9.7 v/min on a Pt button electrode. Fig. 5. Visible absorption spectra obtained by *in situ* electrolysis in the Cary 14 spectrometer. A, background scan; B,  $1.0 \times 10^{-3}$  M N-ethylcarbazole electrolyzed at +1.2v; C,  $5.0 \times 10^{-4}$  M, 9,9'-diethyl-3,3'-dicarbazyl electrolyzed at +1.2v.

within experimental error. The quantitative aspect of these systems is further illustrated in Fig. 6. The cyclic polarogram is that of a solution of N-ethylcarbazole that has been exhaustively electrolyzed at +1.4v vs. SCE. The scan is initiated in the cathodic direction; a large wave due to reduction of protons is first encountered. The peak current corresponds to 1.11 millimoles of protons per millimole of N-ethylcarbazole by comparison with a picric acid calibration curve (25). This is consistent with the proposed mechanism. In addition, the dicarbazyl waves shown on the anodic-going scan have peak currents whose magnitude indicate a concentration just half that of the parent carbazole, within experimental error. Since the coupling reaction is bimolecular, this is to be expected.

Electrochemical and spectroscopic data for the methyl, isopropyl, and phenyl derivatives are identical to the N-ethylcarbazole data. The 9,9'-dimethyl-3,3'-dicarbazyl was synthesized also and compared with the electrochemical oxidation product from N-methylcarbazole.

Table II summarizes the spectral data characterizing the various 3,3'-dicarbazyls. The shorter wavelength bands,  $\lambda_1$ , were generally much sharper and the other

-C <sub>6</sub> H <sub>5</sub>	411	800

group,  $\lambda_2$ , was characterized by broadness and ill-defined shoulders toward the blue.

The N-phenyl derivative is of some interest from an HMO viewpoint. If it is assumed that the molecule were planar (no twist of the phenyl ring), the electron density ( $c^2$ ) is greater at the *para* position on the N-phenyl ring (0.096) than at the 3-position in the carbazole nucleus (0.074). However, with a moderate twist of about 20°-25°, the electron density is considerably greater in the carbazole portion of the molecule, and one would now expect to obtain a 3,3'-dicarbazyl upon electrochemical oxidation of N-phenylcarbazole. A fair degree of twisting is really to be expected because of steric crowding of the phenyl ring with the 1- and 8-position protons and, in fact, isolation of the electrolysis product from a controlled-potential oxidation of N-phenyl carbazole and analysis of its infrared spectrum shows that 9,9'-diphenyl-3,3'-dicarbazyl is the electrolysis product.

The remaining N-substituted carbazoles, *viz.*, N-acetyl-, N-benzoyl-, N-nitroso-, and N-vinylcarbazole, all exhibit complex electrochemical behavior. It may well be that the N-substituents are taking part in the chemical reactions following the initial electron transfers. Their electrochemical data are listed in Table I, but no serious attempts were made to characterize their anodic oxidation pathways. Each appears to be a formidable problem in itself!

#### Acknowledgment

Special thanks are due to Southern Dyestuff Company for the donation of several carbazoles and to Dr. S. H. Tucker for helpful suggestions and encouragement. Technical assistance from Dr. P. Maitland and S. Creason are appreciated. Financial support through a Frederick Gardner Cottrell Research Corporation grant and PRF Grant No. 1039-G3 are also gratefully acknowledged.

Manuscript received July 8, 1968.

Any discussion of this paper will appear in a Discussion section to be published in the June 1969 JOURNAL.

## Electrochemical Behavior of H<sub>2</sub>O in Nonaqueous Electrolyte

Brian Burrows\* and Susan Kirkland

Tyco Laboratories, Inc., Waltham, Massachusetts

### ABSTRACT

The electrochemical behavior of trace quantities of water (1-30 mM) in LiClO<sub>4</sub>-propylene carbonate solutions was studied *via* chronopotentiometric and cyclic voltammetric techniques. It was observed that, with platinum electrodes, the chronopotentiometric constant increased with increasing current density up to a constant limiting value at high current densities. Analysis of the cyclic voltammetric results showed analogous behavior. The reaction product of H<sub>2</sub>O reduction was inferred to be a porous, insoluble film of LiOH. This layer apparently acts to block part of the electrode surface thereby increasing the effective current density, decreasing  $\tau$  and hence  $i\tau^{1/2}$ . From the concentration dependence of  $i\tau^{1/2}$  and of  $i_p/v^{1/2}$  it was further inferred that strong complexes were formed between water and Li<sup>+</sup> ion which decreased the activity coefficient of H<sub>2</sub>O. Current reversal subsequent to the reduction step showed an oxidation step which may be associated with an adsorbed film of atomic hydrogen on the platinum surface.

The present interest in high energy density batteries based on lithium anodes has generated much activity in the area of aprotic organic solvents, particularly in the use of propylene carbonate (4-methyldioxolone-2) as a solvent medium. Little work pertaining to electrode reactions in this medium has been reported in the open literature (1), due, in part, to the unavailability of solvent with sufficient purity. Recent improvements in purification have reduced the major impurity content to less than 2 ppm H<sub>2</sub>O and  $\leq$  12 ppm propylene glycol (2). The behavior of these substances on smooth electrodes can now be studied with reasonable precision.

Water is a particularly ubiquitous impurity in aprotic organic solvents; hence its behavior is a matter of interest in relation to any electrochemical investigation in these media. In this paper we present the results of chronopotentiometric and cyclic voltammetric investigations in a PC/LiClO<sub>4</sub> solution containing H<sub>2</sub>O. The concentration of H<sub>2</sub>O was varied over the range 10<sup>-3</sup> to 3 x 10<sup>-2</sup>M, *i.e.*, from 20 to 500 ppm. Dey (3) has published a report on the electrochemical behavior of H<sub>2</sub>O in the same solution but at higher concentrations.

### Experimental

The cell, contained inside a recirculating argon-atmosphere dry box (Vacuum Atmosphere Corporation) was operated at 28° ± 0.2°C.

Chronopotentiograms were recorded on an X-Y recorder (Houston Omnigraphic, model HR-98T). A unity-gain follower, constructed from an operational amplifier (Philbrick, type P65AU), was used in the potential measuring circuit to avoid undue loading of the reference electrode-working electrode cell. A constant-current power source (Electronic Measurements, model C623) supplied the current at voltages up to 400v. A toggle switch was adequate to switch in the constant current, since transition times less than 0.5 sec were not measured.

The cyclic voltammograms were recorded on the same X-Y recorder. The cathode follower described above was used to increase the effective input impedance of the recorder. A triangular waveform from a function generator (Exact Electronics, Inc., type 255) was fed into the input of a Wenking potentiostat (type 61RS) to give a potentiostatic *i-v* curve.

The electrochemical cell had three compartments with the middle (working electrode) compartment separated from the reference electrode compartment by a Luggin capillary and separated from the counter electrode compartment by a fritted glass junction.

The reference electrode used in all the experiments was based on the Li/Li<sup>+</sup> couple. This was formed by simply immersing a Li rod in the PC/LiClO<sub>4</sub> solution (4). A Pt foil was used as the counter electrode. The working electrode for the cyclic voltammetric scans was made up from 0.05 cm diameter Pt wire sealed into Pyrex. Lengths of wire up to 1 cm were left exposed. The working electrode for the chronopotentiometric experiments was a Beckman No. 39723 Pt disk electrode (0.204 cm<sup>2</sup>) mounted horizontally in the working electrode compartment just above the Luggin capillary. The electrode was polished with alumina powder on a lapping wheel before use. Before each measurement it was also necessary to clean the electrode by dipping it into conc. HNO<sub>3</sub>, followed by washes in distilled H<sub>2</sub>O and in acetone. When the electrode was not cleaned after each measurement of transition time or current-peak height, irreproducible and poorly defined curves were recorded.

The solutions of LiClO<sub>4</sub> in PC were made up from distilled PC (2) and anhydrous LiClO<sub>4</sub> (K & K Laboratories, Inc.) and then dried by passing twice over ground Linde 4A Molecular Sieves. Flame photometric analysis showed a negligible loss of Li<sup>+</sup> as a result of ion exchange processes with the sieves. After two passes the transition time corresponding to H<sub>2</sub>O (or glycol) was not detectable. However, some water (or glycol) was detected by the more sensitive cyclic voltammetric technique (see below).

\* Electrochemical Society Active Member.

Portions of this dried PC/LiClO<sub>4</sub> solution were taken and the required concentration of H<sub>2</sub>O added with a syringe. Alternatively, some of the solutions low in H<sub>2</sub>O were made up by a dilution procedure from a solution containing 1000 ppm H<sub>2</sub>O. The results were identical to those obtained in solutions prepared by direct addition.

### Results and Discussion

**Background current.**—The potential at which water was reduced was determined from cyclic voltammograms of the appropriate solutions. An *i-v* trace showing the background current in a PC/LiClO<sub>4</sub> (1M) solution which had been dried over molecular sieves is shown in Fig. 1. The broad reduction peak at +1.4v vs. Li/Li<sup>+</sup> was observed to be diffusion controlled, dependent on solute, and independent of solvent. For example, when Et<sub>4</sub>NClO<sub>4</sub> was used as the supporting electrolyte, no peak was observed. It was present, however, in tetrahydrofuran containing LiClO<sub>4</sub> as supporting electrolyte. The peak was identified as being due to the reduction of residual H<sub>2</sub>O (and/or glycol), since additions of either H<sub>2</sub>O or glycol caused the peak to increase in height. The inhibition of the reduction of H<sub>2</sub>O in Et<sub>4</sub>NClO<sub>4</sub> solution is presumably due to an adsorption effect associated with the Et<sub>4</sub>N<sup>+</sup> cation. In aqueous solution several examples of strong adsorption of Et<sub>4</sub>N<sup>+</sup> ions, with concomitant inhibition of electrode reductions, have been reported (5, 6).

The reduction peak at +0.4v had similar properties to that of the peak at +1.4v; however, it could not be identified with any of the impurities present in the PC (e.g., H<sub>2</sub>O or glycol). The peak was also observed in THF/LiClO<sub>4</sub> solution. Assuming that the peak was caused by an impurity such as another alkali metal cation (present in LiClO<sub>4</sub>), an attempt was made to remove this impurity by electrolysis. A large surface area Pt black electrode (geom. area 4 cm<sup>2</sup>) was held at +0.4v for 30 min in PC/LiClO<sub>4</sub> solution. During this time considerable current flowed (50 ma). A subsequent *i-v* trace showed no change in the peak height. A Hg pool electrode (area approx. 4 cm<sup>2</sup>) which was stirred and held at +0.4v for 30 min also gave rise to considerable current (50 ma). In time this current decreased to near zero. A subsequent cyclic voltammogram showed no change in the peak height on the Pt probe. Cyclic voltammograms on nickel electrodes showed a broad peak at +0.4v, but on gold the peak was observed at +0.2v.

The implication then is that the solvent or impurities in the solvent are not responsible for this peak. Rather only LiClO<sub>4</sub> and platinum are involved. More specifically the peak at +0.4v vs. Li/Li<sup>+</sup> appeared to be due to Li<sup>+</sup> ion reduction at the Pt electrode surface, resulting, presumably, in the formation of a Li-Pt alloy. Further evidence in support of this

Fig. 1. Background *i-v* scan in 1M LiClO<sub>4</sub>/PC solution, dried over 4A molecular sieves. Scan rate 80 mv sec<sup>-1</sup>.

conclusion was obtained from an experiment where Pt black electrodes, which had been held at +0.4v, subsequently gassed vigorously when immersed in H<sub>2</sub>O. Similar conclusions regarding Li-Pt alloy formation have been reached from studies on the anodic-cathodic efficiencies of the Li/Li<sup>+</sup> ion reaction on Pt substrates (7).

**Cyclic voltammetry.**—A typical cyclic voltammogram in PC/LiClO<sub>4</sub>(1M) solution containing H<sub>2</sub>O is shown in Fig. 2. The H<sub>2</sub>O reduction peak is well defined and a reverse (oxidation) peak is also apparent. The relationship between peak current and voltage scan rate under linear diffusion conditions is given by (8)

$$i_p = KD^{1/2} C v^{1/2} \quad [1]$$

where  $i_p$  is in amp cm<sup>-2</sup>,  $D$  is the diffusion coefficient in cm<sup>2</sup> sec<sup>-1</sup>,  $C$  is the bulk concentration of electroactive species in moles cm<sup>-3</sup>,  $v$  is in volts sec<sup>-1</sup>, and  $K$  is a proportionality constant which depends on the nature of the electrode process and of the products of the reaction.  $i_p/v^{1/2}$  should be a constant independent of  $v^{1/2}$  for a given  $C$  provided that no mechanistic complications are present. Plots of  $i_p/v^{1/2}$  vs.  $v^{1/2}$  for a number of different H<sub>2</sub>O concentrations are shown in Fig. 3. This increase of  $i_p/v^{1/2}$  with  $v^{1/2}$  up to a constant limiting value will be discussed below in the context of the chronopotentiometric results. The use of a cylindrical electrode meant that the diffusion conditions were not exactly linear. This did not, however, affect the qualitative agreement of the results with the chronopotentiometric observations (see below).

The limiting values of  $i_p/v^{1/2}$  plotted vs.  $C_{H_2O}$  gave a graph with two linear portions (Fig. 4) analogous to Fig. 6 obtained from the galvanostatic experiments. The data were in general, less reproducible than the results obtained using the chronopotentiometric technique. However, apparent concentrations of water down to a few ppm could be detected at sweep rates of  $>0.8$  v sec<sup>-1</sup>.

**Chronopotentiometry.**—The Sand equation is applicable strictly only to conditions of one-dimensional, semi-infinite linear diffusion. Bard (9), in comparing shielded and unshielded planar electrodes, has observed that the chronopotentiometric constant increased at long values of the transition times in the case of unshielded electrodes due to convective effects

Fig. 2. Cyclic voltammogram in 1M LiClO<sub>4</sub>/PC solution containing 100 ppm H<sub>2</sub>O. Scan rate 320 mv sec<sup>-1</sup>.

Fig. 3. Plot of  $i_p/v^{1/2}$  vs.  $v^{1/2}$  for  $H_2O$  reduction in 1M  $LiClO_4/PC$  solutions.

Fig. 4. Plot of limiting  $i_p/v^{1/2}$  values vs.  $H_2O$  concentrations in 1M  $LiClO_4/PC$  solution.

and spherical contributions to diffusion. Lingane (10) subsequently showed that the chronopotentiometric constant experimentally obtained with unshielded, circular, planar electrodes satisfied the equation

$$\frac{i\tau^{1/2}}{C} = \frac{nF\tau^{1/2}D^{1/2}}{2} \left[ 1 + 0.98 \left( \frac{D\tau}{r^2} \right)^{1/2} \right] \quad [2]$$

where the symbols have their usual meaning. Then for there to be an error of <5% in the values of  $i\tau^{1/2}/C$ , the following requirement applies

$$0.98 \left( \frac{D\tau}{r^2} \right)^{1/2} < 0.05$$

This condition ( $\tau$  must be less than 16 sec) was met by the measurements.

A typical chronopotentiogram is shown in Fig. 7. Dey (3), working with higher water concentration, reported that the galvanostatic transient for  $H_2O$  reduction had three distinct plateaus. In the present case these were not observed; however, two plateaus were apparent in the 500 ppm solution.

The significant feature of the chronopotentiometric results as summarized in the  $i\tau^{1/2}$  vs.  $i$  plot (Fig. 5) is the increase of  $i\tau^{1/2}$  with increasing current density up to a constant limiting value. This behavior is unusual and is the reverse of that which occurs when a kinetic step precedes the electrochemical step. An increase of  $i\tau^{1/2}$  with increase of current density can, of course, occur when the reduction of the electroactive species is complicated by the concomitant reduction of an adsorbed film of the species on the electrode (11). This effect, however, becomes more pronounced as the current density increases, whereas in the present case the  $i\tau^{1/2}$  values became constant at the shorter times. Thus electrolysis of an adsorbed film cannot be the explanation here.

A possible interpretation of the observed behavior can be given in terms of changing electrode area. Thus as  $H_2O$  is reduced,  $LiOH$  precipitates on the electrode surface (see below for evidence of  $LiOH$  formation). This layer of  $LiOH$  then blocks some portion of the surface, resulting in a decrease in active electrode surface area. As the surface area is decreased, the effective current density will increase and  $\tau$  will decrease. The decrease in  $\tau$  is apparently large enough to make  $i\tau^{1/2}$  smaller than it would be if there were no blocking effect by  $LiOH$ . At longer times (i.e., lower  $i$ ), the blocking effect would be more pronounced, as observed. A similar explanation holds for the cyclic voltammetric results (see Fig. 3).

Evidence for the formation of  $LiOH$  was the appearance of a violet-pink coloration on the surface after immersing an electrode at which  $H_2O$  had been reduced in phenolphthalein solution. Dey (3) used this same criterion for the formation of  $LiOH$  but reported the development of a blue coloration. The same violet-pink coloration was also observed when some drops of phenolphthalein were added to a  $PC/LiClO_4$  solution in contact with added  $LiOH$ . However, it should be noted that the coloration was only observed at the surface of the solid  $LiOH$  and not in the solution. This further indicates the low solubility of  $LiOH$ .

Fig. 5. Plot of  $i\tau^{1/2}$  vs.  $i$  for  $H_2O$  reduction in 1M  $LiClO_4/PC$  solution.

The above explanation can be put on a more quantitative basis. Consider the solution containing 100 ppm H<sub>2</sub>O as an example. For this solution the lowest  $i\tau^{1/2}$  point in Fig. 5 corresponds to  $i = 0.10 \text{ ma cm}^{-2}$ ,  $\tau^{1/2} = 3.7 \text{ sec}^{1/2}$ , and  $i\tau = 1.35 \text{ mc cm}^{-2}$ . The limiting  $i\tau^{1/2}$  value at high  $i$  is  $0.70 \text{ ma cm}^{-2} \text{ sec}^{1/2}$ . Hence the real current density corresponding to  $\tau^{1/2} = 3.7 \text{ sec}$  is at least  $0.70/3.7 = 0.19 \text{ ma cm}^{-2}$  which is double that of the apparent current density. This implies that half of the electrode surface is blocked by precipitated LiOH. A monolayer of LiOH would correspond to about  $0.2 \text{ mc cm}^{-2}$  of charge. The observed charge was  $1.35 \text{ mc cm}^{-2}$ . Thus there is more than enough LiOH available to block half the surface. The fact that not all of the surface was blocked suggests that either the film precipitate is porous or that not all of the LiOH is precipitated on the surface of the electrode.

The above explanation is to some extent supported by the results of H<sub>2</sub>O reduction (conc. 100 ppm) in THF/LiClO<sub>4</sub> solution (Table I). In this solvent LiOH is apparently more soluble so that a blocking effect should not be as pronounced. Indeed  $i\tau^{1/2}$  is relatively constant. Evidence for the relatively higher solubility of LiOH in THF as compared to PC was adduced from conductivity measurements. The ratio of the conductivity of THF equilibrated with LiOH compared to pure THF was approximately double the ratio obtained when PC was used as the solvent. The lower viscosity of THF-LiClO<sub>4</sub> (1M) solutions (1.02 centistokes at 25°C) compared with PC-LiClO<sub>4</sub> (1M) solution (6.01 centistokes at 25°C) would also encourage the dispersion of LiOH away from the electrode surface through convective effects. This lower viscosity, which implies a larger diffusion coefficient, would also explain the larger  $i\tau^{1/2}$  value obtained for a concentration of 100 ppm H<sub>2</sub>O in THF solution as compared with the same concentration in the PC solution.

It was next necessary to account for the actual magnitudes of  $i\tau^{1/2}$  in PC. The Sand equation was therefore used to calculate theoretical values. Assuming that  $D = 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$ ,  $n = 2$ , and  $C = 10^{-3} \text{ M}$  (where any major complications from LiOH formation should be minimal), the  $i\tau^{1/2}$  product is given by

$$i\tau^{1/2} = \frac{nFD^{1/2}\pi^{1/2}C}{2}$$

$$= 9.65 \times 10^4 \times \pi^{1/2} \times (10^{-5})^{1/2} \times 10^{-3} \quad [3]$$

$$\text{i.e., } i\tau^{1/2} = 0.5 \text{ ma cm}^{-2} \text{ sec}^{1/2}.$$

Referring to Fig. 5, it can be seen that this value is in good agreement with observed values at concentrations near  $10^{-3} \text{ M}$ . However, for a tenfold increase in concentration to  $10^{-2} \text{ M}$  (i.e., 180 ppm) the  $i\tau^{1/2}$  product should increase to  $5.0 \text{ ma cm}^{-2} \text{ sec}^{1/2}$ . The observed value for 200 ppm H<sub>2</sub>O was only of the order of  $0.8 \text{ ma cm}^{-2} \text{ sec}^{1/2}$ . Thus as the concentration of added H<sub>2</sub>O is increased, the H<sub>2</sub>O available for electrochemical reduction (i.e., its activity) appears to decrease.

To explain this effect it seems reasonable to suppose that there is a strong attraction between the added H<sub>2</sub>O and Li<sup>+</sup> ions in the electrolyte. The extent of this attraction presumably increases with increasing H<sub>2</sub>O concentration as H<sub>2</sub>O is then more able to

compete with PC molecules for the Li<sup>+</sup> ions. The net result of this attraction would be to form clusters of hydrated Li<sup>+</sup> ions and to decrease the concentration of free, unassociated H<sub>2</sub>O molecules, i.e., to decrease the activity coefficient of H<sub>2</sub>O.

This explanation is consistent with the data shown in Fig. 6, a plot of  $i\tau^{1/2}$  vs. concentration of added water. There are two separate linear sections of the curve, implying two forms of water, i.e., different interactions of water with lithium ions. The cyclic voltammetric results behaved analogously. Thus a plot of  $i_p/v^{1/2}$  vs. H<sub>2</sub>O concentration (see Fig. 4) also had two linear portions.

To confirm this apparent interaction of H<sub>2</sub>O with Li<sup>+</sup> ions rather than with the solvent, the  $i\tau^{1/2}$  behavior of H<sub>2</sub>O in an 0.1M LiClO<sub>4</sub> solution in PC was investigated. The  $i\tau^{1/2}$  vs.  $i$  curves were similar in shape to those observed in 1M LiClO<sub>4</sub> solutions; the limiting  $i\tau^{1/2}$  values observed at high current densities are plotted in Fig. 6.

At low H<sub>2</sub>O concentrations (<50 ppm) there is no significant difference in the  $i\tau^{1/2}$  values in 0.1M and 1M LiClO<sub>4</sub> solutions. Thus H<sub>2</sub>O is not in equilibrium with a lithium ion complex at these concentration levels, or rather if an equilibrium does exist it does not affect the electrochemical availability of H<sub>2</sub>O for reduction. Alternatively, there could be some association of H<sub>2</sub>O with the solvent at these low H<sub>2</sub>O concentrations which again does not affect the availability of H<sub>2</sub>O molecules for electrochemical reduction. This agrees with results of the calculation of  $i\tau^{1/2}$  from Eq. [3]. At higher H<sub>2</sub>O concentrations, however, the  $i\tau^{1/2}$  values in 0.1M LiClO<sub>4</sub> solutions were significantly higher than those in 1M LiClO<sub>4</sub>. Presumably this indicates that H<sub>2</sub>O is interacting with Li<sup>+</sup> ions in the 0.1M LiClO<sub>4</sub> solution to a lesser extent than in the 1.0M LiClO<sub>4</sub> solution. Furthermore the fact that at higher H<sub>2</sub>O concentrations the  $i\tau^{1/2}$  vs. concentration plots are parallel suggests that the same equilibrium is involved at the two LiClO<sub>4</sub> concentrations. This equilibrium is presumably of the form

Using mass balances and the equilibrium expression for a 1:1 complex of Li<sup>+</sup> and H<sub>2</sub>O as represented in [4] it can be shown that  $i\tau^{1/2} \propto C_{\text{H}_2\text{O}}/(K C_{\text{Li}^+} + 1)$ , where  $C_{\text{H}_2\text{O}}$  and  $C_{\text{Li}^+}$  are analytical concentrations of

0.29	11.46	3.29	0.95

Fig. 6. Plot of limiting  $i\tau^{1/2}$  values vs. H<sub>2</sub>O concentration in 0.1M and 1.0M LiClO<sub>4</sub>/PC solutions.

$\text{H}_2\text{O}$  and  $\text{Li}^+$  and  $K$  is the equilibrium constant. Thus for a given  $C_{\text{H}_2\text{O}}$ , decreasing  $C_{\text{Li}^+}$  will have the effect of increasing  $i\tau^{1/2}$  as was observed.

Interpretation of NMR data obtained from experiments in other aprotic organic solvents (*viz.*, dimethylformamide and acetonitrile) lends support to the existence of the above equilibrium. For example, Craig and Richards (12) observed that proton chemical shifts remained constant as the DMF concentration was increased in  $\text{H}_2\text{O}$ -DMF mixtures containing  $\text{LiCl}$ . They concluded that most of the  $\text{H}_2\text{O}$  molecules in the system were directly involved in  $\text{Li}^+$  ion hydration. Another group (13) interpreted the effect of  $\text{H}_2\text{O}$  on  $\text{Li}^+$  ion shifts in  $\text{H}_2\text{O}$ -AN mixtures containing  $\text{LiClO}_4$  to indicate preferential solvation of  $\text{Li}^+$  ions by  $\text{H}_2\text{O}$  as opposed to AN.

Dey (3) has investigated the electrochemical behavior of  $\text{H}_2\text{O}$  in  $\text{PC-LiClO}_4$  (1M) at concentrations substantially higher than those investigated here. His conclusions were generally similar to those reported here, namely, that  $\text{H}_2\text{O}$  exists as a complex with  $\text{Li}^+$  ions in  $\text{PC/LiClO}_4$  solution.

The results of the present chronopotentiometric investigation, as summarized in Fig. 6, can be considered a calibration curve for the quantitative analysis of  $\text{H}_2\text{O}$  in  $\text{PC-LiClO}_4$  solutions. The reproducibility of the method was estimated to be  $\pm 0.4$  in the limiting  $i\tau^{1/2}$  values. This is not sufficiently reproducible however for the method to give more than an approximate estimate of  $\text{H}_2\text{O}$  concentration.

A well-formed transition time was observed when the current was switched from cathodic to anodic. An example is shown in Fig. 7. The behavior of this transition time was as follows. It was found that the ratio of the reduction and oxidation transition times was about 2:1 at the smaller concentration and higher at the larger concentration range ( $\sim 4:1$ ). The ratio is in proportion to the amount of charge passed in the reduction process. The ratio was also found to be smaller at the shorter times (corresponding to the smaller amount of charge passed in the reduction) and larger at the longer times for any given concentration.

The charge associated with the reverse process for a given concentration was  $\sim 0.35$  mc/cm<sup>2</sup> at high current densities and  $\sim 0.45$  mc/cm<sup>2</sup> at the lower current densities. Furthermore, for a given concentration of  $\text{H}_2\text{O}$  the transition time for the reverse process did not

change significantly on stirring, whereas the forward transition time did. These observations imply that the reverse (oxidation) process is associated with an adsorbed layer of a reduction product on the surface of the electrode. The reduction process presumably is

in which adsorbed hydrogen atoms are reduction intermediates (14).

It has been estimated (15) that the oxidation of a monolayer of adsorbed hydrogen on a smooth polycrystalline Pt surface in aqueous solution consumes 0.21 mc/cm<sup>2</sup> of charge. This is of the same order as the 0.35-0.45 mc/cm<sup>2</sup> observed in these experiments.

### Summary

From the background *i-v* scans in propylene carbonate- $\text{LiClO}_4$  solutions, a reduction peak due to  $\text{H}_2\text{O}$  was identified at +1.4v vs.  $\text{Li/Li}^+$  (1M). The reduction peak at +0.4v is apparently due to the formation of a Li-Pt alloy.

The electrochemical behavior of trace quantities of water (1-30 millimolar) was investigated in detail *via* chronopotentiometry and cyclic voltammetry. It was observed that the chronopotentiometric constant increased with increasing current density up to a constant limiting value at high current densities. Analysis of the cyclic voltammetric results showed analogous behavior. These data can be interpreted in terms of a porous, insoluble film of  $\text{LiOH}$  formed by the reduction of water. This layer apparently acts to block part of the electrode surface thereby increasing the effective current density, decreasing  $\tau$  and hence  $i\tau^{1/2}$ .

From the concentration dependence of  $i\tau^{1/2}$  and of  $i_p/v^{1/2}$  it was further inferred that strong complexes were formed between water and  $\text{Li}^+$  ion which decreased the activity coefficient of  $\text{H}_2\text{O}$ . Current reversal subsequent to the reduction step showed an oxidation step which may be associated with an adsorbed film of atomic hydrogen on the platinum surface.

### Acknowledgments

The authors wish to thank both Dr. Raymond Jasinski for his helpful discussions and suggestions and Miss Susan Carroll for providing the distilled solvent. This work was carried out under Contract N00019-67-C-0680 for U. S. Navy Air Systems Command.

Manuscript submitted Feb. 12, 1968; revised manuscript received June 28, 1968. This paper was presented at the Boston Meeting, May 5-19, 1968, as Paper 206.

# Technical Notes

## Further Studies on the Double Layer Capacitance of Zinc in KOH Solutions

T. P. Dirkse\*

Calvin College, Grand Rapids, Michigan

In a recent report dealing with the double layer capacitance (dlc) of zinc electrodes in KOH solutions (1), it was suggested that the lowering of this dlc may be related to improved cycle life of zinc electrodes, especially in silver-zinc batteries. Amalgamation, *e.g.*, which improves the cycle life of zinc electrodes, also brings about a reduction in the double layer capacitance. This work has been continued and further results are reported here. Furthermore, a recent report on the cycle life of silver-zinc cells (2) has made further comparisons possible.

### Experimental

The cell and general procedure was the same as that reported earlier (1). The method used to measure the dlc was the one described by McMullen and Hackerman (3). All measurements were made at room temperature, which was about 25°C.

### Results and Discussion

The first comparison that was made had to do with the effect of the purity of the zinc electrode. Two samples of zinc were used: one had a purity of 99.91% with lead the major impurity and about 0.01% iron; the other had a purity of 99.999%. These samples were compared in both 20% and 30% KOH, Fig. 1 and 2. The lower purity zinc does have a slightly lower dlc, and this seems more pronounced as the potential of the electrode becomes anodic. The following results were all obtained using only the higher purity zinc.

The effect of KOH concentration is shown on Fig. 3. The variation with changing KOH concentration is slightly different from that reported earlier (1), and it is believed that this may partly be due to the higher purity zinc used in this work.

Reference (2) contains results for the cycle life of silver-zinc cells which were cycled in a prescribed manner, the discharge portion of which is referred to as a 60% depth of discharge. Each cycle consisted of a 35-min discharge at 0.36 amp/in<sup>2</sup> followed by an 85-min charge at constant cell voltage which was regulated to provide about 2 or 3% overcharge.

Various surfactant materials were added to the zinc electrodes, and their effect on cycle life was noted. The cells did not fail because of shorting but because of a loss of negative capacity, *i.e.*, the zinc electrodes were no longer able to deliver the desired capacity during the prescribed discharge time. Samples of several of these additives were made available to us and these materials were added to 40% KOH in an

amount equal to 0.1% by weight. The dlc of the zinc electrode was then measured in each of these solutions.

The results obtained by using a series of Emulphogenes are shown on Fig. 4. These substances lowered the dlc of the zinc but by different amounts.

The effects of other additives are shown on Fig. 5. The effect of methacrylic acid in lowering the dlc of zinc was less in 30% KOH than in 40% KOH, and it had no effect on the dlc in 20% KOH. However, its solubility appeared to be greater in 20% than in 40% KOH.

Figure 6 illustrates the comparison between the effect of these additives in lowering the dlc of zinc and their effect in extending the cycle life of silver-zinc cells (2). The correlation, so far as it goes, is

Fig. 1. Double layer capacitance of zinc in 30% KOH

Fig. 2. Double layer capacitance of zinc in 20% KOH

\* Electrochemical Society Life Member.

Fig. 3. Double layer capacitance of zinc at room temperature

Fig. 5. Change in double layer capacitance of zinc due to additives in the 40% KOH electrolyte.

Fig. 4. Effect of some surfactants on the double layer capacitance of zinc in 40% KOH.

reasonably good. The dlc values on Fig. 6 are those at 0 mv on Fig. 4 and 5.

### Conclusions

The results reported here seem to provide added evidence for the suggestion made earlier (1) that additives which lower the dlc of a zinc electrode in KOH solutions also extend the cycle life of silver-zinc cells. Such additives, of course, must also be able to withstand the oxidation-reduction environment existing in such cycling cells. No evidence has been obtained to contradict the earlier suggestion that the effectiveness of these additives is due to their adsorption on the zinc electrode.

### Acknowledgment

This work was made possible by a research grant from the General Electric Company.

## The Reaction of Aluminum with Molten Cryolite

R. J. Snow\*\* and B. J. Welch\*

School of Chemical Technology, University of New South Wales, Kensington, New South Wales, Australia

In this study we have found further information supporting the formation of Na(1,2) as the predominant reducing species when Al reacts with a  $\text{Na}_3\text{AlF}_6$  melt. The Na so formed has been found to enhance the volatilization of NaF from the melt suggesting that the Na exists as a  $\text{Na}_2^+$  cation in the melt and vaporizes as  $\text{Na}_2\text{F}$ . This is consistent with both

Grjotheim's (3) observation that Na is not formed as gas bubbles at the melt-metal interface and the proposal of Thonstad (4) for the solvolysis equilibrium.

This investigation involved simultaneously determining the change in weight of aluminum, weight of cryolite, and the NaF/ $\text{AlF}_3$  weight ratio of the melt. Subsequently each of the weight losses have been correlated with the ratio change for a fixed starting weight of melt. This approach differs from most of the

\*\* Electrochemical Society Student Associate Member.  
\* Electrochemical Society Active Member.

earlier studies which were of kinetic nature and usually neglected the changes induced on the melt by the solvolysis reaction. Being essentially a material balance it has the advantage that time can be eliminated as a dependent parameter thus removing end errors inherent in high temperature kinetic studies. Errors due to small temperature fluctuations are also minimized for the same reason.

### Experimental

The reacting melt and metal were contained in a graphite crucible which was sheathed in an Inconel envelope and purified argon was passed over the crucible at a steady rate. The mixture was heated to 1020°C in a fixed zone of a resistance furnace and held at temperature for varying times. The melts were then quenched and physically separated so that weight changes of each could be determined. The NaF-to- $\text{AlF}_3$  weight ratio of resulting salt sample was then determined by pyrotitrations. For all measurements reproducible conditions of temperature and gas flow rate were employed. The results for starting reacting mixtures of 2g Al + 45g  $\text{Na}_3\text{AlF}_6$  are represented in Fig. 1 and 2.

The data presented have been corrected for changes resulting from vaporization of the melt ( $\text{NaAlF}_4$ ) in the absence of aluminum for the actual experimental melt composition range. In this way the experimental curves represent changes due only to the melt-metal reaction. (Because the ratio of NaF to  $\text{AlF}_3$  continually changes due to both the reaction and the vaporization processes, the correction curve for vaporization in absence of Al was determined for various weight ratios of NaF to  $\text{AlF}_3$ . The actual correction applied to the individual measurements was obtained by integrating the curve for the rate of vaporization between the initial and final compositions for the reaction period.) A small correction (0.02g) was also made for the residual dissolved metal in the melt at the end of the reaction. Because the degree of saturation of the melt was not known the correction applied was one half the saturation solubility of Al in pure cryolite (5). Possible errors due to this correction are less than the experimental accuracy of weight changes which are  $\pm 0.1\text{g}$ . The melt NaF-to- $\text{AlF}_3$  ratio was determined with an accuracy of  $\pm 0.02$  (wt/wt).

### Discussion

The experimental curves have been compared with the curves that would correspond to loss according to each of the following over-all solution and vaporization reactions:

That is, the reducing species escaping from the melt would be  $\text{AlF}$ , Na, or  $\text{Na}_2\text{F}$ .

$\text{AlF}$  formation has been established by studies of the reaction between Al and  $\text{AlF}_3$  (6) while the proposals for formation of Na (1) and  $\text{Na}_2\text{F}$  (4) have been mentioned earlier. Diffusion calculations (7) from reoxidation kinetics (8) show that it is unlikely that Al forms a pyrosol in the fused salt while the above three are the only other solvolysis products probable. Although aluminum could undergo a side reaction by reacting with graphite to form aluminum carbide, tests on the crucibles used showed that this did not occur to a measurable extent during the duration of the experiments.

From the results shown in Fig. 1 (ratio change as a function of salt loss) the curve shows closest agreement with the theoretical curve for  $\text{Na}_2\text{F}$  loss.

In Fig. 2 we find the experimental curve agrees with a second escape mechanism, namely, evolution of Na. While the two curves are conflicting they show clearly that the metal loss cannot be as  $\text{AlF}$  alone.

Fig. 1. Change in NaF/ $\text{AlF}_3$  weight ratio as a function of salt loss: A, theoretical curve for vaporization of  $\text{AlF}$ ; B, theoretical curve for vaporization of Na; C, theoretical curve for vaporization of  $\text{Na}_2\text{F}$ ; D, theoretical curve for vaporization of 30%  $\text{AlF}$  and 70%  $\text{Na}_2\text{F}$ ; E, corrected experimental curve.

Fig. 2. Change in NaF/ $\text{AlF}_3$  weight ratio as a function of Al loss: A, theoretical curve for vaporization of  $\text{AlF}$ ; B, theoretical curve for vaporization of Na; C, theoretical curve for vaporization of  $\text{Na}_2\text{F}$ ; D, theoretical curve for vaporization of 30%  $\text{AlF}$  and 70%  $\text{Na}_2\text{F}$ ; E, corrected experimental curve.

In an attempt to resolve the discrepancy between the two correlations, various combinations of two simultaneously vaporizing species have been tried. Agreement for both experimental curves is obtained only if the metal loss is attributed to both  $\text{AlF}$  and  $\text{Na}_2\text{F}$  in the proportions of approximately 30%  $\text{AlF}$  to 70%  $\text{Na}_2\text{F}$ . The theoretical curves (D) for this composition are also included on the diagrams.

This explanation is consistent with Haupin's findings (2) and also the equilibrium proposed by Thonstad (4). That the Na volatilizes as  $\text{Na}_2\text{F}$  is supported by our finding that the melt becomes more volatile in the presence of Al, and when the condensate is examined by x-ray diffraction it is found that there has been a considerable increase in NaF content.

This would result in dissociation according to the scheme

which would have to favor the right-hand side as the temperature is reduced. Such an explanation would be consistent with Stokes and Franks (1) vapor studies.

To check our findings additional experiments have been carried out using different initial proportions of Al to the cryolite. Although the rate of reaction changed with the different proportions, in all cases

the data were consistent with the experimental curves of Fig. 1 and 2. This supports the suggested proportions of volatilizing species.

Manuscript submitted March 27, 1968; revised manuscript received ca. July 9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## The Diffusion Coefficients of Hypochlorite, Hypochlorous Acid, and Chlorine in Aqueous Media by Chronopotentiometry

M. S. Chao\*

The Dow Chemical Company, Midland, Michigan

In describing the hydrodynamic conditions of the manufacture of chlorate, the diffusion coefficients of its precursors, hypochlorite and hypochlorous acid, will be expected to be important factors. A search of the literature shows that no such data have been reported. Chemically, hypochlorite and hypochlorous acid are related to chlorine through hydrolysis. The published diffusion coefficient of chlorine has been inconsistent and limited in temperature range (1-3). Therefore, it seems logical that the diffusion coefficients of these three species be studied as a group. Besides, the inclusion of values on chlorine will be of use to the related electrochemical process other than chlorate manufacture, such as the production of chlorine.

The present investigation utilized chronopotentiometry to determine the diffusion coefficients. In this instance the Sand equation is applicable

$$D^{1/2} = \frac{2 i \tau^{1/2}}{\pi^{1/2} n F A C} \quad [1]$$

where  $D$  is the diffusion coefficient ( $\text{cm}^2/\text{sec}$ ),  $\tau$  the transition time (sec),  $C$  the concentration ( $\text{mol}/\text{cm}^3$ ) of the electroactive species in the bulk,  $i$  the electrolysis current (amp),  $F$  the Faraday,  $A$  the electrode area ( $\text{cm}^2$ ), and  $n$  the number of Faradays per molar unit of reaction (4). For the reduction processes used in the present study,  $n$  is equal to 2 for chlorine and hypochlorite (5), and is presumably the same for hypochlorous acid.

The dissociation constant of hypochlorous acid

has been cited in Mellor as between  $3 \times 10^{-8}$  and  $4 \times 10^{-8}$  (6). By choosing buffers of proper pH: phosphate (pH 6.10) or carbonate (pH 10.0) either hypochlorous or hypochlorite will be the predominant species.

The hydrolysis of chlorine is governed by the following equilibria with  $K$ 's at 25°

By using a solution 0.975*N* in  $\text{HClO}_4$  and 0.025*N* in  $\text{HCl}$ , the ratio of  $\text{HOCl}$  and  $\text{Cl}_3^-$  to  $\text{Cl}_2$  is approximately 1% (7). It is assumed that at higher temperature the composition of the solution does not change significantly.

\* Electrochemical Society Active Member.  
Key words: chlorine, chronopotentiometry, diffusion coefficient, diffusivity, hypochlorite, hypochlorous acid.

#### Experimental

The electrolysis cell was a 300 ml beakless beaker with a Teflon cover, into which the electrodes and a thermometer were inserted. The working electrode was a shielded platinum disk electrode according to Bard (8). Its geometrical area as calibrated with a  $\text{Fe}^{+3}$  solution by chronopotentiometry (9) was  $0.268 \text{ cm}^2$ , in good agreement with the  $0.267 \text{ cm}^2$  measured by photomicrography. The counter electrode, a spectrographic graphite rod, was enclosed in a glass frit of medium porosity. The reference electrode consisted of a salt bridge and a commercial saturated calomel electrode. The cell was thermostated to  $0.1^\circ\text{C}$ .

The constant current was derived from the +300v output of a Heathkit Operational Amplifier Manifold and a series of dropping resistors. An L&N pH meter (Model 7401) connected to a Sargent Model SR recorder with a chart speed of 12 in./min recorded the chronopotentiograms.

Chlorine of purity 99.8% was obtained from the Dow Chemical Company. Chloride-free lithium hypochlorite, the source for hypochlorite or hypochlorous acid, was prepared from reagent chemicals by W. G. Moore of this laboratory. All the rest of the chemicals were reagent grade. The phosphate and carbonate buffers, as well as the  $\text{HClO}_4 - \text{HCl}$  mixture, all had an ionic strength of unity.

The concentration of the electroactive species was analyzed by the usual KI-thiosulfate titration in acetic acid medium. The viscosity of the solution was determined with a modified Ostwald viscometer.

#### Results and Discussion

Typical chronopotentiograms of hypochlorite, hypochlorous acid, and chlorine are shown in Fig. 1. The transition times were determined by Kuwana's method (10). The  $i\tau^{1/2}$  products remained constant over a 2-3-fold change in current density, indicating the processes are diffusion controlled. Following the reduction of the soluble species, the surface oxides of platinum were also reduced. Because of the complex natures of these oxides, no attempt was made to study them.

The diffusion coefficients of hypochlorite and hypochlorous acid are shown in Fig. 2. Allowing for convection and other uncertainties the precision is estimated at 2-5%. The linear relationship between  $\log D$  ( $\text{cm}^2/\text{sec}$ ) and the reciprocal absolute temperature can be represented by an equation of the form

$$\log D = -a \times 10^3 \times \frac{1}{T} - b \quad [5]$$

Fig. 1. Typical chronopotentiograms of hypochlorite, hypochlorous acid, and chlorine.

Fig. 2. Diffusion coefficients of hypochlorite, hypochlorous acid, and chlorine.

for hypochlorite,  $a = 1.06$  and  $b = 1.40$ ; for hypochlorous acid,  $a = 0.945$  and  $b = 1.72$ .

The diffusion coefficient of chlorine is also shown in Fig. 2. The volatility of chlorine may be one major source of error. The precision is estimated at 5% for values below 60°C and 10% above that. Compared with the data by other workers (Fig. 3), the present values are generally higher by a few per cent. The low value of Hüfner at 16°C, determined in 1897, was cited by the International Critical Tables as "too low" (1). The low value of Vivian and Peaceman (2) was determined in HCl, formation of  $\text{Cl}_3^-$  according to Eq. [4] may have taken place to some extent. It is of interest to note that the diffusion coefficient of hypochlorous acid is about 25% of that of chlorine. Therefore, failure on the part of the earlier workers to suppress the hydrolysis may lead to a lower value. However, considering the variety of techniques used by different workers, the agreement can be considered satisfactory.

The straight line portion (between 15° and 60°C) of the  $\log D$  vs.  $1/T$  plot may again be represented by

Fig. 3. Diffusion coefficient of chlorine by various workers: ● present study; ○ Euler (1897); ▲ Hüfner (1897); \* Vivian and Peaceman (1956); ▽ Davidson and Cullen (1957).

Eq. [5] with  $a = 1.09$  and  $b = 1.08$ .

The activation energy for diffusion may be estimated according to the following equation.

$$D = A \exp(-E/RT) \quad [6]$$

where  $A$  is a constant. The value of  $E$  is 4.9 kcal/mole for hypochlorite, 4.3 kcal/mole for hypochlorous acid, and 5.1 kcal/mole for chlorine.

According to the Stokes-Einstein law (11) the product of the viscosity ( $\eta$ ) and the diffusion coefficient ( $D$ ) is constant for spherical uncharged particles. As shown in Fig. 4, the  $D\eta$  product approaches a constant value in solutions of ionic strength greater than 1.5. The  $D\eta$  product at unit ionic strength is within 10% of those for a large range of concentrations. Therefore, approximate values of the diffusion coefficient in

Fig. 4. Viscosity-diffusion coefficient products at 25°C as a function of ionic strength.

Fig. 5. Viscosity-diffusion coefficient products at unit ionic strength as a function of temperature.

various media may be calculated from the  $D\eta$  product at unit ionic strength, provided the viscosity of the medium has been determined. The data in Fig. 5 may be used for this purpose.

Manuscript submitted May 8, 1968; revised manuscript received ca. Aug. 1, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# On the Effect of Ultraviolet and X-ray Irradiation of Phosphors

George T. Bauer

Research Laboratories, Xerox Corporation, Rochester, New York

## ABSTRACT

The effect of long term ultraviolet and x-ray irradiation on the luminous efficiency, reflectance, and glow curves of several inorganic phosphors were measured. It was found that the decrease of their luminous efficiency caused by irradiation was always accompanied with an increased absorption in the uv and in the visible regions of the spectra. The depreciation of x-rayed phosphors could in most cases partially, and in several phosphors fully, be interpreted in terms of the absorbing effect of centers produced by the irradiation. However, in phosphate types and in magnesium germanate phosphors an additional process contributes to their depreciation. This process is related to the appearance of new peaks on their glow curves. The observed wavelength dependence of the loss in luminous efficiency was measured for several phosphors and in each case could be attributed to color center absorption. The x-ray and uv irradiation resulted qualitatively in the same type of changes in the measured optical data.

It has long been known that the luminescent intensity of phosphors decreases as a result of long term excitation. The depreciation appears for every form of the excitation (i.e., uv, x-rays, cathode rays, or electroluminescence) and often causes a serious problem in certain practical applications. Certain physical and chemical changes caused by uv irradiation of phosphors have been well discussed in the literature (1). A relatively new finding is that in phosphate base materials (2), in activated phosphate phosphors (3, 4), and single crystals (5), color centers are produced when irradiated by x-rays or uv. Some of these centers could be identified from different optical, epr, and ENDOR (6) studies on single crystals. It is believed that one of the main causes of the depreciation of the phosphors is the absorption by color centers of both a part of the exciting energy and a part of the light emitted by the luminescence centers (4).

The relation between color center formation and depreciation has up to now been studied chiefly on phosphate-type phosphors while relatively little data are available for other phosphors. In this work we study certain optical changes which accompany the depreciation of phosphors when irradiated by uv or x-rays. One of the main purposes of the study has been to determine more quantitatively how the absorption of color centers produced by irradiation influence the efficiency of the photoluminescence of the phosphor, and to separate the different processes which result in depreciation. All but one of the phosphors studied were commercial products (Table I).

## Experimental Methods

Previous studies (1, 3, 4) have shown that the luminous efficiency reflectance and glow curves of a number of powder phosphors change on uv or x-ray irradiation. We have completed measurements of these changes on the phosphors listed in Table I. The measurement of the wavelength dependence of relative luminous efficiency of the irradiated phosphors has also provided useful information.

The uv irradiation of the phosphors was carried out in a closed box in nitrogen or air using a low-pressure mercury discharge lamp with a dynasil quartz envelope as radiation source. In the spectral distribution of the lamp, the 2537Å mercury resonance line is dominant; however, a portion of the 1849Å radiation is also passed through the envelope. The phosphor layers were 2 mm thick and were placed in a brass substrate close to the lamp. The intensity of radiation at the surface of the phosphor measured

for 1849 + 2537Å wavelength was  $5000 \mu\text{wcm}^{-2}$ . For studying the effect of x-rays, the samples were irradiated in a Phillips apparatus by 50 keV, 40 ma tungsten x-rays.

The diffuse reflectance measurements were made using a Spex No. 1700-II Czerny-Turner spectrometer with a Sylvania DE350 deuterium lamp as radiation source. For measurement of the reflectance in the visible region, suitable Corning uv absorbing, visible transmitting filters were placed in front of the lamp in order to avoid the excitation of the phosphors. A thick magnesium oxide layer was used as standard.

The plaque brightness of the excited phosphors was measured using a Gamma photometer with an RCA 931A photomultiplier as sensor. The phosphors were excited by a low-pressure mercury discharge lamp through two 2-mm thick Corning U.G. 5 filters. A 2-mm thick Corning CS3-71 filter was set before the photomultiplier to absorb the uv radiation reflected from the phosphor surface. The measurements were relative: the plaque brightnesses of the irradiated samples were compared to those of the unirradiated ones. Because the spectral distribution of the luminescence of the phosphors was found to be not significantly affected by the irradiation, the spectral response of the multiplier-filter combination did not play a role in the measurements. A Hilger Watts Grating monochromator D292 with a deuterium lamp as radiation source was used to measure the excitation spectra. The thermoluminescence measurements were carried out from 25° to 400°C using a special furnace with a heating rate of  $0.5^\circ\text{C sec}^{-1}$ . For the detection of the emitted light of the phosphors, an RCA IP21 photomultiplier Corning CS3-71 filter combination has been used.

## Results

*Effect of irradiation on the diffuse reflectance of phosphor layers.*—The following three series of diffuse reflectance measurements were carried out: (a) after 100 hr of uv irradiation in nitrogen atmosphere; (b) after 16 hr x-raying; and (c) after 16 hr x-ray plus thermal bleaching the phosphors for 1 hr at 400°C. Figures 1 and 2 show the ratio of the diffuse reflectance  $R_i(\lambda)$  of the irradiated phosphors to that of unirradiated samples,  $R(\lambda)$ . This type of representation could indicate the appearance of narrow absorption bands in the irradiated samples (4). It should be noted that the penetration depth of the x-rays is significantly higher than that of the 1849-2537Å radiation. Thus, the reflectance data of x-rayed samples

cannot be directly compared to that of the uv irradiated ones.

Figures 1 and 2 show that, in most cases, the reflectance of the phosphors was decreased (*i.e.*, the absorbance increased) due to the x-ray or uv irradiation. The reflectance of the barium titanium phosphate showed no changes when irradiated by uv and the effect was very small in the case of calcium tungstate. Generally, wide absorption bands are introduced by the irradiation showing some structure in certain cases. The change in the reflectance (except in magnesium germanate) is greater in the uv than in the visible part of the spectrum. The absorption bands of the x-rayed samples partially or completely disappeared after heating for 1 hr at 400°C. Bleaching was more complete for the visible than for the uv reflectance.

*Effect of radiation on the luminous efficiency of the phosphors.*—The relative luminous efficiency of the phosphors can be determined from the relative plaque brightness and from their reflectance at the wavelength of the excitation. Let the plaque brightness of

the unirradiated and irradiated samples be  $I$  and  $I_i$ , respectively. Then the relative luminous efficiency of the irradiated sample with respect to the unirradiated is (7)

$$\frac{L_i}{L} = \frac{I_i}{I} \cdot \frac{1 - R(\lambda)}{1 - R_i(\lambda)} \quad [1]$$

Measurements were made using the above described mercury discharge lamp for excitation after (a) 100 hr uv irradiation, (b) 16 hr x-raying, (c) 16 hr x-raying and bleaching at 400°C for 1 hr. Because the greatest part of the uv energy was emitted by the lamp at 2537Å, the reflectance measured at this wavelength was applied for the calculations. The results are shown in Table I. Comparing the results to those of the reflectance measurements (Fig. 1 and 2), it can be seen that the depreciation of phosphors is always associated with an increase in their absorbance. After thermal bleaching which results in the recovery of the luminous efficiency of the phosphors (Table I), the absorption bands also become weak.

The relative luminous efficiency of the x-ray or uv irradiated phosphor was found to be dependent on the wavelength of the excitation. This wavelength dependence was measured for five phosphors after 16 hr x-ray irradiation. Results are shown in Fig. 3 and 4.

Fig. 1. Relative diffuse reflectance of irradiated phosphors compared with the unirradiated samples: — after 16 hr x-ray irradiation; — — after 16 hr x-ray irradiation and 1 hr bleaching at 400°C; - · - after 100 hr uv irradiation.

Fig. 4. Same as Fig. 3

**Thermoluminescence.**—The following three series of measurements were carried out: (a) after 10-min uv irradiation in the above described chamber in air, (b) after 100-hr uv irradiation in nitrogen atmosphere, and (c) after 2 hr of x-ray irradiation. Figures 5, 6d and 6f show that in phosphate-based phosphors and magnesium germanate, new glow peaks, not present after 10 min of uv irradiation, appear due to the long term uv or x-ray irradiation. The glow curves of the x-rayed and uv irradiated phosphors are very similar. In calcium tungstate and in cadmium borate, similar glow curves were observed after 10 min and after 100 hr uv irradiation. These glow curves differ chiefly in their intensities. However, the glow curves of the x-rayed samples of these phosphors were somewhat different. In silicates, there were no new glow peaks induced by the long term uv or x-ray irradiation (Fig. 7).

#### Calculation of Effect of Absorption of Color Centers on the Luminous Efficiency of Phosphors

The measurements indicate that in the x-rayed phosphors a part of the exciting uv energy and of the emitted light is absorbed in color centers induced by the irradiation. When discussing this effect quantitatively, we assume that the activator concentration in the high efficiency phosphors studied is small, i.e., far from the level where concentration quenching (8) becomes important. It is further assumed that the phosphors contain only a negligible quantity of im-

purities. A part of the exciting radiation is absorbed in the activator centers having concentration  $C$  and average capture cross section  $\sigma(\lambda)$ . Another part is absorbed in color centers with concentration  $C_i$  and average capture cross section of  $\sigma_i(\lambda)$ . The exciting uv energy absorbed in the activators of the x-ray treated phosphors is converted into light energy which leaves the phosphor layer with an efficiency of  $m_a$ . In the untreated phosphors this efficiency is  $m_o$ . We assume that the color centers either give rise to radiationless transitions or they emit the absorbed energy outside of the phosphor's emission band. Let  $a_i(\lambda)$  be the absorption coefficient of the x-ray treated, and  $a(\lambda)$  that of the untreated phosphor, and let  $m_a/m_o = m$ . Then the relative luminous efficiency of the irradiated phosphor layer is

$$\frac{L_i}{L} = m \frac{C \cdot \sigma(\lambda)}{C \cdot \sigma(\lambda) + C_i \sigma_i(\lambda)} = m \cdot \frac{a(\lambda)}{a_i(\lambda)} \quad [2]$$

The absorption coefficient of phosphors can be calculated to a good approximation from the diffuse reflectance of their quasi infinite thick layer (9)

$$a(\lambda) = \frac{1}{l} \frac{\alpha(\lambda)}{1 - \alpha(\lambda)} \cdot \frac{[1 - R(\lambda)]^2}{R(\lambda)} \quad [3]$$

where  $\alpha(\lambda)$  is the Fresnel reflection and  $l$  is the average particle size. Since the penetration depth of x-rays is considerably larger than that of optical rays, the absorption coefficient of the x-rayed phosphor layers may be considered as homogeneous from the viewpoint of absorption measurements. From Eq. [2] and [3]

$$\frac{L_i}{L} = m \cdot \frac{R_i(\lambda) [1 - R(\lambda)]^2}{R(\lambda) [1 - R_i(\lambda)]^2} \quad [4]$$

Fig. 5. Glow curves of phosphors: --- after 10 min uv irradiation; — after 100 hr uv irradiation; - · - after 2 hr x-ray irradiation. (a) calcium halophosphate, (b) barium titanium phosphate, (c) strontium pyrophosphate.

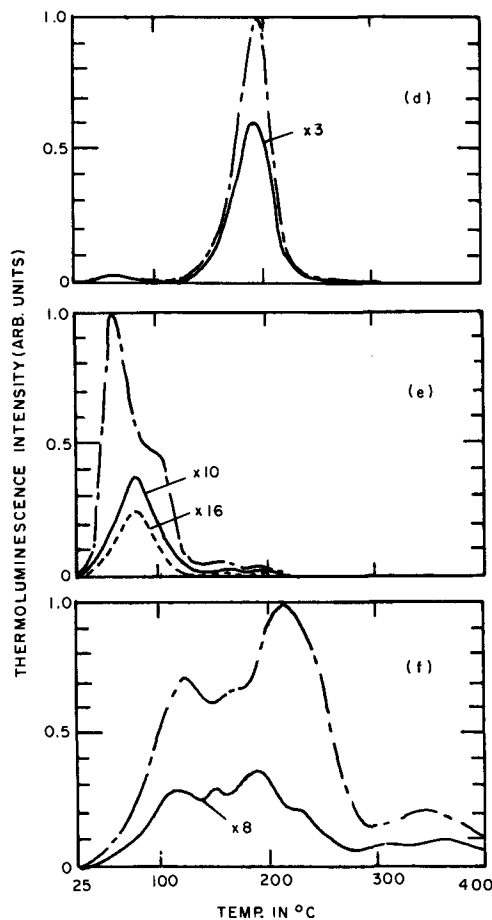

Fig. 6. Glow curves of phosphors: (d) strontium magnesium phosphate, (e) calcium tungstate, (f) magnesium fluorogermanate.

Fig. 7. Glow curves of phosphors: (g) zinc silicate, (h) calcium silicate, (j) cadmium borate.

The luminous efficiency and diffuse reflectance measurements permitted a determination of  $m$  by means of Eq. [4]. Values of  $Li/L$  calculated from the reflectance data and the  $m$  values given in Table I are compared to the measured luminous efficiency curves in Fig. 3 and 4. Very reasonable fits are obtained. In the cases of the magnesium fluorogermanate, cadmium borate, and the silicate phosphors the luminous efficiency was measured only at  $\lambda = 2537\text{\AA}$  excitation and these results were used for determination of  $m$ .

Since the value of  $m$  was found to be less than unity for all of the phosphors studied, then it must follow that the activators in the irradiated phosphors convert the absorbed energy into the output light leaving the layer with less efficiency than before the irradiation. This could be attributed either to the self-absorption of the emitted light in the phosphor layer or to a decrease of the intrinsic efficiency of the luminescent centers.

In order to estimate the loss in the layer due to the self-absorption, we assume on the basis of the reflectance measurements and Eq. [3] that the exciting uv radiation is absorbed in a thin layer of the phosphors. The absorption of this layer at the wavelength of the emission range of the phosphors is practically negligible since  $l \cdot a(\lambda)$  is small. One half of the  $S_i$  luminescent light flux produced in the excited layer leaves the layer in the direction of the source of the excitation (Fig. 8) while the other half leaves in the opposite direction. Taking into account the reflections shown on Fig. 8, the total luminescent light flux leaving the phosphor in the direction of the source of excitation is

$$G_i = \frac{S_i}{2} \frac{1 + R_i(\lambda_v)(2t - 1)}{1 - R_i(\lambda_v)(1 - t)} \quad [5]$$

where  $R_i(\lambda_v)$  is the average reflectance of the x-rayed quasi-infinite thick phosphor layer in its emission

Fig. 8. Model for the calculation of the loss caused by the self-absorption of the emitted light within the phosphor layer.

range and  $t$  is the transmittance of the excited thin layer in the same range. Calculating only the effect of self-absorption it is assumed that the  $S_i$  luminescent light flux produced in the excited thin layer is the same in the irradiated and in the unirradiated phos-

phors. Comparing the  $G_i$  light flux emitted from the x-rayed phosphor to the  $G$  light flux emitted from the untreated one (from Eq. [5])

$$m_v = \frac{G_i}{G} = \frac{1 - R(\lambda_v)(1-t) + R_i(\lambda_v)(2t-1) - R(\lambda_v)R_i(\lambda_v)(2t-1)(1-t)}{1 - R_i(\lambda_v)(1-t) + R(\lambda_v)(2t-1) - R(\lambda_v)R_i(\lambda_v)(2t-1)(1-t)} \quad [6]$$

where  $m_v$  is the value of  $m$  obtained by assuming that the decrease in emission efficiency is due only to the irradiation-induced self-absorption of visible light. As an initial estimate,  $t$  could be taken equal to the transmittance of a layer having a thickness of average particle size (10); however,  $t$  also depends on the type of phosphors and on the method of their preparation. Table I shows the value of  $m_v$  calculated from Eq. [6].  $t = 0.6$  was chosen in the calculations and the values of  $R(\lambda)$  and  $R_i(\lambda)$  were taken at the emission maxima of the phosphors.

Within experimental error, the values of  $m$  and  $m_v$  were found equal for calcium tungstate, zinc silicate, and cadmium borate and for the thermally bleached calcium halophosphate and strontium pyrophosphate phosphors. However, significant differences between  $m$  and  $m_v$  were found in phosphate type and magnesium germanate phosphors. The dependence of the relative luminous efficiency of the x-rayed calcium tungstate phosphor layer on the  $\lambda$  excitation wavelength from Eq. [4] and [6] noting that  $m \approx m_v$  is

$$\frac{L_i}{L} = \frac{R_i(\lambda)[1 - R(\lambda)]^2}{R(\lambda)[1 - R_i(\lambda)]^2} \cdot \frac{1 - R(\lambda_v)(1-t) + R_i(\lambda_v)(2t-1) - R(\lambda_v)R_i(\lambda_v)(2t-1)(1-t)}{1 - R_i(\lambda_v)(1-t) + R(\lambda_v)(2t-1) - R(\lambda_v)R_i(\lambda_v)(2t-1)(1-t)} \quad [7]$$

This equation is also valid for zinc silicate and cadmium borate at least at  $\lambda = 2537\text{\AA}$  excitation and for the thermally bleached calcium halophosphate and strontium pyrophosphate.

### Discussion

According to the measurements on all of the phosphors studied in this work, color centers induced by x-ray irradiation appear to absorb both a part of the exciting uv radiation and a part of the light emitted by the luminescent centers.

Based on the results obtained on single crystals (5, 6), the enhanced absorption in irradiated phosphate type phosphors has been attributed to color centers (3). In our work, the observed increased absorption and the thermal bleachability of the absorption bands also indicate that color centers are formed by the irradiation in the phosphors investigated. The absorption by these centers results in a decreased luminous efficiency in the phosphors. When the excitation occurs at  $2537\text{\AA}$ , the term  $a(\lambda)/a_i(\lambda)$  in Eq. [2] was found to be larger than  $m$  for every phosphor studied. This means that the absorption of the exciting radiation by the color centers results in an efficiency drop smaller than the self-absorption and other processes produce. Exciting the phosphors at longer wavelength in the tail of the excitation band, causes the ratio  $a(\lambda)/a_i(\lambda)$  to become smaller (Fig. 3 and 4). Thus, the absorption of the exciting energy by the color centers make a significantly higher contribution to the whole efficiency loss. While the term  $a(\lambda)/a_i(\lambda)$  does not depend on the structure of the phosphor layer,  $m_v$  is a function of  $R(\lambda_v)$  and  $R_i(\lambda_v)$  [6] which are dependent on the grain size [3].

In the cases of phosphate and magnesium germanate phosphors, the depreciation cannot be completely explained by the direct absorption of color centers. For these phosphors the value of  $m$  was found to be significantly smaller than  $m_v$ . This indicates that the intrinsic efficiency of the luminescent centers are affected by x-ray irradiation. On the glow curves of these phosphors, new peaks appear due to the long

term x-ray or ultraviolet irradiation (Fig. 5, 6d, 6f) indicating interaction between luminescent and color centers. This interaction and its role in the deprecia-

tion of phosphors is not yet perfectly understood (3). A part of the energy absorbed in luminescent centers can probably be transferred to deep traps (11) caused by irradiation which give rise to radiationless transitions (12) or to emission at different wavelengths than that of the luminescent centers.

Ultraviolet irradiation for 100 hr causes very similar, but in most cases, smaller changes in the luminous efficiency, reflectance spectrum, and glow curve of the phosphors than 16 hr of x-ray irradiation. Both forms of irradiation cause basically the same effects. However, the method of absorption analysis used in this study for x-rayed phosphor layers could not be applied to uv irradiated samples. Thus, the role of different effects of irradiation on the depreciation could not be separated quantitatively.

The depreciation of phosphors is one of the limiting factors of the lifetime of luminescent light sources. In this paper, we have taken the decrease in luminous efficiency as a measure of phosphor depreciation. However, independent of their efficiency, a decrease in

the visible reflectance of phosphors due to uv irradiation may also result in a decreased light output in certain types of lamps. In the case of aperture lamps (13) a 1% decrease of the visible reflectance of the coating could cause a 4-8% decrease in lumen radiated through their aperture.

Manuscript received June 17, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Fluorescence of $\text{Eu}^{2+}$ -Activated Phases in Binary Alkaline Earth Orthosilicate Systems

Thomas L. Barry\*

*Sylvania Lighting Center, Sylvania Electric Products Inc., Danvers, Massachusetts*

## ABSTRACT

The dependence of the emission spectra on compositional variations has been studied in binary alkaline earth orthosilicate systems activated by divalent europium. Isotherms at 1200°C were run in the systems (i)  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$ , (ii)  $\text{Ca}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$ , and (iii)  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$ . Phosphors produced in the  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system were considerably more efficient than those in either of the other two systems and consequently were studied in much greater detail. A complete series of crystalline solutions exist between the end-members at 1200°C. The corresponding emission spectra vary in a fairly continuous manner from 505 nm for the pure barium end-member to 575 nm for the pure strontium end-member. X-ray diffraction data revealed complete crystalline solution between  $\beta$ - $\text{Ca}_2\text{SiO}_4$  and  $\text{Sr}_2\text{SiO}_4$  at 1200°C. However, the low level of brightness and the pronounced asymmetry of the emission peaks rendered this system less amenable to a detailed investigation. Emission spectra indicated the formation of an intermediate compound in the  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  system. The existence of this compound,  $\text{Ba}_5\text{Ca}_3\text{Si}_4\text{O}_{16}$ , was verified by x-ray diffraction. The emission spectrum of this compound peaks at a considerably lower wavelength (~490 nm) than those of its bounding compositions. The two later systems were further complicated due to the polymorphism of  $\text{Ca}_2\text{SiO}_4$ . Frequently the  $\text{Ca}_2\text{SiO}_4$  phase was partially converted from  $\beta$ - $\text{Ca}_2\text{SiO}_4$  to  $\gamma$ - $\text{Ca}_2\text{SiO}_4$ .

This work was undertaken in an attempt to study the variation in emission spectra with composition in binary systems exhibiting complete crystalline solution between both end-members. Systems involving the alkaline earth ions were chosen because of the similarity in size between them and divalent europium; also the strongly divalent nature of these ions should favor the incorporation of europium in the divalent state and render it more stable to subsequent treatment. The ionic radii (Ahrens' values) (1) for the ions  $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Ba}^{2+}$ , and  $\text{Eu}^{2+}$  are 0.99, 1.12, 1.34, and 1.12Å, respectively.

Previous studies of divalent europium activation in alkaline earth orthosilicates have been carried out by McKeag and Ranby (2), and Jenkins and McKeag (3). These studies were limited almost exclusively to compositions involving only one alkaline earth ion. Both mention that studies involving combinations of the alkaline earth ions can be used, but these were not investigated fully because of the limited amount and expense of europium compounds at the time. The patent by McKeag and Ranby is more extensive in this area yet lists only nine such compositions. Only the emission colors of these prepared samples are given as complete spectral energy distribution data were not obtained.

A complete series of crystalline solutions between  $\text{Ca}_2\text{SiO}_4$  and  $\text{Ba}_2\text{SiO}_4$  has been reported by Toropov and Kononov (4). They likewise report complete crystalline solution between  $\beta$ - $\text{Ca}_2\text{SiO}_4$  and  $\text{Sr}_2\text{SiO}_4$  (5). An intermediate compound in the  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  system ( $5\text{BaO} \cdot 3\text{CaO} \cdot 4\text{SiO}_2$ ) was reported by Nadachowski and Gyrlicki (6). They showed only limited solubility in  $\text{Ca}_2\text{SiO}_4$  and in the intermediate compound  $\text{Ba}_5\text{Ca}_3\text{Si}_4\text{O}_{16}$ . No previous phase equilibrium data were found on the  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system.

## Experimental

*Starting materials and blend preparation.*—The raw materials employed in this study consisted of luminescent grade alkaline earth carbonates and silicic acid. The other chemicals, europium oxide, and ammonium

\* Electrochemical Society Active Member.

Key words: phosphors alk earth silicates, luminescence alk earth silicates, emission spectra, europium ( $2+$ ) activation, fluorescence europium ( $2+$ ), temperature dependence, equilibrium subsolidus.

chloride were commercial reagent grade materials. The europium oxide was at least 99.9% pure (analyses given by American Potash and Chemical Corporation). The silicic acid was assayed so that the quantities weighed could be compensated for sorbed water.

Sample blends were prepared by dry blending the desired amounts of the constituents in a Model 8000 Spex Mixer/Mill for 15 min. A small amount of glass beads (easily removed after blending by screening) were incorporated in each blend of facilitate mixing.

*Firing procedure.*—The blended samples were pre-fired in alumina boats at 600°C to initiate decomposition of the carbonates and possible reaction with the ammonium chloride flux. The samples were then placed in a silica tube flushed with nitrogen and inserted into a global furnace at 1200°C. At this time the gas flow was adjusted to yield a mixture of 4 volumes of nitrogen to 1 volume of hydrogen. Firing temperatures between 1100° and 1300°C, and firing times of 2 to 12 hr were employed. The most frequent combination was 4 hr at 1200°C. On completion of the firing the silica tube is removed from the furnace, and the sample is allowed to cool close to room temperature with continued flow of the reducing atmosphere.

*Identification and characterization of products.*—X-ray diffraction techniques, using a Norelco diffractometer with filtered  $\text{CuK}_\alpha$  radiation, were employed for phase identification. Fluorescent properties (the excitation spectra and the spectral energy distribution curves) were determined on all samples using methods previously described by Eby (7).

## Results and Discussion

*The  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system.*—An isotherm run at 1200°C in which the composition was varied every 10 m/o (mole per cent) showed complete crystalline solution between these two compounds at this temperature. The x-ray diffraction patterns showed all preparations to result in a single phase material. All of the activator concentrations within the limits employed in this study, 0.005 to 0.10 atom fraction europium, produced efficient phosphors. A constant value of 0.02 was used in this system and in the systems to follow.

The incorporation of a small amount of ammonium chloride in the initial blend greatly accelerates the attainment of equilibrium in the finished sample. The crystallinity of the product is also greatly enhanced due to the fluxing action of the ammonium chloride. This is immediately obvious when the x-ray diffraction patterns of fluxed and unfluxed samples are compared. A more pronounced body color is also characteristic of the well-crystallized samples. The flux concentration used was about 0.25 mole/mole of matrix. Wet chemical analysis showed only a 0.13 w/o (weight per cent)  $\text{Cl}^-$  retained after firing which was water soluble and an additional 0.04 w/o on total analysis. Thus confirming that the ammonium chloride served as a flux and any residual could be substantially removed by water washing.

Differences in hydration properties of these materials were observed on washing to remove the residual chloride. The fluorescence of a sample of

$\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$  is almost completely destroyed by

water washing, while  $\text{Sr}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$  is unaffected by washing. Crystalline solutions containing 50 and 75 m/o  $\text{Sr}_2\text{SiO}_4$  were likewise unaffected by washing. If the crystalline solution contains more than 10 m/o  $\text{Sr}_2\text{SiO}_4$ , then water washing is not detrimental to the fluorescence of the resultant phosphor.

The fluorescent data for 2537Å excitation on the divalent europium activated crystalline solution series prepared are given in Table I. In the table the wavelength given is that of the peak position of the emission spectra,  $W_{h/2}$  is the width at half-height in nanometers, and the intensity factor is the product of the peak height (relative energy units), the scale factor, and the width at half-height. The intensity factors are for a particular set of samples and are given in order to compare luminous output within the series and subsequent series given in later sections of the paper. The reflectivity at 254 nm of all the samples in this series are within the range of 10-20% and are thus all good absorbers and potentially efficient phosphors. Although the reflectivity does contribute, the intensity factors even for one particular composition, are affected more by the method of synthesis.

The data in Table I show a fairly continuous shift in emission wavelength from 505 nm for the pure barium end-member to 575 nm for pure strontium end-member. This continuous shift in wavelength with composition of the crystalline solution is depicted in Fig. 1. Thus, by choosing the proper composition any emission wavelength between 505 nm ( $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$ )

and 575 nm ( $\text{Sr}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$ ) may be obtained. These data show the very marked sensitivity of emission from divalent europium to the matrix composition in this system. The excitation spectrum of  $\text{BaSrSiO}_4:\text{Eu}_{0.02}^{2+}$ , determined on equipment designed by Eby (7), which corrects for instrumental effects and records excitation spectra in terms of relative efficiency, is given in Fig. 2. The excitation spectra of other mem-

bers of this series are very similar to the curve given. The interpretation of such a curve for a divalent europium activated phosphor has recently been fully discussed by Palilla *et al.* (8).

Emission curves of four of these samples are given in Fig. 3. Curves are given for the two end-members and two intermediate crystalline solutions. The curves demonstrate the variation in emission wavelength possible, as well as the broadening of the emission spectra with increasing strontium concentration in the crystalline solution phase. The distinct broadening is still present when these curves are plotted on a frequency scale (rather than wavelength). On a frequency basis the width at half-height varies from  $22 \times 10^3 \text{ cm}^{-1}$  ( $\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$ ) to  $32 \times 10^3 \text{ cm}^{-1}$

Table I. Fluorescent data on compositions in the  $\text{Ba}_2\text{SiO}_4\text{-Sr}_2\text{SiO}_4$  system

0	100	575	106	61.7

Fig. 3. Spectral energy distribution curves of the end-member phases and two intermediate crystalline solution phases in the  $\text{Ba}_2\text{SiO}_4\text{-Sr}_2\text{SiO}_4$  system (2537Å excitation).

Fig. 4. Temperature dependence curves of the end-member phases and two crystalline solution phases in the  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system (2537Å excitation).

( $\text{Sr}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$ ). Curves showing the temperature dependency of these same four samples are given in Fig. 4. These curves show the temperature dependence of the crystalline solution phases to be better than that of either pure end-member. The temperature stability

of the  $\text{BaSrSiO}_4:\text{Eu}_{0.02}^{2+}$  crystalline solution phase prepared in this study is considerably better than that of the corresponding preparation by Jenkins and McKeag (3). A drop of less than 5% was observed in the present work at 100°C, while they reported a drop of 20%. This is believed to be due to the enhanced crystallinity of the samples in this study.

No significant difference in the brightness of a given fluorescent composition was observed between samples in which allowance for the activator concentration was made by removal of a corresponding concentration of a large alkaline earth ion, and when the activator was added in excess of the stoichiometric amounts of alkaline earth ions.

It was also noted in this study that europium could be incorporated in  $\text{Ba}_2\text{SiO}_4$  in the divalent state even when the firing was carried out in pure nitrogen. This was not true for  $\text{Sr}_2\text{SiO}_4$ . Here a reducing atmosphere was required in order that the europium be incorporated in the divalent state. This is somewhat surprising in that the two compounds  $\text{Ba}_2\text{SiO}_4$  and  $\text{Sr}_2\text{SiO}_4$  possess isotypic structures (9) ( $\text{K}_2\text{SO}_4$ -type with space group  $\text{P}_{\text{nam}}$ ), and the ionic radii of strontium and divalent europium are identical (Ahrens' value 1.12Å) while divalent barium is larger (1.34Å).

**Lamp test data.**—Several tests were run on compositions in the  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system in standard 40w fluorescent lamps. Data on four compositions are given in Table II.

The ( $x, y$ ) values are the chromaticity coordinates of the phosphors in lamps. The 1:1 composition

$\text{BaSrSiO}_4:\text{Eu}_{0.02}^{2+}$  has been tested for long-term maintenance. After 1775 hr of burning, it maintained 95.3% of its initial value. The low lumen values for the

$\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$  show it to be more sensitive than the other compositions to the processing necessary for incorporation into fluorescent lamps; also, the detrimental effect of residual chloride which could not be removed because of hydration problems.

Table II. Lamp test data

Composition	$x$	$y$	Lumens		% Maint.
			16 Hr	100 Hr	
$\text{Ba}_2\text{SiO}_4:\text{Eu}_{0.02}^{2+}$	0.198	0.579	1586	1447	91.2%
$\text{BaSrSiO}_4:\text{Eu}_{0.02}^{2+}$	0.272	0.630	3735	3614	96.8
$\text{Ba}_{0.5}\text{Sr}_{1.5}\text{SiO}_4:\text{Eu}_{0.02}^{2+}$	0.360	0.543	3664	3466	94.6

20	80	590	114	44.7
10	90	583	108	47.5
0	100	575	110	48.4

**The  $\text{Sr}_2\text{SiO}_4$ - $\text{Ca}_2\text{SiO}_4$  system.**—The 1200°C isotherm through this system showed complete crystalline solution to exist between  $\text{Sr}_2\text{SiO}_4$  and  $\beta$ - $\text{Ca}_2\text{SiO}_4$ . The intensity of fluorescence from these samples was considerably less than that in the previous system discussed, as seen by comparison of intensity factors with those of Table I. The data obtained on the divalent europium activated crystalline solutions prepared are given in Table III.

The terms in Table III are the same as those in Table I. The widths of the emission peaks in this system are considerably broader than those in the previous system and are decidedly asymmetric, possibly indicative of emission from divalent europium in two different crystallographic sites in the structure. The broadness of the peaks contributes very heavily to the total output from these samples since the peak heights are relatively low. This system was not studied at length due to the difficulties in attaining equilibrium, the polymorphism of  $\text{Ca}_2\text{SiO}_4$ , and the low luminous level of the initial phosphor samples prepared.

**The  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  system.**—Much of what has been said about difficulties in the previous system applies here. The fluorescent data on the divalent europium activated compositions prepared in this system are given in Table IV.

The fluorescence data in this table show large inconsistencies in these samples. However, due to the low level of fluorescence of all compositions in this system, no attempt to reconcile the data was made. The only noteworthy feature is the formation of an intermediate compound in this system. The formation of the compound was indicated in the emission data obtained and was verified by x-ray diffraction data. The large shift in the emission spectra for the 30 m/o  $\text{Ca}_2\text{SiO}_4$ -70 m/o  $\text{Ba}_2\text{SiO}_4$  composition over that of adjacent compositions indicated such an occurrence in this compositional region. A review of the literature showed disagreement over the appearance of a compound in this system. However, the compound  $\text{Ba}_5\text{Ca}_3\text{Si}_4\text{O}_{16}$  had been reported by Nadachowski and Grylicki (6), and the data here tend to corroborate this composition.

### Summary

1. Complete crystalline solubility was detected in 1200°C subsolidus isotherms in the systems  $\text{Ba}_2\text{SiO}_4$ -

Table IV. Fluorescent data on compositions in the  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  system

$\text{Ca}_2\text{SiO}_4$	Mole % $\text{Ba}_2\text{SiO}_4$	$\lambda$ Peak mn	$W_{h/2}$ mn	Int. factor Arbitrary units
100	0	508	108	27.2
90	10	546	144	20.9
80	20	534	144	9.1
70	30	540	140	10.1
60	40	525	132	17.4
50	50	523	136	25.1
40	60	522	140	37.5
30	70	491	138	53.0
20	80	532	84	47.0
10	90	527	78	38.1
0	100	510	66	39.5

$\text{Sr}_2\text{SiO}_4$  and  $\text{Ca}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$ . Emission spectra indicated the formation of an intermediate compound ( $\text{Ba}_5\text{Ca}_3\text{Si}_4\text{O}_{16}$ ) in the  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  system. The existence of this compound was confirmed by x-ray diffraction studies.

2. The fluxing action of the  $\text{NH}_4\text{Cl}$ , which greatly enhances the crystallinity of the samples, brings the fluorescence, due to 2537Å excitation, to a level where it can be considered for application in fluorescent lamps. Also, extremely good maintenance is characteristic of the well-crystallized materials.

3. Fluorescent properties of some crystalline solutions, such as intensity of emission and temperature dependency, have been shown to be enhanced over those of the end-member phases.

4. Crystalline solutions in the  $\text{Ba}_2\text{SiO}_4$ - $\text{Sr}_2\text{SiO}_4$  system activated by divalent europium have been shown to produce phosphors potentially useful in fluorescent lamp applications. Divalent europium activated phosphors in both the  $\text{Sr}_2\text{SiO}_4$ - $\text{Ca}_2\text{SiO}_4$  and  $\text{Ca}_2\text{SiO}_4$ - $\text{Ba}_2\text{SiO}_4$  systems are much less efficient and seemingly unimportant commercially.

#### Acknowledgment

The author gratefully acknowledges the encouragement and advice given by Dr. K. H. Butler and Dr. M. J. B. Thomas throughout this study. Sample prepara-

tion and spectral determinations were carried out with the assistance of Mr. A. Rudis, and x-ray diffraction data collected by Miss M. Skeadas.

Manuscript submitted May 22, 1968; revised manuscript received July 11, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 55.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## The Defect Structure of GaP Crystals Grown from Gallium Solutions, Vapor Phase and Liquid Phase Epitaxial Deposition

Robert H. Saul

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

#### ABSTRACT

The defect structure of GaP crystals grown from gallium solutions, vapor phase and liquid phase epitaxial deposition is described. Etchants have been used to demarcate emergent dislocations, stacking faults, and p-n and n-n<sup>+</sup> junctions. Crystals grown from gallium solutions are inhomogeneous with respect to defect structure and contain substantial dislocation-free regions. Evidence is cited which indicates that some dislocations are introduced during growth whereas others are apparently generated at high stress regions during cooling. It is demonstrated that vapor phase epitaxial deposition on GaP substrates is capable of yielding nearly dislocation-free crystals containing no stacking faults. The high density of defects observed in crystals grown on GaAs substrates is attributed to the heteroepitaxial mode of growth, in particular, the difference in thermal contraction of the growth layer and substrate on cooling from the growth temperature. GaP diodes fabricated by liquid-phase epitaxy, in contrast to those formed by vapor-phase epitaxy, do not contain interfacial dislocations at the growth-substrate interface, i.e., p-n junction.

The electrical and optical properties of semiconductors are highly dependent on the dislocation structure in these crystals (1). For example, laser emission and the improved laser efficiency of GaAs diodes after annealing has been correlated with dislocations located in the vicinity of the p-n junction (2, 3). Although there has been considerable interest in GaP for electrooptic devices, the defect structure in these crystals has not been studied in detail probably because of the lack of a reliable etchant for revealing dislocations. Solutions of aqua regia or halogen saturated methanol have been used (4); however, there is little evidence supporting the correlation of etch pits and individual dislocations, and it has been found that the density of etch pits may be reproducible only after annealing (5). This article reports several etchants which (i) reveal dislocations and stacking faults, (ii) can be used for nonselective chemical polishing, and (iii) delineate p-n and n-n<sup>+</sup> junctions in GaP

crystals. Etch pits not associated with dislocations are also reported. The defect structure of crystals grown by techniques which are currently being used for luminescent diodes is then described and some evidence which elucidates the sources of dislocations is provided.

#### Experimental

Crystals of GaP were grown by the slow cooling of saturated gallium solutions (6), vapor phase (7, 8) and liquid phase (9) epitaxial deposition. All crystals were polished, terminating with 0.1μ diamond paste, on either the Ga{111} or P{111} face.<sup>1</sup> Several crystals were subsequently chemically polished to remove the damaged surface layer which resulted in the elimination of certain nondislocation etch pits (described below). The etchants which were found to be most

<sup>1</sup> The Ga{111} and P{111} face designate the octahedral planes terminating with gallium or phosphorus atoms, respectively.

Table I. Etchants for gallium phosphide

Etchant	Reference	Comments
1. 10 ml H <sub>2</sub> O, 40 mg AgNO <sub>3</sub> , 5g CrO <sub>3</sub> , 8 ml HF at 75°C	(10)	Ga{111}, P{111}: dislocations, stacking faults (15-60 min); delineates p-n and n-n <sup>+</sup> junctions (1-5 min)
2. 8 ml H <sub>2</sub> O, 10 mg AgNO <sub>3</sub> , 6 ml HNO <sub>3</sub> , 4 ml HF at 60°C	(11)	Ga{111}, P{111}: dislocations, stacking faults (1-3 min)
3. 50 ml H <sub>2</sub> O, 6g KOH, 4g K <sub>3</sub> Fe (CN) <sub>6</sub> at 100°C	(12)	Ga{111}: dislocations (1-2 min); P{111}: polish (20-25 μ/hr)
4. 10 ml H <sub>2</sub> O, 10 ml HCl, 5 ml HNO <sub>3</sub> at 45°-50°C	—	Ga{111}: general pitting; P{111}: polish (2-5 μ/min)

reliable are listed in Table I and represent slight departures from those cited previously for GaAs and Ge. The higher temperatures and changes in the composition of the etchants are required to retard precipitates which tend to accumulate on the etched surfaces. The preparation of etchant 4 is rather critical, and the prescribed order should be followed. Moreover, if the color of the solution is dark yellow (NO<sub>2</sub> evolution), the etching rate is too rapid and selective etching of incipient scratches occurs. Experience has shown that the evolution of NO<sub>2</sub> is indicative of either the etchant temperature being too high, excessive HNO<sub>3</sub>, or contamination of the containing vessel. A clear to pale yellow color assures the nonselective attack required for polishing.

### Results and Discussion

*Revelation of dislocations.*—In establishing the correspondence of etch pits produced by etchants 1 and 2 to the site of emergent dislocations, it was demonstrated that (i) etch pits follow continuous lines as they are etched progressively deeper into the crystal,<sup>2</sup> (ii) the density of pits is markedly increased by deformation, and (iii) there is a 1:1 correspondence of etch pits on opposite {111} faces of a thinned crystal. Etchant 1 demarcates dislocations inclined to the surface by etch pit trails as in Fig. 1a and reveals dislocations nearly parallel to {111} surfaces as in Fig. 1b.

*Polarity of dislocations.*—Since etchant 3 has been shown (13) to reveal dislocations on the Ga{111} face, it is of interest to compare the etch figure derived by this etchant with that produced by etchant 1. Figures 2a and 2b were obtained after immersion in etchant 1 followed by immersion in etchant 3, respectively. While all pits produced by etchant 1 correspond to dislocations it is clear that not all dislocations are revealed by this etchant. Haasen (14) has pointed out that incomplete electron orbitals of either all group III atoms or all group V atoms are associated with dislocations in III-V compounds having the zinc blende structure. Moreover, there is experimental evidence suggesting that an etchant may reveal only one type of dislocation (15). Thus it is plausible that the difference between the etch figures derived by etchants 1 and 3 is a consequence of the polarity of dislocations. Although etchants 1 and 2 reveal dislocations on all octahedral faces, the density of etch pits on the P{111} face is generally higher (by as much as a factor of 7) than on the Ga{111} face. These observations have been confirmed in crystals of uniform dislocation density (verified by etching angle-lapped surfaces) and provides additional evidence for the selective etching of only one type of dislocation.

*Revelation of stacking faults.*—Figure 3 illustrates the linear etch grooves frequently observed in (vapor phase) epitaxially deposited GaP crystals after immersion in etchants 1 and 2. Since the etch grooves on

a {111} surface lie along <110> directions and frequently terminate with a dislocation etch pit, they are believed to be the etch traces of stacking faults. Pits which are coincident with the etch grooves, as in Fig. 3, may be indicative of impurity segregation at stacking faults.

*Nondislocation etch pits.*—Figure 4a depicts the irregularly shaped pits obtained on a Ga{111} face after immersion in etchant 1 for 15 min. Etching for an additional 30 min tends to obscure these pits and reveals additional pits not unlike the dislocation etch pits found on the P{111} face (see Fig. 4b). After chemically removing ~10μ, the crystal was re-etched (see Fig. 4c). The one to one correspondence of pits in Fig. 4b and 4c indicates that the pits formed after prolonged etching correspond to emergent dislocations. In light of the observation that the extent of surface damage resulting from mechanical abrasion is generally greater for the group III surface compared to the group V surface (16), it is likely that the irregular shaped pits observed on the Ga{111} face are a manifestation of surface damage. This interpretation for the origin of these pits is substantiated by the appearance of identical nondislocation pits on the P{111} face when the polishing cloth was contaminated and the elimination of these pits by prior chemical polishing. It is believed that these pits have previously been attributed to dislocations [cf Fig. 5 of Ref. (17)].

Fig. 1. Etch pits corresponding to dislocations inclined to the surface (a) (top) and a dislocation nearly parallel to the surface (b) (bottom).

<sup>2</sup> This was accomplished by correlating etch pits obtained prior to and subsequent to chemical polishing that obscures previous pits.

Fig. 2. Etch pits on the Ga{111} face after immersion in etchant 1 (a) (top) followed by immersion in etchant 3 (b) (bottom).

Fig. 3. Stacking fault traces and dislocation etch pits in an epitaxially deposited crystal.

Nondislocation etch pits are also revealed by warm aqua regia which has been reported to reveal dislocations (5). A solution-grown crystal was immersed in aqua regia for short periods until distinct pits appeared on the P{111} face; continued etching did

Fig. 4. Etch pits on the Ga{111} face after immersion in etchant 1 for 15 min (a) (top) and 45 min (b) (center). Same area after removing 10 μm and re-etching (c) (bottom).

not increase the number of these pits appreciably. The crystal was then immersed in etchant 1 (which has been shown to reveal dislocations) in an attempt to correlate the pits produced by aqua regia with dislocations. The large pits in Fig. 5 were produced by aqua regia and the small dark pits correspond to emergent dislocations. Although aqua regia does reveal some dislocations (center of figure), not all pits

Fig. 5. Etch pits on the P{111} face after immersion in aqua regia (large pits) and etchant 1 (small dark pits).

are associated with dislocations (top of figure). Unfortunately, a visual distinction between these two types of pits cannot be readily made. Moreover, many dislocations are not revealed by aqua regia (bottom of figure). Thus aqua regia is considered to be unsuitable for revealing dislocations in GaP.

For several crystals, minute pits (less than  $1\mu$  in diameter) have been observed in addition to the dislocation etch pits revealed by etchant 1. Further etching does not enlarge these pits and, in fact, completely changes their arrangement. Since the depth of these pits is  $\sim 1-2\mu$ , it is tempting to speculate that these pits are due to impurity and/or vacancy clusters. In this connection, it is noteworthy that pits of this type have been observed in Ge crystals where they have been correlated to oxygen content (18). Anticipating that the minute etch pits observed in GaP might be attributable to oxygen, a correlation of oxygen concentration and pit density was sought.

Crystals of GaP were grown from gallium solutions containing 0.07 m/o (mole per cent) Zn and varying amounts of  $Ga_2O_3$  up to 0.04 m/o. (The addition of  $Ga_2O_3$  is presumed to increase the oxygen concentration in the crystals.) To avoid erroneous etch figures due to contamination or surface damage, approximately  $30\mu$  was removed by chemical polishing. Crystals were immersed in etchant 1 for 30 min which resulted in the dissolution of  $3.3\mu$ . Although pits differed in size, ranging from 0.1 to  $1\mu$ , all pits were counted irrespective of size. No systematic variation of pit size was observed. The measured pit density was consistently in the range  $0.3-6.7 \times 10^5 \text{ cm}^{-2}$ . No systematic variation of pit density with added  $Ga_2O_3$  was found. Moreover, the pit density varied by as much as an order of magnitude for a given specimen, and thus it is doubtful that the pits represent an intrinsic property of the crystal. The origin of the pits is tentatively ascribed to precipitates formed during etching.

*Delineation of p-n and n-n<sup>+</sup> junctions.*—In the course of etching GaP crystals of varying dopant level, the rate of attack of etchant 1 was found to depend on the net carrier concentration, the etching rate being highest in lightly doped n-type material and lowest in p-type material. The difference in etching rates results in a step at p-n and n-n<sup>+</sup> junctions on angle-lapped surfaces, thus sharply delineating these boundaries. The step height is a function of etching time, but has been determined by interferometry to be less than  $0.1\mu$  in height. An etching time of less than 3 min is usually used since the demarcation becomes diffuse after prolonged etching. Etch pits which appear after prolonged etching

are larger in the more rapidly attacked layer. Etchant 2, on the other hand, is insensitive to doping level: junctions are not delineated and etch pits are practically the same size.

*Dislocations in solution-grown GaP.*—Crystals grown from saturated gallium solutions (6) have inhomogeneous dislocation morphologies: most crystals contain large areas which are dislocation free, small areas of uniform dislocation density ( $\sim 10^4 \text{ cm}^{-2}$ ), and localized areas of very high dislocation density ( $>10^6 \text{ cm}^{-2}$ ) at high stress regions typically at voids (as in Fig. 6a) or channels (as in Fig. 6b). Such regions are believed to correspond to gallium which was entrapped as a consequence of the dendritic nature of growth and constitutional supercooling. More rarely, crystals have a high dislocation density distributed homogeneously. In one case, substantial polygonization at the periphery of a platelet was evident (see Fig. 7) implying that these dislocations were introduced at high temperatures. The location of the polygonized walls at the edge of the crystal is particularly significant. Platelet growth is believed to occur over the temperature range  $1150^\circ-900^\circ\text{C}$ , the periphery presumably freezing at the lower temperatures. It is doubtful that self-diffusion near  $900^\circ\text{C}$  ( $T/T_m = 0.67$ ) is sufficient to account for the extensive polygonization;

Fig. 6. Dislocation etch pits in solution-grown GaP crystals showing a high density of dislocations at a void (a) (top) and channel (b) (bottom).

Fig. 7. Polygonized walls near the periphery of a solution-grown GaP crystal.

hence, crystal growth is apparently complete at a substantially higher temperature. Since these crystals are strain free, as evidenced by the lack of birefringence, it is believed that the perfection is due to the lack of physical constraint (which can cause large strains upon cooling) imposed by the molten gallium.

**Dislocations and stacking faults in vapor-grown GaP.**—Crystals grown by vapor-phase epitaxial deposition onto {111} oriented GaAs substrates (7,8) consistently contain a rather uniform distribution of dislocations in the range  $2 \times 10^5$ – $2 \times 10^6$   $\text{cm}^{-2}$  (compared to  $3 \times 10^4$   $\text{cm}^{-2}$  in the substrate), considerable strain and frequently stacking faults. In an attempt to determine if the gross defect structure can be ascribed to the growth conditions *per se* (deposition rate, thermal gradient, substrate preparation, etc.), crystals were grown on dislocation-free (solution grown) GaP substrates. Figure 8 is a contiguous series of photomicrographs of an angle lapped surface showing the defect structure of such a crystal. The substrate remains nearly dislocation free, and the growth layer is free of stacking faults and contains dislocations fewer than  $10^2$   $\text{cm}^{-2}$  albeit a high dislocation density appears at the substrate-growth interface. (The shallow, noncrystallographic pits which appear in the figure are the result of surface damage and are not to be confused with dislocation etch pits.) Another crystal contained stacking faults and dislocations; however, the density of these defects was nevertheless several orders of magnitude lower than for crystals grown on GaAs substrates. A high density of dislocations was also coincident with the substrate-growth interface. Where an inadvertent air leak into the growth chamber resulted in contamination and excessive growth rates, a very high density of stacking faults and dislocations was evident at the substrate-growth interface. The dislocation density decreased with distance from this interface to a final value of  $6 \times 10^4$   $\text{cm}^{-2}$ . In most cases the overgrowth or peripheral deposit is highly faulted and is demarcated by interfacial dislocations ( $\sim 3 \times 10^3$   $\text{cm}^{-1}$ ).

The above observations indicate that the gross defect structure which typifies crystals grown on GaAs substrates is not ascribable to the growth conditions,

Fig. 8. Etched angle-lapped surface of a GaP crystal (left) grown by vapor deposition on a nearly dislocation-free GaP substrate (right). The high density of etch pits is coincident with the substrate-growth interface.

and it is concluded that the heteroepitaxial structure, i.e., the discontinuity in lattice parameter at the substrate-growth interface and the difference in thermal contraction of GaP and GaAs on cooling from the growth temperature, gives rise to the observed structure.

The lattice mismatch of  $\sim 4\%$  at the growth temperature may be accommodated by three sets of interfacial dislocations aligned along  $\langle 211 \rangle$  directions, each set containing a linear density of  $\sim 9 \times 10^6$   $\text{cm}^{-1}$ . The occurrence of a mixed crystal region, i.e.,  $\text{GaP}_x\text{As}_{1-x}$ , could substantially lower the density of interfacial dislocations by reducing the magnitude of the local internal stresses. Examination of GaP crystals after removal of the GaAs seed has not revealed any interfacial dislocations, presumably because the material containing them has been removed by lapping or etching. (Dislocations are present at the original growth interface even in the case of deposition on GaP as noted above.) On the other hand, dislocations resulting from the "bending" of the growth layer on cooling would tend to be distributed throughout the bulk as observed. The strain birefringence of a GaP layer grown with a partially converted seed (to give a  $\text{GaP}_x\text{As}_{1-x}$  transition region) clearly shows a substantial residual bending stress (19). Since this bending stress vanishes on removal of the GaAs seed, leaving a much smaller random strain (19), the curvature of the stripped GaP crystal provides a measure of the plastic deformation which occurred at high temperatures in order to relieve the concomitant bending stress. Assuming that plastic deformation does not occur below  $600^\circ\text{C}$  and that the difference in thermal expansion coefficients of GaP and GaAs near the growth temperature is approximately equal to that at room temperature, the maximum residual radius of curvature of a typical GaP crystal which was grown at  $1100^\circ\text{C}$  (7) is computed to be 65 cm. The minimum density of dislocations which is compatible with this curvature is  $\sim 3 \times 10^5$   $\text{cm}^{-2}$ ; however, owing to the interaction of dislocations on congruent slip planes (the neutral plane is of the {111} type and hence at least three slip systems are activated) and the lack of annihilation of excess dislocations, the dislocation density could be up to an order of magnitude higher. Thus, one could conceivably account for the observed dislocation density in terms of thermally induced strains alone. The fact that stripped crystals frequently exhibit a radius of curvature of  $\lesssim 20$  cm and that a rather complex strain pattern is evident in crystals which were grown without deliberate seed conversion (19) indicates that the observed defect structure involves other sources as well.

Figure 9a shows a rather uniform distribution of dislocations aligned along congruent slip planes in a vapor-grown crystal. Comparison of this figure with Fig. 9b, which corresponds to the same area after  $\sim 10\mu$  was chemically removed, reveals the detailed rearrangements of etch pits corresponding to the circuitous path of dislocations caused by mutual interactions and dislocation reactions. Figure 9c, which represents a different area of the same crystal, shows several etch pits which can be followed to a depth in excess of  $30\mu$ ; these pits appear in the center of the halos or remnants of prior etching. The fact that the corresponding dislocations are practically straight over such a large distance suggests that they were present prior to the "forest" of dislocations. It is thus speculated that the straight dislocations were present at the growth temperature and subsequently locked by impurity segregation; the forest dislocations were then generated on cooling. The more rapid growth rate of etch pits associated with the straight dislocations ( $\sim 2X$  faster than for the forest dislocations) implies greater impurity segregation and thus lends support to this view.

In an earlier study, Gershenzon and Mikulyak (4) reported that, in vapor-grown GaP crystals, the re-

Fig. 9. Dislocation etch pits in a vapor-grown GaP crystal (a) (top); same area after  $10\mu$  was removed by chemical polishing and followed by subsequent etching to reveal dislocations (b) (center); dislocation etch pits in a different area of the same crystal (c) (bottom).

gions of minimum strain birefringence lie along specific crystallographic directions, and from deformation experiments they concluded that the strain minima correspond to traces of active slip planes. We find that for crystals grown by halogen transport (8) the regions of minimum strain birefringence lie along

$\langle 110 \rangle$  and  $\langle 211 \rangle$  directions which could correspond to the traces of congruent  $\{111\}$  and  $\{110\}$  slip planes, respectively. While subsequent etching indicates that dislocations tend to be aligned along  $\langle 110 \rangle$  slip traces, there is not a lower density of active slip planes in the regions of maximum birefringence as would be anticipated from the findings of Gershenzon and Mikulyak. Rather, there is a coincidence of stacking fault traces with these regions. There is not, however, a 1:1 correspondence between the strain pattern in the bulk and stacking fault traces on the viewed surface.

Comparison of the stacking fault morphologies on the substrate and growth faces of a  $\sim 150\mu$  thick crystal reveals that (i) many of the faults propagate through the growth layer, (ii) the density of faults is lower on the growth face, and (iii) not all fault traces on the growth face can be correlated to fault traces on the substrate face. These observations imply that, whereas most faults originate at the substrate-growth interfaces, many faults are generated within the deposited layer perhaps providing a mechanism of stress relief.

*Dislocations and stacking faults in GaP grown by liquid phase epitaxy.*—Crystals grown by liquid phase epitaxy (tipping) (9) have fewer defects than the GaP substrates on which they are grown. For example, a dislocation density of  $2 \times 10^6 \text{ cm}^{-2}$  is reduced by a factor of about 3 in a depth of less than  $5\mu$  as in Fig. 10. In contrast, the temperature gradient zone-melting or travelling solvent method reduces the dislocation density from an initial value of  $8 \times 10^4 \text{ cm}^{-2}$  by a factor of 8 over a depth of  $\sim 10^3\mu$  in GaAs crystals (20). The stacking fault density is not reduced in the tipped layer, i.e., faulted regions propagate into the tipped layer as in Fig. 11. Layers grown on dislocation-free (solution-grown) substrates contain no stacking faults and are essentially dislocation free. In this case dislocations tend to be isolated (straight or as half loops) or aligned along slip traces at voids.

It has been shown above that dislocations consistently appear at the original growth interface in crystals grown by vapor phase epitaxy. These dislocations may arise from the discontinuity in lattice parameter associated with differences in doping levels of the substrate and deposited layers. If this were the case, dislocations should also be observed in comparable tipped layers. Indeed, interfacial dislocations (ascribed to lattice mismatch) and precipitates have been observed in GaAs p-n junctions fabricated by vapor deposition as well as tipping (2). Dislocations and precipitates (electrically inactive species) confined to

Fig. 10. Dislocation etch pits in a angle-lapped ( $3^\circ$ ) GaP crystal containing a p-n junction which was fabricated by tipping a Te-doped n layer (top) onto a vapor-grown Zn-doped p layer (bottom).

Fig. 11. Trace of a stacking fault in the substrate (bottom) which propagated into the tipped layer (top).

the junction region may have important consequences with regard to electrooptic properties; hence, GaP diodes fabricated by tipping have been carefully examined for these defects. Etching of angle-lapped samples has revealed no dislocations or precipitates in the vicinity of the junction plane in as-grown and annealed (8 hr at 600°C) diodes fabricated from dislocation-free substrates. Both etchants 1 and 2 were used since it was thought that, for the former, etch pits at the junction may be obscured by the difference in etching rates of the p- and n-regions.

Assuming that there are no concentration gradients except in the p-n transition region, the density of dislocations  $\rho$  in the transition region is given by (21)

$$\rho = \frac{1}{a^2} \sum_{i=n,p} \frac{\partial a}{\partial c_i} \frac{\partial c_i}{\partial x} \quad [1]$$

where  $a$  denotes the lattice parameter,  $c_p$  and  $c_n$  denote the respective concentration of p-dopant and n-dopant, and  $\partial c_i / \partial x$  denotes the concentration gradient in the transition region. Accordingly, the dislocation density is not directly a function of  $c_n - c_p$ , but depends on the concentration gradient of both donor and acceptor species in the transition region. Thus the presence or absence of interfacial dislocations depends upon the concentration gradients established during the fabrication of the diodes. The lack of interfacial dislocations as described above is apparently due to the lack of steep concentration gradients in these diodes.

### Conclusions

The large dislocation free areas (40-80% of a crystal) found in GaP crystals grown from gallium solution indicates that this method potentially offers a means of growing near-perfect crystals; however,

better control of the growth conditions is required to eliminate gallium occlusions and the probable inhomogeneous dopant distribution. The high density of dislocations and stacking faults present in crystals grown by vapor phase epitaxial deposition on GaAs substrates appears not to be due to the method of growth but rather the presence of a heteroepitaxial structure, in particular, the difference in thermal contraction of GaP and GaAs on cooling from the growth temperature. Liquid phase epitaxy is advantageous for GaP diode fabrication since, in contrast to vapor phase epitaxy, no dislocations are introduced at the substrate-growth interface (p-n junction), at least for diodes fabricated on dislocation free substrates.

### Acknowledgment

The author is indebted to L. Derick, L. C. Luther, and M. Kowalchik for supplying the crystals and to F. A. Trumbore and helpful comments. The author extends thanks to F. K. Reinhart for stimulating discussions about his unpublished work on the residual strain patterns in vapor-grown GaP.

Manuscript submitted March 18, 1968; revised manuscript received June 17, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Recent News Paper 291.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# A Method for Determining Sodium Content of Semiconductor Processing Materials

Bernard Yurash\* and Bruce E. Deal\*

*Fairchild Semiconductor Research and Development Laboratory, Palo Alto, California*

## ABSTRACT

A refined flame spectrophotometric method has been used to analyze and control sodium content in materials associated with the processing of semiconductor devices. Several examples of materials analyzed are presented which include water oxidation ambients, quartz oxidation tubes, various organic and inorganic solvents, and sedimented glasses. Very good correlations are obtained between sodium content of these materials and corresponding electrical stability of MOS structures. The method is relatively inexpensive and simple to use, with a detection limit in water of 0.05 ppb sodium.

Attention has been focused on ion transport phenomena and the effect of alkali ions, particularly sodium, on the behavior of surface sensitive, semiconductor devices (1, 2). Especially sensitive to such contamination are metal-oxide-semiconductor (MOS) structures, but any type of passivated device can be affected by the migration of ions through the passivating oxide layer. Every processing step during the fabrication of these devices is a potential source of contamination. Thus, any materials used in the fabrication are suspect in regard to such ions as sodium. These materials include water, etchants, organic and inorganic solvents, diffusion sources, furnace tubes and boats, gaseous ambients, metals used as field plates or interconnections, and encapsulation materials. A method of analysis for sodium in these processing materials and the control (and minimization) of such sodium would be considered an important requirement for producing electrically stable devices.

Analyses of sodium in silicon and silicon dioxide using neutron activation or mass spectrography have been reported by a number of investigators (3-7). However, many laboratories do not have this type of equipment. Therefore, a method of sodium analysis which makes use of a flame spectrophotometer, a common laboratory tool, has been refined for determining sodium content at low levels. As a result, we have been able to analyze and control sodium content of various materials employed during the fabrication of semiconductor devices. The results have provided very good agreement with corresponding data obtained by other methods of analysis. A brief description of the flame photometric method of sodium analysis will be given along with procedures for preparing various types of samples. Several examples are presented showing the comparison of sodium content obtained by this method and that indicated by MOS C-V analysis (8).

## Method

A literature search revealed several reports describing the analysis of sodium in aqueous media in the low parts per billion concentration by flame photometric techniques (9-11). It was obvious that instrumental conditions and sample treatment were critical and had to be strictly controlled for accurate results.

The instrument chosen for this investigation was the Beckman Model DU spectrophotometer. This instrument as delivered did not prove satisfactory, so modifications were made. The photomultiplier tube was specially selected for electronic stability. A medium-bore, oxyhydrogen burner was used. The pressure controller supplied with the instrument did not give reproducible settings at low pressures, yet re-

producible pressures and flow rates of the gases to the burner are required for stability of the flame. A flowmeter with needle valve control was installed in the hydrogen gas line to assure gas flow stability. Optimum oxygen and hydrogen flow rates and pressures depend on the individual instrument and must be determined empirically.

Ambient air drawn into the burner housing also affects signal stability at low sodium concentrations. A filtered air supply plenum chamber for the burner housing was constructed according to Rice (11). Existing Fiberglas acoustic absorber pads inside the burner housing were covered with thin Teflon sheets. A light proof tunnel was installed between the burner housing and the entrance slit to cut down on stray light. All instrument housing joints at the sample compartment end were covered with black plastic tape to eliminate light leaks, and a Teflon-covered, aluminum sheet was made to seal the floor of the burner chamber. During sample aspiration, the sample insertion opening was closed with a small removable panel. In later work, a sharp cut optical filter was added to the optical path in the cell holder compartment just before the photomultiplier shutter to eliminate stray light below 510 m $\mu$ . This addition improved the stability of the signal with very little loss of sensitivity. The flame exhaust guard was placed in a sheet metal duct or exhaust flue to prevent dust particles from falling into the burner housing during an analysis.

In the preparation of the standard calibration curve, two types of standards have been used: a sodium fluoride, reagent-grade material dried, weighed, and carefully diluted to known volumes; and a commercially available aqueous sodium chloride solution of known concentration diluted carefully to provide working standards. All dilutions are carried out using calibrated polyethylene graduated cylinders and pipets because Pyrex volumetric flasks and pipets contribute significant sodium to standards in the part per billion range. Polyethylene bottles in which standards are kept are wrapped in aluminum foil to prevent transport of sodium from the hands through the wall during handling.

The instrument is carefully tuned to the sodium emission line using one of the sodium standards, and then the slide wire % T (per cent transmittance) dial set at 10% T for the "zero" content water from a high-purity water machine. Standards are then run and % T vs. sodium content plotted.

For aspiration into the flame, 5 ml plastic disposable beakers are used which have been soaked for 5 min in the high-purity water machine. Stainless steel Teflon tipped tongs are used to manipulate the small beakers because we have found that merely touching them with the fingers introduces detectable amounts of sodium. Water from the bottle containing the so-

\* Electrochemical Society Active Members.

dium standard is poured into the clean 5 ml beaker, and this in turn is placed in the sample positioning device of the flame photometer. After the sample holder lever is actuated to bring the sample to the aspirator tube, a small panel is placed to cover the sample insertion opening to exclude unfiltered air. Null meter oscillations are pronounced at low signal levels and high instrument sensitivity settings, but with practice an experienced operator can obtain reproducible results and duplicate his calibration curves repeatedly. Our experience has been that with standards or samples which are not affected by environmental conditions, including sampling techniques and accidental contamination, etc., the standard deviation in the range 1-100 ppb is  $\pm 0.4$  ppb. Calibration curves of two ranges of sodium concentration are shown in Fig. 1.

An independent cross check of our standard calibration curve in the part per billion range was obtained by an isotope dilution analysis performed by Aerojet General Nucleonics of San Ramon, California. A sample of radioactive aqueous sodium chloride provided by Oak Ridge National Laboratories was analyzed by Aerojet General and then by us on our flame photometer when the material was safe to handle. Agreement was very good, as shown in Fig. 2.

High-purity water is especially important in the preparation of calibration curves at low sodium levels because one needs to approach zero content sodium for establishing the best signal to noise ratio for sub-nanogram quantities. The standard addition technique does not work well if one is unsure of the absolute concentrations of standard solutions. The source of our high-purity water for preparation of standards, reagents, and for washing samples, plastic beakers, and storage bottles is a water treatment machine as described by Koontz and Sullivan (12). This machine continuously recirculates water in a covered system through filters and ion-exchange resins to provide water very near to theoretical purity.

An excellent discussion of the production of large quantities of high-purity water is found in a report by Simon and Calmon (13). Although they report that the total electrolyte specification may be  $< 20$  ppb as NaCl, it is claimed that a typical loop inlet of a large factory size recirculating deionized water system shows no sodium. Our actual analyses indicate about 0.5 ppb in a properly operating system, with only 0.05 ppb of sodium in the water of the

Fig. 1. Flame photometric calibration curves for two ranges of sodium ion concentration.

Fig. 2. Agreement between two methods of analysis for aqueous samples of NaCl.

small closed system used for the preparation of standards. If we take a water sample of 0.5 ml, in volume, we find our detection limit to be 0.025 nanogram of sodium.

### Procedure

Sample preparation is extremely important in all stages of the analysis for sodium. This has also been observed by Osborne *et al.* (4) in their activation analysis and by Yon *et al.* (6), who mention finding fractional parts per million levels of sodium in the nitric acid and water used in their work. We have found that surface contamination of samples and sample containers by the ambient laboratory environment and by ordinary handling during an analysis is so variable and at times so severe that a wash or pretreatment in the high-purity recirculating water machine is required before acceptable reproducibility of bulk values could be obtained. Avoidance of contamination is practiced by minimizing open exposure of the samples, reagents, equipment, and containers.

Following is a brief description of methods used to collect or prepare for analysis various types of materials associated with semiconductor device processing.

**Water.**—For our studies of the sodium content of water taken from wet oxidation furnaces, special precautions have to be taken. All equipment is made of quartz, including the furnace tube, the inlet boiling flask, (Pyrex flasks were used initially), and the outlet condenser and receiver. Samples of condensate collected in the receiver after a wet oxidation of silicon are transferred to a prewashed, aluminum foil covered, polyethylene bottle. This is taken to the analytical laboratory where it is introduced into the flame photometer in the same manner as described in the preparation of the calibration curve. A calibration curve is run each day that an analysis is performed (see Fig. 1). The emissivity or % T value found for the sample is compared with the calibration curve to determine the concentration of sodium in the sample. The standard deviation for a given sample collected in the above manner has been found to be  $\pm 1.6$  ppb.

**Quartz.**—Samples of quartz furnace tubes have been analyzed by etching the surface with hydrofluoric acid, soaking the specimen in the reservoir of the water machine for 30 min, and then dissolving a known amount of sample in hydrofluoric acid in a platinum crucible. The sample is taken to dryness on a hot plate, and the residue taken up in a known amount of water for aspiration into the flame of the burner. For optimum results, the hydrofluoric acid should be prepared by gaseous diffusion of anhydrous

hydrogen fluoride into high-purity water using Teflon tubing and vessels.

An independent check of our procedure was obtained by a neutron activation analysis of synthetic  $\text{SiO}_2$  grains prepared from silicon tetrachloride. The activation analysis by the General Atomic Division of General Dynamics Corp. showed  $3.29 \pm 0.03$  ppm and our flame photometric analysis yielded  $3.3 \pm 0.5$  ppm.

**Solvents.**—Analysis of solvents presents a slightly different problem because of enhancement or suppression effects by the solvent in the flame. A known volume is evaporated in a clean platinum dish and the residue taken up in high-purity water for aspiration into the flame. Here again, extreme care must be exercised to prevent contamination from the ambient and skin contact. All manipulations are performed with clean Teflon-tipped tongs, and the platinum crucibles are kept partially covered with platinum lids during the evaporation.

**Glasses.**—Most glasses used in semiconductor processing have appreciable sodium; therefore, reagent grade acids may be used in their dissolution. Reagent blanks must, of course, be run to eliminate the sodium contribution by the reagents. Sample treatment and handling is similar to the quartz analysis described above.

**MOS C-V Analysis.**—Briefly, the procedure for measuring effects of contamination on MOS (metal-oxide-semiconductor) structures using the capacitance-voltage method of analysis (1) is as follows. The MOS capacitor is prepared by thermally oxidizing single crystal silicon (approximately 1 ohm-cm resistivity) to  $0.2\mu$ . The silicon is generally lapped, cleaned, and chemically polished before oxidation. Metal field plates (usually aluminum) are deposited on the oxide surface in diameters ranging from 125 to  $750\mu$  diameter. Aluminum is also deposited on the back side of the silicon where the oxide has been removed. The sample is then annealed at  $550^\circ\text{C}$  in  $\text{N}_2$  for 2 min to assure backside ohmic contact and to minimize fast surface state density. At this point, the devices may be tested to determine prior processing effects, or may be subjected to further processing steps.

Stress tests themselves are accomplished by first plotting the C-V characteristics of the MOS capacitor. The initial curve is translated along the voltage axis from the theoretical case reflecting the fixed surface state charge  $Q_{ss}$ , the work function difference  $\phi_{ms}$ , and possibly some impurity ions  $Q_o$  in the bulk of the oxide. The devices are then subjected to low positive bias (5v) at  $300^\circ\text{C}$  for 2 min and the C-V curve again plotted. The mobile ions move to the silicon and cause the silicon surface to become more n-type. The C-V curve moves in the negative direction. The device is then stressed with a negative bias at  $300^\circ\text{C}$ , and the ions are drawn to the metal field plate. The total mobile ion content is now a function of the voltage difference of the C-V plots after positive and negative stress, as is shown in Fig. 3. Generally, the mobile ions will be on the oxide surface or in the oxide very close to the field plate. Thus, a measure of  $Q_o$  is obtained by a comparison of the initial C-V curve and that after positive bias stress.

#### Examples

The importance of controlling and minimizing impurity ion content, *i.e.*, sodium ions, during semiconductor device fabrication was emphasized in the Introduction. It was pointed out that each processing step is a potential source of sodium. The method of sodium analysis described above has been successfully used for a majority of the materials associated with the processing of semiconductor devices. In many such cases, a direct correlation has been obtained between the sodium content of the particular processing material and device electrical characteristics. In partic-

Fig. 3. Method for determining impurity ion concentration  $Q_o$  in MOS structure by capacitance-voltage method. Case I represents initial condition; case II is after positive bias stress test; and case III is after negative bias stress test.

ular, a measure of the latter has been obtained using the MOS capacitance-voltage method of analysis, since this type of measurement, in turn, has been directly correlated with actual device stability (2, 14, 15).

Listed below are several examples which demonstrate the use of this method of analysis for determining sodium content of materials employed in conjunction with semiconductor processing. In some of these cases, corresponding electrical stability data as obtained using MOS structures are also presented. Thus, the degree of correlation between the two analysis methods may be ascertained.

**Water**—Water is used in two important ways during the fabrication of semiconductor devices. One is as a rinse after treatment of the device structure and related materials in inorganic and organic solvents. This case will be discussed later in the Solvent section.

The other use of water is during thermal oxidation of silicon, which can be carried out either in dry oxygen or oxygen (or inert gas) bubbled through water. The latter, called wet oxygen, provides a much more rapid oxidation rate (16). The sodium content of the water carried into the oxidation tube will be very important in regards to the resulting oxide purity. Furthermore, any additional sodium picked up by this wet ambient in the gas lines or the quartz tube will also contribute to the oxide contamination. For this reason, experiments were conducted to relate the sodium content of the water used in thermal oxidation, before entering and after leaving the oxidation tube, and electrical stability of MOS structures oxidized at the same time. The tube was transparent, commercial-grade fused quartz (see Quartz section below).

Table I lists typical sodium content of deionized water collected at various stages of thermal oxidation of silicon. Two important facts can be noted from these data. First, while the initially high-purity water

Table I. Sodium concentration in various water samples used for silicon oxidation

Collection point of water	Na <sup>+</sup> content, ppb
From line (deionized water)	<1
Pyrex bubbler	300-500
Quartz* bubbler	10-50
Distillate from either bubbler	<10
Through quartz ox. tube, $1200^\circ\text{C}$	10-40
Through quartz ox. tube, $920^\circ\text{C}$	5-15

\* Transparent commercial-grade fused quartz.

Table II. Relationship of contamination  $Q_o/q$  in thermal oxides and sodium content of water collected from exit of oxidation tube during oxidation

Oxidation temp, °C	MOS drift, $Q_o/q$ , cm <sup>-2</sup>	Na <sup>+</sup> content in water, ppb
1200	$5 \times 10^{11}$	35
920	$2 \times 10^{11}$	12

can be contaminated by the flask, a fairly efficient distillation occurs. Second, a distinct difference in sodium content can be obtained between the water passing through the quartz oxidation tube at 920° and 1200°C, the latter being appreciably greater at any given time.

Corresponding instability data for MOS structures are listed for specific cases in Table II, along with Na<sup>+</sup> content of water collected after passing through the oxidation tube. The oxides were prepared at the two temperatures by oxidizing with O<sub>2</sub> bubbling through 95°C water for the times required to produce 0.2 $\mu$  layers [4¼ min at 1200°C, 45 min at 920°C (16)]. The  $Q_o/q$  values (in number of charges per cm<sup>2</sup>) were obtained by measuring the voltage displacement of capacitance-voltage plots of MOS structures after stressing at  $\pm 50$  v/ $\mu$  for 3 min at 300°C (1).

These results show a direct relationship between the contamination in the oxides as measured by MOS stress tests and the sodium analysis of the water collected from the end of the quartz tube. It is proposed that the greater amount of contamination obtained during the 1200°C oxidations in the case of these experiments was due to a faster etch rate of the quartz by the wet ambient. Thus, more of the sodium contained in the quartz was incorporated in the oxide during its formation. The amount of sodium coming from the water should actually be less at 1200°C, since the oxidation time for a given oxide thickness is much less than at 920°C while the flow rates were the same. Additional experiments which involved placing the silicon samples at 920°C ahead or behind a 1200°C region in the tube also confirmed that more contamination was coming from the quartz at 1200°C.

An interesting result obtained during these experiments was a profile of sodium in the wet oxides. This was obtained by MOS C-V stress measurements of oxides before and after etching off thin layers of the oxide in dilute hydrofluoric acid.<sup>1</sup> The data for the oxides prepared at the two temperatures are listed in Table III.

The results in Table III show first the total difference in  $Q_o/q$  for the two temperatures. They also show that at 1200°C, the contamination extends deeper into the 0.2 $\mu$  oxide, and 200Å must be etched off to remove it. At 920°C, the contamination is contained in the outer 50Å. In both cases, the sodium remains in the outer portion of the oxide due to the proposed field during thermal oxidation (16). Similar findings have been reported for experiments in which neutron activation analysis has been employed (4, 6, 7).

Two other effects were established during experiments relating drift of MOS structures and sodium analysis of water. One was that, if silicon slices were stacked one on top of another, the inside oxides pro-

<sup>1</sup> 1 part conc (49%) HF, 10 parts deionized H<sub>2</sub>O.

Table III. Profile of mobile ion concentration in 0.2 $\mu$  wet thermal oxides obtained by MOS stress tests

1200	0	$4.5 \times 10^{11}$
1200	50	$2.6 \times 10^{11}$
1200	100	$1.2 \times 10^{11}$
1200	150	$0.5 \times 10^{11}$
1200	200	$< 0.1 \times 10^{11}$
1200	600	$< 0.1 \times 10^{11}$

duced in these sandwich arrangements were found to be relatively free from ion drift, i.e., sodium. Thus, it appears that, while the same thickness oxide can be produced on a "masked" or blocked surface, the sodium apparently does not contaminate this oxide.

The second effect noted was that caused by subsequent treatment of contaminated, wet oxides in dry O<sub>2</sub>, N<sub>2</sub>, and argon. It was found that a subsequent 15-min treatment at 1200°C of a 0.2 $\mu$ , 1200°C wet oxide in either argon or nitrogen would eliminate more than 90% of the contamination. On the other hand, 80 min in dry O<sub>2</sub> at the same temperature would remove only 75% of the sodium. These findings agree with data reported by Schmidt (17).

**Quartz.**—Since the analyses described above indicated that the quartz tube, boat, and other items used for high-temperature oxidations could contribute sodium to the oxide (especially in a wet ambient), the sodium content in quartz was determined. Three different "grades" of fused silica or quartz were checked. As expected, the optical grade quartz from two sources contains in the order of 1 ppb sodium. The commercial grade of transparent fused quartz contains about 1 ppm, while the translucent, commercial grade contains 15 ppm or more sodium. The use of the low sodium, optical grade quartz would obviously result in a minimum amount of sodium contamination. However, its use would depend on weighing its high cost against the actual stability requirements for the devices being processed. In any case, rigid conditions of cleanliness still must be maintained both in precleaning of quartz tube, boat, and in the oxidation process itself.

**Solvents.**—Various liquids including organic solvents, inorganic acids, and water are used for rinsing, cleaning, and etching device structures throughout the fabrication of semiconductor devices. As a result these solvents are a very likely source of ionic contamination. Experiments have therefore been carried out to relate MOS electrical stability to sodium in solvents as measured by the flame photometric method.

One experiment involved relating MOS stability to some of the standard sodium solutions used for calibration purposes (see Fig. 1). Oxidized silicon samples were rinsed in solutions containing 11, 46, and 92 ppb sodium as well as in deionized water (0.5 ppb sodium). For each of the four solutions, one sample was blown dry in N<sub>2</sub> after rinsing, while the solution on another was allowed to evaporate in a laminar flow hood. Aluminum dots were then evaporated on the treated oxides and the total impurity concentration  $Q_o$  was determined by MOS stress measurements. Results are plotted in Fig. 4.

Reproducibility for the "blow-dry-in-N<sub>2</sub>" case was about  $\pm 20\%$ . The spread was larger where the solution was evaporated as would be expected. However, average values of  $Q_o$  still provide good linear relationships with sodium content for both cases. The total contamination for those samples where the solution was evaporated is a little over ten times that of the rinse and N<sub>2</sub>-dry set. The thickness of the aqueous film was calculated from the  $Q_o/q$  values to be about 10 $\mu$  for the samples where the solution was evaporated, assuming all sodium remained on the oxide surface.

For the purpose of relating sodium content of other solvents to MOS stability, standard 0.2 $\mu$  thermal oxides were rinsed in the solvent being evaluated. In the case of organic solvents and water, they were allowed to dry, and aluminum dots were immediately deposited on the oxide surface. The acid treatments were followed by thorough DI water rinses and then air dried. Approximately 50Å of oxide was removed by the 1:10 HF:H<sub>2</sub>O treatment; in all other cases, no oxide was removed due to the solvent treatment. Typical results of these tests are given in Table IV where the concentration of mobile ions in the oxide,

Fig. 4. Relationship between sodium content in standard solution used to rinse oxidized silicon samples and ionic contamination  $Q_o/q$  measured by stress tests of subsequently prepared MOS capacitors.

$Q_o/q$ , as measured by MOS temperature stress tests, and sodium content of the solvent are tabulated.

Representative samples of three classes of solvents, water, inorganic acids, and organic compounds, are included in Table IV. In each case solvents with low and higher sodium contents provide corresponding low and higher amounts of MOS drift. This same correlation has been found for a variety of other solvents, the total amount of contamination varying from lot-to-lot.

An interesting comparison may be made between the data obtained for tap water and the results of Fig. 4. The slope of the relationship of the "blow-dry-in- $N_2$ " case of Fig. 4 is 0.0455. If the ratio of  $Q_o/q$  to sodium content of the tap water listed in Table IV is calculated, it turns out to be 0.049. This means the tap water values would fit an extrapolated curve in Fig. 4 very well, even at the much higher sodium content value.

An additional experiment was carried out, the results of which support the data in Table IV. A number of clean MOS structures were prepared with small diameter ( $250\mu$ ) aluminum field plates. After annealing at  $550^\circ C$  in  $N_2$  and dicing, the measured drift was less than 0.1v. The dice were then rinsed in various solvents and stressed at  $300^\circ C$ . Although the resulting C-V curves were now distorted, the average amounts of drift were in the same order for various solvents as those treated with the solvents prior to metallization. Typical curves are shown in Fig. 5. For these structures, the contamination was believed to be due to some ionic species diffusing in from the edge of the field plate under the applied field. The source of the ions was therefore assumed to be the solvents used to rinse the devices.

Gregor (18) and Hofstein (19) have also studied the effect of organic solvents on MOS stability. Gregor's results for a series of organic solvents show the general effect that the more basic the solvent,

Table IV. Relationship of contamination  $Q_o/q$  in thermal oxides and sodium content of various solvents used to treat oxide surface prior to metallization

Solvent	MOS drift $Q_o/q$ , $cm^{-2}$	Na <sup>+</sup> content, ppb
DI water	$<1 \times 10^{10}$	0.4
Tap water	$>6 \times 10^{12}$	1300
Trichloroethylene	$<1 \times 10^{10}$	0.1-1.0
Acetone	$5-15 \times 10^{11}$	10-50
1:10 HF acid + DI water	$<1 \times 10^{10}$	1.5
Sulfuric acid + DI water	$2-5 \times 10^{11}$	40

the more adverse effect on MOS stability. Thus, he and Hofstein both propose some reaction between the metal (aluminum) and the treated oxide to release an active positive species such as hydrogen. However, the correlation obtained in the present work between sodium content of the organic solvents and MOS instability would suggest that the more active solvents might dissolve more sodium and thus would lead to increased contamination of the oxides.

**Glasses.**—Sodium content in glasses deposited by sedimentation techniques on device structures has been successfully analyzed and controlled by the flame photometric method (20). These glasses, based on  $PbO$ ,  $B_2O_3$ ,  $Al_2O_3$ ,  $SiO_2$  combinations, have been reproducibly prepared with sodium content below 10 ppm. This amount of sodium will still permit considerable drift of MOS structures (21).

An effort was made to compare the sodium analysis obtained on bulk material (glass frit) with a thin film ( $2.0\mu$ ) deposited on silicon slices. The latter is approaching the limit of the analysis since the expected sodium content of the solution used to dissolve the glass film would be in the low parts per billion range. The results are shown in Table V for two glasses of different purity. It can be noted that the relative sodium contents between the two glasses are the same for the bulk and film, although the absolute values for the film are lower. This is possibly due to an error in background and lower accuracy obtained in the film analysis, or leaching during the sedimentation process.

Attempts have also been made to determine sodium content in thermal oxides and vapor-deposited oxides. However, all analyses result in about the same value, 1 ppm. The MOS drifts vary over a wide range and should correspond to  $Na^+$  contents of less than 1 ppb to 1 ppm for the samples analyzed. As was the case with the glass determinations, 1 ppm in the oxide film actually corresponds to 1 ppb in the HF solution in which the film was dissolved. Thus, the resulting value of sodium content may or may not be significant when the very small weight of oxide being analyzed is considered. Efforts are being made to increase the sensitivity of sodium by the flame photometric technique so that dielectric films (in the 0.1- $1.0\mu$  thickness range) on silicon can be analyzed.<sup>2</sup>

### Conclusions

By suitable refinement, the flame spectrophotometer can be used to analyze and control sodium in semi-

<sup>2</sup> Donega et al. (22) have just reported in a Recent News Paper at the Boston Meeting of the Society that they have used the flame spectrophotometric method to determine sodium content of thermal oxides on silicon. Their detection limit for sodium in thermal oxides was the equivalent of  $8 \times 10^{11}$  Na atoms/ $cm^2$ . For oxide films in the thickness range of 0.1 to  $1.0\mu$ , this detection limit agrees with our findings above. The oxides analyzed by Donega, however, contained considerably more sodium, i.e., 10-100 ppm, than those analyzed in this investigation, i.e.,  $<1$  ppm.

Table V. Sodium content of sedimented glass frit and film

Batch No.	Bulk frit	2.0 $\mu$ Film
285	41 $\pm$ 2 ppm	23 $\pm$ 5 ppm
286	12 $\pm$ 2 ppm	8 $\pm$ 3 ppm

conductor processing materials. With a sufficient amount of sample, it is thus possible to measure sodium concentration down to 1 ppb or less, a value necessary for fabricating electrically stable, surface sensitive devices such as MOS transistors. Such processing materials as water used for oxidation, quartz tubes and accessories, solvents used for cleaning semiconductor devices, and glasses used for passivating device surfaces have been successfully analyzed for sodium content. In turn, it has been shown that a good correlation exists between the sodium content in these materials and resulting device stability as determined by MOS capacitance-voltage techniques. This correlation has been obtained even for cases where ionic species other than sodium have been postulated to be the cause of the instability, such as the treatment of oxide surfaces with various solvents.

This method of sodium analysis is relatively inexpensive, as well as easy and rapid to carry out when compared with such techniques as neutron activation analysis, mass spectrometry, and the like. By taking reasonable precautions, reproducible and accurate results can be obtained with minimum difficulty. One of the most important factors in this type of analysis is the use of high-purity water, both in establishing a "zero" sodium content reference point for the analyses and in obtaining minimum contamination during device processing. Sodium content of specially purified deionized water used as standards for these analyses has consistently been in the 0.05 ppb range, while the deionized water used on a larger scale for semiconductor processing has been shown to contain approximately 0.5 ppb sodium.

#### Acknowledgment

The authors wish to acknowledge the preliminary development involving the flame photometric method carried out by K. E. Lemons and G. Bobos. R. Ceynowa conducted most of the flame analyses reported in this paper, and M. Sklar conducted the MOS sample preparation and analyses. Finally, the authors wish

to thank Dr. Harry Sello for helpful advice and encouragement during the course of this work.

Manuscript received June 10, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# A Theoretical Model of the Three-Point Probe Breakdown Technique

P. A. Schumann, Jr.\*

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

## ABSTRACT

A review is presented of available data for the three-point probe for silicon which indicate that the technique as commonly practiced is greatly influenced by thermal considerations. From the data an empirical model is developed involving the concept of constant power at breakdown. The voltage is accounted for by a combination of a spreading resistance and a contact or barrier voltage. Breakdowns are shown to exist in both forward and reverse directions, and the model is applied to both. The model is shown to be self-consistent, if reasonable values of the radius of contact and measured power are used. This model is used to explain the slope of the calibration curve, effects of layer thickness on breakdown voltage, and the effects of pressure on breakdown voltage. A simple explanation for the turnover or breakdown voltage is proposed, based on the intrinsic temperature, and it is shown that this temperature is achieved under the probe for the current levels commonly used.

The three-point probe (1-7) is a well-known instrument for the measurement of  $n/n^+$  or  $p/p^+$  semiconductor epitaxial structures. It has been most widely used for silicon, but has also been applied to germanium (6) and gallium arsenide (5). Other modifications of the technique (7) involving fewer point contacts and substituting broad area contacts have also been used. In all these studies, it has been assumed that the point-metal semiconductor contact can be treated as a step pn junction (2, 4) or a Schottky barrier diode (7). Very little mention is made of the forward characteristics, although some curves are shown (2). Primarily, the authors have been occupied with the effects of various factors on the reverse characteristics. There are many effects which would indicate that a junction theory is not applicable to the three-point probe as commonly used in the 0.1 to 1.0 ohm-cm resistivity range. A model is proposed herein which minimizes any junction or barrier effects and stresses the thermal conditions under which the measurement is performed.

The important factors which must be explained by any model are:

1. The slope of the calibration curve
2. The fact that n- and p-type semiconductors for the same impurity concentration yield different breakdown voltages
3. The high level of current needed to achieve breakdown
4. The effects of pressure which are different for epitaxial and bulk samples
5. The effect of duty cycle on the breakdown voltage
6. The effects of temperature on the breakdown voltage
7. The effects of epitaxial layer thickness on breakdown voltage
8. The fact that the power at breakdown is a constant and is different on epitaxial and bulk samples
9. The melting or near melting of the semiconductor material under the probe.

The calibration curve, which is necessary because the technique is empirical, has been determined by all the authors referenced above for various materials. The curves are summarized in Table I for the resistivity range 0.1 to 1.0 ohm-cm, which will be the restricted range of interest for this paper. The reason for this restriction is that the data at low resistivity are not

always reliable and the calibration curve bends above 1 ohm-cm. Over the 0.1-1.0 ohm-cm range, the calibration curve can be represented by a simple function

$$V = A\rho^B \quad [1]$$

The slope of the  $\log V - \log \rho$  curve varies, depends on the author, but the average is 0.54. This is much too low for a step junction. Miller (8) has a value of  $-0.66$  for the dependence of breakdown voltage on impurity concentration. If the assumption is made that, for this range the impurity concentration is inversely proportional to the resistivity, the dependence on resistivity should be 0.66.

It was shown in an earlier report (4) that the breakdown voltage was not the same for n- and p-type silicon of the same concentration. Compared with Miller's data, the three-point probe gave higher breakdowns for low resistivity material and lower breakdowns for high resistivity material, with the break point being about 1 ohm-cm. A true pn junction might differ from Miller's curve because of the size of the point contact (9, 10), but both p and n material should be the same.

Very high current levels are required to achieve breakdowns for the three-point probe. Current levels range from 20 to 100 ma, depending on the resistivity and type of probe.

The effects of pressure on three-point breakdown voltage have been studied by several authors (4, 6). It has been found that an increase in point loading decreases the breakdown voltage for both bulk and epitaxial material, but the decrease is greater for the epitaxial material. This decrease was also less for high resistivity material.

Duty cycle plays an important role in determining the breakdown voltage. As the duty cycle is decreased the breakdown voltage increases (6-11). It has been

shown (11) that the breakdown voltage continues to increase even if the pulsewidth is decreased to 0.1  $\mu\text{sec}$  holding the repetition rate constant at 15 Hz.

Ambient temperature effects have not been discussed in much detail, but recent work (7, 11) has shown that an increase in temperature decreases the breakdown voltage, contrary to the results expected from a junction. Frank (7) explains this decrease in terms of a Schottky barrier diode and a change in the mobility with temperature.

It has been noted that decreasing epitaxial layer thickness decreases the breakdown voltage for certain ranges of thickness and resistivity (2-4, 6). It has generally been assumed that this is due to depletion width limiting, which Shields (12) has worked out in detail for a  $p/n/n^+$  structure. Comparisons between this model and experimental data for the three-point probe (4, 6) have been successful for the most part. The original model proposed by Brownson (2) is in error as he does not account for any change in voltage once the depletion region has reached the substrate. These comparisons are clouded, however, because the change in resistivity from the substrate to the surface of the layer is not a step function. For the layer resistivities and thicknesses where depletion width limiting should occur, the profile should be most graded, i.e. nonstep function. Also the surface resistivity will increase with an increase in thickness in this region just because of the shape of the profile.

Data presented in this paper show that the power, product of voltage and current, at breakdown is nearly a constant. It is also shown that this power will be higher for epitaxial  $n/n^+$  layers than for non-epitaxial wafers of the same resistivity and will be a function of layer thickness. There is no correspondence to this effect for a pn junction.

Photographs in another report (11) indicate that rather severe melting of the semiconductor can occur under the forward and reverse biased points if the electrical measurement is not made properly. This indicates a very high rise in temperature under the point even under ideal conditions.

#### Basic Considerations

Beginning with the statement that the power at breakdown is a constant and is different on epitaxial and bulk samples, we can make use of the simple equations for the spreading resistance (13-15) of a point contact for this configuration to propose a simple model.

The spreading resistance voltage of a flat circular contact of radius  $a$  in a three-point probe configuration is given by

$$V = \frac{I\rho}{4a} K \quad [2]$$

where  $V$  = spreading resistance voltage in volts,  $I$  = current in amperes,  $\rho$  = resistivity in ohm-cm,  $a$  = radius of contact in centimeters, and  $K$  = dimensionless correction factor.

The dimensionless correction factor is a function of geometry and resistivity structure of the sample and is discussed in detail elsewhere (15).

It is known that the breakdown voltage and resistivity can be related in a simple fashion, Eq. [1], where  $A$  and  $B$  are empirically determined constants having the units of volts/(ohm-cm) $^{1/B}$  and of a pure number, respectively. Combining [1] and [2] and solving for the current results in

$$I = \frac{4a A\rho^{B-1}}{K} \quad [3]$$

Solving for the power

$$P = VI = \frac{4a A^2\rho^{2B-1}}{K} \quad [4]$$

In order for the power to be independent of the resistivity,  $2B - 1 = 0$  or  $B = \frac{1}{2}$ . The actual average

value obtained in Table I was 0.54, which suggests that the power should be independent of resistivity. Note that the dimensionless correction factor appears in the denominator. For bulk material,  $K = 1$  and no effect is noted. However, for an  $n/n^+$  epitaxial structure,  $K$  is a positive number less than one, which would increase the power and would be a function of layer thickness, as stated in item 8. The equation is also interesting because there is no mention of forward or reverse biased conditions. A detailed study of forward characteristics showed that breakdowns do occur in both directions. Figures 1 and 2 are representative samples of both forward and reverse characteristics for  $n$ - and  $p$ -type silicon. The breakdowns in the forward direction were measured by taking the reading in the same fashion as for the reverse, i.e., ignoring the fact that it is supposed to be a forward. The reverse characteristics remained relatively unchanged throughout this process, provided the sample did not heat up too much. Both forward and reverse could be held simultaneously in breakdown with no drift. These measurements were made on chemically polished wafers with an a-c system (2, 3).

The forward and reverse breakdown voltage levels and the shape of the characteristics were almost the same. However, there was a consistent difference with the reverse level being higher than the forward. The linearity of the curve right out to the breakdown was better for  $n$ -type than for  $p$ -type.

#### Empirical Model

Because the forward and reverse breakdown levels are not the same, the simple model must be altered somewhat. If it is assumed that there is a contact or barrier resistance in the reverse direction which is not present in the forward direction, a better empirical

Fig. 1. Three-point probe I-V characteristics for a 0.233 ohm-cm  $n$ -type sample. Current is recorded vertically (50 ma/cm) and voltage horizontally (10 v/cm).

Fig. 2. Three-point probe I-V characteristics for a 0.206 ohm-cm  $p$ -type sample. Current is recorded vertically (50 ma/cm) and voltage horizontally (5 v/cm).

model can be developed. This contact resistance is due to the metal-semiconductor contact but will not be discussed here. Introducing the subscripts R for reverse, F for forward, and C for contact, the voltages and currents at breakdown are related by

$$V_F = \frac{I_F \rho}{4a} K \quad [5]$$

$$V_R = \frac{I_R \rho}{4a} K + V_C \quad [6]$$

The powers become

$$P_F = \frac{4a A_F^2 \rho^2 B_F^{-1}}{K} \quad [7]$$

$$P_R = \frac{4a A_R^2}{K} \left[ 1 - \frac{V_C}{V_R} \right] \rho^{2B_R-1} \quad [8]$$

Assuming that these are independent of resistivity,  $B_R = B_F = \frac{1}{2}$ , and solving for the breakdown voltages

$$V_F = \sqrt{\frac{\rho K P_F}{4a}} \quad [9]$$

$$V_R = \sqrt{\frac{\rho K P_R}{4a} + \frac{V_C^2}{4}} + \frac{V_C}{2} \quad [10]$$

Using the known relationships for  $V_F$  and  $V_R$  on resistivity,  $V_C$  may be calculated

$$V_C = A_R \left[ 1 - \frac{P_R A_F^2}{P_F A_R^2} \right] \rho^{0.5} \quad [11]$$

or

$$V_C = A_C \rho^{0.5} \quad [12]$$

An assumption is being made here that is not necessarily valid. By forcing the power to be a constant, as determined experimentally,  $V_C$  is forced into a square-root dependence on resistivity. A study of Eq. [8] will show that  $B_R$  can have values different from  $\frac{1}{2}$  still maintaining constant power as long as  $V_C$  varies in an appropriate manner. Also the power is not quite constant. All of this could result in a different dependence of  $V_C$  on resistivity, but the data or the model are not considered good enough to warrant this detail.

The equations may also be solved for the current dependence, resulting in

$$I_F = C_F \rho^{-0.5} \quad [13]$$

$$I_R = C_R \rho^{-0.5} \quad [14]$$

or

$$I_F = \frac{4a A_F}{K} \rho^{-0.5} \quad [15]$$

$$I_R = \frac{4a (A_R - A_C)}{K} \rho^{-0.5} \quad [16]$$

#### Comparison with Experiment

These basic equations can then be fitted to the data as obtained. The data used for this comparison were taken from measurements on n- and p-type chemically polished silicon wafers. The samples had resistivities between 0.1 and 1.2 ohm-cm. The probe was a modified Dumas P4-85, as described in an earlier report (4), operated at a loading of 35g per point. Using an a-c system (2) and oscilloscope display, five measurements were made for each point. The standard deviation was calculated and included on the graph. The variation in the data is high in most cases because of variations in both the material and the probe.

Figures 3 and 4 show the power obtained as the product of the voltage and current at breakdown as a function of resistivity for n-type silicon. To use the model for calculation, the effective radius of contact must be known. Figure 5 shows the radius of contact

Fig. 3. Forward breakdown power as a function of resistivity for n-type silicon.

Fig. 4. Reverse breakdown power as a function of resistivity for n-type silicon.

Fig. 5. Radius of contact calculated from spreading resistance at low levels for n-type silicon for this probe.

obtained from Eq. [2] and measurements of the current at 10 mv on the same samples, using the same probe at the same loading, as a function of resistivity. For n-type silicon over this range, the radius of contact is nearly constant. This has been reported earlier for the spreading resistance measurement (15, 16) and is confirmed here. The average radii of contacts are  $1.3 \pm 0.2\mu$  and  $2.4 \pm 1.2\mu$  for n- and p-type, respectively. The approximation of constant radius is better for n-type and is within experimental error. Using these values for the radii of contact and the  $A_F$  and  $A_R$  determined experimentally results in the solid curves shown in Fig. 3 and 4. Table II shows the comparison between the experimental averages and those obtained by the model.

Table II. Comparison of experimental averages and those obtained by model

A and B are constants from Eq. [1].  
C is a constant from Eq. [13].  
 $A_C$  is a constant from Eq. [12].

Figure 6 and 7 are plots of the breakdown voltage as a function of resistivity for n-type silicon. The solid line in each case is a least squares fit of Eq. [9] and [10] to the data. Table II shows the validity of this approximation by comparing the values of the constants obtained from fitting Eq. [1] to the data.

The current dependence on resistivity is shown in Fig. 8 and 9, and the results of the current dependence are summarized in Table II. A least squares fit of Eq. [13] and [14] yields results comparable to the model as calculated from Eq. [15] and [16]. Table II also shows the values of the constant  $A_C$  obtained from the model and experimental data using Eq. [11].

A comparison between the reverse power levels obtained on bulk and epitaxial layers is shown in Table III. The correction factors were obtained from previously published results on the spreading resistance (15).

Equation [10] can be studied in more detail to explain some of the additional phenomena observed with the three-point probe. It is clear that since  $V_C$  has a square-root dependence on resistivity, so does  $V_R$ . The correction factor  $K$  appears in the numerator, so as  $K$  decreases, so does the breakdown voltage.

For an  $n/n^+$  structure,  $K$  is always a positive number less than one and becomes small for a fixed radius of contact as the layer thickness is decreased. A representative graph is shown in Fig. 10. Thus the dependence on layer thickness discussed in statement 7 can be explained at least qualitatively by the change in the spreading resistance correction factors. This same argument can be used to describe the dependence of the breakdown voltage on pressure. For a bulk sample,  $K = 1$  and a change in the loading will change the radius of contact. An increase in load will increase the  $a$  and thus decrease the breakdown voltage. For  $n/n^+$  epitaxial material, this will also be true but, in addition,  $K$  will be decreasing (Fig. 10). The effects of increasing pressure will be more pronounced on epitaxial material than on bulk.

#### Theoretical Basis for Model

Since much of the data presented here and in other papers would indicate that thermal effects play a dominant role in determining the characteristics of point contact breakdown as commonly measured with the three-point probe, it does not seem unreasonable that the predominate effect is thermal and that the

three-point probe measures the intrinsic temperature of the semiconductor. The intrinsic temperature for the purpose of this discussion will be defined as the temperature above room temperature at which the resistivity is a maximum. For silicon, this is shown in Fig. 11. The curve was obtained from data by Hoffman, Reuschel, and Rupprecht (17), Putley and Mitchell (18), and Morin and Maita (19). The data on individual samples shown only for visualization were obtained from Gardner (20).

Analogous to the spreading resistance equation is the equation for heat flow (21)

$$T = \frac{Q}{4\lambda r_o} \quad [17]$$

where  $T$  is the temperature in degrees,  $Q$  is the heat input in watts,  $\lambda$  is thermal conductivity in watts/cm °K, and  $r_o$  is the radius of contact of heat source. This is the steady-state temperature, and its application in this case is certainly open to question. First, it is not clear that we are in a steady-state condition. And, second, the power is not all generated at the contact; it is generated in a rather complicated manner throughout the material.

The temperature under the contact  $T_C$  is the sum of this temperature and the ambient temperature  $T_o$ .

$$T_C = T + T_o \quad [18]$$

The amount of power generated should be the heat input in Eq. [17]. The fact that the heat is not all generated at the contact can be accounted for by letting  $r_o > a$ .

$$T_C = T_o + \frac{P}{4\lambda r_o} \quad [19]$$

Solving for the power

$$P = 4\lambda r_o (T_C - T_o) \quad [20]$$

For the power to be constant,  $\lambda (T_C - T_o)$  must be a constant. If  $T_C$  is the intrinsic temperature, it must

Fig. 10. Spreading resistance correction factor,  $K$ , as a function of  $H_1 =$  layer thickness/radius of contact for  $S = 1000 =$  probe spacing/radius of contact;  $H_2 = \infty =$  substrate thickness/radius of contact; and various values of  $k_1$  where  $k_1 = (\rho_2 - \rho_1)/(\rho_2 + \rho_1)$  with  $\rho_1 =$  layer resistivity, and  $\rho_2 =$  substrate resistivity.

Fig. 11. Resistivity as a function of absolute temperature for several silicon samples.

vary with resistivity as indicated in Fig. 11. However,  $\lambda$  also varies with temperature almost as the inverse, and the product remains relatively constant, as indicated in Fig. 12. The range for the intrinsic temperature for this resistivity range falls between 550° and 750°K. (The average  $\lambda T$  for this temperature range is  $445 \pm 35$  w/cm.) The thermal conductivity data were taken from Glassbrenner and Slack (22) for high-resistivity silicon. The effect of doping on the high-temperature portion of the thermal conductivity curve probably is not significant.

Another simple model can be built to examine the time dependence of the temperature increase. If it is assumed that all the power is dissipated uniformly, with a hemisphere of radius  $r_o$  and with no chance for heat conduction to occur, the temperature rise becomes

$$\frac{\Delta T}{\Delta t} = \frac{P}{vCd} \quad [21]$$

where  $P$  is the power dissipated,  $v$  is the volume,  $C$  is the specific heat, and  $d$  is the density. Using a specific heat of 0.2 cal/g °K for silicon, this equation becomes

$$\frac{\Delta T}{\Delta t} = \frac{3P}{2\pi r_o^3 Cd} = \frac{250 P \times 10^9}{r_o^3} \text{ °K/sec} \quad [22]$$

where  $P$  is in watts and  $r_o$  is in microns. For the

Fig. 12. The product of thermal conductivity and absolute temperature as a function of absolute temperature for silicon.

p-type silicon studied here,  $r_0 \approx 6\mu$  and  $P \approx 1w$

$$\frac{\Delta T}{\Delta t} \approx 1.16 \times 10^9 \text{ }^\circ\text{K/sec} \quad [23]$$

In an earlier work (11), use of pulse techniques showed that it took approximately a microsecond to reach thermal breakdown. For 1  $\mu\text{sec}$  in this model,  $\Delta T \approx 1200^\circ\text{K}$ , which is the right order of magnitude for thermal effects to become important and even destructive breakdown to occur. The same paper pointed out that approximately 3  $\mu\text{sec}$  must elapse before the silicon is melted. The heat of fusion of silicon is about 431 cal/g. Using the same volume as above, an energy of  $1.9 \times 10^{-6}$  w sec is needed to melt the volume of a hemisphere of radius  $r_0$ . Thus if 3  $\mu\text{sec}$  are needed to melt the silicon, a power of about 0.6w must be expended to accomplish this. The remaining 0.4w must be used to bring the sample up in temperature, so that the temperature rise would be about  $1400^\circ\text{K}$ , which when added to the  $300^\circ\text{K}$  ambient is about the melting point.

The same type of time dependence, although on a larger time scale, was observed by Agatsuma (23) for point contacts.

### Discussion

Of the many approximations and assumptions made in this model, the most important are:

1. The radius of contact as determined by the spreading resistance is the true electrical radius of contact.
2. The effects of pressure on the resistivity are ignored.
3. The resistivity used in the model calculations is the resistivity of the sample at room temperature.
4. No account is made of charge accumulation and barrier effects in the model. These are all combined into the  $V_C$  term.

The approximations made in trying to justify the model theoretically are perhaps even larger. The two cases considered are certainly the two extremes of heating. The first steady-state approximation will only be good for long times, and the rate of temperature calculation will only be good for the first few microseconds of heating. Both of these, however, still have the following major assumptions in common:

1. The thermal conductivity or heat capacity is independent of doping level.
2. The power is generated uniformly within a radius  $r_0$ .

There are still some factors the theoretical model does not explain. The most important is that the voltage at forward breakdown should be the same for n- and p-type silicon as predicted by Eq. [5]. It is probable that the effective radius of contact determined from spreading resistance is not the true electrical radius of contact. The calibration curve used for spreading resistance measurements would indicate that it is not (14-16). However, as yet there is no good means to separate the true spreading resistance from the contact resistance. The use of this radius probably also masks the other assumptions made in the model or the effects cancel each other out to allow such good fit. This error does not really become apparent until the thermal effects are considered.

The simple spreading-resistance model does not rule out the possibility that other phenomena could cause avalanche breakdown or that the breakdown could be a Zener effect. The maximum field under a planar contact occurs at the silicon-contact interface and is given by

$$E = \frac{I\rho}{\pi a^2} \quad [24]$$

or, written another way,

$$E = \frac{4V}{\pi a} \quad [25]$$

For Zener breakdown, field would be a constant, i.e., there would exist a critical field, so that, if  $a = \text{constant}$ , breakdown voltage must be constant. Thus the two concepts are not compatible.

Avalanche breakdown can occur because of a current constriction, and several papers have been written (24-28) describing the concept and measurement of the negative resistance. It is not the purpose to go into detail here of these theories and observations but to state that in all cases these effects were connected with a current saturation. The charge carriers reach a maximum velocity which is independent of the applied field. Although the fields due to the spreading resistance contact are extremely high, of the order of  $10^6$  v/cm, no current saturation effects were observed. Also, the experimenters searching for the avalanche effect had to use low duty cycles in order to observe their effects and avoid heating.

It is also possible that a straightforward avalanche effect may be occurring due to the high fields present. This would also seem improbable, because a simple model for a hemispherical contact based on a single ionization rate of the formula  $E = \theta e^{-\phi/E}$ , yields the following relationship between parameters

$$a = \frac{V}{2\phi} \ln \frac{\theta a V}{4\phi} \quad [26]$$

Since  $a, \theta$ , and  $\phi$  are constants, Eq. [30] would indicate that the breakdown voltage should be a constant. This, of course, is due to the simple way that the voltage and current are related in the spreading resistance.

Another effect observed in this laboratory (29) is that the point contact will oscillate. This oscillation can sometimes be audible, i.e., the point is vibrating. This has also been observed as current oscillations. Similar results have been reported for other point contacts (29, 30-32). A model for this effect described by Gundjian (33, 34) is based on the spreading-resistance field and the electrostrictive property of the semiconductor. The conditions for oscillations are very complex and probably explain why the effect is not always observed. Several times during the measurements presented in this paper, the audible oscillation was observed.

It is also possible that the self-heating model proposed by Hunter (35-37) and expanded on by others (38-39) for point contact diodes is applicable. This model is based on similar arguments of self-heating and the fact that an isothermal saturation current is never observed. It does not discuss the forward characteristic and is only qualitatively able to describe the breakdown phenomenon. In either case it is still a thermal phenomenon.

Henisch (38) discusses similar heating effects for point-contact diodes and compares various models of the turnover voltage. He presents data which show that the contact temperature is a constant at the breakdown or turnover voltage for a given sample as a function of ambient temperature. He implies that this may be attributed to the onset of intrinsic conduction.

The empirical model of the three-point probe as commonly used points to the spreading resistance as being the principal manner in which the voltage is built up. From this evidence and the fact that breakdowns occur in both forward and reverse biased directions, it would appear that the only reasonable explanation of the breakdown is a heating effect. In normal use this heating effect increases the temperature to the intrinsic temperature, but in extreme cases it can melt the semiconductor.

### Acknowledgment

The author would like to thank Miss Lucy A. Pietrogallo, Mr. M. R. Poponiak, Mr. C. P. Schneider, and Mr. A. Dupnock for the experimental data presented and Dr. E. E. Gardner and Mr. J. F. Hallenback, Jr., for many helpful discussions of this problem.

Manuscript submitted Feb. 20, 1968; revised manuscript received Aug. 1, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Technical Notes

### The Cathodoluminescence Spectra and Coordination of $Mn^{2+}$ , $Fe^{3+}$ , and $Cr^{3+}$ in $\beta LiAl_5O_8$

P. M. Jaffe\*

Zenith Radio Corporation, Chicago, Illinois

Manganese activated phosphors may show essentially three different emissions: a red or a green band which is broad and structureless or a narrow structured red band. The broad band emissions are believed to be due to  $Mn^{2+}$  and the structured narrow band emission to  $Mn^{4+}$  (1-3). Linwood and Weyl have postulated that the green band emission is due to  $Mn^{2+}$  in tetrahedral coordination in the host lattice and the red band emission to octahedral coordination (4).

Recently, Hummel and Sarver have reported on the luminescence of the isoelectronic  $Fe^{3+}$  and  $Mn^{2+}$  ions in the normal spinel  $MgAl_2O_4$  (5). They found that activation by Mn resulted only in a green emission and by Fe in both a green and a red emission. The two green emissions had the same peak wavelengths and

half-widths. Based on the ideas mentioned above, Hummel and Sarver concluded from these data that the Mn was 4 coordinated and the Fe was both 4 and 6 coordinated in  $MgAl_2O_4$ .<sup>1</sup>

The high-temperature ( $\alpha$ ) form of  $LiAl_5O_8$  also forms a spinel (6) while the low-temperature ( $\beta$ ) form is more ordered (7). The  $\alpha$  form has the inverse spinel structure with 8 Al in tetrahedral sites and 4 Li plus 12 Al in octahedral sites. In the spinel-like  $\beta$  form, we may still consider the structure to be made up of a cubic close-packed oxygen lattice which contains both octahedral and tetrahedral holes. However, the exact relationship and location of the Li and Al ions is not known. In the inverse  $LiFe_5O_8$  spinel, the high-temperature form has the octahedrally coordi-

\* Electrochemical Society Active Member.

<sup>1</sup> In a spinel, the cations may only occupy the octahedral and tetrahedral holes that are present in the close-packed oxygen lattice.

nated Li and Fe randomly orientated; in the low-temperature form they are ordered (6).

From Hummel and Sarver's work plus the fact that  $\text{Fe}^{3+}$  prefers tetrahedral coordination (8, 9), one would expect the emission from  $\text{Fe}^{3+}$  activated  $\text{LiAl}_5\text{O}_8$  to be mainly green at low  $\text{Fe}^{3+}$  concentrations. However, Mochel (10), in his paper on air-fired  $\text{LiAl}_5\text{O}_8:\text{Fe}^{3+}$ , reports the photoluminescent spectrum to consist of only a red and a blue band.<sup>2</sup> There is evidence, to be published at a later date, which indicates that this blue emission is due either to host emission or to an impurity.

In this study I have prepared  $\beta\text{LiAl}_5\text{O}_8$  and tried to incorporate individually the two pairs of isoelectronic ions  $\text{Mn}^{2+}$ ,  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$ ,  $\text{Mn}^{4+}$ . The goal was to try to correlate the cathodoluminescent emission with the respective activator coordination. However, no information can be obtained on the relative occupancy of these sites. The reason is that the intensity of emission from a site need not be directly proportional to its population.

Phosphors were prepared from reagent grade  $\text{Al}(\text{OH})_3$ ,  $\text{Li}_2\text{CO}_3$ ,  $\text{FeSO}_4$ ,  $\text{CrO}_3$ , and  $\text{MnSO}_4$  by firing at  $1200^\circ\text{C}$  for 2 hr. The firing atmospheres were  $\text{N}_2$ ,  $\text{O}_2$ , and 3:1  $\text{H}_2$ - $\text{N}_2$ . The stoichiometry of the phosphors was based on  $\text{LiAl}_{5-x}\text{Fe}_{5x}\text{O}_8$  where  $x$  was 0.002 [0.2 a/o (atomic per cent)]. Emission spectra were obtained in a demountable cathode-ray tube operated at 25 kv using a  $\frac{1}{4}$  meter Jarrel-Ash monochromator equipped with  $100\mu$  slits and a 7326 photomultiplier. All spectra were corrected for the detector response and monochromator errors. All measurements were made at room temperature.

#### Mn Activation

Firing in  $\text{N}_2$ ,  $\text{O}_2$ , or  $\text{H}_2$ - $\text{N}_2$  results in phosphors having essentially the same green band emission spectra, Fig. 1. There is no sign of structure or of a red band. The half-width of the emission, 30 nm, and the emission peak, 520 nm, are about the same as those obtained with  $\text{MgAl}_2\text{O}_4:\text{Mn}$  and  $\text{ZnAl}_2\text{O}_4:\text{Mn}$  (5).

The lack of a structured red emission in the Mn activated  $\text{LiAl}_5\text{O}_8$  phosphors indicates that no  $\text{Mn}^{4+}$  is present. Because the Mn emission in  $\text{LiAl}_5\text{O}_8$  is similar to that of  $\text{Mn}^{2+}$  in  $\text{ZnAl}_2\text{O}_4$  and  $\text{MgAl}_2\text{O}_4$ , we may assume that Mn has the same valency and coordination in these three hosts, namely, divalent and in tetrahedral coordination.

#### Fe Activation

The spectra of samples fired in  $\text{N}_2$  and  $\text{O}_2$  were essentially the same, consisting of a strong red band and a very weak green band peaking around 660 and 520 nm, respectively, Fig. 2. The  $\text{N}_2$ - $\text{H}_2$  fired samples showed a slight broadening of the red emission band, a slightly stronger green emission, and a new band in the IR.<sup>3</sup> Another phosphor containing 0.01 a/o Fe and fired in air showed a slightly stronger green emission than the air-fired sample containing 0.2 a/o Fe. Cooling to liquid nitrogen temperature had no effect on the intensities of the two emission bands.

The bulk of the Fe in  $\text{LiAl}_5\text{O}_8$  is most likely trivalent. It is present mainly in octahedral coordination, as indicated by the red emission, in spite of the known preference of  $\text{Fe}^{3+}$  for tetrahedral coordination (8, 9). Some  $\text{Fe}^{3+}$  is also present in tetrahedral coordination as evidenced by the weak green emission. The low intensity of the green emission is not due to concentration quenching since it increased only slightly when the Fe concentration was decreased to 0.01 a/o. There is no temperature quenching of the green emission since cooling had no effect on its intensity. Firing in  $\text{N}_2 + \text{H}_2$  may result in the formation of some divalent Fe as indicated by the appearance of the new near IR band. Gergely has found that Fe, presumably divalent, in ZnS causes an emission in the near IR (11). This is

<sup>2</sup> R. H. Datta has also investigated the photoluminescence of this system, *Bull. Am. Ceramic Soc.*, 44, #4 (1965), Abstract 26-B-65.  
<sup>3</sup> The spectrum of this IR emission was not determined.

Fig. 1. Emission spectra of  $\beta\text{LiAl}_5\text{O}_8:\text{Mn}$  fired in  $\text{N}_2$ ,  $\text{O}_2$ , and  $\text{N}_2$ - $\text{H}_2$  atmospheres.

Fig. 2. Emission spectra of  $\beta\text{LiAl}_5\text{O}_8:\text{Fe}$  fired in  $\text{N}_2$ - $\text{H}_2$  and air atmospheres.

different from the emission due to  $\text{Fe}^{3+}$  in ZnS (12) which is in the visible, peak wavelength about 660 nm (13).

#### Cr Activation

The emission spectra from  $\text{N}_2 + \text{H}_2$  and  $\text{O}_2$  fired samples are shown in Fig. 3. The emission is characterized by a weak broad band with three main superimposed lines which are invariant with firing atmosphere.

The spectra of the Cr activated  $\text{LiAl}_5\text{O}_8$  phosphors is typical of that expected for  $\text{Cr}^{3+}$  in octahedral coordination (6, 14). However, comparing these spectra with those of  $\text{Cr}^{3+}$  in  $\text{Al}_2\text{O}_3$  and  $\text{MgAl}_2\text{O}_4$  shows that the main line at 718 nm is shifted to longer wavelengths by approximately 23 and 30 nm, respectively (14). This shift might be due to a slight "loosening" of the close packed oxygens, resulting in a slightly larger octahedral hole. This has the effect of decreasing the Dq value for Cr which would result in a shift of the spectrum to lower frequencies (longer wavelengths) (9, 15).

#### Acknowledgment

The author wishes to thank Miss K. Wolejko for her aid in sample preparation, Mr. Larry Flemming for obtaining the emission spectra, and Dr. Gerda Arai for the x-ray diffraction analysis.

## Thermoluminescence of Sintered Alumina

Charles R. Whitworth and Ivan B. Cutler

University of Utah, Salt Lake City, Utah

Thermoluminescence might be defined as the emission of light from a substance when it is warmed, usually at a constant rate, after having been subjected to some type of exciting radiation at a relatively low temperature. The data are most often presented in the form of a glow curve, which is a plot of emitted radiation intensity *vs.* temperature.

Several contributions occur in the literature concerning the use of manganese as a luminescent activator in alumina-based compounds (1). Kelley and Laubitz (2) used thermoluminescence to study the defect structure of pure and slightly doped alumina. Rieke and Daniels (3) obtained a rough correlation between the area under a glow curve and the amount of a given phase present. Atlas and Firestone (4) presented a correlation between various added impurities and the glow peaks they produced. The present work is concerned with the effects of additions of manganese oxide (up to 5600 ppm) and sodium. The manganese concentration is presented as ppm manganese because its valence state in the samples is unknown.

The samples used in this study were prepared from high-purity ( $\text{SiO}_2 < 0.0015\%$ ,  $\text{Fe}_2\text{O}_3 < 0.001\%$ ,  $\text{TiO}_2 < 0.001\%$ ,  $\text{P}_2\text{O}_5 < 0.001\%$ ,  $\text{Na}_2\text{O} < 0.003\%$ ) alpha alumina designated R-13 as supplied by AIAG (Aluminum-Industrie-Aktien-Gesellschaft). A major problem encountered in preparing homogeneous samples was the inadvertent introduction of  $\text{Na}_2\text{O}$  resulting in a tendency towards exaggerated grain growth producing grains as large as 1 mm. To minimize this problem, all handling was done in plastic containers. The alumina was doped with manganese by suspending it in a solution of 99.99% manganese metal in reagent grade  $\text{HNO}_3$ , then precipitating  $\text{Mn}(\text{OH})_2$  with  $\text{NH}_4\text{OH}$ . The resulting slurry was vigorously agitated for 15 min then dried and calcined at  $800^\circ\text{C}$  for 12 hr. The alumina for sample (13) was prepared by the hydrothermal oxidation of 99.999% aluminum metal. Disks (1 mm thick  $\times$  22 mm diameter) were pressed at 15,000 psig and each was surrounded with material of like composition to prevent excessive evaporation of the manganese additions at higher temperatures during sintering. Two series of disks were pressed: one series was fired in air, the other in an atmosphere containing sodium vapor. A small crucible containing the disks was placed inside a larger crucible and surrounded by alumina doped with 1000 ppm  $\text{Na}_2\text{CO}_3$ . Each series of disks was separately fired at  $1650^\circ\text{C}$  for 2 hr, and the products were polished on a 600

grit diamond lap to make their surfaces uniform. The manganese concentration of each fired disk was determined by x-ray fluorescence: all were then cut into squares (4.5 mm square  $\times$  0.5 mm thick) to give equal radiating surfaces. The squares were cleaned by boiling them in HCl for 30 min, followed by a rinse in distilled water; they were then heated to  $1000^\circ\text{C}$  to remove any water that might contribute to thermoluminescence (3). After calcining, the samples were placed in small plastic vials and activated with the radiation from a cobalt-60 source (145,000 roentgens). It was later determined that irradiation with 50 kv x-rays from a platinum tube was adequate to activate this type of alumina.

The apparatus was basically a light-tight box with a housing for a photomultiplier tube mounted on the top. The sample holder was mounted in an inset in a movable rod that slid horizontally through two holes in opposite sides of the box. Electrical and thermocouple leads were fed into the box through this sliding rod. The rod extended completely through the box and was long enough to keep the seal light-tight during removal of the sample holder section. This arrangement prevented exposure of the activated photomultiplier tube to the direct light of the room, preserving its sensitivity. The sample holder, which also served as the heater, was a strip of stainless steel cut in the shape of a dogbone so that heating was confined to the narrow section of the strip where the sample was placed. The iron-constantan thermocouple was in physical contact with the bottom of the heating strip. Because of its location, the thermocouple indicated a higher temperature than that of the radiating surface of the sample. For more accurate work, a second thermocouple temporarily placed at the radiating surface, might be used to calibrate the thermocouple touching the heater. Although it was not convenient to use an exact linear heating rate, the rate was the same for all samples; consistency was achieved by attaching a small motor to the variac controlling the voltage to the heating strip.

An EMI 9558B photomultiplier tube was used to measure the radiation emitted by the sample as it was heated. The photomultiplier tube was powered by a Kepco Inc. model ABC 1500M voltage regulated supply, and the activating voltage was nominally 1200v. The outputs from the thermocouple and the photomultiplier tube were recorded by a model 135 Mosley Autograph to produce the glow curves. The temperature was calibrated with the output from an L&N 8691 mv potentiometer.

Key words: alumina, manganese, sodium, thermoluminescence.

Fig. 1. Glow curves of samples fired in a sodium-free atmosphere. Each curve was started at 0 intensity, ppm Mn: (A) 0; (B) 710; (C) 1080; (D) 2310; (E) 3690; (F) 6740.

In practice, the sample, mounted on the heating strip, was positioned 3 in. below the photomultiplier tube by adjusting the sliding rod. The sample was then heated to 250°C at an approximate rate of 100°C/min. Since no allowance was made for the temperature of the radiating surface lagging behind that of the heater, the temperatures of the measured glow peaks are somewhat high. This error was not considered to be significant inasmuch as comparative results rather than absolute values were the objective.

In Fig. 1, glow curves are shown for a series of samples, sintered in a sodium-free atmosphere. The only sample exhibiting any glow peaks is the undoped R-13 alumina (curve 1). The addition of manganese appears to suppress the thermoluminescence characteristic of the untreated alumina. It was supposed that the peak shown in Fig. 1 might be caused by sodium; therefore, additional sodium was introduced into the alumina to prevent complete suppression by low concentrations of manganese. Different sodium concentrations were obtained by firing in atmospheres having different vapor pressures of sodium, and it was found that the sodium induced thermoluminescence reached a maximum for concentrations  $1000 < \text{Na}$ . The low thermoluminescence exhibited by the hydrothermally produced alumina reflects its low sodium content. The rise in intensity at 250°C is the beginning of a background radiation and was verified by making a run without a sample on the heater.

Apparatus was designed to accommodate Control-Data, sharp-cut-off filters between the sample and the photomultiplier tube. A series of these filters were used in an attempt to determine the wavelength distribution of the light corresponding to each peak. Since Rieke and Daniels noted that the radiation emitted from their alumina samples was light blue to blue green, filters in the orange to red region were selected to maximize absorption. The results were inconclusive: the only effect noticed was a reduc-

Fig. 2. Glow curves of samples fired in a sodium atmosphere. Each curve was started at 0 intensity, ppm Mn: (A) 0; (B) 430; (C) 1370; (D) 1950; (E) 2735; (F) 5630; (G) pure hydrothermally produced alumina.

tion of the height of the major peaks, particularly near 104°C. Since this effect occurred with all of the filters used, the absorption is probably caused by the silicate structure of the glass rather than by the colorants.

Several conclusions can now be drawn:

1. The addition of manganese decreases the thermoluminescence of alumina across the entire glow curve. Manganese thereby acts as a poison for this process rather than as a fluorescence activator as is usually the case.
2. The introduction of sodium (by firing in an atmosphere containing sodium vapor) increases the thermoluminescence of alumina, and introduces a new peak near 210°C. With sodium additions, a higher concentration of manganese is required to suppress the thermoluminescence completely.
3. The hydrothermally produced alumina contains less sodium than R-13, which is reported to contain 30 ppm.

## A Low-Temperature Nonpreferential Gaseous Etchant for Silicon

T. L. Chu\*<sup>1</sup>

*Electronic Sciences Center, Southern Methodist University, Dallas, Texas*

The cleanliness and perfection of the surface of silicon substrates are important in many device fabrication processes, such as epitaxial growth, preparation of MIS (metal-insulator-semiconductor) structures, etc. For example, foreign impurity particles and defects on the substrate surface have been shown to cause structural defects in epitaxial silicon and high interface charge densities in MIS structures (1, 2). Since clean surfaces cannot be readily prepared and maintained by conventional techniques, silicon substrates are frequently etched *in situ* prior to the deposition process. Anhydrous hydrogen chloride and water vapor have been used as *in situ* etchants for silicon with varying degrees of success (3-5). However, high substrate temperatures, 1150°C or above, are required in both cases to obtain structureless surfaces. In searching for a nonpreferential gaseous etchant effective for silicon at lower temperatures, hydrogen sulfide at low partial pressures in a hydrogen atmosphere has been found to be satisfactory. Some preliminary results on the etching of silicon by hydrogen sulfide are reported in this communication.

The reaction between silicon and hydrogen sulfide at high temperatures is similar to that between silicon and water vapor (4). The reaction product is silicon disulfide; however in the presence of excess silicon, silicon disulfide further reacts with silicon to form the volatile monosulfide. The chemical reactions and the associated standard free energy changes (kcal/mole) in the temperature range 298°-1100°K (6), are as follows

	$\Delta G^{\circ}_{298^{\circ}\text{K}}$	$\Delta G^{\circ}_{500^{\circ}\text{K}}$	$\Delta G^{\circ}_{800^{\circ}\text{K}}$	$\Delta G^{\circ}_{1000^{\circ}\text{K}}$
$\text{Si (s)} + 2\text{H}_2\text{S (g)} =$				
$\text{SiS}_2\text{ (s)} + 2\text{H}_2\text{ (g)}$	-26.0	-21.5	-15.9	-10.9
$\text{Si (s)} + \text{SiS}_2\text{ (s)} =$				
$2\text{SiS (g)}$	51.1	33.9	9.2	-14.9

Both reactions are thermochemically feasible at temperatures above 1000°K. In fact, the reaction between silicon and silicon disulfide has been found to take place readily to completion under vacuum at 850°C (7). Thus, at low partial pressures of hydrogen sulfide and at temperatures above 1000°K, silicon is oxidized to the volatile silicon monosulfide. Because of the fav-

orable thermochemical and kinetic factors, the etching of silicon by hydrogen sulfide can be achieved at temperatures considerably below that required by the use of water vapor.

Mixtures of hydrogen and hydrogen sulfides containing up to 0.5% hydrogen sulfide were used in the etching of silicon in a flow system. The silicon substrates were n-type, 10-40 ohm-cm, and had main faces of {111} orientation. The substrates, mechanically lapped and chemically polished in the usual manner, were supported on a silicon-coated graphite susceptor in a fused silica reaction tube, and the susceptor was heated externally by an rf generator. During the etching process, the flow rate of hydrogen was 20 l/min, and the substrate temperature was varied in the range of 850°-1050°C. Depending on the experimental conditions, silicon was removed from the substrate surface at a rate of up to about 3  $\mu$ /min. Optical microscope examinations indicate that the resulting surface obtained at etching temperatures higher than about 950°C is clean and structureless, and is similar to the original surface in appearance. Thus, hydrogen sulfide at low partial pressures in a hydrogen atmosphere is a nonpreferential etchant for silicon at relatively low temperatures. Details of this etching process will be discussed in a subsequent publication.

Manuscript received March 5, 1968. Publication was deferred at the authors request of April 17, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# A Semi-Empirical Mathematical Model for Predicting the EMF of Small Silver Chloride-Magnesium Cells

Duane W. Faletti and Michael A. Gackstetter

*Applied Physics Laboratory, University of Washington, Seattle, Washington*

## ABSTRACT

A method has been developed for predicting the emf of small silver chloride-magnesium cells, under a constant current load, as a function of current density, temperature, electrolyte composition, and degree of exhaustion. Over a current density range of 0.116 ascm to 0.527 ascm, and a temperature range of 4°-65°C, this method gives excellent agreement with experimental emf-time traces, to a cutoff voltage of 0.75v. This technique promises to provide the foundation for a new design method for AgCl-Mg sea water-activated batteries.

The Applied Physics Laboratory of the University of Washington is engaged in an effort to develop improved design methods for high-drain water-activated magnesium-silver chloride batteries which are less dependent on prototype testing than the design methods now available. A Semi-Empirical Mathematical Model (SEMM) is presented here which promises to be the foundation for the new design methods.

A brief description of the reactions involved in this type of battery and their method of construction is given in an earlier paper (1). In another paper (2), the authors give information on the composition and electrical conductivity of the characteristic electrolytes.

High drain AgCl-Mg batteries are characterized by temporal and spatial variations in current density, temperature, electrolyte composition, and degree of expenditure. In order to develop an improved quantitative design method for AgCl-Mg sea water batteries based on numerical analysis, a method of predicting the emf of small AgCl-Mg cells over the range of operating conditions found in full-size batteries is required. The results of a program developing and verifying such a method for the case of constant current discharges are presented here. This method not only promises to be useful for the design of small high-drain cells and batteries, but represents an important step toward the ultimate goal of computer design of large high-drain AgCl-Mg water-activated batteries.

### Semi-Empirical Mathematical Model

SEMM predicts discharge characteristics of a AgCl-Mg cell by dividing the discharge into three regions (Fig. 1). In region No. 1 of Fig. 1, the mathematical model, Eq. [8], is followed. In region No. 2 a phenomenon termed the Mid-Run Voltage Anomaly (MRVA) occurs under certain operating conditions. In region No. 3 of Fig. 1 the voltage decay caused by exhaustion of the AgCl occurs. All cells discharged in this study were cathode limited.

Figure 2 delineates the basis for the mathematical model of a typical cell in a high-drain AgCl-Mg battery. In this type of battery [see ref. (1)], electronic contact to the cathode is achieved by pressing a sheet of metal, generally silver, against the back of the silver chloride cathode. The contact resistance between the electronic conductor and the cathode is designated  $R_1$ . Since silver chloride is a poor conductor, AgCl cathodes for large high-drain batteries are prepared by perforating them with holes 0.0825 cm in diameter and located 0.635 cm apart. After perforation, the silver chloride is treated by an appropriate reducing solution to give a very thin layer of silver over the entire surface of the cathode. This process, which reduces only a small fraction of the silver chloride

(~1.0%), results in an acceptably low, but unknown, resistance  $R_2$ .  $R_2$  decreases as the discharge progresses because of the additional silver formed on the cathode by the electrochemical reduction of silver chloride. An additional contact resistance,  $R_3$ , exists between the back of the magnesium anode and the conducting metal sheet (generally silver).

Two additional resistances occur in the AgCl-Mg cell during discharge:  $R_s$ , which is the resistance of the electrolyte retained in the sponge silver (a term applied to the exhausted portion of the silver chloride cathode), and  $R_e$ , the resistance of the electrolyte in the space between the electrodes.

Note that the following model is based on the assumption of uniform conditions over the entire cell. Because of this assumption, the cross-sectional area of the cells studied was made as small as mechanical practicality permitted.

To account for the role of area in the contact resistances  $R_1$ ,  $R_2$ , and  $R_3$ , specific contact resistances  $R_1'$ ,  $R_2'$ , and  $R_3'$  are defined and used as follows

$$\begin{aligned} R_1 &= R_1'/A \\ R_2 &= R_2'/A \\ R_3 &= R_3'/A \end{aligned} \quad [1]$$

where  $A$  is the cell area. Similarly,  $R_s$  and  $R_e$  are given by

$$\begin{aligned} R_s &= \rho_s(X/A) \\ R_e &= L(K \cdot A) \end{aligned} \quad [2]$$

where  $X$  is the depth of the sponge silver layer,  $L$  is the electrode separation distance,  $K$  is the electrical conductivity of the electrolyte in the gap sep-

Fig. 1. Generalized discharge characteristics of a silver chloride-magnesium cell under constant current load.

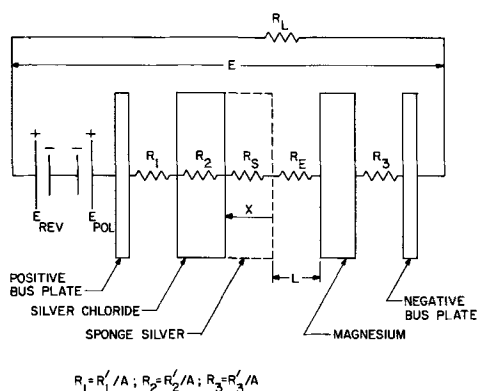

Fig. 2. Electrical analog of a magnesium-silver chloride cell.

arating the electrodes and  $\rho_s$  is the specific resistance of the sponge silver-electrolyte matrix (not the specific resistance of the electrolyte filling the voids in the sponge silver).

Based on the circuit depicted in Fig. 2,  $E$ , the emf of a small AgCl-Mg cell, is given by

$$E = E_{\text{rev}} - E_{\text{pol}} - (CD) (R_1' + R_2' + R_3' + \rho_s X + L/K) \quad [3]$$

where  $E_{\text{rev}}$  is the thermodynamically reversible emf of the AgCl-Mg couple,  $E_{\text{pol}}$  is the total emf loss from polarization at both electrodes and  $CD$  is the current density,  $I/A$ .

Let  $X_0$  be the initial sponge silver thickness (formed by the chemical reduction described above),  $L_0$  be the initial electrode separation distance and  $\eta$  be the anode efficiency defined as the ratio of the predicted (from Faraday's law) anode weight loss to the observed weight loss.  $X$  and  $L$  at time  $t$  are then given by (assuming cell discharge begins at time  $t = 0$ )

$$X = X_0 + W_c \lambda / (d_c F) = X_0 + (2.67 \cdot 10^{-4}) \lambda \quad [4]$$

$$L = L_0 + W_a \lambda / (\eta d_a F) = L_0 + (7.24 \cdot 10^{-5}) (\lambda / \eta) \quad [5]$$

where  $W_c$ ,  $W_a$  = equivalent weights of the AgCl cathode (143.3 g/equiv) and Mg anode (12.16 g/equiv), respectively,  $d_c$ ,  $d_a$  = densities of the AgCl cathode (5.56 g/cm<sup>3</sup>) and Mg anode (1.74 g/cm<sup>3</sup>), respectively,  $F$  = Faraday's constant,  $9.65 \times 10^4$  C/equiv, and  $\lambda = \int_0^t (CD) dt$ .

It should be noted that the equivalent weight of pure magnesium, 12.16 g/equiv, was used for  $W_a$ , whereas the AZ61 alloy (nominal composition: 6% Al, 1% Zn, 0.2% Mn, and 92.8% Mg) used for anode material has a nominal equivalent weight of 12.63 g/equiv. However, since the same value of  $W_a$  used in Eq. [5] was used for calculating the anode efficiency, the variation in the composition of AZ61 alloy is the only source of error. The range of composition allowed by present specifications is not considered significant. Substituting Eq. [4] and [5] into Eq. [3], the following relationship for  $E$  results

$$E = E_{\text{rev}} - E_{\text{pol}} - (CD) (R_1' + R_2' + R_3') - CD (\rho_s X_0 + L_0/K) - (CD) \{2.67 \rho_s + 0.724 / (\eta \cdot K)\} (10^{-4}) \lambda \quad [6]$$

At this point it is worthwhile to introduce the term  $E_0$ , defined as the emf of a silver chloride-magnesium cell with an interelectrode separation,  $L$ , of zero at time zero (hence  $L_0 = 0.0$ ,  $X = X_0$ ,  $\lambda = 0.0$ ).

$$E_0 = E_{\text{rev}} - E_{\text{pol}} - (CD) (R_1' + R_2' + R_3') - (CD) (\rho_s X_0) \quad [7]$$

Since magnesium is a highly irreversible electrode in aqueous solutions, the magnitude of  $E_{\text{pol}}$  is on the order of 1v and is a function of temperature, electrolyte composition, and current density.  $R_1'$  and  $R_3'$  are functions of the pressure used to compress the com-

ponents of the cell together and the cleanliness of the contact surfaces. Also,  $X_0$  and  $R_2'$  (at  $\lambda = 0$ ) are functions of the technique used to reduce the silver chloride surface. Combining Eq. [6] and [7]

$$E = E_0 - (CD) \{L_0/K + 10^{-4} [2.67 \rho_s + 0.724 / (\eta \cdot K)] (\lambda)\} \quad [8]$$

Equation [8] makes clear the importance of considering the voltage loss across the sponge silver matrix, determined by  $\rho_s$ , as well as the voltage loss across the gap separating the electrodes determined by  $K$ . It will be shown later that, under most conditions likely to be encountered by a AgCl-Mg water-activated battery,  $\rho_s$  is approximately 10-20 ohm-cm,  $\eta$  is approximately 0.7 and, from ref. (2),  $K$  is approximately 0.02 to 0.25 mho/cm. Hence, the magnitude of the terms  $2.67 \rho_s$  and  $0.724 / (\eta \cdot K)$  will be in the range of 25-55 and 4-50, respectively. Thus the two sources of voltage losses are roughly equivalent.

An examination of Eq. [8] reveals that the emf of a silver chloride-magnesium cell is a function of three empirically determined variables  $E_0$ ,  $\rho_s$ , and  $\eta$ . If  $CD$  and  $K$  are held constant, and if  $E_0$ ,  $\rho_s$ , and  $\eta$  do not change with time, Eq. [8] predicts a linear time-voltage trace. However, two significant nonlinearities were observed. The first of these resulted from a poorly understood phenomenon, the Mid-Run Voltage Anomaly (MRVA); the second was the expected drop in voltage on exhaustion of the silver chloride cathode.

The MRVA has been successfully described with the help of several quantities (Fig. 1) which have been empirically related to electrolyte composition and operating conditions (see Presentation of Results).

The voltage correction required to account for the nonlinearity due to cathode exhaustion was empirically determined as a function of the remaining cathode capacity.

Given the electrolyte composition, operating temperature, and current density, the following procedure is used to predict the voltage output *vs.* time of a small AgCl-Mg cell undergoing a constant current discharge. From ref. (2), determine the electrolyte conductivity,  $K$ , and, from the correlations given later in this paper, determine  $\rho_s$ ,  $\eta$ ,  $E_0$ ,  $\theta_B$ ,  $E_M$ ,  $\theta_M$ , and  $E_C$ . Then, referring to Fig. 1, use Eq. [8] to establish the straight line A-G. Point B is found on this line at time  $\theta_B$ , and point C is found by dropping  $E_M$  volts below the line at time  $\theta_M$ . A straight line parallel to and  $E_C$  volts below line A-G is drawn, and its intersection with a horizontal line drawn through point C locates point D. Finally, to the line A-B-C-D-H, the necessary correction for cathode exhaustion is applied as the remaining cathode capacity (determined from the elapsed discharge time, the current density, the thickness of the silver chloride cathode, and Faraday's law) diminishes, typically yielding a curve similar to E-F of Fig. 1. The emf-time trace is then given by curve A-B-C-D-E-F (solid line).

Although the discussion has been limited to the case of small cells at constant current, this method offers promise of use in the design of full size batteries by applying numerical techniques with the aid of computers.

The results obtained in predicting the emf of small silver chloride-magnesium cells by this semi-empirical mathematical model are presented in the body of this paper.

### Apparatus

The apparatus consisted of (a) an electrolyte flow system, (b) the cell assembly, (c) a device for maintaining a known stacking pressure on the cell assembly, and (d) a constant current electrical system with related electrical measuring equipment.

*Electrolyte flow system.*—The electrolyte flow system provided a constant flow of electrolyte at a constant temperature to the cell during discharge. Motive

Fig. 3. Device for applying compressive load—cell assembly in place.

force for the flow was provided by displacement from a reservoir by pressurized nitrogen. The requisite cooling and/or heating was provided by stainless steel tubing wrapped with electrical heating tape or coiled in an ice bath. Valving was provided for bypassing the cell. Electrolyte temperatures entering and leaving the cell were measured with copper-constantan thermocouples accurate to about  $\pm 0.1^\circ\text{C}$ . All components in contact with the electrolyte were constructed of inert plastics, glass, and/or stainless steel to minimize electrolyte contamination.

#### Device for compressive loading of the cell assembly.

—Since  $R_1$  and  $R_3$  (Fig. 2) are functions of the stacking pressure, it was necessary to design a device capable of applying to the cell assembly reproducible compressive loads, independent of operating conditions. This device is shown in Fig. 3. A known stacking force was applied to the cell assembly by turning the loading bolt until a given reading was obtained on the dial indicator. Transverse stresses were minimized by the use of ball bearings between the cantilever beams and the bearing plates. The relationship between the compressive force and the dial reading was determined to an accuracy of  $\pm 5\%$  by a calibrated load machine.

**Cell assembly.**—An exploded view of the cell assembly is shown in Fig. 4. Both the AZ61 magnesium alloy anodes and the silver chloride cathodes were  $0.953 \pm 0.003$  cm wide by  $3.385 \pm 0.003$  cm long.

Fig. 4. Exploded view of cell assembly

The total thickness of the micarta shim used in the positive bus plate assembly, the silver foil sheets used for the positive and negative leads, the platinum shim, the anode, and the cathode exceeded the thickness of the Teflon spacer by approximately 0.008 cm. A 0.363 cm thick rubber gasket ensured only negligible variations in stacking pressure across the entire cell assembly.

Electrical contact was made to the magnesium anodes in large AgCl-Mg batteries by laying 0.0025 cm sheets of silver foil on the back sides of the anodes and cementing the sheets to the anode around the periphery. This method did not give reproducible results with small cells, possibly because of surface contamination with cement or vapors from the cement. To avoid this a platinum shim with a watertight gasket was used instead. This technique gave acceptable results.

**Electrical system and instrumentation.**—All discharges were made under conditions of constant (within  $\pm 0.3\%$ ) cell current which were achieved by a constant current power supply and a series connected resistance. Current measurements were made to  $\pm 0.3\%$  accuracy with a reference ammeter.

Cell voltages were recorded on an X-Y recorder and, together with the thermocouple outputs, on a 12-channel strip chart recorder. Both recorders were referenced at 1-min intervals against a standard mercury cell.

**Conductivity equipment.**—The equipment used in determining the conductivities of the electrolytes was identical to that described in ref. (2).

#### Procedure

**Preparation of electrolytes.**—Electrolytes were prepared by adding up to 70g of magnesium chloride per liter to artificial sea water electrolytes whose chlorinities were  $4.5^{0/00}$ ,  $9.00^{0/00}$ , and  $19.00^{0/00}$ . The term "added  $\text{MgCl}_2$  [see ref. (2) for procedural details], which will be used henceforth and denoted by the symbol, CM, is defined as the grams of  $\text{MgCl}_2$  added per liter of sea water at  $25^\circ\text{C}$ . The composition of a given electrolyte will be given by "chlorinity-added  $\text{MgCl}_2$ " (for example 4.5-23.0).

**Preparation of electrodes.**—All anodes were fabricated from one batch of AZ61A alloy. Silver chloride from five batches was used. Two of these batches have nominal thicknesses of  $0.0520 \pm 0.0030$  cm and  $0.0546 \pm 0.0030$  cm and are both referred to herein as "thick" or 0.053 cm silver chloride. The remaining three batches had nominal thicknesses of  $0.0381 \pm 0.0030$  cm and are referred to as "thin" or 0.038 cm silver chloride.

The silver chloride, which was received in the perforated and reduced condition, was cut into approximately  $4.45 \times 2.54$  cm pieces and then beaded prior to being cut to its final dimensions. Beading of the thick (batches D and E) and thin (batches A, B, and C) silver chloride was accomplished with 0.045 and 0.059 cm thick micarta guides, respectively. Each guide had holes of slightly larger diameter than the glass beads located on 0.318 cm centers. Beads of a narrow range of diameters, 0.076–0.084 cm, were placed in the holes in the micarta guides and then driven into the silver chloride with a vise and two hardened steel blocks. The bead height was determined for each cathode by subtracting the thickness of the silver chloride sheet from the thickness of the beaded silver chloride cathode. Generally, the total variation in bead height on an individual cathode was less than 0.0018 cm and the interelectrode separation was in the range of 0.0404–0.0440 cm and 0.0500–0.0546 cm for the thick and thin batches of silver chloride, respectively.

The surface of the magnesium anode was cleaned by sanding both sides followed by an acetone rinse. Immediately after cleaning (always within  $\frac{1}{2}$  hr),

the cells were assembled and the discharge carried out.

**Discharge procedure.**—The nominal flow rates varied from 70 to 100 ml/min with variations of  $\pm 10\%$  occurring during the discharges. The flow rates were sufficiently high that the cell emf was, for all practical purposes, not affected by flow rate.

All discharges reported herein were conducted at a compression loading of 50 psi.

Power supply operation and the electrolyte flow rate and temperature were stabilized with the current and electrolyte bypassing the cell. At this point the electrolyte flow was switched to the cell. As soon as the outlet temperature had stabilized, electrical discharge of the cell was initiated. The inlet temperature of the electrolyte was held constant to within  $\pm 0.1^\circ\text{C}$  except in the case of a few discharges in which temperature variations up to  $\pm 0.3^\circ\text{C}$  occurred.

When the battery emf fell to the cutoff voltage (usually 0.0v), the discharge was stopped and the cell disassembled as quickly as possible. The post-run magnesium weight was determined by the two techniques given in ref. (1). The first technique includes washing and mechanical cleaning with a nylon brush; the second includes a 30-60 sec dip in a 30% (by weight) solution of  $\text{CrO}_3$  in water (in some of the early discharges this technique was not used). The anode efficiency was calculated from the post-run anode weight as in ref. (1).

All calculations were based on the average of the inlet and the effluent temperatures. During passage of the electrolyte through the cell assembly, its temperatures dropped by about  $2.5^\circ$  at  $65^\circ\text{C}$ ,  $1^\circ$  at  $45^\circ\text{C}$ , and increased by about  $0.4^\circ$  at  $25^\circ\text{C}$ , and about  $2^\circ$  at  $5^\circ\text{C}$ . Hence the temperature rise or fall across the cell assembly was the largest contributor to the uncertainty of the estimate of the operating temperature.

### Presentation of Results

A condensation of the results of this study is presented in Fig. 5 through 10 and in Tables I through III. A more complete summary of the results, including the time-voltage traces of all the discharges appropriate to this study, is found in ref. (3).

### Discussion of Results

**Experimental reproducibility.**—Let the term "discharge pair" refer to two discharges made under identical conditions with cathodes and anodes fabricated from the same batches of silver chloride and magnesium. The term "agreement" is then defined as the percentage of the average elapsed discharge time at a voltage cutoff of 0.75v (the elapsed discharge times at cutoff for the individual discharges of a discharge pair generally agreed to within 4%) over which the individual cell voltages of the discharge pair agreed to within a given voltage tolerance.

Of the 34 possible discharge pairs (from this study), the agreement was at least 93% for all but two with a voltage tolerance of 0.05v and at least 75% for all but four with a voltage tolerance of 0.03v.

$E_0$ .— $E_0$  was approximated by the equation

$$E_0 = E' + 0.129 (0.271 - CD) \quad [9]$$

Values of  $E'$  (which are best estimates of  $E_0$  at a current density of 0.271 ascm) are given in Table I. Evidence supporting the use of Eq. [9] is presented in Fig. 5. A substantial part of the data scatter of Fig. 5 is attributable to errors arising from uncertainties of the electrode separation. For example, an error in the electrode separation of 0.001 cm could give rise to errors in  $E_0$  up to 0.02v. Another important source of scatter in both  $E_0$  and  $\rho_s$  is associated with determining the best linear fit to the experimental voltage traces. Despite the scatter, it is apparent that the

\* Values in parentheses are interpolated or extrapolated values.

linear correction for the effect of current density in Eq. [9] improves the prediction of  $E_0$ .

Examination of Eq. [7] shows several ways in which a dependence of  $E_0$  on current density can arise. Since tests showed that reducing the stacking pressure from 65 to 10 psi did not affect  $E_0$ , it is likely that the contact resistances  $R_1$  and  $R_3$  were too small to be responsible for the current density dependence of  $E_0$ . This dependence probably arises from increased electrode polarization through  $R_s$  (at time equal to zero), and  $R_2'$  might contribute to the current density dependence. The temperature and magnesium chloride content of the electrolyte can affect  $E_0$  by changing  $E_{\text{pol}}$  and/or  $E_{\text{rev}}$  as well as affecting  $E_0$  by increasing or decreasing the magnitude of the IR drop across  $X_p$ .

The hydrogen released by the AZ61 during discharge decreases the effective conductivity of the electrolyte. However, calculations (assuming uniform dispersion of the hydrogen) show that this would account for only 12% of the dependency of  $E'$  on current density. Hydrogen evolution could account for the decrease in  $E'$  with current density if the gas were dispersed in the electrolyte in such a manner that its effect on the internal resistance of the cell was increased (e.g., by forming a film on the anode).

**Anode efficiency.**—Figure 6 gives anode efficiencies of AZ61 magnesium alloy [ $\text{CrO}_3$  cleaning method, see

Fig. 5. Effect of current density on the differences between values of  $E'$  from Table I and experimental values of  $E_0$ . The solid line gives the values of  $E_0 - E'$  predicted by Eq. [9].

Fig. 6. Anode efficiencies determined by the chromate cleaning method.

ref. (1)]. Evidence of a large drop in anode efficiency of high temperature is given by the two data points at 65°C. However, the results obtained at 65°C must be used with some caution because there is much more clogging at this temperature, which made it difficult to obtain reliable anode efficiency data (all anode efficiencies obtained for discharges exhibiting clogging were presumed unreliable), and the strong effect that the type of cleaning method used had on the value of anode efficiency obtained (see the discussion immediately below).

The values of anode efficiency obtained with the  $\text{CrO}_3$  cleaning method were, for temperatures of 45°C and below, 1 to 3% less than those obtained with the mechanical cleaning method. In the two discharges at 65°C where anode efficiencies were determined by both methods, the  $\text{CrO}_3$  cleaning method gave values of anode efficiency 9.3 and 10.4% lower than the anode efficiencies obtained by the mechanical cleaning method. No comparative values between mechanical and  $\text{CrO}_3$  cleaning were obtained at 55°C.

$\rho_s$ .—Figure 7 presents values of  $\rho_s$  as a function of temperature and current density. The experimentally determined values of  $\rho_s$  exhibited scatter which was large when compared to the effects of current density for values of current density of 0.232 ascm and above, primarily because of the sensitivity of the value of  $\rho_s$  obtained to the value of the slope of the "best line" drawn through the emf-time trace. In spite of this, current density was retained as a parameter since better results were obtained when this was done. More will be said about this in the Simplifications of the SEMM.

Empirical equations for  $\rho_s$  ( $CD \geq 0.116$  ascm) were developed; they are as follows:

Fig. 7.  $\rho_s$  as a function of temperature and current density.

for  $T < 12.5^\circ\text{C}$

$$\rho_s = (0.1062 CD^{0.176} + 0.002667T - 0.0598)^{-1} \quad [10a]$$

for  $T \geq 12.5^\circ\text{C}$

$$\rho_s = (41.05)/[1.388(\ln T + 0.6162)CD^{0.176} - 1.088] \quad [10b]$$

It is noteworthy that six cases of negative  $\rho_s$  values were observed at temperatures equal to or less than 25°C. Negative values of  $\rho_s$  arise when the observed value of  $dE/d\theta$  is less than that portion of the calculated value of  $dE/d\theta$  arising from the increasing electrode separation associated with the dissolution of magnesium. Three of the above cases of negative  $\rho_s$  are associated with electrolyte 4.5-0.0 (*i.e.*, 4.5% salinity 0.0 g/liter of added  $\text{MgCl}_2$ ), two with electrolyte 4.5-11.5 and one with electrolyte 9.0-11.5. Negative values of  $\rho_s$  cannot be attributed to the low conductivities of the electrolytes since positive values of  $\rho_s$  were obtained in many discharges with electrolytes of much lower conductivity (*e.g.*, the discharges made at 5°C). A comparison of identical discharges indicates that this behavior may be batch sensitive (*e.g.*, under identical conditions  $\rho_s$  for batch A ranged from -1.8 to -5.7 ohm-cm while  $\rho_s$  for batch C ranged from +13.3 to +16.4 ohm-cm).

*Mid-run voltage anomaly (MRVA).*—The nonlinearity of the MRVA region is taken into account by the quantities  $\theta_M$ ,  $E_M$ ,  $E_C$ , and  $(\theta_M - \theta_B)$ , used in accordance with the procedure given in the SEMM section.<sup>1</sup>

The location of  $\theta_M$  is given by the empirically determined equation

$$(CD)^{2\theta_M} = (4.27 CHL - 4.05)(10^{-4}) \exp [4.29 \cdot CHL^{-0.1363}(T + 273.2 - N \cdot CHL/5) \cdot 10^{-2}] \quad [12]$$

where  $N$  is equal to 0.0 for 0.053 cm thick silver chloride and to 1.0 for 0.038 cm thick silver chloride. Figures 8 and 9 compare Eq. [12] with the experimental data.

The relation

$$\theta_M - \theta_B = 23.3/CD \quad [13]$$

was used to determine  $\theta_B$  once  $\theta_M$  was determined.

The dependence of the magnitude of  $E_M$  on temperature is adequately described by the following empirical relation

$$E_M = \max \{0; (CD)[52.0 + 2.0(CM)^{0.5} - 1.6T](10^{-2})\} \quad [14]$$

The relation

$$E_C = 0.6E_M \quad [15]$$

gives adequate results.

*Effect of the silver chloride batch on the MRVA.*—Using thin silver chloride results in considerable batch-to-batch variations in the extent and location of the MRVA. No such variation was observed with thick silver chloride, although the possibility of batch-to-batch variations cannot be ruled out because only two batches were tested. Work is now underway to determine the cause of these variations. Evidence that the heat-treatment history of the silver chloride plays a role has been discovered. It must be emphasized that the use of  $N = 0.0$  for the thick silver chloride and  $N = 1.0$  for the thin silver chloride in Eq. [12] is based on experience gained with these few batches of  $\text{AgCl}$ . Furthermore, in the absence of experimental data, any extrapolation of  $N$  for thicknesses of  $\text{AgCl}$  lying outside of this range of thickness is not recommended. In short, the limiting factor in predicting the MRVA is the batch-to-batch variation in the cathode behavior of the silver chloride. A quantitative study of this variability will be difficult because the process methods used for producing cathode-grade rolled sil-

<sup>1</sup> Equations [12] through [15] apply only over the range of temperatures and chlorinities studied.

**Voltage corrections for cathode exhaustion.**—A set of experimental discharges was selected for which the only apparent deviation from the linear voltage-time trace predicted by Eq. [8] was that owing to cathode exhaustion, i.e., for which no MRVA was observed. For each of these discharges, the voltage deviation from linearity was plotted vs. the remaining cathode capacity (calculated on the basis of 100% cathode efficiency) to obtain a curve of best fit as shown by the eight representative discharges in Fig. 10. The values of voltage corrections used to account for cathode exhaustion (as illustrated by region No. 3 of Fig. 1) were taken from this curve.

**Accuracy of the SEMM.**—It is necessary to define some quantity that will provide a measure of the degree of agreement between the model predictions and the experimental results. The quantity chosen for

Fig. 10. Comparison of the cathode exhaustion correction to those calculated from the emf's of several cathode limited discharges (high temperature and high electrolyte conductivity).

this purpose, henceforth called "agreement," was the per cent of "the duration of discharge to  $E_{co}$ " during which the experimental and predicted emf's agreed to within a given voltage tolerance. The duration of discharge to  $E_{co}$  is defined as the time, measured from the start of the discharge, at which the emf predicted by the semi-empirical model dropped to the cutoff voltage.

In typical battery design, the thickness (hence the amount of silver chloride) is controlled to about  $\pm 5\%$ . Other important dimensions, such as the electrode spacing, are held to about the same tolerance. Furthermore, large high-drain batteries are generally designed with an electrode spacing of 0.059 cm because smaller spacings increase the danger of electrical shorts and of the cells becoming clogged with reaction products. When these considerations are taken into account, a reasonable criterion is that the predicted and observed emf's of a cell with an electrode spacing of 0.059 cm agree to within 0.05v for 90% or more of the duration of the discharge to a cutoff voltage of 0.75v.

The model was tested against 108 discharges using the thick silver chloride and 39 discharges using thin silver chloride. Satisfactory agreement, as defined above, was obtained for 107 and 29 of these discharges, using thick and thin silver chloride, respectively. The discharge conditions of temperature, chlorinity, magnesium chloride concentration, and current density for which satisfactory agreement was obtained are given in Table II. Table III lists all discharges in which the agreement fell below 90% (11 out of a total of 147 discharges). Two of these discharges failed to pass because of errors in  $E_0$ .

The remaining discharges which, significantly, were from the same batch of thin silver chloride, fall into two groups. The first of these exhibited a phenomenon in which the slope of the time-voltage trace,  $dE/d\theta$ , suddenly decreased at some period during the discharge. If values of  $\rho_s$  are calculated for this region of decreased  $dE/d\theta$ , negative values of  $\rho_s$  often resulted (see the discussion of  $\rho_s$ ). The cause for this phenomenon is not known at present. Inspection of all the discharges indicates, however, that it is negligible at either 19%/ $\infty$  chlorinity or at temperatures above 30°C. The two discharges which appear on Table III used thin silver chloride cathodes from a batch which was characterized by an extremely early onset of the change in the  $dE/d\theta$  compared to discharges made with other batches of silver chloride.

The use of the agreement as defined in this paper somewhat obscures the magnitude of this effect, since, because of space considerations, the duration of the discharge was based on the time at which the emf predicted by the model dropped to 0.75v. If the agreement is based on the time at which the observed emf

\* 90% or better agreement with voltage tolerance of 0.05v and  $E_{co} = 0.75v$ .

† An "x" means a single discharge; an "(n)" means n discharges.

falls to 0.75v (adjusted to an electrode spacing of 0.059 cm), (a) agreement values of 49 and 54% are obtained for discharges number 199 and 205, respectively, and (b) the value of  $E_{co}$  at which 90% agreement is reached becomes 0.83v for both discharges. It should be noted, however, that this source of error is not as serious as first appears, since (a) it leads to an underestimation of the voltage, which would lead to conservative battery designs, and (b) it is not important unless operating voltages of 0.83v or less are contemplated. Studies are underway to obtain more information about the causes of the decrease in  $dE/d\theta$ .

The discharges in group III on Table III failed to agree because of: (a) abrupt voltage decays which occurred earlier than predicted by Fig. 10 and (b) atypical MRVA behavior for one batch of thin silver chloride which was characterized by large observed values of  $E_M$  and low observed values of  $\theta_M$  (early onset of the MRVA). This gave rise, in some cases, to a serious lack of agreement between the model and the observed emf. The lack of agreement of the discharges shown in group III of Table III was due mainly to the early onset of MRVA for the one batch

of silver chloride with, in general, about one-third of the error due to an early voltage decay.

Of the other two batches of thin silver chloride studied, one followed the MRVA predictions reasonably well, i.e., Eq. [12], [13], [14], and [15]; the other lay almost midway between the predictions of the MRVA for the thick and the thin silver chloride as good results were obtained when either  $N = 0.0$  or 1.0 was used in Eq. [12].

Note that all but five of the discharges in Table III agree at the 90% level if  $E_{co}$  is raised to 0.85v, and all but two agree at the 90% level at an  $E_{co}$  of 0.92v.

In summary, the primary cause for failure to reach agreement was the variations between the batches of silver chloride which gave rise to the variations in the MRVA. In spite of this only 2 out of 147 discharges failed to agree at the 90% level for electrode spacings commonly used in sea water-activated silver chloride batteries when an  $E_{co}$  of 0.92 is used. SEMM is now being extended to the more general case of discharges where changes in current density, electrolyte composition, and operating temperature occur.

The extension of this model to include the use of alternate anodes, e.g., zinc, appears to be straightforward; some work with zinc has been done at this Laboratory.

### Simplifications to the SEMM

The model presented herein was developed with the objective of predicting the voltage of a silver chloride AZ61 magnesium alloy water-activated battery to within 0.05v (preferably 0.03v) to a cutoff voltage (based on the SEMM) of 0.75v. Several simplifications to the SEMM can be made if higher cutoff voltages, lower per cent agreements or greater error tolerances can be accepted. The following comments should be used as guidelines only as parameters such as geometry, electrolyte composition, etc., affect the loss of accuracy for a given simplification.

If a value of anode efficiency of 0.73 is used, the degradation in accuracy will be about 0.005v for temperatures under 60°C. At 65°C an error of about 0.03v will occur under some operating conditions. It bears mention that the effect of anode efficiency on the temperature distribution in a large battery may be very important since the secondary reactions (which lead to the observed anode efficiencies) are an important source of heat.

The correction for the effect of current density on  $E_0$  (Eq. [9]) can be neglected if the voltage tolerance is increased to 0.08v.

Similarly, for current densities of 0.23 and above, the values of  $\rho_s$  presented for 0.310 ascm can be used if the voltage tolerance is increased to 0.08v (though in most cases, 90% agreement will still be achieved with the 0.05v tolerance). A more detailed error analysis should be carried out before attempting any similar type simplification below 0.23 ascm.

Since the cathode exhaustion corrections (Fig. 10) exceed 0.05v at the value of remaining cathode capacity equal to about 15% of the total capacity of the "thin" silver chloride, some sort of correction of this type appears necessary in most cases. Alterations to the corrections presented on Fig. 10 suitable for specific design problems can be developed as needed.

In most cases the corrections for the MRVA can be neglected above 35°C with little loss in accuracy; however they are very important over the temperature range of 10°-28°C. (Below 10°C the main effects of the MRVA generally occur after the voltage has fallen below 0.75v; hence generally little accuracy loss will occur if they are neglected.) Between 10° and 28°C the MRVA effects often occur when the emf is still high and, if the MRVA corrections are neglected, serious losses in agreement will occur unless the cutoff voltage is raised to about 1.0-1.05v for an adiabatically operated battery. An error analysis is strongly recommended before attempting

any simplifications to the MRVA corrections as the agreement obtained is highly sensitive to electrolyte composition and electrode separation.

### Conclusions

A semi-empirical mathematical model for predicting the emf of small silver chloride AZ61 magnesium alloy cells, discharged under a constant current load, has thus been developed. Excellent agreement was obtained over a range of current densities of 0.116-0.527 ascm from 5° to 65°C. The range of chlorinities and magnesium chloride concentrations studied was more than adequate to allow safe extrapolation to any set of electrolyte conditions likely to be encountered in a large, high-drain water activated AgCl-Mg battery.

Two deviations from the linear time-voltage trace predicted by the equivalent circuit on which the mathematical model was based were (a) the expected voltage decay which occurs on exhaustion of the cathode and (b) the MRVA, a drop in voltage which occurs prior to exhaustion of the cathode under some operating conditions. These have been predicted reasonably well by empirically developed corrections (hence the term semi-empirical mathematical model), but room for improvement exists. The MRVA was found to be dependent on the batch of silver chloride used and, under some operating conditions, an early voltage decay took place prior to the exhaustion of the silver chloride cathode. Another source of error was a very slowly decaying voltage trace which caused the model to predict low values of emf. All three of these problem areas are under study, especially the batch-to-batch variations in the MRVA. Since errors arising from batch-to-batch variations in silver chloride were the most important, the accuracy of the model is primarily limited by the reproducibility of the cathode grade silver chloride presently available.

Studies are also underway to determine the adequacy of the model for discharges where changes in current density, temperature, and electrolyte composition occur; the results to date appear promising.

## Electrocatalysts for the Direct Electrochemical Oxidation of n-Octane in Fuel Cells

Elton J. Cairns\*<sup>1</sup> and John Paynter\*

General Electric Research and Development Center, Schenectady, New York

### ABSTRACT

Until very recently, the direct oxidation of hydrocarbons in fuel cells required high loadings of platinum in the anodes, making such fuel cells prohibitively expensive. This paper describes some progress toward acceptably low loadings of high-activity platinum electrocatalysts for the direct anodic oxidation of liquid n-octane. The activity of both supported and unsupported platinum, prepared in various ways, has been compared to that of commercial platinum black. Investigations of carbon substrates of widely varying specific areas showed that an increase in the specific area of the substrate yields a corresponding increase in electrocatalyst activity, up to at least 200 m<sup>2</sup>/g. Certain preparations of platinum on a carbon support show activities of six to eighteen times that obtained from commercial platinum black. No current or voltage cycling has been encountered when 36 m/o hydrofluoric acid at 105°C has been used as the electrolyte, in contrast to the behavior with other acidic electrolytes.

The direct anodic oxidation of saturated hydrocarbons at practical current densities (tens to hundreds of ma/cm<sup>2</sup>) has been possible only since 1963 (1-14). In general, it has been found necessary to employ platinum electrocatalysts, strong acid electrolytes, and temperatures above about 100°C in order to obtain reasonable reaction rates. Even when these elevated temperatures and acidic electrolytes were used, it was still required (until just recently) that relatively large amounts of platinum be used in the electrodes in the range of 40-200 mg/cm<sup>2</sup>. The electrolytes which have been found useful with hydrocarbon fuels are dilute sulfuric acid (3N, 95°C) (7), phosphoric acid (1, 2, 4, 5, 8-10, 13), cesium fluoride-hydrofluoric acid mixtures (3, 6, 11, 12), and hydrofluoric acid (6, 12, 14). The saturated hydrocarbon fuels which have shown the greatest reactivity in fuel cells have been ethane (12, 14-17), propane (12, 14-17), and butane (12, 14, 16, 17), and consequently these have been the most frequently studied.

Even though the anodic oxidation of propane at current densities in excess of 500 ma/cm<sup>2</sup> has been achieved at temperatures as low as 105°C (14), this performance was obtained with an anode containing 102 mg Pt/cm<sup>2</sup>. This platinum loading and those used in similar investigations were too high to make hydrocarbon fuel cells commercially feasible. Consequently, there has been a continuing effort to decrease the platinum content of fuel-cell anodes for use with hydrocarbons, without a proportional decrease in anode performance. The achievement of a tenfold increase in current per unit weight of platinum (above that obtained with commercial Pt black) at an anode potential of 0.4v vs. r.h.e. and at a loading of about 10 mg Pt/cm<sup>2</sup> has been reported for a graphite-supported electrocatalyst when used with propane at 105°C in an HF electrolyte (14).

Because liquid hydrocarbon fuels are more convenient to handle and are more readily available than the gaseous fuels, the investigations of more effective use of platinum in hydrocarbon fuel cell anodes were extended to include n-octane (bp 125.7°C) as a representative hydrocarbon fuel which is a liquid in the fuel chamber of the cell at operating temperature (105°C). The use of higher activity forms of unsupported platinum and platinum supported on both graphitic and nongraphitic carbon powders has been investigated. Carbon is particularly attractive for use as an electrocatalyst support because it is one of the few materials which is inexpensive in high-area form, electronically conducting, and resistant to corrosion by hot strong acids under the electrochemical conditions found at hydrocarbon anodes. The employment of platinoid elements other than platinum (9, 14) and of platinoid-element alloys (9, 13, 18) has been found to be an unrewarding approach and was not pursued in this work.

### Experimental

The electrolyte used in this investigation was the HF-H<sub>2</sub>O maximum-boiling azeotrope (36 m/o HF), which boils at 112°C (20, 21) and has a resistivity of 1.8 ohm-cm (20). The azeotrope was chosen because its composition will remain uniform and constant in the pores of the electrodes. The fluoride anion is not expected to adsorb on the platinum (22, 23) thereby leaving a maximum fraction of the electrocatalyst surface available for adsorption, surface reaction, and oxidation of fuel (24, 25). Access of the fuel to this surface is facilitated by the relatively high solubility of hydrocarbons in HF-H<sub>2</sub>O solution (26). These advantages contribute to the high performance on hydrocarbons which can be obtained with this electrolyte at relatively low temperatures (105°C). This feature is of importance in minimizing the sintering of highly active electrocatalysts which has been found to occur in other acids at higher temperature (19).

Fig. 1. Schematic diagram of fuel-cell apparatus

The HF-H<sub>2</sub>O azeotrope was prepared from Baker and Adamson reagent grade 48 w/o (weight per cent) hydrofluoric acid, containing less than 20 ppm impurities, and from quartz-redistilled water.

All of the apparatus which came into contact with the electrolyte was made of polytetrafluoroethylene (PTFE) in order to prevent any contamination of the electrolyte by dissolved materials. The PTFE gas compartments were circular, 3 mm deep, and had an area of 11.38 cm<sup>2</sup>; the PTFE electrolyte compartment was the same size. The thin, PTFE-bonded electrodes were held in place between the gas compartments and the electrolyte compartment by means of Monel end plates and bolts. The cell was assembled as shown in Fig. 1 of ref. (12). No gaskets were necessary because the PTFE surfaces formed leak-tight seals against one another.

The assembled fuel cell and an identical cell containing two reversible hydrogen reference electrodes (PTFE-bonded Pt black) were mounted in the apparatus shown schematically in Fig. 1. The forced-convection air thermostat maintained the apparatus at 105°C. This temperature was chosen in order to maximize the reaction rate of the hydrocarbon fuel, while maintaining the proper water vapor pressure in order to avoid the (thermodynamically) possible deposition of carbon (or carbon-rich residue) from the fuel onto the electrocatalyst surface (27-30). The oxidant, electrolytic grade oxygen, 99.6 m/o minimum purity, was metered to the cathode through a needle valve and was monitored by means of a capillary-tube flowmeter. The Phillips research grade 99.85 m/o minimum purity<sup>2</sup> n-octane liquid fuel was fed to the anode by means of a constant-speed (0.01%) syringe drive. The gas streams leaving the cell passed through PTFE traps to remove any liquids and then to water bubblers which provided a seal from the atmosphere. The exit streams could be sampled and analyzed by a vapor phase chromatograph as desired.

The electrolyte flowed by gravity from an upper PTFE reservoir to the cells, passing upward through them and into a lower reservoir, to be returned to its starting point by an all-PTFE bellows pump. The flow rate was 2-3 cell volumes per minute and was controlled by the electrolyte head.

The electrodes were all of the thin (0.15-0.38 mm) PTFE-bonded type, containing a 45-mesh platinum screen as a current collector. A thin, porous PTFE film (~ 0.3 mg/cm<sup>2</sup>) was bonded to the fuel (or oxidant) side of the electrode in order to maintain hydrostatic stability. The structure of the electrodes was similar to that of other PTFE-bonded electrodes (14, 31), but the preparation methods were modified as necessary to accommodate the specific characteristics of the electrocatalyst materials. In general, the electrocatalysts prepared by the authors were maintained in an oxidized form during electrode fabrication in order to

prevent sintering of the very small (< 100Å) platinum crystallites. The oxidized form of platinum was maintained during the KOH dissolution of the aluminum foil backing by holding the electrode potential above that required for oxygen evolution in the KOH stripping bath; the hydrogen was evolved from a remote counter electrode. In most cases, the platinum was gently reduced to the elemental form by electrochemical and/or chemical methods after the electrode was mounted in the fuel cell apparatus.

Both unsupported and supported forms of high-area platinum were used as electrocatalysts. The support materials were various forms of carbon black, both graphitic and nongraphitic.

The unsupported platinum was of two types: commercial platinum black (~ 20 m<sup>2</sup>/g), which served as a standard of comparison, and Adams catalyst (14, 32-38) (PtO<sub>2</sub> · H<sub>2</sub>O), which was fabricated into electrodes and subsequently reduced *in situ* to form a high-area platinum black.

The supported electrocatalysts were prepared by the deposition of a platinum salt onto the carbon surface from a solution of platinum diammine dinitrite (J. Bishop & Co.) in 50 w/o nitric acid, followed by roasting in air to obtain an oxidized form of the supported platinum. The concentration of the platinum salt in solution was determined by the weight per cent Pt/C desired and by the amount of solvent required to give a thick slurry with the substrate (2-3 ml/g C). As a guide in selecting appropriate thermal decomposition and oxidation temperatures, a thermogravimetric analysis was performed on the material obtained from the evaporation of a solution of platinum diammine dinitrite in 50 w/o nitric acid. The results indicated that a minimum temperature for the thermal-oxidative transformation of the salt to platinum dioxide would be above 160°C, probably near 200°C. Higher temperatures may be of interest because of their possible effect on the specific activity of the resultant electrocatalyst. Table I and Fig. 2 summarize the preparation conditions for some of the supported electrocatalysts that were used in this work.

A few commercially available carbon-supported platinum catalysts were also evaluated. No detailed information was available from the suppliers concerning the preparation methods, but it is believed that platinum salts were deposited from solution and were then reduced by a gas such as hydrogen.

Some properties of the carbon supports investigated are summarized in Table II. Half of the carbons tested were graphitic; half were nongraphitic. The material obtained from American Cyanamid Company served as the substrate in earlier propane investigations (14), and the n-octane results reported below can be compared directly to the earlier propane results.

The electrical measurements of electrocatalyst performance were obtained with the aid of a 60 Hz modified Kordes-Marko interrupter (39, 40), yielding the potentials of the anode *vs.* the H<sub>2</sub> reference electrode ( $E_{a-r}$ ), the cathode *vs.* the H<sub>2</sub> reference electrode ( $E_{c-r}$ ), and the anode *vs.* the cathode ( $E_{a-c}$ ), all on a resistance-free basis. The use of a frequency of interruption as low as 60 Hz can lead to high values of  $E_{c-r}$  and  $E_{a-c}$  and low values of  $E_{a-r}$  under some conditions at low platinum loadings (41). The magnitude of this error was found to be less than 2% of the values of the readings under the conditions used in the investigations reported here.

All of the results reported below are on a resistance-free basis unless specified otherwise. The reference electrode was always reversible hydrogen in the same electrolyte (36 m/o HF) at the same temperature (105°C). The current-voltage data were taken at steady state, which was usually achieved within 5 min after changing the current. In general, the current was increased in a stepwise manner, starting from open circuit. The resistance-included cell voltages ( $E_{cell}$ ) can be estimated from the resistance-free ( $E_{a-c}$ ) val-

<sup>2</sup> The principal impurities were 0.13 m/o isononanes and 0.02 m/o isooctanes.

$$E_{\text{cell}} = E_{a-c} - i\rho l \quad [1]$$

where  $i$  is the current density,  $\rho$  is the resistivity of the electrolyte, 1.8 ohm-cm; and  $l$  is the interelectrode distance, 0.3 cm. The small resistance of the electrodes is ignored in Eq. [1].

### Results and Discussion

**Unsupported electrocatalysts.**—Commercially available platinum black with a surface area of 20 m<sup>2</sup>/g was adopted as a standard against which the results with other electrocatalysts were compared. It was previously shown that over the range 10-100 mg Pt/cm<sup>2</sup>, the current density for propane oxidation in 36 m/o HF (14) at a given overvoltage was directly proportional to the electrocatalyst loading. This same effect has been noted in general with other saturated hydrocarbon fuels and unsupported electrocatalysts (14). The direct proportionality between current density and electrocatalyst loading for platinum black forms the basis for electrocatalyst comparisons using as criteria the specific current (ma/mg Pt) and the effectiveness ratio  $\left( \frac{\text{ma/mg Pt in test catalyst}}{\text{ma/mg commercial Pt black}} \right)$ . The results presented below will serve to illustrate the calculation and use of the specific current and the effectiveness ratio.

Fig. 2. Generalized time-temperature profile used for the preparation of carbon-supported platinum electrocatalysts.

The performance of liquid n-octane on commercial platinum black, at a loading of 25.8 mg Pt/cm<sup>2</sup> is shown in Fig. 3. These data are representative of those adopted as the standard of comparison, and correspond to 0.27 ma/mg Pt at  $E_{a-r} = 0.5v$ . By definition, the effectiveness ratio for platinum black is unity. The curve showing the resistance-free voltage difference between the anode and cathode,  $E_{a-c}$ , was obtained using an average of the results from several standard cathodes containing commercial platinum black at a loading of 51 mg Pt/cm<sup>2</sup>. This use of a standard cathode current density-voltage curve allows comparisons to be made among anodes on the basis of either the anode data alone or on the basis of cell performance (e.g., mw/cm<sup>2</sup> at a given  $E_{a-c}$ ).

The performance of an anode containing 10.2 mg Pt/cm<sup>2</sup> reduced from Adams catalyst is also shown in Fig. 3. Note that for anode potentials below 0.56v, the electrode prepared from PtO<sub>2</sub> · H<sub>2</sub>O yielded higher current densities than the electrode of commercial Pt black, even though the Pt loading was much higher for the commercial Pt black electrode. The specific current (designated  $i^*$ ) for the Pt black electrode at  $E_{a-r} = 0.5v$  was 0.27 ma/mg Pt, while that for the electrode made from PtO<sub>2</sub> · H<sub>2</sub>O was 0.90 ma/mg Pt.

Fig. 3. Current density-voltage curves for n-octane on two unsupported platinum electrocatalysts.

Fig. 4. Current density-voltage curve for n-octane on platinum black prepared from the reduction of Adams catalyst.

The quotient of specific currents yields an effectiveness ratio of 3.3 for the Adams catalyst electrode at  $E_{a-r} = 0.5v$ . This means that at any given Pt content, the n-octane current density at  $E_{a-r} = 0.5v$  for an electrode made from Adams catalyst will be 3.3 times that for an electrode made from commercial Pt black, providing that the effectiveness ratio is constant, as was found for propane on various electrocatalysts (14). This represents a reduction of a factor of 3.3 in the platinum requirement (in the anode) for a given amount of power.

The encouraging results with Adams catalyst at low Pt loadings led to further work at high loadings, in an attempt to verify the constancy of the effectiveness ratio over a wide range of loadings found for this catalyst when used for propane oxidation (14). Figure 4 shows the current density-voltage curves for a cell with an anode containing 102 mg Pt/cm<sup>2</sup> from Adams catalyst. Current densities in excess of 100 ma/cm<sup>2</sup> were obtained at (resistance-free) cell potentials near 0.3v. This represents a performance well into the practical range, but still with impractical platinum loadings. The specific current at  $E_{a-r} = 0.5v$  was 0.78 ma/mg Pt, corresponding to an effectiveness ratio of 2.9 (vs. 3.3 at 10.2 mg Pt/cm<sup>2</sup>). The effectiveness ratio was almost the same as that for the 10.2 mg Pt/cm<sup>2</sup> electrode, verifying the previous observation of constant specific current over a wide range of loadings for unsupported electrocatalysts when used with propane (14). It is interesting to observe that the same effectiveness ratio of 3 was found for commercial Adams catalyst when used for gaseous propane (14), which may hint at a similarity in the rate-determining steps

for the over-all anodic oxidation of propane and octane. The results obtained with the unsupported electrocatalysts are summarized in the first three rows of Table III.

**Supported electrocatalysts.**—The improvement in electrocatalytic activity of platinum when prepared from an oxidized form such as Adams catalyst, and the improvements obtained in earlier work with propane when carbon electrocatalyst supports were used (14) led to an attempt to combine the two types of activity enhancement. Two kinds of finely divided carbons were investigated as platinum supports: graphitized and ungraphitized carbons. In general, the graphitic carbons have lower electrical resistivity, lower volatiles content, and are easier to fabricate into electrodes. The graphitic carbon obtained from American Cyanamid was investigated first and was used for the development of electrode preparation procedures. Some of the characteristics of this carbon are given in Table II; additional information can be found in ref. (14) and (42).

A number of electrodes were prepared using electrocatalysts supported on the graphitic powder from American Cyanamid (11.4 m<sup>2</sup>/g). The electrocatalysts were prepared as described in the experimental section above, using various ratios of platinum to carbon. In addition, two electrocatalysts supplied by American Cyanamid using the same support were tested (10 w/o Pt/C and 50 w/o Pt/C). The results of the experiments using the American Cyanamid graphitic carbon support are summarized in Table III in the rows labeled Preps 20 to 22, and CYAN. In the case of CYAN (improved), the results in Table III are the best from a group of twelve electrodes; in the cases of Preps 20-22, the results are from single electrodes. The electrode Prep 20, 28 w/o Pt/C showed the best performance, and the best of the CYAN 50 w/o Pt/C electrodes was next best. The voltage-specific current curves for these two electrocatalysts are shown in Fig. 5. The Prep 20, 28 w/o Pt/C shows the highest currents per unit weight of platinum, while the CYAN 50 w/o Pt/C and the Pt from Adams catalyst show very similar performances. The effectiveness ratio of Prep 20, 28 w/o Pt/C was 18.5 at  $E_{a-r} = 0.4v$  and 6.0 at  $E_{a-r} = 0.5v$ , indicating that the greatest improvements in specific current are evident at the lower anode overvoltages. The lower effectiveness ratios and specific currents for Prep 20 — 42 w/o Pt/C (shown in Table III) were probably caused by the fact that zone E of Table I was eliminated in the preparation of this electrocatalyst, as an experiment on the effect of the final roasting temperature on activity. Evidently, temperatures of at least 200°C result in higher activity electrocatalysts than those roasted at lower temperatures.

<sup>a</sup> The subscript g indicates graphitic carbon. The carbon was graphitized by heat treatment at 2700°C for 2 hr in an inert atmosphere.

<sup>b</sup> The results for these electrocatalysts represent an average of two or three cells each.

<sup>c</sup> Before deposition of electrocatalyst.

Fig. 5. Voltage-specific current curves for n-octane on two graphite-supported platinum electrocatalysts compared to the results using Pt from  $\text{PtO}_2 \cdot \text{H}_2\text{O}$ .

After completing the study of various platinum-to-carbon ratios (10-50 w/o) on the  $11.4 \text{ m}^2/\text{g}$  graphite, an investigation was made concerning the effect of increasing the graphite specific surface area on electrocatalyst activity. The higher specific area graphites were obtained from the Cabot Corporation and had specific areas of 23.7, 68.4, and  $212 \text{ m}^2/\text{g}$ . A group of four electrocatalysts was prepared starting with a sample of each of the graphitic carbons listed in Table II, and making use of the same platinum deposition techniques for all. All of the electrodes were prepared in the same way and tested in the same apparatus. These electrodes are designated as Preps 22, 30, 40 and 50 in Table III. All had a nominal 30 w/o Pt/C electrocatalyst, with Pt loadings in the range 10-17  $\text{mg}/\text{cm}^2$ .

The specific currents for the oxidation of liquid n-octane at anode vs. reference potentials of 0.4 and 0.5 v are shown in Fig. 6 as a function of the specific surface area of the graphitic carbon substrate. The specific current increases with substrate specific area, but at a rate lower than direct proportionality. The specific current approximately doubles for an increase from  $11.4$  to  $212 \text{ m}^2/\text{g}$ . A search for still higher specific area graphites was not fruitful, but did lead to the investigation of nongraphitic carbons, which are available in higher specific area forms.

Fig. 6. Specific current for n-octane oxidation on graphite-supported platinum, as a function of the specific area of the graphite.

Four nongraphitic carbon blacks (Cabot Corporation), having specific areas of 42, 110, 380, and  $850 \text{ m}^2/\text{g}$ , were used as substrates in the preparation of electrocatalysts. Some modification of preparation procedures was necessary because of the tendency of the nongraphitic carbon substrates to oxidize rapidly in air when heated above  $200^\circ\text{C}$  in the presence of platinum compounds deposited on the carbon surface. Because of the necessity of modifying the electrocatalyst preparation procedures, this group of electrodes also contained one prepared using an electrocatalyst supported on a graphitized substrate ( $212 \text{ m}^2/\text{g}$ ) for comparison. One other change from previous procedures was the use of a slower *in situ* reduction of the platinum oxides. These electrodes are designated as Preps 51, 60, 70, 80, and 90 in Table III. All had a nominal 30 w/o Pt/C electrocatalyst, with Pt loadings in the range 10-15  $\text{mg}/\text{cm}^2$ .

In relation to the tendency of the carbon-supported electrocatalysts to oxidize in air when heated, it was suspected that some changes in the electrocatalysts might take place even in the absence of gross effects visible to the unaided eye. In order to investigate this possibility, the electrocatalysts (after deposition of Pt) were examined by means of an electron microscope, and it was found that in some cases there was a significant increase in electrocatalyst particle size as a result of the platinum deposition procedures. The extent of particle size increase (sintering) was related to the volatiles content of the carbon (Table II). Note in Table II that for Prep 60, which had 13% volatiles, the mean carbon particle size increased from 120 to  $506 \text{ \AA}$ , while the other substrates with lower volatile contents sintered to a much smaller extent. It was found that the increase in particle size (decrease in specific area) was accompanied by a weight loss which was equal to the volatiles content calculated from the values listed in Table II. Evidently, the volatiles were catalytically oxidized on the Pt crystallites. The heat of combustion raised the local temperature sufficiently to cause sintering of the substrate, and probably also of the platinum crystallites.

Because of the loss of specific surface of the substrate during the electrocatalyst preparation procedure, it was necessary to correlate the n-octane anode performance with the particle size after activation, rather than specific area before activation. The average particle diameters in column 5 of Table II were used in the preparation of Fig. 7. Note that the results for Prep 60 are similar to those for Prep 70 indicating that there would be no correlation of performance on the basis of specific areas before performance (see Table II), but the expected correlation is found on the basis of reciprocal substrate particle diameter after activa-

Fig. 7. Specific current for n-octane oxidation on carbon-supported platinum electrocatalysts as a function of reciprocal substrate particle diameter.

tion. (Note that reciprocal particle diameter is proportional to specific area.) The results in Fig. 7 show that increasing the specific area of the ungraphitized carbon substrate increases the specific current of n-octane, at least up to about 300 m<sup>2</sup>/g corresponding to a reciprocal particle diameter of  $6 \times 10^{-3} \text{ \AA}^{-1}$  (see Table II and Fig. 7), and that specific currents of about 1.4 ma/mg Pt can be obtained at  $E_{a-r} = 0.5\text{v}$  with the 212 m<sup>2</sup>/g graphitic support. Each data point in Fig. 7 is the average of results from two different anodes prepared in slightly different ways from the same electrocatalyst. The differences among pairs of results averaged about 10%. It is evident that Prep 51 yielded better results than Prep 50 (Table III), probably because of the slower *in situ* reduction of the Pt in Prep 51.

The correlation between specific current on n-octane and substrate specific surface area probably indicates a relationship between the specific current and the specific area of the platinum. (The specific surface area of the platinum could not be determined directly by either the chemisorption of hydrogen or by electron photomicrographs because of experimental difficulties with both approaches.) For a given weight fraction of platinum on carbon, the specific surface area of the platinum probably increases with increasing carbon specific surface area, because the larger carbon area allows more room for each platinum crystallite, and therefore larger distances between platinum crystallites are obtained. This condition makes it more difficult for the Pt crystallites to coalesce (or sinter together), and therefore the high specific area of the platinum is maintained due to the lower probability of sintering during the heat-treatment stages of electrocatalyst deposition and electrode preparation.

The voltage-specific current curves for the electrocatalysts supported on the two highest-area nongraphitic carbons (after Pt deposition, Preps 80 and 90) and on the highest-area graphitic carbon (Prep 51) are compared in Fig. 8. Prep 51 shows the highest performance of this group and is comparable to the performance level of Prep 20, 28 w/o Pt/C, Fig. 5. Probably a combination of the electrocatalyst preparation procedures used for Prep 20, 28 w/o Pt/C with the substrate of Prep 51 would result in a higher performance electrocatalyst at low overvoltages.

With respect to the use of carbon substrates with specific surface areas above 200 m<sup>2</sup>/g, it is suggested that the volatiles be removed by heating the substrate in vacuum before deposition of the platinum, increasing the probability that the high surface area of the carbon will be retained during subsequent heat-treatment. It may also be possible to use a gas mixture of lower oxygen content than that of air in the activation procedure, reducing the tendency to oxidize the re-

Fig. 8. Voltage-specific current curves for the two best nongraphitic carbon-supported platinum and a correspondingly prepared graphite-supported platinum.

Fig. 9. Current density (at  $E_{a-r} = 0.5\text{v}$ )-platinum loading plot for all electrocatalysts tested on n-octane.

sidual volatiles and/or the substrate. Further work on optimization of electrode structures using high area substrates is likely to lead to improved performance, because the structures used in this work were optimized for the 11.4 m<sup>2</sup>/g graphite.

The results of all of the experiments reported here are summarized in Fig. 9 in terms of the n-octane oxidation current density at  $E_{a-r} = 0.5\text{v}$  as a function of platinum loading in the anode. The straight lines of unit slope indicate a constant specific current. Note that the line for Adams catalyst corresponds to an effectiveness ratio of about 3. There are not sufficient data for the various supported electrocatalysts to draw lines of constant preparation method for various loadings, etc. It can be seen from Fig. 9 that many of the supported electrocatalysts were not as active as platinum prepared from Adams catalyst, but 28 w/o Pt/C, Prep 20, and 30 w/o Pt/C, Prep 51, indicate that rather high activities can be obtained at platinum loadings near 10 mg Pt/cm<sup>2</sup>.

In this work with liquid n-octane using 36 m/o HF as the electrolyte, no voltage or current cycling has been observed under any conditions of operation. This is significant and in marked contrast to the cycling observed with saturated hydrocarbon fuels in other electrolytes such as sulfuric acid (7) and phosphoric acid (43-45).

### Conclusions

1. The use of platinum black obtained by the controlled *in situ* reduction of Adams catalyst provides an electrocatalyst with an activity for the anodic oxidation of liquid n-octane of about 3 times that of commercial platinum black, in agreement with a similar ratio found earlier for propane oxidation.
2. Carbon (both graphitic and nongraphitic) is an effective electrocatalyst support, providing a stable (in 37 m/o HF at 105°C) support for high-activity platinum. The activity of the carbon-supported electrocatalysts for liquid octane oxidation increases with increasing substrate specific surface area, up to at least 212 m<sup>2</sup>/g. This effect is probably due to the fact that the higher specific area substrates provide sufficient area for the very small Pt crystallites to exist without sintering together.
3. Certain carbon-supported electrocatalysts are effective in reducing the amount of platinum required for a given octane performance by factors

of 6 to 18. Further improvements are likely by use of higher specific area carbon substrates.

- No cycling of the cell current or potential has been observed with liquid octane under any conditions of operations.

#### Acknowledgment

It is a pleasure to thank E. J. McInerney and J. R. Morgan for their help with many of the experiments, Dr. E. L. Simons and Mrs. V. B. Hughes for their assistance in the thermogravimetric analysis, and Dr. W. T. Grubb for information concerning deposition of platinum salts. They are also grateful to W. G. Burbine and W. E. Campaigne of the Cabot Corporation for their generous cooperation in providing most of the support materials and to R. J. Haldeman and V. J. Cable of the American Cyanamid Company for samples of one of the supports and some of the electrocatalysts.

This work is a part of the program under contracts DA-44-099-AMC-479(T) and DA-44-009-ENG-4909, ARPA Order No. 247 with the U.S. Army Mobility Equipment Research and Development Laboratories, Fort Belvoir, Virginia, to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plants for operation on ambient air and hydrocarbon fuels.

Manuscript submitted May 23, 1968; revised manuscript received Aug. 5, 1968. This paper was presented in part at the Philadelphia Meeting, Oct. 9-14, 1966, as Paper 8.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# Electrochemical Oxidation of Fuels in Liquid Ammonia

M. H. Miles\* and P. M. Kellett

Naval Weapons Center Corona Laboratories, Corona, California

## ABSTRACT

Overvoltage measurements for the hydrogen and nitrogen evolution reactions in acid ( $\text{NH}_4\text{SCN}$ ) liquid ammonia on more than thirty electrode surfaces permit the evaluation of these surfaces as catalysts for the electrochemical oxidation of hydrogen and ammonia in this electrolyte, as well as yielding the electrostability regions available for fundamental electrochemical studies on these surfaces. Testing of various fuels on ten selected electrode surfaces in acid liquid ammonia showed that hydrazine could be oxidized on rhodium and platinum, 1,2-diphenylhydrazine is oxidizable on mercury, and borohydrides show activity on rhenium and platinum. Constant current oxidation in stirred acid ammonia solutions yields almost 4 electrons per molecule of hydrazine, 2 electrons per molecule of 1,2-diphenylhydrazine, and 2 to 3 electrons per molecule of potassium borohydride. The activation energies are about 15 kcal/mole for the oxidation of  $\text{KBH}_4$  on platinum and 5 kcal/mole for the oxidation of 1, 2-diphenylhydrazine on mercury. The rate of the oxidation of hydrazine on platinum in acid liquid ammonia solutions does not appear to follow the Arrhenius temperature dependence.

Most fuel cell research has been centered on systems using solid oxide, molten carbonate, or aqueous electrolytes (1, 2). Research data on low temperature fuel cell systems using nonaqueous electrolytes are limited (3). The high conductivities and solubilities attainable in liquid ammonia (4, 5) make this solvent attractive for fuel cells; therefore, fundamental investigations in liquid ammonia were begun.

## Experimental

Inorganic salt solutions of liquid ammonia were used in which the vapor pressure of  $\text{NH}_3$  at 25°C was below 1 atm (5, 6). These solutions were prepared by condensing anhydrous ammonia (Matheson Company, 99.99%) onto the vacuum-dried salt (Baker reagent grade). Most measurements were made in  $\text{NH}_4\text{SCN}$  solutions at 25°C. At this temperature the mole ratio of  $\text{NH}_3$  to  $\text{NH}_4\text{SCN}$  was 2.0 (8.5M  $\text{NH}_4\text{SCN}$ ). Other chemicals used include Fisher certified  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$  (99.7%), Metal Hydrides  $\text{KBH}_4$  (97+%), and Eastman practical hydrazobenzene washed with ligroine to remove azobenzene.

The electrochemical measurements were made in a glass cell in which the working and counter electrode compartments were separated by a glass frit. Most of the metals used for the working electrodes had purities of 99.9%. Electrical contacts to copper leads were made by spot welding, soldering, or with a mercury contact. The electrodes were sealed in glass tubing using Bipax<sup>1</sup> epoxy (BA-2112). A platinum counter electrode was always employed. The reference electrode used was Pb/saturated  $\text{PbNO}_3$  with two glass microcracks separating the reference electrode,  $\text{NH}_3\text{-LiNO}_3$  salt bridge, and solution. Due to the high impedance of this reference electrode (3M ohm), a unity-gain follower with input impedance of  $10^{12}$  ohms was constructed from an operational amplifier (Philbrick Researches, Inc., Type EP 25 AU) and used in the potential-measuring circuit.

The cyclic voltammetric curves were obtained using an electronic triangular wave generator to program a Wenking potentiostat (Model 63 TRS), and the i-v curves were recorded on an X-Y recorder. Most cyclic voltammograms were obtained using a scan rate of 125 mv/sec.

## Electrostability Results

Thermodynamically, there is only a 0.04v potential difference at 25°C between the electrochemical reac-

tions where  $\text{NH}_3$  is reduced to  $\text{H}_2$  and oxidized to  $\text{N}_2$  (4). Kinetically, these reactions are slow on most electrode surfaces; therefore, a much larger potential range is available for electrochemical studies in this solvent.

Electrostability results for over thirty electrode surfaces in acid liquid ammonia solutions at 25.0°C are given in Table I. Oxidation is represented above the center line and reduction below the line. Except for pyrolytic graphite and nickel boride, these are all metallic surfaces. Four interesting observations can be made from Table I.

First, the potential region between the reduction of  $\text{NH}_4^+$  and the oxidation of  $\text{NH}_3$  or of the electrode surface defines the electrostability region for that surface in this electrolyte at 25°C. Electrochemical studies outside this region cannot readily be made. For example, Table I defines an electrostability region for Pt of -0.5 to +1.6v, for Mo of -1.0 to +1.3v, and for Hg of -1.7 to +0.8v, all with respect to the Pb/saturated  $\text{PbNO}_3$  reference electrode. The electrostability regions limited by the  $\text{H}_2$  and  $\text{N}_2$  evolution reactions are not very sensitive to the potential sweep rate, or to the ammonium (acid) salt used as long as its anion is not easily oxidized. Experiments at -35°C showed that the electrostability region is also independent of the acid salt concentration for concentrations above 0.1M. The

Key words: Ammonia, borohydrides, electrocatalysts, electrostability, fuels, hydrazine, hydrazobenzene, hydrogen, metals, oxidation.

<sup>1</sup> From Tra-Con, Inc., Medford, Massachusetts.

electrochemical stability region, of course, increases with decreasing temperature. For example, a 60°C drop in temperature gives about a 10% increase in the electrochemical stability region of Pt. Electrode oxidation rather than solvent oxidation is more likely to determine the anodic limit as the temperature or sweep rate increases.

Second, Table I shows which structural materials are useful in acid liquid ammonia fuel cells or batteries. The starred materials (limiting anodic potential due to electrode oxidation) which oxidize at low potentials should be avoided. For example, structural parts of Fe, Cu, or Ni will give corrosion problems in acid ammonia, while Al, Ti, and Ta are quite inert in this electrolyte.

Third, Table I enables one to evaluate the various electrode surfaces as catalysts for the oxidation of  $\text{NH}_3$ . Excluding the starred materials, the more negative in potential the listing of the materials above the line, the more effective they are in catalyzing the oxidation of  $\text{NH}_3$ . Therefore, from Table I, the best catalyst for  $\text{NH}_3$  oxidation is Ga, followed by Re, then V, and Mo. Even on Ga, however, the overvoltage for  $\text{NH}_3$  oxidation in acid ammonia is approximately 0.7v at 25°C, and improved electrocatalysts are needed before this fuel can be used effectively at ambient temperatures. At higher temperatures (150°C) in aqueous KOH solutions, ammonia is a useful fuel on platinum catalysts (7). Our results suggest that less expensive electrocatalysts (Ga, V, Mo) may be more effective than Pt for this oxidation of  $\text{NH}_3$ .

Fourth, the evaluation of the various electrode surfaces as catalysts for the oxidation of hydrogen in acid ammonia can be made indirectly from Table I. For the

general reaction  $R \rightleftharpoons 0 + ne$ , the equilibrium constant,

$K = k_f/k_b$ , is a thermodynamic quantity unchanged by catalysis; hence, a catalyst that increases  $k_f$  will also increase  $k_b$ . The electrochemical oxidation of hydrogen in acid ammonia,  $\frac{1}{2}\text{H}_2 + \text{NH}_3 \rightleftharpoons \text{NH}_4^+ + e^-$ , is the reverse of the hydrogen evolution reaction; hence, effective electrocatalysts for the reverse reaction will also be effective for the forward reaction. Therefore, the more positive in potential the listing of the materials below the line in Table I, the more effective they will be in catalyzing the electrochemical oxidation of hydrogen in acid liquid ammonia electrolytes. Of the electrocatalysts tested, Pt and Pd are the best for this reaction. The exchange current,  $i_0$ , determined both by Tafel and low overpotential methods (8), for the hydrogen reaction on Pt in acid ammonia is  $10^{-3}$  amp/geometrical  $\text{cm}^2$ , about the same as in aqueous solutions. This indicates that hydrogen as a fuel should be about as effective in acid ammonia as in aqueous solutions.

### Fuel Oxidation

The fuels investigated for possible electrochemical oxidation in acid liquid ammonia include methanol and several other organic molecules with hydroxyl groups, acetylene, potassium borohydride, hydrazine sulfate, and 1,2-diphenyl hydrazine, all of which are soluble in liquid ammonia. Each of these substances was tested for oxidation on ten electrode surfaces selected from various groups of the periodic table. Cyclic voltammetry is especially useful for such screening, and the results using this method are summarized in Table II. The results for the various electrode surfaces indicate that in liquid ammonia, as in aqueous electrolytes, platinum and other precious metals are the best catalytic surfaces.

The results for the various fuels in Table II suggest that inorganic fuels are more easily oxidized in liquid ammonia than carbonaceous fuels. No definite electrochemical oxidation of an organic substance was observed, although such reactions occur readily in aqueous solutions. From studies of the electrochemical oxidation of methanol on platinum in aqueous electrolytes,

Table II. Results from testing various fuel-electrode combinations for electrochemical oxidation in liquid  $\text{NH}_3\text{-NH}_4\text{SCN}$ . Positive results for fuel oxidation are indicated by "yes," negative results by "—," and questionable results by "Q." Carbon surface is pyrolytic graphite.

$\text{KBH}_4$	—	—	—	Yes	—	Yes	Yes	Q	—	—

Bagotzky and Vassilyev postulate that the slow step is the oxidation of carbon-containing chemisorbed residues by chemisorbed OH fragments produced from the solvent (9). If the reaction mechanism in liquid ammonia is analogous, it is reasonable that adsorbed  $\text{NH}_2$  species are not as effective oxidizing agents as adsorbed OH species; hence, the electrochemical oxidation of carbonaceous fuels would involve a higher energy barrier in liquid ammonia than in water. In general, the electrochemical oxidation of carbonaceous fuels will probably be kinetically most favorable in solvents containing fluorine, chlorine, or oxygen atoms. Other solvents such as liquid ammonia should be useful for fuels such as hydrazine, hydrogen, and metals since for these fuels the solvent is not directly involved in the oxidation reaction.

Figure 1 shows typical curves for constant current oxidation of  $\text{KBH}_4$ ,  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$ , and  $\text{C}_6\text{H}_5\text{NHNHC}_6\text{H}_5$  in stirred acid ammonia solutions. For the electrochemical oxidation of  $\text{KBH}_4$  and  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$ , platinum electrodes of about 50  $\text{cm}^2$  geometrical area were used, while 1,2-diphenylhydrazine was oxidized on a mercury pool of about 3  $\text{cm}^2$  area. The arithmetic means for these experiments are  $1.8 \pm 0.3$  electrons/molecule for  $\text{C}_6\text{H}_5\text{NHNHC}_6\text{H}_5$ ,  $2.4 \pm 0.4$  electrons/molecule for  $\text{KBH}_4$ , and  $3.7 \pm 0.2$  electrons/molecule for  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$ , where the limits are the 95% confidence interval within which the true population mean would lie, assuming only random errors. The net oxidation reaction for hydrazine in acid ammonia is therefore

and for 1,2-diphenylhydrazine

where  $\text{H}^+$  represents the ammoniated proton.

The net reaction for  $\text{KBH}_4$  is uncertain; however, hydrogen evolution is observed when  $\text{KBH}_4$  is added to acid liquid ammonia solutions, probably produced

Fig. 1. Constant current oxidation of  $\text{KBH}_4$ ,  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$ , and  $\text{C}_6\text{H}_5\text{NHNHC}_6\text{H}_5$  in stirred  $\text{NH}_3\text{-NH}_4\text{SCN}$ .  $I = 1.00$  ma;  $T = 25.0^\circ\text{C}$ .

Fig. 2. Graph of  $\log I$  vs.  $1000/T$  for the electrochemical oxidation of 1,2-diphenylhydrazine on Hg in stirred  $\text{NH}_3\text{-NH}_4\text{SCN}$ .

by the reaction  $\text{NH}_4^+ + \text{BH}_4^- \rightarrow \text{BH}_3\cdot\text{NH}_3 + \text{H}_2$ . The electrochemical activity remains even after the hydrogen evolution has ceased, indicating that  $\text{BH}_3\cdot\text{NH}_3$  is the reactive substance. No hydrogen evolution and no electrochemical oxidation of  $\text{KBH}_4$  are observed in neutral ( $\text{NaSCN}$ ) liquid ammonia solutions.

#### Temperature Effect

Figure 2 shows the graph of  $\log I$  vs.  $1/T$  for the electrochemical oxidation of 0.02M 1,2-diphenylhydrazine on a 3 cm<sup>2</sup> mercury pool at approximately constant overpotential. The current  $I$  is that recorded 15 sec after beginning the oxidation at 0.1v overpotential in stirred acid ( $\text{NH}_4\text{SCN}$ ) ammonia solutions. From the slope of the line in Fig. 2, an Arrhenius activation energy of about 5 kcal/mole is calculated at this overpotential.

For the electrochemical oxidation of  $\text{KBH}_4$  on platinum, an approximate value of about 15 kcal/mole for the energy of activation was determined. The results, however, were not as reproducible as for the oxidation of 1,2-diphenylhydrazine. This high value for the activation energy reflects a need for great improvement in the catalysis of this reaction.

The rate of the electrochemical oxidation of hydrazine on platinum in acid liquid ammonia does not show the expected Arrhenius temperature dependence. In fact, the rate of the hydrazine oxidation reaction diminishes as the temperature increases. This behavior is not uncommon for heterogeneous reactions where

the rate-determining step involves reaction in the adsorbed state. This decrease in rate with increase in temperature is often the result of the unfavorable effect of temperature on the chemical adsorptions (10).

#### Summary

The main results of these experiments can be summarized by the following statements.

1. Electroactivity regions in acid liquid ammonia solutions for over thirty electrode surfaces are defined.
2. Carbonaceous fuels are difficult to oxidize in liquid ammonia.
3. For the electrochemical oxidation of  $\text{NH}_3$  and  $\text{KBH}_4$ , better electrocatalysts are needed.
4. Hydrogen and hydrazine show promise as fuels in liquid ammonia electrolytes and merit further study.

#### Acknowledgments

The authors wish to express their thanks to Dr. William S. Harris and Dr. Richard E. Panzer for many helpful discussions and suggestions.

# Changes in the Microstructure of a Sintered Silver Electrode after Repeated Cycling at a Low Current

C. P. Wales\* and A. C. Simon\*

Naval Research Laboratory, Washington, D. C.

## ABSTRACT

Cross sections of Ag electrodes were examined by optical microscopy. Most small particles present in an unused sintered Ag electrode were completely oxidized to AgO during the first charge, but electrode capacity then decreased markedly during the next few cycles at the 20-hr rate in 35% KOH. Slow discharges resulted in the formation of large granular Ag particles which did not oxidize as readily or extensively as small Ag particles. Voids were small and well distributed in the unused electrode, but with repeated cycling the voids became large as active material clumped. Grid corrosion occurred but did not impair performance.

Silver-zinc and silver-cadmium cells are important as high capacity power sources, but their full capabilities are not always realized, for reasons not fully understood. Cell capacity often decreases with use. Discharge performance appears to be influenced by the charging method and by conditions of the previous discharge. Since these cells are normally constructed with an excess of negative active material, performance is usually limited by the silver electrode. The present investigation was undertaken in the belief that changes in crystal morphology during the life of the silver electrode are related to changes in electrode performance. If a relationship can be established, it may be possible to determine and control the optimum structure for a given type of performance in order to improve the charge acceptance and capacity of the silver electrode.

Optical microscopy has been used successfully as a tool for solving problems connected with the lead-acid storage battery (1, 2). Special techniques were developed that have aided considerably in understanding the mechanisms of corrosion and crystallogeneses that occur in the lead-acid system (3, 4). Electron microscopy of replica films has been used to describe the surface and back side of silver electroplated on sheet platinum and then charged and discharged to various conditions while in alkaline solution (5). The present work used optical microscopy of cross sections of sintered silver electrodes manufactured for silver-zinc storage batteries and applies to conditions that can develop when such batteries are used.

Porous electrodes cannot be ground and polished successfully in preparation for microscopic examination unless the voids within the electrode are filled with a solid material. Since the techniques being used for the microscopic study of lead-acid batteries require heat for curing the plastic used in the impregnation of the electrode samples, the instability of the silver oxide electrode at elevated temperature indicated that difficulty might be experienced. Both Ag<sub>2</sub>O and AgO are known to decompose when heated and to have increasing rates of decomposition with increasing temperature (6). Since AgO, the more unstable of the two oxides, decomposes more rapidly when in alkaline solution (7) difficulty in washing the electrodes free from KOH electrolyte might also cause problems. In addition to decomposition of the silver oxides which might occur when the samples are heated, there might also be reaction between the silver oxides and the plastic, before the plastic hardened, or decomposition during the time before the sample is finally polished satisfactorily for ex-

amination. While these factors had to be considered in sample preparation, the difficulty was less than anticipated.

The products resulting from anodic oxidation of Ag electrodes and the cathodic reduction of silver oxide electrodes in alkaline solutions were identified previously by subjecting the electrodes to x-ray diffraction after removal from a cell (8) and by x-ray diffraction of an electrode in a cell which permitted x-ray examination simultaneously with electrochemical oxidation and reduction (9). These studies showed that during a charge the Ag was oxidized first to Ag<sub>2</sub>O and then to AgO, and that during a discharge AgO was reduced first to Ag<sub>2</sub>O and then to Ag. There was no evidence of a silver suboxide, an oxidation state higher than AgO, a solid solution, or an alloy of oxygen and silver. These x-ray diffraction studies have eased the problem of microscopic examination since only the three phases Ag, Ag<sub>2</sub>O, and AgO were expected to be present and needed to be identified.

The present report describes changes in the structure of an unused sintered silver electrode when the electrode was charged and discharged at a relatively low rate. The changes are illustrated mainly by showing differences in the form of silver present in discharged electrodes, but changes that occurred in the appearance of oxide formations are also given. The charge and discharge processes as such are not illustrated in detail here, but are the subject of later reports.

## Experimental Procedure

The silver electrodes used for the microscopic examination were all of the same size and type. The electrodes had been manufactured commercially for silver-zinc storage batteries that were designed to discharge at comparatively low rates, requiring at least 1 hr for a complete discharge. The electrodes were constructed in the customary way that the manufacturer used for small cells, but details of the process were considered proprietary. Electrode dimensions were 41.5 mm wide by 38.0 mm high by 0.8 mm thick. The electrodes consisted of sintered Ag particles with a grid of expanded sheet Ag. The grid was much closer to one surface of an electrode than to the other surface. The theoretical capacity of an electrode, based on the amount of sintered Ag present, was 2.9 amp-hr.

A piece of plastic 53 x 52 x 3.2 mm was made into a U-shape by cutting out a section 43 x 43 mm. This plastic U was wrapped with five layers of treated cellulose separator to slow the diffusion of soluble Ag species. The top of the plastic U was open so that an electrode could be removed and reinserted without unwrapping the separator when it was desired to cut a sample from the electrode. Two other sintered Ag electrodes of the same size were wrapped with the

\* Electrochemical Society Active Member.

Key words: silver electrode, silver oxides, storage batteries, microstructure.

cellulose separator and put on each side of a removable electrode. These two electrodes were connected in parallel and served as counter electrodes. Since the counter electrodes were being reduced at the same time as a test electrode was being oxidized, and *vice versa*, little gas was produced in a cell except at the end of charge and discharge. The electrodes fit loosely in a plastic cell, together with a reference electrode of Ag/Ag<sub>2</sub>O. The work was done at approximately 25°C in an excess of 35% KOH solution.

The removable electrodes were charged and discharged individually at the constant current which required 20 hr for a complete charge or a complete discharge. Since the capacity of a previously unused electrode gradually declined, progressively lower values of charge and discharge current were used during the first few cycles. Capacity declined more slowly after about 5 cycles and became relatively constant after 8 to 10 cycles. Samples approximately 19 x 21 mm were cut from a removable electrode at various times, for microscopic examination. The remainder of the electrode was then returned to the cell and placed within the separator as before. Current was lowered by an amount sufficient to compensate for the removal of each sample, so that current density on the remainder of the electrode was unchanged.

The cells described above were used to obtain 16 samples of Ag electrodes that had been cycled a low number of times before removing a portion of the electrode. Four samples of an electrode that had been cycled over 200 times were taken from a cell in which the test electrode had been wrapped directly with cellulose separator and which had only a single counter electrode. The test electrode in this cell had been given 217 complete charges to oxygen evolution followed by complete discharges before the first sample was removed for microscopic examination during cycle 218. Over half of the charges were done at the 20-hr current with the remainder taking from 20 to 30 hr. The first 137 discharges were at the 20-hr rate, then followed 45 discharges at the 1-hr rate, and the remainder of the discharges were again done at the 20-hr rate.

Each sample was handled separately to avoid delay in microscopic examination. After a sample was cut from an electrode, the sample was immediately washed in 4 to 6 changes of distilled water to remove the KOH solution and then dried in a vacuum for 1 hr. A dry sample was placed in a 38 mm diameter by 52 mm deep cavity in an aluminum mold and held upright by surrounding the sample with Lucite pellets. While under a vacuum, the sample was impregnated with an epoxy resin.<sup>1</sup> The impregnated sample was returned to atmospheric pressure and transferred to an oven at 40°C for 8 hr to cure the plastic. Although several liquid polyesters and epoxy resins have been tried as the impregnating plastic, none were wholly satisfactory. Liquid polyesters can be obtained which have low viscosity and form a clear, hard plastic when cured, but of the polyesters tried all reacted slowly with the silver oxides before the plastic hardened. If the electrode had only a thin layer of black Ag<sub>2</sub>O on its surface, sufficient reaction took place between the Ag<sub>2</sub>O and the polyester that the electrode surface usually lightened noticeably. Epoxy resins have the disadvantages of a higher viscosity which makes complete impregnation more difficult, and of being opaque after solidifying. Epoxy resins were used for an impregnation plastic, however, because they were less reactive with Ag<sub>2</sub>O and AgO.

After the plastic had cured, a cross section of the electrode sample was prepared. The sample was ground successively on 120, 240, 400, and 600 mesh silicon carbide abrasive papers and was finally wet polished using Geoscience 9 micron boron carbide<sup>2</sup>

on a lap of Buehler Texmet.<sup>3</sup> This was followed by dry polishing on a sponge rubber lap charged with Linde 0.3 $\mu$  Alumina powder.<sup>4</sup> The sample was then examined by optical microscopy and the appearance of significant areas recorded by photography.

### Results and Discussion

No noticeable decomposition of silver or its oxides was observed when they were entirely within the embedding plastic. Where exposed at the polished surface, however, the system changed slowly as metallic Ag tarnished and AgO was reduced to Ag<sub>2</sub>O, often with simultaneous oxidation of nearby metallic Ag to Ag<sub>2</sub>O. Ag<sub>2</sub>O was the most stable form. For most purposes these slowly occurring changes offered no difficulty, because several days were required for appreciable changes and observations could easily be completed within this time. If it was necessary to re-examine a sample that had changed at the exposed surface, the original appearance could again be restored by regrinding the sample with fine mesh silicon carbide papers and repolishing. Often repolishing alone was sufficient to restore the original appearance.

The three phases Ag, Ag<sub>2</sub>O, and AgO were quite distinct from one another and easily identified by the optical microscope. When observed under bright field vertical illumination in the manner used for most metallographic specimens, metallic Ag had practically specular reflectance. The reflectivity of the two oxides was considerably less than that of the Ag, but the oxides were readily differentiated since AgO was much brighter than Ag<sub>2</sub>O. In polarized light the Ag appeared much darker but was brighter than Ag<sub>2</sub>O or AgO, while the Ag<sub>2</sub>O was the darkest constituent. Neither Ag nor Ag<sub>2</sub>O exhibited polarization colors, but under polarized light and with an interference plate the AgO showed strong color variations from one grain to another. The Ag<sub>2</sub>O crystals were much smaller than the AgO crystals.

Individual crystals could not be observed at the relatively low magnification of 250X or less, but these low magnifications were useful because they revealed changes in aggregation that took place, the appearance and disappearance of large voids in the active material, evidence of uneven reaction rates, and other features of interest. At higher magnifications the true microstructure of the electrode could be observed. Provided that magnification was sufficient, individual crystals could be detected as well as changes in crystal form during oxidation and reduction. The highest magnification used in the present work was 1600X.

The appearance of an unused sintered Ag electrode is shown at low magnification in Fig. 1. This and all subsequent photographs are of cross sections through the electrode and, therefore, also show cross sections through individual crystals or other particles of which the electrode is composed. In the unused electrode the Ag was present in the wide range of sizes from approximately 0.5 to 100 $\mu$ , which many of the particles too small to be individually visible at 100X magnification. While the proportion of large to small particles varied considerably in different areas of an electrode, the general appearance of the structure remained fairly uniform. At higher magnification it can be seen that the major portion of the Ag particles were quite small (Fig. 2). Many of the small particles appeared to form agglomerates with a very definite outline about the same size as the large Ag particles. The agglomerates were quite porous and consisted of individual particles with considerable variation in size and shape. At the highest magnification used in the present work, the individual particles of Ag in an unused electrode could be seen more clearly (Fig. 3). Many of the particles had their smallest dimension in the range 1.5–2 $\mu$ . Most of the voids in the unused

Fig. 1. Structure of a commercially prepared, sintered Ag electrode that had never been used. Electrode surfaces are at the top and bottom of the photograph. The large white area is a cross section of the grid, and the white particles are Ag active material. The dark background represents areas filled by the impregnation plastic and, therefore, areas that were void. The lines forming squares indicate  $238\mu$  separation. The original magnification before reproduction was 100X.

Fig. 2. Portion of the unused electrode of Fig. 1 at higher (400X) original magnification, showing that many Ag particles were quite small and some had clumped together into larger masses. The lines forming squares indicate  $60\mu$  separation.

electrode were quite small and well distributed among the smaller particles of Ag.

The electrode structure had changed markedly in particle size and porosity after the first charge to oxygen evolution and discharge back to metallic Ag using the 20-hr rate of current. A discharge was ended when potential fell to  $-300$  mv *vs.* the Ag/Ag<sub>2</sub>O reference electrode, a potential equivalent to an endpoint of 1.2-1.3v for a typical Ag-Zn cell. Over half of the Ag was present as larger granular particles at the end of the first discharge, although many small Ag particles were also present (Fig. 4). There was much variation in the electrode with some areas having many more small particles than other areas, so that

Fig. 3. Area of small Ag particles in the unused electrode of Fig. 1 and 2 at 1600X original magnification. The Ag particles were very irregularly shaped and had many sizes. The lines forming squares indicate  $15\mu$  separation in this and all other photographs that had an original magnification of 1600X before reproduction.

Fig. 4. Area of an electrode at the end of the first discharge. Many large Ag particles formed during the discharge at the 20-hr rate although small particles also formed. Compare with Fig. 3 at the same magnification.

no area could be specified as being truly typical of the entire electrode. Figure 4 gives an idea of the size range of the particles that formed during the first discharge. Many of the granular particles had convolutions on at least a portion of their surfaces. Although some small particles were still present, the small particles produced by electrolytic reduction did not resemble the small particles of the unused electrode (compare Fig. 3 and 4). The large particles found in the unused electrode (Fig. 1, 2) were still present, but none are included in the area shown in Fig. 4. Since a small amount of additional capacity could have been removed if the discharge had ended at a lower potential, no doubt traces of oxide still remained. Oxides could not be detected by optical microscopy after a slow discharge to the usual endpoint, however, nor by x-ray diffraction in earlier work (8,9).

During the second charge an electrode almost always accepted fewer ampere-hours before potential rose to oxygen evolution than during the initial charge of a sintered Ag electrode. Electrode capacity tended to decline for several cycles when the 20-hr discharge rate was used. In the initial cycle in 35% KOH, the capacity obtained was from 67 to 87% of the capacity theoretically possible from the sintered Ag, and was usually in the 70–80% range, averaging 75%. At the end of cycle 5 at the 20-hr rate, capacity was usually only 50–63% of the capacity theoretically possible, averaging 56%. By cycle 10 capacity of an electrode had become relatively constant somewhere in the range of 43–58% of the capacity theoretically possible, averaging 50%. Following this decrease to relatively constant values, capacity tended to increase irregularly. The increase was slow and only became evident when electrodes were cycled many times. In the period from cycle 70 to 120 the capacity had increased sufficiently that it usually averaged 55% of that theoretically possible.

During the first five cycles, while the electrode was losing capacity most rapidly, the Ag particles present at the end of the discharges noticeably changed in appearance. The greatest change occurred during the first discharge and has already been illustrated (Fig. 3 and 4). The Ag formed during the second discharge at the 20-hr rate had approximately the same range of particle sizes as the Ag formed during the first discharge, but more of the large, granular particles had clumped together (Fig. 5). The large particles residual from the unused electrode (lower left of Fig. 5) showed evidence of attack at their surfaces after two cycles. By the end of the fifth discharge most Ag active material was present as large, granular particles, and many particles had clumped together in agglomerates composed of several particles (Fig. 6). Increasingly large void spaces had formed between the agglomerates. The large particles residual from the unused electrode gradually decreased in size and number in the early cycles as a result of continued attack at their surfaces. Comparison of Fig. 1 and 6 shows that particle size became more uniform with repeated cycling at the 20-hr rate. The fine particles originally present had disappeared al-

Fig. 5. Appearance of an electrode at the end of the second discharge. Although individual Ag particles had approximately the same size range as they did after the first discharge at the 20-hr rate, more particles had clumped together during the second discharge. Lines forming the squares indicate  $30\mu$  separation. The original magnification was 800X. Compare with Fig. 4 but note difference in magnification.

Fig. 6. Cross section including the grid at the end of the fifth discharge. Most Ag was present at large particles. Electrode surfaces are at the top and bottom of the photograph. Compare with Fig. 1 at the same magnification.

though some fine particles having a different appearance could be found.

The capacity loss was the direct result of the formation of large Ag particles in place of the small particles originally present in the electrode. Microscopic examination of Ag electrodes after a rapid discharge showed that small Ag particles formed when the discharge current was high (10). This finding agreed with the results of x-ray diffraction which showed that particle size varies inversely with current density (9). Since the discharges were done at a relatively low current density in the present work, conditions within the electrode promoted the formation of large Ag particles as the silver oxides were reduced. The majority of the active material was present as AgO at the end of a charge, although particles of Ag covered with oxide remained also. During discharge the AgO was reduced to Ag<sub>2</sub>O and the Ag<sub>2</sub>O reduced to Ag. Growth of Ag particles during a slow discharge is illustrated in Fig. 7 by an electrode that had been discharged at the 20-hr rate for approximately 13 hr. At this point the electrode was composed largely of Ag and Ag<sub>2</sub>O with a small amount of AgO still present. The Ag particle at the lower left in Fig. 7 has the angular, irregular outline that was characteristic of Ag particles that remained in an electrode at the end of a charge. This particle was separated from the electrolyte by a tight coating of Ag<sub>2</sub>O. Ag particles with access to the electrolyte increased in size as Ag<sub>2</sub>O disappeared from the immediate vicinity of the particles. The Ag particle shown in cross section at the upper center of Fig. 7 had the rounded, convoluted form typical of a particle produced by slow electrolytic reduction. Note that this particle retained its original angularity at the upper left where the Ag still contacted the Ag<sub>2</sub>O. The cavity that largely surrounded this growing particle illustrates the fact that metallic Ag occupies less volume than Ag<sub>2</sub>O and indicates that the oxide went into solution before it deposited as Ag during slow electrolytic reduction. The angular form of Ag shown at the lower left in Fig. 7 had entirely disappeared by the end of a discharge.

After the first few discharges at the 20-hr rate the appearance of the large granular Ag particles that were present in discharged electrodes did not change appreciably. An electrode discharged once at the 20-hr rate contained granular particles approximately the

Fig. 7. Ag particles in an electrode discharged 65% at the 20-hr rate. Ag was the lightest shade in the photograph,  $\text{Ag}_2\text{O}$  dark gray, and the impregnation plastic was black. Small patches of  $\text{AgO}$  remaining in the  $\text{Ag}_2\text{O}$  are shown as a gray shade intermediate between Ag and  $\text{Ag}_2\text{O}$ . Compare Ag particle newly formed by electrolytic reduction (upper) with Ag particle that had not oxidized completely in the previous charge (lower left). Original magnification 1600X.

Fig. 9. Three forms of Ag present on discharged electrode after 218 cycles. Large granular particles are in the center and near the grid member at upper right. Fine dendritic particles are at the top center, while coarser dendritic particles are at the bottom. Compare with Fig. 1 and 6 at the same magnification.

Fig. 8. Large granular Ag particles present in many areas of a discharged electrode after 218 cycles. Some particles were larger than those shown here. Compare with Fig. 4 at the same magnification.

same size as the large particles in an electrode cycled over 200 times (Fig. 8). This electrode had been discharged at the 20-hr rate for 172 times, including the previous 35 discharges, and contained Ag in three forms (Fig. 9). The large granular particles shown in Fig. 8 were joined in a network similar to what a dendritic growth would form, but it was also possible that the network resulted from individual crystals contacting one another while growing. Since the actual surfaces of the large particles contained many small, faceted crystals, it was also possible that much smaller crystals had aggregated to form these granular structures, but cross sections of the granular crystals did not indicate that the large particles were composed of many small crystals.

Fig. 10. Fine dendritic crystals of Ag present in many areas of the discharged electrode of Fig. 9. Original magnification 1600X.

In addition to large particles such as those shown at high magnification in Fig. 8, many areas contained small dendritic crystals that were closely packed (Fig. 9 and 10). Less common were the coarse dendritic crystals of Ag which were found in some areas of this electrode (Fig. 11). The coarse dendritic crystals had a definite tendency to assume rectilinear forms. In the discharged electrode that had been cycled 218 times, approximately one-sixth of the area consisted of these coarse dendritic Ag crystals and the remainder of the area was equally divided between the fine dendritic crystals and the large granular particles. Although this electrode previously had been discharged 45 times at the 1-hr rate and fine Ag particles had formed under these conditions, it was highly unlikely that any of these fine particles were still present after 35 consecutive discharges at the 20-hr rate, since many large Ag particles form after only a single slow discharge. Furthermore, small dendrites such as are shown in Fig. 10 were not found

Fig. 11. Coarse dendritic crystals of Ag present in some areas of the discharged electrode of Fig. 9. Angles of approximately 90 degrees were often present. Compare with Fig. 8 and 10 at the same magnification.

in a sample of the same electrode removed at the end of the previous charge. Remnants of both types of large particle were present at the end of the previous charge, with most remnants coming from the granular type illustrated in Fig. 8 and remnants from the coarse dendritic type illustrated in Fig. 11 being much less common. It was concluded that the small crystals of the type shown in Fig. 10 were newly nucleated during the discharge and originated in areas in which few if any Ag particles had remained at the end of the previous charge.

Few of the very small dendritic particles were coexistent with the larger particles in the discharged electrode. Discharged electrodes that had been cycled only a few times contained small dendritic particles, but not in large amounts. For example, after the fifth discharge at the 20-hr rate about 5% of the electrode area contained small particles that had dendritic characteristics (Fig. 6). These small Ag particles had a configuration more like those shown in Fig. 11 than those in Fig. 10 and were intermediate in size between the two types illustrated. These small particles were found at both the center and surface of an electrode.

The voids in the electrode had become significantly larger with repeated cycling. The change in void or pore size can be seen by comparing the compacted structure of the unused electrode (Fig. 1) to the structure with large voids obtained after five cycles (Fig. 6) and to the structure with larger voids obtained in over 200 cycles (Fig. 9). The electrode shown in Fig. 9 had increased in thickness by approximately 20% during the many cycles it had undergone in a loosely fitting cell case. The consequent increase in pore size may have been a factor in a greater proportion of Ag forming as small particles in this electrode than the proportion found in electrodes cycled a relatively low number of times. The large particles shown in Fig. 8 and 9 were not clumped together to the extent that particles had clumped in an electrode after five slow discharges (Fig. 6). An electrode with fewer large Ag particles, such as is shown in Fig. 9, should charge to a greater extent than an electrode composed mostly of large particles. This was probably the reason that capacity of electrodes cycled many times increased slowly after reaching a minimum value.

An electrode that was not completely discharged but in which a substantial amount of oxide remained would not have formed as many large Ag particles

during a discharge as an electrode discharged to 100% of available capacity. A partially discharged electrode, such as the one shown in Fig. 7, should oxidize more readily than electrodes with many large Ag particles, such as Fig. 4, 5, and 8. Fewer large particles being present is very likely to be the main reason for the well-known fact that silver batteries cycled at 50–75% depth of discharge have a better life than the same batteries cycled at 100% depth of discharge, the depth used in the present work.

Figures 1, 6, and 9 all include portions of the grid of expanded Ag sheet metal. The relative size of the grid section shown was not significant, since the apparent size depended both on the angle of sectioning and the location in the Ag sheet where the cut was made. Most of the grid sections were the length shown in Fig. 6, but many were twice this length as in Fig. 1 and 9. The smooth and regular outline of the grid section in the unused electrode (Fig. 1) had disappeared by the time that the electrode had been cycled five times. Grid corrosion as the result of penetrating attack during the first five cycles was evident from the roughened, irregular grid outline shown in Fig. 6. After an electrode had been cycled over 200 times the grid outline had become very irregular and the original cross section of the grid had been greatly reduced (Fig. 9). Although much grid corrosion had occurred, there was no evidence that the usefulness of the electrode had been particularly impaired by this corrosion.

Since electrodes examined in various states of charge and discharge did not indicate that reactions take place preferentially at the grids, at least at the low rates of charge and discharge used in the present work, many areas of the electrode must have been in good electrical contact with the grid even though in the photographs they do not appear to be in contact. Particles that appeared to be isolated reacted to the same extent as areas where the active material particles obviously touched each other. The connections for the particles must have been above or below the plane of the cross sections. Although only one side of the silver electrode faced the counter electrode in the cell that contained a single counter electrode instead of two, reactions were not limited to that one side nor was reaction on that side favored particularly when the electrode was charged or discharged. The similarity between the two surfaces of the silver electrode in this cell probably resulted from the high porosity of the electrode and from the relatively low current densities. Under the conditions used, adjacent areas of an electrode had more differences than there were between the two surfaces.

The size and distribution of the Ag particles present in an electrode at the beginning of a charge had a strong effect on oxide formation. X-ray diffraction studies (8, 9) have shown that, during a constant current charge in alkaline solution, the Ag is oxidized first to  $\text{Ag}_2\text{O}$  at a potential plateau that remains relatively constant at a value a little above the  $\text{Ag}/\text{Ag}_2\text{O}$  equilibrium. After most or all of the Ag has a coating of  $\text{Ag}_2\text{O}$ , potential rises sharply until it exceeds the  $\text{Ag}_2\text{O}/\text{AgO}$  equilibrium value. At the higher potential AgO begins to form and then potential decreases slightly from a maximum or peak to a second plateau. Much of the remaining Ag oxidizes to  $\text{Ag}_2\text{O}$  and then to AgO at this second potential plateau. Finally the potential rises to a third plateau and the main reaction becomes oxygen evolution. Figure 12 gives the appearance of a previously unused sintered Ag electrode after charging to the potential peak that begins the second potential plateau. Electrodes charged to this point contained only Ag and  $\text{Ag}_2\text{O}$ . Almost all of the Ag had been covered by  $\text{Ag}_2\text{O}$  crystals. Some Ag particles larger than those shown in Fig. 12 were also present (Fig. 1, 2). The large Ag particles tended to have thinner layers of  $\text{Ag}_2\text{O}$  on their surfaces than the small particles, but the unused electrode was largely composed of small particles. Samples removed

Fig. 12.  $\text{Ag}_2\text{O}$  that has formed on Ag during the first charge of a previously unused sintered Ag electrode. Electrode was charged to the potential peak that begins  $\text{Ag}_2\text{O}/\text{AgO}$  potential plateau. Ag was lightest shade in photograph,  $\text{Ag}_2\text{O}$  dark gray, and impregnation plastic appears as black. Compare with Fig. 3. Original magnification 1600X.

from electrodes charged part way to the potential peak indicated that small Ag particles were oxidized preferentially.

After an electrode had been charged and discharged several times at the 20-hr rate the Ag particles were present as large, granular particles and many had clumped together in agglomerates (Fig. 5 and 6). An electrode that had been cycled five times and had reached this condition is shown in Fig. 13 after being charged to the potential peak that precedes the second potential plateau. Much less  $\text{Ag}_2\text{O}$  was present on this electrode than was on the electrode shown in Fig. 12. The capacity which an electrode accepted before charge potential reached the peak that began the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau decreased markedly during the first few cycles at the 20-rate. On the sixth charge this capacity was only one-third as large as on the first

Fig. 13.  $\text{Ag}_2\text{O}$  that formed on Ag during sixth charge when electrode was charged to the potential peak that begins  $\text{Ag}_2\text{O}/\text{AgO}$  potential plateau. Compare with Fig. 12 at the same magnification.

charge. The progressive decrease in the charge capacity accepted before reaching the potential peak was the result of the increase in size of the Ag particles that formed during the slow discharges. Figure 13 shows that the small particles had oxidized to a greater extent than the large particles. Although the large particles had convoluted surfaces which gave relatively large surface areas, only a small proportion of a large particle oxidized at the  $\text{Ag}/\text{Ag}_2\text{O}$  potential plateau despite the penetrating attack that had occurred on the surface of these particles. The large particles such as those shown in Fig. 13 did not oxidize extensively until charge potential rose to the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau.

The appearance of an electrode after it was charged to oxygen evolution depended greatly on the size of Ag particles present before the charge began. At the end of the initial charge of a previously unused sintered silver electrode, most of the smaller Ag particles had disappeared while the larger particles had not been oxidized completely. Figure 14 illustrates, as well as one photograph can, the general appearance of an electrode at the end of the first charge. The size and distribution of the Ag particles varied from area to area. All of the remaining Ag particles were surrounded by a thin layer of  $\text{Ag}_2\text{O}$  with no clearly defined crystal structure. This  $\text{Ag}_2\text{O}$  was in turn surrounded by a more or less complete layer composed of relatively large AgO crystals which tended to have angular forms. Under polarized light it could be seen that what appears to be large AgO crystals in Fig. 14 actually consisted of several smaller crystals. Comparison of Fig. 14 to Fig. 3 and 12 shows that the AgO crystals tended to fill the voids originally present in the electrode. Complete oxidation of all Ag particles probably did not occur because AgO crystals blocked internal channels and formed tight coatings on the Ag, thus limiting access of the KOH solution to the Ag. No areas were found where  $\text{Ag}_2\text{O}$  and Ag alone were present at the end of a charge at the 20-hr rate.

A single discharge at the 20-hr rate resulted in sufficient change in Ag particle size that the appearance of the charged electrode at the second cycle had changed markedly. Many more large Ag particles remained at the end of the second charge than had

Fig. 14. Oxides present after oxygen evolution began at end of first charge of a sintered Ag electrode. At left are two Ag particles (lightest shade) that had not oxidized completely. Most of the electrode consisted of AgO crystals (medium gray). A thin layer of  $\text{Ag}_2\text{O}$  (dark gray) separated Ag from AgO. Impregnation plastic appears as black. Original magnification 1600X.

remained at the end of the first charge, and no large areas were found that consisted of AgO without Ag such as the area shown on the right half of Fig. 14. As the large clumps of AgO were reduced to Ag<sub>2</sub>O and then to Ag during discharge, Ag particles tended to form in groups with the result that large voids occurred adjacent to the particles. Changes continued to take place during the next few cycles at the 20-hr rate as the Ag particles clumped together into agglomerates. A typical view of the changes that have occurred after several cycles is shown in Fig. 15 for the sixth charge. The charged electrode had changed from a closely joined mass of AgO crystals with numerous small voids in the AgO (Fig. 14) to a structure of large voids and clumps of Ag surrounded by AgO, with very little porosity in the AgO (Fig. 15). Many of the Ag particles which remained at the end of the sixth charge were still joined where they had grown together during earlier discharges. Small particles also remained, but were less common. Every area of AgO crystals had formed as a dense but not very thick layer around the Ag. As always, a thin layer of Ag<sub>2</sub>O separated the Ag from the AgO. Oxides had formed on the surface of small voids within the large Ag particles. Presumably the small voids within the Ag had been formed when adjacent Ag particles grew together. On the first charge the growth of AgO had been much more extensive than the growth shown in Fig. 15 and gave the appearance of having attacked the Ag to a greater depth. More AgO formed on the first charge because a large portion of the Ag particles in the unused electrode was small. When Ag particles had grown larger after slow discharges, less oxidation was required to cover the large particles with an AgO layer that limited access of electrolyte to the Ag.

Additional cycles at the 20-hr rate gave comparatively little further change. The main difference between the electrode that had been cycled over 200 times and an electrode cycled five or six times was in the large voids that had formed with the additional cycling (Fig. 16) although there was also more variation in Ag particles from one area to another. Most areas resembled Fig. 15 or the left half of Fig. 14, depending on whether the area had been one of small or large Ag before the charge.

Only one type of silver electrode was used in the present investigation, since the purpose did not in-

Fig. 15. Electrode appearance after oxygen evolution began at end of sixth charge. The large Ag particles that had formed during slow discharges did not oxidize as extensively as the small Ag particles originally present. Compare with Fig. 14 at the same magnification.

clude studying effects of different initial electrode structures. The changes that occurred in the first few charge-discharge cycles suggested that small changes in the average size of the particles used in manufacturing Ag electrodes for secondary cells would only have an effect on capacity of the initial few cycles when the 20-hr rate was used for discharges, because of the tendency to form a limited size range of Ag particles as AgO was reduced during discharge. A large increase in starting particle size should be avoided because capacity would be decreased significantly as a result of the smaller surface area available for oxidation during charge.

### Summary

In an unused sintered Ag electrode particle sizes ranged from approximately 0.5–100 $\mu$ , with most particles having their smallest dimension in the range 1.5–2 $\mu$ . After the first charge to oxygen evolution and discharge back to Ag using the 20-hr current most Ag was present as large granular particles in the size range 10–25 $\mu$  although smaller and larger particles were also present. Electrode capacity decreased during the first five cycles as large granular particles of Ag formed and clumped together.

Capacity loss was the direct result of large Ag particles forming during slow discharges in place of the small particles originally present. After about five discharges at the 20-hr rate particle appearance did not change appreciably, and capacity gradually stopped decreasing. The large particles residual from the unused electrode gradually decreased in size and number because of continued attack at their surfaces. An electrode cycled over 200 times had many granular particles approximately the same size as those formed during the first discharge, although small dendritic Ag crystals were also common.

Most voids in the unused electrode were quite small and well distributed, but the voids became significantly larger with repeated cycling, and the electrode increased in thickness. The original cross section of the Ag grid greatly decreased as the result of penetrating attack in an electrode cycled over 200 times, but conductivity was still good.

Small Ag particles were oxidized more readily and more extensively than large particles. At the end of the first charge to oxygen evolution, most of the smaller Ag particles originally present had oxidized completely to AgO. A single discharge at the 20-hr rate resulted in sufficient particle size change that many more

large particles remained at the end of the second charge than at the end of the first. During the fifth charge an electrode accepted only three-fourths as much capacity as during the first charge, and only one-third as much Ag<sub>2</sub>O formed before potential rose and AgO began to form. The Ag particles that remained at the end of a charge were always surrounded by a thin layer of Ag<sub>2</sub>O with no clearly defined crystal structure. This Ag<sub>2</sub>O was surrounded by a layer of relatively large AgO crystals.

Manuscript submitted June 7, 1968; revised manuscript received July 20, 1968. This paper was presented at the Montreal Meeting, Oct. 6-11, 1968, as Paper 372.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## The Formation and Characterization of the Tetrahydroxyargentate (III) Ion in Alkaline Solution

G. L. Cohen\*<sup>1</sup> and G. Atkinson

U. S. Naval Ordnance Laboratory, White Oak, Maryland, and  
Department of Chemistry, University of Maryland, College Park, Maryland, respectively

## ABSTRACT

When smooth silver metal is anodically oxidized in 12M KOH solution at 70 ma/cm<sup>2</sup>, a solution containing silver all in the +3 oxidation state results. The Ag (III) species was shown to be Ag(OH)<sub>4</sub><sup>-</sup> by a polarographic method involving the variation of half-wave potential with ligand concentration.

Except for complexes with periodate (1) or tellurate (2), the literature contains no direct evidence for the presence in alkaline solution of a species of silver with an oxidation state higher than one. Dirkse (3) postulated the presence of a species of silver (II) in basic solutions resulting from AgO dissolution. However, by measurement of the magnetic properties of such solutions, McMillan (4) showed that no silver (II) species was present. He postulated the existence of the species Ag(OH)<sub>4</sub><sup>-</sup>, but offered no direct proof for the existence of this ion. Yost (5) showed kinetic evidence for a transient Ag (III) species, formed during Ag (I) catalyzed persulfate oxidation of Cr (III) (5), ammonia (6), and VO<sup>++</sup> (7), and Carman (8) came to the same conclusion when he studied the auto-oxidation of (NH<sub>4</sub>)<sub>2</sub>S<sub>2</sub>O<sub>8</sub> in the presence of Ag (I). Other workers (9-11) have interpreted similar results in terms of Ag (II) and sulfate radical ion (SO<sub>4</sub><sup>-</sup>) intermediates, rather than a silver (III) species.

A series of papers by Noyes and co-workers (12-16) published between 1935 and 1937 described a detailed study of the chemistry of higher oxidation states of silver in acid solution. In the first of these (12), they showed that ozone oxidizes AgNO<sub>3</sub> in nitric acid solution to AgO<sup>+</sup>, which reacts with Ag<sup>+</sup> according to the following mechanism

They further showed (13) that the silver in the salt produced in the above reaction is almost all in the plus two oxidation state when the concentration of nitric acid is between 1 and 4M. This was demonstrated by titration with TiNO<sub>3</sub> which is oxidized by silver (II) but not by concentrated nitric acid. Dundon

and Gryder (17) studied the kinetics of this silver (II)-thallium (I) reaction. They reported that the oxidation to thallium (III) could occur by means of a mechanism involving silver (III) and equilibrium reaction [2], with direct oxidation of thallium (I) to thallium (III). They prefer, however, a mechanism involving two one-electron steps with thallium (II) and the NO<sub>3</sub><sup>-</sup> free radical as intermediates.

When AgO, which is a mixed oxide containing equimolar amounts of Ag (I) and Ag (III) (18), is dissolved in acid solution, the silver is found to be all in the plus two oxidation state (19). AgO is only slightly soluble in alkaline solution (20), but reacts, in the presence of a coordinating ligand such as periodate (21), to form a silver (III) complex stable in alkaline solution. This difference in behavior in acid and in alkali media is in agreement with Eq. [2], which shows that Ag (II) which is present in acid, disproportionates to Ag (I) and Ag (III) in alkaline solution.

This present research was initiated as part of an investigation of the chemistry and electrochemistry of higher oxidation states of silver in alkaline solution, especially in relation to the behavior of silver oxide as an alkaline battery cathode material. Casey and Moroz (22) reported the electrochemical formation of Ag<sub>2</sub>O<sub>3</sub> when sheet silver metal is electrically oxidized at 15 ma/cm<sup>2</sup> at -40°C in eutectic KOH-H<sub>2</sub>O. At higher temperature, or at lower current density, they found only AgO. Kazakevich, Yablokova, and Bagot'skii (23) demonstrated that Ag<sub>2</sub>O<sub>3</sub> was formed during asymmetric anodization of silver metal at relatively high current density. However, neither paper discusses the possibility of formation of a soluble silver (III) species. On the basis of preliminary results, Hills (24) suggested that a colored solution containing a species of silver in an oxidation state higher than plus one could be formed in concentrated potassium hydroxide solution by electrical oxidation of silver metal at high current density. He did not define the conditions for formation of this species nor did he know the oxi-

dation state of silver which was present. The object of the research described herein was to prepare such a soluble species, ascertain the oxidation state of the silver contained in it, and determine the stoichiometry of the species.

### Experimental

**Chemicals.**—Potassium hydroxide solutions were prepared, except where otherwise indicated, from Baker Analyzed 45% potassium hydroxide solution which was analyzed by acidimetric titration and found to be 12.00M. The silver foil used was Handy and Harman sheet fine silver (1 mil thick), and the silver powder was Handy and Harman Silpowder 120. Potassium metal, 99.99% pure, was supplied by the United Mineral and Chemical Corporation. The metal was sealed under argon in specially made double-tipped glass ampoules containing 20g of potassium. All other chemicals used were Baker Analyzed reagents.

Water used in these experiments was redistilled from alkaline permanganate solution.

Potassium bis(periodato) argentate (III)  $[K_3H_4Ag(IO_6)_2 \cdot 3H_2O]$  was prepared as described by Cohen and Atkinson (21).

The saturated  $KIO_4$  solution used for colorimetric determinations was analyzed by iodimetric titration and found to be  $3 \times 10^{-2}M$ . (This solution is designated solution B.)

**Equipment used.**—The d-c power supply used for preparation of silver (III) solutions, was model 865B of Harrison Laboratories, Incorporated, and has a range from 0 to 0.6 amp and from 0 to 40v.

Polarographic measurements were made on a Metrohm Polarecord Model E261 with a rotating platinum microelectrode and a saturated calomel reference electrode. The glove box used was manufactured by the Kewaunee Scientific Equipment Corporation, and was modified so that electrical connections for polarography and electrolysis could be made from the interior without openings in the box.

Temperature for the polarographic runs was controlled by use of a Bronwill constant temperature circulator.

Spectra were measured on a Perkin-Elmer Model 202 uv-visible dual beam recording spectrophotometer. Absorptivity measurements for the colorimetric determinations of silver (III) were made on a Beckman Model DU spectrophotometer with photomultiplier and DU power supply attachments.

**Preparation of tetrahydroxyargentate (III) solutions.**—The silver (III) species was prepared by anodizing a silver electrode at a current density of 70 ma/cm<sup>2</sup> of smooth silver surface (apparent area) against a platinum strip in 45% KOH solution. A cell, such as is illustrated in Fig. 1, was used in order to separate the anode and cathode compartments.

The electrolysis was carried out until the solution in the compartment containing the silver anode had become yellow and contained a black suspension. In no case did the yellow color migrate through the U-tube into the compartment containing the platinum cathode. On completion of electrolysis, the solution in the anode compartment was filtered through a fine porosity fritted glass filter, yielding a clear yellow solution (solution A) and a black residue.

**Preparation of solutions for spectral measurements.**—Solutions for measurement of spectra of bis(periodato)argentate (III) were prepared as follows: 0.0120g of  $K_3H_4Ag(IO_6)_2 \cdot 3H_2O$  was added to a 25 ml volumetric flask. The solution was brought to volume with water and a 5 ml portion was rediluted to 50 ml with water, yielding a solution  $6.58 \times 10^{-5}M$  (solution 1). For measurement of spectrum of bis(periodato) argentate (III) formed from solution A, the following method was used. To 20 ml of solution B was added 5 ml of solution A, and the mixture diluted to 25 ml with water. A 5 ml aliquot was diluted to 50 ml with water (solution 2).

Fig. 1. Cell for silver (III) formation

Solutions for the measurement of spectra of diluted samples of solution A were prepared as shown in Table I. The required amount of 45% KOH solution was added to each volumetric flask, and the flask was filled to within 2 ml of volume with water. A 1 ml portion of solution A was added to each flask just before measurement of the spectrum, and the solution was brought to volume with water. A blank, consisting of a KOH solution of the same concentration as the solution whose spectrum was being studied was prepared in advance and used as a reference in the determination of the spectra of the silver (III) solutions. The exact concentration of silver (III) in solution A used for these spectral measurements was determined by a colorimetric method described below prior to each spectral measurement.

**Preparation of solutions for test of Beer's law for bis(periodato)argentate (III).**—To 15 ml of solution B in a 25 ml volumetric flask was added 0.0195g of  $K_3H_4Ag(IO_6)_2 \cdot 3H_2O$ . To this solution was added 5 ml of 45% KOH solution, and the solution brought to volume with solution B (solution 3). Into a 25 ml volumetric flask was placed 5 ml of 45% KOH solution, and the solution brought to volume with solution B (solution 4). Solutions 3 and 4 were mixed in 50 ml volumetric flasks as shown in Table II and the solutions brought to volume with water. The absorbance of each of the ten solutions was measured at 362 m $\mu$  using water as a reference. From these solutions, the absorptivity of the complex silver (III) salt was found to be constant over the range studied. Solutions prepared in the same manner as solution 2 were used to routinely determine the concentration of silver (III) in preparation of solution A.

**Gravimetric silver chloride analysis.**—Concentrated nitric acid was added dropwise to 150 ml of solution A contained in a 600 ml beaker in an ice bath until

the solution was clear and colorless. To this solution was added about 0.1 ml of concentrated HCl solution. The resultant AgCl precipitate was digested on a steam bath for 3 hr, and recovered by decanting most of the liquid and filtering the remainder of the hot solution through a fine porosity, fritted glass filter crucible. The hot filtrate and decantate, were combined and diluted with about 100 ml of water, whereupon further AgCl precipitated. This was digested for 3 hr on a steam bath and recovered in the same filter crucible used for the first AgCl precipitate. Further dilution yielded no additional AgCl. The precipitate was washed with  $10^{-3}M$  HCl and dried to constant weight. The validity of the method was demonstrated by dissolving silver nitrate in water and mixing the solution with 150 ml of 45% KOH solution so that the amount of silver in the solution was about the same as the amount of silver (III) in solution A. This suspension of silver (I) oxide in 45% KOH solution was treated in the manner described for solution A, and the gravimetric determination showed that all of the silver put in the solution was recovered as silver chloride.

**Redox method using silver metal.**—To 100 ml of solution A in a 250 ml beaker was added about 0.1g of silver metal powder weighed exactly. The mixture was set in the dark for 18 hr, after which time 1 drop of Sterox surfactant solution was added in order to facilitate washing of the silver metal powder from the beaker. The solution was filtered through a tared, fine porosity, fritted glass filter crucible and washed with about 50 ml of 1:20 ammonia solution. The solid silver metal remaining behind was dried to constant weight, and the amount of silver metal that had reacted with solution A was determined by difference.

**Polarographic analysis.**—A solution 1.0M in KOH was prepared by dilution of 20.82 ml of 45% KOH solution to 250 ml with freshly boiled distilled water. This solution was electrolytically oxygenated using two platinum electrodes with the cell shown in Fig. 1. Electrolysis at 0.5 amp was carried out for about 1.5 hr, and the solution in the anode compartment (solution 5) was used for polarography. To a 100 ml portion of solution 5 was added about 1g of  $Ag_2O$ , and the mixture was stirred for 3 hr, after which it was filtered through a fine porosity fritted glass filter, yielding a clear solution (solution 6). By diluting 20.9 ml of solution A to 250 ml with water, a silver (III) solution with the same concentration of KOH as solutions 5 and 6 was prepared (solution 7). Polarograms were recorded for solutions 5, 6, and 7 in the potential span between +0.5 and -0.5v vs. a saturated calomel electrode (SCE) using a rotating platinum microelectrode. The SCE was prepared using redistilled mercury and was separated from the solution by an agar gel- $KNO_3$  salt bridge.

**Concentration of silver (III).**—Solutions of KOH concentration 1.2, 3.0, and 6.0M were prepared by dilution of 45% KOH solution with freshly boiled distilled water. Silver metal was anodically oxidized in these solutions using the cell shown in Fig. 1. After

electrolysis for 1.5 hr at 71 ma/cm<sup>2</sup>, the solution in the anode compartment was filtered. The filtered solution was analyzed for silver (III) using a modified version of the colorimetric method, so that the concentration of KOH,  $KIO_4$ , and silver (III) in the solutions used for absorbance measurements was within the limits of Beer's law applicability.

**Identification of silver (III) species by polarography.**—Solution A was prepared in the glove box under  $CO_2$  free argon atmosphere using the cell shown in Fig. 1. A solution of 2.4M  $KNO_3$  was prepared by dissolving 121.3g of  $KNO_3$  in 500 ml of water. Solutions for polarographic runs at two different constant ionic strengths of 1.2 and 2.4M were prepared using 12.00M KOH solution, 2.4M  $KNO_3$  solution, and solution A, and polarograms were run at 27.2°C in the glove box on each solution immediately after its preparation. The rotating platinum microelectrode used was cleaned in concentrated nitric acid after each polarogram was recorded. The concentration of silver (III) in the solutions was determined by use of the colorimetric method on solution A.

**Preparation of carbonate free potassium hydroxide solution.**—Carbonate-free potassium hydroxide solutions were prepared in the glove box under an atmosphere of argon fed into the box through a cylinder containing Fisher "Indicarb"  $CO_2$  absorbant material. Argon was passed through the box constantly during all work in which it was used, and a positive pressure of argon was maintained in the box at all times.

Water for use in preparation of carbonate-free potassium hydroxide solution was prepared by boiling doubly distilled water under vacuum for 5 min, sealing the boiling container while still hot, and placing the container in the glove box. An ampoule containing 20g of potassium metal, a small heater made especially for the potassium ampoule, a 50 ml graduated cylinder, a propipette bulb, a fine porosity fritted glass filter crucible, a filter flask, the cell shown in Fig. 1 including a 15 ml beaker, and the apparatus shown in Fig. 2 along with a sufficient number of beakers, spatulas, and clamps were placed in the glove box, and the box was flushed with argon for 14 hr. After this time, the tips were broken off of the double tipped ampoule containing potassium, the ampoule was placed in the heater, and the potassium melted and collected in a beaker. Into the cell shown in Fig. 2 was placed 36 ml of water, and ice-cold water was circulated through the glass jacket for about 3 hr. The silver funnel tube was placed in the polyethylene cup, and small pieces of potassium metal were dropped into the water using a stainless steel spatula. The silver tube protected the polyethylene cup from the potassium metal, and the funnel prevented solution from splattering due to the violent reaction between water and potassium. After about 6 hr, the 20g of potassium had been added to the solution, yielding a solution which

Fig. 2. Cup for preparation of carbonate-free KOH solution

was found, by acidimetric analysis, to be 11.7M KOH. About 35 ml of solution were produced (solution C).

The cell shown in Fig. 1 was filled with solution C, and electrolysis with silver metal was performed at about 0.5 amp for 45 min. The solution was filtered, and the concentration of silver (III) in the solution was determined colorimetrically. To a second preparation of solution C was added 0.02g of  $K_2CO_3$ , and electrolysis was performed as before. Electrolysis was also performed in the same manner using Baker Analyzed 45% KOH solution.

**Polarographic study of effect of carbonate on silver (III).**—The concentration of carbonate in Baker Analyzed 45% potassium hydroxide solution was estimated by adding known amounts of  $K_2CO_3$  to a series of 45% KOH solutions and measuring the absorptivity at 226  $m\mu$ , where  $CO_3^{2-}$  has a sharp absorbance peak, using freshly boiled water as a reference. A Perkin-Elmer Model 202 dual beam recording spectrophotometer with range-extending filters in the reference beam was used for these experiments.

Solutions of  $KNO_3$  and  $K_2CO_3$ , such that the total ionic strength was 1.0M, with the  $K_2CO_3$  concentration varying from 0.28M to 0, were prepared in the glove box. A series of solutions for polarographic study were prepared by mixing 5 ml of each of the above  $K_2CO_3$ - $KNO_3$  solutions with 5 ml of freshly prepared solution A in a 10 ml volumetric flask and diluting to volume with water, so that the final concentrations were as shown in Table III. Polarograms were run on each solution in the glove box at a constant temperature of 27.2°C in the potential span from +0.75 to -0.25v vs. SCE.

### Results

**Presence of silver (III).**—Solution A was a clear yellow solution, and, immediately after preparation, contained no colloidal matter, as evidenced by the lack of Tyndall light scattering in the solution. When some solution A was added to a saturated solution of potassium periodate, a deeper yellow colored solution resulted. This solution exhibited absorption maxima at 362 and 255  $m\mu$ , which corresponded with the spectrum previously reported by Cohen and Atkinson (21) and by Papalardo and Losi (25) for solutions of bis(periodato)argentate (III) salts. The maximum at 215  $m\mu$  previously reported for these salts may have been obscured by the presence of a strong absorption due to excess periodate at 221  $m\mu$  (26). Figure 3 shows a comparison of the spectrum of a solution of a bis(periodato)argentate (III) salt with a spectrum resulting from the reaction of solution A with periodate. This spectral comparison shows that a silver complex was formed when solution A was treated with a solution containing a ligand which stabilizes silver (III). This implied that silver (III) was present in solution A. By use of a colorimetric method, a wet chemical redox method, and polarographic method, all of the silver in solution A was shown to be in the plus three oxidation state.

**Demonstration of silver (III) as the only oxidation state of silver present.**—**Colorimetric method.**—Potassium bis(periodato)argentate (III) was prepared

Table III. Solutions for polarographic study of effect of carbonate on silver (III)

[KOH] = 6M in each solution [Silver (III)] = $1.06 \times 10^{-3}M$ in each solution Total ionic strength of each solution = 6.5M	
[ $K_2CO_3$ ] M	[ $KNO_3$ ] M
$3.1 \times 10^{-3}$	0.05
$4.7 \times 10^{-3}$	0.49
$19.8 \times 10^{-3}$	0.44
$86.4 \times 10^{-3}$	0.24
$169.7 \times 10^{-3}$	0

Fig. 3. Spectra of bis(periodato)argentate formed in two ways

by reaction of AgO with  $KIO_4$  in alkaline solution (21). This salt was found to obey Beer's law at 362  $m\mu$ , with a molar absorptivity of  $1.52 \pm 0.03 \times 10^4$  l mole<sup>-1</sup> cm<sup>-1</sup> when the total concentration of periodate was about  $2 \times 10^{-3}M$ , the concentration of hydroxide was about 0.25M, and the concentration of the silver salt was between  $10^{-5}M$  and  $10^{-4}M$ . All colorimetric measurements were made using solutions of the above concentrations. Thus, when some solution A was quantitatively diluted with periodate solution so that the final solution concentrations were as above, the concentrations of silver in solution A which reacted to form the complex could be determined. The total concentration of silver in solution A could be determined gravimetrically as chloride. For two typical preparations of solution A, the concentrations of silver found by each method were as follows:

	Gravimetric chloride M	Colorimetry M
Preparation 1	$3.16 \times 10^{-3}$	$3.21 \times 10^{-3}$
Preparation 2	$3.31 \times 10^{-3}$	$3.38 \times 10^{-3}$

The agreement between the methods of analysis showed that all of the silver in solution A reacted with the periodate to form the silver (III) complex compound.

**Redox method.**—The silver (III) present in AgO oxidizes silver metal to silver (I) oxide (27). Therefore, a silver (III) species present in solution might oxidize silver metal to silver (I) according to the general reaction

Assuming the stoichiometry of reaction [3], the amount of silver (III) present in solution A could be determined as previously described. The total concentration of silver was again determined by gravimetric analysis as chloride. The concentrations of silver found for two typical preparations of solution A were as follows:

	Gravimetric chloride M	Reaction with silver metal M
Preparation 3	$0.98 \times 10^{-3}$	$1.00 \times 10^{-3}$
Preparation 4	$1.02 \times 10^{-3}$	$1.04 \times 10^{-3}$

This agreement between these two analyses showed that all of the silver in solution A was in the form of silver (III).

The agreement of the gravimetric analysis with both the redox analysis and the colorimetric determination shows that the colorimetric method can be used to determine the amount of silver (III) present in solution A. This colorimetric method was used routinely for the determination of silver (III) concentration in subsequent work.

**Polarographic method.**—During the preparation of solution A, oxygen was evolved at the anode, and so the solution contained some dissolved oxygen. Silver (III) oxidizes  $NH_4OH$  to  $N_2$  and  $NO_3^-$  (28), and, there-

Fig. 4. Polarographic curves in 1M KOH solution

fore, might possibly oxidize  $N_2$  to  $NO_3^-$ . Thus, the following experiments were performed without passing  $N_2$  through the solutions to remove dissolved oxygen. In order to test whether the oxygen would affect the polarographic results, oxygen was dissolved in a potassium hydroxide solution by electrolysis using cell A with two platinum electrodes. Polarograms were run on solutions diluted with water so that the concentration of KOH was a constant 1.0M. Figure 4 shows a typical series of results. Curve c is a polarogram run on oxygenated KOH solution, and illustrates that the oxygen reduction wave will not interfere with the results. Curve b is a polarogram run on 1.0M KOH solution containing oxygen and silver (I), prepared by dissolving silver (I) oxide in it. There is one wave preceding the oxygen wave at about  $-0.1$  vs. SCE, which is close to the value reported by Amlie and Ruetschi (20) for the silver (I) half-wave potential. Curve a is a polarogram run on a diluted portion of solution A. Two waves are seen in this curve. The second is close to the potential of the silver (I) wave in curve b. The first wave, occurring at a more positive potential, is twice the height of the second. Thus, if the solution initially contained only one species which is polarographically reduced in the range of potential scanned, and the second wave is due to the one electron reduction of silver (I) to silver (0), then the first wave corresponds to a two-electron reduction process. This can be ascribed to the reduction of silver (III) to silver (I). These results support the chemical and colorimetric results showing that all of the silver in solution A is in the plus three oxidation state. The concentration of silver in the solution used for curve a was determined by the colorimetric method to be  $1.86 \times 10^{-4}M$ .

The wide potential span of the silver (III) reduction wave (from about  $+0.46v$  to about  $0.15v$  vs. SCE) indicates that the reduction of silver (III) to silver (I) at the rotating platinum electrode is irreversible.

**Spectra.**—Solution A is a clear yellow solution and exhibits one absorption maximum in the ultraviolet region of the spectrum shown in Fig. 5. For the range

Fig. 5. Spectrum of silver (III) solution

of hydroxide and silver (III) concentrations studied, the wavelength of maximum absorption remains constant at  $271 m\mu$ , with a molar absorptivity of  $1.17 \pm 0.08 \times 10^4 l \text{ mole}^{-1} \text{ cm}^{-1}$ .

**Effect of carbonate on silver (III) species.**—An extrapolation of a plot of concentration of carbonate added to Baker Analyzed 45% potassium hydroxide solution vs. absorptivity at  $226 m\mu$  showed that the 45% KOH solution used for this experiment had a concentration of about  $6.2 \times 10^{-3} M K_2CO_3$ . Since this concentration is of the same order of magnitude as that of the silver (III) formed electrolytically, a series of experiments was performed to determine if the carbonate was coordinated with the silver (III) in solution. Preliminary experiments, performed with no control of atmosphere, had indicated that the addition of potassium carbonate to potassium hydroxide solution changed the amount of silver (III) formed. However, since potassium hydroxide solution absorbs carbon dioxide from the air, with conversion to carbonate ion, the concentration of carbonate in these preliminary experiments was not known. Carbonate was shown to have no direct effect on the silver (III) by use of carbonate free potassium hydroxide solution, and not to be coordinated with silver (III) by a polarographic method.

**Use of Carbonate-free potassium hydroxide solution.**—The same amount of silver (III) (about  $3 \times 10^{-3} M$ ), as determined by the colorimetric method, was electrolytically formed in carbonate-free potassium hydroxide solution (prepared by direct reaction of potassium metal with water) as in Baker Analyzed potassium hydroxide solutions containing carbonate. This indicated that carbonate is not necessary for formation of the silver (III) species.

**Polarographic resolution of carbonate problem.**—Crow and Westwood (29) describe a polarographic method for the study of complex ions in solution. The method is based on the shift in half-wave potential with changing concentration of coordinating ligand, while keeping total ionic strength constant. If the half-wave potential does not change, then the component of the solution whose concentration was varied is not a ligand. To investigate whether carbonate acts as a coordinating ligand with silver (III), six solutions in which the concentration of carbonate was varied from  $6.2 \times 10^{-3}M$  to  $1.7 \times 10^{-1}M$  were prepared. This work was carried out in the  $CO_2$  free argon atmosphere. The concentration of KOH was kept constant at 6M, and the total ionic strength was kept constant at 6.2M by use of potassium nitrate. The polarographic half-wave potential determined by a least squares fitting method did not vary for the six concentrations of carbonate studied. The half-wave potential was found to be  $+0.191 \pm 0.005v$  vs. SCE. This experiment showed that the carbonate was not a ligand which coordinates with silver (III) in the solutions studied. Similar results were obtained for 3 and 1.2M potassium hydroxide solutions.

All of the following experiments using potassium hydroxide solution were performed under  $CO_2$  free argon atmosphere.

**Concentration of silver (III).**—The variation of the concentration of silver with concentration of hydroxide ion is compared with the saturation concentration of silver (I) oxide reported by Amlie and Ruetschi (20) in Fig. 6. These results show that the concentration of the silver (III) species formed electrolytically increases with increasing hydroxide concentration, as opposed to the silver (I) species, dissolved in alkaline solution by mechanical shaking of silver (I) oxide, whose concentration reaches a maximum at about 6M KOH and then decreases at higher concentrations.

**Identification of tetrahydroxyargentate (III) species.**—The polarographic method for the study of complex

Fig. 6. Variation of concentration of silver with concentration of KOH.

ions in solution described by Crow and Westwood (29) was used to identify the silver (III) hydroxy species formed by electrolytic oxidation of silver metal in potassium hydroxide electrolyte.

A series of solutions with constant concentration of silver (III) and constant ionic strength maintained with  $\text{KNO}_3$ , but varying concentrations of potassium hydroxide was prepared, and a polarogram taken on each solution immediately after its preparation. The polarographic data was fitted by a least-squares method to the Heyrovsky equation for irreversible reactions

$$i = i_1 / [1 + \exp(\alpha n F (E - E_{1/2}) / RT)] \quad [4]$$

where:

- $i$  = current
- $i_1$  = polarographic limiting current
- $\alpha$  = measure of irreversibility
- $n$  = number of electrons per mole involved in the polarographic reaction
- $F$  = Faraday's constant
- $E$  = potential
- $E_{1/2}$  = polarographic half-wave potential
- $R$  = ideal gas constant
- $T$  = absolute temperature.

Experiments run at two different constant ionic strengths, 1.2 and 2.4M with the concentration of KOH ranging from 0.12 to 2.4M, gave the same results. Table IV shows the values of half-wave potential,  $E_{1/2}$ , and  $\alpha n$  found from the least squares curve fit. Values of  $\alpha$  were calculated assuming that the polarographic wave being studied represents a two-electron reaction, the reduction of silver (III) to silver (I) according to Eq. [5].

Table IV. Results of curve fit of polarographic data

[OH <sup>-</sup> ] M	$E_{1/2}$ , v vs. SCE	$\alpha n$	$\alpha$
(a) Total ionic strength = 1.2M, [Ag(III)] = $5.8 \times 10^{-3}$ M			
0.12	0.4273	1.234	0.617
0.24	0.3927	1.204	0.602
0.48	0.3698	1.198	0.599
0.60	0.3629	1.226	0.613
0.72	0.3413	1.246	0.623
0.96	0.3317	1.208	0.604
1.20	0.3140	1.190	0.595
(b) Total ionic strength = 2.4M, [Ag(III)] = $1.15 \times 10^{-4}$ M			
0.24	0.3977	1.228	0.614
0.48	0.3610	1.184	0.592
0.96	0.3435	1.238	0.619
1.20	0.3220	1.228	0.614
1.44	0.3180	1.232	0.616
1.92	0.3136	1.206	0.603
2.40	0.2977	1.240	0.620
		$1.218 \pm 0.018$	$0.609 \pm 0.009$

Fig. 7. Polarographic wave for silver (III)

$\alpha$  was found to be constant throughout the series of concentrations studied, and was determined to be  $0.609 \pm 0.009$ .

Figure 7 is an example of a typical polarographic run, and shows a comparison of the experimental data with a least-squares curve fit. Curve a is the experimental polarogram, and curve b was constructed using the values of  $E_{1/2}$ ,  $\alpha n$  and  $i_1$  determined by the least-squares curve fit.

Figure 8 is a plot of the half-wave potential of the silver (III) ion against the logarithm of the concentration of hydroxide ion, for the two ionic strengths used. The linearity of the data indicates that only one complex species is present in the solutions under study. The number of ligands is determined from the slope of the line, which is defined by

$$\frac{\Delta E_{1/2}}{\Delta \log C_{\text{OH}^-}} = \frac{-(p-q)2.303 RT}{\alpha n F} \quad [6]$$

where  $p$  and  $q$  are the ligand numbers shown in Eq. [5]. The slope was calculated by a least squares fit of the data and found to be  $-0.09975$ . The experiments were run at  $27.2^\circ\text{C}$ , and using the value of  $\alpha n$  shown in Table III,  $(p-q)$ , the difference in ligand number between the silver (I) and silver (III) species, was calculated to be  $2.041 \approx 2$ . Antikainen and co-workers (30) found that in 1.5M potassium hydroxide solutions, the silver (I) species present is  $\text{Ag}(\text{OH})_2^-$ , and they report that there is no evidence to show the presence of any other silver (I) species up to at least 5M KOH. Thus, the silver (III) species has a formula of  $\text{Ag}(\text{OH})_4^-$  based on the two ligand difference found from the slope in Fig. 8.

### Summary

When silver metal is electrolytically oxidized at about  $70 \text{ ma/cm}^2$  in potassium hydroxide solution, the silver (III) complex ion, tetrahydroxyargentate (III)

Fig. 8.  $E_{1/2}$  vs.  $\log [\text{OH}^-]$  for silver (III) at two total strengths

[Ag(OH)<sub>4</sub><sup>-</sup>] is formed. Solutions of the species are yellow, with an intense absorption band centered at 271 mμ ( $\epsilon = 1.17 \times 10^4$  l mole<sup>-1</sup> cm<sup>-1</sup>). The concentration of Ag(OH)<sub>4</sub><sup>-</sup> that can be formed increases with increasing KOH concentration between 1.2 and 12M. In 12M KOH solution, the concentration of Ag(OH)<sub>4</sub><sup>-</sup> is found to be  $3.2 \times 10^{-3}$ M, compared with  $0.39 \times 10^{-3}$ M reported for the silver (I) species Ag(OH)<sub>2</sub><sup>-</sup> in the same concentration of KOH. No evidence was found for coordination of silver (III) with carbonate.

Manuscript submitted May 21, 1968; revised manuscript received Aug. 9, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 43. This paper was abstracted from a thesis submitted by one of the authors (G.L.C.) to the Faculty of the Graduate School of the University of Maryland in partial fulfillment of the requirements for the Ph.D. degree, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Galvanostatic Transients in Passive Iron

J. H. Bartlett\* and J. R. Hudson

Department of Physics, University of Alabama, University, Alabama

#### ABSTRACT

Galvanostatic transients have been recorded for iron passive in 2N H<sub>2</sub>SO<sub>4</sub>. Comparison with the Dewald theory of anodic oxidation is made and this theory is found to be inapplicable because (i) space charge effects are important and (ii) the zero-field current varies much more rapidly than the theory predicts. Both overshoot and undershoot decay exponentially. (The overshoot disappears if the constant current is applied at a late stage of an open-circuit break.)

The nature and behavior of the layer (s) on passive iron are matters which still require experimental work and theoretical analysis. Even though both electrical (1) and optical (2) experiments have led to the conclusion that there is a layer, usually many atoms thick, on the surface of passive iron, the detailed mechanism of how ions move through this layer remains to be elucidated.

If we could explain quantitatively all the transient phenomena which occur, then we could be confident that we know what is actually happening. Such phenomena are the galvanostatic transients (potential vs. time at constant current), (ii) the potentiostatic transients (current vs. time at constant potential), (iii) optical transients (ellipsometric data vs. time), and (iv) the possible photoconduction due to irradiation by uv light.

The anodic passivation of iron shows features which are common to oxidation of tantalum and other metals. In particular, the galvanostatic oxidation curves for

iron in neutral solution and for tantalum (in general) look very much alike. Consequently, if we can devise an acceptable theory of anodic oxidation for any one metal, the chances are that it will have a great measure of validity for other metals.

The present work is concerned mainly with the presentation of further results on galvanostatic transients in iron and with the phenomenon of overshoot. New evidence is adduced which indicates that space charge effects are of importance.

#### Experimental Equipment and Procedures

Iron anodes were prepared from single crystals of pure iron purchased from Research Crystals, Inc., Richmond, Virginia. These crystals which came as rods 0.3 in. in diameter and 2 to 3 in. long were machined to form cylinders 0.20 in. in diameter and 0.20 in. high. A 1/16 in. hole was drilled through the axis to allow passage of a 1/16 in. steel rod which was used to make electrical contact with the sample and to hold the anode assembly together, as shown in Fig. 1. Teflon

\* Electrochemical Society Active Member.

Fig. 1. Anode assembly

gaskets were used between the ends of the sample and the glass tubes, as shown. This was to prevent leakage of electrolyte around the edges of the sample and therefore changes of the surface area of the anode. The glass tube cap at the bottom of the assembly consists of a steel nut completely sealed from the electrolyte by many layers of epoxy. This cap is checked often for any leakage current by assembling the anode without a sample and testing it in the electrolyte for any current which might be leaking around or through the epoxy. The pressure on the gaskets is applied by adjusting the nut at the top of the assembly. This type of anode construction gave leak-tight anodes which have remained in continuous use for 15 days before leakage currents developed either at the edges of the sample or in the epoxy. Such leakage currents can be recognized by an increase in the steady-state current, which in a typical anode might increase from 9 to  $9.5 \mu\text{a}/\text{cm}^2$  in an hour while the current had been holding constant at  $9 \mu\text{a}/\text{cm}^2$  for days. The anode area exposed to the electrolyte was  $0.81 \text{ cm}^2$ . A design similar to this was first used by Feller and Osterwald (3).

The cell in which the anode was used consisted of a five neck-jacketed 500 ml flask equipped with standard tapered joints so that any neck being used could be sealed off. A reversible hydrogen electrode made from a square of platinized platinum foil, of approximately  $3 \text{ cm}^2$  surface area, was used at the cathode. A 0.1N mercurous sulfate electrode was used as a reference electrode for all potential measurements. The sulfate electrode was used so as to exclude the chlorine ion found in the calomel electrode.

To remove oxygen and other dissolved gases as well as to provide a stirring action, hydrogen gas was bubbled continuously through the electrolyte. It was introduced through a fritted glass diffusion tube at a rate of about  $5 \text{ cm}^3/\text{min}$  and allowed to escape through a tube submerged in water.

The electrolyte used was prepared from distilled water which had been subsequently passed through a Barnsted 8902 mixed bed demineralizer. The sulfuric acid used was of reagent grade. Unless otherwise noted data were taken in a  $2N \text{ H}_2\text{SO}_4$  electrolyte.

The circuit layout for all electrical measurements is shown schematically in Fig. 2. The potentiostat consists of a 25-ohm 10-turn Helipot in parallel with a bank of twelve 2v Willard rechargeable wet cells wired to produce 4v. The equivalent resistance of the potentiostat is approximately 10 ohms. A potentiostat

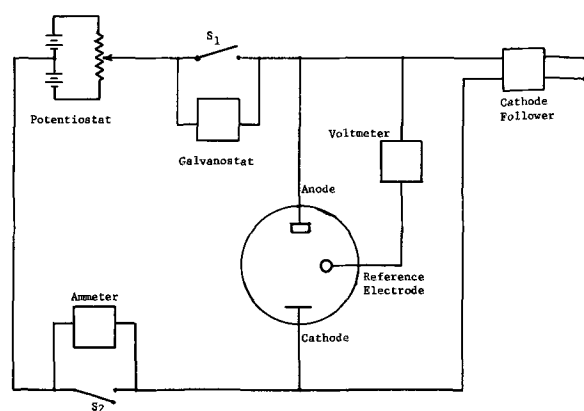

Fig. 2. Schematic circuit

of this type must be used with a reversible electrode as it does not directly control the anode reference potential.

The galvanostat consists of a variable resistor in series with a 180v battery bank. This arrangement holds the current constant within 0.5% for all transients of interest. Switching from potentiostatic conditions to galvanostatic conditions is accomplished by shorting out the galvanostat with switch  $S_1$ .

Potential measurements were made with a Keithley d-c VTVM Model 200B with an input impedance of more than  $10^{14}$  ohms. The current was measured with a Keithley Micro-Microammeter Model 414. This was removed from the circuit by closing switch  $S_2$ . Potential variations were recorded on a Sanborn Chart Recorder Model 7700 with a 8803A low level preamplifier capable of recording  $1 \mu\text{v}/\text{mm}$ . The rise time of the recorder was 20 msec for the potential variations which we recorded. Since this time is much shorter than the observed times (of the order of seconds) to the potential maximum, our plots show the potentials after all the transients have died out. A battery operated cathode follower with a bandwidth of over 100 kc was used to isolate the cell from the recording equipment. The follower used a 6F5 with a grid current of less than  $10^{-9}$  amp. The noise level at the recorder pen was about  $50 \mu\text{v}$ . This equipment was first assembled and used by Ord and Bartlett at the University of Illinois.

To take a series of measurements the equipment is turned on and allowed to stabilize. The anode is first passivated in a fresh acid solution and then transferred to the cell through which hydrogen has been bubbled for at least 12 hr. The potential is set at zero, with respect to the reference electrode, to allow the layer to be reduced to its smallest thickness. After about 1 hr the current has reached a constant value of about  $50 \mu\text{a}$ . The potential at which a measurement is to be taken is then set and the current is allowed to reach the steady-state value. After the measurement is taken new conditions are set and the anode again allowed to reach the steady-state. The time between measurements taken this way is from about 30-60 min. All voltages referred to in this paper are potential differences between the anode and the mercurous sulfate reference electrode.

### Dewald Theory of Transients

*Galvanostatic transients.*—With the anode initially passive and the constant steady-state current flowing, we may switch to a lower or a higher constant current. In the former case, the potential decreases rapidly to a plateau sloping downward and the anode eventually goes active. Figure 3 shows an example of this where the new applied current equals zero. If the applied current is greater than the steady-state value, one observes a rapid increase in the potential followed by a much slower exponential change in the opposite direction to a minimum, then the assumption

Fig. 3. Open-circuit break, potential vs. time

of a linear rise representing layer growth. This rise of the potential to a maximum and the subsequent decay to the final state will be defined as overshoot. If at some point along this transient the current is switched back to the steady-state value, the potential decreases rapidly, passes through a minimum and then increases to a new steady-state value. This decrease of the potential to a minimum and the subsequent increase to the steady-state value will be defined as undershoot. Figure 4 shows both an overshoot and undershoot transient, and particular values of  $V$  are labelled by appropriate symbols.

Originally, Cabrera and Mott (4) had assumed (A) that there is a high electric field present in the layer, (B) the layer is a uniform lattice, and (C) that only one type of ion is mobile and moves by jumps from one interstitial position to the next. On this basis, they obtained the following relation for the current at any point in the layer

$$i = q\mu_0 n e^{\beta E} \quad [1]$$

where  $q$  is the charge on the ion,  $\beta = aq/kT$ , with  $k =$  Boltzmann's constant,  $T =$  absolute temperature, and  $a$  the "jump distance,"  $2a$  is the distance between successive interstitial positions,  $\mu_0 = 2a\nu e^{-aU/kT}$ ,  $\nu$  is the vibrational frequency of the ion,  $U$  is the activation energy for motion between interstitial positions in the absence of the electric field,  $E$  is the electric field,  $n$  is the concentration of mobile ions.

Furthermore, using Poisson's equation and the equation of continuity one can derive the following relation between the internal current,  $i$  the external cur-

Fig. 4. Galvanostatic transient, potential vs. time. (Overshoot occurs when the current is suddenly raised to a new constant value, and undershoot when the current is suddenly reduced to its initial steady-state value).

rent,  $I$  and the electric field

$$\frac{\partial E}{\partial t} \Big|_z = \frac{1}{KK_0} (I - i) \quad [2]$$

where  $K$  is the dielectric constant of the film,  $K_0$  is the permittivity of free space, and  $z$  is the distance normal to the metal surface.

Dewald (5, 6) made the additional assumptions (D) that the field is constant across the layer and (E) that Frenkel defects are created in the layer at the rate

$$\frac{dn_+}{dt} = (N_0 - m)\nu e^{-[W - E\lambda q]/kT} \quad [3]$$

where  $N_0$  is the concentration of lattice sites,  $m$  is the vacancy concentration,  $W$  is the activation energy for the creation of an ion-vacancy pair,  $\lambda$  is the distance from the equilibrium position to the maximum in the potential energy diagram of an ion around a lattice site.

The rate of annihilation of the carriers is

$$\frac{dn_-}{dt} = \frac{-i\sigma m}{q} = \frac{dm_-}{dt} \quad [4]$$

where  $\sigma$  is the cross section for ion capture by a vacancy. The net rate of change of the vacancy concentration with time is then

$$\frac{dm}{dt} = (N_0 - m)\nu e^{-[W - E\lambda q]/kT} - \frac{i\sigma m}{q} \quad [5]$$

For simplicity, the electric field is assumed to be uniform across the layer. Making the above substitutions for  $\mu_0$  and  $\beta$  and combining Eq. [1], [2], and [5] we have

$$\frac{dE}{dt} = \frac{1}{KK_0} (I - 2nq\nu e^{-[U - Ea q]/kT}) \quad [6]$$

$$\frac{dn}{dt} = N_0\nu e^{-[W - E\lambda q]/kT} - 2\sigma a\nu n^2 e^{-[U - Ea q]/kT} \quad [7]$$

For a galvanostatic transient, where the ratio of the applied current to the steady-state current is  $p$ , we may write Eq. [6] and [7] in dimensionless form as

$$\frac{dy}{dx} = p - Ze^y \quad [8]$$

$$\frac{dZ}{dx} = B[e^{\alpha y} - Z^2 e^y] \quad [9]$$

where  $x = \frac{I_0 t}{KK_0} \frac{qa}{kT}$ ,  $y = (E - E_0)aq/kt$ ,  $Z = n/n_0$ ,

$\alpha = \lambda/a$ ,  $B = \sigma kTKK_0/aq^2$ ,  $I_0$  is the initial current density,  $E_0$  is the initial electric field,  $n_0$  is the initial carrier concentration.

A reasonably good first-order solution of Eq. [8] and [9] is possible for values of  $B$  less than about 0.01. This will be the case if, as we expect, the cross section  $\sigma$  is of the order of atomic dimensions. In this case  $Z$  will hardly change at all in the initial stages of the transient, while initially  $y$  will change rapidly. Subsequently as  $y$  increases,  $dy/dx$  will decrease, eventually going through zero. From then on  $y$  can change only slowly as  $Z$  changes. For values of  $x$  beyond the maximum in  $y$  we may then approximate  $y$ , using Eq. [8], as

$$e^y \approx p/Z \quad [10]$$

If this is substituted in [9], we have

$$(dZ^{\alpha+1}/dx) + p(\alpha + 1)B(Z^{\alpha+1} - p^{\alpha-1}) = 0 \quad [11]$$

The quantity  $Z^{\alpha+1}$  approaches  $p^{\alpha-1}$  as  $t \rightarrow \infty$ , and the decay constant is  $p(\alpha + 1)B$ . In fact, the equation for  $Z^{\alpha+1}$  is

$$Z^{\alpha+1} = p^{\alpha-1} - (p^{\alpha-1} - 1)e^{-p(\alpha+1)Bx} \quad [12]$$

So, if  $p > 0$ ,  $Z$  increases from unity to the value  $p^{(\alpha-1)/(\alpha+1)}$ . According to Dewald, "when  $y$  is at its maximum, the value of  $p(\alpha + 1)Bx$  is considerably less than unity and so can be set equal to zero." In this case,  $Z$  will not have changed much from its original value of unity and so, from Eq. [10]

$$y_{\max} = \ln p \quad [13]$$

In general

$$y = y_{\max} - \ln Z \quad [14]$$

If in [12] we make the approximation  $\ln(1 + A) = A$ , then from [14] we have

$$y = (2/\alpha + 1) \ln p + [1/(\alpha + 1)](1 - p^{1-\alpha})e^{-p(\alpha+1)Bx} \quad [15]$$

**Comparison with Experiment**

*Initial jump.*—From assumption (D), the potential drop across the layer is  $V = ED$ , where  $D$  is the thickness. From Eq. [13]

$$(E - E_0)_{t=0} = (kT/eq) \ln(I/I_0) \\ V_2 - V_1 = (\Delta V)_{t=0} = (kT/eq)D \ln(I/I_0) \quad [16]$$

Experimentally, as seen in Fig. 5, one obtains proportionality with  $\ln p$ , with  $D$  fixed.

However, according to Eq. [16],  $V_2 - V_1$  should be equal to zero when the thickness is zero, which according to Ord and Bartlett (2) is when  $V = -0.055v$ . Figure 6 shows the results obtained by applying different current densities to an anode in the steady state at different passive potentials. These results are very reproducible, and the points shown are averages of many individual results. If the curves for the various current ratios are extrapolated back to the lower voltage axis, they do not have a common zero intercept, as is predicted by Dewald.

There are perhaps two reasons for the discrepancy between theory and experiment, based on work by Ord and Bartlett (1). [They expressed the current (when transient effects have died out) as

$$i = i_0 \exp(v/v_0),$$

where  $v$  is the potential difference across the layer and  $i_0$  and  $v_0$  are parameters determined from experiment. Comparison with Eq. [1] shows that the quantity  $v/v_0$  is proportional to the field  $E$ , while the coefficient  $i_0$ , which we can call the zero-field current (because  $i$  would equal  $i_0$  if  $E$  were equal to zero), is proportional to the concentration  $n$ .] The first reason is that, while the layer thickness cannot have changed appreciably when the potential maximum is reached, the parameter  $v_0$  of Ord and Bartlett has changed markedly [see Fig. 11, ref. (1)]. The consequence is that the field does not have the value  $v/D$ , i.e., the field across the activation barrier does not equal the average field across the layer and so there must exist a space charge. The second reason is that the zero-field current  $i_0$  has also changed significantly by the time the maximum is reached [see Fig. 12, ref. (1)], so that the mobile ion concentration  $n$  would also have to change by the same percentage, whereas Dewald assumed this change to be negligible. Our re-

Fig. 5. Current ratio vs. initial jump of potential

Fig. 6. Initial jump of potential vs. initial potential

sults therefore call into question the correctness of the Frenkel defect mechanism of Eq. [9].

*Overshoot decay.*—A further test of the Dewald theory is accounting for the shape of the overshoot decay (from the potential maximum to the minimum). The data are somewhat difficult to reproduce, but if the same anode is used all the time, the results can be duplicated within 10%. An enlarged view of the overshoot decay is shown in Fig. 7. A semilog plot of this curve shows it to be exponential to the point A with an asymptote about 10 mv down from the maximum. It seems reasonable to assume that the point A, where the potential deviates from an exponential, is where the layer starts to grow. To test this hypothesis the linear rise following the minimum is extrapolated back to the point B directly below A. The potential at B corresponds to the asymptotic value of the exponential prior to A. Now starting at A the linear voltage curve,  $V_B$ , is subtracted from the recorded potential curve. This results in  $V_A$  which turns out to be a continuation of the exponential down to A. This would seem to verify the fact that the actual potential curve is the sum of two curves, one representing the

Fig. 7. Section of galvanostatic curve showing overshoot decay and layer growth, potential vs. time.

Fig. 8. Overshoot decay constant vs. initial potential

growth of the layer and the other an exponential decay of the potential with time, which may be represented by the equation

$$V - V_f = Ae^{-bt} \quad [17]$$

The value of  $A$  was found to be 13 mv for all current ratios and values of the passive potential.

The exponent  $b$ , if it is compared with Dewald's theory, should be equal to  $-pBx(1 + \alpha)$ , i.e., proportional to the current ratio but independent of thickness. Experiment does show a proportionality to  $p$ ,

Fig. 9. Time to start of layer growth vs. current ratio

Fig. 10. Time to start of layer growth vs. initial potential

but a linear increase with  $V$  and hence with thickness (see Fig. 8).

The time before the layer growth starts was found to be inversely proportional to the current ratio, as shown in Fig. 9, and the dependence on the thickness is shown in Fig. 10.

It may be mentioned that the undershoot behaves in the same general way as the overshoot, except that there is little if any complication due to layer growth. The rapid drop is at first capacitive and the total amount to the minimum is in accordance with a relation similar to Eq. [16]. The rise from the minimum approaches exponentially the final value, in the manner given by

$$V_s - V = Ce^{-bt}$$

The decay constant  $b$  was found to depend on the initial passive potential and hence on the layer thickness.

Finally, overshoot can be observed to vanish if one applies a constant current at a late stage of an open-circuit break. In Fig. 11 the lower curve shows how the potential changes with time if the anode is ini-

Fig. 11. Galvanostatic curves for constant current applied at various phases of an open-circuit break.

tially passive and the circuit is interrupted. The other curves show the change when the same constant current, greater than that in the steady state, is applied. The right-hand curve shows no overshoot. This may be due to the relative absence of charge carriers in the layer at the time the circuit is again closed.

*Validity of the Dewald theory.*—As we have shown, experiments with galvanostatic transients in iron are not in accord with the predictions of Dewald (*loc.cit.*). This may be due (i) to the existence of space charge and (ii) to the fact that the zero-field current, and hence the mobile ion concentration, changes very appreciably during the rise to the voltage maximum.

Furthermore, it is not known for iron that just one kind of ion moves, but in other systems (tantalum, niobium, aluminum, tungsten) for which we do have evidence (7), it has been shown that both metal and oxygen ions are mobile, and so the Dewald theory would have to be modified for them. These systems are not strictly comparable to iron, because they are irreducible and iron is reducible, but the charging curves are very similar in character.

The Dewald theory has also been questioned by Dignam (8) on the basis of his experiments with tantalum.

## Field Ion Microscopy Study of the Formation of Oxide Particles on Tungsten

S. S. Brenner and W. J. McVeagh

*Edgar C. Bain Laboratory for Fundamental Research,  
United States Steel Corporation, Research Center, Monroeville, Pennsylvania*

### ABSTRACT

The induction period for the formation of oxide particles on tungsten was found to be inversely proportional to  $(p_{O_2})^{0.8}$  and exponentially related to  $1/T$  indicating an activation energy of  $21 \pm 2$  kcal/mole. The particles appear to be irregularly shaped, and their distribution is crystallographically nearly homogeneous. It is proposed that the length of the induction period is determined primarily by the rate of penetration of oxygen into the tungsten lattice.

The formation of isolated oxide particles preceding the growth of a continuous film has been observed on a number of metal surfaces which are exposed to a mildly oxidizing environment. Indeed this phenomenon may be common to all metals. Reviews of this subject and summaries of the experimental results can be found in ref. (1-5).

Oxide particle formation has also been observed on tungsten surfaces by one of us (6) (S.S.B.) using field ion microscopy (FIM) and by Rausch and Moazed (7) and Rausch (8) using field emission microscopy (FEM). These studies have shown that in common with other gas-metal systems there is an induction period associated with the appearance of particles of the reaction product. The present paper is an extension of the earlier FIM work and discusses in particular the temperature and pressure dependence of this induction period.

### Experimental

*Apparatus.*—A Müller field ion microscope using helium as the imaging gas and operated at 77°K was used in this investigation. It deviated from the standard design by the use of copper-gasketed stainless steel flanges as shown in Fig. 1. The residual gas pressure in the vacuum system after bakeout and prior to the oxidation experiments was less than  $1 \times 10^{-9}$  Torr. Oxygen was introduced into the system either by diffusion through a heated silver tube or from a bottle of spectroscopically pure gas. Care was taken to minimize the production of CO at the pressure gauges either by using thermocouple gauges or by intermit-

tently using thoria-coated ion gauges operated at low emission currents.

The field emitter was heated by thermal conduction from the supporting wire loop (Fig. 1), and its temperature was determined from the resistivity change of a small section of the loop in contact with the spot-welded specimen. For short heating periods a temperature pulser with a rise time of about 0.2 sec was used.

*Procedure.*—Prior to each oxidation experiment the tungsten tip was field evaporated, after which the potential was reduced to ground level and the oxygen pressure was adjusted to the desired level between  $10^{-6}$  and 1 Torr. Since this adjustment required at least 10 min it is certain (9) that the surface of the field emitter became covered with adsorbed oxygen. After heating in oxygen, the specimen was cooled rapidly, and the oxygen pressure was reduced to less than  $10^{-7}$  Torr before the tip was examined by removing in succession monatomic layers of metal using pulsed field evaporation. When the heat-treatment produced significant amounts of oxide, the specimen was flashed for a short period above 1200°C to vaporize the oxide prior to the next experiment. It must be emphasized that during the oxidation treatment the applied potential was always zero.

### Results

*Structural observations-oxygen adsorption.*—A clean field-evaporated tungsten surface is shown in the micrograph of Fig. 2a. The adsorption of oxygen caused the appearance of many randomly distributed ioniza-

Fig. 1. Müller field ion microscope using copper-gasketed flanges

tion centers (Fig. 2b). Whether these ionization centers represent the chemisorbed oxygen atoms or displaced tungsten atoms is still a matter of conjecture (10-12). The effects of oxygen adsorption could be eliminated (Fig. 2c) by the field evaporation of one to two (110) layers (2.2-4.5Å) at the apex of the tip. If after an oxidation treatment the perfect surface was restored by the removal of no more than 2 atomic layers of tungsten, it was assumed that only chemisorption and not oxidation has occurred.

**Oxide formation.**—Oxidation manifested itself in two ways: (i) by the appearance of dark regions in the ion images and (ii) if the oxidation treatment was more severe, by a decrease in the radius of curvature,  $r$ , of the field emitter. The dark regions have previously been interpreted (6) to be the images of the depressions or holes left by oxide particles that were evaporated by the imaging field (Fig. 3). The decrease in the radius of curvature is believed to be due to the formation and subsequent field-evaporation of a more continuous (although not necessarily compact) oxide layer. When the thickness of the oxide layer is only a

Fig. 3. Formation of surface holes caused by the field-evaporation of oxide particles.

Fig. 4. Decrease of radius of curvature of field-emitter caused by the formation of a continuous oxide film and its subsequent removal by field-evaporation.

fraction of  $r_1$ , the change in  $r$  equals the depth of metal oxidized (Fig. 4).

**Shape and distribution of oxide particles.**—A typical example of a tungsten surface after heating for 10 min at 960°K in  $10^{-4}$  Torr oxygen is shown in the sequence of photographs in Fig. 5. When the imaging potential was first applied, the ion image contained many dark areas and some bright spots due to adsorbed gas atoms or displaced substrate atoms (Fig. 5a). As the voltage was raised, many of the bright spots disappeared and the edges of the (110) planes became visible. Field evaporation of three (110) planes (Fig. 5c) removed most of the dark areas, except for some isolated regions, such as indicated by the arrows. The deepest of the remaining holes persisted to a depth of about 20Å. In other experiments holes were observed up to 30Å in depth. In addition to the deeper holes the oxidation and subsequent field evaporation also caused the formation of many shallow fissures and depressions less than 7Å deep and extending more than 100Å over the surface (Fig. 5b).

It is evident from these micrographs (Fig. 5) that the shape of the holes, i.e., the oxide particles, is highly

Fig. 2. Effect of chemisorption of oxygen on field-evaporated tungsten surface. Tip exposed to  $8 \times 10^{-3}$  Torr  $O_2$  for 19 hr at 500°K: a (left) clean surface; b (center) after adsorption; c (right) after removal of 4.5Å of metal.

Fig. 5. Corrosion of tungsten surface exposed to  $10^{-4}$  Torr oxygen at  $960^\circ\text{K}$  for 10 min.  $\Delta h$  refers to the depth of field evaporation: left,  $\Delta h = 0$ ; center,  $\Delta h = 2.2\text{\AA}$ ; right,  $\Delta h = 6.7\text{\AA}$ .

irregular, possibly on account of preferential field evaporation at the sides of the holes (oxide-metal interface). Because of the irregular shape it was difficult to assess the total number of particles per unit area. The number of deeper holes on the projected surface area was usually of the order of ten, giving a particle density of approximately  $10^{11}/\text{cm}^2$ . The incidence of holes appeared to be slightly greater at the (110) steps and near the  $\langle 112 \rangle$  poles; however, no strong crystallographic preference was found. Since the low-index planes normally appear dark in the ion images, the incidence on these planes could not be determined. Particles did not appear to form preferentially at grain boundaries, although some of the particles in contact with boundaries were unusually large.

**Pressure and temperature dependence of oxide formation.**—Oxide particles were observed only after an induction period,  $t_i$ , which is both pressure and temperature dependent. The magnitude of  $t_i$  was determined from a series of experiments in which the temperature and pressure were held constant and the time was varied. The shortest time necessary to give a definite indication of oxide formation (the criterion for this was stated earlier) was taken as  $t_i$ . In Fig. 6  $t_i$  is plotted as a function of pressure at  $1000^\circ\text{K}$ ; the uncertainty in  $t_i$  is indicated by the spread between the pairs of closed and open circles, which represent minimum time to detect oxidation and the maximum time at which no oxidation was observed, respectively. The data are represented by

$$t_i = 0.16 p^{-0.8} (1000^\circ\text{K}; p \text{ in Torr})$$

Less complete data at  $650^\circ$  and  $700^\circ\text{K}$  indicate a similar pressure dependence for oxygen pressures in the range from 0.01 to 100 Torr.<sup>1</sup>

The temperature dependence of  $t_i$  was determined in a similar manner and is shown in Fig. 7 for  $p$  equal to  $10^{-4}$  and 1 Torr. At both pressures the data can be represented reasonably well by an Arrhenius-type equation yielding an activation energy of  $21 \pm 2$  kcal/mole. At the pressure of 1 Torr a temperature correction was applied to account for the heat loss due to gas conduction. This correction only shifted the intercept of the  $\log t_i - 1/T$  plot, but did not appreciably affect its slope.

**Oxide film formation.**—In some experiments the oxidation was allowed to proceed until a continuous film was formed resulting in a decrease in the radius of curvature of the field emitter. The radius of curvature,  $r$ , may be calculated from the number of steps between two planes of known orientation (13). The minimum detectable value of  $\Delta r$  is about  $20\text{\AA}$ . A typical example of the decrease in radius of curvature with oxidation is shown in Fig. 8 in which the average radius of curva-

ture,  $r$ , decreased from  $360$  to  $200\text{\AA}$ . The apparent shift of the grain boundary is due to the recession of the apex and the change of the intersection of the boundary with the surface.

In Fig. 9  $\Delta r$  is shown as a function of time at  $700^\circ\text{K}$  and  $1.2 \times 10^{-2}$  Torr oxygen. The linear relationship indicates that the rate of oxidation is constant at least up to a depth of  $180\text{\AA}$  and suggests that the film is still porous at that thickness.

### Discussion

The results of this study show that the induction period for the formation of oxide particles on tungsten is related to temperature and pressure in a manner similar to that for other metals such as iron (14), copper (15-17), and tantalum (18). The greater the oxygen pressure and the higher the temperature the shorter is the induction period,  $t_i$ . Contrary to an earlier publication by one of us (6) (S.S.B.), there is no evidence for a critical pressure associated with the formation of oxide particles; the magnitude of  $t_i$  depends only on kinetic factors.

Values of  $t_i$  obtained in this study are appreciably greater than those observed by Rausch (8) using FEM. The reason for this is uncertain but may be a result of the larger (20 to 50 times) surface areas that are observed with the field-emission microscope.

Despite the numerous publications on oxide initiation it is still uncertain what process takes place and what the state of the surface is during the induction period. Several investigators (1, 15, 19) have concluded that a continuous, randomly oriented oxide film first forms on the metal, and then oriented oxide particles nucleate and grow within or from this primary oxide layer. However, Lawless (4) concluded from careful reflection electron diffraction studies made on copper

Fig. 6. Oxygen pressure dependence of the induction period at  $1000^\circ\text{K}$ .

<sup>1</sup> The dissociation pressure of  $\text{WO}_2$  at  $1000^\circ\text{K}$  is about  $10^{-15}$  Torr (33). Hence all experiments were performed under conditions far from equilibrium.

Fig. 7. Temperature dependence of the induction period at  $10^{-4}$  and 1 Torr oxygen.

that during the induction period not more than  $10\text{\AA}$  of oxide is present on the metal surface. Lawless, as well as Mitchell (17) and Van Der Schrick (16), concluded that the most likely process occurring during the induction period of copper is the dissolution of oxygen into the subsurface layer to form a supersaturated metal-oxygen solution. At a sufficiently large supersaturation, precipitation of oxide particles occurs. A similar explanation was given by Kofstad (18) for the nucleation of tantalum suboxide platelets. In this case it could be shown that the concentration of oxygen in solution in the metal near the surface was considerably larger than the solubility of oxygen in the presence of  $Ta_2O_5$ .

Within the limits of detection ( $\sim 20\text{\AA}$ ) the results of this study show that a continuous thin film of oxide was not present during the induction period, and it is also suggested that the induction period is associated with the solution of oxygen into the surface layer of the metal. The solution occurs by the penetration of oxygen atoms from the adsorbed layer into the first few lattice planes. Deeper penetration of the dissolved oxygen into the bulk of the metal is prevented by the low thermal diffusivity of the gas atoms in the metal. The metal-oxygen solution layer at the surface corresponds to the "rearranged" or "reconstructed" surfaces postulated by some (20-24) to explain low energy electron diffraction (LEED) results.

The penetration of oxygen into tungsten was observed by Zingerman and Ishchuk (25) in a series of experiments involving work function measurements. Penetration was observed at temperatures as low as  $850^\circ\text{K}$ . At  $1040^\circ\text{K}$  oxygen penetration occurred over a period of at least 10 min when the surface was exposed to a beam of oxygen the intensity of which was equivalent to a pressure of about  $3 \times 10^{-9}$  Torr. The number of injected atoms was estimated to correspond to about two monolayers of adsorbed atoms.

Neither the temperature dependence nor the pressure dependence of the rate of oxygen penetration was determined by Zingerman and Ishchuk. It is therefore not possible to confirm at this time whether the controlling step of the formation of oxide particles on tungsten is indeed the rate of oxygen penetration from the chemisorbed layer into the metal lattice.

If oxygen penetration is the controlling step then its pressure dependence differs from that of normal gas-metal diffusion where a  $p^{0.5}$  dependence is expected for a diatomic gas. The  $p^{0.8}$  dependence found in this study is not understood but it is nearly equal to the  $p^{0.7}$  dependence found by Singleton (26) for the rate of interaction of oxygen with tungsten filaments at  $1250^\circ\text{K}$  in which a similar process may proceed oxidation.

Neither the rate of penetration of oxygen atoms into metals nor the concentration of injected atoms just below the surface can be obtained from the bulk properties of the gas-metal system. With nickel, Roberts and Wells (27) reported that oxygen penetration occurs at temperatures below  $300^\circ\text{K}$  with an activation energy of only 2 to 15 kcal/mole depending on the amount of injected oxygen. Delchar and Tompkins (28) proposed that the incorporation of oxygen into the nickel lattice is facilitated by the electrical double layer at the surface. The activation energy for incorporation is decreased by  $\frac{1}{2} qV$  where  $q$  is the virtual charge of the adatom and  $V$  the potential difference across the double layer. They concluded that  $q$  is equal to  $0.3e$  where  $e$  is the electronic charge. To reconcile the large difference between the calculated and measured rates of incorporation they assumed that a large negative activation entropy accompanies the incorporation process. They suggested that this entropy term may be indicative of a cooperative phenomena in which the atoms on the surface undergo a concerted movement which enlarges the aperture through which the adatom can pass.

The penetration of chemisorbed oxygen at  $298^\circ\text{K}$  into metals other than nickel, such as copper, iron, chromium, and molybdenum was reported by Quinn and Roberts (29), and the anomalous surface solution rate compared to normal gas diffusion appears to be general in nature.

Fig. 8. Reduction in radius of curvature due to oxide film formation. Apparent shift of boundary is caused by recession of apex of tip, 15 hr at  $650^\circ\text{K}$  in  $1.5 \times 10^{-2}$  Torr oxygen. Left, before  $r \approx 360\text{\AA}$ ; right,  $r \approx 200\text{\AA}$ .

Fig. 9. Decrease of radius of curvature due to field-evaporation of oxide film formed on tungsten emitter at 700°K and  $1.2 \times 10^{-2}$  Torr oxygen.

While it appears reasonable to conclude that the length of the induction period preceding the observation of oxide particles on tungsten is determined by the rate of penetration of chemisorbed oxygen into the metal lattice, it is recognized that other explanations may be equally valid. For instance the rate-controlling step may be the nucleation process itself, i.e., the formation of the distinct oxide phase and the formation of the metal-oxide interface (30). The induction period may also be associated with the time to form a sufficiently large number of nuclei ( $> 10^{10}/\text{cm}^2$ ) or with the time necessary to cause sufficient thickening of the nuclei ( $> 5\text{\AA}$ ) to be discernible in the ion microscope. The rate of oxide growth may therefore determine the length of the induction period. The data now available do not make it possible to choose conclusively between these processes.

**Morphology and density of oxide particles.**—The shape of the oxide particles during their early stage of growth cannot be determined unambiguously by FIM because of possible field-evaporation effects. The ion micrographs suggest that the particle shapes are quite irregular. Polygonally shaped oxide particles have been reported but usually of much larger dimensions and their shapes are the result of their prolonged growth. Irregularly shaped oxide particles have been observed (31) on copper especially on high-index planes during the very early stages of corrosion. The growth of oxide particles on metals has been discussed by Rheed (32). It is obvious that the lateral growth rate of the particles will be considerably greater than their rate of thickening since the latter must occur by bulk diffusion or metal-oxide interface diffusion, while the former depends mostly on surface diffusion. Our observation of shallow fissures and depressions on oxidized tungsten surfaces indicates rapid lateral growth which is consistent with this prediction. However, the fact that the rate of metal consumption was still constant after the corrosion of 180Å of metal at 700°K and  $1.2 \times 10^{-2}$  Torr  $\text{O}_2$  suggests that the lateral growth was still incomplete at this stage.

The concentration of oxide particles formed on some metals (3, 4) is a function of crystal orientation. The absence of such an effect in this study may be due to one or more of the following factors: (i) the number of particles that were observed was too small to determine their statistical distribution; (ii) particles on the low-index planes such as {100}, {110} and {112} are not observable; and (iii) the field-evaporated surfaces are highly stepped surfaces on which epitaxial growth would be difficult. The use of field emitters of smaller curvatures which would allow viewing larger areas would be helpful in studies of particle concentration.

## Summary

The initial oxidation of tungsten occurs by the formation of oxide particles which field evaporate on the application of the imaging voltage in FIM, leaving behind holes in the surface. Oxide particles are observed after a induction period which is inversely proportional to the 0.8 power of the oxygen pressure. The activation energy associated with their appearance is  $21 \pm 2$  kcal/mole, independent of the oxygen pressure. No strong crystallographic effects were observed in the particle density. The results of the study are consistent with the hypothesis that the induction period is associated with the penetration of oxygen into the metal lattice to form a supersaturated metal-oxygen solution from which oxide nuclei precipitate.

## Acknowledgment

The authors are grateful to Mr. H. G. Grendon of this laboratory for his very able assistance in constructing and maintaining the experimental equipment.

Manuscript received June 19, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## The Thermodynamic Interaction between Zinc and Indium in Dilute Solution in Molten Lead

H. W. Slager, J. V. Gluck, and R. D. Pehlke

Boeing Company, Seattle, Washington, Tecumseh Products Research Laboratories, Ann Arbor, Michigan, and Department of Chemical and Metallurgical Engineering, University of Michigan, Ann Arbor, Michigan, respectively

A study has been conducted on the effect of small additions of indium on the thermodynamic activity of zinc in dilute solution in molten lead at 550°C. The present work is a continuation of an investigation of various third element interactions on zinc dissolved in lead (1-3). A previous investigation had considered the same third element interactions with zinc dissolved in molten bismuth (4). Although the lead-zinc binary system has been studied several times, and a number of lead-zinc-j ternary systems have also been investigated, there appears to be no previously reported thermodynamic studies in the literature on any region of the lead-zinc-indium system.

The experiments were conducted in high-temperature galvanic cells represented as follows:

Zn (pure reference standard)	Zn <sup>++</sup> (as 1.5 m/o ZnCl <sub>2</sub> ) in LiCl-KCl eutectic (fused salt electrolyte)	Zn + In in Pb (molten alloy)
------------------------------------	--	---------------------------------

The experimental apparatus, a multi-electrode system employing alumina refractories and contained in a Vycor tube under a helium atmosphere, has been described previously (1, 5), as have been the experimental procedures and precautions (2, 4, 5), and the methods of data reduction (4, 5). Experimental measurements were made over a temperature range of 450°-650°C. The linear dependence of the electromotive force (emf) on temperature was verified by statistical techniques of regression. The 90% confidence limit for the emf at 550°C was 0.17 mv on the average over the composition range investigated.

The experimental results summarized in Table I include the interpolated emf at 550°C and the temperature dependence of emf. A previous correlation of the results from 28 binary electrodes had shown that up to 0.0375 mole fraction zinc, the limiting activity coefficient of zinc in lead is given by the relation (1, 2)

$$\log \gamma^{\circ} \text{Zn} = \frac{1215}{T \cdot K} - 0.418 \quad [1]$$

The expected emf's and temperature dependence were calculated from this correlation and are compared with the present results in Table I for the measurements made on binary electrodes. Since the effect of the indium addition was to decrease the cell potential, the activity and activity coefficient of zinc were increased and thus the interaction is a positive one. A plot showing the effect of the indium addition on the activity coefficient of zinc is presented in Fig. 1 for alloys where the zinc content was fixed at 0.015

or 0.025 mole fraction. The relation is linear to 0.05 mole fraction indium and does not depend on the zinc concentration. This indicates that the influence of indium is substantially confined to a first-order effect. The slope of the relation yields Wagner's first-order interaction parameter at 550°C (6)

$$(\text{in Pb}) \left( \frac{\partial \ln \gamma_{\text{Zn}}}{\partial X_{\text{In}}} \right)_{\substack{X_{\text{In}}=0 \\ X_{\text{Zn}} < 0.025}} = \frac{\text{In}}{\epsilon_{\text{Zn}}} \cong + 2.7 \pm 0.3 \quad [2]$$

The temperature dependence of the effect is slight and the parameter decreases with increasing temperature. The temperature dependence is approximately expressed by the relation

$$\frac{\text{In}}{\epsilon_{\text{Zn}}} \cong \frac{490 \pm 160}{T \cdot K} + 2.1 \quad [3]$$

In both the sign and magnitude of the interaction, the effect of indium on the activity of zinc was similar in bismuth as a solvent [at 550°C  $\frac{\text{In}}{\epsilon_{\text{Zn}}} = + 2.2$  (in Bi)] (4).

Experimental measurements were also made on alloys where zinc was fixed at 0.0375 or 0.050 mole fraction. The same quantitative effect of the indium addition was observed; however, an anomalous and apparently reproducible effect caused the emf's of all the electrodes, both binary and ternary, in those cells to be shifted uniformly several millivolts higher. This effect cannot be explained by displacement reactions because the emf is shifted in the opposite direction (7). The quantitative values of the zinc-indium interaction in these cells was identical to that reported above for the more dilute solution. Further work is

warranted to clarify the thermodynamic behavior in this system.

Since the data in Table I suggest a decreasing trend in the emf-*vs.*-temperature slope with increasing indium content, there might be a detectable entropy

interaction in this system (8). Such an effect would have to be confirmed by additional free energy measurements and by calorimetry to establish the enthalpy interactions, if any.

Manuscript submitted July 1, 1968; revised manuscript received Aug. 3, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 114, No. 8 and 9 (August and September), and Vol. 115, No. 2, 4, and 5 (February, April, and May).

### Overpotential-Time Variation for Galvanostatic Charging with Potential Dependent Capacitance

Leonard Nanis and Philippe Javet, (pp. 810-812, Vol. 114, No. 8)

**S. K. Rangarajan**<sup>1</sup>: We offer the following comments pertaining to the validity of the equations used and the correctness of the solutions given by the authors: (A) Whereas it is true that the "total" current  $J_T$  is the algebraic sum of the "Faradaic" current  $J_F$  and the "charging" current  $J_C$ , care should be exercised to ensure consistency of sign-conventions while stating the dependence of  $J_C$  and  $J_F$  on  $\eta$  explicitly.

For example, if the convention " $\eta$ : positive when cathodic;  $\eta$ : potential of the electrolyte/electrode" is chosen

$$J_F = J_o \left[ \exp\left(\frac{-\alpha ZF\eta}{RT}\right) - \exp\left(\frac{(1-\alpha)ZF\eta}{RT}\right) \right] \quad [1]$$

but

$$J_C = -C \frac{d\eta}{dt}, \quad (C: \text{positive}) \quad [2]$$

and not

$$J_C = +C \frac{d\eta}{dt} \quad [3]$$

as used by the authors. The equation to be solved is therefore

$$J_T = J_o \left[ \exp\left(\frac{-\alpha ZF\eta}{RT}\right) - 1 \right] - C \frac{d\eta}{dt} \quad [4]$$

(for the case  $\alpha \approx 1$ ) and not Eq. [5] of the authors.

There have been other instances<sup>2</sup> where such an incorrect equation is quoted. Four forms of expressing

<sup>1</sup> Central Electrochemical Research Institute, Karaikudi-3, S. Rly, India.

<sup>2</sup> J. O'M. Bockris and A. Damjanovic, "Modern Aspects of Electrochemistry," Vol. 3, J. O'M. Bockris and B. E. Conway, Editors, p. 233, Eq. [6], Butterworths, London (1964); A. D. Graves, G. J. Hills, and D. Inman, "Advances in Electrochemistry," Vol. IV, P. Delahay, Editor, p. 116, Eq. [34] and [35], Interscience Publishers (1966).

$J_f - \eta$  relationship are possible<sup>3,4</sup> depending on the convention chosen. The sign to be adopted for  $C \frac{d\eta}{dt}$  is also dependent on this. A working rule can be that the sign of  $C \frac{d\eta}{dt}$  is the same as the sign of  $(\partial J_f / \partial \eta)$ :

(B) To explain how the authors are able to compare their solution favorably with that of Karasyk, it should be pointed out that their results (Eq. [6], p. 811) is not the solution of their equation (Eq. [5], p. 811) but is a solution of the corrected equation! As a matter of fact, the solution of Nanis and Javet's equation turns out to be

$$\eta = \frac{RT}{\alpha ZF} \ln \left[ \frac{\exp\left[\frac{\alpha ZF(J_o + J_T)t}{RTC}\right] + \frac{J_o}{J_T}}{1 + J_o/J_T} \right] \quad [5]$$

(Note the behavior of  $\eta$  with  $t \rightarrow \infty$ ). The proper  $\eta - t$  is, of course, that given by Karasyk. (C) Equation [10] of the authors is also to be modified as

$$\begin{aligned} & C_o b \eta + C_1 b \eta^2 + \ln(1 - I e^{-b\eta}) \\ & \cdot (C_o + 2C_1 \eta) - C_o \ln(1 - I) \\ & + \frac{2C_1}{b} [L_2(I) - L_2(I e^{-b\eta})] = -\frac{\alpha ZF(J_o + J_T)t}{RT}; \alpha \approx 1 \end{aligned} \quad [6]$$

where

$$L_2(Z) = \sum_{n=1}^{\infty} Z^n / n^2 \quad [7]$$

is Euler's dilogarithm.

We hasten to add that Eq. [6] is a solution of the corrected equation, *viz.*, Eq. [4] given above, and not the equation purported to be solved by the authors.

The extension to the condition  $\alpha \neq 1$  is direct.

<sup>3</sup> S. K. Rangarajan and K. S. G. Doss, *Electrochem. Acta.*, **7**, 201 (1962). A misprint in the definitions of  $C_{21}$  and  $C_{22}$  is to be corrected. Read under  $C_{21}$ ,  $C_{22}$  columns in Table I "net current taken as positive when anodic."

<sup>4</sup> S. K. Rangarajan and K. S. G. Doss, *Bull. of Nat. Inst. Sci. (India)*, **29**, 120 (1961)

Fig. 2. Diagram of the apparatus used to study the anodic oxidation of methanol in deaerated acid solution which incorporates the specimen holder shown in Fig. 1: A, polarization cell; B, reference electrode; C, mercury safety valve; D, nitrogen deoxygenator; E, preelectrolysis cell(s); F, nitrogen gas scrubber; G, electrolyte scrubber; H, heat exchanger; J, enclosed flow inducer; K, seals to atmosphere; L, specimen holder; < gas flow; << electrolyte flow.

and out of the cell to the gas scrubbers. Diffusion of any generated gases to the specimen was thereby made more difficult.

Figure 2 shows a typical arrangement utilizing these holders. In this particular figure the apparatus was built to study the anodic oxidation of methanol in deaerated, acid solutions. While one holder was in use in the apparatus another was being cleaned, and assembled ready for the next specimen.

**W. D. France, Jr.<sup>8</sup>:** The author appreciates the interest E. W. Brooman has shown in our specimen holder for precise polarization measurements on metal sheets and foils. However, several comments regarding the design that Brooman is publishing in this discussion section are pertinent. Apparently his assembly leaks around the specimen when the Teflon deforms at this interface since a silicone rubber gasket (F) is placed behind the specimen (E). Unfortunately such solution leakage causes crevice effects and can result in erroneous data.<sup>8</sup> We avoided this problem by using polycarbonate and a replaceable Teflon gasket in front of the specimen. Also, unlike our published design, the holder suggested by Brooman provides a horizontal cavity that will accumulate corrosion products on the specimen. Such an occurrence becomes rather critical here due to the proximity of the capillary orifice (D) for potential measurement and control. Additional advantages of our holder include rapid and effective assembly and accommodation in conventional polarization cells, such as the one proposed by Greene,<sup>9</sup> which is available commercially<sup>10</sup> and is used in many electrochemistry and corrosion laboratories.<sup>11</sup> Although the versatility of Brooman's alternative design is somewhat limited, we have found the miniaturization of the electrochemical cell interesting and are pleased that features of our specimen holder were an integral part of this assembly.

## Adherence and Porosity in Ion Plated Gold

C. F. Schroeder and J. E. McDonald  
(pp. 889-892, Vol. 114, No. 9)

**John L. Miles<sup>12</sup>:** The name of "ion plating" given to the process developed by Mattox<sup>13-17</sup> seems to me to be somewhat misleading. Electroplating could reasonably be called ion plating since only positively charged current carriers are plated out. However, taking the figures from footnote 17 we see that this is far from being the case in "ion plating." The rate of deposition of gold is  $2 \mu/\text{min}$  at a current density of  $0.5 \text{ ma}/\text{cm}^2$ . With the liberal assumption that half of this current is carried by gold ions Faraday's law shows that only 1% of the deposited gold atoms are ionized. The calculated amount of charged gold reaching the cathode cannot be increased by assuming the formation of ionic dimers, since the  $\text{Au}_2$  content of gold vapor has been shown to be about 0.1%.<sup>18</sup>

Thus, although the good adherence of deposited films results from ion bombardment, the excellent throwing power of the method is virtually independent of the presence of ions. These points were readily demonstrated by performing an ion plating experiment in argon with the workpiece unconnected to the cathode and not in the cathode dark space of the glow discharge. It is clearly the scattering of the gold atoms due to their short mean free path in the argon environment rather than electrostatic attraction which causes fairly uniform coatings to form on irregularly shaped workpieces. "Scatter plating" would seem to be a more logical and less misleading name for this process. (Support for this work by Greenfield Components Corporation is gratefully acknowledged.)

**Donald M. Mattox<sup>19</sup>:** The authors of the referenced paper have asked me to reply to the letter expressing criticism of the term "ion plating." I must confess that the name ion plating for this process began as a colloquialism, but since everything must be called something it has gradually gained some acceptance as a name, at least on an informal basis. The name is generally applied to a process in which the substrate is being bombarded by a flux of high energy ions sufficient to cause appreciable sputtering both before and during the actual deposition. The necessary flux depends on the substrate material, gas discharge conditions, and contamination in the system.

It is felt that the principal benefits obtained by the ion plating process are: (a) the ability to sputter clean the surface and maintain it "clean" until the first monolayer of film material is formed; (b) provide a high energy flux to the substrate surface thus enhancing diffusion, chemical reaction, etc., and (c) alter the surface and interfacial structure and thus change the interaction mechanisms and rates. The principal useful result seems to be obtaining good adherence in systems where other techniques do not work because of barrier layers, insoluble materials, etc.

I agree that the actual ionization of gold atoms is probably of little consequence, but I don't think that the term "ion plating" is any more misleading than most other terms applied to deposition techniques. As a matter of fact, most names for deposition techniques seem to apply to the environment, i.e., vacuum deposition, plasma spraying, chemical vapor deposition, rather than what actually happens to the depositing material.

As to the throwing power of the ion plating process, I am inclined to think that an entrainment mechanism

<sup>12</sup> Arthur D. Little, Inc., Acorn Park, Cambridge, Mass.

<sup>19</sup> Ceramics and Surface Physics Division, Sandia Corp., Sandia Base, Albuquerque N. M.

in the gas discharge is more important than the scattering. If one does the deposition in a gas atmosphere without the discharge, one obtains a finely divided particulate deposit which has little structural integrity and obtains a lower deposition efficiency than is obtained with the gas discharge present.

In summary I would like to say that since the process has some defining characteristics, however nebulous they may be, it does deserve a name and that "ion plating" is as good as any and more lyrical than most.

### Investigations of Electrocrystallization at Silver Electrodes

W. M. Krebs and D. K. Roe (pp. 892-899, Vol. 114, No. 9)

**D. J. Astley and J. H. Harrison**<sup>20</sup>: In the paper by Krebs and Roe the authors postulated that the formation of nuclei weakly bound to the underlying substrate may be involved in the electrocrystallization of Ag on an Ag single crystal. The experiment consisted of sweeping the potential anodic from the reversible potential then cathodic and anodic again. Figure 4 of their paper shows an anodic current peak corresponding to the dissolution of the nuclei before the main anodic dissolution of the substrate.

However, Budewski *et al.*<sup>21</sup> were unable to find evidence for nucleation on crystals which had a large number of dislocations. It did occur to us that it might be possible to reproduce the sweep curves of Krebs and Roe by a qualitative argument as follows. In a potentiostatic sweep experiment starting from a stationary cathodic current an anodic current peak would be observed before the main dissolution if the rate of change of  $C^0$ , the  $Ag^+$  concentration at the surface, outstripped the supply of material by diffusion from the bulk of solution, Fig. 1a, 1b, and 1c. To test this hypothesis sweep curves for the metal deposition case were calculated assuming the Nernst equation between the silver ions at the interface and the metal which has an activity ( ) = 1 because of the large number of lattice building positions, and solving

$$\frac{\partial C}{\partial t} = D \left( \frac{\partial^2 C}{\partial x^2} \right) \quad \dots [1]$$

with the appropriate conditions:

$$\begin{aligned} C^0 &= C^* \exp[-zF(\eta_i + wt)/RT]; \\ x &= \delta, \quad C = C^*; \\ i &= 2FAD(\partial C/\partial x)_{x=0} \end{aligned}$$

where  $C^*$  is the bulk silver concentration and the other symbols are usual,  $\eta$  positive for cathodic overpotential. This was solved by a finite difference method<sup>22</sup> by digital computation. The theoretical curves are shown in Fig. 2. These have been calculated by starting at  $t = 0$  with a stationary anodic current, and sweeping cathodic and back again, which essentially reproduces the Krebs and Roe experiment. The curves have some interesting features. The expected peaks only show as small inflections on the anodic going current. At sweeps slower than  $10 \text{ mv sec}^{-1}$  (not shown in Fig. 2) the anodic and cathodic going currents between  $\eta = +10$  and  $-20$  mv superimpose without hysteresis, and the currents are fairly linear with potential (or time) and pass through the point  $\eta = 0$ .

Experimental and calculated data is shown in Fig. 3 for an electropolished Ag single crystal in  $0.01M \text{ Ag}(\text{ClO}_4)$  in  $1M \text{ HClO}_4$  at  $100 \text{ mv sec}^{-1}$  sweep rate with gas bubbling to maintain a Nernst diffusion layer. The fit of the two curves is reasonable. At slow sweeps the curves superimpose without any sign of a

maximum. The essential difference between our measurements and those of Krebs and Roe is that their cell arrangement consisted of a spherical Ag single crystal (formed by melting) in contact with a small drop of the  $\text{Ag}^+$  solution. It would seem to us that this arrangement is liable to changes in contact angle and consequently electrode area with change in potential.

A comparison of the calculated curves with the data of Krebs and Roe shows that, assuming  $\delta = 10^{-3}$  cm, their currents are very much lower (by more than a factor of 10) in the cathodic region and it is clear that the anodic region is very much passivated. It would seem that two possibilities could explain this behavior; either the surface has few dislocations in it or the active sites at dislocations have become blocked by adsorption of impurities. It seems unlikely that few dislocations could be achieved by melting. In any case dissolution at dislocations to form etch pits and the reverse process on deposition would only affect the above theory by making the curves increase more steeply with time during the anodic sweep with no maximum. The second possibility would require nucleation during the cathodic sweep.

At low sweep rates the currents should in any case pass through the  $i$ - $\eta$  origin. Our electrodes behave exactly as a reversible system. It must be concluded that the surfaces of Krebs and Roe were not typical. It seems likely that their surfaces were severely inhibited.

**W. Michael Krebs<sup>23</sup> and David K. Roe<sup>24</sup>:** It has been shown previously that under certain conditions, silver, freshly deposited on a silver substrate, appears to be more labile than the substrate. This was clearly revealed by a series of cyclic current-voltage curves in which anodic peaks appeared following cathodic polarization, but not before. Furthermore, the charge represented by the anodic peaks was found to agree quantitatively with the amount of silver deposited during the immediately preceding cathodic scan. These measurements were made using a probe technique to form a bridge of electrolyte between bulk electrolyte, containing the silver reference-counter electrode, and selected areas on a spherical silver single crystal, as has been described in the paper under discussion. The measurements under discussion were carried out on stepped regions surrounding the (111) facets. Astley and Harrison have attempted to explain the anodic stripping peak phenomenon in terms of the  $\text{Ag}^+$  concentration profile resulting from the cathodic-anodic sequence. Their calculations, however, are based on stirred solution resulting in a Nernst diffusion layer of constant thickness. This is at variance with our experimental conditions in which stirring was not employed nor even possible due to the unusual cell configuration.

The fact that their calculations predict no hysteresis at low scan rates is sufficient to discount such a hypothesis. In addition, a simple consideration of the time intervals involved in our measurements at low scan rates (0.1-10 mv/sec) is sufficient to demonstrate the inapplicability of a mechanism which necessarily assumes large and sharp concentration gradients.

It is rather surprising that Astley and Harrison make a point of comparing current densities, noting that those observed by us are a power of ten lower than theirs, since one of the main points of our work is that deposition on the stepped regions does not proceed in a layer-like fashion, but that it commences at active sites on the step edges giving rise to the hemispherical or mound-shaped deposits revealed in Fig. 3a, b, of the discussed paper. The actual active electrode area is, therefore, very much smaller than electrolyte contact area in the initial stages of depo-

sition, and is continually changing. This is true for both the cathodic process and the anodic process, although substrate removal does contribute increasingly as the potential becomes more anodic. It is this assumption of constantly changing electrode area which is essential to the derivations presented in the paper under discussion, and the evidence for mound-like discontinuous growth is clearly shown in the photomicrographs.

The derivations do not include any reference to simultaneous substrate removal, thus making it unnecessary to define the activity of the deposit with respect to the substrate. It would be difficult to incorporate such a parameter in the derivation since an *a priori* assignment of deposit activity, and its variation with coverage, would have to be made. It was, therefore, decided that the least ambiguous method of attack was to treat the deposit alone, thus assuming the electrochemical behavior of the substrate to be unchanged. In comparing calculated with experimental curves, the substrate contribution was subtracted out of the latter using the initial anodic curve (before any deposition). This initial anodic curve could be reproduced fairly well by repeating the anodic scan after stripping off the deposit.

Budewski *et al.*,<sup>25</sup> have shown that nearly dislocation free (111) facets of silver can be prepared by growing the crystal electrolytically. We claim the same perfection for our thermally prepared (111) facets. Similar measurements made exclusively on these facets, to be presented in a future paper, reveal that up to 60 mv overvoltage is required before deposition commences, indicating a pronounced paucity of growth sites. In addition, double layer capacity measurements yield values which are consistent with those obtained by other workers<sup>26</sup> suggesting that both their surfaces and ours were either equally clean or equally contaminated. The fact that the faces of the steps are parallel to the facet, and possibly of the same perfection, could explain deposition being preferentially restricted to the edges of these steps.

The reproducibility of cyclic current voltage curves exhibiting stripping behavior furnishes additional evidence that contamination is of minimal importance, if any at all. In addition, the much more favorable electrode area/electrolyte volume, noted in the original paper, tends to decrease accordingly the susceptibility of the system to impurities.

Cyclic curves which were obtained on random areas of the silver crystals, areas on which faceting was not present, showed no hysteresis. These regions undoubtedly consist of micro steps, which were, however, not observable and approximate a polycrystalline specimen. Indeed, there was little difference between curves obtained on random areas of single crystal samples and those measured on polycrystalline specimens of silver. This is the behavior expected for a surface containing many growth sites.

### Effect of Hydrogen Absorbed by Electrode and Electrolyte on Hydrogen Coverage

D. J. BenDaniel and F. G. Will (pp. 909-915, Vol. 114, No. 9; pp. 1271-1272, Vol. 114, No. 12); S. Schuldiner (pp. 916-917, Vol. 114, No. 9)

**G. Dubpernell<sup>27</sup>:** The continued insistence on a small and functional solubility of hydrogen in platinum at room temperature seems something of a travesty on the ever increasing need to convert electrochemistry from an art to a science. Some facts which should be considered more seriously than in the past are listed below.

1. The solubility determinations at high temperatures clearly show that there is no appreciable solu-

<sup>24</sup> Present address: Oregon Graduate Center, Portland, Oregon.

bility at room temperature. Thus Sieverts and Jurisch [BenDaniel and Will's ref. (7)] determined the relatively small solubility of hydrogen in platinum at temperatures of 827°-1342°C. A determination of the solubility at 409°C was considered uncertain because of its smallness. Efforts to determine a solubility at room temperature were fruitless, and Sieverts and Jurisch concluded that "compact platinum does not dissolve any measurable quantity of hydrogen at room temperature."

Sieverts and Jurisch plotted their results for the solubility of hydrogen in platinum in such a way that they showed a zero solubility at 800°C. Schuldiner's ref. (8) (D. P. Smith, "Hydrogen in Metals," 1948) replots the Sieverts and Jurisch data in such a way as to indicate zero solubility at 600° or 400°C (p. 35). If the five best measurements made by Sieverts and Jurisch are plotted on a logarithmic scale they give a reasonably good straight line plot which can easily be extrapolated from 800°C down to room temperature. Such an extrapolation would seem to indicate a solubility at room temperature of about  $28 \times 10^{-10}$  grams of hydrogen per gram of platinum ( $3 \times 10^{-8}$  moles  $H_2/cm^3$  Pt) if this figure has any meaning. In their discussion, BenDaniel and Will give much lower figures, but do not make clear their method of extrapolation.

2. BenDaniel and Will's ref. (8) (the Smithell's book of 1937) contains a description on p. 148 of an experiment by Berry based on the fact that platinum will not absorb any electrolytic hydrogen evolved on it in 5% sulfuric acid solution at 6 ma/cm<sup>2</sup>.

3. BenDaniel and Will give five references (9-13) to the older work on the solubility and diffusion coefficient of electrolytic hydrogen through platinum membranes near room temperature. A comprehensive survey of such work on the permeability of metal membranes was made in 1933<sup>28</sup>, including these five references and many others. It was concluded from this survey and the experimental work done that ". . . electromotively active hydrogen and oxygen do not diffuse through solid metals."

4. Schuldiner [ref. (3)] points out that several workers have found that hydrogen does not diffuse through platinum membranes if they are clean or if the sulfuric acid electrolyte used is pure. If hydrogen has any solubility in platinum at room temperature it should certainly be evident under these conditions. Since the lack of any diffusion or solubility under these conditions is accepted, there can hardly be diffusion under other conditions unless they include damage to the membrane.

5. Schuldiner [ref. (8)] refers to Professor D. P. Smith's book on the extremely low solubility at 400°C, and yet fails to consider the solubility at room temperature as essentially zero. Professor Smith discusses cathodic occlusion by platinum on pp. 79-80 and concludes: "Nearly all indications point to a real, but extremely small, occlusion at ordinary temperatures and to the probability that this is purely rift occlusion unaccompanied by any appreciable solubility in the undisturbed lattice."

Again in a personal communication in 1949 Professor Smith said: "We certainly seem to be in agreement as to the lack of solubility, in the sense of interstitial distribution of hydrogen, in the lattices of platinum and other metals which absorb hydrogen endothermically, and the view that hydrogen (and oxygen) pass through these metals by way of some sort of crevice; although I may perhaps go farther than you would care to accompany me in considering the crevices ("rifts") something else than mere accidental defects in the lattice."

Surely the theory of the hydrogen electrode behavior can be developed on the basis of the physical

and chemical surface properties of the metal, without insisting on some solubility of hydrogen in the lattice at room temperature.

**F. G. Will and D. J. BenDaniel:** While Dr. Dubpernell does not dispute that hydrogen is slightly soluble in platinum at elevated temperatures (i.e., between 827° and 1342°C), he maintains that the solubility at room temperature is "essentially zero." In fact, Dr. Dubpernell<sup>29</sup> restates his conclusion from an earlier literature survey and his own work on platinum and palladium that "electromotively active hydrogen and oxygen do not diffuse through solid metals."

This view is particularly surprising with respect to the permeation of electrolytically evolved hydrogen through palladium. The solubility and diffusivity of hydrogen in this metal are so large, even at temperatures below 100°C, that they have been established beyond doubt by a large number of investigators [compare ref. (14-18), (20, 21) of our rebuttal].<sup>30</sup>

Since the permeation rates of hydrogen through platinum are about 4 orders of magnitude smaller than through palladium, it is understandable that relatively few investigators have been able to establish unambiguously the diffusion of hydrogen through platinum. For the purpose of our discussion here, we may disregard older work on the subject [earlier ref. (11) and (20-23) in our rebuttal] and only consider the recent findings of Vetter [earlier ref. (12)] and Gileadi *et al.* [earlier ref. (13)].

Certainly, there is some disagreement with respect to the exact magnitude of solubility ( $10^{-5}$  moles  $H_2/cm^3$  Pt at 25°C vs.  $2 \cdot 10^{-6}$  moles/cm<sup>3</sup> at 70°) and diffusivity ( $3 \cdot 10^{-8}$  cm<sup>2</sup>/sec at 25°C vs.  $10^{-18}$  cm<sup>2</sup>/sec at 70°). However, in permeation studies such disagreement is not uncommon, due to the difficulties in producing similar states of the surface and the metal texture. Most strikingly, both investigators find that (a) the steady-state permeation rates are inversely proportional to the thickness of the platinum foils and (b) the half-rise times of the permeation transients are proportional to the square of the thickness. This behavior is typical for a diffusion process, and it is difficult for us to see how it can be interpreted on any other reasonable basis.

We will now comment on some remaining specific points of Dr. Dubpernell.

1. With regard to our method of extrapolation, we plotted Sieverts' original data [earlier ref. (27)] in the usual semi-log plot, i.e., the logarithm of the solubility against 1/T, and extrapolated the resulting straight line (between 1033 and 1342°C) to 25°C. Thus, we arrived at a solubility of  $4 \cdot 10^{-17}$  moles  $H_2/cm^3$  Pt. This extremely low value was discarded for the purpose of our analysis. Parenthetically, Dr. Dubpernell, in extrapolating Sieverts' data, finds a value which is 9 orders of magnitude higher than ours. This might be due to an error in his conversion of the unit mgH<sub>2</sub>/100 gPt, as used by Sieverts, into moles  $H_2/cm^3$  Pt.

2. Berry<sup>31</sup> merely measured the occlusion of hydrogen by Pd-Au alloys by forming the difference in the amounts of hydrogen evolved by the same current from a Pd-Au cathode and a Pt cathode. He did not concern himself with H<sub>2</sub> absorption by Pt. The volumes occluded by the alloys were found to range from 5 to 150 cm<sup>3</sup>H<sub>2</sub>/g alloy. The corresponding volume absorbed by Pt is only 0.01 cm<sup>3</sup>H<sub>2</sub>/g Pt (based on Vetter's solubility data which we used in our analysis). Hence, Berry's implicit assumption that the absorption of H<sub>2</sub> by Pt can be neglected in his experiments is fully justified. But this assumption can hardly be interpreted as a "fact that platinum will not absorb any electrolytic hydrogen."

<sup>28</sup> G. Dubpernell, "The Mechanism of the Penetration of Electrolytic Polarization Through Thin Metal Sheets," Dissertation, University of Michigan, 1933; A. L. Ferguson and G. Dubpernell, *Trans. Electrochem. Soc.*, **64**, 221 (1933).

<sup>29</sup> A. L. Ferguson and G. Dubpernell, *Trans. Electrochem. Soc.*, **64**, 221 (1933).

<sup>30</sup> F. G. Will and D. J. BenDaniel, *This Journal*, **114**, 1271 (1967).

<sup>31</sup> A. J. Berry, *J. Chem. Soc.*, **99**, 463 (1911).

Point 3 of the discussion has already been answered, points 4 and 5 are not addressed to us.

Finally, with regard to Dr. Dubpernell's concluding remark, we state that our analysis, based on diffusion of hydrogen into platinum, leads to a quantitative interpretation of recent transient measurements on platinum by Schuldiner and Warner [earlier ref. (25)]. Surely, we welcome any alternate quantitative interpretation of those experimental findings.

### Two Remarks on the Resistive Contribution to Overpotential

Benson R. Sundheim (pp. 158-160, Vol. 115, No. 2)

**R. Piontelli**<sup>32</sup>: This paper recalls very opportunely the attention of the experimental electrochemists to the existence and importance of the systematic errors involved in overvoltage measurements by means of the Luggin-Haber capillary.

This matter has been dealt with in great detail in a large number of papers from this laboratory.<sup>33</sup>

The experiments carried out to prove the theoretical conclusions have fully confirmed the quantitative importance of the systematic errors introduced when the screen-effect is exasperated, the Luggin-Haber capillary being very near or pressed against the electrode surface.

Our research work has led also to the realization of arrangements, suitable for reducing the systematic errors to a very acceptable minimum.

The principle of these arrangements is recalled in Fig. 1. in which also the traces on the drawing plane of the equipotential surfaces<sup>34</sup>, together with the ones of the current lines, are represented.

The problem of eliminating the "resistive contribution," without introducing "shielding effects" has found, therefore, practical solutions.

According to the practice of this Laboratory (for more than 18 years), in all of the cases in which the electrode material must be treated by a careful policy, the "side-channel capillary" (Fig. 1a) is especially suitable. On a regular surface this capillary leads to a very efficient shielding of the underlying surface, while reducing the resistive contribution to that of just a solution layer of (10/40)  $\mu$ .

The only restriction in the application of this device concerns the cases in which the electrode surface undergoes strong passivation phenomena, by formation of covering layers.

In these cases, the eventual intervention of "crevice effects" must be taken into account.

In view of the strong equivalent resistance of the layers themselves, and of the improved throwing power of the anodic process, however, one may then

<sup>34</sup> Experimentally determined on models. Also the essentially "operative meaning" of these equipotential surfaces is discussed in the above mentioned papers.

simply displace the probe from the electrode surface in the order of 1 to 2 mm, neglecting or correcting the ohmic drop contribution to the measured overvoltage.

The parasitic capacitive effect, involved by very quick measurements, may be reasonably reduced by using a double wall probe.

In many cases also an arrangement of the type indicated in Fig. 1c may correspond to practical requirements.<sup>35</sup>

Of course, the extremely short time-constant of the resistive contribution to the overvoltage allows its correction or direct compensation<sup>36</sup>, a route which we too are following in the overvoltage measurements on liquid metal electrodes, especially in melts<sup>37</sup>, when the arrangements above cannot be applied.

In the very numerous cases in which the so-called "classical techniques" for measuring the overvoltages are still the most reliable, exhaustive, and adequate in giving information on practical problems, the cell geometry and thus the capillary form and placement deserve the most careful attention by the experimental electrochemist.

The compatibility of these requirements with those of a careful prepurification of the solution and eventually of the electrode surface preparation has been attained in some cell types realized here.<sup>38</sup>

### Influence of Thin Noble Metal Films on Zirconium Oxidation

A. Fiegna and P. Weisgerber (pp. 369-371, Vol. 115, No. 4)

**B. Cox**<sup>39</sup>: Fiegna and Weisgerber show ignorance not only of previous work on the effect of evaporated metal contacts on the oxidation of zirconium, but also of previous studies of the oxidation of zirconium in water vapor. Although experiments in water vapor are not numerous, there are at least two sources of directly comparable data<sup>40,41</sup> and a further two studies at higher temperatures.<sup>42,43</sup> However, whilst they may perhaps be forgiven for failing to locate these references, they should have been aware of the previous instances where enhanced oxidation of zirconium resulted from contact with noble metals<sup>44-46</sup> since this is the primary subject of their study.

In this respect their results agree with previous studies<sup>46</sup> which showed no enhancement of the oxidation rate in oxygen for thin gold films, but a large increase in oxidation rate for thicker films. The reasons for this discrepancy may become evident if we consider the possible explanations of the phenomenon.

Fig. 1. M = electrode material;  $\Sigma$  = capillary; heavy full lines = traces of the equipotential surfaces; interrupted lines = current lines; (a) side channel capillary; (b) back capillary; and (c) back capillary occluded.

The explanations offered by the authors make the *a priori* assumption that only transport of oxygen through the oxide is important in the oxidation of zirconium. Thus, they ignore the reverse electronic current and the effect which a conducting surface layer might have on it. Recent evidence<sup>47</sup> has shown that the electronic current flows at only a few sites in the oxide ( $\sim 10^2/\text{cm}^2$ ) on zirconium. These sites have been tentatively related to local segregation of impurities, by analogy with Zircaloy-2, where the  $\sim 10^4$  sites/ $\text{cm}^2$  for electronic conduction have been positively identified with the sites of second phase particles resulting from the alloying additions. Since iron is generally the most prominent transition metal impurity in crystal-bar zirconium, this metal is possibly the source of the conducting impurities in this case too.

The ionic transport process is, by comparison, far more uniform, although it proceeds by the transport of oxygen ions through the poorly crystalline (or amorphous) matrix between the monoclinic  $\text{ZrO}_2$  crystallites.<sup>48,49</sup> Recent studies have shown that when  $\text{O}^{17}$  is diffused into an oxide formed in  $\text{O}^{16}$  saturation is not attained at the oxide-gas interface.<sup>48</sup> Thus, the process occurring at this interface is apparently slow compared with the inward diffusion of oxygen. The over-all process occurring at this interface in oxygen is given by

Thus the presence of not only oxygen vacancies but also electrons is required at the points of oxygen entry (i.e., oxide crystallite boundaries).

Since the electrons are transported through the oxide film at a relatively few flaws they must reach the reaction site by surface diffusion. This surface diffusion may be the slow step which results in the failure to maintain equilibrium at the outer oxide interface. Any process which speeded up surface diffusion would permit the fraction of mobile oxygen atoms at the surface to approach saturation. The oxygen concentration at the inner interface will be set independently by the conditions of equilibrium at this interface, and, therefore, an increase in the boundary concentration of mobile oxygen at the outer interface will result in an increase in the diffusion of oxygen ions through the oxide, and hence an increase of the oxidation rate.

However, this explanation predicts that any metal film continuous enough to give good surface conductivity would result in an increase in the oxidation rate. This was not found by the authors for either silver or gold contacts in oxygen, and possibly not in water vapor either since their oxidation rate for the uncoated specimen is apparently a factor of two lower than would be expected.<sup>40,41</sup> Draley *et al.*, did observe enhanced attack with thick, but not thin, gold contacts<sup>44,46</sup> in line with the above prediction. The significant feature of the gold contacts used by Fiegna and Weisgerber is probably the thickness,  $\sim 300\text{\AA}$ , compared with contacts  $\sim 6400\text{\AA}$  thick which gave enhanced oxidation at Argonne National Laboratory.

In addition to the observation by Fiegna and Weisgerber of diffusion of gold into growing zirconia films, earlier work by Dalgaard which demonstrated physical welding of gold probes onto growing zirconia films<sup>45</sup> gave positive evidence for this phenomenon. Thus it is possible that following diffusion of the thin gold films into the oxide there was insufficient change in surface conduction to result in an increase in the oxidation rate. This could be checked by varying the initial thickness of evaporated metal. The increase effected by the platinum contact in oxygen may result

from a greater surface conductivity during oxidation in this instance.

The difference between the apparent behavior of metallic contacts in oxygen and water vapor may result from an error in the curve for the uncoated zirconium specimens in water vapor. Other studies<sup>40,41</sup> predict a weight gain about twice as high in water vapor, and indicate little difference between the oxidation curves for oxygen and water vapor at low pressures.<sup>41-43</sup> The authors do not indicate whether the curves they report were repeated, or what was the reproducibility of their results in water vapor.

**A. Fiegna and P. Weisgerber:** Our oxidations in oxygen and in water vapor were made several times and final weight gains never differed more than 10%.

But it is a common experience with oxidation of pure metals that deviations of a factor of 2 and more are to be expected, if factors as the purity grade of the reactants, the method of specimen and surface preparation, or temperature gradients in the reaction zone are not standardized.

Because of the important influence of these conditions, it seems unduly to conclude errors in our experiments because they differ by a factor of 2 from data found elsewhere. Moreover, the data Cox cited were found not only under different experimental conditions as mentioned but also with different parameters as temperature, vapor pressure, and reaction time so that additional uncertainties have to be taken into account which result from errors of the rather complex extrapolations.

As final conclusion it is to say that our experimental data from oxidation of gold and silver coated zirconium in oxygen do not fulfill the prediction derived from the theory of Cox, that increased reaction rates result from increased surface conductivity of electrons.

### The Standard Potential of the Silver-Silver Chloride Electrode in N-N Dimethylacetamide at 25°C

B. Scrosati, G. Pecci, and G. Pistoia  
(pp. 506-507, Vol. 115, No. 5)

**Robert S. Alwitt<sup>50</sup>:** The authors claim to have determined  $E^\circ$  for the  $\text{AgCl}/\text{Ag}$  electrode in dimethylacetamide (DMA) by using the same classical techniques that have proved so successful when working with protic solvents such as water, alcohols, formamide<sup>51</sup>, and N-methylacetamide.<sup>52</sup> However, dipolar aprotic solvents, such as DMA, have some properties very different from protic solvents<sup>53</sup> and the same experimental techniques cannot necessarily be applied. The two factors that require the closest attention are indicated below.

1. Hydrogen chloride is a weak acid in aprotic solvents. For example, the  $\text{pK}_a$  of  $\text{HCl}$  at 25°C is 3.55 in dimethylformamide (DMF) and 8.94 in acetonitrile.<sup>53</sup> The authors treat their data as if  $\text{HCl}$  were completely dissociated in DMA solutions. Did they verify this by independent measurements?

2. Silver chloride is soluble in DMF to the extent of about 0.01g/100g DMF<sup>54</sup>, and is quite soluble in other aprotic solvents in the presence of excess chloride.<sup>55</sup> It is obviously undesirable to use a  $\text{AgCl}/\text{Ag}$  reference electrode in solutions in which  $\text{AgCl}$  has appreciable solubility. Did the authors find that  $\text{AgCl}$  was insoluble in solutions of  $\text{HCl}$  in DMA?

The authors report a slope of  $-0.640$  for a plot of  $E'$  vs.  $m_{\text{HCl}}$ . This is a considerably larger slope than is usually obtained for such a plot. For the same cell as used by the authors, but with other solvents, this slope has been reported as  $-0.08$  with water<sup>56</sup>,  $-0.05$  with formamide<sup>51</sup>, and  $-0.03$  with N-methylacetamide<sup>52</sup>. A plot of  $E'$  vs.  $m$  is used to make essentially second-order corrections to the value of  $E^\circ$ , and would be

<sup>56</sup> R. A. Robinson and R. H. Stokes, "Electrolyte Solutions," 2nd Ed., p. 192, Butterworths, London (1959).

expected to have a small slope. We suggest that the factors discussed above contribute to the large slope that was obtained.

This seems a suitable place to report an observation made in our laboratory when trying to measure pH in DMF solutions. We found that general purpose glass electrodes (0-11 pH range) did not behave reversibly in DMF solutions. An E2 glass electrode recommended for alkaline conditions (Coleman 3-424) was found to be reversible, as demonstrated by a response of 59 mv per decade change in hydrogen ion concentration.

### ABSTRACT

The electrical conductivity of an ion exchange membrane containing polystyrenesulfonic acid was studied as a function of two primary variables: temperature and extent of water absorption. The conductivity of dry membrane obeys an Arrhenius relation in the range of  $28^\circ < T < 55^\circ\text{C}$  with an activation energy of approximately 1 ev. A semi-empirical equation was derived to predict the variation of conductivity with water absorption. This equation gives a good description of the data over a range of 7 orders of magnitude ( $10^{-8} < \sigma < 10^{-1} \text{ ohm}^{-1}\text{-cm}^{-1}$ ). The net volume change accompanying water absorption was also measured and its behavior can be qualitatively correlated to that of conductivity.

The study of electrical conductivity and other transport properties in polar polymers has long been of interest. Early studies on the conductivity of textile fibers (1-4) have been extended by now to a variety of biological polymers (5, 6). In these experiments, the nature of the charge carriers is often a major question, and the role of absorbed water is very important. The development of ion exchange materials has led to a consideration of similar problems in these highly ionic polymers (7). Conductivity and diffusion coefficient studies have been made on bead and rod samples of these polymers (8-11) and also on ion exchange membranes containing them (12-15). In addition, the important role of water in the transport and selectivity properties of such materials gave rise to some rather thorough investigations into the thermodynamics of the water absorption process for cross-linked polystyrenesulfonic acid (16-19). However, the exact details of the transport processes are still not totally understood (7, 20).

We report here an experimental and theoretical study of the electrical conductivity of a polystyrenesulfonic acid ion exchange membrane. The membrane was not immersed in solution, as in most previous investigations, but was exposed to varying partial pressures of water vapor. The extent of water absorption was varied from complete dryness to saturation, a broader range than has previously been studied with regard to ion exchange membranes. The effects of temperature, applied voltage, and duration of current flow were also investigated.

A theoretical analysis was made in order to predict the effect of water absorption on conductivity. Several treatments of this kind have been made previously. Among them are attempts to correlate changes in conductivity with the dielectric constant (3, 5, 14), gaps in water pathways for conduction (4), and the viscosity of "pore" fluid (4, 9). Only the first approach is reasonable for describing an ion exchange membrane over broad ranges of water absorption, and it requires a knowledge of both the dielectric constant and a somewhat indefinite polarization radius about the charge carriers in order to predict conductivity. We have therefore tried a new approach which makes use of the theory of absolute reaction rates (21). The conduction and absorption processes are linked via the free energy of absorption, and the semi-empirical equations so derived are in reasonably good agreement with experimental results.

**Key words:** Absorption of water, activation energy, electrical conductivity, free energy of absorption, free energy of activation, ion exchanging substances, membrane, sulfonated styrene polymers, sulfuric acid, conductivity volume.

<sup>2</sup>Present address: Polymer Research Institute and Department of Chemical Engineering, Polytechnic Institute of Brooklyn, Brooklyn, New York.

As a further aid in understanding the relationship between conduction and water absorption, we have measured the net volume change for absorption. This quantity is qualitatively correlated with conduction via a hydration sphere model.

The ion exchange membrane selected for study consisted of approximately 25% by weight of polystyrenesulfonic acid (PSA) supported in a matrix of polyethylene. We assume that the effects of the polyethylene matrix on conductivity are only indirect (separating adjacent PSA molecules or reducing the effective dielectric constant, for example) in view of its very low conductivity in the pure state (approximately  $10^8$  less than the smallest membrane conductivity measured). Therefore, the conduction mechanism will be primarily related to properties of the PSA molecule.

The electrode reactions that are believed to occur in water-saturated cross-linked PSA are (8):

In the absolutely dry membrane (if such a state can be achieved without degradation) these reactions would be impossible. Although other electrode reactions could take place involving the oxidation of the  $\text{RSO}_3^-$  group (22), they also involve water. Therefore, at least a very small amount of water seems essential for sustained ionic conduction, and we have investigated both voltage and time variation of conductivity in order to verify this mechanism of conduction in the "dry" state obtained with our experimental conditions.

### Theory

We wish to derive an equation predicting the variation of specific conductivity with water absorption. As the indicator of water absorption, we use the moles of water absorbed per equivalent of PSA in the membrane ( $n$ ). The theory of absolute reaction rates (21) will be used to derive this equation, although it is probable that several other formalisms could be used to arrive at the same final result.

The basic "reaction" involved in conduction is assumed to be the passage of a hydrogen ion over an energy barrier between two more stable points in the membrane separated by some distance,  $\lambda$ . The rigorous application of reaction rate theory would thus require a knowledge of the statistical distribution of all possible types of ion movement (that is, a knowledge of the activation energy and jump distance for each type of motion and its relative frequency of occurrence). Such an exact treatment would automatically include abnormal hydrogen ion transport (by Grotthuss conduction). However, such knowledge is

not available for the complex polymer-water mixture under study, and we choose to use effective activation energies and jump distances to describe the motion of hydrogen ions along or between PSA molecules.

Abnormal transport thus remains as a separate problem which arises only at higher extents of water absorption. Abnormal transport in aqueous solutions has been analyzed using the theory of absolute reaction rates (23), and the results obtained for  $\sigma$  differ significantly from the assumptions above only in that a specific jump distance and free energy of activation are involved, these being connected with the reaction transferring a hydrogen ion from one water molecule to the next. We neglect abnormal conduction in the remainder of this derivation, since it cannot occur for  $n < \sim 1$  and does not occur for most cations other than  $H^+$ . It must, of course, be considered in comparing experiment and theory for the membrane at hand, however.

If we now make use of the approximate validity of the Nernst-Einstein equation relating conductivity and self-diffusion coefficient (13), reaction rate theory gives as a final result

$$\sigma = [(cq^2\lambda^2)/h] \exp[-\Delta F^\ddagger/RT] \quad [1]$$

where:  $\sigma$  = specific conductivity ( $\text{ohm}^{-1} \text{cm}^{-1}$ ),  $c$  = concentration of charge carriers ( $\text{cm}^{-3}$ ),  $q$  = electronic charge (C),  $\lambda$  = effective jump distance (cm),  $h$  = Planck's constant (J-s),  $\Delta F^\ddagger$  = effective free energy of activation (cal/mole),  $R$  = gas constant (cal/mole-°K),  $T$  = temperature (°K).

The experimental activation energy, ( $E_x$ ), can now be determined in the standard way as

$$E_x = -R \partial \ln \sigma / \partial (1/T) \quad [2]$$

This gives

$$E_x = \Delta H^\ddagger \cong \Delta E^\ddagger \quad [3]$$

where:  $\Delta H^\ddagger$  = effective enthalpy of activation (cal/mole),  $\Delta E^\ddagger$  = effective internal energy of activation (cal/mole).

Thus we arrive at an Arrhenius expression for conductivity

$$\sigma = \sigma_o \exp[-E_x/RT] \quad [4]$$

where

$$\sigma_o = [(cq^2\lambda^2)/h] \exp[\Delta S^\ddagger/R] \quad [5]$$

$\Delta S^\ddagger$  = effective entropy of activation (cal/mole - °K).

The only parameters in Eq. [1] which will be significantly affected by water absorption are  $c$  and  $\Delta F^\ddagger$ . The PSA molecule is a very rigid structure (24), and therefore the jump distance along the molecule will be little changed by absorption of water. The contribution of jumps between molecules to the conductivity is difficult to estimate, but one can make a rough calculation of the change in this jump distance as water is absorbed. The average of this distance should be roughly proportional to  $1/(c)^{1/3}$ . Since our results indicate that this latter quantity changes by only a factor of 2 in going from very dry to completely saturated membrane (whereas conductivity changes by a factor of  $10^7$ ) we will assume  $\lambda$  to be constant.

The variation of  $c$  with water absorption is due simply to the expansion of the membrane as water enters the polymer matrix. The effect of this expansion on  $\sigma$  can be termed a dilution affect.

The qualitative variation of  $\Delta F^\ddagger$  with water absorption can be deduced by using the dry membrane as a reference state and considering the changes which take place upon absorbing an average of  $n$  molecules of water per each sulfonic acid group. Let  $\sigma_D$  and  $\Delta F_D^\ddagger$  refer to the dry state. In this state the effective free energy of activation should be a maximum, since any water absorption results in partial or complete ionization of the sulfonic acid groups, thereby lowering the energy barrier for hydrogen ion motion. It has, in fact, been shown that all water molecules absorbed by cross-linked PSA in the early stages of absorption ( $0 < n < 4$ ) are attached to the hydrogen

ion in an ordered chain structure or hydration sphere (18).

A quantitative prediction of the dependence of  $\Delta F^\ddagger$  on  $n$  is rather difficult to make but a reasonable assumption proves to be that

$$\Delta F^\ddagger = \Delta F_D^\ddagger + \beta \Delta F_A \quad [6]$$

where  $\beta$  = empirical constant ( $>0$ ),  $\Delta F_A$  = free energy change for the reaction:

Since  $\Delta F_A$  is in general negative this equation shows the proper reduction in  $\Delta F^\ddagger$  with increase of  $n$ . This assumption links thermodynamically the conduction and absorption processes and implies that both  $\Delta S^\ddagger$  and  $\Delta H^\ddagger$  are altered by water absorption, in contrast to an earlier hypothesis wherein  $\Delta H^\ddagger$  was assumed to be the quantity primarily affected (14).

Combining Eq. [1] and [6] gives

$$\sigma = [(cq^2\lambda^2)/h] \exp[-(\Delta F_D^\ddagger + \beta \Delta F_A)/RT] \quad [7]$$

or, since

$$\sigma_D = [(c_D q^2 \lambda^2)/h] \exp[-\Delta F_D^\ddagger/RT] \quad [8]$$

we can rewrite Eq. [7] as

$$\sigma = \sigma_D (c/c_D) \exp[-\beta \Delta F_A/RT] \quad [9]$$

The assumption of Eq. [6] can be verified qualitatively by a consideration of previous work on conductivity and water absorption of ion exchange materials containing sulfonic acid. It has been found (14) that for the range of water activity  $0.2 < a_{H_2O} < 1.0$ ,  $\ln \sigma$  is proportional to  $a_{H_2O}$ . Furthermore,  $\Delta F_A$  is approximately proportional to  $a_{H_2O}$  in this region [ $3 < n < n(\text{saturation})$ ] (16, 17). Combining these results shows that we can write  $\sigma \sim \exp[-\beta \Delta F_A/RT]$ .

Equation [9] may be used to predict the behavior of  $\sigma$  with  $n$  or  $T$ , provided we can estimate  $\beta$  empirically. Its applicability is illustrated by Fig. 1, where it has been used to fit conductivity data for sulfuric acid (25). The calculated curve is based on Eq. [9] with  $\beta = 0.48$  and experimental data for  $c/c_D$  (26) and  $\Delta F_A$  (27). The agreement is reasonably good, especially in view of the formation of a stable

Fig. 1. Comparison of sulfuric acid conductivity from ref. (25) (solid line) to values calculated with our Eq. [9] (dotted line).

monohydrate ( $n = 1$ ), and the fact that conduction occurs not only by normal hydrogen ion transfer but also by anion transfer and Grotthuss conduction. To be sure, the theory is not strictly applicable as derived above, but it nevertheless fits the data reasonably well.

No data are available on  $\Delta F_A$  for the particular membrane material investigated here. However, a check of similar data for low cross-linkage (2% divinylbenzene) PSA ion exchange materials (17) [which reach the same approximate value of  $n$  (saturation)] shows that  $\Delta F_A(n)$  at constant  $T$  can be well approximated by

$$\Delta F_A = \Delta F_A^0 [1 - \exp(-n/n_0)] \quad [10]$$

where:  $\Delta F_A^0$  = asymptotic free energy of absorption at high  $n$  (cal/mole),  $n_0$  = empirical constant. The validity of this approximation is demonstrated in Fig. 2 where experimental values are compared to a curve calculated with Eq. [10] and the values  $\Delta F_A^0 = 6900$  cal,  $n_0 = 1.61$ . The difference between the two is never greater than 10% of  $\Delta F_A$  (exptl). We now assume that the same relationship can be used to describe  $\Delta F_A$  for the membrane and arrive at the following equation for  $\sigma$

$$\sigma = \sigma_D(c/c_D) \exp[-\beta\Delta F_A^0(1 - \exp(-n/n_0))/RT] \quad [11]$$

We thus have a relationship with essentially 2 empirical constants ( $\beta\Delta F_A^0$  and  $n_0$ ).

The form of Eq. [11] can be further justified from an empirical point of view by taking its logarithm for small  $n$

$$\ln \sigma = A - [(\beta\Delta F_A^0)/(RTn_0)]n \quad [12]$$

where  $A$  is a constant provided  $c/c_D$  is relatively constant in the region  $n \ll n_0$ . For low extents of water absorption, work on a variety of substances [biological polymers (5) and polyamide resins (15), for example] has shown that  $\ln \sigma$  is proportional to the weight per cent of water absorbed ( $m$ ). Since  $m$  is proportional to  $n$  for small  $n$ , this result is equivalent to Eq. [12].

Since the exponential term in Eq. [11] approaches a constant value at high  $n$ , conductivity should level off as  $n$  increases and, depending on the behavior of  $c/c_D$ , could perhaps exhibit a maximum. Such behavior has been observed for polymethacrylic ion exchangers (28) and proteins (5).

A further quantity that can be used to study the variation of conductivity with water absorption is the net volume change on mixing one equivalent of dry membrane with  $n$  moles of water ( $\Delta v_A$ ) divided by  $n$ . We denote this quantity by  $\Delta v$  so

$$\Delta v = \Delta v_A/n \quad [13]$$

$\Delta v$  is useful in that it can be used as a measure of how tightly absorbed water molecules are packed around hydrogen ions. A negative value indicates some kind

Fig. 2. Comparison of free energy of absorption data from ref. (17) (solid line) to values calculated with our Eq. [10] (dotted line).

of net ordering relative to liquid water and dry membrane. If  $\Delta v$  has a minimum, the  $n$  value at the minimum would represent approximately the number of water molecules which can be accommodated in an ordered, densely packed hydration sphere about the hydrogen ion. Above this  $n$ , absorbed water would tend to enhance the dilution effect as opposed to specifically interacting with hydrogen ions and increasing conductivity.

### Experimental

The membrane used in this investigation was type C-60 (American Machine and Foundry Company). Its composition has been described previously (see early paragraphs). The membrane was purified by five batchwise washings with deionized water. The final concentration of ionic impurities in the interstitial water within the membrane was estimated from the conductivity of the deionized water after the final washings and was found to be negligible.

Rectangular strips of membrane were then placed in various pre-equilibration enclosures, wherein they were brought to the desired temperature and extent of water absorption by either being suspended over saturated salt solutions (for  $n > 0$ ) or by being pumped down to a pressure of approximately 30  $\mu$ Hg at 55°C (for  $n \approx 0$ ).

With a stainless steel die, rectangular samples were cut from the above strips. All strips were cut with their conduction directions parallel to the same axis in the original membrane sheet to minimize anisotropy effects. Thus, all samples had exactly the same dimensions except for thickness, which varied with water absorption. The samples were 0.5 cm wide with a conductive length of 3.0 cm between electrodes.

The sample was then clamped at each end between two platinum-plated electrodes. The electrodes compressed about 0.5 cm<sup>2</sup> of membrane material at each end under constant pressure. The pressure developed between the electrodes was sufficient to compress samples of high water content to approximately half their original thickness, thereby indicating good electrical contact. Temperatures were measured at four points near the sample with thermocouples. The accuracy of these measurements was  $\pm 0.1^\circ\text{C}$ , and the differences among the four readings were never greater than  $0.2^\circ\text{C}$ .

A sample was then placed in the sample enclosure of Fig. 3, wherein it was maintained at essentially the same temperature and extent of water absorption as during pre-equilibration. Most conductivity measurements were made in this enclosure. The enclosure temperature was held constant to  $\pm 0.1^\circ\text{C}$  by means of a recirculating oil system. For measurements on dry membrane samples, valves 2, 3, and 4 were closed and valve 1 open. For other measurements, valves 2, 3, and 4 were open and valve 1 closed. In the latter cases, recirculating nitrogen gas was contacted with

Fig. 3. System used for regulating temperature and water absorption.

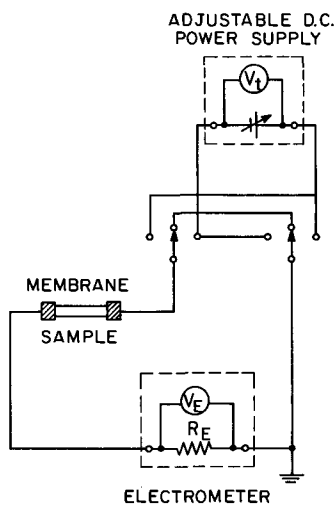

Fig. 4. Circuit for measurement of conductivity

the same saturated salt solution used in pre-equilibration and then passed over the sample.

Several measurements were also made with the sample outside the enclosure and under a burette which slowly dripped deionized water to ensure complete saturation.

The circuit used for measuring conductivity is shown in Fig. 4, where the operation of each unit is indicated in terms of its functional equivalents. With the control switch in its central position the electrometer could be used to measure any polarization voltage ( $V_{pol}$ ) generated within the sample by the passage of current. ( $V_{pol}$  decayed slowly with time, requiring 5-10 min to disappear. The left or right positions of the control switch applied plus or minus d-c voltages to the sample for conductivity measurements. In order to avoid long-term polarization of the sample, the voltage was reversed for each successive measurement. For a given value of the total voltage ( $V_t$ ), conductivity measurements were made in both directions and the average quoted as our final result. The deviation between the two measurements was always well within experimental error. The only electrical quantities measured were thus  $V_t$  and the electrometer voltage,  $V_E$ .  $R_E$  was a calibrated resistor variable in decade steps, thereby permitting calculation of the sample current  $I_s$ . The sample voltage  $V_s$  could be varied by varying  $V_t$ .

As the application of a d-c voltage to the sample will give rise to decaying capacitive currents, a check was made of the duration of such currents to ensure that they introduced no significant error in our conductivity measurements. The time constant calculated with an experimental value of 30 as the approximate static dielectric constant for dry membrane (29) is approximately  $10^{-4}$  sec. This value is small enough with respect to the measuring times involved ( $\geq 0.1$  sec) that we can neglect capacitive currents.

The time dependence of  $I_s$  is indicated in Fig. 5 for dry and wet membrane. Since the sample current decreased rapidly with time after the application of the voltage step, we have chosen to report conductivity values corresponding to the maximum values of  $I_s$  registered on the electrometer before the decrease began. This choice minimized any errors due to sample polarization as well as eliminating the effect of capacitive currents, as we have mentioned. Our choice of  $I_s$  value was checked by comparison to a-c measurements at 60 and 1000 Hz. For 10 saturated samples, the d-c, 60 Hz, and 1000 Hz conductivity values all agreed to within  $\pm 10\%$ . These results are consistent with previous comparisons of this type spanning the range d.c. to 500,000 Hz (8, 30). Inasmuch as the transient effects on conductivity should be largest for

Fig. 5. Effect of an extended application of d-c voltage on the current passing through membrane samples.  $T = 28.3^\circ\text{C}$  for both cases. In (a) the sample was dry, in (b) it contained 7.02 moles of water per equivalent.

saturated samples, our measuring technique was quite adequate.

The times required to reach maximum current were less than 10 sec for dry measurements and less than 0.5 sec for wet measurements. The total time of voltage application was about 10 sec, at which time  $V_{pol}$  never exceeded 30 mv, a negligible value compared to  $V_s$  which was  $\geq 0.8\text{v}$  for all cases. Conductivities were calculated with the difference of sample voltage ( $V_s$ ) and decomposition voltage ( $V_D$ ) as the pertinent applied voltage. The decomposition voltage was defined in a standard way, as the intercept of a straight line through current-voltage data (8). Such a plot is shown in Fig. 6. The data at all extents of water absorption were quite well described by straight lines, so  $V_D$  could be unambiguously determined for all cases. Excluding any property variations from sample to sample, the reproducibility of our conductivity values should be  $\pm 10\%$ . The absolute accuracy is  $\pm 15\%$ .

In view of the fact that both heat transfer and mass transfer were taking place at the sample surfaces, the conductivity of a given sample changed with time after placement in the enclosure. Therefore, measurements were taken until the fractional change per hour in conductivity was less than 0.01 for dry measurements and 0.04 for wet measurements to ensure a stable system. The lower rate for dry samples provided for a closer approach to  $n = 0$ . Such mass transfer

Fig. 6. Variation of sample current with voltage magnitude for a typical membrane sample ( $T = 28.3^\circ\text{C}$ , dry).

equilibrium was not essential for wet samples, since  $n$  was measured directly in these cases.

After electrical measurements were completed, the sample was removed from the enclosure and its thickness and weight were measured. Thicknesses varied from 0.023 to 0.031 cm and weights from 0.041 to 0.071g. The wet samples were then dried in the vacuum desiccator of Fig. 3 at a temperature of 55°C until their weight had stabilized. This weight was then used in calculating  $n$ . The exchange capacity of each sample was then measured by standard methods. From these measurements the density ( $\rho$ ),  $n$ ,  $c/c_D$  and  $\Delta v$  were easily obtained. The approximate accuracies of these measurements were:  $\rho \pm 0.05$  g/cc,  $n \pm 0.15$ ,  $c/c_D \pm 0.17$ ,  $\Delta v \pm 6.3$  cc.

A sample was tested at only one water absorption before being discarded.

### Results and Discussion

As mentioned previously, plots of  $V_s$  vs.  $I_s$  were linear for  $5 < V_s < 35$  V. The decomposition voltages obtained from these plots were not found to vary in any systematic way with  $n$ , but the accuracy of the  $V_D$  determinations was not particularly high. All values are contained within  $V_D = 0.77 \pm 0.58$  v.

The lack of systematic variation of  $V_D$  with  $n$  could indicate that the same electrode reactions are responsible for current flow in both wet and "dry" samples and also make it fairly certain that current flow is ionic even in such a "dry" membrane. The latter result is further verified by the rapid fall of current with time after voltage application as shown in Fig. 5(a).

Previous measurements of conductivity in water-immersed beads of cross-linked PSA have indicated  $V_D \approx 2.0$  v (8). A similar value was obtained in measurements on textile fibers (4). However, both these measurements were made at effectively very large times after application of a d-c voltage, which could explain the higher value. The systems studied were also sufficiently different from this membrane that no real contradiction exists.

Figure 7 presents the results of conductivity measurements at various temperatures. There is no systematic deviation of the data from straight lines. Least-square fits gave the  $E_x$  values of Table I. An increase of  $E_x$  with  $\rho$  is apparent, possibly due to the difficulty of obtaining membrane samples of identical residual water contents, especially under our moderate drying conditions (corresponding to  $a_{H_2O} \leq 10^{-3}$ ). The less dense samples would correspond to samples of higher residual water content and therefore lower  $E_x$ . A value of  $E_x = 0.99$  ev thus probably represents conduction in the driest state observed. This value is of the same order as those obtained from similar

Fig. 7. Effect of temperature on the conductivity of dry membrane samples (see Table I).

Table I. Density and experimental activation energy values for four dry samples. Activation energies determined from Fig. 7

Sample No.	$\rho$ , g/cc	$E_x$ , cal	$E_x$ , ev
1	1.12	18,100	0.783
2	1.11	15,900	0.691
3	1.14	22,700	0.983
4	1.19	22,900	0.993

measurements on a variety of dry polar polymers: 1.3 ev for cytochrome C (1), 0.8-1.1 ev for sodium deoxyribonucleic acid (6), 1.0-1.4 ev for various textile fibers (4), and 2.5 ev for synthetic polyamides (15).

Figure 8 indicates the variation of  $c/c_D$  with  $n$ . As assumed in the derivation of Eq. [12],  $c/c_D$  is relatively constant for  $0 < n < 0.5$ .

Figure 9 shows the effect of water absorption on specific conductivity. The slight scatter of the data probably indicates some property variations from sample to sample, but not a sufficient amount to obscure the systematic variation of  $\sigma$  with  $n$ .

Fig. 8. Effect of water absorption on the ratio of wet ionic concentration to dry ionic concentration in the membrane.

Fig. 9. Effect of water absorption on membrane conductivity ( $T = 28.3^\circ\text{C}$ ). One curve is through the data (— — —); the solid and dotted curves are calculated.

The calculated curves in Fig. 9 were obtained from Eq. [11] with  $c/c_D$  values from the curve of Fig. 6 and  $\sigma_D = 1.06 \times 10^{-8} \text{ ohm}^{-1}\text{-cm}^{-1}$ . The empirical constants used were:  $\beta\Delta F_A^\circ = 10,340 \text{ cal}$ ,  $n_o = 3.69$  for the solid curve, and  $\beta\Delta F_A^\circ = 8,515 \text{ cal}$ ,  $n_o = 1.61$  for the dotted curve. Two theoretical curves are shown to indicate the different types of agreement that can be obtained with this equation. The solid curve gives a reasonable description of the data over the entire range of  $n$ , but is off by as much as a factor of 10 in some places. The dotted curve, on the other hand, agrees much better with the data in the region  $0 < n < 5$ , and is too low by about a factor of 10 for  $n > 10$ . One possible explanation for this is that abnormal hydrogen ion conduction is fully operative for  $n > 5$ . Since our theory does not include abnormal conduction, it would be expected to agree well in the low  $n$  region and be too low in the high  $n$  region. The solid curve would then represent an attempt to extend the theory beyond its original assumptions, and the fact that this curve agrees fairly well with the data is somewhat fortuitous. In fact, measurements on sodium-form membranes of the same type investigated here give a better fit of theory to experiment, and a factor of 7 difference in conductivities at high  $n$  (31), indicating almost certainly that abnormal conduction occurs in the hydrogen form. These results disagree with a recent hypothesis that membrane inhomogeneity may seriously disrupt Grotthuss conduction chains (20). It is of further interest that the parameters  $\beta\Delta F_s^\circ$  and  $n_o$  used in calculating the dotted curve in Fig. 9 agree quite well with those used to fit the experimental data of Fig. 2 on low cross-linkage PSA. The fact that PSA of this cross-linkage (2% divinylbenzene) also reaches approximately the same  $n$  value on being saturated with water (17) further verifies the similarity between the two materials and indicates that  $\beta$  could be quite close to unity for the membrane.

If we consider the dotted curve in Fig. 9 to represent the conduction process exclusive of abnormal conduction, it is possible to check the variation of  $\Delta S^\ddagger$  with water absorption in an approximate way. Our dry conductivity measurements indicate a value of  $\lambda^2 \exp[\Delta S_D^\ddagger/R] = 3.06 \times 10^{-10}\text{-cm}^2$ . Sodium ion self-diffusion coefficient measurements on saturated PSA beads of 4% divinylbenzene cross-linkage give a value of  $\lambda^2 \exp[\Delta S^\ddagger/R] = 3.61 \times 10^{-16} \text{ cm}^2$  (11). As sodium and hydrogen ions move in quantitatively the same fashion if the effects of abnormal conduction are excluded (32), we might expect the value of  $\lambda^2 \exp[\Delta S^\ddagger/R]$  for dry PSA beads to be reasonably close to our value for dry membrane. The  $10^6$  factor between the two values quoted is quite probably due to changes in  $\Delta S^\ddagger$  with water absorption and related only partially to fundamental structural or ionic differences between the two materials. To estimate  $\lambda^2 \exp[\Delta S^\ddagger/R]$  for dry PSA, we extend our assumption in Eq. [6] to

$$\Delta S^\ddagger = \Delta S_D^\ddagger + \beta\Delta S_A \quad [14]$$

Assuming for this case also that  $\beta \approx 1$ , and using experimental data for  $\Delta S_A$  (17), we calculate that  $\lambda^2 \exp[\Delta S_D^\ddagger/R] = 5.03 \times 10^{-10} \text{ cm}^2$ . The excellent agreement of this number with our result for dry membrane is no doubt somewhat accidental, but nonetheless further justifies the use of equations such as [6] and [14]. An experimental study involving measurements of conductivity,  $E_x$  values over a range of  $n$ , and thermodynamic functions of absorption for the same material would be the only truly accurate test of these equations, however.

Conductivity measurements on membranes consisting of phenolsulfonic acid polymerization products (9) show some similarities to the present results. These studies were made on materials which would absorb far more water at saturation than the membrane studied in this work and all measurements were carried out in this high absorption region ( $n > 40$ ). It

was found that  $\sigma$  increased when  $n$  was decreased from very high values. This indicates some sort of maximum in conductivity, as there is little doubt that  $\sigma$  must decrease when  $n$  becomes very small. The higher saturation  $n$  values of the phenolsulfonic materials permit a much larger dilution effect than in the membrane, and thus the maximum in conductivity occurs. The results of these previous measurements also indicate abnormal hydrogen ion conduction, since the equivalent conductance of the hydrogen form is about 6.3 times that of the sodium form.

The variation of  $\Delta v$  with  $n$  is shown in Fig. 10. The general shape of the curve drawn through the experimental data agrees quite well with a curve calculated from more accurate experimental data on cross-linked PSA of 10% divinylbenzene content (16). It is to be expected that the minimum in  $\Delta v$  for this highly cross-linked PSA would be lower than the minimum for the membrane, since the cross-linkages inhibit motion of the PSA molecules relative to one another, thereby reducing the number of water molecules which can enter into an ordered structure about a hydrogen ion. The significance of the approximate minimum shown in the membrane curve is that it occurs at a value of  $n$  very close to the value where  $\sigma$  levels off. Absorbed water increases conductivity by specifically interacting with the hydrogen ion and thereby facilitating ionization. This interaction probably occurs up to a certain extent of hydration for each ion. Past this extent, absorbed water acts more to enhance the dilution effect and the conductivity levels off and may begin to decrease. These ideas are very qualitative and can be put on a quantitative basis only by considering equilibria between water molecules and the hydrogen ion, as has been done previously in the analysis of thermodynamic data (18, 19). One such calculation for hydrogen ions in water gives a hydration number of 7.3 (33) in fair agreement with the minimum in  $\Delta v$  and the levelling off point in  $\sigma$ . For  $n > 7$ , it should also be noted that water molecules could be specifically attracted to the  $-\text{SO}_3^-$  groups attached to the polymer chain. This interaction would probably be small, however, due to the small volume available between adjacent  $-\text{SO}_3^-$  groups along the polymer chain (24). Also, since the hydrogen ions should all be essentially dissociated by  $n \approx 7$ , this additional interaction should serve primarily to enhance the dilution effect.

### Conclusions

The voltage and time dependence of specific conductivity for this PSA-based membrane indicate a

Fig. 10. Variation of the net volume change for absorption per mole of water absorbed with total water absorbed. The solid curve represents data taken in this investigation. The dotted curve was calculated with data from ref. (16).

similar mode of ionic conduction over the entire range of water absorption we have studied. The temperature dependence of conductivity for dry membrane is well-described by an Arrhenius relation between 25° and 55°C. The activation energy in this case is approximately 1 ev. The semi-empirical equations we have derived to relate conductivity and water absorption *via* the free energy of absorption give a reasonably good fit to the membrane data, and could be of use in describing a wide variety of ionically conducting polymers which absorb water. The net volume change for absorption per mole of water absorbed exhibits a minimum at approximately that extent of water absorption at which membrane conductivity levels off. This can be explained by the filling of hydration spheres about hydrogen ions.

### Acknowledgments

The authors wish to express their gratitude to the Office of Saline Water, United States Department of the Interior, for financial support. They also thank Mr. J. Ampaya for making the a-c conductivity measurements.

The results presented here are taken from a thesis by C. S. Fadley, submitted in partial fulfillment of the requirements for the M.S. degree at the University of California, Berkeley.

# Luminescence of Divalent Europium in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> System

Costas C. Lagos\*

Phosphor Research Laboratory, Sylvania Lighting Center, Danvers, Massachusetts

## ABSTRACT

The binary and ternary compounds in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system were activated with divalent europium and examined for luminescence under 2537 and 3650 Å excitation. Three compounds, Ba<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, the low-temperature form of Ba<sub>3</sub>P<sub>4</sub>O<sub>13</sub>, and BaMgP<sub>2</sub>O<sub>7</sub> produced bright phosphors with blue emission. Many other compounds in the ternary system also fluoresced blue, but with reduced intensities.

Very little work has been previously reported on the luminescence of phosphates activated with divalent europium. In 1967, Wanmaker and ter Vrugt (1) reported on the uv and cathodo excitation of the divalent europium activated pyrophosphates of Ca, Sr, Ba, Zn, Cd, and Mg; Gorbacheva (2) in 1966 presented information on the uv excitation of the divalent europium activated orthophosphates of strontium and magnesium; and Nazarova (3) in 1961 published on the uv and cathodo excitation of the pyro-, meta-, and orthophosphates of strontium. To our knowledge no work has been reported on the divalent europium activation of compounds in either the BaO-P<sub>2</sub>O<sub>5</sub> or BaO-MgO-P<sub>2</sub>O<sub>5</sub> systems. Hoffman (4) in 1963 reported the use of europium as an activator in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system, but the europium was probably trivalent because only red emission was mentioned.

The primary interest of the present study was the development of phosphors for application in fluorescent or HPMV lamps. Compounds which did not show any emission under 2537 or 3650 Å excitation were not investigated further.

Some of the better phosphors in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system were bright enough for fluorescent lamp applications. These phosphors were: Ba<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup>, the low-temperature form of Ba<sub>3</sub>P<sub>4</sub>O<sub>13</sub>:Eu<sup>+2</sup>, BaMg<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup>, Ba<sub>2</sub>MgP<sub>4</sub>O<sub>13</sub>:Eu<sup>+2</sup>, and BaMgP<sub>2</sub>O<sub>7</sub>:Eu<sup>+2</sup>. All other compounds produced either no luminescence at all or very weak divalent or trivalent europium emissions.

## Experimental

The chemicals used in the preparation of the phosphors were luminescent grade BaHPO<sub>4</sub> and BaCO<sub>3</sub>, reagent grade (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub> and 3MgCO<sub>3</sub>·Mg(OH)<sub>2</sub>·3H<sub>2</sub>O, and 99.9% pure Eu<sub>2</sub>O<sub>3</sub>. Phosphor blends were prepared by dry mixing of the raw materials; no wet precipitations were made. Formulations were made up to stoichiometry and no deliberate excess of anion was used in any of the preparations. The ratio of activator-to-matrix cation in moles was 0.02 to 1, i.e., for every mole of total cation 0.02 moles of Eu were added as Eu<sub>2</sub>O<sub>3</sub>.

Firing of all blend mixtures was made in two steps: (i) a low-temperature pre firing usually for 3 hr at 700°C in a stagnant air atmosphere to prevent spewing and subsequent loss of material and also to allow the 3MgCO<sub>3</sub>·Mg(OH)<sub>2</sub>·3H<sub>2</sub>O and (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub> which have low decomposition temperatures to react more readily with the other raw materials; (ii) a final higher temperature firing in a 1% H<sub>2</sub>-99% N<sub>2</sub> reducing gas mixture flowing over the samples with the firing temperature depending on the compound that is being prepared. Between firings all samples were remixed by a thorough grinding with a mortar and pestle.

Spectral energy distribution curves were run on the luminescent phosphor samples using an emission spectral radiometer designed by Eby (5). The emission

band peak height intensities of the phosphor samples were compared to the emission band peak height intensity of the high brightness Zn<sub>2</sub>SiO<sub>4</sub>:Mn phosphor, which peaks at 527 nm and is used as a control for our radiometer. All phosphor emission intensities in this paper are expressed as peak height percentages of the peak height of the Zn<sub>2</sub>SiO<sub>4</sub>:Mn radiometer standard phosphor. This comparison is not an absolutely correct comparison in some cases because of wavelength-energy differences between the phosphor samples and the Zn<sub>2</sub>SiO<sub>4</sub>:Mn standard, but for the majority of the phosphors being discussed here this method is a great improvement over the use of a plaque tester where differences between narrow and wide emission band widths play a misleading role in brightness comparisons and evaluations. Half-height widths and peak height intensities of the emission bands of some well-known phosphors were measured on our radiometer and were also included here as references for the phosphors reported in this paper.

Finally, x-ray diffraction patterns were obtained on all fired samples using copper K $\alpha$ -radiation. The x-ray diffraction angle scan was varied from a 2 $\theta$  of 2° to a 2 $\theta$  of 60°, which was quite sufficient for proper identification of the compounds and polymorphs.

## Results and Summary

There were a total of fourteen compounds and polymorphs in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> ternary system which were prepared with divalent europium as the activator. In order to simplify their presentation the compounds have been separated into four categories: (i) metaphosphates and gamma compound, (ii) tetraphosphates, (iii) pyrophosphates, and (iv) orthophosphates.

*Metaphosphates and gamma compound.*—Two metaphosphate compounds Mg(PO<sub>3</sub>)<sub>2</sub> (6) and Ba(PO<sub>3</sub>)<sub>2</sub> (7) and the  $\gamma$  compound which had the composition 6.3 BaO-1.0 MgO-2.7 P<sub>2</sub>O<sub>5</sub> (4) were tested with divalent europium as the activator. Of these three compounds only the barium metaphosphate showed any fluorescence which could be attributed to divalent europium. Figure 1 shows the emission curve for this phosphor under 2537 Å excitation. The emission band of the phosphor peaked at 375 nm with a half-height width of 31 nm and a peak height intensity only 5% of the peak height of the radiometer standard, Zn<sub>2</sub>SiO<sub>4</sub>:Mn. The uv emission of the Ba(PO<sub>3</sub>)<sub>2</sub>:Eu<sup>+2</sup> phosphor was quite low when compared to the reference phosphor BaSi<sub>2</sub>O<sub>5</sub>:Pb which peaked at 355 nm with a half-height width of 41 nm and was 205% of the Zn<sub>2</sub>SiO<sub>4</sub>:Mn standard. When visually observed under 2537 Å excitation, the Ba(PO<sub>3</sub>)<sub>2</sub>:Eu<sup>+2</sup> phosphor had a weak violet emission.

The other two compounds Mg(PO<sub>3</sub>)<sub>2</sub> and the  $\gamma$  compound (6.3 BaO-1.0 MgO-2.7 P<sub>2</sub>O<sub>5</sub>) were not activated by divalent europium. Under 2537 Å excitation the only emission that was observed was a weak red emission which, when examined with the spectral radiometer, was found to be the typical line emissions of trivalent europium.

Fig. 1. Spectral energy distribution of the emission of  $\text{Ba}(\text{PO}_3)_2:\text{Eu}^{+2}$ ; 2537Å excitation

**Tetraphosphates.**—There are three tetraphosphate compounds that exist in the  $\text{BaO-MgO-P}_2\text{O}_5$  ternary system. These are the  $\text{Ba}_2\text{MgP}_4\text{O}_{13}$  (4) compound and the high- and low-temperature polymorphic forms of  $\text{Ba}_3\text{P}_4\text{O}_{13}$  (8) whose transition temperature is at 870°C.

Activation of the high- and low-temperature forms of  $\text{Ba}_3\text{P}_4\text{O}_{13}$  with divalent europium resulted in two interesting emission curves (Fig. 2). The high-temperature form of  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$  gave a very wide emission band of 197 nm half-height width with the band peak located at 575 nm. Because of this unusually wide emission curve the phosphor emitted a fairly bright yellow when observed under 2537Å excitation, but its emission band peak height intensity was only 7.4% of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  radiometer standard and 38% of the reference phosphor  $\text{CaSiO}_3:\text{Pb, Mn}$  which peaked at 618 nm with a half-height width of 87 nm. The position of this wide emission band was also unusual in that it was located further towards the longer wavelengths than were the emission bands of practically all of the other divalent europium phosphors which were found in the  $\text{BaO-MgO-P}_2\text{O}_5$  system. Most of these other emission bands were located in the 400-450 nm region of the spectrum.

The low-temperature form of  $\text{Ba}_3\text{P}_4\text{O}_{13}$  also gave a very unusual emission curve with divalent europium (Fig. 2). Its emission band was located at 438 nm, and its intensity was 18% of the peak height intensity of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  standard. The half-height width measurement was not too meaningful in this case because of the extreme asymmetry of the emission curve towards the long wavelength end of the spectrum. This asymmetry appeared to be caused by the presence of another less intense emission band in the vicinity of 500-510 nm, and this band plus the main

Fig. 2. Spectral energy distribution of the emission of:  $\text{Ba}_2\text{MgP}_4\text{O}_{13}:\text{Eu}^{+2}$ , curve A;  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$ , high-temperature form, curve B;  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$ , low-temperature form, curve C; 2537Å excitation

band at 438 nm combined to give a single wide curve with a long tail. X-ray diffraction data of this phosphor corresponded to the data of Harrison (8) for the low-temperature form of  $\text{Ba}_3\text{P}_4\text{O}_{13}$ , and there were no other extraneous phases present.

This double emission band curve might have been the result of divalent europium emission from two different cationic sites in the compound, but since no crystallographic structure determinations had been made on the compound, no definite conclusions could be drawn.

The wide emission curve of the low temperature  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$  material resulted in a phosphor which had a moderately bright blue-white emission when visually observed under 2537Å excitation. Plaque test brightness measurements were made on this phosphor and compared to similar measurements made on the well-known  $\text{Ca}_5\text{F}(\text{PO}_4)_3:\text{Sb}$  phosphor which had a wide emission band at 494 nm with a half-height width of 116 nm.

	Plaque		
	Red	Green	Blue
$\text{Ca}_5\text{F}(\text{PO}_4)_3:\text{Sb}$	100%	100%	100%
$\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$	105%	111%	125%

These data showed the divalent europium activated material to be slightly brighter and more blue than the  $\text{Ca}_5\text{F}(\text{PO}_4)_3:\text{Sb}$  phosphor which is used in fluorescent lamps for color correcting purposes. Use of the low temperature  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$  phosphor in place of  $\text{Ca}_5\text{F}(\text{PO}_4)_3:\text{Sb}$  in fluorescent lamp phosphor blends would subsequently yield more efficient fluorescent lamps.

Divalent europium activation of  $\text{Ba}_2\text{MgP}_4\text{O}_{13}$  resulted in a phosphor with an emission band at 403 nm and a half-height width of 28 nm with a peak height intensity of 59% of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  standard (Fig. 2). This phosphor fluoresced a moderately bright deep violet when viewed under 2537Å excitation, and it was one of the brighter divalent europium activated phosphors in the  $\text{BaO-MgO-P}_2\text{O}_5$  system.

The emission properties of the barium magnesium tetraphosphate phosphor were radically different from those of either of the barium tetraphosphates. The emission band intensity of the magnesium containing phosphor was greatly increased by a factor of more than three over the low-temperature barium tetraphosphate phosphor and by a factor of more than six over the high-temperature barium tetraphosphate phosphor, while the band width of the magnesium containing material was decreased considerably by factors of one-fifth and one-seventh of the low- and high-temperature forms of barium tetraphosphate, respectively. Apparently, the replacement in the  $\text{Ba}_3\text{P}_4\text{O}_{13}$  compounds of even only one of the three of the larger ionic radius barium cations by the smaller magnesium cation to form the barium-magnesium compound changed the structures of the high and low barium tetraphosphates quite drastically so that there was no similarity at all between the magnesium containing and either of the nonmagnesium containing crystal structures and their subsequent emission properties.

**Pyrophosphates.**—Four pyrophosphates exist in the  $\text{BaO-MgO-P}_2\text{O}_5$  ternary system. These compounds are  $\text{Mg}_2\text{P}_2\text{O}_7$  (6),  $\text{BaMgP}_2\text{O}_7$  (4), and  $\text{Ba}_2\text{P}_2\text{O}_7$  (9), which exist in two polymorphic forms,  $\alpha$  which is the low temperature form, and  $\delta$  which is the high-temperature form. The  $\alpha$  to  $\delta$  transition temperature is at 790°C.

Here again, as it was previously in the case of the magnesium metaphosphate compound and the  $\gamma$  compound, it was not possible to reduce the trivalent europium to divalent europium in the  $\text{Mg}_2\text{P}_2\text{O}_7$  compound. With 2537Å excitation the only fluorescence that was observed in the europium activated  $\text{Mg}_2\text{P}_2\text{O}_7$  material was an extremely weak red fluorescence which on examination by the spectral radiometer was found to be the typical line emissions of plus three europium.

Fig. 3. Spectral energy distribution of the emission of:  $\text{BaMgP}_2\text{O}_7:\text{Eu}^{+2}$ , curve A;  $\text{Ba}_2\text{P}_2\text{O}_7:\text{Eu}^{+2}$ , curve B; 2537Å excitation

The  $\delta$ - $\text{Ba}_2\text{P}_2\text{O}_7$  compound was completely dead to 2537Å excitation while the  $\alpha$ - $\text{Ba}_2\text{P}_2\text{O}_7$  compound had a fair white-blue emission.  $\alpha$ - $\text{Ba}_2\text{P}_2\text{O}_7$  had an emission band which peaked at 406 nm with a peak height intensity 11.4% of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  standard and a half-height width of 32 nm. Figure 3 shows the emission curve for this phosphor.

$\text{BaMgP}_2\text{O}_7:\text{Eu}^{+2}$  whose emission curve is also given in Fig. 3 was one of the brightest phosphors in the  $\text{BaO-MgO-P}_2\text{O}_5$  system. The phosphor appeared a brilliant deep violet when viewed under 2537Å excitation, and it had an emission peak at 402 nm with a half-height width of 45 nm and a peak height intensity 103% of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  standard. When compared to the reference phosphor  $\text{CaWO}_4$  which peaked at 422 nm with a half-height width of 116 nm, the  $\text{BaMgP}_2\text{O}_7:\text{Eu}^{+2}$  phosphor was approximately three times as intense.

**Orthophosphates.**—There are four orthophosphate compounds in the  $\text{BaO-MgO-P}_2\text{O}_5$  ternary system:  $\text{Ba}_3(\text{PO}_4)_2$  (10),  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2$  (4),  $\text{BaMg}_2(\text{PO}_4)_2$  (4), and  $\text{Mg}_3(\text{PO}_4)_2$  (6).

Table I lists the emission properties of the divalent europium activation of these compounds and Fig. 4 gives the spectral energy distribution curves. Two reference phosphors,  $\text{CaWO}_4$  and  $\text{CaSiO}_3:\text{Pb, Mn}$  were also included in the table for comparison purposes,  $\text{CaWO}_4$  for the experimental phosphors in the blue region of the spectrum and the  $\text{CaSiO}_3:\text{Pb, Mn}$  for the  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2$  phosphor which peaked at 585 nm.

The  $\text{Ba}_3(\text{PO}_4)_2:\text{Eu}^{+2}$  phosphor was the brightest phosphor found in the  $\text{BaO-MgO-P}_2\text{O}_5$  system. It was 138.5% of the  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  radiometer standard and over four times as intense as the  $\text{CaWO}_4$  reference phosphor.

Divalent europium activation of the  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2$  compound resulted in a wide band emission phosphor whose spectral energy distribution curve was similar in width to the low-temperature  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$  phosphor and similar in width and emission to the high-temperature  $\text{Ba}_3\text{P}_4\text{O}_{13}:\text{Eu}^{+2}$  phosphor. The emission band peak height of  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2:\text{Eu}^{+2}$  was only about half as intense as the  $\text{CaSiO}_3:\text{Pb, Mn}$  reference phosphor, but because of the extreme width of its emission band, the  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2:\text{Eu}^{+2}$  phosphor ap-

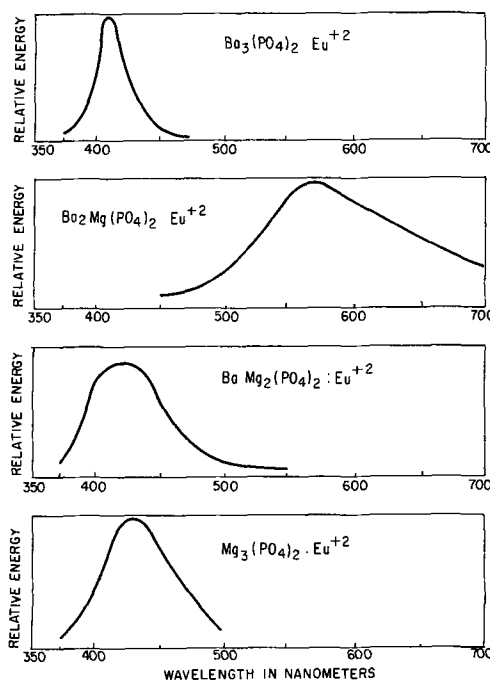

Fig. 4. Spectral energy distribution of the emission of  $\text{Ba}_3(\text{PO}_4)_2:\text{Eu}^{+2}$ ,  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2:\text{Eu}^{+2}$ ,  $\text{BaMg}_2(\text{PO}_4)_2:\text{Eu}^{+2}$ , and  $\text{Mg}_3(\text{PO}_4)_2:\text{Eu}^{+2}$ ; 2537Å excitation.

peared a moderately bright yellow when visually observed under 2537Å excitation.

A phosphor with a half-height width of 77 nm and an emission peak at 418 nm was obtained with  $\text{BaMg}_2(\text{PO}_4)_2:\text{Eu}^{+2}$ . This phosphor was about three-fourths as intense as the  $\text{CaWO}_4$  reference phosphor and its emission band width half-height of 77 nm was wider than usual for a divalent europium activated phosphor with an emission in the near uv-blue region of the spectrum. All of the other phosphors in the  $\text{BaO-MgO-P}_2\text{O}_5$  system which peaked in this same region of the spectrum had considerably smaller emission band half-height widths varying from 31 to 47 nm.

The final member of the orthophosphate phosphor group was  $\text{Mg}_3(\text{PO}_4)_2:\text{Eu}^{+2}$ . Its intensity was less than half of the  $\text{CaWO}_4$  reference phosphor, and its emission band peak was located at 425 nm with a half-height width of 47 nm. Magnesium orthophosphate was the only pure magnesium containing compound which gave an emission with divalent europium activation. The other two magnesium compounds  $\text{Mg}(\text{PO}_3)$  and  $\text{Mg}_2\text{P}_2\text{O}_7$  which were discussed previously could not be activated with divalent europium but instead gave weak red emissions which were found to be trivalent europium line emissions.

All of the divalent europium activated phosphors in the  $\text{BaO-MgO-P}_2\text{O}_5$  system which fluoresced under 2537Å excitation were also found to fluoresce quite strongly under 3650Å excitation. Emission characteristics, such as band location and band width were found to be the same under 3650Å excitation as they were under 2537Å excitation.

The yellow luminescence of the  $\text{Ba}_2\text{Mg}(\text{PO}_4)_2:\text{Eu}^{+2}$  phosphor under 3650Å excitation was found to be reduced greatly when the phosphor was heated to 300°C, ruling out its applicability in high pressure mercury lamps. No other temperature-dependence studies were attempted.

Introduction of the divalent europium activated phosphors into fluorescent lamps posed no particular problems in lamp processing or lamp life. Normal lamp processing conditions were not severe enough to re-oxidize the europium from a valence of plus two to plus three and subsequently change the emission color and decrease the brightness of the phosphor. Table II compares the 40-w fluorescent lamp lumen-life data

Table II. Comparison of data

Phosphor	100 Hours			300 Hours	
	0 Hours lms	Lumens	% of 0 Hours	Lumens	% of 0 Hours
Ba <sub>3</sub> (PO <sub>4</sub> ) <sub>2</sub> :Eu <sup>+2</sup> Cool White Ca Halophosphate	310	300	96.8	294	94.8
	3299	3234	98.0	3148	95.4

obtained for the intense narrow emission band Ba<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup> phosphor to similar data obtained for a typical cool-white halophosphate phosphor.

Because of the disparity in emission band widths between the phosphors, the total lumen output of the Ba<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup> phosphor was understandably lower than that of the halophosphate phosphor, but the per cent of zero hour results were virtually the same for both phosphors at 100 hr and again at 300 hr.

A detailed examination and comparison of the emission bands of the various divalent europium activated phosphors which were found in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system indicated that the intensities and widths of the divalent europium emission bands of practically all of the phosphors in the system appeared to be a function of the emission band location in the visible spectrum. When the divalent europium emission band was located at the shorter wavelength end of the spectrum, the emission band was quite narrow and intense. On the other hand, when the emission band was located at the longer wavelength end of the spectrum, the band was quite wide and of fairly low intensity. Examples of the former were Ba<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup>, BaMgP<sub>2</sub>O<sub>7</sub>:Eu<sup>+2</sup>, and Ba<sub>2</sub>MgP<sub>4</sub>O<sub>13</sub>:Eu<sup>+2</sup>, while examples of the latter were Ba<sub>2</sub>Mg(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup> and both the high- and low-temperature forms of Ba<sub>3</sub>P<sub>4</sub>O<sub>13</sub>:Eu<sup>+2</sup>.

The location of the divalent europium emission band in the spectrum is probably dependent on the coordination of the cations which the divalent europium is replacing in the crystal lattice and also on the crystal structure of the host compounds. Since the crystallographic structures of very few of the fourteen compounds and polymorphs in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system have been determined and since the determination of such crystal structures was not within the scope of this work, no conclusions could be drawn with regards to the effects of different crystal structures on the luminescence of the divalent europium ion.

The emission data obtained from the divalent europium activation of the fourteen compounds and polymorphs in the BaO-MgO-P<sub>2</sub>O<sub>5</sub> system are summarized in Table III. Data on three reference phosphors BaSi<sub>2</sub>O<sub>5</sub>:Pb, CaSiO<sub>3</sub>:Pb, Mn, and CaWO<sub>4</sub> are also included for comparative analyses.

# Fluorescence of Fe, Co, and Ni in Reduced Germanate Glass

C. Hirayama and F. E. Camp

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

## ABSTRACT

Red fluorescence has been observed in a reduced germanate glass doped with iron, cobalt, and nickel. The reduced, undoped glass also fluoresced in the red. There was a strong concentration dependence of the fluorescence intensity and quantum efficiency. The fluorescent center appears to be associated with oxygen vacancy in the host.

The fluorescence in glasses produced by certain transition metals and rare earth ions is well known. In nearly all cases the fluorescence in glass resembles that in a crystalline host where the activator is coordinated by oxygens. Not reported in the literature to date, however, is the fluorescence arising from an iron activator site in a glass; there is one mention (1) of a greenish fluorescence in a silicate glass, which probably arises from an impurity other than iron. The fluorescence of  $\text{Ni}^{2+}$  and  $\text{Co}^{2+}$  in glass is also relatively unknown. Fischer, in a patent (2), describes a red and orange fluorescence, respectively, for  $\text{Ni}^{2+}$  in glass.

Iron is generally known to be a killer of fluorescence at concentrations higher than about  $10^{-4}\text{M}$  in crystalline hosts. However, red fluorescence (3) from  $\text{Fe}^{3+}$  in  $\text{Al}_2\text{O}_3$ -containing phosphors, and red (4) and infrared (5) fluorescence from  $\text{Fe}^{2+}$  in ZnS have been reported. The fluorescence of  $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$  in crystalline hosts has been observed in a few cases (6). Depending on the host, the former emits in the yellow or red, while  $\text{Ni}^{2+}$  emits in the yellow, red, or infrared. In all instances the activator concentration was very low.

This paper reports the observations of strong red fluorescence arising from  $\text{Fe}^{2+}$ ,  $\text{Ni}^{\text{I}}$  and  $\text{Co}^{\text{I}}$  in a germanate glass of composition  $66\text{GeO}_2 \cdot 17\text{K}_2\text{O} \cdot 17\text{BaO}$  prepared under strongly reducing conditions. The absorption and fluorescence are now reported, and a later report (7) will present the electron spin resonance (ESR) spectra which supports some of the conclusions herewith. Only a brief summary of the esr results is presented here.

## Experimental

**Preparation.**—The glasses of base composition  $66\text{GeO}_2 \cdot 17\text{K}_2\text{O} \cdot 17\text{BaO}$  were prepared in 50-g batches by fusing the ingredients at  $1250^\circ\text{C}$  in fused silica or in recrystallized alumina crucibles in a globar furnace. Although the properties of the glasses in both crucibles were the same, most of the samples were melted in alumina. Aside from the semiconductor grade of  $\text{GeO}_2$ , the chemicals were of reagent grade. For the oxidized samples, appropriate amounts of  $\text{GeO}_2$ ,  $\text{BaCO}_3$ ,  $\text{K}_2\text{CO}_3$ , and  $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  were mixed and fused for  $\frac{1}{2}$  to 1 hr in air in an open crucible. For the reduced glasses,  $\text{GeO}_2$ ,  $\text{Ba}(\text{Ac})_2 \cdot \text{H}_2\text{O}$ ,  $\text{KAc}$ , and  $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$  were fused for  $\frac{1}{2}$  to 1 hr in a covered crucible. The dissociation of the acetate in the covered crucible was sufficient to maintain a strongly reducing atmosphere. The iron concentration varied from 0.0005 to 0.75 w/o (weight per cent) Fe. At the low concentrations the iron salt was dissolved in water and aliquots added to the mixture. The  $\text{Mn}^{2+}$  and  $\text{Ni}^{2+}$  were added as the acetates while  $\text{Co}^{2+}$  and  $\text{Cr}^{3+}$  were added as the nitrate. The latter four ions were added only in 0.01 w/o as the metal, in both reduced and oxidized glasses.

All samples were cast into disks, and annealed at  $500^\circ\text{C}$ . The samples were subsequently cut and prepared for the different measurements. The grinding

and polishing of the flat samples were made with butyl alcohol as the vehicle.

Two samples each from the oxidized and reduced glasses were analyzed for  $\text{BaO}$ ,  $\text{K}_2\text{O}$ , and  $\text{R}_2\text{O}_3$  (including  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$ ); the  $\text{GeO}_2$  content, because there is no accurate analytical method for Ge, was calculated as the difference.

**Measurements.**—The optical absorption, fluorescence and excitation spectra were obtained on polished samples of approximately 3.5 mm thickness. The visible and ultraviolet absorption spectra were obtained on a Cary model 14 spectrophotometer, and the infrared spectra were obtained on a Perkin-Elmer 521. Most of the fluorescence and excitation spectra were obtained on a Jarrel-Ash 0.5m grating spectrometer (the Excifluor). The fluorescence was corrected for spectral sensitivity on a liquid nitrogen-cooled Si detector. The excitation spectra were obtained by monochromatically exciting the fluorescence with a 900 W, Hanovia, xenon short-arc lamp, and corrected so that the excitation spectra were proportional to the fluorescence per incident photon rate. Fluorescence was also measured by exciting the sample with 365 nm radiation from a Beckmann DU spectrophotometer, then detecting the emitted light with appropriate photocells in the region 550–1000 nm. The latter measurements were made at room temperature and at  $77^\circ\text{K}$ .

Relative fluorescence brightness measurements were made with a Photo Research Spectra Brightness meter on powdered material. This plaque test was made on equal volumes of samples packed in a black-painted brass cup at a fixed, focused distance from the meter. The relative quantum efficiency measurements were made on quasi-infinitely thick layers of powder at room temperature. The samples were excited by 365 nm radiation, and the detection of emitted and reflected light was made with a silicon photodiode whose sensitivity was practically flat, within 10%, to 800 nm. Above the latter wave length, the sensitivity decreased fairly rapidly.

Electron spin resonance measurements were made on solid samples at  $77^\circ$  and at  $4.3^\circ\text{K}$  on a superheterodyne x-band spectrometer.

## Results

The glasses prepared in oxidizing atmosphere were all clear and possessed the color characteristic of the transition metal ion in glass (8). The reduced glasses were usually clear, with some bubbles in the quenched glass. The color of most of the latter glasses was slightly yellow. The Co- and Mn-containing glasses were colorless. The reduced glasses were readily soluble in water and were soft when samples were cut on a carborundum wheel. In contrast, the oxidized glasses were only slightly attacked by water during the grinding and polishing of samples.

Table I shows the analyses of four of the glasses prepared in both oxidizing and reducing atmospheres. The analyses are also compared with the nominal composition of the glass without addition of transition metal ion. The analytical molar ratio  $\text{BaO}/\text{K}_2\text{O}$  is 1.10

<sup>1</sup> Since the valence states of nickel and cobalt in our fluorescent glasses have not been established, we will refer to Co and Ni without specifying the valence.

Table I. Analyses of oxidized and reduced glasses and density

\* By difference.

in the oxidized glasses, whereas this ratio is 1.14 in the reduced glasses. This increase in the ratio shows that at least 4.4% of K<sub>2</sub>O was lost in the melting process. The loss occurs in part by volatilization of K<sub>2</sub>O itself, and probably in part by the reduction and volatilization as potassium vapor.

From the standpoint of thermodynamic stability, the potassium and barium are most probably in their normal valence states. However, germanium has been known to occur in both tetra- and divalent states in GeO<sub>2</sub> glass (9). By assuming that no barium or germanium was lost in the glasses the value of  $x$  in GeO<sub>2-x</sub> was calculated, based on the Ge/Ba ratio. As shown in Table I, the value of  $x$  was about 1.1. This value is obviously too high in view of the absence of color in the undoped reduced glass. It could very well be that considerable germanium was volatilized as GeO since this species is known to have a high vapor pressure (10).

In one preparation, considerable metal globules were found in the quenched glass. The emission analysis showed the metal to be predominantly Ge, with little or no Ba or K. The glass samples on which spectroscopic and density measurements were made were free from metallic Ge, as shown by the absence of Ge esr absorption.

There was a significant decrease in density of the glass when prepared in a reducing atmosphere. The densities of two glasses are shown in Table I. Similar values were obtained for other glasses, and the ratio of density of the oxidized to the reduced glasses was around 1.04. With a loss of at least 10 w/o in the reduced glass, this ratio would be expected to be higher since the reduced glass should have a much lower density. This of course assumes that the structure of the glass is not changed. It may be inferred, therefore, that the glass structure is pulled in to a more compact one as the result of the loss of oxygen.

**Absorption spectra.**—The absorption spectra of the glasses containing Fe, Co, Ni, and Mn, and that with no added transition metal ion are shown in Fig. 1. The curves are normalized for approximately the same sample thickness. Curve 1, for the undoped glass which was prepared in oxidizing atmosphere, is typical for most glasses prepared from reagent grade

Fig. 1. Absorption spectra of glasses

materials melted in air. However, the reduced glass, curve 2, shows intrinsic absorption starting at about 50 nm longer wavelength. Curve 3, for the reduced glass containing 0.001% Fe, is almost identical to curve 2, except for a slightly stronger absorption at around 400 nm. This absorption could have been due to scattering since some of the samples contained more bubbles than others. The reduced glass containing 0.01% Co was colorless, as seen in curve 5. The oxidized glass containing 0.01% Co was a deep blue, typical of Co<sup>2+</sup> in glasses. Curve 7, for the reduced Ni-doped glass, has a shoulder at around 450 nm, and the cutoff is not as sharp as in the other reduced glasses. The oxidized glass containing 0.01% Ni<sup>2+</sup> was purple, while the reduced glass was a light yellow. The spectrum for the oxidized glass containing 0.2% Fe, curve 8, shows two shoulders which arise from the Fe<sup>3+</sup> absorption bands at around 435 and 385 nm. The reduced glass containing 0.2% Fe has a sharp cutoff near 500 nm. Both glasses containing 0.2% Fe show the broad, near infrared tail of the Fe<sup>2+</sup> absorption which has its maximum at 1000 nm.

There are large differences in the short wavelength region between glasses prepared in oxidizing and in reducing atmospheres. Strong absorption due to charge-transfer appears at considerably longer wavelength in the reduced glasses; the cutoff increases significantly with the transition metal ion concentration. It should be noted that Fe<sup>2+</sup> does not absorb between 300 and 600 nm.

The strong charge-transfer absorption in the reduced glasses must arise from a center associated with the divalent transition metal ion. The absence of visible absorption in the reduced 0.01% Co-containing glass is surprising in view of the intense color usually associated with this ion in glass.

Figure 2 shows the infrared absorption spectra of the reduced and oxidized glasses in which no transition metal ion was added. The spectra for reduced and oxidized glasses doped with transition metal ions were identical to the corresponding glasses shown in Fig. 2. The peaks for Ge-O-Ge antisymmetric stretching frequency in both glasses appear at about 750 cm<sup>-1</sup>. The latter frequency is lower than the 800 cm<sup>-1</sup> found for this peak in alkali germanate glasses (11). There is a flat region between 900 and 1000 cm<sup>-1</sup> in the reduced glasses, whereas the oxidized glasses show

Fig. 2. Infrared absorption spectra of glasses 66GeO<sub>2</sub>·17K<sub>2</sub>O·17BaO: (a) oxidized glass; (b) reduced glass.

only a slight shoulder at  $1000\text{ cm}^{-1}$ . Although the difference in infrared absorption shows some difference in the germanate glass structure, the exact origin of the broad, flat infrared absorption in the reduced glass is not known at present.

*esr.*—Certain results of the esr measurements are pertinent: (A) At  $4^\circ\text{K}$  the reduced glass with no added transition metal showed only a strong, highly symmetrical, sharp line of about 10 gauss width at  $g = 1.9975$ . This line was still present at  $77^\circ\text{K}$ . It saturated at low microwave powers at both temperatures. This sharp line was very similar to the resonance originating from oxygen vacancies in vitreous  $\text{GeO}_2$  (12). There was no resonance at  $g = 4.3$ , nor a broad resonance at  $g = 2$ . (B) At  $4^\circ\text{K}$  the reduced glass containing 0.1% Fe showed a weak, narrow line of about 0.9 gauss superimposed on a broad line centered at  $g = 2$ . The lines did not saturate even at the highest microwave power input. In addition to the  $g = 2$  resonance, there was a very weak absorption at  $g = 4.3$ , which was about 20 gauss wide. At  $77^\circ\text{K}$  all of the resonances disappeared, except a very weak absorption at  $g = 2$ , which was observed only at very high gain. (C) The oxidized glass containing 0.01% Fe, at  $4^\circ$  and at  $77^\circ\text{K}$ , showed resonances at  $g = 2$  and 4.3, the latter approximately 20 gauss wide, while the  $g = 2$  line was very broad. These resonances are typical of  $\text{Fe}^{3+}$  in glasses (13).

*Fluorescence.*—All of the above glasses prepared in silica and alumina crucibles in oxidizing atmosphere showed no fluorescence on excitation with 254 and 365 nm radiation. However, the glass prepared in a platinum crucible showed a weak pinkish-white fluorescence with 365 nm excitation. Addition of 0.1%  $\text{PtCl}_4$  to the glass prepared in a silica crucible also showed the same fluorescence.

When prepared under reducing atmosphere, the undoped glass had a weak orange-red fluorescence with 365 nm excitation. On adding increasing amounts of iron the fluorescence of the reduced glasses became stronger, up to 0.2% Fe. Beyond the latter, the fluorescent brightness started to decrease rapidly. The glasses doped with 0.01%  $\text{Mn}^{2+}$  and  $\text{Cr}^{3+}$  showed only a very weak orange-red fluorescence which was weaker than that of the undoped glass. The glasses containing Ni and Co showed strong red and yellow-orange fluorescence, respectively. Figure 3 shows the relative brightness of the emission of Fe-containing glasses at room temperature, as measured on powder samples with the Spectra Brightness meter. The meter has an S4 response, so that its sensitivity to the glass emission is very low.

The room temperature excitation and fluorescent spectra of the reduced glasses with no added transi-

Fig. 3. Brightness dependence of reduced glass on Fe concentration; 0.01% Fe =  $4.1 \times 10^{18}$  ions/cc.

tion metal and those containing 0.01% of Fe, Co, and Ni are shown in Fig. 4-7, respectively. The excitation bands are all similar except for slight shifts in peak position and in the width. The Ni-doped glass has an excitation band almost twice that for the other three glasses. The excitation bands of all of the glasses have a tail that extends into the visible. In the Fe-doped glass, there is also a weak excitation band at 500 nm.

Fig. 4. Excitation and fluorescence spectra of undoped reduced glass.

Fig. 5. Excitation and fluorescence spectra of reduced glass doped with 0.01% Fe.

Fig. 6. Excitation and fluorescence spectra of reduced glass doped with 0.01% Co.

Fig. 7. Excitation and fluorescence spectra of reduced glass doped with 0.01% Ni.

The fluorescent bands are all very broad; those for the glasses doped with Fe and Ni, and the undoped glass are similar and occur between  $1.1$  and  $1.8 \times 10^4$   $\text{cm}^{-1}$ . The fluorescent band for the Co-doped glass is slightly broader than that in the other three glasses, and is shifted to shorter wavelength. The yellow-orange fluorescence of the latter glass results from the shift to the shorter wavelength. The shape of the fluorescent bands in all of the glasses suggests that the bands are composites of several components.

In iron-containing glasses, the fluorescent band at room temperature remained in the same wavelength region up to Fe concentration of 0.2%. At 0.4% Fe the band shifted to shorter wavelength by about 50 nm. At 77°K the fluorescent bands of glasses containing 0.1% and less Fe were shifted to longer wavelengths by 40–80 nm, while the shift at 0.4% Fe was only about 10 nm. The intensity of the fluorescence in the glasses doped with less than 0.1% Fe increased by three to fivefold at 77°K, whereas the increase was only about 50% above 0.1% Fe.

Table II records the relative quantum efficiency of some of the glasses. These values are probably low because of the decreased spectral sensitivity of the silicon photodetector. There is a strong dependence of the quantum efficiency on the iron content.

### Discussion

The strong red fluorescence from Fe, Ni, and Co in the germanate glasses appears to be associated with the highly reduced nature of the host. There was no fluorescence observed at these low activator concentrations in phosphate and silicate glasses prepared under similar reducing conditions. The weak orange-red fluorescence from the  $\text{Mn}^{2+}$  is typical for this ion in glasses; its fluorescent intensity in the reduced germanate at 0.01%  $\text{Mn}^{2+}$  was very low compared to the glasses doped with the other three activators. In fact, the fluorescent intensity of the Mn-doped glass was significantly lower than that in the undoped glass.

The germanate glass system is very complex, compared to the silicates, phosphates, and vitreous  $\text{GeO}_2$ , because of the existence of both four- and six-coordinated germanium. The structure of the reduced germanate glasses is further complicated by the appar-

ently large deficiency of oxygen. One could also state that there is apparently a mixture of  $\text{Ge}^{4+}$  and  $\text{Ge}^{2+}$ . The sharp esr absorption at  $g = 1.9975$  in the reduced, undoped glass is somewhat similar to that observed in irradiated vitreous  $\text{GeO}_2$  (12). In the latter, all of the Ge is four-coordinated. It has been suggested by Weeks and Purcell that an oxygen vacancy is created on irradiation with electrons or x-ray, and that an electron is trapped by a Ge atom, giving rise to the  $g = 1.9975$  resonance. When pure  $\text{GeO}_2$  is prepared under slightly reducing conditions, the glass has an absorption band at 244.5 nm (9). This absorption, also found in irradiated  $\text{GeO}_2$ , is attributed (12) to reduced (or oxygen-deficient) germanium oxide. The  $g = 1.9975$  resonance is associated with the oxygen deficient state of hexagonal and of pure, vitreous  $\text{GeO}_2$ . We did not observe the optical absorption at 244.5 nm because of the absorption edge at longer wavelengths.

As shown in Fig. 1, the absorption edge of the Fe-doped glasses has a strong dependence on the iron concentration. The excitation band, however, remains essentially in the same region as in Fig. 5. The concentration dependence was not studied on the Co and Ni-doped glasses. The shift in absorption edge to longer wavelength suggests that the increasing Fe concentration creates defect sites of progressively lower energy. Similar observations have been recently reported for  $\text{Fe}^{2+}$  doped fosterite (14). No electrical measurements have been made as yet, so it is not known if the iron-doped glass is photoconducting.

The exact nature of the fluorescent center in the reduced glasses is difficult to conjecture at present, but the centers seem to be of similar nature in the glasses doped with either Fe, Co, or Ni. The valence state of  $\text{Fe}^{2+}$  is established from the esr absorption of the reduced glass. The concentration of  $\text{Fe}^{3+}$  in the latter is extremely low, in view of the very weak absorption at  $g = 4.3$  observed only at 4°K. The exact valence states of the nickel and cobalt are not clearly established at present, although these ions are normally divalent in glasses. The extremely weak  $\text{Ni}^{2+}$  absorption and the absence of  $\text{Co}^{2+}$  absorption in these glasses cannot be explained in the absence of more definitive data, such as the magnetic properties.

The fluorescence in the  $\text{Fe}^{2+}$ -doped glasses has certain resemblances (3) to that in  $\text{Li}_2\text{O} \cdot 5\text{Al}_2\text{O}_3 \cdot \text{Fe}$ , where the fluorescent center is associated with  $\text{Fe}^{3+}$ . The excitation band in the aluminate is centered at around 300 nm, as compared to around 365 nm in the glass; the fluorescent band in both materials is located in approximately the same region. The excitation and fluorescent bands in the glass, although of the same shape, are broader than that for the  $\text{Fe}^{3+}$  in the aluminate. The optical and fluorescent bands in glasses are generally broader than in crystals, and there are often slight shifts in the wavelengths.

Ferrous ion acts as a hole trap in glasses (15), with the formation of  $\text{Fe}^{3+}$ . The  $\text{Fe}^{2+}$  fluorescence in ZnS has been attributed to the capture of a hole by the  $\text{Fe}^{2+}$ , with subsequent red emission of the excited  $\text{Fe}^{2+}$ -hole pair on returning to the ground state (4). In the absence of esr data on the excited Fe-doped glasses it is not possible to assign a similar mechanism to the  $\text{Fe}^{2+}$  fluorescence in the reduced glass. That the  $\text{Fe}^{2+}$  is an activator is clear from the strong concentration dependence of the fluorescence. The absence of fluorescence in the oxidized glasses conclusively shows that  $\text{Fe}^{3+}$  itself does not fluoresce in the glass. The  $\text{Fe}^{3+}$  in this instance may be occupying sites quite different than that of  $\text{Fe}^{2+}$  in the reduced glass.

The  $\text{Mn}^{2+}$  ion in a glass also acts as a hole trap (16). The decrease in fluorescence in the glass containing this ion may well be due to  $\text{Mn}^{2+}$ -hole pair formation, if this state returns to the ground state by a nonradiative process. The latter then would compete with the normal  $\text{Mn}^{2+}$  radiative process.

Any mechanism for the observed bright fluorescence in the Fe-, Co-, and Ni-doped, and suppressed fluores-

Table II. Relative quantum efficiency,  $\eta$ , of reduced glasses

Dopant	Concentration, %	$\eta$
Fe	0.01	0.13
Fe	0.1	0.41
Ni	0.01	0.11
Co	0.01	0.035

cence in the Mn-containing glasses, must be consistent and account for the phenomenon in all cases. If a metal ion-hole pair is the fluorescent center, the formation of the hole must also be explained. In the absence of more information, it is not possible at present to explain the fluorescent mechanism. The association of the  $\text{Fe}^{2+}$ , Co, and Ni with a defect center seems to be required for the fluorescent center.

The absence of visible absorption in the Co-doped, reduced glass must also be explained, since this seems to be required for the bright fluorescence from this glass. The  $\text{Co}^{2+}$  in four-coordination is blue, while the six-coordinated ion is pink. When the colorless, reduced glass was remelted in air, the blue color was obtained. The glass, like all of the remelted and oxidized glasses, was not fluorescent.

#### Acknowledgment

The authors thank W. Lehmann for some of the fluorescent measurements and for discussions; R. Perevuznik and N. T. Melamed for the excitation and fluorescence spectra; and G. R. Wagner for the esr measurements.

Manuscript received Aug. 9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

## Emission Spectra of Individual Phosphor Particles

Andre C. Boucharde\*

*Sylvania Electric Products Incorporated, Danvers, Massachusetts*

#### ABSTRACT

Measurement of the emission (350-750 nanometers) from single 5-50 $\mu$  particles of various phosphor systems under 2537 $\text{\AA}$  excitation has been achieved utilizing a modified fiber optic microspectroradiometer. The system greatly facilitates identification of phosphor components in blends often employed in fluorescent lamps and has enabled positive identification of most phosphors from their respective emission spectra. Minor secondary phases present in experimental phosphors, which had heretofore been impossible to verify with standard spectroradiometric equipment, have now become readily identifiable. Successive stages of phosphor activation of the system  $\text{Ca}_5(\text{X})(\text{PO}_4)_3:\text{Sb}^{+3}, \text{Mn}^{+2}$  have been explored with variations in spectral characteristics of particles occurring not only in different locations of the firing vessel, but among adjacent grains within a small volume. Particles from standard cool white fluorescent lamps have been found to exhibit slight variations in  $\text{Sb}^{+3}$  to  $\text{Mn}^{+2}$  emission ratios resulting in possible luminous efficiency losses. Brightness profile data across individual cool white phosphor grains, utilizing a 1.2 $\mu$  measurement probe area have indicated variations of the order of 10-15% difference across single grains. Brightness data from particle to particle have also indicated substantial differences.

#### Experimental

A schematic illustration of the equipment used in our experiments is shown in Fig. 1. The phosphor excitation source consisted of a Model 11 Sc-1L "Pen Ray" quartz, low-pressure Hg arc lamp. Maximum uv intensities for phosphor excitation were obtained in the apparatus by removing the substage of a standard petrographic microscope, and vertically mounting the Pen Ray lamp in as close a proximity to the microscope object slide as possible. The object slide consisted of a 1 in. x 2 in. x 3 mm 9863 Corning uv filter which served a twofold purpose of filtering the visible Hg lines from the exciting source as well as a mounting medium for the phosphor particles. All samples to be investigated were either dry mounted or immersed in high uv transmitting cp glycerin to the top surface of the filter.

\* Electrochemical Society Active Member.

Key words: Microspectroradiometer, spectral energy distribution, phosphor inhomogeneity, cool white halophosphate.

The visible light generated by the excited phosphor particle was brought to a focus in the image plane of the microscope eye lens, where a centrally located small fiber optic probe (5 $\mu$  measurement area) picked up and fed the light from the area to be measured into an external fiber optic light pipe coupled to a motorized Bausch and Lomb grating monochromator, 1350 grooves/mm with bandwidth of approximately 20 nm using a 1.34 mm exit slit. The dispersed light from the single particle was picked up at the exit slit of the monochromator and amplified by a 9558 A EMI photomultiplier tube with a built-in 4 sec time constant to obtain acceptable signal to noise properties. All spectral energy distribution (SED) measurements were automatically recorded on a standard x-y recorder, and scanning speeds of 20 nm/min were found necessary to obtain repeatable spectra. It was found that the sensitivity of the system was dependent on the optical transmission of the equipment as well

Fig. 1. Diagram of apparatus

as the quantum efficiency and spectral emission bandwidth of the particular phosphors under investigation.

### Applications and Results

This tool has been found useful in identifying phosphor components present in blend type fluorescent lamps, especially the deluxe types, employing up to six compositionally different phosphors. The identification of all these phosphor components by x-ray techniques or chemical analyses is tedious due to the percentage of components present, as well as the similarity in crystal structure of the particular phosphors. The use of the microspectroradiometer in conjunction with the uv microscope has facilitated the task of phosphor identification and yielded a good estimate (by count) of the percentage of the individual phosphors used in the particular blends. Identification techniques consisted of mounting the phosphor blend on the uv filter object slide, traversing the microscope stage until the probe measurement area coincided with the phosphor particle image, and recording the SED of the various color emitting particles. From a comparison of the SED spectra of the phosphor particles with SED spectra of standard phosphor systems, rapid identification of all particles present in a particular blend was obtained. As an example, Fig. 2 illustrates the SED of a deluxe type fluorescent lamp obtained from a standard radiometer. Figure 2A obtained from our experimental apparatus resolves the standard SED curve of Fig. 2 into the various emitting components.

Use for this instrument has been found in the field of new phosphor development. In many instances the instrument has yielded information virtually impossible to determine with standard spectroradiometric equipment. Minor extraneous phases, oftentimes giving rise to variations in the spectral emission of particles, are readily identifiable with this tool. The question of multiple emission band spectra, whether arising from nonequivalent sites, or from extraneous impurity phases can often be resolved with the use of this instrument. In Fig. 3 and 3A comparisons of the

Fig. 3. Experimental phosphor standard SED measurement

Fig. 3A. Single particle emission curves of experimental phosphor

SED of an experimental phosphor obtained from a standard *vs.* the experimental radiometer indicates that the SED curve of Fig. 3 was actually a composite of five closely overlapping emission bands. The spectra in Fig. 4 and 4A, also obtained from an experimental phosphor, similarly illustrate the usefulness of the single particle radiometer in separating various phases and substantiating the existence and locations of very weak emission bands.

The radiometer has been employed in the field of standard phosphor improvement also. Recent experiments were conducted on the successive stages of activation of the system  $\text{Ca}_5(\text{X})(\text{PO}_4)_3:\text{Sb}^{+3}, \text{Mn}^{+2}$  to determine if any spectral color changes occurred during the solid-state reaction of the many constituents used during the formation of the phosphor. Samples for investigation were prepared by formulating a standard 4500°K cool white halophosphate blend and mix-

Fig. 4. Experimental phosphor standard SED measurement

Fig. 4A. Single particle emission curves of experimental phosphor

ing all ingredients for 30 min in a Spex mixer mill. All samples were fired in 1 x 5 in. zircon boats at temperatures ranging from 1400° to 2200°F in 100°C-steps. Particular interest was devoted to the SED spectra of the underfired samples for indications of possible initial preferential diffusion of Sb, Mn, Cl, F into the apatite lattice. It was observed that variations, due to possible blending techniques and thermal gradients existing in the firing vessels, yielded too great a disparity in emission colors among particles to justify any conclusions as to diffusion mechanisms occurring during the activation processes. Not only were variations in spectral compositions found in various locations of the firing vessels, but differences occurred among adjacent phosphor particles within a small volume. Generally, the differences in color were attributed to variations in the ratio of the Sb to Mn emission bands.

To substantiate that the differences found in our experimental firings were present in larger production vessels, fired under more ideal conditions, a sample production fired vessel was broken into various sections and analyzed for spectral inhomogeneities. Although it was found that the emission spectra of the majority of particles were generally very similar, some large differences in the SED of individual grains were found in various locations of the firing vessel as illustrated in Fig. 5. It should be emphasized that these differences occurred in proportions no greater than ½% of the total phosphor volume in the vessel. The SED spectra only indicate some of the largest variations that might be found utilizing standard firing techniques.

Particles from cool white fluorescent lamps were very closely examined also for minor spectral variations. It was established that most particles possessed slight but significant variations in their Sb to Mn emissions band ratios. Figure 6 illustrates typical small SED variations obtained from particles present in cool white fluorescent lamps.

An investigation of the brightness of individual halophosphate grains was also conducted by removing the Bausch and Lomb monochromator from the optical

Fig. 7. Fluorescent lamp brightness as a function of halophosphate composition.

train and feeding the undispersed light from the single particles to the 9558 PM tube. This mode of operation enabled us to utilize probe measurement areas of 1.2 $\mu$ . Scans across individual grains and from particle to particle resulted in brightness differences of 10-15% in some cases.

### Discussion

The significance of the SED variations found among particles in cool white halophosphate lamps can be realized by an examination of Fig. 7 wherein the lumen output vs. color composition of four standard halophosphate phosphors are plotted. The rather abrupt drop in lumen output for the daylight lamps is a result of the shift in spectral character of this phosphor away from the peak of the eye sensitivity curve. Particles with SED's intermediate between cool white halo and daylight halo in the same lamp, which were found in our investigation and presented in Fig. 6, strongly indicate suspected luminosity losses occurring in cool white lamps due to these offcolored species. No quantitative data as to gains in lumens that would result by removal of these particles have been obtained to date.

The observed differences in brightness from particle to particle and across individual grains can be attributed to the varying uv scattering properties of the individual grains. Particles with irregular external morphologies and possible minor internal extraneous phases with slightly varying refractive indices, such as  $\beta$  calcium pyrophosphate may in fact internally scatter a greater proportion of the incident uv radiation thus giving rise to increased uv absorption of the individual particles.

## The Effect of Heat-Treatment on Transistor Low Current Gain with Various Ambients and Contamination

A. A. Bergh<sup>\*.1</sup> and C. Y. Bartholomew

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

### ABSTRACT

In a planar transistor low current d-c gain is the most sensitive parameter to changes in the properties of the oxide-silicon interface. It is dominated by the nonideal base current,  $I_{BN}$ . In the transistors investigated here,  $I_{BN}$  is made up of a Sah-Noyce-Shockley recombination-generation current ( $I_{SNS}$ ) and a channel current ( $I_{CH}$ ). The two components can be separated by analyzing the temperature dependence of  $I_{BN}$ , making it possible to determine the failure mechanism of the transistor gain degradation.

In order to control gain degradation, a correlation was sought between the components of  $I_{BN}$  and physical processes affecting the Si-SiO<sub>2</sub> interface. This paper shows the effect of heat-treatment in various ambients on  $I_{BN}$ . Heat-treatment in hydrogen and water vapor improve the gain primarily by reducing the recombination-generation current. This improved gain corresponds to the state of a transistor completed by standard processing. The high transistor gain may be degraded by baking in dry inert gases or with sodium contamination. Baking in inert gases increases the recombination-generation component of  $I_{BN}$ . Hydrogen ambient accelerates, and water vapor impedes the migration of sodium through the oxide relative to dry inert gases. A model is presented to explain the effect of hydrogen on the diffusion of sodium in the oxide. Experiments with MOS capacitors are in good agreement with transistor results.

The understanding and control of the Si-SiO<sub>2</sub> interface strongly affects the performance of semiconductor devices. Changes in the surface state (1) and surface charge (1) densities influence both initial device characteristics and reliability. Physical measurements (2) and radioactive tracer experiments (3) have shown that the major source of the surface charges is the diffusion of alkali ions through the oxide to the Si-SiO<sub>2</sub> interface (1, 2). The surface states on the other hand are probably associated with lattice defects (4) and unsaturated silicon bonds (5) at the interface. It follows, therefore, that the surface charge density can be reduced by the control of impurities during processing, while the surface states can be affected by treatments altering the structure and the stoichiometry of the oxide, such as heat-treatments in various ambients.

The effects of sodium concentration and heat-treatment in various ambients have been evaluated on npn planar transistors by monitoring low current d-c gain ( $h_{FE}$ ). The following discussion is divided into three parts. (i) First, the correlation between the oxide-silicon interface and the low current gain is discussed. (ii) This is followed by the effect of sodium contamination and the heat-treatment in various ambients on  $h_{FE}$ , and on the flat band voltage on MOS capacitors. (iii) Finally, a mechanism is offered for the migration of sodium ions through the oxide to explain the effect of the ambient on the diffusion rate.

#### Low Current D-C Gain ( $h_{FE}$ )

Low current d-c gain ( $h_{FE}$ ) is the most sensitive device parameter under all aging conditions used in this experiment.  $h_{FE}$  is defined as

$$h_{FE} = I_C/I_B \quad [1]$$

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Bell Telephone Laboratories, Inc., Murray Hill, New Jersey.

where  $I_C$  and  $I_B$  are the collector and base currents, respectively. Both components of  $h_{FE}$  can usually be described by the formula

$$I = I^0 \exp(qV_{EB}/nkT) \quad [2]$$

where  $I^0$  and  $n$  are constants,  $V_{EB}$  is the emitter to base potential, and  $q$ ,  $k$ , and  $T$  have their usual meaning.  $I_C$  was unchanged in all aging experiments. Similar observation was reported by Reddi in a detailed study of the effect of surface properties on low current gain (6). Figure 1 depicts a typical  $I_B - I_C$  plot after the manner of Iwersen *et al.* (7).  $I_B$  is seen to consist of an "ideal" component,  $I_{BI}$ , ( $n = 1$ ), and a "nonideal" component,  $I_{BN}$  ( $n > 1$ ). All the chemical and thermal treatments discussed below affected only the nonideal component,  $I_{BN}$ , and hence the low current gain. The parameters characterizing  $I_{BN}$ , *i.e.*,  $I_{BN}^0$  and  $n$ , are readily determined from the  $I_B - I_C$  plot (Fig. 1).

The nonideal base current has two components closely related to fixed charge and surface state densities, respectively. They are the channel current and the recombination-generation current in the junction space charge region (7-9).

The theory of space-charge recombination-generation currents was developed by Sah, Noyce, and Shockley (8), and Sah (11), and recently extended by Evans and Landsberg (12) and by Morgan (13). The temperature dependence of this component,  $I_{SNS}$ , (after Sah, Noyce, and Shockley) is determined by the temperature dependence of the intrinsic carrier density,  $n_i$ . The activation energy,  $E_a$ , of  $I_{SNS}$  is then to a first approximation equal to one-half of the band gap energy, or 0.6 eV (11). A typical value of  $n$  for the  $I_{SNS}$  current is about 1.5 at room temperature as found in our experiment and reported elsewhere (7, 10).

Fig. 1. Typical  $I_B - I_C$  curves

It is shown in the Appendix that the temperature dependence of the current in a channel can be described by the following equation

$$E_{a, ch} = \frac{E_g}{2} + 2 \left( 2.75 \frac{kT}{q} - |\phi_s| \right) \quad [3]$$

where  $E_g$  is the band gap energy and  $\phi_s$  is the surface potential. The activation energy,  $E_{a, ch}$  as a function of surface potential is plotted in Fig. 2. In general, the enhancement in surface inversion results in a monotonically decreasing activation energy below the value of  $E_g/2$ .

The variation of  $n$  with increasing channel current is discussed in ref. (9) and (10). Depending on the geometry of the junction and on the extent of the inversion,  $n$  increases to values significantly larger than 2. Values of  $n$  as high as 4.9 have been observed in our experiments.

A typical plot of  $I_{BN}^0$  vs.  $1/T$  is shown in Fig. 3. At elevated temperatures the recombination-generation current dominates while below room temperature the channel current becomes important. Typical values of the components of the nonideal base current for normal and degraded devices are given in Table I.

**Experimental**

*Description of the transistors.*—The experiments were carried out on an npn silicon planar transistor. A schematic diagram is shown in Fig. 4. The transistor has ring-dot geometry, and it is bonded to a TO-18 header. As indicated by the activation energy

Fig. 2. Activation energy of the channel current,  $E_{a, ch}$  as a function of the surface potential,  $\phi_s$ .

Fig. 3. Arrhenius plot of  $I_{BN}^0$

of  $I_{BN}$ , the units have a small built-in channel as prepared. The value of  $E_a$  is lower than the expected value for generation-recombination current due to a channel component (see Fig. 3).

In order to investigate the effect of this channel on the gain, special transistors were fabricated of the same design except for an aluminum field plate over the oxide of the emitter-base junction. The peak in the recombination-generation current as a function of field plate voltage, observed by Sah (10) and Reddi (14), was not seen on our units (Fig. 5), indicating that the surface was not entirely inverted. No evidence of such a peak was found in the ambient-bake experiment of the transistors used without field plates. All the treatments described below resulted in a monotonic change in gain.

*Contamination and heat-treatments.*—The transistors were cleaned in hot solvents, (trichloroethylene, acetone, alcohol) followed by a cascade rinse in low conductivity water and dried in filtered nitrogen. The clean units were split into two groups. One group was kept clean as control, and the units of the second group were contaminated by evaporating a 5 microliter drop of a 0.02M NaCl solution. Assuming a uniform sodium distribution over the entire header and wafer surface this corresponds to approximately  $5 \times 10^{16}$  sodium atoms/cm<sup>2</sup>. The sodium in fact was not uniformly distributed; small crystallites formed over the surface with a higher density of crystallites over the metal contacts. The sodium concentration over the SiO<sub>2</sub> was probably closer to  $5 \times 10^{15}$  atoms/cm<sup>2</sup>. Some of the experiments were later repeated with vacuum evaporated NaCl. The salt in this case formed a uniform layer over the entire surface, the gain degradation results, however, were similar with the two methods.

The transistor leads were welded to the ports of a specially built Vac-Ion station, and thus all transistors were exposed to the identical ambient. The vacuum station was flushed with high-purity gases at a rate of 1.5 l/min. The dry gases had a water vapor content of less than 1 ppm. The wet gases were saturated with water vapor at room temperature. The baking cycle lasted for 16 hr at 350°C.

Table I. Typical values of  $I_{BN}^0$ ,  $E_a$ , and  $n$  for the different components of  $I_{BN}$

$I_{BN}$ component	$I_{BN}^0$ , 300°K (amp)	$V_a$ (ev)	$n$
Recombination-generation	$10^{-13}$ - $10^{-12}$	0.7	1.5
Channel*	$10^{-10}$ - $10^{-5}$	0-0.6	2-4

\* Values depend on the degree of inversion and on the geometry of the junction. The values given here are typical for degraded devices.

Fig. 4. Silicon planar transistor schematic diagram

Fig. 5.  $I_B$  as a function of field plate voltage. Field plate over the emitter junction of an npn planar transistor.

The transistor aging conditions were also applied for MOS capacitors. High resistivity p-type slices were oxidized to form approximately 1800Å of oxide, cleaned similar to the transistors and split into 3 pieces. One piece was sodium contaminated by NaCl evaporation and the other two pieces were kept clean. The sodium contaminated pieces and one of the clean pieces received a temperature-ambient treatment and the second clean piece was kept as a control. The heat-treatments in this case lasted for 2 hr at 450°C. Ten-mil diameter aluminum dots were then simultaneously evaporated over all three pieces to determine the flat band voltages.

### Results

A summary of the aging experiments is given in Table II. Not shown in the table are transistors with more than  $10^{17}$  atoms/cm<sup>2</sup> of evaporated sodium. The results can be listed as follows.

**Sodium contaminated transistors.**—(A) High (over  $10^{17}$  atoms/cm<sup>2</sup> concentration of sodium degrades the gain in all ambients under our aging conditions; (B) gain degradation occurs only in hydrogen ambient on transistors contaminated with  $\sim 10^{16}$  atoms of Na/cm<sup>2</sup>; (C) sodium contaminated units degraded in hydrogen or dry nitrogen at any sodium level can be partially recovered with water vapor (in N<sub>2</sub> or O<sub>2</sub>); (D) phosphorous glass reduces the gain degradation in hydrogen (Table III).

The different parameters of base current can be analyzed with the help of Table IV. Wet and dry forming gas showed identical results. Comparing the results of Table IV with the trends summarized in the

Table II. Changes in  $h_{FE}$  ( $I_C = 10^{-5}$  amp) after heating for 16 hr at 350°C (average of 3 transistors)

No. of experiments	Ambient	$h_{FE}$ , Final/ $h_{FE}$ , Initial

\* Contamination level  $> 10^{17}$  atoms Na/cm<sup>2</sup>.

section on Low Current D-C Gain the following results are obtained. Sodium gives rise to a channel current, and the effect of sodium is enhanced by the presence of hydrogen.

**Sodium contaminated MOS capacitors.**—The above results were substantiated by the MOS capacitor experiments. Table V shows the results. A large shift occurred in the flat band voltage after heat-treatment in dry N<sub>2</sub> and dry FG. A smaller shift was observed in wet FG and no shift appeared in wet N<sub>2</sub>. Increasing the sodium concentration to higher levels or aging at higher temperatures results, however, in a large shift of flat band voltage in all ambients.

**Noncontaminated transistors.**—The results obtained with noncontaminated devices (Table II) can be summarized as follows:

Table V. Position of the flat band voltage on MOS capacitors after baking for 2 hr at 450°C before metal evaporation

Ambient	Flat band voltage			Thickness (Å)
	Not baked	Baked, clean	Baked, sodium contaminated	
Wet N <sub>2</sub>	5.0	5.0	4.0	1900
Wet FG	5.7	4.5	16.2	1870
Dry N <sub>2</sub>	5.2	4.5	20.0	1650
Dry FG	6.2	6.5	21.3	1950

1. Water vapor and hydrogen improve the gain during heat-treatment. Baking in dry inert gas has no appreciable effect.

2. Dry ambients other than hydrogen ( $N_2$ ,  $O_2$ , vacuum) degrade the gain previously improved in water vapor or hydrogen.

3. Both the improvement and the degradation of gain are reversible.

The relative change in the values of  $I_{BN}^0$  at various temperatures is listed in Table VI. The change becomes larger with increasing temperatures in both wet nitrogen and dry forming gas. This indicates that the major effect of the baking is the reduction of the recombination-generation component of the base current.

### Mechanism

There are numerous attempts in the literature to explain the MOS device results in terms of a physical model (4, 6, 16, 19-21). Some of the proposed mechanisms help to explain our results for noncontaminated transistors. None of the models accounts, however, for the observed effect of hydrogen on the migration of sodium through the oxide.

There is a controversy in the literature regarding the effect of hydrogen on the Si-SiO<sub>2</sub> interface. Some authors observe a decrease in fast states at the interface (4, 5, 16) or increase in low current gain (17) on annealing in hydrogen or water vapor. Contrary to these results an inversion layer has been reported external to the metal contact on a p-type MOS capacitor after heat-treatments in hydrogen (18, 19). Blum *et al.* (20) observed that forming gas baking turned the collector surface more n-type. Busen and Lindmayer (21) used this observation to support their hypothesis that H<sup>+</sup> might be the source of the fixed positive charge at the Si-SiO<sub>2</sub> interface.

Our results indicate that the effect of hydrogen depends on the contamination level of the device. On clean transistors hydrogen improves gain by reducing the generation-recombination current. This can be explained by the saturation of dangling silicon bonds close to the Si-SiO<sub>2</sub> interface through the formation of Si-H bonds (4, 5, 16).

On contaminated units hydrogen "activates" the sodium which in turn degrades the gain. It is very likely that the degradation attributed to hydrogen in earlier experiments (19-21) was in fact caused by sodium. In order to explain the "activation" of sodium by hydrogen let us examine some features of amorphous SiO<sub>2</sub>.

Sodium ions migrating to the Si-SiO<sub>2</sub> interface can induce a negative charge in the bulk silicon. We shall be concerned therefore with the degree of ionization of the sodium, and the migration of the ions through the oxide. In amorphous SiO<sub>2</sub> the adjacent silicon atoms are bridged by an oxygen atom. At defect sites or if silicon is replaced by a trivalent metal such as aluminum ( $Al^{3+}$ ), the oxygen is connected only to one silicon. The second valence of such a nonbridging oxygen is usually occupied by a monovalent species such as sodium or hydrogen. Another site for sodium in SiO<sub>2</sub> is at a normal interstitial position. Based on the differences in electronegativity between sodium and oxygen, the O-Na bond has approximately a 63% ionic character. This is a lower value than the almost

fully ionized sodium in an interstitial position. In addition, sodium ions attached to nonbridging oxygens occupy a lower energy level and have a lower mobility in the oxide than the interstitial ions. It can be expected, therefore, that sodium is more "active" in an interstitial position than in the O-Na bond.

The permeability of hydrogen through fused quartz has been thoroughly investigated (22) with close agreement on both permeability and activation energy data. Similar to sodium ions, hydrogen might occupy interstitial sites, or it can be accommodated in the form of isolated OH groups. The direct exchange of alkali and hydrogen has been demonstrated in high-temperature electrolysis (23). Alkali ions are removed from the anode and migrate to the cathode in vitreous silica. Infrared measurements showed that as sodium is removed from the anode it is replaced by hydrogen, present at Si-OH groups.

It follows that in the absence of hydrogen the alkali ions occupy low energy vacancy sites resulting in a low mobility. In the presence of hydrogen some of the alkali ions are forced into the high energy interstitial sites, thus increasing their ionic character and mobility. It should be noted that the pronounced effect of hydrogen is only present at moderate temperatures and sodium concentrations. At high temperatures the vacancy migration becomes appreciably fast, and at high sodium concentration the vacancy sites are saturated leaving a fraction of the sodium ions in interstitial position.

The improvement in gain during heat-treatment in water vapor on sodium contaminated devices previously degraded in hydrogen might be associated with vacancy formation by the water vapor. This can be accomplished by either facilitating the degassing of hydrogen from the oxide or by the formation of new vacancy sites (nonbridging oxygen).

### Discussion and Conclusion

Transistor low current d-c gain is dominated by the nonideal component of the base current. This in turn is made up of a Sah-Noyce-Shockley recombination current and a channel current. The two components can be separated by analyzing the temperature dependence of  $I_{BN}$ .

Hydrogen and water vapor bakes improve the gain primarily by reducing the recombination current. Baking with sodium contamination degrades gain; hydrogen accelerates the degradation and water vapor impedes it. Sodium baked transistors degrade by an increase in the channel component of  $I_{BN}$ .

It is suggested that hydrogen enhances sodium migration in SiO<sub>2</sub> by displacing Na from vacancy sites in the oxide; Na is forced into interstitial sites where it is more mobile and fully ionized.

The technique of analyzing  $I_{BN}$  as a function of temperature offers a means of investigating transistors which have degraded low current gain. Thus degradation mechanism may be identified on transistors from production rejects and on life test failures.

### Acknowledgment

Acknowledgment is made to N. Carthage for heat-treating the transistors and making electrical measurements, to B. J. Snyder for sample preparation and sodium contamination, and to J. H. Burchill for MOS measurements.

Manuscript received April 10, 1968; second revised manuscript received ca. Aug. 1, 1968. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966, as a Late News Paper.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

### APPENDIX

In this appendix, the following equation for the activation energy of a channel will be derived.

Table VI. Temperature dependence of the change in  $I_{BN}^0$  on heat-treatment

350°C, 16 hr, noncontaminated transistors

Ambient	Temp, °C	$I_{BN}^0$ Final/ $I_{BN}^0$ Initial
Wet N <sub>2</sub>	-15	0.90
	30	0.59
	75	0.24
Dry FG	-15	1.10
	30	0.56
	75	0.14

$$E_{a, ch} = \frac{E_g}{2} + 2 \left[ 2.75 \frac{kT}{q} - |\Phi_s| \right] \quad [A-1]$$

where  $E_g$  = band gap energy in ev.  $\Phi_s$  = surface potential in ev.  $E_{a, ch}$  = activation energy in ev, and  $q$ ,  $k$ , and  $T$  have their usual meanings.

The derivation is given for a p-type inversion layer on n-type layer on p-type material.

At pinch-off, the channel current is proportional to the square of the mobile charge density (24)

$$I_p = K \mu q^2 Q_p^2 \quad [A-2]$$

where  $\mu$  = mobility of the holes in the inversion layer.  $Q_p$  = mobile charge density in  $\text{cm}^{-2}$ .  $I_p$  = channel current in amperes.  $K$  = a constant. In terms of the Kingston-Neustadter theory (25)

$$Q_p = n_i L_D G(u_s, u_B) \quad [A-3]$$

where  $Q_p$  = mobile charge density in  $\text{cm}^{-2}$ .  $n_i$  = electron (or hole) density in intrinsic material,  $\text{cm}^{-3}$ .  $L_D$  = Intrinsic Debye length in cm.  $G(u_s, u_B)$  = a function defined by Kingston and Neustadter (25).  $u_B$  = Fermi level minus midgap potential for the bulk material in  $kT/q$  units.  $u_s$  = Fermi level minus midgap potential for the surface in  $kT/q$  units. For an accumulated surface,  $u_s$  is  $-$  for p-type and  $+$  for n-type material; for a depleted (or inverted) surface, the reverse relationship holds.

The activation energy of  $I_p$ ,  $E_{a, ch}$  is

$$E_{a, ch} = - \frac{k}{q} \frac{d}{d(1/T)} \ln I_p \quad [A-4]$$

The temperature dependence of quantities entering into Eq. [A-2] is given in Eq. [A-5] and [A-8] below.

$$n_i = CT^{3/2} \exp \left[ \frac{-qE_g}{2kT} \right] \quad [A-5]$$

where  $C$  = a constant.

$$L_D = \left[ \frac{\epsilon kT}{2q^2 n_i} \right] \quad [A-6]$$

where  $\epsilon$  = permittivity of silicon.

For the case where the mobility is dominated by the impurities in the silicon,

$$\mu \sim T^{3/2} \quad [A-7]$$

The function  $G(u_s, u_B)$  cannot be expressed in closed form, but has been accurately tabulated by Mattauch *et al.* (27). By a numerical analysis based on Mattauch's tables, it has been determined that to a good approximation

$$\frac{d}{d(1/T)} \ln G(u_s, u_B) = \frac{q}{k} |\Phi_s| \quad [A-8]$$

To a good approximation, this result is independent of  $u_B$ .

Then, using [A-2] to [A-8], after some manipulation, Eq. [A-1] results.

$$E_{a, ch} = \frac{E_g}{2} + 2 \left[ 2.75 \frac{kT}{q} - |\Phi_s| \right] \quad [A-9]$$

## Growth and Properties of Nb<sub>2</sub>O<sub>5</sub> Thin Film Capacitors

H. R. Brunner, F. P. Emmenegger,\* M. L. A. Robinson, and H. Röttschi

Laboratories RCA, Ltd., Zurich, Switzerland

The reduction in the area occupied by the capacitors in an integrated circuit by using a high permittivity material is a well established problem. Although many materials and methods of preparation (1) have been tried, the established insulators SiO<sub>2</sub> and Si<sub>3</sub>N<sub>4</sub> have yet to be seriously challenged, except for specialized purposes (2).

The present paper reports work in which halogen transport reactions, a technique powerful in the preparation of single crystals of new compounds and epitaxial layers (3), have been used for the first time to prepare thin oxide films. Films of Nb<sub>2</sub>O<sub>5</sub>, Ta<sub>2</sub>O<sub>5</sub>, TiO<sub>2</sub>, and ZrO<sub>2</sub> have been successfully prepared. Of these Nb<sub>2</sub>O<sub>5</sub> has been least studied, and an investigation into its potential as a thin film capacitor is reported here.

### Growth of Nb<sub>2</sub>O<sub>5</sub> Films in a Flow System

Nb<sub>2</sub>O<sub>5</sub> may be deposited by either of the following two reactions

$x = 2.33-5$  depending on temperature and chlorine pressure (4).

For the chemical deposition of Nb<sub>2</sub>O<sub>5</sub>, a low but manageable concentration of a gaseous niobium compound is needed. Reaction [2] goes completely to the right at all temperatures in question. In order to generate a low concentration of gaseous NbCl<sub>x</sub>, very low chlorine concentrations in an inert gas carrier stream would have to be monitored carefully and good, or at least reproducible, contact between chlorine and the niobium source would have to be ensured.

From the equilibrium constant of reaction [1] (5) it can be calculated that the equilibrium pressure of NbOCl<sub>3</sub> is around 0.3% of the chlorine pressure at around 850°C. Therefore low concentrations of the volatile niobium species NbOCl<sub>3</sub> can be generated by easy to control chlorine pressures, and sufficient contact between chlorine and niobium source is not critical.

Reaction [1] was therefore used to generate the volatile niobium species for the chemical deposition of Nb<sub>2</sub>O<sub>5</sub> films. Growth of Nb<sub>2</sub>O<sub>5</sub> films took place in the apparatus shown in Fig. 1. It consists of a system of quartz tubing heated by split ovens. Gas supply is through calibrated flow meters.

A gas mixture consisting of 3% Cl<sub>2</sub> and 97% argon was streamed at a flow rate of 100 cm<sup>3</sup>/min over a boat containing Nb<sub>2</sub>O<sub>5</sub> powder (Ciba optical quality 99.9%). After entering the deposition zone, the argon stream carrying the NbOCl<sub>3</sub> was mixed with pure oxygen flowing at a rate of 70 cm<sup>3</sup>/min. Reaction of the oxygen with the NbOCl<sub>3</sub> took place preferentially on the substrate and on the walls of the quartz tubing, generating a microcrystalline, well-adherent Nb<sub>2</sub>O<sub>5</sub> film.

Platinum foil or polished {111} wafers of n-type silicon (Sb, 0.01 ohm cm) were used as substrates. In some experiments the silicon was covered with a thin evaporated metal film or a cermet layer (see the next section). Usually four silicon substrates 10 x 5 x 1 mm were mounted on the quartz holder by a drop of sodium silicate solution. Useful growth rates of Nb<sub>2</sub>O<sub>5</sub> films were observed in the temperature range 700°-1100°C with source and deposition zone at the same temperature as measured by thermocouples I, III, and IV (Fig. 1).

Additional features (only used in the preliminary investigation of the Nb<sub>2</sub>O<sub>5</sub> film growth) of the growth apparatus are the possibility to add, through furnace II, a third component into the reaction chamber and to keep the substrate temperature below that of the reaction chamber by aircooling the substrate holder.

After preliminary evaluation of the uniformity of growth and film thickness measurement under the microscope, Nb<sub>2</sub>O<sub>5</sub> capacitors were completed by the following standard procedure. A matrix of top electrodes of aluminum, gold or, indium, 0.2 x 0.2 mm square and with 0.6 mm separation, was evaporated onto the film. The bottom electrode was provided by the silicon substrate, the back of which was sandblasted and completely covered with a thin film of Hg-In alloy. Samples were mounted between gold pressure contacts in a screened holder. Three terminal capacity and loss measurements were made between 20 Hz and 500 kHz, and 2 terminal measurements between 1 MHz and 100 MHz using standard laboratory equipment.

Fig. 1. Schematic drawing of the apparatus used for the chemical deposition of niobium oxide films.

\* For these thicker films the low-frequency dielectric constant is given instead of the capacitance per unit area.

† The spread in the capacitance and loss factors represents the extreme values measured on a particular substrate.

### Properties of Nb<sub>2</sub>O<sub>5</sub> Films

Preliminary studies were made by growing thick (5-50 $\mu$ ) films on platinum foil (e.g., Table I, sample 3 to 5). These films were grown at temperatures of 900°-1000°C where the transport rate was highest, a typical rate being 10  $\mu$ /hr. The films were polycrystalline needles oriented with the needle axis perpendicular to the substrate, and were identified by x-ray analysis, as the H-modification of Nb<sub>2</sub>O<sub>5</sub>. As with crystals of this modification grown in a closed system (6), the dielectric properties were dominated by interfacial polarization effects. However, in contrast to the closed system, in which it was desired to produce large crystals, the polarization effects could be removed either by growing films at high oxygen pressures or by annealing in oxygen at 1000°C, which produces films with dielectric constant of  $100 \pm 20$ , with loss factors of 0.03 at 1 kHz and breakdown voltages of greater than  $5 \times 10^5$  v/cm. The value of the low-frequency dielectric constant is in good agreement with that deduced from measurements on bulk material (6).

Similar films grown on silicon, however, always showed interfacial polarization effects and high losses (Table I, sample 27). This was at first considered to be due to the incorporation of some silicon into the Nb<sub>2</sub>O<sub>5</sub> crystallites, similarly to B-modification Nb<sub>2</sub>O<sub>5</sub> crystals (7), but this was later disproved (see below). However, the polarization was greatly reduced by covering the silicon substrate with a thin evaporated metal film (Table I, samples 31, 37, 56) prior to deposition of the Nb<sub>2</sub>O<sub>5</sub>. 50-200Å of iron, chromium or titanium was found to be satisfactory. At the same time it was found that the presence of these metals, and particularly of iron, greatly improved the uniformity of nucleation of the Nb<sub>2</sub>O<sub>5</sub>. However, the frequency dependence of the capacity and loss tangent of films grown on thin iron films was complicated by a relaxation amounting to typically 10% in capacitance in the megahertz region arising from the presence of the thin iron oxide film under the Nb<sub>2</sub>O<sub>5</sub>.

Interfacial polarization effects were best eliminated, by using a rigorous cleaning procedure developed by Zaininger and co-workers (8) (Table I, sample 61, 62, 84), for the reduction of the number of surface states on silicon, especially those due to sodium. It was again noticeable that the uniformity of nucleation of the Nb<sub>2</sub>O<sub>5</sub> was greatly improved on silicon substrates which had been cleaned in this way. If a thin iron film (50-200Å) was evaporated onto such thoroughly cleaned silicon wafers, prior to the deposition of the Nb<sub>2</sub>O<sub>5</sub> layer, almost no further improvement of the uniformity of the Nb<sub>2</sub>O<sub>5</sub> layers could be detected on electron microscope photographs. Therefore the evaporation of the iron film was dispensed with.

The correlation of the removal of interfacial polarization effects with the great improvement in uniform-

ity of growth, and, in the case of the carefully cleaned silicon, with the reduction in the density of surface states is quite remarkable. Although much more experimental work is clearly necessary, this result may be of general significance.

Once the problem of interfacial polarization had been solved, it was found that the capacity per unit area on partially masked substrates together with frequency dependence and thickness dependence capacity measurements indicated the formation of about 100-200Å of SiO<sub>2</sub> under the Nb<sub>2</sub>O<sub>5</sub> films during growth. This SiO<sub>2</sub> layer always formed even when the temperature of the furnace was reduced to below 750°C where clean silicon is not easily oxidized in a dry atmosphere (9, 10). It is tentatively concluded that the oxidation is either catalyzed by the chlorine or by the niobate reaction products [compare ref. (8)].

The presence of the SiO<sub>2</sub> layer under any Nb<sub>2</sub>O<sub>5</sub> film grown by chlorine transport method is naturally very limiting. Capacities greater than that of the SiO<sub>2</sub> alone cannot be achieved without the use of an additional electrode between the SiO<sub>2</sub> and the Nb<sub>2</sub>O<sub>5</sub>. Unfortunately trials with a number of conductive substrates failed to reproduce the uniform quality of the Nb<sub>2</sub>O<sub>5</sub> films grown on silicon, so that some effort was directed into optimizing the uniformity of the Nb<sub>2</sub>O<sub>5</sub> films with rigorously cleaned silicon, as a substrate, using temperature and reaction rates as parameters. The best films produced showed no crystalline structure in magnifications up to 1000X, and the capacity per unit area was reproducible within  $\pm 10\%$ . Their frequency response shown in Fig. 2 is consistent with a composite dielectric of about 100Å of SiO<sub>2</sub> (dielectric constant ~5) and about 2000Å of H-modification Nb<sub>2</sub>O<sub>5</sub> [dielectric constant ~120 (6)].

Fig. 2. Frequency dependence of the capacity and loss factor of an Nb<sub>2</sub>O<sub>5</sub> film grown on n-type silicon at 850°C. The top electrodes were evaporated gold, and the substrate formed the bottom electrode.

Fig. 3. Capacitance per unit area plotted against d-c breakdown voltage for niobium oxide capacitors on silicon. Each point is an average value of 5-10 measurements on a given sample. The dotted curve was calculated for Nb<sub>2</sub>O<sub>5</sub> layers using the following values for the breakdown voltage and the dielectric constant:  $V_B = 5 \cdot 10^5$  v/cm and  $\epsilon = 120$ . [see section on Properties of Nb<sub>2</sub>O<sub>5</sub> Films and ref. (6)] The solid curve shows what can be achieved at present using Si/SiO<sub>2</sub> capacitors.

However, as can be seen from Fig. 3 the relation between breakdown voltage and capacity per unit area value of most of the layers were more characteristic of SiO<sub>2</sub> than of Nb<sub>2</sub>O<sub>5</sub>, and it was suspected that this was due to the presence of large numbers of pinholes in the Nb<sub>2</sub>O<sub>5</sub> layers. This was eventually confirmed by growing Nb<sub>2</sub>O<sub>5</sub> on platinum/palladium cermet deposited on silicon as a base electrode. This cermet mixture retains its conductive properties, and its smoothness up to temperatures in excess of 1000°C and Nb<sub>2</sub>O<sub>5</sub> layers grown on it were optically very similar to those grown on silicon. Their breakdown voltages were much lower than for the layers grown on oxidized silicon, thus confirming the above hypothesis. Further confirmation was provided by electron microscope studies.

#### Discussion

High permittivity, low loss materials are necessarily crystalline (well ordered). Thus, if the present-day capacitor films are to be improved fundamentally, one should aim at the deposition of crystalline dielectrics.

Therefore an attempt has been made to deposit crystalline Nb<sub>2</sub>O<sub>5</sub>-films [Nb<sub>2</sub>O<sub>5</sub> is known to have outstanding dielectric properties, see ref. (6)] on silicon by chlorine transport. Metal oxides deposited by halogen transport will always tend to be crystalline because of the high deposition temperature which is required to achieve fast and complete reaction be-

tween metal halide (or oxyhalide) and oxygen. Only very few metals will form glassy, amorphous oxides at elevated temperatures.

In the case of Nb<sub>2</sub>O<sub>5</sub>-capacitors it was found that thin polycrystalline films suffered from low breakdown voltage. Low breakdown voltage will be difficult to overcome in polycrystalline thin films for the following reasons.

1. It is virtually impossible to achieve sufficiently dense packing of the individual crystallites to yield a pinhole-free film.

2. Impurities tend to collect at grain boundaries thereby creating regions of increased conductivity.

It is therefore concluded that only epitaxial films will have the desired high capacity and high breakdown voltage properties.

Crystallinity, the first of the two requirements for improved dielectric films, is easily fulfilled by depositing oxide films using the halogen transport method. Epitaxy, the second requirement, has not yet been achieved, but it is not completely unfeasible.

#### Acknowledgments

It is a pleasure to acknowledge the advice of Dr. R. Nitsche and Dr. W. J. Merz in carrying out this work. The authors should also like to thank E. R. Lewin for taking the electron microscope photographs, J. L. Vossen for supplying the cermet substrates, K. H. Zaininger for useful discussions on the preparation of silicon surfaces, and, last but not least, D. Richman for initiating the project.

Manuscript received July 1, 1968; revised manuscript received Aug. 2, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

Fig. 1. The dislocation network generated by the diffusion of phosphorus into a (111) silicon surface.

Shockley<sup>6</sup> has shown that the elastic energy released by gliding a dislocation with a Burgers vector  $b$ , a distance  $r$  down the slip plane is

$$E_s = \sqrt{2}\mu[(1+\nu)/(1-\nu)]br e_o \quad [2]$$

where  $\mu$  is the shear modulus of elasticity,  $\nu$  is Poisson's ratio, and  $e_o$  is the elastic strain. In order to estimate  $E_g$  we need to consider in more detail the dislocation configurations which are generated by the diffusion of phosphorus in silicon.

The six slip systems which are usually observed<sup>5-7</sup> when phosphorus diffusion takes place into the (111) surface of a silicon crystal are illustrated schematically with a tetrahedron of {111} planes in Fig. 1. The plane ABC represents the crystal surface. Dislocations  $L_1$ ,  $L_2$ , and  $L_3$ , can lie along the directions AB, BC, and CA, respectively, with Burgers vectors  $b_1$ ,  $b_2$ , and  $b_3$ , respectively, of magnitude  $a/2$ , along the remaining  $\langle 110 \rangle$  directions, where  $a$  is the lattice constant. The corresponding glide planes are ABD, BCD, and CAD, respectively. Thus a dislocation line,  $L_1$ , along AB can have a Burgers vector,  $b_1$ , along either DA or DB, etc. The dislocation intersections which occur in this configuration and result in the formation of edge jogs have been described elsewhere.<sup>17</sup>

The energy dissipated by vacancy generation when a unit length of one of these dislocations containing  $p$  edge jogs glides a distance  $r$  down the slip plane has been previously<sup>2</sup> estimated as

$$E_g = 2\sqrt{2}rp E_v/\sqrt{3}a \quad [3]$$

where  $E_v$  is the energy of formation of a vacancy.

By substituting Eq. [2] and [3] into the criterion expressed by Eq. [1], it is seen that a dislocation will continue to glide only if it has a jog concentration

$$p \leq (\sqrt{3}ab\mu e_o/2E_v)[(1+\nu)/(1-\nu)] \quad [4]$$

This criterion can be used, as follows, to estimate the critical surface concentration at which the work hardening mechanism begins to operate. Then, as a test of the model, the result can be compared with the critical surface concentration observed by Duffy *et al.* at which the retarded diffusion phenomenon begins.

When a significant number of dislocations with jog concentrations near this value accumulate on an atomic plane the energy criterion expressed by Eq. [1] can continue to be satisfied by the formation of a network of dislocations which glide into the crystal simultaneously, thus substantially reducing the jog

concentration. It is possible, in this way, for relief of the diffusion-induced stress to continue by dislocation glide with a significantly reduced rate of vacancy generation, and a consequent reduction in the amount of anomalous diffusion. Thus, according to this interpretation, the two cases illustrated in Fig. 2 of the paper under discussion correspond to one surface concentration below the critical value and another above it. After the drive-in stage, the steeper curve, which corresponds to the higher dislocation density, exhibits the shallower phosphorus diffusion of the two, as would be expected from a reduction in the amount of anomalous diffusion due to the formation of the dislocation network.

We have previously established<sup>2</sup> that a dislocation which has moved from the crystal surface to a position at the front of the dislocation network during the diffusion of phosphorus from a constant surface concentration  $C_o$  would be likely to have a jog concentration of approximately

$$p = (1/\sqrt{3})(\beta/\alpha)C_o \quad [5]$$

where  $\beta$  is the solute lattice contraction coefficient, and  $\alpha$  is the component parallel to the crystal surface of the Burgers vector of the dislocations which are generated.

Substituting for  $p$  from Eq. [4], the condition that the jog concentration should be substantially reduced by the formation of a suitable dislocation network becomes

$$C_o \leq (3\alpha ab\mu e_o/2\beta E_v)[(1+\nu)/(1-\nu)] \quad [6]$$

By substituting suitable values in Eq. [6] it can be shown<sup>2</sup> that the critical surface concentration varies from  $1.2 \times 10^{21}$  atom/cm<sup>3</sup> at 1000°C to  $2.2 \times 10^{20}$  atom/cm<sup>3</sup> at 1250°C. These values are in good agreement with the value of about  $10^{21}$  atom/cm<sup>3</sup> at 970°C which is obtained from Fig. 2 of the paper.

Thus, to summarize, we consider that in the low phosphorus concentration range in which no dislocations are generated, the enhancement of the rate of phosphorus diffusion reported by Duffy, Barson and Schwuttke<sup>3</sup> is explicable in terms of field aided diffusion. At higher surface concentrations, on the basis of the present model, the dislocation density would be expected to increase with the surface concentration and produce anomalously fast diffusion. Ragged junctions would result from the localized enhanced diffusion produced by the glide of individual heavily jogged dislocations into the crystal. However, with surface concentrations in excess of the critical value, the movement of these dislocations would be prevented by the formation of the dislocation network. Thus, the formation of the dislocation network would simultaneously produce a reduction in the degree of anomalous diffusion and more uniform junctions. Thus, most of the observations can be adequately explained in terms of this model.

**M. C. Duffy, F. Barson, J. M. Fairfield, and G. H. Schwuttke:** We appreciate the comments of Dr. Parker; unfortunately his publications,<sup>19</sup> (in which he applied a generalized concept of Balluffi and Ruoff<sup>20</sup> to diffusion into single crystal diamond type lattices), were not available until after our revised manuscript was submitted. However, we do have a few clarifying comments.

It was not our purpose to explain completely the anomalous enhancement of diffusion at the intermediately high concentrations but only in so far as such explanations would help elucidate the retarded diffusion at the highest concentrations.<sup>21</sup> However, since this question has been opened, we suggest that a significant

<sup>19</sup> T. J. Parker, *J. Appl. Phys.*, **38**, 3475 (1967); *J. Appl. Phys.*, **38**, 3471 (1967); and *J. Appl. Phys.*, **39**, 2043 (1968).

<sup>20</sup> R. W. Balluffi and A. L. Ruoff, *J. Appl. Phys.*, **34**, 1634 (1963).

<sup>21</sup> M. C. Duffy, F. Barson, J. M. Fairfield, and G. H. Schwuttke, *This Journal*, **115**, 84 (1968).

mechanism of diffusion enhancement, in addition to the effects of field and lattice strain discussed above by Parker, is through an enhanced equilibrium vacancy concentration in the regions of high N-type doping (e.g., phosphorus) which is caused by the excess electrons through a mass action principle.<sup>22</sup> Incidentally, in our investigation the background concentration was less than the intrinsic value and does not enter explicitly into calculations of effective diffusion coefficients as influenced by built-in electric field.

At any rate, it is the possible strain enhancement that is of principle interest to explain the diffusion retardation. We suggested,<sup>21</sup> as one possible mechanism, that the formation of the small cell diffusion induced dislocation network [see Fig. 3 of ref. (21)] may well reduce the magnitude of the strain enhancement of diffusivity by rendering the dislocations individually less mobile. It is gratifying that Dr. Parker finds this suggestion to be quantitatively feasible through his proposed mechanism. However, we still feel that the suggestion is speculative owing to the following uncertainties: (a) the assumption of substitutional diffusion at these extremely high impurity concentrations and in the presence of precipitates is, at best, problematical; (b) the kinetics of the dislocation formation in our case are not steady state; thus, the quantitative applicability of Prussin's model is unjustified; and (c) there are vacancy sinks in addition to the crystal surface, for example in the formation of vacancy type dislocation loops; thus, there will be a vacancy annihilation rate of uncertain magnitude.

#### Impedance for Tunnel Exchange of Electrons Across the Annealed Ta/Ta<sub>2</sub>O<sub>5</sub> Interface

K. Lehovc (pp. 192-199, Vol. 115, No. 2)

**D. M. Smyth**<sup>23</sup>: Lehovc proposes to explain the impedance properties of heat-treated, anodized tantalum by means of a tunneling process across the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. The essential difference between this mechanism and the previously proposed exponential conductivity gradient<sup>24,25</sup> is in the spatial distribution of the controlling process within the oxide. The conductivity model assumes that there is an effective dielectric thickness which is obtained from the observed equivalent series capacitance and the parallel plate equation; the rest of the oxide thickness is effectively short-circuited. The short-circuited region generally amounts to a few hundred angstroms (18% of the total thickness) for samples heat-treated in air. The tunneling model, on the other hand, implies that the active region is confined to the oxide within a few tens of angstroms of the Ta-Ta<sub>2</sub>O<sub>5</sub> interface (about 1% of the oxide thickness). Since both models can explain the basic experimental observations, it is important to search for experiments which might distinguish between them. I would like to describe two experiments which give an indication of how far the dielectric losses extend into the oxide.

First, when anodized tantalum is heat-treated in vacuum, subsequent capacitance measurements made near room temperature behave as if the oxide film were completely short-circuited. The question is, is this a true electronic short-circuit, or does it merely indicate extremely high dielectric losses, perhaps still located near the Ta-Ta<sub>2</sub>O<sub>5</sub> interface? To answer this question, we have heated a tantalum sample, anodized to 75v, in vacuum at 450° and then applied several small Ni dots (~ 0.2 cm<sup>2</sup>) to the lower half of the sample by electroless deposition. All five electrode dots became d-c short-circuits when 1-2v were applied (Ta<sup>+</sup>). This means either that the oxide film was conducting throughout, or that it was badly damaged by

the heat-treatment. In order to disprove the latter, the same sample was reheated at 400° in air and Ni dots were then applied to the upper half. One dot broke down at about 25v; the other four supported maximum voltages between 75 and 80v. Apparently most of the oxide had been restored to an insulating condition as expected from the conductivity model.

The only difference between the vacuum-heated samples and the air-heated samples is the ambient atmosphere during heat-treatment. When the heating is done in vacuum, it appears that both the vacuum and the tantalum are sufficiently good reducing agents to render the oxide sufficiently conducting to affect its dielectric properties. There is no reason to expect the tantalum to react any differently when the heating atmosphere is changed to air. The only difference is that the oxide at the air interface is more highly oxidized and hence less conducting. It is reasonable to expect a steep conductivity gradient to result from such a change in oxygen activity across these thin films.

The other experiment involves the behavior of tantalum samples anodized in concentrated H<sub>3</sub>PO<sub>4</sub> solutions. It is well established that the resulting oxide film consists of an outer portion which contains large amounts of phosphorus, and a portion next to the metal which contains no phosphorus. In the case of anodization in 85% H<sub>3</sub>PO<sub>4</sub> (~ 14.7M) the phosphorus-free region makes up about a third of the total thickness.<sup>26</sup> When such a sample is heat-treated in air, the dielectric properties are in accord with a conductivity gradient which has split into two parts: a shallow, inner gradient, and a steep outer gradient. By stepwise dissolution of the oxide of a sample anodized 75v in a H<sub>3</sub>PO<sub>4</sub> solution containing P<sup>32</sup>, the boundary between the two conductivity gradients has been identified with the boundary between the phosphorus-containing and phosphorus-free oxide.<sup>27</sup> In fact, as the oxide was chemically thinned, the residual radioactivity went to zero simultaneously with the reciprocal series capacitance, a measure of the effective dielectric thickness. Thus the remaining 500Å of phosphorus-free oxide was an effective short-circuit. The interference color of the sample at this point was consistent with such a thickness. The splitting of the conductivity profile into two slopes for these cases has been attributed to a proposed difference in the mobility of oxygen in the phosphorus-free and phosphorus-containing layers during the heat-treatment.<sup>27</sup> This proposal has subsequently been confirmed by Pawel.<sup>28</sup>

It should be stressed that the times and temperatures of heat-treatment are similar for all of these samples, and that the environment at the Ta-Ta<sub>2</sub>O<sub>5</sub> interface is exactly the same for all cases.

These two experimental observations indicate that the region of high dielectric losses in the heat-treated, anodic oxide film on tantalum can extend across hundreds, and even thousands, of angstroms of the oxide film. Such an extension is in accord with the model of a conductivity gradient, and these observations are readily accommodated by this model. It is difficult to see how they can be explained by the tunneling model. Lehovc proposes that the model of a conductivity profile may indeed be the correct one for the two cases described here, whereas the tunneling model might be valid for "ordinary annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures." Keeping in mind that there is a continuous and gradual change of dielectric properties with the ambient oxygen pressure during heat-treatment and with the H<sub>3</sub>PO<sub>4</sub> concentration in the anodization electrolyte, it seems unnecessary to invoke a new theory which can explain only one end of a range of properties when an existing model is compatible with all of the observations.

**K. Lehovec:** D. Smyth discusses two extreme cases of annealed Ta/Ta<sub>2</sub>O<sub>5</sub> samples where dielectric losses arise from conduction, namely (i) Ta/Ta<sub>2</sub>O<sub>5</sub> annealed in a reducing ambient (i.e., vacuum) resulting in a reduction of the entire oxide film, and (ii) Ta<sub>2</sub>O<sub>5</sub> films grown anodically in a concentrated phosphoric acid solution and annealed in air, resulting in reduction of the phosphorus-free inner oxide region. As already mentioned in my paper, I agree with Smyth on the applicability of the conductivity model to the dielectric losses in these two extreme cases.

Smyth points out that in the case of ordinary (i.e., not phosphorus-rich) anodic oxide samples annealed in an oxidizing atmosphere such as air "a steep conductivity gradient results from the change in oxygen activity across these thin films." It seems to me that the steepness of this gradient, i.e., whether the significantly reduced oxide extends over a few tens of angstroms or over a few hundreds of angstroms will determine whether the tunnel model or the conductivity model applies. I do not know of any past experiments which clarify this point.

A theoretical distinction between the two models is not possible without understanding the mechanism of oxygen transport from an oxidizing ambient to the tantalum during the anneal. My attempt<sup>29</sup> to interpret available experimental data to provide a model leading to an exponential oxygen vacancy distribution such as postulated by Smyth *et al.*, was less than fully successful. Therefore, I searched for another interpretation of Smyth's impedance measurements resulting in the tunneling model. This does not rule out, of course, the possibility that a mechanism leading to an exponential vacancy distribution may yet be found, e.g., by a suitable dependence of oxygen vacancy diffusion constant on concentration. Incidentally, the tunnel model proposed by me postulates an inverse-square dependence of the receptor concentration on the position in the oxide adjacent to the tantalum interface in order to provide an exponential conductivity profile and the observed Schottky plot; the

<sup>29</sup> K. Lehovec, *This Journal*, 115, 520 (1968).

origin of this space dependence has not been accounted for either.

In the case of the heavily doped phosphorus-containing samples, there appears to be a discontinuity in the oxygen transport through the oxide at the boundary between the phosphorus-containing outer region and the phosphorus-free inner region. In such a case, the oxidizing ambient atmosphere and the reducing tantalum metal may indeed cause a nearly homogeneous reduction of the inner region, with an abrupt change to a very nearly stoichiometric outer region. However, I would be hesitant to generalize this behavior of an extremely phosphorus-rich sample to "normal" films, where such a pronounced oxygen transport barrier may not be present in the outer film region.

Smyth sees in the gradual change of the "conductivity profile" with phosphorus content an indication of the same underlying mechanism. It is conceivable, however, that two different mechanisms, conduction losses in case of phosphorus-rich oxides and interface tunneling losses in case of phosphorus-free oxide, are superimposed with a gradual transition arising from the relative weights of these two contributions, these weights varying with phosphorus concentration in the forming electrolyte.

In summary, I question the generalization of the two extreme cases discussed by Smyth to the structures on which the measurements analyzed by me have been made. I believe that a clarification should be sought along the following lines: (a) an understanding of the oxygen transport during anneal in an oxidizing atmosphere; (b) electrical measurements on samples of oxide thickness of about 100Å or less, and (c) more extensive measurements of Schottky plots as function of temperature, and of the associated time lags.

In conclusion, I would like to point out again that the tunneling model has been offered by me as a possible alternative for the conduction model. In my opinion, the evidence existing at present does not permit a clear-cut rejection of one or the other of these two models, except in certain extreme cases.

### Polymers: Their Structure and Dielectric Properties

C. A. Buehler

3M Company, Saint Paul, Minnesota

#### ABSTRACT

Polymers, with their high molecular weight and great lengths *vs.* relatively small diameters, tend to have very complex physical and dielectric properties. The dielectric properties, like the mechanical properties, are dependent on the mobility of their constituent parts and are therefore quite sensitive to both temperature and frequency. The effects of glass transition temperature, melting point, impurities, and atomic structure on the dielectric properties are discussed with specific examples from the literature. Conduction and breakdown are covered rather briefly with emphasis on the need for fundamental structural studies in this area.

Polymers may be simply defined as very high viscosity liquids or solids of intermediate or high molecular weight (1). They are made by the chemical union of large numbers of small molecules (monomers) to form a macromolecule. Two general methods of preparing these materials may be described (see Fig. 1). Addition polymerization makes use of unsaturated compounds as monomers and involves their combination without rearrangement of the atoms in the structure. It is normally a fast chain reaction occurring *via* activated free radical or ionic intermediates. Monomeric units add rapidly one after another to a growing chain, and interaction between such chains either does not occur or results in the cessation of growth of one or both chains. On the other hand, condensation polymerization is normally a stepwise, relatively slow reaction. It is best described as a growth process which usually involves the splitting off of a small molecule. Molecules of any size may interact to yield larger molecules capable of further reaction to yield still bigger molecules.

Polymers which are commercially useful usually have molecular weights which vary from 10,000 to 1,000,000. The ultimate molecular weight in one single molecule is actually the result of a series of random events. This usually results in a distribution of molecular weights in a given sample, as shown in Fig. 2 (2). Several methods of describing the molecular weights of a polymer are also illustrated in this figure [for further information on these methods consult Billmeyer (1)]. The most unusual characteristic of these macromolecules is their unique structure. Take for example polymethylene, which has  $-\text{CH}_2-$  units connected together to form a chain 40,000Å long and a diameter of only 4.9Å. A good analogy (3) would be a snarled clothesline 150 ft long and 3/16 in. in diameter. With so many possible conformations available to it, what usually results is a jumbled mass (see Fig. 3) (4). It has been possible to describe mathematically the conformations of such a molecule. If one calculates (3) the end to end distance in the same clothesline analogy, assuming free rotation about bonds, only 1½ ft would separate the two ends (in

solution or melt). An increase in the length of the hypothetical clothesline to almost 1¼ miles increases the end to end distance to only 10-15 ft. Of course, there is not complete free rotation about bonds, but calculations such as this form the foundation for a basic understanding of polymer molecules.

Nonpolymeric materials that form simple crystals usually have a well-defined crystalline melting point. Above this temperature the material is liquid, and the molecular structure does not have a well-defined space lattice. In such a liquid state there is not complete randomness as in a gas; however, there is a lack of any long range order. Below the crystallization temperature we find the well-defined spatial geometry of the crystalline state. Some polymer structures, as we have just discussed, also exhibit this kind of behavior. As long as the polymer molecules have a repetitive pattern and they can move into a regular conformation, the material can become crystalline below a given temperature.

However, crystallization in polymers usually requires a high degree of symmetry (see Fig. 4) as found in materials such as polyethylene, polytetrafluoroethylene, polyvinylidene fluoride, and polyvinylidene chloride. These materials all have a regular structure, and they also possess a high degree of symmetry. They crystallize readily; in fact, polyethylene is so prone to crystallization that it cannot be obtained completely in the amorphous form even with shock cooling of a thin film in liquid air.

Addition polymers of the  $(\text{CH}_2-\text{CHX})_x$  type are most often prepared in the amorphous condition, for

Fig. 4. Atomic structure of some crystalline polymers

although they are composed of chemically identical repeating units, they are in general sterically irregular. Thus, the CH-X groups will be found to occur along the chain randomly in the d- or l-configuration. Such geometric irregularities prevent crystallization unless the X is very small, as is the case in polyvinyl fluoride. However, polymers of the  $(\text{CH}_2\text{CHX})_x$  type are not always found to be sterically irregular. Under certain conditions it is possible to control the ionic or free radical polymerization so that the chains have all one configuration or regularly alternating d- and l-configurations (see Fig. 5). However, more often than not, the structures of polymers tend to be amorphous in character. In the cooling of such polymers there is no sudden rearrangement of the molecules, as in crystallization, but rather a steady loss of mobility

Fig. 5. Monosubstituted ethylenic polymers in three potential configurations, top to bottom, isotactic, syndiotactic and atactic.

until there is no longer fluid resistance to molecular motion. The resistance to motion becomes so high that the material is solid-like in every sense of the word. This transition (1), commonly called Tg (glass transition temperature), is in a thermodynamic sense like a second order transition in that the energy, heat content, volume, and entropy plus many other properties show a discontinuity in slope when plotted vs. temperature (see Fig. 6). However, the analogy to thermodynamic quantities can be misleading since no phase transition is involved.

Since the transition (5) is not sharp, the Tg is generally taken as the mid-point of the temperature interval over which the discontinuity takes place. It is generally believed that at the glass transition temperature all large-scale backbone chain motion ceases, and the long range conformation at this point becomes fixed for all lower temperatures.

The mechanical properties of polymers are directly determined by the molecular mobility of the constituent groups (5); crystallinity is important only in a secondary sense. A material in which all groups are rigidly fixed is brittle irrespective of whether it is crystalline, glassy, or both. In order, therefore, to estimate the effect of temperature (including "room temperature") on the mechanical and the dielectric properties of a proposed or existing polymer, it is very important to have an understanding of the fundamental molecular motions of polymers and how they are influenced by temperature and frequency.

The close relationship between the mechanical and electrical properties of polymers is linked basically to the close association of both properties to their fundamental molecular motions. Although the source of dielectric properties (dielectric constant,  $\epsilon'$  and loss,  $\epsilon''$ ) is electronic, atomic, orientational, and ionic polarizations (see Fig. 7), the major contribution in most polymers is obviously from the latter two polarizations. The ability of dipoles to orient in an applied field is directly dependent on their fundamental mobility as a function of temperature and frequency. Therefore the dielectric properties are closely related to the fundamental motions of the polymer structure. (An excellent treatise on the

Fig. 6. Volume-temperature curve of polystyrene

Fig. 7. Schematic representation of a hypothetical insulation having all four kinds of polarization showing the effects of frequency on the dielectric properties,  $\epsilon'$  and  $\epsilon''$ .

mechanical and dielectric effects in polymers was recently published by McCrum *et al.* (6) and should be consulted for a more detailed examination of these properties.)

Debye (7)<sup>1</sup> originally suggested that the high dielectric constant of such compounds as water and alcohols is caused by permanent dipoles in the molecules themselves since the square of the index of refraction (due to electronic polarization) in water, for example, is only 1.77, while the dielectric constant, measured at radio frequencies, is 78. In a simple liquid such as glycerol (8) the effect of temperature and frequency on the dielectric properties is illustrated (see Fig. 8). In the case of polymers in the amorphous state, which is often described as a very viscous liquid, the result is a broadening of the loss peak due to the multiple set of relaxation times rather than a single relaxation (see Fig. 9) (9). Polymers through their multiple transitions, as we discussed earlier, serve to complicate the situation further. This is not to say simple molecules do not have such transitions, but because of the complexity introduced by the mere size of the polymer molecule it is imperative that each transition be separated and examined.

In nonpolar polymers (10) the ideal case is fairly straight-forward (see Fig. 10). As the temperature is increased, the dielectric constant or permittivity ( $\epsilon'$ ) decreases slowly because of the decrease in density and its effect on the number of dipoles per unit volume. There is a sharp jog in the curve at the melting point because of the further decrease in density in the liquid state. One might expect a similar jog at the glass transition. Within the range of radio frequencies, no loss maximum should develop since no permanent dipoles are present. Interfacial polarization [see ref. (7) for further details] may be observed if impurities were present, especially at the low frequencies. Polyethylene may be classified as a nonpolar polymer although a small dielectric loss ( $\tan \delta \sim 10^{-4}$ ) has been generally reported. It has been shown quite conclusively that most, if not all, of this loss is due to the presence of extraneous dipoles (11), most probably carbonyl groups introduced through accidental oxidation during preparation of the polymer. The dielectric properties at low frequency (see Fig. 11) (12) require very careful measurements since the loss is extremely low. Fairly evident is the change in loss tangent ( $\tan \delta = \epsilon''/\epsilon'$ ) as the material proceeds through melting point ( $T_M$ ) around 100°C along with loss maxima at 0° and -80°C. The two low-temperature maxima have been labeled as  $\alpha$  (0°C) and  $\gamma$  (-80°C) loss regions. The fundamental source of these loss maxima is still questionable, especially the one at 0°C. The  $\gamma$  loss is generally associated with

<sup>1</sup> It should be noted that the dipolar molecules show only a slight preferential orientation in the field direction. Debye pointed out at a full field intensity of 1 v/cm the effect equals alignment of one dipole moment in 5,000,000 in the field direction; this fractional orientation would suffice to produce a dielectric constant of 80.

a local relaxation mode of the main chain in the solid state of the polymer involving movement of a few monomer units. The  $\alpha$  process has been associated with the glass transition.

The results with polyethylene are substantiated with other nonpolar polymers such as polyisobutylene (11) and polytetrafluoroethylene (11). In the latter case, this material has come closest to showing the ideal behavior predicted for nonpolar polymers probably because of greater purity during preparation. However, even in this case where the loss is extremely low, it has been possible, via very low-frequency, low-temperature measurements, to detect transitions in the crystalline phase. Since the loss is extremely low, there is little effect on the dielectric properties other than to slightly lower the dielectric constant due to a decrease in density.

In the case of polar materials, the situation is far more complex, yet the dielectric properties are much easier to measure, because the dipoles produce substantial changes as they go through various stages of mobility. Inspection of the ideal cases serves to simplify our discussion (Fig. 12 a+b) (10).

At high temperature thermal energy agitates the dipoles so violently that the electric field has relatively less effect on them. As temperature decreases,  $\epsilon'_s$  (static dielectric constant) increases until structural changes such as crystallization or the glass transition decreases the influence of the electric field. In crystalline polymers, unlike simple frozen liquids or glassy polymers, dipoles which are partially immobile at lower temperature tend to be freed as the temperature is increased (Fig. 12a, Case IIa). These dipoles are easily influenced by electric field, the increasing mobility with increasing temperature is usually so high that it overcomes the opposite effect of increased thermal agitation so that  $\epsilon'_s$  increases as the temperature increases. A similar effect occurs with rigid glassy polymers (Fig. 12b, Case IIIb) with stiffly attached dipoles. On the other hand, in some highly imperfect crystalline lattices, rather symmetrical dipoles may have considerable freedom so that  $\epsilon'_s$  follow Case Ia. In glassy polymers with rotatable side groups, such as polymethylmethacrylate, the main structure may become glassy, but still considerable freedom may exist in the side groups.

Polymethylmethacrylate (PMMA) has been studied rather extensively with regard to both its dielectric and mechanical properties by a large number of researchers. One of the most thorough pieces of work was published by Deutsch and co-workers (13). Two transitions were observed and at 1000 Hz, the  $\alpha$  and  $\beta$  transitions were at 120° and 50°C, respectively (see Fig. 13) (13). The  $\alpha$  transition we have defined earlier while the  $\beta$  transition has been associated with the relaxation process associated with the polar side groups. An important additional piece of information from another source (14) about the nature of the  $\alpha$  transition concerns the effect of addition of a plasticizer. At a given frequency of measurement, the addition of up to 25% by weight of dibutyl phthalate caused a decrease in the temperature of the  $\alpha$  loss

Fig. 12. Effect of temperature on the static (low frequency) dielectric constant of polar compounds (dotted curves are for high-frequency dielectric constant for comparison) (10).

Fig. 13. Dielectric properties of PMMA (log freq. = 1.9) (13)

maximum by about 30°C, while little if any effect was noted in the case of the  $\beta$  loss maximum. The same effect has been verified in other polymers both through electrical and other measurements. PMMA also exhibits a  $\gamma$  loss region (11), but we will not discuss it here.

Polystyrene (atactic) represents the case where a rigidly attached dipole is joined to the main chain. This material is an outstanding insulating material and has found wide use in the electrical industry. Polystyrene is generally considered to have only one dispersion region, which would be consistent with the expected behavior of one-phase polymer without independently orientable polar side groups (see Fig. 14).

In the case of crystalline polymers, a most interesting case is that of poly(chlorotrifluoroethylene). Its properties are in many respects similar to polytetrafluoroethylene, but the presence of a small permanent dipole gives rise to dielectric loss and dispersion. Also, the substitution of a chlorine atom gives a point of possible stereoisomerism which, apparently because of the close similarity in size of the chlorine and fluorine atoms, does not prevent crystallization but does result in a much less highly ordered crystal. While high molecular weight PCTFE has a crystalline mp at about 220°C, one sample of fractionated "Fluorolube" with a molecular weight of 980 had a melting point of 22°C. This low molecular weight material, which had a 10 Hz dielectric constant of 3 at 40°C above its melting point, was found to have a dielectric constant of almost 6 below the crystalline melting point, at about -10°C (see Fig. 15) (15). These and other results were interpreted as indicating rotation of the polar molecules within the crystalline phase, as has so often been observed in organic solids. In this case, an enhanced dipole moment on freezing results from alignment of the neighboring dipoles on each molecule in the crystalline phase, whereas the dipoles tend to adopt a lower energy configuration involving partial cancellation of these dipoles in the liquid state. The same effect has been observed in high molecular weight material but not to such a high degree.

The area of "microstructure" and how it is related to the dielectric properties of materials is large in itself, and it would be impossible to discuss this area in detail here. However, two recent reports (16, 17) illustrate a different approach and represent an attempt to understand dielectric properties

Fig. 14. Polystyrene ( $T_g = 79^\circ - 80^\circ\text{C}$ )

Fig. 15. Dependence on dielectric constant of temperature at 10 kc. Liquid fluororubane samples 1, 2, and 3 (15).

vs. structure with a specific objective in mind; synthesis of higher dielectric constant materials (see Fig. 16).

By comparing the dielectric constants of a given series of fluorinated polymers at the same frequency and at temperatures equally above their  $T_g$ 's, it is possible to see a distinct effect of the stereochemical size of the dipole on the dielectric constant. Studies such as this and those discussed earlier should bring the day closer when the polymer scientist will be able to synthesize materials based on a specified list of desired dielectric properties.

Conspicuous by their absence in this discussion are two other areas properly classed under the title "dielectric properties of polymers", i.e., conduction and breakdown. There are two reasons for this, one being the rather obvious choice of the author who feels that more detailed explanation of a particular area is of greater benefit than a cursory attempt to cover all areas. The second reason is a shortage of fundamental structural work on both conductance and breakdown in insulating dielectrics. One reason for this lack of structural data is that practical breakdown, whether in thin films or thicker sections, tends to be governed by factors such as electrode geometry, testing procedures, physical integrity of the sample, etc., rather than a molecular structural one (18). As for conduction, suffice it to say that there have been only a few papers which have dealt with truly pure materials and they have been most interesting (19). However, the problem of impurities as sources of charge carriers continues to leave this field in a state of uncertainty. This problem as to the nature of the charge carrier ultimately questions much of the data on the effects of crystallinity, polarity, crosslinking, etc., on conduction from a structural viewpoint.

Fig. 16. Dielectric constant and  $\tan \delta$  of various fluorocarbon polymers based on monomers shown (17).

In conclusion, the development of the theory of the dielectric properties of polymers is an area of considerable interest and activity. Further information on some of the areas listed below should be very interesting as well as contributing significantly to the field of dielectric properties of polymers (20).

1. What effect do dipoles in the backbone itself have on the dielectric properties, particularly in  $\alpha$  dispersion region?

2. The influence of crosslinking is insufficiently known. It should, according to theory, have much more influence on the  $\alpha$  than on the  $\beta$  transition.

3. With the recent availability of stereoregular polymers, many interesting questions should be answerable, such as testing the theory relating the distribution of relaxation times for the  $\beta$  band to microscopical heterogeneity, and the entropy of activation to a destruction of local order.

4. A class of polymers in which there is a considerable and increasing degree of interest is that in which the polymer chain is conjugated and the possibility of appreciable conductivity exists. Theoretical and experimental dielectric studies on these polymers, both in the solid state and in solution, are needed as a basis for understanding their microscopic electrical and electronic properties.

5. Are there other transitions in polymers as one approaches the point where all molecular motion ceases?

Manuscript submitted Mar. 28, 1968; revised manuscript received May 16, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Abstract 4.

## Internal Photoemission as a Tool for the Study of Insulators

Alvin M. Goodman

RCA Laboratories, Princeton, New Jersey

### ABSTRACT

Photoemission of electrons or holes from a conducting electrode into an adjoining insulator can be used to determine information about the energy-band relationships at the interface between the conductor and the insulator and about carrier transport in the insulator. The basic theory of the measurement techniques is discussed, and some experiments employing these techniques (using silicon dioxide as the insulator) are described.

If one is interested in the study<sup>1</sup> of insulators he is quickly struck by the following realization: Many of the most interesting electronic properties may be investigated only by making the insulator somewhat conducting. The principal objective of this paper is to describe (i) a method for introducing controlled conductivity into a normally insulating medium and (ii) what may be learned from concomitant electrical measurements.

The major process considered is that of *internal photoemission*, i.e., the photoemission of mobile electrons or holes into an insulator from an adjacent conducting medium. As a preliminary, however, some of the basic aspects of external photoemission (photoemission into vacuum) from metals and semiconductors are briefly reviewed. The treatment of internal photoemission considers first, the possible internal photoemission processes. This is followed by a description of a number of experiments in which these processes occur and what can be learned from them about the electronic transport properties of insulators and about the properties of interfaces between insulators and noninsulators (metals and semiconductors).

The scope of this paper is somewhat narrower than that which would be desirable for a complete discussion of internal photoemission.<sup>2</sup> The emphasis in what follows is directed principally toward the study of insulators; this is somewhat different from the usual studies involving photoemission in which the major concern is with the properties of the photoemitting electrode.

### External Photoemission

**Metals.**—The process of photoelectric emission into vacuum or, more simply, external photoemission is illustrated in Fig. 1 which shows a simplified model of an energy band diagram in the vicinity of a metal-vacuum interface. The electron energy is plotted against distance perpendicular to the interface. A photon impinges on the metal surface and is absorbed in the metal giving its energy  $h\nu$  to an electron; the electron then has sufficient energy to surmount the

potential barrier at the metal surface and enter the vacuum. The energy difference  $e\phi$  between the Fermi level  $E_F$  and the vacuum level is called the work function or, more particularly, the *vacuum value of the work function* to distinguish it from an effective value which will be considered shortly in connection with internal photoemission.

In the analysis of the photoemission of electrons from metals, Fowler (1, 2) assumed that (i) the metal can be represented by the Sommerfeld free electron model (one simple conduction band with a single effective mass), (ii) the photoemission is independent of the depth at which the photon is absorbed, and (iii) the yield (electrons emitted per absorbed photon—a number less than one) is proportional to the density of electrons within the metal which have thermal velocity components  $v_x$  normal to the emitting surface such that  $1/2 mv_x^2 + h\nu > e\phi$ . He found that for a given photon flux, the photoemitted current is given to a good approximation by  $I = AT^2 f(x)$  where  $x = (h\nu - e\phi)/kT$ ,  $A$  is a constant,  $k$  is Boltzmann's constant,  $T$  is absolute temperature, and

$$f(x) = e^x - \frac{e^{2x}}{2^2} + \frac{e^{3x}}{3^2} - \dots \quad x < 0$$

$$f(x) = \frac{\pi^2}{6} + \frac{x^2}{2} \left( e^{-x} - \frac{e^{-2x}}{2^2} + \frac{e^{-3x}}{3^2} - \dots \right) \quad x > 0$$

One can think of  $h\nu_0 = e\phi$  as a "threshold energy" and  $x$  as the amount by which the energy of an incoming photon exceeds the threshold energy measured in units of thermal energy  $kT$ . It is helpful to make two observations about Fowler's result: First,  $I \propto f(x)$  for constant temperature  $T$ , and second, for large  $x$  (say  $x \geq 8$ ), only one term in  $f(x)$  is important, the

Fig. 1. Photoelectric emission into vacuum

<sup>1</sup> Much of the recent interest in the properties of insulators, particularly thin films, has been engendered by the technological importance of insulating layers in MIS (metal-insulator-semiconductor) charge controlled devices.

<sup>2</sup> There are other aspects of internal photoemission which, although important, are not covered in this paper. Among these are the use of internal photoemission in the study of barrier heights at metal-semiconductor contacts and at semiconductor heterojunctions, and in the study of hot electrons and holes in metals. A more general treatment including an historical background of "Injection by Internal Photoemission" by Richard Williams will appear as a chapter in a forthcoming volume of the series "Physics of III-V Compounds."

Fig. 2. Square root of the yield [or  $f(x)$ ] vs. photon energy above threshold.

$x^2$  term. Thus, if one plots the value of the square root of  $f(x)$  vs.  $x$ , a straight line is obtained for large  $x$ .

In Fig. 2, the square root of  $f(x)$  is plotted against  $x$ . The curvature at the bottom of the plot is due to the spread in the occupation probability of the electron energy states near the Fermi level in the metal due to finite temperature; the curved portion is sometimes referred to as a "thermal tail." In practice, in order to evaluate the threshold energy, one would plot the square root of the experimentally determined values of the photocurrent per photon, against  $x$  and extrapolate the best straight line through the data points to an intersection with the  $x$ -axis.

**Semiconductors.**—The foregoing discussion of photoemission applies only to metals. The considerably more complex theory of photoemission from semiconductors has been treated by Kane (3). He found that for a "real" semiconductor (like silicon) it was necessary to consider a variety of photoelectron production and scattering mechanisms. He concluded that the yield (electrons emitted per photon absorbed) may vary as the  $p$  power of photon energy above the threshold, where  $p$  may have the value 1, 3/2, 2, or 5/2 depending on the excitation and scattering mechanisms involved. In addition, more than one mechanism may be involved in the same energy range, complicating matters still further. If there is a space charge layer in the semiconductor adjacent to the emitting surface, this may also significantly affect the energy dependence of the yield curve.

In Kane's work it was assumed that the semiconductor was at  $0^\circ\text{K}$  and that the photoemitted electrons originated from the valence band and/or filled surface states. The expected effect of finite temperature would be in some cases to produce a "thermal tail" on the curve of  $(\text{yield})^{1/p}$  vs.  $x$  such as that found by Fowler in the case of photoemission from metals.

It is also possible to treat the case of photoemission from a narrow band of filled levels, e.g., a somewhat degenerate conduction band. In this case it can be shown that to a good approximation, the yield should increase linearly with photon energy above threshold (4).

An example of photoemission from tungsten and silicon from the work of Gobeli and Allen (5) is shown in Fig. 3. In each case the square root of the yield is plotted against photon energy. It is clear that for both tungsten and heavily doped p-type silicon an excellent straight line dependence is obtained allow-

Fig. 3. Square root of the yield vs. photon energy for tungsten and silicon [from ref. (5)].

ing the unambiguous evaluation of a threshold energy. The heavily doped n-type silicon exhibits a straight line dependence of photon energies far above threshold with a large tail at lower energy values. The tail is due to photoemission from filled surface states while an extrapolation of the straight line portion would give the threshold for photoemission from the valence band. The high resistivity silicon presents a much more complicated situation to analyze; the experimentally determined yield is due to a combination of three mechanisms each having a different energy dependence and each being dominant in a different energy range.

This brief look at photoemission into vacuum may be summarized in a crude way by saying that although it is possible for the results to be rather complicated, it is also possible to arrange an experiment that gives results which are simple to analyze, e.g., photoemission from metals or heavily doped silicon. Looking ahead for a moment to the design of an experiment involving internal photoemission, it is advantageous to bear in mind those electrodes from which the electron emission yield dependence on photon energy is a relatively simple one.

### Internal Photoemission

**Possible processes.**—In Fig. 4 the electron energy is plotted vs. distance normal to an interface for 6 dif-

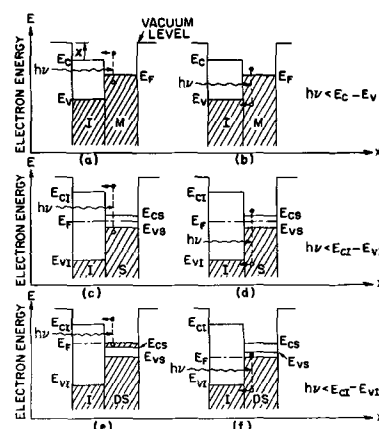

Fig. 4. Some internal photoemission processes: (a) electrons from a metal into an insulator conduction band; (b) holes from a metal into an insulator valence band; (c) electrons from a semiconductor valence band into an insulator conduction band; (d) holes from a semiconductor conduction band into an insulator valence band; (e) electrons from a degenerate n-type semiconductor conduction band into an insulator conduction band; (f) holes from a degenerate p-type semiconductor valence band into an insulator valence band. The symbols I, M, S, and DS in the figure denote, respectively, insulator, metal, semiconductor, and degenerate semiconductor.

ferent examples of the internal photoemission process. In Fig. 4 (a) is illustrated the photoemission of an electron from a metal into an insulator. A photon is absorbed in the metal transferring its energy to an electron which is then able to enter the insulator conduction band. Note that the threshold energy for this process  $e\phi_T$  is, according to this simple model (6), the vacuum value of the metal work function  $e\phi_M$  minus the electron affinity,  $\chi$ .

$$e\phi_T = e\phi_M - \chi \quad [1]$$

We may think of  $e\phi_T$  as an effective work function for internal photoemission i.e., as a work function of the metal with respect to the insulator conduction band.

In Fig. 4 (b) the process of "hole emission" from a metal into an insulator is shown. Here an electron receives the photon energy and undergoes a transition to a previously unoccupied state in the conduction band, leaving a deep hole, which may then enter the insulator valence band.

In Fig. 4 (c) an electron is photoemitted from the valence band of a semiconductor to the conduction band of an insulator. In Fig. 4 (d) a hole is photoemitted from the conduction band of a semiconductor to the valence band of an insulator. If the semiconductor is degenerate, two other processes are possible; the photoemission of an electron from the conduction band of the degenerate n-type semiconductor as shown in Fig. 4 (e) and the photoemission of a hole from the valence band of a degenerate p-type semiconductor as shown in Fig. 4 (f).

Although it is obvious, it may be worth mentioning that the internal hole photoemission processes (b), (d), and (f) have no vacuum analogues.

All of the internal photoemission processes discussed thus far have been "volume" processes. It is, in principle at least, possible to have photoemission of holes or electrons from internal surface states at a semiconductor-insulator interface.

**Experiments.**—The experiments to be described in this section (7-13) have been carried out mainly on layers of  $\text{SiO}_2$  which were fabricated by thermal oxidation of silicon in steam. The experimental techniques, however, should be applicable quite generally to the study of insulators.

A typical experimental arrangement is shown in Fig. 5. The silicon dioxide layer (of several microns thickness) is sandwiched between a degenerate silicon base wafer and a semitransparent evaporated metal counterelectrode. The metal is positively biased with respect to the silicon so that electrons photoemitted into the oxide from the silicon will drift through the oxide toward the metal counterelectrode. The electrometer measures the resultant current flow in the external circuit.

The corresponding energy band diagram is shown in Fig. 6. The diagram is qualitatively correct but quantitatively somewhat out of scale.

The plot of photocurrent versus photon energy shown in Fig. 7 is a typical one. The undulations in

Fig. 5. Schematic circuit diagram and construction drawing of sample.

Fig. 6. Energy band diagram of a metal-insulator-semiconductor sandwich with bias voltage applied (metal  $\oplus$ ).

Fig. 7. Photocurrent vs. photon energy for a silicon-silicon dioxide-gold sandwich with positive bias applied to the gold.

the photocurrent are due to the silicon-oxide-metal sandwich structure acting as an optical interferometer. It is easy to show (9) that the thickness  $l$  of the oxide layer can be computed from the formula

$$l = Mhc/2n(E_{N+M} - E_N) \quad [2]$$

where  $h$  is Planck's constant,  $c$  is the velocity of light in vacuum,  $n$  is the index of refraction, and  $E_N$  and  $E_{N+M}$  are the photon energies corresponding to the photocurrent peaks when the layer is  $N$  and  $N+M$  half-wavelengths thick, respectively. Thus, the oxide thickness value falls out of the internal photoemission measurement as a "bonus."

If an envelope of the photocurrent is normalized with respect to the photon flux, the yield curve is obtained, and this may be analyzed to obtain a threshold value. This will be done shortly but first consider the effect of reversing the bias voltage as shown in Fig. 8. Here the field is in the opposite direction and electrons photoemitted from the metal will drift through the oxide toward the silicon. A spectral distribution of the photocurrent similar to but not identical with that in Fig. 7 is obtained.

In Fig. 9 the square root of each of the yield curves obtained from the photocurrent envelopes is plotted against photon energy. The threshold value obtained

Fig. 8. Energy band diagram of a metal-insulator-semiconductor sandwich with bias voltage applied (metal  $\ominus$ ).

Fig. 9. Envelopes of (photocurrent per incident photon)<sup>1/2</sup> vs. photon energy for a silicon-silicon dioxide-gold sandwich.

with the gold negative is associated with the energy difference between the conduction band in the oxide and the Fermi level in the metal at the metal-SiO<sub>2</sub> interface (8, 9). The threshold energy with the silicon negative is associated with the energy difference between the conduction band in the oxide and the valence band in the silicon at the silicon-SiO<sub>2</sub> interface (7, 8). In a similar manner, the threshold energy for photoemission of electrons into SiO<sub>2</sub> from a variety of metals may be determined as shown in Fig. 10. If the threshold energies are plotted against the metal work functions, the value of the electron affinity  $\chi$

Fig. 10. Envelopes of (photocurrent per incident photon)<sup>1/2</sup> vs. photon energy for nine metals.

may be determined from Eq. [1] and it turns out to be 1.0 eV for silicon dioxide (9).

It is important in experiments of this type to ask the following question: Are the observed currents due to the photoemission of holes or electrons? In the work on SiO<sub>2</sub> the answer was obtained from the observation that the threshold energy was dependent upon which metal was used for the counterelectrode *only when the metal was negative*; thus it was known that in this case the carriers came from the metal and that the carriers photoemitted from the metal must have been electrons. When the metal was positive the threshold energy was independent of which metal was used and the carriers must have been coming from the silicon which was negative and were therefore electrons.

In order to unambiguously observe hole emission into silicon dioxide it was necessary to suppress the electron emission from the negative electrode. This was accomplished by using water as the negative electrode as shown in Fig. 11. Since water is quite transparent in the ultraviolet region of the spectrum for photon energies less than 6 eV, the photon energy cannot be transferred to the electrons in the water and no electrons can be photoemitted from the water. When the electron emission was suppressed in this way, a new and higher threshold energy was obtained corresponding to the photoemission of holes from silicon into silicon dioxide (10). This threshold energy is interpreted as the energy difference between the silicon conduction band and the oxide valence band at the silicon-SiO<sub>2</sub> interface.

At an abrupt interface between a metal and an insulator the photoemission threshold energy is a function of the voltage applied across the insulator because an electron (or hole) in the insulator near the interface is acted on by two forces, one due to the field in the insulator and the other due to the image charge induced in the metal. This is illustrated in Fig. 12. The resultant lowering of the work function (Schottky effect) is according to simple electrostatic theory

$$\Delta\phi = \frac{1}{2} (eE/\pi K\epsilon_0)^{1/2} \quad [3]$$

where  $E$  is the electric field in the insulator,  $e$  is the magnitude of the electronic charge,  $\epsilon_0$  is the permittivity of free space, and  $K$  is the effective image force relative dielectric constant. A similar description can be given for an abrupt interface between a semiconductor and an insulator. In Fig. 13 the decrease in the photoelectric threshold energy is plotted against the square root of the electric field strength in the insulator at 8 different points for each of 3 samples. The theoretical Schottky effect is indicated by the three straight lines, each corresponding to a particular value

Fig. 11. Silicon-silicon dioxide-water cell for photoelectric measurements.

Fig. 12. Schottky effect at a metal-insulator interface

Fig. 13. Decrease in phototreshold energy vs. (electric field)<sup>1/2</sup>

of  $K$ . The value  $K = 1$  would be correct for emission into a vacuum and the value  $K = 3.8$  is the low-frequency relative dielectric constant for silicon dioxide. The value  $K = 2.15$  corresponds to the average of the slopes of the best straight-line fits for each sample. Presumably the photoemitted carrier passes through the potential maximum in too short a time for the low-frequency dielectric constant to be a valid parameter for describing the polarization of the oxide. Similar measurements (but with less scatter in the results) were subsequently carried out by Mead *et al.* (11) who inferred from their data the value  $K = 2.1$ .

The shift in the photoemission threshold energy with electric field has been used by Williams to observe the presence and drift of positive ions in silicon dioxide layers (12). There were two steps in the experiment. First, the oxide layer to be studied was incorporated into a sandwich structure as shown in Fig. 5. The threshold energy for photoemission of electrons from the p-type silicon into the silicon dioxide at a particular value of applied voltage was then determined. The second step was to heat the sample (to 200°C) with a positive voltage applied to the gold counter electrode. The sample was then cooled to room temperature (maintaining the applied field). The threshold energy for electron photoemission was then redetermined under the original conditions; it was found to have lowered dramatically. The mechanism responsible for the threshold shift was the redistribution of positive ion impurities in the oxide. These ions became more mobile due to the rise in temperature and drifted under the influence of the applied field, accumulating in the oxide near the silicon-SiO<sub>2</sub> interface. This produced a strong electric field in the oxide adjacent to the interface lowering the photoemissive threshold by Schottky effect and possibly by inverting the silicon at the surface from p-type to degenerate n-type giving

Fig. 14. Photocurrent vs. applied voltage. ○ -raw data (uncorrected), ● -corrected values using  $K = 2.15$ .

rise to photoemission from the silicon conduction band as well as the valence band. Thus, internal photoemission can be a useful tool for the detection of mobile ionic impurities in insulators.

If, for a given photon energy, the photocurrent is measured as a function of voltage across the sample, a curve is obtained which rises steeply at first, then bends toward the voltage axis but continues to rise at a decreasing rate. A typical set of data is shown in Fig. 14. The upper set of points (open circles) is the raw data. The current rises with increasing sample voltage for two reasons: (i) the increasing field lowers the energy threshold for photoemission by Schottky effect (as discussed previously) and thus, causes an increase in the current photoemitted into the oxide, and (ii) the mean drift range (or Schubweg) of the carriers in the oxide increases directly with the electric field enhancing the photocurrent measured in the external circuit. It is possible to separate the two effects if the form of one of them is known. Here the photocurrent has been corrected to eliminate the Schottky effect assuming that the yield is proportional to the square of the photon energy above the threshold and an effective value for the image force relative dielectric constant  $K = 2.15$ . These are the filled in circles.

The mean drift range (or Schubweg)  $w$  is the average distance that the carriers drift in the electric field before they are captured, *i.e.*, immobilized due to trapping or recombination. Thus

$$w_{\pm} = \mu_{\pm} E \tau_{\pm} = \mu_{\pm} \tau_{\pm} V/l \quad [4]$$

where  $\mu$  is the mobility (subscript + for holes and - for electrons),  $V$  is the applied voltage,  $l$  is the oxide thickness, and  $\tau$  is the mean time an electron spends in the oxide conduction band (or a hole spends in the valence band) before immobilization by deep trapping. If  $V_0$  is defined as that value of  $V$  at which  $w = l$ , then the theoretical form of the corrected photocurrent  $I$  vs. the applied voltage  $V$  should be

$$I/I_0 = (V/V_0) (1 - e^{-V/V_0}) \quad [5]$$

where

$$V_0 = l^2/\mu\tau \quad [6]$$

and  $I_0$  is the photoemitted current in the absence of Schottky effect.

The experimental data for electron emission for three samples are shown in Fig. 15 fitted to the theoretical curve by adjusting  $I_0$  and  $V_0$ . The results of this type of experiment indicate that  $\mu_{-}\tau_{-} \sim 10^{-9}$  cm<sup>2</sup>/v for electrons and  $\mu_{+}\tau_{+} \sim 10^{-10}$  cm<sup>2</sup>/v for holes.

Williams has used internal photoemission to study in some detail the transport and trapping properties of electrons in SiO<sub>2</sub> layers (7). By applying only a weak drift field in the oxide he found that most of the photoemitted electrons could be trapped rather than drifted entirely through the oxide. He then illumi-

Fig. 15. Normalized photocurrent vs. normalized voltage

nated the sample with light of photon energy less than the photoemission threshold value releasing the trapped electrons. By measuring the released charge he determined that the trap density was  $\sim 3 \times 10^{14}/\text{cm}^3$ , a remarkably low number for a noncrystalline material. By measuring the spectral response of the charge release process he found a threshold value of 2.0 eV indicating that this was the minimum depth of the traps below the oxide conduction band in his samples. By studying the kinetics of the trapping process, he was able to determine a value for the capture cross section of the traps,  $S = 1.3 \times 10^{-12} \text{ cm}^2$ . This was then used to estimate a mobility value. The value was either 17 or 34  $\text{cm}^2/\text{v-sec}$  depending on whether the trapping center was doubly or singly charged. The actual charge on the trapping center is not known, leaving an ambiguity in the mobility of a factor of two. Nevertheless, the fact that the mobility is of the order of or greater than 10  $\text{cm}^2/\text{v-sec}$  indicated that another, more direct mobility measurement might be made and, in fact, inspired the development of a modified Hall measurement particularly suited for use with insulator films (13).

A cross-sectional view of the experimental Hall effect arrangement is shown in Fig. 16. The metal counter electrodes are opaque and define the light pattern on the photoemitting silicon surface. If the potentials applied to the counter electrodes are equal and the incoming light is of normal incidence, the circuit is balanced when there is no magnetic field applied, and the electron paths follow the electric field lines as shown. If a magnetic field is applied normal to the plane of the figure, the electron paths will be altered and the currents to the two counter electrodes will no longer be balanced; more current will flow to one than to the other. The difference between the counter electrode currents can then be quantitatively related to the mobility of the electrons in the oxide. The average value for the mobility of electrons in  $\text{SiO}_2$  determined in this way was  $\sim 29 \text{ cm}^2/\text{v-sec}$ . This value is in good agreement with the estimate previously obtained by Williams from trapping studies.

Although the emphasis in this discussion has been on  $\text{SiO}_2$ , the experimental techniques described and others employing internal photoemission as the basic tool have been and are being used to investigate other insulators. Among these are the oxides of aluminum, niobium, tantalum, and titanium, as well as some organic materials such as anthracene and tetracene. Also, internal photoemission has been used to investigate the properties of diamond, silicon carbide, silicon, germanium, and many of the III-V, II-VI, and I-VII compounds. Whether some of these materials should be considered insulators or semiconductors is of course a moot point which need not concern us here.

There are, of course, other experiments in which internal photoemission has been used as an investigative tool. Although a complete discussion of them is beyond the scope of this paper, there are two which

Fig. 16. Cross-sectional sketch of sample geometry and electron paths for a Hall-effect electron mobility measurement in a silicon dioxide layer. The magnetic field, when applied, is normal to the plane of the figure.

should at least be mentioned because it seems likely that more use will be made of them in the future. One is the work of Williams and Dresner (14) who utilized the spectral variation of internal photoemission to obtain information about the structure of the multiple narrow energy bands in an organic insulator, anthracene. The second is a study of the variation of electron photoemission from Al into thin (40-100 Å)  $\text{Al}_2\text{O}_3$  films with photon energy and electric field. Work on this subject has been described by several groups (15-18). Their results were interpreted in terms of the effective work function at the interface and the mean free path for electrons in the  $\text{Al}_2\text{O}_3$  conduction band. There is considerable disagreement in the results. For example, Schuermeyer *et al.* interpreted their results in terms of an electron-phonon scattering mechanism and thereby inferred a mean free path of 10 Å. On the other hand, Ludwig and Korneffel obtained data which could be interpreted only in terms of a much longer mean free path. Some or all of the discrepancies may of course be due to differences in the  $\text{Al}_2\text{O}_3$  layers. Despite the apparent disagreement in results, the techniques employed show promise for use in the study of other very thin insulating films.

In summary, a number of experimental techniques have been described in which internal photoemission can be used as a very effective tool for the study of insulator properties.

### Alkali Metal Ion Sources

Julius Perel

*Electro-Optical Systems, Inc., Pasadena, California*

#### ABSTRACT

The development of alkali metal ion sources has been greatly accelerated in the past decade because of the interest in these ions in basic research and more important because of cesium ion engine development for space propulsion. Three techniques used to generate alkali metal ions are described. The porous tungsten surface ionization source, highly developed for electric propulsion, has generated ion beams of over 1 amp of cesium and is being used to produce other alkali metal ions. The electron bombardment engine, or low-pressure discharge source, has produced high currents of  $\text{Cs}^+$ ,  $\text{Na}^+$ , and  $\text{Hg}^+$  and is used to generate other ions. The liquid metal hydrodynamic spray technique, also studied as an electric propulsion thruster, is used to produce high current densities from a very small source and generates some molecular ions. The operational levels of the various engines and their modification for use as laboratory ion sources are described.

*Brief survey.*—Alkali metal ion source technology has been greatly advanced in order to use high-velocity ions to produce thrust from ion engines for manipulating and propelling space and orbital vehicles. The aims in the development of ion engines which do not differ greatly from those in developing ion sources are examined in this report with the emphasis placed on the generation of alkali metal ions and the description of ion engines and their features as ion sources.

The two most used methods of generating ions for ion engines are surface ionization and electron impact ionization. Efficient surface ionization is applicable for elements having low ionization potentials such as the alkali metals. The technique of ionization by electron impact in a gaseous discharge is applicable for producing a wide range of ion species including molecular ions. A third method, discussed in this report, is the generation of charged particles from the surface of a liquid by the application of high electric fields. Heavy charged particles are generally produced from organic liquids while ions are generally produced from liquid metals, with the alkali metals being particularly suitable using this latter method.

The alkali metals comprise a family of elements each of which have a single electron in the outer or valence shell. The ease with which the single outer electron can be removed to form an ion is indicated by the low first ionization potentials which are listed in Table I. The second ionization potentials are higher than the first by factors ranging from 15 to 5 going from Li to Cs. Therefore singly ionized alkali metals can be generated without producing an appreciable number of doubly ionized species in a low voltage discharge. In addition the first ionization potentials are somewhat less than refractory metal work functions and/or surface work functions increased by adsorbed layers of  $\text{O}_2$ , a condition required for efficient surface ionization.

Table I also contains the atomic number, atomic weight, and melting points of the alkali metals. Cs and Rb are highly reactive and must be handled under an inert atmosphere. The others can be stored in oil or kerosene and can be handled in air under relatively dry conditions with inert atmosphere handling recommended.

*Ion engine and ion source characteristics.*—An ion engine is characterized in terms of parameters such as thrust, power, weight, efficiency, etc. Since an engine is designed to operate on a space vehicle, the emphasized features include reliability, long life, and low power consumption. Laboratory lifetime tests have shown that engines can operate reliably for thousands of hours with little degradation in performance.

Ion engine accelerating voltages are usually limited to several kilovolts because of mission considerations and to minimize breakdown problems. With these constraints in voltage the desired currents and thrust levels are obtained by using large ion emission areas and multibeam electrode systems. Accel-decel electrode configurations are typically used with ions generated by an ionizer at +3 kv, an accel electrode at -1 to -8 kv, and possibly a decel electrode at ground potential. The accel serves as an electron trap to prevent electrons in the ion beam from backstreaming to the ionizing region and sometimes to increase the

engine perveance in order to extract high beam currents.

In space both current neutralization and beam space charge neutralization, required to obtain thrust, are achieved by electron emission. Emitted electron currents must be equal to the ion beam current to prevent excessive charging of the spacecraft. A large rise in the potential of a spacecraft with respect to the ambient potential degrades the ion emission energy and could ultimately result in beam turn-around with loss of thrust. Beam space charge causes the ions in the beam to diverge and could also result in a degradation of thrust. Thus, the electrons neutralize the ion beam, which results in a highly ionized, low-density plasma ( $\approx 10^9$  particles/cm<sup>3</sup>). Electrons are obtained from a separate source located near the ion engine, with emission regulated by the positive potential of the ion beam.

Parameters which characterize an ion engine as a thruster system are examined in terms of ion source operational parameters. The thrust ( $F$ ) produced by an ion engine is the force required to accelerate a beam of particles to a velocity ( $v$ ) and is given by

$$F = \dot{m}v \quad [1]$$

where  $\dot{m}$  is the ion beam mass flow rate. The mass flow rate in terms of the ion beam current ( $i$ ) is given by

$$\dot{m} = \frac{m}{e} i \quad [2]$$

where  $m$  is the ion mass and  $e$  is the charge, and  $e/m$  is the particle charge-to-mass ratio.

In terms of measurable operating parameters, the thrust is given by

$$F = (2m/e)^{1/2} i V^{1/2} \quad [3]$$

where  $V$  is the accelerating voltage and  $eV = mv^2/2$ .

Equation [3] shows the advantage, in achieving greater thrust, of using particles having a low charge-to-mass ratio such as Cs and Hg, which are  $7.21 \times 10^5$  and  $4.77 \times 10^5$  coulombs/kg, respectively. Even lower charge-to-mass ratios are achieved by generating heavy particles from a liquid using the electrohydrodynamic technique. Small ion engines have been developed that produce a few micropounds of thrust, with large ones producing thrusts up to a few tenths of a pound. For example, at an accelerating voltage of 4 kv, a Cs ion engine requires an ion beam current of 42 ma to produce 1 mlb (0.454g) of thrust.

Another term used to characterize the operation of an ion engine is the specific impulse ( $I_{sp}$ ), defined as the ratio of thrust to propellant weight flow rate ( $\dot{M}g$ ) and given by

$$I_{sp} = \dot{m}v/\dot{M}g \quad [4]$$

The term  $\dot{M}$  is the total mass flow rate and is equal to the ion mass flow rate plus the neutral particle flow rate, with  $g$  being the gravitational acceleration at the surface of the earth. This latter term is a constant independent of operating environment such as space and is used to relate the engine operation to the weight of the propellant as part of the payload for liftoff from the earth. The parameters discussed above are sufficiently interdependent so that a change in one affects the others. Optimization is made by trade-off considerations. For example, the propellant weight

and power available, determined by mission requirements, can be used to select an ion engine type and its operating levels.

Another important parameter is the mass utilization efficiency ( $\eta$ ), given by  $m/\dot{M}$ . When  $\eta \approx 1$ , as in the case for surface ionization engines, the specific impulse is proportional to the ion exhaust velocity. Using the operating parameters for the thruster example given above, the specific impulse is approximately 8000 sec, and about 4 lb of propellant is required for continuous operation during 1 year with a total impulse of  $3 \times 10^4$  lb-sec.

Mass utilization efficiencies generally range from 85% to nearly 100%. This efficiency is high enough in terms of propellant usage, but low neutral fractions ( $1 - \eta$ ) are required for long-life ion engines, since the emission of neutral particles contributes to the erosion of ion engine electrodes, which can severely limit the lifetime. A slow ion, generated in the inter-electrode region by a charge transfer collision between a fast ion and a slow atom, is likely to impinge on an electrode and produce sputtering. This removes electrode material, weakening the electrode, and the sputtered material may form harmful deposits on sensitive surfaces such as insulators, ionizers, and cathodes.

#### Surface Ionization Sources

*Fundamentals of surface ionization.*—The surface ionization process of ion generation depends primarily on the difference between the work function of the surface and the ionization potential of the atoms to be ionized. The process can be illustrated by considering the metal to be a potential well filled with electrons up to an energy level called the Fermi level. The potential difference between the Fermi level and the space just outside the metal is the energy that is required to remove an electron from the metal and is known as the work function of the metal ( $\Phi$ ). The energy required to remove an electron from an atom is known as the ionization potential ( $I$ ).

When the work function of the metal is greater than the ionization potential of an atom located at the metal surface (i.e.,  $\Phi > I$ ), the most loosely bound atomic electron has a high probability of transferring to the metal so that the particle is desorbed from the surface as an ion. The ratio of the number of ions ( $n_p$ ) to the number of atoms ( $n_a$ ) desorbed is given quantitatively by the Saha-Langmuir equation (1) which may be expressed as

$$\frac{n_p}{n_a} = \left( \frac{w_p}{w_a} \right) \exp [(\Phi - I)/kT] \quad [5]$$

where the weighting factor for each state ( $w$ ) is equal to  $2J + 1$ , with  $J$  being the inner quantum number (or total angular momentum) of the ion or atom, and  $T$  the temperature.

For alkali metal atoms  $J = 1/2$ , while for alkali metal ions  $J = 0$  so that  $w_p/w_a = 1/2$  and Eq. [5] reduces to

$$\frac{n_p}{n_a} = \frac{1}{2} \exp \left( \frac{\Phi - I}{kT} \right) \quad [6]$$

The ionization potentials of the alkali metals are well defined and are given in Table I. The work function of a metal is not so well ordered and depends on the conditions at the surface of the metal. The work function of "clean" tungsten is about 4.6 ev, but the presence of adsorbed atoms on the surface can increase or decrease the work function depending on the characteristics of the composite surface produced. The adsorption of alkali metal atoms on a tungsten surface tends to decrease the effective work function, the amount of decrease depending on the concentration of alkali atoms on the surface. This concentration is defined in terms of the fraction of a monolayer coverage ( $\theta$ ), where a monolayer on tungsten is about  $4.5 \times 10^{14}$  atoms/cm<sup>2</sup>. The effective work function of

tungsten decreases very rapidly as the coverage exceeds a few per cent of a monolayer so that the ratio of ions to atoms desorbed from the composite surface decreases greatly with small changes in coverage. The coverage is therefore quite critical, and it is necessary to control it by controlling temperature and/or the rate at which alkali metal atoms are supplied to the surface.

The effect of coverage on ion and atom emission rates from solid tungsten with cesium atoms supplied to the surface is shown in Fig. 1. The ion emission rate increases nearly linearly up to a coverage of about 1% of a monolayer with only a small increase in the atom emission rate. As the coverage increases, the effective work function of the surface decreases, with a decrease in ion emission occurring above a 2% coverage. Here an instability occurs. As the coverage increases, the ion emission rate decreases, further increasing the coverage, and so on. Thus, the emission mode changes from point a to point b, and the ion emission drops sharply. Surface ionization is inefficient at coverages above point a. With increasing temperatures the curves increase appreciably toward high emission rates, and the peak near point a shifts only slightly toward higher coverage.

Efficient and stable ion emission is obtained at or below 1% of a monolayer. In this coverage region, the mean time that a particle remains on the surface before desorption is approximately 100 times longer for the emission of an atom than an ion. The ion desorption time,  $\tau_i$ , decreases with increasing surface temperature ( $T$ ) and is given by

$$\tau_i = \tau_0 \exp(Q/kT) \quad [7]$$

where  $Q$  is the energy required to desorb an ion, and  $\tau_0$  is the extrapolated desorption time at  $T^{-1} = 0$ .

In this low coverage region the emitted ion current density,  $j$ , as a function of coverage,  $N$  in atoms/cm<sup>2</sup> is given by

$$j = eN/\tau_i \quad [8]$$

where  $e$  is the charge of the ion and the  $\tau_i$  dependence on the temperature is given by Eq. [7]. To determine an approximate ion emission upper limit, the value of  $N$  at 1% of a monolayer is about  $4.5 \times 10^{12}$  particles/cm<sup>2</sup>. Desorption measurements extrapolated to 1400°K show the ion desorption time ranging from  $2 \times 10^{-5}$  to  $10^{-4}$  sec with variations probably due to surface contamination (2, 3). Using Eq. [8] to find  $j/e$ , the

Fig. 1. Cesium ion and atom emission from a tungsten surface as a function of the surface coverage in fraction of a monolayer. The region of stable and efficient ion emission operation is below 0.02 of a monolayer.

upper limit ion emission rate at this temperature ranges from  $4.5 \times 10^{16}$  to  $2.25 \times 10^{15}$  ions/cm<sup>2</sup>-sec, which is consistent with the curve of Fig. 1.

In the operation of a surface ionization source, currents, voltages, and temperatures are first determined for stable and efficient modes. Consider a flow of Cs atoms onto a tungsten surface whose temperature is controllable. A sufficiently high voltage is applied between the ionizer and an ion collector to assure emission-limited current flow. At a fixed atom impingement rate  $\mu_1$  (atoms/cm<sup>2</sup>-sec), the temperature of the ionizer is decreased from a very high value. Figure 2 illustrates a typical ion emission current variation with the surface temperature. The ion current density does not vary appreciably with temperatures down to a value  $T_1$ . In this plateau region where the emission is stable, the ion current is approximately equal to the atom flow rate and the coverage is below about 1%. At the knee of a given curve for a temperature  $T_1$ , the coverage corresponds to the peak near point a in Fig. 1. With further lowering of the temperature, the ion current decreases sharply and the atom emission rate increases corresponding to operation at point b in Fig. 1. Reversing the process and increasing the temperature from a low value gives a very similar emission curve except that the knee is shifted toward a higher temperature. The hysteresis occurs because the change from high to low coverage operation requires higher temperatures to desorb sufficient atoms. At a higher atom flow rate,  $\mu_2$ , the  $T_1$  knee shifts toward a higher temperature ( $T_2$ ) as illustrated in Fig. 2. The lower temperature knee ( $T_1$ ) is the lowest temperature at which efficient surface ionization occurs for a given beam current density. The position of the knee can be estimated at each current density using Eq. [8] and desorption time data. Adsorbed contaminants such as O<sub>2</sub> or C can affect the position of the knees and/or the ionization efficiency.

An adsorbed layer of O<sub>2</sub> increases the work function of most refractory metals. The work function of tungsten can be increased to values over 6 eV with a stable layer of O<sub>2</sub>. Thus, oxygenating a hot tungsten surface makes it possible to efficiently produce ions from atoms whose ionization potentials are below 6 eV and somewhat less efficiently for those slightly above this value. This includes all of the alkali metals, indium, gallium, and several other elements which are not reactive with hot tungsten.

Fig. 2. Ion emission current density versus ionizer temperature for two atom impingement rates  $\mu_1$  and  $\mu_2$ . At an atom impingement  $\mu_1$  a hysteresis loop occurs between the decreasing and increasing temperature cycles. The knee of the curve at  $T_1$  is the lowest temperature for stable and efficient operation. The dashed curve shows the change with a higher atom impingement rate with  $T_2$  being the lowest stable and efficient operating temperature at  $\mu_2$ .

**Types of surface ionization sources.**—A surface ionization source is designed and operated according to the principles discussed in the section on Fundamentals of surface ionization and by Worlock (4). The ionizer temperature and the vapor feed rate are selected to maintain an adsorbed Cs coverage near 1% of a monolayer with the ion current emission limited.

Front feed techniques, in which an atom beam impinges on a heated solid refractory surface to produce ions, were found to be inadequate for ion engines because the ion beam interaction with the atoms caused excessive electrode erosion and other problems. A porous tungsten ionizer was introduced to avoid this troublesome interaction between the two beams (5).

The porous tungsten ionizer is made from slabs of sintered tungsten granules which are cut to shape and brazed into a crucible manifold. Cs vapor is distributed by the manifold to the rear of the porous tungsten, operated at about 1100°C. The vapor percolates through the hot ionizer and ions are formed at the surface and in the pores. Ionizers made of granules of different sizes and shapes have been fabricated and tested in an effort to obtain low neutral fraction and high performance at low power (6, 7).

In some cases ion generation was found to occur predominantly in the pores (8, 9) and resulted in ion current densities in excess of those obtained from a solid tungsten surface. Other refractory metals and alloys have also been investigated to find higher ionization efficiencies (10).

Figure 3 shows a typical surface ionization engine configuration with a zero-gravity feed system. The delivery rate is controlled by the feed rate heater, which determines the vapor pressure at the porous ionizer. The sastrugi ionizer shown in the diagram is a large slab of porous tungsten machine-ground to form spherical concavities. This shape was found to optimize focusing of the ion beam for the current densities and voltages of an operating ion engine (11-13). The ionizer is operated at positive voltages from 2 to 4 kv which determine the kinetic energy of the ions (i.e., exhaust velocity). The accel electrode is maintained at several kilovolts negative and the decel at ground potential. Individual beams are formed in the electrode region which merge to a single large beam several cm downstream. Figure 3 also shows a neutralizer which emits electrons into the ion beam to assure beam neutrality and to prevent charging of a spacecraft. Tests in vacuum chambers do not require neutralizers, since sufficient electrons for ion beam

neutralization are provided by secondary emission from ion impingement on the ion beam collector.

The reservoir and feed system shown in Fig. 3 are capable of operating on earth or under zero-gravity conditions. The reservoir is heated to above the Cs melting point, and the liquid Cs wets the radial fins which converge toward the porous rod. Since surface tension forces tend to minimize a surface area, the liquid flows toward the rod. It fills the porous rod for the same reason and is vaporized from the end by heat from the feed rate control heater. This type of feed system is used to supply Cs for the electron bombardment ion engine and for the discharge type neutralizer, both discussed in the section on Electron bombardment ion engines.

To provide a low neutral fraction and assure that the ion current is controlled by the feed rate, ion engines are operated in an emission-limited, although near a space-charge-limited mode. Design criteria stemming from analysis of space-charge-limited operation provide a good approximation for discussion.

Space-charge-limited current density ( $j$ ) given by the Child-Langmuir equation, can be written as

$$j = \frac{PV^{3/2}}{d^2} \quad [9]$$

where  $d$  is the distance between ionizer and accel electrode and  $P$  is the perveance in units of  $A/V^{3/2}$ . The perveance is proportional to the square root of the ion charge-to-mass ratio.

To avoid low fields at the beam axis near the ionizer, the aspect ratio, or ratio of  $d$  to the beam aperture diameter, is limited to values equal to or greater than one. For  $Cs^+$ , a perveance of about  $5 \times 10^{-9} A/V^{3/2}$  is a practical value for the extraction and acceleration of stable beams using circular apertures. Choosing an emission surface area equal to  $d^2$ , the current that can be obtained through a single aperture at 4 kv is about 1 ma (from Eq. [9]). At an emission current density of 2 ma/cm<sup>2</sup> the emission area is limited to about 0.5 cm<sup>2</sup> with an electrode spacing of about 0.8 cm. To achieve higher currents a multi-aperture electrode system is used to form up to several hundred beams. To obtain multiple ionizing surfaces, a single crucible is made with many porous tungsten ionizer buttons or a large-area porous tungsten slab is machined to form separate concave emitting surfaces as in the sastrugi ionizer shown in Fig. 3. To obtain a higher current through each aperture, an accel-decel electrode system is used, since the extracted current may be space-charge-limited by the potential between ionizer and ground potential. By applying a high negative voltage to the accel electrode, the extraction field is increased without increasing the net energy of the ions in the beam. Nevertheless beam focusing is affected by the accel potential.

Surface ionization engine emission current densities are typically below 5 ma/cm<sup>2</sup>, with total beam currents determined by the emission area. A single-beam microthruster generates about 1 ma, providing several  $\mu$ lb of thrust (14). A large-area engine tested at EOS produced 3.8 amp of beam current to provide about 0.1 lb of thrust. Many engines have been developed to fill the gap between these two.

Single-beam  $Cs^+$  sources have been developed to study emission characteristics and for application studies of ion beam interaction phenomena. Special ionizers composed of tungsten spherical powder were used to produce current densities up to 80 ma/cm<sup>2</sup> for an ionizer temperature just above 1200°C (15). Charge transfer collisions, ion sputtering, secondary electron emission, and ion implantation studies were conducted using porous tungsten ion sources to generate  $Cs^+$ ,  $Rb^+$ , and  $K^+$  (16-19). Modification of this type source was made to permit high-temperature operation ( $> 1200^\circ C$ ), and an  $O_2$  spray on the ionizer was introduced so that ion beams of the rest of the

Fig. 3. Schematic of a multibeam surface ionization engine with zero-gravity feed system. Ions emitted from hot porous tungsten surface are accelerated by the electrodes to form individual ion beams. These beams merge downstream into a single large beam which is neutralized by the introduction of electrons.

alkali metals and other species could be generated (20, 21). Total currents of about 0.3 ma of  $\text{Li}^+$  were obtained from a 0.475-in.-diameter porous tungsten ionizer operated at a temperature of  $1200^\circ\text{C}$  and with an  $\text{O}_2$  impingement rate of about  $10^{15}$  particles/cm<sup>2</sup>-sec. This source was operated up to about 20 kv with little change in the current above 3 kv. A special source was constructed and operated with reservoir and ionizer at  $> 1200^\circ\text{C}$  to generate the required vapor pressure and ionize indium (22). Up to 0.5 ma of  $\text{In}^+$  was obtained with the current being feedrate limited.

#### Low-Pressure Discharge Sources

**Fundamentals of ion generation.**—A discharge source used to produce ion beams is applicable for those species which can be introduced as gas or vapor. Ions, generated by electron bombardment, are extracted from the discharge and accelerated to produce an ion beam. When the vapor is composed of a single atomic specie, such as in the case of the alkali metals, the number of singly charged ions can be enhanced and the fraction of emitted multiply charged ions can be minimized by optimizing the discharge mode.

To sustain a gaseous discharge, electrons are emitted from a cathode into a gas and accelerated to the anode by the application of an electric field. Electrons collide with the gas atoms and some of these collisions result in ionization of the atom. The electron removed from the atom will also be accelerated and will participate in further ionization processes. Ions are accelerated toward the cathode, and the current flow through the discharge is carried by both electrons and ions. Because of their much lower mass, the current flow of electrons will greatly exceed that of the ions.

The probability that an electron will collide with and ionize an atom depends on the product of the atom density, the electron path length through the gas, and the ionization collision cross section. This cross section, the effective physical area presented by the atom to the oncoming electron, depends on the electron energy (23). The ionization cross sections of atoms have several distinct features. Thresholds (or onset energies) occur at the ionization potential with cross sections rising rapidly to a maximum at an electron energy about five times the ionization potential, then slowly decreasing with increasing energy. Thus, as an electron is accelerated toward the anode in a gas discharge the probability that the electron undergoes an ionizing collision is affected by the gas density and the electric field. To sustain the discharge, the field and gas density must be such that the energy gained between collisions is high enough for ionization to occur. This is enhanced by increasing the field and/or increasing the mean free path (average path length between collisions) by decreasing the gas density. The number of collisions at a given gas density can be increased by lengthening the total path traversed by each electron, using a magnetic field which causes the electron to spiral and be constrained from reaching the anode. Thus, a discharge can be operated at an optimum condition for producing desired current densities by varying gas pressure, applied discharge voltage, magnetic field, etc.

Because the electrons travel more rapidly than the ions, the region where the ions are generated tends to become more positive than it would be due to the electric field between cathode and anode. Electrons escape rapidly enough to increase the potential of this region to somewhat above that of the anode, forming a nearly field-free plasma region. Because the plasma region is at a somewhat higher potential than the anode, it also constrains the electron flow to the anode. This is a self-regulating process, since an excessive loss of electrons increases the potential of the plasma region, which in turn further constrains the electron loss to the anode.

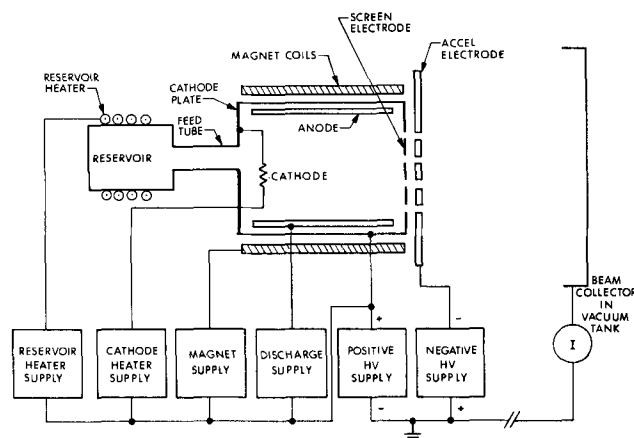

Fig. 4. Schematic diagram of low pressure discharge ion source with associated power supplies.

Ions are extracted out of the edge of the plasma through a region called the plasma sheath. Figure 4 illustrates schematically a typical low-pressure discharge source. The cathode in the discharge chamber is electrically connected to the enclosing cylinder, and the cylindrical anode is contained within the chamber. The magnetic field is coaxial with the cylinders. The screen electrode at the cathode potential aids in forming the plasma sheath from which the ions are extracted. Since the accel electrode is negative by several kilovolts with respect to the screen, positive ions are accelerated and electrons are retarded. Thus, the plasma sheath shape or the meniscus at the screen aperture is affected by the ion current extracted.

The meniscus is determined by the plasma ion density, the aperture configuration, and the field between the screen and accel electrodes. Good focusing of the ion beam occurs when the meniscus is concave. This general shape and the formation of the ion beam using an accel-decel electrode system are essentially the same as described in the section on Types of surface ionization sources for the surface ionization source.

**Electron bombardment ion engines.**—In the electron bombardment ion engine, a low-pressure discharge is used to generate ions which are extracted and accelerated to produce a beam. This type of engine differs from the surface ionization engine only in the means of ionization, the rest of the features being nearly the same. Bombardment engines have been developed to use Cs or Hg as the propellant, with some differences in components and operating modes to accommodate the particular vapor used. Both these elements provide the heavy ions desired for propulsion. The discharges are optimized to provide a predominance of singly charged ions with a minimum of emitted neutral atoms. Cs shows some advantage over Hg because of its lower ionization potential and higher ratio of second to first ionization potentials.

An electron bombardment ion engine (Fig. 4) is composed of a reservoir for propellant storage, a feed system, a discharge chamber for producing ions, and an ion acceleration electrode system. The reservoir containing the propellant in liquid form can be either the laboratory type or the zero-gravity type discussed in the above mentioned. The vapor is generally delivered to the discharge at or through the cathode, depending on the type of cathode used. The gas pressure, in a typical Cs discharge operating between 7 and 15v, is maintained between  $10^{-4}$  and  $10^{-3}$  Torr to provide an extracted ion current density of between 1 and 10 ma/cm<sup>2</sup>. The axial magnetic field, generally near  $10^{-3}$  Wb/m<sup>2</sup>, maintains the electrons in a long spiraling trajectory to increase the probability of ionization collisions. As the electrons collide and lose

energy, they tend to drift toward the anode, where they are lost from the discharge. Ions are also lost from the discharge when they strike a surface and re-enter the discharge as atoms. Ions, atoms, and electrons drift toward the screen electrode, where the electrons are repelled, the ions are extracted by the electrode field, and the neutral atoms escape. A beam collector located at the end of the vacuum chamber is used to measure the ion beam current and absorb the beam energy. To enhance the emission of ions over that of atoms, diverging magnetic fields have been used to increase the flow of charged particles toward the screen (24). This tends to decrease the neutral fraction and/or the discharge power by increasing the ionization efficiency.

Mass utilization efficiencies of 85-95% have been achieved with these engines. Beam currents, obtained by using a broad-area source having many apertures, up to 1A of  $\text{Cs}^+$  and 10A of Hg, have been produced by bombardment engines.

Because a large portion of the discharge power is generally consumed in heating the cathode, attention was given to the development of low-power cathodes. As a result, several types of cathodes have been developed and used with bombardment engines. Refractory wire and oxide-coated filaments were used initially with Cs and are still used with Hg. In the early Cs engines the vapor was directed toward the cathode, the adsorbed Cs coating decreasing the electron emission work function. This lowers the cathode operating temperature with a net saving of power. In the Hg engine the vapor flow is directed away from the cathode because the adsorbed Hg coating increases the filament work function. A further improvement in cathodes was made by using an autocathode, wherein Cs vapor is fed through a refractory metal cathode which is heated by ion bombardment from the discharge (24). The discharge is operated at low voltages (6-8v) so that ion sputtering of the cathode is negligibly small. This cathode is operable only over a limited range of discharge modes suitable for an ion engine stabilized by an electronic control system.

Another electron source known as the discharge cathode or discharge neutralizer is capable of emitting very large electron currents (25, 26). Cesium vapor is fed into a small enclosed chamber heated to about 600°C. The cesiated surface at this temperature is capable of emitting high electron current densities. An aperture approximately 0.02 cm in diameter allows particles to escape from the chamber. When a relatively low electric field is applied outside the chamber aperture, a discharge strikes and the plasma is emitted. Electron currents of several amps are readily drawn from this device with electron-to-atom (and electron-to-ion) emission ratios in the range of several hundred to one. When used as a cathode this discharge electron emitter is regulated to introduce Cs vapor,  $\text{Cs}^+$ , and electrons at rates required for the main chamber discharge. When it is used to neutralize the ion beam outside the ion engine, a plasma bridge to the ion beam is formed, resulting in good coupling with only a few volts potential difference between the beam and neutralizer.

Electron bombardment ion engines have been developed to produce ion beams of from 1 ma to 1 amp. A series of Cs microthrusters was developed, the smallest having a single beam aperture, to operate efficiently in the range from 10 to 100  $\mu\text{lb}$  of thrust (26). Other engines generating hundreds of ma of beam current have been developed in investigating cathode types, discharge modes, and electrodes to increase performance efficiency (27). Large Hg engines with source diameters up to 50 cm produce up to several amps of beam current (28). Cs engines have been life-tested for over 8000 hr of continuous operation and terminated only because the propellant was exhausted (29).

A 1-amp beam of  $\text{Na}^+$  was produced at EOS by an ion engine modified to operate at somewhat higher temperatures. The source was operated with 4 kv applied to the ionizer and about 1 kv to the accel electrode. The multibeam electrode system contained over 500 apertures and was heated to about 300°C to prevent condensation and thereby obtain stable operation. Other species such as Kr, Ar,  $\text{N}_2$ , and  $\text{H}_2$  (30) in addition to others not reported, have been used with standard ion engines.

#### Electrohydrodynamic Ion Source

Investigations conducted to generate heavy charged particles having charge-to-mass ratios a factor of approximately 100 below that of  $\text{Cs}^+$  are aimed at developing a thruster which operates at a specific impulse of about 1000 sec. This type of thruster can produce a higher thrust per unit power than the two types of ion engines described above, but it requires higher mass flow rates.

Heavy charged particles are generated by the application of intense electric fields at the surface of a conducting liquid (31-33). The intense electric field is achieved at nominal voltages (2-10 kv) by using high-curvature particle emitters such as capillary needles. Organic fluids such as glycerol, doped with salts or acids, have been used to produce charged particles over a wide range of charge-to-mass ratios up to  $10^5$  C/kg. Since the charged particle beam contains a distribution of charge-to-mass ratios, time-of-flight (TOF) techniques in addition to current and voltage measurements are employed to determine thruster operational parameters. Alkali metals used as the liquid produce ions predominately at high-current densities (32).

The state of the art in this field is not as advanced as those of the surface ionization and electron bombardment ion engines. For this reason generalizations are not drawn from the limited data available.

The experimental arrangement for charged particle generation and testing is shown in Fig. 5. Fluid flow to the tip of a capillary needle emitter is controlled by a pressure feed system. High voltage (2-10 kv) is applied to the emitter with an extractor electrode maintained at several hundred volts negative. The extractor aids in forming the electric field at the needle tip and prevents electrons in the particle beam from backstreaming to the emitter. It is important to prevent backstreaming electrons from impinging upon the emitter because they cause excessive emitter heating and also errors in measuring emitter ion current. A shielded collector is provided to measure part of the beam current and determine the charge-to-mass distribution using TOF analysis. The emitter potential is brought to ground by means of the shorting switch,

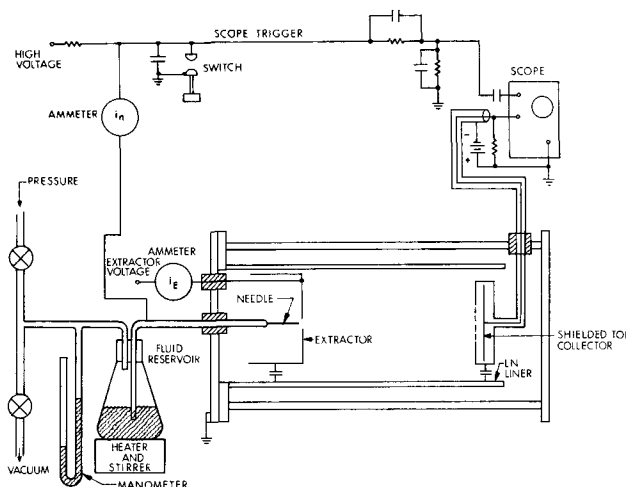

Fig. 5. Schematic diagram of electrohydrodynamic ion source experiments showing the arrangement for measuring time of flight.

and the subsequent current decay is observed on the oscilloscope. This provides the beam particle velocity distribution, from which the charge-to-mass ratio distribution can be obtained. Emitter tips are fabricated from capillary tubing made of stainless steel, platinum, or tungsten ranging in size from  $2.5 \times 10^{-3}$  to  $2 \times 10^{-2}$  cm ID and from  $7.5 \times 10^{-3}$  to  $4.5 \times 10^{-2}$  cm OD. The tips are tapered by grinding to provide a narrow, rounded rim.

The interaction between the conductive liquid and the metal surface at the emitter tip under high field conditions results in the electrohydrodynamic emission of charged particles. The electric fields at the emitter tips are somewhat below  $10^6$  v/cm, which is insufficient to extract charged particles or ions by field emission. Instabilities can occur at the liquid surface which is under tension because of high field and opposing surface tension forces. As the liquid develops a surface protuberance, the electrical force at the peak increases with the distance from the average surface level. This can grow into a liquid spike with dimensions one or two orders of magnitudes below those of the emitter. With the effective electric field at these spikes greater than  $10^7$  v/cm, ions can be extracted by field emission. The space charge of the emitted ions lowers the field at the spike to either limit the current flow or allow the spike to collapse to be regenerated a short time later. Conductivity, surface tension, and emitter tip size determine the applied voltage required to produce emission and also the average size of the particles emitted. Ions are generated from liquid alkali metals because of their high conductivities, high surface tension, and good wetting properties. No positive feed system pressure was required in the cesium tests, with only sufficient pressure applied initially to fill the feed system lines. The liquid metal then replenished itself at the needle tip by self-sustaining capillary and surface tension forces.

Needle currents of  $270 \mu\text{a}$  at 4.4 kv were obtained using a  $2.5 \times 10^{-3}$  cm needle, and  $200 \mu\text{a}$  at 4.03 kv using the  $10^{-2}$  cm ID needle with a 0.16 cm extractor aperture. In all of the tests the charged particle beam consisted almost wholly of  $\text{Cs}^+$  ions. Figure 6 shows two TOF traces showing  $\text{Cs}^+$ ,  $\text{Cs}^{+2}$ , and  $\text{Cs}^{+3}$  at 4.03 kv and  $\text{Cs}^+$  alone at 7.8 kv. No attempt was made to focus the beam, with the result that only a few per cent of the ions impinged upon the collector. Onset of spraying occurred at about 0.9 kv for the  $2.5 \times 10^{-3}$  cm ID needle.

In conjunction with the spraying of cesium ions, the neutral cesium yield was measured directly with neutral cesium detector used for similar measurements with ion engines. The measurements show that the neutral fraction of the total mass flow rate varied from less than 1.8 to 3.8% for the case where the emitter temperature was between  $100^\circ$ - $200^\circ\text{C}$ . Above  $200^\circ\text{C}$  the neutral fraction was nearly 100%, and the cesium

spray from the emitter showed a visible glow. At the lower temperatures the spray was not visible, indicating a correlation of the neutral yield with the visible spray. The transition between the two operating conditions was abrupt and showed considerable hysteresis. The glow indicates the presence of a discharge which heats the emitter tip, evaporating copious quantities of neutral cesium.
