If [11] were the operative process, then stirring would enable the passive film to be formed more rapidly, shortening (or in any case not increasing)  $\tau_{\text{ox}}$ . On the other hand with [10] as the process, stirring would have the effect of removing some of the Cu<sup>2+</sup> ions from the vicinity of the electrode surface or of removing some of the CuF<sub>2</sub> before it had precipitated on the surface. In either event the effect would be to increase  $\tau_{\text{ox}}$ , as was observed. Thus the film of CuF<sub>2</sub> was most likely formed *via* the dissolution of Cu to Cu<sup>2+</sup> ions. The same argument can be applied to explain the observed increase of anodic charge with decreasing scan rates.

The results of the galvanostatic charging experiments on individual electrodes are summarized in Table IV. The interesting points to note are that  $i\tau$  decreases with increasing  $i$ , while  $i\tau^{1/2}$  increases with increasing  $i$ . This indicates that processes controlled by diffusion become increasingly important at higher current densities. This is at variance with the usual observation that either  $i\tau$  or  $i\tau^{1/2}$  is constant with increasing  $i$  during the formation of porous (or non-continuous) anodic films (16). Generally, at low  $i$  (large  $\tau$ ) diffusion is more important and  $i\tau^{1/2}$  is constant. At large  $i$  (small  $\tau$ ) it is usually found that  $i\tau$  is constant.

The explanation for the observed behavior in the present case probably involves the influence of a rate-limiting step associated with the crystallization of the precipitated CuF<sub>2</sub> (21).

**Tafel parameters.**—As shown in Fig. 6, the CuF<sub>2</sub> electrode comes to a steady potential within approximately 1 sec after the application of a constant current. At low current densities, *e.g.*, 2  $\mu\text{amp}/\text{cm}^2$ , this potential was constant for over 1 hr. It was therefore possible to characterize the initial surface in terms of the Tafel parameters by exposing the surface to a series of constant current pulses of sufficient duration (*e.g.*, 2 sec) to establish a steady potential, but not so long as to consume a substantial portion of the surface. The anodic polarization behavior was determined first, followed by the cathodic behavior.

These Tafel parameters represent a complex combination of overpotentials involving the dissolution of copper metal, the potential dependence of nucleation and growth of the anodic CuF<sub>2</sub> film, and possibly other processes. Nevertheless, this representation is convenient for summarizing experimental data.

A Tafel plot is given in Fig. 7. Tafel behavior was obtained for both anodic and cathodic processes. It can be seen that the anodic and cathodic processes have

different intercepts on the current axis and hence different apparent exchange current densities. This is indicative of two different processes which may or may not be multistep processes (22). The apparent exchange current density for the anodic process is  $3.0 \times 10^{-6}$  amp/cm<sup>2</sup> and for the cathodic process,  $2.4 \times 10^{-6}$  amp/cm<sup>2</sup>. The anodic Tafel slope is 20 mv and the cathodic Tafel slope 42 mv. The apparent exchange current density for the formation of NiF<sub>2</sub> at a nickel electrode in anhydrous HF containing 0.01M NaF is of the same order of magnitude (9), namely  $3.7 \times 10^{-6}$  amp/cm<sup>2</sup>.

### Conclusions

The Cu/CuF<sub>2</sub>(s) couple is a reliable reference electrode in basic, anhydrous HF. The electrode meets the requirements of satisfactory polarization and has a meaningful thermodynamic potential *vs.* an H<sub>2</sub> electrode in the same solution. The value measured, +276  $\pm$  5 mv agrees well with that calculated from thermodynamic data at 25°C.

The formation of an insoluble anodic film at a Cu electrode in a 1M KF solution in HF at 0°C was demonstrated by cyclic voltammetry and chronopotentiometry. A film thickness of  $4 \times 10^{-6}$  cm (400Å) was estimated for the initial anodic formation of CuF<sub>2</sub>. Anodic-cathodic cycling of Cu electrodes gave rise to a significant roughening of the electrode surface as shown by *i*-E curves, E-t curves, and differential capacitance measurements on cycled electrodes. X-ray analyses of these films confirmed the presence of crystalline copper fluoride.

Evidence from the chronopotentiometric and cyclic voltammetric experiments indicates that the anodic formation of CuF<sub>2</sub> proceeds *via* a soluble intermediate according to the following mechanism

rather than through the surface reaction of Cu with adsorbed HF<sub>2</sub><sup>-</sup>. During the formation of CuF<sub>2</sub>,  $i\tau$  decreased and  $i\tau^{1/2}$  increased with increasing  $i$  over the range 10 to 50 ma/cm<sup>2</sup>.

The polarization behavior of Cu electrodes in basic HF solution showed that film formation can be approximated by Tafel lines with an apparent exchange

current density for the anodic process of about  $3.0 \times 10^{-6}$  amp/cm<sup>2</sup> and a Tafel slope of 20 mv.

The properties of the anodic film of CuF<sub>2</sub> formed in basic HF solutions are similar to the properties observed for noncontinuous, anodic films formed in aqueous solutions (21). Thus such films tend to be thick ( $>10^{-6}$  cm) and crystalline, have low resistance to current flow during film formation, and their formation leads to surface roughening.

## LEED Studies, Adsorption of Carbon Monoxide on the Tungsten (112) Face

Chuan C. Chang

Bell Telephone Laboratories, Murray Hill, New Jersey

#### ABSTRACT

Carbon monoxide adsorbs on the clean tungsten (112) face with an initial sticking probability of  $>0.9$  at room temperature and desorbs with heat in three stages, the W(112)- $\alpha$ ,  $-\beta_1$ , and  $-\beta_2$  at 400°, 1000°, and 1200°K with about  $5 \times 10^{14}$  molecules/cm<sup>2</sup> in each state at maximum coverage. Room temperature adsorption is nondissociative and almost random. Heating a CO covered surface produces well defined C(6x4), P(2x1), C(2x4) and "Complex" structures. The  $\alpha$ -CO does not contribute directly to any diffraction pattern. The  $\beta_1$  is associated with the P(2x1) and C(2x4) structures, and an irreversible temperature activated conversion at about 1000°K produces  $\beta_2$  molecules; these are responsible for the C(6x4) and Complex structures. Experiments with (112) substrates containing adsorbed oxygen show that CO does not react to produce CO<sub>2</sub>, that CO does not adsorb onto an adsorbed oxygen atom and that in the presence of oxygen not all exposed tungsten atoms adsorb CO. The (112) surface is composed of two exposed (112) planes, and by covering only the second layer tungsten atoms with oxygen, it was found that CO adsorbs on the topmost layer as well as on the second layer. Molecules adsorbed on the top layer desorb as  $\beta_1$  and the maximum number of  $\beta_2$  molecules on the surface was proportional to the number of second layer tungsten atoms not covered by oxygen.

Low Energy Electron Diffraction (LEED) studies of carbon monoxide adsorption on the tungsten (112) face are of interest because of the possibilities of obtaining reliable values for sticking probabilities and coverages and of studying the atomistics of the adsorption process. Adsorption of CO on the (110) (1, 2) and (100) (3) faces of this bcc metal has been studied with LEED. The CO-W system has also been investi-

gated by other methods, notably flash desorption (4-14), field microscopy (15-19), and calorimetry (20).

The present investigation is an extension of the work on the oxidation of the tungsten (112) face (21) and is part of a wider program in which the interaction of oxygen, carbon monoxide, and nitrogen with this face was studied (22). We are concerned here with adsorption of CO on the clean tungsten

surface, and also on surfaces previously exposed to oxygen.

### Experimental Procedure

A tungsten crystal was cut to expose a (112) face to a precision of about  $0.1^\circ$ . The thickness was 0.15 mm and the surface area  $4 \times 14$  mm. The ends of the crystal were welded to tungsten supports. The crystal was heated with a.c. and the temperature could be found from tungsten-rhenium thermocouple wires welded to the side not studied by electron diffraction. The studies were made in a Varian LEED chamber equipped with a gas handling system, a quadrupole gas analyzer, and an ion gauge. During exposure of the crystal to CO, the total amount of active residual gases could be maintained (22a) at below 1% for CO pressures above  $2 \times 10^{-8}$  Torr. The crystal was cleaned by repeated oxidation followed by flashing above  $2200^\circ\text{K}$ . Electron micrographs of the cleaned surface showed no discernible features down to a resolution of  $70\text{\AA}$ . Since large numbers of steps and other imperfections smaller than  $70\text{\AA}$  would have been detected with LEED, it is concluded that the surface was effectively atomically smooth.

### Adsorption on the Clean Surface

The clean surface was found to have the ideal bcc (112) configuration (22b). A marble model of this surface is shown in Fig. 1. This surface consists of two exposed (112) planes; each plane is made up of parallel rows of close-packed atoms and the inter-row distance is a relatively large  $4.46\text{\AA}$ . Thus the  $[\bar{1}\bar{1}\bar{1}]$  close-packing direction (vertical in the photograph) and the  $[1\bar{1}0]$  direction (horizontal) are "non-degenerate;" this, together with the fact that the unit cell vectors are orthogonal, make this a most appropriate surface for LEED work.

*Flash desorption.*—Much information not obtainable from LEED can be obtained from flash off experiments; these are presented first [for descriptions of flash off methods, see ref. (23, 24)].

Three pressure bursts were found in flash desorption, as shown in Fig. 2. These are the  $W(112)\text{-CO-}\alpha$ ,  $-\beta_1$ , and  $-\beta_2$  with desorption temperatures of  $400^\circ$ ,  $1000^\circ$ , and  $1200^\circ\text{K}$ . These temperatures correspond closely to those for the  $\alpha$ ,  $\beta_1$ , and  $\beta_2$  peaks from polycrystalline tungsten (4, 9). Known desorption temperatures of various peaks from single crystal faces and from polycrystalline tungsten are shown in Table I.

Fig. 1. Marble model of the bcc (112) face. The central rectangle outlines a surface unit mesh. The close packed rows of top layer atoms are separated by open channels or troughs. The asymmetric positioning of the second layer with respect to the topmost layer introduces an asymmetric intensity distribution in diffraction patterns observed at normal incidence.

Fig. 2. Flash desorption from the (112) face after different exposures to CO (the exposure unit 1L =  $10^{-6}$  Torr-sec). Heating rate  $300^\circ\text{K/sec}$ , except for the top trace. The zero of pressure has been changed for each curve to avoid overlapping.

It was found in the present experiments that most of the  $\alpha$ -CO on the surface can be "pumped off" in good vacuum even after a heavy exposure. Also, the  $\alpha$  desorption temperature falls from about  $500^\circ\text{K}$  to below  $400^\circ\text{K}$  with increasing coverage. These observations indicate that for this physisorbed component, there is a dynamic balance between adsorption and desorption. In contrast,  $\beta$ -CO molecules do not spontaneously desorb at room temperature. We can therefore conclude that a firmly bound state already exists after room temperature adsorption.

Others have also found that the  $\alpha$  peak height and desorption temperatures are pressure and exposure dependent (8, 10), and in addition, that the  $\beta$ -CO adsorbs as an immobile layer (15, 16) and that CO does not dissociate upon adsorption (4, 15, 16, 26). For the (112), the  $\beta$  desorption temperatures are independent of coverage. At maximum coverage  $\beta_1$  and  $\beta_2$  contain equal amounts as measured by comparing areas under flash off curves.

*Sticking probability and coverage.*—Sticking probabilities and coverages were measured in three ways; flash desorption, gas uptake (22c), and analyses of changes in diffraction patterns. Results from the first two methods for the initial sticking probability  $S(O)$  and saturation coverage  $\sigma_0$  are presented in Group A of Table II; this group lists results obtained from measurements of changes in CO pressure. The data for the present results are summarized in Fig. 3. Results from diffraction pattern studies (next section) are given in Group B of the table with results of several other workers; this group did not depend primarily on measurements of changes in CO pressure. In addition, they are concerned only with the  $\beta$  component.

Entries in Group B show remarkable agreement; in contrast, values in Group A show scatter and are consistently low, especially for  $S(O)$ . The source of error for Group A is the well known wall desorption (and adsorption) of CO. This is why  $S(O)$  is affected more and workers who reduced these effects obtained the highest values for  $S(O)$ , ref. (6, 7) of Table II. In the present experiments, wall desorption is known to be appreciable from the slow response of the pressure to

\* Not values given in ref. (1), as those were "normalized" to agree with some of the results of Group A above; values presented here were obtained by comparing areas under flash off curves from the (110) and (112) faces, since LEED observations on the (110) do not readily give coverages as for the (100) and (112).

sudden changes in CO leak rate, as compared to the rapid response for oxygen.

**LEED observations.**—CO adsorbed at room temperature produces a diffuse diffraction pattern with no well defined extra spots and with high background intensity. The bright background is indicative of disorder. This is very different from the sharp patterns with high contrast seen after oxygen adsorption (21). Sharp diffraction patterns are, however, seen after heating.

In experiments involving heating, the crystal was given various exposures to CO at room temperature and then heated to progressively higher temperatures in good vacuum. Well defined C(6x4), P(2x1) and C(2x4) patterns were found with this treatment; in addition, a "Complex" pattern was found which has no well defined symmetry. These are displayed in Fig. 4. Much of the data can be summarized in a temperature-exposure diagram showing the conditions under which each pattern is observed; this diagram is shown in Fig. 5. Significant findings about the surface structures are presented in Table III.

The two most important results are that each structure can be associated with a particular gas burst observed in flash desorption and that for three of the structures, their coverages have been found.

Fig. 3. Amounts of adsorbed CO against exposure, obtained from uptake and flash off curves. Arrows show the minimum exposures at which the  $\beta_1$  and  $\alpha$  peaks appear on the flash off curves. Calibrated using LEED results by assigning the value of  $\frac{1}{2}$  monolayer to the amount absorbed after 1.2L.

Fig. 4. Diffraction patterns from CO adsorption. (A) clean surface, Miller indices shown on some of the spots. (B) after saturation exposure at room temperature. (C) to (F), the C(2x4), Complex, C(6x4) and P(2x1) patterns. All taken at 80v except (E) and (F), at 81v, normal incidence.

Fig. 5. Temperature-exposure ranges in which various CO patterns appear for initial room temperature exposures shown on the abscissa followed by heating to progressively higher temperatures in good vacuum.

As an example of how the entries in the table were obtained, consider the P(2x1). This pattern will develop to its best if the crystal is heated to about 750°K after an exposure of 1.2L (1L =  $10^{-6}$  Torr-sec), see Fig. 5. Since a P(2x1) symmetry represents multiples of  $\frac{1}{2}$  monolayer of scatterers (1 monolayer =  $8 \times 10^{14}/\text{cm}^2$  on this face) and 1.2L represents 0.57 monolayer of molecular collisions with the crystal, the coverage must be  $\frac{1}{2}$  monolayer. The average sticking probability up to  $\frac{1}{2}$  monolayer is then about 0.9. The P(2x1) is stable up to about 1000°K (Fig. 5) when it changes to a weak Complex pattern with no detectable gas evo-

Table III. CO structures on the (112) face

Pattern	Exposure, L	Coverage, monolayer	Destruction temperature, °K	Associated F. O. peak
C(6 × 4)	0.6	1/4	1200	$\beta_2$
P(2 × 1)	1.2	1/2	1000	$\beta_1$
C(2 × 4)	>1.4	5/8 to 10/8	1000	$\beta_1$
Complex	>1.5	5/8	1200	$\beta_2$

lution and then to a C(6x4) at about 1200°K with loss of some CO. Because the destruction temperature of the P(2x1) coincides with the  $\beta_1$  desorption temperature, we are led to associate the P(2x1) with the  $\beta_1$ -CO.

It is unmistakable that  $\beta_2$  molecules are responsible for the C(6x4) and Complex structures since all the  $\beta_1$  molecules have been desorbed when either of these patterns is seen. However, the  $\beta_1$  can only be loosely associated with its structures. Strong supporting evidence that  $\beta_1$  molecules produce the P(2x1) and C(2x4) comes from the fact that the  $\beta_1$  desorption temperature is the same as the destruction temperature for these structures. Further evidence will be presented in the section on LEED observations and surface structures.

The C(2x4) pattern first appears at a coverage of about  $\frac{5}{8}$  monolayers. Additional molecules, up to full coverage, do not substantially affect the diffraction pattern. This is one example of the many possible pitfalls wherein coverage estimates based on diffraction patterns alone can go wrong. Fortunately, for the P(2x1), a unique value could be found so that the flash off data could be calibrated at  $\frac{1}{2}$  monolayer. This calibration is, therefore, all important and a separate check of its correctness will be provided in the section on LEED observations and surface coverage.

The Complex pattern was so named because it has no well defined symmetry. It is nevertheless interesting, as adsorbed nitrogen produces a practically identical pattern (22d). Note that this unusual pattern (Fig. 4D) consists of streaky features quite unlike the spot patterns normally observed in LEED. It is therefore surprising that two gases give this same strange pattern. A little investigation shows, however, that these gases have much in common. First, CO and N<sub>2</sub> are iso-electronic. Second, they have been associated with the concept of surface complexes which arose out of attempts to account for the kinetics of the nitrogen-tungsten system (28,29) and the results from isotopic mixing experiments with CO (13) and N<sub>2</sub> (30,31).

Conditions under which isotopic mixing becomes appreciable correspond to conditions for the formation of the Complex structures for both CO and N<sub>2</sub>. Under these same conditions it is generally believed that both atoms of the nitrogen molecule are in contact with the metal. Since the CO-Complex pattern indicates that CO has the same configuration, it is concluded that both atoms of this molecule also contact the substrate in the  $\beta_2$  state.

Diffraction pattern studies do not give direct information on the coverage for the Complex structure as it has no well defined symmetry. The coverage was estimated to be about  $\frac{5}{8}$  monolayer by comparing the flash desorption amount with that from  $\frac{1}{2}$  monolayer coverage.

**Surface structures.**—Of the four CO structures on the clean surface, the P(2x1) is simplest. It is like the oxygen P(2x1)  $\frac{1}{2}$  monolayer structure so that every trough site h,k with h even is occupied by a CO molecule. Accordingly, the intensity-voltage curves from these two P(2x1) patterns are quite similar. Although the tungsten surface is undisturbed in the P(2x1) structure, the possibility of reconstruction (32, 33) has not been ruled out for the other three structures. Note, however, that because of the simplicity of the P(2x1) structure and the large minimum distance of 4.46Å between scatterers, the conclusion that this structure requires  $\frac{1}{2}$  monolayer of adsorbates is expected to remain valid whether the surface is reconstructed or not.

The C(2x4), C(6x4), and Complex patterns show a diversity of behavior which indicates that not enough is as yet known about them for a meaningful structure analysis.

Fig. 6. CO flash off from oxygen structures after saturation exposure at room temperature. Heating rate 300°K/sec. (a) to (e) in order of decreasing oxygen content.

A simple model that can account for all of the present results is the one in which  $\beta_1$  molecules adsorb at room temperature undissociated, with only the carbon contacting the metal. A temperature activated transformation to the  $\beta_2$  occurs after heating to about 1000°K and in this state both carbon and oxygen contact the metal. In the Complex structure,  $\beta_2$  "molecules" agglomerate into surface stabilized complexes that can be studied at room temperature.

### Adsorption onto Oxygen Structures

Experiments in which CO is adsorbed on a surface previously covered by oxygen might seem to have special interest because of this bearing on the catalytic formation (2) of CO<sub>2</sub>. These experiments could also provide a check for the CO coverage estimates because the oxygen coverages are quite reliably known. In carrying out such experiments, the oxygen surface structures (21, 22e) were used as substrates. These are the facet structures produced by exposing a hot crystal to oxygen and five nonfacet structures.

**Flash desorption.**—No CO<sub>2</sub> was observed to flash off from any of the oxygen structures and repeated adsorption and desorption of CO left the surface oxygen content undiminished. In most cases, the original oxygen structure remained apparently undisturbed, as reported earlier (2). Thus no oxygen could be removed by CO from these structures.

The flash off data of Fig. 6 shows that only one  $\beta$  peak desorbs from the oxygen structures. These structures, together with their oxygen coverages and their per cent of tungsten atoms still uncovered, are listed in Table IV. The amounts of  $\beta$ -CO that adsorb are shown in row 4 as a per cent of the maximum that adsorbs on the clean surface.

Figure 6 shows that the  $\beta_2$  peak is suppressed by pre-adsorption of oxygen and that the observed  $\beta$  desorption occurs essentially at the  $\beta_1$  temperature [actually, almost 100°K lower, as also happens in the case of CO on W(110)-O[ $\frac{1}{2}$ ] structure; compare Fig. 5 of ref. (1) with Fig. 3B of ref. (2)]. Accordingly, we shall see below that the  $\beta_2$  structures are never seen.

Table IV shows that the per cent of adsorbed CO decreases faster than the per cent of exposed tungsten atoms as more of the surface is covered with oxygen.

Table IV.  $\beta$ -CO flash off from the oxygen structures

1. Clean	P(2 x 1)	P(1 x 1)	P(1 x 4)	P(1 x 2)	P(1 x 3)	Facet
0	$\frac{1}{2}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	1-2/3	~2
100	75	50	38	25	17	0
100	80	40	15	3	0	0

1. Oxygen structures; 2. oxygen coverage in monolayers; 3. per cent of exposed tungsten atoms; 4. per cent of  $\beta$ -CO observed to flash off; and 5. amounts of adsorbed  $\beta$ -CO as predicted from diffraction pattern observations (section on LEED observations and surface structures).

**LEED observations and surface structures.**—The above flash off experiments show that adsorbed oxygen inhibits CO adsorption. We now examine this in more detail as the (112) face is gradually covered with more and more oxygen atoms.

We start by covering half of the second layer tungsten atoms with oxygen. This is accomplished by using the oxygen P(2x1) structure which is constructed by placing an oxygen atom into every other trough site, thus exposing 75% of the original 2 monolayers of surface tungsten atoms.

Adsorption of CO on the P(2x1) results in a P(1x1) pattern so that the spaces between oxygen atoms have become filled with CO. Heating this P(1x1) produces a C(2x4) as with adsorption on the clean surface. This C(2x4) is destroyed near 900°K with desorption of about  $\frac{3}{8}$  monolayer of CO, leaving a second, much sharper, P(1x1). If we hypothesize that CO does not stick to an adsorbed oxygen, then all the CO desorbed during the formation of this P(1x1) was initially adsorbed on the top layer tungsten atoms. Here is a second evidence that molecules adsorbed on the top layer desorb essentially as  $\beta_1$  and that these molecules produce the C(2x4) pattern. We are now ready to perform a very important experiment, since all the excess CO has now been removed so that the remaining P(1x1) must be a monolayer structure.

When all the CO is flashed off from this second P(1x1), the area under the flash off curve is equal to that from the P(2x1)-CO structure. This serves as a check for the  $\frac{1}{2}$  monolayer calibration of the CO flash off, as the only other calibration used the extremely streaky P(2x1)-CO pattern (Fig. 4F) which could not be made as sharp and bright as the oxygen P(2x1). Unlike the case with CO, the  $\frac{1}{2}$  monolayer estimate for the P(2x1) oxygen structure could be checked with the uptake method, and most important, it was shown that the P(2x1) oxygen structure covered the entire surface. Moreover, a deviation from  $\frac{1}{2}$  monolayer of only 5% would be easily detectable for the P(2x1) oxygen pattern (22f).

In the above P(1x1)-O[ $\frac{1}{2}$ ] + CO [ $\frac{1}{2}$ ] structure, the CO is lodged into the spaces between adsorbed oxygen atoms so that the CO molecule has an effective diameter of less than about 2.8Å, much smaller than the 3.2-4.1Å obtained from several other methods.

Next we use the P(1x1)-O[1] structure in which the troughs are completely filled with a monolayer of oxygen atoms so that only the close packed rows of top layer tungsten atoms are exposed. With this substrate, the C(2x4) is observed, but not the P(2x1). This again shows that the  $\beta_1$  and C(2x4) are associated with the top layer tungsten atoms and that molecules responsible for the P(2x1) are located above the second layer tungsten atoms. All these conclusions, however, depend on the hypothesis that CO does not adsorb onto the oxygen atoms. This is quite clearly shown in the following experiment in which an oxygen structure with the next higher coverage, the P(1x4)-O[ $\frac{1}{4}$ ], is used.

The P(1x4) is constructed by covering every fourth top tungsten row on the P(1x1)-O[1], say rows 0, 4, 8, . . . , with oxygen. Upon adsorption of CO, this pattern changes to a P(1x2) so that rows 2, 6, 10, . . . become covered with CO, leaving 1, 3, 5, . . . still bare. Thus about 13% of the original surface tungsten atoms adsorb CO.

Adding more oxygen, we use the P(1x2)-O[ $\frac{1}{2}$ ] structure in which only every second top row is bare, and the P(1x3)-O[ $\frac{1}{3}$ ] structure in which only every third row is bare. Since CO does not adsorb on these surfaces, not all exposed tungsten atoms can accept CO although these actively adsorb oxygen.

Finally, the oxygen faceted surface exposes to the CO only (110)-type planes covered with a monolayer of oxygen atoms. Failure to find any CO adsorption on

faceted surfaces again confirms the hypothesis that CO does not stick to an adsorbed oxygen.

Enough was described above so that entries in row 5 of Table IV can be found from a knowledge of the oxygen structures and the diffraction pattern changes accompanying CO adsorption. A tacit assumption was made throughout that adsorbates scatter slow electrons sufficiently to produce the observed patterns. That this assumption is valid is most dramatically illustrated by the close match in Table IV between the observed flash off amounts in row 4 and the predicted values in row 5, since the predictions were based on models arrived at from diffraction pattern analyses.

# Environmental and Reaction Studies on Electrochemical Cells Based on Solid Charge-Transfer Complexes

F. Gutmann,<sup>1</sup> A. M. Hermann,<sup>2</sup> and A. Rembaum

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

## ABSTRACT

Solid state electrochemical cells using metal anodes with charge transfer complexes as cathodes which were previously reported have been further studied. The presence of the  $I^-$  ion has been verified in cells with iodine as the acceptor. Quantitative recovery of the reaction product in amounts proportional to the total charge delivered, substantiates the originally proposed reaction mechanism. Long time decay data under a steady load as well as under a pulsed load, extending over periods of up to nine months, are presented. It is shown that the performance of the cells is considerably improved by the admission of vapors of high permittivity liquids into the anode-electrolyte interface. Evidence is presented that the effect is primarily due to improved availability of reactant at the electrode surface.

We have previously reported (1) data on solid state electrochemical cells using metal anodes and a charge transfer complex as cathode. In the present communication, we wish to present further results on cells of the type Mg/Phenothiazine- $I_2$ /Pt. The well-known phenothiazine-iodine charge transfer complex (2) has the advantage of high electronic conductivity; however, donors other than phenothiazine have also been employed yielding similar results.

## Experimental

The cells were assembled in the holders previously described (1); the complex was produced by intimately mixing reagent grade phenothiazine and iodine as received in the stoichiometries indicated below.

The currents and voltages were measured by means of a Hewlett Packard 412A-VTVM unless stated otherwise.

## Reaction Mechanism

We have proposed a reaction mechanism (1) involving the  $I^-$  ion. In order to support this contention,  $MgI_2$  was recovered thus:

A cell was prepared using a 1:2 phenothiazine:iodine complex and then continuously discharged in ambient atmosphere and at room temperature over a period of nine months into a constant 31.6 ohm load; i.e., for this cell, virtually a short circuit load. The integration of the area under the current vs. time curve showed that a total of 216 coulombs had been delivered by this cell. The cell was then dismantled and analyzed for  $MgI_2$  (the electrolyte) by extracting the contents with distilled water. This solution was stirred, filtered, and the filtrate was treated with aqueous ammonia and an excess of  $(NH_4)_2HPO_4$  was then added. The precipitate formed was filtered, dried, and analyzed for Mg and for phosphate. The recovery was 190 mg of  $MgNH_4PO_4$  corresponding to the passage of 282 coulombs. Thus, the difference of 66 coulombs must have been consumed in a side reaction. This reaction is most likely an internal corrosion process at the Mg anode, probably associated with traces of water present in the ambient atmosphere.

The above data, therefore, support the reaction mechanism which was based on the formation of  $MgI_2$  (1).

## Long Time Decay Curves. Effect of Solvent Vapors

The above test commenced with the rather low short circuit current density of  $560 \mu A/cm^2$ ; after two days, the short circuit density was of the order of  $30 \mu A/cm^2$ ;

after nine months, the current density had dropped to about  $4 \mu A/cm^2$ . The initial open circuit voltage was 1.7v; after one week, it recovered to a value of 1.5v after removal of the load for a few seconds. This recovery voltage was maintained to  $\pm 0.1v$  for seven months of the total test period. After nine months, the recovery open circuit voltage had dropped to 1.2v. The results of a further decay test are shown in Fig. 1. These data refer to another cell of the type Mg/phenothiazine:iodine 1:2/Pt, but in an atmosphere saturated with acetonitrile vapor. The cell had an initial open circuit voltage of 1.7v. Its voltage under a continuous load of 5000 ohm was recorded over a period of 415 hr. The voltage is seen to keep substantially constant over about 10 hr whence it commences to decay approximately linearly at a rate of about 7 mv/hr. This rate is then maintained over about 70 hr.

A further series of discharge tests was performed using an electromechanical oscillator (3) as the load. A typical oscillogram is reported in Fig. 2. This oscillator draws a current pulse of 200-300  $\mu A$  of 6-8 msec duration at a repetition frequency of 6  $sec^{-1}$ ; its impedance is partly inductive, causing the transient waveshape of the sharp spikes. The discharge test was carried out at room temperature in (uncontrolled) laboratory atmosphere. The cell, with initial open circuit voltage 1.62v and short circuit current 3.4 ma, operated in a room atmosphere with the oscillator load for 480 hr. At this point, the open circuit voltage

Fig. 1. Decay of the terminal voltage for the system Mg/phenothiazine;  $I_2$  1:2/Pt. The test was conducted in saturated vapors of acetonitrile under a constant load of 5000 ohm.

had dropped to 0.5v. Upon exposure without load to a high humidity atmosphere for 24 hr, the open circuit voltage recovered completely. Continuing the test under load in the high humidity environment, 550 hr were required for the voltage to drop to 0.5v. The difference  $\Delta V$  between open circuit and loaded voltage remained fairly constant, even though the open circuit voltage itself dropped. Total operating time was 1032 hr (43 days) of which 552 hr occurred in a humid atmosphere. Another cell was tested with a purely resistive load of 4700 ohm, which was periodically connected to the battery by a switching circuit (8 msec "on", 172 msec "off"). The open circuit voltage was 1.59v, and the current through a 10 ohm load was 4.2 ma. In room temperature, an open circuit voltage of 0.5v was reached after 192 hr. The cell was then subjected for 24 hr to the humidity treatment described above. Only an additional 48 hr of operation in room atmosphere were obtained before the open circuit voltage again dropped to 0.5v. Recharging with  $500 \mu\text{a}$  for 72 hr did not restore the cell. Total accumulated operating time was 250 hr, all in laboratory atmosphere.

In this experiment, carried out in uncontrolled laboratory atmosphere,  $\Delta V$  increased significantly with time.

In the experiment carried out in a controlled, humid atmosphere, the wave forms obtained remained constant and showed no variation with time, *i.e.*, there was no difference in the shape nor in the amplitude of the voltage pulses as measured by connecting an oscilloscope across the cell throughout the duration of the test.

The difference  $\Delta V$  between the terminal voltage under a load  $R_L$  and the voltage  $V'$  to which the cell recovers just before the start of the following pulse thus remains constant though the recovery voltage itself decreases approximately linearly during the test. We shall now investigate the conditions under which one could expect  $\Delta V$  to be constant with time.  $\Delta V$  represents the voltage drop across the internal resistance due to the current pulse

$$\Delta V = \frac{V'}{\frac{\partial V}{\partial I} + R_L} \frac{\partial V}{\partial I} \quad [1]$$

Since the decay of  $V'$  is approximately linear<sup>3</sup> with time  $t$ , we may write an explicit decay function in

<sup>3</sup> Prima facie one would expect the decay to be exponential; the linear decay characteristic observed during a limited time interval thus might well be the equivalent to taking only the first, linear, term in an exponential series. Since Fig. 1 indicates that such a linear approximation does hold for the time interval considered, the following analysis will apply to the same degree of approximation.

terms of an open circuit voltage  $V$

$$V' = V(1 - \alpha t) \quad [2]$$

where  $\alpha$  is a decay constant. Since  $\Delta V$  is independent of time

$$\left. \frac{\partial \Delta V}{\partial t} \right|_I = 0 \quad [3]$$

Hence

$$(1 - \alpha t) \left( \frac{\partial V}{\partial I} + R_L \right) \frac{\partial^2 V}{\partial I \partial t} - \alpha \frac{\partial V}{\partial I} \left( \frac{\partial V}{\partial I} + R_L \right) - \frac{\partial V}{\partial I} (1 - \alpha t) \frac{\partial^2 V}{\partial I \partial t} = 0 \quad [4]$$

Since this must hold for all values of  $t$ , the terms containing  $t$  explicitly must vanish

$$(1 - \alpha t) R_L \frac{\partial^2 V}{\partial I \partial t} = 0 \quad [5]$$

$$\therefore \frac{\partial}{\partial t} \frac{\partial V}{\partial I} = 0 \quad [6]$$

Thus the dynamic internal resistance must remain constant with time. This leaves only one term remaining in Eq. [4]

$$\alpha \frac{\partial V}{\partial I} \left( \frac{\partial V}{\partial I} + R_L \right) = 0 \quad [7]$$

so that

$$\frac{\partial V}{\partial I} = -R_L \quad [8]$$

The second condition for the time independence of  $\Delta V$  (Eq. [8]) therefore is the requirement that the load resistance matches the internal dynamic resistance of the cell. The latter quantity is, of course, negative since the cell is an active circuit element; an increase in current is accompanied by a drop in cell voltage. To the extent that this very simplified analysis holds—see footnote—the constancy of the voltage drop  $\Delta V$  during the tests in a humid atmosphere is thus seen to be associated with the dynamic internal resistance of the cell remaining constant, plus the rather fortuitous approximate equality between the values of the load resistance and the dynamic internal cell resistance. We note that the latter quantity remains constant in the humid environment though not in the uncontrolled laboratory atmosphere. Since the dynamic internal resistance ( $\partial V/\partial I$ ) is the sum of a constant ohmic series resistance plus a polarization or diffusion resistance term, it follows that the diffusion resistance is held constant in the presence of a vapor of high permittivity liquid, but not in its absence. Hence the admission of solvent, although not necessarily water, vapor tends to assist the diffusion processes, causing a substantially constant and improved rate of diffusion of  $I^-$  ions into the reaction site. The decay involves the shift of the entire polarization curve to lower voltage values, parallel to itself, without a change in its slopes.

Further experiments aimed at determining the influence of gases and vapors on the performance of these cells showed that the complete removal of all solvent and water vapors reduces the short circuit current by 2 to 3 orders of magnitude below the value recorded in ambient laboratory atmosphere (1) (see Fig. 3). Likewise, the introduction of benzene or  $\text{CCl}_4$  vapor into the otherwise dry and solvent free system causes no increase in the short circuit current density. However, dry vapors of acetone, methylalcohol, or acetonitrile cause the current density to rise to values of up to several 100 ma/cm<sup>2</sup>, higher by about an order of magnitude than the best current densities obtainable in an uncontrolled room atmosphere. Water vapor has a similar effect. In brief, it appears that the presence of vapors of liquids of high permittivity improves

the performance of these cells while vapors of low permittivity liquids do not affect the short circuit current densities available as compared to those under vacuum or dry conditions.

Thus, e.g., a cell prepared and tested in air gave a short circuit current of 4.0 ma which, upon drying out with  $\text{CaCl}_2$  dropped to 50  $\mu\text{a}$ . Introduction of methanol vapor raised the current to 70 ma. Likewise, admission of acetonitrile vapor into a dried and solvent-free cell raised the current from 50  $\mu\text{a}$  to 50 ma.

Moreover, the open circuit voltages of cells kept in a solvent-free environment produced by either evacuating or exposure to a drying agent such as  $\text{CaCl}_2$ , drop from the thermodynamical value of 1.85v to values in the vicinity of 1.2v. There is no increase in open circuit voltage nor short circuit current on admission of vapors of benzene or  $\text{CCl}_4$ .

Figure 3 illustrates the effect of admission of acetonitrile vapor on the short-time decay of the current into a constant 5000 ohm load, with vapor pressure as the parameter: the cells were kept in an evacuated glass vessel and acetonitrile vapor at controlled pressures was then admitted.

The beneficial effect of a high permittivity solvent vapor atmosphere must be due to the permeation of the vapors into the anode-electrolyte interface. This contention is supported by the following observations: (i) corrosion of the electrode surface starts at the edges and thence penetrates inwards; (ii) assembly of a complete cell under high pressure in a hydraulic press yields cells with characteristics essentially those of cells maintained in a completely solvent free environment; (iii) insertion of a semipermeable membrane, say a thin sheet of cellulose or of polypropylene-acrylic acid graft copolymer, between the Mg anode and the solid, tends to raise the value of the short circuit current considerably; the open circuit voltage likewise is brought even closer to its thermodynamical value of 1.87v. Insertion of such a separator anywhere else but directly into the anode-solid interface causes both open circuit voltage and short circuit current to decrease. It appears that the separator acts as a wick assisting the penetration of solvent vapor into the interface. Cells assembled with the separator extruding beyond the electrode and then wetted with acetonitrile produced current densities of the order of hundreds of  $\text{ma}/\text{cm}^2$ , significantly in excess of the performance of untreated cells; (iv) the constancy of the polarization resistance in the presence of vapors, discussed above, indicates that such vapors are effective in assisting processes within the reaction zone near the anode.

The introduction of vapor of a high permittivity solvent may either increase the reaction rate in the energy producing reaction (1)

or it may retard poisoning of the electrode surface by assisting in the removal of the reaction product, *viz.*,  $\text{MgI}_2$ . However, the voltage pulse waveforms obtained are considerably different from those expected in a regime in which poisoning of the electrode surface is the main effect. Such waveforms have been reported, e.g., by Schuldner and Hoare (4). The time constants involved here (see Fig. 2) are too long, by at least a factor of a hundred, to be entirely caused by electrode poisoning. Moreover, the admission of such vapors into a solvent-free cell causes an immediate and sudden rise in the current density, far too fast for an effect associated with the dissolution of the  $\text{MgI}_2$ .

Thus, it appears that this effect involves an increase in the rate of the first step of the above reaction sequence, which is the rate-determining step. More specifically, the energy of the activated complex  $\text{MgI}^-$

Fig. 3. Current decay curve for the system Mg/phenothiazine;  $\text{I}_2$  1:2/Pt. The cell was operated into a constant load of 5000 ohm at various vapor pressures of acetonitrile.

must be substantially lowered: this may occur by solvation or, perhaps more likely, by an increase in the polarization energy of the activated complex, since only highly polarizable molecules enhance the current.

This suggestion is supported by the work of Hale and Mehl (5) who ascribe current limitation in a Redox organic electrolyte system to either diffusion limitation or to a reorientation of the solvation shell of the reactant. Thus, the vapor in the present case might well form an adsorbed liquid thin film yielding sufficient surface solvation energy (6) to facilitate the reaction: the solvated ion then becomes isoenergetic with an appropriate energy band of the solid (5).

Another contributing factor to such a "flat-band condition" would be changes in the work function and electron affinity of both the metal anode and of the charge transfer complex: high permittivity media are known (7) to be active in this respect; thus an adsorbed water layer changes the work function of a solid polymer by several hundred millivolts (8).

During each current pulse of the pulse experiment,  $1.3 \times 10^{13}$  electrons were consumed. At the anode surface, even assuming complete coverage, about  $6 \times 10^{11}$   $\text{I}^-$  ions are available. Thus, these data refer to a regime of diffusion control. Furthermore, consider a cell discharged continuously into a matched load, corresponding to a reaction rate (1) of  $1.5 \times 10^{15}$  ions  $\text{cm}^{-2} \text{sec}^{-1}$ , and a calculated diffusion layer (1) of 0.05 cm thick containing  $2.7 \times 10^{16}$  ions. At these current densities, diffusion would be rate determining.

In the solid system, it is to be expected that diffusion limitation sets in at lower overvoltages already than in a corresponding liquid system: indeed, the exchange current density  $i_0$  obtained (1) for the present, solid, system is of the order of  $10^{-5}$  amp- $\text{cm}^{-2}$ , while Vetter (9) reports values of the order of  $10^{-2}$  to  $10^{-3}$  amp- $\text{cm}^{-2}$  for a liquid iodine/iodide Redox system. Since (9)

$$\left( \frac{\partial \log i_0}{\partial \log [\text{I}^-]} \right)_{E=\text{const}} \cong 1 \quad [10]$$

it appears that it is the exhaustion of the  $\text{I}^-$  supply at the anode surface which causes the current to become diffusion limited.

Thus, at the higher current densities, where the current tends to become diffusion controlled, the introduction of vapor also involves an improved diffusion rate. At least in part, this is due to the increased diffusion gradient caused by the increase in reaction rate discussed above. However, it may well be that a liquid layer at the interface as such substantially assists in the diffusion processes.

## Oxidation of Hydrogen on a Passive Platinum Electrode

Sigmund Schuldiner\*

Naval Research Laboratory, Washington, D. C.

#### ABSTRACT

Under potentiostatic, steady-state conditions and at anodic potentials above 0.7v (NHE), the rate of oxidation of molecular hydrogen decreases at a high activity Pt electrode in 1M H<sub>2</sub>SO<sub>4</sub>. It is shown that this decrease is not owing to the formation of oxygen species on the electrode surface. It is believed that this passive behavior of Pt is due to anion adsorption, at least between 0.7 and 1.2v. Depending on potential and previous potential sequence, passivity in this region is evidently sensitive to the amount of sulfate ion adsorbed, its heat of adsorption, and the presence of dermasorbed oxygen. At higher potentials both sorbed oxygen species and sulfate ion may be present and may contribute to the passivity. In the 0.7-1.2v passive region, hydrogen oxidation is electrochemical. There is no significant chemical oxidation via an oxygen intermediate.

A steady-state electrochemical investigation (1) in a high-purity closed system (2) showed very slow oxidation of water on Pt in helium-saturated 1M H<sub>2</sub>SO<sub>4</sub> in the potential region from 0.46 to 1.6v (*vs.* NHE). That work (1) established the solvent (water) reaction rates in this potential region. Since the oxidation of water occurs at such slow rates, it appears that on the addition of an easily oxidizable species to the system, the oxidation of this added species would predominate.

Several papers (3,4) by Wroblowa *et al.* demonstrated that even though the rate of hydrocarbon oxidation is increased as the potential is increased to about 0.9v, the rate of oxidation decreases at higher potentials. They postulated that this decrease in reaction rate was caused by the formation of a Pt oxide which passivated the surface. Even though the work was done at 80°C, compared to the previously mentioned study (1) on water oxidation, which was at 26°C, there is a question as to why an oxide should be formed in the presence of an oxidizable species in the potential region of interest.

The answer to this question is, of course, a matter of mechanisms. If water oxidation is rate-controlling, then in the presence of a species which is electrochemically inert but which is chemically oxidized rapidly by the oxidation product of water on Pt, the rate of water oxidation may be increased. However, in such a case the accumulation of the oxidation product of water would not occur and could not cause passivation of the surface. If the oxidizable species is electrochemically oxidized faster than water and a significant accumulation of an oxygen species from water occurs the reaction may be retarded. However, it is difficult to conceive of an oxidation product of water on a Pt surface which would not be very easily re-

duced, so that chemical reaction of water oxidation products with added oxidizable species is very likely. In any case, if the current density is much greater at a given potential in the presence of an added oxidizable species, the very slow oxidation of water plus the high reactivity of resulting oxygen species makes the passivation of the surface by an oxide or oxidation product of water hardly feasible.

Anodic passivation of a surface has been explained in another possible way by Frumkin (5). He believes that passivation could be caused by the saturation of the free valencies of the electrode surface by chemisorbed anions. Anodic passivation of Pt for the hydrogen reaction has been repeatedly observed by many investigators [see review by Frumkin (6)]. Aikazyan and Fedorova (7) and Wicke and Weblus (8) attributed this passivation to either adsorption of anions or the appearance of surface oxides. Frumkin (6) claims that at high disk-electrode rotation rates the drop in the current maxima can occur at potentials of about 0.05v, which is much too low for an oxide formation and he believes must be due to anion adsorption. Frumkin and co-workers believe that passivation by oxygen occurs at potentials of about 0.8v.

Kazarinov and Balashova (9) showed that as the potential of platinumized Pt became more positive, the concentration of adsorbed sulfate ion increased linearly until a potential of 0.8v was reached. At higher potentials the sulfate ion concentration decreased. They interpreted this decrease as due to the formation of an oxygen species on the surface (their work was done in N<sub>2</sub>-saturated solutions of H<sub>2</sub>SO<sub>4</sub>) which caused a partial displacement of SO<sub>4</sub><sup>=</sup>. On smooth Pt they found that at potentials above 1.5v that there was a sharp increase in adsorbed SO<sub>4</sub><sup>=</sup> which they attributed to the incorporation of these anions in the oxides on the surface. Here one can ask

\* Electrochemical Society Active Member.

the question: "If an oxidizable species (other than water) is present will it, under steady potentiostatic conditions, interfere with the formation of oxygen species on the surface and influence the adsorption of the sulfate ion?"

To try to answer the question of water oxidation in the presence of other oxidizable species and to try to gain some further insight into the passivation of Pt, it was decided to study further the oxidation of hydrogen in the passive Pt region. Hydrogen was selected because it is easily oxidized on active Pt and its maximum rate of oxidation of  $2 \times 10^{-3}$  amp/cm<sup>2</sup> (true area basis) in H<sub>2</sub>SO<sub>4</sub> is from 2 to 7 orders of magnitude greater than water oxidation (1) in the same potential region. Use of the high-purity closed system (1, 2) developed at this Laboratory would permit long-time steady-state measurements where relatively slow sorption phenomena could affect electrode behavior. This system also allowed a determination of the hysteresis, when high potentials are decreased, noted by Frumkin and Aikazyan (10).

### Experimental and Results

The experimental setup and conditions were the same as described in ref. (1), except that a constant flow of hydrogen, purified by flowing through heated Pd-Ag tubes and saturated with pure water, replaced helium. It was found that an N<sub>2</sub> atmosphere in the environment box was unnecessary and part of the data was taken with the front panel removed. The hydrogen flow into the cell remained at about 40 ml/min until a constant current was reached under potentiostatic control. The time required ranged from a quarter of an hour to many hours, depending both on the set potential and the previous sequence of potentials. The hydrogen flow rate was then increased to well over 1000 ml/min and the constant current recorded. Potentiostatic control was by a Pt/H<sub>2</sub> wire electrode in the cell. The sulfuric acid solution was one molar, the temperature  $25^\circ \pm 2^\circ\text{C}$ , and the true (11) area of the three Pt bead working electrodes used were each close to 0.2 cm<sup>2</sup>.

The experimental results, which are steady-state values, are shown in Fig 1. Figure 1 is for the case of very rapid stirring with H<sub>2</sub> and gives potentiostatic current density vs. potential relations under conditions where diffusion effects in solution are minimized. For the slopes shown,  $b = \Delta E / \Delta \log i$ . The  $b = -0.025$  and  $0.025$  values shown are the well-known Tafel slopes (12) in the cathodic and anodic polarization regions, respectively. At anodic potentials above 40 mv, a limiting current density of  $2 \times 10^{-3}$  amp/cm<sup>2</sup> is observed up to a potential of about 0.7v. At potentials above this value, the current density decreases, at first slowly up to 1.0v, then rapidly along the slope designated as  $b = -0.11$  down to a second limiting current density of about  $1.5 \times 10^{-5}$  amp/cm<sup>2</sup>. At potentials above 1.6v ( $b = 0.13$  slope) the normal oxygen evolution reaction is observed. The diamond-shaped symbols show that potential reversal within a given region gave the same current densities.

After the oxygen evolution region was reached, a subsequent decrease in potentials gave the hysteresis shown. The time required to obtain steady-state for each point in this region ranged from a few hours to a day. The scatter of points and especially the two paths shown in the potential range from 1.16 to 0.88v appeared to be real. Using the same electrode a consistent set of points on either path was followed for a particular run. The path shown by the solid line, however, was favored over the dotted line. The broken line shown in Fig. 1 comes from Fig. 1 of ref. (1) and represents the potential vs. current density relation found in a pure helium-saturated solution.

### Discussion

A comparison of Fig. 1 with the data shown by Frumkin and Aikazyan (6, 10) for hydrogen ionization

Fig. 1. Steady-state potentiostated current density vs. potential relation on Pt in hydrogen-saturated 1M. H<sub>2</sub>SO<sub>4</sub>·H<sub>2</sub> flow rate > 1000 ml/min: ○ cathodic current, △ anodic current, increasing applied potentials; ▽ anodic current, decreasing applied potentials; ◇ anodic current, intermediary reversal of applied potential values. Broken line is relation in helium-saturated solution (1), where hysteresis line to the right is for increasing applied potentials, to the left for decreasing applied potentials. See text for meaning of dotted line.

on a smooth Pt disk electrode in 1N H<sub>2</sub>SO<sub>4</sub> at a rotation speed of 20,000 rpm shows some important differences. Figure 1 shows a maximum current density from 0.04 to 0.7v of 2 ma/cm<sup>2</sup> (since this current density is on a true area basis it is equivalent to about 4 ma on a geometric area basis). This limiting current density is essentially the same as the Frumkin and Aikazyan value of 3.8 ma/cm<sup>2</sup> (geometric area). In the Frumkin and Aikazyan case, however, the current density maximum is at 0.05v and there is a continuous dropping off of current density with increasing potential up to 1.2v. Figure 1 shows a constant current density at 2 ma/cm<sup>2</sup> up to 0.7v (for both the increasing and decreasing sequence of potentials) followed by a slow decrease and then a linear log decrease in current density up to 1.2v.

The essentially equivalent maximum current densities found by Frumkin and Aikazyan and this work show that the Pt electrodes were of equal activity. The important difference is that Frumkin and Aikazyan anodically and cathodically pre-electrolyzed their electrode just before taking measurements, which were then taken in a matter of minutes at each potential setting. With the high purity system, long time steady-state measurements were possible because poisoning of the electrode did not occur (as, for example, evidenced by the constancy of the maximum current density for long periods of time). Whether the Frumkin and Aikazyan decrease in current density (from 0.05 to 0.7v) was due to impurity adsorption or a lack of true steady-state conditions at the electrode is uncertain.

Considering Pt passivation above 0.7v, the possibility of a stable oxygen species remaining on the surface is remote. In the first place, the oxidation of water, which appears to be limited by slow discharge (1), occurs at rates from about five to one order of magnitude slower. In addition, Schuldiner and Warner (13) have shown that oxygen chemisorbed on Pt reacts rapidly with molecular hydrogen. Warner and Schuldiner (14) have shown also that the reaction rate is potential independent and zero order in both hydrogen and chemisorbed oxygen when the initial fractional coverage with chemisorbed oxygen is less than 0.8. Reaction rates of chemisorbed oxygen with hy-

drogen in this particular system for the three different working electrodes used were 0.4, 1.2, and 8 ma/cm<sup>2</sup>. All three electrodes gave virtually the same potential vs. current density results.

The chemical rate of reaction of any oxygen which may be formed on the surface with hydrogen would with a few exceptions always be faster than the rate of anodic hydrogen oxidation. Hence, there is little possibility that chemisorbed oxygen or an oxygen species exists on the surface at least up to a potential of 1.2v. This analysis does not, of course, prove that an oxygen species may not be formed which rapidly oxidizes the hydrogen and that the rate-controlling process depends either on the rate of formation of this oxygen species or its reaction rate with hydrogen. However, it is very unlikely that the anodic hydrogen reaction under these conditions would be slower than the oxidation of water. (It will subsequently be shown that in this region a chemical oxidation of H<sub>2</sub> with an oxygen intermediate does not occur.) These results show that the oxidation of Pt or the formation and adsorption of oxygen species are not the cause of the Pt passivation and retardation of the anodic hydrogen oxidation reaction at least up to 1.2v.

The cause of passivation is much more likely the anion adsorption explanation as given by Frumkin (5); specifically, the adsorption of sulfate ion as was demonstrated by Kazarinov and Balashova (9). In the Kazarinov and Balashova paper a dropping off of the amount of sulfate ion adsorbed above 0.8v was observed. However, this was done in a nitrogen-saturated solution where formation and adsorption of an oxygen species and the partial replacement of sulfate are possible. In a hydrogen-saturated solution, a residue of oxygen would not remain on the surface so that as the potential increased beyond 0.8v, an increase in the amount of sulfate would be expected. And, in fact, as was shown by Kazarinov and Balashova, at higher potentials the coverage with sulfate ion can increase even in the presence of oxygen. With the elimination of a chemisorbed oxygen species, or Pt oxide, the bonding and coverage of the surface with sulfate ion should increase and is a reasonable explanation of the increased passivity shown in Fig. 1. The limiting current density from 1.2 to  $\approx$  1.8v can be due to a saturation of the surface with sulfate ion.

It should be noted that the  $b = -0.11$  and  $-0.04$  slopes in Fig. 1 are not Tafel slopes. The fact that the rate of hydrogen oxidation decreases with increasing potential demonstrates that the rates are not controlled by the exponential overvoltage term in the kinetic equation. The controlling term is obviously in the free energy of activation for the oxidation of hydrogen. As the potential increases, the free energy of activation can increase because of the increased coverage with sulfate ion and because of the increase in bonding of the sulfate ion with the surface.

In the oxygen generating region ( $b = 0.13$ ) the presence of hydrogen has no apparent effect on the rate of oxidation of water. There is no "so-called" depolarization effect. This must be because the combined sulfate and oxygen sorption in this region is so extensive that significant anodic oxidation of hydrogen is virtually completely blocked. The data also show that the oxidation of water is primarily under charge transfer control. Otherwise, the chemical reaction of hydrogen with oxygen on the surface could influence the rate. In this region current densities were independent of stirring rate which also indicates virtually complete kinetic control.

The effects of dermasorbed oxygen (15) can be seen in the Fig. 1 data. Once the potential exceeds 1.8v, extensive dermasorption occurs and hysteresis results. In the potential range from 1.7 to 1.2v, the rate of hydrogen oxidation is reduced by about one-half. From about 1.16 down to 0.88v either the solid or dotted line was followed. Evidently the amount or distribution of

dermasorbed oxygen may vary from run to run and may markedly influence the passivity behavior of the electrode. This influence of dermasorbed oxygen is evinced also by the scatter of points, which were, however, consistent for a particular run, in the entire region from 1.7 to 0.88v.

Something remarkable occurs in the  $b = -0.04$  region. At current density values greater than  $1.5 \times 10^{-5}$  amp/cm<sup>2</sup>, the potential required for the oxidation of hydrogen at a given current density can be as much as 0.3v less than in the  $b = -0.11$  region. In the  $b = -0.04$  region most of the dermasorbed oxygen would be removed, but a trace must remain because one can go up and down in potential in this region and remain on the  $b = -0.04$  line. Once the intersection at about 0.8v is reached, increasing potentials will follow the path leading to the  $b = -0.11$  slope. This eliminates the possibility of an impurity in the region of decreasing potential. However, at the same potentials on the increasing potential arm of the curve, the current densities are considerably higher. The lower current densities in the  $b = -0.11$  region are evidently due to increased sulfate ion adsorption. Hence in the  $b = -0.04$  region, the presence of dermasorbed oxygen plus the lower sulfate ion adsorption reduces the activation energy (potential) required to oxidize hydrogen at a given rate. However, at a given amount of sulfate ion adsorption the rate of hydrogen oxidation would always be lower in the presence of dermasorbed oxygen.

Another interesting consequence of this region is that the previous work (1) in helium-saturated solution showed that in the presence of dermasorbed oxygen a given rate of oxidation of water to an oxygen species (which was not retarded by increased sulfate ion adsorption) always occurred at a higher potential. If the oxidation of hydrogen took place via an intermediate oxygen species, then in the presence of dermasorbed oxygen a given rate of hydrogen oxidation should never occur at a lower potential. Since in the  $b = -0.04$  region oxidation of hydrogen at a given rate can occur at a lower potential than in the  $b = -0.11$  region [which is free of dermasorbed oxygen (1)] the oxidation cannot be through an oxygen intermediate, but must involve a direct electrochemical oxidation of hydrogen. Another conclusion is that pulsing or other electrochemical activation procedures of electrodes may do more than just clean the surface.

The catalytic properties of platinum are strongly affected by adsorbed sulfate ions and by dermasorbed oxygen. The relationships are very complex, but it appears that a narrowing down of possibilities is resulting. Since information is available concerning very slow solvent oxidation and relatively fast oxidation of the ideal fuel, hydrogen, similar studies made with organic fuels of intermediate oxidizability should be revealing.

Manuscript received Sept. 28, 1967; revised manuscript received Nov. 20, 1967. This paper will be presented at the Boston Meeting, May 5-9, 1968, as Abstract No. 185.

## Technical Notes

### The Li/Li<sup>+</sup> Reference Electrode in Propylene Carbonate

Brian Burrows\* and Raymond Jasinski\*

Tyco Laboratories, Inc., Waltham, Massachusetts

Recent investigations of the Li(Hg)/Li<sup>+</sup> electrode couple in LiCl-DMSO solutions (1) indicate that the electrochemical reaction

has a relatively high exchange current density, thereby making the system suitable for use as a reference electrode. It is reasonable to expect that the exchange current density of the same electrode couple in LiClO<sub>4</sub>-PC solutions would also be high enough to allow its use as a reference electrode. However, for simplicity in use, a solid electrode would be preferred.

The evaluation of a reference electrode of the metal-metal ion type (in absence of a liquid junction) involves showing that (i) potential differences between pairs of the same electrodes in the same electrolyte solution are reproducibly small and constant over long periods; (ii) the electrode potential responds to varying cation concentrations in accordance with the Nernst equation; (iii) the passage of small amounts of current (microamperes) through the electrode does not permanently polarize it.

#### Experimental

All electrochemical measurements and associated materials handling were carried out in a water and oxygen free (<1 ppm) argon-atmosphere dry box at 28°C (Vacuum Atmospheres Corporation).

Both "anhydrous" LiClO<sub>4</sub> (K&K Laboratories 99.9%) and dried LiClO<sub>4</sub> (Anderson Physics Laboratories) were used to make up solutions. The purified LiClO<sub>4</sub> was prepared from 99.9% LiClO<sub>4</sub>, recrystallized three times from water, and heated to just below the melting point in a vacuum over a period of several days to remove water. Finally, the sample was fused in vacuum and sealed in an argon atmosphere. This crystalline LiClO<sub>4</sub>, obtained from Anderson Physics Laboratories, contained approximately 0.0015% water (15 ppm) and less than 0.0005% chloride. Both "as-received" PC (Matheson, Coleman and Bell) and distilled PC were used to make up 1M solutions with the dried LiClO<sub>4</sub>.

A conventional three-compartment Pyrex glass cell was used, except where stated otherwise. The test lithium electrode was placed in the middle compartment, the reference compartment contacted the middle

compartment through a Luggin capillary, and the counter electrode was in the third compartment. A cathode follower was employed to avoid undue loading of the reference electrode-working electrode cell. The unity-gain follower was constructed from an operational amplifier (Philbrick Researches, Inc., Type P65AU); the input impedance of this device was 33 Mohm.

#### Results

An electrodeposited Li (on a Pt-metal substrate)-Li<sup>+</sup> ion couple was first investigated for use as a reference electrode. Initially, experiments were carried out in 1M solutions of LiClO<sub>4</sub> in distilled PC, in a beaker using Pt foil counter and pseudoreference electrodes. Under these conditions, it was found that the residual current was <60 μa cm<sup>-2</sup> up to -3.0v vs. Pt foil electrode. At -3.6 to -3.8v vs. Pt, a deposit of lithium became visible with the concurrent evolution of gas. Gas evolution during the electrodeposition of lithium was also reported by Selim *et al.* (2). The bias potentials between four of the electroplated lithium electrodes were ± 80 mv for periods of time up to 2 hr.

The next set of experiments was carried out in a 1M solution of LiClO<sub>4</sub> in distilled PC, which had been passed over lithium powder. Currents of 60 μa cm<sup>-2</sup> were observed up to -2.4v vs. Pt and a Li deposit became visible at about -3.2v. No gassing was observed during the deposition of lithium; however, no significant improvement in the potential difference between electroplated lithium electrodes was observed.

Up to this point no effort had been made to separate the counter electrode and the reaction products arising at this electrode from reaching the working electrode. When this was done by the use of a fritted glass plug in a three-compartment cell, lithium was deposited on Pt wire electrodes (area 0.2 cm<sup>2</sup>) from the same solution. For example, when a current of >1 ma cm<sup>-2</sup> was used to form a relatively thick and coherent deposit of Li without gassing, a stable potential difference of ±15 mv was obtained.

Lithium was then deposited onto two platinum foils (area = 1 cm<sup>2</sup>) from a 1M solution of LiClO<sub>4</sub> in PC at current densities of 1 ma/cm<sup>2</sup>, and the potential difference was monitored in a fresh solution. After about 3 hr a stable difference of 23 mv developed and remained steady for a period of 10 hr before the experi-

\* Electrochemical Society Active Member.

ment was discontinued. Polarization tests indicated that the electrodes had a very poor response; considerable hysteresis was observed.

Electrodes were then prepared from Li powder with a copper wire forming the contact to the external circuit. The electrode consisted of a glass tube 0.5 cm in diameter and drawn to a tip of 0.1 cm at one end. A plug of glass wool was placed in the contracted end, and powdered lithium was poured over the plug to a depth of about 0.5 cm. A copper wire spiral contact was inserted and another plug of glass wool pressed over the top of the lithium. Two electrodes of this type, when immersed in a 1M solution of  $\text{LiClO}_4$  in PC, had a potential difference of 1 mv, which remained steady for 10 hr.

Polarization tests were carried out on the lithium powder electrodes by applying a small constant current from a constant current power supply (Electronic Measurement Model C623). The polarization was measured on a differential d-c voltmeter (John Fluke Model 825A). The results are shown in Fig. 1.

The linear relation between overpotential and current as well as the absence of significant hysteresis indicate that the electrodes were behaving reversibly. It will be noticed, however, that the inverse slope has a value of  $2.4 \times 10^6$  ohms. This large value of resistance is probably due in large part to a poor contact between the lithium powder and the copper.

Finally, reference electrodes based on bulk lithium ribbon as a substrate were investigated. The Li ribbon (K&K Laboratories, Inc., 99.9%, approximately 3 mm diameter) was cleaned with acetone before being passed into the dry box. Inside the box the surface was scraped with a spatula until it was bright and metallic in appearance. Three electrodes were then placed in a cell containing distilled PC (1M  $\text{LiClO}_4$ ). The potential differences between these three electrodes were then monitored over a period of several days. It was found that the potential difference between any pair was always  $<1$  mv. Furthermore, it was found that when a fresh electrode was added to the solution after those already present had been submerged for several days, the potential differences were still  $<1$  mv.

A Li electrode in "wet"  $\text{LiClO}_4$  solution rapidly developed a dark gray film on its surface, accompanied by visible gassing. After the gassing subsided, the potential difference with respect to a fresh Li electrode was always  $<1$  mv. The gray film dried to a white

Fig. 1. Micropolarization test on a lithium powder reference electrode in  $\text{LiClO}_4/\text{PC}$  solution at  $28^\circ\text{C}$ .

Fig. 2. Micropolarization test on a Li wire electrode (area approx.  $2 \text{ cm}^2$ ) in  $\text{LiClO}_4/\text{PC}$  solution at  $28^\circ\text{C}$ .

color after the electrode was removed from the solution.

Having established that the bias potentials were small and reproducible, we next carried out polarization tests on the solid Li electrodes. It can be seen (Fig. 2) that there is a linear relation between overpotential and current, indicating that the electrodes were behaving reversibly; there was no significant hysteresis. The fact that the line does not go through the origin is due to the slight bias in potential between two lithium rods. A comparison of Fig. 1 and 2 shows that the Li ribbon electrode structure is a considerable improvement over the Li powder structure and is also much simpler to set up.

### Summary

Three forms of  $\text{Li}/\text{Li}^+$  electrodes were evaluated as reference electrodes in 1M lithium perchlorate-propylene carbonate solutions. Electrodeposited lithium proved to be very susceptible to poisoning by impurities in the electrolyte and by those generated at the counter electrode. An electrode constructed from lithium powder in a glass tube was stable over prolonged periods of time and showed little hysteresis in the micropolarization tests. However, the ohmic resistance was high, due presumably to poor contact with the copper lead wire.

A lithium ribbon electrode, scraped clean before immersion in solution, was satisfactory for most work and was quite simple to prepare. Hysteresis in the micropolarization tests was negligible ( $<1$  mv). Replicate electrodes gave potential differences less than 1 mv for extended periods of time (days). The electrode potential was also quite stable in the presence of sufficient water impurity to give visible gassing. The Nernst behavior of the  $\text{Li}/\text{Li}^+$  couple in PC has been established by others (3).

## A New Technique for Studying the Rate of Gas Evolution Reactions

N. Marincic\*

P. R. Mallory & Co., Inc., Laboratory for Physical Science, Burlington, Massachusetts

Low rate gassing processes were found difficult to study, whenever the amount of gas, consumed or liberated by chemical reaction, was used as an indicator of the reaction rate. The proper choice of the gas measuring technique is of particular importance in the case when the control of the gaseous reaction participant stands as the only practical alternative. A typical example of this kind is the corrosion reaction of a zinc electrode in battery systems, in an alkaline electrolyte containing an appreciable concentration of dissolved zinc (1). A significant quantity of gas is evolved in this corrosion reaction before the change of the zinc concentration in solution becomes measurable. The reaction rate measurement through the depletion of the metallic zinc, as one of the possibilities, is of no practical value in this case due to an undefined distribution of the corrosion products between the liquid and the solid phase.

Gassing also occurs in rechargeable battery systems during charging processes. The quantity of gas produced in the latest phase of charging (or overcharging) is of crucial importance for the battery performance, particularly when a sealed structure is employed. The participation of the gassing processes in the overall energy consumption during the charging could easily be estimated, provided an accurate method was available for measuring the amount of gas evolved. A more convenient and eventually more accurate method is needed for this type of study than the usual gas coulometry with direct volume reading of the quantity of gas collected (2).

The two examples mentioned above dictated the design of the technique for the gas measurement described in this paper.

A very detailed study of the gas coulometer has been done in the past (3) as a part of general effort to establish the true value of the Faraday. The weight of mercury displaced by the hydrogen-oxygen mixture evolved in an electrolysis reaction was measured. A balance of a remarkable high capacity-accuracy relation was used in this method among other precautions undertaken to maximize the accuracy of the measurement. A limitation of the method, however, rested on the fact that the displaced mercury was being collected in drops coming out of a capillary with the single drop weight being anywhere between 1 and 20 mg.

Several other basic studies have been done on coulometric technique dealing either with the problem of the impurities incorporated in silver deposits in the silver coulometer (4, 5) or with the other experimental conditions concerning the accuracy of the measurement (6, 9). The hydrogen-oxygen coulometer was thoroughly re-examined (10, 11) long after the basic study of the instrument has been done (3). It was found to be a sensitive instrument, if all the influencing factors were under control. No major change in

the *modus operandi* was suggested, apart from the very careful evaluation of the performance determining factors.

The method employed in this work was designed for the determination of small amounts of gas produced either in a corrosion reaction in solution or as a by-product of an electrochemical reaction. It is based on the measurement of the change of buoyancy due to the gas collected under a glass bell, immersed in the solution. The method can be applied in any reaction rate study, whenever gas is involved, either as a reaction product or one of its participants.

### Theoretical

A schematic representation of the technique employed is shown in Fig. 1. An increase of the volume of gas, generated under the bell ( $V - V_0$ ) will result in a buoyancy change ( $\Delta G$ ) under constant pressure and temperature.

$$\Delta G = (V - V_0)u_0 \quad [1]$$

if  $u_0$  is the density of the liquid in which the bell is immersed. The total quantity of gas under the bell at the beginning of the experiment can be expressed as

$$n_0 = (P_{b0} + \Delta H u_0) V_0 / RT \quad [2]$$

where  $n_0$  is the number of moles,  $P_{b0}$  is the initial barometric pressure  $\Delta H u_0$  is the hydrostatic component of the total pressure of the gas. With the number of moles of  $n_g$  of the gas generated during the experiment,  $n_v$  moles of vapor will be formed over the liquid in order that constant vapor pressure be preserved. These two quantities are related to each other as follows

$$n_v = n_g P_v / (P_b + \Delta H u_0 - P_v) \quad [3]$$

where  $P_v$  is the vapor pressure of the liquid and  $P_b$

Fig. 1. Schematic representation of the gas measuring technique.

\* Electrochemical Society Active Member.

is the actual barometric pressure at the moment of the measurement. Since the total quantity of gas under the bell is related to the volume of the gas in the manner

$$V = (n_o + n_g + n_v)RT / (P_b + \Delta H u_o) \quad [4]$$

Eq. [2] and [3] with Eq. [4] lead to the expression

$$V = V_o (P_{b_o} + \Delta H u_o) / (P_b + \Delta H u_o) + n_g RT / (P_b + \Delta H u_o - P_v) \quad [5]$$

Equation [5] gives with Eq. [1] after rearranging a final expression relating the moles of the gas generated at the measured buoyancy change

$$n_g = \Delta G (P_b + \Delta H u_o - P_v) / u_o RT + V_o (P_b + \Delta H u_o - P_v) (P_b - P_{b_o}) / (P_b + \Delta H u_o) RT + V_1 C \quad [6]$$

The  $V_1 C$ —member of the right-hand side of Eq. [6] is added to the expression afterward in order to provide the correction for gas solubility ( $C$ ) in a given volume of liquid ( $V_1$ ).

Certain correction factors can be eliminated from the general expression (6) depending on the conditions of the experiment and the accuracy requirements.

(a) The barometric pressure change during the course of the experiment ( $P_b - P_{b_o}$ ) becomes irrelevant in high reaction rate measurements, when the experiment is completed in a short period of time, or when the barometric pressure is otherwise stable during the experiment. In such a case no calibration of the initial volume is necessary.

(b) The initial volume of the gas ( $V_o$ ) can be eliminated from the expression if the bell is completely filled with the solution at the beginning of the experiment. This also eliminates the need for barometric pressure change correction, ( $P_{b_o}$ ) and *vice versa*.

(c) The hydrostatic pressure ( $\Delta H u_o$ ) depends on the design of the bell and can be made negligibly small for the majority of the experimental requirements particularly when low density solutions are used. A 100 mm difference between the inside and the outside liquid level means 1% difference in pressure reading under standard pressure and temperature conditions.

(d) The correction for the gas solubility is of some importance depending on the nature of the gas. Since hydrogen evolution occurs in a majority of metallic corrosion processes, its low solubility in a variety of the electrolytes (12) has no significant influence on the results of the measurement.

(e) The vapor pressure of the solution has to be known in order to estimate its influence on the results of the measurement. It is well-defined for a large number of solutions and can also be calculated for dilute solutions.

The general expression (6) is reduced to

$$n_g = \Delta G P_b / u_o RT \quad [7]$$

when a high degree of accuracy of the measurement is not required, *i.e.*, under the conditions described above. Reduced Eq. [7] shows the direct transfer of each ml of the gas generated into 1g difference in the buoyancy recorded on the balance.

### Experiments and Results

The validity of the experimental technique was tested in a cell similar to the one represented in Fig. 2.

Two platinum electrodes were used to generate hydrogen electrolytically with the anode situated outside the bell. The central tube with the stopcock at the end was used for bleeding the bell in order to flood the electrode. It also provided the means for removal of the gas collected under the bell without dismounting the cell. The testing was done with 3M KOH and the results are shown in Fig. 3.

Fig. 2. Experimental set-up for the cell gassing measurement

Fig. 3. Comparison of the results with the theoretical hydrogen evolution rate.

The discrepancy between the experimental points and the theoretical line illustrates the effect of the correction factors, summarized in general Eq. [6]. The accuracy of the measurement is proved to be higher than required for the experimental conditions given.

The set-up shown in Fig. 2 was used for the evaluation of experimental galvanic cells, *i.e.*, for gas evolution measurement in the course of charging of rechargeable cells. The platinum electrodes were used only as leads to the cell electrodes in this type of measurement. They were, obviously, not flooded in this case. The initial free volume in the bell had to be calibrated ( $V_o$ ) for an accurate gas quantity calculation. A typical charging curve for an alkaline  $MnO_2$ -zinc cell is represented in Fig. 4 accompanied with the corresponding gas generation curve. The charging process was continued beyond the practical voltage cut-off point in order to follow the gas evolution curve all the way to water electrolysis. The ultimate slope of the gassing curve represents a gas evolution rate of 1.07 ml/min and is in good agreement with the theoretical gas evolution rate of 1.05 ml/min for the given set of the experimental conditions.

### Conclusion

The measurement method described above is found to be reliable for gas evolution studies. In fact, an accuracy of the measurement can be achieved beyond that required for the majority of practical problems. It offers a means of registering the gas bubbles as they are generated with no need to collect the gas at

Fig. 4. Typical charging curve for an alkaline  $\text{MnO}_2$ -zinc system with the corresponding gas generation curve.

certain particular section of the measuring device. This seems to be very convenient in the study of porous electrodes where the collection of the gas generated represents the major obstacle to reliable quantity measurements.

A recently published paper (13) describes the technique for the study of the rechargeable electrodes by measuring the buoyancy change of the electrode material during the metal-metal oxide transformation. That technique combined with the gas measuring technique described in this work could be utilized for a simultaneous recording of the solid-state transformation rate and the accompanying gas evolution rate in more detailed studies of electrode and/or the corrosion processes. The schematic representation of the set-up proposed is illustrated in Fig. 5.

Two analytical balances (or recording balances) could be used; one for the gas measurement, and one for the solid electrode transformation measurement. The corrosion of the electrodes in practical galvanic cells could be studied by this combined method in order to establish the corrosion product distribution between the liquid and the solid phase. The simultaneous gas evolution measurement could be an additional means of a net corrosion rate measurement in a system metal/electrolyte in the absence of oxygen.

The usefulness of the method in coulometric measurements can be illustrated by comparison with the electrogravimetry with copper as an example. A 1 amp-sec equivalent of copper amounts to 0.33 mg weighed directly on the balance. When the equivalent quantity of hydrogen is measured as in the present

Fig. 5. Proposed set-up for the simultaneous recording of the gas evolution rate and the solid-state transformation rate.

method, 1 amp-sec results in a change of buoyancy of 116 mg. This represents the increase in the sensitivity of the measurement by factor of 350.

## Influence of Thin Noble Metal Films on Zirconium Oxidation

A. Fiegna<sup>1</sup> and P. Weisgerber

EURATOM-CCR, Ispra, Italy

Attempts were made for several years to measure electrical properties of oxides on metal surfaces during the oxide forming reaction between metal and gas phase (1-5). In those cases where the current density or the dielectric capacitance were investigated, the area of current flow was limited by a suitable con-

tact. Some investigators (4,5) used noble metal films deposited by evaporation techniques on the metal surfaces. Joergensen (4) observed that thin films of platinum, deposited by cathodic sputtering, did not alter the reaction rate of zinc single crystal faces in oxygen.

In order to find suitable contacts for the measurements of electrical properties of zirconium oxide on zirconium metal during the oxide forming reactions,

Key words: Reaction kinetics, oxidation, zirconium, metal films, gold, silver, platinum, cathode sputtering, markers.  
<sup>1</sup> Present address: Centro di Studi sulla Corrosione—Istituto Chimico dell'Università di Ferrara—Ferrara—Italy.

the influence of the metallic deposits on the reaction rate had to be investigated. At first sight a possible decrease of the reaction rate was expected, assuming that the noble metals blocked the access of the oxidant to the zirconium.

### Experimental Procedure

Sheets 0.1 x 15 x 50 mm were made from crystal bar zirconium by repeated rolling, cleaning of the surface by electropolishing, and annealing at 750°C in vacuum ( $p < 10^{-5}$  Torr).

Different series of samples were coated on both sides with uniform films of platinum, gold, silver, palladium, iridium, or rhodium by cathodic sputtering in high-purity argon. The thickness of the noble metal film deposits could be roughly estimated between 100 and 300 Å from the transparency of the underlying glass plates, which served as target supports during the sputtering process. This was confirmed by later measurements carried out with a quartz crystal monitor.

Thickness control during the sputtering process was achieved by resistance monitoring between silver paint contacts of 1 cm length and 1 cm distance. All Pt and Au deposits were stopped at a resistance of 100 ohm and those of Ag at 30 ohm.

Thermogravimetric experiments were carried out in a continuously recording thermobalance. The oxygen atmosphere in the balance was established by filling the preevacuated system with high-purity oxygen to a pressure of 10 Torr. The water vapor atmosphere was made from distilled water, degassed by boiling in vacuum in a glass flask. The latter was then held at 11.2°C by a cryostat and connected to the preevacuated system. The temperature regulation of the cryostat maintained the pressure in the system automatically at 10 Torr.

For every experiment a series of 6 specimens, corresponding to a total surface area of 90 cm<sup>2</sup>, was inserted on a platinum specimen holder into the thermobalance. The reaction temperature was in all cases 450°C and the duration of the experiments between 100 and 120 hr.

### Experimental Results

Weight gains for the experiments in oxygen atmosphere are plotted in Fig. 1 on double logarithmic scale. Values for noncoated zirconium were in reasonable agreement with the literature (6). The reproducibility between series of specimens from the same preparation lot was within the precision of the thermobalance. After the oxidation process the specimens were covered with the usual black oxide.

The weight gain of the platinum coated specimens was about two times higher than that of the uncoated zirconium while the order of the reaction did not change considerably. After the oxidation the surface of the specimens were metallic, brilliantly reflecting, and only slightly darker than platinum coated, but nonoxidized specimens. It can therefore be concluded that at least the greater part of the deposited platinum remained unaltered at the oxide-gas interface.

Fig. 1. Oxidation in dry oxygen at  $P_{O_2} = 10$  Torr and  $T = 450^\circ\text{C}$ .

Fig. 2. Oxidation in water vapor at  $P_{H_2O} = 10$  Torr and  $T = 450^\circ\text{C}$ .

The weight gain of the gold coated specimens differed only slightly from that of uncoated specimens. The surface after oxidation was that of the normal black oxide with a few isolated small areas of a slight gold tint. Here the original metal deposit had almost completely disappeared, probably by diffusion into the zirconium oxide.

The weight gain of the silver coated specimens agreed with that of the uncoated specimens for the first 24 hr of the oxidation process. Afterward a rapid increase in the reaction rate took place, approaching linearity with time. The oxidized specimens looked brilliantly metallic, but at several places aggregates of white powdery material were found. This is similar to the "post transition corrosion" observed during the aqueous corrosion of zirconium. Obviously the same phenomenon occurred here as an effect of the silver film.

The results of the oxidation experiments in water vapor are plotted in Fig. 2. Recently experiments in water vapor of 10 mm Hg were carried out (8). Results are not comparable because that work concerned the early stages of the oxidation process, and observation times and temperatures differ too much from our conditions. Despite the lack of literature values for the oxidation of zirconium in water vapor at pressures lower than 1 atm, the weight gains found seem to be reasonable. Compared with weight gains at 100 and 1 atm at 450°C which differ by a factor of about 40 (6), these values at 0.001 atm differ by a factor of 38 from those at 1 atm.

In water vapor all noble metal coated specimens had an increased reaction rate.

The surface of the platinum and silver covered specimens were brilliantly metallic and only slightly darker than before oxidation. "Break-away" phenomena were not found. The gold again disappeared leaving only a few gold tinted spots at some places.

The reaction constants followed Eq. [1]

$$m^n = (k t) \quad [1]$$

where  $m$  = mass of oxide formed in g/cm<sup>2</sup>,  $t$  = time in sec, and  $n$  and  $k$  are reaction constants given in Tables I and II. The time during which these constants are valid is also indicated.

The hydrogen uptake of the specimens oxidized in water vapor was analyzed, and the data are given in Table III. The yield was calculated from the total weight gain, assuming 100% uptake for the case that all hydrogen formed from the water would be absorbed. The relatively low yield in the case of platinum may be due to the fact that, during this experiment,

Table I. Reaction constants for the oxidation at 450°C in dry oxygen ( $P_{O_2} = 10$  Torr) following equation  $m^n = k t$

	$n$	$k[(\text{g cm}^{-2})^n \text{sec}^{-1}]$	Validity (hr)
Uncoated	2.18	$1.4 \cdot 10^{-12}$	1-100

Uncoated	80	13
Platinum coated	69	4.5
Gold coated	73	10.2
Silver coated	251	15.5

a vacuum pump was connected to the system with a needle valve. The water vapor was drawn off continuously at a constant pressure of 10 Torr in the system, but had the effect of keeping the partial pressure of hydrogen involved from the reaction at a lower value. Because of the failure of the pump the other experiments were carried out in the static system, i.e., with increasing partial pressure of hydrogen during reaction.

Oxidation of specimens coated with palladium, rhodium, and iridium were expected to form the stable noble metal oxides (7).

### Conclusions

Thin noble metal film deposits of 100-300Å thickness on zirconium did not block the surface from reaction with oxygen and water vapor at 450°C. This is not surprising if one takes into account that film deposits in that thickness range are not uniform, but consist of isolated nuclei. Instead of blocking oxygen, a catalytic effect was observed which resulted in an increase of the reaction rate for platinum and silver coated samples in water vapor, and for platinum coated samples in oxygen. Silver coating did not influence the rate in oxygen in the initial phase, but later on transition to "breakaway corrosion" began.

The catalyzing effect could be explained by different assumptions:

1. The metal deposits increase the adsorption of oxygen or water at the oxide-gas interface.
2. The metal deposits catalyze the ionization of adsorbed oxygen or water at the oxide-gas interface.
3. The metal deposits produce stresses in the underlying oxide influencing the number and mobility of dislocations.
4. Small fractions of noble metal ions diffusing into the oxide increase the number of oxygen ion vacancies and thereby the mobility of oxygen.
5. The metal deposits emit electrons into the oxide increasing the oxygen vacancy concentration and the mobility of oxygen.

Whichever of these explanations is right, the influence of the deposits on the oxide has to be taken into account when measuring electrical properties. Because there is little hope of eliminating these effects, and their magnitude in the case of zirconium is within the limits known to result from different surface treatments or specimen preparations, platinum seems to be the most suitable contact material.

The behavior of the gold deposits excludes application at reaction temperatures on zirconium.

On the other hand, care has to be taken in the choice of noble metals for inert marker experiments to determine the mobile ion species during oxide forming reactions. It is shown here, that different noble metals could lead to contradictory conclusions.

## Multiple Twin Structures in Electrodeposited Silver Dendrites

J. Smit, F. Ogburn,\* and C. J. Bechtoldt

National Bureau of Standards, Washington, D. C.

The structure of electrodeposited dendrites of FCC metals, particularly of silver, has been the subject of several communications (1-7). These investigations have been conducted on dendrites produced from both fused salt and aqueous systems. The dendrites are described as being usually in one of two forms, i.e., acicular and growing in the  $\langle 110 \rangle$  direction or planar and growing in the  $\langle 112 \rangle$  direction. Twinning in these dendrites has not been uniformly reported. With respect to silver dendrites formed in fused salt systems, Bockris (2), on the basis of x-ray diffraction and metallographic evidence, reports twinning in the planar form dendrites. Reddy (7) also reports twinning, but on the basis of metallographic evidence alone, as does Faust and John (8) in their examination of dendrites supplied by Hudson (3). In aqueous systems Kikuchi (6) has observed twinning in planar

form dendrites growing in the  $\langle 112 \rangle$  direction. Wranglen, however, does not report twinning (1,4). Faust *et al.* (9) report observing twinning in the form of crossed lamella within the matrix of a single orientation. In the last case the lamella are each in twin relation to the matrix but not in twin relation to each other. In no case has multiple twinning, i.e., more than three orientations about a common zone axis, been reported in silver.

Faust and John (10) describe multiple twinning configurations in semiconductor FCC materials deposited from the melt. They classify twinning modes or configurations as follows: (i) Class I twinning, in which  $\{111\}$  composition planes appear to radiate from a central point and are  $70^\circ 32'$  apart. The orientations are pie shaped and mutually exclusive. (ii) Class II twinning, in which  $\{111\}$  composition planes are parallel. In this case one orientation is minor to another

\* Electrochemical Society Active Member.

Fig. 1. Class I twinning. Four orientations. Dashed lines indicate  $\{111\}$  composition planes.  $\langle 110 \rangle$  direction normal to paper.

Fig. 2. Class II twinning. Two orientations. Dashed lines indicate  $\{111\}$  composition planes.  $\langle 110 \rangle$  direction normal to paper.

and contained within it in the form of a band or lamella.

Figures 1 and 2 are sketches of idealized cases of both classes of twinning.

It is the purpose of this communication to report experimental observations of the structure of silver dendrites electrocrystallized from aqueous solutions with reference to the classes of Faust and John. This investigation was undertaken to supplement our fragmentary knowledge of the roll of growth twins in the formation of electrodeposited dendrites.

#### Description of Apparatus and Techniques

Electrocrystallization was conducted in Pyrex vessels 44 mm in diameter and 80 mm high. The dendrites were produced on silver wire cathodes in 70 ml of 0.5M  $\text{AgNO}_3$ . The solution was prepared from reagent grade  $\text{AgNO}_3$  and distilled water. A silver wire in a Luggin capillary was used as a reference electrode. The tip of this electrode was positioned approximately halfway between the two active electrodes and was used to maintain potentiostatic control of the system during deposition. The potential values reported here include the IR drop between the reference electrode and cathode, which varies substantially as the dendrite grows toward the anode. Dendritic growth was induced at cathode potentials of at least 300 mv and then maintained potentiostatically at approximately 160 mv. Growth was permitted to proceed until the dendrites attained a length of at least 1 cm. Dendritic growth often proceeded at a rapid pace and has been observed here at rates up to 1.2 mm/min. After growth termination the dendrites were removed carefully from the electrolytic solution, washed in distilled water, air dried, and mounted with the base end secured in clay plugs fixed to the inner surface of polyethylene bottle caps. These caps were then secured to 4 or 6 dram vials. The dendrites were now fully enclosed and protected against mechanical shocks and corrosion. The dendrites remained thus secured until such time as detailed optical goniometric, x-ray diffraction, and metallographic examinations were undertaken.

#### Observations

In the course of this investigation 38 dendrites were examined. The dendrites ranged from one-fourth to one millimeter thick and were at least one centimeter long. All specimens contained bright shiny well-defined facets. Preliminary two circle optical goniometric surveys and x-ray diffraction examinations (precession alignment and rotating crystal patterns) indicated the dendrites to be fundamentally twin crystals with composition planes and growth axis parallel to the  $\langle 110 \rangle$  direction. Although the full extent of multiple twinning is not necessarily revealed by the use of optical equipment alone, the optical data did indicate in all cases the existence of twinning. All dendrites examined were of acicular form and were clearly faceted, mainly on the  $\langle 110 \rangle$  zone. The most frequently observed facets on this zone were the  $\{111\}$  facets, then the  $\{100\}$  and  $\{112\}$  facets;  $\{110\}$  facets were seen also, but only rarely. As many as six orientations in twin relation were identified in this manner. Low orders of twinning, that is, two and three orientations in twin relation, are exhibited generally in those crystals having relatively large smooth bright surfaces. These crystals frequently appeared x shaped in cross section with crevasses extending down the entire crystal length. High orders of twinning, that is, four and more orientations in twin relation, are characteristic of crystals having jagged appearing surfaces containing many nodes or knobby protuberances.

Zero level  $\langle 110 \rangle$  Weissenberg patterns of the dendrites confirmed and, in some cases, expanded on the preliminary findings. The extent of twinning was determined from the number and position of the  $\{111\}$  spots. The  $\langle 110 \rangle$  zone of a single orientation (FCC) contains in a  $180^\circ$  interval two  $\{111\}$  spots, providing the interval does not start on a spot. Each additional orientation in twin relation generates one new  $\{111\}$  spot. The  $\{111\}$  spot common to two orientations represents the composition plane. Up to eight orientations in twin relation were revealed in this way. Figures 3, 4, 5, and 6 are zero level  $\langle 110 \rangle$  Weissenberg patterns showing 2, 4, 6, and 7 orientations, respectively. The film translation is approximately 100 mm (200 degrees).  $K_\alpha$  molybdenum radiation was used to produce the patterns. This radiation was selected principally because of the atomic number and irregular thickness of the dendritic material. In photographs 5 and 6 some streaking is observable between  $\{111\}$  spots 3.6 mm (7.4 degrees) apart. It is slight and has been enhanced by both over exposure of the original photo-

Fig. 3. Zero level.  $\{111\}$  Weissenberg diffraction pattern showing two orientations in twin relation.

Fig. 5. Zero level.  $\{110\}$  Weissenberg diffraction pattern showing six orientations in twin relation.

Fig. 6. Zero level.  $\{110\}$  Weissenberg diffraction pattern showing seven orientations in twin relation.

graphs and by reproduction. Nonetheless it may be indicative of strains in the orientations involved.

In the majority of cases the number of orientations discerned optically was the same as the number of orientations as determined from the Weissenberg patterns. This was particularly so for the low orders of twinning. The majority rule held for the higher orders of twinning as well except that in several cases more orientations were revealed on the Weissenberg patterns than were displayed optically.

A determination of the consistency of twinning through a dendrite was made by examining some dendrites at two positions along the growth axis. Weissenberg  $\{110\}$  zero level patterns were obtained of these dendrites near the growth tip and in the base region. In each case the number and position of the orientations at the tip agreed with the number and position at the base.

The classes of twins as described by Faust and John (10) and detailed here in the introduction were observed in metallographic sections taken normal to the growth axis of dendrites electrodeposited during this investigation.

Figure 7 is an example of Class I twinning showing five orientations about an axis. The observations here reported were made on specimens mounted, ground, and polished according to standard metallographic practices. The details of the structure were most often, though not consistently, brought out using an etchant prepared by combining, just prior to use, at a ratio of 1:1 a 5% solution of KCN in distilled water with a 5% solution of  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  in distilled water. However, no etching system and schedule used produced good results consistently. It appeared that simple twin boundaries could not be clearly developed consistently. The maximum number of related orientations observed in Class I type specimens was six. This was in agreement with both the optical and x-ray data for that specimen. The maximum number of orientations observed in Class II type specimens was three. This also was in agreement with optical and x-ray data. In the latter specimen two orientations appeared as  $10\mu$  wide crossed lamella in a third predominant orientation. This same specimen showed only one orientation on a 27-hr exposure Weissenberg pattern taken using a Mo target tube at 50 kv and 15 ma. An increase of exposure time to 90 hr at the same conditions brought out faintly the two orientations of the lamella forms.

Dendrites containing both classes of twins simultaneously were also observed. This is illustrated in Fig. 8 and 9.

Fig. 7. Class I twinning showing five orientations about a central axis. X1500 before reduction.

Fig. 9. Combination of Class I and II twinning. Five orientations. Dashed lines indicate  $\{111\}$  composition planes.  $\langle 110 \rangle$  direction normal to paper.

### Discussion

This note has brought to attention modes of multiple twinning as encountered in the electrocrystallization of silver from aqueous solution. Multiple twinning involving up to eight orientations is reported. No exception to twinning was uncovered among the 38 silver dendrites examined during this study. Every one was made up of two or more crystals in twin relation with all the composition planes parallel to the growth axis. Our observations were, of course, limited to a specific set of conditions and to rapidly growing dendrites. Hence, we cannot make any generalized statement concerning all dendritic growth. The inference here, however, is that the twinned structure is involved in the growth mechanism. We are also impressed by the fact that in the literature, wherever dendritic growth by electrodeposition has been rapid, *i.e.* mm/hr, a twinned structure has been present. This has been reported by Barton and Bockris (2) (silver), Reddy (7) (silver), Ogburn *et al.* (5) (lead), and Bechtoldt *et al.* (11) (molybdenum). From these and other experimental observations it is evident that twinning plays an important role in the growth process. It exerts a profound influence on the shapes of dendrites, on their directions of growth, and on the

Fig. 10. Composite Class I twinning. Twelve orientations. Two axes of twinning. Dashed lines indicate  $\{111\}$  composition planes.  $\langle 110 \rangle$  direction normal to paper.

cathodic polarization. Where twin lamella occur, the twin plane re-entrant-edge mechanism of Faust and John seems adequate. The same mechanism may also be applicable to the radiating twin structure, although it remains to be shown that faceting suitable for re-entrant edges occurs.  $\{111\}$  faceting is suitable for twin lamella, but not for radiating twin structures. However, electrodeposited silver develops other facets, such as  $\{571\}$  observed by von Dauber (12) and by us.

One may ask how many twin related orientations are possible in a dendrite. We have detected eight and no more, but there is no reason to think that more than eight could not occur. At this time the only rules that we can apply to this twinning are (i) the composition planes are  $\{111\}$  and (ii) they are parallel to the growth axis. Faust *et al.* (9) show that in the case of radial twinning, a mismatch boundary or void must occur. With no more restrictions, it is very easy to conceive of a variety of twin configurations, many of which include more than eight orientations. For example, Fig. 10 shows twelve orientations associated with two centers for radial twinning and lamella.

# Time-Temperature Superposition Theory for Electrets

Bernhard Gross

National Nuclear Energy Commission of Brazil, Rio de Janeiro, Brazil

## ABSTRACT

The previous theory applies to isothermal behavior of dielectrics. It correlates current transients and dielectric loss curves obtained at different, but constant temperatures. A theory of nonisothermal effects is, however, needed to describe the conductivity glow curves during heating or the current transient during the thermal release of a "frozen-in" charge. The outline of such a theory is developed in the present paper. It is based on the principles of linearity and of charge invariance. Charge invariance means that the amount of charge which can be released by reheating a dielectric containing a frozen-in charge is a state variable depending only on the state of the system at the time when the reheating begins. The relaxation time can then be expressed in terms of a time- and temperature-independent distribution parameter. The generalized distribution function, which corresponds to the distribution of relaxation times of the isothermal system, is a function only of the distribution parameter and therefore independent of temperature. The formalism of rate theory is used to obtain an explicit expression for the relaxation time in terms of temperature and of activation energy. A simple mathematical model is obtained using an empirical expression for the distribution function. To account for the extremely strong temperature dependence of the current one must assume that states with high activation energies are much more frequent than states with low energies.

The isothermal behavior of dielectrics under different types of stress, in the time and frequency domains, has been investigated extensively. At an early stage of the theory, Wagner (1) formulated his "Law of Corresponding States" by which he was able to correlate discharge current and dielectric loss curves at different, but constant temperatures. In the analogous case of linear viscoelasticity a similar method has yielded "master" curves which correctly describe the behavior of systems over wide ranges of time, frequency, and temperature (2). The method is now called time-temperature superposition theory. The behavior of electrets is, however, characterized by nonisothermal transitions to which the theory in its present form does not apply (3). The lack of an adequate analytic theory of nonisothermal effects makes it difficult to obtain a systematic presentation of experimental results. In the present paper an attempt is made to formulate such a theory. For numerical applications an explicit expression for the distribution of relaxation times must be given. It is shown how such an expression can be obtained under rather general conditions and how it leads to a simple mathematical model.

### Charge Invariance

The theory is based on the postulate of charge invariance: The amount of charge which can be released by reheating an electret containing a "frozen-in" charge is a constant which depends only on the state of the system at the time when the reheating begins, not on subsequent heating rate and temperature. This assumption is by no means trivial although it seems to have been made implicitly by most authors on the subject. Thus it seems worth while to present here the experimental evidence (4) in some detail and subsequently to give a mathematical formulation.

*Experimental.*—Experiments were made with samples of filtered yellow prime carnauba wax with painted-on silver electrodes, of 1 mm thickness and 20 cm<sup>2</sup> area, under a voltage of 118v.

Figure 1 gives heating transients for different heating rates. Samples were first polarized at room temperature for 24 hr; subsequently the temperature was raised as shown in the bottom part of Fig. 1. The voltage was applied during the heating period. Currents increased strongly with increasing heating rate

and reached peak values when the temperature became constant. The final constant value of the current represents the ohmic conductance. Thus when the heating rate was very low, the transient became obliterated by the ohmic current. The current transients indicated that the polarization of the system increased due to the increase in temperature although the applied voltage remained constant.

Figure 2 gives current as a function of temperature, during heating and during cooling. The heating curves are derived from the corresponding curves of Fig. 1. During all measurements, i.e., during heating and during cooling, the same constant voltage was applied. For the cooling curves, samples were charged at 60.5°C during 13 hr before the temperature was reduced. All cooling curves are identical although cooling rates varied within a wide range of values. This absence of any current transient during cooling, contrasting strongly to what happens during heating, proves that the polarization of the sample remains constant if the temperature is reduced while the voltage remains applied. Obviously if there was any change in polarization this would have to manifest

itself by a depolarization or discharge transient in the same way as the polarization of the sample gives a charging transient.

Figure 3 gives depolarization curves in short-circuit following polarization experiments during which charge was "frozen-in" under different cooling conditions. Samples were charged at 60.5°C during 3 hr, cooled to room temperature with different cooling rates, and shorted. They were kept in short-circuit and subsequently reheated under identical conditions. Depolarization curves, as shown in Fig. 3, are approximately identical and indicate no systematic dependence on cooling rate.

These experiments show that the storage capacitance is independent of temperature during cooling. Further direct evidence has been obtained by Murphy (5). He found that the time integral over the depolarization current of a series of identically polarized samples was

Fig. 3. Depolarization curves. Polarization time: 3 hr at 60.5°C. Average cooling rates (with voltage applied): for curve 2, 0.22°C/min; for curve 3, 0.55°C/min; for curve 4, 0.48°C/min. For curve 1 the sample was charged at room temperature.

independent of the rate of reheating in short-circuit between 0.19 and 0.75°C/min.

**Theoretical.**—An absorptive dielectric which has been polarized at a given (high) temperature and subsequently cooled and shorted, contains at the moment of the short-circuit (taken as  $t = 0$ ) a frozen-in or stored charge  $q(0)$ . This charge is defined as the time-integral over the transient component of the charging current. Thus it depends on the electrical and thermal treatment for  $t < 0$ , but is always the same for a given polarization process. The system is discharged by reheating in short-circuit. The temperature during this period is an arbitrary function of time  $T(t)$ . The discharge current  $J(t, T)$  is a function of time and temperature, different temperature functions giving different discharge currents. The released charge is defined as the time integral over the discharge transient, i.e., as  $\int_0^\infty J ds$ . There is no *a priori* reason to assume that the released charge is always the same, independently of the temperature function  $T(t)$  and that a unique value can be assigned to it. But in the case of charge invariance, the released charge is a constant which depends only on the initial state of the system at the moment of the short-circuit, not on subsequent heating rate and temperature. Under these conditions the released charge is equal to the stored charge and one has

$$\int_0^\infty J[s, T(s)] ds = q(0) \quad [1a]$$

where  $q(0)$  is a constant which depends only on the values of the system parameters at  $t = 0$ . If  $t_0$  is an arbitrary time  $0 < t_0 < \infty$  one has also

$$\int_{t_0}^\infty J[s, T(s)] ds = q(0) - \int_0^{t_0} J[s, T(s)] ds = q(t_0) \quad [1b]$$

$q(t_0)$  is the charge released between the arbitrary time  $t_0$  and infinity; according to Eq. [1b] this depends only on the thermal treatment prior to  $t_0$ , not on what might happen afterward. Therefore if charge invariance applies at the time  $t = 0$ , it applies also for any later time  $t_0$ . Since  $t_0$  is arbitrary we shall write briefly

$$\int_t^\infty J(s) ds = q(t) \quad [2a]$$

$$J = -dq/dt \quad [2b]$$

$q$  is a state variable which depends on the state of the system at time  $t$ ,  $Jdt$  is a total differential.

We shall exclude the case of resonance absorption. Thus we consider systems containing only two types of parameters, a dissipative (ohmic) one and a charge-storing (capacitive) one, i.e., pure relaxation systems. Transformation of electrostatic into electromagnetic energy is excluded. Under these conditions the released charge has always the same polarity, is uniformly decreasing, bounded, and disappears for  $t \rightarrow \infty$ . This gives the relations, for  $t > 0$ ,

$$M \cong q(t) \cong 0; dq/dt \leq 0; q(\infty) = 0; J \cong 0 \quad [2c]$$

where  $M$  is finite.

### Superposition Theory

**Linearity.**—In this paper the electret is treated as a linear electrical system, in line with the author's theory which considers the nonisothermal charging and discharging transients of solid dielectrics in the context of the general theory of dielectric anomalies (6). The application of the principle of linearity has already been successful in the treatment of dielectric absorption, open-circuit behavior of absorptive dielectrics (7) and electret polarization (8) at different, but constant temperatures. It appears also as a convenient basis for the discussion of the nonisothermal transient currents characteristics of electret behavior.

Linear systems are defined as systems which can be described by means of linear differential equations. Systems with a finite or infinite number of lumped parameters correspond, respectively, to a finite or an infinite set of total differential equations; systems with continuously distributed parameters correspond to partial differential equations. The knowledge of the linearity of these equations provides one with important information without a knowledge of the detailed structure of the physical system. Linear systems are conveniently discussed in terms of electrical network analogues. The network analogue of an electret is a two-terminal, passive, pure relaxation system. The current transient produced by a unit voltage step is called indicial admittance. The purpose of this paper is, therefore, to give an expression for the nonisothermal indicial admittance.

*Isothermal.*—System parameters change with temperature, but are constant, *i.e.*, time-independent, for all measurements performed with constant temperature throughout. Thus under isothermal conditions a linear system theory applies in its conventional form. Consider a system composed of a finite number of lumped parameters. This is described by a set of total differential equations, of the first order, containing mesh currents and applied voltage. The relation between the applied voltage  $V(t)$  and the external current  $J(t)$  is obtained by the elimination of all other currents. This gives (9) the linear differential equation with constant coefficients

$$\sum_{m=0}^n a_m d^m J/dt^m = \sum_{m=0}^{n'} b_m d^m V/dt^m \quad [3a]$$

The short-circuit current, for  $V \equiv 0$ , is the solution of the homogeneous equation

$$\sum_{m=0}^n a_m d^m J/dt^m = 0 \quad [3b]$$

the solution of which is

$$J = \sum_{i=1}^n (q_i/\tau_i) \exp(-t/\tau_i) \quad [4]$$

The  $\tau_i$  are the relaxation times, the  $q_i$  are the integration constants giving the initial charges of the individual systems, and  $\tau_i > 0$ ,  $q_i \geq 0$ . The open-circuit voltage, from which the potential of the unshielded electret could be obtained, is given by the differential equation in  $V(t)$  obtained by putting  $J \equiv 0$ .

A system with continuously distributed parameters has a continuous distribution of relaxation times. The short-circuit current is obtained by a generalization of Eq. [4], replacing the sum by an integral and  $q_i$  by  $dq(\tau)$ , where  $\tau$  now is a continuous variable. This gives the integral transform

$$J = \int_0^\infty \phi(t, \tau) \frac{dq}{d\tau} d\tau \quad [5]$$

where  $dq/d\tau$  is the distribution function of relaxation times  $\tau$ . The kernel

$$\phi(t, \tau) = (1/\tau) \exp(-t/\tau) \quad [6a]$$

is the solution of the differential equation

$$d\phi/dt + \phi/\tau = 0 \quad [6b]$$

that satisfies the normalization condition

$$\int_0^\infty \phi(t, \tau) d\tau = 1 \quad [6c]$$

*Nonisothermal lumped parameter system.*—The electret effect is typically nonisothermal. During the course of the experiment the temperature is a func-

tion of time; therefore the system parameters are time-dependent. This obliges one to generalize the theory and to reformulate the expressions for the distribution function and the kernel of the integral-transform representation for the current.

The time-dependence of the system parameters does not affect the linearity of the system. Therefore the relation between  $J$  and  $V$  has the same form as before, but the coefficients of the differential equation are now functions of time. The same applies to the differential equation for the short-circuit current. Thus it is sufficient to replace the constant coefficients  $a_m$  by time-dependent coefficients  $k_m(t)$ . This gives for the current the equation

$$\sum_{m=0}^n k_m(t) d^m J/dt^m = 0, \quad t > 0 \quad [7]$$

The time  $t = 0$  is taken as the moment when the applied voltage is removed and the system is short-circuited. The solution has the form

$$J = \sum_{i=1}^n A_i \phi_i(t) \quad [8]$$

where the  $\phi_i$  are linearly independent particular solutions of Eq. [7].  $A_i$  are the integration constants which define the state of the system for  $t = 0$ . This is supposed to be always the same, *i.e.*, the system shall have been completely polarized with a given constant voltage before the stored charge is released. Now we consider two depolarization experiments, corresponding to two temperature-time functions  $T^{(1)}(t)$  and  $T^{(2)}(t)$  which shall be identical for  $0 \leq t \leq t_0$ , but different for  $t_0 < t < \infty$ .

Thus

$$T^{(1)}(t) = T^{(2)}(t) \quad 0 \leq t \leq t_0 \quad [9a]$$

$$T^{(1)}(t) \neq T^{(2)}(t) \quad t_0 < t < \infty \quad [9b]$$

The coefficients  $k_m$  will therefore also be identical for  $0 \leq t \leq t_0$  and different for  $t > t_0$ . Under these conditions one has two solutions

$$J^{(1)} = \sum_{i=1}^n A_i \phi_i^{(1)}(t) \quad \left. \begin{array}{l} \\ \\ \end{array} \right\} t_0 < t < \infty \quad [10a]$$

$$J^{(2)} = \sum_{i=1}^n A_i \phi_i^{(2)}(t) \quad [10b]$$

$$J^{(1)}(t) = J^{(2)}(t) \quad 0 \leq t \leq t_0 \quad [10c]$$

The functions  $\phi_i^{(1)}$  and  $\phi_i^{(2)}$  in the interval  $t_0 < t < \infty$  are different because they correspond to different temperature-time functions, but the integration constants  $A_i$  are the same in both cases because the initial state of the system is the same (Fig. 4). The released charge as a function of time is given by

$$q^{(1)}(t) = \sum_{i=1}^n \int_t^\infty A_i \phi_i^{(1)}(t) dt \quad [11a]$$

$$q^{(2)}(t) = \sum_{i=1}^n \int_t^\infty A_i \phi_i^{(2)}(t) dt \quad [11b]$$

Charge invariance requires that

$$q^{(1)}(t) = q^{(2)}(t) = q(t), \quad 0 \leq t \leq t_0 \quad [12]$$

or

$$\sum_{i=1}^n A_i \int_t^\infty \phi_i^{(1)}(t) dt - \sum_{i=1}^n A_i \int_t^\infty \phi_i^{(2)}(t) dt = 0, \quad 0 \leq t \leq t_0 \quad [13]$$

Since the  $A_i$  are arbitrary constants, it follows that

$$\int_t^\infty A_i \phi_i^{(1)}(t) dt = \int_t^\infty A_i \phi_i^{(2)}(t) dt = q_i(t), \quad 0 \leq t \leq t_0, \quad i = 1, 2, \dots, n \quad [14]$$

Fig. 4. Temperature, charge, and current for different heating rates.

independent of the particular temperature-time function  $T(t)$ , and

$$A_i \phi_i(t) = -dq_i/dt \tag{15a}$$

$$q(t) = \sum_1^n q_i(t) \tag{15b}$$

So far the two "test" functions  $T^{(1)}$  and  $T^{(2)}$  were arbitrary for  $t \geq t_0$ . Now consider a function  $T^{(2)}$  which is constant for  $t_0 < t < \infty$ . The corresponding isothermal relaxation current is given by a series of real exponentials with positive amplitudes. The integral over each term is also positive and equals  $q_i(t)$  since relation [14] is valid for any function  $T(t)$ , in particular the function  $T = \text{const}$ . It follows that

$$M_i > q_i(t) \geq 0; \quad q_i(\infty) = 0 \tag{16}$$

Since  $t_0$  was arbitrary, charge invariance applies to each particular solution  $A_i \phi_i(t)$  in the whole discharge interval.

Any function subject to these conditions can be written as

$$q_i(t) = q_i(0) \exp[-F_i(t)] \tag{17}$$

where  $F_i$  is a continuous function and  $q_i(0)$  is positive. Writing  $dF_i/dt = 1/\tau_i$  this gives

$$J(t) = \sum_1^n [q_i(0)/\tau_i(t)] \exp[-\int_0^t ds/\tau_i(s)] \tag{18}$$

The integration constants  $A_i$  have been replaced by the initial charges  $q_i(0)$ .

The case of an infinite number of lumped parameters does not present any difficulty, the series in Eq. [18] then extending from 1 to infinity.

*Relaxation times as state variables.*—If the temperature is constant, equal to  $T_0$ , the isothermal current is

$$J = \sum_1^n [q_i(0)/\tau_i(T_0)] \exp[-t/\tau_i(T_0)] \tag{19}$$

in accordance with Eq. [3] and [5], the  $\tau_i$  being the relaxation times for the temperature  $T_0$ .

If the temperature is not constant, the functions  $\tau_i$  might depend on the temperature and its derivatives and, in addition, explicitly on time. If  $\tau_i$  depends explicitly on time, an instantaneous variation of  $T$  is followed by a delayed variation of  $\tau_i$ . If  $\tau_i$  depends on the heating and cooling rates, the same value of  $T$  gives different values of  $\tau_i$ . Here we shall exclude these effects and assume that the  $\tau_i$  depend only on the value of  $T$  itself. The functions  $\tau_i$  of the nonisothermal system at any given temperature are then identical with the relaxation times of the isothermal system at the same temperature; since the latter are always positive,

the  $\tau_i$  are always positive and  $dq_i/dt \leq 0$ . With this assumption we postulate the existence of relaxation times as state variables. This is justified within the context of rate theory, as discussed below. It is, however, not a necessary consequence of the assumption that the system parameters, or network elements in the case of the electrical network analogue, are state parameters, because the coefficients  $k_m(t)$  of the differential Eq. [7] in general contain the values of the system parameters at a given temperature and their temperature derivatives.

*Network representation.*—It is easy to find an electrical network model which represents Eq. [18] when all  $\tau_i$  are positive. Consider the parallel arrangement of independent "relaxators" of Fig. 5. The differential equation for the short-circuit current in branch  $i$  is

$$dJ_i/dt + J_i [1/R_i C_i] + d \ln(R_i C_i)/dt = 0 \tag{20}$$

which gives

$$J_i(t) = [q_i(0)/R_i C_i] \exp \left[ -\int_0^t ds/R_i C_i \right] \tag{21}$$

where  $q_i(0)$  is the charge of the capacitor  $C_i$  at  $t = 0$ . Equation [21] becomes identical with Eq. [19] if one takes

$$\tau_i = R_i C_i \tag{22}$$

The network elements  $R_i$  and  $C_i$  are always positive. Equation [22] can, therefore, be satisfied only if  $\tau_i$  is positive. This condition is fulfilled according to the previous discussion. Therefore any system whose current is given by expression [19] with  $\tau_i > 0$  can be represented by the network of Fig. 5. A more detailed discussion of network representations will be given in a subsequent paper. Here it might be mentioned in passing that any "impulsive" network (10) is charge-invariant. A charge-invariant system, whose polarization current contains a steady-state component, can therefore always be represented by an impulsive network connected in parallel with a pure resistance.

The two types of parameters appear in the equations only in the form of the product  $R_i C_i$ . Therefore short-circuit measurements do not allow one to discover whether both are temperature-dependent or only one of them, i.e.,  $R_i$ . The situation is different when an external voltage is applied. Consider a sample which has been polarized at temperature  $T_2$  with the constant voltage  $U_0$ . At the end of the polarization period the total charge is  $q_2 = U_0 C_0(T_2) + U_0 \sum_1^n C_i(T_2)$ . Subsequently the temperature shall be reduced to  $T_1$ . The corresponding final charge is  $q_1 = U_0 C_0(T_1) + U_0 \sum_1^n C_i(T_1)$ . If the  $C$ 's depend on temperature,  $q_2 \neq q_1$ , the charge difference  $\Delta q = q_2 - q_1$  flows through the external circuit and a current results. A distinction must be made between the effects of a temperature dependence of  $C_0$  and of the  $C_i$ ,  $i \geq 1$ .  $C_0$ , which rep-

Fig. 5. Network representation

resents the high-frequency dielectric constant, is not connected in series with a resistive element. If it is a function of temperature, the corresponding current  $U_o(dC_o/dT)dT/dt$  is proportional to the rate of temperature change, but it is an "in-phase" current. Like the "ohmic" current  $U_o R_o(T)$  it becomes constant when the temperature becomes constant. The  $C_i$ ,  $i \geq 1$ , are in series with resistive elements. Their temperature dependence is associated with an "out-of-phase" current which extends beyond the period during which the temperature changes with time, i.e., a transient current. In our experiments the current was found to be independent of the rate of temperature change during cooling and became constant at the same time as temperature. Therefore within the precision of these experiments all capacitive elements remained constant and the temperature effect was due entirely to the dissipative elements.

### Continuous Systems

*Distribution function.*—The transition to continuous systems is made by considering a dense distribution of infinitesimal elements each characterized by a relaxation time and an amplitude factor  $dq$ , the latter being the contribution of that system to the polarization charge. In the isothermal case one could associate  $dq$  directly with  $\tau$ , writing  $dq = (dq/d\tau)d\tau$ , and thus obtain an integral of type [3]. When  $\tau$  is a function of temperature, and thus implicitly of time, this procedure makes the spectrum time-dependent and would lead to a violation of charge invariance unless limiting conditions are introduced subsequently. The difficulty is avoided by introducing a time- and temperature-independent parameter  $U$ . The relaxation time is a function of both  $U$  and  $T(t)$ , while the amplitude factor is a function of  $U$  alone, i.e.

$$\tau = \tau[U, T(t)] \quad [23a]$$

$$dq = (dq/dU)dU \quad [23b]$$

Replacing in Eq. [18]  $q_i(0)$  by  $dq(U)$ ,  $\tau_i$  by  $\tau(U, T)$ , and the series by an integral one obtains the integral transform

$$J(t) = \int_0^\infty \phi(t, U) \frac{dq}{dU} dU \quad [24a]$$

$$\phi(t, U) = \frac{1}{\tau[U, T(t)]} \exp \left[ - \int_0^t \frac{ds}{\tau[U, T(s)]} \right] \quad [24b]$$

The condition of charge invariance is fulfilled because the amplitude factor  $dq/dU$  is independent of time and

$$\int_t^\infty \phi(t, U) dt = \exp \left[ - \int_0^t \frac{ds}{\tau[U, T(s)]} \right] \quad [25]$$

Equation [25] expresses the integral over the interval  $t$  to  $\infty$  on the left side in terms of an integral over the interval 0 to  $t$  on the right side. The kernel itself is the integral of the differential equation

$$d\phi/dt + \phi/f(t) = 0 \quad [26a]$$

$$1/f(t) = (1/\tau) + d \ln \tau \quad [26b]$$

These relations generalize the corresponding relations [3]–[6]. A heuristic method of derivation could, therefore, start with Eq. [23], [24a], and [26a], with the additional conditions (a) that the differential Eq. [26a] for the kernel  $\phi$  transforms into the isothermal Eq. [5] and (b) that  $\phi$  is charge-invariant. These conditions give for  $f(t)$  the relation [26b] and for  $\phi$  the expression [24b].

*Distribution parameter.*—To get an explicit expression for  $\phi$  one can use the formalism of rate theory (11) writing

$$\tau = (h/kT) \exp [F/RT] \quad [27]$$

where  $F$  is the molar free energy increase for the ac-

tivated system,  $R$  the gas constant,  $k$  the Boltzmann constant,  $h$  Planck's constant, and  $T$  the absolute temperature. Since  $F = U - TS$ , where  $U$  is the molar activation energy and  $S$  the entropy increase one has

$$\tau = \tau_o \exp U/RT \quad [28]$$

with

$$\tau_o = (h/kT) \exp (-S/R) \quad [29]$$

A distribution of relaxation times corresponds to a system of energy states with different activation energies and entropy increases. In the general case (12) one would have to introduce distributions for both  $U$  and  $S$ . The usual treatment considers, however, only a single distribution of energy levels. Paralleling this treatment we consider only a distribution of activation energies, identifying activation energy with the parameter  $U$  in Eq. [23] and taking a single value  $S$ , an average value.

One might object that Eq. [28] does not lead to a law of corresponding states as has been found by many authors. Such a law is obtained if the temperature dependence is the same for all values of  $\tau$ , i.e.,  $\tau = \tau_o U$ . Here  $U$  is a dimensionless parameter, the temperature function  $\tau_o(T)$  is usually assumed to be exponential. This alternative will, however, not be discussed in this paper.

It is worth noting that for a single relaxation time and uniform heating rate the system of Eq. [24] and [28] becomes identical with the function that has been used to describe current glow curves and thermoluminescence with monomolecular kinetics (13).

### Model Distribution Function

Froehlich (14) has considered a model assuming a dilute solution of dipolar molecules in an amorphous solid, each molecule having two equilibrium positions with opposite dipole directions and equal energy in the ground level. He assumed the potential barrier between the two positions to have different heights equally distributed between two extreme values, or what is equivalent an equal distribution of the number of molecules over the energy interval. This gives a continuous distribution of energy levels with activation energies between a minimum value  $U_1$  and a maximum value  $U_2$  and a population of dipolar molecules  $N(U)$  independent of  $U$ . Then  $dq = eN_o dU / (U_2 - U_1)$  where  $N_o$  is the total number of molecules and  $e$  the electron charge. This expression can be generalized by abandoning the restriction  $N(U) = \text{const}$  and writing

$$dq = neN_o U^{n-1} dU / (U_2^n - U_1^n) \quad [30]$$

where  $n \geq 1$  is a constant coefficient. This Eq. [30] is more general than the above model. It also applies for instance to the case where one has a number of charge carriers with equilibrium positions in potential wells separated by barriers of different heights. For  $n = 1$  one has Froehlich's expression. Equation [30] satisfies the normalization condition  $q = \int_{U_1}^{U_2} dq = eN_o$ . Since from Eq. [28],  $U = RT \ln \tau/\tau_o$ , one has also

$$dq = \frac{neN_o (RT)^n}{U_2^n - U_1^n} \ln^{n-1} (\tau/\tau_o) d \ln (\tau/\tau_o) \quad [31]$$

Substitution into Eq. [24] gives for  $T = \text{constant}$

$$J = \frac{neN_o (RT)^n}{U_2^n - U_1^n} \int_{\tau_1}^{\tau_2} \frac{\exp [-t/\tau]}{\tau \ln^{n-1} (\tau/\tau_o)} d \ln (\tau/\tau_o) \quad [32]$$

where

$$\tau_i = \tau_o \exp [U_i/RT] \quad i = 1, 2 \quad [33]$$

The logarithmic term in Eq. [32] is slowly varying compared with the rest of the integrand. For an approximate evaluation of the integral this term will

be taken out of the integral, with that value of  $\tau$  for which  $\exp(-t/\tau) = 1/e$ , i.e., for  $\tau = t$ . This gives

$$J = \frac{neN_0(RT)^n}{U_2^n - U_1^n} \ln^{n-1}(t/\tau_0) \int_{\tau_1}^{\tau_2} \frac{\exp(-t/\tau)}{\tau} d \ln \tau/\tau_0 \quad [34]$$

and after integration

$$J = \frac{neN_0(RT)^n}{U_2^n - U_1^n} \frac{\ln^{n-1}(t/\tau_0)}{t} [\exp(-t/\tau_2) - \exp(-t/\tau_1)] \quad [35]$$

This expression satisfies the condition of charge invariance. The factor in square brackets is approximately a "unit box" function, i.e., it equals unity for  $\tau_2 \cong t \cong \tau_1$  and 0 for  $t$  outside the interval. Therefore one has

$$q = \int_0^\infty J dt = \frac{neN_0(RT)^n}{U_2^n - U_1^n} \int_{\tau_1}^{\tau_2} \ln^{n-1}(t/\tau_0) d \ln(t/\tau_0) = eN_0 \quad [36]$$

For  $n = 1$  one obtains correctly Froehlich's formula

$$J = \frac{eN_0RT}{U_2 - U_1} \frac{[\exp(-t/\tau_2) - \exp(-t/\tau_1)]}{t} \quad [37]$$

To discuss Eq. [35] consider first the time dependence. According to what has been said about the square bracket term, the current at any temperature is given by

$$J = \begin{cases} 0 & t > \tau_2 \\ c(1/t) \ln^{n-1}(t/\tau_0) & \tau_2 > t > \tau_1 \\ 0 & \tau_2 > t \end{cases} \quad [38]$$

Within a limited interval of time  $J$  decreases approximately like  $1/t$ , while over a wider range the influence of the logarithmic factor makes  $J$  decrease with time somewhat slower than  $1/t$ . This behavior is in agreement with most experiments which give  $J \sim (1/t^m)$  with  $m$  slightly less than 1.

Currents at different temperatures differ by a constant factor  $(RT)^n$ . To assure charge conservation, the increase in current amplitude must be compensated by a decrease in width of the interval  $\tau_1 - \tau_2$ , as is shown by Eq. [38]. This is again in qualitative agreement with experiment.

The temperature dependence of the current is certainly much stronger than would be given by a linear term, as in Eq. [37]. Therefore the exponent  $n$  must be considerably greater than unity, and the generalization  $dq \sim U^{n-1}dU$  with  $n > 1$  is in the right direction, although possibly an exponential increase would fit better the observed data. Since  $dq = edN(U)$ , one has also  $N(U) \sim U^n$  and, instead of an equipartition of energy, one has a much higher occupation of states with high activation energy than with low activation energy. The power law, however, does not give the right increase; a function  $N \sim \exp(cU)$  should give a better representation of the experimental situation.

### Conclusions

The discussion has been in terms of electrets. Electret behavior is a general property of solid dielectrics, like dielectric absorption and dielectric loss, and caused by the same mechanism as these effects. Froehlich's

theory and its generalization, as presented here, are charge-invariant and refer to dielectrics in general. The principle of charge invariance might not be rigorously valid in all cases, but in most is a good approximation. The conclusions of the present paper are, therefore, of interest to dielectric theory in general. Some consequences will be examined in following papers.

Physics Department, Escola Engenharia, Sao Carlos, Sao Paulo, Brazil

## ABSTRACT

The behavior of alkali-halide electrets of KCl/Sr and double doped KCl/Ca, OH is investigated by the glow peak discharge method of Fieschi, Bucci *et al.* (1) (ionic thermal conductivity method or ITC). In this case a complete analysis of the trapped polarization is possible quantitatively. The electret polarization is due to impurity vacancy dipoles. It is shown that the electret behavior in this case can be used as a very powerful tool to investigate the motion of defects in the solid matrix. As an application, the dipole diffusion to form higher aggregates is studied by a thermal annealing technique. By studying the variation of the electret released charge for various temperatures it is shown that trimers (3 dipole aggregates) are formed. The reaction is found to be of third order, and the activation energy for defect motion is (0.71 eV). The dipole relaxation frequency at 0°K is  $10^{-13}$  sec $^{-1}$ . All data agree very well with that obtained by other techniques and confirms the results of Dryden and Cook (2). In the case of double-doped systems, it is shown that the ITC method allows a quantitative determination of the solid-state reaction between OH and Ca. A correlation between F center formation by x-irradiation and electret behavior is also found, showing that the reaction is probably the precipitation of Ca(OH) $_2$  in the matrix leading to dipole destruction and quenching of the color center production. This is perhaps the only case in which the electret behavior is completely understood in a quantitative way, and, used as a tool, to obtain important solid-state parameters such as relaxation times, number of defects in the matrix, activation energies, and to investigate defect production and reactions in the solid state.

In a series of very complete and fundamental papers Fieschi Bucci *et al.* (1) established the foundations of the ITC (ionic thermal conductivity) method. The present paper is an application of their method using electret behavior and ITC as a tool to investigate solid-state problems. The electret trapped polarization arises in this case from the well-established presence of dipoles in the solid matrix. These dipoles are associated with impurity-vacancy complexes. In Fig. 1 this is indicated for the case of a fcc lattice such as that of KCl. It is seen that the addition of the divalent impurity (indicated by a double-charge in Fig. 1) such as Ca, Sr, Mg, Cd is associated with the presence of an additional positive ion vacancy to satisfy charge conservation in the matrix. This impurity may be added to the melt when the crystal is grown by techniques such as the Kyropoulos technique, or can be diffused into the material at temperatures near the melting point (3). Depending on the temperature and association energy the vacancy may be in a nearest neighbor position to the divalent impurity. In the case of the fcc lattice this will correspond to a dipole oriented in a general 110 position. Because of ionic diffusion this dipole can change its orientation. It is found that the reorientation is due mainly to positive ion mobility, or if we want, to vacancy jumps around the more or less fixed divalent impurity. To this process we can associate of course a thermal activation energy (related to the potential function seen by the vacancy in its neighborhood), a relaxation time, and eventually even an activation energy connected with the motion of the entire entity. In the physics of defects in solids this is a classical problem which has been extensively investigated (4). Other configurations of the IV (impurity vacancy complex) are also possible, in which the vacancy is at a next-neighbor distance ( $n^2$  complex), or next-next-neighbor distance ( $n^3$  complex), and these also have associated dipole moments, relaxation times and other corresponding parameters, and in some phenomena may play a prominent role. The presence

of the IV complex has also been detected by lattice expansion effects (5), by the use of the photoelastic technique of color center investigation (6), by dielectric relaxation measurements (7), by magnetic resonance (8), by dielectric absorption measurements (9) as well as by internal friction measurements (10). The ITC technique is however the most powerful one in our opinion. It is also very straightforward experimentally. The detection limit for dipoles is surprisingly small, in some cases concentrations as low as  $10^{15}$  dipoles/cm $^3$  can be detected.

The essential points related to the theoretical interpretation of the peaks have been discussed by Fieschi, Bucci *et al.* (1), and we will only summarize here the main results that are needed for the objectives of the present paper.

Fig. 1. Divalent impurity and associated positive ion-vacancy in a fcc alkali halide. The dipole moment (arrow) is along a (100) direction.

The electret polarization and depolarization by the glow peak obtained while heating the sample is conducted in the same way as first introduced by Gross in his now classical papers (11). In the case of the alkali-halides doped with divalent impurities, we know however that (a) by applying the polarization field we are orienting at the polarization temperature,  $T_p$ , a certain fraction of the IV dipoles in total number per unit volume  $N_d$ . If the temperature is high enough, we can suppose these dipoles to be rotating freely in the matrix. If the concentration is not too high, we can safely assume that these dipoles do not interact with each other. The relaxation time for dipole reorientation will be given by

$$\tau = \tau_0 \exp E/kT \quad [1]$$

(b) When we cool the electret under the applied field to a lower temperature  $T_1$  the relaxation time may change drastically (see Eq. [1]), and the oriented dipole configuration and its associated polarization will be frozen in the matrix.

If we now switch off the external field, we shall be left with the frozen polarization due to the orientation of the IV dipoles. If we then warm the electret, the relaxation time of the dipoles will gradually decrease and a displacement current will be observed in the external circuit because of the polarization change. This current  $i(t)$  is a function of temperature  $T$  and time  $t$  (we assume a constant heating rate) and is given by [see ref. (1)]

$$i(t) = N_d \frac{p^2 E_p}{3kT_p} \left[ \tau_0 \exp \left\{ \frac{E}{kT} \right\} \right]^{-1} \times \exp \left( - \int_0^t \left[ b \tau_0 \exp \left\{ \frac{E}{kT'} \right\} \right]^{-1} dT' \right) \quad [2]$$

This follows directly from the unimolecular nature of the dipole orientation process. The factor 1/3 is due to the hypothesis of freely rotating dipoles of moment. As expected intuitively this  $i(t)$  will present a maximum at a certain temperature  $T_m$ , the glow peak function being asymmetric in time (or temperature). The maximum peak position in temperature is related to the activation energy,  $E$ , heating rate,  $b$ , and relaxation time in the following way

$$T_m = \left\{ \frac{bE\tau(T_m)}{k} \right\}^{1/2} \quad [3]$$

It is very interesting to observe that the maximum peak position temperature is independent of the polarization temperature  $T_p$  and of the polarization field  $E_p$ . The activation energy can be obtained from the glow-peak in two independent ways. The easiest and most direct way is to calculate it from the initial rise in current. The low temperature tail of the band, at temperatures away from  $T_m$ , is given by

$$i(T) = i_0 \exp (-E/kT) \quad [4]$$

The other way to obtain  $E$  is by a global analysis of the whole band, which is much more difficult and requires a pure band form. That is, no overlapping bands may be present, so that Eq. [1] is valid during all of the charge release process.

When these conditions are satisfied we can apply the following relation

$$\ln \left[ \int_t^\infty i(t') dt' \right] - \ln i(T) = \ln \tau_0 + E/kT \quad [5]$$

The equation above expresses the  $\ln$  of the relaxation time  $\tau(T)$  as a function of the observed glow in an integral form. By plotting the latter as a function of  $1/T$  a straight line is obtained that furnishes directly the activation energy and  $\tau_0$ . This process is more cumbersome because several graphical integrations of the

band have to be performed. It is, however, independent of the heating rate. Bucci and Fieschi (1) have shown in the case of overlapping bands that the bands can be properly "cleaned" by a proper choice of the polarization temperature  $T_p$ , and by letting the lower temperature bands discharge and subsequently recooling to obtain the next band.

Finally, the total number of dipoles in the electret can also be found with good precision from the area of the band. At saturation the total polarization  $P_0$  is given by the following relation

$$P_0 = N_d (1/3 p^2 E_p)/kT_p \quad [6]$$

Thus by measuring  $P_0$  from the underlying area of the band  $N_d$  the total number of dipoles per unit volume can be obtained, if their dipole moment is known. In the case of the IV complex this is known.  $E_p$  and  $T_p$  as above are the polarizing field and temperature.

Equation [6] above is important if we wish to investigate the variation of the number of dipoles associated with some particular phenomenon like a solid-state reaction or defect production that may be dependent on the dipole sources.

### Experimental

The samples used were grown in our Laboratory at S. Carlos by the pulling or Kyropoulos technique from the melt. In the case of doped samples the impurity was added to the melt in the desired concentration. In some cases where necessary the direct analysis of the impurity in the solid was made by spectrophotometric or activation analysis techniques and will be described when appropriate. The samples were cleaved in thin plates of thickness approximately 1 mm and area of circa 1 cm<sup>2</sup> along a (100) plane. Aquadag or alcohol-dag electrodes were painted to obtain good electrical contact with the electrodes. The field was applied to the sample in vacuum or in a controlled atmosphere of dry N<sub>2</sub>, and the electrodes were held together by magnetic attraction so that no dielectric was present at the site where the temperature would be cycling. The current was measured with a Keithley 603 electrometer. The warming rate was kept constant and of the order of 0.1°K/sec, which was found to be the ideal rate for the quantitative and reproducible measurements obtained. Reproducibility for the currents and peaks was of the order of 5% or better. The activation energies could be measured to within 0.05 eV.

For the radiation damage of the samples to produce color centers, a 100 kv tungsten tube was used with proper filtration to ensure uniformity of defect production. The experimental sequence was the following. The sample was polarized at a desired temperature  $T_p$  for a certain time  $t_p$  (usually a few minutes) under a certain polarizing field  $E_p$ . The temperature was then lowered by pouring liquid nitrogen into the Dewar which contained the whole experimental assembly. After the crystal attained the lower temperature  $T_1$  the field was switched off, and the crystal warmed at a constant rate. The current due to the dipole relaxation which appeared in the form of glow peaks was then continuously recorded as well as the temperature. For convenience two recorders were used. One a X-Y recorder for  $i(T)$  and the other a recorder for the temperature as a function of time, so that the warming rate was directly observed during the experiments. The temperature was measured with an iron-constantan thermocouple situated in one of the electrodes. It is important in this work that the samples receive the proper thermal treatment. As shown in this paper the dipoles can aggregate to form dimers, trimers, or the divalent metal may precipitate in various sites like grain boundaries, dislocations, and other favorable places. It is then essential with an old sample, or a sample that is cleaved from a certain block which received no special thermal treatment, to

warm it to a temperature where the dipoles and the impurities will be dissolved properly in the matrix. This was done in an oven under controlled temperature and atmosphere conditions. The crystal was then quenched to room temperature or slowly cooled, depending on the type of experiment to be performed as will be described below. The optical measurements were made using a Beckman DK-2 double-beam automatic recording spectrophotometer in the range of 200 nm to  $3\mu$ .

### Results

**Dipole aggregation in KCl/Sr.**—It was shown by Cook and Dryden using a dielectric loss method that the IV dipoles in KCl/Sr aggregated to form trimers. Because of this aggregation process the resulting trimer has a negligible dipole moment, and thus the total polarization in our samples should decrease with their formation. This should be a temperature dependent process because of the thermal activation energy involved in the diffusion mechanism. In our ITC measurements the total area under the glow corresponding to isolated dipoles should then diminish with the aggregation process. We thus measured the polarization  $P_0$  as a function of time  $t$ . We kept the samples at different temperatures  $T$ . This polarization aging diminished, as expected, with time, as is shown in the results of Fig. 2. The particular way in which we plotted our results is related to the equations of the association process that will be discussed below. The results of Fig. 2 were obtained by polarizing the crystal always at the same temperature  $T_p$  for the same polarization time  $t_p$ . After the desired thermal treatment the polarization  $P$  was measured under the same field for all experiments. The crystal was then taken to a constant-temperature oven for the required length of time (days, hours, or minutes, depending on the temperature). After this time a new ITC measurement was made and the sample returned to the oven to continue with the aging process at a constant temperature.

**Ca Precipitation with OH in KCl.**—The OH impurity is now one of the more important defects in the physics of alkali halides. Luty *et al.* (12), Feher *et al.* (13), and Kanzig *et al.* (14) studied important paraelectric, paraelastic, and cooling effects of the OH dipole in alkali halides. Kuhn and Luty were the first to explain the apparent paradoxical behavior of the electrical conductivity of some of these solids as a function of temperature, by assuming a solid state reaction between Ca and OH ions. The same argument was used by Ikeya to explain the absence of F center sensitization in Cd containing samples. In the present work we give direct experimental evidence for this reaction

Fig. 2. Decay of polarization for a fixed temperature (293°K) as a function of time (KCl:Sr).

Table I. Results

Sample	CaCl <sub>2</sub> (10 <sup>-3</sup> M)	KOH(10 <sup>-3</sup> M)	Polarization (arbitrary units)
A	1.0	2.0	0.2
B	1.0	1.0	20.0
C	1.0	0.5	40.0

using the electret behavior. For this, we doubly doped KCl with Ca and OH in different proportions. We then measured the ITC band corresponding to the Ca IV complexes as a function of their different concentrations. Results are shown in Table I.

It is seen that we used concentrations corresponding to partial (OH)<sub>2</sub>Ca formation and complete reaction stoichiometry. While it was possible to detect directly the total amount of Ca in the solid by chemical analysis, the presence of free Ca was inferred in the following indirect way: The OH ion has an electronic absorption band in the uv region of the spectrum when substitutionally dissolved in the alkali halide. This OH absorption was extensively studied by many workers (15), and its oscillator strength is well known. The OH ion also has a vibrational absorption band in the near infrared portion of the spectrum. The precipitation of OH by Ca destroys the electronic absorption, but the vibrational band is still present. By measuring in both regions of the spectrum, we were able thus to distinguish between "free" OH and the precipitated OH.

### Discussion and Conclusions

**Dipole aggregation in KCl/Sr.**—The reaction for trimer formation is that of a third order reaction

$$\frac{dc}{dt} = -Kc^3 \quad [7]$$

where  $c$  is the dipole concentration,  $t$  is the time, and  $K$  a proportionality rate parameter. The polarization  $P$  that is proportional to dipole concentration is then obtained as a function of time by integration of Eq. [7] above as

$$P^{-2} = P_0^{-2} + 2\alpha^2 Kt \quad [8]$$

where  $\alpha$  is a proportionality factor between  $P$  and the number of dipoles per unit volume, and  $P_0$  is the polarization immediately after thermal quenching. Following Cook and Dryden we assume the reaction is diffusion controlled and set

$$K = A_d \exp(-E_d/kT)$$

Using Eq. [7] with this value for  $K$ , we get

$$C^{-2} - C_0^{-2} = 2A_d t \exp(-E_d/kT)$$

We can now define a half-life  $t_{1/2}$ , for the reaction at the time where  $C = C_0/2$ . This is given by

$$t_{1/2} = \frac{3}{2C_0^2 A_d} \exp(E_d/kT) \quad [9]$$

We can thus determine  $t_{1/2}$  from Eq. [8]. That Eq. [8] is followed is shown by the results of Fig. 2. If we get  $t_{1/2}$  as a function of temperature from Eq. [9], we can obtain the relevant quantities  $A_d$  and  $E_d$ . At the same time a new check of the whole model is provided. In Fig. 3 we show the results for several temperatures.

Our values for  $A_d$  and  $E_d$  and those determined by Cook and Dryden are in excellent agreement with each other.

The reaction is thus of third order, the process is diffusion controlled, and the electret polarization  $P$  and its quantitative analysis provided all the relevant conclusions in excellent agreement with other techniques.

**Ca precipitation with OH in KCl.**—It is clearly seen that polarization  $P$  increased from sample A to C, that

Fig. 3. Polarization half-life in hours as a function of the inverse of the absolute annealing temperature. Activation energy is 0.71 eV (KCl:Sr).

is, in the expected direction, if the  $(\text{OH})_2 \text{Ca}$  compound stoichiometry is considered. In order to understand further and discuss this result we decided to make another experiment: It is known that the "free" Ca ion sensitizes F-center production. In a recent paper Ikeya (16) has shown in part that the presence of OH in Cd crystals hindered the F-center sensitization by precipitation. We thus make an experimental analysis of the F-center growth curves and 100 kv x-ray irradiation for the different doubly doped samples. Ikeya showed that the square of the extrapolated optical density at zero time was proportional to the free Ca content in the samples. In order to discuss our results further we plotted this magnitude as a function of the electret polarization  $P$  as measured by the glow-peak technique

If the precipitation reaction was really being followed by the electret polarization, there should be a direct proportionality between the free Ca as measured by the F-center growth curves and  $P$ .

The results of the experiments are shown in Fig. 4. These results taken together with those of Table I

Fig. 4. Square of extrapolated optical density for the F band as a function of polarization for sample A ( $\text{KCl} + 1 \times 10^{-3} \text{M CaCl}_2 + 2 \times 10^{-3} \text{M KOH}$ ); B ( $1 \times 10^{-3} \text{M CaCl}_2 + 1 \times 10^{-3} \text{M KOH}$ ); and C ( $1 \times 10^{-3} \text{M CaCl}_2 + 0.5 \times 10^{-3} \text{M KOH}$ ).

show that we have detected the defect reaction directly from the electret behavior.

We think this paper exemplifies that in the case of the alkali-halides the electret behavior is not only very well understood quantitatively but can even be used as a powerful tool to investigate solid-state physics and solid-state chemistry phenomena. We are now in the process of investigating new phenomena using alkali-halide electrets, such as: (a) action of an electric field to break dipole aggregates; (b), action of the internal electric field of the electret on defects like the F center; (c) presence of negative ion vacancy divalent negative-ion dipoles in alkali halides; and (d) investigation of electret behavior due to impurity-vacancy dipoles in other inorganic materials like ZnO and MgO.

We hope that this paper will encourage other investigators in the field of electrets to join efforts in this very promising area.

#### Acknowledgments

The authors are deeply grateful to Dr. C. Bucci and Dr. M. Ferreira de Souza for helpful and valuable discussions and experimental suggestions; to all our colleagues at S. Carlos and especially to Dr. G. Leal Ferreira for several discussions; to C. Bicegli, Sebastiao Pereira, Carlos Trombella, and Salvador Sanchez Vera for technical help, and to Bartyra de Oliveira for secretarial help during the preparation of this paper.

This work was done under ONR contract and partial support of C. N. Pq. and Fapesp.

Manuscript received Sept. 7, 1967; revised manuscript Dec. 6, 1967. This paper was presented at the Electrets Symposium at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 123. Part of this work was done to fulfill the requirements for the Ph.D. degree of one of the Authors (N. J.) at the University, S. Paulo, S. Carlos.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Studies on HF-Doped Ice Thermoelectrets

S. Mascarenhas

Physics Department, Escola Engenharia, Sao Carlos, Sao Paulo, Brazil

and C. Arguello<sup>1</sup>

Faculdade de Ciencias, Rio Claro, Sao Paulo, Brazil

## ABSTRACT

Pure and doped ice thermoelectrets were prepared at different polarization temperatures ( $-10^{\circ}$  to  $-135^{\circ}\text{C}$ ). Stored charge was then investigated by the glow peak method. A main band was observed at  $-50^{\circ}\text{C}$ , with a total charge of  $10^{-6}$  to  $10^{-8}$  coulombs/cc depending on doping. The total charge released by the glow varied with the square root of HF concentration indicating that the  $\text{OH}^{-}$  and  $\text{H}_3\text{O}^{+}$  ions are responsible for the effect. Space charge formation was also shown to be associated with the electret behavior by investigating the influence of sample thickness on the polarization and of the temperature of the glow peak maximum on polarization temperature.

In recent papers (1) Gellin and the present authors reported observations on the ice thermoelectret. Riehl and co-workers (2) also reported recently on the behavior of ice subjected to thermal changes under electric fields and claimed to have observed ferroelectric behavior in ice. Pinatti and Mascarenhas (3) described the behavior of ice crystals during growth from the melt and reported strong electrical effects. In the present work we report on the ice thermoelectret, using the glow peak discharge method, and demonstrate that the effect is strongly dependent on or related to the HF doping of the samples. The nature of the trapped polarization that is released during the thermal glow was investigated by the analysis of the variation of the charge with concentration of the dopant as well as by changing the thickness of the sample and the polarization temperature. In view of the claim for ferroelectric behavior of ice made by Riehl and collaborators this is a very important question to be decided. Our investigations on the Costa Ribeiro effect in ice and its possible importance for the explanation of atmospheric electricity also stimulated the present investigations.

## Experimental

We have designed and constructed a special Dewar in which the ice single crystals were grown and the electret was prepared and measured. This is shown in Fig. 1. Initially, the bottom electrode E was positioned with the desired separation from the top electrode M by means of a ring stopper R, movable through the vacuum seal S. Both the bottom electrode E and the top one contained small Alnico magnets M so that the bottom one was maintained in position by magnetic attraction. This was a very convenient way of obtaining variable interelectrode distance and of avoiding any insulator in this part of the Dewar where the temperature would be cycling. The top electrode was the ground connection for the electrometer and the lower one was the high insulation electrode. The lead from E came out of the Dewar through a Teflon insulator I. V are vacuum connections. LS are levelling screws and W are windows through which the ice single crystal could be observed under polarized light with an optical system. Liquid nitrogen or any proper coolant was introduced inside the stainless steel tube T. The whole system was enclosed in a metal cylinder C. The liquid to be solidified (either pure water or HF solution) was initially placed between the two electrodes. At this time the ring-stopper would still be maintaining the proper electrode separation. A coolant was then introduced inside T causing solidification of the liquid. After com-

plete solidification the ring R was raised. The quality of the single crystal was then ascertained with the polarized light system. In this way we were able to grow very good single crystals of thicknesses ranging from 0.5 to 2 mm. The current was measured with a Keithley 603 electrometer and a  $10^9$  ohm grid resistor. The electrodes were platinum or palladium covered and their area approximately  $3\text{ cm}^2$ . What we call pure water in this paper is doubly distilled water from a quartz still of conductivity circa  $10^{-6}$  mhos/cm. Nitrogen gas was introduced in the Dewar in order to maintain good thermal contact to the sample during the warm up and cooling.

## Results

A typical experimental sequence would be as follows: The electric field  $E$  was applied to the sample

Fig. 1. Apparatus for single-crystal growth and electret preparation and measurement. T, stainless steel tube; I, Teflon insulator; S vacuum seal; C, external metal cylinder; R, ring-stopper; W, optical window; M, magnet; E, electrode (platinum or palladium); LS, levelling screws; V, vacuum outlets.

for a specified time at the chosen polarization temperature  $T_p$ . The crystal was then cooled under the electric field to *circa*  $-100^\circ\text{C}$ . The electric field was then switched off and the crystal warmed up to  $-10^\circ\text{C}$  again. During the warm up the current was constantly monitored and both the temperature and the current were recorded on a X-Y recorder so that the glow peaks could be directly observed.

Immediately after formation the ice single crystal would present some charge, probably due to the Costa Ribeiro effect. When this charge had dissipated the external field was applied. The discharge of the electret under its own field to produce the glow peaks was first used by Gross (4). A very well-defined and reproducible discharge was observed here peaking at around  $-50^\circ\text{C}$ , as is shown in Fig. 2. In the same figure the larger peak is connected with HF doping. After observing the discharge with pure water, we decided to investigate the possible influence of defects on the electret behavior, and also to look for possible ferroelectric behavior. We decided to dope the samples with HF. Much larger peaks were then observed with HF doped ice in concentrations ranging from  $2.5 \times 10^{-6}$  to  $10^{-4}\text{M}$ . The total integrated charge under the glow peak is shown as a function of concentration in Table I.

One can see that the effect of doping is rather large and that the integrated charge may change by two orders of magnitude in the range of concentrations used. The polarization time  $t_p$ , the polarization temperature  $T_p$ , the thickness and the applied voltage  $V_p$ , were kept constant in these experiments.

We have also investigated, due to reasons mentioned in the discussion section of this paper, the influence of the thickness of the sample on the total measured charge  $Q$  of the glow. The results shown in Fig. 5 were obtained for a constant field of  $335\text{ v/cm}$  for all samples. The linear behavior of  $Q$  with thickness will help us to clarify the nature of the trapped charge.

### Discussion

As is discussed below, in order to decide on the nature of the phenomenon, or more specifically on the nature of the trapped polarization of the ice thermoelectret the HF doping proved to be very important. It is known from previous theories on the physics of

ice (5) that HF doping will change the concentration of d and l defects (Bjerrum defects) as well as the concentration of ionic states ( $\text{OH}^-$  and  $\text{H}_3\text{O}^+$ ). From thermodynamic arguments it is expected that the d and l defects will change their concentration in a linear way with HF doping, while the ionic states will change with the square root of HF concentration. If we were dealing with orientation of dipoles which would be directly related to d and l defects our effect might be expected to depend on a linear way on HF doping.

The results of Table I are plotted on a double logarithmic scale in Fig. 3. From it we clearly see a square root dependence was found. This indicates that probably we are dealing with an effect related to  $\text{OH}^-$  and  $\text{H}_3\text{O}^+$  ionic carriers. This would tend to indicate that we are not dealing with a dipole orientation effect, or in fact, with any collective dipole effect that might even lead us to think of ferroelectric behavior. On the other hand, we are led to conclude that space-charge effects due to the motion of ionic carriers (specially the more mobile  $\text{OH}_3^+$ ) may be the main cause of the electret behavior.

In order to investigate this point further we did one more experiment. It is known that space-charge glow-peaks do not present a constant peak-position temperature, but rather this is strongly dependent on the polarization temperature (6). Keeping the warming rate cycle reproducible, because this is known to affect slightly the peak-position, we obtained several electret glows by varying the polarization temperature from  $-88^\circ$  to  $-26^\circ\text{C}$ . We found large changes in the corresponding peak position as shown in Fig. 4. Again this indicates space-charge behavior.

Finally, the experiment described by Fig. 5, in which we found a linear dependence of the charge  $Q$  on thickness seems to us to rule out any possibility of uniform polarization and thus reinforces very strongly the case for space charge as the main cause for the electret behavior.

When we tried to apply the Fieschi and Bucci dipole model (6) to our results, applying their expression for the total charge, we calculated an absurd concentration of  $10^{25}$  dipoles/cm<sup>3</sup>, assuming a dipole moment of one Debye. The peaks also do not allow the determination of any single activation energy  $E$ .

We thus conclude that: the electret effect in ice is greatly enhanced by HF doping; the electret charge can be released by glow peaks around  $-50^\circ\text{C}$  depending on the polarization temperature; the nature of the electret charge is related to space-charge effects; the nature of the space charge is connected to  $\text{H}_3\text{O}^+$

Table I. Integrated charge under the glow peak

$2.5 \times 10^{-6}$	$3.5 \times 10^{-7}$
$5.0 \times 10^{-6}$	$7.2 \times 10^{-7}$
$1.0 \times 10^{-5}$	$8.5 \times 10^{-7}$
$5.0 \times 10^{-5}$	$10.5 \times 10^{-7}$
$10^{-4}$	$1.75 \times 10^{-6}$

Fig. 3. Dependence of released charge  $Q$  on HF doping. A square root-dependence is found. The dashed line indicates a linear function (see text for discussion).

Fig. 4. Dependence of temperature of maximum peak position  $T_m$  on polarization temperature  $T_p$  for a HF doped sample ( $10^{-5}M$ ).

and  $OH^-$  ionic states. We also found that a claim for ferroelectric behavior of ice (2) cannot be substantiated. Explanation of the present effects using dipoles would require an enormous number, indicating the absence of a collective effect.

It is our opinion that any claim for ferroelectricity would have to include a very careful study of the influence of sample thickness and possibly doping to check for possible space-charge effects.

Finally, we think that the present results may be important for the understanding of the Costa Ribeiro effect in ice (3), in which large currents and voltages appear during phase changes. The fields at the solid-liquid interface may be effective in producing space-charge effects similar to those described here. In this respect it is interesting to point out that a large change in the freezing potentials due to the Costa Ribeiro effect has in fact been reported in the literature (7). We are proceeding with our investigations, trying to detect directly the presence of the space charge by doping the ice with chemical dye indicators.

Fig. 5. Dependence of the released charge  $Q$  on the sample thickness  $t$ , indicating a space-charge effect.

## Glow Peak Analysis of Pure and Doped Naphthalene Thermoelectret

M. Campos, G. Leal Ferreira, and S. Mascarenhas

Physics Department, Escola Engenharia, Sao Carlos, Sao Paulo, Brazil

#### ABSTRACT

Polarization current for pure and doped naphthalene thermoelectrets is investigated. The thermal depolarization of the electret is used as a technique to investigate trapped polarization. Doped crystals with alpha and beta naphthol present new independent peaks in addition to the pure matrix peaks. The peaks are analyzed quantitatively for total integrated charge and activation energy by the initial rise method. The OH vibrational band of the impurities was used as an optical probe to detect their presence in the solid. Charges trapped in the dielectric absorption process corrected for the released charge at the low-temperature depolarization, compare satisfactorily with the total integrated glow peak charge for both pure and doped samples. It was possible to differentiate between alpha and beta naphthol through the electret behavior using the glow peak position and activation energy of the peaks. The electret state is shown to be due to electronic carriers, trapped in a set or sets of exponentially distributed traps, as indicated by the  $at^n$  dependence of the polarization current on time.

Naphthalene is a very important example of a pure substance, an organic molecular semiconductor, exhibiting electret behavior. Naphthalene was first reported to present natural electret behavior by Costa

Ribeiro (1) and Tavares (2). Baldus (3), and, later, Mascarenhas (4) also reported on its electret properties. Extensive photoconductivity studies on this substance were carried out by Tavares in a very in-

teresting series of papers (5). Its general semiconductor properties were investigated by Pick (6) and Riehl (7). Mascarenhas and Freitas reported (8) anisotropic electrical properties of the material during phase changes. In many ways naphthalene is an excellent system for electret studies. It forms very good single crystals from the melt (9), it is easily orientable (10); it can be purified by several techniques such as zone melting, chromatography and sublimation (11); it has a very well-known electronic and molecular structure (12); and is a known electronic organic semiconductor (13). The conduction mechanism in the dark is still somewhat obscure, but this is a general question still to be solved for most molecular solids, where it is very difficult to distinguish among tunneling, hopping, or a trap-controlled mechanism (14). In this work we make an analysis of the electret state in oriented naphthalene crystals by the glow peak technique. For the first time, to our knowledge, controlled doping is introduced in an organic semiconductor electret system and independent glows obtained due to the specific dopant. Furthermore, the presence of the dopant can be monitored by optical analysis. For this purpose we availed ourselves of the presence of a very well-defined and prominent vibrational absorption band of OH radicals in the dopant, in our case alpha and beta naphthol.

### Experimental

Single crystal plates were grown by the Tavares (2) technique from double sublimed C. P. naphthalene. From a large plate, analyzed by polarized light, good single crystal areas were chosen and cut. The samples all had the same orientation, that of the cleavage plane in the plane of the plate. The samples were polished to an optical finish with alcohol. We used crystals of approximately 0.5 mm thickness and areas varying from 4 to 9 cm<sup>2</sup>. In the case of the doped samples, alpha or beta naphthol were added to the melt, and the presence of the dopant was ascertained from optical analysis in a Beckman DK 2 automatic spectrophotometer. These substances present an absorption band in the near infrared due to the presence of an OH radical, as shown in Fig. 1. The spectrum of pure naphthalene is also shown for comparison.

The crystals were painted with conducting silver on both faces. One one of the faces a guard ring was used. This is essential because of the high specific bulk resistance of naphthalene. Spurious or undesirable surface effects are thus avoided.

A special system was built for preparing the electret and for the measurement of the release of charge. This permitted the measurement of conductivity, electret preparation, glow peak investigations, and dielectric absorption measurements at variable or constant

Fig. 1. Optical absorption of pure naphthalene, (curve I); doped with alpha naphthol, (curve II); and doped with beta naphthol (curve III).

Fig. 2. System for electret production and measurements: a, Teflon insulation; b, brass walls; c, graphite electrodes; d, magnets for electrode assembly; e, guard ring; f, crystal (see text).

temperature in a vacuum or in a controlled atmosphere (Fig. 2).

The crystal (f) was placed between two graphite electrodes and the guard ring. The electrodes and the crystal were held together by the attraction of two small magnets (d) and (g). The guard ring was connected to an outer metal tube insulated by Teflon on the top plate of the system (see Fig. 2). The top central electrode was grounded, and the guard ring and the lower measuring electrode were insulated practically at the same potential, so that surface currents were negligible. The whole assembly was shielded by a metal case. An outer jacket (b) allowed water circulation from a precision Haake thermostat. The temperature of the sample was maintained constant to within 0.2°C during polarization. A liquid coolant could be introduced into tube T and the crystal brought to a low temperature. The temperature was measured by a properly insulated thermocouple placed in the lower electrode which also served as a lead for the electrometer. Electrical measurements were made using a Cary 31 vibrating reed electrometer with a 10<sup>11</sup> ohm resistor. The current was recorded with a Brown potentiometer. Dry nitrogen gas was used inside the inner container to avoid sublimation of the samples and insure good thermal conductivity.

The measurements comprised the following three steps: (a) During polarization, the exponential current decay was recorded as a function of time at a chosen temperature,  $T_p$ , until it approached a constant value. (b) While maintaining the field, the sample was cooled to a lower temperature,  $T_1$ . Then the field was removed, and the depolarization current recorded as a function of time. (c) Finally, the crystal was heated at a constant rate, and this depolarization current recorded. The whole sequence was very reproducible, and it was found that the proper stabilization of the polarization temperature to 0.2° was essential for this purpose.

### Results

We usually performed the whole sequence described above after previous warming of fresh samples to 60°C to empty all traps and release all accumulated charges due to growth, polishing, and handling. Results for the polarization current for pure naphthalene are shown in Fig. 3. Typical depolarization behavior for two different temperatures is also shown. The polarization current approached a constant current asymptotically under the applied field, and in the case of depolarization the current decayed to zero under no field. Similar results were found for the doped samples and are discussed below in more detail. Samples were then warmed under a constant rate. Very prominent

Fig. 3. Polarization current for pure naphthalene (curve I: 305°K); depolarization current at 305°K (curve II), and 280°K (curve III).

Fig. 4. Glow peaks obtained with pure naphthalene (I), doped with alpha-naphthol (II), and doped with beta-naphthol (III). Also shown is temperature  $T$  as a function of time during warm-up.

peaks were found for all samples. Figure 4 shows glow peaks obtained for both pure and doped samples. It is seen that the pure matrix peaks are present in the doped samples and that a new peak appears at an intermediate temperature. This peak was found to depend on the presence of the dopant.

### Discussion

With the quantitative results of the polarization, depolarization, and glow peaks in our possession, we can now proceed to a quantitative analysis of the electret behavior. As a first step we should try to understand, at least partially, the polarization mechanism. To do this the data were analyzed in a log plot of the total current minus the constant final direct current *vs.* time *j* to investigate the dielectric absorption current. From this figure two straight lines are obtained. The total charge  $Q_p$  trapped in the dielectric via the dielectric absorption mechanism can also be determined.

From the lower temperature depolarization current as a function of time (Fig. 3) a value for the charge  $Q_d$  released from the dielectric at this temperature can be found. Finally, from the glow peak curves the total integrated charge  $Q_g$  that was released from the dielectric during warm up is calculated. Table I shows the values of  $Q_p$ ,  $Q_d$  and  $Q_g$  for pure naphthalene. Within the experimental errors common for this type of experiment (order of 5-10%) the relation

$$Q_g = Q_p - Q_d$$

is satisfied. A similar analysis was done for the doped samples. The polarization behavior of these samples showed the same general behavior as that of the pure

Table I. Charges due to impurities

Kv/cm	Type	$Q_p$ $10^{-10}$ coul.	$Q_d$ $10^{-10}$ coul.	$Q_g$ $10^{-10}$ coul.	$Q_i$ $10^{-10}$ coul.
1.08	doped with $\alpha$ naphthol	1.24	0.96	0.23	1.19
0.54	doped with $\beta$ naphthol	1.08	0.81	0.31	1.12
1.08	pure	6.24	5.07	1.06	6.13

samples. Again depolarization currents at the low temperature and the glow peak allowed us to obtain  $Q_p$ ,  $Q_d$ , and  $Q_g$ . These magnitudes are shown in Table I. The glow peaks were also analyzed to determine the activation energy in the following way: If the internal field is approximately constant for temperatures well away from the maximum peak position, the initial rise method may be applied to determine a trap depth. In this case the current, at the initial rise of the peak, is given by

$$i = i_0 \exp -E/kT$$

This analysis was applied to the main pure naphthalene band (peaking at 308°K) and consistent and reproducible values of the activation energy obtained. Good results were also obtained for the impurity peaks of alpha and beta naphthol. Experimental difficulties prevented a proper analysis of the lower temperature pure naphthalene peak. We hope to do this in the near future. The activation energies found were reproducible to within 0.05 eV. Since the field is not constant during the glow, especially near the maximum, other methods will have to be used to analyze the peak for trapping cross section, activation energy, and other parameters. The complete analysis of the functional form of the peak depends on a model for the trapped polarization of the electret and the way in which the internal field varies with time.

It is interesting to observe that the alpha and beta naphthol maximum temperatures are slightly different, and that the activation energies for the corresponding glow peaks are also different. This shows the sensitivity of the glow discharge method of analysis of the electret. The results above can be summarized in the following way:

1. The naphthalene thermoelectret can be analyzed very conveniently by the glow peak technique. Two bands are present for the range of temperatures studied, the main band being situated at 308°K.

2. Activation energies can be obtained consistently from the glow by an initial rise method of analysis. The total charge associated with the glows is of the order of  $10^{-10}$  coulombs for fields of the order of 1 kv/cm. The activation energy for the main band is 0.75 eV, the same as that found for the thermal activation energy of the conductivity itself.

3. Controlled doping of the naphthalene thermoelectret with alpha and beta naphthol resulted in the appearance of independent peaks for each impurity. The total charge under the new glow was found to add to the dielectric absorption and to be of the same order of magnitude as that of the pure naphthalene main band for concentrations of  $10^{-2}$  molecules of impurity per molecules of naphthalene in the melt. The presence of the impurity in the matrix was monitored by the vibrational absorption band of the OH radical of the naphthol. No oscillator strength is available for this band so the concentration cannot be quoted. The activation energies for both peaks were measured and found to be noticeably different (Table II). This indicates that the method may constitute in the future a very sensitive technique for the investigation of impurities in solids.

We would like now to present some possible inferences from the above results. It seems that in the present case the electret behavior cannot be ascribed to dipoles or ions, but rather to electron or hole carriers trapped in defects or impurity levels in the solid. Considering a charge per unit volume of  $10^{-11}$

Table II. Activation energies (in eV)

Pure	Doped with $\alpha$ naphthol	Doped with $\beta$ naphthol
0.75	0.65	0.47

coulombs/cm in our electret samples about  $10^8$  to  $10^9$  carriers/cm<sup>3</sup> are associated with the effect. This exceedingly small number points out the following: (a) the enormous sensitivity of the glow peak analysis of the electret to detect defects or impurities, compared to other methods used in physics like E.P.R., optical analysis or electrical conductivity; only luminescence effects can probably be compared with the present technique; (b) that practically any way of purifying the matrix will be useless, because no purification method is available for this range of concentration. Besides, the number of structural or thermodynamical defects in the solid is probably much larger than the above number. Thus an essential and perhaps unique way to proceed with investigations of this type is to dope the solid in a controlled manner, as we have done.

From the results presented here one cannot decide whether electrons or holes are the predominant mechanism. Nothing can be said concerning the nature of the trapping levels introduced by alpha or beta naphthol. New experiments, in which selective filling of electron and hole trap is possible, are now being carried out (15). With this new technique we hope to clear up the latter questions. To measure the concentration of the dopants in the solid a determination of the oscillator strength of the optical absorption of the OH ion is necessary.

Finally, using Tavares' data on natural naphthalene electrets, it was shown that these samples also followed the same polarization behavior as the thermoelectret. It is perhaps appropriate to point out that similar (at<sup>n</sup>) behavior was found for ice electrets (16), carnauba wax electrets (17), our pure and doped naphthalene thermoelectrets and, as mentioned above, for natural electrets (10) obtained from the Costa Ribeiro effect. In the case of naphthalene, this tends to show that the same traps or sets of traps are involved in both phenomena. The anisotropy of the thermoelectret could then be expected, in view of the anisotropy of the Costa Ribeiro effect as found by Mascarenhas and Freitas (8). This is also being investigated in our laboratory.

This problem brings into discussion the question of the mobility of the carriers in naphthalene. Our samples showed the same activation energy for conductivity as that found by Riehl. Since we found the

definite presence of trapping centers as revealed by the polarization and glow peak behavior of the electret, it would seem that the mobility is also trap-controlled. The fact that the thermal activation energy for the conductivity coincided with the glow peak activation energy for the case of pure naphthalene (0.75 eV) is in agreement with the above observation. Finally the possible space-charge nature of the phenomenon is being investigated

## Effect of Low Pressure on Surface Charge of Electrets

Robert A. Draughn and Avery Catlin

Department of Materials Science, School of Engineering and Applied Science,  
University of Virginia, Charlottesville, Virginia

#### ABSTRACT

Electrets prepared from Mylar and a polystyrene material were exposed to low pressure. The effective surface charge of the electrets decreased as the pressure was lowered. It is proposed that the charge decrease is due to either desorption of charge sources from the electret surfaces or spark breakdown on the electret surface.

When electrets are exposed to pressures less than atmospheric, the magnitude of the effective surface charge is reduced. Previous investigators (1-3) have suggested that this effect is due to neutralization of a portion of the surface charge by ions formed by spark

breakdown in the air gap between the electret surface and adjacent electrodes. This paper presents experimental evidence which shows that this is not a suitable explanation for the observed charge decrease. The data show that the charge decrease is due to either

Fig. 1. Relationship of effective surface charge and pressure of surrounding air. Forming field: 140 kv/cm for 30 sec at 23°C.

desorption of ions from the electret surface or spark breakdown on the electret surface.

### Experimental

The electret materials used in this study were a commercially obtained polystyrene material<sup>1</sup> and Mylar.<sup>2</sup> Infrared, x-ray, and chemical analysis of the polystyrene material showed it to be polystyrene containing 10% by weight TiO<sub>2</sub>. The polystyrene sheet was 5 × 10<sup>-2</sup> cm thick and the Mylar thickness either 2.6 × 10<sup>-2</sup> cm or 1.3 × 10<sup>-2</sup> cm. The dielectric constants, measured at 1 kc were: polystyrene, 3.2; Mylar, 3.3.

The electrets were formed by positioning the specimens between guarded machined brass electrodes of 20 cm<sup>2</sup> area and applying a voltage of 5-7 kv across the electrodes. Most of the electrets were prepared by applying the high field for 30 sec at room temperature (23°, ±1°C) and room relative humidity (25%, ±3%).

The movable electrode of the dissectible capacitor used to measure the effective surface charge was of machined brass with a surface area of 5 cm<sup>2</sup>. Surface charge measurements were made both at reduced pressures and at atmospheric pressure following exposure of the electret to reduced pressure.

All specimens were stored with their surfaces exposed to the environment, i.e., in the unshielded condition.

### Results and Discussion

Figure 1 shows the behavior of the effective surface charge when a polystyrene electret was formed at atmospheric pressure, then exposed to low pressure. The charge measurements were made at the pressures indicated. The dissectible capacitor arrangement employed allowed the specimen to be stored between measurements with both of its surfaces freely exposed to the vacuum. During storage, the measuring electrode was positioned 5 cm above the electret surface. All specimens formed at atmospheric pressure exhibited a homocharge which was maintained throughout the period of observation. The data shown are taken from the negatively charged side of the electret. For graphic clarity, all data are shown as positive numbers. All effects reported in this paper were observed for both surfaces of the electrets.

As is shown in Fig. 1, the effective surface charge ( $Q$ ) of the electret decreased as the pressure was lowered. Below 2.7 Torr, no further changes of  $Q$  occurred as the pressure was lowered to a minimum of 2 × 10<sup>-5</sup> Torr.

Following each sudden drop in the magnitude of  $Q$ , the charge partially recovers. The recovery results from the response of the internal polarization to a de-

crease in the internal field of the electret. The removal of a portion of the surface charge at low pressures causes a reduction in the internal field of the electret thereby allowing a partial decay of the internal polarization. Since the contribution of internal polarization to effective surface charge is opposite in sign to the real charge on the electret surface, the decay of internal polarization appears as a growth of effective surface charge. The response of internal polarization to changes in internal field has been treated phenomenologically by other authors (4-6). A theory of dielectric aftereffect (7, 8) has been applied to the polarization decrease by one of the present authors (9).

There are two apparent explanations for the drop in  $Q$  as a function of pressure. The drops could be due to neutralization of surface charge by ions produced by spark breakdown of the air in the vicinity of the electret. This breakdown could occur in the gap between the measuring electrode and the electret surface or it could possibly occur on the electret surface between regions having different charge intensity. Also, desorption of ions from the electret surface could produce the observed effects.

For experiments in which the dissectible capacitor is used to measure  $Q$  at reduced pressure (as in Fig. 1), the occurrence of spark breakdown between the electret surface and the measuring electrode seems quite feasible. However, the following analysis of the experimental conditions shows that such sparking probably does not occur.

Figure 2 compares a plot of the voltage between the measuring electrode and the electret surface with the voltage required to initiate spark breakdown. The external voltage of the electret was calculated using the expression (3, 10)

$$E_1 = \frac{-Q_1}{\epsilon_1 \left[ \frac{\epsilon(d_1\epsilon_2 + d_2\epsilon_1)}{\epsilon_1\epsilon_2 L} + 1 \right]}$$

where:  $E_1$  = field between the electret surface and the movable induction electrode of the dissectible capacitor (in volts/m);  $Q_1$  = effective surface charge of the electret (in coul/m<sup>2</sup>);  $d_1$  = distance between the electret surface and the induction electrode (in m);  $d_2$  = distance between the electret surface and the stationary electrode (in m).  $d_2$  is taken as 0.01 cm in this calculation;  $L$  = thickness of electret (in m);  $\epsilon$  = permittivity of the electret material (in coul<sup>2</sup>/Newton-m),  $\epsilon_1, \epsilon_2$  = permittivities of the media adjacent to the electret surfaces. In these experiments,  $\epsilon_1 = \epsilon_2 = \epsilon_0$ , where  $\epsilon_0$  is the permittivity of free space.

The voltage ( $V_1$ ) between the electret surface and the induction electrode is given by

$$V_1 = E_1 d_1$$

Fig. 2. Comparison of external voltage of electret and voltage required to initiate spark breakdown. Closest approach of the curves occurs at  $d_1 = 2 \times 10^{-2}$  cm where the difference between voltage required to initiate spark breakdown and electret voltage is 200v.

<sup>1</sup> Cadillac Plastics and Chemical Company, Detroit, Michigan.

<sup>2</sup> Mylar is a registered trademark of E. I. du Pont de Nemours & Company.

The value of  $Q$  is taken from the large charge drop ( $Q$  decreasing from  $3.2 \times 10^{-9}$  coul/cm<sup>2</sup> to  $2.0 \times 10^{-9}$  coul/cm<sup>2</sup>) of Fig. 1. The spark voltage curve is taken from the literature (11) with the assumption that the observed drop in  $Q$  occurred at the minimum pressure of 84 Torr. As Fig. 2 shows, the spark breakdown voltage curve and the electret voltage curve do not intersect for any value of  $d_1$ . Thus no breakdown could occur to produce the observed charge drop. This same analysis was applied to many charge-pressure conditions at which  $Q$  drops were observed, and it was found that the spark voltage curve and the electret voltage curve never intersected.

Another series of experiments showed that the effective surface charge of Mylar and polystyrene electrets decreased with decreasing pressure when the electrets were positioned in the vacuum bell jar in such a way that the distance between the electret surfaces and any conductor ranged from 4.5 to 40 cm. With these separation distances, the external electret field which could act to produce spark breakdown was quite small. The electrets were evacuated to a given pressure, then returned to atmospheric pressure, where the effective surface charge was measured. The charge measurements were made at atmospheric pressure in order to insure that breakdown could not occur during the measurement. Even though the possibility of spark breakdown between the electret surface and a nearby conductor was eliminated in these experiments, the effective surface charge still decreased as a function of pressure. The charge decreased slightly as the pressure was lowered from atmospheric and underwent a large decrease in the pressure range of 1-10 Torr.

The occurrence of spark breakdown between an electret surface and nearby metal depends on the pressure of the surrounding air, the length of the available discharge path, and the magnitude of the external electric field of the electret. The external field in turn depends on the magnitude of the effective surface charge, according to expression [1]. The data shown in Fig. 3 show that the occurrence of the charge drops do not depend on the magnitude of the external field of the electret. These data were obtained from a polystyrene electret formed by application of 140 kv/cm for 4 hr at 105°C. These forming conditions produce a large internal polarization of the electret. On removal of the forming field, the effective surface charge ( $Q$ ) of the unshielded electret initially increased due to relaxation of the internal polarization. When  $Q$  equalled  $4.6 \times 10^{-9}$  coul/cm<sup>2</sup>, the electret was evacuated to 43 Torr and then returned to atmospheric pressure. Measurement of  $Q$  at atmospheric pressure showed that the evacuation had caused a charge drop.  $Q$  resumed its slow increase in magnitude as the electret was held in room atmosphere with its surfaces ex-

Fig. 3. Effect of reduced pressure on effective surface charge of polystyrene electret.

posed. When  $Q$  had grown to  $4.7 \times 10^{-9}$  coul/cm<sup>2</sup>, the bell jar containing the electret was evacuated to 41 Torr, again returned to atmospheric pressure and  $Q$  measured. It was found that the charge had not been affected by the second evacuation. The process was repeated as  $Q$  continued to increase, and no further reduction of the charge was observed until the electret was evacuated to 26 Torr. Evacuation to 26 Torr produced the second charge drop shown in Fig. 3. The process was then continued to lower pressures. If the charge drop on the initial evacuation was due to spark breakdown between the electret surface and nearby conductors, then another charge drop should have occurred on the second evacuation where the external field of the electret was slightly higher and the pressure slightly lower. The fact that no further charge drop was observed until the pressure was lowered to 26 Torr, even though the external field of the electret was continuously increasing, appears to support an ion desorption mechanism for the charge drops. If a desorption mechanism is active, then  $Q$  should not drop on the second evacuation because the initial evacuation would desorb all ions which could be desorbed in that pressure range. According to this theory, further ion desorption did not occur until the pressure was reduced to 26 Torr.

It would be expected that the forming conditions employed for electrets of this paper would produce an uneven distribution of surface charge, thus the charge decreases might be due to spark breakdown between regions of different charge intensity on the electret surface. However, an uneven distribution of surface charge would provide a continuous distribution of possible spark distances, thus for the electret of Fig. 3, for pressures between 43 and 26 Torr, there should exist some distance for which the potential would be sufficient to initiate spark breakdown and thereby cause charge drops. The absence of any indication of charge decrease between the pressures where large charge drops are observed apparently opposes spark breakdown along the electret surface as the source of the charge drops.

Figure 4 depicts the behavior of the effective surface charge when electrets are exposed to gases other than air. Both Mylar and polystyrene electrets were formed in room atmosphere and placed in oxygen, nitrogen, and helium at atmospheric pressure. The results for polystyrene electrets are shown in Fig. 4. The surface charge of Mylar electrets behaved similarly. Exposure of the electrets to oxygen and nitrogen caused small drops in  $Q$ , and exposure to helium caused a more drastic charge decrease. When the electrets were rapidly evacuated to  $10^{-2}$  Torr, the charge dropped further. The potential required to initiate spark breakdown in these gases is less than that required in air. The sparking potential is significantly lower in helium, where for a distance of  $10^{-2}$  cm sparking will occur at a potential of 170v, while in air at atmospheric pressure, 900v are required (11). In view of this, spark

Fig. 4. Effect of oxygen, nitrogen, and helium on effective surface charge of polystyrene electrets.

Fig. 5. Effective surface charge of polystyrene electrets formed in various environments. Forming field: 140 kv/cm for 30 sec at 23°C.

breakdown on the electret surface might account for the initial charge drops of Fig. 4. However, spark breakdown by itself does not adequately explain the later drops in surface charge. One of the authors has proposed a theory of ion desorption to account for the drops in surface charge when electrets are exposed to reduced pressure (9). According to this theory, it appears that ion desorption is a significant contributor to the second charge drops of Fig. 4.

That oxygen, nitrogen, and water are primary sources of electret surface charge is shown by the data of Fig. 5. Here is shown the effective surface charge of polystyrene electrets formed in room atmosphere, dry air, and a vacuum of  $2 \times 10^{-5}$  Torr. Since the charge is less for the electret formed and stored in dry air than for the electret formed and stored at 23% relative humidity, water vapor must be a significant source of the surface charge. Similarly, the low (in fact initially negative) value of charge for the vacuum formed electret shows that the components of air are major sources of surface charge.

### Summary

Experiments reported in this paper yielded the following results:

1. The magnitudes of external fields of the electrets studied are not sufficient to initiate spark breakdown.
2. The occurrence of charge drops does not depend on the distance between the electret surface and nearby conductors.

3. The charge drops are not controlled by the magnitude of the effective surface charge (and hence the external field) of the electret.

4. Charge decreases occur at atmospheric pressure in environments other than air.

5. Oxygen, nitrogen, and water are primary sources of electret surface charge.

The results lead to the conclusion that the decrease in effective surface charge observed when electrets are exposed to low pressure is not the result of spark breakdown between the electret surface and nearby conductors. The data indicate that the charge drops are due to ion desorption. However, the experiments do not definitely distinguish between the mechanisms of ion desorption and spark breakdown on the electret surface as sources of the charge drops. There are apparently no previously reported studies of conditions present in the experiments of this paper, i.e., the room temperature exposure to reduced pressure of a polymer having a significant concentration of gaseous ions on its surfaces. In view of this lack of available information, further investigations are required in order to show the relative importance of the surface breakdown and desorption processes in causing the observed charge decrease.

# Measurement of Quantum Efficiencies of $\text{Eu}^{3+}$ -Activated Phosphors Using Excitation to Selected $\text{Eu}^{3+}$ -Levels

A. Bril, G. Blasse, and J. A. A. Bertens

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

## ABSTRACT

A method to determine the efficiency of the red  $\text{Eu}^{3+}$ -fluorescence of phosphor powders using excitation of the  $^5D_1$ -,  $^5D_2$ -, and  $^5L_7$ -levels is described. These efficiencies were compared with those found with short-wave ultraviolet excitation, in order to study the transfer of the absorbed energy to the europium ion.

The quantum efficiency of a fluorescent substance is generally defined as the ratio of the number of emitted quanta to the number of absorbed exciting quanta, while the radiant efficiency (energy-conversion efficiency) is defined as the ratio of the corresponding radiant powers. The measurement of quantum efficiency is simple in principle but sometimes rather difficult in practice (1, 2)! One of the difficulties in measurement of efficiencies of powders is the determination of the absorption of the exciting radiation. Phosphors such as are used in fluorescent lamps gives the least difficulties because they have both a high light output and a high absorption in the host lattice or in the activators (2). This means that small spurious absorptions (e.g., absorptions in contaminations which do not give rise to fluorescence) play only a minor role. Problems arise when activator absorptions are low in comparison with absorptions of the host or of contaminations. This is the case in the rare earth activated phosphors when they are excited in the narrow energy levels of the rare earth ions themselves.

In this paper a method is described for the measurement of efficiencies of  $\text{Eu}^{3+}$ -activated phosphor powders when excited in the  $^5D_1$ -,  $^5D_2$ -, and  $^5L_7$ -levels (see Fig. 1) which are very narrow (about  $10 \text{ cm}^{-1}$ ) and for which the absorption is only some per cent. (The absorption at the  $^5D_3$ -level is generally too weak, in accordance with the selection rules, for the determination of the efficiency.) It is of interest to determine these efficiencies for phosphors which have a low efficiency under short-wave u.v.- and cathode-ray excitation to see where the exciting energy is lost. Excitation at the  $^5D_0$ -level has not been considered because fluorescence and absorption cannot be easily separated in the case of powders. Moreover, the absorption at the  $^5D_0$ -level is very weak. Measurements of this type with selective excitation at  $\text{Eu}^{3+}$ -levels have been performed for liquids (Eu-chelates) by Dawson, Kropp, and Windsor (3).

## Apparatus and Method

The experiments are carried out by use of a Perkin-Elmer grating spectrophotometer model 13G, which we modified slightly and used in single beam mode. The Nernst filament with mirror was replaced by a tungsten-iodine lamp in combination with a quartz lens, so that more energy was obtained in the short wavelength region. A Bausch and Lomb grating, blazed at 500 nm and with 600 grooves/mm, was used.

The phosphor was placed behind the exit slit (see Fig. 2), so that it was irradiated monochromatically. To reduce stray light to a still lower level a Schott VG 12 filter was placed in the exciting beam, to absorb energy in the longer wavelength region.

Two measurements were carried out for each  $\text{Eu}^{3+}$ -absorption region of every phosphor:

1. The excitation spectrum. The fluorescent radiation emitted by the phosphor was collected and measured

as a function of the exciting wavelength with a photomultiplier tube (EMI, Type 9558 Q), in front of which a filter was placed (4 mm Schott OG 5) which transmitted only the orange and red fluorescent energy while absorbing the exciting energy. A curve of the type given in Fig. 3a was then obtained.

2. The diffuse reflection spectrum. In this measurement only one thing was different from the previous measurement: The OG 5 filter is replaced by a VG 12 filter, which transmitted only the exciting energy and absorbed the fluorescence. Everything else remained the same (lamp current, photomultiplier voltage, etc.). Then the absorption curve as a function of wavelength was obtained, as shown in Fig. 3b.

The width of the peaks in the excitation spectrum are found to be equal to the corresponding peaks in the reflection spectrum. We have described earlier (2) that for powder phosphors the angular distribution of the reflected radiation is the same as that of the fluorescence (nearly Lambertian distribution).

As has been said in the introduction, the radiant efficiency is the ratio of the emitted power and the power absorbed from the exciting radiation. The emitted power is determined by the maximum ordinate  $U_{em}$  of the peak in the excitation spectrum with two corrections: (i) The transmission  $\tau_{OG5}$  of the filter used is not unity and moreover it varies as a function of the wavelength of the emission. (ii) The response  $G(\lambda)$  of the photomultiplier, given in  $\mu\text{a}/\mu\text{w}$ , varies as a function of wavelength. Therefore the total emitted power is

$$E = U_{em} \frac{\int_{em} \rho(\lambda) d\lambda}{\int_{em} \rho(\lambda) G(\lambda) \tau_{OG5}(\lambda) d\lambda}$$

where  $\rho(\lambda) d\lambda$  is the relative emitted power in a region  $d\lambda$  at wavelength  $\lambda$ , derived from the spectral energy distribution curve. The integration has to be extended over the total spectral region of the emission.

Fig. 1. Part of the energy level scheme of the  $\text{Eu}^{3+}$ -ion

Fig. 2. Schematic diagram of experimental arrangement: p.m., photomultiplier; ph, phosphor; and f, filters.

Fig. 3. Relative light output of  $\text{Eu}^{3+}$ -emission (curve a) and diffuse reflection (curve b) as a function of wavelength for  $\text{YVO}_4\text{-Eu}$ . For curve b the zero line is suppressed (the absorption peak has a depth of about 13%).

The radiant energy absorbed from the excited beam is determined by the peak height  $U_{\text{abs}}$  of the diffuse reflection spectrum, corrected in a similar way for (i) the transmission  $\tau_{\text{VG}12}$  of the filter used, and (ii) for the response  $G$  of the photomultiplier in the excitation region. Because the width of the excitation peak is only a few angstrom units, we can take here the transmission and response at the peak wavelength  $\lambda_{\text{exc}}$ . Thus the absorbed power is proportional to

$$A = U_{\text{abs}}/G(\lambda_{\text{exc}}) \cdot \tau_{\text{VG}12}$$

The radiant efficiency  $\eta$  is then determined by

$$\eta = \frac{E}{A} = \frac{U_{\text{em}} \cdot \tau_{\text{VG}12} \cdot G(\lambda_{\text{exc}}) \cdot \int_{\text{em}} \rho(\lambda) d\lambda}{U_{\text{abs}} \cdot \int_{\text{em}} \rho(\lambda) G(\lambda) \tau_{\text{OG}5}(\lambda) d\lambda}$$

The quantum efficiency  $q$  is found by multiplying the radiant efficiency with

$$q/\eta = \frac{\int_{\text{em}} \lambda \rho(\lambda) d\lambda}{\lambda_{\text{exc}} \int_{\text{em}} \rho(\lambda) d\lambda}$$

being the ratio of the energy of the exciting and the emitted quanta. The response of the photomultiplier was determined by comparing its output with that of a photocell calibrated by the National Physical Laboratory in Teddington (England). The spectral energy distributions for most phosphors were measured up to  $\lambda \approx 720$  nm. Those of  $\text{Gd}_2\text{O}_3\text{-Eu}$  and  $\text{YVO}_4\text{-Eu}$  were measured up to 900 nm. We found that the intensities of the  ${}^5D_0 \rightarrow {}^7F_5$  and  ${}^5D_0 \rightarrow {}^7F_6$  lines located in this region were negligible, in accordance with theoretical considerations of Ofelt (4). Therefore we ignored these lines in the case of the other phosphors, too.

The error in this type of measurement will be of the order of 25%. This large error is caused by the very low value of the absorption, as has been already mentioned in the introduction.

## Results and Discussion

When exciting in the  ${}^5D_2$  ( $\lambda = 465$  nm) and  ${}^5D_1$  ( $\lambda = 535$  nm)  $\text{Eu}^{3+}$ -levels quantum efficiencies of about 100% were measured for  $\text{Gd}_2\text{O}_3\text{-Eu}$ ,  $\text{Y}_2\text{O}_3\text{-Eu}$ , and  $\text{YVO}_4\text{-Eu}$  with the method described in the previous section. This is in agreement with the high efficiency figures found for these phosphors when excited with cathode rays or short wave u.v. radiation (quantum efficiency  $q = 70\%$ ) (5). For  $\text{YVO}_4\text{-Eu}$  the spectral energy distributions were measured for excitation with  $\lambda = 525$  nm,  $\lambda = 465$  nm,  $\lambda = 395$  nm and for short wave u.v. radiation ( $\lambda = 254$  nm). No differences between these distributions were found, within the limits of experimental accuracy.

It is assumed that this is valid for all phosphors. The same correction (see previous section) is applied in determining the radiant efficiencies for different excitations. The emission peaks in the regions near 595, 610-620, and 700 nm are all taken into account.

There are other phosphors which have a lower quantum efficiency for short wave u.v. excitation, e.g.  $\text{Y}_{0.8}\text{Eu}_{0.2}\text{Al}_3\text{B}_4\text{O}_{12}$  with  $q = 35\%$ . When excited in the selected  $\text{Eu}^{3+}$ -levels, however,  $\text{Y}_{0.8}\text{Eu}_{0.2}\text{Al}_3\text{B}_4\text{O}_{12}$  and even  $\text{EuAl}_3\text{B}_4\text{O}_{12}$  have a quantum efficiency near 100%.

In the phosphors mentioned above and many others evidently practically no radiationless processes occur from the  ${}^5D_1$  and  ${}^5D_2$  levels.

Excitation in the  ${}^5L_7$ -level ( $\lambda = 395$  nm) gives also quantum efficiencies near 100% in many cases:  $\text{YAl}_3\text{B}_4\text{O}_{12}\text{-Eu}$ ,  $\text{Gd}_2\text{O}_3\text{-Eu}$ ,  $\text{YPO}_4\text{-Eu}$ ,  $\text{YNbO}_4\text{-Eu}$ . However, difficulties arise when the  ${}^5L_7$ -absorption is superimposed on the host lattice absorption or a tail of this absorption, as is the case in substances like  $\text{YVO}_4\text{-Eu}$ ,  $\text{Y}_2\text{WO}_6\text{-Eu}$ , and  $\text{Gd}_2\text{WO}_6\text{-Eu}$  (see the survey spectrum of  $\text{Y}_2\text{WO}_6\text{-Eu}$  in Fig. 4). This curve has not been used for the calculation of the efficiency; for that purpose higher resolved spectra with suppressed zero line are determined as given in Fig. 3). If we take as absorption the area of the narrow absorption peak as is done for the  ${}^5D_2$  and  ${}^5D_1$  absorption (see Fig. 3, the area under the dashed line), apparent efficiencies of about 200% are obtained. Since there is no reason to expect quantum efficiencies higher than 100%, our method seems not to work, if the rare earth absorption coincides with the host lattice absorption. This can be explained at least partly by the fact that the procedure used is not valid in cases where there is considerable absorption in the host lattice: To determine  $U_{\text{abs}}$  of the narrow peak the dashed line, connecting the host lattice reflection at both sides of this peak, is considered as a separation between activator absorption (narrow band) and host lattice absorption. However, following common absorption rules, in the presence of additional absorption, the host lattice cannot absorb as many photons as would be the case without it. Hence the activator absorption, as has been determined in this way, is underestimated leading to quantum efficiency figures which are too high.

An interesting case is the comparison of the efficiencies of  $\text{Gd}_2\text{WO}_6\text{-Eu}$  and  $\text{Y}_2\text{WO}_6\text{-Eu}$ . We found for

Fig. 4. Reflection spectrum of  $Y_2WO_6$ -Eu (survey spectrum with low resolving power).

both phosphors quantum efficiency values near 100%, when they are excited in the selected  $^5D_2$  and  $^5D_1$ -levels. When excited in the broad u.v. excitation band  $Y_2WO_6$ -Eu is a reasonably efficient phosphor ( $q = 55\%$ ), while  $Gd_2WO_6$ -Eu is not ( $q = 10\%$ ). These results are in agreement with our earlier given explanation concerning the different energy transfer efficiency from the host lattice to the  $Eu^{3+}$  centers (7). The transfer from the tungstate group to the  $Eu^{3+}$ -ion is efficient, if the angle Eu-O-W is about  $180^\circ$  as is the

case in  $Y_2WO_6$ -Eu, whereas it is not efficient when this angle is  $90^\circ$  as in  $Gd_2WO_6$ -Eu. Our measurements confirm this difference in energy transfer efficiency, since both phosphors show efficiencies near 100%, when the  $Eu^{3+}$  ions are directly excited in the selected  $^5D_2$  and  $^5D_1$  levels.

The difference between the results of Dawson, Kropp, and Windsor (2) for Eu-chelates and ours for oxides is that we generally find no increase of efficiency from the  $^5L_7$ - to lower excitation levels, whereas they do find such an increase. Apparently the population of the  $^5D_0$ -level from the higher levels is not much different in our phosphors.

#### Acknowledgments

The authors wish to express their thanks to the Reviewer of this Journal for suggesting an explanation for the apparent efficiencies higher than 100%. Further they are greatly indebted to Dr. W. L. Wanmaker and Mr. J. Broos for the preparation of some of the phosphors and to Dr. W. C. Nieuwpoort for stimulating discussions.

Manuscript received Aug. 3, 1967; revised manuscript received Oct. 16, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Kinetics of Hydrolysis of Single Crystal $CaF_2$ from $1000^\circ$ to $1120^\circ C$

D. R. Messier<sup>1</sup>

Argonne National Laboratory, Argonne, Illinois

#### ABSTRACT

The kinetics of the reaction  $CaF_2(s) + H_2O(g) = CaO(s) + 2HF(g)$  were determined on single crystal  $CaF_2$  specimens by a gravimetric technique in the temperature range from  $1000^\circ$  to  $1120^\circ C$  at water vapor partial pressures from 1 to 20 Torr. Parabolic rate behavior was observed; i.e., the reaction rate, which is initially parabolic, eventually becomes linear. The parabolic and linear rates were both found to be dependent on the partial pressure of water vapor. Activation energy values of 63.6 and 38.4 kcal/mole, respectively, were obtained for the parabolic and linear reaction periods. The complexity of the reaction mechanism prohibits assigning the activation energy values to specific processes.

A literature survey reveals considerable interest in the role of oxygen and hydroxyl ion impurities in producing optical effects in calcium fluoride (1-6). Bontinck (1) reported the only measurements which have been made on the kinetics of the hydrolysis of  $CaF_2$ .

He showed that the net reaction responsible for the rapid oxidation of  $CaF_2$  in air at high temperatures is

Bontinck's measurements were made on powder specimens in air containing a low but unspecified partial pressure of water vapor. The present measurements were undertaken to provide kinetic data on single crystal specimens in atmospheres containing known partial pressures of water vapor.

<sup>1</sup>At the time the experimental work was done, the writer was Graduate Research Assistant in the Inorganic Materials Research Division, Lawrence Radiation Laboratory and in the Department of Mineral Technology, University of California at Berkeley. He is now Assistant Ceramic Engineer, Metallurgy Division, Argonne National Laboratory, Argonne, Illinois.

### Experimental Procedure

Specimens were fabricated from single crystal  $\text{CaF}_2$  (Harshaw Chemical Company). Specimen blanks in the form of thin plates were made by cleaving the crystals along parallel [111] planes. The blanks were then diamond-sawed parallel to [110] and [112] planes to form square plates. The plates were ground to their final dimensions in a slurry of 600 mesh silicon carbide and water. Although  $\text{CaF}_2$  reacts readily with water vapor at elevated temperatures, it is unreactive with water at room temperature. The approximate dimensions of the specimens were  $9 \times 9 \times 2$  mm. The dimensions of each specimen were determined to within 0.01 mm with a micrometer.

The kinetics of the hydrolysis reaction were determined by following the weight loss of a specimen as a function of time. The quartz spring weight-loss apparatus that was used is described elsewhere (7).

A run was initiated by heating a specimen to the desired reaction temperature in flowing, dry argon. The reaction was started by introducing water vapor at the desired partial pressure. A gas flow rate of 400 cc/min was used for all of the runs. At the end of a run the atmosphere was again changed to dry argon and the furnace power was shut off.

### Results

Figure 1 is a schematic representation of a typical section from a quenched, reacted specimen. The outer region, labeled zone 1, contained precipitate particles of uniform size and concentration in a transparent matrix. Zone 2 represents the fluorescent region shown by Adler and Kveta (2) to contain dissolved oxygen. Zone 3 contains unreacted  $\text{CaF}_2$ . Under no circumstances was a single phase product layer observed.

X-ray diffraction patterns showed that the precipitate was  $\text{CaO}$ . Although  $\text{Ca}(\text{OH})_2$  is another possible reaction product (4), none was observed.

Figure 2 shows the results of all but two of the reaction runs. The latter duplicate two of the runs shown, and were omitted for the sake of clarity. Figure 2 illustrates the typical parabolic rate behavior that obtained in every run.

Figure 3 shows plots of weight-loss vs. the square root of time for the initial period assuming that a parabolic rate law applies. Although data from four runs at high water vapor pressures were arbitrarily selected for Fig. 3, the fit was equally good for all of the data.

Table I contains the rate data for runs made at various water vapor partial pressures in the temperature range from  $1000^\circ$  to  $1120^\circ\text{C}$ . The parabolic rates,  $R_p$ , were obtained from the slopes of plots of weight loss vs. the square root of time. The linear rates,  $R_l$ , were calculated from the slopes of the linear portions of the weight-loss plots. Both sets of rates were normalized for surface area. The surface area, which was assumed to be equal to the initial surface area, was calculated from measured dimensions.

### Discussion

The results of this and earlier studies (2, 3, 8) indicate that oxygen is highly soluble in  $\text{CaF}_2$  at elevated temperatures. Existing evidence also indicates that oxygen can be substituted for  $\text{F}^-$  as  $\text{O}^{--}$  (with the formation of anion vacancies) (2, 3, 5, 6) and as  $\text{OH}^-$  (3, 4, 6). It is therefore evident that the mechanism of the hydrolysis process is more complex than

Fig. 1. Appearance of the cross section of a typical  $\text{CaF}_2$  specimen after hydrolysis.

was previously thought (1) and that a detailed description of the process requires more experimental data than are presently available. The following discussion attempts to point out some of the complexities involved in the interpretation of the results, and to suggest the existence of possible reaction mechanisms not heretofore considered.

The qualitative observation that the precipitate particles found in quenched specimens in this and a previous investigation (8) were uniform in size and distribution suggests that the precipitate formed only on quenching. If the precipitate had existed at the temperature of reaction, one would expect the precipitate particles to be larger in the region of higher oxygen concentration near the surface of the specimen. One might also expect such a size gradient to result from slower cooling which would allow more time for growth of the precipitate. Indeed, Bruch et al., (5) observed just such a gradient in specimens that were cooled slowly.

If, for the purpose of calculation, it is assumed that all of the oxygen was dissolved as O<sup>2-</sup>, minimum values for the solubility of oxygen in CaF<sub>2</sub> can be estimated from the maximum observed weight losses. These values are in the range from 5 to 20 m/o (mole per cent).

The parabolic rate behavior demonstrated by the curves in Fig. 2 was also observed by Bontinck (1) in experiments on the hydrolysis of CaF<sub>2</sub> powder specimens over a similar temperature range. Bontinck ascribed the parabolic to linear rate transition to saturation of the specimen with oxygen and formation of a precipitate. The present results, however, are inconsistent with this interpretation because they indicate that the transition is dependent on the partial pressure of water vapor, while the solubility limit should be independent of pressure. Furthermore, one would expect the growth of precipitate particles to exhibit nonlinear kinetics (9) instead of the linear kinetics actually observed.

It is evident from Fig. 2 that the extent of reaction at the transition point is dependent on both temperature and water vapor pressure. Unfortunately, the breaks in the curves cannot be established with sufficient precision to deduce quantitative relationships. One can see qualitatively, however, that the transition point weight-loss is inversely proportional to pressure under isothermal conditions, and directly proportional to temperature under isobaric conditions.

Bontinck (1) suggested that the initial stage of the hydrolysis process involved the substitution of OH<sup>-</sup> for F<sup>-</sup> at the crystal surface with the formation of one molecule of HF gas. He also interpreted his measurements as indicating that the OH<sup>-</sup> disappeared after several hours of heating and that the final net reaction was

or

However, Wickersheim and Hanking (4) presented clear evidence that OH<sup>-</sup> exists in the CaF<sub>2</sub> even after prolonged heating. They reported that the OH<sup>-</sup> absorption band at 3650 cm<sup>-1</sup> was at least as strong after 6 hr of heating as it was after 4 hr of heating at 1020°C, and that the disappearance of the peak observed by Bontinck was actually a result of an increase in background. The ESR and EPR measurements of Sierró (3, 6) on gadolinium doped CaF<sub>2</sub> also indicate the presence of OH<sup>-</sup> within CaF<sub>2</sub> crystals after hydrolysis. Sierró's measurements further indicate that OH<sup>-</sup> decomposes within the crystal to form O<sup>2-</sup>. Presumably, the decomposition process results in the formation of anion vacancies and HF along with O<sup>2-</sup>.

The magnitudes of the weight losses obtained in this study indicate that decomposition of OH<sup>-</sup> must be

occurring throughout the course of the reaction. The mere substitution of a hydroxyl ion (M.W. = 17) for a fluoride ion (A.W. = 19) could not account for the large weight changes which were observed.

On the basis of existing data, one can list a number of rate processes that may be involved in the over-all hydrolysis reaction. Some of these are: (i) chemisorption of water vapor and desorption of HF; (ii) surface reaction to form  $\text{OH}^-$  and HF; (iii) surface reaction to form  $\text{O}^{--}$ , anion vacancies and HF; (iv) diffusion of  $\text{O}^{--}$ ,  $\text{OH}^-$ , and anion vacancies into the crystal; (v) diffusion of  $\text{F}^-$  toward the surface by the interstitial mechanism proposed by Ure (10); (vi) internal decomposition of  $\text{OH}^-$  to yield  $\text{O}^{--}$ , anion vacancies, and HF; and (vii) diffusion of HF out of the crystal.

The following discussion deals with the parabolic and linear portions of the reaction with respect to the possible rate-controlling mechanisms listed above.

The parabolic character of the initial reaction period suggests that a diffusion process is rate controlling; if a surface-reaction process were rate controlling, a linear rate law would be observed (11). Interpretation of the parabolic weight-loss rates therefore requires relating the weight loss data to a diffusion coefficient and identifying the diffusing species.

The parabolic rate exhibited a strong dependence on the partial pressure of water vapor with a tendency toward a limiting value at the higher pressures. Similar pressure dependencies have been observed for reactions in which a chemisorption equilibrium step precedes the rate-controlling one. (7, 12). If the rate is assumed to be proportional to the extent of surface coverage by the reacting gas, and if the surface concentration is expressed by the Langmuir adsorption isotherm, the applicable rate expression is (7)

$$-\frac{P}{R_p} = \frac{kT}{k_p K_c \sigma_0} + \frac{P}{k_p \sigma_0} \quad [3]$$

where  $P$  is the partial pressure of water vapor,  $R_p$  is the parabolic reaction rate,  $k$  is Boltzmann's constant,  $T$  is the absolute temperature,  $k_p$  is the parabolic rate constant,  $K_c$  is the chemisorption equilibrium constant, and  $\sigma_0$  is the concentration of reactive surface sites. Equation [3] predicts that a plot of  $P/R_p$  vs.  $P$  should yield a straight line of slope equal to  $1/k_p \sigma_0$ . Figure 4 shows that the parabolic rate data fit Eq. [3].

Fig. 4. Plots of  $P/R_p$  vs.  $P$  according to Eq. [1]

If it is assumed that the parabolic period corresponds to steady-state diffusion in a semi-infinite medium, the applicable rate expression is (13)

$$R_p = \left( \frac{D_i}{\pi t} \right)^{1/2} C_i \quad [4]$$

where  $D_i$  is the diffusion coefficient,  $C_i$  is the concentration per unit volume of the diffusing species adjacent to the surface, and  $t$  is the time. As Eq. [3] was derived from the expression  $R_p = k_p (\sigma/t^{1/2})$ ,  $D_i$  can be related to  $k_p$  by

$$k_p \sigma = (D_i/\pi)^{1/2} C_i \quad [5]$$

When the surface is saturated with chemisorbed water vapor,  $\sigma = \sigma_0$ , and  $C_i$  is the concentration of the diffusing species present at saturation.

Values of  $k_p \sigma_0$  (arbitrary units) were obtained from the reciprocal slopes of the lines given in Fig. 4. It was assumed that  $\sigma_0$  was constant. Figure 5 shows a semilog plot of  $(k_p \sigma_0)^2$  vs.  $1/T$ . According to Eq. [3],  $(k_p \sigma_0)^2$  should be proportional to  $D_i C_i^2$ . If it is assumed that  $D_i = D_0 \exp(\Delta H_D/RT)$ , and  $C_i = C_0 \exp(\Delta H_c/RT)$ , the activation energy obtained from Fig. 5 is the sum of terms for diffusion and carrier concentration. It was calculated that  $(\Delta H_D + 2\Delta H_c) = 63.6$  kcal.

Although, in principle, values for  $K_c$  are obtainable from Fig. 4, the intercepts could not be established with sufficient precision to do so.

An unambiguous identification of the diffusing species is not possible by evaluation of the parabolic rate data. If one assumes that the surface concentration of carriers is independent of temperature, the activation energy of 63.6 kcal/mole obtained here is close to the value of 67 kcal/mole for interstitial diffusion of argon in  $\text{CaF}_2$  obtained by other investigators (14, 15). This correlation would suggest that the interstitial diffusion of HF out of the crystal is rate-controlling. On the other hand, if the diffusion of  $\text{OH}^-$  or  $\text{O}^{--}$  and anion vacancies were rate controlling, one would expect an activation energy close to that for self diffusion of  $\text{F}^-$  in  $\text{CaF}_2$ , i.e., 46 kcal/mole (10, 15, 16). Because the value obtained is a composite one, the latter possibility is not ruled out.

The dependence of the linear reaction rate on the partial pressure of water vapor is clearly different than

Fig. 5. Arrhenius plots of the rate data for the parabolic and linear reaction stages.

Fig. 6.  $R_1$  vs.  $P^{1/2}$  according to Eq. [5]

the dependence of the parabolic rate. As shown in Fig. 6, the linear reaction rate is proportional to the square root of the partial pressure of water vapor. Assuming a rate expression of the form

$$R_1 = k_1 P^{1/2} \quad [6]$$

rate constants were calculated from the lines in Fig. 6. The Arrhenius plot shown in Fig. 5 yielded a value of 38.4 kcal/mole for the apparent activation energy.

The interpretation of the linear reaction period is uncertain. It could correspond to rate control by a surface reaction process of the type given in Eq. [1] and [2], i.e., reaction at the surface to form substituted oxygen and anion vacancies. If such were the case, Eq. [2] indicates that the concentration of dissolved oxygen would be proportional to the square root of

the partial pressure of water vapor. An enthalpy of 38 kcal/mole that was obtained by Mollwo for the formation of F centers in  $\text{CaF}_2$  was quoted by Bontinck (1). It appears, however, that detailed speculation about the mechanism that gives linear kinetics is unwarranted at the present time.

#### Acknowledgments

## Low-Temperature Silicon Epitaxy

R. G. Frieser\*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

#### ABSTRACT

Highly oriented large-area silicon films have been deposited onto single crystal Si,  $\langle 111 \rangle$  substrates. Illumination of the substrates with a mercury vapor lamp during deposition appeared to be essential for obtaining oriented films. The deposition was accomplished by an  $\text{H}_2$  reduction of  $\text{Si}_2\text{Cl}_6$ . The energy of activation for this reaction was found to be 35.7 kcal/mole  $\pm 5\%$ . Utmost chemical cleanliness of the substrate surface is essential and more critical than for high temperature deposition.

The objective of this work was to explore the possibility of growing single crystal films of silicon by a simple chemical vapor phase deposition at temperatures considerably below those presently employed ( $< 900^\circ\text{C}$ ). Such a technique would supplement and extend existing semiconductor technology and would permit the manufacture of devices with properties presently not feasible with existing techniques. The following examples will illustrate these points. Low temperature silicon films would permit formation of abrupt, almost perfect step junctions on silicon, by reducing migration of impurities from the

substrate into the epitaxial layer during formation of the film. Another possibility would be the prevention of junction movements, if such are already present in the substrate, while depositing new semiconductor material. The same technology would permit formation of metal base- or metal gate-transistor structures in one apparatus in a continuous operation. This is not possible at present, because temperatures needed to obtain single crystal silicon are high enough to form silicides, thus destroying the thin ( $\sim 400\text{\AA}$ ) metal layer (base).

*Prior technology.*—Reports of low temperature silicon (Lot Si) deposition in the literature usually

\* Electrochemical Society Active Member.

deal with temperatures of about 850°C (1). These results have been achieved by sputtering, evaporation, or sublimation. A few investigators, however, reported deposition temperatures below 850°C (1-4).

All these techniques involve cumbersome, expensive, and especially sophisticated equipment. For these reasons, such techniques limit the depositions usually to small area films. Deposition rates are quoted as correspondingly slow if mentioned at all.

Therefore, chemical vapor deposition (CVD) seemed to be a more promising technique to achieve the goal of a simple, flexible, open tube, flow process of depositing single crystal silicon at low temperatures. However, no oriented, much less single crystal, silicon films are reported in the literature below 900°-1000°C by CVD (6). The one exception is Nakanuma (7), who deposited silicon epitaxially at 850°C after having deposited a 0.2 $\mu$  layer of silicon at 1200°C. This makes Nakanuma's technique less generally applicable than one wherein the total deposition occurs at the lower temperature.

### Experimental

**Substrate**—Silicon substrates used were <111> oriented, 0.007 ohm-cm, p-type, ~ 3 cm diameter. Conductivity and type were chosen in order to easily measure thickness by infrared spectroscopy and more readily see the junction after angle lapping and staining. Because the source material (Si<sub>2</sub>Cl<sub>6</sub>) was not doped, deposited silicon layers were expected to be n-type, as is usually the case with SiCl<sub>4</sub> or SiHCl<sub>3</sub>.

**Reagents**—Pure line nitrogen was used for flushing the apparatus. Bottled hydrogen was passed through a palladium hydrogen purifier (Surfass Model L-15-D) prior to use. Anhydrous HCl as well as SiHCl<sub>3</sub> (electronic grade purity) were supplied by Pittsburgh Materials and Chemical Company. SiCl<sub>4</sub> used, was obtained from Sylvania and (1%) SiH<sub>4</sub> in H<sub>2</sub> from Matheson Company. Disiliconhexachloride (Si<sub>2</sub>Cl<sub>6</sub>) was supplied by K and K Chemicals.

Si<sub>2</sub>Cl<sub>6</sub> was chosen as the source material for several reasons. This compound has an extended liquid range (-1° to 144°C). Control of the vapor pressure, and, therefore, of the concentration of Si<sub>2</sub>Cl<sub>6</sub> in H<sub>2</sub> carrier gas, becomes simply a matter of controlling the source temperature. If the Si-Si bond remains intact, and there are indications it may (8, 9), and if film growth is by way of a two-dimensional nucleation process (10), then Si<sub>2</sub>Cl<sub>6</sub> may have an advantage over monosilicon compounds as a source material. Furthermore, Si<sub>2</sub>Cl<sub>6</sub> has been reported to be readily decomposed at 450°C to Si, SiCl<sub>4</sub>, and Cl<sub>2</sub> (12). This reaction is presumed to be surface catalyzed.

**Light source**.—To supply other than thermal energy to the substrate, ultraviolet light was a reasonable choice. While it would not increase the deposition temperature, it would aid in the decomposition of the Si<sub>2</sub>Cl<sub>6</sub> molecule. This expectation seemed justified, because u.v. light of 3160Å corresponding to 92 kcal should strip the chlorines from the molecule. The bond energy of the Si-Cl bond is 91 kcal/mole for SiCl<sub>4</sub>. Furthermore, the u.v. illumination may be expected to have an effect on the surface nucleation as well since the energy of 3160Å radiation corresponds to about the work function of Si (4.1 eV = 95 kcal).

A Hanovia Utility Model Lamp (100w) was used as a light source. This lamp employs a U shaped quartz mercury-arc tube. To achieve selectivity of wavelength, a set of 8 monopass u.v. interference filters from Optics Technology were used. These filters covered the range of 230-370 m $\mu$ . Their half width was rated at 6-10% of peak wavelength, transmission at peak was 10-22%. Two additional blocking filters were employed, one blocking u.v., the other visible light.

**System**.—The deposition apparatus was of the conventional upright, one-slice quartz reactor. A silicon pedestal with a molybdenum insert was used in-

stead of graphite to eliminate possible carbon contamination, which could cause spurious nucleation during deposition. Evidence of this has been reported in the literature (10). Deposition temperatures were measured with an Iron IR pyrometer directly on the surface during deposition.

**Substrate preparation**.—Lustro-polished silicon substrates were further subjected to the following routine: The substrates were first degreased in hot organic solvents. To remove any polishing compound embedded in the surface (*i. e.*, alumina, zirconia) the substrates were subjected to a copper displacement plating step and the copper was subsequently removed (11). Since this left a pitted surface, the substrates were chemically polished (5-20 min in 5% HF in HNO<sub>3</sub>) to a smooth mirror finish by removing a total of 3-10 mils from both surfaces. The final thickness of substrates was ~ 8 mils. Immediately after chemical polishing, these substrates were quenched in a solution of anhydrous methanol saturated with iodine (12). The substrates were placed wet in the reactor and iodine was sublimed off at temperatures below 600°C in a stream of H<sub>2</sub>.

HCl etching was performed *in situ* at 1175°C using a 6% (vol.) mixture of anhydrous HCl and H<sub>2</sub>, about 3 mils of material were removed.

All substrates were handled with Teflon tweezers to minimize mechanical damage.

**Characterization**.—Deposited silicon films were characterized visually, electrically and crystallographically. Surface structure and roughness were examined on the Leitz metallograph, or under the Reichert microscope, using a Nomarski polarization interferometer. Occasionally, the surface smoothness was studied using the "Talysurf." Thickness measurements of deposited films were determined either by angle lapping on a 3° block, staining, and using an interference fringe technique (13), or directly by IR spectrophotometry (Beckman, IR 10).

The electrical properties were observed in the customary manner with a four-point and hot-point probe.

Low angle reflection electron diffraction techniques were used to study the degree of orientation of the films.

### Results

Films having a high degree of orientation were achieved when Si<sub>2</sub>Cl<sub>6</sub> was used as a source at a deposition temperature of 700°C in the presence of u.v. illumination. This conclusion was based on reflection electron diffraction studies as shown in Fig. 1a. The films were also evaluated by angle lapping and staining as shown in Fig. 1b. This 3.4 $\mu$  thick film is seen to be well defined and uniform in depth.

Possible evidence that the interface is abrupt is shown in Fig. 2. This picture shows two IR interference fringe curves of Si films of comparable thickness on similar substrates. Their only difference is that one was deposited at 700°C from a Si<sub>2</sub>Cl<sub>6</sub> source in the presence of u.v., the other at 1100°C from SiCl<sub>4</sub> with no illumination. The fact that the Lot Si film shows many more distinct absorption peaks can be interpreted to mean an abrupt "interface" between film and substrate. In the absence of u.v. illumination, the deposition rate is about 1/2 of that with u. v. light (1  $\mu$ /hr) and the resulting films were polycrystalline in nature (Fig. 1c).

**Preferred conditions**.—The above experiments are taken as evidence that highly oriented Si films can be deposited at 700°-800°C under the following conditions: source Si<sub>2</sub>Cl<sub>6</sub>, source temperature 10°C (2 Torr), H<sub>2</sub> flow rate 1.5 l/min, and u. v. illumination of substrate during deposition. All subsequent information will refer to these conditions unless otherwise specified.

Table I summarizes the observations made when using various silicon halides as source materials, such as doped (n- and p-) as well as undoped SiCl<sub>4</sub>,

Fig. 2. Comparison of IR interference fringe measurement of Lot Si film and high temperature deposited silicon film.

$\text{SiHCl}_3$ , and  $\text{SiH}_4$ .  $\text{H}_2$  flow rates and source temperatures were varied to result in a gas stream composition that would correspond (assuming the Si-Si bond breaks) to the preferred concentration of  $\text{Si}_2\text{Cl}_6$ .

A recent report (14) describes single crystal films of Si on Si at temperatures as low as  $740^\circ\text{C}$  using  $\text{SiCl}_4$  as a source (0.6% in  $\text{H}_2$ ) and u.v. illumination. No flow rates were indicated. This experiment was repeated at two flow rates (0.5 and 1.5 l/min), but continuous films were not observed, only occasional isolated crystallites.

Either no deposits at all or polycrystalline films were obtained at deposition temperatures of  $700^\circ\text{C}$  when source material was used containing one Si atom only. At higher temperatures, oriented and single crystal films were obtained as was expected from previous published accounts.

**General appearance of lot Si films.**—The quality of the surface varied greatly; the higher the deposition temperature the greater was the aggregation, and the rougher the final surface. At  $700^\circ\text{C}$ , the surfaces were consistently smooth with a surface roughness of about  $100\text{\AA}$  according to Talysurf measurements (Fig. 1d). The surfaces were metallic and highly reflective,

Table I. Effect of source material on structure of epitaxial films

Source	Dep. temp.	Film Structure	
		With u.v.	No u.v.
$\text{SiCl}_4$	700 900 1000	No dep. No dep. Oriented	
$\text{SiCl}_4$ (n-type)	(5 ppm $\text{AsBr}_3$ ) 700 900 1000 1100	No dep. Polycrystalline Oriented Oriented	Polycrystalline Polycrystalline Single crystal
$\text{SiCl}_4$ (p-type)	(30 ppm $\text{BBr}_3$ ) 1100	Isolated crystals on surface	Single crystal
$\text{SiHCl}_3$	700 1000	No dep. Polycrystalline	No dep. Polycrystalline with some orientation
$\text{SiH}_4$	700	Polycrystalline	Polycrystalline
$\text{Si}_2\text{Cl}_6$	700	Oriented	Polycrystalline

although they showed a milky white, but still specular appearance.

**General information.**—The resistivity of the deposited films varied greatly (from 0.04 to 0.8 ohm-cm). All deposits were found to be n-type. The only exceptions were those which were HCl etched (*in situ*) as a final surface preparation step. These surfaces were all p-type.

Deposition rates, also, varied greatly ( $0.4$ – $2.5 \mu/\text{hr}$ ), but were reasonably constant for each batch of  $\text{Si}_2\text{Cl}_6$  and varied linearly with the deposition temperature (Fig. 3) in the range of  $600^\circ$ – $1000^\circ\text{C}$ . From this data, a tentative activation energy of  $35.7 \text{ kcal/mole} \pm 5\%$  was calculated.

**Substrate predeposition treatment.**—Various substrate treatments prior to deposition under preferred conditions were evaluated by reflection electron diffraction techniques of deposited films. Unbroken diffraction rings were considered evidence of polycrystallinity, segmented rings indicated orientation; the closer the "arc pattern" was to a "spot pattern" the higher the orientation assigned to the film in question. Using these criteria, the following observations were made:

Omission of the copper displacement plating step would invariably result in unequivocal polycrystalline

Fig. 3. Deposition rate vs. deposition temperature of Lot Si films

films, regardless of other surface preparation. Even a final HCl etching step did not prevent the formation of polycrystalline films. This may indicate that particles of polishing compound left behind after chemical or HCl etching still contaminated the surface and were apparently only removed by copper displacement plating. Finishing the substrate preparation with an alcohol quench (without  $I_2$ ) gave ambiguous results; resulting films might be completely polycrystalline or a mixture of oriented and polycrystalline materials. However, when the alcohol was permitted to dry prior to insertion in the reactor, only polycrystalline films were noted. These observations were not changed if the alcohol step (dry or wet) were followed by HCl etching in situ. On the other hand, it appears that a consistently high degree of orientation was obtained free from any polycrystalline material when the substrate was treated in the following manner: copper displacement plating, chemical polishing, quenching in  $I_2$ -saturated methanol, insertion wet in the reactor in an argon atmosphere, and removal of  $I_2$  by heating the substrate to below 600°C ( $\sim 550^\circ\text{C}$ ) in  $H_2$ .

**Effect of Wavelength.**—Using the above surface preparation and the preferred deposition conditions, the best oriented films with no evidence of polycrystallinity were observed when a 230  $m\mu$  narrow band pass filter was employed. Judging by the electron diffraction pictures, the orientation decreased and polycrystallinity increased with an increase in the passing wavelength of the optical filter. Figure 4 shows two representations of reflection electron diffraction pictures of films deposited with the aid of a 230  $m\mu$  filter in one case and, in the other, with the aid of a 360  $m\mu$  filter. The inference from these pictures is that wavelengths below 230  $m\mu$  may even be more advantageous.

### Summary and Conclusions

It is obviously too early to draw any firm conclusions concerning the mechanisms of this reaction. However, certain inferences can be made on the basis of the above work and the following facts emerged:

a. Highly oriented silicon films can be deposited on single crystal silicon substrates at deposition temperatures of  $\sim 650^\circ\text{--}800^\circ\text{C}$  provided u.v. illumination is employed during the deposition and the silicon source is  $Si_2Cl_6$ .

b. Surface treatment of substrates appears to be more critical when depositing at  $700^\circ\text{C}$  than at  $1000^\circ\text{C}$ . Therefore, lapping debris must be removed. Marked improvement in crystalline perfections was obtained by copper displacement plating that was not observed with wet chemical etching or in situ HCl high temperature etching. Elimination of a polishing step using oxides other than  $SiO_2$  should eliminate this problem.

To prevent formation of an oxide layer prior to deposition, quenching the chemically polished substrate in an alcohol solution saturated with  $I_2$  was found to be necessary.

Fig. 4. Reflection electron diffraction pictures of Lot Si films deposited under 230 and 370  $m\mu$  illumination.

c. The relatively large variations in electrical and physical properties expressed in the variation of resistivities and deposition rates indicate that the source material was not sufficiently pure and varied from batch to batch. For this reason, inferences about the kinetics are very tentative.

d. Oriented epitaxial films were obtained only when: (i) the substrate was illuminated (with u. v. light) during the deposition, and (ii) Lot Si oriented films were obtained only when  $Si_2Cl_6$  was used as the source. No deposit was obtained at  $700^\circ\text{C}$  using  $SiCl_4$  or  $SiHCl_3$  sources and only polycrystalline films were obtained using  $SiH_4$  at  $700^\circ\text{C}$ . One might expect that the Si-Si bond (42 kcal/mole) would break easily when illuminated with u. v. light. Yet the dissociation energy for  $Si_2Cl_6$  is reported to be 85 kcal/mole (9). Indications from organic reactions with  $Si_2Cl_6$  are that the Si-Si bond is not as easily broken as one might expect from thermodynamic considerations alone. A large activation energy could account for the observed stability of the Si-Si bond. Steric hindrance of the Cl atoms as well as electronic effect from this ( $p \rightarrow d$ ) $\pi$  bond could account for this high activation energy. It appears then that the Si-Si bond may survive and thus play an important part in the oriented growth of the nuclei.

Furthermore, the effect of the light indicates that the reaction is surface catalyzed. In view of the fact that the energy is almost the same as that of the work function (4.1 eV or 95 kcal/mole) of Si, it appears that this could be further evidence for the surface model for Si proposed by Chung and Haneman (15). The light quanta may indeed draw electrons to the surface and produce a surface which may, for all intents and purposes, appear to the oncoming atoms like a plane through the crystal. In other words, on a statistical basis the effect of the light may be that each surface atom has now a "dangling bond" most of the time as compared to one for every five surface atoms (15). Thus, the oncoming Si atoms do not have to search about for a favorable site, but could stay where they land. If all sites are equivalent, growth is then oriented at all nucleation sites in the same manner.

### Acknowledgments

The author would like to express his appreciation to J. J. Casey, R. P. Auty, and F. W. Anderson for stimulating discussions and for their interpretations of the electron diffraction data. The assistance of T. Horner and C. Sweeney must be acknowledged for their help in the preparation of the epitaxial layers, and the electron diffraction data, respectively. And, finally, thanks are due to W. Bracht for his advice on the substrate preparation.

## Influence of Substrate Temperature on GaAs Epitaxial Deposition Rates

Don W. Shaw

Texas Instruments Incorporated, Dallas, Texas

### ABSTRACT

The effects of substrate temperature on the GaAs deposition rates were studied for {111}A, {112}A, {113}A, {115}, {100}, {113}B, {112}B, and {111}B substrate orientations. An open tube chloride transport system with elemental gallium and arsenic sources was employed. This apparatus allowed independent control over the gallium monochloride, arsenic, and hydrogen chloride partial pressures. The sensitivity of the deposition rate to substrate orientation is observed to be strongly temperature dependent. Experimental evidence is provided which indicates that the deposition rate is kinetically limited in the temperature range from 725° to 800°C.

Recent stress has been placed on improved material quality in order to realize the numerous potential applications for gallium arsenide. At present, vapor phase epitaxial deposition is the most successful method for production of such high quality material. However, continued material improvements have become increasingly difficult due to the need for fundamental information concerning the deposition process itself. In order to partially satisfy this need, a fundamental study concerning the influence of substrate temperature on the GaAs deposition rate was carried out. An investigation of this nature is a logical initial step toward understanding the basic nature of an epitaxial process.

Numerous investigators have studied GaAs epitaxial deposition processes. However, detailed studies concerning the effects of a single variable are rare. Magomedov and Sheftal (1) studied the effect of substrate temperature on the GaAs deposition rate using an open tube iodide process. The deposition rate was found to pass through a maximum as the substrate temperature was raised from 570° up to 690°C. Taylor (2) observed a similar effect with a chloride transport system. In the present study, an effort was made to isolate the substrate temperature as a single variable and study its effect on the deposition rate. The effects of substrate orientation and flow rate on the deposition rate were then related to the rate-temperature data.

### Experimental

The apparatus shown in Fig. 1 was employed throughout the study. It was designed to allow independent control of the partial pressures of the gallium and arsenic species. The arsenic partial pressure was controlled by the flow rate of hydrogen over the elemental arsenic source and the temperature of the source. Transport experiments were carried out to establish empirically the arsenic transport rate as a function of the source temperature and hydrogen flow rate. The results indicated complete saturation of the hydrogen stream with arsenic up to the maximum flow rate studied (300 ml/min). The HCl used for gallium transport was obtained by reduction of AsCl<sub>3</sub>

with hydrogen at a temperature > 900°C. Transport experiments established that one gram atom of gallium was transported for each mole of HCl entering the gallium source chamber. This indicated complete formation of GaCl at the temperature of the gallium source (900°C). Additional experiments established that complete reduction of AsCl<sub>3</sub> occurred in the reduction tube. The arsenic obtained from AsCl<sub>3</sub> reduction was condensed on the reduction tube walls and did not enter the main reaction tube with the HCl. These transport experiments enabled calculation of the initial gallium monochloride partial pressure from the vapor pressure of AsCl<sub>3</sub> at the bubbler temperature and the hydrogen flow rate through the bubbler. The purity of the elemental source materials was rated at 99.9999%. Redistilled arsenic trichloride was utilized. In all of the experiments to be described the initial vapor composition was  $P_{\text{GaCl}}^0 = 7.9 \times 10^{-3}$  atm and  $P_{\text{As}_4}^0 = 3.7 \times 10^{-3}$  atm. Unless otherwise specified, the total flow rate was constant at 0.383 l/min.

Care was taken to prevent extraneous deposition of GaAs on the tube walls between the substrate holder and the source material as well as on the substrate holder itself. Prevention of this deposition was essential because such wall deposits would deplete the gas

Fig. 1. Experimental apparatus for epitaxial deposition

stream of reactants before reaching the substrate region. The wall deposition was prevented by adding HCl to the gas stream. This HCl, which was also obtained by reduction of  $\text{AsCl}_3$ , entered the flush input of the reaction tube and did not react with the gallium source. In all of the experiments the HCl initial partial pressure was  $3.0 \times 10^{-3}$  atm. Since growth occurred only on the GaAs substrate, the deposition process may be treated as a special case of heterogeneous catalysis. However, unlike ordinary heterogeneous catalysis a considerable amount of information concerning the nature of the single crystal catalyst surface is available.

Usually four substrate orientations were simultaneously subjected to deposition in each run. Preliminary experiments established that the deposition rates were independent of the relative positions of the substrates on the holder. The substrates were vapor etched prior to deposition by raising the substrate temperature to  $850^\circ\text{C}$ . All temperatures were controlled to  $\pm 1^\circ\text{C}$ . Initial experiments established that the deposit thicknesses were linear functions of time up to 90 min. Thus 1 hr runs were employed and the rate was computed from the deposit thickness. Thickness measurements for the thicker deposits were obtained from measurement of cleaved cross-sections after the interface was revealed by anodic oxidation. For the thinner specimens angle-lapping and anodic oxidation were employed. The thickness was checked on the angle-lapped samples by interferometry. The reproducibility of the deposition rates for a given set of conditions was approximately 10%.

Chromium doped and tin doped substrates, oriented to within  $0.5^\circ$  of the desired direction, were used in all runs. Generally, with large area substrates growth in the direction perpendicular to the substrate surface is actually the result of the lateral propagation of steps across the surface. These steps may be inherent in the substrate prior to deposition (because of small errors in orientation), or they may result from a two-dimensional nucleation process. Accordingly, in an investigation of chemical transport epitaxial growth, the concept of surface steps must be considered. This may be accomplished by intentionally introducing steps whose nature and number could be resolved theoretically. For example, a  $\{112\}$  GaAs surface may be considered to be composed of  $\{100\}$  unit steps together with twice as many  $\{111\}$  steps (3). Likewise, the  $\{113\}$  surface consists of equal numbers of  $\{100\}$  and  $\{111\}$  steps and the  $\{115\}$  has a  $\{100\}:\{111\}$  ratio of 2:1. Accordingly, a self-consistent series was chosen for study which consisted of  $\{100\}$ ,  $\{115\}$ ,  $\{113\}$ ,  $\{112\}$ , and  $\{111\}$  orientations. However, the polarity of the  $\{111\}$  planes must be considered. Polarity effects should decrease in the order:  $\{111\}$ ,  $\{112\}$ ,  $\{113\}$ , and  $\{115\}$ ; with the  $\{100\}$  surface being essentially nonpolar. Indeed, the  $\{115\}$  was sufficiently nonpolar that no differences were observed in deposition rate between the front and back surfaces of a  $\{115\}$  substrate when both surfaces were polished. The following eight substrate orientations were employed:  $\{111\}$ A,  $\{112\}$ A,  $\{113\}$ A,  $\{115\}$ ,  $\{100\}$ ,  $\{113\}$ B,  $\{112\}$ B,  $\{111\}$ B. The "A" designation indicates the gallium face or the surface terminating in more gallium than arsenic atoms. Arsenic rich surfaces are designated as "B" orientations.

All substrates were polished with sodium hypochlorite on a rotating Pellon cloth in the manner described by Reisman and Rohr (4). After final polishing, the substrate orientation was again checked to determine if any failed to meet the  $0.5^\circ$  misorientation limitation.

### Results and Discussion

Figure 2 shows the results obtained as the temperature is varied at constant vapor composition for  $\{100\}$ ,  $\{115\}$ ,  $\{113\}$ A, and  $\{112\}$ A substrates. The rates for all four orientations increase with increasing temperature up to a maximum at approximately  $800^\circ\text{C}$ . Further in-

Fig. 2. Effect of substrate temperature on the  $\{112\}$ A,  $\{113\}$ A,  $\{115\}$ , and  $\{100\}$  deposition rates.

creases in temperature resulted in sharply reduced deposition rates until etching occurred near  $850^\circ\text{C}$ . The  $\{111\}$ A deposition rate exhibited a similar temperature dependence with the exception that, in general, the rate was much greater than for the other orientations. This dependence is shown in Fig. 3. Finally, the deposition rate variations as a function of temperature for  $\{100\}$ ,  $\{112\}$ B, and  $\{113\}$ B substrates are shown in Fig. 4. The  $\{100\}$  was studied together with the  $\{111\}$ B orientations as well as with the  $\{111\}$ A in order to provide a reference. In addition, this permitted a check on reproducibility of the data, since the B orientations were studied several weeks after completion of the A series. Comparison of Fig. 2 and 4 reveals that similar results were obtained for both experiments. However, good quantitative agreement was obtained only in the low temperature regions before the peaks on the  $\{100\}$  rate-temperature curves. For this reason quantitative comparison of deposition rates between the  $\{111\}$ B and  $\{111\}$ A orientations was limited to the low temperature region ( $725^\circ\text{C}$ ). In general, the B orientations exhibited the same temperature dependence as the A series. The  $\{111\}$ B orientation behaved anomalously in comparison with the others. Its rate never exceeded  $6 \mu/\text{hr}$  over the entire temperature range.

Fig. 3. Effect of substrate temperature on the  $\{111\}$ A deposition rate.

Fig. 4. Effect of substrate temperature on the {113}B, {112}B, and {100} deposition rates.

In the low temperature region before the maximum, the GaAs deposition rate shows a strong orientation dependence. The extent of this effect may be judged from the deposition rates at 750°C as shown in Fig. 5. However, beyond the maxima in the temperature curves, the orientation effects diminish and the curves for all orientations tend to converge. At temperatures below 700°C poor crystal perfection was obvious. However, the higher index orientations had much better surface appearances at these low temperatures. In general, over the entire temperature range from 700° up to 800°C the brightest, most defect-free surfaces were obtained on the {113}A substrates.

The steps involved in nonequilibrium vapor growth processes are generally divided into diffusion and surface reaction steps. Diffusion steps include diffusion of the reactants through the gas up to the substrate surface and diffusion of the products away from the surface. The surface reaction steps consist of adsorption, surface reactions, and desorption. All steps occur in series and if any step is significantly slower than the other steps, it will define the over-all deposition rate. Thus, depending on which is the slow step, deposition processes are often said to be diffusion controlled or surface reaction (kinetically) controlled. In addition to these two divisions, one should also consider a process where the rate is not limited by either a diffusion step or a surface reaction step, but which goes to equilibrium. In this case, the extent of deposition is limited by input rates of the reactants.

Fig. 5. Effect of substrate orientation on the GaAs deposition rate at 750°C.

Diffusion controlled processes are generally encountered where flow conditions are unfavorable or where adsorption-desorption processes and surface reactions are rapid. Such processes ideally exhibit rates relatively insensitive to temperature and thus have low activation energies. In addition, the reaction rates for diffusion-controlled mechanisms are independent of the substrate orientation (5). Kinetically controlled processes have relatively high activation energies. Since the slow steps either involve the substrate surface or take place on it, the over-all rates for kinetically controlled processes should vary with the crystallographic orientation of the surface. Unfortunately, deposition processes are sometimes so complicated that it is difficult to describe a given process in terms of a single rate limiting step.

The wide differences in deposition rates for various orientations indicate that the rates measured in low temperature regions before the maxima in the curves shown in Fig. 2-4 may represent kinetically controlled processes. This conclusion is further supported by the relatively high activation energies deduced from the slopes of the curves in the low temperature regions. These activation energies range from 15-40 kcal/mole which is in the range expected for surface limited kinetics.

Certainly the system is far from equilibrium in the low temperature region. Computer calculations were carried out to determine the extent of deposition as a function of temperature assuming an equilibrium system. The calculations were based on the actual input rates used in the experiments and the following species were considered: GaCl(g), GaCl<sub>3</sub>(g), H<sub>2</sub>(g), As<sub>4</sub>(g), As<sub>2</sub>(g), HCl(g), Cl<sub>2</sub>(g), and GaAs(s). The thermodynamic values were taken from Day's compilation (6). The results are shown in Fig. 6. Over the entire temperature range the equilibrium extent of deposition decreases with increasing temperature. Experimentally, such a rate-temperature dependence is observed only at higher temperatures (Fig. 2-4).

In order to distinguish further diffusion and surface limited kinetics, a series of experiments was carried out to determine the influence of flow rate on the deposition rate. These experiments were carried out at 750°C, i.e., well within the region where the deposition rate increases with increasing substrate temperature. The total flow rate was increased from 210 up to 840 ml/min while the partial pressures of all reactant species were held constant. Since the reaction tube was unchanged, the linear gas stream velocities and the reactant input rates were varied in this experiment. If the deposition rates were limited by a diffusion process, the rates should increase as the gas stream velocity is increased due to a reduction in the thickness of the diffusion boundary. The results are shown

Fig. 6. Calculated extent of deposition as a function of temperature assuming equilibrium.

Fig. 7. Effect of total flow rate on the GaAs deposition rates at 750°C.

in Fig. 7. As is evident, the deposition rate is practically independent of the total flow rate. This is also indicative of a kinetically controlled process. This experiment was repeated for the B type orientations with similar results.

Flow rate independence is a necessary but insufficient condition for elimination of diffusion controlled processes since it could be due to peculiar flow conditions such as poor mixing at high flows (7). However, all available evidence is consistent with the concept of a kinetically controlled deposition process in the region where the deposition rate increases with increasing substrate temperature. This evidence may be summarized as (i) a strong dependence of the deposition rate on the substrate orientation, (ii) rapidly increasing deposition rate with increasing substrate temperature, and (iii) insensitivity of the deposition rate to the total gas flow rate.

The rate behavior in high temperature region beyond the maximum may indicate a close approach to equilibrium. Within experimental error the high temperature regions of the curves approximate the shape of the equilibrium curve (Fig. 6) in this region. However, the decreasing rate at high temperatures could also be due to an activated etching process whose rate increases with increasing temperature and becomes the dominant process at temperatures above 800°C. The fact that the {111}B rate was found to be low and relatively constant over the entire temperature range remains unexplained. One possibility is that an impurity is selectively adsorbed at the critical growth sites on the {111}B surface. Perhaps the answer may be found by a study of the effects of gas composition on epitaxial growth. This study is now in progress.

The variation of the deposition rates as a function of the substrate orientation is interesting. The high {111}A deposition rates attest to the ease of arsenic addition to the growing surface. For an ideal {111}A surface, an incoming arsenic makes fewer surface bonds than with any other orientation. However, this same {111}A surface has the greatest deposition rate for the reactant gas composition used in this study. The decrease in polarity effects is also obvious in this series as the surface deviates by greater amounts from a {111} toward the nearest {100}. Thus the differences between the A and B surfaces at 750°C were {111} = 85  $\mu$ /hr, {112} = 43  $\mu$ /hr, and {113} = 3  $\mu$ /hr. This trend confirms the earlier results which indicated no significant polarity effects for the {115} orientation. The increase in deposition rate in the vicinity of the {113}B orientation on the curve shown in Fig. 5 offers support for Sangster's theoretical predictions (3). Thus {113} is a favorable orientation for crystal growth since it tends to combine the good nucleation characteristics of a {100} with the favorable surface packing and stoichiometry of the {111}. Further clarification of the effects of orientation and surface polarity must await completion of the study concerning the effects of vapor composition on the deposition rate.

#### Acknowledgments

The author wishes to thank Mr. N. Tetlow for supplying the chemical equilibrium computer program used to construct Fig. 6. In addition, the assistance of Mr. D. G. Vieaux with the experimental work is acknowledged. Appreciation is extended to Drs. L. G. Bailey, R. C. Bracken, and G. O. Krause for their helpful suggestions and discussions.

## ABSTRACT

The diffusion of phosphorus into epitaxial silicon has been investigated by evaluating the electrical and structural characteristics of the epitaxial diffused guard-ring junctions. The effects of stacking faults in epitaxial silicon on the junction characteristics were found to depend on the surface condition of the epitaxial layer before diffusion. Localized breakdown, as evidenced by light emission, was observed at the stacking fault grooves only when the epitaxial layer was etched before diffusion. Stacking faults were also found to be transformed into other defects after diffusion; chemical etching of the epitaxial layer also had a great influence on this transformation. Dislocations were observed in the phosphorus-diffused regions. The dislocations occur in hexagonal networks parallel to the diffusion front and come to the surface at the intersection of the junction and the surface in planar devices. Guarded junctions formed by these phosphorus diffusions exhibit localized breakdown with microplasma phenomena. The dislocation density was determined and correlated reasonably well with Prussin's model.

The diffusion technique is used in the further processing of epitaxial silicon for the fabrication of many devices. The diffusion of dopants into silicon crystals to yield high surface concentrations is known to generate dislocations in the crystal (1-8), and a model relating the distribution of dislocations to the diffusion profile has been proposed by Prussin (1). Since other structural defects, such as stacking faults, are frequently present in epitaxial silicon, these defects may undergo transformation during the diffusion process and affect the device performance. In this work, the effects of the diffusion of phosphorus into epitaxial silicon have been studied by evaluating the electrical and structural characteristics of epitaxial diffused planar junctions. The experimental approaches and results are discussed below.

## Experimental

A guard-ring test junction shown in Fig. 1 was used for the study of the effects of phosphorus diffusion into epitaxial silicon. This junction design was first used by Goetzberger *et al.* (9) to evaluate resistivity variations in silicon crystals by observing light patterns associated with the reverse breakdown of fabricated devices. In the guarded junction device the outer or guard junction is diffused more deeply than the main central junction and thus has a higher breakdown voltage. The breakdown voltage of the central junction is not limited by surface breakdown or the cylindrical edge (10-13) of a planar junction. Because of the guard junction, the shallow junction would break down uniformly except for imperfections or localized resistivity variations. For visual observation it is necessary to have the shallow junction near enough to the surface (less than 1  $\mu\text{m}$ ) so that the light generated in the junction is not totally absorbed in the silicon.

Six groups of epitaxial silicon wafers were prepared for the fabrication of planar epitaxial diffused devices by depositing 15  $\mu\text{m}$  of 0.1 ohm-cm p-type epitaxial layers on p-type substrates, as shown in Table I. Dislocation and stacking fault densities were determined by microscopic counts from one Sirtl etched wafer from each epitaxial group. Groups 1, 3, and 5 specimens were prepared under carefully controlled conditions, and the epitaxial layers were essentially free from stacking faults and had a dislocation density similar to that of the substrate. (Groups 1 and 3,

however, were deposited on float-zone substrates and had relatively high dislocation densities.) In the other groups, the mechanical damage generated during the lapping of substrates was intentionally not completely removed, and the epitaxial layers had high concentrations of stacking faults,  $3-6 \times 10^4 \text{ cm}^{-2}$ , and also high dislocation densities. The epitaxial material was diffused without any etching of the silicon, except for Groups 5 and 6 wafers which were etched, prior to diffusion, with the Sirtl etch (14). The Sirtl etch reveals dislocations and stacking faults in epitaxial silicon in the form of pits and grooves, respectively.

The epitaxial wafers were oxidized for 2 hr in wet argon at 1200°C. The oxide thickness was 12,000 Å. A window with an I.D. of 50  $\mu\text{m}$  and an O.D. of 640  $\mu\text{m}$  was opened for the guard-ring diffusion, as shown in Fig. 1. A phosphorus predeposition was done for 30 min at 1000°C in an open-tube system using  $\text{P}_2\text{O}_5$  as a source and nitrogen as a carrier gas. The  $\text{P}_2\text{O}_5$  was removed by boiling in  $\text{H}_2\text{O}$ , leaving the original oxide. A redistribution diffusion of 4 hr at 1200°C was done with the first hour in a wet ambient. This gave guard junctions of 12-13  $\mu\text{m}$  depth.

A window for the main junction was etched with a diameter of 410  $\mu\text{m}$  centered over the guard-ring. A two-step phosphorus diffusion was carried out with the predeposition at 900°C for 30 min and the redistribution in a wet ambient for 20 min at 1000°C. The depth of the main junctions diffused in this way was less than 1  $\mu\text{m}$ . A window for contact to the guarded structure, 130  $\mu\text{m}$  I.D. and 380  $\mu\text{m}$  O.D., was etched, and an aluminum layer was vapor deposited. Aluminum was removed from all areas except in the window and then alloyed at 605°C.

For most examinations a pressure contact was made to the devices with a fine tip probe. Reverse voltage was applied to the junction and the breakdown light observed through a light microscope. In order to obtain smaller working distances and to allow observations at greater magnification, some devices were mounted

on TO-18 headers with gold leads bonded to the aluminum alloyed ring contact.

Replica and thinning techniques of sample preparation for the examination of stacking faults and dislocations by the transmission electron microscope (TEM) method have been described elsewhere (15, 16). Transmission electron micrographs will be referred to as TEM. Specimens for light microscope observation were prepared by dissolving the oxide in HF and etching very lightly (5-10 sec) in Sirtl etch (14). Light micrographs will be designated as LM.

### Results

**Generation of light in reverse breakdown.**—In nearly all of the phosphorus-diffused guarded junctions under reverse breakdown, microplasmas (9, 17) were observed at the periphery of the junction, *i.e.*, the intersection of the shallow  $n^+$  diffusion and the guard junction. This region corresponds to the region labeled A in Fig. 1, and as seen from the figure, occurs inside the step in the surface caused by the oxidation during the redistribution diffusion of the guard junction. These microplasmas can be seen in Fig. 2. In some phosphorus-diffused junctions, the concentration of microplasmas at the periphery was more prevalent than in others. Most junctions had at least a few

Fig. 2. Microplasma from epitaxial, phosphorus-diffused guarded junctions, epitaxial layer not etched before diffusion: (a, top) guarded  $N^+P$  junction with aluminum contact, (b, center) randomly distributed microplasma from a Group 2 wafer, and (c, bottom) microplasma concentrated at the periphery of a junction (region A in Fig. 1) on a Group 1 wafer.

microplasmas in this region. In other devices of Group 1 through 3, microplasmas appeared randomly distributed as shown in Fig. 2(b). The wafers of Groups 1 through 3 all showed microplasmas distributed either randomly or at the periphery as shown in Fig. 2. No pattern characteristic of stacking faults was observed on Group 2 wafers. Again, note that the extent of the breakdown region in Fig. 3(c) is smaller than the step in the silicon surface visible in Fig. 3(a).

Groups 5 and 6 were etched prior to diffusion of the guarded junctions with the Sirtl etch in order to reveal the stacking faults and dislocations. The light emission from the junctions of Group 6 which contained a large number of stacking faults are shown in Fig. 3. Note that the light appears to come from the bottom of the etch groove of the stacking fault and the bottom of the dislocation etch pits. Thus light comes from only part of the stacking fault on the left center and none from the one on the right center. As the reverse voltage was increased, light first appeared in one of the dislocation pits (at B in Fig. 3(b)). Figure 3(c) shows that as the voltage was further increased, light appeared in the other dis-

Fig. 4. Light emission from a device on a Group 4 wafer: (a, top) breakdown generated light with bright field illumination, and (b, bottom) breakdown generated light only. No patterns characteristic of stacking faults were observed.

location pits and the stacking fault groove and finally the microplasma at the periphery appeared.

Figure 3 shows that the light associated with the stacking fault appears to be continuous lines not made up of individual points and is more intense at the apices of the fault. Observations as a function of applied reverse voltage showed that the light appeared at the apices before it appeared in the grooves.

Group 4 wafers which also had a large number of stacking faults and dislocations, but were not etched prior to diffusion, did not show any of the well-defined triangular patterns observed in the Group 6 wafers, but yielded diffusion patterns of light modified by the rough surface structure evident in Fig. 4. The lack of well-defined triangular patterns is also evident in Fig. 2 which shows a device from a Group 2 wafer. Group 2 wafers were not etched prior to diffusion.

*Dislocation generation in the diffusion process.*—Figure 5 shows an alignment cross after diffusion treatment, oxide mask removal in HF, and a short Sirtl etch. Many small pits can be observed in the cross areas as well as in a region approximately 20  $\mu\text{m}$  outside the cross area. In Fig. 6 a network of fine lines can be seen running from the cross area into the surrounding regions protected during diffusion by the oxide mask. These lines always end at a small pit. The cross section and the phosphorus con-

Fig. 5. Alignment cross on a Group 3 wafer after the oxide removal and a 1 min Sirtl etch. Note that the etch figures are concentrated only in and near the phosphorus-diffused areas.

Fig. 6. Schematic cross-section through phosphorus-diffused epitaxial layer shown in Fig. 5. Schematic phosphorus concentration profile is on the right.

centration profile in the double-diffused region is also given schematically in Fig. 6. Region A indicates the undiffused area, region B the area under the oxide mask of the first diffusion treatment which was phosphorus-diffused by the lateral double-diffused area underneath the second oxide mask, and region E the double-diffused area. The surface steps resulted from the oxidation treatment to form the various oxide masks.

After light microscope examination, similar areas on the same wafer were thinned from the substrate side for TEM examination. The maximum thickness of a TEM specimen is indicated in Fig. 6, from which the layers examined by TEM can be deduced. Figure 7 is a TEM from an area close to the outer edge of the alignment cross. Dislocation lines and networks are revealed in the region B, see Fig. 7(a). In the single-diffused region C, see Fig. 7(b), several dislocation networks of varying mesh size appear to be arranged on top of each other, Fig. 7(b). In the TEM of Fig. 7(c), the regions C, D, and E are visible. Clearly, a decrease in the network mesh size in region D can be seen, while remnants of coarse and fine networks are present in the double-diffused region E. The smaller mesh size in region D can be explained by a phosphorus concentration gradient parallel to the layer surface due to lateral diffusion underneath the oxide mask.

*Modification of stacking faults.*—The appearance of a test diode area in the epitaxial layers containing high numbers of stacking faults (Group 4 wafers) after oxide removal and a short Sirtl etch is shown in Fig. 8. Stacking fault triangles can be seen in the undiffused regions. However, in the diffused regions the stacking fault triangles are completely absent. Only a few traces of stacking fault lines in the single-diffused region can be seen, while in the double-diffused regions numerous faint lines oriented along  $\langle 211 \rangle$  directions ending in small etch pits can be seen. The star-like configuration of the lines seen in Fig. 8 are almost exactly the same size as the stacking fault triangles. This suggests a correlation of the stars to the former sites of the stacking fault tetrahedrons. The faint lines may represent the remaining crystallographic defects after a rearrangement in the fault area during the diffusion treatment.

Fig. 7. TEM of various regions shown in Fig. 5 and 6. The letter designations at the right identify the regions labeled in Fig. 6: (a, top) low dislocation density region A, (b, center) note the superposition of networks of different mesh sizes, (c bottom) note the smaller mesh density in region D.

Further evidence of the modification of stacking faults after diffusion is shown in Fig. 9. A phosphorus-diffused epitaxial layer that had been etched prior to diffusion to reveal the stacking fault defects was etched a second time after the diffusion. The initially sharply grooved etch lines became flat-bottomed. In addition, many faint lines were revealed, oriented along  $\langle 211 \rangle$  directions and ending in small pits.

Figure 10(a) is a TEM typical of stacking faults in epitaxial wafers which were not phosphorus-diffused. Figure 10(b) is a TEM of the remnant of a stacking fault in a phosphorus-diffused wafer of Group 4. The banded contrast of Fig. 10(a) and the absence of it in Fig. 10(b) is typical of all the observations. Note that in Fig. 10(b) one of the dislocations of the network generated by phosphorus diffusion is parallel to the stacking fault remnant indicating the possibility of some sort of interaction of the fault and dislocation. A TEM of the bottom of a stacking fault groove of a phosphorus-diffused region of a Group 6 wafer is shown in Fig. 11. The dislocations tend to lie in  $\langle 211 \rangle$  directions which is the same as shown in the LM of Fig. 9.

#### Discussion

In the groups of wafers which were not Sirtl etched before diffusion, microplasmas were observed predominately near the periphery of the guarded diode (at A in Fig. 1). A plausible explanation for these microplasmas is that they occur at dislocations generated during the phosphorus-diffusion of the guard

Fig. 8. LM showing the etch figures of a Group 4 wafer Sirtl etched after the phosphorus diffusion. The stacking fault grooves in the undiffused region and the remnant of a stacking fault (single straight line) in the single-diffused area (region C in Fig. 6) are shown in (a, top); (b, bottom) shows details of a double-diffused area, note fault lines ending in small etch pits often pointing in three  $\langle 211 \rangle$  directions.

Fig. 9. Etch figures in a phosphorus-diffused epitaxial layer, Sirtl etched prior to diffusion. Note the flat-bottomed triangle etch grooves and faint lines in  $\langle 211 \rangle$  directions ending in small etch pits.

junction. The generation of these dislocations could result from the phosphorus diffusion itself, as discussed later in this section, and/or from strain resulting from the difference of coefficient of expansion of Si and  $\text{SiO}_2$  (18). Region A of Fig. 1 corresponds to the boundary between the regions A and B of Fig. 6 where the dislocations are inclined to the surface because the phosphorus gradient of the guard junction diffusion is perpendicular to the surface. Thus these dislocations would intersect the shallow junction and possibly serve as sites for localized breakdown.

Regarding the light associated with the stacking faults and dislocation etch pits of wafers etched before diffusion, one explanation is that breakdown occurs because of the curvature of the junction (10-13) resulting from the surface contouring. Evidence of the effect of etching on surface topography can be seen in Fig. 12. The groove profile was deduced from the contrast effects produced by shadow casting the Si surface with Pd (at an angle of  $45^\circ$ ) prior to the

Fig. 10. (a, top) TEM of stacking faults showing banded contrast typical of undiffused material, (b, bottom) TEM of a remnant of a stacking fault in phosphorus-diffused area of a Group 6 wafer (same as diffraction condition).

Fig. 11. TEM of the bottom of an etch groove of a Group 6 wafer. Note that dislocations tend to be in  $\langle 211 \rangle$  directions. Only the bottom of the groove can be seen because other areas are too thick for electron transmission.

carbon deposition for a replica. This contrast was interpreted as shown in Fig. 13(a) which allowed a determination of the depth of the etch groove. As can be seen from the schematic in Fig. 13(b), the outer slope of the etch groove deviates only slightly from the (111) stacking fault plane, while the inner, heavily faceted slope seems not to correspond to any low-index crystal plane. Sharp lines at the bottom of the grooves are clearly visible, revealing the V-shaped form of the groove.

Since the main junction of the guarded junction is  $1 \mu\text{m}$  or less deep, it can be seen from Fig. 13(b) that the junction will have a small radius of curvature at the bottom of the groove and will consequently have a lower breakdown voltage. It is also apparent from Fig. 12(a) that the curvature of the diffused junction at the intersection of the grooves will be greater than along the grooves themselves. Thus the light from reverse breakdown would appear first and be more intense at these points as was observed in Fig. 3. Queisser and Goetzberger (19) observed light only from the apices of stacking faults. Since in their samples they did not observe light from all apices they conjectured that the breakdown might be due to

Fig. 12. Electron micrograph of a direct carbon replica of a Group 6 wafer showing (a, top) a stacking fault etch groove, and (b, bottom) a dislocation etch pit.

Fig. 13. Profile of a stacking fault etch groove resulting from the Sirtl etch of an epitaxial silicon layer. precipitates such as heavy metals or  $\text{SiO}_2$  at the stair-rod dislocation bundles that exist there. Since the stacking faults were visible in the micrographs of their diodes, the wafers were undoubtedly subject to some etching during the processing and thus breakdown at the apices might occur for the same reasons (i.e., curvature of the junctions) postulated above. On the other hand, in our junctions dislocations were present in the grooves as well as at the apices, and thus precipitation at the dislocations or the dislocations themselves might also be responsible for the preferential breakdown.

The uniformity of the light from the grooves favors the curved junction hypothesis. Further support for this hypothesis comes from the fact that no light emission corresponding to stacking faults was evident in those wafers which were etched prior to diffusion. However, this argument may be partially negated by the difference in the configuration of dislocations gen-

erated in the two types of wafers during the diffusion process (compare Fig. 10 and 11).

We also feel that the curved junction hypothesis is the explanation for the intense light observed at the dislocation pits such as seen in Fig. 3. The curvature of the junction at the bottom of such a pit should be large as is apparent from the replica of a dislocation pit shown in Fig. 12(b).

We do not intend to argue that breakdown cannot occur at dislocations. In fact, it appears likely that the breakdown at the edge of the guarded junctions occurs as a direct or indirect result of the dislocations generated ahead of the phosphorus-diffusion front during the diffusion of the deeper guard junction or at the edge of the oxide window (18). The fact that dislocations occur beyond the extent of the phosphorus diffusion under the oxide can be determined from Fig. 6. In Fig. 3(c) it will be noted that the microplasma which might be associated with these dislocations is less intense and occurs at a higher reverse voltage than the light associated with the dislocation etch pits in the central part of the junction.

The total number of dislocations generated by the two-step phosphorus diffusion shown in Fig. 7 agrees quite well with the model proposed by Prussin (1). Prussin derives a formula for the total number of dislocations  $N$  per unit length in a diffused layer which is given by

$$N = \beta/\alpha [C_s - C(b)] \quad [1]$$

where  $\beta$  is the linear lattice contraction coefficient,  $\alpha$  is the component in  $z$  direction (any arbitrary direction in the plane of the diffusion),  $C$  is the surface concentration of the solute, and  $C(b)$  is the concentration at the point  $b$ , which is a point in the direction of the diffusion at which the strain from the point to the surface is relieved by the generation of dislocations. If as in a TEM examination of a relatively deeply diffused layer we look at a region of thickness  $t$  which is less than  $b$ , then [1] becomes

$$N = \beta/\alpha [C_s - C(t)] \quad [2]$$

The thickness of the specimen examined by TEM lies between 0.5 and 1.0  $\mu$ . We assume that the maximum value of  $t$  in [1] which would influence the generation of dislocations in this layer would be about 1.5  $\mu$ . The diffusion profile calculated from the sheet resistivity junction depth and background resistivity using Irving's (20) curves and assuming a Gaussian distribution is

$$C = 2 \times 10^{20} \exp \left[ \frac{-x^2}{13.8 \mu^2} \right]$$

from which  $C_s - C(1.5\mu) = 3 \times 10^{19}$ . The linear contraction is given by

$$\beta = \left[ 1 - \frac{r_{\text{sol}}}{r_{\text{Si}}} \right] N^{-1} \quad [3]$$

where  $r_{\text{sol}}$  is the radius of the solute,  $r_{\text{Si}}$  is the radius of the silicon, and  $N$  is the atom concentration of silicon ( $5 \times 10^{22}$  atom/cm<sup>3</sup>). Lawrence (7) calculates  $\beta$  using a volumetric contraction or  $\beta = [1 - (r_{\text{sol}}/r_{\text{Si}})^3] N^{-1}$  which appears inconsistent with the model of Prussin. Using Queisser's (2) proposed value of 1.07Å for the radius of the ionized phosphorus donor and 1.17Å for the radius of silicon and [3],  $\beta$  equals  $1.7 \times 10^{-24}$  cm<sup>3</sup>/atom.

Joshi and Wilhelm (5) determined that the dislocations forming regular hexagonal arrays in phosphorus-diffused wafers were almost pure edge type. If we assume the dislocations in Fig. 7 are almost pure edge type and measure the number of dislocations per centimeter ( $N$ ) in a plane perpendicular to the dislocations, then  $\alpha$  is equal to the magnitude of the Burgers vector, or approximately  $4 \times 10^{-8}$  cm.

Substituting the above values of  $\alpha$ ,  $\beta$ , and  $C_s - C(1.5\mu)$  into [2] gives  $N \sim 1 \times 10^3$  dislocations/cm.

In Fig. 7(b) there are 7 lines crossing the line perpendicular to the dislocations which is 10  $\mu$  in length yielding a value of  $7 \times 10^3$  dislocations/cm for  $N$ . The agreement between the measured and calculated values of  $N$  is relatively good considering the approximations involved. Joshi and Wilhelm (5) also found reasonably good correlation between the density of dislocations near the surface and that calculated from Prussin's model.

The fact that there is some sort of transformation of stacking faults in epitaxial layers, both as-grown and Sirtl-etched before diffusion, is evident from the LM and TEM results. The fact that etch grooves were not developed by the Sirtl etch in the as-grown wafers and became flat-bottomed in the previously Sirtl-etched wafers indicates a change in the lattice energy associated with the stacking faults. Further evidence of some rearrangement of the lattice structure is evident from the change in contrast patterns of the stacking fault after phosphorus diffusion as shown in Fig. 10. Further evidence of a relationship between stacking faults and dislocations are the star-like patterns observed in Fig. 8 and the lines perpendicular to the fault sides in Fig. 9.

It has been shown that this transformation takes place only in the phosphorus-diffused regions. Thus it is probable that the transformation is a result of interaction of the stacking faults with the dislocations generated by the phosphorus diffusion. There is some evidence for such a hypothesis in that a dislocation line is parallel to the stacking fault remnant in Fig. 10(b).

We propose the interaction of dislocations and stacking faults and dislocations generated by the phosphorus diffusion as a possibility for the transformation and not as a model. The exact mechanism of the transformation cannot be deduced from this work.

### Summary and Conclusions

1. Microplasmas were observed most frequently near the periphery of the phosphorus-diffused guarded junctions. These microplasmas may have resulted from dislocations generated by the phosphorus diffusion of the guard junction intersecting the shallow-diffused junction.

2. No light from preferential breakdown characteristic of the pattern of stacking faults was observed in wafers which were not etched prior to diffusion. Figure 2(b) is typical of devices on such unetched wafers and shows no triangular patterns.

3. In wafers Sirtl-etched before diffusion, light was observed at the bottom of stacking fault grooves and dislocation etch pits. The preferential breakdown was attributed to the curvature of the shallow junction resulting from the junction following the surface contour.

4. The density of dislocations generated as a result of the mismatch of the atomic radii of phosphorus and silicon and the gradient present from the diffusion process was determined and compared with the model of Prussin. Experimental and calculated values compared favorably.

5. A change in the nature of stacking faults resulting from phosphorus diffusion was observed. From etching results it was concluded that the lattice energy as associated with the fault was decreased or redistributed.

## ABSTRACT

Dislocations have been found to extend for considerable distances outside of planar diffused structures in silicon and to affect the electrical properties of the diffused junctions. The mechanism of dislocation propagation outside of phosphorus-diffused structures has been studied by x-ray diffraction microscopy and other techniques. It is shown that these dislocations are propagated through an anomalously large compressive stress that results from large strains in some high-concentration phosphorus-diffused structures. These strains cannot be attributed to the residual effects of substitutional phosphorus atomic mismatch with the silicon lattice. The anomalous stress and dislocations usually appear after an oxidizing diffusion or drive-in cycle at temperatures less than 1150°C. Also, the dislocations are much less likely to occur in (100) or (110) oriented surfaces as opposed to (111) surfaces.

In the semiconductor industry, impurity diffusion is a very common fabrication process for transistors and diodes. Typical diffusions result in localized lattice strain, which often is relieved through the formation of dislocations and other lattice disorder. Principally, the strain is believed to result from the mismatch between the ionic radius of an impurity atom that is occupying a substitutional site and the covalent radius of the silicon (1, 2). The dislocations usually appear as dislocation networks confined within the diffused structure and often are accompanied by precipitation effects, which may also relieve the crystallographic strain. This type of crystal disorder has been widely studied, particularly for phosphorus and boron as the diffusants, by employing a variety of techniques (3-11). In addition, other investigators have reported that dislocations may propagate outside the diffused areas: both below the diffusion front and, for planar structures, laterally under the oxide diffusion mask (12-16). This latter phenomenon is important in semiconductor device fabrication since these dislocations would extend through the electrical junctions of the devices and have potential deleterious effects on the electrical characteristics of the devices.

There has been some confusion about these "outside" dislocations (*i.e.*, outside the diffusion structure) with respect to (i) their nature, (ii) the mechanism by which they form and propagate, and (iii) the conditions under which they occur. However, recently

these questions have been at least partially clarified and resolved. In an earlier report (16) we presented evidence that the dislocations outside the diffused structure are distinct from and often in addition to the diffusion-induced dislocation networks within the structure and that they nucleate at the boundaries of the planar structures and propagate outward. Also, Schwuttke and Wilhelm (17) have recently confirmed by electron microscopy that the dislocations of the networks within the diffused area bend up to the surface at the planar boundaries and do not extend significantly into the undiffused regions.

The outward propagation of the outside dislocations is by means of macroscopic stress transmitted from the diffused structure. Lawrence (18) has suggested that this stress results from relatively small residual strains not fully relieved by crystal disorder within the diffused area. He further states that, in otherwise unstrained material, the residual strain necessary to nucleate outside dislocations is only realized when the total concentration of diffusant is greater than about  $5 \times 10^{16} \text{ cm}^{-2}$  for both boron and phosphorus. However, Duffy *et al.* (19) have observed these outside dislocations for total concentrations less than  $3 \times 10^{16} \text{ cm}^{-2}$  of phosphorus. Furthermore, recent measurements of lattice contraction by Cohen (20) tend to indicate that the maximum stress in diffused areas, similar to those investigated by both Lawrence and Duffy, is in itself not excessively greater than the yield stress of silicon at elevated temperatures, which is about  $2 \times 10^9 \text{ dynes/cm}^2$ , as estimated from an extrapolation

Key words: semiconductor, silicon, diffusion, dislocations, stress, strain.

\* Electrochemical Society Active Member.

of data of Pearson *et al.* (21) or from the investigations of Patel and Chaudhuri (22).

It would seem improbable that smaller residual strains would generate sufficient stress to nucleate and propagate dislocations to significant distances outside the diffused areas. Joshi *et al.* (23) have reported residual strains in phosphorus-diffused areas of  $\sim 4 \times 10^{-4}$  which would result in stresses that are marginally sufficient for dislocation formation; however, these authors have apparently used total concentrations well above  $5 \times 10^{16} \text{ cm}^{-2}$ . Thus, the conditions and the mechanism by which the dislocations form outside the diffused structure are still unclear, and further study is required.

These outside dislocations, around the periphery of diffused emitters (emitter edge dislocations) have been directly correlated with a reduction in transistor gain ( $\beta$  or  $h_{fe}$ ) (19, 24). In addition, since they extend through the base of a transistor, they may encourage emitter-to-collector shorts, i.e., pipes, through a possible localized dislocation-enhanced diffusion mechanism (25). Also, they may influence the characteristics of the collector junction. Indeed, Loro (26) has reported a collector junction degradation that can be attributed to dislocations extending through the collector junction caused by the emitter diffusion. Finally, for the case of modern integrated circuitry, this type of dislocation may extend from one device or isolation diffusion into another and create potential coupling problems. Therefore, we have further investigated these outside dislocations, principally for boron and phosphorus as diffusants, with emphasis on understanding both the mechanism and the control of their formation. We have studied the nucleation and propagation of these dislocations and their relationship to diffusion conditions, crystal disorder inside the diffused structure, and the macroscopic strains as independently determined. This report describes our investigation.

### Experimental Procedure

Silicon slices were cut from dislocation-free Czochralski or Lopex single crystals, lapped, and chemically polished to remove surface damage and strain. Wafer orientations were mainly (111), but (110) and (100) orientations were used in a few specific experiments; thicknesses were between 0.5 and 1.0 mm.

Both blanket diffusions over entire wafers and planar diffusions using standard oxide masking techniques were performed; masking oxides were grown in steam at  $1000^\circ\text{C}$ . Most diffusions were accomplished by a two-step process consisting of a deposition and a drive-in cycle similar to that reported previously (19, 27). The deposition cycle was  $970^\circ\text{C}$  for phosphorus and  $1100^\circ\text{C}$  for boron; impurity sources were phosphorus oxychloride, phosphorus pentoxide, or diborane; and the ambient was nitrogen with a small amount ( $\sim 1\%$ ) of oxygen. The drive-in cycle was usually  $970^\circ\text{C}$  for  $1\frac{1}{4}$  hr in an oxidizing ambient; however, some experiments were conducted using temperatures of up to  $1200^\circ\text{C}$  with decreasing times. Also, inert ambients were used for a few special experiments. Finally, some diffusions were made using the evacuated capsule technique (28) with a powdered silicon alloy as the source and, generally, with similar times and temperatures as above, though a few such diffusions were made for very long times.

Junction depths were measured by beveling and copper staining, and sheet resistances were measured by a four-point probe. In all cases, the surface concentrations were at, or very near, saturation. An example of a phosphorus profile is shown in Fig. 1. The total concentrations were determined by activation analysis [see ref (19)]; and the electrically active concentrations were determined by incremental sheet resistance measurements (29) and an extrapolation of Irwin's curve to these high concentrations. The electrically active curve is an approximation, since the ac-

Fig. 1. Diffused phosphorus concentration profiles after a drive-in cycle of  $1\frac{1}{4}$  hr at  $970^\circ\text{C}$  in an oxidizing ambient. Total concentrations were determined by activation analysis, and electrically active concentrations were determined by incremental sheet resistance measurements.

Fig. 2. Transmission diffraction contrast around planar diffused structures: a (top), schematic diagram of diffused structure exerting a compressive strain on surrounding crystal; b (bottom), x-ray topograph of similar structure.

curacy of this extrapolation is uncertain; however, it would be safe to say that a significant amount of phosphorus is not electrically active and thus exists in a state other than substitutional, in agreement with pre-

vious investigations (29, 30). It is not possible to discuss strain contribution of a single representative atom because the state of a significant portion of them is unknown.

The crystallographic damage in and around the diffused areas was investigated by x-ray transmission diffraction microscopy, using scanning oscillator technique (SOT) (9) to record topographs of entire wafers, and by transmission electron microscopy (4, 8). SOT topographs were used extensively to study dislocation and precipitation structure in a manner described previously (9, 31) and to analyze strain effects as described in the next paragraph. Electron microscopy was used to examine the crystal structure of the surface layers of some representative samples. Specimens for electron microscopy were chemically thinned from the reverse side to about 2000Å.

Strain effects were determined by the sign of anomalous x-ray diffraction contrast around the boundary discontinuity of planar structures and by the degree of bowing induced in a wafer by a blanket-diffused layer on one side. For the first technique, Howard and Schwuttke (32, 33) have shown that the apparent sign of anomalous transmitted x-ray diffraction contrast (i.e., either dark or light contrast for an anomalously strong or weak diffracted x-ray beam) can be used to determine the direction of lattice plane curvature, which is due to strains. Hence, the nature of anomalous x-ray contrast on SOT topographs can be used to determine the sense of lattice strain. An example is illustrated in Fig. 2a and b in which a diffused structure exerts a compressive strain on the surrounding lattice, bending the lattice planes in the indicated direction. Following Howard and Schwuttke, the diffracted contrast will be high when the diffraction vector  $\bar{g}$  (or a significant component of  $\bar{g}$ ) has the same direction as the radius of curvature of the strained lattice planes, as at point "A," and will result in a black line on the topograph, Fig. 2b. When the direction of  $\bar{g}$  is opposite to the radius of lattice plane curvature, as at point "B," the contrast is low and results in a white line. Therefore, the white-black contrast across the diffused boundaries in the direction of  $\bar{g}$  (Fig. 2b) is indicative of compressive strain around the diffused structure. Similarly a black-white contrast, in the same direction, indicates tensile strain. For the present study, this technique was used to determine the sense of the strain only although, in principle, it could be used for quantitative strain measurements as well.

In addition, the magnitude of the stress in a diffused layer was studied by measuring the degree to which a blanket-diffused layer macroscopically strains a wafer. The bowing of a wafer owing to a very thin diffused layer was determined by measuring wafer curvature before and after the layer was removed, employing a light section microscope and a technique developed by Glang *et al.* (34). The data were interpreted by regarding this diffused layer as a thin film of some other material deposited on the silicon wafer as the substrate and using elastic plate theory to analyze the stress-strain relationships of this system in a manner first used by Stoney (35) for thin deposited metal films, and subsequently improved and used by others for a variety of materials (36). Accordingly, the deflection  $\delta$  of a circular wafer under strain from a thin film is given by

$$\delta = 3 \left( \frac{1 - \nu}{E} \right) \frac{t_f}{t_s^2} \rho^2 \sigma_f \quad [1]$$

where  $E$  and  $\nu$  are Young's modulus and Poisson's ratio of silicon;  $t_f$  and  $t_s$  are the thicknesses of the film and substrate;  $\rho$  is the distance from the center; and  $\sigma_f$  is the stress in the film. Assuming  $t_f \ll t_s$  and following Stoney's analysis, one can relate the maxi-

mum stress in the wafer to the film stress by

$$\sigma_s(\max) = -4 \sigma_f \left( \frac{t_f}{t_s} \right) \quad [2]$$

Equations [1] and [2] can be used to relate deflection to stress in the diffused layer and the wafer. For our application, very thin layers (0.1-0.3 $\mu$ ) were removed by anodic sectioning in order to determine the distribution of stress in the diffused layer. The effective ratio  $t_f/t_s$  was less than  $10^{-3}$ ; and the substrate can be considered as unchanged by the removal of the thin layers. Deflection measurements were taken every 25 mils along a  $\langle 110 \rangle$  and a  $\langle 11\bar{2} \rangle$  diameter of (111) wafers to about 50 mils from an edge. The experimental uncertainty of each deflection measurement is  $\pm 0.5\mu$  (34); and the final uncertainties can be judged accordingly.

## Results

Generally, phosphorus diffusions, in which maximum or near maximum surface concentrations and oxidizing ambients were used, resulted in dislocations outside the planar diffused structure (i.e., outside dislocations) even when the total electrically active phosphorus concentration was  $2 \times 10^{16} \text{ cm}^{-2}$  or a little lower. Their formation was not significantly affected by the presence or absence of the original mask during drive-in. These dislocations have been described in ref. (16); and a detailed analysis of their physical structure will be published elsewhere. They are illustrated by the contrast pattern in Fig. 3a around the boundaries of the planar structures, which are the triangles and the circular area, and also by the relatively straight lines in the electron micrographs, Fig. 3b and c. The abnormal contrast within the planar areas in Fig. 3a and the network pattern at the extreme right of Fig. 3c are due to the normal, interior diffusion-induced dislocations. The occurrence of the outside dislocations can be directly related to the conditions of the process steps, as will be described in more detail later in this section.

The dislocations themselves appear as dislocation loops in the primary slip planes  $\{111\}$ . They extend laterally out into the undiffused regions for distances of  $\sim 300\mu$  and perpendicularly down into the silicon for distances up to  $20\mu$  from the surface as shown in Fig. 4, in which the indicated amounts have been removed by controlling etching. (Note that the diffusion-induced dislocations within the diffused regions are confined to within  $0.5\mu$  of the surface or about 1/3 of the junction depth, in agreement with other investigators.) Therefore, the outside dislocations would extend well through the active regions of a transistor with this type of phosphorus diffusion as the emitter, and they should logically cause potential problems for transistor electrical properties through either a degradation of gain through carrier recombination in the base, poor collector junction quality, or pipes owing to an enhanced diffusion in the dislocation areas. The mode of dislocation propagation was primarily through slip in the plane of diffusion. It is interesting to note that the presence of metallic impurities tended to restrict the outward propagation of the dislocations. Figure 5 shows a topograph and an electron micrograph of outside dislocation loops where an excessive amount of gold was present. The loops appear to be pinned at specific points, presumably by small metallic precipitates that are smaller than the resolution of this micrograph, i.e.,  $< 50\text{Å}$ . A similar phenomenon has been reported by Batavin (37), who found evidence that  $\text{SiO}_2$  particles inhibited the propagation of dislocations outside of boron diffused areas.

Empirically, the presence of the outside dislocations was accompanied by an anomalous macroscopic strain effect associated with the planar diffused structure: in Fig. 3a, the white-black strain pattern across the windows in the direction of  $\bar{g}$  is indicative of a com-

Fig. 4. SOT x-ray topograph of diffused structures similar to Fig. 3 with the following thicknesses of surface removed: a, nothing removed; b,  $0.5\mu$ ; c,  $10.0\mu$ ; d,  $19.0\mu$ .

Fig. 3. High-concentration phosphorus structures; impurity profile and diffusion procedure are similar to that of the example in Fig. 1; triangle side =  $0.5\text{ cm}$ : a (top), SOT x-ray topograph (220) reflection; b (center), electron micrograph of undiffused area about  $60\mu$  from diffusion boundary; c (bottom), electron micrograph of a small section at the planar boundary.

pressive strain surrounding the diffused structure. However, as seen in Fig. 4, areas a and b, the stress switches to tensile when  $0.5\mu$  is removed from the surface. The compressive nature is unexpected since a substitutional phosphorus atom in the silicon lattice has a smaller ionic radius than the silicon covalent radius and should stretch the neighboring covalent bonds, resulting in a tensile strain effect around the periphery.

The actual compressive effect can be seen more clearly in Fig. 6b, which is the topograph of a two-cycle planar diffusion with only a very small amount of oxygen in the ambient of the drive-in cycle

Fig. 5. Phosphorus diffused structures with large amounts of gold added: a (top), x-ray topograph; b (bottom), electron micrograph outside of diffused area.

( $970^\circ\text{C}$ ). Here is a case of stress that is anomalous in sense but not of sufficient degree to cause outside dislocations. Figure 6a is an x-ray topograph of the same structure with the oxide diffusion mask still on the wafer surface, indicating that the oxide mask opposes and, in this case, reverses the resultant strain. This is logical since the strain in a thermally grown oxide mask is compressive (38) and would tend to bend the lattice planes toward the center of a window (opposite to the case illustrated in Fig. 6b). In practice, when the anomalous strain, i.e., compressive, approaches a value sufficient to cause outside dislocations, it dominates over the influence from the mask.

Fig. 6. SOT x-ray topograph of high-concentration phosphorus-diffused structures illustrating anomalous strain effects: a (top), oxide mask on wafer; b (bottom), oxide mask removed.

However, the formation of dislocations reduces its magnitude and may return the strain to a case dominated by the oxide mask; thus, the apparent strain, or stress, may switch sign according to the formation of dislocations or the removal of the mask, giving the effect of "stress jumping" (33).

Conversely, dislocations around boron diffused structures appear only for deep diffusions performed at the higher temperatures ( $1200^{\circ}\text{C}$ ) from maximum surface concentrations regardless of the diffusion technique used. Figure 7a is the SOT topograph of a section of planar boron diffused wafer whose profile is shown in Fig. 7b. The degree of dislocation around the outside is variable. Lesser junction depths, e.g.,  $< 8\mu$  for a similar profile, yield much fewer or no dislocations. The dislocations extend for about the same distances as phosphorus but appear in a variety of forms.

Irrespective of dislocation formation, the strain around boron diffused structures was always tensile, as would be expected, since boron also has a small ionic radius relative to silicon. These dislocations around boron diffused structures were not studied as extensively, but they appear to be caused by tensile stress which may well result from residual strain effects of the substitutional boron atoms when total concentrations greater than  $10^{17}\text{ cm}^{-2}$  are involved.

Finally, the specific relationship of the phosphorus process steps to the anomalous strain will be described in the final paragraphs of this section. First in (111) oriented wafers, after an open-tube deposition cycle only, the macroscopic strain is anomalous in sign, i.e., compressive, but not of sufficient magnitude to cause dislocations, a case similar to that shown in Fig. 6. After an oxidizing drive-in at lower temperatures, at about  $1000^{\circ}\text{C}$ , both dislocation and anomalous strain effects almost always appeared. The degree of stress in these phosphorus diffused layers was determined by measurements of bowing of blanket-diffused wafers,

Fig. 7. a (top), SOT x-ray topograph of high concentration, deep boron diffused planar structure; b (bottom), electrically active impurity profile, total concentration is  $\sim 1.3 \times 10^{17}\text{ cm}^{-2}$ .

whose diffusion utilized this two-cycle process with an oxidizing drive-in at  $970^{\circ}\text{C}$ . The stress was compressive, bowing the wafer down away from the diffused side, in agreement with that indicated by the sign of the x-ray contrast, and the values ranged from  $3\text{--}8 \times 10^9$  dynes/cm $^2$ . This high stress was confined to within about  $0.5\mu$  of the surface, confirming the apparent stress switching in Fig. 4 by the removal of  $0.5\mu$  of surface. Figure 8a shows the actual deflection of one wafer; each deflection value represents the average of two values taken at opposite points, i.e.,  $+\rho$  and  $-\rho$ , in the manner of Glang *et al.* (34). Also shown are "deflection" values taken on an undiffused wafer to illustrate qualitatively the sensitivity for this application. The crystallographic direction, along which the deflection was measured, had no measurable influence. Figure 8b shows stress values on a few wafers as a function of distance from the surface. There is considerable scatter, sometimes even on the same wafer, but the values are generally equal to or greater than  $3 \times 10^9$  dynes/cm $^2$ , above the yield stress of silicon. By way of comparison, stress values in boron diffused layers were around  $1.5 \times 10^9$  dynes/cm $^2$  and were tensile, as expected.

If inhomogeneous precipitation occurred within the phosphorus planar structure, the anomalous strain was less, and the peripheral dislocation loops were much less likely to occur. In particular, if many points of large precipitates appeared within the diffusion, shown

Fig. 8. Data from wafer bowing experiments: a (top), closed circles are deflection values of blanket phosphorus diffused wafer and open circles are similar measurements of an undiffused wafer; b (bottom), stress values as a function of depth in phosphorus diffused wafers.

in Fig. 9 by the points of abnormally high contrast in two of the planar triangles, the peripheral dislocations did not occur; and the macroscopic stress was tensile, in contrast to the normal case without large precipitates. These precipitates normally did not occur if the diffusion system was clean and reasonably careful procedures were employed. They appeared to be nucleated at or near the surface through contaminants or cool areas on the wafer during the deposition cycle. Sheet resistance and junction depth measurements showed that the electrically active phosphorus concentration was not significantly affected by the formation of the large precipitates. Figure 9b is a transmission electron micrograph of a section of one such large precipitate, which is amorphous in structure except for a small portion just outside the main precipitate which appears as platelets oriented parallel to  $\{111\}$  planes. Conversely, electron micrographs of interior areas of the more common planar structures, those that caused compressive strain and outside dislocations, revealed very few visible precipitates of any size. Since all of these high-concentration diffusions contain significant amounts of phosphorus in excess of that which is electrically active, as indicated by Fig. 1 and by the investigations of others (29,30), excess phosphorus in the more common diffused structures must exist either interstitially as single atoms or in small clusters ( $<20\text{\AA}$ ).

In addition, certain modifications in the diffusion procedure could reduce or eliminate the peripheral outside dislocations. These conditions are, in themselves, significant; they are specified here and discussed in the next section. First, the dislocations usually did not occur on wafers oriented in the (100) or (110) plane though the strain was still compressive. Second, if the drive-in cycle utilized a nonoxidizing ambient, strain decreased significantly, sometimes switching to tensile; and the outside dislocations again did not form. Total concentrations were comparable

Fig. 9. Phosphorus planar diffused structures, two of which have large precipitates: a (top), x-ray topograph; b (bottom), electron micrograph of a section of one large precipitate, precipitate is indicated by white area since it dissolved during thinning operation.

to the case of an oxidizing ambient illustrated in Fig. 1 or for the wafer in Fig. 3. Third, if the drive-in cycle was done at higher temperatures ( $1150^{\circ}\text{--}1200^{\circ}\text{C}$ ), regardless of the ambient the dislocations did not form; and the stress was tensile ( $<10^9$  dynes/cm $^2$ ) even for concentrations greater than  $5 \times 10^{16}$  cm $^{-2}$ . Finally the evacuated sealed capsule diffusion process did not produce the outside dislocation loops, except in a few cases where excessively long diffusion times were employed, which yielded junction depths of greater than  $10\mu$ . The strain around all these structures was tensile, similar to the case of boron. However, if a wafer was phosphorus diffused by a capsule technique with high surface concentration and subsequently oxidized at  $1000^{\circ}\text{C}$ , the outside dislocations appeared; and the strain switched to compressive. This did not happen for boron capsule diffused wafers.

### Discussion

First, in order to relate the macroscopic stress measured experimentally in blanket-diffused layers to the stress in undiffused material around planar structures, the stress-strain conditions of the problem, which are illustrated in Fig. 10a, must be considered in some detail. In this way, the stress available for dislocation formation can be estimated and compared with the results.

The surface loading at the sides required to confine the planar structure is represented by  $F'$  in Fig. 10b, and a reactive force  $F$  is exerted on the undiffused material, also at the planar boundaries. The shearing

interaction in the  $x$ - $z$  plane is of lesser degree owing to both the lower value of shearing modulus in silicon and the reduction of coherency across the  $x$ - $z$  plane through the formation of the interior diffusion induced dislocation networks. Thus, the forces at the side boundaries of the planar structure are related to the stress in the film by

$$F' = -F \approx - \int_0^a \sigma_f dy \quad [3]$$

where  $F$  is in units of force per unit length and  $a$  is the effective depth of anomalous stress. In order to find the stresses at a given distance  $r$  from the diffusion boundary, certain limitations of the dimensions can be made in order to simplify the problem. The dimensions of interest are greater than the electrical junction depth and roughly limited by the maximum dislocation propagation. Therefore, the problem can be restricted by

$$\begin{aligned} y_{(\max)} &\approx 20\mu \ll t \\ x_{(\max)} = z_{(\max)} &\approx 200\mu \ll D \\ x_{(\min)} = y_{(\min)} = z_{(\min)} &> 2a \end{aligned} \quad [4]$$

where  $D$  represents the wafer diameter ( $\sim 2$  cm) and  $t$  represents the wafer thickness ( $> 0.5$  mm). Based on these limitations, we can regard the substrate as a semi-infinite body. Now the two-dimensional problem is treated by considering a thin (with respect to  $l$ ) slab at  $z = 0$  and analyzing the stress distribution around the origin, see Fig. 10b. It would be reasonable from inequalities [4] that the shear force can be considered as concentrated at the surface, i.e.,  $a \rightarrow 0$ . With this assumption, the problem is similar to that first solved by Flamant (39), following whom the stress distributions are

$$\begin{aligned} \sigma_x &= - \frac{2F}{\pi} \frac{x^3}{(x^2 + y^2)^2} \\ \sigma_y &= - \frac{2F}{\pi} \frac{xy^2}{(x^2 + y^2)^2} \\ \tau_{xy} &= - \frac{2F}{\pi} \frac{x^2y}{(x^2 + y^2)^2} \end{aligned} \quad [5a]$$

and the maximum shear stress would be given by

$$\tau_{(\max)} = \frac{-F}{\pi} \frac{x}{(x^2 + y^2)} \quad [5b]$$

The applicability of assuming that the force is concentrated at the surface can best be shown by actually considering a distributed stress. This is shown in the Appendix (see Eq. [6]), and it is seen that Eq. [5] can be used to estimate the stresses in the undiffused areas of the silicon when only one edge of the planar structure is near the point of interest, a case that includes the greater portion of the problem. The effects of surface loading at other boundaries can be calculated by superposition of two-dimensional-type solutions. For example, the effect of the planar boundary at the opposite side,  $x = -w$ , is not significant until  $r$  becomes comparable to  $w$ . For  $r > w$ , the stresses fall off more rapidly with distance; and, for  $r \gg w$ , the stresses fall off as  $x^{-2}$  instead of  $x^{-1}$  as would be dictated by Eq. [5]. The effects of surface loading at perpendicular surfaces,  $z = \pm (\frac{1}{2})l$ , are of similar magnitude.

If the reasonable assumption is made that the stresses in the planar structures are similar in magnitude to the stresses in the blanket diffused layers, it is seen that stresses can be above the yield stress of silicon in the neighborhood of the planar boundary and can remain greater than the flow stress (22) for considerable distances into the undiffused areas. It is important to note that precise quantitative comparison is inappropriate in this application, since these dis-

Fig. 10. a (top), Schematic diagram of stress effects from a planar structure; b (bottom), cross section at  $z = 0$ .

locations propagated at elevated temperatures and the stress measurements were made at room temperature. However, it is logical that these anomalous compressive stresses directly cause the deeply penetrating dislocations at the edges of the appropriate phosphorus diffused planar structures. The stresses decrease as the inverse of the distance in the direction of applied force

$$\sigma_x \sim \tau_{(\max)} \sim x^{-1} \quad (x > y = \text{const.})$$

and as the inverse of the distance squared perpendicular to the applied force

$$\sigma_y \sim \tau_{(\max)} \sim y^{-2} \quad (y > x = \text{const.} \neq 0)$$

The distribution of dislocations qualitatively conforms with these relations; dislocations extend considerable distances in both directions but considerably further parallel to the surface, i.e., in the direction of applied force. For smaller diffused structures, the stresses and dislocation distribution fall off more rapidly, as has been confirmed experimentally; but the dislocations still extend well through the base of a transistor with the resulting deleterious effects. The fact that dislocation formation is most favored for (111) oriented wafers as opposed to (100) and (110) is most likely because, for the case of (111) wafers, the applied force is in the plane of the primary slip system.

It is apparent from this investigation that the high stress, which causes dislocations outside of relatively shallow phosphorus emitter type diffusions, cannot result from residual strains from substitutional atomic phosphorus atoms but must result through some other mechanism that is dependent upon procedure. This conclusion might appear to be contradictory to Lawrence's investigation (18); however, it is not: Lawrence studied high temperature ( $1200^\circ\text{C}$ ) diffusions exclusively and, thus, did not consider the dislocations

that are of primary interest in this investigation. It is possible that dislocations outside of deep boron structures are related to residual mismatch strains of substitutional atoms. The measured stress values in boron diffused silicon ( $\sim 1.5 \times 10^9$  dynes/cm<sup>2</sup>) would indicate that sufficient stress might be available.

At this time, the source of the anomalous compressive strain is uncertain; however, it might be speculated that it is related to the phosphorus atoms in excess of the substitutional (see Fig. 1) as is suggested by the requirements of maximum concentrations and an oxidizing ambient. The oxidation of the phosphorus diffused surfaces would even result in a supersaturation of excess phosphorus since the advancing oxide front rejects phosphorus (40). Assuming that the excess phosphorus in this supersaturated state exists interstitially or as very small ( $< 20\text{\AA}$ ) interstitial type clusters, it could dilate the lattice and cause compressive strain around the planar structures. If larger areas of incoherent precipitation exist, these could act as sinks for the excess phosphorus that would otherwise dilate the lattice structure to induce compressive strain and, therefore, result in the expected lower tensile strains and no outside dislocations.

### Summary

An anomalous, compressive macroscopic strain appeared around high concentration (though relatively shallow) phosphorus emitter-type diffused structures when an oxidizing diffusion or drive-in cycle was employed at temperatures less than 1150°C. This compressive stress cannot be due to residual strains from substitutional phosphorus atoms. It was often found to be of sufficient magnitude to cause dislocation nucleation and propagation for significant distances into the undiffused silicon; such dislocations commonly occurred in (111) oriented silicon wafers but were much less likely to occur in (100) and (110). The probability of dislocation formation outside of the diffused areas is significantly reduced if the diffusion or drive-in cycles are performed in an inert ambient or at higher temperatures, i.e., in the neighborhood of 1200°C.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX

We now establish the applicability of regarding the force as concentrated at the surface, and, thereby, the stress distributions [5]. If the magnitude of the stress is assumed constant down to  $a$  where it abruptly drops to zero,  $a$  is still considered small compared to  $r$ ; and the origin is adjusted slightly to

$$(0, -a/2, 0)$$

Then, Flamant's solution becomes

$$\sigma_x = \frac{-2\sigma_f}{\pi} \int_{-a/2}^{+a/2} \frac{x^3}{[x^2 + (y - \zeta)^2]^2} d\zeta \quad [6]$$

with similar expressions for  $\sigma_y$  and  $\tau_{xy}$ .

It is readily seen that Eq. [6] goes quickly to Eq. [5] as  $a$  is allowed to go to zero. For the application of this investigation, the force can be regarded as concentrated at the surface.

We also wish to point out that, with respect to the three-dimensional problem, a more rigorous approach would involve considering a distribution of concentrated point forces acting at the surface of the semi-

infinite substrate and using the principle of superposition, see Timoshenko and Goodier (41). Such solutions are not difficult; but they are long, appear burdensome, and tend to distract from the physical significance of the problem. The requirements of this investigation do not require this degree of rigor.

# Preparation and Properties of Thin Film Boron Nitride

Myron J. Rand\* and James F. Roberts

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

## ABSTRACT

Clear, vitreous films of boron nitride up to 6000Å thick have been deposited on a variety of substrates at 600°-1000°C by a reaction between diborane and ammonia in hydrogen or inert carrier gas. Deposition rate may be readily adjusted to 50-1000 Å/min. Most samples were made at either 600° or 800°, with some attendant variation in film properties. The 600° material contains some residual B-H bonding. The film is essentially amorphous to electron diffraction. The refractive index is 1.7-1.8, the 1 MHz dielectric constant  $\sim 3\frac{1}{2}$ , the dielectric strength  $\sim 5 \times 10^6$  v/cm, and the 25°C resistivity  $\geq 10^{14}$  ohm-cm. The band gap is 3.8 eV and the phonon temperature in the neighborhood of 2000°K. For semiconductor junction protection boron nitride has no advantage over silicon nitride. 600° deposition directly on Si has produced surface charges as low as  $4 \times 10^{11}$ /cm<sup>2</sup>, but there are room-temperature drifts, and high-field conduction also. BN deposited at 800° on Si is electrically similar to silicon nitride. Etching of BN film also presents the same problems as does silicon nitride. BN is not as good a barrier against sodium ion permeation. Attack by atmospheric moisture over a long period has varied from insignificant to extensive conversion to orthoboric acid.

BN film on Si dopes the substrate with boron at temperatures above 900°C in inert ambient. Uniform junction depths are produced. D-C conductivity in 500-4000Å films has been studied from room temperature to 270°C. With fields  $\geq 10^6$  v/cm BN film shows stable, nonohmic conductivity which is independent of polarity. The 25°C d-c conduction is describable over at least seven decades of current by  $J \propto E^n$ ,  $n = 13-15$ , where  $J$  = current density,  $E$  = field strength. The 600°-deposited BN is the more conductive and can carry 0.1 amp/cm<sup>2</sup> indefinitely.  $\log J$  vs.  $E^{1/2}$  at 25° is linear, and the slope of the curve is in good agreement with the theoretical value for a Frenkel-Poole conduction mechanism. Possible use of BN as a thin film varistor is discussed.

The preparation and properties of pyrolytic boron nitride have been reviewed in ref. (1). BN, ordinarily regarded as an insulator, may also be considered a wide band-gap III-V semiconductor, and it displays multiband electro-, photo-, and cathode-ray luminescence (2). The crystal structure is very similar to that of graphite. Data on the pure compound are thus of intrinsic interest for potential electronics uses, but much of the literature on conventional commercial BN is valid only for the particular sample studied because of the oxide impurity and the strong anisotropy resulting from hot-pressing.

There is very little formally published work on thin film boron nitride. Films less than 1 $\mu$  thick have been prepared by Haberecht *et al.* (3) and characterized as capacitor dielectrics. The method used was a low-pressure, static pyrolysis of B-trichloroborazine vapor on a substrate heated to 700°-1400°C. The films were microcrystalline, with a minimal degree of short-range order (so-called "turbostratic") to x-rays. They probably contained residual chlorine. Crystalline films have also been made at Raytheon Company (4) from  $\text{BCl}_3 + \text{NH}_3$  at 1100°-1300°C.

We report here the first results of a study of thin film boron nitride made by vapor deposition from a reaction between diborane and ammonia. This system was chosen because high-purity reactants are available, and because the product should not be contaminated by anything except, possibly, residual bonded hydrogen. Also, a favorable free energy change offers the hope that the reaction will be complete at relatively low temperatures. The over-all reaction is

The reaction occurs in separable steps (5). At room

temperature there is immediate formation of a stable white solid borohydride, the diammoniate of diborane

which at  $\geq 200^\circ$  rearranges to the ring compound  $\text{B}_3\text{N}_3\text{H}_6$  (borazine), and some polymeric material  $(\text{BNH}_2)_n$ . Stronger heating drives off the hydrogen progressively, forming polymeric  $(\text{BNH})_n$  and finally BN.

The results reported here summarize some eighty runs in a single-slice deposition apparatus. The many variables of operation have not been investigated exhaustively, but it is evident that a smooth, transparent, and adherent thin film is obtained reliably over a considerable range of conditions. The potential applications for which the material has been examined include semiconductor surface protection and sodium diffusion barrier, boron diffusion source, and thin film dielectric or varistor. Most films were 1000-6000Å thick.

## Deposition of Thin Film BN

*Apparatus.*—Figure 1 is a simplified schematic diagram of the apparatus. The substrate rests on a molybdenum pedestal which is inductively heated at 3 Mc. The reaction vessel is fused silica; all tubing is stainless steel. An important feature is the mixing of the reactants only after they enter the reactor and the heating of the reactor wall to at least 200°C. This prevents the deposition of the solid borohydride compound and is essential in obtaining a vitreous film. The substrate is heated after establishing the ammonia flow, with the diborane introduced last and turned off first. Without adequate ammonia a smooth film of amorphous boron is deposited. A green color in the burnoff flame is a sensitive indicator of the presence of gaseous boron compounds.

*Deposition conditions.*—The reaction was carried out at 600° to 1080°C, with most of the work at 600°

Key words: Boron nitride, thin films, vapor deposition, conduction, varistors.

\* Electrochemical Society Active Member.

Fig. 1. Schematic diagram of deposition equipment

and 800°. The substrate was usually silicon, but Ta, Mo, Ge, and fused silica were also coated. Film thicknesses were monitored continuously during growth: at 600° simply by color, and at  $\geq 800^\circ$  by measuring emitted light intensity fluctuations at 6000Å caused by interference in the growing film (6). Hydrogen ambient was used most commonly and is preferred at present on the basis of film properties, but the reaction was also successful in nitrogen or helium. For these latter the tank diborane diluent was nitrogen, so that the only hydrogen present was the reaction by-product. Other conditions of operation are given in Table I.

**Rates.**—Observed deposition rates are not true kinetic rates since they vary with transport rate of reactants. Furthermore, there is considerable evidence that there is a reaction at the heated tube wall. Deposition rate is sensitive to the proximity of the wall: in a straight-walled tube the rate is 2-4 times faster than in the slightly bulged tube (see Fig. 1). BN films are more nonuniform than SiO<sub>2</sub> or silicon nitride films made in the same equipment at the same temperature. Furthermore, a freshly cleaned reaction tube depresses the deposition rate. All these observations suggest a reactant, probably borazine, being supplied by a local wall reaction.

The 800° deposition rate is only about 1.5 times faster than the 600° rate, and the 1000° rate is slower than the 800° (probably because of premature reaction at some distance from the substrate). The rate is proportional to the diborane concentration, but the influence of ammonia is anomalous. The ammonia concentration used was at least ten times that of B<sub>2</sub>H<sub>6</sub>, yet in the NH<sub>3</sub>/B<sub>2</sub>H<sub>6</sub> = 10-20 range the rate was sensitive to NH<sub>3</sub> concentration. Furthermore, the proportionality is inverse (more NH<sub>3</sub> decreased the rate, and to a power greater than one). Probably ammonia, or one of its pyrolysis products, acts as a chain terminator for some free-radical mechanism. At any rate, it is evident that the reaction sequence is complicated and that the conditions used are unsuitable for a study of kinetics.

Boron nitride deposition, like silicon nitride deposition from SiH<sub>4</sub> and NH<sub>3</sub>, is much slower in the presence of traces of water vapor. One tank of so-called anhydrous ammonia gave persistent low deposition

Table I. Operating conditions

	Range	Most common
Total flow rate, l/min	0.5-4.5	3.0
Linear velocity, cm/sec	1-10	6.8
$\% \text{ B}_2\text{H}_6$	0.01-0.2	0.04
$\% \text{ NH}_3$	0.4-5	0.7
NH <sub>3</sub> /B <sub>2</sub> H <sub>6</sub>	10-80	17
Deposition rate, Å/min	50-700 (in H <sub>2</sub> or He)	125-600
	200-1900 (in N <sub>2</sub> )	~1000

rates; when it was transferred to another apparatus used for Si<sub>3</sub>N<sub>4</sub> deposition, rates were one-third normal, and tests indicated that the film was actually mostly SiO<sub>2</sub>. This result is typical of the presence of moisture, of the order of 200 ppm.

### Physical Properties of the Film

**Spectra.**—The identification of the deposited film as boron nitride rests primarily on examination by infrared spectra and electron diffraction. Spectra of commercial boron nitrides may be found in ref. (7-9). Our thin-film spectra are shown in Fig. 2. The chief features are a strong asymmetric band near 1380 cm<sup>-1</sup>, undoubtedly the B-N stretch, and a weaker, sharper band near 790 cm<sup>-1</sup>. Both are considerably broader in the film deposited at 600° and shifted to slightly lower frequencies, indicating a more disordered structure on the atomic level. The weak absorption at 3430 cm<sup>-1</sup> is most probably hydroxyl impurity, strongly H-bonded, for example adsorbed molecular water. In addition, the 600° film shows a band at 2500 cm<sup>-1</sup>, the B-H stretching region, and thus contains some residual hydrogen-containing polymeric material.

**Crystallinity.**—Grazing-angle electron diffraction shows broad, diffuse rings whose positions are in agreement with the established pattern for hexagonal boron nitride. From line widths the crystallite sizes (near the surface) are estimated as follows:

Deposition temp, °C	600	800	900	950
Size, Å ( $\pm 15\%$ )	10	20	30	65

The 600° BN film thus has about as much crystalline order as steam-grown silica. The figures above are for hydrogen ambient; films made in nitrogen have a larger crystallite size, but no value more than 80Å has been found for any deposition conditions.

**Band gap.**—No published measurement of the band gap of hexagonal boron nitride could be found. A BN film 0.6μ thick was deposited at 800° on fused silica to study transmission in the 185-750 mμ range. There are no bands in the visible. Absorption commences at about 340 mμ, but the absorption edge is not as sharply defined as for crystalline materials. Figure 3 is a plot of the square root of the absorption coefficient vs. the photon energy. There is a discontinuity in slope similar to those shown by Si and Ge (10). From the two intercepts on the zero absorption axis (11) an energy gap of 3.8 eV is calculated. The phonon temperature is about 2000°K, but the absorption data are not of the precision required for good accuracy in this figure.

**Refractive index.**—Film refractive index, as determined by ellipsometer, varies considerably. Hexagonal BN, with its graphite-like structure, is highly anisotropic; furthermore, the degree of crystallinity varies with deposition temperature. Results below are

Fig. 2. Infrared spectra of boron nitride films deposited at 900°C (upper curve) and 600°C. The curves have been displaced for clarity.

Fig. 3. Macfarlane-Roberts plot of absorption edge of BN deposited at 800°C.

reliable to  $\pm 0.03$ :

Deposition temp. °C	950	900	800	600
Refractive index, 541 $\mu\text{m}$	1.70	1.73	1.75	1.80

These values are for films deposited in hydrogen. Films made in nitrogen at 800° have crystallite sizes like those made in hydrogen at 950°, and correspondingly show  $n \sim 1.70$ .

**Adherence.**—Generally, BN film adherence to the substrate has been entirely satisfactory. An occasional occurrence of peeling during etching indicates that it is not so adherent as deposited silica or silicon nitride. Adherence to Ge substrates, however, was unsatisfactory, possibly because of nitriding. Although film appearance was normal immediately after deposition, if the film was disturbed, *e.g.*, by tweezers, local puckering and reticulation appeared instantly. In the course of a few days this effect spread entirely across the Ge slice.

**Surface properties.**—BN films are quite hydrophobic. Water contact angles from 42° to as high as 80° have been measured, even after many days' exposure to atmospheric moisture.

Film surfaces are quite smooth. Relatively few surface features were visible to 8000X electron microscopy, and even these few were low hillocks rather than fissures or other kinds of film discontinuities.

**Sodium drift and diffusion experiments.**—Tests of the film as a diffusion barrier were carried out with  $^{22}\text{NaCl}$ . Unlike silica films, however, diffusion of sodium in a voltage field and straight thermal diffusion gave very different pictures of the permeability. At 400°C, with the surface bias plate at +4 to +10v (field about  $10^5$  v/cm) for 1 hr, no sodium ion drift was detected in any boron nitride film. No charge storage was detected.

Thermal diffusion profiles are shown in Fig. 4. The data show considerable scatter, but it is immediately evident that deposition temperature influences the result. In the film deposited at 850° the steep drop in Na ion concentration with depth is like that shown by an oxygen-free pyrolytic silicon nitride. Note, however, the single datum point, at 2100Å, which is a decade higher than the previous one and which seems to indicate a pileup of sodium at some sort of barrier, since beyond this point none could be detected. The film structure was examined by step-etching and electron diffraction, and it was found that the crystallite size was  $\sim 30\text{Å}$  at the original surface but decreased with depth; at 2100Å and beyond the film was essentially amorphous, *i.e.*, size  $< 10\text{Å}$ . This correlation between crystallinity and permeability has also been reported recently for silicon nitride films. (12)

Boron nitride deposited at 600° is not a barrier to sodium ion diffusion. All the profiles are relatively flat, even the one for diffusion conditions of 1 hr at 400° instead of 22 hr at 600°.

Fig. 4. Sodium diffusion profiles in boron nitride films: ---○--- 5000Å film deposited at 850°, diffused 22 hr at 600°C in forming gas; —●— 4100Å film deposited at 600°, diffused as before; —△— two samples of a 3100Å film deposited at 600°, diffused as before; —X— 4500Å film deposited at 600°, diffused 1 hr at 400°C in room air.

### Chemical Properties

**Etching.**—Bulk boron nitride is considered highly resistant to all aqueous acids and bases and is slowly attacked by high concentrations of water vapor. Thin film BN behaves similarly. Buffered HF etches at  $< 10$  Å/min. Some samples could be etched at  $\sim 35$  Å/min by 3% hydrogen peroxide at 80°C, but this solution is destructive to conventional etch-resist films. A deposited silica film might be used for masking, but if this method is chosen, one might as well etch with hot phosphoric acid, as is done with silicon nitride (13). Boiling  $\text{H}_3\text{PO}_4$  at 180° etches boron nitride at about 150 Å/min.

A BN film on silicon was exposed to boiling methanol vapor for 1½ hr with no change in appearance, thickness, or film weight ( $\pm 1\%$  sensitivity). This treatment would have dissolved any boric oxide. With a 2-hr exposure to 100° steam or boiling water there was little thickness change, but the film became hazy. Microscopic examination revealed numerous shallow blisters or craters, with film fragments curled back at the edges, as if lateral attack (or separation of laminae) were the chief effect.

**Anodization.**—Since BN film is difficult to etch, several attempts to convert it to the oxide by anodization (14) were made. All failed because the film peeled from the substrate. This is further evidence that boron nitride adherence is not so tight as that of silicon nitride.

**Silicon doping.**—From free energy data one would predict that silicon may reduce boron nitride to boron and form  $\text{Si}_3\text{N}_4$ . In other words, if BN is deposited on Si at temperatures at which diffusion rates of boron in Si are significant, the substrate may be doped. This does indeed occur: with deposition at 900° and above, the rather flat capacitance-voltage traces invariably obtained in MIS measurements indicated plainly that the substrate surface was low-resistivity p-type.

Figure 5 shows results of two experiments on deliberate doping of 4 ohm-cm n-type silicon from a BN

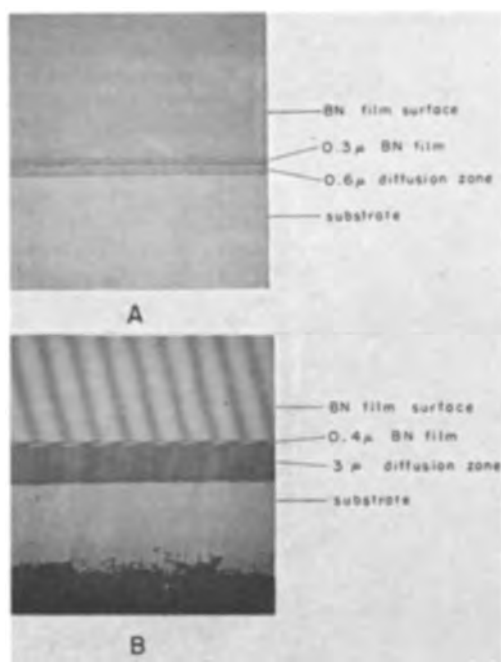

Fig. 5. Angle-lapped and stained sections showing use of boron nitride film as a diffusion source. (A) 1½ hr in nitrogen, 1100°, (B) 2 hr, 1150° helium.

film source. The upper picture is the angle-lapped and stained interface after 1½ hr in nitrogen at 1100°C; for the lower, 2 hr at 1150° in helium. Junction depths are quite uniform. There was little change in the appearance of the deposited film.

Boron nitride film should thus be useful as a restricted area boron diffusion source. The diffusion should be carried out in inert ambient; any water or oxygen present would convert the nitride to the oxide, and the high vapor pressure of the oxide would result in some doping outside the desired area. As a solid diffusion source BN has the advantages of thermal stability, constant composition, and simplicity of deposition compared to B<sub>2</sub>O<sub>3</sub>-SiO<sub>2</sub> codeposits.

**Weathering phenomena.**—It has already been mentioned that boron nitride, in both massive and thin film form, is slowly attacked by water vapor. Thus there are grounds for concern about BN film stability with prolonged exposure to the atmosphere. Indeed, changes with time are observed; these appear to depend on the conditions of deposition, and probably on other factors as well. They range from the trivial to the catastrophic.

A freshly deposited BN film is not as hard as SiO<sub>2</sub> or Si<sub>3</sub>N<sub>4</sub>, but it is not readily scratched by stainless steel tweezer tips. It will remain this way indefinitely if stored in a desiccator. If stored in room ambient, it will become soft enough to scratch in a few weeks. A broad, shallow absorption band develops near 3300 cm<sup>-1</sup> in the spectrum; this is hydrogen-bonded hydroxyl, and indicates adsorption or absorption of molecular water. There are no other significant spectrum changes.

Some specimens have shown a much more serious form of attack, whose manifestation is the appearance of single-crystal boric acid (identified by electron diffraction) growing out of the film surface. A particularly severe example is shown in Fig. 6. B<sub>2</sub>O<sub>3</sub> and HBO<sub>2</sub> are probably intermediates, judging by the behavior during heating and cooling cycles. Such extensive hydrolytic attack is seldom seen in films deposited in hydrogen at 600°. Perhaps one in four of the 800° films eventually showed a few crystals. But almost all the films made in inert ambient, nitrogen or helium, developed serious cases of the boric acid pox, some in only one or two weeks. For this reason the deposition

Fig. 6. Boric acid crystals growing from a boron nitride film made in nitrogen at 670°, after 5 months exposure to room atmosphere. Magnification ca. 150X.

of films in inert ambient was not pursued, even though it should produce a purer product. The presence of residual bonded hydrogen seems to be associated with BN film resistance to water attack.

### Electrical Properties

**Surface charge.**—Most of the BN films were deposited on silicon, and a number of samples of MIS capacitor structures were made by evaporating 10 mil diameter Al field plates onto the film. Adherence of the Al was normal. In some cases the substrate was oxidized in steam at 1000° to provide a 1000Å SiO<sub>2</sub> layer under the nitride deposited afterwards. A summary of the MIS results appears in Table II.

Films deposited on bare Si in hydrogen at or above 800°C behave electrically like those of silica or silicon nitride in showing the so-called anomalous shift as the bias range is increased in the negative direction, and also in showing hysteresis loops as the scan is retraced. The interfacial surface charge was high, in the 2-5x10<sup>12</sup> range.

BN deposited over SiO<sub>2</sub> gave C-V traces which shifted with time as though some sort of slow polarization or structural alteration were occurring at room temperature. A similar effect has been observed with thick phosphorus-glass layers on SiO<sub>2</sub> (15), and also on lead glass (16), but only at elevated temperatures. On one sample measurements of the flat-band voltage shift as a function of field-plate voltage and time were made. The extent of shift was the same when the sample was held at +25 or -25v, although of course the directions were opposite. At a given voltage the shift was linear with log time, at least up to 2 hr.

Table II. Summary of MIS measurements (measuring frequency = 1 MHz)

Dep'n temp, °C	Ambient	Substrate	Capacitors	Surface charge density (× 10 <sup>-11</sup> cm <sup>-2</sup> )	Comments
900	H <sub>2</sub>	SiO <sub>2</sub> /Si	3	5.3-6.9	Shifts with time
850	H <sub>2</sub>	Si	4	23-25	Normal curve
800	H <sub>2</sub>	Si	20	32-52	Normal curve

800	N <sub>2</sub>	Si	5	7.5-8	Anomalous behavior, see text
800	He	Si	3	4	Conduction; capacity drift
600	H <sub>2</sub>	Si	16	4-8	
600	H <sub>2</sub>	SiO <sub>2</sub> /Si	6	6.4-6.9	Shifts with time
	H <sub>2</sub>	fast states*	2	1.0-1.1	

\* By the technique of ref. (25).

The sample deposited on bare Si in nitrogen exhibited a different sort of anomaly. Scans from 0 to  $-15\text{v}$  looked normal, but at higher negative voltages the insulator capacitance decreased. After stress at  $30\text{v}$  or more a pronounced knee appeared in the step of the C-V trace, and the capacitance had decreased by 20%. These effects may be due to film conductivity. The same sample measured two months later, after boric acid crystals had appeared, was highly conducting at  $1\text{v}$ . The inert-ambient deposits did have low surface charges, as Table II indicates, but because of susceptibility to hydrolysis they were not further investigated.

BN deposited in hydrogen on bare Si at  $600^\circ$  was also in the  $4\text{-}8 \times 10^{11}$  surface charge range, but here the evidence of high conductivity was pronounced; the samples could not be measured on a capacitance bridge, and required a capacitance meter such as the Boonton Model 71A. A typical C-V curve for these samples is shown in Fig. 7. The usual limiting insulator capacitance does not seem to be reached. (The curves finally do level off at about  $-40\text{v}$ , however.) Some upward drift of capacitance is seen at constant large negative bias.

**Dielectric constant.**—On conducting samples like those just described no accurate dielectric constant can be determined. For  $800\text{-}1800\text{\AA}$  BN deposited at  $800^\circ\text{C}$  on Si some twenty measurements on three different samples at  $1\text{ MHz}$  gave  $K = 3.7 \pm 0.3$  (range).

**Dielectric strength.**—The "room temperature" breakdown strength of BN deposited at  $800^\circ$  is  $6 \times 10^6\text{ v/cm}$ , and of the film deposited at  $600^\circ$ ,  $4 \times 10^6\text{ v/cm}$ . These values are probably low because of resistive heating of the film by high-field conduction. This property, which is shown to a surprising degree for a material ordinarily considered an insulator, is perhaps the most interesting feature of these films, and is discussed in detail in the next section.

### Nonohmic Conductivity

Recently there have been reports of high-field nonohmic d-c conductivity in thin films of silicon nitride made by the  $\text{SiH}_4\text{-NH}_3$  process (17), the  $\text{SiCl}_4\text{-NH}_3$  process (18, 19), and by reactive sputtering (20, 21). Evaporated  $\text{SiO}_x$  insulating films also show the phenomenon (22). Conductivity depends strongly on conditions of film deposition, and there are conflicting results on whether it is polarity-dependent. Various conduction mechanisms have been proposed, particularly the Frenkel-Poole and Schottky types. Obviously, present knowledge is fragmentary, but at any rate it seems to be widely known that silicon nitride films can pass considerable current (by semiconductor standards) without destruction, and thus have a built-in protection against occasional overload.

Thin film boron nitride, as described here, also shows stable, strongly nonohmic high-field conductivity, to such an extent that films of  $1000\text{\AA}$  or thinner may be useful in integrated circuits as thin varistors or voltage-limiters. As with the other films, the conduc-

Fig. 7. Typical MIS curve for BN deposited at  $600^\circ\text{C}$  on Si

tivity depends on deposition conditions, particularly the deposition temperature, and thus must be governed largely by the structure of the film. The effects of thickness, electrode material and area, polarity, and temperature were also examined and are summarized below.

**Method of measurement.**—The voltage source was a bank of dry cells discharging through a  $20\text{K}$  potentiometer which allowed selection of any appropriate applied potential over the range  $0\text{-}500\text{v}$ . This potential was read on a Keithley 610B electrometer. The current in the sample circuit was read on a Keithley 414 micromicroammeter. A 1-megohm resistor in the measuring circuit protected the instruments against surges caused by sample breakdown. For conductivity work the film samples were deposited on  $0.001\text{ ohm-cm}$  n-type silicon and an array of 10 and 20-mil aluminum or gold electrodes applied by evaporation through a mask. The back of the Si slice was coated with evaporated gold. The sample was mounted in a micrometer-drive positioner and the electrode dots contacted with a 7-mil brass probe.

For measurements at elevated temperatures the Si slice was scribed and broken into chips containing two dots each. After a brief ultrasonic cleaning to remove scribing debris the chips were mounted on TO-18 headers and gold wire bonded to the electrode. Conventional mounting and bonding techniques and temperatures had no adverse effect on the BN films. The assembly was mounted in a small copper oven and measurements taken at various temperatures between  $75^\circ$  and  $270^\circ\text{C}$ .

Measurements were always made by scanning the current-voltage curve several times with both increasing and decreasing voltages, and frequently points were taken out of sequence. The first application of high field caused a permanent decrease in resistance; thereafter the samples were quite stable. For this reason each sample was aged ("formed," in the language of some authors) at  $10^{-1}\text{-}10^{-2}\text{ amp/cm}^2$  for a few minutes before the measurements were begun.

At no time was any emission of light observed.

**Effect of certain parameters.**—Film deposition temperature has a strong effect on conductivity. Most of the samples measured had been prepared at either  $800^\circ$  or  $600^\circ$ ; the latter has about  $10^4$  times greater high-field conductivity at a given field strength. However, the ohmic component, i.e., the conductivity at  $\leq 10^5\text{ v/cm}$ , is about the same. Conductivity increases with temperature, with an activation energy of  $1.0\text{-}1.1\text{ ev}$  in the ohmic region. In the nonohmic regions this quantity decreases with increasing field strength.

Changing from Al to Au electrodes had no effect on the conductivity. Increasing the area fourfold also had no effect on the current density vs. field strength curves. Reversing polarity had little or no effect: with some samples a few per cent difference was observed, but the curves were of the same form. Varying film thicknesses from  $500\text{ to }4000\text{\AA}$  was also without effect, as long as field strength was considered.

**Results and discussion.**—Figures 8 and 9 summarize the results of many measurements on films deposited at  $800^\circ$  and  $600^\circ\text{C}$ , respectively. It is evident that up to  $\sim 10^5\text{ v/cm}$  BN film shows only minute and ohmic electronic conductivity. Resistivities are  $\geq 10^{14}\text{ ohm-cm}$  at room temperature and  $\sim 10^{12}\text{ ohm-cm}$  at  $200^\circ\text{C}$ . At higher fields this behavior is gradually overwhelmed by a conductivity describable by  $J \propto E^n$ , where  $n = 13\text{-}15$ . The transition is more gradual for the film deposited at  $600^\circ$ , and occurs at lower fields. The negative resistance in the breakdown region is not stable.

For a varistor the  $600^\circ$  film would be preferred, since it is both more conductive and more stable. A  $1000\text{\AA}$ -thick film should be capable of dissipating up to  $\sim 15\text{ w/cm}^2$  continuously. As an aid in visualizing the possible use of the BN film, Fig. 10 presents its charac-

Fig. 8. D-C conductivity of 500-4000Å BN films deposited at 800°C on 0.001 ohm-cm n-Si.

Fig. 9. D-C conductivity of 2000Å BN film deposited at 600°C on 0.001 ohm-cm n-Si.

Fig. 10. Characteristics of 1000Å BN film as a varistor. Silicon carbide and regulator diode devices, reduced to the same area, are included for comparison. (Identifications are Western Electric Co. codes.)

teristics on the same scale with those of commercially available silicon carbide varistors and a regulator diode reverse characteristic. For comparability all of the devices have been reduced to the same active-element area,  $10^{-3}$  cm<sup>2</sup>. It is evident that the BN film, particularly the 600° film, occupies a potentially useful intermediate position between the others; furthermore, the SiC varistor and the Zener diode are not currently manufactured in thin film form. Note that for the SiC device the current varies as about the fourth power of the voltage; for 600° BN the exponent at room temperature is about 13; and for the diode it varies from near unity to 50 or more.

Many of the experimental observations given above have implications for the mechanism of conduction. For example, the fact that the current does not de-

crease with time, coupled with its nonohmic behavior, rules out any large contribution from ionic conduction. Models of space-charge limited flow (23) predict current density dependence varying between  $V^2/l^3$  and  $V^3/l^5$ , depending on region and on whether a single or double-injection model is assumed ( $l$  is the thickness). This seems rather far removed from the  $J \propto (V/l)^{13}$  dependence observed. An impurity-band conduction mechanism would have a low activation energy and would give an ohmic characteristic.

In Fig. 11 the room temperature conductivity data are replotted as log current density vs. the square root of field strength. Very good straight lines are obtained over seven decades of current for both the 600° and 800°-deposited films. Two possible mechanisms have this characteristic: conductivity limited by electron emission into the insulator from the electrode (Schottky emission), or by the field-assisted thermal excitation of electrons from traps into the conduction band of the insulator (Frenkel-Poole effect).

The Schottky emission equation may be written

$$J = AT^2 \exp \left\{ -\frac{e}{kT} \left[ \phi - \left( \frac{eE}{4\pi\epsilon_i} \right)^{1/2} \right] \right\}$$

where  $J$  = current density,  $A$  = the Richardson-Dushman constant, theoretically 120 amp cm<sup>-2</sup> deg<sup>-2</sup> for emission into a vacuum,  $T$  = absolute temperature,  $e$  = electronic charge,  $k$  = Boltzmann constant,  $\phi$  = barrier height,  $E$  = field strength,  $\epsilon_i$  = permittivity of the insulator =  $K\epsilon_0$ ,  $K$  = dielectric constant of the insulator,  $\epsilon_0$  = permittivity of free space =  $8.85 \times 10^{-12}$  farad/meter. At a given temperature the Schottky equation yields

$$\ln J = \text{constant} + \frac{e^{3/2}}{2kT(\pi\epsilon_i)^{1/2}} \cdot E^{1/2} \quad [1]$$

For the Frenkel-Poole effect the barrier lowering in the presence of a field (24) is  $2(e^3E/4\pi\epsilon_i)^{1/2}$ , that is, twice that for Schottky emission. The difference is a consequence of considering the positively charged trap fixed in position as the electron is removed from it, instead of considering the electron moving away from an image charge in the conductor. As a result, the Frenkel-Poole equation corresponding to Eq. [1] lacks the 2 in the denominator. Thus in principle the two kinds of conduction could be distinguished by the value of the slope of the  $\ln J$  vs. (field strength)<sup>1/2</sup> plot. Some authors argue that there are so many assumptions involved both in equations and the method of measurement that a mere factor of 2 does not offer safe grounds for decision.

Fig. 11. Schottky plot of room-temperature d-c conductivity of BN film.

When the high-frequency (optical) dielectric constants of the BN film are used, the theoretical slope of Eq. [1] is calculated to be  $0.82 \times 10^{-3}$  (v/meter) $^{-1/2}$  for the 600° BN and  $0.84 \times 10^{-3}$  for the 800° BN. These values would of course be  $1.66 \times 10^{-3}$  if the factor of 2 is removed. The experimental slopes (Fig. 11) are  $1.77 \times 10^{-3}$  for 600° BN and  $1.52 \times 10^{-3}$  for 800° BN. The results are thus in better agreement with a Frenkel-Poole than with a Schottky-type conduction mechanism.

#### Acknowledgments

The authors are indebted to H. E. Nigh for MIS measurements, to J. Drobek for electron microscopy and electron diffraction, to J. V. Dalton for radiosodium drift and diffusion work, and to P. F. Schmidt for film anodization experiments. In addition, much helpful discussion and advice were provided by L. P. Adda, M. C. Waltz, and P. F. Schmidt. Dr. R. Haberecht of Texas Instruments kindly supplied copies of the talks cited in ref. (3).

## Intense Interjunction Strain in Phosphorus-Diffused Silicon

E. D. Jungbluth\* and H. C. Chiao\*

#### ABSTRACT

Extensive strain effects are revealed by x-ray topography in the areas between shallow junctions formed by selective-area phosphorus diffusion in silicon. Diffusion-induced strains extend at least  $500\mu$  laterally into the non-diffused portion of the substrate and penetrate to  $1/4$  of the junction depth. Unusual x-ray contrast effects are observed in that both extinction contrast and Borrmann effects simultaneously operate to reveal strain gradients when the lattice adjusts to compensate for stresses introduced by impurity diffusion. These residual unrelieved stresses can be minimized by stress-relief mechanisms involving the generation of dislocations.

Previous investigators have demonstrated that planar impurity diffusion techniques can introduce imperfections into semiconductor substrates (1-3). Dislocation arrays and precipitates can result from the diffusion of impurity atoms of boron and phosphorus into silicon. These defects are generally at-

tributed to stresses arising from solute concentration gradients and total impurity content. Similar effects may also occur when zinc is diffused into GaAs (4). Diffusions are normally accomplished by selectively diffusing through windows opened up in oxide masks by photolithographic techniques. Strain effects at the boundaries of Si-SiO<sub>2</sub> interfaces have been analyzed

\* Electrochemical Society Active Member.

by x-ray topography (5). One would normally expect that subsequent diffusions through the oxide windows would result in lattice defects which would be confined to the diffused area. Recently, Lawrence has shown that impurity diffusions cause dislocation formation not only within the diffused region but also outside or in the nondiffused portion of the matrix (6). He observed that impurity-induced lattice strain contributes to dislocation formation in nondiffused zones wherein the dislocations appear as parallel or intersecting lines. Joshi *et al.* (7) have measured residual strain levels in phosphorus diffused silicon by means of x-ray line-broadening. The observed broadening results from residual strains only and is attributed to insufficient penetration of the diffusion-induced dislocations from inside the diffused layers.

In this paper, direct evidence of the effects of residual strain in phosphorus diffused silicon is presented by means of x-ray transmission topography (8). The residual strain is distributed into the nondiffused zones but is not as well defined as the deformed regions reported by Lawrence (6). Indeed, deformations large enough to create dislocations do not occur in the present case. Residual strains, hereafter referred to as interjunction strains, are shown to arise as a consequence of the diffusion process and are intimately related to the creation of diffusion-induced dislocations.

### Experimental

The silicon wafers used in this study were Czochralski grown and solution doped with boron to an average concentration ranging from  $10^{19}$  to  $2 \times 10^{15}$  atoms/cm<sup>3</sup>. The wafers were oriented for the (111) plane and polished either electrochemically or mechanically. The results reported are independent of surface preparation and substrate doping concentration. The diffusion masks were formed by thermal oxidation at 1100°C in a wet oxygen ambient. The resulting oxide thickness was 5000Å.

The diffusion windows were opened in the oxide by KTR photoresist and etching techniques. The photomask pattern consisted of large square or triangular windows 0.200 in. on a side or circles of 0.200 in. diameter. The diagonal corners of the square windows are oriented approximately in the  $[\bar{1}10]$  and  $[11\bar{2}]$  directions.

Standard diffusion techniques using a P<sub>2</sub>O<sub>5</sub> vapor source and N<sub>2</sub> carrier gas were employed. Temperature and time of diffusions were 1100°C and 1 hr, respectively, resulting in measured junction depths in the order of 2μ. The electrically measured surface concentrations were about  $5 \times 10^{20}$  atoms/cm<sup>3</sup>, although the actual impurity content is probably higher (9).

Crystal defects were analyzed using an x-ray transmission topographical method similar to the Lang method (10). Molybdenum K<sub>α1</sub> radiation was employed under the condition that  $\mu t \approx 1$  ( $\mu$  is the linear absorption coefficient and  $t$  the thickness of the wafer) so that the normal expected mode of diffraction would be by extinction contrast. In practice, this means that structurally imperfect regions should diffract x-rays more intensely than perfect regions. Frequently a reversal of x-ray contrast or a reduction of x-ray intensity accompanying strained regions is simultaneously observed with intensity enhancement. This reduction of x-ray intensity is known as the Borrmann effect. Similar simultaneous displays have been observed to sharply delineate window patterns cut into SiO<sub>2</sub> masks on silicon substrates (5).

### Results

Several investigators have demonstrated that silicon exists in a state of compression due to a mismatch in thermal expansion coefficients when SiO<sub>2</sub> is thermally grown on Si substrates. Blech and Meieran (11) critically analyzed x-ray topographical displays of

strains at oxide steps on Si, and x-ray contrast effects at edges of thin films grown or deposited on single crystal substrates have been attributed by Haruta (12) to strain gradients. Substrates which are in a uniform state of compression due to thin films covering the entire substrate appear in x-ray topographs similar to topographs recorded prior to thin film deposition. Strain gradients, at oxide edges for instance, give rise to x-ray intensities which sharply define the window patterns cut into the oxide. This is clearly demonstrated in Fig. 1 where the contrast is relatively uniform between windows formed in an SiO<sub>2</sub> diffusion mask on silicon. The diffraction vectors are indicated in each figure. Frequently, even after a high concentration emitter type diffusion, the observed contrast appears similar to Fig. 1 except within the diffused areas where diffusion-induced dislocations are observed. That is, the contrast between diffused junctions remains unchanged which implies an unaltered substrate perfection.

In the course of this study, a characteristic type of interjunction strain associated with the diffusion process was observed. The remaining portions of this paper characterize the strain gradient responsible for the observed contrast effects and describes the conditions necessary to control the occurrence of these effects. Finally, a mechanism is suggested to explain these interjunction strain effects.

The x-ray topograph of Fig. 2 was recorded after diffusion. There are obviously two distinct differences in the defect display when compared to Fig. 1: (i) diffusion-induced dislocation arrays are confined to each diode area, and (ii) pronounced dark regions, at each corner of the diffusion mask, extend into the nondiffused portion of the matrix. These dark regions or strain lobes are the so-called interjunction strains. The visibility of such effects in x-ray topographs is a consequence of the strain gradients which result from the lattice adjustment to stresses introduced by the impurity diffusant.

The visibility of strain gradients is also strongly dependent on the reflection chosen. In Fig. 3 the characteristic pattern is completely dissimilar in both its geometrical shape and recorded contrast. Between the four corners of four different junctions the contrast not only reverses (*i.e.*, Borrmann effect is operative) but also the strain gradient appears as a four cornered re-entrant curve which extends over 2500μ to the adjacent junction areas. However, between parallel sides of adjacent junctions the x-ray contrast is dark, indicating diffraction by extinction contrast.

Fig. 1. X-ray topographical displays of strain gradients at oxide edges cut into an SiO<sub>2</sub> diffusion mask on Si;  $\bar{g} = [\bar{1}10]$ .

Fig. 2. Pronounced interjunction strain gradients (strain lobes) which extend laterally  $500\mu$  into the nondiffused matrix at the four corners of the diffusion mask;  $\bar{g} = [11\bar{2}]$ .

Fig. 4. Interjunction strain lobes visible by extinction contrast in a direction paralleling  $\bar{g}$  and by Borrmann effects in a direction perpendicular to  $\bar{g}$ ; arrow indicates reverse contrast within the diffused area;  $\bar{g} = [11\bar{1}]$ .

Fig. 3. Contrast variation of interjunction strain gradients for  $\bar{g} = [21\bar{1}]$ ; visibility by extinction contrast between parallel sides of adjacent junctions and by Borrmann effects between four corners of four adjacent junctions.

Fig. 5. Corresponds to Fig. 4 except that the oxide has been chemically removed; all four interjunction strain lobes are visible by extinction contrast only;  $\bar{g} = [11\bar{1}]$ .

The four strain lobes again appear in Fig. 4 when the operating diffraction vector  $\bar{g}$  is  $[11\bar{1}]$ . Now however, the two lobes parallel to  $\bar{g}$  (at areas 2 and 4) are visible by extinction contrast (dark regions) while the two lobes perpendicular to  $\bar{g}$  (at areas 1 and 3) are visible over large areas by Borrmann effects (white regions) and by extinction contrast at the tips of the sharp corners. An indication of inelasticity is observed in Fig. 5 where all four strain lobes are visible after chemically removing the oxide. Apparently a portion of the strain is built into the oxide as indicated by the visibility of all four strain lobes by extinction contrast ( $\bar{g} = [11\bar{1}]$ ) in contradistinction to the observation made in Fig. 4. Note also that the strain gradient defining the  $\text{SiO}_2$  window pattern is still visible even though the  $\text{SiO}_2$  has been removed. The intense interjunction strain concentration lies on  $\{111\}$  planes and arises as a consequence of the diffusion cycle. The strain is inelastic inasmuch as it is equally well observed after removing the oxide mask, although the character of the strain pattern does depend on whether

the diffusion mask is intact or removed from the substrate (compare Fig. 4 and 5).

Generally, each highly faulted diffused area contributes to an enhanced x-ray intensity (Fig. 5) which may not be directly related to the diffusion-induced line defects. However, the intensity within the junction areas at the sharp corners appears to reverse contrast or appear white (see arrow in Fig. 4 and 5) while outside the junction the strain contrast is dark. Apparently the fault vector corresponding to the strain lobes is directional. That is, the fault vector is tilting the lattice planes in different directions at the corner boundary separating the diffused/nondiffused matrix.

So far, three distinct strain effects, other than dislocation formation, have been observed: (i) strain gradients which sharply delineate oxide boundaries (Fig. 1); (ii) extensive residual strain effects at oxide boundaries which extend outside and into the diffused areas (Fig. 4 and 5), and (iii) an additional strain built into the oxide due to the diffusion cycle (Fig. 4 and 5).

Fig. 6. Low vapor pressure phosphorus diffusion revealing pronounced interjunction strain gradients and no diffusion-induced dislocations;  $\bar{g} = [111]$ .

Using similar diffusion conditions, the occurrence of interjunction strains was found to be independent of the cooling rate. Also under simulated diffusion conditions (without the vapor source), these strain effects were not observed. However, by changing only the vapor pressure of the source it was possible not only to control the occurrence of interjunction strains but it was also possible to control the generation of diffusion-induced dislocations (13). Under low vapor pressure (Fig. 6) no diffusion-induced dislocation arrays are detected by x-ray topography. However the interjunction strain effects are quite pronounced and their occurrence is independent of the particular shape of the window openings. Only the character of the strain pattern is altered by window geometry. The dark spots throughout the wafer are defect markings introduced during the surface polishing. Under high vapor pressure (Fig. 7) each diode is highly dislocated or faulted as evidenced by the excessive intensity within each junction area. However no interjunction strain is evident. Juleff and LaPierre (14) have observed the extension of strain, originating at locally diffused regions in the Si substrate, into epitaxial Si layers

Fig. 7. High vapor pressure phosphorus diffusion revealing no interjunction strain gradients and highly faulted junction areas;  $\bar{g} = [111]$ .

grown over the diffused Si substrate. Even in this case the observed strain effects clearly define the diffused junction geometry, although in some cases diffusion-induced dislocations do propagate laterally from the junction into the non-diffused areas of Si.

### Discussion

The deformed regions between diffused junction areas are clearly related to the generation of dislocations within the junction area. These dislocations are caused by the contraction of the silicon lattice due to the diffusion of smaller phosphorus atoms. The difference in the tetrahedral covalent radii between Si and P is 0.07Å. Joshi et al. (7) have reported that the lattice parameter of Si decreases with increased amounts of phosphorus when solution doping techniques are employed in growing Si crystals. Furthermore, the lattice parameter,  $a_0$ , in phosphorus diffused Si (very high concentrations) more nearly corresponds to the value of  $a_0$  in lightly solution doped Si, probably as a consequence of strain relief and lattice relaxation when diffusion-induced dislocations are

Fig. 8. X-ray topographs recorded after removal of  $1.3\mu$  of Si; (a) junction area sectioned from sample shown in Fig. 2; (b) junction area sectioned from sample shown.

formed. Joshi *et al.* (7) have measured by x-ray line broadening techniques the average strain levels associated with diffusion-induced dislocations and an additional residual strain in diffused silicon layers. The interjunction strain effects observed in our x-ray topographs confirm the existence of these residual strains. Such residual strains are distributed laterally into the nondiffused matrix. The dependence of these strains on the absence of misfit-type dislocations agrees with their observations of lattice parameter variations *vs.* dopant level. Joshi interprets the presence of residual strains in thin surface layers as being due to an insufficient penetration of the diffusion-induced dislocations (7). The distribution of dislocations in samples which showed interjunction strain (*i.e.*, Fig. 2) and samples without interjunction strain (*i.e.*, Fig. 7) was measured by x-ray topography after shallow Si layers were removed by anodic oxidation techniques. A series of topographs were recorded after each incremental removal of 1000Å of Si. In Fig. 8, 1.3 $\mu$  of Si have been removed from the diffused side (junction depth  $x_j = 2\mu$ ) of each specimen shown in Fig. 2 and 7. Most of the dislocations have been removed in Fig. 8a while a high density still remains in Fig. 8b indicating a movement of dislocations deeper into the substrate toward the junction. The interjunction strains seen in Fig. 2 are no longer visible after 0.5 $\mu$  of Si has been removed.

A final observation should be made. The interjunction strains observed in this report do not appear similar to the deformations, observed by Lawrence (6), which result in dislocations formed within highly restricted zones of the nondiffused matrix. He has observed that total impurity stress relief is affected by the type of dislocation formed. Our observations imply that total stress relief, resulting in minimum impurity-induced strain in the nondiffused lattice, occurs when the junction is heavily faulted. This seems to be a consequence of the total number of dislocations formed and their movement into the substrate. Relaxation of solute lattice contraction stresses is affected by the generation of dislocations which, under the conditions stated, balance the impurity-induced strain due to solute indiffusion.

### Summary

Extensive interjunction strain gradients are manifestly observed by x-ray topography. The visibility of such strains is dependent on both the strain gradients due to high concentration impurity diffusions and on the operating reflection employed. Their occurrence is dependent on the magnitude of the unrelieved residual stress which can be compensated by stress-relief generation of dislocations. The depth of penetration of such strains is about  $\frac{1}{4}$  of the junction depth and extends at least 500 $\mu$  laterally from the junction-area boundary.

## Technical Notes

### Phase Transformations in the System $\text{Cu}_2\text{S}-\text{Ag}_2\text{S}$

R. B. Graf

United Aircraft Corporation, Research Laboratories, East Hartford, Connecticut

Both end members of the system  $\text{Cu}_2\text{S}-\text{Ag}_2\text{S}$  have been of interest for many years as naturally occurring minerals as well as for their electrical properties.  $\text{Cu}_2\text{S}$  has been of importance as a rectifier material and  $\text{Ag}_2\text{S}$  is a semiconductor that has a polymorphic transformation at 177°C. This phase transformation is accompanied by an abrupt electrical resistivity change of about 3 orders of magnitude and has been mentioned as being suitable for a-c switching applications (1). In addition to this phase transformation, it was considered that the equilibrium diagram (2) (Fig. 1) might contain other invariant points which would exhibit interesting electrical properties. The points selected for this investigation were: the eutectoid reaction between acanthite ( $\text{Ag}_2\text{S}$ ) and jalpaite ( $\text{Cu}_{0.45}\text{Ag}_{1.55}\text{S}$ ) to form argentite at 106°; the phase transformation in jalpaite to form argentite at 117°; and the eutectoid reaction between orthorhombic chal-

cocite ( $\text{Cu}_2\text{S}$ ) and stromeyerite ( $\text{CuAgS}$ ) (not shown in Fig. 1) at 67°. The transformation of acanthite ( $\text{Ag}_2\text{S}$ ) to argentite was investigated using thin films as well as bulk pieces to determine if the large change in resistivity could be obtained easily in thin film samples.

The compounds were formed by reacting the elements (99.999% purity) in evacuated and sealed glass tubes. The reactants were sintered at 400°C until none of the free elements remained visible, and the formation of the compounds was verified by powder x-ray diffraction. The samples for resistivity measurements were fabricated by compressing powders which had been filed from the sintered ingots. The powder compacts, which were 0.250 in. in diameter and 0.125 in. long, were pressed in a split die so constructed as to make it possible to press a chromel-alumel thermocouple into the center of the pellet. At this same time

Fig. 1. The system  $\text{Cu}_{0.45}\text{Ag}_{1.55}\text{S}-\text{Ag}_2\text{S}$

gold powder was pressed onto either side of the pellet to form electrodes. The thin films of  $\text{Ag}_2\text{S}$  were formed by evaporating silver onto glass substrates which were then heated with sulfur at  $200^\circ\text{C}$  in sealed glass tubes. Electrodes of silver paste were spaced on the film so as to make the sample resistance about 10,000 ohms at approximately  $170^\circ$ . Because of the known ionic conductivity in  $\text{Ag}_2\text{S}$ , the electrical resistivity measurements were made by passing a constant, 60 cycle current of 100 ma through the samples and measuring the voltage change as a function of temperature. The voltage was measured with a Moseley log converter and the output of the log converter was plotted against the output of the thermocouple on a Moseley x-y plotter. Such an arrangement makes it possible to obtain the transformation time for a sample of a given size. A heating rate of  $5^\circ\text{C}/\text{min}$  was used for all samples.

The resistance changes on heating the samples vs. temperature are shown in Fig. 2. The eutectoid reaction between acanthite and jalpaite (curve A) begins at  $106^\circ$  and is essentially over at  $110^\circ$ . On cooling the sample, the reverse reaction exhibits about  $12^\circ$  hysteresis, measured at the mid-point of the highest slope. Heating and cooling the sample through 12 cycles does not change the characteristics of the plot; the heating curve is almost exactly reproduced and the cooling curve is reproduced to within  $\pm 1.5^\circ$ . Jalpaite, which also transforms to argentite on heating, has a resistance change as shown by curve B. The transformation begins at  $117^\circ$  and is over at  $120^\circ$ . There is about  $7^\circ$  hysteresis on cooling. Curve C in Fig. 2 depicts the resistance change in a thin film of  $\text{Ag}_2\text{S}$  on a  $\frac{1}{4}$  in. square glass substrate as it was heated through the transition temperature of  $177^\circ$ . This reaction occurs

Fig. 2. Resistance vs. temperature for: A, acanthite-jalpaite eutectoid reaction; B, transformation of jalpaite to argentite; C, transformation of acanthite to argentite in thin film form.

over a temperature span of  $3^\circ$  and the reverse reaction had about  $6^\circ$  hysteresis. The transformation in a sample of  $\text{Ag}_2\text{S}$  0.125 in. thick and 0.250 in. in diameter occurred over a temperature span of  $2^\circ$  or  $3^\circ\text{C}$ . The eutectoid reaction between orthorhombic chalcocite ( $\text{Cu}_2\text{S}$ ) and stromeyerite ( $\text{CuAgS}$ ) at  $67^\circ$  to form hexagonal high-chalcocite (not shown in Fig. 2) is accompanied by an increase in resistance of less than one order of magnitude and does not occur as quickly as the others, being spread over a temperature range of  $20^\circ$ .

These results indicate that by using invariant points on a phase diagram, it may be possible to obtain solid-solid reactions which would be suitable for a-c switching in those cases where switching time is not so important. The transformation times may be varied by using thin films of the materials on the proper substrates.

## Gas Phase Etching of Sapphire

### II. Fluorinated Hydrocarbons

H. M. Manasevit

*Autonetics, A Division of North American Rockwell Corporation, Anaheim, California*

Of various processes and techniques that have been used to etch and/or polish inorganic oxide systems, the least used but probably the most desirable approach is a gas phase process. Until quite recently, no gas phase etchant was reported in the literature that would etch-polish sapphire at what might be con-

sidered a reasonable rate (about  $1 \mu\text{m}/\text{min}$ ). However, studies in our laboratories have indicated that a host of different gas-phase etchants will etch-polish sapphire. The successful etch-polishing of sapphire with sulfur tetrafluoride ( $\text{SF}_4$ ) and sulfur hexafluoride ( $\text{SF}_6$ ) has already been reported (1). Only two ori-

entations were studied,  $(11\bar{2}3)$  and  $(1\bar{1}02)$  of sapphire, with the former showing preferential polish while the latter etched under comparable conditions.

Since the probable aluminum product of etching with the sulfur fluorides is  $AlF_3$  (indications of  $AlF_3$  epitaxy on  $Al_2O_3$  were obtained at temperatures of  $1150^\circ C$ ) (1), it was anticipated that other fluorine containing compounds were possible sapphire etchants. From a fundamental point of view, knowledge of the etching capability of hydrogen fluoride and fluorine would be interesting, but their reactivity with Pyrex and quartz deterred study with these materials in our epitaxial system. Therefore, we chose to consider the etching potential afforded by a most readily available group of fluorine containing compounds, the fluorinated hydrocarbons. These compounds are relatively inexpensive, have low toxicity levels, are easily handled, seem to be stable at room temperature, and are commercially available in a reasonably good purity.

To date, seventeen fluorocarbon gases have been examined as possible etch-polish agents for sapphire. As will be shown, some of these have a potential as dislocation etchants for different sapphire orientations.

### Experimental

Studies were performed in a vertical reactor system similar to that previously described (2). It includes a tank of inert carrier gas, such as helium, upstream from a tank of the "etchant" to be studied. These are connected via Matheson No. 607 and No. 600 flowmeters, respectively, to a stainless steel manifold joined to the quartz reactor by a Teflon connector. For liquid fluorinated hydrocarbons, a portion of the carrier gas is bubbled through the liquid stored in a stainless steel container, passed into the flowing ambient kept at approximately one atmosphere total pressure, and directed into the reactor. Carrier gas flow rates were arbitrarily set at 2.5 liters/min. The gases are passed over a substrate resting on an  $Al_2O_3$  spacer covering a carbon pedestal inductively heated to the etching temperature. The spacer seems to help provide a more even heat distribution and to reduce reaction between the etching gases and the carbon pedestal. Pedestal temperatures were measured with an optical pyrometer, and uncorrected values are reported. The actual substrate temperature is estimated to be  $50^\circ$ – $100^\circ$  lower than the observed  $1450^\circ C$  etching temperature used to compare the etch-polishing ability of the fluorinated hydrocarbons.

To facilitate the experiments, the studies included mostly those fluorinated hydrocarbons that have relatively low boiling points. The effect of etching-gas concentrations up to about 1 m/o (mole per cent) was investigated and compared with all of the fluorinated hydrocarbons noted in Table I.

### Results and Discussion

Carbon tetrafluoride ( $CF_4$ ) was the only fluorinated hydrocarbon in Table I that did not attack sapphire

Table I. Fluorinated hydrocarbons studied as etchants for sapphire at  $1450^\circ C$

Chemical formula	Common name
$CHF_3$	Fluoroform
$CHClF_2$	Chlorodifluoromethane
$CHCl_2F$	Dichlorofluoromethane
$CH_2F_2$	Methylene fluoride
$CClF_3$	Chlorotrifluoromethane
$CCl_2F_2$	Dichlorodifluoromethane
$CBF_3$	Bromotrifluoromethane
$CF_4$	Carbon tetrafluoride
$C_2F_6$	Hexafluoroethane
$C_2ClF_5$	Chlorotrifluoroethylene
$C_2ClF_4$	Monochloropentafluoroethane
$C_2Cl_2F_4$	1, 1, 2-Trichlorotrifluoroethane
$C_2Cl_2F_4$	1, 2-Dichlorotetrafluoroethane
$C_3F_8$	Perfluoropropane
$C_4F_{10}$	Hexafluoroacetone
$C_4F_8$	Octafluorocyclobutane
$C_4F_8$	Perfluorobutene-2

Fig. 1. Dislocation structure revealed by etching with hexafluoroacetone ( $C_3F_8O$ ) for (a)  $(10\bar{1}4)$  sapphire; (b)  $(01\bar{1}2)$  sapphire.

at  $1450^\circ C$  during a 30-min period at 0.5 m/o concentration with either He or  $H_2$  as the carrier gas. The other compounds were found to etch and/or polish sapphire to different degrees in helium. Some of the etchants revealed major defects in the sapphire, others left carbonaceous residues, and some revealed dislocation arrays.

As with the sulfur fluorides, selectivity for sapphire orientation was also demonstrated by the fluorocarbon etchants. For example, hexafluoroacetone polished  $(11\bar{2}3)$  sapphire but roughened both  $(10\bar{1}4)$  and  $(01\bar{1}2)$  Verneuil sapphire at the same gas concentration. The effect of this etching is indicated in Fig. 1, both a and b.

By bubbling He through the liquid fluorocarbon 1, 1, 2-trichlorotrifluoroethane ( $C_2Cl_3F_3$ ) equilibrated at  $0^\circ C$  and passing the gases over the heated substrate, considerable etching was found for the  $(10\bar{1}4)$  and  $(11\bar{2}0)$  sapphire (Fig. 2).  $C_2Cl_2F_4$ , 1, 2-dichlorotetrafluoroethane, revealed structure in basal plane ( $0^\circ$ ) sapphire (Fig. 3a) and an unusual oval-type defect structure in  $(01\bar{1}2)$  sapphire (Fig. 3b).

Except for Fig. 3b, the figures referred to heretofore have been found to be typical surface etch characteristics for the different sapphire orientations noted and, in general, are produced by almost all of the fluorocarbon etchants, especially when concentrations exceeding 1 m/o are used. Reasonable polishing of most orientations studied, however, has been achieved with many of the fluorocarbons when etchant concentrations are kept below about 0.5 m/o. As might be expected, less etch-pitting and surface character were

Fig. 2. Dislocation structure revealed by etching with trichlorofluoroethane ( $C_2Cl_3F_3$ ) for (a)  $(10\bar{1}4)$  sapphire; (b)  $(11\bar{2}0)$  sapphire.

Fig. 3. Dislocation structure as revealed by etching with 1, 2-dichlorotetrafluoroethane ( $C_2Cl_2F_4$ ) for (a)  $(0001)$  sapphire; (b)  $(01\bar{1}2)$  sapphire.

Fig. 4. Defect structure revealed in basal plane Czochralski ruby by etching with chlorotrifluoromethane ( $\text{CClF}_3$ ).

obtained when good quality Czochralski sapphire was exposed to the etchants. This is demonstrated in Fig. 4 for basal plane Czochralski ruby etched by monochlorotrifluoromethane ( $\text{CClF}_3$ ). The origin of the defect that caused the large hexagonal pits, which are prominent in a field of comparatively few pyramidal etch pits, is not known. Figure 5 was produced by etching (0112) sapphire with octafluorocyclobutane ( $\text{C}_4\text{F}_8$ ). The tombstone-like etch pits were usually found to be characteristic of this orientation. The oval pits produced in (0112) sapphire by 1, 2-dichlorotetrafluoroethane ( $\text{C}_2\text{Cl}_2\text{F}_4$ ) (Fig. 3b) may have been caused by a different type of etching species and reaction.

The reactivity of chlorotrifluoromethane ( $\text{CClF}_3$ ) as compared to  $\text{CF}_4$  is undoubtedly due to the weakening of the C-F bond by the presence of the less electronegative Cl ion in the molecule. Although hexafluoroethane ( $\text{C}_2\text{F}_6$ ) is completely saturated like  $\text{CF}_4$ , the C-C bond is susceptible to rupture, thereby providing the reactive species.

It was observed that when linear C-C double bonds or C-H bonds are present in the structure of the fluorinated hydrocarbon, etching also produced sooty surfaces, especially at the higher gas concentrations. Some of the minor carbon contamination may be attributed to impurities in the gas, but major carbon deposits are more likely due to the cleavage of these bonds in the bulk material. Therefore, complete saturation of the C atoms by halogens, at least one of which is fluorine, seems to be required in choosing

Fig. 5. Effect of etching (0112) sapphire with octafluorocyclobutane ( $\text{C}_4\text{F}_8$ ).

a fluorocarbon etchant: for example, hexafluoroethane ( $\text{C}_2\text{F}_6$ ), perfluoropropane ( $\text{C}_3\text{F}_8$ ), dichlorodifluoromethane ( $\text{CCl}_2\text{F}_2$ ), and/or monochloropentafluoroethane ( $\text{C}_2\text{ClF}_5$ ). Octafluorocyclobutane ( $\text{C}_4\text{F}_8$ ), a fluorocarbon with a ring structure, produced some dark product at  $1450^\circ\text{C}$  but etched sapphire at a rather rapid rate at relatively low concentrations compared to the linear chained materials studied. This suggests a weaker C-C bond in the ring structure, with bond breakage making more fluoride per molecule per unit time available for etching. It was also observed that 1, 2-dichlorotetrafluoroethane ( $\text{C}_2\text{Cl}_2\text{F}_4$ ) possessed the capability of etching sapphire at about  $0.1 \mu\text{m}/\text{min}$  at temperatures as low as  $950^\circ\text{C}$  (observed uncorrected optical pyrometer reading). (Other highly fluorinated hydrocarbons in the group have not been evaluated at this relatively low temperature.) It is not known if a change in the etching mechanism occurred at  $950^\circ\text{C}$ , producing aluminum products other than  $\text{AlF}_3$ . This might be the case if different carbon-fluorine radicals are produced, e.g.,  $\cdot\text{CF}_2$  (difluorocarbene) or  $\cdot\text{CF}_3$  (trifluoromethyl radical), at different temperatures.

It is indeed difficult to write reasonable equations to explain the etching of sapphire without knowing the products of the reaction with the fluorinated hydrocarbons. Some of the products that collected on the cool reactor wall could be vacuum distilled at room temperature; some seemed water soluble; others had to be scraped off the walls or undercut with  $\text{HF-HNO}_3$  solutions for removal. It is probable that many of the reactions involve, as previously suggested, the formation of free radicals containing at least one carbon-fluorine bond that might react with  $\text{Al}_2\text{O}_3$  to produce  $\text{AlF}_3$  (volatile at  $1450^\circ\text{C}$ ) and other products. For dichlorodifluoromethane, a plausible reaction scheme is proposed by the following equations

If more complex fluorinating agents are used as etchants, a study of the reaction products could disclose new materials, perhaps polymers containing aluminum-carbon bonds as well as other fluorinated carbon by-products.

#### Addendum

Under the etching conditions previously described, a number of inorganic fluorides other than  $\text{SF}_4$  and  $\text{SF}_6$  were also found to etch sapphire. These include the chlorine fluorides ( $\text{ClF}_3$  and  $\text{ClF}_5$ ), nitrogen trifluoride ( $\text{NF}_3$ ), and phosphorus pentafluoride ( $\text{PF}_5$ ). These, of course, produce no organic by-products but introduce in some cases a problem in handling because of their room temperature chemical reactivity with glass flowmeters and other materials.

#### Conclusions

The etching capabilities of a number of fluorinated hydrocarbons have been demonstrated. These materials show promise of being new reagents for evaluating the quality and improving the surfaces of sapphire prior to its use as a substrate for epitaxy.

## Thermally Activated Diffusion of Electronic Carriers in Iron Phosphate Glasses

Gary S. Snow\*<sup>1</sup>

Department of Ceramic Engineering and Materials Research Laboratory,  
University of Illinois, Urbana, Illinois

Hansen (1) recently measured conductivity and Seebeck coefficient on phosphate glasses containing 45 m/o (mole per cent) P<sub>2</sub>O<sub>5</sub>. The remaining 55 m/o consisted of FeO and MgO in various proportions. In the 45% P<sub>2</sub>O<sub>5</sub>-55% FeO composition the ratio of [Fe<sup>3+</sup>] to [Fe<sup>2+</sup>] was varied over a wide range. This data offers an excellent opportunity to check the agreement between the experimentally observed dependence of resistivity on valence state distribution and that predicted by the hopping model. Hansen discussed his data qualitatively in terms of the hopping mechanism; however, there are inconsistencies in his discussion which should be clarified.

If the electronic carriers move by a thermally activated diffusion process, the conductivity can be written

$$\sigma = \frac{nq^2d^2zP\nu e^{-\Delta E/kT}}{6kT} \quad [1]$$

where  $n$  is the carrier concentration,  $q$  is the charge on the carrier,  $d$  is the jump distance,  $z$  is the number of nearest neighbor sites,  $P$  is the probability that a particular nearest neighbor site will be available to receive a carrier,  $k$  is Boltzmann's constant,  $T$  is the absolute temperature,  $\nu$  is a frequency factor characteristic of the lattice vibrations, and  $\Delta E$  is the energy necessary to remove the lattice distortion around the trapped carrier. In this equation Hansen omitted the factor  $P$  which is extremely dependent on the valence state distribution. Evaluation of this factor allows one to obtain a quantitative fit between Eq. [1] and Hansen's experimental data.

In the iron phosphate glasses studied by Hansen let  $x$  be the fraction of the iron ions which are in the Fe<sup>3+</sup> state, let  $y$  be the fraction of the cations which are iron, and let  $c_0$  be the total concentration of cations. Then if one assumes that conduction occurs by hopping of electrons from Fe<sup>2+</sup> sites to Fe<sup>3+</sup> sites, the carrier concentration will be equal to the concentration of Fe<sup>2+</sup> ions; thus  $n = (1-x)y c_0$ . Assuming that phosphorous ions and iron ions of either valence have equal probability of being on any given cation site, the probability that a particular nearest neighbor site will be available to receive a carrier is just equal to the fraction of the cation sites which are occupied by Fe<sup>3+</sup> ions; thus  $P = xy$ . Using these relations, Eq. [1] then becomes

$$\sigma = K e^{-\Delta E/kT} y^2 (1-x) x \quad [2]$$

where

$$K = \frac{c_0 q^2 d^2 z \nu}{6kT} \quad [3]$$

It should be noted that the same equation results if the carriers are assumed to be holes moving from Fe<sup>3+</sup>

sites to Fe<sup>2+</sup> sites, in which case  $n = xyc_0$  and  $P = (1-x)y$ .

In Fig. 1 and 2 the data of Hansen is compared with this theory. In plotting Eq. [2],  $\Delta E$  was obtained as a function of  $x$  and  $y$  from Hansen's data, and  $K$  was chosen as 563 (ohm-cm)<sup>-1</sup>. There is excellent agreement between the experimental data and the calculated points. From Fig. 1 it is apparent that another transport mechanism becomes dominant below  $y = 0.05$ .

Taking  $K = 563$  (ohm-cm)<sup>-1</sup> an order-of-magnitude value for  $\nu$  can easily be calculated from Eq. [3]. Assuming a simple cubic distribution of cation sites and taking  $c_0$  as approximately 10<sup>22</sup> cm<sup>-3</sup>, then  $z = 6$  and  $d = 4.7 \times 10^{-8}$  cm. The other parameters are known constants. The resulting value for  $\nu$  is  $6.5 \times 10^{12}$  sec<sup>-1</sup> which is in good agreement with the expected value of the vibrational frequency of the lattice.

Since  $d$  can be treated as independent of  $x$  and  $y$ , it appears likely that electronic transfer always occurs between nearest neighbor iron sites, at least for  $y > 0.05$  (10 m/o FeO).

Allersma and Mackenzie (2) have shown that the Seebeck coefficient data which Hansen obtained for iron phosphate glasses qualitatively fits the following equation developed by Heikes (3) for the hopping

Fig. 1. Logarithm of resistivity at 200°C as a function of the fraction of the total cations which are iron. Experimental data was taken from Fig. 1 of ref. (1). Theoretical points were calculated from Eq. [2] using the  $\Delta E$  values from Fig. 1 of ref. (1) and taking  $K = 563$  (ohm-cm)<sup>-1</sup>.

Fig. 2. Variation of resistivity with  $x = [\text{Fe}^{3+}]/[\text{Fe}_{\text{total}}]$  at  $200^\circ\text{C}$  for glasses containing 55% FeO-45%  $\text{P}_2\text{O}_5$ . Experimental data was taken from Fig. 4 of ref. (1). Theoretical points were calculated from Eq. [2] using  $\Delta E$  values from Fig. 3 of ref. (1) and taking  $K = 563 (\text{ohm-cm})^{-1}$ .

mechanism

$$\alpha = \frac{k}{q} \ln \frac{n_0 - n}{n} \quad [4]$$

In Eq. [4]  $\alpha$  is the Seebeck coefficient,  $n$  is the concentration of carriers (equal to  $[1-x]yc_0$  if the carriers are electrons and equal to  $xyz_0$  if they are holes),  $n_0$  is the concentration of accessible sites (equal to  $yc_0$  in either case), and  $q$  has the sign of the charge carrier. It is worth noting that Eq. [4] becomes

$$\alpha = \frac{-k}{|q|} \ln \frac{x}{1-x} \quad [5]$$

and fits the data over the entire range of  $x$  whether the carriers are holes or electrons; thus, it is not neces-

sary that the sign of the carriers change when the Seebeck coefficient goes from positive to negative as was concluded by previous investigators (1, 2). From the currently available data no conclusions can be drawn concerning the sign of the charge carrier.

In order to calculate the carrier mobility, Hansen obtained the carrier concentration from the equation  $n = n_0 \exp(-q\alpha/k)$ . He took  $n_0$  as the absolute difference between the ferric and ferrous concentrations. This assumption contradicts the data since it would result in an infinite resistivity at  $x = 0.5$  rather than a minimum as shown in Fig. 2. Hansen obtained values for the frequency factor  $\nu$  which were extremely dependent on  $\Delta E$  and on his choice of valence state distribution. In the present analysis  $\nu$  is independent of these parameters as one would expect.

This treatment yields a carrier mobility which (at  $200^\circ\text{C}$  in the 55% FeO glass) varies from  $1.3 \times 10^{-8} \text{ cm}^2/\text{v-sec}$  to zero as the concentration of carriers goes from zero to  $yc_0$ .

The correlation between Hansen's data and Eq. [2] and [5] strongly supports the treatment of electronic conduction in the iron phosphate glasses as a thermally activated diffusion process. It appears doubtful that conduction in a partially filled  $3d$  band would have this dependence on valence state distribution.

## Brief Communications

### Impurity Heterogeneities and Multiple-Beam Interferometry

D. C. Johnston, A. F. Witt,\* and H. C. Gatos\*

Department of Metallurgy and Center for Materials Science and Engineering,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

Multiple-beam interferometry (1) combined with high resolution etching techniques has been successfully employed for revealing relative microscopic concentration changes of impurities in InSb. In view of the fact that "rate striations" intentionally introduced into single crystals allow the precise determination of microscopic rates of crystal growth (2), it was possible to demonstrate further in the present study that multiple-beam interferometry can directly reveal relationships between microscopic rates of growth and impurity concentration. The impurity present in the crystals was tellurium (about  $10^{17}/\text{cm}^3$ ).

\* Electrochemical Society Active Member.

Figure 1 depicts the "off-core" region of a single crystal of InSb pulled in the  $\langle 111 \rangle$  direction with seed rotation and subjected to controlled vibrations (frequency 12 per sec). The interference fringes were aligned in a vertical direction (1). In this way a uniform impurity distribution or complete absence of impurities would be reflected by the appearance of straight and parallel interference fringes aligned from top to bottom (a perfectly flat semiconductor surface after etching). Under the present experimental conditions a relative decrease or increase in impurity concentration (depressions or elevations on the etched semiconductor surface, respectively) will appear as

Fig. 1. Interferogram of an "off-core" region of InSb grown in the  $\langle 111 \rangle$  direction (top to bottom) exhibiting pronounced "remelt" rotational striations, B. The abrupt interference fringe deflections to the left, A, associated with the rotational striations reflect a sharp decrease in impurity concentration. The "rate striations" are also clearly seen (see text). Magnification 700X.

deflections of the fringes to the left and right, respectively. Tellurium impurities decrease the etching rate of InSb under the present experimental conditions. Figure 1 shows abrupt fringe deflections to the left, A, which are associated with slightly curved rotational striations, B, traversing from left to right. The rate striations are readily visible as small spikes emanating from the fringes. Thus the fringe pattern permits the simultaneous determination of microscopic growth rates and the associated impurity concentration changes.

The information contained in the interferogram of Fig. 1 can best be extracted by analyzing the pattern of the individual fringes running from top to bottom (along the growth axis). The separation of the rate striations reflects the growth rate changes associated with rotational striations as discussed in detail elsewhere (2). It can readily be seen that immediately below each remelt striation the growth rate assumes very small values which gradually increase (increasing spacing of subsequent spikes proceeding from top to bottom) before they become very small again at the next striation. The abrupt fringe deflections to the left associated with rotational striations indicate a sharp drop in impurity concentration in the area of decreased growth rate. With increasing growth rate (below the remelt striations) the fringes move to the right indicating a relative increase in impurity concentration. The observed concentration changes on either side of each striation is consistent with the corresponding growth rate changes discussed in detail elsewhere (2).

Figure 2 depicts the "off-core" to "on-core" transition region in a single crystal (InSb) pulled in the  $\langle 111 \rangle$  direction with seed rotation (no rate striations were introduced). On the left-hand side, A, (off-core region) the impurity concentration decrease associated with the rotational striation is clearly vis-

Fig. 2. Interferogram of an etched "off-core" to "on-core" transition region of InSb grown in the  $\langle 111 \rangle$  direction (top to bottom). Note impurity concentration changes in the off-core region (on the left side, A) associated with rotational striations (same as in Fig. 1). The on-core regions, B, exhibit strong fringe deflections to the right corresponding to increased impurity concentration. Within the core regions very pronounced impurity concentration variations are visible (changes in slopes of the deflected interference fringes). A small but readily visible impurity concentration decrease is present in the off-core region adjacent to the "core" region, C. See text. Magnification ca. 470X.

ible. The on-core regions, B, (increasing in area from left to right) are characterized by the strong fringe deflections to the right which correspond to a marked increase in impurity concentration. This region which grows under a relatively constant vertical microscopic growth rate (2) exhibits impurity concentration fluctuations which clearly are not related to vertical growth rate changes and thus indicate the operation of a growth mechanism different from that in the off-core region. Unexplained is also the small impurity concentration decrease in the off-core, C, region just preceding the transition to the "core" region.

The ultimate value of the present-type interferogram depends on the availability of quantitative relationships between etching rates and impurity concentration for varying etching times. Actually in our experiments it was found that the ratio of the interference fringe deflections remained constant for a given impurity concentration change over a wide range of etching times (30 sec to 3 min) and etchant compositions. Consequently it appears that the relative dependence of the etching rate on impurity concentration is invariant. Thus it is expected that etching rate calibrations with known impurity concentrations will permit the determination of absolute impurity concentrations and concentration changes on a micro-scale.

# On the Trapping Level Disposition in Cadmium Sulfide

Paul A. Faeth<sup>1</sup>

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

The tendency has been to consider trapping states in CdS as being in different classes depending on their position within the energy gap (1) and the particular phenomena being observed. It appears, however, that there is a regularity in their values and that these states might be considered as part of a single energy scheme. Such an idea has been proposed by Klasens (2) among others for luminescent and trapping centers in ZnS.

The electron trapping level disposition within the band gap of CdS has been found to include the values of 0.05, 0.14, 0.25, 0.41, 0.63, and 0.83 eV (3). These values are the averages obtained using various experimental techniques and several methods of calculation, and are given as energy displacements,  $E_i$ , from the conduction band. Deeper states have been established which are thought to act as hole traps (1). Studies involving the deeper states indicate these levels occur at  $E_i = 1.2$  eV (1, 4) and 1.56 eV (1, 5). A self-activated luminescent level at 1.98 eV has been reported by Lehmann (6). Usually all levels do not appear simultaneously in one crystal although that could happen. When levels do appear, however, they occur very near the values mentioned above and are listed in Table I.

A study of trapping states in cadmium sulfide (7) revealed that the experimentally determined trap energies can be related to one another and to the band gap energy  $E_g$  of 2.4 eV. The disposition of energy levels can be represented by the equation

$$E_i = a - (bi - ci^2) \quad [1]$$

where  $a$ ,  $b$ , and  $c$  are constants and  $i$  is a whole number which numbers successive energy levels  $E_i$ . A similar formulation is used for preliminary evaluations of molecular spectra (8). The constants of Eq. [1] can be determined from the values of  $E_i$  in Table I. The choice of a starting point for the energy level progression is arbitrary. As an example, a case for  $i = 0$  is given at line 11 in Table I for which situation  $a = 2.406$ ,  $b = 0.475$ , and  $c = 0.0238$  eV. A level at 0.031 eV (1) is generated which might be related to the exciton level observed by Reynolds *et al.* (9) at about 0.028 eV or the optical absorption reported at  $\sim 40\mu$  by Manabe *et al.* (10). The wavelengths in microns corresponding to  $E_i$  and  $E_g - E_i$  are listed in Table I and represent regions where photoactivity is observed in CdS.

The energy scheme suggested above may represent part of a band system, in a spectroscopic sense, extending across the energy gap of CdS. A plot of Eq. [1] is parabolic and is suggestive of similar parabolas observed for molecular species such as CN and CuH, for example (8). As the conduction band is approached from the valence band, a "band head" appears to be formed by the trap levels near the conduction band. The system could be tied to the conduction band or the valence band or both. The system limit at the valence band is not as well defined. Fine structure associated with these levels seems likely in view of the recent work of Bryant and Cox (11) involving luminescent emission from CdS. Such structure associated with all levels might give the appearance of a continuous trapping spectrum. Assignments due to

\* More recent studies concerning this level indicate this value may be larger; 0.86 eV (14).

specific transitions, however, are not available at this time.

The exact identity of the species involving the energy scheme suggested above is unknown. The levels have been postulated as states of complex impurity-vacancy systems in the bulk. The addition of impurities to crystals stimulates the development of these levels. They seem to occur even in the absence of deliberate doping. The incorporation of impurities might cause slight shifting (Franck-Condon) of potential minima associated with the trapping centers, thus causing some transitions to be unlikely while others are more likely to occur. Previous studies of electrical properties of CdS as affected by sorbed gases have indicated a possible correlation between the amounts of sorbed gases and the appearance of trapped electron populations (7, 12, 13). Such studies suggest the traps may be related to surface states.

### Remarks on the Theory of Electrophoretic Deposition

William F. Pickard

*Department of Electrical Engineering, Washington University, Saint Louis, Missouri*

#### ABSTRACT

Following a definition of "electrophoretic," electrophoretic deposition is discussed as a three-step process: (i) the charging phase in which the particles to be deposited are given a net electrostatic charge; (ii) the transporting phase in which the now charged particles are moved in some specified fashion; and (iii) the collecting phase in which the transported particles reach their destinations and are discharged. The characteristics of each of these phases are discussed, and various illustrative examples are given.

The term "electrophoretic" is commonly used to designate those motion phenomena which arise from the direct coulombic action of an electric field on unneutralized charge contained in matter. Thus, either

$$\vec{F} = Q\vec{E} \quad \text{or} \quad \vec{F} = \int_V \rho\vec{E}dV + \int_S \eta\vec{E}dS \quad [1]$$

(particle)                      (extended region)

will provide a fundamental description of the causative process; in this equation,  $\vec{F}$  is the force produced by the electric field  $\vec{E}$  acting either on the total charge  $Q$  of a particle or on the volume ( $\rho$ ) and surface ( $\eta$ ) densities of free charge which characterize an extended region. However, the utilization of electrophoretic force for particle deposition depends not so much on elegant solutions of this equation coupled with the laws of mechanics as it does on careful practical engineering within which the nature of electrophoretic motion is but one of several important factors. For this reason, and also because of the great diversity of possible applications, electrophoretic deposition as a field has resisted formalization. Even so, it is useful to analyze an electrophoretic process by splitting it somewhat arbitrarily into three phases: (i) a "charging" phase within which the particles (objects, entities, things, etc.) to be deposited are charged and started on their trajectories; (ii) a "transporting" phase within which the particles are moved near to some specified destination (it is within this phase that Eq. [1] finds its chief utility); and (iii) a "collecting" phase within which the particle trajectories terminate and the particles are discharged.

These three phases are discussed sequentially in the next three sections of this paper. To make the discussion exhaustive will not, however, be possible since books could be devoted to any one of the phases. Neither will it be possible to erect an elegant mathematical framework within which to cast the discussions since much of the underlying electrochemical theory is but inadequately developed; and, in any event, the associated mathematics is decidedly nonlinear. Rather, the author will attempt to characterize

the types of problems encountered and to outline some of the methods of solution developed to date.

Finally, before proceeding to descriptions of the several phases of deposition, it is informative to consider a simple example of an electrophoretic process. In the 1740's G. M. Bose (1) discovered the capillary siphon effect illustrated in Fig. 1. Here the efflux of water from a nozzle fastened to a metal container is much increased by applying a high voltage to the container; in addition, the formerly thin stream breaks up into a cone of spray. (That this phenomenon is electrophoretic can also be inferred from the fact that the region adjacent to the orifice often appears luminous when viewed under low light intensities.) The splitting then can be made as follows: (a) the metal container, functioning as an "emitter," injects charge into the liquid which is then coulombically pushed outward away from the nozzle; the container is thus the precursor of the gun used in modern electrocoating; (b) the charged liquid droplets then move away toward the basin under the influence of gravity and of the applied electric field. Since particle trajectory, not particle deformation, is important here and since the electric field will be essentially constant over the particle, the particle form of Eq. [1] is the more appropriate; and (c) the basin, functioning as a "collector," receives the droplets and bleeds off their charge.

#### *The Charging Phase*

A feature common to most electrophoretic systems is a metallic electrode called an emitter which injects free charge into the system. This charge is transferred, either by conduction or by an electrochemical reac-

REVIEW  
SECTION

Fig. 1. The capillary siphon as illustrated in an old print (2). *Vide text.*

tion, to matter coming into fairly intimate contact with the emitter. In the former case the electrode design is most often dictated by mechanical considerations, although it is necessary that the surface be kept clean of any nonconducting films which would inhibit charge transfer; in the latter it is commonly controlled by the need for a high surface field and suitably reactive electrode material to enhance the reaction, and for this reason electrodes with small curvature radii are preferred.

If the particles charged at the emitter surface are the ones on which the charge was desired, the charging process can be termed "direct"; otherwise it can be termed "indirect" since one or more charge transfers will be needed to effect the desired charging. As stated above, the three criteria for designing a direct charging process are (i) that there be no insulating barrier at the emitter surface, (ii) that the surface field be high enough to effect the transfer, and (iii) that, in the case of an electrochemical reaction, the emitter surface be compatible with the particles to be charged. In the case of an indirect process the charge is acquired by capturing directly charged particles dielectrophoretically. Thus, a directly charged particle, moving into the neighborhood of a particle to be indirectly charged, induces a dipolar charge distribution on it and in consequence is attracted; if the trajectories of the two particles were appropriate initially, this interaction will lead to trajectory modifications terminating in collision and capture. Obviously, emitter design for an indirect process will emphasize the production of high densities of directly charged particles since this will promote indirect charging.

Two examples will serve to make these considerations more concrete. First, a classic example of a direct charging process is given by the static field, conductance separator (3) used in a variety of mineral purification processes; this is illustrated in Fig. 2. A mixture of conducting (solid dots) and insulating (hollow dots) particles is dumped onto a revolving charged cylinder. The conducting particles are directly charged at once and are drawn off toward the other electrode, falling eventually into hopper C; the insulating particles are weakly held to the revolving electrode by a dielectrophoretic interaction with its modest surface field until they have been rotated far enough for gravity to draw them off into hopper I. Second, the electrostatic precipitation of flue dust (4, 5) provides an excellent example of an indirect

Fig. 2. Schematic illustration of a conductance separator. *Vide text.*

charging process; this is illustrated schematically in Fig. 3. Here a high voltage corona wire is run up the center of a grounded pipe. Gas, flowing axially in the pipe, is ionized by the wire and the resultant ions repelled into the gas stream where, electrodiffusing, they collide with and/or are attracted to particles of dust. The dust particles so charged are then attracted to the pipe where they are collected.

#### The Transporting Phase

In the transporting phase the trajectories of individual charged particles are considered. Each trajectory is specified by a set of initial conditions and the equation

$$\mu \frac{d^2 \vec{r}}{dt^2} = QV\vec{E}_o(\vec{r};t) + \vec{M}(\vec{r};t) - \lambda \left( \frac{d\vec{r}}{dt} - \vec{v} \right) \quad [2]$$

where  $\vec{r}$  is a vector describing the particle's position,  $\mu$  is the particle's mass,  $V$  is a scaling factor to describe the magnitude of the electric field,  $\vec{E}_o$  is the value of the applied field when  $V = 1$ ,  $\vec{M}$  is the mechanical (gravitational, convective, etc.) force, and  $\lambda$  is the coefficient of viscous drag and  $\vec{v}$  the velocity of the medium surrounding the particle. In addition, of course, it is also necessary to set up and solve equations for  $\vec{v}$ ,  $\vec{E}_o$ , and  $\vec{M}$ ; these equations are coupled to Eq. [2] since (i)  $\vec{E}_o$  is influenced by space charge which is in turn influenced by the density of charged particles, and since (ii) by Newton's third law the viscous retardation which the particle experiences produces an acceleration of the fluid surrounding it. Obviously Eq. [2] and its subsidiary equations form a system too complicated to admit of a useful closed form solution in any significant number of cases, and one is reduced to analyzing it to extract rules of thumb.

First, although  $\vec{M}$  and  $\vec{v}$  can be thought of as being in some sense mechanical perturbations on the basic electrophoretic process, they are of considerable significance.  $\vec{M}$  includes, for example, the force of gravity, constraints introduced by various surfaces, and buoyancy. Of these, gravity and buoyancy are the more important, mechanical constraints normally being significant only in the charging and collecting phases. As an illustration, gravity is of prime importance in electrostatic ore beneficiation, the separation normally being effected using crossed electrical and gravitational fields. Conversely, gravitation is much less important in the electrodeposition of paint from aqueous media since its effects on the paint particles tend to be annulled by the buoyancy of the water.  $\vec{v}$  is often one of the parameters of the system as, for example, in the case of electroprecipitation of flue dust. However, it

may be due largely, or in significant part, to motions set up in the fluid by the electrophoretic process itself, and in this case it could impair process efficiency. It has, for instance, been found (6) that conduction currents as small as 1 pA/cm<sup>2</sup> can produce in insulating liquids motions so large as to render uninterpretable the usual carrier mobility measurements; and there is no reason to suppose that similarly significant effects will not exist at the much higher currents used in electrodeposition.

Second, if one neglects  $\vec{M}$  and  $\vec{v}$ , Eq. [2] becomes

$$\mu \frac{d^2 \vec{r}}{dt^2} + \lambda \frac{d \vec{r}}{dt} = QV \vec{E}_o(\vec{r}) P(\omega t) \quad [3]$$

if the physically realistic assumption of periodic  $E_o$  is made. The inertia and viscous drag terms on the left of Eq. [3] can sometimes be manipulated by changing the size of the objects transported, but size is often dictated by other factors. The relative importance of these terms depends on the exact application, but, in

processes where  $\vec{M}$  is neglected, drag normally predominates.

The term on the right of Eq. [3] is the one over which the engineer has greatest control, it being possible (i) to manipulate  $Q$  and  $V$  to some extent, (ii) to specify arbitrarily the periodic function  $P(\omega t)$ , and (iii) to vary  $\vec{E}_o(\vec{r})$  over a wide range by designing so-called "field electrodes" which may or may not include prominently the emitter and collector. The optimal settings of these quantities vary greatly from application to application. Normally, however, the a-c components of  $P(\omega t)$  produces a primarily oscillatory motion of the charged particle, the amplitude of the oscillation decreasing as  $1/\omega$ ; the d-c component produces the desired translation. To increase efficiency, then,  $P(\omega t)$  should possess a moderately low ripple factor unless transient peaks are useful in promoting better particle charging as in electroprecipitation. Also,  $|\vec{E}_o(\vec{r})|$  is commonly adjusted to be monotonically decreasing along a particle trajectory so that the particle will tend not to acquire a new charge at or near the collector and subsequently move off on a new trajectory.

Finally, if the device has been capably engineered, then the charged particles will arrive in the neighborhood of the collector with some suitable spatial distribution. This may be relatively loosely specified as, for instance, in the case of the separator shown in Fig. 2 where it is necessary merely to get the conducting particles into hopper C. Or it may be relatively stringent as, for instance, in the case of electrically depositing a uniform coating of paint in metal parts moving along an assembly line.

An example of these considerations is provided by the electrostatic precipitator (cf. Fig. 3). Here the principal velocity is axial, and mechanical forces are not of primary importance if the gas velocity is sufficiently high and if turbulence is suppressed; in practice these conditions are not always easy to fulfill (5). Inertial effects are normally outweighed by viscous drag, but reentrainment of precipitated particles in the gas stream is a real problem, and hence the collector field should be kept low. On the other hand, it is desirable to have as large a  $Q$  as possible, and this is facilitated by emitter fields strong enough to produce ionization. Thus, the coaxial geometry shown produces

a most suitable  $\vec{E}_o$ .  $VP(\omega t)$  is commonly adjusted to give a d-c level near sparkover and an a-c level producing, near the emitter, copious ionization at waveform crests and quenching of any sparkover at minima. Finally, the criteria on the distribution of transported particles at the collector are very loose, it being re-

Fig. 3. Schematic illustration of an electrostatic precipitator. *Vide text.*

quired merely that there be no radical nonuniformities over the collector surface.

#### The Collecting Phase

In the collecting phase the transported particles settle on a surface which normally bleeds off their net charge. Thus, in some limited time after touchdown, the electrical force holding the particle has shifted from electrophoretic toward dielectrophoretic and the particles are held by (i) adhesive, (ii) dielectrophoretic, and (iii) other mechanical forces. Cases in which adhesion predominates represent electrocoating processes, while those in which dielectrophoresis predominates usually represent electroseparation processes. "Other mechanical forces" could include, for example, the vertical component of gravity holding the particle in a surface depression or small surface hairs which tend to trap the particles; an illustration of the latter would be an electrostatically dusted plant leaf [cf. 7, 8]. The problems of collection arising in these several cases are radically different.

In electrocoating applications [cf. (9)] there is no question of designing the collector since this has normally been set by the requirements of the product into which it is to be assembled or by other forces beyond the engineer's control: all one can try to do is work with the existing constraints. It is normally required (i) that the coating be of some specified thickness, (ii) that it be of some specified uniformity, and (iii) that the process be as efficient as possible. Thickness is commonly controlled by adjusting the coating time, that is, either the collector or the emitter is moved or the unit is turned off when the coating is thick enough. Uniformity is often provided by the insulating properties of the coating which reduce the surface electric field as the coating thickens thus promoting deposition elsewhere; that is, the asperities on the collector's front surface will be coated first, followed by smooth areas on the front and ultimately by the rear surface and various recesses. In addition, coating uniformity can obviously be aided by rotating the collector or by causing the emitter to revolve around it. In many processes, electrostatic crop dusting, for example, the increase of efficiency compared to the no field case is so great that one is not strongly motivated toward optimization. But, if it is necessary to optimize one should use suitable carriers for the coating material, properly prepare the collector's surface as, for example, by degreasing, and have a good charging phase.

In electroseparation adhesion is not commonly a problem, and the requirements on particle distribution are typically much simpler, being "not too nonuniform" for electroprecipitation and "into the correct

hopper" for ore beneficiation. Moreover, one is able to control to a large extent the collector shape. There are two problems of note. First, lightweight conducting particles tend to acquire the collector's charge and be repelled toward the emitter. And second, the particles collected may be held to the collector's surface by slow charge loss or other electrical processes, and build up a thick and undesirable coating. The designer's job is then to produce a collector which disposes of the particles in an acceptable manner, and, to this end, three expedients have been adopted. First, the collector is so arranged that gravity will tend to pull the particle off in a suitable direction; thus, the precipitator shown in Fig. 3 should be arranged vertically rather than horizontally. Second, the surface electric field of the bare collector is made as small as possible since recharging of the collected particles commonly increases with this quantity; thus, where recharging is a problem, it is designed with large curvature radii. Third, where necessary, the collected particles can be dislodged mechanically and allowed to drop under the influence of gravity; thus, the collectors in flue dust precipitators are commonly subjected to a mechanical rapping.

#### Conclusion

Rather than boldly assaying the *tour de force* of knotting together this diversity of loose ends, I would like to conclude with a description of yet another class of experiments which will serve to explain why in defining "electrophoretic" at the start of this paper I chose to stipulate that the action of the electric field on the entity transported be "direct" and "Coulombic."

Specifically, many organisms exhibit galvanotactic behavior; that is to say, they tend to move in predictable directions in an applied electric field. This phenomenon has long been known (10), and appears, like the phenomena discussed above, to have commercial application (11). An interesting example of galvanotaxis is provided (12) by the motile colonial alga *Volvox* which, when subjected to an electric field, swim toward and accumulate at the cathode, unless surprisingly, they have been conditioned by several days of suitable light deprivation, in which case they move toward the anode.

From this one might conclude that the galvanotactic response could be described as "behavioral" or "voltage-

tional." But, recent researches (13) have indicated that galvanotaxis in ciliates is often the result of a reversal of ciliary beat related to cytoplasmic depolarization. In either case, it would seem that the phenomenon is electrophysiological or electropsychological in nature rather than electrophysical.

And hence the restrictions imposed in defining "electrophoretic" served to rule out those depositional phenomena which, though incontestably electrical in origin, are not readily explained by the direct action of the applied electric field on the net free charge of the transported object.

Manuscript received November 28, 1967. This paper was presented at the Dielectro- and Electrophoretic Deposition Symposium at the Chicago Meeting, October 15-19, 1967, as Abstract 144.

Any discussion of this paper will appear in the Discussion Section to be published in the December 1968 JOURNAL.

## Unsolved Problems Concerning Metal Surfaces and Corrosion<sup>1</sup>

Herbert H. Uhlig\*

Department of Metallurgy and Materials Science,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

Almost any worthwhile discipline, whether in the humanities or in the sciences, has its unsolved problems. And it is often true that an inventory of the contributions made by any viable discipline reveals many additional contributions that would be welcome were they available. The study of metal surface properties and of metal reaction rates (corrosion) fits this description. On a practical level, a quick survey shows

that research on metal surfaces has already contributed appreciably to the development of catalysts for chemical processing, to the reduction of friction and wear of metals, and to prolonging the life and safety of metal equipment exposed to aggressive environments. On a scientific level, the relation between adsorption on transition metal alloys and unfilled d electron levels has contributed better insight into both the mechanism of catalysis (1) and the nature of passive films (2-4) accounting for the excellent corrosion resistance of chromium, titanium,

<sup>1</sup> Presented at Dedication of Graduate Center for Materials Research, University of Missouri, Rolla, Mo., October 31, 1967.

\* Electrochemical Society Active Member.

stainless steels, Monels, and related metals.<sup>2</sup> Furthermore, current knowledge of heterogeneous reaction rates has been appreciably advanced by the well-established electrochemical theory of corrosion and by the Wagner theory of metal oxidation at elevated temperatures. Increased meaning has been given to potential and polarization measurements beyond anything available during the early development of classical electrochemistry. As a result, it is now possible to calculate instantaneous reaction rates from rapid polarization data, a technique that proves especially valuable in assessing metals for use in the human body. Advances in electrode kinetics have contributed a clearer insight into factors which add efficiency to corrosion inhibitors. On the other hand, they also identify with devices such as the fuel cell which has captured public attention because of its high theoretical efficiency and its possible alleviation of air pollution. But the advances which are necessary to move the fuel cell out of the laboratory into large-scale commercial use, still remain undiscovered among the properties of metal surfaces.

### Advances in Corrosion Science and Engineering

To list all of the many technological advances that have benefitted from corrosion research is not my present purpose. In a brief outline such as this, one should however at least mention the advent of the rust-resistant stainless steels which first appeared on the scene about 50 years ago as a result of empirical probing. They made an initial major impact on the synthetic nitric acid industry, on design of cutlery and hospital equipment, and on architectural and automotive trim. Similarly the technique of cathodic protection, a long-established development resulting from basic studies of electrochemistry by Sir Humphrey Davy, has made it feasible to transport gas and oil, as is now done, over thousands of miles through buried steel piping securely guaranteed against corrosion. Any unpredictable deterioration of such piping is not tolerable because of catastrophic consequences, particularly with internal gas pressures reaching 1000 psi. Furthermore the classical galvanized corrosion-resistant coatings on steel, first patented in France as early as 1836, still find increasing use today for marine and atmospheric exposures. Some recent applications extend the life and safety of steel automobile frames and accessory equipment exposed to corrosive salt applied to snow-laden streets of northern climates. Mention can also be made of corrosion control methods applied to steam boilers such as deaeration of feed water and the addition of various chemical inhibitors in order to increase the efficiency and safety of boiler operation and at the same time to materially reduce the cost of generated power. It is not always realized that use of commercial corrosion inhibitors in a variety of industries, including the utilities, plays an important part in supporting our industrial economy.

<sup>2</sup> For illustration, the good catalytic properties of Pd for the ortho-para hydrogen conversion are retained, more or less, by Pd-Au alloys so long as the d band of electronic energy levels in Pd remain unfilled. At 60 A/o (atom per cent) Au, the d band becomes filled by donor electrons of alloyed Au, resulting in poorer catalytic properties for alloys of this or higher Au compositions, paralleling the properties of pure Au (1).

Similarly, in the Cu-Ni alloy system, the alloys are passive so long as the d band of energy levels remain unfilled (2, 3). Passivity in this case is measured by an observed passive current density lower in value than a critical current density needed to achieve passivity in polarization curves for the alloys in 1N H<sub>2</sub>SO<sub>4</sub> (Fig. 1). As Cu is added to Ni, the single 4s electron of the Cu atom fills the 1.6 vacancies per surface atom of Ni, increasing the critical current density and also the passive current density (Fig. 2). At the composition at which the d band is 100% filled, or any composition above this value, the passive current densities disappear (or critical and passive current densities intersect) and the alloys up to and including pure Cu are therefore not passive. Other elements alloyed with Cu-Ni alloys may also be a source of donor electrons. In single-phase solid solution alloys, it is observed that alloyed Zn contributes 2 electrons per atom (4), (and hence one Zn is equivalent to two Cu atoms in the Ni alloy), Al contributes 3 electrons (5), Ga contributes 3 electrons, and Ge contributes 4 electrons (6) per atom as is expected from the number of electrons in the outermost orbits of these elements. In each case, the alloy loses its passive characteristics very near to the composition corresponding to 100% filled d band. These results support the view that the passive film on such alloys has an adsorbed structure rather than a structure consisting of a single or mixed stoichiometric metal oxide.

Fig. 1. Potentiostatic anodic polarization curves for 78.3% Ni-Cu, 49.9% Ni-Cu (unfilled d bands) and 30.4% Ni-Cu (filled d band) in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C. Rates of potential change as shown.

Fig. 2. Critical current densities and passive current densities for Cu-Ni alloys in 1N H<sub>2</sub>SO<sub>4</sub>, 25°C. The d band of electronic energy levels is filled by electrons from Cu at about 60% Cu.

They are employed, for example, to increase the life of automotive engines (as added to lubricating oils), heat exchangers, storage tanks, distribution piping, air conditioning equipment, pickling tanks, and steam lines.

Recent corrosion research has produced titanium alloys containing a few tenths per cent palladium with greatly improved resistance to aggressive acids. Alloyed steels are available, much less expensive than stainless steels, which do not need painting or other types of maintenance. They make use of an adherent natural rust film which essentially protects the underlying metal from further attack. Their promise derives from the present high labor costs of painting which, over the life of a steel structure, may exceed the original cost of construction. Mention might also be made of anodic protection, a new technique for corrosion control in the chemical industry which resulted from fundamental studies of passivity. Using a moderate electric current at controlled potential, it is possible to employ ordinary steels in contact with hot corrosive acids avoiding the extremely high reaction rates which otherwise occur. Cathodic protection in similar applications require uneconomically high current densities attended by undesirable gas evolution.

### Unsolved Problems

The number of unsolved problems relating to metal surfaces is limited only by human imagination. Potentially important advances could obviously be made through improved catalysts, better lubricants, and more efficient corrosion inhibitors, to name but a few. And it should also be recognized perhaps that any scientific breakthrough on knowledge of surfaces has an immediate impact on several fields rather than on one field alone. Hence fundamental research in corrosion, about which the writer is most familiar, is in position to benefit present knowledge of catalysis (e.g., effect of d electron vacancies, mentioned earlier, or the structure and composition of initially formed films on metals) or of our present understanding of lubrication and wear (through studies of mechanically activated chemical reactions such as occur in fretting corrosion or in cavitation-erosion) or of devices which depend on electron emission (through studies of surface films).

The unsolved problems of today which exert pressure for some satisfactory practical solution are usually approached either empirically or more effectively through some depth of scientific understanding. Basically, the most important unsolved problem of metal surfaces is the achievement of an adequate scientific understanding. Is the passive film on stainless steels a metal oxide or is it instead an adsorbed complex of oxygen and water? It makes a great difference if one plans to expend development funds for improving protective surface films by the particular approaches of anodizing or of low-temperature oxidation. Or what is the optimum chemical structure of a nontoxic corrosion inhibitor suited to avoid rusty water in steel distribution mains? Polyphosphates, the action of which is little understood, are used by many communities, but how should one best go about finding a better inhibitor? Or to cite a more spectacular example, by what basic mechanism do high-strength metals fail unexpectedly by cracking when exposed to natural environments? Does an electrochemical mechanism apply, or does a brittle surface film continuously rupture, or does the surface instead undergo reduction in energy (hence favoring the crack process) because of environmental adsorption? All three mechanisms have been suggested. The practical problem presents a serious bottleneck to engineering designs making use of high-strength materials whether for the aircraft, hydrospace or aerospace programs. If one includes threatened stress corrosion cracking of high-nickel alloys used for atomic energy installations, it is obvious that this unsolved surface problem alone affects progress in practically every important outpost of modern technology. Again, the best approach to overcoming environmental cracking depends very much on which mechanism is finally shown to apply. Otherwise, the approach remains a shotgun effort with scattered results.

At least three scientific areas must be expanded if a more satisfactory background on surface problems is to become available. These are: (a) studies of electrode kinetics, (b) studies on the nature of initially formed surface films on metals, (c) studies of how metals subject to a tensile stress interact with their environments.

Under the subject of electrode kinetics, more general quantitative information is needed, including that related to adsorption and desorption of ions and of organic complexes on metals as a function of applied potential. Additional information is required, for example, on factors both within the metal and within the environment which influence the Tafel constants expressing anodic dissolution rates of metals.

Regarding surface films, more information is needed on the composition and structure of passive films common to the stainless steels, and which are also germane to the phenomenally passive metals like tantalum and hafnium. For thicker oxide films which form at elevated temperatures, the question arises as to the role of space charges, reaching a distance of

10,000Å into the oxide, on both surface properties and on the oxidation mechanism. How do small additions of rare earth metals improve the spalling characteristics of oxide films, thereby improving high temperature oxidation resistance? What is the nature of the chemical reaction between metals and their environment during fretting corrosion (caused by sliding surfaces)? It is known that in air at room temperature, iron frets to form particles of metallic iron and of  $\alpha$   $\text{Fe}_2\text{O}_3$ , but in  $\text{H}_2\text{S}$  it is  $\text{FeS}$  that forms and in  $\text{CO}_2$  the reaction product is  $\text{FeCO}_3$ .

In problems of environmental cracking, called stress corrosion cracking, what is the role of complex ions and what part does the corrosion potential play in determining initiation or rate of cracking? What are detailed factors in the metal which determine whether dislocations emerge and which determine their half life at a metal surface during which adsorption presumably occurs? What are the effects of impurities, lattice structure and alloying components on densities of emergent dislocations? What are the chemical properties of surface dislocations which account for  $\text{NO}_3^-$  adsorbing, or otherwise interacting with iron, causing subsequent cracking, and which also account for the ineffectiveness of  $\text{Cl}^-$  to cause the same damage? Or in austenitic stainless steels, which are essentially iron-base alloys, what are the properties of surface imperfections which make  $\text{Cl}^-$  damaging and  $\text{NO}_3^-$  nondamaging?

### Conclusions

Fundamental knowledge necessary to solve various surface problems of the kind described have traditionally been supported on a hit-or-miss basis fluctuating with the number of military or industrial crises at any given moment. The modest accumulated science of metal surfaces presently at hand has been helpful, but unfortunately not adequate to contribute what is needed for continuing technological progress. The establishment of materials science centers, of which the present center at the University of Missouri is a welcome example, promises to supply more of the science which is now missing. Contributions of such research centers to surface properties, and to corrosion problems in particular, are patiently awaited by many of those who hope to use materials to optimum advantage when exposed, as they most always are, to some environment which affects their ultimate properties and useful life. In the long run, increased attention to chemical and surface properties of materials, on par with mechanical or physical properties, will lead to a better evaluation of the environmental effects which are becoming increasingly important to modern engineering design. This kind of information must be available, of course, for both metallic and nonmetallic materials, because all materials are subject to some degree of environmental damage, the extent of which sensitively bears on their satisfactory incorporation into some machine or structure.

At one time I recommended (7) that corrosion research would greatly benefit through the continuous support provided by a National Institute of Corrosion Control established on a smaller scale but similar to our well-known National Institutes of Health. Perhaps the need for such an Institute is made less urgent by the several materials science centers which have since been established. Yet the variety of problems which are inherent to advanced materials and which fully occupy present research facilities all over the nation, suggest that a special coordinated research effort at such a national center with specific emphasis on chemical and surface properties deserves further consideration. The added functions which such an Institute could provide, for example, are (A) detailed expert attention to corrosion engineering problems of broad public concern affecting the many small businesses and communities unlikely to undertake a broad range research program on their own initiative. (B) The effective dissemination of general corrosion control know-how to all those able to make use of it. (C) The

support and prosecution of fundamental research on properties of surfaces supplying new knowledge not only on metal reaction rates but also on other properties of value to related scientific disciplines similarly concerned with surface behavior.

In whatever way it is finally accomplished, we stand as a nation to benefit from research programs, considered in depth, which bring the many disciplines of the physical sciences to bear on solutions of surface problems. Only a relatively short time ago these problems, including corrosion phenomena, were considered, like the weather, to be unpredictable and hardly amenable to scientific insight. The dedication of this Graduate Center of Materials Research at Rolla symbolizes our entry into a more enlightened era of materials research.

## DIVISION NEWS

### Dielectrics and Insulation Division

The Annual Luncheon and Business Meeting of the Dielectrics and Insulation Division will be held during the Spring Meeting of the Society in Boston, Mass., May 5-9, 1968. As a continuation of the policy of offering an outstanding speaker for the occasion, Jerome B. Wiesner, Provost of the Massachusetts Institute of Technology and former Scientific Advisor to Presidents Kennedy and Johnson, will speak on a topic of current interest. Dr. Wiesner is internationally known for his interest in the relationships between scientific and governmental affairs.

During the Business Meeting the presentation of the first T. D. Callinan Award will be made. Details on the award are given below.

The Luncheon and Business Meeting will be held in the Bay State Room of the Statler Hilton Hotel from 12:15 to 2:00 P.M. on Monday, May 6. Tickets may be purchased in the Registration area at the Statler Hilton.

Donald M. Smyth,  
Secretary

### T. D. Callinan Award Of the Dielectrics and Insulation Division

In recognition of their contributions to the study of anodic oxide growth mechanisms, J. A. Davies and J. P. S. Pringle, Atomic Energy of Canada, Ltd., Chalk River Nuclear Laboratory, Chalk River, Ont., Canada, have been selected as joint recipients of the T. D. Callinan Award. Their work, which was reported in a group of separate and joint publications, extended over the period 1962 through 1967. Within this period Dr. Davies and Dr. Pringle developed and used Beta-ray spectroscopy and radio-tracer techniques as an experimental tool for the study of anodic oxide growth mechanisms. The reliability of the results obtained with this technique

is perhaps its most outstanding feature and has substantially contributed to an understanding of the mechanism involved.

Dr. Pringle's recent participation at the 1967 Dallas Meeting was based on a continuation and extension of these techniques and dealt with the concentration profiles of atomic species within anodic oxide tantalum film. His presentation was well received and represented one of the outstanding contributions at the Divisional level.

With the presentation of this award, the Dielectrics and Insulation Division inaugurates a new program which originated during Dr. B. Eichbaum's Chairmanship. The Division through this award seeks recognition of recent meaningful contributions. Consistent with these objectives the award bears the name Thomas D. Callinan who during his life generously contributed both his time and energy to the growth and development of the Division in addition to being its Divisional Editor on the JOURNAL and member of the Board of Directors of the Society.

Presentation of the T. D. Callinan Award will take place at the Division Luncheon and Business Meeting being held in the Spring of 1968.

Edward M. DeSilva,  
Vice-Chairman

### Industrial Electrolytic Division

The Nominating Committee of the Industrial Electrolytic Division, comprised of E. F. Kiefer, V. J. Cable and R. M. Hunter, Chairman, presents the following slate of nominees for the two-year terms for each of the offices listed:

Chairman—T. R. Beck, Boeing Scientific Research Laboratories, Seattle, Wash.

Vice-Chairman—J. H. Nichols, Monsanto Co., St. Louis, Mo.

Secretary-Treasurer—R. N. Hyer, Vulcan Materials, Co., P. O. Box 545, Wichita, Ka., J. H. Sullivan, Dow Chemical Co., Midland, Mich., and L. E. Vaaler, Union Carbide Corp., P.O. Box 6116, Cleveland, Ohio.

The election of officers will be held at the Division's annual luncheon and

business meeting May 8, 1968 during the Boston Meeting of the Society.

Clifford A. Hampel,  
Chairman

## SECTION NEWS

### Chicago Section

On January 11, 1968 the Chicago Section met at the Chicago Engineers Club to hear Z. Andrew Foroulis, Esso Research and Engineering Co., Florham Park, N. J., present a paper "On the Kinetics of Iron Dissolution in Acid Chloride Solutions."

The following is a summary:

The mechanism of the corrosion of iron in acid chloride solutions is examined in detail. Galvanostatic transients are used to investigate dissolution kinetics. Influences of potential, pH and ferrous iron concentration on steady-state dissolution and deposition reactions are illustrated. Dependency of the hydrogen evolution reaction on pH and potential are also considered for this system.

On February 15, 1968 the Chicago Section met at the Chicago Engineers Club, to hear Dr. James H. Greenwald, St. Catherine Hospital, Heart

# The Anodic Behavior of Zinc in KOH Solutions

T. P. Dirkse,\* David De Wit, and R. Shoemaker

Calvin College, Grand Rapids, Michigan

## ABSTRACT

The anodic behavior of zinc in strongly alkaline solutions was studied making special note of the limiting current density and of the overvoltage for the zinc/zincate reaction. The effect of temperature, KOH concentration, presence of zincate, and amalgamation on these values was measured. Under the conditions studied, zincate ion diffusion away from the electrode controls the limiting current density. The overvoltage at amalgamated electrodes is that for the charge transfer reaction, while at nonamalgamated electrodes it is due to adatom diffusion.

In developing and designing alkaline batteries using zinc anodes, there are several modifications that can be made to improve the performance of the system. One such modification is the amalgamation of the zinc electrode. This is done in practically all zinc-alkaline batteries. The purpose is to raise the hydrogen overvoltage and thus reduce the corrosion or open-circuit reaction. This amalgamation, however, may also affect the other zinc electrode processes.

A review of the published literature revealed that few factual data are available to show what effect electrolyte concentration, amalgamation, zincate concentration, and temperature have on the anodic processes of the zinc/zincate electrode. For this reason a program of work was undertaken to obtain such information, and the results are reported here.

It is generally agreed that the anodic zinc processes in an alkaline solution consist of at least: (a) the formation of the charge transfer product, probably zinc hydroxide; (b) the dissolution of this product in the electrolyte; and (c) the formation finally of a passivating layer, either by precipitation from the electrolyte or because of inability of the electrolyte to dissolve the charge transfer product as fast as it is formed. While this model serves to account satisfactorily and qualitatively for most observations made on the zinc electrode, still there is little agreement as to the details of these various steps. Furthermore, it has been difficult to get sufficient experimental information to describe some of these processes in detail.

## Experimental

Two methods were used to study the zinc electrode processes.

**Interrupter.**—An interrupted d.c. was used to study the overvoltage of the zinc electrode processes. The circuit has been described (1). A standard resistor was placed in the circuit, and the voltage drop across this was measured on an oscilloscope to determine the current rate. All traces on the oscilloscope were photographed, and in calculating the overvoltage, correction was made for the internal IR drop. The cell, Fig. 1, held about 20 ml of electrolyte. The working zinc electrode area was the cross-sectional area of a 0.063-in. diameter zinc wire encased in a Teflon tube. This was polished smooth on an emery cloth (3/0) before use in the cell. The reference electrode was a 1-in. length of similar wire which had previously been amalgamated. It was held in a polyethylene tube. The auxiliary electrode was a circular zinc sheet, about 0.75 in. diameter, embedded in the bottom of the Plexiglas cell case. In making a series of measurements the current was first increased in several steps then decreased, and finally increased again. In the anodic direction measurements were discontinued when the electrode became passive or a limiting current density was reached.

**Sine wave.**—In the second approach to the study of the zinc electrode reactions, the method of Kordes and Marko (2) was used. A zinc wire served as the reference electrode in some instances, while in others a HgO/Hg reference was used. The latter was connected to the cell by a capillary and contained the same KOH concentration as the cell. The cell case was 8.8 x 5.4 x 2.3 cm. The counter electrodes were two commercial zinc electrodes, 4 x 5 cm, and these were encased in fibrous sausage casing separator. The working electrode, amalgamated where required by dipping it for 30 sec in a solution containing 50 g/l of HgCl<sub>2</sub>, was inserted between these electrodes. The current was increased manually at prescribed time intervals and the polarization (IR free) of the working zinc electrode was measured. A typical anodic curve is shown on Fig. 2.

## Results

In making measurements on the anodic processes, two values were used for comparisons: (a) the limiting current density (*a* in Fig. 2); and (b) the overvoltage associated with the formation of zincate. For convenience this latter was taken as the overvoltage at a current density of 50 ma/in<sup>2</sup> (*b* in Fig. 2). These values were all obtained by use of the sine wave pulse tester method.

Four variables were considered: (i) KOH concentration; (ii) zincate concentration; (iii) effect of amalgamation; and (iv) temperature. A summary of the results at room temperature is given on Fig. 3 and 4.

**Limiting current density.**—The limiting current density (lcd), Fig. 3, shows a general tendency to decrease markedly with increasing KOH concentration in the range of 30-45%. Below 30% KOH the lcd varies somewhat erratically with KOH concentration. For KOH solutions saturated with ZnO there is no apparent effect of KOH concentration on lcd in solutions of 20-30% KOH. Furthermore, the presence of appre-

ciable amounts of zincate in the solution results in a slightly lower lcd for plain zinc electrodes but has no significant effect on the lcd of amalgamated zinc electrodes.

**Zincate overvoltage.**—The overvoltage for the zincate reaction, Fig. 4, shows irregularities with KOH concentration. But in all cases it is lower at the amalgamated electrodes. This is true in the presence as well as in the absence of zincate ions. The overvoltages in KOH solutions containing no zincate originally (open symbols, Fig. 4) are subject to some uncertainty because of the uncertainty in the open circuit voltage in plain KOH solutions. Since no zincate is present, it is possible that no equilibrium potential for the zinc/zincate reaction is obtained. However, a fairly constant potential was obtained at the beginning of each run, and this value was within the experimental uncertainty of that which was obtained by extrapolation of the potentials obtained in solutions containing varying amounts of zincate.

**Temperature effect.**—These anodic processes were also studied over the temperature range of 0–50°C. The lcd did increase with temperature for both types of

electrodes but the difference between amalgamated and nonamalgamated zinc became less as the temperature was lowered, Fig. 5. The effect of temperature on the overvoltage of the zinc/zincate reaction is very slight.

### Discussion

The results obtained in this study for nonamalgamated electrodes can readily be accounted for and explained in terms of the generally accepted outline of the mechanism for the anodic zinc reactions as outlined in the introductory paragraphs. However, the effects of amalgamation on the zinc electrode performance cannot be so readily explained in terms of this scheme. The effects are two:

1. Amalgamation raises the lcd, except at temperatures near 0°C.

2. Amalgamation lowers the overvoltage for the zinc/zincate reaction.

The extensive work of Hampson *et al.* (5) suggests a possible explanation for these phenomena. This explanation assumes that the oxidation of nonamalgamated zinc begins with the movement of zinc atoms from the kink sites (lattice dissolution points, *e.g.*, screw dislocations) to become mobile surface atoms with a low coordination number (adatoms).

These adatoms readily adsorb  $\text{OH}^-$  ions and this may stabilize them.

Metallic zinc electrodes have a high double layer capacity (5a). This results from the charge transfer reaction, Eq. [3], which may proceed in two one-electron stages.

$i_0$  for reaction [3] is of the order of 200 ma/cm<sup>2</sup> (5b).

Reaction [3], which is in agreement with the work of Gerischer (6), is followed by

and

As the zincate concentration increases, a further reaction occurs (3).

The rate-controlling processes may be [1], [4], or [5]. Reaction [3] is likely not rate controlling because of the high value for  $i_0$ . Reaction [2] probably is also a fast reaction.

The anodic oxidation of amalgamated zinc electrodes proceeds by a somewhat different mechanism because the surface is different. Amalgamation "smooths out" the surface or makes it approach a liquid. Consequently atoms can dissolve at any point on the surface. There are no kink sites and no adatoms. Furthermore, there is no evidence for OH<sup>-</sup> adsorption at a zinc amalgam electrode, in contrast to a nonamalgamated electrode (5d). Therefore the first step likely is

The Zn(OH)<sub>2</sub> is not necessarily adsorbed and goes into solution

This is then followed by reactions [5] and [6].

The fact that the variation of lcd with KOH concentration, Fig. 3, is the same for both types of electrodes suggests that the same process is rate-limiting in each case. This could be reaction [4] or [8]. Reaction [5] is a fast reaction and reaction [6] is too slow to take any part in the results we obtained.

Reactions [4] and [8] are step (b) in the anodic process outlined in the introductory paragraphs. The rate of dissolution of the charge transfer product is an important factor especially because of the apparent high solubility of this substance and the slow decomposition of the resulting solute species (3). It is reasonable to expect that this rate of dissolution will decrease with decreasing temperature. This qualitatively accounts for the temperature effect on the lcd. Unfortunately, no quantitative data are available to evaluate this suggestion.

However, the rate of dissolution of the charge transfer product will also depend on the zincate concentration in the layer of electrolyte in contact with the electrode surface. In order for the charge transfer product to continue to dissolve, it is necessary that the zincate ions diffuse away from the electrode. The diffusion of zincate ions from the electrode thus controls the lcd because it affects the rate of dissolution of the charge transfer product. The shape of the curves on Fig. 2 does suggest such a diffusion controlled process.

The diffusion currents and the diffusion coefficients for zincate ions have been measured by a polarographic method over a range of temperatures and KOH concentrations (7). These values for the diffusion coefficients at 25°C are included on Fig. 3 and 5.

There is a marked similarity between the variation of lcd and of diffusion coefficient with KOH concen-

tration at the higher concentrations. There is likewise a similarity between these values as a function of temperature, Fig. 5. Thus it is reasonable to conclude that the lcd's observed in our work can be explained by the diffusion control of the zincate ion (4). In our work, convection as well as diffusion undoubtedly played a role and so the processes cannot be expected to be strictly or only diffusion controlled.

It was noted also that the lcd was higher at the amalgamated electrodes. This is likely a surface area effect. Amalgamation produces more reaction sites on the surface. This larger available area serves to reduce the actual current density at which the electrode is being oxidized. The current densities used in Fig. 2, for example, are calculated on the basis of the gross geometrical area. A lower current density would give rise to a lower overvoltage, Fig. 2. In either event, the result would be to give a higher lcd at the amalgamated electrodes.

It may be argued that if the above explanation is correct, then the presence of zincate ions in the solution should result in a lower lcd. A solution already containing zincate ions can dissolve fewer additional zincate ions (from the electrode reaction) than can a solution which originally contained no zincate ions. There is some evidence for this at the plain zinc electrodes, Fig. 3. The fact that this effect is so slight is explained by the high solubility of the charge transfer product. This substance gives zincate concentrations considerably higher than those obtained by saturating aqueous KOH with ZnO (3).

The difference in overvoltage for the zinc/zincate reaction at the two types of electrodes can be explained by the difference in the mechanism of the reaction at the two electrodes. The overvoltage, or energy barrier, for nonamalgamated zinc electrodes is associated with reaction [1] while for amalgamated electrodes it is associated with reaction [7], the charge transfer reaction.

### Acknowledgment

This work was sponsored and supported by the U.S. Air Force Aero Propulsion Laboratories. The authors also wish to thank Dr. N. A. Hampson for his many helpful discussions and suggestions.

Manuscript received Aug. 9, 1967; revised manuscript received Nov. 13, 1967. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 27.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Solubility and Complex Formation of AgCl in Propylene Carbonate-Water Mixtures

James N. Butler,\* David R. Cogley,\*\* and Walter Zurosky

Corporate Research Division, Tyco Laboratories, Inc. Waltham, Massachusetts

## ABSTRACT

The solubility and complex formation equilibria of silver chloride in propylene carbonate-water mixtures (0.004 to 3.57M H<sub>2</sub>O) have been studied potentiometrically in a constant ionic medium of 0.1M tetraethylammonium perchlorate, at 25°C. The complexes are predominately mononuclear, and the principal species in solution is AgCl<sub>2</sub><sup>-</sup>. The over-all complex formation constants β<sub>n</sub> (n = 1,2,3) decrease and the solubility product K<sub>so</sub> increases with increasing water concentration. Approximate empirical expressions describing these changes are: log K<sub>so</sub> = -20.0 + 3.25 √C<sub>H<sub>2</sub>O</sub> and log β<sub>2</sub> = +21.2 - 4.87 √C<sub>H<sub>2</sub>O</sub>. The intrinsic solubility of AgCl (K<sub>s1</sub>) is 10<sup>-4.7</sup>, essentially independent of the water content of the solvent.

Although the dielectric constant of propylene carbonate [ε = 64.4 (1)] is nearly as large as that of water (ε = 78.54), the solubility and complex formation equilibria of silver chloride are vastly different in the two solvents. Our studies (2) have established that mononuclear complexes predominate in solutions containing excess chloride and have provided accurate values of the equilibrium constants in anhydrous propylene carbonate. These constants are summarized in Table I and are compared with the corresponding constants for aqueous solutions (3, 4). Although the solubility product (K<sub>so</sub>) is more than ten orders of magnitude smaller in propylene carbonate than in water, the complex AgCl<sub>2</sub><sup>-</sup> is so stable that the solubility equilibrium of AgCl in excess chloride, represented by the reaction

(equilibrium constant K<sub>s2</sub>) is six orders of magnitude greater in propylene carbonate.

These dramatic differences in equilibrium constants reflect large differences in solvation of ions in the two solvents, and their detailed variation is of interest in the general context of solvation theory. In addition, the current interest in silver chloride both as a reference electrode and as a battery cathode material in aprotic electrolytes (5-9), has prompted us to study these equilibria in mixtures of propylene carbonate with water.

## Experimental

Propylene carbonate was obtained from Matheson, Coleman, and Bell, and purified by distillation, as described in detail elsewhere (10). Gas chromatographic analysis indicated that the purified solvent contained less than 10 ppm organic impurities and water. Silver perchlorate (Chemical Procurement), tetraethyl ammonium chloride (Eastman), and tetraethyl ammonium perchlorate (Eastman) were dried over anhydrous CaSO<sub>4</sub> in a desiccator before solutions were prepared. Solutions were analyzed (± 0.1%) for chloride ion by potentiometric titration with aqueous silver nitrate, and for silver ion (± 0.2%) by potentiometric titration with the propylene carbonate-chloride solutions of known concentration. Mixtures of propylene carbonate with triple-distilled water were prepared by weight, and their density measured with a pycnometer. The density values (Table II) were used in converting to molar concentrations.

The cell consisted of two electrode compartments connected by a salt bridge with coarse glass frits at each end. One of the electrode compartments con-

tained a Teflon-coated magnetic stirrer, and the entire cell was jacketed and maintained at 25.0° ± 0.1°C by means of a Haake circulating thermostat. Solution preparation, storage, and all experiments were carried out in a dry nitrogen atmosphere in a glovebox. Etched silver wires were used for electrodes in both compartments, and a uniform ionic strength of 0.100M was maintained in all three compartments with Et<sub>4</sub>NClO<sub>4</sub>. The reference compartment contained either Ag<sup>+</sup> at approximately 0.004M concentration or Cl<sup>-</sup> saturated with AgCl at the same concentration. The compartment with the stirrer contained various concentrations of Ag<sup>+</sup> and Cl<sup>-</sup> which were added from 2 ml RGI micrometer burettes containing 0.1M AgClO<sub>4</sub> or 0.1M Et<sub>4</sub>NCl in the same solvent mixture as was used for the supporting electrolyte. Potentials were measured with a Fluke high-impedance differential voltmeter, and were usually steady to within 0.1 mv.

## Results

The results of nine experiments in different solvent mixtures are summarized in Table III. The values given in the table were selected to give a representative shape of both the saturated and unsaturated portions of the titration curve. Sufficient data have been given to permit future workers to make different statistical curve-fitting calculations, but when measurements were so closely spaced that they provided no additional information, the extra points were elim-

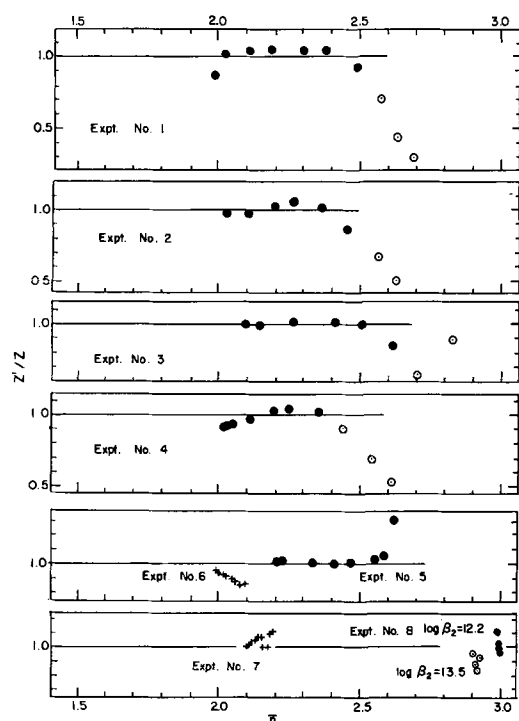

Fig. 1. Variation of experimental measurements from theoretical Eq. [2-4]. The detailed data are given in Table III and the constants used for the theoretical curves are given in Table IV.

rides bound to a silver ion, defined by the equation

$$\bar{n} = \frac{C_{Cl^-} [Cl^-]}{C_{Ag}} \quad [5]$$

i.e.,  $\bar{n} = 2$  corresponds to the predominance of  $AgCl_2^-$  and  $\bar{n} = 3$  to the predominance of  $AgCl_3^-$ . For a good fit, the values of  $Z'/Z$  should be normally distributed about unity. The constants were obtained with the set of crosses or solid points, the open points being discarded.

Systematic deviations from the theoretical equations were observed at high values of  $\bar{n}$  (high  $C_{Cl^-}/C_{Ag}$  ratios). Similar deviations were observed previously (2) and were attributed to the failure of the constant ionic medium assumption. However, the deviations are smaller for experiment 5, even though the total concentrations are nearly ten times larger than in experiment 4. One possible explanation is that complexes of higher  $\bar{n}$ , possibly polynuclear, may exist in solutions of high chloride-to-silver ratio, but these are of less importance as the water content is increased.

The predominance of mononuclear complexes has been confirmed in experiments 5 and 6. The to-

tal concentrations in 5 were approximately ten times those in 6, and the combined sets of data were fitted with the same three constants. The values of  $Z'/Z$  agreed (Fig. 1) to within 10%, although a slightly different set of constants would have produced a better fit to experiment 6. The slight difference, which appears to be outside the precision of the individual experiments, may reflect small amounts of polynuclear complexes, but is small enough to be accounted for by systematic errors in the measurements.

The value of  $\beta_1$  calculated from experiment 7 is uncertain, but is probably less than  $10^{14}$ . Saturation of the solution at low  $C_{Ag}/C_{Cl^-}$  ratios made it difficult to cover a wide range of  $\bar{n}$  without doing experiments in very dilute solutions; and since these would be subject to systematic errors from impurities in the solvent and supporting electrolyte, they were not attempted. The constants  $\beta_n$  calculated from experiments 8 and 9 are uncertain for the same reason. The best fit to experiment 3 was obtained with  $\log \beta_2 = 12.2$ , but an almost equally good fit was obtained with  $\log \beta_2 = 13.5$  (see Fig. 1). Thus we have indicated in Table IV that  $\log \beta_2$  is between 12 and 14. Since a large excess of chloride is present and  $\bar{n}$  is nearly 3,  $\log \beta_3$  is more certain. For this set of data  $\beta_1$  could not be determined, but it is almost certainly less than  $\beta_2$ .

In experiment 9, the shape of the curve was not even close to the theoretical, and no amount of parameter adjustment (within reasonable values) could make  $Z'/Z$  close to unity for all three points. Therefore we assumed that  $\bar{n} = 3$  and hence that the complex  $AgCl_3^-$  predominates. This gave  $\log \beta_3 = 14.2 \pm 0.5$ , which we have listed in Table IV.  $\beta_2$  and  $\beta_1$  are probably less than  $10^{12}$ , but more detailed studies of these solutions with high water concentrations are required before accurate estimates of the constants are possible.

From each point obtained in the saturated region, a value of the solubility product  $K_{s0}$  can be obtained by solving the equation (2)

$$(C_{Cl^-} - C_{Ag} + [Ag^+])[Ag^+]^2 = K_{s0}(1 + \beta_2 K_{s0})[Ag^+] + 2\beta_3 K_{s0}^3 \quad [6]$$

using Newton's approximation method. These values are shown in Fig. 2 and 3. Systematic variations of  $-\log K_{s0}$  to smaller values as  $C_{Ag}/C_{Cl^-}$  increases are observed in all the experiments, but were greatest for the lowest and highest water content. Similar deviations were observed before (2) but no simple explanation is apparent. The values of the solubility product listed in Table IV were obtained from the region close to the saturation point.

Values of the constant  $K_{s2}$  were obtained by combining the experimental values of  $\beta_2$  and  $K_{s0}$  according to the relation

### Discussion

The results of our experiments have shown a smooth variation in all the equilibrium constants as the concentration of water increases. The constants obtained in this study with the lowest water concentration are in agreement with those obtained previously (2); and for water contents below  $10^{-2}M$ , the constants vary by an amount approximately equal to the experimental error.

Although no simple equilibrium or structural model predicts the form of the equations, a convenient empirical expression of the dependence on water concentration is a linear function of the square root of  $C_{H_2O}$ . A similar dependence has been observed for the standard potential of the Ag/AgCl electrode in ethanol-water mixtures (12). Approximate expressions for the constants obtained in this work are

$$\log \beta_1 = +15.3 - 3.25 \sqrt{C_{H_2O}}$$

$$\log \beta_2 = 21.1 - 4.87 \sqrt{C_{H_2O}}$$

$$\log \beta_3 = 23.75 - 7.55 \sqrt{C_{H_2O}} \text{ for } C_{H_2O} < 0.5M$$

$$\log K_{s0} = -20.0 + 3.25 \sqrt{C_{H_2O}}$$

$$\log K_{s1} = -4.7$$

$$\log K_{s2} = +1.1 - 1.62 \sqrt{C_{H_2O}}$$

$$\log K_{s3} = +3.75 - 4.3 \sqrt{C_{H_2O}} \text{ for } C_{H_2O} < 0.5M$$

These equations give the experimental values of the constants within approximately  $\pm 0.5$  logarithmic units and are convenient for rough interpolation or extrapolation.

Figure 4 is a graphical representation of the results of this study, calculated using the above empirical expressions. Curves showing the solubility  $S$  of AgCl as a function of the concentration of added chloride  $C$  are drawn for solvents of various composition. In solutions of moderate chloride concentration ( $10^{-2}M$ ), the solubility of AgCl decreases by about a factor of 20 as the solvent is changed from pure propylene carbonate to propylene carbonate containing 3M  $H_2O$ , and by an additional factor of 1000 as the solvent is changed to pure  $H_2O$ . It is curious coincidence, however, that the solubility of AgCl in the absence of added chloride (left of diagram) is almost exactly the same ( $2 \times 10^{-5}M$ ), independent of the composition of the solvent. This coincidence is all the more remarkable because in propylene carbonate the predominant species are undissociated AgCl molecules, and in water the predominant species are  $Ag^+$  and  $Cl^-$  ions.

Although large changes are observed as the water concentration is increased from zero to the two-phase boundary (approximately 3.6M), the equilibrium constants for solubility and complex formation of silver chloride in this water-saturated propylene carbonate solution are still very different from those in pure water. Since the solutions on opposite sides of the miscibility gap are in equilibrium, this implies that similar dramatic changes in equilibrium constants would be found if small amounts of propylene carbonate were added to water.

A qualitative explanation of these large changes may be found in a discussion of the factors influencing the free energy of solvation of ions in the mixed solvents. The solubility product  $K_{s0}$  reflects the free energy change for the reaction

and is larger (less negative  $\log K_{s0}$ ) the more strongly the ions are solvated. Thus a medium of higher dielectric constant, or stronger specific interactions be-

Fig. 4. Solubility ( $S$ ) of silver chloride in propylene carbonate water mixtures containing excess chloride of concentration  $C$ . These curves were calculated using the equilibrium constants in Table IV.

tween the ions and solvent, would tend to increase  $K_{s0}$ . As the medium is changed from propylene carbonate to water, the dielectric constant changes very little, but the hydrogen bonding of the solvent to chloride ions is very much less in propylene carbonate than in water. Thus we may attribute the changes in  $K_{s0}$  which we observe largely to the differences in hydrogen bonding between chloride ion and solvent. Since propylene carbonate is probably a relatively weakly coordinating ligand, the free energy of solvation of the cation probably does not change very much as the composition of the solvent changes. Of course, the separation of the observed variation in  $K_{s0}$  into contributions from solvation of cation or anion is a non-thermodynamic procedure, and we can discuss rigorously only the variation of the sum of the two free energies of solvation.

The other constant for which simple qualitative arguments may be clearly made is  $K_{s2}$ , which reflects the free energy change for the reaction

Here we observe directly the difference in free energy of solvation for two anions. If there were no specific interactions with the solvent, we would expect  $K_{s2}$  to be somewhat greater than unity, simply because  $\text{AgCl}_2^-$  is a larger ion than  $\text{Cl}^-$ . As the dielectric constant of the medium increases, we would expect the effect of size to be less, and thus expect  $K_{s2}$  to approach closer to unity. As is clear from Table IV, the observed values of  $K_{s2}$  decrease below unity at water concentrations around 0.5M, and are nearly five orders of magnitude smaller than unity in pure water (Table I). Hydrogen bonding of the solvent to  $\text{Cl}^-$  would tend to decrease  $K_{s2}$ , and this apparently causes the overwhelming change as the solvent is changed from propylene carbonate to water. Coordination of the solvent to silver would be expected to increase  $K_{s2}$ , and this may be a partial contribution to observed value  $K_{s2} = 10$  in the anhydrous solvent, but is certainly a much smaller effect than hydrogen bonding. This observation tends to confirm our previous statement that most of the increase in  $K_{s0}$  with increasing water content was attributable to increased solvation of  $\text{Cl}^-$  and not  $\text{Ag}^+$ .

The intrinsic solubility of AgCl ( $K_{s1} = \beta_1 K_{s0}$ ) reflects the free energy of solvation of the neutral complex AgCl, and this varies only slightly over the range from anhydrous propylene carbonate ( $K_{s1} = 10^{-5}$ ) to water ( $K_{s1} = 10^{-6.5}$ ). If anything, this variation implies that the coordinate bonding of propylene carbonate to silver is greater than water, but the effect is much smaller than the variations involving the solvation of the chloride ion.

Since these experiments were carried out in a constant ionic medium of 0.1M  $\text{Et}_4\text{NClO}_4$ , it is of interest to estimate the effect of the tetraethylammonium and perchlorate ions on the observed concentration equilibrium constants. The effect of ionic strength can be

estimated from the Debye-Hückel theory and is essentially the same for all the solvent mixtures. At zero ionic strength,  $\log \beta_1$  and  $\log \beta_2$  would be approximately 0.35 units greater and  $\log K_{s0}$  would be approximately 0.35 units more negative. The effect of ionic strength on the constants  $\beta_3$ ,  $K_{s1}$ , and  $K_{s2}$  is negligible in the range where the Debye-Hückel theory is applicable. Ion pairing with the supporting electrolyte would tend to increase  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$ , and decrease  $K_{s0}$ , but have little effect on  $K_{s1}$ ,  $K_{s2}$ , and  $K_{s3}$ . However, since the dielectric constant of these solvent mixtures is high, and since little evidence for ion pairing between alkali metal, tetraalkyl ammonium, halide, or perchlorate ions, has been observed in water, the effects of ion pairing on the measurements described here is probably very small.

As is well-known (5-8), the solubility of AgCl can be suppressed by using electrolytes such as  $\text{LiAlCl}_4$  which have a low concentration of free chloride ion. Studies are now in progress which are intended to elucidate the equilibria in such systems.

### ABSTRACT

The anodic oxidation of nickel hydroxide in pure lithium hydroxide electrolytes produces an n-type semiconductor. The anodic oxidation involves lithium migration into the active material. The beta phase is characterized at room temperature by Seebeck coefficients near  $-100 \mu\text{V}/^\circ\text{K}$  and electrical conductivities of 1 mho/cm. This is in contrast to the positive Seebeck coefficient for lithium nickelate.

The nickel hydroxide positive electrode is considered to involve a divalent  $\text{Ni}(\text{OH})_2$  and a trivalent nickelate discharge and charge state. The designation beta phase was used by Tuomi (1) to describe the oxidized state without giving an explicit chemical composition formulation. Variations in the electrochemical processing conditions can modify the beta phase structural characteristics. The beta phase, however, appeared to be consistently an n-type semiconductor through hot point probe tests. On the other hand, the beneficial effects of LiOH additions to the battery electrolyte frequently are attributed to "p" type semiconduction enhancement in the charged phase as noted in Li doped NiO.

The following brief electrical property study was performed to clarify the experimental problem.

### Experimental

The oxidized product formed from crystalline  $\text{Ni}(\text{OH})_2$  during charge in pure LiOH electrolytes is structurally related to lithium nickelate (1). An Edison tubular positive electrode set was charged at 25° and 85°C in 5M LiOH using a 300 ma rate for 216 hr (69.8 amp-hr) to give complete oxidation to trivalent beta phase. After charging, the active material was removed, pulverized, and fractionated to beta plus nickel flake using magnetic separation. The beta powder was processed further to give the four samples: (a) C:uw, a 25°C charge unwashed; (b) C:w, a 25°C charge washed with distilled water; (c) H:uw, a 85°C charge unwashed; and (d) H:w, a 85°C charge washed with distilled water. The chemical analyses and x-ray diffraction examinations were performed on portions using earlier procedures (1). One sample set was fired in oxygen at 850°C for 16 hr.

Samples compressed into the annulus between two contact rings were used to measure the electrical properties. The Seebeck coefficient was calculated from the temperature and voltage differences measured when the center ring was heated. The electrical conductivity measurement involved a four point probe using very low frequency a-c current to minimize contact resistance effects.

The chemical analysis results are summarized in Table I, while the electrical and structural observations appear in Table II. The sample titled  $\text{Li}_x\text{Ni}_{1-x}\text{O}$  was formed by repeated grinding and refiring of a NiO-LiC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> mixture at 850°C in oxygen for a 12 hr total time.

### Discussion

The material structure depended on the processing. The initial product was identified as small particle size beta phase with the hexagonal lithium nickelate structure. Firing in oxygen converted three samples to the cubic NiO phase with  $x < 0.3$  in  $\text{Li}_x\text{Ni}_{1-x}\text{O}$ , and

one to a hexagonal lithium nickelate at  $x = 0.41$ . The reaction product of NiO and LiC<sub>2</sub>H<sub>3</sub>O<sub>2</sub> was hexagonal nickelate at  $x = 0.45$ . The general observations are consistent with the prior investigators (2). However, the hexagonal unit cell volumes were 6% greater than anticipated.

The electrochemical oxidation in LiOH converted the  $\text{Ni}(\text{OH})_2$  to a trivalent oxide with a 2.86 to 3.07 valence as shown in Table I. This was accompanied by a nickel content decrease from 63.4% to 56-59%. This is higher than 53.9% for  $\text{HNiO}_2 \cdot \text{H}_2\text{O}$  and less than 74% for  $\text{HNiO}_2$  or 60.1 for  $\text{LiNiO}_2$ . Since no attempt was made to remove sorbed water the solid phase is more consistently viewed as an anhydrous oxide than a simple hydrate such as  $\text{Ni}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ .

The C:uw and C:w 25°C product has a lower lithium content than the 85°C material. The difference in Li content for the washed and unwashed materials could not readily be explained by extraneous Li<sub>2</sub>CO<sub>3</sub> formation. The comparable product valence states suggest protons effectively exchange for Li. The data clearly indicate Li sorption during charge. A loaded tube impregnated with electrolyte and dried as above contained only 0.16% Li.

The lithium to nickel molar ratio varied from 0.2 to 0.7 for dried materials and did not change during 850°C firing. This ratio is not consistent with viewing the reaction product as  $\text{LiNiO}_2$ . On the other hand, the charged phase lithium content implies oxidation in LiOH electrolyte is best not simply viewed as proton migration out of  $\text{Ni}(\text{OH})_2$  to form an  $\text{HNiO}_2$  phase. Rather hydroxyl at the double layer reacts with protons forming water while lithium ions make transitions into the active phase interior. Process details depend on the charge distribution through solid-electrolyte interphase.

The 850°C oxygen atmosphere firing process increased the nickel content to the 70% range with corresponding lithium percentage increases. By contrast, the nickel valence dropped to 2.2-2.5 from 3. The cubic fired products  $\text{Li}_x\text{Ni}_{1-x}\text{O}$  with  $x < 0.3$  showed calculated  $x$  values based on both Li and Ni were consistent with the nickel valence determination. The fired H:uw sample with the highest Li content corresponded to hexagonal  $\text{Li}_{0.41}\text{Ni}_{0.59}\text{O}$ . After firing the measured and calculated (% Li in  $\text{Li}_x\text{Ni}_{1-x}\text{O}$ ) valence states are related as shown in Table III. The valence change and structural modifications are consistent with a  $(\text{H,Li})_x\text{Ni}_{1-x}\text{O}$  containing sorbed H<sub>2</sub>O transformation to  $\text{Li}_x\text{Ni}_{1-x}\text{O}$  accompanied by water and oxygen evolution.

The electrical measurements, Table II, provide more detailed insight into the problem complexity. Conventionally, the addition of lithium to NiO is viewed as introducing holes into the band structure (i.e.,  $\text{Ni}^{+3}$

local sites) and forming a p-type semiconductor (3). The anodic oxidation, however, converted the Ni(OH)<sub>2</sub> insulator to a high electrical conductivity n-type semiconductor. The reaction product has a negative Seebeck coefficient varying from -58 to -107  $\mu\text{V}/^\circ\text{C}$  at 0.7-5.0 mho/cm. The firing process produces the expected p-type conduction with S between +97 to +137  $\mu\text{V}/^\circ\text{C}$  and  $\sigma$  near 0.7 mho/cm. This compares to +70  $\mu\text{V}/^\circ\text{C}$  at 0.16 mho/cm for the direct reaction product Li<sub>0.45</sub>Ni<sub>0.55</sub>O. Lower nickel valence state fired products are also p-type. Thus, the LiOH electrolyte modification of the charged phase does not involve the anticipated semiconductor doping effect (4). It should be noted that Richardson (5) observed that the higher valence state precipitated nickelic oxides are also n-type semiconductors as has been previously noted for the KOH anodic oxidation product (6).

Even for a pure LiOH electrolyte the electrochemically oxidized Ni(OH)<sub>2</sub> is an n-type semiconductor beta phase. The semiconductor gross features are not under drastic control by alkali cation content. The n-to p-type transformation on heat treatment suggests the lattice or local electronic coordination imperfection depends on the hydrogen ion distribution effect on local band structure.

The characteristic Li<sub>x</sub>Ni<sub>1-x</sub>O composition formed by firing at 850°C is consistent with a trivalent nickel stabilization by local site symmetry conditions. The p-type conductivity for 0 < x < 0.5 is not simply interpretable as trivalent ion promotion through the local band electrostatic neutrality condition as in slightly Li doped NiO.

The recent results of Bosman and Crevecoeur (7) indicate a band model rather than the thermally activated carrier hopping model applies to nickel oxide. The detailed study of anodic oxidation products as well as the simple Li<sub>x</sub>Ni<sub>1-x</sub>O system could provide considerable insight into electronic processes in electrochemical systems. The local site symmetry constraints in high density, well-ordered, lithium nickel-

ates are markedly stronger than in the less crystalline anodic product which frequently can approach an amorphous structure having only first and second nearest neighbor symmetry. The dilemma is accentuated when it is noted that the case of trivalent nickel oxidation to tetravalent alpha phase depends on electrolyte composition and electrode processing. Clearly interpreting chemical additive effects as altering semiconductor processes is questionable without detailed study.

The high electrical conductivity of the oxidized phase does not necessarily inhibit mass transport in the relevant electrochemical processes. A high electronically active site density is implied by the high conductivity with the probable low carrier mobility along with contact resistance in the fine grain material. Under such conditions, a variety of unusual behaviors related to imperfection densities would not be surprising. The space charge distributions within the compounds during cycling will depend partially on the electronic transport properties interactions with the mass transport as well as the interphase phenomena including Peltier effects, and the electronic-ionic exchange processes.

Detailed studies on the importance of impurity banding, metallic conduction, etc. to electrode behavior may be undertaken through a systems approach to the problem. The interpretation of n-type high conductivity in the anodic oxidation product with p-type in the cubic and hexagonal divalent-trivalent nickel solid solution of Li<sub>x</sub>Ni<sub>1-x</sub>O compounds requires a detailed knowledge of imperfection structure relationships to band structure. It should be emphasized that the semiconductor under consideration is an extremely complex chemical and structural system reflecting the formation conditions. A priori the system is not conceptually related to ceramic or single crystal cubic NiO. Rather the material represents a solid solution with nonstoichiometric characteristics and considerable disorder in the system Ni-O-Li-H. Mott's review (8) on electrons in disordered structures brings attention on to one class of problems to be solved. The mass and charge transport in the electrochemical oxidation-reduction process provides a general phase transformation kinetics problem.

### Acknowledgments

The assistance of J. Bronson and L. Middlecamp in the experimental work is gratefully acknowledged. The analytical services were provided through the cooperation of B. D. Brummet. The research benefited from discussions with Drs. G. T. Croft, J. B. Johnson, and P. F. Grieger at the T. A. Edison Research Laboratory. The continued support of Dr. D. W. Collier is appreciated. Special acknowledgments are due to W. W. Smith and associates of the Electric Storage Battery Company for their encouragement and support during the preparation of this paper for publication.

Manuscript received June 19, 1967; revised manuscript received Dec. 11, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## ABSTRACT

The electrolysis of ammonium bifluoride in anhydrous hydrogen fluoride (AHF) was investigated. Polarization curves of Monel in solutions of  $\text{NH}_4\text{HF}_2$  in AHF did not show any diffusion-limited regions indicative of a potential-dependent stepwise reaction. The results of this study indicate that the fluorination of  $\text{NH}_4\text{HF}_2$  in AHF occurs by a radical mechanism involving anodically generated fluorine. Chronopotentiometric data, current-potential curves, and product yields *vs.* time curves, indicate that the fluorinating agent, during electrolysis, is a "loose" complex between  $\cdot\text{F}$  and  $\text{NiF}_2$  and/or  $\text{CuF}_2$ . *Trans-N}\_2\text{F}\_2* was the only N-F product formed from the electrolysis of  $\text{NH}_4\text{HF}_2$  in AHF.

The use of anhydrous hydrogen fluoride (AHF) as a solvent for the electrolysis of ammonium salts has not been investigated in much detail. Several investigators have reported using AHF as a solvent for the electrolysis of  $\text{NH}_4\text{HF}_2$  (1, 2) but their results indicated that the solvent was not anhydrous. Several electrolyses (3, 4) have been performed using molten  $\text{NH}_4\text{HF}_2$ ; however, they were not reported in much detail either.

Anhydrous HF has many properties which make it a valuable solvent system for studying the chemistry of both organic and inorganic fluorine-containing species. Among these are its ability to dissolve a variety of ionic and covalent compounds in significant amounts and its ionizing powers toward dissolved ionic species. In both of these aspects, it is very similar to water. Also, like water, its self-dissociation constant is small, so that the activity of ionic species contributed directly by AHF to a system under study will be low. Such properties are particularly valuable to an electrochemical approach for studying reaction kinetics in AHF, since the more "waterlike" the solvent system, the more applicable will be past electrochemical experience.

In this investigation an attempt was made to determine the electrochemical mechanism involved in the anodic fluorination of  $\text{NH}_4\text{HF}_2$  dissolved in AHF. A free radical mechanism involving fluorine atoms has long been recognized by many workers as the mechanism involved in the electrochemical fluorination of organic materials in HF (5). Some workers claim the fluorinating agent is a higher valent metal fluoride or metal fluoride compound. Cotton (6) suggests that a nickel anode in HF and KF might form  $\text{K}_2\text{NiF}_6$  and  $\text{K}_3\text{NiF}_6$  which could act as fluorinating agents at the electrode surface. However, none of these higher valent fluorides have ever been identified. Of course, it is possible that these fluorides might be next to the metal and covered with the normal valency metal fluoride such that electron diffraction studies or other analytical devices would not detect them.

## Experimental

The system developed for handling and storing the HF and the electrolytic cells used in this work has been previously described (7, 8). The electrolytic cells were constructed of Kel-F and Teflon with Teflon fit-

tings and valves. All tubing in contact with the cells was either Teflon or Kel-F.

Anhydrous HF was prepared, using commercial HF, by a distillation and electrolysis procedure similar to that of Rogers, Johnson, and Evans (9). Conductivity of AHF prepared in this manner was usually around  $10^{-5}$  ohm<sup>-1</sup> cm<sup>-1</sup>. Water concentration was estimated from an empirical relation given by Ukaji and Kageyama (10).

Monel (alloy No. 400), in the form of 0.125 in. rod, was used as the working electrode. Previously reported data (8, 11) indicates that Monel is probably the most desirable anode material for use in AHF. The Monel electrodes were prepared by mechanical sanding and buffing to a smooth surface. Then they were degreased in hot benzene, washed with distilled water, and vacuum dried. Nickel screen was used for the auxiliary electrode.

The reference electrode used was the Hg/Hg<sub>2</sub>F<sub>2</sub> electrode. Initial work on this electrode was reported by Koerber and DeVries (12); details of construction and performance have been discussed previously (8, 13).

Volatile electrolysis products were analyzed using a Beckman IR 5-A infrared spectrometer, an F & M gas chromatograph (Model 720 with a nickel block), and a modified Electrochemical Corporation mass spectrometer (Model 21-620). A description of the techniques involved in these analyses has been reported (7, 8). Cryogenic programming (using 2 coiled, 7 ft, ¼ in. OD Monel tubes) from -196°C to room temperature was used to separate the volatile products for identification by IR and mass spectral methods. A 70 ft column packed with 50% Halocarbon Oil 13-21 on 30-50 mesh Kel-F molding powder at 0°C, was used for quantitative GC analysis of the volatile products (14). Irtran-2 (Eastman Kodak Company) was used as the liquid and gas IR cell window material.

A unique IR liquid cell was developed in this laboratory to analyze the soluble products (15).

All ammonia used for the  $\text{NH}_4\text{HF}_2$ -AHF solutions was double-distilled and all potentials were *vs.* Hg/Hg<sub>2</sub>F<sub>2</sub> at -20°C.

## Results

A typical steady-state polarization curve for Monel in AHF is shown in Fig. 1. The current increase past ~2.8v is due mainly to F<sub>2</sub> evolution. A hysteresis is noted when reverse polarization is done rapidly, indicating existence of a film on the electrode surface. The passive-type region between open circuit and

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Gulf South Research Institute, New Iberia, Louisiana.

Fig. 1. Polarization curves for Monel in AHF

$\sim 2.8$ v is due mainly to formation of a metal fluoride film. Weight losses for Monel between open circuit and 2.8v were similar to those at open circuit. A typical anodic polarization curve for a Monel electrode in AHF for only 30 min is shown in Fig. 2. The current density peak at  $\sim 1.4$ v indicates an initial film formation. Curves run after an electrode had been in AHF for at least 2 hr did not exhibit this peak.

Anodic polarization curves were made in solutions of  $\text{NH}_3$  dissolved in AHF to determine if the fluorination of  $\text{NH}_4^+$  proceeded in a stepwise fashion as a function of potential. Liquid IR spectra showed that  $\text{NH}_3$  dissolved in AHF formed  $\text{NH}_4\text{HF}_2$  and possibly some  $\text{NH}_4\text{H}_2\text{F}_3$  (7, 8). Two typical steady-state polarization curves made in a 1M solution of  $\text{NH}_4\text{HF}_2$  in AHF are shown in Fig. 3. A plateau-like region can be seen between 3.4 and 3.8v. This current limited region was noted in all polarization curves run in AHF- $\text{NH}_4\text{HF}_2$  solutions; however, its magnitude was not dependent on the  $\text{NH}_4\text{HF}_2$  concentration. Fast polarization curves were also made with a voltage increase of 0.9 v/min. Figure 4 shows two fast anodic polarization curves made in 0.1M  $\text{NH}_4\text{HF}_2$  in AHF.

Galvanostatic cathodic reduction curves were made in an attempt to clarify the diffusion-limited region described above. Reduction curves for Monel, polarized anodically at 2, 4, 5, and 6v in 0.021M  $\text{NH}_4\text{HF}_2$  in AHF, are shown in Fig. 5. The potential arrest at  $\sim 2.7$ v

Fig. 2. Polarization curve for Monel (in AHF for 30 min)

Fig. 3. Anodic polarization curves of Monel in 1M  $\text{NH}_4\text{HF}_2$  in AHFFig. 4. Fast anodic polarization curves of Monel in 0.1M  $\text{NH}_4\text{HF}_2$  in AHF.

is close to the reduction potential for fluorine according to Fig. 1. As shown in Fig. 6, the cathodic charge required for reduction appears to depend on the total charge passed at 6v rather than the increment of charge passed between reductions. These results indicated that a species other than the metal fluoride was being reduced during these reduction experiments.

If the potential arrest at  $\sim 2.7$ v was due to the reduction of fluorine, it should be possible to reach a state where the metal fluoride film would be saturated with fluorine. This effect is shown in Fig. 7. It should be noted that 154 coulombs were passed at 6.0v and a cathodic current applied until the potential returned to approximately the initial open circuit potential before the runs in Fig. 7 were made. Once the metal

Fig. 5. Stripping curves for Monel electrodes polarized anodically in 0.021M NH<sub>4</sub>HF<sub>2</sub> in AHF.

Fig. 6. Cathodic stripping of Monel electrodes from +6.0v in 2.13 X 10<sup>-2</sup>M NH<sub>4</sub>HF<sub>2</sub> in AHF.

fluoride film is saturated, it should be possible to decrease the applied anodic charge and thus have a decrease in the cathodic charge required to reduce the sorbed fluorine. This is shown in runs 3 to 8 of Fig. 7. In Table I, values obtained from reduction measurements in 0.01M NH<sub>4</sub>HF<sub>2</sub> in AHF are given. It can be seen from the table that as the anodic charge and anodic charge begins to approach unity. Also, it should be noted that the anodic and cathodic charges for 6.0 v/2 sec and 4.0 v/30 sec were almost identical.

Constant potential electrolyses were performed using various concentrations of NH<sub>4</sub><sup>+</sup> and anodic potentials. Initially these electrolyses were made in order to identify the products formed. As described above, a cryogenic GC column was utilized for this work. After the volatile products were identified, the coulombic yields of the products were determined as a function of time using a 70 ft Halocarbon Oil Kel-F powder GC column.

None of the liquid IR spectra indicated the presence of any soluble electrolysis products (7, 8). Liquid spectra taken before and after extended electrolysis were identical except for the relative size of the NH<sub>4</sub><sup>+</sup> absorption bands.

Figures 8, 9, and 10 show the yields of the anodic products formed from the electrolysis of 0.1M and

Fig. 8. Yield of 5.0v electrolysis products as a function of time

Fig. 9. Yield of 7.0v electrolysis products as a function of time

Fig. 10. Yield of 9.0v electrolysis products as a function of time

1.0M solutions of  $\text{NH}_4\text{HF}_2$  in AHF at potentials of 5.0, 7.0, and 9.0v. Table II summarizes these results giving the net current efficiency for each of the electrolysis products. The equivalent weight of the metal fluoride was calculated assuming formation of  $\text{NiF}_2$  and  $\text{CuF}_2$ . The current density range given in Table II is the variation of the observed current densities during electrolysis. Most of these runs had a lower current initially. During electrolysis, the current usually increased with time until a relatively constant current region was reached.

### Discussion

Polarization curves of Monel in solutions of  $\text{NH}_4\text{HF}_2$  in AHF were made in an attempt to detect a potential-dependent stepwise reaction (see Fig. 3 and 4). A plateau-like region was noted around 4.0v; however, it did not appear to be dependent on the  $\text{NH}_4\text{HF}_2$  concentration. Polarization curves of metals or alloys in solutions of ammonium salts in HF could not be found in the literature for comparison. Constant potential electrolyses at 5.0v, in 0.1M and 1.0M solutions of  $\text{NH}_4\text{HF}_2$  in AHF, produced no volatile or soluble N-F or nitrogen containing species. Thus, it was concluded that the constant current region was probably due to a phenomena not directly related to the presence of  $\text{NH}_4\text{HF}_2$ .

Fast polarization curves were made to see if the lack of a thick fluoride film (the type formed during steady-state polarization) would result in different anodic polarization characteristics. The only differences noted were a broader plateau region around 4v and erratic behavior in the slope of the curve past the plateau region. Both of these changes are probably due to the inability of the system to reach equilibrium conditions during the fast scan (0.9 v/min.) Points taken for the steady-state curves were recorded after approximately 20 min at each potential.

The galvanostatic reduction curves presented above indicate that both metal fluoride and fluorine were formed on the electrode surface during anodic charging. When cathodic current was applied, only the trapped or sorbed fluorine was reduced. Continuous anodic charging resulted in more sorbed or trapped fluorine, this being due to the increasing film thickness. Experiments performed on nickel anodes in HF indicated similar phenomena (8, 16).

Constant potential electrolyses showed that *trans*- $\text{N}_2\text{F}_2$  was the only N-F species formed during the electrolysis of  $\text{NH}_4\text{HF}_2$  in AHF. Previously reported data (7, 8) indicated that the formation of  $\text{N}_2\text{F}_2$  decreased rapidly with the addition of increasing concentrations of water. Also, as the water concentration increased, increasing amounts of  $\text{OF}_2$  and  $\text{NF}_3$  were formed. The "induction period" (the time required for the yields to reach a constant value) noted in Fig. 10 and 11, are typical of electrolytic fluorination studies reported by other workers (1, 17, 18) including two studies on the electrolysis of molten  $\text{NH}_4\text{HF}_2$  (3, 4).

The effect of increasing current density on the yield of  $\text{N}_2\text{F}_2$  should be noted (see Table II). A previously

reported study of the electrolysis of molten  $\text{NH}_4\text{HF}_2$  (3) stated that a minimum current density of 30 ma/cm<sup>2</sup> was required in order to obtain N-F species.

From the data presented above, it is concluded that the electrolytic fluorination of  $\text{NH}_4^+$  in AHF occurs by chemical reaction with anodically formed fluorine. A free radical mechanism is thought to occur in the electrochemical fluorination of organic materials in HF (5). Some workers claim that the fluorinating agent is a higher valent metal fluoride or metal fluoride compound (6). Another possibility for the identity of the fluorinating agent for this study is a loose complex between  $\text{NiF}_2$ ,  $\text{CuF}_2$ , and  $\cdot\text{F}$  or  $\text{F}_2$  (5).

If the agent was a loose complex, fluorination would occur between the complex and the substrate adsorbed on the anodic film. This type process would thus require an induction period for buildup of the film containing the complexed  $\text{NiF}_2$  and/or  $\text{CuF}_2$ . Initially, low yields of fluorinated species would occur due to the small amount of film on the anode. As the film increased, so would the concentration of fluorinating agent in the film, thus increasing the yield of fluorinated species.

If the fluorination process were due only to  $\text{F}_2$  formed at the anode, there would be no need for the relatively long induction periods noted in Fig. 9 and 10. If fluorination occurred due to formation of higher metal fluorides, it is still difficult to explain the long induction periods. Of course, it is possible that the loose complex involved  $\text{F}_2$  instead of  $\cdot\text{F}$ . However, if a complex is formed, the more active fluorine radical would be preferred to the molecule. This would also help to explain previously reported data (8, 16) where an anodically charged (in KF-AHF solution) Ni electrode was put under vacuum and then returned to the electrolytic cell and cathodically reduced. Very little of the sorbed fluorine had been removed from the film as a result of the vacuum.

Morrow and co-workers studied reactions between  $\text{F}_2$  and  $\text{NH}_3$  in a copper T-shaped reactor (19). They were able to form  $\text{NF}_3$ ,  $\text{N}_2\text{F}_4$ ,  $\text{N}_2\text{F}_2$ , and  $\text{HNF}_2$  along with small amounts of  $\text{N}_2$  and HF. With an excess of  $\text{NH}_3$  only  $\text{N}_2\text{F}_4$ ,  $\text{N}_2\text{F}_2$  and  $\text{HNF}_2$  were formed. When an excess of fluorine was used only  $\text{NF}_3$  and  $\text{NH}_4\text{F}$  were formed. They concluded that the initial step in these reactions was the formation of  $\cdot\text{F}$  from  $\text{F}_2$ . The copper reactor could have acted as a catalyst for the dissociation.

A reason for excess fluorine, in the above reactions, to hinder  $\text{N}_2\text{F}_2$  formation might be that large amounts of fluorine result in relatively fewer fluorine radicals to react with  $\text{NH}_3$ . This might also explain the effect of water on the yields of  $\text{NF}_3$  and *trans*- $\text{N}_2\text{F}_2$  in liquid HF. In aqueous HF, there should be fewer fluorine atoms in the film, thus decreasing the yield of any species dependent on  $\cdot\text{F}$  for its formation.

### Conclusions

In view of the above data, the following mechanism is proposed for the formation of  $\text{N}_2\text{F}_2$  in these studies. This mechanism is similar to that proposed by Morrow (19) and Colburn (4).

The first step in the mechanism above occurs at the electrode surface as a result of an anodic bias equal to or greater than the fluorine evolution poten-

tial. As a result of our experiments, it is felt that the fluorine radicals utilized in step [2] are associated in a loose complex with  $\text{NiF}_2$  and/or  $\text{CuF}_2$  in the anodic film. By use of bond dissociation energies given by Wilson (2), the following values were calculated (in units of kcal/mole) for the heats of formation of steps [2] to [6]: [2]  $-78$ , [3]  $-62.4$ , [4]  $347.8$ , [5]  $-107.9$ , and [6]  $-662$ . Upon addition of these values,  $-562.5$  kcal/mole is obtained for  $\Delta H_f$  of the net equation given in step [7]. Another factor which makes this mechanism more probable is that  $\text{NH}_2\text{F}$  formation has never been observed. If fluorine gas were the fluorinating agent in step [2], the heat of formation would be reduced to  $-31$  kcal/mole, making the initial step of this mechanism less favorable.

Why *trans*- $\text{N}_2\text{F}_2$  is formed instead of *cis*- $\text{N}_2\text{F}_2$  is difficult to explain. One answer might be that either the metals (Ni, Cu, Hg, or Pt) or metal fluorides present in the electrolytic cells catalyzed the formation of *trans*- $\text{N}_2\text{F}_2$  from any *cis*- $\text{N}_2\text{F}_2$  that was formed. It is also possible that under the experimental conditions used, the *trans* isomer required the least energy. *Cis*- $\text{N}_2\text{F}_2$  is reported to be the more active form of  $\text{N}_2\text{F}_2$  (20).

#### ABSTRACT

It could be demonstrated that the initial period of oxidation of nickel at  $400^\circ$  and  $500^\circ\text{C}$  is governed by a logarithmic rate law. However, after approximately 5 hr at  $400^\circ\text{C}$  and 1 hr at  $500^\circ\text{C}$  the rate of oxidation changes into a fourth power rate law ruling in a special oxide-thickness region. This rate law can be understood if a negative space charge, caused by nickel-ion vacancies, in the growing  $\text{NiO}$  layer is assumed and if the current of nickel-ion vacancies from the surface of the oxide layer to the metal-oxide interface is caused predominantly by an electric field established over the layer. The experimental results of the oxidation of nickel are in fair agreement with the proposed mechanism.

During the oxidation of nickel, generally, the metal is covered with a practically pore-free coherent oxide layer of  $\text{NiO}$  in which the reacting components, nickel and oxygen, are spatially separated from one another

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Chemistry Department, Marathwada University, Aurangabad, India.

so that one of the reactants, nickel or oxygen, or both, must diffuse through the oxide layer. The oxidation rate of nickel is slower than that of most other metals. Since nickel oxide is a p-type semiconductor, the assumption of the existence of electron holes  $|e|^\ominus$  and nickel-ion vacancies  $|\text{Ni}|^\ominus$  in nickel oxide is

justified (1). Accordingly, a preferred diffusion of nickel ions and electrons via vacancies and holes, respectively, should occur during the oxide growth causing a parabolic rate law if the oxide layer is thick enough so that this diffusion process is rate-determining. Such a rate law was found at high temperatures when a rather thick oxide layer was formed (2).

As could be demonstrated, however, the oxidation of nickel between 400° and 500°C in the thin oxide film region cannot be evaluated by a parabolic rate law. By a log-log representation of the oxide layer thickness *vs.* the time, a rate law was found to lie between  $t^{1/3}$  and  $t^{1/4}$  indicating that under these experimental conditions additional phenomena become predominant. Oxidation experiments with nickel at 400°C in oxygen at various gas pressures performed by Engell, Hauffe, and Ilschner (3) showed a rate law of the form

$$\xi \sim t^{1/3.7}$$

where  $\xi$  is the thickness of the oxide layer formed in time *t*. This rate law was found up to 1000Å thickness of the oxide. The kinetics of oxidation obtained at 475°C by Gulbransen and Andrew (4) also obeys this time law up to an oxide layer thickness corresponding to 13  $\mu\text{g}/\text{cm}^2$ . For thicknesses larger than this value, a transition to the parabolic rate law has been found by us (3). In this investigation, however, such a transition could not be detected because the oxidation time was not long enough. Below 400°C, several authors could evaluate their experimental results by a logarithmic rate law, especially when the thickness of the oxide layer was very small (< 50Å) (5) or also larger than 200Å (6).

The nickel oxidation at 400°C was repeated and enlarged by 500°C experiments. As shall be demonstrated from the theoretical viewpoint below, the nickel oxidation in the thin oxide layer region can be described by a fourth power rate law ( $\Delta\xi^4 \sim t + \text{const}$ ). This was, indeed, the case for the oxidation experiments performed at 400° and 500°C at various oxygen pressures.

### Experimental

A Sartorius vacuum microbalance was used which operated automatically and recorded the changes in the weight of the sample with time. The sensitivity of the balance could be varied between 1 and 100  $\mu\text{g}$  for a maximum load of 1g. The balance was connected with a flexible red brass tube to enable a horizontal movement of the balance in order to center the sample, suspended by a glass fiber, in the glass reaction tube. The temperature of the latter was controlled to  $\pm 0.5^\circ\text{C}$  by means of a regulated furnace. A grounded steel block was used near the constant temperature zone to minimize the temperature gradient in the reaction vessel. All experiments have been performed in oxygen with  $\text{N}_2 < 1\%$ , in a static system, where  $\text{H}_2\text{O}$  and  $\text{CO}_2$  have been removed by a cooling trap. Because of the large gas reservoir, the uptake of oxygen by the sample during oxidation did not cause a change of pressure in the reaction vessel. The vacuum system consisted of a mechanical pump and an oil diffusion pump with a cooling trap containing solid  $\text{CO}_2$  in acetone.

Pressures higher than 1 Torr were read on a mercury manometer, separated from the rest of the system by another cooling trap while those between 1 and  $10^{-3}$  Torr were measured with a thermotron valve supplied by Leyboldt. For pressures below  $10^{-3}$  Torr an ionization gauge of Heraeus was used. In order to decrease the gas turbulence and convection currents in the system, the portion of the reaction vessel passing through the zone of the temperature gradient was made narrower than the rest by connecting a 20 cm long piece of 7 mm diameter glass tube above the reaction vessel of 32 mm diameter. In addition,

such an arrangement prevents a significant flux of hot gas from the reaction chamber to the balance.

Pure nickel sheets (99.9% Ni), 0.2 mm thick, were supplied by the courtesy of Vacuumschmelze AG, Hanau, who provided the following analysis in weight per cent: 0.061 Fe, 0.001 Mn, 0.0045 Si, 0.001 Cu, 0.007 Co, 0.029 C, and 0.044 Mg. Specimens  $2 \times 2.7 \text{ cm}^2$ , weighing nearly 950 mg were degreased and abraded under pure benzene with emery paper of 6/0. Subsequently, the grinding dust was wiped off by a piece of filter paper. They were then dried at room temperature in vacuum. Since before suspension, the sample had to pass through the hot zone of the reaction vessel, oxygen free pure nitrogen was continuously passed through the system during hanging in order to avoid any uncontrolled preoxidation.

After suspending the nickel sample, the reaction vessel was closed, evacuated, and the furnace moved into the required position. The sample was then reduced in hydrogen at 1 atm for 15 to 20 min and later annealed for 1 hr at a pressure of  $10^{-3}$  Torr. Oxygen was then introduced into the reaction chamber to start the reaction. Experiments have been carried out at 400° and 500°C at various oxygen pressures between 50 and 700 Torr.

Since the attainment of pressure equilibrium in the system, after introducing oxygen, took nearly 2-3 min, the initial weight was found by extrapolation for the experiments at 400°C. The rate of oxidation at 500°C was fast enough to make the extrapolation inaccurate. Therefore, the initial readings were taken in an inert nitrogen atmosphere at the same pressure employed for oxidation.

### Results

For illustration of our results, the rate of oxide growth is plotted both as weight increase per square centimeter,  $\Delta m/A$ , and as thickness,  $\xi$ , of the oxide layer *vs.* time. While  $\Delta m/A$  is represented in  $\mu\text{g}/\text{cm}^2$ , the thickness  $\xi$  is in angström (Å) units. For the calculation of  $\xi$ , a roughness factor *r* of 2 has been assumed as an empirical average surface increase. Therefore, in all graphical representations, 1  $\mu\text{g}/\text{cm}^2$  of weight increase corresponds to 31.4Å.

Unfortunately, the oxidation experiments at 400°C had poor reproducibility of the order of  $\pm 25\%$ . The reason for the lack of reproducibility is not yet known. No oxygen-pressure dependence of the oxidation rate could be derived at 400°C since the expected change of the rate lies within the limits of reproducibility. At 500°C, however, a significant dependence of the oxidation rate on the oxygen pressure has been observed.

For the evaluation of the measurements, different rate laws have to be considered. The first period of oxidation is found best represented by a logarithmic rate law

$$\Delta m/A = k_1 \ln(t + t_0) + \text{const} \quad [1]$$

$k_1$  is a constant and  $t_0$  must be evaluated by trial and error. In Fig. 1 and 2, the measuring data at 400° and 500°C are plotted in a semilogarithmic diagram. The constants  $k_1$  and  $t_0$  are summarized in Table I. As can be seen from Fig. 3 and 4, the following larger periods of oxidation can be evaluated by a fourth power rate law

$$(\Delta m/A)^4 = k_0(t + t_0) \quad [2]$$

According to Eq. [2], the measuring points are plotted as  $(\Delta m/A)^4$  *vs.* the time *t*. The values of  $k_0$  in Table I have been calculated from the slopes of the straight lines in Fig. 3 and 4. Furthermore, the time *t* and the oxide-layer thickness  $\xi$  for the transfer from the logarithmic to the fourth power rate law are summarized.

As can be seen from Fig. 4, the kinetics of the oxidation obtained both by Gulbransen and Andrew and by us (4, 3), can be represented by the same rate law. While the absolute values of the rate of oxidation

Fig. 1. Semi-logarithmic plot of the rate of oxidation of nickel at 400°C and various oxygen pressures. Only the first 5 hr of oxidation have been plotted since later on deviations from the straight lines occur.  $t_0$  was determined by trial and error.

Fig. 2. Semi-logarithmic plot of the rate of oxidation of nickel at 500°C and various oxygen pressures. Only the first 2 hr of oxidation have been plotted since later on deviations from the straight lines occur.  $t_0$  was determined by trial and error.

quoted in (3) are in fair agreement with the present data, those of Gulbransen and Andrew are smaller in spite of the higher temperature (475°C). Obviously, this discrepancy is caused by the higher iron content of our nickel samples. A high impurity of a trivalent metal causes an increase in the rate of oxidation but has no influence on the time law.

Finally, in Fig. 5 there is represented the oxygen-pressure dependence of the rate constant of the fourth power rate law. The reproducibility is not good. But the increase of the rate with increasing oxygen pressure can be clearly demonstrated.

### Discussion

According to other oxidation experiments with nickel, the oxide layer growth was expected to follow a logarithmic rate law at the very beginning of oxidation. The period of this rate law becomes smaller with increasing temperature. At 500°C this period lasted only approximately 1 hr while at 400°C the period was about 4 hr. The isothermal logarithmic rate constants are nearly independent of the oxygen pressure (see Table I). The understanding of the logarithmic rate law is at present not satisfying in spite of the large effort in theoretical treatment (7-9, 11, 12). This

\* Calculated with the estimated value for the surface roughness  $r = 2$ .

unsatisfying situation was discussed by Hauffe and Schottky (10).

After the logarithmic period of oxidation, the experimental data obtained at longer exposure time both at 400° and 500°C fit very well the relation of the fourth power rate law derived below. Furthermore, it is predicted by our theory that the validity of the fourth power rate law is limited. At a certain thickness of the oxide layer, it starts to obey the rate law and approximately after doubling the thickness of the oxide layer, the rate law is no longer valid. At 400°C, the validity of the fourth power rate law could

Fig. 3. Oxidation of nickel at 500°C and different oxygen pressures. In order to demonstrate the validity of the fourth power rate law,  $(\Delta m/A)^4$  is plotted vs. time.

Fig. 4. Oxidation of nickel at 400°C.  $(\Delta m/A)^4$  vs. time is plotted. The reproducibility of these experiments was unsatisfactory ( $\pm 25\%$ ), but nevertheless, each experiment followed the fourth power rate law. Only two curves are represented as examples. As comparison to other measurements, the lines I and II are plotted from experimental data obtained by Gulbransen and Andrew and by Engell *et al.*, respectively.

Fig. 5. Oxygen-pressure dependence of the rate of oxidation at 500°C.  $k_0^{1/4}$  is plotted vs.  $p_{O_2}$ .

be observed after the thickness had reached about 500Å and at 500°C, about 1000Å. That is in rather good agreement with the theoretically predicted value given below. Since the oxidation rate became rather slow with increasing thickness of the oxide layer, we did not wait for the doubling of the initial thickness. The change into the parabolic rate law at longer oxidation time has been found.

In the present paper, the mechanism of the dependence of the rate of oxidation on the oxygen pressure is not discussed because more experimental data are necessary. In spite of the scattering of the values around the straight line in Fig. 5, the oxygen pressure dependence of  $k_0$  is demonstrated.

**The fourth power rate law.**—Under the assumption that the corresponding chemical equilibrium is established at the phase boundaries  $O_2/NiO$  and  $NiO/Ni$ , the ambipolar diffusion and/or the electric field transport of nickel ions via nickel-ion vacancies  $[Ni]''$  and electron holes  $|e|^\circ$  must be the rate-determining step of the oxidation. The rate of oxidation is proportional to the flux of nickel ions,  $j_{[Ni]''}$ , via nickel-ion vacancies. In the following derived equations,  $x$  shall de-

note the local coordinate perpendicular to the surface ( $NiO/O_2$ ) of the sample with  $x = 0$  at the surface and  $x = \xi$  at the interface  $NiO/Ni$ . As already discussed (10, 15),  $j_{[Ni]''}$  can be written as a function of  $x$

$$j_{[Ni]''}(x) = -D_{[Ni]''} \frac{dc_{[Ni]''}(x)}{dx} - c_{[Ni]''} u_{[Ni]''} \frac{dV(x)}{dx} \quad [3a]$$

$D_{[Ni]''}$ ,  $c_{[Ni]''}$ , and  $u_{[Ni]''}$  are the diffusion coefficient, the concentration, and the mobility of the nickel-ion vacancies, respectively, and  $V$  is the electrical potential. A similar equation can be employed for the description of the flux of holes. Both relations have to be combined with the Poisson equation

$$\frac{d^2V}{dx^2} = -\frac{1}{\epsilon\epsilon_0} (z_{[Ni]''} c_{[Ni]''} + c_+)e \quad [3b]$$

which results in rather complex integro-differential equations (15, 10, 11).  $z_{[Ni]''}$  ( $= -2$ ) is the valence of the nickel-ion vacancy,  $e$  the elementary charge,  $c_+$  the concentration of electron holes,  $\epsilon_0$  the permittivity of free space, and  $\epsilon$  the dielectric constant.

Since the mathematical evaluation yields in equations which cannot be tested directly by available experimental data, we have decided to introduce physically reasonable simplifications supplying time laws which can be employed for the evaluation of oxidation experiments.<sup>2</sup> Therefore, the following two cases have been introduced

$$c_+ \gg z_{[Ni]''} c_{[Ni]''} \quad [4a]$$

and

$$c_+ \ll z_{[Ni]''} c_{[Ni]''} \quad [4b]$$

The first case is characterized by a strong chemisorption of oxygen and by a positive space charge in the  $NiO$  layer. This results in a cubic rate law (3). As can be seen from the experimental data, both in the former (3) and in the present paper, the obtained data fit better the  $(\Delta m/A)^4 \sim t$  rate law which is derived below under the validity of condition [4b]. This condition is characterized by a negative space charge in the  $NiO$  layer usually involved in an ambipolar diffusion of ionic and electronic species. Under our experimental conditions, such space-charge layers can have a thickness of several hundreds or thousands of angstroms depending on the disorder of the oxide lattice (16).

It is assumed, as in the metal semiconductor-rectifier theory, that the position of the valence band in  $NiO$  with respect to the Fermi level in the metal is independent of the thickness of the oxide, and, to our approximation, the doping of the oxide. It is, furthermore, similarly assumed that the surface state due to the oxygen ion pins the Fermi potential at the oxide-gas interface, independent of oxide thickness. Furthermore, it is speculated that the energy levels of electrons on the adsorbed oxygen are deep, so the Fermi potential is pinned near the valence band at the oxide-gas interface, closer than the pinning of the Fermi potential at the oxide-metal interface. It is also assumed that the acceptors in  $NiO$  are reasonably shallow.

In the mathematical analysis below, the p-type situation is specified, as the system to be analyzed, although of course the n-type case will be similar. In

<sup>2</sup>With this approximation we digress from the approach of Fromhold, who considered in detail the influence of space charge effects in oxide growth (11). In the cited work, no approximation was made and numerical methods of solution were therefore required. The present approximation, limiting the range of validity of the expression is not a drawback as the range of validity is where space charge effects show the strongest influence. Because of the approximation analytical methods become possible. The characterization of oxide growth is then separated into three parts, first the region of very thin oxide (parabolic), second an intermediate region dominated by space charge effects (present work), and third, the region of thick oxides dominated by diffusion (parabolic). Analysis of the laws for the transition between these regions requires numerical methods.

the following, we substituted  $j_{\text{Ni}^{2+}} = c_{\text{Ni}^{2+}}$ , etc. by  $j$ ,  $c$ , etc. We assume the current of nickel-ion vacancies from the surface to the metal is predominantly driven by the electric field. Therefore, we write

$$\left| D \frac{dc}{dx} \right| \ll \left| c u \frac{dV}{dx} \right| \quad [4c]$$

Thus with Eq. [3a] we obtain

$$j(x) = -c u dV/dx \quad [5]$$

With the relation, fulfilled in the first approximation (10)

$$dj(x)/dx = 0$$

we obtain

$$\frac{dc}{dx} \frac{dV}{dx} + c \frac{d^2V}{dx^2} = 0$$

Inserting  $dV/dx$  from Eq. [5] and  $d^2V/dx^2$  from the Poisson relation

$$\frac{d^2V}{dx^2} = -\frac{zce}{\epsilon\epsilon_0} \quad [6]$$

yields

$$\frac{dc}{dx} = -\frac{\alpha}{2} c^3 \quad \text{with} \quad \alpha = \frac{2zeu}{j\epsilon\epsilon_0} \quad [7]$$

Integration with the limiting condition that the density of nickel-ion vacancies is constant at the surface, i.e.

$$c = c_0 \text{ for } x = 0 \text{ at the interface gas/oxide}$$

supplies

$$c = 1/(\alpha x + 1/c_0^2)^{1/2} \quad [8]$$

By insertion of Eq. [5],  $dV/dx$  and  $V$  itself become calculable

$$\frac{dV}{dx} = -\frac{j}{u} (\alpha x + 1/c_0^2)^{1/2} \quad [9]$$

Integration with the boundary condition

$$V = 0 \text{ for } x = 0$$

supplies

$$\beta V = (\alpha x + 1/c_0^2)^{3/2} - 1/c_0^3 \quad [10a]$$

with

$$\beta = -\frac{3}{2j} \alpha u = -3zeu^2/(\epsilon\epsilon_0 j^2) > 0 \quad [10b]$$

From our model we conclude that the difference of the valence band in NiO at both the interfaces, NiO/O<sub>2</sub> and NiO/Ni, is constant, which leads to a boundary condition of the form

$$V = V_0 \quad \text{at } x = \xi$$

where  $V_0$  is a constant potential (with respect to the potential at the surface) at the metal-oxide interface, and  $\xi$  represents the locus of the oxide-metal interface, i.e.  $\xi$  is the width of the NiO layer. Therefore, Eq. [10] can be reformulated

$$\beta V_0 = (\alpha\xi + 1/c_0^2)^{3/2} - 1/c_0^3 \quad [11]$$

This equation is a fundamental one because it brings the interrelation between the cation flux  $j$  and the other entities  $c_0$ ,  $V_0$ , and  $u$  as the dominant variables.

In order to avoid an equation of the 3rd order during the evaluation of  $j$ , the following reasonable assumption is allowed

$$c_0 \gg (\alpha\xi)^{-1/2} \approx c(\xi)$$

which is equivalent to the relation

$$\alpha\xi \gg 1/c_0^2 \quad [12]$$

Therefore, Eq. [11] will be modified to

$$\beta V_0 = (\alpha\xi)^{3/2} \quad [13]$$

By raising to second power and inserting  $\alpha$  and  $\beta$

from Eq. [7] and [10], we obtain

$$j = \frac{9\epsilon\epsilon_0 u V_0^2}{8ze} \cdot \frac{1}{\xi^3} \quad [14]$$

and with the relation

$$j = c_{\text{Ni}} d\xi/dt \quad [15]$$

where  $c_{\text{Ni}}$  is the concentration of nickel ions in the oxide, finally, the fourth power rate law reads

$$\frac{d\xi}{dt} = \frac{k_0}{4} \cdot \frac{1}{\xi^3} \quad [16]$$

with

$$k_0 = \frac{9\epsilon\epsilon_0 u V_0^2}{2z e c_{\text{Ni}}} \quad [17]$$

or integrated

$$\xi^4 = k_0(t + t_0) \quad [18a]$$

or

$$\xi = k_0^{1/4}(t + t_0)^{1/4} \quad [18b]$$

with  $t_0$  as integration constant.

For further considerations, it is necessary to investigate the limits of the applicability of Eq. [18]. By inserting Eq. [5] into the dissimilar terms [4c] and substituting  $dc/dx$  by Eq. [7], then we obtain with the Nernst-Einstein relation

$$j^2 \gg \frac{u^2 kT c^3}{\epsilon\epsilon_0} \quad [19]$$

Since in the interior of the oxide layer  $c_0 \cong c(x)$ , the applicability of this relation is permitted only if condition [19] is fulfilled. With Eq. [14], it follows

$$\xi^6 \ll \left(\frac{9}{8}\right)^2 \frac{(\epsilon\epsilon_0)^3 V_0^4}{(ze)^2 kT c_0^3}$$

and we obtain for the upper limit of  $\xi$

$$\xi < \gamma \left| \frac{3zeV_0}{kT} \right|^{1/6} \quad [20]$$

with

$$\gamma = \left\{ \frac{3}{4} \left| \frac{\epsilon\epsilon_0 V_0}{z e c_0} \right| \right\}^{1/2} \quad [20a]$$

Correspondingly, we obtain under consideration of Eq. [14] with the relation [12] if  $\alpha$  from Eq. [7] is inserted

$$\xi^4 \gg \left( \frac{3}{4} \frac{\epsilon\epsilon_0 V_0}{z e c_0} \right)^2$$

or with Eq. [20a]

$$\xi^4 \gg \gamma^4$$

and finally, we obtain for the lower limit of  $\xi$

$$\xi > \gamma \quad [21]$$

Therefore, the validity of Eq. [18] is given by

$$|3zeV_0/kT|^{1/6} > \xi/\gamma > 1 \quad [22]$$

From the relation [22], it can be concluded that the  $\xi^4$  rate law is applicable only in a small region of oxide thickness. With the data  $V_0 = 1\text{v}$ ,  $c_0 = 10^{17} \text{ cm}^{-3}$ ,  $\epsilon = 3$ ,  $T = 800^\circ\text{K}$ , and  $z = -2$ , we obtain for

$$\gamma \approx 3 \cdot 10^{-6} \text{ cm}$$

and for

$$|3zeV_0/kT|^{1/6} = 2$$

By means of these values and Eq. [22], it can be seen that the law should be obeyed after an oxide thickness of 300Å has been built up. Furthermore, the thickness of the oxide layer where the validity of the  $\xi^4$  rate law ceases, should be double the thickness at which it starts, i.e., when the oxide layer has grown approximately by a factor of 2.

According to our experiments at 400°C, the kinetics of oxidation fit the relation  $\xi^4$  vs.  $t$  rather well when

the thickness of the oxide layer has attained nearly 400Å. For higher temperatures, the validity region of this time law is shifted to lower thicknesses of the oxide layer. Engell, Hauffe, and Ilschner (3) have also found for the oxidation of nickel at 400°C a fourth power rate law ( $\Delta m \sim t^{1/3.7} - t^{1/3.9}$ ) which changed later on to a parabolic one.

Another parabolic rate law should govern if the following relation is valid

$$\alpha \xi \ll 1/c_0^2 \quad [12a]$$

instead of Eq. [12] which is a presupposition of the fourth power rate law. Such a parabolic rate law was first formulated by Cabrera and Mott (13). Relation [12a] is equivalent with

$$c = c_0 \quad [8a]$$

and

$$dV(x)/dx = -j/(uc_0) \quad [9a]$$

Such a field-aided parabolic rate law could be found for the oxidation of zinc (14). Recently, Fromhold (18) has generalized the discussion on the validity of the parabolic rate law.

In order to compare our rate constant  $k_0$  to the data available in the literature, we tried to calculate  $k_0$  with the aid of the Nernst-Einstein equation and the relation between the tracer-diffusion coefficient and the component-diffusion coefficient  $D_{Ni}^3$

$$k_0 = \frac{9 \epsilon \epsilon_0 D_{Ni} V_0^2}{2ckT}$$

$D_{Ni}$  can be estimated from tracer-diffusion measurements carried out by Lindner and Akerström (19) between 740° and 1400°C, by Choy and Moore (20) between 1000° and 1400°C, and by Klotsman, Timofeef, and Trakhtenberg (21) between 1200° and 1400°C if the diffusion data are extrapolated to 500° and 400°C, a procedure in many respects doubtful. From the extrapolation of the data of the last mentioned authors, the following values for  $D_{Ni}$  have been obtained:  $10^{-19}$  (400°C) and  $10^{-17}$  (500°C)  $\text{cm}^2/\text{sec}$ . The corresponding values of Choy and Moore are an order of magnitude higher and those of Lindner and Akerström an order of magnitude lower.

If we employ the data of  $c_{Ni} \equiv c$  published by Schlosser (22) ( $c = 4 \cdot 10^{14}$  at 400°C and  $c = 1 \cdot 10^{15}$   $\text{cm}^{-3}$  at 500°C) and take  $\epsilon = 3$  and  $V_0 = 1v$ , then the following values for  $k_0$  are obtained

$$\left. \begin{aligned} k_0 &= 1.2 \cdot 10^4 \mu\text{g}^4 \text{cm}^{-8} \text{h}^{-1} \text{ at } 400^\circ\text{C} \\ k_0 &= 4 \cdot 10^5 \mu\text{g}^4 \text{cm}^{-8} \text{h}^{-1} \text{ at } 500^\circ\text{C} \end{aligned} \right\} \text{and 1 atm air}$$

As can be seen by comparison of these data with those in Table I, in spite of the rough extrapolation, the agreement is rather good.

Summarizing we may conclude that the oxidation of nickel should start in analogy to the oxidation of zinc (14) with a field-aided parabolic rate law and changes into a fourth power rate law. After this period, a parabolic rate law again rules, but now under the condition of a diffusion-controlled mechanism.

<sup>3</sup> This relation has been derived explicitly by Schottky (10).

Unfortunately, the kinetics of the nickel oxidation at the very beginning with oxide thicknesses below 300Å does not obey the parabolic plot as expected in analogy for the oxidation of zinc. But this result is not confusing since in the first period of oxidation, nucleation, and oxide needle formation can become predominant causing a logarithmic rate law (12). For the oxidation of bismuth (17), however, the rate of oxide layer growth between 175° and 250°C at 30 Torr oxygen can be represented from the very beginning up to 10-13  $\mu\text{g}/\text{cm}^2$  by a parabolic rate law and later on by a fourth power rate law.

### Acknowledgment

We are greatly indebted to the Deutsche Forschungsgemeinschaft for supplying the experimental equipment and the Max-Buchner-Forschungstiftung for the financial support to one of us (R.S.) Furthermore, we wish to thank Hüttenwerk Oberhausen AG for the salary of Dr. L. Pethe during his stay at the Institute.

Manuscript received Oct. 19, 1967; revised manuscript received ca. Jan. 16, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Ignition Behavior of Plutonium Metal and Certain Binary Alloys

J. G. Schnizlein and D. F. Fischer

Argonne National Laboratory, Argonne, Illinois

## ABSTRACT

The ignition behavior of plutonium and binary alloys containing nominally 2 a/o additives was studied by two methods in air and oxygen. Ignition temperatures in both air and oxygen lie in two regimes. Cubes, 5 mm on an edge, ignite near 500°C while thin foils, less than 0.2 mm thick, ignite near 300°C. The transition from one regime to the other occurs sharply at a specific area that depends on whether ignition takes place in air or in oxygen. The existence of two regimes is consistent with a change of oxidation kinetics between 300° and 400°C which is characterized by a minimum in oxidation rate near 400°C. The effects of additives are sometimes significant and must be considered in each regime and on the position of the transition between them. In the high temperature regime: (i) Increased resistance to ignition and oxidation is found on addition of aluminum, copper, gallium, or silicon; (ii) The same ignition and oxidation behavior as plutonium occurs with addition of nickel, chromium, uranium, cerium, or iron; and (iii) Decreased resistance to ignition and oxidation results from addition of carbon, cobalt or manganese. In the low temperature regime: (i) Increased resistance to ignition and oxidation is produced by additions of aluminum, cerium, carbon, cobalt, gallium, manganese or possibly chromium; (ii) The same ignition and oxidation behavior as plutonium is obtained with addition of nickel or silicon; and (iii) Decreased resistance to ignition and oxidation follows from addition of iron or uranium.

The transition from the high temperature regime to the low temperature regime does not occur in air for alloys of aluminum, cerium, carbon, or cobalt for specimens with specific areas of up to about 1 cm<sup>2</sup>/g. Addition of silicon, nickel, manganese, or uranium have little influence on the transition in air which occurs at a specific area of 1.5 cm<sup>2</sup>/g for pure plutonium. The presence of moisture had a negligible effect on the ignition temperatures of pure plutonium and the aluminum alloy.

The increasing use of plutonium in the nuclear energy program and the concomitant handling makes the development of safe handling procedures imperative. Accidental ignition of the metal is a hazard (1) per se and the possibility of dispersing extremely toxic fine particulate plutonium oxide extends the danger. Moreover, inordinately large expenses of time, money, and manpower in the past have been incurred in the decontamination procedures which must follow accidental ignition of the metal.

The literature on ignition of plutonium is largely restricted to reports of the USAEC and UKAEA. The first direct study of the ignition of plutonium was reported by Dempsey (2). Earlier, Dempsey and Kay (3) observed ignition during an experiment intended to be isothermal at 487°C. Ignition occurred after oxidation had proceeded for about 300 min. During a study of the particulate material produced during the burning of plutonium, Carter, Foy, and Stewart (4) observed ignition temperatures of turnings and small billets.

Thompson (5) observed ignitions to occur between 230° and 420°C in oxygen and between 310° and 505°C in air at 35% relative humidity. No positive correlations between temperature and weight, area, or rate of heating were observed. In atmospheres containing less than 6.5% oxygen in argon, no ignition occurred below 900°C. Above about 10% oxygen the ignition temperatures were between 400° and 500°C. Rhude (6) found that in a glovebox with only 5% oxygen in nitrogen the metal will burn readily. At the 1% level combustion will not continue unless heat is supplied. Cope (7) has developed a ternary eutectic salt mixture which shows promise (8) as a dry powder extinguisher for some plutonium fires. The problems of airborne particulate plutonium have recently been reviewed by Mishima (9) in the United States and Stewart (10) in Great Britain.

Although oxidation studies of plutonium alloys have been reported (11-14) at somewhat elevated temperatures, the only ignition studies of binary alloys are those by Dempsey (2) and Carter *et al.* (4) in which an aluminum additive was used to stabilize the delta phase of plutonium.

The present study of the ignition characteristics of plutonium and certain alloys was undertaken in conjunction with a study of the kinetics of isothermal oxidation (15) to aid in evaluating hazards in handling plutonium. Two experimental methods were developed for determining ignition temperatures. In addition to the study of pure plutonium, the influence of potential impurities and possible additives was appraised by the study of a series of binary alloys containing nominally 2 a/o (atom per cent) of various elements. Some elements were chosen because they are typical impurities in plutonium; other elements were chosen to study the effects of a given series in the periodic chart. Additives of aluminum, carbon, cerium, chromium, cobalt, copper, iron, gallium, manganese, manganese, nickel, silicon, uranium, and zinc were used.

## Materials and Procedures

Because of the extreme toxicity of plutonium, all experiments were performed in gloveboxes. To avoid accidental ignitions or oxidation of metal surfaces, a dry nitrogen atmosphere was used. Oxygen or air and helium were used directly from gas cylinders except in experiments where the moisture content was controlled. The contents of each cylinder used were analyzed by mass spectrometry to avoid accidental contaminants.

The plutonium and alloy cubes and foil specimens were prepared at Hanford.<sup>1</sup> Specially selected reactor

<sup>1</sup> Preparations were under the supervision of R. R. King, P. G. Pallmer, T. Nelson, R. W. Stewart, and O. J. Wick, General Electric Company, Hanford Atomic Products Division, Richland, Washington.

grade plutonium was used to minimize impurity content of both pure plutonium samples and binary alloy samples. Analyses of plutonium used for preparation of samples and of alloys are compared with typical reactor grade plutonium in Table I. Pure plutonium specimens were in the form of 5 mm cubes and 3 x 20 mm sections of foils having thicknesses ranging from 1 to 0.1 mm.

The binary alloys of plutonium contained nominally 2 a/o of various chosen elements. Additives of aluminum, carbon, cerium, chromium, cobalt, copper, iron, gallium, magnesium, manganese, nickel, silicon, uranium, and zinc were of the highest purity available. The additive element content was determined at Hanford by the most accurate method then known. The binary alloys were used in this study in the form of 5 mm cubes and such foils as it was possible to fabricate. For the manganese alloy it was possible to prepare samples with thickness down to 0.07 mm (17.2 cm<sup>2</sup>/g specific area), whereas for the uranium alloy, the thinnest foil that could be produced was 0.89 mm thick (1.9 cm<sup>2</sup>/g specific area).

The ignition experiments are a kind of thermal analysis originally used by Fassel (16) for magnesium alloys. Two methods were used: The first, in which the oxidizing gas was present during the heating, is called a burning-curve experiment; the second method is called a shielded ignition experiment because the oxidizing gas was excluded by helium until the test temperature was reached. These methods have previously been used for the study of ignition of uranium and its alloys (17-19) and were found to provide reproducible results. Burning-curve and shielded-ignition experiments were performed with air or oxygen.

In the burning-curve experiment, the specimen was supported on a thermocouple in a vertical tube furnace and was heated at a programmed rate in a flowing oxidizing gas until ignition occurred. The programming was such that the temperature of an inert sample increased at a uniform rate (usually 10 deg/min). The heat of oxidation of a reactive sample caused an increase of temperature (self-heating) above the control temperature. An increase of oxidation rate caused an increase of the slope of the temperature-time trace. When ignition occurred, the slope rapidly approached an infinite value and the sample usually self-heated to its maximum burning temperature. The ignition temperature was determined graphically from the temperature-time trace as the intersection of the pre-ignition heating curve with the post-ignition self-heating curve. Some thermogravimetric experiments were performed in this manner on a thermobalance equipped with a transducer to permit simultaneous weight and temperature measurement (20). A platinum crucible was hung under the sample to avoid loss of weight due to dropping oxide.

In a shielded-ignition experiment the sample was heated to the test temperature in a protective atmosphere of helium. The protective gas was then rapidly

replaced by the oxidant to determine whether ignition occurred at the test temperature. For these experiments the ignition temperature is reported as the range between the highest temperature at which ignition did not occur and the lowest temperature at which ignition did occur.

## Experimental Results

Comparison of the temperature-time curves of various samples in an oxidizing atmosphere provides a measure of the relative oxidation rate and ignition behavior. The relative oxidation rate can be assessed by the extent of self-heating or temperature increase above the control temperature at a particular time. The ignition behavior of various samples can be compared by consideration of the temperature or time of sudden temperature increase. Burning curves in air for 5 mm cubes of plutonium and a plutonium-silicon alloy are illustrated in Fig. 1. The ignition temperature for pure plutonium was found to be 508°C and for the silicon alloy, 544°C.

After ignition in air the resulting oxide was considerably larger than the original metal sample and had numerous protuberances. Figure 2 illustrates the appearance of a 5 mm cube in the platinum crucible before and after ignition at 508°C in air.

*Pure plutonium.*—Burning-curve and shielded-ignition experiments were performed with pure plutonium specimens in both air and oxygen. The specimens were 5 mm cubes and 3 x 20 mm sections of foils having thickness of 1, 0.5, 0.22, 0.17, and 0.13 mm. Ignition temperatures determined by both methods in air and oxygen are listed in Table II. In most cases ignition temperatures determined by the shielded method are somewhat lower than those obtained by the burning-curve method. Ignition temperatures obtained by the burning-curve method are plotted as a function of specific area of the sample in Fig. 3. Ignition data from Dempsey and Kay (3) and from Carter, Foy, and Stewart (4) are also included for comparison. The variation of ignition temperature with specific area yields a step function instead of a gradual change over the range studied. Ignition occurs in one of two regimes, one at about 300°C (282°-322°) and the other at about 500°C (468°-535°). The transition from one regime to the other occurs at a specific area of

<sup>b</sup> Samples were polished with 600 grit SiC paper; all others as received.

1.5 cm<sup>2</sup>/g in air and at 6.0 cm<sup>2</sup>/g in oxygen. The sharpness of the change is illustrated in Fig. 4 where two burning curves for 1.0 mm thick (1.5 cm<sup>2</sup>/g) foil specimens heated in air are shown. At this specific area the ignition might occur in either regime although the difference of specific area of the two samples was indistinguishable. It will be noted that the thermal effects of plutonium phase transitions can be detected on the curves. These were observed in most experiments and provide assurance of good contact between the thermocouple and the sample.

The 0.22 mm thick foil gave anomalous results in air. Its ignition temperature in air was consistently in

Fig. 3. Ignition temperatures of plutonium by the burning-curve method.

Fig. 4. Burning-curve ignitions in air of 1 mm thick pure plutonium foil specimens, specific area 1.5 cm<sup>2</sup>/g.

the high temperature regime even though its specific area, 5.3 cm<sup>2</sup>/g, was considerably greater than the 1.5 cm<sup>2</sup>/g point of transition for other foil samples. No explanation for this anomalous behavior was found.

In air the ignition temperatures in the low temperature regime are somewhat lower than in oxygen. However, in the high temperature regime no difference is observed. Ignition results reported by Dempsey and Kay (3) and by Carter, Foy, and Stewart (4) were generally consistent with the other results plotted in Fig. 3.

Shielded-ignition temperatures (Table II) are appreciably lower than burning-curve ignition temperatures in the high temperature regime but are only slightly lower in the low temperature regime.

**Plutonium binary alloys.**—All chosen alloys were available in the form of 5 mm cubes. However, it was impossible to fabricate some of the alloys into foils as thin as was desired. Burning-curve experiments were performed in both air and oxygen for all cubes and foils. Shielded-ignition experiments were performed in both air and oxygen for most foils. Because of the large number of samples required to define a narrow temperature range between ignition and nonignition, only a few cubes were studied in this manner; the range of shielded-ignition temperature for a few of the foils is also larger than desirable.

Results of ignition temperature determinations for the alloys are presented in Table III. The additive elements were intended to be 2 a/o but in some cases segregation, evaporation, or reaction with crucible material altered the final concentration. The analyzed (or estimated if no satisfactory analytical procedure was available) content of the additive and the specific area of the samples are included.

For samples in the form of 5 mm cubes ignition temperatures lie in the high temperature regime, and additives have only small effects on the ignition temperature; the greatest effects were found for aluminum, nickel, and cobalt. The ignition temperature of the 3.4 a/o aluminum-plutonium alloy was 60° higher than that of the plutonium base metal. The 2 a/o gallium-plutonium, 2.4 a/o copper-plutonium, and the 1.2 a/o silicon-plutonium alloys ignited at temperatures about 30° higher than did the base metal. In contrast, the 1.8 a/o cobalt and 1.8 a/o nickel alloy ignition temperatures were 30°-40° lower than that of the plutonium base metal. Additives of cerium, carbon, chromium, iron, magnesium, manganese, uranium, and zinc had little effect.

Appraisal of the effect of variation of specific area on ignition temperature for most of the alloys is possible by considering the data on foils. Ignition temperatures were plotted as a function of the logarithm of specific area and a composite trace of the behavior in air for the various additives is presented in Fig. 5. The shapes of the curves are similar to those for pure plutonium except for alloys of aluminum, cerium, carbon, cobalt, and gallium. The transition from the high temperature regime to the low temperature regime does not occur for samples of these alloys with specific areas up to about 10 cm<sup>2</sup>/g. The addition of silicon to plutonium causes a shift of the transition in air from a specific area of 1.5 cm<sup>2</sup>/g for pure plutonium to 4 cm<sup>2</sup>/g for the alloy. Additions of nickel, manganese, and uranium to plutonium cause no change in the transition region in air.

In oxygen the transition to the low temperature regime for the alloys occurs at lower specific areas than it does for pure plutonium.

**Effect of moisture on ignition behavior of plutonium and plutonium 3.4 a/o aluminum alloy.**—To appraise the effect of moisture on the ignition of plutonium and its alloys, burning curves have been obtained in air saturated with moisture at room temperature (20,000 ppm water). Isothermal studies (15) have shown

<sup>a</sup> Indicated as the highest temperature at which ignition did not occur and the lowest temperature at which ignition did occur.

<sup>b</sup> Estimated content, no satisfactory analysis performed.

<sup>c</sup> Sample completely oxidized or disintegrated before ignition occurred.

<sup>d</sup> There was a thermal spike of 150° at 309°C with no visual ignition. Another spike of 80° was observed at 610°C with no visual ignition.

<sup>e</sup> Insufficient samples were available to determine lower limit of shielded ignition range.

that the presence of moisture increases the linear rate of oxidation at temperatures below 200°C, but has negligible effects at higher temperatures.

Although burning curves indicate that ignition occurs in slightly shorter periods of time in moist air, the graphic method of defining ignition temperatures yields values for experiments carried out in dry air which are essentially identical with those for experiments carried out in moist air. These temperatures, determined by the burning-curve method, are given in Table IV.

### Discussion and Summary

Two experimental procedures were used to define the temperatures at which the ignition of plutonium occurs. The first, which is a thermal analysis of the sample heated in an oxidizing atmosphere, is called a burning-curve experiment. In the second, the temperature at which ignition occurs if suddenly exposed to an oxidizing gas, is called shielded-ignition temperature.

*Pure plutonium.*—The ignition temperatures determined by the burning-curve method for pure pluto-

nium in air or oxygen lie in two regimes: about 500°C for large samples with low specific area, and at about 300°C for thin foils with high specific areas. The existence of these two ignition temperature regimes is consistent with the isothermal oxidation behavior of plutonium (15). A change in the oxidation kinetics occurs just above 300°C. The oxidation rate decreases sharply between 350° and 450°C and the oxide is more protective above 400°C. Evidently, the rate of heat generation by oxidation in the region of 300°C is just sufficient to cause ignition of specimens having large specific areas. Specimens having smaller specific areas have greater thermal inertia, and the temperature increase caused by self-heating occurs more slowly. This allows the formation of a more protective oxide at temperatures near 400°C, where there is a minimum in the oxidation rate. The decreased oxidation rate prevents ignition from occurring until the sample temperature is increased by external heating beyond 450°C whereupon the oxidation rate again rapidly increases with increasing temperature.

For samples igniting in the high temperature regime with the burning-curve method, shielded-ignition tem-

Fig. 5. Effect of additives on ignition behavior in air of plutonium. Each curve labeled with additive element present nominally at 2 a/o conc.

peratures are noticeably lower. In the low temperature regime shielded- and burning-curve experiments provide similar ignition temperatures.

**Binary alloys.**—Because the ignition temperatures fall in two regimes (consistent with the two regimes observed in the isothermal oxidation), it is necessary to consider the influence of an additive on each regime and on the transition region.

In the high temperature regime the influence of the additives (using the behavior of pure plutonium as the standard for comparison) were as follows:

(i) Increased resistance to ignition and oxidation; aluminum, copper, gallium, and silicon.

(ii) The same ignition and oxidation behavior as plutonium; nickel, chromium, uranium, cerium, and iron.

(iii) Decreased resistance to ignition and oxidation; cobalt, carbon, and manganese.

In the low temperature regime, the influence of the additives was as follows:

(i) Increased resistance to ignition and oxidation; aluminum, cerium, carbon, cobalt, gallium, manganese, and possibly chromium.

(ii) The same ignition and oxidation behavior as plutonium; nickel and silicon.

(iii) Decreased resistance to ignition and oxidation; iron and uranium.

The transition from the high temperature regime to the low temperature regime does not occur in air for alloys of aluminum, cerium, carbon, and cobalt for specimens with specific areas of up to approximately 10 cm<sup>2</sup>/g. The addition of silicon to plutonium causes a shift of the transition in air from the specific area of 2 cm<sup>2</sup>/g for pure plutonium to 4 cm<sup>2</sup>/g for the alloy. Additions of nickel, manganese, and uranium to plutonium caused no change in the transition point from that of pure plutonium.

**Moisture.**—The presence of moisture in air has negligible effect on ignition temperatures of plutonium and of a plutonium-3.4 a/o aluminum alloy as determined by burning-curve experiments. Because isothermal studies (15) have shown that the presence

Table IV. Temperature determined by burning-curve method

		Burning-curve ignition temperature, °C	
		In dry air	In wet air
Pu	5 mm cube	524	522
Pu	0.11 mm foil	283	282
Pu-3.4 a/o Al	5 mm cube	585, 590	569

of moisture has negligible effects on the oxidation kinetics above 220°C, ignition temperatures of samples above 220°C in dry air will not be affected by moisture. It must be pointed out that it does not follow that long term corrosion by moist air or water vapor will not influence the ignition of plutonium.

### Acknowledgments

The encouragement of R. C. Vogel, the advice of L. Baker, Jr., and the assistance of J. D. Bingle are gratefully acknowledged. In addition, the authors appreciate the services of the many persons who maintained the glovebox facility, obtained materials, and performed analyses.

Manuscript received March 20, 1967; revised manuscript received ca. Nov. 16, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1968 JOURNAL.

# A Film-Thickness Determination of Nitrogen Diffusion in Zirconium Nitride

C. J. Rosa\* and W. C. Hagel\*

Metallurgy Division, University of Denver Research Institute, Denver, Colorado

## ABSTRACT

Calculations of the diffusion coefficient for nitrogen in zirconium nitride are given in terms of a unidirectional, two-phase, volume-diffusion model. These calculations require the knowledge of both the thicknesses of nitride films and of nitrogen diffusion coefficients in the underlying zirconium metal. The values obtained can be represented by  $D_{N \rightarrow ZrN} = 7.87 \times 10^{-5} \exp(-35,900/RT)$  cm<sup>2</sup>/sec for the temperature range of 650°-850°C. Zirconium nitriding kinetics for extended exposures up to 900 hr are also reported. The portion of nitrogen confined to the  $\alpha$ -zirconium phase amounts to about 80 w/o of the total nitrogen consumed during the over-all nitriding process.

The zirconium-nitrogen reaction has not attracted the interest of many investigators. Gulbransen and Andrew (1) described this metal-gas reaction in the temperature range of 400°-825°C and Dravnieks (2) studied the kinetics at 862°-1043°C. Mallett *et al.* (3) measured the rate of surface reaction of zirconium with nitrogen in the range of 975°-1640°C at 1 atm pressure. All these investigators report that the reaction conformed strictly to a parabolic relationship and that the reaction rate was much slower than with oxygen. These experiments were carried out for short time exposures, up to 7 hr.

More recently, Rosa and Smeltzer (4) investigated nitriding kinetics in terms of models based on the growth of the reaction product layer and simultaneous dissolution of the reactant in the metal substrate. They found that over the temperature range 750°-1000°C, and for exposures up to 170 hr, the reaction obeys the parabolic rate law. Using microhardness measurements, they determined the diffusion coefficient of nitrogen in  $\alpha$ -zirconium as  $D_{N^{\alpha-Zr}} = 0.15 \exp(-54,100/RT)$  cm<sup>2</sup>/sec, which to the best knowledge of the present authors is the only relationship available at this time.

The purpose of this investigation is to evaluate the diffusion coefficients of nitrogen in hypostoichiometric zirconium nitride for the temperature range of 650°-850°C in terms of data from nitriding kinetics and from the growth rates of the nitride layer. A comprehensive model relevant to the forthcoming calculations is presented.

## Experimental

The commonly used gravimetric method has been employed for measuring nitriding kinetics of  $2 \times 1 \times 0.2$  cm, 99.93 w/o (weight per cent) pure, zirconium samples. High-purity, better than 99.9 v/o (volume per cent) pure, nitrogen was passed through a cold trap and glass columns containing silica gel and phosphorous pentoxide to remove residual water vapor. Before exposing to nitrogen at a pressure of 400 Torr, specimens were treated by wet abrasion on 200 through 600-grit silicon carbide papers followed by final polishing on 8 and  $1\mu$  diamond-dust impregnated laps, acetone washing, and careful drying to avoid water stains.

To prevent formation of a gap between the metal and mounting material, whenever microscopic measurements of nitride thicknesses had to be taken, all samples are cold mounted in "Hysol" self-setting epoxy resin and prepared for metallography by using methods advised by Cprek (5) and Evans (6). Final polishing, for scale thickness measurements, was per-

formed by  $1\mu$  diamond-dust and vibrator polishing with  $0.05\mu$  gamma-alumina solution.

To accentuate the mount/specimen interface, the nitrided surfaces were coated with dyed "Eastman 910" adhesive diluted in "GA-1A" accelerator and allowed to harden for a few hours. Dark blue recorder ink was used as a dye. Measurements of nitride thicknesses were made by projection on a metallographic glass screen or by using a filar micrometer eyepiece on sections cut at an angle of 6° with respect to the normal surface.

The zirconium nitride, although quite thin, covered the metal substrate uniformly, and no appreciable edge or corner effects could be observed. X-ray analyses, using Ni-filtered Cu radiation, showed that the yellow film formed on heating zirconium in nitrogen was ZrN having  $a_0 = 4.56\text{\AA}$  for the fcc structure. This evidence then eliminated the possibility of formation of ZrO(NO<sub>3</sub>)<sub>2</sub>·2H<sub>2</sub>O, Zr<sub>2</sub>O<sub>3</sub>(NO<sub>3</sub>)<sub>2</sub>·5H<sub>2</sub>O, and Zr(NO<sub>3</sub>)<sub>4</sub>·5H<sub>2</sub>O nitrates reported by Elinson and Petrov (7).

## Theoretical

Figure 1 shows schematically the zirconium-nitrogen equilibrium phase diagram and the associated semi-infinite diffusion couple formed during nitriding of zirconium at temperature  $T$ . Assuming that the nitrogen diffusion coefficients  $D_{II}$  and  $D_I$  are independent of nitrogen concentration,  $c$ , the equations for the two concentration curves in the nitride and in the metal can be obtained from solution of Fick's second law. These are given by

$$c_I = k_1 - B_I \operatorname{erf}(x/2\sqrt{D_I t}) \text{ at } 0 < x < \infty \quad [1]$$

Fig. 1. Schematic presentation of zirconium-nitrogen equilibrium phase diagram and associated diffusion couple formed during nitriding of zirconium at temperature  $T$  and for time  $\infty > t > 0$ .

\* Electrochemical Society Active Member.

for the metal phase (I) and

$$c_{II} = k_2 - B_{II} \operatorname{erf} (x/2\sqrt{D_{II}t}) \text{ at } 0 < x < x_1 \quad [2]$$

for the zirconium nitride phase (II).

In terms of the nomenclature used in these equations,  $k_1$  and  $k_2$  represent the values of  $c$ 's at the surface, i.e., where  $x = 0$ .  $D_{II}$  and  $D_I$  are diffusion coefficients of nitrogen in phases II and I, respectively, and  $B_{II} = k_2 - c_{II}(\infty)$  and  $B_I = k_1 - C_I^I$ . All remaining symbols used follow directly from inspection of Fig. 1.

Diffusion analysis applicable to this type of a system has been advanced by Wagner (8) and applied by many investigators (4, 9, 10). At time  $0 < t < \infty$ , subject to boundary conditions, Eq. [1] and [2] must satisfy

$$c_I = k_1 \text{ and } c_{II} = k_2 \cong C_{II}^{II} \quad [3]$$

for  $x = 0$ , and similarly at  $x > 0$

$$c_I = C_I^I \text{ and } c_{II} = c_{II}(\infty) \quad [4]$$

for  $t = 0$ .

Considering the flux at the  $\alpha$ -zirconium/zirconium nitride interface  $x_1$ , one can write for the mass balance that

$$D_I \frac{\partial c_I}{\partial x} \Big|_{x=x_1+0} - D_{II} \frac{\partial c_{II}}{\partial x} \Big|_{x=x_1-0} = \delta \dot{x}_1 \quad [5]$$

where  $\delta = C_{II}^I - C_I^{II}$  and  $\dot{x}_1$  is the rate of movement of  $x_1$ .

In a previous investigation (4) describing the partition of nitrogen between metal and the nitride phase, it has been shown that the portion of nitrogen confined to the  $\alpha$ -zirconium phase can be expressed as

$$(k_p)_{\alpha-Zr} = 2 B_I \sqrt{D_I/\pi} \exp(-\gamma^2 D_{II}/D_I) \quad [6]$$

In this equation,  $(k_p)_{\alpha-Zr} = \Delta m/A\sqrt{t}$  represents the parabolic rate constant for nitrogen weight gain ( $\Delta m$ ) per unit area ( $A$ ) within time ( $t$ ).  $\gamma$  is a proportionality constant as in Eq. [8] and

$$B_I = k_1 - C_I^I = \frac{C_{II}^{II} - C_I^I}{\operatorname{erfc}(x_1/\sqrt{D_I t})} \quad [7]$$

which can be evaluated if the movement of interface  $x_1$  and  $D_I$  are known.

Should one neglect the small volume change associated with conversion of zirconium metal to zirconium nitride (calculated Pilling-Bedworth ratio:  $V_{ZrN}/V_{\alpha-Zr} = 1.05$ ), then the two values of  $x$  in Eq. [1] and [2] become equal at the nitride/metal interface. Consequently, it follows directly from Eq. [6] that

$$\gamma' \sqrt{D_I} = \gamma \sqrt{D_{II}} = \gamma_{\text{expt}'}/2 \quad [8]$$

where  $\gamma_{\text{expt}'}$  is the experimentally measured slope of  $x_1$  vs.  $\sqrt{t}$ , and

$$\gamma' = [\ln(2 B_I \sqrt{D_I/\pi}) - \ln(k_p)_{\alpha-Zr}]^{1/2} \quad [9]$$

In terms of conditions implied by Eq. [3] and [8] we can express the difference of nitrogen concentration as a function of distance  $x$  from the surface. Thus at  $x = x_1$  we have

$$C_{II}^{II} - C_I^I = (k_1 - C_I^I) (1 - \operatorname{erf} \gamma') \quad [10]$$

for the metal phase, and similarly for the nitride phase

$$C_{II}^{II} - C_{II}^I = B_{II} \operatorname{erf} \gamma \quad [11]$$

Differentiating Eq. [1] and [2] with respect to  $x$  and making use of the mass balance Eq. [5], one obtains in terms of relationship [8] that

$$\frac{(C_{II}^{II} - C_{II}^I) (\operatorname{erf} \gamma)'}{\gamma \operatorname{erf} \gamma} - \frac{(C_I^{II} - C_I^I) (\operatorname{erf} \gamma)'}{\gamma' \operatorname{erfc} \gamma'} = 2\delta \quad [12]$$

where the index "prime" behind parentheses is being used to designate the derivative of the respective error functions, e.g.  $(\operatorname{erf} \gamma)' = 2(\pi)^{-1/2} \exp -\gamma^2$ .

Equation [12] may be simplified by introducing the following arbitrary definitions

$$\xi(\gamma) = (\operatorname{erf} \gamma)'/2 \gamma \operatorname{erf} \gamma \quad [13]$$

and

$$\xi(\gamma') = (\operatorname{erf} \gamma')'/2 \gamma' \operatorname{erf} \gamma' \quad [14]$$

and therefore

$$(C_{II}^{II} - C_{II}^I) \xi(\gamma) - (C_I^{II} - C_I^I) \xi(\gamma') = \delta \quad [15]$$

Knowledge of  $D_I$  and  $\gamma_{\text{expt}'}$  allows one to evaluate the proportionality constant  $\gamma'$  from Eq. [8], and consequently calculation of  $\xi(\gamma')$  becomes possible. For a given value of  $\xi(\gamma')$ , one obtains a corresponding value of  $\xi(\gamma)$  by virtue of Eq. [15] because the nitrogen concentration differences are known. The unique value of  $\gamma$  satisfying relationship [13] may be obtained by means of a graphical solution, e.g., by plotting  $\exp(-\gamma^2)/\sqrt{\pi} \gamma \xi(\gamma)$  and  $\operatorname{erf} \gamma$  vs.  $\gamma$ . Consequently, we can determine the diffusion coefficient,  $D_{II}$ , of nitrogen in zirconium nitride from relationship [8].

### Evaluation of Nitrogen Diffusivity in ZrN

Nitriding kinetics for  $\alpha$ -zirconium in the temperature range 650°-850°C are shown in Fig. 2 together with the evaluated portion of nitrogen confined to the metal phase. Zirconium exhibits an exceptionally large solubility for nitrogen, above 20 a/o (atomic per cent), and accordingly the amount of nitrogen taken up by the metal is about 80 w/o of the total nitrogen consumed during the nitriding process.

Figure 3 is a plot of ZrN thicknesses formed at different temperatures as a function of nitriding time. Visual inspection of these figures indicates that, to a good approximation, parabolic relationships are obeyed for both the nitride growth and nitrogen dissolution in the metal. This then implies that volume diffusion of nitrogen may be the controlling factor in the nitriding mechanism of zirconium.

Densities of  $\alpha$ -zirconium and ZrN are 6.5 (11) and 7.09 (12) g/cm<sup>3</sup>, respectively. The boundary concentrations of nitrogen in zirconium nitride and in the metal saturated with nitrogen are summarized in Table I and were obtained from the Zr-N<sub>2</sub> equilibrium phase diagram (13). The initial concentration of nitrogen in the zirconium samples used was  $C_I^I = 0.65 \times 10^{-5}$  gN/cm<sup>3</sup>. Values for nitrogen diffusion coefficients in  $\alpha$ -zirconium were taken from ref. (4) and those for  $\gamma_{\text{expt}'}$  from Fig. 3.

Knowledge of these experimental data makes possible the evaluation of the remaining parameters:  $\gamma'$ ;

Fig. 2. Nitriding rates of zirconium at different temperatures. Solid lines, total nitrogen uptake; dashed lines, nitrogen dissolved in  $\alpha$ -zirconium; open circles, from ref. (4); closed circles, from this study.

Fig. 3. Zirconium-nitride thicknesses for various nitriding times and temperatures. Open circles, from ref. (4); closed circles, from this study.

$\xi(\gamma)$ ;  $\xi(\gamma)$ ;  $B_I(x=0)$  and hence  $(k_p)_{\alpha-Zr}$ . The numerical values thus obtained are summarized in Table II.

Figure 4 shows the graphical solution of Eq. [13] for arbitrary values of  $\gamma$ . The unique results for  $\gamma$ , at various temperatures, which satisfy this equation are obtained from intersections of the exponential functions and are also recorded in Table II.

The values for diffusion coefficients of nitrogen in hypostoichiometric ZrN, obtained under conditions of nitriding polycrystalline  $\alpha$ -zirconium for exposures up to 900 hr, are represented in Fig. 5 in Arrhenius form. The method of least squares has been employed to obtain an expression for the diffusion coefficient, this is

$$D_{II} = 7.87 \times 10^{-5} \exp(-35,900/RT) \text{ cm}^2/\text{sec} \quad [16]$$

for the temperature range of 650°-850°C

While deriving the mathematical expressions it was tacitly assumed that the treatment of semi-infinite plate is applicable to the 2 mm-thick zirconium samples. Figure 6 which is a plot of concentration of nitrogen within the metal phase, at limiting temperatures of 850° and 650°C, provides satisfactory justification for this premise.

**Discussion of Results**

In the absence of other measurements of nitrogen diffusion in zirconium nitride it is difficult to assess how closely the calculated values of  $D_{II}$  approximate those from experimental evidence. The knowledge of

error arising by considering the diffusion coefficient  $D_{II}$  as a concentration independent factor would be of particular interest.

The accuracy of evaluation of  $D_{II}$  depends on the precision with which the value of  $D_I$  is known. Com-

parison of the latter value from microhardness measurements with that from kinetic data shows appreciable discrepancy as depicted by Fig. 5. The  $D_I$  value from microhardness determinations is lower by a factor of 4 to 22 for the temperature range of interest. A question then arises which of these two values should be employed in evaluating  $D_{II}$ .

Results from Fig. 2 indicate that as much as 80% of the total amount of nitrogen consumed is confined to the metal phase. Consequently, when evaluating  $D_I$  (see appendix), omission of the thin ZrN film formed in the initial stages of nitriding seems to be plausible. However, inspection of Eq. [4A] in the appendix reveals that  $D_I$  is strongly dependent on the accuracy with which the total nitrogen uptake,  $M_I$ , can be measured, and unfortunately this is not very high. The following example will accentuate this point. Reference (2) gives for the total nitrogen uptake  $M_I = 3.91 \times 10^{-5}$  for 2-hr exposure at 862°C, or  $M_I \approx 3.0 \times 10^{-5}$  gN/cm<sup>2</sup> if extrapolated to 825°C. This value is to be compared with  $M_I = 8.32 \times 10^{-5}$  gN/cm<sup>2</sup> at 825°C for 2 hr exposure from ref. (1). It means that at the temperature considered  $D_I$  can vary from  $1.04 \times 10^{-11}$  to about  $1.5 \times 10^{-12}$  cm<sup>2</sup>/sec. The latter value is in close agreement with that from microhardness determinations. Due to the paucity of precise and consistent kinetic studies, the value of  $D_I$  resulting from microhardness measurements has been employed for evaluating  $D_{II}$ .

Some mention should be made about the accuracy of  $D_{II}$  in terms of errors in  $C_{II}^I$ . The  $\alpha + \text{ZrN}_{1-x}/\text{ZrN}_{1-x}$  phase boundary is drawn as a dashed line indicating poor accuracy. This phase boundary has been determined from the limited x-ray investigations by Domagala et al. (14), who believe that its position is accurate within  $\pm 0.5$  w/o N for the temperature range of 1600°-1850°C and that it reaches nearly stoichiometric ZrN at temperatures below 600°C. Unfortunately, for the temperatures of this study, it is impossible to evaluate the errors attached to  $D_{II}$  by considering the positive deviation from  $C_{II}^I$ , because this would mean the presence of hyperstoichiometric ZrN and the existence of such a compound has never been reported. It is, however, possible to account for the negative value of  $-0.5$  w/o N, and thus, e.g., at 850°C the value of  $D_{II} = 3.1 \times 10^{-12}$  cm<sup>2</sup>/sec as compared with  $D_{II} = 8.4 \times 10^{-12}$  for the average value of  $C_{II}^I$ .

The value of 35.9 kcal/mole for the diffusion activation energy could indicate an interstitial type of diffusion. This, however, seems to be highly improbable if we consider the relatively closely packed ZrN fcc lattice. The formation of hypostoichiometric zirconium nitride during the nitriding process provides a vacancy-type structure, and accordingly diffusion of nitrogen via nitrogen vacancies appears to be a more plausible mechanism for diffusion. In this case, the activation energy will consist of two terms: the energy of formation of vacancies and the energy required to move the diffusing species across these vacancies.

Diffusion across the  $\alpha$ -zirconium structure is seen to be very sensitive to temperature change, in accord with what one would expect from the rate of diffusion through hcp lattice of the metal.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

#### APPENDIX

According to Fick's first law the quantity of nitrogen  $M_I$ , which penetrated metal per unit area at the end of time  $t$  can be expressed as

$$M_I = -D_I \int_0^t \left( \frac{\partial c_I}{\partial x} \right)_{x=x_1} dt \quad [1A]$$

If we assume that the concentration of nitrogen  $C_I^I = 0$  (about 1 ppm in our samples), then we can write in terms of Eq. [1] that

$$\frac{\partial c_I}{\partial x_1} = -\frac{k_1}{\sqrt{\pi D_I t}} \exp - (\gamma')^2 \quad [2A]$$

for  $x_1 = 2 \gamma' \sqrt{D_I t}$ .

Substituting [2A] into [1A] yields

$$M_I = \frac{2k_1 \sqrt{D_I t}}{\sqrt{\pi}} \exp - (\gamma')^2 + C \quad [3A]$$

where  $C = 0$  if  $t = 0$ .

Expressing  $k_1 = C_I^{II}$  when  $x_1 = 0$  (i.e., no nitride film) we have

$$D_I = \pi M_I^2 / 4t (C_I^{II})_{x_1=0}^2 \quad [4A]$$

This relationship is of the form sometimes used for evaluation of diffusivity in the metal assuming that the film thickness is negligible. We shall utilize this equation in determining  $D_I$  for nitrogen diffusion in  $\alpha$ -zirconium for short exposure times.

As already mentioned in the text, Gulbransen and Andrew obtained a strictly parabolic relationship for nitriding kinetics up to 2-hr exposures. In view of the present investigation, the estimated thicknesses of nitride films formed on their samples are given in Table III. Included also are values for  $D_I$  resulting from solution of Eq. [4A]. Utilizing the principle of least squares, the diffusion coefficient for nitrogen diffusion in  $\alpha$ -zirconium may be represented as  $D_I = 5 \times 10^{-4} \exp (-38,000/RT)$  cm<sup>2</sup>/sec.

# The Properties of Oxide Films Formed on a Zirconium-2.7 w/o Niobium Alloy in the Temperature Range 300°-500°C

M. G. Cowgill<sup>1</sup> and W. W. Smeltzer\*

## ABSTRACT

Electron microscopy techniques were employed to determine the morphologies and structures of oxide films formed on martensitic and Widmanstätten alloys in an oxygen atmosphere. Morphological development of a film in the very early stages of its formation was dependent on surface preparation, the substructure of an alloy being replicated by the film formed on a pickled specimen. Pustules occurred in the oxide films with their growth being confined to the  $\alpha'$ -Zr phase of Widmanstätten alloys. Also, films on this alloy phase in comparison to those on a martensitic specimen commenced cracking at smaller thicknesses. The films consisted of monoclinic zirconia and, in addition, a second phase which was either tetragonal zirconia or an intramolecular oxide of zirconia and niobium pentoxide. This latter oxide occurred as small crystallites 50-150Å in diameter.

The reaction kinetics were previously reported for martensitic and several Widmanstätten alloys oxidized at temperatures in the range 300°-500°C (1). Little difference was found between the oxidation rates of these alloys in the early stages of the reaction, but prolonged exposures demonstrated that the martensitic alloys consisting of  $\alpha'$ -Zr oxidized much more rapidly in the range of linear kinetics, the linear kinetics of the Widmanstätten alloys decreasing with increasing amounts of proeutectoid  $\alpha$ -Zr. This latter phase oxidized at much slower rates than  $\alpha'$ -Zr. The oxide layer consisted essentially of monoclinic zirconia, and the formation of oxide pustules on martensitic specimens was the only distinct feature indicating a difference in the mode of oxide formation on differently structured alloys. The purpose of this investigation was to gain more detailed information by the techniques of electron microscopy on the structural properties of the oxide films and on their role as barriers to oxidation processes.

## Experimental

The electron microscopy studies were of two types: replication studies of oxide film surfaces and transmission microscopy of oxide films stripped from the alloys. For the former, two-stage replication was used, the parlodion film being shadowed at 20° to the surface with gold-palladium, before carbon evaporation at right angles to the surface. Transmission studies necessitated first coating the oxidized surface of the specimen with carbon in order to strengthen the thin film. The stripping of the oxide from the metal was then performed with a solution of 10% bromine in ethyl acetate held at 75°C.

Microscopy was carried out on a Siemens Elmiskop I operating with voltages of 80 kv for replicas and 100 kv for thin oxide films. In order to facilitate accurate measurement of lattice spacings by selected area diffraction, gold was evaporated on the oxide to provide a standard diffraction pattern. Distance measurements on the patterns were made with a Joyce recording densitometer.

The alloy material, the procedures for preparing alloys in martensitic and Widmanstätten structures, surface preparation, and oxidation of specimens in oxygen at 1 atm pressure have been described in a previous paper (1). The aqueous pickling solution, 30 v/o H<sub>2</sub>SO<sub>4</sub>, 30 v/o HNO<sub>3</sub>, and 10 v/o HF, was held at a temperature in the range 68°-75°C. Weight gains of specimens by oxidation were converted to approximate average film thicknesses based upon the factor  $1\mu\text{g O/cm}^2 = 62\text{Å}$ .

## Results

*Oxide film morphologies.*—The changes in the topographies of specimens oxidized at 400°C were studied from the initial protective stage of film formation, through the transition region, and into the final stage where oxidation approximated to linear kinetics (1).

Representative surfaces of martensitic specimens and the film at various stages of oxidation are shown in Fig. 1-3. Although the surfaces of mechanically polished specimens were featureless, surfaces of pickled specimens showed areas of selective etching at the boundaries of the martensite plates. Irrespective of

Fig. 1. Surface replicas of pickled martensitic alloy surfaces after oxidation at 400°C. Oxygen uptake: top, unoxidized, 26,665X; middle, 0.10 mgO/cm<sup>2</sup>, 14,665X; bottom, 0.20 mgO/cm<sup>2</sup>, 14,665X.

Fig. 2. Surface replicas of mechanically polished martensitic alloy surfaces after oxidation at 400°C. Oxygen uptake: top, unoxidized; middle, 0.09 mgO/cm<sup>2</sup>; bottom, 0.15 mgO/cm<sup>2</sup>. 14,665X.

Fig. 3. Typical surface replica of martensitic specimen oxidized to the range of linear kinetics. Oxygen uptake: 1.56 mgO/cm<sup>2</sup>. 14,665X.

surface treatment, the films were uneven in the initial stages of the reaction, Fig. 1b and 2b, exhibiting pustular growths with sizes varying from grain to grain. In addition to pustules, fine cracks were to be observed in the films as the specimens were progressively oxidized into the period for transition to linear kinetics, Fig. 1c and 2c. At long times, a film exhibited an uneven surface populated with cracks, Fig. 3.

A similar series of micrographs for the Widmanstatten alloys is illustrated in Fig. 4. There was not a noticeable difference between the pickled and unpickled surfaces, other than that, with the former type of specimen, the alloy structure could be more easily distinguished. Micrographs of films formed on both alloy phases, Fig. 4b, demonstrated that the films were considerably thicker on the  $\alpha'$ -Zr phase even at small oxygen uptakes. Moreover, the films formed on this phase were characterized by pustules as previously shown for the martensitic specimens. Cracking of this oxide became very extensive before any evidence was found for cracking of the oxide formed on the  $\alpha$ -Zr phase, Fig. 4c, and even occurred in films thinner than those formed on martensitic specimens. For example,

Fig. 4. Surface replicas of mechanically polished Widmanstatten alloy surfaces after oxidation at 400°C. Oxygen uptake: top, unoxidized, 25,330X; middle, 0.01 mgO/cm<sup>2</sup>, 14,665X; bottom, 0.2 mgO/cm<sup>2</sup>, 2,665X. The pustular oxide and extensively cracked oxide occur on the  $\alpha'$ -Zr alloy phase.

cracks were readily observable in a 1500Å film on an alloy containing 30 v/o  $\alpha$ -Zr, whereas evidence was only found for the initiation of cracking in films corresponding to approximately 2500Å on martensitic specimens.

*Oxide film structures.*—Films formed at 300°C and with thicknesses varying from 100 to 800Å were examined by the transmission technique. Their appearance was dependent on the surface preparation of the specimens. A film stripped from a specimen whose surface was mechanically polished was relatively featureless. On the other hand, the films stripped from pickled specimens exhibited structures related to the alloy microstructures. The microstructures of the martensitic and Widmanstatten alloys replicated by their oxide films are illustrated in Fig. 5. Absence of electron transmission through the films at alloy transformation boundaries indicated enhanced oxide growth in these regions.

Selected area diffraction spot patterns obtained from films formed on alloy pickled surfaces could often be indexed as monoclinic zirconia (2-4). It was also possible to index some patterns as a mixture of monoclinic zirconia and another phase. Most of the spots could be accounted as coming from the monoclinic oxide, but one pair of spots arose from planes with d-spacing of 2.95Å. Such a lattice spacing would be compatible with the (111) spacing of tetragonal zirconia (5), or, possibly, of the mixed oxide 6ZrO<sub>2</sub>·Nb<sub>2</sub>O<sub>5</sub> (6). A typical diffraction pattern from a film containing both oxides is illustrated in Fig. 6. In the case of a mechanically polished surface, the diffraction patterns were those of a polycrystalline oxide and they could be indexed generally as monoclinic zirconia.

In the earlier reported paper (1), examination by a recording x-ray diffractometer of the surfaces of

Fig. 5. Electron transmission micrographs of oxide films stripped from pickled alloys oxidized at 300°C: top, martensite, 0.001 mgO/cm<sup>2</sup>; bottom, Widmanstätten structure, 0.002 mgO/cm<sup>2</sup>. 13,330X.

Fig. 6. Selected area diffraction pattern from film formed on pickled martensitic alloy oxidized at 300°C. Oxygen uptake: 0.004 mgO/cm<sup>2</sup>. Symbols m and t refer to monoclinic and tetragonal oxide, respectively.

specimens oxidized for extended exposures to form scales demonstrated that monoclinic zirconia was the major reaction product, little evidence being found for the existence of another oxide phase. To gain more detailed information, powder x-ray diffraction experiments were carried out on scales formed at the temperatures of 300°, 400° and 500°C on both martensitic and Widmanstätten specimens. The patterns from oxide formed under all these conditions were similar and reflections were consistently obtained from a plane with lattice spacing 2.94-2.95Å in addition to those of monoclinic zirconia. This is the same value as that found by electron diffraction from thin films and the existence of a tetragonal oxide in both monoclinic zirconia films and scales is considered definite.

Fig. 7. Dark field transmission micrograph from oxide film formed on pickled martensitic alloy oxidized at 300°C showing crystallites of tetragonal oxide at alloy transformation boundaries. 20,000X.

Attempts were made to locate the tetragonal crystallites in the films formed on pickled specimens by dark field electron microscopy. This was done using the diffraction spots from the (111) plane of this phase as all other planes gave rise to spots coincident, or nearly coincident, with spots from monoclinic zirconia. Examination of many films demonstrated that this oxide was distributed as small crystallites in a size range between 50 and 150Å at areas bounding transformation boundaries in a martensitic alloy, Fig. 7, and over the main surface, the distribution appearing to be dependent on the orientation of the alloy matrix surface. Although several films stripped from specimens with Widmanstätten structures were composed of both monoclinic and tetragonal oxide, it was impossible to form conclusions regarding the distribution of crystallites.

### Discussion

Oxide pustules in the films on martensitic specimens were found previously by light microscopy to be the only distinct feature indicating a difference in the mode of oxide formation on different structured alloys (1). The current observations at the high magnifications of an electron microscope show that pustules also occur in films on Widmanstätten alloys, albeit not on such a large scale and then only on  $\alpha'$ -Zr. The size of these pustules was restricted to about 0.1-0.2 $\mu$ , whereas those on martensitic specimens ranged upwards to 0.5 $\mu$  by electron microscopy and 500 $\mu$  by light microscopy. Apparently both the mode of oxide formation and the properties of the films differ. Film growth on martensitic alloys was characterized by the lateral growth of pustules. On the other hand, pustules in the  $\alpha'$ -Zr phase of the Widmanstätten specimens attained smaller ultimate size before cracking of the film occurred at a relatively small thickness.

Film growth was uneven on all alloy structures with enhanced oxide growth occurring about the transformation boundaries in the alloy microstructures. These latter regions would exhibit niobium enrichment brought about during quenching and/or tempering at reaction temperatures. This enrichment would eventually lead to the segregation of  $\beta$ -Nb (92 w/o Nb) which may play a role in oxide formation in these regions. Since the crystallites of the tetragonal oxide phase, an allotropic modification of zirconia or the double oxide, 6ZrO<sub>2</sub>·Nb<sub>2</sub>O<sub>5</sub> were distributed both around transformation boundaries and on the martensitic plates, niobium may only dissolve in the tetragonal zirconia, without leading to the formation of the double oxide.

The crystallite size of the tetragonal oxide was small lying in the range 50 to 150Å. This observation stimulates comparison with other work despite the limitation of not being able to distinguish whether this phase

was an allotropic modification of zirconia or an intramolecular oxide. A tetragonal oxide was reported by Schwartz *et al.* (7) to occur on zirconium oxidized in water at 400°C and by Korobkov *et al.* (8) on zirconium and alloys containing titanium, aluminum and tin oxidized in air at temperatures between 300°-1100°C. Its transformation to a monoclinic structure was suggested by these investigators as the cause for film breakdown. This supposition would not appear to be valid for the alloy of the present investigation because the films formed before the breakaway region in a reaction curve consisted largely of monoclinic zirconia with only small amounts of tetragonal oxide.

To account for the diverse features of film formation, account must be given to the alloy phases upon which oxide is forming. The films on the  $\alpha$ -Zr phase of Widmanstätten alloys, which would be most homogeneous with respect to niobium concentration, were more uniform than those on the  $\alpha'$ -Zr phase or the fully martensitic alloy. The niobium content of  $\alpha'$ -Zr depends upon the annealing treatment for the alloy and was approximately 4 w/o compared with 2.7 w/o for martensite. Thus a higher degree of niobium enrichment in the zirconia film on  $\alpha'$ -Zr is to be expected. The oxide in this film may exhibit the same properties as shown by Douglass (9) for zirconia where metal additives decreased its plasticity. A similar decrease in oxide plasticity possibly played a role in determining the most extensive cracking of the film on the  $\alpha'$ -Zr phase at the earliest stage of reaction. It would appear, however, that the cracks observable by electron microscopy did not play a dominant role in determining the protective properties of the total film because the linear oxidation kinetics of a marten-

sitic alloy were much larger than those for the Widmanstätten alloys (1).

## The Attraction of Liquids by Electric Fields

E. P. Damm, Jr.

*Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York*

### ABSTRACT

The attraction of liquids by electric fields is studied. The time between application of electric field and liquid contact with electrode (response time) serves as the basis for determining the effects of various system parameters. Variation of response time with electrode voltage and with air gap is plotted for a high-dielectric-constant liquid. It is shown that response time is largely independent of the liquid's conductivity, solids concentration, particle size and particle polarity of dissolved or dispersed solids in water. Response time does vary significantly with viscosity, and, up to certain field strengths, with the surface tension of the liquid. Also, for the liquids used in these experiments, response times were lowest for liquids having highest dielectric constants and highest for those with lowest dielectric constants, if viscosity effects are taken into consideration. The evaporation rate or the presence of vapor molecules of a volatile nonpolar or only slightly polar liquid also appears to increase the response time. However, the presence of polarizable materials dispersed in a liquid of low polarity such as toluene produces a decrease in the response time of the liquid.

It has long been known that liquids can be influenced by electric fields. The phenomenon of "ink flying" in the printing industry (1) and the rise of the level of the liquid with oil-insulated high-tension equipment are examples. Swan (2), Schott and Kaghan (3) have also reported some interesting experiments with this phenomenon.

Pohl (4-8) and Kok (9) have experimented with and tried to develop a theoretical mechanism for the motion of particles in dielectric liquids by high-intensity divergent fields. The motion of these particles was, at least initially, the result of a phenomenon which Pohl called dielectrophoresis. The term dielec-

trophoresis was defined as the motion of electrically polarized matter in a nonuniform field, in contrast to electrophoresis, which is defined as the phenomenon of the migration of charged particles through a fluid under the influence of an electric field. While both phenomena were known, the experiments of Pohl served to emphasize that polarization effects, while somewhat neglected in the area of particle motion in an electric field, were of practical use and could account for certain occurrences which otherwise might be loosely accounted for only by electrophoresis. There is little record (10) of work on the attraction of highly conducting liquids by divergent electric fields and

especially on the quantitative comparison of their characteristics with those of dielectric liquids under an applied electric field.

This paper describes several experiments with liquids of varying dielectric constant and conductivity. The system variables of electrode voltage and gap are discussed, as well as the liquid variables of conductivity, surface tension, viscosity, particle polarity, solids concentration, and particle size of the dissolved or dispersed phase. The importance of the dielectric constant of the liquid and the evaporation rate of liquids with extremely low dielectric constant are also shown. The response time of the liquid is used as the dependent variable to quantitatively define the system behavior. Response time in this paper refers to the time interval between the initiation of the attraction voltage and the contact of the attraction electrode by liquid.

#### A Simple Model

In attempting to understand how response time is related to the properties of dielectric liquids and the electric fields that attract them, the equation for the force between a point charge and an unbounded, planar dielectric medium provides useful clues. This equation is given by (11)

$$F = \frac{1}{4\pi K_0 K_1} \frac{K_1 - K_2}{K_1 + K_2} \frac{q^2}{a^2}$$

where  $K_0$  = the permittivity of free space;  $K_1$  = the dielectric constant of the material between the point charge and the plane;  $K_2$  = the dielectric constant of the planar dielectric medium;  $q$  = the charge at the point; and  $a$  = the distance between the point charge and the plane of the dielectric.

While more rigorous equations can be developed to explain the phenomenon whereby, for example, the geometry of one of the equipotential surfaces of the point charge is assumed to be the geometry of the attraction electrode, the simple model does illustrate that, for a given  $q$  and  $a$ , the attractive force decreases significantly only when  $K_2$  approaches  $K_1$ . For example, if the medium between the point charge and the planar surface is air ( $K_1 = 1$ ) and the dielectric is water ( $K_2 = 80$ ), the attractive force is  $79/81 = 97.5\%$  of the force available if  $K_2$  were infinite. For the case of glycerine (98%) ( $K_2 = 43$ ), the force is  $42/44 = 95.5\%$  of that available if  $K_2$  were infinite. Hence, it could be expected that response time, which is inversely related to the attracting force, will not vary significantly for different liquids of low viscosity and high dielectric constant. Also, from this simple model one would expect that changes in conductivity, liquid depth, and solids concentration in a high-dielectric-constant liquid will not radically affect response time. On the other hand, it may be expected that surface tension and viscosity, which are not shown in this equation, might be important factors affecting the response time.

In the case of low-dielectric-constant liquids such as toluene ( $K_2 = 2.4$ ), any factors which significantly alter the dielectric constant of either the liquid or the air gap would be expected to seriously affect response time. For example, condensation in the air could alter  $K_1$  enough to cause a significant change in response time.

#### High-Dielectric-Constant Liquids

**Characteristic curves.**—In our initial experiments, we studied the response time of a high-dielectric-constant liquid as a function of air gap and applied voltage. A 1% aqueous solution of the colloidal electrolyte, crystal violet, extra pure,<sup>1</sup> was chosen as representative of this class of liquids. In order to minimize the effect of surface tension, we added a surfactant to the

<sup>1</sup> A product of du Pont de Nemours & Co., Wilmington, Delaware.

Fig. 1. Responsometer

solution. With 1% Fluorochemical L-1006<sup>2</sup> (nonionic) it was possible to bring the surface tension as low as 23.4 dynes/cm (measured with a DuNuoy-type tensiometer).

To measure response times, an instrument called a responsometer was devised (Fig. 1). A petri dish contains the liquid to be tested and a brass, flat-disk electrode. The upper, attracting electrode is a micrometer head ground to a conical tip (0.021 in. radius, 45° taper) to provide a divergent electrical field. The accuracy of the vertical adjustment is to the nearest 0.0001 in. A 5000v d-c power supply with a 10-Mohm current-limiting resistor is used to supply the voltage, which is controlled with a standard powerstat. An oscilloscope connected to the attracting electrode is used to monitor the voltage.

When voltage is applied to the micrometer head, the oscilloscope trace rises accordingly and remains at the upper level until the attracted liquid makes contact with the electrode. At this time the circuit is electrically shorted, and the trace drops back to zero. Response times can be measured directly from photographs of the oscilloscope trace (Fig. 2). We found that the response times of reasonably polar liquids having specific conductivities as low as  $2 \times 10^{-8}$  mho/cm could be directly measured with this instrument.

The characteristic curves of the water and crystal violet solution are given in Fig. 3 and 4, which show response time as a function of air gap and applied voltage, respectively.

**Effect of solution properties.**—Since surface tension and viscosity resist the attracting force of the electric field, they were expected to have an important effect on response time. The response time *vs.* surface tension characteristic was determined for the aqueous crystal violet solution. Different amounts of surfactant were added to vary the surface tension over the range from 76 to 23.4 dynes/cm. Figure 5 shows that the variation in surface tension has a significant effect on response time only for low values of applied voltage. Above 500v, the slopes of the response time *vs.* surface tension curves are close to zero. The limiting effect of the restraining forces at low surface tension is observed in Fig. 6, which shows the maximum gap through which the aqueous crystal violet solution with minimum surface tension can be attracted for various voltages.

The effect of viscosity on response time was measured in an experiment which used different concentrations of glycerine in water to provide a range of viscous solutions. Figure 7 shows that response time increased linearly by a factor of about 3 as the viscosity was increased from 1.7 to 360 centipoise.

Other solution properties that were checked included conductivity, concentration of colloidal particles, and size of dissolved or dispersed particles. Response time was virtually independent of these properties. To test the effect of conductivity, potas-

sium chloride was titrated into demineralized water. As the conductivity of the solution was varied from 6 to 3000  $\mu$ mhos (monitored during titration by a conductance bridge with dip-type cells), response time remained relatively constant (Fig. 8).

The concentration of crystal violet in water was varied from 0 to 1% to test the possibility that the concentration of colloidal electrolyte in a liquid could significantly affect response time. It did not (Fig. 9).

In none of the experiments with solution properties of high-dielectric-constant liquids was there a difference in response time which could be attributed to the size of the particles in solution. The solutions studied had particles that ranged from ions to colloidal electrolytes to colloids to coarse particles.

*Effect of electric field properties.*—The simple model of the attraction process assumes a point electrode.

Fig. 4. At small gaps, the response time decreases rapidly as attracting potential increases in the range from 250 to 500v (aqueous solution).

Fig. 5. Effect of surface tension on response time decreases with increasing voltage (0.004 in. gap, aqueous solution).

Fig. 6. As attracting potential increases, the maximum gap at which liquid will jump increases (aqueous solution).

Electrode geometry, however, is important in a real system. Therefore, variations in the electrode geometry and their effect on response time were studied. When the electrode was altered from a conical tip with 0.021 in. radius to a hemisphere with 0.115 in. radius to a flat surface, the response time increased accordingly. The effect of these gross changes is to make the attracting force weaker by reducing the divergence of the field and the results in Table I are not unexpected based on a model using a dielectric-constant relationship. However, a much subtler change in electrode geometry produced an interesting result. When the radius of the tip of the conical micrometer head was reduced from 0.021 to 0.008 in., the response time was significantly higher for the smaller tip (Table II). This seems to indicate the

Fig. 7. Response time increases with increasing viscosity (surface tension corrected to 39.1 dynes/cm, 0.004 in. gap, aqueous solution).

Fig. 8. Specific conductance has no effect on response time in the range from 6 μmhos/cm to 3000 μmhos/cm (0.004 in. gap, surface tension corrected to 75.0 dynes/cm).

existence of an inflection point in the variation of response time with electrode diameter. Perhaps the divergence of the electric field with the smaller-radius electrode is great enough to result in such a substantial decrease in the field near the surface of the liquid that the high acceleration caused by the field near the tip is not enough to compensate.

Also, to find out whether variation in liquid depth would change the shape of the field, we measured response time at several liquid depths from 0.2509 to 0.0076 in. No change was noted. It was concluded that for relatively conductive liquids, the liquid surface itself could be assumed to act as the ground electrode. In fact, removing the brass-disk electrode from the

petri dish has almost no effect on response time as long as the liquid makes contact with an electrical ground.

Finally, an experiment was run to test the possibility that a negatively charged attraction electrode would produce different response times than did the positively charged ones. Different behavior would not be unexpected since it has been observed in the breakdown voltages of point-plane surfaces in air (12) and in some work with liquids (13, 14) where large changes in the refractive index of the liquids occurred with a negatively charged point but not with a positively charged point. Figure 10 shows that, in general, response times obtained with negative potential on the attraction electrode were lower than those with positive potential. However, response times were much more erratic for the negative potentials. In addition, in our experiments, response time results already obtained for the aqueous crystal violet solution at an attracting voltage of +500v were compared with those response times obtained for the negatively charged colloidal electrolyte, Amaranth Red U.S.P. in a 1% aqueous solution at +500v. For equivalent surface tensions they were identical.

Low-Dielectric-Constant Liquids

If the simple model suggested earlier for the liquid attraction process is at all realistic, a large increase in response time should be noticed as the dielectric constant of liquids closely approaches that of air. Our experiments with low-dielectric-constant liquids bore out this suggestion. However, it was necessary to use a different means of measuring response time for these liquids. Since low-dielectric-constant liquids have low conductivity, no change in voltage could be observed on the oscilloscope when the liquid made contact with the attracting electrode. So, a detection system utilizing a high-speed movie camera was used. In this system a timer on the camera triggered the electrode voltage after the film had accelerated to a reasonably constant speed. Timing lights were used to determine the speed of the film at the time of attraction. An oscilloscope trace identifying the time at which voltage was applied to the electrode was superimposed on the

Fig. 10. Negative potentials give lower (but more erratic) response times than do positive potentials (aqueous solution).

film by means of a side-viewing port of the camera (Fig. 11).

*Effect of liquid properties.*—Viscosity is a measure of the internal friction of the liquid. Therefore, if the attraction phenomenon is dependent on dipole forces, the relaxation time of the dipoles can become very important in viscous liquids having low dielectric constants. The polarization forces in an electric field can

Fig. 11. Photographs of high-speed movies taken with a Fastax Model WF-17 camera. Film speed was 8000 frames per second. The dark area in the upper portion of the photo is the attraction electrode. The lower dark area is the reflection of the attraction electrode in the liquid. The white line in the left of center is the oscilloscope trace which was superimposed on the film. The shift in the position of this line took place at the time of the application of the pulse. Top, 0 sec; center, 3.0 msec; bottom, 4.5 msec.

be separated into two components: one slow-acting and the other fast. The fast polarization consists largely of electronic distortion because of the displacement of electrons relative to the positive nucleus. The slow polarization consists of dipole orientation in the electric field and in some respect depends on the frictional resistance of the medium to changes in molecular orientation.

With small-chain polar molecules, the dipole forces are usually strong enough to overcome viscosity forces in a short period of time, e.g.,  $10^{-11}$  to  $10^{-6}$  sec. With nonpolar or only slightly polar liquids, however, dipole forces are quite small. Thus the dipoles of very viscous nonpolar and slightly polar liquids can remain in a semi-oriented state minutes after the external field is removed. This is especially true of long chain molecules. Further complications arise because trace polarizing materials, including air bubbles, can change the effective dipole moment and thus the relaxation time of the molecules (15).

We ran into trouble in experimenting with the effect of viscosity on response time for low-dielectric-constant liquids. We had thought that the dimethyl silicones would be useful liquids for this type of study because their viscosity can be varied over a wide range without changing the dielectric constant by much. However, the results obtained were very unreliable, apparently because of the hysteresis effects mentioned above. Toluene ( $K_2 = 2.4$ ), the liquid we used for several subsequent experiments, could not be used to study viscosity. Also, it was not possible to vary surface tension and conductivity significantly, so the effects of these properties were not studied either.

The significance that various additives have on the response time of toluene is shown in Table III. Materials having different particle sizes and solubilities were dissolved or dispersed in toluene. It appears that response time decreases accordingly as the particles have greater polarizing power. The most marked effect on response time was produced by the presence of colloid particles.

Table IV shows that ambient conditions also have a great effect on the response time of toluene. It is possible that the variation is caused by water condensed from the atmosphere by evaporating molecules of the liquid. This condensation could change the dielectric constant of the air gap enough to significantly alter the attracting force on the liquid. Another explanation is that air-vapor electrophoresis-dielectrophoresis occurring at high relative humidity and/or high vapor pressure of solvent produces a down pressure [the "electric wind" described by Pohl (5)]. The importance of evaporation rate was noted when hexane ( $K_2 = 1.9$ ), which has a high evaporation rate, was

Table III. Effect of additives in toluene on response time

Additive	Response time in msec

Flat	0.0283	0.0273

compared with toluene. The maximum gap across which the hexane could jump at 500v was only 0.0025 in. as compared with 0.0123 in. for toluene. Furthermore, when the level of the toluene was raised to the top of the container, response time increased sharply, no matter where the ground electrode was placed. Hence, it appears that for low-dielectric-constant liquids an increase in evaporation rate, whether it is inherent or caused by greater exposure of the liquid to air currents, increases response time.

**Electric field effects.**—The effect of electrode geometry on the maximum gap of toluene was also studied (Table V). The electrodes were the same as those used in the electrode geometry study for liquids with high-dielectric constants. The results showed that the maximum gap through which the liquid could be attracted increased in this order: pointed, rounded, and flat attraction electrode. This seemed to indicate that for these three electrodes, the more uniform the field, the longer the response time, but the higher the maximum gap through which the liquid can be attracted. One possible reason is that while more-divergent fields produce a higher acceleration, less force is available at the surface of the liquid to overcome surface tension. It should be kept in mind that the mass of the liquid attracted may be varying with the radius of the attraction electrode.

As another consideration, if electrode-to-electrode distance is very critical, a difference in maximum gap should be noticed as the depth of toluene is varied. While the surface of a conductive liquid can be expected to act as a ground electrode, this is certainly not true for the low-conductivity liquids. No great difference in maximum gap was noticed when the depth of toluene was varied from 0.250 to 0.019 in. at 500v. Furthermore, when the ground disk was removed from the petri dish the liquid continued to jump under the applied potential. This indicates that for the depths of liquid studied, as long as some reference ground is present, the electrode-to-liquid distance is more important than electrode-to-electrode distance.

A study of some liquids having dielectric constants in the range between what have been called high- and low-dielectric-constant liquids was performed. Response times of these liquids are given in Table VI.

### Conclusion

It has been shown that response time is largely independent of the conductivity, solids concentration, and particle size of dissolved or dispersed materials in a highly polar liquid such as water, although response time does vary with the surface tension and viscosity of the liquid. However, above a certain field strength, surface tension plays a minor role in determining the rate of attraction. In addition, studies with high-, intermediate-, and low-dielectric constant liquids, have shown that response time appears to be lowest for liquids with high-dielectric constants and *vice versa*. Also, the evaporation rate or the presence of vapor molecules of a volatile nonpolar or only slightly polar liquid appears to increase the response

Table VI. Response times for liquids with intermediate dielectric constants

time. However, the presence of particles capable of producing polarization effects in a low-polarity liquid reduces this effect and produces a decrease in the response time of the liquid.

Based on the above data and the fact that the effects of electrical polarity within the liquid appear to be negligible or at least quite obscure, a stand can be taken that the phenomenon studied was largely dielectrophoresis. An analogy can be drawn to the work of Pohl (4-8) if the air between the attraction electrode and the liquid is considered as the fluid of low-dielectric constant and the liquid attracted is considered as a large, easily deformable particle.

# Evidence of Nickel Phosphide $\text{Ni}_2\text{P}$ in As-plated Electroless Nickel

J.-P. Randin and H. E. Hintermann\*

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

## ABSTRACT

The dissolution rate of as-plated electroless nickel containing between 3.2 and 12.5 w/o phosphorus is studied in hydrochloric acid. Two reaction rates can be distinguished: first the dissolution of the nickel phase (fast), second that of a phase containing 21 w/o phosphorus whose stoichiometry corresponds to the composition of the nickel phosphide  $\text{Ni}_2\text{P}$  (slow). The  $\text{Ni}_2\text{P}$  content of the as-plated electroless nickel corresponds to the entirety of phosphorus bonded to nickel.

In a previous publication (1) the study of electroless nickel by differential thermal analysis revealed that the heat evolution during the heating corresponds to 11-17% of the heat of formation of  $\text{Ni}_3\text{P}$ , which is the final reaction product. According to this data and the findings of Graham, Lindsay, and Read (2) we proposed that as-plated electroless nickel might be a supersaturated solid solution of phosphorus in nickel. This state could be considered as a metastable intermediate state between that of a mixture of nickel plus phosphorus and that of the equilibrium system of nickel plus  $\text{Ni}_3\text{P}$ . We suggested (1) that the intermediate state could include phosphorus atoms chemically bonded to nickel atoms as a phosphide since 83-89% of the heat of formation of the stable state of nickel plus  $\text{Ni}_3\text{P}$  is released.

In this study it is shown how the dissolution rate of electroless nickel in hydrochloric acid allows to establish the nature of the chemical state of phosphorus in the as-plated alloy.

## Experimental Procedure

**Preparation of deposits.**—An acid bath of the following composition was used:  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ : 30 g/l;  $\text{CH}_2(\text{OH})\text{COOH}$ : 30 g/l;  $\text{COOH}(\text{CH}_2)_2\text{COOH}$ : 10 g/l;  $\text{NaF}$ : 3 g/l;  $\text{NaOH}$  to adjust the desired pH. The reducing agent was sodium hypophosphite, added to the bath as a concentrated solution of 500 g/l at constant rate. The temperature of the bath was 94°C. If the pH and the nickel concentration are kept constant during the entire deposition time, coatings of uniform phosphorus distribution are obtained (3). By adjusting the pH of the bath between 5.0 and 4.0, deposits with phosphorus contents between 3.5 and 11.4 w/o (weight per cent) are produced for an introduction rate of the hypophosphite of 0.05 M/hr. For the deposition at pH 5.0, the concentration of the glycolic acid has to be increased in regard to the concentration at lower pH to prevent the precipitation of the orthophosphite. At pH 5.0 the bath of the aforementioned composition was used and the nickel concentration was kept constant during the entire reaction time by addition of a solution containing: 500 g/l  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ , 500 cm<sup>3</sup> of a 56 w/o aqueous solution of glycolic acid completed to 1000 cm<sup>3</sup> with demineralized water. For lower pH, an aqueous solution of  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$  at a concentration of 800 g/l was used. If the orthophosphite which precipitates during the deposition from the bath with normal concentration is dissolved in the bath at pH  $\approx$  4, the residue of dissolution in 7.8N hydrochloric acid at room temperature contains about 23 w/o phosphorus whereas it contains only 21 w/o if the solvent is at boiling temperature. As will be seen further on, the phosphorus content of the residue represents 21 w/o for both solution temperatures, providing that the orthophosphite precipitation in the bath is prevented.

Powdery samples were prepared by seeding the bath with palladium chloride. The powders used were previously ground and screened to obtain particles smaller than 37  $\mu\text{m}$  (400 mesh ASTM).

**Dissolutions and analyses.**—The dissolutions of electroless nickel are made in hydrochloric acid either at room temperature and slightly agitated, or at boiling temperature. The amount of hydrochloric acid used is twice as high as that required assuming that electroless nickel contains only nickel. The acid concentrations reported in this work always are the initial values. During the dissolution these concentrations may decrease by one half if all the powder is dissolved. For each run, the amount of electroless nickel used is 5 or 10 mM depending on the acid concentration.

After the test, the residue is filtered on Millipore,<sup>1</sup> then oxidized with the filter in nitric acid. The Millipore filters have been used because the as-plated deposit of electroless nickel consists of very small crystals. Moreover the oxidation of the residue with the filter is more practical and safer (avoiding any loss of substance) than the use of ordinary filters. By the Tyndall effect, we made sure that the filtration was efficacious, i.e., that no solid particles of colloidal size of the residue had passed the filter.

The nickel and the phosphorus are spectrophotometrically determined by the dimethylglyoxime oxidizing agent method (4) and the molybdenum blue method using the ascorbic acid as a reducing agent (5), respectively. The relative error is of  $\pm 1\%$  for each element.

We verified that, under our experimental conditions, no phosphine  $\text{PH}_3$  was produced, or in negligible amounts only.

The nickel and the phosphorus of both the residue and the filtrate of one particular test were determined in order to check the material balance. In further experiments the nickel and the phosphorus were determined only from the residue.

Moreover, we verified that the sum of the phosphorus plus the nickel corresponds to the weight of the residue. At this point, difficulties have arisen with the residues from electroless nickel with initial phosphorus contents of about 4 w/o. These residues, washed with demineralized water then dried in air at 70°C, present a difference from 10 to 17% between their weight and the sum nickel plus phosphorus analytically determined. The reason for this discrepancy is the oxidation of the residue during its drying. It could be shown that the oxidized precipitate can be reduced at 600°C in hydrogen. The undesired oxidation can be avoided by maintaining the residue during and after the filtration continuously under a film of water. The wet slurry is then transferred into an oven and

<sup>1</sup> Millipore Filter Corporation, Bedford, Massachusetts, (Type GS WP 04700, Mean Pore Size 0.22  $\mu\text{m}$ .)

\* Electrochemical Society Active Member.

dried at 700°C during 1 hr under vacuum, and cooled when still under reduced pressure. By the heat treatment the powder is recrystallized and its activity and ease to oxidize are decreased. For powders thus treated the analytical results for nickel and phosphorus add up to 100% of the weighed sample. The reactivity of the residue is unique for electroless nickel deposits containing about 4 w/o phosphorus. This phenomenon certainly comes from the following fact. After a certain time of deposition at pH 5.0, a spontaneous seeding of the bath occurs and leads to a deposition of much finer particles than those issuing from the palladium nucleates.

### Results

*As-plated electroless nickel.*—The dissolution of electroless nickel in hydrochloric acid is studied as a time dependent function with the acid concentration, the initial phosphorus contents of the deposited alloys, and the solvent temperature as parameters.

*Influence of the HCl concentration at room temperature.*—Figure 1 shows that for an initial phosphorus content of 3.26 w/o, the rate of dissolution at the beginning of the reaction is the faster the higher the concentration of the acid. After a certain time, a maximum of the rate of dissolution occurs for a concentration of 2.0N. For a concentration of 7.8N (azeotropic mixture,  $d = 1.12 \text{ g/cm}^3$ ), the curve is composed of two linear sections of different slope. Figure 2 shows the phosphorus content in the residue which increases rapidly with the dissolution time to approach a limiting value. After a certain time, the residue has the same composition as what is analyzed in the solution. Therefore the dissolution curve showing two intersecting straight lines (Fig. 1) can be explained by the successive dissolutions of two phases: first the nickel one and second a phase containing about 21 w/o phosphorus, that is to say a compound with the stoichiometry of the nickel phosphide Ni<sub>2</sub>P (20.87 w/o P). The linear extrapolation at time zero of the second section of the straight line (Fig. 1) yields the initial content of the phosphide phase present in the alloy. The calculated value obtained by supposing that all phosphorus initially present in the alloy is bonded to the nickel as the nickel phosphide Ni<sub>2</sub>P, indicated down at right of Fig. 1, agrees well with the extrapolated value.

*Influence of the initial phosphorus content of electroless nickel at room temperature.*—The results obtained with a sample containing 3.26 w/o phosphorus are reported on Fig. 1 and 2; Fig. 3 shows the same types of curves combined in a single figure for a sample containing 6.85 w/o phosphorus dissolved in 7.8N hy-

Fig. 3. Phosphorus content of the residue as a function of the time and dissolution rate of as-plated electroless nickel with an initial phosphorus content of 6.85 w/o at room temperature (21°C) in 7.8N HCl. ○ w/o P in residue, ● residue/initial mass in per cent.

drochloric acid. Again the limiting value for the phosphorus content in the residue reaches about 21 w/o corresponding to the nickel phosphide Ni<sub>2</sub>P. The extrapolated value pertinent to the initial Ni<sub>2</sub>P content present in the electroless nickel and drawn from the time when the phosphorus content of the residue varies no more, corresponds well to the calculated value for 6.85 w/o phosphorus, supposing the totality of the initial phosphorus is bonded to nickel at Ni<sub>2</sub>P.

For phosphorus contents higher than 8 w/o, the dissolution time is very long and the separation less efficacious than for alloys with lower phosphorus contents.

*Influence of the HCl concentration at boiling temperature.*—As an example the dissolution of electroless nickel of 12.5 w/o initial phosphorus content in boiling acid is reported. For acid concentration  $\leq 2N$  it is found that the higher the acid concentration, the more rapid the dissolution rate (Fig. 4). For a concentration of 7.8N, the dissolution rate is more rapid initially than for an acid concentration of 2.0N. The most efficacious separation of the two phases initially present in the as-plated alloy is realized at boiling temperature with an acid concentration of 7.8N. The

Fig. 4. Dissolution rate at boiling temperature of as-plated electroless nickel with an initial phosphorus content of 12.5 w/o. Legend same as Fig. 1.

same phenomenon was already observed with samples dissolved at room temperature (Fig. 1). The phosphorus content of the residue as a function of the time of dissolution shows that the limiting value reaches 20.9 w/o phosphorus which exactly corresponds to the stoichiometric composition of the nickel phosphide  $\text{Ni}_2\text{P}$  (Fig. 5). Again, the extrapolated value of the initial content of the  $\text{Ni}_2\text{P}$  phase corresponds to the calculated one, assuming that all the phosphorus is present as  $\text{Ni}_2\text{P}$ . In the case under discussion, the curve is not a segment of a straight line any longer hence the extrapolation has to be made from the time when the phosphorus content of the residue varies no more (upper curve of Fig. 6).

*Influence of the initial phosphorus content of electroless nickel at boiling temperature.*—Samples containing 8.78, 6.85, and 3.26 w/o phosphorus are studied in an acid concentration of 7.8N (Fig. 6, 7, and 8). For all these contents, the dissolution leads to the isolation of a  $\text{Ni}_2\text{P}$  phase. The extrapolated values of the initial contents of  $\text{Ni}_2\text{P}$  phase in the as-plated alloys agree well with the calculated values, assuming that all phosphorus is present as  $\text{Ni}_2\text{P}$ .

*Heat-treated electroless nickel.*—The method of dissolution in hydrochloric acid is applied to heat-treated electroless nickel, whose structure and chem-

ical composition are well established. The heat treatment was conducted under a vacuum better than  $10^{-3}$  Torr for 5 hr, at  $800^\circ\text{C}$ .

Samples containing 3.71, 8.78, and 12.5 w/o phosphorus are dissolved in 7.8N hydrochloric acid (Fig. 9, 10, and 11). For each of these phosphorus contents,

Fig. 9. Phosphorus content of the residue as a function of the time and dissolution rate of heat-treated electroless nickel with an initial phosphorus content of 3.71 w/o at room temperature (24°C) in 7.8N HCl. Legend same as Fig. 3.

Fig. 10. Phosphorus content of the residue as a function of the time and dissolution rate of heat-treated electroless nickel with an initial phosphorus content of 8.78 w/o at room temperature (24°C) in 7.8N HCl. Legend same as Fig. 3.

Fig. 11. Phosphorus content of the residue as a function of the time and dissolution rate of heat-treated electroless nickel with an initial phosphorus content of 12.5 w/o at room temperature (24°C) in 7.8N HCl. Legend same as Fig. 3.

the dissolution leads to the isolation of a phase containing about 15 w/o phosphorus in good agreement with the stoichiometry of the nickel phosphide Ni<sub>3</sub>P (14.96 w/o P). The extrapolated values of the initial contents of the Ni<sub>3</sub>P phase in the heat-treated electroless nickel correspond well to the calculated values,

supposing all the phosphorus is present as Ni<sub>3</sub>P. These results confirm those obtained by the x-ray method (1).

### Discussion and Conclusions

For all the phosphorus contents of the electroless nickel studied, and independently of the temperature of dissolution, a nickel phosphide phase whose stoichiometry corresponds to Ni<sub>2</sub>P could be isolated. In as-plated electroless nickel, nickel phosphide Ni<sub>2</sub>P is best separated from nickel by using 7.8N hydrochloric acid as a solvent, for low phosphorus alloys at room temperature, and for high phosphorus alloys at boiling temperature. The Ni<sub>2</sub>P content of the as-plated electroless nickel accounts for all the phosphorus present in the samples.

The identification of the nickel phosphide Ni<sub>2</sub>P as such is the residue of dissolution of as-plated electroless nickel was also attempted by x-ray diffraction analysis and DTA.

The x-ray diffraction study of the residue of dissolution leads to the results of Table I. The small number of lines observed and the accuracy of their position for the nonheat-treated residue do not allow one to assert the presence of Ni<sub>2</sub>P only. The x-ray diagram obtained from a sample annealed for 24 hr at 800°C in hydrogen confirms the previously found line positions for the nonheat-treated residue. It reveals however an additional number of diffraction lines of Ni<sub>2</sub>P as well as some of Ni<sub>12</sub>P<sub>5</sub> which is formed during the heat treatment. The positions of the lines measured on the residue of dissolution and the calculated values of Ni<sub>2</sub>P agree within 1%. The relative intensities of the observed values on the residue compare reasonably well with those tabulated. Thus, the residue of dissolution of as-plated electroless nickel consists of Ni<sub>2</sub>P; it contains no nickel and no other nickel phosphide.

A DTA curve of the residue of dissolution does not show any deviation. An as-plated electroless nickel alloy containing about 8 w/o phosphorus was reconstituted by mechanically mixing a residue of dissolution and a carbonyl-nickel powder, then studied by DTA. The exothermic energy evolved between 520° and 640°C corresponds to about 5.7 kcal/mole Ni<sub>3</sub>P, the reaction product being identified as Ni<sub>3</sub>P. In a previous work (1) a DTA study of electroless nickel revealed two reaction areas in the energy vs. temperature diagram: one below 300°C, the other above 300°C. The reaction heat of the former was called Q<sub>1</sub>, that of the latter Q<sub>2</sub>. The heat Q<sub>2</sub> = 5.9 kcal/mole Ni<sub>3</sub>P is proportional to the phosphorus content of the electroless nickel. Q<sub>1</sub> passes through a maximum at about 8 w/o phosphorus and vanishes thereafter at a concentration higher than 10 w/o. The total heat of reaction Q<sub>1</sub> + Q<sub>2</sub> for alloys with less than 8 w/o phosphorus is 8.9 kcal/mole Ni<sub>3</sub>P.

\* Less accurate measurement.

The heats  $Q_1$  and  $Q_2$  obtained below 400°C are difficult to compare with the value reported in the present work which was measured between 520° and 640°C, since specific heat data of nickel phosphides are not available. However, the energy of 5.7 kcal/mole  $Ni_3P$  evolved during heating of a mixture of  $Ni_2P$  plus nickel corresponds to the heat previously called  $Q_2$ , i.e., 5.9 kcal/mole  $Ni_3P$ . The energy of the reaction

more or less corresponds to the heat previously called  $Q_1 + Q_2$ , i.e., 8.9 kcal/mole  $Ni_3P$ .

The comparison of results of the dissolution rates with those obtained by DTA (1) leads to the following comments. The DTA study (1) revealed two reaction areas for phosphorus contents below 10 w/o while only one such area was observed above this concentration. According to the results of the present study showing that the as-plated electroless nickel has the same qualitative composition for any phosphorus content, the two reaction areas previously observed for phosphorus contents below 10 w/o could eventually correspond to the formation of  $Ni_5P_2$  from  $Ni_2P$  and of  $Ni_3P$  from  $Ni_5P_2$ . This hypothesis would not explain the case of phosphorus contents higher than 10 w/o. In order to verify this supposition, samples containing 3.26, 7.32, and 12.5 w/o phosphorus, respectively, were analyzed after heating up to 285°C under the same conditions as those used in the DTA study, i.e., a heating rate of 2°/min. This temperature delimits the two reaction areas. After dissolution in 7.8N hydrochloric acid at boiling temperature, the three samples lead to a residue with the stoichiometry of  $Ni_2P$ . These very samples further investigated under the same experimental conditions after heating up to a temperature high enough to allow a complete reaction, i.e., 500°C, leave a dissolution residue whose stoichiometry corresponds to that of  $Ni_3P$ . The intermediate state of the  $Ni_5P_2$  does not represent any one of the two reaction areas and, therefore, cannot be isolated by controlling merely the temperature of the heat treatment.

As a consequence, the heat previously called  $Q_2$  which is proportional to the phosphorus content of the electroless nickel may correspond to the reaction:  $Ni_2P + Ni = Ni_3P$ , though the measured energy is only 5.9 kcal/mole  $Ni_3P$ , i.e., about 70% of that indicated by Weibke and Schrag (8). This hypothesis is supported by the fact that the energy evolved during the rise of temperature of a reconstituted electroless nickel alloy from  $Ni_2P$  plus nickel leads to a value close to the heat  $Q_2$ . The discrepancy between our energy result and that of Weibke and Schrag can possibly be explained by the fact that the heats of formation cannot be compared at the same temperature (see above). The heat previously called  $Q_1$  could be explained by the reaction of a little amount of phosphorus as a solid solution in the nickel producing a nickel phosphide  $Ni_2P$  or/and  $Ni_3P$ . The maximum

energy of the heat  $Q_1$  which occurs for phosphorus contents of about 8 w/o, could correspond to a free phosphorus content <0.5 w/o.

The accuracy of the analytical results concerning the  $Ni_2P$  phase content in the as-plated alloys would allow the presence of a little amount of phosphorus not bonded to nickel. The presence of elementary phosphorus in the freshly prepared residue of dissolution, in amounts more important than only traces, cannot be measured either by reaction with sodium hydroxide, or by solubility in absolute alcohol. In carbon disulfide, the maximum solubility observed in a dissolution residue of electroless nickel with an initial phosphorus content of 4.41 w/o in 7.8N hydrochloric acid at room temperature is <0.02 w/o phosphorus in regard to the initial mass of electroless nickel. Therefore it might be concluded that the as-plated electroless nickel contains only very little phosphorus in the elementary state, the rest being bonded to nickel as nickel phosphide  $Ni_2P$ .

The temperature at which the electroless nickel is deposited, in this study at 94°C, has perhaps an influence on the nature of the chemical bond between phosphorus and nickel in the as-plated state. This parameter has not been investigated.

#### Acknowledgment

The authors wish to thank Professor P. Dinichert, Director of the L.S.R.H. for his advice and interest in this work and permission to publish this paper. They also thank Mr. J.-P. Renaud and Dr. M. Delaloye for helpful discussions and for providing facilities. They acknowledge the valuable assistance of Mr. J. C. Jaquet in the x-ray analysis and of Mr. A. Verbay in differential thermal analysis.

Manuscript received Nov. 8, 1967; revised manuscript received Jan. 22, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Electroless Nickel Plating on Silicon

Hitoo Iwasa, Masami Yokozawa, and Iwao Teramoto

Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka, Japan

## ABSTRACT

In the study of electroless Ni plating of Si wafers with p-n junctions using conventional solutions, a pronounced difference in plating rate between p- and n-type surfaces is observed. Further experiments show that rate difference probably should not only be attributed to the photovoltaic effect generated at the p-n junctions but also to the electronegativity difference between p- and n-type Si. The latter effect can be changed by addition of such material as  $\text{NH}_4\text{SCN}$  or  $2\text{NH}_4\text{-EDTA}$  to the plating solution. Whereas  $\text{SCN}^-$  addition increases the rate difference, EDTA addition decreases it. This fact which can be put to practical use gives an extra support for the explanation given above.

Electrical connections to Si transistors up to now are often made by Au-Al thermocompression bonds. Another technique uses a simple method: electroless Ni plating followed by soldering. Advantages are the excellent chemical and mechanical properties of the connections. Also the cost of the processing is much lower than of the thermocompression bonding technique. However, this latter technique is not now widely used.

Since Sullivan and Eigler (1) first applied the electroless Ni plating to Si, one of the difficulties often found for actual Si devices has been the difference in plating rate between adjacent p- and n-type surfaces. Silverman (2) reported that, during Au plating by autocatalytic reduction, the difference in plating rate between adjacent p- and n-type Si surfaces was changed by strong illumination owing to the created photovoltaic effect at the p-n junction. We observed a similar effect in the electroless Ni plating as have other observers.

The theory of electroless plating has not been well defined yet, although many explanations have been proposed. For example, Gutzeit's explanation (3), based on the autocatalytic reduction of Ni ions, may be clear for the acidic solution, but in an alkaline solution hypophosphite is spontaneously oxidized at an elevated temperature. Moreover, the effect of photovoltage on plating rate can hardly be explained by the argument that a nickel ion is reduced only by an atomic hydrogen.

One of the most promising models for the process in an alkaline bath (4) may be that in which the reactions involved are divided into anodic and cathodic reactions, forming many local cells at the interface between substrate and solution, as indicated in Fig. 1. The different reaction occurring can be summed up as follows:

1. Diffusion of reactants to the interface

2. Oxidation of  $\text{H}_2\text{PO}_2^-$  (anodic)

3. Migration of the electrons in the substrate

4. Reduction of  $\text{Ni}^{++}$  and  $\text{H}^+$  (cathodic)

5. Diffusion of reaction products from the interface into the solution. Similar oxidation and reduction processes may occur if instead of electrons, holes move in the opposite direction in the substrate. The electron (or hole) migration in the substrate and the transfer through the interface will be determined by: (a) electron concentration within the substrate; (b) thin oxide layers on the substrate; (c) photovoltage at the

p-n junctions; (d) electronegativity of the substrate. If electron (or hole) migration determines the deposition rate, one can easily imagine that this rate will be different for adjacent p- and n-type substrate materials. For this reason we studied the possibility of diminishing the difference in plating rate by transferring the rate-determining step from the migration in the substrate to one of the other steps of the reaction occurring inside the solution.

Results of experiments carried out to analyze the effect of each of these factors are reported below.

## Experimental Procedures

The composition of the plating bath used in the present experiment is substantially the same as that of the Brenner solution (5), that is

$\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$	30 g/l
$\text{NH}_4\text{Cl}$	50 g/l
$(\text{NH}_4)_2\text{HC}_6\text{H}_5\text{O}_7$	65 g/l
$\text{NaH}_2\text{PO}_2 \cdot \text{H}_2\text{O}$	10 g/l

The bath is heated to a temperature of  $90^\circ\text{C}$ , at which temperature about 200 cc of  $\text{NH}_4\text{OH}$  is added to 1000 cc of the plating solution; the bath temperature is then elevated to  $95^\circ\text{C}$ , at which temperature the Si sample is immersed in the bath for 30 sec. Ni films plated in this way were 1000-2000Å thick.

Si wafers with polished surfaces were used as samples; they were cleaned by etching slightly and rinsing with distilled water and methyl alcohol. Then the wafers were stored in isopropyl alcohol. Prior to plating, the wafer was dipped in  $\text{NH}_4\text{F}$  solution (50%) for 30 sec and again rinsed thoroughly with methyl alcohol. The whole process was carried out without drying the wafer surfaces until the plating was completed to protect the Si surfaces from oxidation and staining.

The Ni film thickness for thick films was measured by the conventional interference method. For thin films the autoradiographic method was applied by making use of radioactive  $\text{Ni}^{63}$  in the plating bath.

Electrode potentials were measured using a saturated calomel electrode as the standard electrode. The

Fig. 1. Schematic representation of the "local cell" model

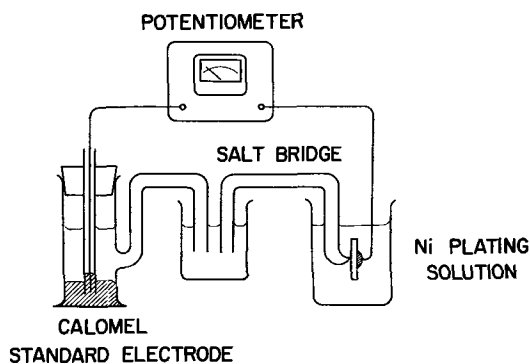

Fig. 2. Experimental arrangement for measuring electrode potentials.

schematic arrangement for this measurement is shown in Fig. 2; the electrical connection on the back side of the Si wafer was made by means of Ni plating and soldering.

The reduction potential of  $\text{Ni}^{++}$  in the plating solution was estimated by measuring the current-voltage characteristics of the solutions without the hypophosphite. The current through two Pt plates with an area of  $1 \text{ cm}^2$ , placed  $1 \text{ cm}$  apart from each other, as a function of applied voltage was traced on an X-Y recorder.

### Results

**Migration of charge carriers in the Si substrate.—Thin oxide films on silicon.**—A p-type surface is more likely covered with an oxide film than an n-type surface. Plating on a p-type surface was hardly possible without a cleaning treatment to remove the oxide. Cleaning the surface with HF or  $\text{NH}_4\text{F}$  solution or adding  $0.1$  to  $0.2 \text{ mol/l}$  of  $\text{F}^-$  to the plating bath made the plating reproducible (6), and Ni film was easily plated even on p-type surface. However, any cleaning treatment could not eliminate the difference in plating rate between p- and n-type surfaces.

**Electron concentration in silicon.**—If electrons would act as charge carriers in the substrate, the plating rate on p-type should be much smaller than that on n-type Si. However, a rather small difference in plating rate was found between separated p- and n-type surfaces.

Strong illumination on semiconductors generates electron and hole pairs and makes the conduction type intrinsic. The plating rate on p-type silicon was not affected by illumination, showing that the electron concentration above a certain value has only small effect on the plating rate.

**Photovoltage at the p-n junction.**—With illumination on a p-n junction the plating rate on adjacent p- and n-type materials proved to be different. The difference increases with an increase of illumination density, suggesting a contribution of the photovoltaic effect. The plating rate on the n-type material was found to be higher than on the adjacent p-type material. However, an appreciable small difference was still found under weak room light.

**Electronegativity of silicon.**—The electronegativity of p-type Si is greater than that of n-type Si. It seems feasible that the electronegativity difference between p- and n-type Si causes a difference in rate of electron transfer from Si to  $\text{Ni}^{++}$  and consequently gives rise to a difference in plating rate.

Summarizing we may say that the difference in plating rate observed between adjacent p- and n-type surfaces as far as the substrate is concerned is due to the photovoltage generated at the p-n junction, and possibly to the difference in electronegativity between p- and n-type Si.

**Rate limitations imposed by the solution.—Effect of Ni concentration.**—The concentration of  $\text{NiCl}_2$  in the

plating solutions was reduced. It was found that the ratio of the plating rates on adjacent p- and n-type materials changed only slightly with  $\text{Ni}^{++}$  concentration.

**Effect of additives in the plating solution.**—The ammonium salt of EDTA was added to the plating solution. The observed plating rate and its ratio on adjacent p- and n-type materials are shown in Fig. 3 and Fig. 6, respectively. The ratio increased to unity with increasing concentration of EDTA. The plating rate on p-type showed a maximum at an EDTA concentration of  $5 \text{ g/l}$ , whereas on n-type material it was constant. Further addition of EDTA resulted in a remarkable decrease in plating rate, and no films were grown at an EDTA concentration above  $10 \text{ g/l}$ , corresponding to one third of  $\text{Ni}^{++}$  concentration; film growth stopped completely. Figure 4 represents autoradiographs of plated Ni: (a) without EDTA and (b) with EDTA ( $6 \text{ g/l}$ ). Figure 5 shows the thickness of films on both types of the p-n junction (a) without EDTA, (b) with EDTA ( $6 \text{ g/l}$ ) and (c) with EDTA ( $10 \text{ g/l}$ ).

The electrode potential of the half-cell of the system

was measured. Addition of EDTA to this system made the potential more negative, as shown in Fig. 7.

The relative deposition voltages of Ni were obtained from the I-E characteristics of different  $\text{H}_2\text{PO}_2^-$ -free solution. The results shown in Fig. 8 indicate a tendency similar to those based on the half-cells in solutions with  $\text{H}_2\text{PO}_2^-$ .

Fig. 3. Plating rate on p- and n-type Si as a function of concentration of EDTA added to the solution.

Fig. 4. Autoradiographs of plated Ni on Si: (a) with the EDTA-free solution, (b) with the EDTA-added solution ( $6 \text{ g/l}$ ).

Fig. 5. Relative thickness of Ni films plated on p- and n-type Si: (a) with the EDTA-free solution, (b) with the EDTA-added solution (6 g/l), (c) with the EDTA-added solution (10 g/l).

Fig. 6. Thickness ratio of Ni films plated p- and n-type Si as a function of concentration of EDTA added to the solution.

Fig. 7. Electrode potential as a function of concentration of EDTA added to the solution.

Ni-EDTA<sup>++</sup> gives a larger negative value to the electrode potential than Ni(NH<sub>3</sub>)<sub>4</sub><sup>++</sup>. One may expect that the addition of SCN<sup>-</sup> to the plating solution will cause an opposite effect to EDTA, and that the difference in plating rate will increase with increasing SCN<sup>-</sup> concentration. Figure 9 shows a photograph

Fig. 8. Dependence of the electrode potential on complex formers, citrate, NH<sub>3</sub>, and EDTA, added to the solution.

Fig. 9. Photograph of the plated Ni with the SCN<sup>-</sup>-added solution.

of an SCN<sup>-</sup> solution; the difference was remarkably enhanced and the p-n junction was plainly revealed.

### Discussion

The difference in plating rate of electroless nickel between p- and n-type surfaces under strong illumination can be attributed substantially to the photovoltage generated at p-n junctions. However, this may not be the only cause for the rate difference, because the appreciable difference was observed in plating rate even under weak room light, where the photovoltage is negligibly small. Two different causes, as previously described, would be considered. One concerns the surface condition of substrate silicon. The surface of silicon is usually covered with thin oxide layers, which impede the plating reaction. However, it was found that careful cleaning can prevent the effect of oxide. The alternative cause is due to redox potential of the substrate. With some exceptions, electroless nickel plating is more easily applied to less electronegative materials, being consistent with the result observed on p- and n-Si. Thus, both the photovoltage generated at p-n junctions and the electronegativity difference between p- and n-substrates may affect the plating rate in a similar way. The effect of potential difference between p- and n-types, however, will appear relatively to the potential of nickel ions. When the potential required for reduction of nickel ions is larger than the potential difference between the substrates, the plating rates on both surfaces are small and consequently the rate difference becomes negligible in comparison with the plating rates.

From this view point, the effect of addition of EDTA can be explained as follows. By addition of EDTA salt to the plating solution, the nickel complex ion changes its form from Ni(NH<sub>3</sub>)<sub>4</sub><sup>++</sup> to Ni-EDTA<sup>++</sup> making the potential more negative (or less noble). The potential difference between p- and n-type surfaces relative to the reduction potential of the complex ions apparently decreases, resulting in diminished difference in plating rate.

On the contrary, Ni(SCN)<sub>2</sub> formed by addition of SCN salt makes the potential more positive. This gives rise to faster plating and enhanced rate difference between p- and n-substrates.

### Conclusion

It is probable that the difference in plating rate between adjacent p- and n-type surfaces may be attributed to the electronegativity difference between p- and n-type Si as well as to the photovoltage generated at p-n junctions. This difference can be suppressed by addition of EDTA to the plating solution. The stable Ni-EDTA<sup>++</sup> complex then formed in the solution elevates the redox potential to such a high value that the electronegativity difference and the photovoltage will have a negligible effect.

## The Measurement of Diffusion Coefficients in Binary Liquid Metals with a Concentration Cell

John B. Edwards,<sup>†</sup> Edward E. Huccke\*  
and Joseph J. Martin

Department of Chemical and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan

### ABSTRACT

An experimental technique has been developed for measurement of diffusion coefficients in liquid metals. A liquid metal concentration cell was designed to measure cell potential and discharge current while insuring that diffusion in the cathode was the over-all rate limiting process. The technique was used to obtain diffusion coefficients in three binary liquid metal systems; potassium-mercury, sodium-lead, and sodium-tin.

Unlike the study of diffusion in aqueous and in organic systems, it is not possible to use optical methods to study diffusion in liquid metals. The principal advantage of optical methods is that it is possible to determine the rate at which material enters the diffusion path. From this rate, anomalies such as disturbances during the initial stages of the experiment can be detected. A number of methods have been developed to measure diffusion coefficients for liquid metals in which only the over-all concentration change and/or the total quantity of diffusate is accessible. One of the authors has presented an extensive review and critique of these methods (1).

In this paper the development of a new technique for measuring diffusion coefficients of binary liquid metal systems is described. A liquid metal concentration cell with a capillary cathode is discharged at constant potential. The diffusion coefficients are calculated from the cell potential and discharge current. The unique contribution of this technique is that it allows measurement of the rate at which diffusate enters the diffusion path, and thus, detection of anomalies in the diffusion process. The technique has been utilized for measurement of coefficients in three binary systems; potassium-mercury, sodium-lead, and sodium-tin.

### Experimental

**Technique.**—A liquid metal concentration cell may be constructed with a pure alkali metal anode, A, a fused salt electrolyte containing cations of A<sup>+</sup> only, and an alloy of A with a heavier metal B. The cell is written as

For a given metal couple, the reversible (open circuit) potential of such a cell, theoretically depends

<sup>†</sup> Electrochemical Society Student Member.  
\* Electrochemical Society Active Member.

only on its temperature and the atomic fraction of A in the cathode alloy at the cathode-electrolyte interface. When current flows, reversible conditions no longer exist and the cell potential differs from its equilibrium value due to resistance, concentration and activation polarization.

A concentration cell of this type, together with the appropriate solution of Fick's second law, may be utilized to determine the diffusion coefficient of A through the alloy A(B) if the following conditions are met. First, the cell design must insure that diffusion of A through A(B) in the cathode is rate controlling. Second, the relationship between discharge current and quantity of alkali metal transferred from anode to cathode must be known. Third, the relationship between reversible cell potential and cathode composition must be known.

Table I summarizes the liquid metal systems investigated, the fused salt electrolytes used, and the temperature ranges studied.

Thermodynamic data are available for each of the metal couples (2) from which the equilibrium cell potential may be calculated as a function of cathode composition. Concentration units of gram atoms alkali metal per cubic centimeter of alloy were used. Alloy densities were obtained from (3, 4) for potassium amalgams. For the sodium-lead and sodium-tin al-

Table I. Summary of the liquid metal systems

Diffusion couple	Anode	Electrolyte	Cathode	Temp. °K
K in K (Hg)	K	KOH-KI-KBr	K (Hg)	500, 550, 600
Na in Na (Pb)	Na	NaOH NaI-NaCl	Na (Pb)	625, 903
Na in Na (Sn)	Na	NaOH NaI-NaCl	Na (Sn)	625, 903

loys, experimental data were not available, and densities were estimated by linear interpolation of the pure component densities on a mole fraction basis.

High current efficiencies with respect to  $A^+$  were obtained by the use of discharge potentials well below the decomposition potentials of the fused salts, and by selection of salts with cations of  $A^+$  only. The ionization potentials of sodium and potassium reveal that oxidation states greater than +1 did not occur. The solubility of alkali metals in the fused salts over the temperature ranges investigated was not large enough to affect the current efficiencies appreciably. The current densities obtained in this investigation were less than 1 amp/cm<sup>2</sup>, while exchange currents in metal-metal ion systems are often 1-4 amp/cm<sup>2</sup>. Therefore, activation polarization was assumed not to be rate limiting. The high specific conductivities of the molten salts gave low values of resistance polarization. Finally, the capillary cathode geometry was used to insure that concentration polarization of A diffusing through A(B) was the over-all limiting step during cell discharge.

**Apparatus.**—A typical diffusion cell is shown in Fig. 1. To preclude phase inversions the most dense phase must be located on the bottom and the least dense on the top. The cathode compartment was constructed from quartz tubes. These were examined under a binocular microscope, only sections with uniform bore were selected. The activity of the alkali metal in the cathode was lowered by the heavy metal addition, and the alloy did not attack the quartz. The anode compartment which was exposed to pure alkali metal was constructed of alumina. A new cell was constructed for each experiment.

The lead or tin was heated in a graphite crucible to remove surface oxides and dissolved gases. The sodium was weighed under dry box conditions and transferred under n-pentane with the lead or tin to the furnace. The heated charge was stirred to assure uniform composition after which the cathode compartments were filled by submerging them in the alloy and applying a positive pressure. The potassium amalgams were pre-

Fig. 1. Diffusion cell

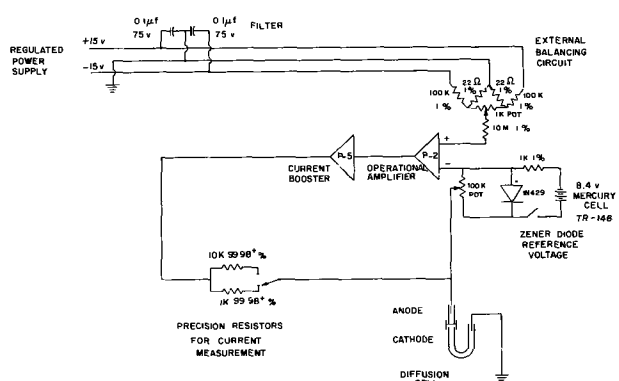

Fig. 2. Potentiostat circuit

pared in quartz rather than graphite crucibles since potassium readily forms lamellar compounds with graphite (6). The fused salts were prepared from reagents weighed in the dry box and heated in graphite crucibles. The matrices were impregnated by immersing them in the melt and pressurizing with argon. Each cell was assembled under dry box conditions.

Constant discharge potentials were obtained with a voltage follower circuit as shown in Fig. 2. This was constructed from a differential input operational amplifier and a current booster amplifier. This negative feedback circuit was capable of handling discharge currents to 20 ma. A Zener reference source was used to select the discharge potential. The discharge current was determined by measuring the potential drop across a precision resistor in the feedback circuit.

The 3-in. diameter furnace had three independently controlled windings. Power to the furnace was regulated with a proportional controller such that it was possible to maintain a stable gradient of 0.5°C/in. in the central portion of the furnace. The Vycor sleeve used to contain the cell was evacuated to less than a micron before pressurizing with high-purity argon.

**Mathematical formulation.**—For the case where concentration polarization of the cathode is rate limiting, the capillary may be treated as a one-dimensional semi-infinite diffusion path. Fick's second law applies.

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad [1]$$

If the cathode-electrolyte interface is the origin and the cell is discharged at constant potential, the concentration profile in the cathode at any point  $x$  and time  $t$  is (7)

$$C(x,t) = \left[ C_0 + (C_s - C_0) \operatorname{erfc} \frac{x}{2\sqrt{Dt}} \right] \quad [2]$$

where  $C_0$  and  $C_s$  are, respectively, the initial cathode alloy concentration and the concentration at the cathode-electrolyte interface for time greater than zero. The flux  $J(0,t)$  at the interface is obtained by differentiating Eq. [2]

$$J(0,t) = (C_s - C_0) \left( \frac{D}{\pi t} \right)^{1/2} \quad [3]$$

In this solution it is assumed that the diffusion coefficient is independent of concentration and that no volume changes occur during diffusion. Experimentally the error due to these assumptions is minimized by using small concentration intervals ( $C_s - C_0$ ).

At small times Eq. [3] predicts  $J(0,t) \rightarrow \infty$  as  $t \rightarrow 0$ . However, for small times the resistance polarization in the electrolyte becomes small compared to the over-all cell potential. This occurs as the concentration gradient in the cathode becomes progressively smaller.

The one-dimensional treatment above implies the cathode-electrolyte interface is planar and perpendicular

ular to the axis of the capillary. Surface energy will lead to a nonplanar interface. A contact angle of  $127^\circ$  has been reported for a lead drop on a quartz surface covered with KCl-NaCl (8). Few data on other systems are available. Based on the single result for the lead-salt couple, the cathode-electrolyte interface would tend to be convex with respect to the cathode alloy. The perturbations introduced by a nonplanar interface were investigated by considering the diffusion path to be a semi-infinite cylinder terminating in a hemispherical surface at the bounded end. An analytical solution of Fick's law for this geometry is greatly complicated by the boundary conditions at the bounded end. A computer solution, however, was obtained using the implicit alternating direction technique (9). Figure 3 compares the flux obtained for the case of the hemispherical nonlinear interface to that for the one-dimensional case. A diffusivity of  $1 \times 10^{-5}$  cm<sup>2</sup>/sec was used. For a hemispherical interface, initially the flux is larger than Eq. [3] predicts due to the contribution of radial diffusion. However, for times in excess of a few hundred seconds the two become indistinguishable as diffusion in the cylindrical capillary becomes rate limiting.

### Results and Discussion

A typical current-time discharge curve is shown in Fig. 4. The general shape conforms to that predicted by mathematical analysis. For small times,  $t < 10$  sec, the flux (current/diffusion path area) is smaller than Eq. [3] predicts due to ohmic polarization in the electrolyte. For the time interval  $10 < t < 100$  sec, the flux is greater than Eq. [3] predicts due to the contribution of the larger area of a nonplanar interface. For  $t > 100$  sec, the discharge current behaves as is expected for one-dimensional diffusion. Equation [3] was solved to obtain the diffusion coefficient,  $D$ , explicitly. Calculation of the coefficients was based on

Fig. 3. Flux for coupled diffusion problem

Fig. 4. Typical discharge curve

that portion of the curve which is a straight line on a plot of  $\log i$  vs.  $\log t$ . The open-circuit potential of the cell was not stable. Presumably this was due to the small but finite solubility of the alkali metal anode in the fused salt electrolyte.

Activation polarization was assumed to be negligible and the current efficiency was taken as 100%. Both these assumptions seem reasonable in view of available data in the literature for liquid metal concentration cells. Concentration intervals ( $C_s - C_0$ ) of from 4 to 8 m/o (mole per cent) alkali metal were used. This lower limit was determined by the smallest concentration interval which gave stable cell discharge characteristics. In each of the systems investigated two or more cells were run at a common point to insure reproducibility and to compare results from cells with 1.0 and 1.6 mm diameter diffusion paths. In no case was the path diameter found to affect the results significantly.

Coefficients for the diffusion of potassium in potassium-amalgams are shown in Fig. 5. The values of the diffusion coefficient at infinite dilution were calculated from the Stokes-Einstein equation using the viscosity reported in (10) and the Pauling ionic radius of potassium (11). The results are compared with the smoothed data of Bonilla *et al.* (3). Both investigations report a maximum in the diffusion coefficient close to  $N_K = 0.30$ . The phase diagram (2) shows a congruently melting compound  $Hg_2K$  at  $N_K = 0.33$ . Thermodynamic data (2) reveal that negative deviations from Raoult's law exist for this system. Diffusion coefficients have been measured as a function of composition for two other systems which show negative deviations from Raoult's law, Hg-Tl (12) and Bi-Pb (13). In both cases a maximum exists.

For the range  $0.25 < N_K < 0.35$ , Bonilla *et al.* report much higher values than were found in the present investigation. Diffusion coefficients over a wide range of compositions have been reported for the following binary liquid metal systems; Hg-Tl (12), Bi-Sn (13), In-Sn (14, 15, 16), Bi-Pb (13, 17, 18), Zn-Hg (19), Pb-Sn (13), and Na-Pb (20). With the exception of one investigation, Pb-Bi (13), in no case did the diffusion coefficients vary by more than a factor of 2.2 over the composition range. In this exception the variation was more than an order of magnitude. However, the investigators noted that large concentration gradients inherent in the experimental method probably gave rise to convection currents. Large variations in the value of the diffusion coefficient with composition are common in solids where marked structure changes can occur. In liquids where the atoms are less rigidly bound the variations are not expected to be as pronounced. Variations of an order of magnitude are not expected. Several investigators (21-24) have observed convection effects with liquid metals in diffusion paths of greater than 2-mm diam-

Fig. 5. Diffusion coefficients for potassium in potassium amalgams.

Table II. Activation energy and pre-exponential,  $D_0$ 

System	N	$D_0$ , cm <sup>2</sup> /sec	E, cal/g atom
K-Hg	0.165	$3.7 \times 10^{-4}$	2100
Na-Pb	0.120	$2.0 \times 10^{-4}$	2500
Na-Sn	0.160	$1.9 \times 10^{-4}$	1900

eter. Convection may result from the presence of vibrations or from negative temperature gradients (top end cooler) as small as 0.1°C/cm (25). The data of Bonilla *et al.* were obtained in paths of 1/2 and 1/4-in. diameter which greatly increases the possibility of convection. They maintained a small positive temperature gradient to reduce the possibility of convection as was done in the present investigation. However, the potassium-mercury system is strongly exothermic and liberation of heat occurs during diffusion of the components. This heat liberation is most likely to be pronounced where compounds exist in the solid state, such as Hg<sub>2</sub>K, and may persist into the liquid state. Analogous thermal generation conditions exist in the electromobility experiments where internal heat liberation results from ohmic heating by the high current densities. Several investigators have noted the existence of convection in liquid metals under these conditions (26-29). On the basis of these considerations, the explanation for the inordinately high coefficients reported by Bonilla *et al.* in the range  $0.25 < N_K < 0.35$  may be convection resulting from a combination of a large diameter diffusion path and exothermic heat liberation causing local temperature disturbances. The discrepancy between the coefficient of diffusion at infinite dilution reported in the two investigations is explained by the choice of different sources for the viscosity data used in the calculation.

The coefficients obtained for diffusion of sodium in sodium-lead are shown in Fig. 6. The values at infinite dilution were calculated from the Stokes-Einstein equation using viscosity data from (30) and the Pauling ionic radius of sodium (11). Results are compared with values reported by Morachevsky (20) who used the capillary reservoir technique and sectioned the path after diffusion for chemical analysis. His concentration gradients were as large as 40 a/o (atom per cent) sodium. The sodium-lead system exhibits large negative deviations from Raoult's law. The minimum in Morachevsky's data is not consistent with this as explained earlier. Rather, a maximum as was obtained in the present investigation is expected.

The coefficients obtained for the diffusion of sodium in sodium-tin are shown in Fig. 7. No other investigators have reported diffusion coefficients for this system.

The data for each of the three systems can be represented by the Arrhenius equation

Fig. 6. Diffusion coefficients for sodium in sodium-lead alloys

Fig. 7. Diffusion coefficients for sodium in sodium-tin alloys

$$D = D_0 e^{-E/RT} \quad [4]$$

The activation energy,  $E$ , and the pre-exponential,  $D_0$ , are given in Table II for each of the systems at the indicated mole fraction of alkali metal,  $N$ .

### Summary

A method has been developed of measuring diffusion coefficients in binary liquid metals. This method, unlike others available, allows observation of the rate at which diffusate enters the diffusion path and detection of anomalous effects which may occur particularly in the early stages of the experiment. The electrical measurements of current and potential are substituted for the traditional chemical or radiochemical analyses. Since very small quantities of diffusate enter the diffusion path during an experiment, typically  $10^{-4}$ g, the advantage of measuring electrical quantities over chemical analysis for this small a composition change is apparent. The method has been tested on three liquid metal systems, potassium-mercury, sodium-lead, and sodium-tin. It was found to give results consistent with available thermodynamic data and theoretical models. The concentration cells were discharged at constant potential in this investigation. They could, however, be discharged at constant current providing the appropriate solution of Fick's law is used in analysis of the data.

## The Mechanism of Oscillatory Behavior During the Anodic Oxidation of Formaldehyde

Herbert F. Hunger\*

*U. S. Army Electronics Command, Fort Monmouth, New Jersey*

### ABSTRACT

Galvanostatic studies of formaldehyde half-elements in sulfuric acid at room temperature were made. In addition to kinetic measurements with constant bulk concentration of formaldehyde, adsorption and desorption experiments were performed. The oscillatory behavior is described in terms of current-potential characteristics and potential transients. Two reaction sequences are postulated to explain the oscillations. In path I a catalytic decomposition step and in path II a diffusion-readsorption step are suggested as the coupling steps which are required to continue the oscillations. At potentials of or above +0.8v vs. SHE, the participation of the oxidized platinum surface in the oxidation of formaldehyde becomes noticeable. From adsorption and desorption experiments it can be concluded that readsorption from a liquid film on top of the ad-layer is essential for the occurrence of the first oscillation. This excludes the coupling mechanism of path I.

In previous papers we have reported on oscillation phenomena occurring during the anodic oxidation of formaldehyde in sulfuric acid at platinum electrodes and room temperature (1, 2). The objective of this paper is to report on further work concerning the reaction mechanism.

### Experimental

The half element investigated can be presented by the scheme

and the cell used to study the oscillation phenomena by

It contained either a smooth or platinized platinum electrode in an anolyte consisting of 1M formaldehyde in 3.75M sulfuric acid. The anolyte was separated by a cation exchange membrane (Nepton CR-61 from Ionics Incorporated) or a sintered glass disk from a catholyte of the same composition. A smooth platinum cathode was placed into the catholyte. Both

smooth and platinized platinum electrodes were made from platinum-foil (0.076 cm thickness with a geometrical cross section area of 1 cm<sup>2</sup>, except otherwise noted). A hydrogen reference electrode of the type described by Giner was arranged in a separate electrolyte compartment (3.75M H<sub>2</sub>SO<sub>4</sub>) and connected with a properly arranged Luggin capillary to the anode (3). The Giner hydrogen electrode was 26 mv negative to SHE. One type of experimental cell was constructed from Lucite except the gasketing material (Teflon or rubber) (4). The adsorption and desorption experiments were performed in glass-H-cells (E. H. Sargent & Company) with standard glass joints and controlled atmosphere (CO<sub>2</sub> or argon). The electrodes were platinized in a controlled manner (5). Nominal amounts up to 30 mg platinum black per square centimeter of geometrical area were electrolytically deposited. These nominal amounts correspond to the electrical charge passed during platinization. Corrections for the Faradaic efficiency showed that 10 mg platinum/cm<sup>2</sup> nominal correspond to 3.05 mg/cm<sup>2</sup> and 30 mg/cm<sup>2</sup> nominal to 7.5 mg/cm<sup>2</sup>. The experiments were conducted at controlled temperature conditions (21° and 25°C). The chemicals used to prepare the electrodes and the electrolytes were of highest purity grade commercially available.

\* Electrochemical Society Active Member.

A precision current source (Model CS-12, North Hills, Electronics, Inc.) was used to control the current ( $1 \mu\text{a}$ -999 ma) between the working anode and the counter electrode. A potentiometric recorder (Model FW 5A-3332 from Texas Instruments, Inc.) was used for measuring the stationary anode potentials and the potential transients *vs.* the reference electrode.

In addition to the kinetic measurements with constant bulk concentration of formaldehyde, adsorption experiments, similar to those performed by Pavela and Breiter for methanol were made (6, 7). Adsorption of formaldehyde at platinized platinum took place from the electrolyte (1M  $\text{CH}_2\text{O}$  in 3.75M  $\text{H}_2\text{SO}_4$ ) under open circuit conditions. Adsorption times were in the range of 1 to 900 sec. After adsorption the electrodes were dipped shortly in 3.75M  $\text{H}_2\text{SO}_4$  in order to remove the adherent liquid and transferred immediately into the anode chamber of the cell which contained in this case only 3.75M sulfuric acid as the electrolyte. A preset circuit permitted to oxidize the adsorbed organic species immediately at constant current just above the threshold current for the oscillations (50 ma). The voltage maxima of the pulsations under these conditions were about 0.78v *vs.* SHE. Thus, as shown later, strong participation of an oxidized surface state in the mechanism was avoided.

The dipping procedure described above did not completely eliminate the adherent liquid film as desorption experiments showed; however, this technique proved to be useful to obtain a defined amount of organic species at the electrode.

Desorption experiments in order to determine the amount of adherent liquid film in addition to the ad-layer after rinsing were also made. For this purpose the adsorption time was held at 300 sec, a time which was required to obtain constant amounts (saturation coverage plus liquid film) of organic species at the electrodes. After adsorption the electrode was dipped for time periods of 1-10,980 sec in  $\text{H}_2\text{SO}_4$  to obtain removal of the adherent film and desorption of the ad-layer. The remaining organic amount was stripped off as described before. It was noticed from a plot of  $\log \mu\text{C}/\text{cm}^2$  of anodically oxidized organic species *vs.* time that up to 15 sec of desorption a significant amount of liquid film was still present. A rapid decrease in the amount of organic species was observed up to 300 sec. After that the curve followed the desorption relationship

$$\log(\mu\text{C}/\text{cm}^2)_t = \log(\mu\text{C}/\text{cm}^2)_{t=0} - k_{DT} \quad [3]$$

Extrapolation of the straight line to  $t=0$ , permitted to measure the  $(\mu\text{C}/\text{cm}^2)_{t=0} = 182 \mu\text{C}/\text{cm}^2$ . We shall refer to this value in the following as the ad-layer in contrast to the amount of organic species at the electrode which can consist of the ad-layer plus a liquid film. Rinsing for one second reduced the original liquid film ( $t=0$ , no rinsing) from about  $1443 \mu\text{C}/\text{cm}^2$  to  $976$ - $1020 \mu\text{C}/\text{cm}^2$  corresponding to about 5.5 ad-layers.

Before each adsorption or desorption experiment, the electrochemical surface area of the electrode was estimated. The following procedure was used. The electrode was submitted to cathodic charging at 50 ma for 1 min, followed immediately by an anodic current of 50 ma. The voltage trace was recorded. The transients permitted to determine the electrical charges corresponding to the anodic oxidation of hydrogen (0-0.3v *vs.* SHE) and that of the anodic oxidation of the platinum surface, noticeable at about +0.8v and ending at about +1.6v with the evolution of oxygen. All these events are clearly marked by a change in the slopes of the transient. The length of the latter region corresponds to the build up of a monolayer of oxygen. Using the value of  $420 \mu\text{C}/\text{cm}^2$  corresponding to one oxygen monolayer, the absolute electrochemical surface area could be estimated. This theoretical value of  $420 \mu\text{C}/\text{cm}^2$  was found to be in excellent agreement with our experimental data. When cathodic hydrogen

transients were compared with anodic oxygen transients, it was found that an oxygen coverage corresponding to one monolayer was reached at about 1.6v *vs.* SHE. In this comparison a hydrogen monolayer corresponded to  $210 \mu\text{C}/\text{cm}^2$  of real platinum surface (8).

It was further checked to what degree the charge in the oxygen transient depended on the current density used. The current was varied between 5 and 500 ma, corresponding to a current density range of 2-200  $\mu\text{a}/\text{cm}^2$  (the average real surface area of the electrode being  $2.5 \cdot 10^3 \text{ cm}^2$ ). Between 5 and 200 ma the mean error was 2.87%. Negative deviations up to -23.3% were observed at 500 ma. The current of 50 ma normally used in the surface area determination corresponds to 13.8 - 50  $\mu\text{a}/\text{cm}^2$  for the range of surface areas observed for platinum black in our experimentation ( $10^3$  -  $3.2 \cdot 10^3 \text{ cm}^2$ ) per electrode.

## Results and Discussion

*Kinetic measurements with constant bulk concentration of formaldehyde.*—The current-potential curves, both for smooth and platinized platinum are shown in Fig. 1 and 2. The open circuit potentials of the formaldehyde anodes are varying from +0.07 to +0.49v, specifically for smooth platinum, and from +0.175 to +0.33v for platinized platinum. Analogy

Fig. 1. Galvanostatic current-potential curve for smooth platinum electrode (1  $\text{cm}^2$  cross section) in 1M  $\text{CH}_2\text{O}$ , 3.75M  $\text{H}_2\text{SO}_4$  at 21°C. Potential measured *vs.* hydrogen reference electrode (-0.026v).

Fig. 2. Galvanostatic current-potential curve for platinized platinum electrode (3  $\text{cm}^2$  cross section) in 1M  $\text{CH}_2\text{O}$ , 3.75M  $\text{H}_2\text{SO}_4$  at 21°C. Potential measured *vs.* hydrogen reference electrode (-0.026v).

with formic acid supports the hypothesis that these potentials are mixed potentials caused perhaps by the simultaneous low-potential anodic oxidation of the organic specie with cathodic deposition of hydrogen (9, 10).

The current-potential curves, both for smooth and platinized platinum, showed a stationary region up to a threshold current of  $70 \mu\text{a}$  and  $20 \text{ ma}$ , respectively. The slope  $b$ , in the stationary region is  $100 \pm 5 \text{ mv}$  per decade of current for all three types of electrodes, corresponding approximately to a  $2.3 (2RT/F)$  value. Since the slopes for smooth platinum and platinized platinum are identical, no effects of electrode porosity on the value of the slope were observed (11). Thus the platinized platinum electrodes can be considered essentially as nonporous. The estimated exchange current density values, obtained by extrapolation of the stationary Tafel slopes to the reversible potential for formaldehyde oxidation were  $10^{-11} \text{ a/cm}^2$  for smooth platinum and  $7.5 \cdot 10^{-9} \text{ a/cm}^2$  as an average value for platinized platinum. Similar data are reported for the anodic oxidation of formic acid at platinum electrodes. (9, 12).

Oscillatory behavior expressed in periodic voltage transients was observed at higher current densities. For platinized platinum these potential transients range from  $+0.22$  to  $+1.02 \text{ v}$  vs. the hydrogen reference electrode. An upper and a lower curve limit the oscillation region. These two curves represent stable states according to the theory of stability of electrode states (13).

The slope of the upper curve,  $b_2$ , is about  $215 \text{ mv}$  per decade of current for platinized platinum and approximately  $250 \text{ mv}$  for smooth platinum. Such slopes obtained under nonsteady-state conditions, however, can not be used as a diagnostic tool for the reaction mechanism.

The lower boundaries of the oscillation planes approach at first more negative potentials when the current is increased. Above  $100 \text{ ma}$  the potentials become again more positive in the case of platinized platinum. The new slope corresponds approximately to that of the upper boundary. In the case of smooth platinum, a similar behavior is observed up to  $220 \mu\text{a}$ . Then the lower boundary becomes ill-defined.

A second transition region is observed at higher currents, at about  $400 \mu\text{a}$  for smooth platinum and between  $400$  and  $500 \text{ ma}$  for platinized platinum, indicating electrode surface oxidation and leading finally to oxygen evolution.

It was noticed that the intersection between the stationary part of the  $V - \log i$  curve and the threshold current gave another interesting characteristic which we termed  $V_{3/4}$  potential.

In analyzing the potential transients in the oscillation region (Fig. 3 and 4), the following approach was used. Besides measuring the coulombs per oscillation cycle, the coulombs corresponding to  $\frac{3}{4}\tau$  ( $\tau =$  time for one cycle) were determined for various currents and the corresponding potential values were registered. They were found to be identical with the  $V_{3/4}$  potentials. The  $V_{3/4}$  potential levels shown in Fig. 1 and 2 divide the initial oscillation planes in two parts. The upper part corresponding to  $\frac{3}{4}\tau$  and the lower one to  $\frac{1}{4}\tau$ , a  $3e^-/1e^-$  ratio.

For smooth platinum the results are recorded in Table I. In the last column, the process frequency is noted. The  $V_{3/4}$  level, average value calculated from Table I:  $\bar{V}_{3/4} = +0.654$ .

Results for platinized platinum are given in Table II. The voltage transients are larger than in the case of smooth platinum and  $\bar{V}_{3/4} = +0.542 \text{ v}$ .

Figure 5 relates the upper oxidation potential (last figure in column 3, Table I and II) to the millicoulombs per cycle. A strong increase in the amount of species oxidized occurs above  $+0.8 \text{ v}$  in the case of smooth platinum and above  $+0.9 \text{ v}$  in the case of

Fig. 3. Potential transients. Smooth platinum electrode potential  $V$  measured vs. hydrogen reference electrode ( $-0.026 \text{ v}$ ), recorder speed  $24 \text{ in./min}$ : (a)  $i = 70 \mu\text{a}$ , (b)  $i = 200 \mu\text{a}$ , and (c)  $i = 400 \mu\text{a}$ .

Fig. 4. Potential transients. Platinized platinum electrode potential measured vs. hydrogen reference electrode ( $-0.026 \text{ v}$ ), recorder speed  $24 \text{ in./min}$ : (a)  $i = 20 \text{ ma}$ , (b)  $i = 30 \text{ ma}$ , and (c)  $i = 400 \text{ ma}$ .

platinized platinum. This increase in millicoulombs per cycle is related to the onset of increasing oxygen coverage and participation of the oxidized electrode surface in the oxidation of organic species. Breiter and Becker report that anodic oxidation of platinum in acid electrolytes becomes noticeable at  $+0.7$  and the surface coverage becomes a monolayer at about  $+1.5 \text{ v}$  (14).

With the increase in millicoulombs per cycle a change in the shape of the voltage transients is observed (Fig. 3 and 4): For smooth platinum at 70 μA, a symmetrical transient and at 400 μA, a flat, extended potential maximum. For platinized platinum a relatively slow attainment of a potential maximum is observed at low current densities and the return to less positive potentials is rapid (Fig. 4a, b). At higher current densities this return is delayed by an additional small pulsation next to the potential maximum (Fig. 4c).

Certain conclusions with respect to the mechanism of the oscillations can be made from the kinetic behavior: The oscillatory behavior of formaldehyde at

Fig. 5. mCb/cycle vs. upper oxidation potential: (a) smooth Pt, (b) platinized Pt.

platinum electrodes is a special case of a general phenomenon, the periodic electrode process. At least two electrode processes have to occur simultaneously to result in a periodic process (15). Periodic behavior can also be observed by coupling more than two parallel reactions. Coupling means that the reaction rates depend mutually on the condition of the parallel reactions, following a periodic function of time. The rate determining step of the periodic process has therefore also to be time dependent.

The complete anodic oxidation of formaldehyde is a 4e<sup>-</sup> process

The occurrences within the low current region of the oscillation plane can be formulated by two postulated reaction sequences:

The postulated reaction path I considers a chemical step as the coupling step, path II a diffusion-adsorption step. The coupling step is required to continue the periodic electrode process and is the reason for the reverse of the potential during oscillations.

Path I is an extension to the mechanisms proposed by Mueller and Conway for the anodic oxidation of formic acid (12, 16-18)

## Path I

The anodic oxidation of formaldehyde occurs through the electron transfer steps (a), (b), (c), or (c<sup>1</sup>) and results in formation of adsorbed formate radicals, sometimes identified with the so-called "blocking intermediate." Build up of the blocking intermediate occurs up to a critical surface concentration (17). After this is reached, rapid catalytical decomposition of this specie to carbon dioxide and hydrogen occurs. This leads to a rapid change in surface coverage from partially oxygenated organic species to hydrogen in step (d), the coupling step. The anodic oxidation of hydrogen occurs at a less positive potential. Anodic oxidation of hydrogen has been observed in that potential region during periodic phenomena (19). Partially oxygenated hydrocarbons as methanol and formic acid adsorb at platinum from acid solutions in the potential region of +0.1 to +0.6v vs. SHE (7, 20). The surface coverage is high at the less positive potentials, but decreases with increasing positive potential. Thus reabsorption of organic species (f) can occur in this potential region simultaneously with step (e) and the oscillations are continued.

Path II postulates the stepwise anodic oxidation of formaldehyde with participation of the anodically oxidized platinum surface at the more positive potentials.

## Path II

Steps (a), (b), (c), and (g) are charge transfer steps. Step (f) is a diffusion-adsorption step. Coupling occurs here as a consequence of step (g) through step (f).

From experiments in which the anode was driven by an external emf, the behavior during simultaneous current and voltage oscillations was studied (1, 2). It was observed that the anodic current decreases with increasing anodic polarization during one oscillation cycle. This indicates inhibition of the oxidation of

the organic species by a small, but increasing coverage of the electrode with oxygen species. Since adsorption of organic species is known to occur at the less positive potentials, adsorption will decrease with increasing positive potential during a cycle and finally become zero. Then only the previously adsorbed amount of organic species becomes completely oxidized in step (g) and depletion of the surface of organic species leads finally to re-adsorption at less positive potentials through step (f). The original maximum current is observed and a new cycle starts. These occurrences are also reflected in the potential transients (Fig. 3) and marked in Fig. 4.

Above +0.8v noticeable surface oxidation was observed probably by discharge of water. Such reactions shift the three to one electron ratio observed previously to a higher value. An analysis of the potential transients above +0.9v showed ratios up to  $13e^-/1e^-$  for the original  $V_{3/4}$  level. These occurrences explain the change in the shape of the potential transients with increasing positive potential (Fig. 3c, Fig. 4c). Correspondingly the apparent increase of the  $V_{3/4}$  potential above an upper oxidation potential of 0.9v (Table II) is due to these reactions.

Adsorption and desorption experiments, discussed in the following, permitted to distinguish between the coupling steps of the mechanisms.

**Adsorption and desorption experiments.**—Two general types of potential transients were noted after adsorption of formaldehyde. In case of short adsorption times (1 to 5 sec in case of electrode A), no oscillations were observed, but after longer periods one to four pulses, depending on the length of the adsorption time, were obtained (Fig. 6a, b). In the first case (a), the potential rose fast from open circuit potential to about +0.7v, followed by a plateau region and above +0.8v by platinum surface oxidation. The latter was marked by a change in the slope of the transient. Above +1.62v visible oxygen evolution occurred. In the second case (b), potential oscillations between +0.47 and +0.78v replaced the plateau region. The

Fig. 6a. Potential transient. Platinumized platinum electrode adsorption time: 5 sec,  $i = 50$  ma. Potential measured vs. hydrogen reference electrode ( $-0.026v$ ), recorder speed 24 in./min.

Fig. 6b. Potential transient. Platinumized platinum electrode adsorption time: 420 sec,  $i = 50$  ma. Potential measured vs. hydrogen reference electrode ( $-0.026v$ ), recorder speed 24 in./min.

average potential for start of visible carbon dioxide evolution was +0.757v for the given current density. At about +1.05v, this gas evolution ceased. In the case of electrode B, which had a larger surface area than A, up to ten pulses were observed. The frequency of the oscillations decreased somewhat with the order of the pulses.

The millicoulombs of organic species oxidized between open circuit potential and onset of surface oxidation (time  $\tau_1$ ) are a function of the adsorption time.

The amounts of organic species oxidized during various phases of the oscillations were estimated by dividing the potential transients in certain segments (Fig. 6b). Segment A was termed the preoscillation period, D the (potential) decrease period, B the (potential) build up period, and X the after oscillation period. B plus D form one oscillation cycle. A and B were found to be identical. Coulometric analysis of the segments was done in two ways. For electrode A only the averaged values of D, B, and X over all oscillations were computed. For electrode B this was done also, but in addition a range of values for D, B, and X considering the frequency dampening effect observed for the pulses with higher order was calculated. The results are given in Table III.

Desorption experiments with electrode C were also evaluated coulometrically as in the case of electrode B. The results are compared with those of the adsorption experiments in Table III. In detail the pulse analysis of the desorption experiments gave the results shown in Table IV.

Analysis of the data yielded the following conclusions concerning the mechanism of the oscillations.

The after oscillation period ranges from 174 to about  $400 \mu C/cm^2$ . The first oscillation occurred when a total organic amount of about  $400 \mu C/cm^2$  had adsorbed or was still adsorbed at the electrode. Thus the critical amount required at the electrode to make one oscillation lies around  $400 \mu C/cm^2$ . Any amount in surplus of the critical one led to additional oscillations and/or an after oscillation period in accordance with Table III.

Relating these data to specific coverage estimates leads to the following. Assuming complete oxidation of formaldehyde to carbon dioxide (4), one coulomb corresponds to  $7.78 \cdot 10^{-5}g$   $CH_2O$ . One  $CH_2O$  molecule weighs  $5.10 \cdot 10^{-23}g$ . The area requirement for one formaldehyde molecule adsorbed on the platinum surface,

Table III. Coulometric analysis of the segments of the voltage transients

Surface area, $cm^2$	Electrode A $1.94 \cdot 10^3$	Electrode B $3.05 \cdot 10^3$	Electrode C $2.46 \cdot 10^4$
Oscillation period $\mu C/cm^2$	76	84*	94*
Decrease period $\mu C/cm^2$	20	27.9	—
Build up period $\mu C/cm^2$	56	56.1	—
After oscillation period $\mu C/cm^2$	200	278-400	174-346

\* Considering the frequency dampening effect, the value observed for the first oscillation was at  $46 \mu C/cm^2$  for B and  $59 \mu C/cm^2$  for C, respectively.

Table IV. Coulometric analysis of desorption experiments

Desorption time, sec	Number of pulses	Total pulse-charge ( $\tau_1 - X$ ), $\mu C/cm^2$	After oscillation period (X), $\mu C/cm^2$	Average $\mu C/cm^2$ /pulse
0	14	1451	174	104
0	10	934	346	93
1	8	645	322	81

7	3	353	244	118
15	1	84	322	84
30	0		258	

attached to two surface atoms, is about  $15\text{\AA}^2$ . On one square centimeter of absolute surface area we can accommodate  $6.66 \cdot 10^{14}$  molecules of formaldehyde. This corresponds to  $3.33 \cdot 10^{-8}\text{g CH}_2\text{O}$  or  $4.28 \cdot 10^{-4}\text{Cb}$ . Thus the electrical charge connected with the anodic oxidation of formaldehyde if a 2 site adsorption would occur is  $428\ \mu\text{C}/\text{cm}^2$ . If one site attachment occurred, the formaldehyde monolayer would give  $856\ \mu\text{C}/\text{cm}^2$ .

According to these data, the value of the ad-layer ( $182\ \mu\text{C}/\text{cm}^2$ ) indicates that the platinum surface is only partially covered with the adsorbed organic species (to about 21%). During one pulse about one half of the ad-layer is oxidized. The critical amount about doubles the value of the ad-layer.

This means that readsorption from a liquid film on top of the ad-layer is essential for the occurrence of the first oscillation. This excludes the coupling mechanism of path I where the first oscillation would occur by self-decomposition of the "blocking" intermediate formed by partial oxidation of the ad-layer. The coupling mechanism suggested in path II is therefore probable.

## Seebeck Coefficient of a $(\text{ZrO}_2)_{0.85}(\text{CaO})_{0.15}$ Electrolyte Thermocell\*

R. J. Ruka, J. E. Bauerle, and L. Dykstra

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

#### ABSTRACT

The Seebeck coefficients of thermocells of the type

were measured at temperatures near  $1000^\circ\text{C}$ . In these cells x represents any of several oxygen-inert gas or hydrogen-water-inert gas mixtures. It was found that the change in Seebeck coefficient corresponding to a change in the partial molar entropy of oxygen in the gas at the electrodes agreed closely with the values predicted from irreversible thermodynamic theory. Two principal assumptions were made in applying the theory to these cells: (i) that the transported entropy of the oxygen ions in the electrolyte was constant for the different gas mixtures used, and (ii) that gas-solid reactions were at equilibrium at each electrode. The temperature dependence of the Seebeck voltage was found to be small.

An electrochemical cell with identical electrodes develops an emf when the electrodes are at different temperatures. The thermal emf per degree temperature difference is termed the Seebeck coefficient. Holtan (1) and others (2, 3) have derived equations based on irreversible thermodynamics for the Seebeck coefficient in such thermocells.

Measurement of the Seebeck coefficient gives information on the simultaneous transfer of charge and

heat in the oxide electrolyte, allowing us, e.g., to calculate the Peltier-type heat transfer during isothermal operation of a related galvanic cell.

The purpose of this paper is a comparison of the experimentally with theoretically determined difference in Seebeck coefficient which results from a change in the partial molar entropy of oxygen in the gas phase at the electrodes of a thermocell with  $(\text{ZrO}_2)_{0.85}(\text{CaO})_{0.15}$  electrolyte and gas-platinum electrodes. The temperature dependence of the Seebeck voltage is also examined briefly.  $(\text{ZrO}_2)_{0.85}(\text{CaO})_{0.15}$  is

Key words: Seebeck coefficient; zirconia; thermocell.

\* Supported by ARPA through the Office of Naval Research.

an attractive oxide for this study since necessary experimental information on transference numbers of ions and electrons in the oxide and on electrode reactions of corresponding galvanic cells is already available. Several studies of this electrolyte are of particular significance for the interpretation of the present paper. These include contributions by Wagner and co-workers (4) on cell emf, Rhodes and Carter (8) on cation diffusion, Kingery and co-workers (5) on oxygen ion diffusion, Weissbart and Ruka (6) on oxygen concentration cells, and Schmalzried (7) on electrolyte stability to oxidizing and reducing atmospheres. Essential information from these papers for consideration of our current experiments is that conduction in the oxide is due almost 100% to oxygen vacancy or ion migration (4, 8, 5) over the temperature range of interest to the present experiments, i.e., 700°-1280°C, that electrode reactions with oxygen or hydrogen-water using this oxide as electrolyte of a galvanic cell with platinum electrodes can be made essentially reversible (6) and that the oxide is stable to oxidizing or reducing atmospheres at oxygen partial pressures between 1 atm and the order or 10<sup>-22</sup> atm (7).

Reinhold and co-workers (9) and Holtan (1) have experimentally measured the thermal emf of several halogen-containing solid electrolytes. Holtan concludes from this data that transported entropy terms are either small or absent in these cells. On the other hand, Patrick and Lawson (10), and Christy and co-workers (11) present Seebeck coefficient data for pure and doped AgBr and AgCl thermocells with Ag electrodes which apparently contain sizable entropy of transport terms at some temperatures. Significant data on oxide thermocells for comparison has not been available.

Consider the following thermocell

where  $x_{O_2}$  is an oxygen containing atmosphere at the electrodes such as pure O<sub>2</sub>, air, an H<sub>2</sub>-H<sub>2</sub>O mixture, etc., Pt represents the platinum electrodes and leads, and (ZrO<sub>2</sub>)<sub>0.85</sub>(CaO)<sub>0.15</sub> is the oxide electrolyte with conductivity resulting almost exclusively from diffusion of O<sup>=</sup> ions.

The measured value of the thermal emf  $\Delta\phi$  in this thermocell is a function of three individual potentials as given by the relationship

$$\Delta\phi = \Delta\phi_{(O^=,E)} - \Delta\phi_{(e^-,Pt)} + \Delta\phi_c \quad [B]$$

where  $\Delta\phi_{(O^=,E)}$  is an emf across the electrolyte resulting from the thermally induced flow of O<sup>=</sup> ions,  $\Delta\phi_{(e^-,Pt)}$  is an emf across the platinum metal electrodes and leads, due to thermally induced flow of electrons, and  $\Delta\phi_c$  is the difference between contact potentials of the two electrolyte-electrode interfaces at the two temperatures.

Holtan (1), Lidiard and co-workers (2, 3) have derived general equations for thermal emf in thermocells, and we list below pertinent equations for the above thermocell as adapted from their considerations.<sup>1</sup> The equations are simplified by assuming that electronic conductivity is nil, that chemical diffusion gradients do not occur, and that O<sup>=</sup> is the only diffusing ionic species. The treatment assumes that the reference frame for diffusion is a plane in the lattice. This is also consistent with a choice of the positive ions as reference since these remain essentially immobile. For a small difference in electrode temperatures

$$\Delta\phi_{(O^=,E)} = \frac{\Delta T}{F} \left[ \frac{1}{2} \bar{S}_{O^=} - \frac{1}{2} s_{O^=} \right]$$

Thermal emf across electrolyte [1]

<sup>1</sup> It is of interest to note that the derivations of Eq. [1-4] involve electrochemical potentials, and there is a term  $e\phi'$  in each electrochemical potential for the usually accidentally occurring electrical state of the system. However, these terms all cancel in the final results and the partial molar entropies of the ions or electrons in Eq. [1-5] do not contain the extra term  $e\phi'$  which would otherwise give an indeterminate character to the entropy terms.

$$\Delta\phi_{(e^-,Pt)} = \frac{\Delta T}{F} \left[ \bar{S}_{(e^-,Pt)} - s_{(e^-,Pt)} \right]$$

Reverse thermal emf across platinum electrodes and leads [2]

$$\Delta\phi_c = \frac{\Delta T}{F} \left[ -\frac{1}{4} \bar{S}_{O_2} + \frac{1}{2} s_{O^=} - s_{(e^-,Pt)} \right]$$

Difference between contact potentials at the two electrodes [3]

By combining expressions [1], [2], and [3] into Eq. [B], we obtain

$$\frac{\Delta\phi}{\Delta T} = \frac{1}{F} \left[ \frac{1}{2} \bar{S}_{O^=} - \bar{S}_{(e^-,Pt)} - \frac{1}{4} \bar{S}_{O_2} \right]$$

Seebeck coefficient<sup>2</sup> of thermocell [4]

where  $\Delta T$  is the temperature of the hot electrode minus that of the cold electrode,  $F$  is the Faraday,  $\bar{S}_{O^=}$  and  $\bar{S}_{(e^-,Pt)}$  are the transported entropies of O<sup>=</sup> ions and electrons, respectively, in the electrolyte, and  $\bar{S}_{O_2}$  is the partial molar entropy of O<sub>2</sub> in the gaseous atmosphere at the electrodes. With the restrictions listed,  $\bar{S}_{O_2}$  represents the partial molar entropy of oxygen in a pure oxygen atmosphere or in a gas mixture such as H<sub>2</sub>-H<sub>2</sub>O-N<sub>2</sub>. In the latter mixture the calculation of  $\bar{S}_{O_2}$  involves the reacting species, namely O<sub>2</sub>, H<sub>2</sub>O, and H<sub>2</sub> of the gas mixture, but is independent of the "inert" component N<sub>2</sub>. For the purpose of calculation,  $\bar{S}_{O_2}$  is defined in a conventional way as the change in entropy of the oxygen-containing gas mixture at the electrode per mole of oxygen added, with the addition being made at constant temperature and pressure and in such small quantity that the composition of the gas mixture remains essentially the same.

While the absolute Seebeck coefficient cannot as yet be calculated, the Seebeck coefficient difference for two gas mixtures  $(d\phi/dT)_{gas 1} - (d\phi/dT)_{gas 2}$  can in principle be calculated for a range of oxygen partial pressures over which the electrolyte and electrode material remain invariant. Under these conditions  $\bar{S}_{O^=}$  is constant, and applying Eq. [4] to two different gas atmospheres at the same temperature, we obtain by subtraction

$$\left( \frac{d\phi}{dT} \right)_{gas 1} - \left( \frac{d\phi}{dT} \right)_{gas 2 (ref.)} = \left( \frac{\bar{S}_{O_2}}{4F} \right)_{gas 2 (ref.)} - \left( \frac{\bar{S}_{O_2}}{4F} \right)_{gas 1} \quad [5]$$

where in our present experiments gas 2 is a convenient reference gas, pure O<sub>2</sub> at atmospheric pressure, and where the electrode reaction is written to involve a reversible 4-electron step

Relation [5] contains no entropy of transport terms and  $\bar{S}_{O_2}$  values can be calculated from data available in standard thermodynamic tabulations.

$\bar{S}_{O^=}$ , the transported entropy of the oxygen ion, cannot be directly calculated from present theory. However, the quantities measured in the current experiments enable us to obtain from Eq. [4] experimental values for  $\bar{S}_{O^=}$ , since  $\bar{S}_{O_2}$  is a known value and

<sup>2</sup>  $\Delta\phi/\Delta T$ , the Seebeck coefficient is considered positive if the hot terminal is positive.

$\bar{S}_{(e^-, Pt)}$  is known from experimental and theoretical considerations of others based on comparison with a lead superconductor which serves as a reference having a Seebeck coefficient of zero (13).  $\bar{S}_{O=}$  is composed of both kinetic and thermodynamic terms which are related to the heat of transport  $Q^*$  by

$$\begin{aligned} \bar{S}_{O=} &= + \frac{Q^*_{O=}}{T} + \bar{s}_{O=} \\ &\cong \frac{Q^*_{O=}}{T} + s_{O=}^{-vib.} + \bar{s}_{O=}^{config.} \quad [6] \end{aligned}$$

where  $\bar{s}_{O=}$  is the partial molar entropy of the oxygen ion,  $s_{O=}^{-vib.}$  and  $\bar{s}_{O=}^{config.}$  are the partial molar entropies of vibration and configurational entropy respectively of the  $O=$  ion, and  $Q^*_{O=}$ , the heat of transport, is a kinetic term depending on details of the heat transfer by the  $O=$  ion diffusing along the temperature gradient.

No satisfactory theoretical treatment has yet been proposed to evaluate quantitatively the heat of transport term in any systems of this nature. Haga (12) proposed a "thermodynamic" treatment which appears to give semiquantitative agreement between experimental and theoretical results for some silver halide systems. However, Haga's use of the Zener-Wert analysis has been criticized both from the standpoint of mathematics (15) and applicability to the framework of the derivation (16). Agreement found by Haga thus would appear to be fortuitous or at best of an empirical nature. To account properly for the continuous interactions of the diffusing ionic species with the lattice, a theory based on lattice dynamics rather than purely thermochemical reasoning appears to be necessary.

Wirtz (14) proposed a physical model of the transport process, but gave no quantitative treatment.

Gonzalez and Oriani (18) criticize the Wirtz model and discuss  $Q^*$  in terms of the mechanism by which activation energy is dissipated back into the lattice. They conclude that the ratio of the heat of transport to the activation energy for migration is a function of the ratios of the mean free paths of phonons and electrons to the jump distance of the diffusing atom.  $Q^*$  may be positive or negative according to this concept.

### Experimental

**Specimens.**—Three specimens of  $(ZrO_2)_{0.85}(CaO)_{0.15}$  were used in the measurements. Specimen 1 was prepared by fusing  $(ZrO_2)_{0.85}(CaO)_{0.15}$  powder in an arc image furnace to give a dense polycrystalline sample. The powder used for this was prepared by sintering and grinding a properly proportioned mixture of  $ZrO_2$  (major impurity, 0.1% Si) and  $CaCO_3$  (major impurity, 0.1% Sr). Specimen 2 was prepared by sintering the appropriate mixture of  $ZrO_2$  (major impurity, < 0.09% Fe) and  $CaCO_3$  (major impurity, 0.1% Sr). The sintering treatment consisted of 2 hr at 1400°C, 12 hr at 2000°C, and an annealing of 2 days at 1400°C, all in  $O_2$  atmosphere. Specimen 3 was purer, containing about 50 ppm combined impurities of Fe, Si, Mg, Al, and Cu, and was sintered in the arc image furnace to eliminate contamination by furnace wall materials. Specimens were ground to a disk form of 1 mm thickness and 9 mm diameter.

**Atmospheres.**—In the course of the measurements a variety of atmospheres were used, each flowed through the system at a rate of approximately 250 cc per minute. The volume of the system was about 500 cc.

For the  $O_2$ -inert gas atmospheres, tank gas mixtures, made to specification by the Matheson Company were employed.

For the  $H_2$ - $H_2O$  inert gas atmospheres, tank gas mixtures of  $H_2$ -inert gas were passed through a cooled

Fig. 1. Apparatus for high temperature Seebeck coefficient measurements.

water bubbler which introduced the  $H_2O$  component but avoided saturation.

The constitution of each atmosphere was checked by mass spectrometric analysis of a sample. Water content of the atmospheres was determined by standard adsorption and weighing methods on the effluent gases from the system.

**Apparatus and technique.**—Seebeck coefficient measurements were carried out with the apparatus shown schematically in Fig. 1. The specimen was situated between the polished faces of two platinum blocks. On the upper block a close-fitting alumina cylinder acted as a compression weight and in addition carried a heater winding for controlling the temperature gradient of the specimen. The lower block was supported by a calcia stabilized zirconia cone pivot which insured that the specimen and blocks were aligned for uniform contact pressure at all times.

The specimen thermal emf was measured by means of 0.020 in. Pt wires attached to the Pt blocks. To measure the temperature of each block at a point as near to the specimen as possible, a 0.020 in. Pt-10% Rh wire was led into the block through alumina-insulating tubing. The end of this wire was then bonded to the block by means of two small Pt plugs. This produced an internal junction near the interface, whose lead wires were the Pt-10% Rh wire and the previously mentioned Pt wire. These details are shown in Fig. 1.

Each measurement was taken at two or more specimen temperature gradients which corrects for thermocouple mismatch and eliminates other stray thermal or galvanic emf's (17). With this procedure a change of one microvolt in the specimen Seebeck coefficient was easily detectable.

### Results and Discussion

Equation [5] has been experimentally verified over a wide range of gas compositions as shown by the data in Fig. 2. In Fig. 2 the Seebeck coefficient difference  $(d\phi/dT)_{(mixture)} - (d\phi/dT)_{(pure O_2)}$  at open circuit, atmosphere pressures of  $730 \pm 2$  Torr and about 1005°C, is plotted vs.  $[\bar{S}_{O_2(mix.)} - \bar{S}_{O_2(pure O_2)}]$  for several mixtures of oxygen and inert gas, and for water-hydrogen-nitrogen mixtures. The solid line in this figure is a theoretical line calculated from Eq. [5] assuming the following over-all reversible electrode reactions for the  $O_2$ -inert gas and  $H_2$ - $H_2O$ - $N_2$  mixtures respectively

Fig. 2. Difference in Seebeck coefficient vs. difference in partial molar entropy of oxygen for various gas mixtures for thermocell  $X(\bar{S}_{\text{O}_2})$ , Pt ||  $(\text{ZrO}_2)_{0.85}(\text{CaO})_{0.15}$  || Pt,  $X(\bar{S}_{\text{O}_2})$ . Temperature range 1000°-1005°C,  $\sim 730$  Torr—Total pressure for all atmospheres. Experimental points:  $\circ$  specimen 1,  $\triangle$  specimen 2,  $\square$  specimen 3 (high purity).  $\bar{S}_{\text{O}_2}$  in calories per mol per degree K.

All experimental points in Fig. 2 fit the calculated line within the probable error of measurement and gas analysis except for the points at 1.9% H<sub>2</sub>O-98.1% H<sub>2</sub> and 1.7% H<sub>2</sub>O-98.3% H<sub>2</sub>. These mixtures are the most reducing atmospheres used (equivalent equilibrium oxygen partial pressure is  $\sim 10^{-18.1}$  atm at 1000°C), and it is possible that the electrolyte is being slightly altered chemically. Since data of Schmalzried (7) indicate that appreciable reduction does not occur until about  $10^{-22}$  atm O<sub>2</sub> partial pressure for this electrolyte, it is possible that impurities are at least in part responsible for the deviation. The highest purity specimen used, No. 3, gave a much smaller deviation from the theoretical value which is consistent with this viewpoint.

The information obtained in these measurements indicates that our assumption of a constant transported entropy,  $\bar{S}_{\text{O}^\ominus}$ , for a wide range of partial pressures of oxygen is valid. This allows us to determine an "experimental" value of  $\bar{S}_{\text{O}^\ominus}$  directly from Eq. [4] since the other terms of the equation can be measured or calculated.

While the difference values  $(\frac{d\phi}{dT})_{\text{mixture}} - (\frac{d\phi}{dT})_{\text{pure O}_2}$  were, except for the point noted, consistent for all specimens, the experimental value of  $\bar{S}_{\text{O}^\ominus}$  in cal deg<sup>-1</sup> mole<sup>-1</sup>, varied from 10.3 to 10.9 for specimens from batches 1 and 3 to 11.7 for specimen 3, the highest purity specimen. Part of these differences may be linked to subtle temperature-dependent structural changes which are suggested by neutron diffraction and conductivity studies of others (22, 23). To check this point, specimen 1 was cycled between 1250° and 800°C and held for periods up to 14 days. Slow changes

of 3 to 5% in  $\bar{S}_{\text{O}^\ominus}$  were measured. These changes and effects arising from impurities, inhomogeneities (21), differences in crystalline character of the oxides and other sources may contribute to the spread in the values.

An unusual feature of the data is the relatively small temperature dependence of the Seebeck coefficient. As shown in Fig. 3 curve 1,  $\Delta\phi/\Delta T$  changes only a few per cent between temperatures of 700° and 1280°C.

Referring to Eq. [4] and [6], it appears that the term most likely to introduce a large temperature dependence is  $Q^*/T$ . To illustrate this more clearly, Fig. 3 curve 2 gives values of  $\Delta\phi/\Delta T$  as a function of

Fig. 3. Effect of temperature on the Seebeck coefficient

temperature based on the values of  $\bar{S}_{\text{O}_2}$  calculated from JANAF thermochemical tables (19),  $\bar{S}_{\text{e,Pt}}$  for the platinum electrode from the data of Cusack and Kendall (13) and a "calculated" value of  $\bar{S}_{\text{O}^\ominus}$  based on Eq. [6], except that  $Q^*/T$  is neglected,  $\bar{S}_{\text{O}^\ominus}^{\text{config}}$  is assumed to be given by the ideal relation of the form  $R \ln 1-C/C$  where  $C$  is the fraction of filled O<sup>⊖</sup> sites based on the perfect fluorite lattice, and  $\bar{S}_{\text{O}^\ominus}^{\text{vib}}$  is estimated on the basis of equipartition of entropy between ions of the oxide. For lack of specific data on the mixed oxide the entropy is assumed to be about that of a simple mixture of 85 m/o (mole per cent) ZrO<sub>2</sub> (tetragonal) and 15% CaO using thermochemical data assembled by Kelly and King (20) for ZrO<sub>2</sub> and CaO. This simple procedure does not take into account such problems as electronic contribution to the entropy at high temperatures, entropy differences of ions next to vacancies, effect of specimen inhomogeneities (21), possible preferred conduction paths due to the high vacancy concentration and other effects. As a consequence we may expect large errors in the absolute value of  $\bar{S}_{\text{O}^\ominus}$  calculated in this way. However, it would seem that the error due to variation of  $\Delta\phi/\Delta T$  with temperature may be small which would suggest the relative importance of the  $Q_{\text{O}^\ominus}^*/T$  term which might be expected to have a large temperature dependence. It is seen that the temperature dependence of curve 2 is small, similar to the actual experimental data indicating either that  $Q^*/T$  is small or not appreciably temperature dependent. This is clearly speculation, however, since, as indicated, curve 2 can at best give only a poor estimate of the absolute value of this collection of terms due to uncertainties in the procedure for estimating  $\bar{S}_{\text{O}^\ominus}$ . Figure 3 curve 3 shows the relative contribution of the term  $\bar{S}_{\text{O}_2(1 \text{ atm})}/4F$  calculated from thermodynamic data (19) for reference.

This analysis suggests that further information on the problem might come from experimental measurements at lower temperatures where a temperature dependence of  $Q^*/T$  could result in a larger contribution to the Seebeck coefficient and from measurements of contact potentials for the cell and the work function of electrons in platinum as a function of temperature which would give experimental information for evaluating  $\bar{S}_{\text{O}^\ominus}$ .

#### Acknowledgment

The authors wish to thank D. Watt for help with part of the measurements, J. Hrizo and T. Y. Tien for part of the sample preparations, and R. Ure, P. Klemens, and A. Panson for helpful discussions.

Manuscript received Sept. 11, 1967; revision received Jan. 19, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Poisson's Equation as a Condition of Equilibrium in Electrochemical Systems

H. A. Christopher\* and C. W. Shipman

Worcester Polytechnic Institute, Worcester, Massachusetts

## ABSTRACT

The available analyses of the conditions for equilibrium in electrochemical systems do not consider the electrostatic field as a possible variable. Since there is a voltage difference between the electrodes in an electrochemical system, an electrostatic field must be present, and this field must be considered in the treatment of equilibrium because it affects the internal energy of the system. This paper presents an analysis in which the electric displacement vector is included as a possible variable. The results show that Poisson's equation is a condition of equilibrium in addition to the usual conditions of uniformity of the electrochemical potential, the pressure, and the temperature.

The conditions of equilibrium in electrochemical systems (systems which contain charged species and in which there may be electrostatic fields) have been discussed by several authors. In each case the proof is incomplete. Gibbs (1) uses a variational treatment but does not consider the electrostatic field as a possible variation. Guggenheim (2) states that uniformity of the electrochemical potential is a requirement for equilibrium but does not give a detailed proof. He also does not consider the electrostatic field as a possible variable in the system although he later shows that variation of the electric displacement vector can alter the internal (intrinsic) energy. Kirkwood and Oppenheim (3) use a variational analysis but assume as a starting point that the electrochemical potential is the intensive factor for variations in energy with mass addition. Here again, consideration of the electric displacement vector as a possible variable is omitted.

The fact that in an electrochemical cell there is a voltage difference between the electrodes means that there is an electrostatic field present in the system, and this electrostatic field is not always applied but can arise spontaneously. This means that the consequences

of variations in the electric displacement vector must be considered when the equilibrium is considered.

Both ref. (2) and (3) discuss at some length the fact that separate measurement of the electrostatic and chemical potentials cannot be made and that separation of these potentials is, therefore, "nonoperational." Gibbs (1), on the other hand, considers these two potentials separately in his analysis, but in a later note (4) points out that separate measurement is impossible. The present authors take the position that the question of separate measurement is a consequence of rather than a basis for the equilibrium analysis. Further, the use of separate terms for the chemical and electrostatic potentials facilitates the treatment of mass transfer in electrochemical systems (5).

Finally, it is noted that the usual criteria for equilibrium involve terms of the form  $(dE)_{S,V}$ ,  $(dS)_{E,V}$ , or  $(dG)_{p,T}$ , and, therefore, require that some purely thermodynamic property of the system be fixed at the outset. This is restrictive because these restraints cannot be imposed experimentally by direct control.

The present analysis considers the electric displacement vector as a possible variable, and does not require, at the outset, the fixing of any purely thermo-

\* Electrochemical Society Active Member.

dynamic property except as a controlled boundary condition. Separate terms for the chemical and electrostatic potentials are retained for the reasons cited earlier.

### The Conditions for Equilibrium

A general criterion of equilibrium is:

If a system be in such state that any possible variation from that state, within the restrictions that the first law of thermodynamics and any physical constraints be satisfied, requires a violation of the second law of thermodynamics, then such variation cannot occur, and the system is at equilibrium.

The most convenient form of the second law for the present purpose is the inequality of Clausius which, for a real process, is

$$dS - (\delta Q/\tau) > 0 \quad [1]$$

(A table of nomenclature is included at the end of the paper.) In a derivation of this statement by Phillips as quoted by Keenan (6), it is shown that  $\tau$  is the temperature of that part of the system to which heat is transmitted. This does not imply uniformity of temperature in the system or constancy of  $\tau$ , only that there are not multiple sources of heat for the system at different temperatures simultaneously. The entropy term is for the entire system. Equation [1] is, of course, restricted to systems of fixed total mass.

To apply the criterion of equilibrium, we consider a system of constant total mass confined by a piston at an applied pressure,  $P$ . The system will consist of several phases,  $\Phi$  in number (e.g., as a minimum two electrode phases and an electrolyte phase; or for a fuel cell, a fuel phase, an anode phase, an electrolyte phase, a cathode phase, and an oxidant phase). For simplicity, magnetic and gravitational fields are excluded, surface phenomena are neglected, and any variations are in one dimension only. No current passes to an external circuit from the system (i.e., attention is restricted to open-circuit conditions). The system contains several chemical species,  $J$  in number, each of which has a charge per unit mass,  $z_j$ . (The possibility that  $z_j=0$  is not excluded.) Such a system is shown schematically in Fig. 1. In this figure  $X$  is the total length of the system from the fixed boundary at the left to the piston on the right and may vary as the piston moves to maintain the applied pressure,  $P$ ;  $x_{1,\phi}$  and  $x_{2,\phi}$  are the boundaries of one of the phases;  $\delta x$  is an incremental length of the system within one of the phases; and  $x$  is the distance from the fixed boundary to the plane considered. The locations of  $x_{1,\phi}$  and  $x_{2,\phi}$  may, of course, be altered as the system varies. The heat source (or sink) is at the left where the temperature of the system is  $\tau$ . (This heat source may be viewed as a constant temperature bath, but this is unnecessarily restrictive.)

In the system as described several variables are not controlled directly, and changes in these are, therefore,

Fig. 1. Schematic showing system of constant total mass

“possible.” (The term possible variation is used in the sense indicated, i.e., not specified by a fixed parameter. This means that some variations considered possible herein are restricted by the laws of thermodynamics and the material balances.) These possible variations are:

1. The electrostatic field vector,  $\vec{\mathcal{E}}$  and the corresponding electrostatic potentials.
2. Chemical composition. (Changes may be a consequence of migration of a species from one part of the system to another or of chemical reaction.)
3. Thermodynamic properties: entropy, internal (intrinsic) energy, specific volume, pressure, etc.
4. The total volume of the system.

We now seek the state of the system such that for any of the possible variations, there results

$$(\delta Q/\tau) - dS \geq 0 \quad [2]$$

i.e., violation of the second law of thermodynamics.

The possible variations in the system are subject to restraint by: (a) the first law of thermodynamics, (b) the material balances, and (c) the functional relations among the thermodynamic properties. These will be discussed in turn.

(a) The first law of thermodynamics, for the fixed mass system considered herein, may be written

$$\begin{aligned} \delta Q = d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} E_{\phi} \rho_{\phi} A \delta x \\ + d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} (\Psi_{\phi} \rho_{\phi} \sum_{j=1}^J z_j \chi_{j,\phi}) A \delta x \\ + P d \int_0^X A \delta x \quad [3] \\ j = 1, 2, \dots, J \\ \phi = 1, 2, \dots, \Phi \end{aligned}$$

The integral forms have been used to allow for the point-to-point variations in the integrands within a phase, as in electrolyte composition and electrostatic potential. The summations over the various phases are considered because properties may not be continuous at phase boundaries, e.g., electrodes. The only work term is that resulting from expansion of the movable boundary against the fixed, applied pressure,  $P$ . (Note:  $P$  is the pressure applied to the system by the piston, not the pressure of the system at some point inside.) Changes in the internal energy have been distinguished from changes in the potential energy of charged masses in the electrostatic field which may be computed from Coulomb's law. It is important that these latter variations be distinguished from those due to the electrostatic field alone because variations in the electrostatic field will affect the internal energy. While the two effects are not always physically independent (changing the position of a charged particle can alter the electrostatic field vector), they are described by different physical laws.

(b) Any variations in composition must be consistent with the appropriate material balance expressions. A quantitative statement of the material balance is

$$d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \rho_{\phi} \chi_{j,\phi} A \delta x - \sum_{\phi=1}^{\Phi} \sum_{r=1}^R \nu_{j,r} d\xi_{r,\phi} = 0 \quad [4]$$

( $J$  equations)

The possibility that some of the species,  $j$ , do not react chemically ( $\nu_{j,r}=0$ ) is not excluded. The quantities  $\nu_{j,r}$  are the stoichiometric coefficients of the  $j^{\text{th}}$  chemical species in the  $r^{\text{th}}$  independent stoichiometric relation of the form

$$\sum_{j=1}^J \nu_{j,r} M_j = 0 \quad (r = 1, 2, \dots, R) \quad [5]$$

The quantities  $\xi_{r,\phi}$  are the parameters representing variations due to chemical reaction as indicated by the  $r^{\text{th}}$  stoichiometric relation (extent of reaction parameters). These are, in Eq. [4], integral averages over a phase.

It should be noted that either mole or mass units may be used in these equations so long as one is consistent. That is,  $\rho$  is either a mole or mass density,  $\chi_j$  is mole or mass fraction, and  $z_j$  is the charge per mole or per unit of mass of  $j$ . The stoichiometric coefficients,  $\nu_{j,r}$ , must, of course, be changed accordingly.

(c) In order to relate the specific internal energy,  $\bar{E}$ , to the other properties of the system, the necessary relationships among the thermodynamic properties must be given. Further, because these relations are to be applied to individual volumes of the entire system, and because the total mass of the individual volumes may vary, the applicable relationships must apply to variable mass systems. Since these relations are not available elsewhere, the derivations will be given in some detail.

In general the internal energy,  $E$ , is related to the other properties of the system in the usual way, *viz.*

$$E = E(S, V, m_j, \vec{D}) \quad [6]$$

(It should not be inferred that  $S$ ,  $V$ ,  $m_j$ , and  $\vec{D}$  are the independent variables of the electrochemical system

considered; only that fixing  $S$ ,  $V$ ,  $m_j$ , and  $\vec{D}$  fixes the value of  $E$ .) The relevant form for variations of the internal energy is

$$dE = TdS - pdV + \sum_{j=1}^J \mu_j dm_j + \vec{V}\vec{G} \cdot d(\vec{D}) \quad [7]$$

where the last term on the right represents variations in the internal energy due to variations in the electrostatic field (7). Recognizing that the electric displacement vector,  $\vec{D}$ , is related to the electric intensity,  $\vec{G}$ , by

$$\vec{D} = \epsilon \vec{G} \quad [8]$$

one may write Eq. [7] in the alternative forms

$$dE = TdS - pdV + \sum_{j=1}^J \mu_j dm_j + (\vec{V}\vec{D}/\epsilon) \cdot d\vec{D} = TdS - pdV + \sum_{j=1}^J \mu_j dm_j + d(\vec{V}\vec{D}^2/2\epsilon) - (\vec{D}^2/2)d(V/\epsilon) \quad [9]$$

It is important to recognize that Eq. [7] and, therefore, Eq. [9] can be applied only to regions in which the coefficients are single-valued.

Equations [9] may be integrated over a region for which the intensive factors ( $T$ ,  $p$ ,  $\mu_j$ ,  $\vec{D}$ ) are constant to give

$$E = TS - pV + \sum_{j=1}^J \mu_j m_j + \vec{V}\vec{D}^2/2\epsilon - (\vec{D}^2/2)(V/\epsilon) \\ = TS - pV + \sum_{j=1}^J \mu_j m_j \quad [10]$$

(It is striking that in this integration the terms involving the electrostatic field drop out. This is a consequence of the fact that the expression is being applied to a region in which the intensive factors are uniform. While it is clear that the internal energy is altered by the presence of the electrostatic field, the other thermodynamic properties are also altered. Note also that in the integration we are not computing the work required to establish the electrostatic field; it is already present.)

We consider next variations in the properties of the system generally by differentiating [10], *viz.*

$$dE = TdS - pdV + \sum_{j=1}^J \mu_j dm_j \\ + SdT - Vdp + \sum_{j=1}^J m_j d\mu_j$$

Comparison of this equation with [9] requires that

$$0 = SdT - Vdp + \sum_{j=1}^J m_j d\mu_j - (\vec{V}\vec{D}/\epsilon) \cdot d\vec{D} \quad [11]$$

For purposes of utilization in the energy balance (Eq. [3]), the relationships among the specific properties for variable mass systems are required. Such relationships may be obtained by dividing Eq. [10] and [11] by the total mass to obtain

$$\bar{E} = T\bar{S} - p\bar{V} + \sum_{j=1}^J \mu_j \chi_j \quad [12a]$$

$$0 = \bar{S}dT - \bar{V}dp + \sum_{j=1}^J \chi_j d\mu_j - (\vec{V}\vec{D}/\epsilon) \cdot d\vec{D} \quad [12b]$$

Differentiation of Eq. [12a] and subtraction of [12b] from the result gives the desired expression.

$$d\bar{E} = Td\bar{S} - p d\bar{V} + \sum_{j=1}^J \mu_j d\chi_j + (\vec{V}\vec{D}/\epsilon) \cdot d\vec{D} \quad [13]$$

(The reader will note that obtaining Eq. [13] by division of Eq. [9] by the total mass restricts the result to a system of fixed mass. The seemingly circuitous route herein used avoids that problem and makes the result more general.) Equations [12] and [13] constitute the necessary relations among the specific properties. It is emphasized that the chemical potentials,  $\mu_j$ , are functions of the electric displacement,  $\vec{D}$ , and represent the change of internal energy with mass of  $j$  with all of the other variables held constant.

$$\mu_j = (\partial E / \partial m_j)_{S, V, D, m_{k \neq j}}$$

It is important to recognize that an electrostatic field can be imposed on the system without changing its composition.

Returning, now, to the conditions for equilibrium, the nonproperty term,  $\delta Q$ , may be eliminated from the criterion expression [2] by substitution from the energy balance [3]. After multiplication by  $\tau$  the result is

$$d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \bar{E}_{\phi\rho\phi} A \delta x \\ + d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \Psi_{\phi\rho\phi} \left( \sum_{j=1}^J \chi_{j,\phi} z_j \right) A \delta x \\ + P d \int_0^X A \delta x - \tau d \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \bar{S}_{\phi\rho\phi} A \delta x \geq 0 \quad [14]$$

By carrying out the indicated differentiations of Eq. [14] one obtains

$$\begin{aligned}
& \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( d\bar{E}_{\phi} + \Psi_{\phi} \sum_{j=1}^J z_j d\chi_{j,\phi} \right. \\
& \quad \left. + d\Psi_{\phi} \sum_{j=1}^J z_j \chi_{j,\phi} - \tau d\bar{S}_{\phi} \right) \rho_{\phi} A dx \\
& + \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( \bar{E}_{\phi} + \Psi_{\phi} \sum_{j=1}^J z_j \chi_{j,\phi} - \tau \bar{S}_{\phi} \right) d\rho_{\phi} A dx \\
& + \sum_{\phi=1}^{\Phi} \left( \bar{E}_{\phi} \rho_{\phi} + \Psi_{\phi} \rho_{\phi} \sum_{j=1}^J z_j \chi_{j,\phi} - \tau \rho_{\phi} \bar{S}_{\phi} \right)_{x_{2,\phi}} A dx_{2,\phi} \\
& \quad - \sum_{\phi=1}^{\Phi} \left( \bar{E}_{\phi} \rho_{\phi} + \Psi_{\phi} \rho_{\phi} \sum_{j=1}^J z_j \chi_{j,\phi} \right. \\
& \quad \left. - \tau \rho_{\phi} \bar{S}_{\phi} \right)_{x_{1,\phi}} A dx_{1,\phi} + P A dX \geq 0 \quad [15]
\end{aligned}$$

The internal energy may be eliminated from [15] by means of Eq. [12a] and [13] to give

$$\begin{aligned}
& \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( (T_{\phi} - \tau) d\bar{S}_{\phi} + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi}) d\chi_{j,\phi} \right. \\
& \quad \left. + \vec{V}_{\phi} \vec{\mathcal{E}}_{\phi} \cdot d\vec{D}_{\phi} + \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) d\Psi_{\phi} \right) \rho_{\phi} dx \\
& + \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( -p_{\phi} \rho_{\phi} d(1/\rho_{\phi}) - (p_{\phi}/\rho_{\phi}) d\rho_{\phi} \right) dx \\
& \quad + \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( (T_{\phi} - \tau) \bar{S}_{\phi} \right. \\
& + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi}) \chi_{j,\phi} \left. \right) d\rho_{\phi} dx + \sum_{\phi=1}^{\Phi} \left( (T_{\phi} - \tau) \bar{S}_{\phi} \rho_{\phi} \right. \\
& \quad \left. + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi}) \chi_{j,\phi} \rho_{\phi} \right)_{x_{2,\phi}} dx_{2,\phi} \\
& - \sum_{\phi=1}^{\Phi} \left( (T_{\phi} - \tau) \bar{S}_{\phi} \rho_{\phi} + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi}) \chi_{j,\phi} \rho_{\phi} \right)_{x_{1,\phi}} dx_{1,\phi} \\
& \quad - \sum_{\phi=1}^{\Phi} \left( [p_{\phi} (1/\rho_{\phi}) \rho_{\phi}]_{x_{2,\phi}} dx_{2,\phi} \right. \\
& \quad \left. - [p_{\phi} (1/\rho_{\phi}) \rho_{\phi}]_{x_{1,\phi}} dx_{1,\phi} + P dX \right) \geq 0 \quad [16]
\end{aligned}$$

The area term,  $A$ , has been divided out. Note that the second integral on the left of [16] is identically zero. Note also that the sum of the changes in the volumes of the separate phases must be the change in volume of the system.

$$dX = \sum_{\phi=1}^{\Phi} (dx_{2,\phi} - dx_{1,\phi})$$

By means of this expression the last three terms on the left of [16] may be combined, viz.

$$- \sum_{\phi=1}^{\Phi} \left( (p_{\phi} - P)_{x_{2,\phi}} dx_{2,\phi} - (p_{\phi} - P)_{x_{1,\phi}} dx_{1,\phi} \right)$$

The variations ( $d\bar{S}_{\phi}$ ,  $d\chi_{j,\phi}$ ,  $d\vec{D}_{\phi}$ ,  $d\Psi_{\phi}$ , etc.) in Eq. [16] are not all independent. The variations in  $\chi_{j,\phi}$  and  $\rho_{\phi}$  are restricted by Eq. [4] and by the requirement that at any point

$$\sum_{j=1}^J \chi_{j,\phi} = 1 \quad \text{or} \quad \sum_{j=1}^J d\chi_{j,\phi} = 0 \quad [17]$$

Equation [16] as modified, [17], and [4] then indicate an extremum with two conditions of restraint. The inequality [16] indicates that the equilibrium condition is at the minimum value of the function whose variation is given by the left side of [16] with restraints represented by Eq. [4] and [17]. Lagrange's method of multipliers may be used. After carrying out the indicated differentiations in Eq. [4] (there are  $J$  equations) and multiplying each by the arbitrary functions  $\lambda_j$  and after multiplying the differential form of [17] by  $\lambda_{17}$ , the results are subtracted from [16] to yield

$$\begin{aligned}
& \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left[ (T_{\phi} - \tau) d\bar{S}_{\phi} \right. \\
& \quad \left. + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi} - \lambda_j - \lambda_{17}) d\chi_{j,\phi} \right. \\
& \quad \left. + \vec{V}_{\phi} \vec{\mathcal{E}}_{\phi} \cdot d\vec{D}_{\phi} + \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) d\Psi_{\phi} \right] \rho_{\phi} dx \\
& \quad + \sum_{j=1}^J \sum_{\phi=1}^{\Phi} \sum_{r=1}^R \lambda_j \nu_{j,r} d\xi_{r,\phi} \\
& \quad + \sum_{\phi=1}^{\Phi} \int_{x_{1,\phi}}^{x_{2,\phi}} \left( (T_{\phi} - \tau) \bar{S}_{\phi} \right. \\
& \quad \left. + \sum_{j=1}^J (\mu_{j,\phi} + z_j \Psi_{\phi} - \lambda_j) \chi_{j,\phi} \right) d\rho_{\phi} dx \\
& \quad + \sum_{\phi=1}^{\Phi} \left( (T_{\phi} - \tau) \bar{S}_{\phi} + \sum_{j=1}^J (\mu_{j,\phi} \right. \\
& \quad \left. + z_j \Psi_{\phi} - \lambda_j) \chi_{j,\phi} \right)_{x_{2,\phi}} \rho_{x_{2,\phi}} dx_{2,\phi} \\
& \quad - \sum_{\phi=1}^{\Phi} \left( (T_{\phi} - \tau) \bar{S}_{\phi} + \sum_{j=1}^J (\mu_{j,\phi} \right. \\
& \quad \left. + z_j \Psi_{\phi} - \lambda_j) \chi_{j,\phi} \right)_{x_{1,\phi}} \rho_{x_{1,\phi}} dx_{1,\phi} \\
& \quad - \sum_{\phi=1}^{\Phi} \left( (p_{\phi} - P)_{x_{2,\phi}} dx_{2,\phi} - (p_{\phi} - P)_{x_{1,\phi}} dx_{1,\phi} \right) \geq 0 \quad [18]
\end{aligned}$$

The values of the functions  $\lambda_{17}$  and  $\lambda_j$  will be chosen so that the variables in Eq. [18] which are not independent will be eliminated. The function  $\lambda_{17}$  is chosen such that for some particular species, say  $k$ , it is identically equal to the function  $(\mu_{k,\phi} + z_k \Psi_{\phi} - \lambda_k)$  at all points in the system. The values of the functions  $\lambda_j$  are chosen so that the functions  $(\mu_{j,\phi} + z_j \Psi_{\phi} - \lambda_j)$  are identically zero at some point in the system. This procedure effectively eliminates the dependent variables from Eq. [18]; either the variables  $d\bar{S}_{\phi}$ ,  $d\chi_{j,\phi}$ ,  $d\rho_{\phi}$ ,  $d\Psi_{\phi}$ , etc., are independent or their coefficients are identically zero. Satisfaction of Eq. [18] for regions wherein "j" is an actual component ( $d\chi_{j,\phi}$  can take any sign) requires that

- I.  $T_{\phi} = \tau$
- II.  $p_{x_{1,\phi}} = P \quad p_{x_{2,\phi}} = P$
- III.  $\mu_{j,\phi} + z_j \Psi_{\phi} = \lambda_j \quad (j = 1, 2, \dots, J)$
- IV.  $\sum_{j=1}^J \nu_{j,r} \lambda_j = 0 \quad (j = 1, 2, \dots, J)$   
 $(r = 1, 2, \dots, R)$
- V.  $\vec{V}_{\phi} \vec{\mathcal{E}}_{\phi} \cdot d\vec{D}_{\phi} + \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) d\Psi_{\phi} = 0$

These five conditions must obtain at equilibrium. Con-

dition I requires that the temperature be uniform; condition II requires that the pressure at each phase boundary be the pressure applied to the system; condition III is the familiar requirement of uniformity of the electrochemical potential; condition IV (combined with condition III) is the familiar form for chemical equilibrium except that the electrochemical potential  $(\mu_j + z_j\psi)$  appears instead of the chemical potential alone.

Condition V is new and is a consequence of considering the effect of the electrostatic field. Actually condition V reduces to Poisson's equation for a medium of constant permittivity. This may be easily demonstrated by considering adjacent parts of the system and applying condition V in one-dimensional form. Using Eq. [8] and the definition

$$\vec{G}_\phi = -\text{grad}(\psi_\phi)$$

one finds

$$\bar{V}_\phi (-d\psi_\phi/dx) \frac{d}{dx} \left( -\epsilon_\phi \frac{d\psi_\phi}{dx} \right) + \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) (d\psi_\phi/dx) = 0 \quad [19]$$

For constant permittivity this becomes

$$d^2\psi_\phi/dx^2 = - \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) / (\epsilon_\phi \bar{V}_\phi) \quad [20]$$

which is Poisson's equation. Thus, Poisson's equation is a consequence of the equilibrium analysis if the permittivity of the medium is constant. Since permittivity is, in general, dependent on composition, use of [20] implies uniform composition.

The expression deduced directly from [19] without assumption is

$$\frac{d}{dx} (\vec{D}_\phi) = \left( \sum_{j=1}^J z_j \chi_{j,\phi} \right) / \bar{V}_\phi \quad [20a]$$

which may be obtained directly from Maxwell's equations (8). Since the electrostatic field term in Eq. [7] was also obtained by use of Maxwell's equations (5) such a result is not surprising.

Condition V may also be used to develop relations between the electrochemical potential and the other thermodynamic properties. For example, substitution of condition V into Eq. [12b] yields

$$0 = \bar{S}dT - \bar{V}dp + \sum_{j=1}^J \chi_j d(\mu_j + z_j\psi) \quad [21]$$

which is the analog of the Gibbs equation for electrochemical systems. Note that according to Eq. [21] the equilibrium requirements of uniformity of the electrochemical potentials and of the temperature mean that the pressure must also be uniform.

Use of condition V in Eq. [7] gives the relation

$$dE = TdS - pdV + \sum_{j=1}^J \mu_j dm_j - \left( \sum_{j=1}^J z_j m_j \right) d\psi \quad [22]$$

or in Eq. [13]

$$d\bar{E} = Td\bar{S} - p d\bar{V} + \sum_{j=1}^J \mu_j d\chi_j - \left( \sum_{j=1}^J z_j \chi_j \right) d\psi \quad [23]$$

By adding the quantity

$$d \left( \psi \sum_{j=1}^J (z_j m_j) \right)$$

to both sides of [22] one obtains

$$d \left( E + \psi \sum_{j=1}^J z_j m_j \right) = TdS - pdV + \sum_{j=1}^J (\mu_j + z_j\psi) dm_j \quad [24]$$

Equations [21] and [23] may be used to obtain interrelationships among the various properties by relations of the Maxwell type in the usual way.

Equation [24] is effectively the fundamental expression used by Kirkwood and Oppenheim (3) except that their symbol  $E$  represents the group in parenthesis on the left of [24]. The present treatment makes this a consequence of the equilibrium analysis. Kirkwood and Oppenheim state in developing [24] that they make the assumption that the quantity denoted by the symbol  $E$  as used herein depends only on the pressure, temperature, and composition and not on the charge, and point out that verification of the assumption has been obtained from experiment. The present analysis shows that such an assumption is unnecessary. It is emphasized that  $E$  is, in virtue of Eq. [17], dependent on  $\vec{D}$  (5).

Finally, in obtaining conditions I through V it was assumed that all chemical species,  $j$ , are present in all phases. For species which are not actually present in some particular phase,  $\phi_1$ , the sign of  $d\chi_{j,\phi_1}$  can only be positive, and therefore, Eq. [18] will be satisfied if

$$\mu_{j,\phi_1} + z_j\psi_{\phi_1} \geq \lambda_j \quad [25]$$

### Conclusions

The results of an equilibrium analysis in which the electric displacement vector is considered as a possible variable show that the usual conditions of equilibrium involving uniformity of temperature, pressure, and electrochemical potential are unaffected. The treatment also shows that the usual conditions of equilibrium will apply across regions where the electric displacement vector is varying. Furthermore, the analysis yields Poisson's equation (or rather its more general equivalent) as a condition of equilibrium.

# Brief Communications

## The Standard Potential of the Silver-Silver Chloride Electrode in N-N Dimethylacetamide at 25°C

Bruno Scrosati, Gianfranco Pecci, and Gianfranco Pistoia

Istituto di Chimica Fisica ed Elettrochimica, Università di Roma, Roma, Italy

Although interest in nonaqueous electrolytes has been greatly increased in the last few years because of their use in high energy battery systems, relatively few determinations of standard potentials of suitable reference electrodes have been carried out in nonaqueous solvents (1-10).

In this work we extend the series to report the behavior of the silver-silver chloride electrode in N-N-Dimethylacetamide (DMA) at 25°C, with respect to the normal hydrogen electrode using the following cell

From the emf data of cell [1] activity coefficients of HCl solutions in DMA at 25°C have been calculated.

DMA (C. Erba reagent grade) was purified by fractional distillation under reduced pressure (2 mm Hg). The final product had a specific conductance of  $4 \times 10^{-7} \text{ ohm}^{-1}$  in good agreement with the value given in the literature (11).

The HCl gas was obtained by dropping concentrated  $\text{H}_2\text{SO}_4$  on reagent grade NaCl and passing the evolved gas first through concentrated  $\text{H}_2\text{SO}_4$  and finally through two traps at dry ice temperature. The solutions used in cell [1] were prepared by passing HCl gas into DMA. The concentration of HCl was determined by Mohr titrations, after neutralizing with sodium bicarbonate. The reliability of volumetric titrations in DMA has been shown by Pistoia and Scrosati (12).

The cell was an all glass type of the design recommended by Ives and Janz (13). The silver-silver chloride electrodes were of the thermal type and were prepared according to the method described by Ives

and Janz (13). Hydrogen electrodes were prepared in the usual manner (13).

Hydrogen gas was purified by Engelhard Hydrogen Purifier Mod. 0-50 and passed through the cell at a rate of 1-2 bubbles/sec. The emf measurements were made at  $25.00^\circ \pm 0.05^\circ\text{C}$  by a differential voltmeter Keithley 662. The emf readings were taken 30 min after starting the hydrogen flow.

The emf values of cell [1], corrected to 760 mm of pressure, are given in Table I as a function of HCl molality.

The standard potential of the silver-silver chloride electrode was determined by the use of the function  $E'$ , defined by the equation

$$E' = E + \frac{2(2.3026)RT}{F} \log m - \frac{2(2.3026)RT}{F} \alpha \sqrt{m} \\ = E^\circ - \frac{2(2.3026)RT}{F} \beta m \quad [2]$$

Table I. Emf data and activity coefficients for HCl solutions in N-N-dimethylacetamide at 25°C

mHCl	E (volt)	E' (volt)	$\gamma_{\pm}$
0.0052	0.4305	0.1475	0.818
0.0064	0.4183	0.1444	0.843
0.0145	0.3814	0.1422	0.763
0.0204	0.3617	0.1359	0.796
0.0260	0.3500	0.1334	0.784
0.0319	0.3389	0.1297	0.793
0.0348	0.3336	0.1275	0.806
0.0425	0.3224	0.1229	0.821
0.0500	0.3120	0.1178	0.854
0.0584	0.3022	0.1127	0.885

Fig. 1.  $E'$  as a function of HCl molality

where the Debye-Hückel constant  $\alpha$  for DMA at 25°C is 1.526. Figure 1 shows the values of  $E'$  vs. the corresponding values of  $m$ . Extrapolation to zero molality by the method of least squares gives the standard potential of the Ag, AgCl electrode in DMA at 25°C,  $E^\circ$ , as  $0.1500 \pm 0.0006$ v. The best fit of the data corresponds to a straight line with a slope of  $-0.640$  and, consequently, the value of  $\beta$  in Eq. [2] is 5.410. The mean molal activity coefficient,  $\gamma_{\pm}$ , of HCl in DMA at 25°C may be calculated by the equation

$$\log \gamma_{\pm} = \frac{E^\circ - E}{0.1183} - \log m \quad [3]$$

The values of  $\gamma_{\pm}$  obtained by Eq. [3] are listed in Table I. Studies on the properties of the silver-silver chloride and other reference electrodes are being extended in this laboratory to other nonaqueous solvents.

Manuscript received Jan. 18, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Mechanism of the Formation of Zinc Dendrites

A. R. Despic,<sup>1</sup> J. Diggle, and J. O'M. Bockris\*

*Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania*

During Zn dendrite formation at constant overpotential, the current grows exponentially with time, the time constant decreasing with increasing overpotential, concentration of zincate, and temperature.

This is consistent with a model of dendrite initiation according to which the rate of deposition onto any part of a microrough surface entering deeper than the average surface into the diffusion layer, relative to the rate of growth of the average surface, increases exponentially with time. The relative height of a protrusion can be shown to be

$$y = y_0 \exp\left(\frac{t}{\tau}\right) \quad [1]$$

where the time constant  $\tau$ , given by

$$\tau = \frac{\left[\frac{(i_L)_0}{i_0 f_c(\eta)} + \delta_0\right]^2}{\frac{M}{\rho n F} \left[1 - \frac{f_a(\eta)}{f_c(\eta)}\right] (i_L)_0} \quad [2]$$

and where  $y_0$  is the original protrusion height at  $t = 0$ ,  $f_a(\eta) = \exp\left(\frac{(2-\beta)F}{RT}\eta\right)$ ,  $f_c(\eta) = \exp\left(-\frac{\beta F}{RT}\eta\right)$ ,  $(i_L)_0 = nFD_0C_0$ , and  $\delta_0$  is the diffusion layer thickness. Thus the height of the protrusion in-

creases exponentially with time (Fig. 1) until it becomes comparable to the diffusion layer thickness. After this initial process, the protrusion forms its own diffusion layer, the conditions of spherical diffusion to the tip are established, and growth becomes governed by a law of the type derived by Barton and

Fig. 1. Height of protrusions at equal time intervals exhibiting exponential dependence.

\* Electrochemical Society Active Member.

<sup>1</sup> On leave of absence from the University of Beograd (Yugoslavia).

Bockris (1). Such a model avoids the concept of dendrite nucleation.

To test the model, its consequences on the current flowing through the interface, at a given overpotential, were evaluated. It was shown that the current should follow a relationship similar to Eq. [1], i.e.,

$$i = i_{\text{init.}} \left\{ 1 + \left[ \frac{y_0}{\frac{(i_L)_0}{i_0 f_c(\eta)} + \delta_0} \right] \exp\left(\frac{t}{\tau}\right) \right\} \quad [3]$$

where

$$i_{\text{init.}} = \frac{(i_L)_0}{\frac{(i_L)_0}{i_0 f_c(\eta)} + \delta_0} \left( 1 - \frac{f_a(\eta)}{f_c(\eta)} \right) \quad [4]$$

The time constants,  $\tau$ , were extracted from experimental plots, by plotting  $\log(i - i_{\text{init.}})$  vs.  $t$  with  $i_{\text{init.}}$  being taken as equal to the initial current density for that overpotential ( $t = 0$ ). Good straight lines were obtained with slope  $2.3\tau$ .

The dependence of  $\tau$  on overpotential, concentration, and temperature was found to follow quantitatively the dependence predicted from analyzing Eq. [2] in those directions. The diffusion layer thickness was found to be  $\sim 10^{-3}$  cm, which is in the expected range.

To interpret the growth rate data, the Barton-Bockris theory was extended to encompass mixed activation and diffusion control of the current density in the nonlinear regions ( $\eta > 10$  mv) and this for two cases of deposition mechanisms: (a) the single electron discharge of univalent ions (pertinent to silver) and (b) a two-step single electron discharge (pertinent to zinc and other divalent metal depositions). The current density at the dendrite tip, i.e., the rate of propagation of the dendrite, is for (a)

$$i_n = \frac{f_c(\eta) \exp(-1/r_n) - f_a(\eta) \exp(1/r_n)}{K/i_0 + f_c(\eta) r_n \exp(-1/r_n)} \quad [5]$$

and for (b)

$$i_n = \frac{f_c(\eta) - f_a(\eta) \exp(1/r_n)}{K/i_0 + f_c(\eta) r_n} \quad [6]$$

where  $i_n = i/K$ ,  $\tau_n = \frac{RT}{2\gamma V} \cdot r$  and  $K = RTnFDC_0/2\gamma V$ ,

$\gamma$  being the surface tension at the metal-solution interface.

The observed rates of growth for Zn were found to follow relation [6] as far as the dependence on potential concentration and temperature implicit in [6] is concerned.

Important conclusions can be made from an analysis of Eq. [5] and [6], which can be understood from analyzing the graphs in Fig. 2.

(a) The curves showing the relation between tip c.d. (i.e., growth rate) and the tip radius for different overpotentials are found to cross a line indicating the value of the limiting current density  $(i_{L,l})_n$  in Fig. 2 for linear diffusion onto a flat surface at overpotentials coinciding remarkably well with the experimentally observed critical overpotentials (e.g., from Fig. 2b, dendritic growth for Zn would start at 60 mv as ex-

Fig. 2. Dependence of the tip current density on tip radius at different constant overpotentials (a) in the case of silver; (b) in the case of zinc.  $i_{L,l}$  is the limiting current density for diffusion onto a flat surface;  $i_{L,s}$  the limiting current density of spherical diffusion.

perimentally observed). Hence, the criterion for a critical current density of the dendrite tip which grows under activation control, past which the conditions for dendritic growth are established, as well as the criterion for critical overpotential are defined as

$$i_c = i_0[f_c(\eta) - f_a(\eta)] \geq i_{L,l} \quad [7]$$

and

$$-\eta_c \geq \frac{RT}{\beta F} \ln\left(\frac{i_{L,l}}{i_0}\right) \quad [8]$$

The critical current density depends solely on the conditions of diffusion to the flat surface, while the critical overpotential depends also on  $i_0$  for the deposition process.

(b) The difference in mechanism, and even more so the difference in  $i_0$ , results in a significant difference in the range of tip radii in which dendrite formation can occur for the two systems: those for silver show sharp peaks of growth rate in a narrow range of tip radii, while those for zinc show broad plateaus over a wide range of tip radii. This explains the observed difference in the character of the deposit for the two metals: the dendrites of silver are propagating fast at low overpotentials but are scarce, since the probability of the protrusions falling into the right range of radii is small; zinc dendrites are propagating slowly, but they are more abundant because of the high probability of the appearance of a protrusion with radii in the required range.

# Field Ion Microscopical Studies of Exchange Current Density on Iridium

Leonard Nanis

School of Chemical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania

and Philippe Javet

Institute for Direct Energy Conversion, University of Pennsylvania, Philadelphia, Pennsylvania

The recently developed technique of field ion microscopy (FIM) is a powerful tool for the investigation of metal surfaces. In many instances, resolution of individual atoms in the metallic lattice has been possible (1). Recent progress in electrode kinetics has shown the need for models on a true atomic scale for the interpretation of phenomena occurring at the electrified interface.

The use of FIM for electrochemistry provides an opportunity to observe surface effects on a scale in which the elementary electrochemical steps occur. Experiments have been performed based on the sequence:

1. image iridium tip (after shaping to almost perfect hemispherical form and atomic smoothness by field induced evaporation);
2. bring to atmospheric pressure and remove tip from FIM;
3. immerse for specified time in electrolyte with iridium ions;
4. rinse electrolyte from tip;
5. return to FIM and image again.

Changes on the surface have been photographically recorded and compared with those occurring in a "blank" experiment during which the tip is treated in a similar electrolyte, but free of iridium ions.

The rate of exchange of charge at the equilibrium potential between a metal and its ions is the exchange current density, a central concept of electrode kinetics (2). Thus, rearrangement of a previously smooth surface should be expected as atoms from the metal become involved in the exchange of charge. The extent of this perturbation is expected to be an increasing function of the time of contact of the metal with the electrolyte and of the magnitude of the exchange current. FIM prepared iridium tips have been immersed for various times in acid solution (2N H<sub>2</sub>SO<sub>4</sub>) containing 10<sup>-6</sup>M iridium ion. A blank experiment using the same acid without iridium ions has shown that the surface perturbation following a treatment of up to 10 min in electrolyte and 10 min in air extends to a depth of only 3 ± 1 atom layers. An example of a blank experiment is shown by comparing Fig. 1 and 2. The field evaporated (111) region of an iridium tip is shown in Fig. 1. After the tip was brought to atmospheric pressure, it was removed from the FIM, dipped for 3 min in 1N H<sub>2</sub>SO<sub>4</sub> and then returned to the FIM. After reestablishment of the vacuum, one atomic layer was removed by field evaporation, leading to the structure shown in Fig. 2.

The numerous bright spots superimposed on the previous features are most probably displaced iridium atoms. After evaporation of two more atomic layers, bright spots no longer appear and the original image, as in Fig. 1, is obtained. When a field evaporated tip is exposed to air only, bright spots similar to those shown in Fig. 2 appear, but the original image is generally restored after the field evaporation of only two layers.

For the solution containing iridium ions, however, the perturbation extends very much deeper than for blank experiments. The relationship between the time

of contact with solution and the depth of penetration (corrected for blank) is shown in Fig. 3. Correlation of the observed atom redistribution with time of immersion, exchange current density, and, e.g., crystallographic factors is now under study. However, two important features are readily obtained from the immersion experiments:

(A) For brief times of contact (less than 5 min), comparison of the damage which occurs in various crystallographic directions permits ordering of relative exchange current density on different crystal faces as

$$J_o(111) < J_o(100) < J_o(210)$$

A similar order

$$J_o(111) < J_o(100) < J_o(110)$$

has been determined for copper (fcc, as is iridium) by Damjanovic *et al.* (3) in a study of electrodeposition kinetics.

(B) With prolonged contact (greater than 5 min) between the metal and its ions, the formation of "spikes" on the surface has been observed.

Figure 4 shows a field-evaporated clean iridium tip with a central (100) region. The fourfold symmetry decoration is caused by field-stabilized protruding atoms in the [110] directions. The nearly hemispherical tip has an average radius of curvature of about 800Å.

Following imaging, this tip was immersed for 10 min in iridium ion solution as mentioned above. Figure 5 shows the image of the treated tip after the removal of 10 atom layers by field evaporation.

Fig. 1. Field evaporated iridium tip with central (111) region before blank treatment.

Fig. 2. Same as Fig. 1 following 3-min immersion in 1N  $\text{H}_2\text{SO}_4$

Fig. 3. Number of perturbed layers on iridium tip as a function of time of contact with iridium ions.

The two spike regions centered around the [310] direction have smaller radius of curvature than the original tip, i.e., the radius in the upper region of Fig. 5 is 450 to 500 Å with an even smaller radius for the lower region.

The field enhancement associated with the decreased local radius produces an effective increase in image magnification and resolution and permits imaging at much lower potential than for Fig. 4. At the reduced potential, imaging does not occur for the remainder of the tip because of the reduced field. Further field evaporation restores the original image as in Fig. 4. Figure 6 shows the tip after the removal of twenty atom layers from the protruding (310) plane. Features of the original structure (Fig. 4) are increasingly evident. The last traces of over-all irregularities disappear completely after evaporation of the 29th layer.

By postulating a simple model for the transfer of material on the surface, an estimate for the magnitude of the exchange current density may be obtained. It has been observed that a general roughening of the entire surface occurs during the first 5 min of immersion, followed by a growth pattern which favors

Fig. 4. Field ion image of smooth, field evaporated iridium tip before electrochemical treatment; (100) plane in center, (111) planes in picture corners. Image potential 17.3 kv; imaging gas helium 2  $\mu\text{m}$  Hg.

Fig. 5. Iridium tip, same as Fig. 4, after 10 min contact with solution,  $10^{-6}\text{M}$  Ir, followed by return to FIM and field evaporation of 10 atomic layers. The two "spike" growth features are each centered on [310] directions. Imaging potential 11.5 kv.

specific directions (Fig. 5). Accordingly, suppose that all discharge of ions after five minutes takes place at the favored position, causing this region to grow, i.e., a hypothetical separation of the cathodic and anodic components of the exchange current density.

The approximate volume of the spike region may be readily computed from direct measurements of the area at different levels as layers are removed by field evaporation. Using Fig. 4, 5, 6 and images at other levels, assuming a tetravalent iridium ion, an upper limit of  $10^{-4}$   $\text{Acm}^{-2}$  for the exchange current density is obtained.

Fig. 6. Iridium tip, same as Fig. 5 after field evaporation of 20 layers. The structure of Fig. 4 has partially reappeared. Imaging potential 15.5 kv.

It is expected that direct FIM observation of treated electrode surfaces will be helpful in devising models for electrochemical reactions, not only by the observation of the changes induced on the surface by electro-

chemical treatment, but also through consideration of the analogy between the field used for image formation and the field at the electrode-electrolyte interface.

Although there is evidence for the existence of vacancies in Fig. 5, spiral dislocations are apparently absent. Provided the imaging field following electrochemical treatment does not interact to remove dislocations, the mechanism presently accepted for the initiation and continuation of electrolytic growth, requiring spiral dislocations intersecting the growth surface, bears re-examination.

Some of the well-known features of the FIM method such as field-stabilized protruding atoms (fourfold decoration in Fig. 4) and field-induced mechanical stresses require incorporation in models of the electrochemical interface.

# Effect of Ionic Additives on the Heterocharge in Carnauba Wax Thermoelectrets

Preston V. Murphy

Thermo Electron Corporation, Waltham, Massachusetts

## ABSTRACT

Thermopolarization and depolarization studies have been carried out on Carnauba wax electrets with controlled impurity content. While the initial impurity content was found to have little influence on the density of heterocharge, the addition of certain inorganic salts, in 10-50 ppm concentration, increased the heterocharge by factors of 2-5. The temperature dependence of electrical conductivity varied considerably with ion doping, but the heterocharge density in all samples showed the same thermal activation energy for polarization.

Carnauba wax, being a mixture of compounds, is not as ideal a choice as pure compounds. However, its dielectric properties have been studied for many years, and the electret effect has been studied more extensively in Carnauba wax than in any other material. Among the many studies on this material are the early papers of Eguchi (1) which described the main features of the electret effect including charge reversal, existence of a volume polarization, and long polarization lifetime for electrets in short-circuit. Adams (2), who proposed one of the early phenomenological theories, used Carnauba. Gross (3) likewise used the material while developing the currently accepted theories on heterocharge and homocharge (3). Wiseman *et al.* (4) carried out experiments which substantiated the two charge theory of Gross. Gubkin (5), at the same period, studied the effects of short circuiting on charge stability in Carnauba and other materials. In more recent studies, Gross (6) showed that the heterocharge is distributed uniformly throughout the volume of Carnauba electrets. Murphy *et al.* (7) have reported on Carnauba radio-electrets, and Perlman *et al.* (8) extended earlier phenomenological theories on the electret effect in Carnauba.

## Carnauba Wax

Carnauba wax is a natural product obtained from the palm *Copernicia Cerifera* Martins (9). It consists primarily of long-chain esters (10). About two-thirds of these are n-alkanoic acid esters composed predominantly of the n-alcohols, C<sub>32</sub>, C<sub>34</sub>, and C<sub>27</sub>, (listed in decreasing abundance) and the n-acids C<sub>24</sub>, C<sub>28</sub>, C<sub>26</sub>, and C<sub>20</sub>. The remaining third are esters of the  $\omega$ -hydroxy n-alkanoic acids, C<sub>28</sub>, C<sub>24</sub>, and C<sub>26</sub>.

The dielectric constant of Carnauba wax measured at 1 kHz increases from 2.5 at room temperature to a maximum of 3.0 at the melting point (79°-80°C). Dielectric measurements (11) have shown that the  $\omega$ -hydroxy acid esters are oriented in a trans-trans configuration, and that rotation about the chain axis occurs in the solid state.

The highest grade of Carnauba, #1 yellow, has been used in this investigation as well as in earlier work including that of Gross (3). It is common practice to filter the wax to remove dark, particulate matter. However, there have been no reports on the nature of the contaminants, neither the portion removed by filtration nor the portion that inevitably remains in the filtrate. The inorganic contaminant might be expected to contribute significantly to the internal polarization of the wax by providing mobile ions or polarizable, colloidal aggregates.

Samples of Carnauba have been purified by simple filtration, by filtration with diatomaceous silica, and by zone refining. The resultant levels of inorganic im-

purities are shown in Table I. After purification, the wax was cast in the shape of small disks and machined to a size of 1.75 in. diameter by 0.079 in. thickness. Electrodes of Aquadag were applied to the flat surfaces.

## Heterocharge Measurement

The heterocharge was measured by the thermodepolarization technique which was developed by Frei and Groetzinger (12) and used extensively by Gross (3). A rather sophisticated, automatic measuring system shown in Fig. 1 was employed.

Four disks of Carnauba wax were mounted in the chrome-plated copper block, C, (Fig. 1), and measurements of both conductivity and polarization were made. The upper and lower electrodes, of chrome-plated copper, were both mounted symmetrically on 1/8 in.-diameter sapphire spheres which maintained a leakage resistance in excess of 10<sup>14</sup> ohm at 250°C. The symmetrical mounting provided for uniform heat transfer between the electrodes and the surrounding block, and minimized thermal gradients in the samples. The four equivalent sample mounting positions enabled measurements to be made under identical

thermal conditions on samples with different composition.

The temperature could be controlled between the limits of 25° and 250°C by means of the cam-programmed, proportionally-controlled oven, B (Fig. 1). The temperature usually was increased at a rate of either 0.19° or 0.75°C/min during depolarization.

Samples were polarized and depolarized in the same apparatus. In the case of polarization, the upper electrodes were connected in parallel to the output of a Baird Atomic Model 319A, 0-5 kv power supply, D. The lower electrodes were grounded through a high resistance so that conductivity could be measured with the electrometer, G; guard rings were used on the lower electrodes. The standard polarizing voltage for samples 2 mm in thickness was 1 kv.

The temperature of the block and of one of the upper electrodes usually was measured by a thermocouple circuit during depolarization. (The positions indicated by the dotted lines at locations "a", "b", and "c" in Fig. 1 were used.) The reference temperature of 15°C was provided by a constant temperature bath, A. The thermocouple output without additional amplification drove the recorder, H.

The coaxial relay system, F, connected one sample at a time to the input of the Cary model 31 electrometer, G. Each time a relay was energized, the input was shorted for 2 sec by the Cary 3098150 automatic shorting switch in order to suppress transients. Rigid coaxial line with air insulation was used on all of the input circuits.

The usual measurement procedure involved increasing the temperature to some specific value above ambient and applying 1000v bias for a period of 1-65 hr. The value of conductivity measured at either 14 or 36 hr was recorded. The temperature was reduced to the ambient during a 16-hr period. The samples were shorted through the electrometer for 1 hr and decay currents recorded. Finally, the samples were reheated at a linear rate to a maximum of 76°C and depolarization currents recorded. Typical recorder traces showing the depolarization "glow curves" are shown in Fig. 2. The heterocharge was obtained from the time integral of the depolarization current.

#### Dependence of Heterocharge on Initial Impurity Content

The heterocharge was determined for Carnauba wax purified by simple filtration, by filtration with activated silica, and by zone refining. Results are shown in Table II.

Fig. 2. Typical recorder trace showing the temperature of one electrode and the depolarization current for four samples vs. time. The samples were polarized at 50°C for 5 hr, cooled to 25°C, and shorted as indicated. Original curves are color coded.

It will be noted that although the impurity content was reduced by nearly an order of magnitude, there was no significant change in the heterocharge density.

#### Modification of Heterocharge by Added Impurities

A different lot of wax was purified with activated silica and reserved for studies on specific added impurities. Solutions of inorganic halides in methanol were sprayed into molten wax to give additive concentrations of about 50 ppm. Sodium and potassium salts formed precipitates in the wax and were removed by the filtration step. Electrets were prepared by polarization for hours at 5 kv/cm and 72°C.

The measured values of heterocharge density are shown in Table III. It will be noted that the heterocharge was doubled by  $\text{Ca}^{+2}$  and  $\text{Ce}^{+3}$  additive and was increased fivefold by  $\text{Fe}^{+2}$  and  $\text{Fe}^{+3}$  additive. NaCl produced no effect while NaBr increased the heterocharge slightly although analysis for Na showed only 1 ppm.

#### Dependence of Heterocharge on Polarization Temperature

The effect of the polarization temperature on the ultimate polarization charge was determined for a standard, purified sample of wax and for a selected

$\text{FeCl}_2$	50	700
$\text{FeCl}_3$	65	700

Fig. 3. Specific depolarization charge vs. reciprocal polarization temperatures for Carnauba samples doped with inorganic salts. The symbols in column 1 represent values obtained for 2-in. diameter disks banded with 3/32 in. guard rings; in column 2, the values were obtained for 1 3/4 in. disks; in column 3, the values were interpolated from the data of Fig. 7.

number of doped samples. It was shown by Van Calker and Frohlich (13) that a plot of polarization charge versus reciprocal polarization temperature gave a straight line for mixtures of Carnauba wax and resin. Plots of heterocharge density vs. reciprocal temperature are shown in Fig. 3 for doped samples. It will be noted that the lines are all nearly parallel (with the exception of the NaBr sample and the CeCl<sub>3</sub> sample above 60°C). Activation energies for polarization were calculated to be 0.86 ev for undoped and Fe-doped samples, and 0.84 ev for NaCl- and CeCl<sub>3</sub>-doped samples. If the heterocharge were caused by space charge due to the migration of the ionic contaminants, one would expect a wider variation in energies of activation.

In Fig. 4, a similar plot is shown for wax samples treated with ZnCl<sub>2</sub>-docosanol, and with ZnCl<sub>2</sub>-docosanol-FeCl<sub>3</sub>. The docosanol treatment was intended to esterify residual acids and thus increase the probability of precipitating colloidal iron oxide. However, the apparent result was an increase in polarizability in

Fig. 4. Specific depolarization charge vs. reciprocal temperature for Carnauba samples doped with ZnCl<sub>2</sub>-docosanol and ZnCl<sub>2</sub>-docosanol-FeCl<sub>3</sub>.

the 40°-60°C temperature region, presumably due to excess free alcohol.

Decay Current

At the end of each polarization, the samples were held in short-circuit at 25.3°C for a 1-hr period. During this time the decay current was read on the electrometer and recorded in the usual manner. The time variation of the decay current is shown in Fig. 5. The integral of the decay current taken over the 1-hr period is plotted against the reciprocal of the polarization temperature in Fig. 6. The decay current and its time integral reached maximum values at about 40°C and decreased at higher temperatures. This behavior is rather unusual in view of the steadily increasing value of heterocharge. The decrease in decay current might result either from an increasing surface homocharge or from an increase in the stability of heterocharge.

Polarization Time

It is usually assumed that the polarization charge reaches a saturation value at elevated temperatures

Fig. 5. Decay current vs. time for polarized samples of standard and iron-doped wax at 25°C. Polarizing bias was removed at zero time.  $T_p$  is the polarizing temperature and  $m$  the slope of the final portion of the curve.

Fig. 6. Decay charge at 25°C,  $Q_{25^\circ C}$  (given by the decay current at 25°C integrated for 60 min) vs. reciprocal polarizing temperature.

Fig. 7. Depolarization charge,  $Q_t$  vs. polarizing time for samples polarized at 50° and 72°C.

after voltage has been maintained for a few hours. In order to verify this assumption and to explore the lower-temperature region, several samples were polarized repeatedly at 50° and at 72°C for different periods of time. The results (Fig. 7) indicate that the polarizing voltage must be maintained for a very long time at 50°C or below in order to attain saturation. However, a temperature-dependent saturation limit appears to exist, and this limit is approached exponentially in time.

#### Sample Compaction

Carnauba wax is subject to considerable shrinkage when cooled from the melt. It has been postulated that the presence of microscopic voids might lead to interfacial polarization as a result of localized surface conduction. Therefore, we have attempted to alter the degree of compaction by solidifying samples under conditions of both high pressure and vacuum. The heterocharge density for some of these samples is shown in Table IV. It will be noted from the table that the effect of compaction is small; we believe the differences in charge noted in Table IV are within the limits of error for these measurements. The data on vacuum-formed samples are not included because a different batch of wax was involved; indirect evidence, however, has shown no appreciable change in polarization as a result of vacuum-forming.

#### Depolarization Rate

It is well known that the maximum value of depolarization current increases with the rate of heating; however, it has not been established that the time integral of depolarization current is independent of heating rate. Therefore, depolarization measurements were carried out on several identical samples at two different heating rates. The results (shown in Table V) indicate that the measured charge is independent of heating rate within the limits of 0.19° and 0.75°C/min.

#### Sample Conductivity

The dependence of electric conductivity on temperature was determined for purified and impurity-doped

Table IV. Polarization density of compacted Carnauba wax

Forming pressure, psi	Charge density, $\mu\text{coul}\cdot\text{cm}^{-2}$	Sample thickness	
		Before measurement, mm	After measurement, mm
None	0.117	1.83	1.84
10,000	0.093	1.88	1.94
20,000	0.100	1.83	1.89

Table V. Effect of depolarization rate of measured charge

Sample	Measured charge	
	Heating rate 0.19°C·min <sup>-1</sup> , $\mu\text{coul}$	Heating rate 0.75°C·min <sup>-1</sup> , $\mu\text{coul}$
Standard	0.20	0.20
NaCl (doped)	0.21	0.20
CaCl <sub>2</sub> (doped)	0.82	0.82
FeCl <sub>3</sub> (doped)	1.82	1.92

samples of wax. Guard rings were used to prevent surface leakage. The conductivity as a function of reciprocal temperature is shown in Fig. 8 and 9. Values of conductivity were taken after application of bias for periods of 11-36 hr as noted in the figures. The conductivity increased with temperature much more rapidly than did polarization charge (Fig. 3 and 4). The data of Fig. 8 and 9 fail to give straight lines from which activation energies for conduction can be calculated.

#### Discussion

The studies involving purified samples of wax demonstrated that the original inorganic contaminants have little effect on the internal polarization; the in-

Fig. 8. Specific conductivity vs. reciprocal temperature for standard and doped Carnauba samples.

Fig. 9. Specific conductivity vs. reciprocal polarizing temperature for  $\text{ZnCl}_2$ -docosanol and  $\text{ZnCl}_2$ -docosanol- $\text{FeCl}_3$  doped Carnauba samples.

ternal polarization or, heterocharge, is a property of the wax itself.

The heterocharge was changed substantially by inorganic additives, but the mechanism of heterocharge formation remains somewhat elusive. The data suggest that free ions are not contributing to the heterocharge since there was no correlation of charge density with valency. For example,  $\text{Fe}^{+2}$  and  $\text{Fe}^{+3}$  behave identically and cause a larger increase in polarization than do  $\text{Ca}^{+2}$  and  $\text{Ce}^{+3}$ . Also, the conductivities of all samples converge to the same value at high temperature, suggesting a common conduction mechanism characteristic of the wax itself.

The quantity of polarization charge appears to increase exponentially with polarization temperature. It is significant that inorganic additives cause the polarization curves to be displaced to higher values of charge but do not affect the slopes. On the other hand the slopes of the conductivity-temperature curves are much steeper than the slope of the polarization-temperature curves. Also, there is no convergence of the polarization curves at high temperature as there is for the conductivity curves.

In view of the observed exponential dependence of heterocharge density on polarizing temperature, the isothermal decay curves and thermodepolarization "glow" curves were examined for similar exponential dependences. The applicability of luminescence and conductivity glow curve analysis to thermodepolarization curves has been pointed out by the writer (7) and expanded by Bucci *et al.* (14). If depolarization is characterized by a single energy of activation the initial increase of current with temperature should follow a simple exponential law. Also the isothermal, short-circuit, decay current should decrease exponentially with time. The current variations found for Carnauba wax were not exponential in either of these cases. Therefore, although the energy of activation for the thermopolarization process appears to be single

valued, no such discrete energy level is associated with depolarization. While a unique physical mechanism for the heterocharge cannot be established as yet, the data are compatible with a distortable double-well model of the type proposed by Fuchs and Von Hippel (15) in connection with dielectric absorption.

#### ABSTRACT

Heterocharges in the polystyrenesulfonate membrane in its hydrogen, sodium, and silver forms have been measured by means of thermal depolarization. We found that the membrane in sodium form stored the largest amount of electric charges and made for the best ionic membrane electret. Membrane electrets were formed at 60°C in electrical fields of 1.25, 2.5, and 5 kv/cm. In this range the total accumulated charge within the membrane does not depend on the strength of the forming field.

The high dielectric constant of polystyrenesulfonate membranes (1) suggests the possibility that these ionic membranes might be capable of storing large amounts of electric charge. To what extent these electrostatic or internal electric charges can be preserved has not yet been determined. Provided that the charges remain orientated within the membrane after electroformation, then ionic membrane electrets could be prepared. Experiments are now being performed at the Polytechnic to determine the role of the electret

effect in water desalination by electro dialysis and in nonthrombogenic bipolymer materials.

In this paper results are presented of measurements of electric charges, formed on the application of d-c fields ranging from 1.25 to 5.0 kv/cm, in sulfonated polymeric membranes. The method of thermal depolarization was used to measure the stored heterocharges released by the membrane electret (2, 3).

#### Experimental

Sulfonated polymer membranes (AMF, C-60) consisted of approximately 25% by weight of polystyrenesulfonic acid (PSA) supported in a matrix of poly-

ethylene. Fixed negative charges within the membrane are carried by sulfonic ( $\text{SO}_3^-$ ) sites along the PSA molecules. These charges are each balanced by positive counter ions, such as H or Na. Each membrane was purified by five batchwise washings with deionized water. Circular strips of membrane, 1.5 in. in diameter and 0.01 in. thick, were cut, silver-coated on both faces, and then vacuum-dried for 24 hr.

Each membrane was clamped between stainless steel electrodes and a d-c electric field applied to the membrane sample, maintained at  $60^\circ\text{C}$ . After an arbitrary cut-off time of 4 hr, membrane sample was allowed to cool down to  $28^\circ\text{C}$  in the presence of the electroforming field. Membrane charging current and temperature were recorded during electroformation.

Immediately after the forming field was removed, the charged membrane was short-circuited and its discharge current measured at  $28^\circ\text{C}$ . This measurement was continued until the current gradually approached zero. After a 24-hr period, the short-circuited membrane was reheated up to  $60^\circ\text{C}$  and its discharge current measured again. The variations of this current with time were then recorded.

### Results and Discussion

Electroforming of a typical membrane eletret by means of a  $1.25\text{ kv/cm}$  electric field is illustrated in Fig. 1. In the beginning, the charging current decays as it normally would at room temperature. Later, the trend reverses and the current starts to increase in response to rising temperature. It experiences a peak approximately at the same time as the temperature reaches its maximum value. After that, the current gradually decays, forming a small knee close to the point where the cooling starts. After 350 min, the applied electric field is turned off, the specimen shorted, and its discharge current measured.

Figure 2 shows the discharge current as a function of time at  $28^\circ\text{C}$  for various forming field strengths. From this data the stored charge in the cation-exchange membrane is calculated, using the relationship

$$Q = \int_t^\infty J(t) dt \quad [1]$$

where  $Q$  = charge, coulombs,  $J(t)$  = discharge current, amp, and  $t$  = time, sec.

According to classical circuit theory, the discharge current of a short-circuited capacitor follows the equation

$$J(t) = I_0 e^{-t/RC} \quad [2]$$

where  $I_0$  = discharge current at  $t = 0$  and  $RC$  = time constant of capacitor (product of resistance and capacitance).

This current, which decays very fast, is present in the case of eletret discharge. However, an additional anomalous current appears, slowly decreasing with time. To allow for decay of the classical discharge

current, a 4-min period of discharge time was allowed to pass before the data were recorded. The charges released during the 96-min period, corresponding to the area under the curve, are given in the second column of Table I. Higher forming field yields the higher quantity of released charge during the first discharge period. Similar results were also reported on Carnauba wax eletrets (4).

The second discharge was started 24 hr later. Temperature was raised to  $60^\circ\text{C}$ , and the discharge current was measured as shown in Fig. 3. The measurements were conducted for 350 min. For the purpose of charge calculations, all the curves are extrapolated to the point where the discharge current reaches zero. The values of released charges were obtained by graphical integration of the curves in Fig. 3, and are listed in the third column of Table I. These charges are up to 9 times larger than the charges released during the first discharge at room temperature.

The total charge is obtained by addition of released charges listed in the second and third columns of Table I and is tabulated in the fourth column of Table I. It can be seen that the total charge essentially does

Table I. Eletret properties of the sulfonate membrane in sodium form

Forming field strength, kv/cm	Charge (coulombs $\times 10^{-4}$ )			Position of discharge peak, min	Internal field, v/cm $\times 10^4$
	First discharge at $28^\circ\text{C}$	Second discharge at $60^\circ\text{C}$	Total charge		
1.25	0.32	2.98	3.30	90	3.27
2.5	0.54	2.86	3.40	85	3.37
5.0	0.70	2.54	3.24	80	3.21

not vary with the change of forming field strength. The lack of dependence of total charge storage on the strength of the forming field indicates that the membrane probably polarized at the lowest forming field used and reached its saturation level at 1.25 kv/cm. However, the position of the peak of current-time curve seems to be dependent on the strength of forming electric field. This dependence, in minutes, is given in the fifth column of Table I.

Reheating shows dramatically how large quantities of residual charge have been left in the membrane after the first discharge. Apparently, charges were locked in and could not be liberated at room temperature during one day of discharge time. As soon as the temperature was raised, they were released. Therefore, the current surge shown in Fig. 3 indicates the liberation of frozen-in charges during the reheating period.

The corresponding internal electric fields produced by these charges have been calculated using the expression

$$E = 1.13 \times 10^{13} \frac{Q}{A} \quad [3]$$

where  $E$  = internal electric field, v/cm,  $Q$  = charge, coulombs, and  $A$  = area, cm<sup>2</sup>.

The calculated values of internal electric fields are given in the last column of Table I. Charge  $Q$  in Eq. [3] is the total charge listed in the fourth column of Table I.

In Fig. 4 is shown the 350-min reheating period at 53°C for membrane electrets in three ionic forms: Na, Ag, and H. Charging time was 1.5 hr at a forming field strength 1.25 kv/cm. The membrane electret in sodium form stored the largest amount of charge.

We have recently demonstrated excellent blood compatibility with PSA-incorporated elastomeric and thermoplastic membranes. PSA was also grafted to surfaces of common elastomers; these polysulfonated materials have high electrical resistance ( $> 10^7$  ohm-cm) and make ionic electret materials in solution. Their bulk equilibrium water absorption contents are low and, as a result, are relatively impermeable to

Fig. 4. Discharge at 53°C of PSA membrane electrets in three ionic states.

salt and water in 0.1M NaCl, and in human whole blood.

We deduce that the effects of the matrix on ionic electret phenomena are indirect. The plastic matrix separates the adjacent PSA molecules, reduces the effective dielectric constant and imparts mechanical strength and support to the material. It is suggested that the electret effect and good blood compatibility results are primarily related to the electrochemical properties of the PSA molecule. More detailed data and techniques will be reported in a subsequent article.

Manuscript received Aug. 17, 1967; revised manuscript received Feb. 23, 1968. This paper was presented at the Electrets Symposium at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 129.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## On the Origin of an Exponential Vacancy Distribution in Annealed Ta/Ta<sub>2</sub>O<sub>5</sub>-Structures

K. Lehovc\*

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

#### ABSTRACT

An attempt is described to explain the exponential vacancy profile in annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures postulated by Smyth *et al.* by a Boltzmann distribution in a constant electric field arising from the emf of the reaction between tantalum and oxygen during the anneal. Implications of this model for the oxygen uptake during the anneal are discussed and compared to experimental data. While the model is able to account for the origin and the attenuation constant of the observed exponential vacancy profile, it involves still unproven assumptions on space charge compensation and electron conduction mechanism.

Smyth and co-workers (1-4) have analyzed capacitance and loss angle measurements of annealed Ta/Ta<sub>2</sub>O<sub>5</sub>-structures in terms of an exponential conductivity profile at zero d-c bias voltage. The bias voltage dependence of the capacitance was interpreted by means of an exponential oxygen vacancy profile. However, the origin of such a profile has not been clarified.

\* Electrochemical Society Active Member.

Defining an attenuation constant  $K_\sigma$  of the conductivity

$$K_\sigma = -\partial \ln \sigma / \partial (x/d) \quad [1]$$

where  $x$  is the distance of a point in the oxide of conductivity  $\sigma$  from the metal, and  $d$  is the oxide thickness one obtains (1-4)  $K_\sigma$ -values of the order 50. We noted sometime ago (5) that an exponential conductivity profile could arise from a Boltzmann distribution of

carriers of charge  $zq$  in a constant field  $F$ , and that the attenuation constant of this Boltzmann factor,  $zqFd/kT$ , has indeed the same order of magnitude as  $K_S \simeq 50$ , if  $Fd = E$  is taken as the emf of the chemical reaction between tantalum and oxygen. More recent results of Smyth and Shirn (4) suggest that the ionization energy of the oxygen vacancies (which act as donors of electrons) depends on their concentration, and that the attenuation constant of the oxygen vacancy distribution

$$K_s = -\partial \ln N_s / \partial [(x/d)] \quad [2]$$

is only about 30. The subscript  $s$  has been chosen since the vacancy concentration  $N_s$  has been obtained (4) by a Schottky plot (6), i.e., from the bias voltage dependence of capacitance at a constant frequency.

The measurements of Smyth and co-workers (1-4) were made on tantalum anodized at various formation voltages and then annealed at elevated temperatures in the range 300°-400°C for periods ranging from 10 min to several hours. During the anneal, no oxide growth occurred. However, there was a weight increase attributed to oxygen uptake of the tantalum metal (1). Anneal time in the investigated range did not have much influence on the room temperature impedance indicating that a quasistationary state was reached within minutes. Most of the measurements were made on anodic films of the thickness range  $d = 1500$ -3000 Å.

The present paper explores in detail the concept of an exponential vacancy distribution arising from a Boltzmann distribution in a constant field. Its implication on the oxygen uptake during the anneal investigated by Pawel and Campbell (7) and recently by Steidel (8) will also be discussed.

It will be shown that justification of the exponential vacancy profile by a Boltzmann distribution, although enticing at first sight, nevertheless requires a number of ad hoc assumptions, and thus raises problems of its own. However, publication of the present paper, while not leading to a fully convincing model, can be justified by the extensive pertinent experimental work and by the need to investigate critically all consequences of an explanation which appears plausible at first sight.

#### Origin of an Exponential Distribution of Oxygen Vacancies

During the anneal, oxygen is dissolved in the tantalum metal. This creates oxygen vacancies in the adjacent tantalum oxide. These vacancies move toward the outer oxide surface and generate an oxygen flow from the ambient into the tantalum metal. It is well known that tantalum can dissolve large quantities of oxygen (1, 7, 8). Changes of tantalum resistivity and of its temperature coefficient by oxygen uptake have been demonstrated (8). During anneal an emf of a few tenths of a volt (8, 9) appears across the oxide, the tantalum substrate becoming negative. The fact that the electric properties of annealed Ta/Ta<sub>2</sub>O<sub>5</sub>-samples, after cooling to room temperature, do not return to the preannealed state indicates a lack of oxygen uptake of the reduced tantalum oxide from the ambient atmosphere at room temperature.

An exponential vacancy distribution would arise under quasiequilibrium conditions from the Boltzmann factor at a constant field,  $F$

$$[V_0^z] = [V_0^z]_{x=0} \exp(-zqFx/kT) \quad [3]$$

where  $zq$  is the charge of the mobile vacancies of concentration  $[V_0^z]$ .<sup>1</sup> Comparison of [3] with the empirical relation [2] shows that

$$K_S = zqFd/kT \quad [4]$$

By inserting the values  $K_S = 30$  and  $kT/q \simeq 60$  mv at the anneal temperature, we obtain  $zFd \simeq 1.8$ v. Since

the oxide thickness  $d$  is of the order of  $2 \cdot 10^{-5}$  cm for most of the samples investigated by Smyth *et al.* (1-4), we are here concerned with an electric field  $F$  of the order of  $10^5$  v/cm. A space independent field implies absence of a significant space charge density, i.e.,

$$\int \rho \delta x \ll \epsilon \epsilon_0 F \quad [5]$$

the integral extending over the region of constant field. For  $F \simeq 10^5$  v/cm, the right side is about  $2 \cdot 10^{-7}$  C/cm<sup>2</sup> or  $10^{12}$  electron charges per cm<sup>2</sup>. This is much smaller than the number of charges derived from the Schottky profile [2]

$$\int_0^d N_s \delta x = N_s^0 d/K_S \simeq 2 \times 10^{14} \text{ cm}^{-2} \quad [6]$$

where  $N_s^0 = 3 \cdot 10^{20}$  cm<sup>-3</sup>,  $K_S = 30$ , and  $d \simeq 2 \times 10^{-5}$  cm have been used (4). This leaves us with two possibilities:

- The concentration of charged vacancies at the anneal temperature is much smaller than  $N_s$ , derived from the Schottky profile, perhaps due to partial ionization, or else
- There exists a mechanism for compensation of the charge of the mobile vacancies at the anneal temperature. The compensating charge must be immobile or else it would assume a Boltzmann distribution of the opposite slope of that of the mobile oxygen vacancies. Such a charge compensation may indeed arise by means of oxygen vacancies occurring in different charged states as will be pointed out in the Appendix.

#### Implications for the Oxygen Uptake during Anneal

During a quasistationary uptake of oxygen ions *via* a vacancy mechanism, an electron current of equal magnitude flowing from the tantalum outward is necessary for charge compensation. This equality is assured by the establishment of an electric potential of suitable polarity and magnitude. The emf (= difference of the electrochemical potential of electrons at the two boundaries of the oxide divided by charge  $q$ ) becomes identical to the electrostatic potential if the electron concentration is constant with position, the chemical potential (or "diffusion potential") being then zero. This is the situation we visualize in the Ta<sub>2</sub>O<sub>5</sub> during the anneal (or, at least, in the region from which most contributions to the emf arise), for reasons to become clear later. The polarity of the observed emf is such as to generate a field in the oxide driving electrons from the tantalum to the outer oxide, indicating that the electric current is the rate-determining step, at least in a portion of the oxide film. This is in agreement with our previous postulation of a Boltzmann-distribution of oxygen vacancies, which implies quasithermal equilibrium, i.e., the vacancy transport rate is not rate determining. We conclude from the constancy of the electron current  $i_e$  through the oxide and from the constancy of the electric field, postulated to explain the exponential vacancy profile, that the electron concentration

$$n = i_e / q \mu_e F \quad [7]$$

is also a constant, when  $\mu_e$  is the electron mobility. This justifies the relation

$$F = E/l \quad [8]$$

between the electric field, the emf  $E$  and the width  $l$  of the region from which the emf arises and in which the conditions discussed above are realized.

In distinguishing between the oxide thickness  $d$  and the region  $l$  across which the emf arises, we have taken into account the fact that the exponential vacancy profile has not been established experimentally throughout the entire oxide, and that a Boltzmann distribution of vacancy need not exist across the entire oxide.

<sup>1</sup> A different notation has been used for the vacancy concentration in Eq. [3] at the anneal temperature and the concentration of the Schottky profile, since both are not necessarily identical as will be discussed later.

Within the region of width  $l$ , we expect the following inequality between electric ( $\sigma_e$ ) and ionic ( $\sigma_I$ ) conductivities

$$\sigma_e = nq\mu_e \ll \sigma_I = [V_0^z] \cdot zq\mu_I \quad [9]$$

expressing the fact that the electron transport is rate determining. Outside of this region we may well have  $\sigma_e > \sigma_I$ , and  $l$  may then be defined as the position at which

$$\sigma_e = \sigma_I \text{ at } x=l \quad [10]$$

Since  $\mu_e \ll \mu_I$ , one has there  $n \ll [V_0^z]$ . It follows from the Boltzmann distribution [3] that

$$\begin{aligned} E &= kT/zq \ln [V_0^z]_{x=0}/[V_0^z]_{x=l} \\ &= kT/zq \ln \sigma_I(x=0)/\sigma_e(x=l) \end{aligned} \quad [11]$$

where [10] has been used and the ionic mobility  $\mu_I$  was assumed to be independent of the vacancy concentration.

#### Comparison with Experimental Data

The importance of electron conduction for the oxygen transfer rate is in agreement with observations by Pawel and Campbell (7) on oxygen uptake of tantalum protected by an anodic oxide film at elevated temperatures. They found that "anodic films exhibiting low leakage currents were more efficient in protecting the metal from oxidation. Local breakdown at a point of weakness may, instead of being self healing, lead to an accelerated deterioration of the remainder of the film." The latter observation is in accordance with our model if lateral electron conduction along the outer oxide surface may occur.

Additional evidence for the electron transfer being the rate-determining step for oxygen flow through part of the oxide is the electromotive force at the anneal temperature (7, 8, 9).

The emf corresponding to the free energy of the reaction  $2\text{Ta} + 5/2 \text{O}_2 \rightarrow \text{Ta}_2\text{O}_5$  at  $400^\circ\text{C}$  is 1.83v for oxygen-free tantalum and an ambient of 0.2 atm oxygen pressure. The fact that the observed emf (8, 9) is only a fraction of this value can be attributed partially to the outer portion of the oxide film having dominant electronic conduction and partially to oxygen dissolved in tantalum. The end product of the reaction between tantalum and the oxygen ambient at moderate anneal conditions is not tantalum oxide, but oxygen dissolved in tantalum.

Comparing the value  $zFd = 1.8\text{v}$  obtained by [4] from the slope  $K_S$  of the observed (4) Schottky profile at room temperature, with the observed (8, 9) emf during the anneal  $E = F \cdot l \simeq 0.3\text{v}$ , we conclude that for  $z = 1$ :  $l/d \simeq 1/6$ , and  $F \simeq 10^5 \text{ v/cm}$ , while for  $z = 2$ :  $l/d \simeq 1/3$  and  $F \simeq 5 \times 10^4 \text{ v/cm}$ .

The Boltzmann factor for  $E = 0.3\text{v}$  and  $kT/q = 0.06\text{v}$  ( $T \simeq 400^\circ\text{C}$ ) is  $e^{-qE/kT} = 6.7 \times 10^{-3}$  in case that  $z = 1$  and  $e^{-2qE/kT} = 4.6 \times 10^{-5}$  in case that  $z = 2$ . Using  $N_s^0 = 3.10^{20} \text{ cm}^{-3}$ , we arrive at vacancy concentrations at  $x = l$  of  $2.10^{18} \text{ cm}^{-3}$  and  $1.4 \times 10^{16} \text{ cm}^{-3}$  for the cases  $z = 1$  and  $z = 2$ , respectively. Since experimental Schottky profiles have been measured which extend to  $10^{17} \text{ cm}^{-3}$ , we conclude that  $z = 2$ .

The magnitude of  $\sigma_e$  in that part of the oxide where the Boltzmann distribution of vacancies exists can be estimated by extrapolation to  $400^\circ\text{C}$  of data from Fig. 5 or ref. (7). For the film of 1000Å thickness, an oxygen flow of  $10^{-11} \text{ g-moles/cm}^2 \text{ min}$  is obtained, which corresponds to  $1.2 \times 10^{-7} \text{ amp/cm}^2$  (assuming that  $z = 2$ ). Using a field of  $5 \times 10^4 \text{ v/cm}$  for the region where [7] is valid, one arrives at  $\sigma_e \simeq 2.4 \times 10^{-12} \text{ ohm}^{-1} \text{ cm}^{-1}$ .

At room temperature Smyth and Shirn (4) obtain  $\mu_e \simeq 1 \text{ cm}^2/\text{v sec}$ . Using this value as a rough estimate of the mobility at the anneal temperature, one has  $n \simeq 1.5 \times 10^7 \text{ cm}^{-3}$ .

By means of [11], we are able to estimate the vacancy mobility

$$\mu_I \simeq [\sigma_e]_{x=l}/zq[V_0^z]_{x=l} \quad [12]$$

Using the previously estimated value  $[V_0^z]_{x=l} \simeq 1.4 \times 10^{16} \text{ cm}^{-3}$ , one obtains  $\mu_I \simeq 5 \times 10^{-10} \text{ cm}^2/\text{v sec}$  for  $z = 2$ , which is not unreasonable.

For a nondegenerate electronic semiconductor, the band model provides

$$n = N_c \exp[-(\epsilon_c - \epsilon_F)/kT] \quad [13]$$

where  $N_c$  is the density of states (partition sum) for the conduction band and  $\epsilon_c - \epsilon_F$  is the energy difference between the bottom of the conduction band  $\epsilon_c$  and the Fermi level (electrochemical potential per electron)  $\epsilon_F$ . Provided that  $\epsilon_F$  does not depend on temperature and neglecting the small temperature dependence of  $N_c$  vs. that of the exponential term, we obtain an activation energy of  $\epsilon_c - \epsilon_F$ .

Pawel and Campbell (7) find an activation energy for oxygen uptake of 1.96 eV, while Steidel (8) observed 1.5-1.6 eV. Inserting  $n = 1.5 \times 10^7 \text{ cm}^{-3}$ ,  $\epsilon_c - \epsilon_F = 2.0$  and 1.5 eV, respectively, and  $kT/q = 0.06\text{v}$  into [9], one obtains  $N_c = 3.10^{20} \text{ cm}^{-3}$  and  $10^{18} \text{ cm}^{-3}$ , respectively; neither value is objectionable.

The magnitude of the ionic conductivity in the outer oxide film can be estimated if we assume that it is of the same order as that of unannealed anodic oxide films. The anodic oxidation rate depends on field as (10-13)

$$i_I = A'(e^{B'F} - e^{-B'F}) \quad [14]$$

For  $B'F \ll 1$ , one obtains

$$\sigma_I = i_I/F = 2 A'B' \quad [15]$$

Extrapolating the room temperature values (10-13) of  $A' \simeq 5.10^{-19}$  to  $6.10^{-21} \text{ amp/cm}^2$  and  $B' \simeq 5.10^{-6} \text{ cm/v}$  to the anneal temperature of  $400^\circ\text{C}$  by using the activation energy  $U_{A'} = 1.2 \text{ eV}$  (12) for  $A'$  and the inverse absolute temperature dependence (12) for  $B'$ , we obtain  $\sigma_I = 10^{-15}$  to  $10^{-17} \text{ ohm}^{-1} \text{ cm}^{-1}$ . These values are indeed small compared to  $\sigma_e = 2.4 \times 10^{-12} \text{ ohm}^{-1} \text{ cm}^{-1}$ . Thus, it is reasonable to expect that oxygen flow in the outer film region, which is in equilibrium with the oxygen ambient, is limited by ionic flow while in the reduced inner film region it is limited by electron transport.

It should be noted that the electron current  $i_e = nqF$  as the rate-determining step for oxygen flow could lead to a parabolic growth since  $F = E/l$ , provided that  $E$  and  $l$  do not vary with the oxide thickness. Thus, the anneal mechanism here described is not necessarily in disagreement with parabolic growth, which is usually taken as an indication (7) for a growth rate limited by ion diffusion.

#### Difficulties Encountered by the Present Model

A complete clarification of the anneal mechanism requires knowledge of the oxygen flow mechanism in the outer oxide film region, i.e.,  $l < x < d$ , and of the nature and location of the positive charges which generate the constant electric field in the oxide region  $0 < x < l$ .

In the case of a simple diffusion current of vacancies through the outer oxide region

$$\begin{aligned} i_I &\simeq \frac{kT}{zq} \mu_I zq [V_0^z]_{x=l}/(d-l) \\ &= \sigma_e \frac{kT}{zq}/(d-l) \end{aligned} \quad [16]$$

Since  $kT/zq/(d-l) \ll F$  for  $d-l$  of the order of  $d$ , it follows that  $i_I \ll i_e = \sigma_e F$ , while for quasi-stationary oxygen uptake  $i_I = i_e$  is necessary.

It would thus appear that either the field in the outer oxide region is of opposite polarity than that in the inner oxide region, or else the vacancy mobility in the outer oxide region is significantly larger than in the inner region. Arguments for each of these suggestions can be found. Field reversal is not unlikely considering that the rate determining step is electron transport for  $0 < x < l$  and vacancy transport for  $l <$

$x < d$ . A two-layer structure for anodically grown oxide films has been established experimentally by means of tracer studies (14). Some discontinuity in the structure at  $x = l$  is thus quite possible if this position marks the interface between the two-layer structure. It is even conceivable that a positive charge layer might form there. However, these assumptions, while possibly correct, have not yet been proven to be so.

Another difficulty of the present model involves the discrepancy between the rather low electron conductivity at the anneal temperature  $\sigma_e \simeq 2.4 \times 10^{-12}$  ohm $^{-1}$  cm $^{-1}$  in contrast to the fairly high electron conductivity  $\sigma_e \simeq 10^{-7}$  ohm $^{-1}$  cm $^{-1}$  at room temperature in the region adjacent to the tantalum, postulated by ref. (1) to (4). Clearly, this calls for two different conduction mechanisms. Yet both mechanisms must originate from the oxygen vacancies or we lose the relation between vacancy profile established at the anneal and the experimental Schottky profile at room temperature, which formed the starting point of our considerations. It will be shown in the Appendix that space charge neutrality may arise by equal concentrations of  $[V'_0]$  and  $[V''_0]$  vacancies at the anneal, one of them,  $[V''_0]$ , being highly mobile. It is reasonable to expect, therefore, that upon cooling, clustering to  $V^{x_{20}}$  complexes takes place.

To provide space charge neutralization, the Fermi level at the anneal temperature is located halfway between the energy levels of the  $V'_0$  and  $V''_0$  vacancies. On the other hand, at room temperature, the Fermi level would be determined by the ionization equilibrium of the  $V^{x_{20}}$  complexes and thus might be considerably closer to the conduction band, resulting in a large increase in the electron conductivity.

Perhaps the observed (8, 9) decrease of the emf with decreasing temperature in the lower temperature range can be attributed to the increasing dominance of electronic conduction due to clustering. It might arise also, of course, by the decreased ionic mobility, which shifts the position  $x = l$  to smaller values and thus reduces the emf across the region  $0 < x < l$ .

According to the present hypothesis, the Schottky concentration  $N_S$  would be the concentration of ionized clusters  $[V'_{20}]$ . It is believed that at an applied anodic bias voltage a space charge layer forms adjacent to the tantalum metal by depletion of electrons and complete ionization of the  $V_{20}$  clusters. Thus  $N_S = [V'_{20}]$ . If, at the anneal temperature, all clusters are dissociated, then  $[V_0] = 2[V'_{20}] = 2N_S$ . The concentration of mobile doubly charged vacancies,  $[V''_0]$  at the metal boundary would be less, and possibly significantly less, than  $[V_0] = 2N_S$ . The use of  $N_S^0 = 3.10^{20}$  cm $^{-3}$  for  $[V''_0]_{x=0}$  in Eq. [11] is thus not justified and the distinction between  $z = 2$  and  $z = 1$  based thereon becomes questionable. Also, the ionic mobility calculated by [13] might be considerably higher than the numerical estimate based on  $[V''_0] \simeq 1.4 \times 10^{16}$  cm $^{-3}$ .

### Conclusions

The possible origin of an exponential vacancy distribution in annealed Ta/Ta $_2$ O $_5$  samples by means of a Boltzmann distribution of vacancies during the anneal was investigated. If this interpretation is correct, oxygen uptake during the anneal is limited by electron transfer rather than ion diffusion, at least in a portion of the oxide film. This view is consistent with the observed appearance of an emf during the anneal and with the rate of oxygen uptake. However, the electron conductivities at the anneal temperature appear much smaller than those at room temperature. The difficulty could be removed by the unproven hypothesis of clustering of vacancies. It is shown in the Appendix that space charge compensation could occur even at large concentrations of vacancies and is consistent with a Boltzmann distribution of mobile vacancies in a constant field.

In summary, a model has been found which leads to a strictly exponential vacancy profile as postulated

by Smyth *et al.* The model accounts for the order of magnitude of the attenuation distance. It permits significant conclusions in the mechanism of the anneal process. The model includes, however, several speculative features, which cannot be tested by existing experimental data, thus suggesting further experimental work.

Other models, such as tunneling (15), can also account for the electrical measurements of Smyth *et al.* on annealed Ta/Ta $_2$ O $_5$ . Thus it is conceivable that the Schottky distribution and conductivity profile need not necessarily have the straightforward interpretation (1-4) which was accepted in this paper.

### Acknowledgment

The author would like to express his appreciation to D. M. Smyth for making recent experimental results available to him prior to publication and for many stimulating discussions.

Manuscript received Aug. 14, 1967; revised manuscript received ca. Dec. 11, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX

#### Space Charge Compensation by Means of Oxygen Vacancies of Different Valency States

Consider the oxygen vacancy species  $V'_0$ ,  $V''_0$ ,  $V'_0$ , and  $V^{x_0}$  in the notation of Kröger (16). The existence of a single vacancy as either donor or else trap for an electron is well known for the case of F and F $^1$  centers in alkali-halides. A single vacancy can change its charge by "reaction" with electrons, e.g.

Several reactions between vacancies and electrons and the corresponding mass action laws are listed in Table I. Also included, are values for the mass action constants in terms of the energy levels involved using customary (16) notation.

Since the concentrations of the various charged vacancy states are in proportion to each other, and, therefore, to the total vacancy concentration, the zero space charge condition for the case of negligible contributions by electrons provides a value for the electron concentration, which does not depend on the vacancy concentration, but only on the mass action constants, which are space independent. A space independent electron concentration was indeed a key feature of our model. For instance, in the case

$$[V''_0] \simeq [V'_0] \quad [A-2]$$

one has

$$n = \sqrt{K_2 K_3} = N_c e^{-\epsilon_c/kT} e^{+(\epsilon^x + \epsilon'/2kT)} \quad [A-3]$$

Comparison to Eq. [13] shows

$$\epsilon_F = (\epsilon' + \epsilon^x)/2 \quad [A-4]$$

i.e., the Fermi level lies half-way between the  $\epsilon'$  and  $\epsilon^x$  levels, independent of position and vacancy concentration (Fig. 1).

Since the levels  $\epsilon_c$ ,  $\epsilon'$ , and  $\epsilon^x$  at the oxide-tantalum interface and the Fermi level in the tantalum metal are well defined and independent of each other, the assumption that the levels  $\epsilon'$  and  $\epsilon^x$  are an equal distance above and below, respectively, of the Fermi level in the tantalum metal may appear quite arbitrary.

Table I. Electron reactions involving oxygen vacancies and corresponding mass action laws and mass action constants (the energy of electrons in the conduction band and on the  $V'_0$ ,  $V^{x_0}$ ,  $V''_0$  levels are designated by  $\epsilon_c$ ,  $\epsilon'$ ,  $\epsilon^x$  and  $\epsilon^*$ , respectively).

Reaction	Mass action law	$K_i$ ( $i = 1, 2, \text{ or } 3$ )
$V''_0 \rightarrow V'_0 + e$	$[V''_0] \cdot n = K_1 [V'_0]$	$N_c e^{-(\epsilon_c - \epsilon'/kT)}$
$V'_0 \rightarrow V''_0 + e$	$[V'_0] \cdot n = K_2 [V''_0]$	$N_c e^{-(\epsilon_c - \epsilon^x/kT)}$
$V'_0 \rightarrow V^{x_0} + e$	$[V'_0] \cdot n = K_3 [V^{x_0}]$	$N_c e^{-(\epsilon_c - \epsilon^*/kT)}$

Fig. 1. Hypothetical energy level diagram for the Ta/Ta<sub>2</sub>O<sub>5</sub> interface during anneal.  $\epsilon_c$  is the bottom of the electron conduction band,  $\epsilon'$  is the energy level for negatively charged oxygen vacancies, i.e., for the third electron at the vacancy;  $\epsilon^x$  is the level for the second electron at a neutral oxygen vacancy and  $\epsilon^o$  is the energy for the electron at a positively charged vacancy. Doubly positive charged oxygen vacancies are believed to be mobile and assume a Boltzmann distribution in the region  $0 < x < l$ , causing the electromotive force  $E \simeq Fl$ . The emf in the region  $x > l$  is just about shorted by dominant electronic conduction. Electron concentration in the region  $0 < x < l$  is constant, viz., constancy of  $\epsilon_c - \epsilon_F$ . A thin space charge layer in the oxide at the metal boundary (indicated schematically by the upward bending of energy levels) adjusts the Fermi level in the metal to the value of  $(\epsilon' - \epsilon^x)/2$  in the adjacent portion of the neutral oxide.

However, considering the large concentration of vacancies at the interface, a very thin space charge region should suffice to adjust the levels  $\epsilon'$  and  $\epsilon^x$  to positions of equal distance above and below, respectively, of the Fermi level in the adjacent metal. This has been indicated by the upwards bending of the levels in Fig. 1 near the metal interface (assuming a positive space charge).

In order to obtain a Boltzmann distribution of vacancies, we must postulate that only the vacancy species of one sign is mobile. If both positive and negative vacancies were mobile, they would establish two Boltzmann distributions, one decreasing with position and the other increasing with position, while [A-2] requires both species to vary in unison with each other.

A high mobility of positively charged vacancies in contrast to a comparable immobility of negatively charged vacancies can be rationalized as follows: Oxygen vacancies move by jumps of adjacent oxygen ions. A negatively charged vacancy  $V'_o$  repels the adjacent oxygen ions and this suppresses their mobility. The opposite is true for positively charged vacancies and, in particular, of the doubly charged state  $V''_o$ . While the  $V'_o$ -centers are immobile as an entity, their concentration can still change in proportion to that of the mobile  $V''_o$ -centers by the electron transfer reaction

Thus, at a space-independent electron concentration  $n_e$ , the ratios of the concentrations  $[V'_o]$ ,  $[V''_o]$  and  $[V''_o]$  are independent of position irrespective of the total concentration  $[V''_o] + [V'_o] + [V''_o] + [V''_o]$ , which assumes a Boltzmann distribution if only the  $V''_o$  species is mobile. In this manner, the mass action relations (Table I), the zero space charge condition<sup>2</sup> [A-2], the Boltzmann distribution of mobile vacancies [3] and the condition of a space independent electron concentration [7] can all be satisfied.

<sup>2</sup> Equation [A-2] assumes that  $[V''_o] \ll [V'_o]$ . Similar arguments can be advanced in the case that  $[V''_o]$  contributes measurably to the zero space charge condition.

# Silicon Nitride Thin Films from SiCl<sub>4</sub> Plus NH<sub>3</sub>: Preparation and Properties

M. J. Grieco,<sup>1</sup> F. L. Worthing, and B. Schwartz\*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

## ABSTRACT

Silicon nitride thin films have been deposited on silicon substrates by reacting SiCl<sub>4</sub> and NH<sub>3</sub> at 550°-1250°C. The effects of deposition temperature and of SiCl<sub>4</sub> and NH<sub>3</sub> concentrations on the deposition rate have been studied. The etch rate of the deposited films is shown to be a function of the deposition temperature. Electrical evaluation has shown the dielectric strength to be independent of contact area and film thickness and the dielectric constant to be in the range seven to eight. Surface charge plus surface state density values range from 7 to 18 x 10<sup>11</sup>/cm<sup>2</sup>. Nonlinear I-V characteristics of the films have been observed. The deposited films are extremely effective diffusion masks for sodium.

Thin layers of silicon dioxide have found extensive use in the fabrication of semiconductor devices for surface passivation (1), as diffusion masks (2), and as dielectric layers (3). Technological advances and more demanding requirements (4) have led to the need for insulating films with properties superior to those of the oxide. One of the materials currently receiving a great deal of attention as a possible substitute for SiO<sub>2</sub> is silicon nitride. This material has been evaluated for its passivation properties on p-n junctions (5), for its use as a dielectric in a field-effect structure (6), and for its usefulness as a diffusion mask (7, 8), and it has been found to be satisfactory.

From the data in Table I, it is apparent that there are many reactions for forming the nitride that are thermodynamically feasible. However, passing nitrogen or ammonia over solid silicon substrates heated to 1300°C results in extremely thin nitride layers (9), owing to the high efficiency of the material as a diffusion mask. When ammonia is passed over molten silicon, crystals of nitride result, as reported by Kaiser and Thurmond (10), Doo and his co-workers (11) have reported on the deposition of silicon nitride films by the high-temperature reaction of SiH<sub>4</sub> plus NH<sub>3</sub>. A number of investigators (12, 13) have made use of various high-field discharge techniques in order to obtain nitride deposition at low temperatures.

This paper will report on deposited nitride thin films obtained by reacting SiCl<sub>4</sub> and NH<sub>3</sub> in the presence of silicon substrates heated in the temperature range 550°-1225°C. The kinetics of the deposition process will be discussed and the properties of the deposited films will be described.

## Experimental Procedure

Figure 1 is a schematic of the apparatus used for this study; the system was similar to that normally used for silicon epitaxy by the hydrogen reduction of silicon tetrachloride (14). The reaction chamber is shown in Fig. 2; it was an air-cooled, single-walled, 50 mm ID quartz chamber containing a susceptor heated with an externally placed r.f. coil. The susceptor was a high-purity graphite pedestal covered with a quartz sleeve; without the quartz sleeve, NH<sub>3</sub> was adsorbed by the graphite, causing the carbon pedestal to powder and crumble. When a silicon susceptor was used, thick deposits of the nitride formed on the pedestal (the susceptor temperature was normally almost 200°C higher than the substrate temperature), making it necessary to relap the top surface of the susceptor after each run.

Three separate feed lines were used to introduce the reagents into the reaction chamber. In the very early phases of this study, the reagents were mixed together well upstream of the reactor, but it was found that no deposit was formed on the substrate. It was quickly realized that the NH<sub>3</sub> and SiCl<sub>4</sub> were reacting immediately on contact, and most of the reaction products were precipitating out of the gas phase. By converting to the system of individually feeding the reagents into the reaction chamber, nitride deposition on the substrate was achieved.

The outlets of the two feed lines inside the reaction chamber were varied from ½ to 4 in. above the silicon substrate. With the outlets of the feed lines close (~1 in.) to the substrate, films of nonuniform thickness were produced. However, with the substrate approximately 3-4 in. below the feed-line outlets, the layer thickness (~3000Å) varied by only about 200Å across a ½ in. square substrate. These last dimensions for the reactor geometry were maintained throughout these experiments.

The silicon substrates were 10 mils thick, p-type, 2-70 ohm-cm, (111) oriented, and chemically polished with an iodine etch (15). Just before the substrates were loaded into the reactor, they were chemically etched for 2 min in 10:1:HNO<sub>3</sub>:HF, nitric acid quenched, immersed in concentrated HF for 2 min, and finally rinsed in deionized water. After the substrate was loaded, the entire system was purged with nitrogen, then heat-treated in H<sub>2</sub> at the deposition temperature for 30 min. Deposition was initiated after a second purge with nitrogen. The deposition reaction was carried out using nitrogen as the inert carrier of the silicon tetrachloride vapor. A total flow of 2600 cc/min of gas, composed of approximately 150 cc/min of N<sub>2</sub> + SiCl<sub>4</sub> vapor, 50 cc/min of NH<sub>3</sub>, and 2400 cc/min of N<sub>2</sub> bypass, was passed through the reactor. The SiCl<sub>4</sub> bubbler was maintained at -30°C. The maximum deposition temperature of 1000°C was chosen

Table I. Free energy of over-all reactions\*

Fig. 2. Quartz reaction chamber

to avoid any substrate conversion; unless it is otherwise stated, this was the deposition temperature used.

The  $N_2$  and  $H_2$  gases were purified by use of a McGraw-Edison Lectrodryer and an Englehard Industries Deoxo Puridryer, respectively. The  $NH_3$  gas (99.99%), obtained from Matheson Company, Inc., was used as received and did not undergo any subsequent purification.

Films in the thickness range 1000-6000Å were generally used for all the measurements made. Film thickness and refractive index of the nitride films were determined by use of variable angle monochromatic fringe observation (VAMFO) (16). In order to use the VAMFO instrument it was necessary to mask a portion of the substrate during deposition or etch a portion of the film down to the substrate to produce a step in the nitride film. Refractive indices measured by VAMFO were in the range of  $2.00 \pm 0.02$ .

A Carey spectrophotometer (Model 14) was adapted to measure the thickness of the nitride film (17, 18). The visible and ultraviolet regions were used for the measurement of thickness down to about 1500Å. Measurements of thickness by the spectrophotometer and the VAMFO were in agreement to within 200-300Å, with the spectrophotometer always giving the higher value.

In order to make the necessary electrical measurements, gold dots 5000Å thick and 0.004-0.025 in. in diameter were filament evaporated onto the layers. Back contact to the samples was made by gold plating the silicon substrate.<sup>2</sup>

Dielectric strength tests were made using dc potential applied as a voltage ramp, increasing at a constant rate of 100 v/min. The voltage ramp was generated

<sup>2</sup> The plating was accomplished by use of an HF + E55 acid-gold solution (Englehard Industries), followed by 25 msl of alkaline cyanide electroplate gold.

by use of a motor-driven potentiometer, supplied by a regulated high-voltage power supply. The measurements were made using a Keithley Model 610A electrometer and a Hewlett-Packard Model 425A microammeter; the raw data were displayed on a strip chart recorder fed directly from the microammeter. For most tests, the polarity of the gold dot was negative (silicon positive). For the tests described, dielectric breakdown is defined as occurring at that voltage which is sufficient to produce sudden and irreversible damage to the film, resulting in the permanent loss of its normal insulating properties under the contact being tested.

MIS capacitance measurements were made using a Boonton capacitance bridge, Model 74C-S8, operating at a frequency of 100 kc, with a peak-to-peak signal of approximately 10 mv. The technique used was to start at zero and then apply an increasing negative bias to the gold dot until the maximum desired voltage was reached. The bias was then decreased back to zero and on to the maximum positive bias before it was returned finally to zero. From the capacitance-voltage curves the sum of surface charge plus surface state densities was determined from the flat-band condition, as described by Grove *et al.* (19). Dielectric constant values were also computed from the maximum capacitance values of these curves. In some instances, surface state densities were also obtained from conductance curves, as described by Nicollian and Goetzberger (20).

Tests for charge storage were made as previously described by Yamin and Worthing in their study of silicon dioxide (21, 22).

Sodium drift and diffusion experiments were conducted as previously described by Dalton (7).

### Experimental Results of Varying Deposition Conditions

The first part of this study was concerned with the influence of the deposition variables on the kinetics of the process. Figure 3 shows the effect of  $SiCl_4$  partial pressure on the deposition rate with constant  $NH_3$  partial pressure. The mol fraction of  $SiCl_4$  was varied from  $7 \times 10^{-5}$  to  $2 \times 10^{-3}$  while the  $NH_3$  mol fraction was kept at  $4 \times 10^{-2}$ . The slope of the curve illustrated in Fig. 3 is approximately 0.8.

The effect of changing the  $NH$  partial pressure at constant  $SiCl_4$  partial pressure was studied. The mol fraction of the  $NH_3$  was varied from  $4 \times 10^{-3}$  to  $7 \times 10^{-2}$  while the mol fraction of the  $SiCl_4$  was held at  $2 \times 10^{-4}$ . It appeared that varying the  $NH_3$  concentration had no effect on the deposition rate. However, even at the lowest  $NH_3$  concentration there was still an order of magnitude more ammonia than silicon tetrachloride. A second set of conditions was then

Fig. 3. Effect of  $SiCl_4$  partial pressure on deposition rate (at 1000°C and  $NH_3$  partial pressure of 28 Torr).

Fig. 4. Temperature dependence of silicon nitride deposition at  $2 \times 10^{-4} : 4 \times 10^{-2}$  and  $1 \times 10^{-5} : 2 \times 10^{-2}$  mol fractions, respectively, of  $\text{SiCl}_4 : \text{NH}_3$ .

chosen, where the  $\text{NH}_3$  mol fraction was varied from  $2 \times 10^{-3}$  to  $4 \times 10^{-2}$  and the  $\text{SiCl}_4$  mol fraction was maintained at  $2 \times 10^{-3}$ , a factor of 10 higher than in the previous conditions. Again there was no marked effect even when the mol ratio of  $\text{NH}_3$  to  $\text{SiCl}_4$  fell to unity.

The free energy ( $\Delta G^\circ$ ) of the reaction of  $\text{SiCl}_4$  plus  $\text{NH}_3$  to form silicon nitride (see Table I) is negative almost down to room temperature. Figure 4 shows the results of varying the deposition temperature at two different vapor phase concentrations of reagents. The apparent activation energy ( $\Delta H_a$ ) obtained was  $15 \pm 1.5$  kcal/mol.

Silicon nitride films were deposited between  $550^\circ$  and  $1225^\circ\text{C}$  with films ranging in thickness from  $500\text{\AA}$  to  $2\mu$ . The  $2\mu$  thick layer caused a slight bending of  $0.010$  in. thick substrates concave upward; under  $300\times$  magnification, hairlike cracks were readily visible in this film. However, a film  $1.8\mu$  thick deposited on silicon caused no bending of the substrate even though cracks were seen in the film when it was examined under  $300\times$  magnification. When this film was exposed to a water-amine-pyrocatechol etching system (23) at  $95^\circ\text{C}$  for 30 min, additional hairlike cracks started to appear (see Fig. 5). It was possible to observe the

Fig. 5. Photomicrograph of  $1.8\mu$  thick film with "cracks" after it has been etched with water-amine-pyrocatechol system. (Magnification ca.  $200\times$ .)

"growth" of these new cracks as etching proceeded. The crack from lower left to center appeared first and then started to get broader before the crack from upper left to lower right appeared. Still later, the crack from center to upper right appeared, and at this point the etching was terminated. The reason for the way these cracks appeared is not known at this time, but one possible explanation might be the relief of strain by preferential stress corrosion of the sample. Films  $4000\text{\AA}$  thick or less did not show any cracks either before or after exposure to the water-amine-pyrocatechol etching system.

Figure 6 is a plot of the etch rate in concentrated (49%) HF of the samples deposited for the upper curve of Fig. 4. Note that as the deposition temperature decreased the deposition rate decreased but the etch rate of the samples increased.

Optical transmission studies, with a Xenon lamp as a source, were performed on a  $4000\text{\AA}$  thick silicon nitride film deposited on a sapphire substrate; the effective band gap of the film was found to be  $5.6 \pm 0.2$  ev.

In an attempt to identify the crystal nature and chemical composition of the deposited films, transmission electron diffraction and infrared absorption measurements were made. The electron diffraction patterns obtained on films deposited at all the temperatures studied showed only very diffuse rings, which could not be identified, and which indicated that the films were always amorphous. The infrared spectrum obtained on films deposited at  $550^\circ$  and  $1000^\circ\text{C}$  showed the characteristic Si-N band (13) (see Fig. 7). However, it is clearly seen that the films grown at these two temperatures are not identical. This is not surprising in light of the possible mechanisms for the reaction of  $\text{SiCl}_4$  with  $\text{NH}_3$ .

#### Discussion of Deposition Kinetics

The mechanism involved in the deposition of a nitride film from  $\text{SiCl}_4$  and  $\text{NH}_3$  is not understood at this time. Sneed and Brasted (24) indicate that the reactions involved in the formation of silicon nitride are

Fig. 6. Etch rate in concentrated HF of silicon nitride films deposited at different temperatures.

Fig. 7. Infrared analysis spectra: a, spectrum of film deposited at 1000°C; b, silicon substrate blank; c, spectrum of film deposited at 550°C.

Billy (9) claims, however, that at room temperature

which, on continued heating, yields  $\text{Si}_3\text{N}_4$  by stepwise loss of  $\text{NH}_3$  schematically represented by

There is a discrepancy between Billy and Sneed and Brasted about the temperature necessary to obtain the  $\text{Si}_3\text{N}_4$  form; Billy claims that  $\text{Si}_3\text{N}_4$  can be achieved at 1000°C, while Sneed and Brasted say that 1200°C is required.

Billy notes that  $\text{Si}_3\text{N}_4$  can be obtained in the pure form at 550°C by thermally decomposing pure  $\text{SiN}_2\text{H}_2$ , but he also notes that the presence of  $\text{NH}_3$  or  $\text{NH}_4\text{Cl}$  will have a strong influence on the decomposition

mechanism. We have also seen an influence of  $\text{NH}_4\text{Cl}$  on the deposition kinetics. During our depositions, a white powdery material formed on the upper and lower portions inside of the reactor wall. X-ray analysis showed it to be an impure form of  $\text{NH}_4\text{Cl}$ , possibly containing silicon amine compounds but definitely having no silicon oxide, chloride, nitride, or oxynitride. The reactor wall in the area immediately around the pedestal was clear and uncoated. If three or more depositions were attempted without a cleaning of the reaction chamber, the  $\text{NH}_4\text{Cl}$  built up on the reactor wall would begin to flake off onto the silicon substrate. It was therefore instituted as standard procedure that the reactor tube and pedestal shield be cleaned after every run.

In order that the influence of  $\text{NH}_4\text{Cl}$  might be studied, a series of measurements was performed starting with a clean-walled reactor. Silicon tetrachloride and nitrogen were admitted into the reaction chamber while the substrate temperature was maintained at 1000°C. No visible deposit was obtained on the silicon after 30 min under these conditions. Ammonia was then admitted to the reaction chamber in addition to the silicon tetrachloride plus nitrogen, and both the silicon substrate and the walls were coated. The nitride-coated silicon slice was then removed after the reactor was cooled and purged; the  $\text{NH}_4\text{Cl}$  was not cleaned from the reactor walls. A new silicon slice was then placed in the reaction chamber. Again, after the normal nitrogen purge of the system, only nitrogen and silicon tetrachloride were introduced, and this time a very slow deposition of nitride was observed on the silicon slice. These findings indicate that the material deposited on the walls contributes  $\text{NH}_3$  to the ambient.

Another influence of  $\text{NH}_4\text{Cl}$  was observed when the wall of the reaction tube was separately heated with heating tape to 300°-350°C during a deposition. The deposition rate was found to increase by a factor of 5 over that obtained under the equivalent cold-wall conditions.

It is impossible at this time to expound further on the possible reaction mechanism, since no detailed analytical measurements have been made on the film or on the gaseous reaction products.

### Results of Electrical Measurements

The dielectric strength was found to range from about 0.5 to  $1 \times 10^7$  v/cm for all the films tested and to be independent of contact area, film thickness, or conductivity type of the substrate. Samples that were exposed to a water-amine-pyrocatechol etching system at 95°C for 30 min had a negligible pinhole count.<sup>3</sup> This is in agreement with the observed absence of area dependence of breakdown, which might be expected to occur in the presence of defects of the type reported by Lopez (26). Insulating films deposited by other processes have frequently shown a rather strong contact area dependence of dielectric strength.

The absence of a film thickness effect (in the range 1000-6000Å) for the dielectric strength (27) can be explained by the fact that the films were amorphous in structure (28), as was revealed by electron diffraction studies. The dielectric strength was also about the same whether the contact was made positive or negative, although usually the negative polarity was used. Inasmuch as some degree of time dependence of breakdown was found at either polarity, and in view of the rather high current levels sustained prior to breakdown, it appears likely that the true intrinsic value of dielectric strength for these films is somewhat higher than the  $1 \times 10^7$  v/cm value quoted above. Varying the rate of application of potential by a factor of 10 did not change the breakdown levels.

<sup>3</sup> The water-amine-pyrocatechol etching system has been shown to be capable of delineating pinholes or potential pinholes in silicon nitride films (25).

Fig. 8. Curve A, sample M92B—3200Å thick film on a 2 ohm-cm, p-type substrate with a 0.025 in. diameter gold dot and negative polarity on the gold (200°C). Curve B, sample M92B—3200Å thick film on a 2 ohm-cm, p-type substrate with a 0.025 in. diameter gold dot and negative polarity on the gold (room temperature). Curve C, sample M76A—3650Å thick film on a 0.01 ohm-cm, n-type substrate with a 0.018 in. diameter gold dot and negative polarity on the gold (room temperature). Curve D, sample M87A—3800Å thick film on a 70 ohm-cm, p-type substrate with a 0.013 in. diameter gold dot and negative polarity on the gold (room temperature).

In the measurement of dielectric strength, when the applied field reached about  $3 \times 10^6$  v/cm, a rather steep rise in conduction was observed. In Fig. 8 the log of current has been plotted against applied field for several samples; curves B, C, and D show the increase in conduction for three different film samples, all at room temperature, and with negative polarity on the contact dot.<sup>4</sup> The difference in relative levels of these curves at low fields is thought to be due to difference in capacitance. Film thickness for the three samples increases, contact area decreases, and hence capacitance decreases, from left to right. Since potential is being applied by the voltage ramp technique, the current is equal to the charge derivative with respect to time. In other words, the relatively flat portions of the curves observed below a field of about  $3 \times 10^6$  v/cm represent charging current. The conduction phenomena observed at higher fields is probably not related to dielectric failure or thermal breakdown (29) (except possibly in a very small range lying very close to the intrinsic dielectric strength), since it does not cause permanent loss of normal insulating properties of the film. With reference to curve B of Fig. 8, the voltage ramp was stopped when the field reached  $5.6 \times 10^6$  v/cm (arrow), and conduction remained at a level of  $3.5 \times 10^{-6}$  amp for 10 min. Thereafter, the voltage ramp was restarted and the conduction curve was retraced about 10 times between  $10^{-7}$  amp and  $10^{-3}$  amp (dashed portion of the curve). Breakdown eventually occurred when the field was increased to  $6.4 \times 10^6$  v/cm; conduction just prior to breakdown was well in excess of 3.0 ma (full scale of our meter). High conduction phenomena in nitride films have also been observed by Doo and Nichols (30) in films obtained from silicon hydride

<sup>4</sup> The negative polarity was originally chosen for this measurement in an attempt to avoid the type of gradual time-dependent breakdown previously reported (29) for atmospheric-pressure, steam-grown  $\text{SiO}_2$  films. When a few tests were performed on the nitride with the opposite polarity, results similar to those reported here were obtained.

and ammonia and by Hu and Gregor (31) in reactively sputtered nitride films.

In an attempt to learn something of the mechanism of conduction, the sample from which the data for curve B were obtained was heated to 200°C and curve A was obtained. The displacement of the curve to the left at 200°C would seem to rule out impact ionization or avalanche multiplication as the mechanism of conduction; if the latter were responsible one would expect the shift to be in the other direction (32). Tests performed at liquid nitrogen temperature indicate that the high conduction at high fields can be virtually eliminated at low temperature. For one sample tested, with an applied field of  $8.3 \times 10^6$  v/cm, a conduction of  $1.2 \mu\text{a}$  at room temperature decreased to 0.005 na at liquid nitrogen temperature. This would tend to rule out both field emission and impact ionization as mechanisms of conduction. The mechanism tentatively proposed at the present time is deep-trap ionization by field-assisted thermal excitation (Frenkel-Poole effect) (33). The fact that silicon nitride films can show the type of conduction observed here can perhaps be explained by the presence of mechanical strain in the films, as suggested by results obtained with the water-amine-pyrocatechol etching system (see Fig. 5), or by the presence of impurity atoms. It is known that the density of isolated levels or deep traps increases with mechanical strain, with the presence of foreign atoms, and with rise in temperature (34).

The prebreakdown conduction phenomena reported here are not believed to be of the type associated with moisture, since the conduction appears to be only slightly responsive to varying percentages of relative humidity. Furthermore, heating generally causes an increase rather than a decrease in conduction for a given applied potential.

On a good steam-grown oxide on silicon, surface charge densities of  $2-4 \times 10^{11}$  charges/cm<sup>2</sup> and surface state densities of about  $2 \times 10^{11}$  states/cm<sup>2</sup> are obtained from a combination of conductance and capacitance measurements (19, 20). Figure 9 is the result of an MIS capacitance-voltage sweep made on a double dielectric layer (gold-silicon nitride-silicon dioxide-silicon) where the nitride was deposited on top of 1000Å of steam-grown oxide. Note that the value of  $3 \times 10^{11}$ /cm<sup>2</sup> for the sum of surface charge plus surface state density (19) indicates that the deposition of the nitride had no deleterious effects on the surface properties of the already existing Si-SiO<sub>2</sub> interface. For comparison, the normal values of surface charge plus surface state densities obtained when the nitride is deposited on bare silicon at a deposition temperature of 1000°C range from  $7-18 \times 10^{11}$ /cm<sup>2</sup> (see Fig. 10). Samples which have low surface charge densities generally also have low surface state densities. Values of surface charge and surface state densities are found to be fairly uniform among different contact dots on the same sample. Figure 11 is a plot for a nitride deposited on bare silicon at 850°C; the value of  $16 \times 10^{11}$ /cm<sup>2</sup> for the surface charge plus surface state density is

Fig. 9. MIS capacitance curve of a 0.010 in. diameter gold dot on a double dielectric layer (1850Å nitride on 1000Å oxide). The nitride was deposited at 1000°C and the silicon was 1 ohm-cm, p-type. The dielectric constant of the composite layer measures 5.0 and the SC + SS density is  $3 \times 10^{11}$ /cm<sup>2</sup>.

Fig. 10. MIS capacitance curve of a 0.015 in. diameter gold dot on a 1500Å thick nitride layer deposited on 35-40 ohm-cm, p-type silicon at 1000°C. The dielectric constant is 7.3 and the SC + SS density is  $17 \times 10^{11}/\text{cm}^2$ .

Fig. 11. MIS capacitance curve of a 0.015 in. diameter gold dot on a 1750Å thick nitride deposited on 35-40 ohm-cm, p-type silicon at 850°C. The dielectric constant is 7.1 and the SC + SS density is  $16 \times 10^{11}/\text{cm}^2$ .

comparable with those obtained on films grown at 1000°C.

In Fig. 10 and 11, there are indications of an instability in the passivation capabilities of the nitride as evidenced by the hysteresis loop in the capacitance-voltage plot. Carrier injection from the silicon, with subsequent trapping in the nitride, is probably one of the reasons for this behavior (35). In comparison, the data in Fig. 9 are typical of the stability seen in good oxide passivation of a silicon surface. It is still too early in the development of the nitride deposition work to say that this phenomenon is an intrinsic property of silicon nitride rather than a reflection of the level of technology at this time. It is believed that further development is needed to provide a better understanding of the process variables which influence conditions at the silicon-silicon nitride interface.

The value of dielectric constant, computed from the maximum capacitance values of the MIS capacitance curves, ranged from about seven to eight.

No charge storage of the type ascribed to ion drift in  $\text{SiO}_2$  (21, 22) could be found for any of the films tested.

Radioactive sodium drift experiments were carried out at 400°C with +2 to +8v applied to the contact dots for 1 min each. Radiotracer analyses showed that these films provide a barrier to sodium drift under

Fig. 12. Thermal diffusion of Na at 600°C into a steam-grown silicon dioxide film and into a silicon nitride film deposited at 1000°C. Courtesy of J. V. Dalton.

the conditions of voltage, time, and temperature described. Incremental etching and counting after drifting showed that all active sodium was removed with <100Å of the film. Tests conducted in the same manner on  $\text{SiO}_2$  films have shown that sodium drifts through the film and piles up at the Si-SiO<sub>2</sub> interface (36).

Thermal diffusions of Na were carried out at 600°C for 22 hr on the silicon nitride films. Diffusion profiles of the diffused samples showed that thermal diffusion takes place to a much smaller degree than in atmospheric-pressure steam-grown  $\text{SiO}_2$  (Fig. 12). Incremental etching and radiotracer counting of the silicon nitride films after diffusion of the  $\text{Na}^{22}/\text{Na}^{23}$  tracer source showed that all active sodium was removed with <200Å of the film.

### Discussion of Electrical Measurements

The panacea for complete surface passivation and control still has not been found. Silicon nitride does provide a better diffusion mask than silicon dioxide against unwanted impurities, but a penalty must be paid in that surface state and surface charge densities are higher with the former material. Generally, this process has yielded numbers for surface charge plus surface state densities of  $7\text{--}18 \times 10^{11}/\text{cm}^2$  when the deposition was done at 1000°C. Surface charge plus surface state densities of  $10\text{--}16 \times 10^{11}/\text{cm}^2$  were not uncommon when the deposition temperature was dropped to 850°C. It is possible that improvements might result from additional work on the process, but for the present the nitride films seem to have at least one half an order of magnitude more surface charge plus surface state densities than good oxide films. Additionally, the problem of hysteresis effects might also respond to improvements in processing.

### Conclusions

It has been demonstrated that a dielectric film can be deposited very easily on a silicon substrate by reacting  $\text{SiCl}_4 + \text{NH}_3$  at elevated temperatures. Infrared spectra of the films and some of their electrical and optical properties have been determined. The use of the films as protective coatings and as diffusion masks is clearly indicated.

Although some of the kinetics of the process have been determined, the mechanism is still far from clear.

### Acknowledgment

It is a pleasure to thank J. P. Luongo for the infrared measurements; Miss D. Margel for the electron

diffraction and x-ray analyses; G. P. Carey and P. A. Byrnes for MIS capacitance and conductance measurements; A. Frova for the bandgap measurement; and T. M. Buck, S. M. Sze, and M. J. Rand for many helpful suggestions.

Manuscript received June 23, 1967; revised manuscript received Jan. 22, 1968. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966, as Abstract 148.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Phosphors Based on Rare Earth Phosphates Fast Decay Phosphors

R. C. Ropp\*

Westinghouse Electric Corporation, Bloomfield, New Jersey

#### ABSTRACT

Phosphors based on rare earth phosphates and activated by Ce<sup>+3</sup> can be prepared with efficiencies comparable to the previously known P-16 phosphor as well as having operating maintenance characteristics essentially equivalent to it. In addition, the rare earth phosphate phosphors have decay times nearly three times faster than this commercial material. These new materials may open applications in electronic devices not feasible before.

Decay time of luminescent materials is important in many electronic applications, but has little significance in others. For example, it is not critical in 60-cycle fluorescent lamp operation, but is of major concern for devices such as a flying-spot-scanner since it limits the rapidity of rescan of the device.

Decay time can be classified in two broad categories, exponential and logarithmic, the former being proportional to  $e^{-t}$  and the latter to a power function such as  $t^{-2}$  (1). Many luminescent materials possess an exponential decay so that it is common to express a time constant as  $1/e$  (time to decay to 37% of the original intensity,  $I_0$ ), or, alternately, time to decay to 10% of  $I_0$ . Common decay times range from a few milliseconds (e.g., parity forbidden spin reversal of Mn<sup>+2</sup>) to several hundred nanoseconds (e.g., allowed

dipole transitions). Fast decay phosphors in the nanosecond range have usually involved the Ce<sup>+3</sup> activator particularly for cathodoluminescent materials. P-16, a widely used phosphor, is a calcium magnesium silicate activated by Ce<sup>+3</sup> and has a decay time of about 120 nsec. A phosphor with still faster decay time also involved the Ce<sup>+3</sup> activator and was described by Struck (2). Recently, Blasse and Brill, have also described Ce<sup>+3</sup> in Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub> (3) as a fast decay material.

In 1941, the emission of Ce<sup>+3</sup> in 29 different hosts was surveyed by Kroger and Bakker (4). Next followed a survey of ultraviolet emitting phosphors for fluorescent lamp application in 1947 by Clapp and Ginther (5). A fairly comprehensive study of fast decay phosphors for flying spot cathode-ray tubes was made in 1951 by Brill and Klasens (6). The most recent survey covers ultraviolet emission but does not

\* Electrochemical Society Active Member.

mention decay time (7). The present paper presents a survey of the rare earth phosphates, activated by  $Ce^{+3}$ , with particular reference to decay time and emission properties.

### Experimental Methods

**Preparation of phosphors.**—Phosphors were prepared by precipitating solutions of the appropriate rare earths with a dilute solution of phosphoric acid. Mixtures of the ions were made, including a soluble salt of the activator, before precipitation. An excess of phosphate was maintained at all times by adding the rare earth solutions to the phosphoric acid solution. Because of the method of preparation, no mixing or blending steps were necessary prior to firing to obtain a uniform and homogeneous composition. In general, a hydrated product was obtained, but the degree of hydration was a function of the nature of cations present, concentration of reagents, and temperature employed during the course of precipitation. The materials as produced were then fired to form the phosphor composed of the desired solid solution of phosphates. Firing in air was accomplished in open silica crucibles placed at temperature in a large globar furnace.

**Measurements.**—Excitation and emission spectra of photoluminescence were obtained with the aid of a commercial spectrofluorimeter (8) which provided a constant energy beam over the range of 20,000–50,000  $cm^{-1}$  (5000–2000Å) and recorded energy corrected spectra directly. Resolution of the instrument varied from a few angstroms in the ultraviolet to about 10Å in the red region of the spectrum. Intensity data were obtained by instrumental integration of the emission bands by means of an integrator directly attached to the recorder.

Most of the cathode-ray intensity data were obtained in a demountable vacuum system consisting of an electron gun and a turntable carrying the phosphor samples, all located in an evacuated glass chamber. The tetrode gun had a tungsten anode and was located about 20 in. from the final anode. Normal operating voltage was about 20 kv with a beam spot size of 5 mm. The phosphors, located in 1.0-cm holes, were viewed one at a time from the bombarded size by means of a first surface 45° plane mirror, a quartz mirror, and a quartz lens. No charging effects from the defocused beam were observed. Decay time was measured in a separate apparatus employing a pulsed electron beam having a rise time of ½ nsec. Emission from the phosphor caused a response in a separate photomultiplier which was displayed on an oscilloscope. Resolution was not limited by the time-constant of the experimental apparatus.

### Experimental Results

Both  $LaPO_4$  and  $GdPO_4$  are monoclinic and possess the monazite structure;  $YPO_4$  is tetragonal and has the xenotime structure (9).  $Ce^{+3}$  in each, or any combination of the three compounds, yields both photo- and cathodoluminescence, characteristic of the structure. Shown in Fig. 1 are photoluminescence spectra for phosphors containing 5 g-a/o (gram-atomic per cent) of  $Ce^{+3}$  per mol of phosphate. Note that the emission bands peak in the ultraviolet as expected, but that their position is a function of structure and composition. The emission peaks of  $Ce^{+3}$  in  $GdPO_4$  and  $LaPO_4$  are near 3200°, whereas in  $YPO_4$ , they are nearer 3500Å.

The excitation bands are more difficult to analyze. It was shown previously (10) that the excitation bands which appear at highest energy in  $La_2O_3:Gd$  and  $Y_2O_3:Gd$  could be attributed to cationic exciton absorption. A similar explanation was made for  $LaPO_4:Gd$  and  $YPO_4:Gd$  spectra in a prior paper (11) because of identical energy positioning. For  $YPO_4:Ce$  and  $LaPO_4:Ce$  phosphors, the highest energy bands might be caused by absorption due to formation of

Fig. 1. Photoluminescence of some cerium-activated rare earth phosphates.

exciton states or they may be due to crystal field effects on the  $4f^1 \rightarrow 5d^1$  transition of  $Ce^{+3}$ . In addition, these bands could also be attributed to upper excited states of  $Ce^{+3}$  and might well include such transitions as  $4f^1 \rightarrow 6s^1$ .

However, in  $GdPO_4:Ce$  a further solution of the excitation processes can be presented. Excitation in the  $4f^7$  levels (transition:  $^8S_{7/2} \rightarrow ^6I_J$ ) causes both  $Gd^{+3}$  and  $Ce^{+3}$  emission, the latter from energy transferred from excited  $Gd^{+3}$  centers. This can be demonstrated more clearly by considering the effects of  $Ce^{+3}$  concentration in  $GdPO_4$  (typical spectra are given in Fig. 2). At 0.01 g-a/o of  $Ce^{+3}$ , only  $Gd^{+3}$  excitation bands are seen as evidenced by the fact that each produces both  $Gd^{+3}$  and  $Ce^{+3}$  emission. The band at 3105Å is the typical emission found in all  $Gd^{+3}$  containing phosphors (i.e.,  $^6P_J$  levels). However, at 2.5 g-a/o  $Ce^{+3}$ , the  $Ce^{+3}$  band at 3000Å produces only typical  $Ce^{+3}$  emission, whereas the  $Gd^{+3}$  excitation bands at 2740 and 2380Å produce both  $Gd^{+3}$  and  $Ce^{+3}$  emission. Thus, for the various phosphors shown in Fig. 1, one is led to the conclusion that each excitation band at lowest energy is probably due to  $Ce^{+3}$  excitation.

As a photoluminescent material,  $YPO_4:Ce$ , the most efficient phosphor, had an integrated output of only 36% of the commercial  $Ba_3SiO_5:Pb$  phosphor when excited by 2537Å and measured under identical conditions, as shown in Fig. 3.

Cathode-ray excitation produces spectra nearly identical to those from ultraviolet excitation except that the relative intensities of these phosphors vary somewhat more for the former than for the latter mode of excitation. The intensities shown in Fig. 4 are relative to one another whereas those of Fig. 1 were normalized so that the spectra could be more easily compared. Note that the spectra of  $YPO_4:Ce$  and  $LaPO_4:Ce$  are about equal in output intensity but

Fig. 2. Photoluminescence of cerium-activated gadolinium phosphate phosphors.

Fig. 3. Radiometric comparison of ultraviolet emitting phosphors

Fig. 4. Cathodoluminescence of  $Ce^{+3}$  activated phosphors

that of  $GdPO_4:Ce$  is much lower. Thus, in a device such as a cathode-ray tube,  $YPO_4:Ce$  should be much superior to the others when used in combination with an ordinary glass face-plate whose wavelength cutoff is usually about  $3300\text{\AA}$ . That this is true is shown in Fig. 5. Figure 5A shows the relative intensity of  $LaPO_4:Ce$  compared to a standard P-16 phosphor. Figure 5B shows the same phosphor when viewed through a glass face-plate while Fig. 5C shows a  $YPO_4:Ce$  phosphor as compared to the same P-16 phosphor, viewed through a similar glass face-plate of a 5-in. cathode-ray tube.

As shown in Fig. 6 for photoluminescence, the optimum activator concentration for the  $LaPO_4$  and

Fig. 5. Relative cathodoluminescence of  $Ce^{+3}$  activated rare earth phosphates.

Fig. 6. Optimum activator concentration

$GdPO_4$  compounds is about 7.5 g-a/o  $Ce^{+3}$  whereas it is about 5.0 g-a/o in the  $YPO_4$  material. Thus, 6.0 g-a/o  $Ce^{+3}$  represents a reasonable average for the three systems.

In the binary Y-Gd system, as shown in Fig. 7, the  $GdPO_4:Ce_{0.06}$  phosphor has about 10% of the output of the  $YPO_4:Ce_{0.06}$  phosphor as measured by comparison of peak heights. In the ternary Y-Gd-La system, as shown in Fig. 8, two types of emission appear, one

Fig. 7. Relative efficiency of  $Ce^{+3}$  activated rare earth phosphates.

Fig. 8. Luminescent intensity in the ternary system. Emission spectra: type I,  $LaPO_4:Ce$ ; type II,  $YPO_4:Ce$ .

similar to that of  $\text{LaPO}_4:\text{Ce}$  and the other to that of  $\text{YPO}_4:\text{Ce}$ . In this system, the relative peak heights of the ternary compositions were compared under constant energy excitation. In this way, a direct comparison of output was obtained even though wavelength positions of the emission bands changed.

It is interesting to find that no more than 10-15%  $\text{GdPO}_4$  can be tolerated in these systems without adversely affecting the over-all output. The limits of composition, to obtain the best cathodoluminescent phosphor as given in Fig. 8 for the ternary system are:

$$\begin{array}{l} \text{Y}_u \text{Gd}_v \text{La}_w \text{PO}_4 : \text{Ce}_x \\ \hline 95\% > u > 60\% \\ 20\% > v > 0\% \\ 25\% > w > 0\% \\ 15\% > x > 2\% \end{array}$$

At the  $\text{Y}_{0.80}\text{Gd}_{0.10}\text{La}_{0.10}\text{PO}_4:\text{Ce}_{0.06}$  composition, the decay time to  $1/e$  was found to be 40 nsec, when compared to a standard P-16 phosphor whose decay time was measured to be 114 nsec, as shown in Fig. 9. These results were obtained using a gated oscilloscope with photomultiplier, having a  $\frac{1}{2}$  nsec rise time and a 2 nsec pulse width. The decay time of the  $\text{LaPO}_4:\text{Ce}$  phosphor was also measured and found to be 32 nsec. Thus, structure does not seem to have a major effect on decay time.

The operating maintenance efficiency of these phosphors was determined to be similar to that of the standard P-16 phosphor, as shown in Fig. 9. A loss of about 50% of the original intensity occurs within 30 min of initial operation under the operating conditions employed for these cathode-ray tubes. This loss

Fig. 9. Comparison of decay time of two phosphors

Fig. 10. Comparison of maintenance of efficiency of  $\text{Ce}^{+3}$  activated phosphors.

indicated is much larger than those encountered under normal operating conditions. Taylor *et al.* (12) have studied various P-16 phosphors and concluded that the poor maintenance of P-16 phosphors in general was due to a surface degradation of the silicate host materials. In view of the results presented herein, it seems more logical that the operating loss is due to a change in the state of the  $\text{Ce}^{+3}$  activator rather than a change in the host material, particularly since equivalent results were seen and one was a phosphate and the other a silicate.

## Discussion

It has been shown that phosphors based on rare earth phosphates, and activated by  $\text{Ce}^{+3}$ , can be prepared with an output rivaling the P-16 phosphors as well as possessing essentially equivalent operating maintenance characteristics in a cathode-ray tube. In addition, the rare earth phosphate phosphors have decay times nearly three times faster than the best known commercial material P-16.

We can compare the emission properties of these phosphors with those described by Struck (2), who also found fast decay properties for  $\text{Ce}^{+3}$  in  $\text{LaPO}_4$  and  $\text{YPO}_4$ . Struck found identical emission properties for both of these matrices, in contrast to the results presented herein. In Struck's phosphors, the main emission peak occurred close to 3200Å. However, he prepared his materials by solid-state reaction of oxides and phosphates, a method which is certain to produce small amounts of meta and polyphosphates, as has been shown by the extensive and comprehensive work of Thilo (13). In contrast, precipitation from solution produces stoichiometric phosphates and completely different emission properties for  $\text{YPO}_4:\text{Ce}$ . The  $D_{2d}$  site symmetry (14) has a major effect on the transition probabilities so that the lower energy emission band contains the greater part of the total emission energy in  $\text{YPO}_4:\text{Ce}$  while in  $\text{LaPO}_4:\text{Ce}$ , the opposite is true. Since the site symmetry in  $\text{LaPO}_4:\text{Ce}$  is likely to be lower, this leads one to believe that Struck's results could be ascribed to a lower site symmetry in his  $\text{YPO}_4:\text{Ce}$  phosphor, particularly because of the remarkable correspondence of all of his emission bands. One of the probable causes for his results for  $\text{YPO}_4:\text{Ce}$  is nonstoichiometry (*i.e.*, lower symmetry cation site) attendant on the method of preparation employed.

In regard to application, we have found the  $\text{YPO}_4:\text{Ce}$  phosphor to be useful in a one-gun beam-indexing color television tube where the P-16 phosphor cannot be employed because of excessive decay times. In this tube, which is similar to one described previously (15), a mosaic of red-, green-, and blue-emitting-vertical-phosphor-stripes are arranged in a repetitive manner. This screen is aluminized, and a vertical pattern of  $\text{YPO}_4:\text{Ce}$  stripes is superimposed. The ultraviolet emission caused when the electron beam scans past the  $\text{YPO}_4:\text{Ce}$  stripe is picked up by a photomultiplier, and the signal generated is used to modulate the incoming color signals to position the electron beam on the desired color stripe. At the television frequencies employed, a nanosecond decay phosphor is mandatory in order to pinpoint the beam position during each sweep across the screen. The use of the  $\text{YPO}_4:\text{Ce}$  phosphor also obviated the requirement of a quartz window in the tube (and the attendant problems in installing it) in order to pick up the ultraviolet signal. In such a system, we obtained "white" screen brightnesses of 165 ft-L, which is approximately 300% of the current commercial production models.

## Mixed Valence Europium Phosphors

W. A. McAllister\*

Advanced Development Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

## ABSTRACT

Replacement of lanthanum in  $\text{LaPO}_4:\text{Eu}$  phosphors by barium-lithium pairs ( $\text{La}_{1-2x}\text{Ba}_x\text{Eu}_x\text{Li}_x\text{PO}_4$ ) leads to interesting emission characteristics: (i) line emission typical of  $\text{Eu}^{+3}$  for all ultraviolet excitation but most pronounced at short wavelength; (ii) A blue band for excitation wavelengths longer than 266 nm, for certain values of  $x$ ; (iii) a uv band prominent under the same conditions favoring the blue emission. Results of x-ray and microscopic examination indicate a single-phase material. It is concluded that the line emission is due to an  $\text{Eu}^{+3}$  center which receives energy from the host, the bands to different  $\text{Eu}^{+2}$  centers.

The characteristic that makes trivalent rare earth ions attractive as activators in phosphor and laser applications, intense emission in a narrow spectral region, is a barrier to gross spectral shifts. Thus, while local site symmetry can alter the ratios of the intensities of the lines, the perceived colors are in the same range, e.g., orange-red for  $\text{Eu}^{+3}$ , green for  $\text{Tb}^{+3}$ . Drastic spectral changes are associated with changes in oxidation state of the rare earths. Thus  $\text{Eu}^{+2}$  typically has band emission peaked at shorter visible wavelengths than the red lines of  $\text{Eu}^{+3}$ . Coexistence of both species in the same host has not been reported often since the preparative techniques favoring trivalent and divalent europium involve oxidizing and reducing atmospheres, respectively. Jaffe and Banks (1) did include an emission spectrum with both band and line characteristics for hydrogen fired  $\text{CaO}:\text{Eu}$  in a paper on europium activated oxides and sulfides. Similar results, cited herein, were noted when barium-lithium combinations were substituted for lanthanum in  $\text{LaPO}_4:\text{Eu}$ -type phosphors using the raw mix formulation  $\text{La}_{1-2x}\text{Ba}_x\text{Eu}_x\text{Li}_x\text{PO}_4$ . The relative importance of the different emission characteristics, line and band, was found to be a function of europium concentration and excitation energy.

## Experimental

Phosphors were prepared by firing raw mixes of Lindsay Chemical (99.9%)  $\text{La}_2\text{O}_3$ ,  $\text{Eu}_2\text{O}_3$ , and Mallinckrodt  $\text{Li}_2\text{CO}_3$ ,  $\text{BaCO}_3$ , and  $\text{NH}_4\text{H}_2\text{PO}_4$  in an atmosphere consisting of nitrogen-2 v/o (volume per cent) hydrogen at 1250°C, using three 1-hr firings with grinding between firings. In the range  $x = 0.02$  to 0.20 the products were single phase materials in which emission properties varied with excitation wavelength and the magnitude of  $x$ . Details of the emission and

excitation spectra were examined at room temperature and with 254, 298, and 312 nm excitation wavelengths using a facility described previously (2). Reflectance characteristics were compared with a  $\text{BaSO}_4$  standard, in integrating spheres attached to a Cary Model 15 double beam spectrophotometer. X-ray powder diagrams were made using a Philips instrument with Geiger counter detector.

## Results

Phosphors with  $x = 0.06$  to 0.14 exhibited emission in (i) sets of lines in the red with peak intensities at 700, 610, and 595 nm, (ii) a blue band peaked at 480 or 420 nm, (iii) a uv band centered at 385 nm. The relative importance of these spectral features was a function of exciting wavelength and composition. These relationships are summarized as relative numerical intensities of emission peaks in Table I and, in part, by the emission spectra of Fig. 1. (Where the sets of lines are represented by the envelopes. These were not resolved further, the emphasis here being on

the appearance of  $\text{Eu}^{+3}$  and  $\text{Eu}^{+2}$  in the same host rather than on the levels within  $\text{Eu}^{+3}$ .) In the latter presentation, a number of curves were omitted for clarity. Those remaining serve to illustrate the influence of europium concentration and excitation wavelength on emission, it being evident that, in general, high europium concentration and long uv excitation favor the band, and low europium concentration and short wave uv excitation the line, emissions. There is, however, an exception for the peaks under long wave excitation at 312 nm (see Table I), both band and line intensities increasing with concentration although the change is not so pronounced for the latter.

An explanation for this behavior may be found in Fig. 2, the excitation spectrum for emission peaked at 595 nm. This curve strongly resembles a similar one reported for  $\text{LaPO}_4:\text{Eu}$  phosphor (3) and consists of a broad band at short uv wavelengths with structure in the region from 300 to 400 nm. One such peak is at about 312 nm where the band emissions of our phosphors were excited most effectively. The result is the small contribution to the line emission noted above. The excitation spectra for the bands were also determined, the findings being summarized in Fig. 3 and the following comments: (A) The excitation bands for 385 and 420 nm emission peaks are essentially identical. (B) These excitation spectra overlap that of the

Fig. 2. Excitation spectrum for line emission in  $\text{La}_{0.72}\text{Ba}_{0.14}\text{Eu}_{0.14}\text{Li}_{0.14}\text{PO}_4$  phosphor.

Fig. 3. Excitation spectra for emission bands in  $\text{La}_{0.72}\text{Ba}_{0.14}\text{Eu}_{0.14}\text{Li}_{0.14}\text{PO}_4$  phosphor.

480 nm emission peak and both lie within the wavelength range 200-400 nm in which  $\text{Eu}^{+3}$  emission is excited. (C) The 385 nm emission band overlaps the excitation band for emission peaked at 480 nm, but not for that peaking at 420 nm.

Thus all emissions are present to some extent for incident radiation from 200 to 400 nm and the uv and blue band emissions appear together as a result of overlapping excitation spectra. The reasons for the appearance of a band peaked at 420 nm remained unclear so materials in which either barium or europium was omitted were prepared. In Table II we see that, for samples without europium, there is a new emission centered at 335 nm but only for short wave excitation. (The excitation and emission spectra for this band are shown in Fig. 4.) Band emissions are very weak and line and 385 nm uv peaks are totally absent. Samples without barium also have no uv emission, while the line emission is absent for long wave excitation; the most prominent feature in these formulations is the 420 nm band.

The absorption characteristics were next examined, using reflectance measurements on the powders. The diffuse reflectance curves for phosphors with both barium and europium, in the uv region (Fig. 5) are in general agreement with data for  $\text{LaPO}_4:\text{Eu}$  (3). Materials without europium did not absorb well in the short wave region while those without barium absorbed best throughout the entire interval.

### Discussion

The line emission in this host is essentially a duplicate of that presented earlier for  $\text{LaPO}_4:\text{Eu}$  (3). The major peaks, 595 and 700 nm, are due to the  $^5\text{D}_0 - ^7\text{F}_1$  magnetic dipole and  $^5\text{D}_0 - ^7\text{F}_4$  electric dipole transitions, respectively, while 610 nm emission is due to the  $^5\text{D}_0 - ^7\text{F}_2$  electric dipole transition. The occurrence of these lines, in appreciable intensities, in the both  $\text{LaPO}_4$  host and our modified material, is interesting. Recent work on crystal structure sensitivity of  $\text{Eu}^{+3}$  emission (4) associates prominent 610 and 700 nm emission with occupation of sites lacking a center of inversion symmetry ( $\text{YAl}_3\text{B}_4\text{O}_{12}:\text{Eu}$ ), strong 595 nm emission in a host ( $\text{Ba}_2\text{GdNbO}_6$ ) with a center of inversion. The presence of all three in  $\text{LaPO}_4:\text{Eu}$  suggests several different crystallographic sites for the activator.

Fig. 5. Diffuse reflectance spectra for  $\text{La}_{1-2x}\text{Ba}_x\text{Eu}_x\text{Li}_x\text{PO}_4$  phosphors.

The crystal structures of rare earth phosphates have been reported (5, 6), both hexagonal and monoclinic forms being important. The mineral monazite, the  $\text{LaPO}_4:\text{Eu}$  and our barium modification all have the monoclinic structure, with over-all symmetry  $P2/n(C_{2h})$ . The rare earth in monazite is coordinated to the corners of four different phosphate groups by short (2.46Å) bonds and to two additional tetrahedra by four longer (2.66Å) bonds. Thus the local site has inversion symmetry and the strong 595 nm emission is expected for europium in such sites. The appearance of emission expected for sites lacking inversion symmetry must mean that replacement of lanthanum by europium in  $\text{LaPO}_4:\text{Eu}$  produces two types of sites, one having a small deviation from inversion symmetry.

The emission bands noted in  $\text{La}_{1-2x}\text{Ba}_x\text{Eu}_x\text{Li}_x\text{PO}_4$  are to be associated with the presence of  $\text{Eu}^{+2}$ . Such divalent europium emission bands have been reported with peaks at 480 nm in oxides and with various peaks in the range 400-600 nm in halides and silicates (7). This flexibility suggests extension to the near uv as reasonable. Further the excitation peak for the 385 (and 420) nm band is at 310 nm, near the 320 nm absorption peak for  $\text{Eu}^{+2}$  ( $\text{EuCl}_2$ ) in water (8). Interestingly the other broad absorption band found in the same investigation has a maximum at 248 nm so that short wave excitation of the  $\text{Eu}^{+2}$  centers is possible and (see Fig. 1) observed.

There remains the 420 nm emission band for consideration. Since it has an intensity in samples without barium which can be an appreciable fraction of the value noted in phosphors with both europium and barium, the emission must be due to isolated europium centers. While these are primarily  $\text{Eu}^{+2}$  centers, the data in Table II show that there is also 595 nm line emission in samples containing europium alone. Increased excitation wavelength and low europium concentration favor the blue band emission. The structure evident in the emission spectra where this band is pronounced (Fig. 1) indicate that it appears in addition to, rather than instead of, the 385 and 480 nm emission. This implies a second phase but none was de-

tected in the x-ray powder patterns or on microscopic examination under long and short wave excitation. Etching with mineral acids also did not disclose a surface phase different from the bulk material. The appearance of this peak at excitation wavelength-concentration combinations for which the line and band features are changing rapidly may signify disordering of the species substituting for host lanthanum.

The uv band emission peaked at 335 nm in  $\text{La}_{1-2x}\text{Ba}_x\text{Li}_x\text{PO}_4$  phosphors is not evident when europium is also present. The range covered by the band, 310-360 nm, coincides with that in which the other europium band and line emissions are well excited and cannot be isolated when europium is included. Also absorption in europium-containing materials is much better in the range where this host band is excited. The appearance of emission on introduction of Ba-Li pairs does indicate a change in the host favoring absorption in the short wave uv, where phosphates are usually transparent.

While the appearance of  $\text{Eu}^{+2}$  band emission is most simply explained by the use of slightly reducing atmosphere, the number of such bands demands some qualifying statement. A pertinent observation is the absence of any band emission when strontium or calcium were used for barium in a similar series of phosphors. Since the reduction of europium depends on the availability of an electron the appropriate differences between barium and the other alkaline earths, must be sought. One such comparison, that of orbital radii (9) and energy level, is given below with  $\text{La}^{+3}$  included. From the standpoint of energy level and ra-

Chemical species	Orbital radius, Å	Orbital
$\text{Ba}^{+2}$	0.87	5p
$\text{Sr}^{+2}$	0.68	4p
$\text{Ca}^{+2}$	0.54	3p
$\text{La}^{+3}$	0.819	5p

dius the barium is the best match for  $\text{La}^{+3}$ . Further the larger radius of  $\text{Ba}^{+2}$  permits greater overlap with nearly  $\text{O}^{2-}$  ions when barium replaces lanthanum and, as barium (and europium) concentration increases the possibility of the Ba-O-Eu configuration does also.

Now the spectral properties of europium have been investigated and the importance of charge transfer from the  $\text{O}^{2-}$  anion of the absorbing group to  $\text{Eu}^{+3}$  established for both liquids (10) and solids (11). This includes  $\text{LaPO}_4:\text{Eu}$  (3) and, in view of the similarity in  $\text{Eu}^{+3}$  excitation and emission in the two systems, the barium-containing materials we have prepared. This tendency of the oxygen to transfer an electron to europium coupled with the greater overlap of barium with the oxygen may lead to complete transfer, i.e., reduction of  $\text{Eu}^{+3}$  to  $\text{Eu}^{+2}$ , in configurations where barium and europium are separated by an oxygen anion. Exchange between cations separated by an anion have been used to correlate bonding with type of magnetic behavior observed (12) and extended to include optical phenomena such as luminescence quenching (13) and efficiency (14) in rare earth activated solids. It is proposed that the appearance of band emission here is due to a similar mechanism.

#### Acknowledgment

## Zinc Oxide and Zinc-Cadmium Oxide Phosphors

W. Lehmann\*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

### ABSTRACT

Zinc oxide phosphors may emit in four different bands, the ultraviolet near-edge emission, the common green band (possibly involving sulfur), a yellow-orange band due to selenium, and a red to near infrared band due to ammonia. About 10% of ZnO can be replaced by CdO with a corresponding shift, to lower energies, of the optical absorption edge, of the near-edge emission, and of the green emission. The possibility of an impurity activation due to anion substitution is discussed.

The best known luminescence of zinc oxide consists of a rather broad and structureless band in the green centered at about 2.4-2.45 eV. Partial replacement of ZnO by MgO and resulting shift of the green emission toward blue was reported by Smith(1). We have investigated the influence of a similar partial replacement of ZnO by CdO which does not seem to have been reported before.

Zinc oxide itself may emit in, at least, four different emission bands which are shown in Fig. 1. They are:

(a) The near-edge emission, a narrow and somewhat irregularly shaped band in the near-ultraviolet with the peak at about 3.18-3.20 eV at room temperature which is near the optical absorption edge of ZnO (~3.25 eV).

(b) The common green emission band whose origin is still a matter of considerable controversy [a discussion of it is given in ref. (2)].

(c) A yellow-orange band with the peak at 1.95-2.0 eV which appears in the presence of selenium (3, 4).

(d) A red to infrared emission band with the peak at about 1.55 eV which does not seem to have been reported before. We observed this emission in nominally pure ZnO fired in NH<sub>3</sub> at 1000°-1100°C. Similar fringes in either H<sub>2</sub> or N<sub>2</sub> are ineffective.

Our work on the influence of a gradual replacement of ZnO by CdO was limited to the first two of these four bands. The phosphors were prepared by firing either ZnO (luminescent grade purity) or intimate mechanical mixtures of ZnO and CdCO<sub>3</sub> (reagent grade) under conditions facilitating the one or the other emission band.

The green emission of ZnO is known to require slightly reducing firing conditions (5) and is observed to be enhanced by the presence of traces of sulfur (1, 3, 6). However, and in contrast to ZnO, an addition of a trace of sulfur to (Zn,Cd)O gives only poor results. Apparently, the sulfur reacts mainly with the cadmium and keeps it separate as CdS. Therefore, the (Zn,Cd)O phosphors were fired, without deliberate

addition of sulfur, in argon, at about 1100°C. Addition of iodine to facilitate particle growth is permissible and was not observed to have an effect on the emission spectrum which, in every case, consists of a single broad band corresponding to the green band of ZnO with little or no contribution of the near-edge emission.

The preparation conditions used to obtain near-edge emission in (Zn,Cd)O phosphors were those reported for ZnO phosphors (7). This technique completely isolates the near-edge emission with no detectable other emission bands.

Pure CdO ordinarily occurs in the cubic NaCl lattice. It is reported to be soluble in hexagonal ZnO (wurtzite lattice) only up to 4.9% (8). We observed CdO to be soluble in ZnO up to about 10 m/o (molar per cent) as determined by x-ray analysis, by optical reflection spectra, and by luminescence emission spectra. X-ray diffraction spectra of some samples are shown in Fig. 2 where separate lines, corresponding to the NaCl lattice of CdO, are visible at 15%, but not at 10% or below, of CdO added to the ZnO. Higher amounts of added CdO remain undissolved as separate phase which is clearly visible also at the dark body color of the samples. Evaluation of the x-ray spectra permits one to determine mean nearest neighbor dis-

Fig. 4. Optical reflection spectra of ZnO and of ZnO (90%)-CdO (10%).

tances in the lattice. Plotted as a function of the CdO concentration in Fig. 3, they are all, within the accuracy of these measurements, on a straight line connecting the values for ZnO (1.97Å) and the, in reality nonexistent, hexagonal CdO (2.14Å).<sup>1</sup> Hence, Vegard's law is fulfilled at least within the limited range of solubility.

Gradual replacement of ZnO by CdO causes the quantum energy corresponding to the optical absorption edge (or whatever is measured as such under ordinary conditions) to decrease. As a consequence, pure ZnO ordinarily is white, but a solid solution of 90% ZnO-10% CdO is slightly yellow in body color. Some optical reflection spectra demonstrating this shift of the absorption edge are given in Fig. 4.

<sup>1</sup> Determined from the sum of tetrahedral standard radii, Zn = 1.31Å, Cd = 1.48Å, O = 0.66Å.

The approximate peak position of the near-edge emission as a function of the CdO concentration is shown in Fig. 5 and compared with the corresponding shift of the absorption edge. Both curves are approximately parallel. While the near-edge emission of ZnO is in the near ultraviolet, that of a (Zn,Cd)O phosphor containing 10% of CdO is in the visible violet. Two measured actual emission spectra are given in Fig. 6. Gradual replacement of ZnO by CdO causes also the green ZnO emission to move towards lower quantum energies, i.e., toward yellow (Fig. 7). Measured spectra of ZnO, of a (Zn,Cd)O containing 10% of CdO and, for comparison, of a (Zn,Mg)O phosphor containing 20% of MgO, are shown in Fig. 8.

Conclusions to the origin or luminescence in ZnO phosphors may be drawn from these results. Various models have been proposed in the literature linking either the near-edge emission, or the common green

emission, or the yellow-orange emission of ZnO to native lattice defects (*e.g.*, oxygen vacancies) but there seems to be little agreement between the authors. Alternatively, it has been proposed that the green emission band of ZnO might be due to traces of sulfur dissolved in the ZnO lattice (3), and a correlation between the intensity of the green emission and deliberately added sulfur (1, 3, 6) and similar correlations between the yellow-orange emission and deliberately added selenium (3, 4, 6), and between the infrared band and the ammonia atmosphere during firing, undoubtedly do exist. The observation of at least some green emission in ZnO to which no sulfur was intentionally added is not considered to be a sure criterion since sulfur may easily be present in all ordinary "pure" ZnO to start with, or in the carbon black recommended by Leverenz (5), or even in the air, especially of a laboratory. Traces of sulfur in green emitting ZnO are not easily analyzed and may be present only in the ppm range.

The valence band of the predominantly ionic ZnO is mainly determined by the anion, *i.e.*, oxygen. Sulfur and selenium are isoelectronic to oxygen. If they are dissolved in ZnO substituting for oxygen, their effect may be to split states out of the valence band into the forbidden band gap, and particular emission may be due to an electron transition between such state and one of the band edges. Luminescence due to an isoelectronic anion impurity in a II-VI compound, CdS:Te, is known already (9). A similar situation is proposed for the red emission which appears to involve nitrogen and hydrogen (since firing in pure nitrogen, or in pure hydrogen, are ineffective) and which is proposed to be due to N-H pairs. A nitrogen replacing an oxygen atom in ZnO would be an acceptor, an interstitial hydrogen is a donor, consequently, a pair of both would be electrically as neutral as a sulfur or selenium substituting for an oxygen atom.

Gradual replacement of zinc by cadmium shifts the green ZnO emission towards lower energy similar to a corresponding of many emission bands in  $(\text{Zn,Cd})\text{S}$  phosphors which fairly unambiguously can be understood on the basis of a Schön-Klasens type of recombination (10). Hence, at least the green ZnO emission appears to be due to an electron transition from or near the conduction band edge into a valence state of the sulfur located above the upper edge of the valence band of the ZnO. The same probably holds also for the yellow-orange emission due to selenium and for the infrared emission due to ammonia although corresponding investigations involving a gradual replacement of zinc by cadmium are not yet made. The near-edge emission of ZnO and of  $(\text{Zn,Cd})\text{O}$  seems to behave differently in some respects, and its mechanism is still too uncertain to be discussed here.

A more practical consideration concerns the availability of ZnO-type phosphors of various emission colors due to gradual replacement of up to 10 m/o of ZnO by CdO. This shifts the extremely fast near-edge emission of n-type doped ZnO (7) out of the near ultraviolet into the visible violet. The energy efficiency of catholuminescence seems to be little affected by this shift, and although it is not too high (estimated: 1-2%), these materials may be useful in applications where high speed of response ( $\sim 10^{-9}$  sec or shorter) is imperative. By contrast, the efficiency of catholuminescence of green ZnO ( $\sim 6-7\%$ ) reduces to about 2-3%, at best, as soon as some ZnO is replaced by CdO. This lower efficiency of yellowish  $(\text{Zn,Cd})\text{O}$  (made without sulfur) compared to green ZnO (made with sulfur) seems to be due to the resistance of sulfur to be dissolved in the material whenever cadmium is present. At the moment, it is not known whether the situation can be improved.

# Doping of Epitaxial Silicon Films

W. H. Shepherd

Fairchild Semiconductor, Research and Development Laboratory, Palo Alto, California

## ABSTRACT

The doping of epitaxial silicon layers deposited by the hydrogen reduction of  $\text{SiCl}_4$  has been studied. The dopants used were phosphorus, arsenic, and antimony introduced as the trichlorides. In each case for fixed dopant to silicon ratios in the gas phase the film resistivity was found to increase with rising temperature and decrease with increasing growth rates. The results are explained by a model which takes into consideration both the transfer and thermodynamic properties of the reactor system. An analysis of the results then leads to values for the activity coefficients for phosphorus, arsenic and antimony in silicon.

In general, control of resistivity in epitaxial silicon films has not presented any serious problems and, as a result, there has been no strong incentive to investigate the mechanisms involved. Only Raichoudhury and Fergusson (1) have attempted an analysis. Wang *et al.* (2) showed that for a constant arsenic/silicon ratio in the gas phase the resistivity of layers deposited by the hydrogen reduction of  $\text{SiCl}_4$  was sensitive to temperature and to growth rate, but they made no serious attempt to establish the reasons. Nuttall (3) presented similar data for phosphorous and antimony, but again was unable to provide a good explanation for his results. In this paper, a model is proposed which is felt to be of general application. It is tested here for the specific case of layers deposited by the hydrogen reduction of  $\text{SiCl}_4$  and doped with phosphorus, arsenic, or antimony using trihalide sources of the impurities.

## Theory

The resistivity of an epitaxial layer is determined by the relative rates at which silicon and dopant atoms are added to the film. A previous paper (4) considered the processing governing the deposition of silicon by hydrogen reduction of  $\text{SiCl}_4$  in horizontal reactors. Here it will be assumed that the "deposition" of dopant at the silicon surface can be treated in the same manner. It is in order then to review briefly the silicon deposition process.

### Rate of Deposition of Silicon

Figure 1 shows film growth rate plotted logarithmically against  $1/T$   $^\circ\text{K}^{-1}$  for the small, six-wafer horizontal reactor used in this work. This relationship is typical, qualitatively at least, of most multiwafer reactors using hydrogen reduction of  $\text{SiCl}_4$ . The region at lower temperatures in which the growth rate varies exponentially as  $1/T$   $^\circ\text{K}^{-1}$  is called the kinetic region since it is thought that at these temperatures the rate-limiting process is the chemical reaction at the silicon surface. As the temperature is raised the chemical reaction rate increases rapidly, the surface concentration of  $\text{SiCl}_4$  falls, and the concentration gradient of  $\text{SiCl}_4$  normal to the surface steepens in order to meet the requirements of the faster surface reaction. A point is eventually reached where the surface concentration of  $\text{SiCl}_4$  is so much smaller than the bulk concentration that a further decrease in its value produces no noticeable increase in the concentration gradient. In this condition  $\text{SiCl}_4$  is being transferred from the gas stream at the maximum rate possible. It is now the transfer properties of the gas stream which determine the over-all deposition rate, and since these properties vary only slowly with temperature the mass-transfer region is characterized by a very low-temperature sensitivity of growth rate. In Fig. 1 a broken line shows how the growth rate should vary if transport limited throughout the temperature range (4).

In ref. (4) (Eq. 19) a model was developed to describe the deposition process in the mass transfer region. According to this model the rate of deposition,  $G$ , is given by an equation of the form

$$G = \Psi_s x_s - A \{ (1 + 2\Psi_s x_s)^{1/2} - 1 \}^2 \quad [1]$$

The first term on the R.H.S. of the equation represents the flux of silicon toward the growing surface as  $\text{SiCl}_4$  while the second term allows for the fact that silicon is lost from the surface as  $\text{SiCl}_2$ . In Eq. [1]  $\Psi_s$  is a gas transfer coefficient for  $\text{SiCl}_4$  in  $\text{H}_2$  and has the same units as those chosen for  $G$ , e.g.,  $\mu \text{ min}^{-1}$ , since  $x_s$  is the mole ratio of  $\text{SiCl}_4$  in the initial, unreacted gas stream and is dimensionless. The parameter  $A$  contains both thermodynamic and transfer terms but is essentially temperature independent and a constant for a specific deposition system.

For growth rates less than  $1.5 \mu \text{ min}^{-1}$  the second term can be neglected with a resultant error of only a few per cent and even at  $2.5 \mu \text{ min}^{-1}$  the error incurred is less than 20%. For simplicity then it will be assumed for the purposes of this paper that the growth rate is given simply by the first term in Eq. [1], and hence is linear in  $\text{SiCl}_4$  concentration, at least in the mass transfer region.

In the kinetic region the dependence of growth rate on concentration has not been determined. However the rate may be expressed in the form

$$G = f(T, x_s) \Psi_s x_s \quad [2]$$

where  $f$  is a function of temperature and possibly of  $\text{SiCl}_4$  concentration also. The growth rate *vs.* temperature data of Fig. 1 were obtained at a mole ratio of  $\text{SiCl}_4$  of 0.0048 and by conducting the experiments in the present work at the same concentration, (actually at a mole ratio of 0.0050),  $f$  can be determined empirically as the ratio of the actual growth rate to that expected for a mass transfer controlled process at

Fig. 1. Temperature dependence of silicon deposition rate for  $\text{SiCl}_4$  concentration of 0.48 m/o.

the same temperature (i.e., as indicated by the broken line). Actually then, Eq. [2] can be regarded as a general one in which  $f = 1$  in the mass transfer region.

#### Deposition of Dopant

The treatment adopted here parallels that used to develop the model for epitaxial deposition of silicon. That is, it is assumed that the reduction of the dopant compound takes place only at the heated surface, i.e., not in the gas phase or on the reactor walls, that all surface reactions are fast so that rate processes are mass transfer controlled, and that all dopant species at the surface, whether in the silicon or in the adjacent gas phase, are in thermodynamic equilibrium. The assumption that the rate processes are transfer controlled throughout the temperature range employed and that for none of the dopants is there a kinetic region such as observed for silicon is reasonable in view of the ease with which all of the pertinent chlorides are reduced in hydrogen at temperatures well below those of concern in this work. The surface equilibria of concern here are

where  $\text{X} = \text{P, As, or Sb}$  and  $\text{X(ss)}$  represents the dopant in solution at the silicon surface. Volume diffusion in the solid will be ignored. Thermodynamic data (5) indicate that for the experimental conditions used the reduction of the compounds,  $\text{XCl}_3$ , is essentially complete and further that for arsenic and antimony the only gaseous elemental species of interest at the silicon surface are monatomic. For phosphorus, particularly at the lower end of the experimental temperature range, both  $\text{P}$  and  $\text{P}_2$  should be considered, but since the only phosphorus doping data amenable to analysis were taken at the very upper limit of temperature, i.e.,  $1340^\circ\text{C}$ , it happens that in this case also only the monatomic species need be considered.

The situation then is that dopant compound transfers to the surface where it is completely reduced to monatomic elemental dopant. Some of this dopant is incorporated in the growing silicon film while some remains in the gas phase adjacent to the surface and in equilibrium with its solution in the silicon. Since there is a gradient of elemental dopant out from the surface, loss occurs from the surface to the bulk gas stream. In a steady state, which will be assumed to occur instantaneously, the material balance for dopant at the surface requires that the rate of transfer toward the surface in the form of the halide equals the rate of uptake by the film plus the rate of loss in the elemental form to the gas stream.

The rate of transfer of dopant halide to the surface per square centimeter, assuming a model analogous to that for silicon deposition, is

$$F_D = n\psi_D x_d \quad [3]$$

where  $x_d$  is the mole ratio of halide in the gas stream,  $\psi_D$  is the transfer coefficient for the halide in hydrogen, and  $n$  is an integer denoting the number of atoms of dopant per molecule of halide. Since  $n = 1$  for all the halides used, it will be omitted from subsequent equations. With  $\psi_D$  in  $\mu \text{ min}^{-1}$  the flux of dopant  $F_D$  has the same units.

The rate of transfer of elemental dopant away from the surface ( $F_E$  ( $\mu \text{ min}^{-1}$ )) is (ref. 4, Eq. 9)

$$F_E = \psi_E x_E \quad [4]$$

where  $x_E$  is the mole ratio of element in the gaseous equilibrium region close to the surface and  $\psi_E$  the transfer coefficient for elemental dopant.

The rate of incorporation of dopant in the film,  $F_I$ , can be written again in  $\mu \text{ min}^{-1}$ , as

$$F_I = GR_s \quad [5]$$

where  $R_s$  is the atom ratio of dopant in the silicon at the silicon-gas interface. Since we have identical numbers of atoms per cubic centimeter for dopant and silicon the film thickness ratio is identical with the atom ratio.

One further relationship is necessary. It has been assumed that equilibrium exists between gaseous and dissolved dopant, and since both are in monatomic dispersion and in general the solutions are dilute so that Henry's law may be applied, the equilibrium can be expressed in the form.

$$x_E = \gamma R_s \quad [6]$$

In all experiments the ambient pressure was 1 atm so that  $x_E$  is equivalent to a partial pressure of gaseous monatomic dopant in atmospheres and if, for the present purposes, unit activity of the dopant is defined as 1 atm pressure of monatomic species then  $\gamma$  is the activity coefficient for the dopant in silicon.

The dopant material balance previously enunciated is otherwise stated as

$$F_D = F_I + F_E$$

Substituting from Eq. [3] through [6] and rearranging gives

$$\alpha = \frac{R_s}{R_G} = \frac{1}{f(1 + \psi_E \gamma / G)} \frac{\psi_D}{\psi_S} \quad [7]$$

where  $R_G$  is  $x_d/x_s$  the atom ratio of dopant to silicon in the initial gas stream and  $\alpha$  is a distribution coefficient defined in the same manner as that used in conventional crystal growth from a melt. From Eq. [7] it appears that the effects to be investigated are mainly described by the term  $(\psi_E \gamma) / G$  and appear when this term is larger than unity. The behavior of  $\alpha$  for different magnitudes of  $\psi_E \gamma / G$  is considered briefly now.

(a) If  $(\psi_E \gamma) / G \ll 1$ , Eq. [7] simplifies to

$$\alpha = \frac{1}{f} \cdot \frac{\psi_D}{\psi_S} \quad [8]$$

In the mass transfer region where  $f = 1$  the distribution coefficient is simply the ratio of the transfer coefficients for dopant and silicon, and it is not influenced by growth conditions. Further, since the transfer coefficients probably do not differ by much more than a factor of two at the most, it is possible to predict that  $\alpha$  should have values in the range 0.5-2.0. In the kinetic range  $f$  becomes small and  $\alpha$  may increase above this range.

(b) At the other extreme when  $(\psi_E \gamma) / G \gg 1$ , Eq. [7] becomes

$$\alpha = \frac{1}{f} \cdot \frac{G}{\psi_E \gamma} \cdot \frac{\psi_D}{\psi_S} \quad [9]$$

which, since  $G = f\psi_S x_s$ , can be further reduced to

$$\alpha = \frac{\psi_D}{\psi_E} \cdot \frac{x_s}{\gamma} \quad [10]$$

As before  $\psi_D / \psi_E$  can be expected to be close to unity and to remain constant, but now  $\alpha$  is directly proportional to the concentration of  $\text{SiCl}_4$ ,  $x_s$ , and inversely proportional to the activity coefficient  $\gamma$  and hence is very much affected by growth conditions.

(c) The third situation is that in which  $\psi_E \gamma / G \cong 1$ . In this case  $\alpha$  may tend toward situation (a) or (b) depending on the exact conditions of growth.

The critical factor determining the magnitude of  $\psi_E \gamma / G$  is  $\gamma$ . Changing dopants will not affect  $\psi_E$  greatly and though, in principle  $G$  is infinitely variable, in practice growth rates are normally maintained within a narrow range, e.g., 0.3-1.0  $\mu / \text{min}$ . The activity coefficient,  $\gamma$ , however, may be varied over several orders of magnitude either as a function of temperature or dopant. Thus if  $\gamma$  is very large, i.e., the dopant evaporates readily from silicon, then the situa-

tion illustrated in (b) pertains and the distribution coefficient,  $\alpha$ , is sensitive to growth parameters. If  $\gamma$  is small so that the dopant has no tendency to re-evaporate from the silicon, then the situation in (a) holds and  $\alpha$  is insensitive to growth conditions.

### Experimental Details

The experiments were carried out in a small, six-wafer horizontal reactor previously described (4). The arrangement used then was modified by replacing the evaporative  $\text{SiCl}_4$  source with a liquid feed source. The  $\text{SiCl}_4$  flow was metered through a Fischer-Porter 1/16-08 size meter. This feed method was employed in order to maintain a constant atom ratio of dopant to silicon in the gas mixture in the simplest manner. The  $\text{SiCl}_4$  was doped in all cases with the trichloride of the element to be used, i.e., with  $\text{PCl}_3$ ,  $\text{AsCl}_3$ , or  $\text{SbCl}_3$ . First, a master solution was prepared by adding a known volume, approximately 0.5 ml, of the chloride to 1000 ml of undoped  $\text{SiCl}_4$  (better than 100 ohm-cm n-type) in a fused quartz flask. This was shaken and allowed to stand for 24 hr to ensure mixing. The solutions doped with arsenic and antimony were then chemically analyzed and found to be within 20% of the expected concentrations. In the case of the phosphorus master solution, analysis was considered to be too inexact to be worthwhile. The master solutions were diluted further in the same manner to produce the final mixtures. The atom ratios of dopant to silicon used were: phosphorus  $1.1 \times 10^{-6}$ ; arsenic  $1.2 \times 10^{-6}$ ; antimony  $8.8 \times 10^{-6}$ .

Epitaxial layer resistivities were determined from V/I and groove and stain measurements on 15-20 $\mu$  thick deposits grown on boron doped substrates of approximately 1 ohm-cm p-type. Quoted resistivities and growth rates were averaged from measurements on three wafers. Temperatures were measured optically and corrected by amounts varying from 140°C at the highest temperature used to 100°C at the lowest.

### Results

**General discussion.**—Figure 2 shows the influence of deposition temperature on layer resistivity. All experiments were conducted at a constant  $\text{SiCl}_4$  concentration of 0.5 m/o (mole per cent) ( $\cong 1.0 \mu \text{min}^{-1}$  at 1250°C) rather than a constant growth rate, since this was experimentally simpler to control. Phosphorus exhibits virtually no change, antimony, a very marked increase in resistivity with rising temperature, while arsenic is intermediate in behavior. In Fig. 3, the distribution coefficients calculated from the resistivity data are plotted vs. deposition temperature. The most notable feature is the very low value of  $\alpha$  for antimony doping. Reference to the theoretical discussion of Eq. [7] through [10] indicates that for antimony in silicon  $\gamma$  is large and is the predominant factor in  $\alpha$ , for phosphorus  $\gamma$  is small, while for arsenic  $\gamma$  has an intermediate value.

Fig. 2. Temperature dependence of epitaxial layer resistivity for  $\text{SiCl}_4$  concentration = 0.5 m/o ( $\cong 1 \mu \text{min}^{-1}$  at 1250°C).

Fig. 3. Temperature dependence of  $\alpha$  for P, As, and Sb.  $\text{SiCl}_4$  concentration 0.5 m/o ( $\cong 1 \mu \text{min}^{-1}$  at 1250°C).

Figure 4 presents data on the influence of film growth rate on layer resistivity at temperatures in the mass transfer region. For the phosphorus study, a higher than normal temperature had to be employed to obtain readily observable effects. The distribution coefficients calculated from these data are plotted as a function of growth rate in Fig. 5. The results are consistent with those obtained from the temperature dependence of  $\alpha$  on the basis of the proposed doping mechanism. Thus, from Eq. [8] if  $\gamma$  is small,  $\alpha$  should tend to a limiting value, probably in the range 0.5-2.0 at high growth rates. This is observed for phosphorus. If  $\gamma$  is large,  $\alpha$  becomes small and directly proportional to growth rate. The data for antimony satisfy these conditions. For arsenic, the data appear to show a slight curvature, but insufficient to be conclusive and indicate no close approach to a limiting value.

Fig. 4. Growth rate dependence of epitaxial layer resistivity for P(1340°C), As(1240°C), and Sb (1270°C).

Fig. 5. Growth rate dependence of  $\alpha$  for P(1340°C), As(1240°C), and Sb(1270°C).

Calculation of activity coefficients.—Equation [7] can be rearranged to give

$$\gamma = \frac{\Psi_D}{\Psi_E} \left( \frac{1}{\alpha} - \frac{\Psi_S}{\Psi_D} \cdot f \right) x_s \quad [11]$$

This is a convenient form to employ for analysis of the  $\alpha$  vs. temperature data which were obtained for a constant  $x_s$ . The terms in this equation can be evaluated except for  $\Psi_E$  which cannot be separated from  $\gamma$  using any of the present measurements.

For antimony,  $\alpha < 10^{-1}$  at all temperatures investigated, and  $\gamma$  may be approximated from the simplified relationship

$$\gamma = \frac{\Psi_D}{\Psi_E} \cdot \frac{x_s}{\alpha} \quad [12]$$

For phosphorus and arsenic, it is necessary to evaluate the term  $(\Psi_S/\Psi_D) \cdot f$ .

The value of  $f$  can be obtained from Fig. 1 as previously indicated and for phosphorus  $(\Psi_S/\Psi_D)$  can be determined from the high growth rate limit of  $\alpha$  in Fig. 5. However, for phosphorus, the term  $1/\alpha - \Psi_S/\Psi_D \cdot f$  is very much smaller than  $1/\alpha$  or  $\Psi_S/\Psi_D \cdot f$  and the present data are insufficiently accurate to permit a worthwhile analysis except at the highest temperatures used.

For arsenic,  $\Psi_S/\Psi_D$  cannot be obtained from Fig. 5 since no rate limit of  $\alpha$  is observed. However, Eq. [7] may be written in the form

$$\frac{1}{\alpha} = \gamma \cdot \frac{\Psi_E}{\Psi_D} \cdot f \Psi_S \cdot \frac{1}{G} + \frac{\Psi_S}{\Psi_D} \cdot f \quad [13]$$

Hence, a plot of  $\alpha^{-1}$  vs.  $G^{-1}$  should be linear with an intercept on the  $\alpha^{-1}$  axis equal to  $(\Psi_S/\Psi_D) \cdot f$  (in the mass transfer region). Such a plot is shown in Fig. 6 from which a value of  $(\Psi_S/\Psi_D) \approx 0.4$  is measured. This would give the high-growth-rate limit for  $\alpha$ , if it could be achieved, as 2.5 which is reasonable.

Activity coefficients, or at least values of  $(\Psi_E/\Psi_D) \cdot \gamma$ , can be obtained also from Fig. 5, for the temper-

Fig. 6. Plot of  $1/\alpha$  vs.  $1/G$  for As doping at 1240°C

ature used. As the growth rate tends to zero,  $\alpha$  in all cases is given by Eq. [10] so that

$$\frac{d\alpha}{dx_s} = \frac{\Psi_D}{\Psi_E} \cdot \frac{1}{\gamma} \quad [14]$$

But in the mass transfer range  $G = \Psi_S x_s$  hence

$$\gamma \cdot \frac{\Psi_E}{\Psi_D} = \left( \Psi_S \frac{d\alpha}{dG} \right)^{-1} \quad [15]$$

where  $\Psi_S \approx 230 \mu \text{ min}^{-1}$  (4). Using Eq. [15] a value of  $(\Psi_E/\Psi_D) \cdot \gamma$  was calculated for phosphorus at 1340°C, and using Eq. [11] and [12] similar calculations were made for arsenic and antimony over a range of temperatures. The results are plotted in Fig. 7 as  $(\gamma \Psi_E/\Psi_D)$  vs.  $1/T \text{ K}^{-1}$ . We may reasonably make the assumption  $\Psi_E/\Psi_D = 1$ , and as for other ratios of gaseous transfer coefficients the uncertainty introduced should not exceed a factor of 2-3.

The phosphorus data points represented by open squares are calculated from the diffusion data of Coupland, (6), which related surface concentration to pressure of phosphorus vapor and hence can be analyzed to give  $\gamma$ . The data are in surprisingly good agreement with the single point (open circle) obtained in this work.

The data for arsenic and antimony plot linearly in Fig. 7 as they should if they represent activities, and all data are in the expected relative order, i.e.,  $\gamma_{\text{As}} > \gamma_{\text{Sb}} > \gamma_{\text{P}}$  (7).

Although the experiments have been performed using only the chlorides of the doping elements, the proposed doping model, if correct, shows that essentially the same results will be obtained regardless of the compounds used, e.g., hydrides. This is substantiated by the work of Wang *et al.* (2) for  $\text{AsH}_3$  and will still be true if the compound is unstable enough to decompose on the reactor walls so that the dopant passes through in elemental form. This may not be so obvious but an analysis similar to that presented above shows it to be so. Minor differences will result because of different transfer coefficients for various doping compounds but the basic characteristics are determined by the activity coefficient of the dopant which is not dependent on the doping compound employed.

## Effects of Back-Melting on the Dislocation Density in Single Crystals: GaSb

R. S. Mroczkowski,<sup>1</sup> A. F. Witt,\* and H.C. Gatos\*

Department of Metallurgy and, Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

## ABSTRACT

A pronounced reduction in dislocation density was observed in gallium antimonide single crystals after partial back-melting and controlled resolidification. The distribution of dislocations in the parent crystals and regrown sections was studied by etch-pit counting and x-ray topography (Lang method). The observed reduction in dislocation density was explained in terms of the dislocation distribution in the parent crystal and the geometry and thermal conditions of the back-melting process.

A back-melting process has been employed recently for studying the formation of heterojunctions and mixed single crystals of different III-V compounds (1, 2). Since the geometry of the resolidification process and the associated thermal conditions differ from those encountered in Czochralski and other crystal growth techniques it was decided to study the influence of these contrasting growth conditions on the crystalline perfection of the regrown material. Accordingly, single crystal wafers of gallium antimonide were partially melted and regrown with the unmelted rest of the original wafer acting as substrate. These types of conditions are similar to those encountered in the traveling solvent method (3). This paper reports some interesting results concerning density and distribution of dislocations in regrown single crystal wafers.

## Experimental Procedure

Gallium antimonide wafers (1.5 x 2 x 3 mm) with their large faces of (110), (211), and (111) orientation, were chemically etched in a modified CP-4 etchant (5HNO<sub>3</sub> conc.; 3CH<sub>3</sub>COOH; 3HF 48%) and placed between two carbon strip heaters (6 x 1 x 70 mm at a horizontal separation of 10 mm) with independent power supplies. The heaters were installed in a glass chamber in which the back-melting experiments were conducted in a hydrogen atmosphere of about 10 mm Hg overpressure. The back-melting and resolidification processes were observed through an externally mounted binocular microscope with a long working distance objective. During the back-melting experiments the upper carbon strip was first heated to about 1200°C. The resulting temperature gradient between the heated strip and the nonheated lower strip (on which the gallium antimonide was placed) just initiated back-melting of the wafer. By means of a controlled current through the lower strip the temperature gradient between the strips could be adjusted in such a way that the location of the solid-melt interface could be kept in any desired position and could also

be moved at controlled rates. In this way any portion of the gallium antimonide wafer could be melted. After the appropriate region was melted, controlled resolidification was initiated by reversing the melting procedure, i.e., the current through the lower strip was reduced at a rate appropriate for the desired resolidification rate; the actual regrowth rates varied between 1 and 10 in./hr. It was observed that within this range the structural characteristics of the regrown material were independent of the actual growth rate.

The density and distribution of dislocations in the parent crystal and the regrown sections were investigated by etch-pit counting and by x-ray topography employing the Lang technique (4). Etch-pit counting was carried out in a plane normal to the regrowth axis after the wafer was mechanically polished with 0.03 $\mu$  alumina and etched with the above mentioned modified CP-4. The etch-pit distribution was examined by light microscopy under the appropriate magnification. X-ray topography was performed using a Lang camera and an x-ray microfocus unit. Standard Lang transmission geometry was employed. In all instances Ag, K- $\alpha$  radiation was used and the images recorded on nuclear emulsions.

## Results

In a series of experiments gallium antimonide wafers were subjected to back-melting and regrowth with the solid-melt interface normal to the <211> direction. Since the semiconductor melt under the given experimental conditions is only subjected to gravity and surface tension it always assumes the shape of a distorted spherical segment. Because of volume expansion during solidification the regrown single crystals assume a dome-like shape. The regrown wafers were mounted in plastic, polished to expose a (111) plane, and finally etched to reveal dislocations and other defects.

Figure 1 is a photomicrograph of an etched single crystal in which the upper part has been regrown. The lowest position of the crystal-melt interface during the back-melt process can readily be recognized as a curved remelt line which sharply delineates areas

\* Electrochemical Society Active Member.

of high and rather low dislocation densities. Etch-pit counting revealed a varying dislocation density ranging from  $10^3$  to  $10^4$  dislocations per square centimeter in the parent crystal below the remelt line and a dislocation density of close to zero in the adjacent regrown section above the remelt line. Not shown in Fig. 1 is the uppermost part of the regrown crystal in which the dislocation density is very high (due to very rapid solidification), exceeding that of the parent crystal. Since the detection of dislocations in the form of etch-pits requires that individual dislocations intersect the surface under consideration, the absence of dislocation etch-pits in the regrown section could not be considered as indicating complete absence of dislocations.

A (220) x-ray topograph of a regrown crystal of the above series of experiments is shown in Fig. 2. In this topograph the regrown section can be readily differentiated from the parent crystal by the drastic change in dislocation density. However, the dislocation density in the upper part is not as low as appears in Fig. 1. Most of the dislocations in the regrown section are

Fig. 1. Dislocations in parent crystal and regrown section of a gallium antimonide wafer. The curved remelt line separating the two regions is clearly visible. The (111) plane shown is normal to the regrowth axis. Magnification ca. 105X.

Fig. 2. X-ray topograph of partially regrown gallium antimonide wafer. The regrown region exhibits a marked decrease in the dislocation density; Ag,  $K\alpha$  radiation; (220) reflection. Magnification ca. 20X.

observed to run nearly parallel to the regrowth axis and do not intersect the (111) plane on which the etch-pit count was performed.

The relationship between the dislocations in the parent gallium antimonide and the regrown crystals was further investigated by successively regrowing the same wafer in two perpendicular directions, as indicated in Fig. 3. In the first stage of this experiment the section left of the remelt line A (Fig. 3a) was regrown. The wafer was subsequently ground flat on one side, rotated on the heating strip and again remelted perpendicular to the original remelt direction, thus producing the remelt line B (Fig. 3a) on the regrown wafer. A topograph of such a twice regrown single crystal is shown in Fig. 3b. In region I, the unmelted parent crystal, the dislocation density is very high. Regions II and III which were both regrown only once exhibit the previously discussed reduction in dislocation density. Region IV which was twice regrown in different directions shows that the second regrowth process led to a further reduction in the density of dislocations. The very high dislocation density observed in the upper part of Fig. 3b is the result of turbulent, rapid growth which is always observed in the final stages of the resolidification process.

Fig. 3a. Schematic diagram of a twice regrown gallium antimonide wafer corresponding to x-ray topograph of Fig. 3b. A and B are the remelt lines resulting from the first and second back-melting experiments respectively. Region I represents the original parent crystal; region II was once regrown during the first back-melt experiment, region III was once regrown during the second back-melt experiment. Region IV was regrown twice in different directions.

Fig. 3b. X-ray topograph of twice regrown gallium antimonide wafer (corresponding schematic is shown in Fig. 3a). Note the very low dislocation density in the twice regrown section (area IV in Fig. 3a) Ag,  $K\alpha$  radiation; (220) reflection. Magnification ca. 25X.

Fig. 4. X-ray topograph of a gallium antimonide wafer exhibiting a high density of dislocations. Two sets of dislocations can be observed. One set of rather long dislocations appears aligned along the  $\langle 111 \rangle$  growth direction, the other consists of a network of dislocation loops. Ag,  $K\alpha$  radiation (220) reflection. Magnification ca. 40X.

### Discussion

In crystals grown from the melt two types of dislocations are usually observed. The dislocations of the one type propagate from the seed and are generally long and straight. In the second type belong dislocations which are introduced by thermal stresses encountered in crystal growth systems. These latter dislocations assume complex shapes [tangles (5)] and frequently appear as loops or partial loops. They can readily be differentiated from the long and rather straight dislocations previously discussed. The density of dislocations ( $\rho$ ) caused by thermal stress, has been related to the deviation from the average thermal gradient (6),  $\delta\Delta T$  in the growth system as follows

$$\rho = \frac{1}{a} \alpha \delta\Delta T$$

where  $a$  is the lattice constant and  $\alpha = da/dT$  the coefficient of thermal expansion.

While the exact origin of individual dislocations cannot be determined unambiguously because of their complex movement under different stresses, some pertinent observations can be made. Figure 4 is a topograph of a poor quality gallium antimonide single crystal exhibiting a very high dislocation density. Many of the dislocations are straight and aligned along the  $\langle 111 \rangle$  growth direction. On the other hand, a large number of randomly oriented complex shaped dislocations can be observed which are apparently due to the presence of thermal and solidification stresses. The observed reduction of the dislocation density in partially regrown single crystal wafers is attributed to two factors. First all dislocations which originate and terminate within the region subjected to back-melting are eliminated and are not regenerated during the resolidification process. Second, the small size of the wafer and the absence of constraints on the solid-liquid system result in resolidification under significantly reduced thermal and mechanical stress (com-

Fig. 5. X-ray topograph of a twice remelted gallium antimonide wafer of low dislocation density. Back-melting in the direction of the original growth axis (remelt line A) resulted in a material exhibiting essentially the original dislocation density. The second remelt experiment (from right to left) normal to the original growth axis (remelt line B) led to a noticeable reduction in dislocation density. Ag,  $K\alpha$  radiation, (220) reflection. Magnification ca. 25X.

pared to the conditions in Czochralski pulling systems) and are responsible for the absence of stress induced dislocations. The dislocation density in the regrown region is determined by the propagation of dislocations present in the parent crystal with a component along the regrowth direction. Apparently the orientation of the propagated dislocations is largely dependent on their orientation in the parent crystal. In this regard the experiment illustrated in Fig. 5 is of particular interest. Here regrowth along the original growth axis did not noticeably reduce the dislocation density whereas regrowth normal to the growth direction of the parent crystal resulted in substantial reduction in dislocation density.

The type of solidification discussed here under the virtual absence of thermal stresses could prove most useful for the detailed study of dislocation elimination and propagation.

# Diffusion from a Plane, Finite Source into a Second Phase with Special Reference to Oxide-Film Diffusion Sources on Silicon

A. E. Owen<sup>1</sup> and P. F. Schmidt\*<sup>2</sup>

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania

## ABSTRACT

A model is set up for the diffusion from a source of finite thickness into an adjacent second phase of semi-infinite extent. With the principal assumption of no diffusion in or out of the system, a solution is obtained for the diffusion profile in the second phase. It is also assumed that the diffusion coefficients are independent of concentration, but segregation at the inter-phase boundary is taken into account and so also, to a first approximation, is the possibility of precipitation or reaction at the interface. The model predicts a change in the profile from an ERFC to Gaussian shape depending on whether the diffusion length in the source is much less than or much greater than its thickness, i.e., as the diffusion time increases.

The theoretical predictions of the model are compared to tracer diffusion results from phosphorus doped anodic oxide sources on silicon. These experiments were carried out with unprotected (no undoped SiO<sub>2</sub> film covering the source) oxide sources in a sealed quartz tube. Thus the phosphorus initially lost by out-diffusion could not escape from the system altogether, and it is shown that these conditions approximated the boundary condition of no out diffusion. The diffusion results obtained in this way are in agreement with the model.

In recent years interest has grown in the use of doped oxide films as diffusion sources for device fabrication in semiconductors (1-6). These sources can be deposited by a variety of means, such as anodization, pyrolytic decomposition, or reactive sputtering, and offer the advantages of control of the dopant concentration and of low deposition temperatures which do not alter pre-existing diffusion profiles in the semiconductor substrate. Anodic oxidation also provides very accurate control of the oxide thickness and the possibility of depositing the diffusion source only in the windows of a diffusion mark. Electrophoretic deposition of doped oxides (7) is interesting from the materials point of view since it is practically unlimited in its scope as to substrates or dopants. The present paper solves the diffusion equations for the two-phase system: very thin oxide source/semi-infinite substrate, subject to the idealized assumptions of no loss of dopant to the ambient by out-diffusion and of concentration independent diffusion coefficients. Segregation coefficients at the oxide/semiconductor interface, as well as precipitation or compound formation at this interface, however, are taken into account.

The concentration dependence of phosphorus<sup>3</sup> diffusivity in silicon is well known (8-10), and could be taken into consideration in the calculations; very little, however, is known about the strong concentration dependence of phosphorus diffusivity in phosphosilicate glass and in phosphorus doped SiO<sub>2</sub> (11). In the present paper the diffusion coefficients are regarded as concentration independent. This assumption may not be as severe a limitation on the usefulness of the theory as it might appear at first glance, precisely because of the very strong concentration dependence of diffusivity in the oxide. The diffusivity is relatively high in the phosphosilicate composition range (20) but drops sharply just outside this range to very small values of diffusivity in pure SiO<sub>2</sub>. Probably very little phosphorus is supplied by the oxide source to the sil-

icon substrate after the diffusivity in the oxide has become strongly concentration dependent due to the beginning of depletion of the source; from this point on the amount and profile of phosphorus already in the silicon will determine the further development of the profile in the silicon. The strong concentration dependence of diffusivity in the oxide will thus show up mostly as a reduced effective concentration of dopant originally contained in the oxide source.

While the theory proposed is still only an approximation, it is a step closer to being exact than existing theories since it does not treat the oxide source as an infinitely thin plane source. For very short diffusion times, as long as the oxide source is not yet being depleted, it will act like an infinite source, and the resulting profile in the substrate will be a complementary error function (ERFC); for long diffusion times, it may be regarded as an infinitely thin plane source. The effect of the diffusion parameters (oxide thickness, ratio of diffusivities in oxide and substrate, segregation coefficient, and compound or precipitate formation) on the shape of the diffusion profile as a function of time forms the main body of this discussion. It is easy to show that the important parameter, which governs the transition from ERFC to Gaussian is the diffusion length for the impurity in the oxide, i.e.,  $\sqrt{D_1 t}$  (where  $D_1$  is the diffusion coefficient for the impurity in the oxide, and  $t$  is the diffusion time).

## Model and Solution of the Diffusion Equations

To regard the anodic oxide film as equivalent to a plane source is to assume that the impurity can diffuse across the oxide in times short compared with the diffusion time. The validity of such an assumption would obviously depend on the relationship between the diffusion coefficient in the oxide, oxide thickness, and diffusion time. Such an approximation is not expected to be appropriate in all circumstances therefore, and in any more general analysis it is necessary to consider a two-phase system taking into account the properties of the oxide film. The model adopted is shown schematically in Fig. 1, in which phase 1 represents the oxide and phase 2 the silicon. The oxide has a thickness  $l$  (measured negatively from zero), a concentration-independent diffusion coefficient  $D_1$

<sup>3</sup> The experimental work included in this paper deals exclusively with phosphorus; in principle, the theory applies to the diffusion of any other dopant as well.

Fig. 1. Theoretical model for the anodic oxide diffusion source. Region 1 represents oxide with uniform initial concentration of phosphorus  $C_{ox}$  and diffusion coefficient  $D_1$ . Region 2 represents silicon with zero initial concentration of phosphorus and diffusion coefficient  $D_2$ .

for the impurity and an initial uniform<sup>4</sup> concentration of impurity  $C_{ox}$ . The silicon extends from zero to infinity, has a zero initial impurity concentration and a concentration-independent diffusion coefficient for impurity  $D_2$ . The diffusion equations for the system of Fig. 1 are therefore

in region 1

$$\frac{\partial^2 C_1}{\partial x^2} - \frac{1}{D_1} \frac{\partial C_1}{\partial t} = 0 \quad [1]$$

in region 2

$$\frac{\partial^2 C_2}{\partial x^2} - \frac{1}{D_2} \frac{\partial C_2}{\partial t} = 0 \quad [2]$$

and these have to be solved simultaneously with the initial conditions

$$C_1 = C_{ox}; -l < x < 0, t = 0 \quad [3]$$

$$C_2 = 0; x > 0, t = 0 \quad [4]$$

The boundary conditions have been chosen as follows

$$\text{At } x = -l, \frac{dC_1}{dx} = 0 \quad [5]$$

At

$$x = 0, D_1 \frac{dC_1}{dx} = D_2 \frac{dC_2}{dx} \quad [6]$$

and

$$C_1 = mC_2 \quad [7]$$

At

$$x = \infty, C_2 = 0 \quad [8]$$

Boundary conditions [6], [7], and [8] are straightforward and physically reasonable. Condition [6] simply expresses the continuity of flux and [7] the segregation of impurity at the interface, with a segregation coefficient  $m$ . Boundary condition [5], however, which requires that there is no flow of impurity from the oxide to the ambient or *vice versa* requires particular consideration. At first sight this would seem to be an unrealistic condition, but there are indications that it is a fair approximation under the conditions of the experiments described in ref. (1), in which unprotected (cf. below) oxide sources were used in conjunction with sealed quartz diffusion tubes of small volume; in the case of protected oxide sources [see ref. (2)], boundary condition (5) holds almost exactly. Evidence for these points will be mentioned below.

Surprisingly, a complete solution of the diffusion problem set out in Fig. 1 and Eq. [1] to [8] does not appear to have been given before. Carslaw and Jaeger (12) quote ref. (13) for the temperature at the interface of a hot magmatic intrusion into a cold rock (*i.e.*, a parameter corresponding to the concentration  $C_0$  at the silicon-oxide interface) but solutions correspond-

ing to concentration profiles are not available. It should be remarked in passing, therefore, that although the model used here is only an approximation for the oxide film diffusion source situation, it does provide an exact solution (subject to concentration-independent coefficients) to the problem of diffusion from a source sandwiched between two semi-infinite media of a second phase, *i.e.*, two of the models drawn in Fig. 1 placed back-to-back.

Using the Laplace transformation (12) the simultaneous partial differential Eq. [1] and [2] have been solved for the concentration in the phase 2,  $C_2$ , subject to the initial conditions [3] and [4] and the boundary conditions [5] to [8]. The solution is

$$C_2 = \frac{C_{ox}}{2} \frac{(1-\alpha)}{m} \left[ \sum_0^{\infty} (-1)^n \alpha^n \operatorname{erfc} \frac{(2Rln+x)}{2\sqrt{D_2 t}} - \sum_0^{\infty} (-1)^n \alpha^n \operatorname{erfc} \frac{(n+1)2Rl+x}{2\sqrt{D_2 t}} \right] \quad [9]$$

in which  $C_{ox}$ ,  $D_2$ ,  $l$ , and  $m$  have already been defined,  $t$  is the diffusion time, and  $x$  is the depth at which the concentration is  $C_2$ . The parameters  $R$  and  $\alpha$  are given by

$$R = \sqrt{(D_2/D_1)} \quad [10]$$

and

$$\alpha = \frac{(R/m) - 1}{(R/m) + 1} \quad [11]$$

For the purpose of computation Eq. [9] has been expressed in terms of dimensionless parameters

$$\frac{C_2}{C_{ox}} m = \frac{(1-\alpha)}{2} \left[ \sum_0^{\infty} (-1)^n \alpha^n \operatorname{erfc} \frac{[2(R/m)n+x/lm]}{2\sqrt{D_2 t/ml}} - \sum_0^{\infty} (-1)^n \alpha^n \operatorname{erfc} \frac{[2(R/m)(n+1)+x/lm]}{2\sqrt{D_2 t/ml}} \right] \quad [12]$$

Equation [12] has been programmed and the concentration ( $C_2/C_{ox}$ )  $m$  computed as a function of distance ( $x/lm$ ) for various values of time ( $\sqrt{D_2 t/ml}$ ) and the parameter ( $R/m$ ). The diffusion Eq. [12] has the important property that the concentration profile in the phase 2 changes shape from ERFC to Gaussian according to the relationship between the time parameter ( $\sqrt{D_2 t/ml}$ ) and the parameter ( $R/m$ ). For instance, for a given ( $R/m$ ) the profile changes from ERFC to Gaussian as the diffusion time increases and, conversely, for a constant time ( $\sqrt{D_2 t/ml}$ ) the profile changes from Gaussian to ERFC as ( $R/m$ ) increases. In actual practice it is to be expected, of course, that ( $R/m$ ) remains constant while the diffusion time is varied, but for convenience in illustration the change in shape of the profile is shown in Fig. 2 for a constant ( $\sqrt{D_2 t/ml}$ ) = 5 with ( $R/M$ ) varying. Also plotted in Fig. 2 are points corresponding to true Gaussian and ERFC curves, and it will be noticed that the profile of Eq. [12] is approximately intermediate between Gaussian and ERFC when

$$\frac{\sqrt{D_2 t}}{ml} = \frac{R}{m} \quad [13]$$

Substituting for  $R$  ( $=\sqrt{D_2/D_1}$ ) and rearranging gives the set of conditions: if

$$\sqrt{D_1 t} < l, \text{ profile tends to ERFC} \quad [14a]$$

$$\sqrt{D_1 t} \approx l, \text{ profile is intermediate} \quad [14b]$$

$$\sqrt{D_1 t} > l, \text{ profile tends to Gaussian} \quad [14c]$$

Thus the shape of the profile in the phase 2 depends, in fact, only on the diffusion time and the characteris-

<sup>4</sup>It is shown in ref. (1) that the initial distribution of phosphorus in an anodically grown oxide is, in fact, practically uniform.

Fig. 2. Illustrating the change from Gaussian to ERFC form of the profile predicted by Eq. [12] as  $R/m$  varies at constant time,  $(\sqrt{D_2t/ml}) = 5$ .

tics of phase 1 (the oxide). When the diffusion length of impurity in the oxide,  $\sqrt{D_1t}$ , is much less than the thickness of the oxide  $l$  the oxide tends to behave as an infinite source (ERFC), but when the diffusion length is much greater than the thickness of the oxide, it tends to behave as an infinitely thin plane source (Gaussian). Physically these conditions are perfectly reasonable and could have been anticipated from the remarks made at the beginning of this section. Another way of looking at this is to regard the "effective" thickness of the oxide as depending upon time and, through the diffusion coefficient, on temperature.

In device fabrication the impurity surface concentration in the silicon,  $C_o$ , is an important parameter, and this has been plotted in a reduced form in Fig. 3. The surface concentration expressed as  $[(C_o/C_{ox})m]$  is given as a function of time,  $(\sqrt{D_2t/ml})$ , for various values of the parameter  $(R/m)$ . The surface concentration can be written analytically by putting  $(x/lm) = 0$  in Eq. [12] and simplifying, leading to

$$\frac{C_o}{C_{ox}} M = \frac{(1-\alpha)^2}{2} \sum_{n=1}^{\infty} (-\alpha)^{n-1} \operatorname{erf} \frac{nl}{\sqrt{D_1t}} \quad [15]$$

This equation shows that the time variation of the surface concentration depends only on the diffusion time and the characteristics of the oxide. At a given value of  $(R/m)$  the surface concentration is independent of time for very small values of time; in this region the

Fig. 3. Surface concentration as a function of time for different values of  $R/m$  according to Eq. [12]. Also shown for comparison are some experimental points.

oxide will behave as an infinite source. As the time parameter  $(\sqrt{D_2t/ml})$  approaches  $(R/m)$  the surface concentration begins to decrease slowly at first and then more rapidly when  $(\sqrt{D_2t/ml}) = (R/m)$ . When  $(\sqrt{D_2t/ml}) \gg (R/m)$  the surface concentration decreases linearly with the inverse of  $(\sqrt{D_2t/ml})$ , and in this region the oxide behaves as an infinitely thin plane source. Note also that in this region the surface concentration depends only slightly on  $(R/m)$  whereas in the ERFC region it depends strongly on  $(R/m)$ .

The bulk of the work reported in ref. (1), (2), and (14) is concerned with the use of phosphorus-doped anodic oxide films as diffusion source. In early diffusion experiments with P-32 labeled phosphorus, sectioning of the silicon after diffusion revealed the presence of a sharp spike of phosphorus within the first 1-2,000Å of the silicon surface. The material in this spike was subsequently identified as silicon phosphide precipitates by Schmidt and Stickler (15), who also give some examples of the diffusion profile in the Si. Later work (16) showed that precipitates of SiP forming during the initial stages of diffusion on silicon surfaces of any orientation (17, 18) tend to become especially large on (110) surfaces and do not disappear even at long diffusion times; the phosphorus incorporated into these precipitates is lost for the diffusion process. Since the silicon bars, on which experimental work reported here was carried out, had their large surfaces (110) oriented, the SiP precipitates must have formed readily, and this fact presumably accounts for the shift to lower concentrations of the phosphorus diffusion profile observed in the early tracer runs (cf. Fig. 3).

Irrespective of the mechanism by which precipitates or compounds are formed at the interface, their formation results in a certain fraction of the phosphorus flux crossing the oxide/silicon interface being retained at the interface. If such a process takes place, the boundary condition [6] for flux continuity across the oxide/silicon interface must be modified; assuming that the fraction  $K$  of flux retained at the interface is a constant, this boundary condition becomes

$$D_1 \frac{dC_1}{dx} + K D_1 \frac{dC_1}{dx} \Big|_{x=0} = D_2 \frac{dC_2}{dx} \quad [16]$$

Solving the same equations with the boundary condition [16] in place of [6] again leads to Eq. [12] but now the parameter  $\alpha$  is given by

$$\alpha = \frac{(R/m) - (1-K)}{(R/m) + (1-K)} \quad [17]$$

Thus, when  $K$  is zero (no spike formation) Eq. [12] is unchanged as it obviously should be; when  $K = 1$  (all the phosphorus retained at the interface)  $\alpha = 1$  and  $C_2 = 0$ , i.e., there is no diffusion into the silicon, again as expected. The effect of  $K$  in Fig. 3 is to make  $(R/m)$  appear larger than it would otherwise be in the absence of spike formation, i.e., to lower the curves and reduce their slope slightly.

### Discussion: Relevance to Anodic Oxide Diffusion Sources

The theoretical work described herein was initiated during the early stages of development of doped anodic oxide sources (1), when nondoped anodic oxide films, grown on top of the doped source<sup>5</sup> as a protection against out-diffusion, were not yet available. Subsequently it was found that these protective oxide covers, a few hundred angstroms thick, act as complete barriers to out-diffusion into the ambient for any time-temperature diffusion conditions of practical interest (2). This masking ability is, of course, a consequence of the very strong concentration dependence

<sup>5</sup>The anodic formation of nondoped oxide on top of a doped oxide is possible because the anodization of silicon proceeds by cation migration (1).

of phosphorus diffusivity in pure  $\text{SiO}_2$ . In the heavily doped source, on the other hand, the phosphorus diffusivity is relatively high, so that most of the phosphorus has diffused into the silicon before the protective oxide cover is penetrated by phosphorus diffusing outward.

Oxide diffusion sources with protective oxide covers thus come very close to the boundary condition [5] of no diffusion across the oxide/ambient interface; the amount of phosphorus diffusing into the pure  $\text{SiO}_2$  cover is negligible compared to the amount diffusing into the Si substrate. Unfortunately, the experimental work described in ref. (2) was oriented toward process development, and the diffusion times chosen were either not short enough to demonstrate the transition from an ERFC to a Gaussian profile, or not long enough to show the predicted deviation of junction depth from a square-root of time dependence at long diffusion times. This became clear only after conclusion and evaluation of the tracer results; while the results obtained in [2] are not at variance with the theory proposed here, they could not be used to prove the correctness of the theory.

The only tracer work in which very short and very long diffusion times were used are the early tracer runs, made with unprotected oxide sources in sealed small quartz tubes. In these experiments there was an initial very fast loss of phosphorus from the outer surface of the oxide; however, this phosphorus could not escape from the sealed system, and for longer diffusion times there actually occurred some reabsorption of phosphorus from the gas phase by the oxide. The amount of phosphorus reabsorbed was, however, small compared to that left in the system oxide + silicon after the initial fast out-diffusion, and for practical purposes the assumption of "no out-diffusion" appears to be valid after the first 5-10 min of heat-treatment, as will be discussed in more detail below.

It should be noted that the experimental results are quoted only to show that they are not in disagreement with the proposed theory; they are not assumed to prove its validity. Specifically, it should also be noted that the results quoted are not representative of the potential usefulness of doped oxide sources; for practical applications, the reader is referred to ref. (1-6).

Evidence for the approximate validity of boundary condition [5] in the experimental work (unprotected oxide sources about  $1500\text{\AA}$  thick; doping level in the oxide up to  $4 \times 10^{21}/\text{cc}$ ; argon filled quartz tubes; diffusion temperatures of typically  $1175^\circ\text{C}$ ) is then given in Fig. 4 where the amount of phosphorus (in atoms/ $\text{cm}^2$ ) in the silicon, that which remains in the oxide, and the total in oxide plus silicon, is plotted as a function of the square-root of time at  $1175^\circ\text{C}$ . The data of Fig. 4 were obtained from experiments using P-32 as a tracer. Note that the vertical ordinate has been compressed and should, on this scale, extend to three or four times the height shown. These data show that during the very early stages of diffusion there is an extremely rapid loss of phosphorus from the oxide. At times still short compared with the experimental diffusion times, this out-diffusion apparently ceases, however, and eventually there is actually an increase in total phosphorus with time, i.e., there is some in-diffusion. The increase at longer diffusion times, however, is relatively small. The assumption of no out-diffusion implicit in boundary condition (5) therefore appears to be experimentally justifiable at least for comparatively long diffusion times. Support for this was provided by another experiment made under similar conditions in which the phosphorus in the silicon and oxide was measured for diffusion times between 5 and 90 min (in increments of 5 min), and it was found that after the first 5-10 min the total amount of phosphorus in oxide plus silicon became practically constant, i.e., a condition equivalent to Eq. [5].<sup>6</sup> Yet fur-

Fig. 4. Amount of phosphorus found in the silicon, the amount remaining in the oxide, and the total in oxide and silicon as a function of diffusion time.

Fig. 5. Phosphorus profiles in oxide after diffusion: (a)  $1\frac{1}{2}$  hr at  $1175^\circ\text{C}$ ; (b) 5 hr at  $1175^\circ\text{C}$ ; (c) 15  $9/10$  hr at  $1175^\circ\text{C}$ .

ther supporting evidence is to be found in the phosphorus profiles in the oxide, determined after diffusion, by etching oxide away in a step-wise fashion, and counting the radioactive P-32 removed. Three such profiles are shown in Fig. 5; in each case the oxide was grown by the method of ref. (1), to a thickness of  $1450\text{\AA}$  and was found to have a phosphorus concentration before diffusion of  $2.2\text{--}2.5 \times 10^{21}$  atoms/ $\text{cm}^3$ . The original phosphorus concentration is shown by the horizontal lines in Fig. 5. Figures 5(a), 5(b), and 5(c) correspond to diffusion times of 1.5, 5, and 15.9 hr at  $1175^\circ\text{C}$  in an argon-filled sealed quartz tube. The data of Fig. 5 are not very accurate, due to some nonuniformity in the local dissolution rate of the oxide, and the profile has deliberately been drawn in horizontal at the outer surface to conform with boundary condition [5], but at least they fairly conclusively indicate a situation corresponding to no out-diffusion. The effective concentration of phosphorus in the oxide,  $C_{ox}$  will, of course, be less than that initially present. According to the data of Fig. 4 about 80% of the original phosphorus is lost from the oxide-silicon system and consequently in the samples of Fig. 5, for instance,  $C_{ox}$  would be approximately  $5 \times 10^{20}$  atoms of phosphorus  $\text{cm}^{-3}$ , as indicated.

The fact that the phosphorus concentration at the outer surface of the oxide remained high for all diffusion times is undoubtedly due to the sealed tube operation; it would not have remained high in an open flow system. Diffusion of phosphorus into the dense quartz of the tube walls is very slow, so that out-

<sup>6</sup> The authors are indebted to their colleague, T. W. O'Keefe, for carrying out these measurements.

diffusion will have practically stopped as soon as saturation of the gas phase and internal tube surfaces with  $P_2O_5$  occurred. Eventually some of the phosphorus pentoxide on tube walls and in the gas phase becomes available for back-in-diffusion as the concentration in the oxide source drops due to diffusion into the Si substrate.

Note that the diffusion must be carried out in an inert ambient: diffusion in air would lead to the formation of new oxide at the  $SiO_2/Si$  interface, and to a much more complicated situation.

It is not quite clear which factor is mostly responsible for the approximate constancy of the total amount of phosphorus in oxide plus silicon after the first 5-10 min of heat-treatment. It may be due to a relatively slow transport of phosphorus across the outer oxide surface due to a shallow diffusion gradient, but it is also possible that the outer surface of the oxide underwent a drastic structural change during the initial stage of rapid out-diffusion of phosphorus, and that the diffusivity of phosphorus in this surface layer became strongly different from its initial value.

An assessment of Eq. [12] can be obtained from a comparison of predicted junction depths and surface concentrations with those obtained experimentally. The samples of Fig. 5, for instance, were prepared on 2 ohm-cm p-type material, and gave the junction depths plotted on a reduced scale, as a function of time, in Fig. 6. In obtaining this figure the diffusion coefficient of phosphorus in silicon at 1175°C was taken to be  $10^{-12}$  cm<sup>2</sup>/sec (19), oxide thickness  $l = 1450\text{Å}$ , and  $m$  was taken as 0.3. (In six samples  $m$  was found experimentally to vary between 0.2 and 0.4 with a mean of approximately 0.3). From the data of Irvin (20) the base concentration of 2 ohm-cm p-type silicon is  $7.00 \times 10^{15}$  atoms/cc and thus, at the junction, the dimensionless concentration parameter of Eq. [12] has a value

$$\frac{C_B}{C_{ox}} m \approx 4 \times 10^{-6}$$

where  $C_{ox}$  has been given the effective value for the samples of Fig. 5 (i.e.,  $5 \times 10^{20}$  atoms/cc) and  $C_B$  is the concentration at the junction. Predicted values for the junction depth were then obtained graphically by plotting  $(C/C_{ox})m$  vs. the reduced depth  $x/lm$  for various values of the time parameter  $\sqrt{D_2t/ml}$  at particular values of  $(R/m)$ , and reading off the depth corresponding to the above reduced concentration. Theoretical curves obtained in this way for  $(R/m)$  equal to 10 and 20 are also drawn in Fig. 6, and the

Fig. 6. Junction depths as a function of time in terms of the parameters of Eq. [12]. Comparison with the predictions of Eq. [12] with  $(R/m) = 10$  and 20 and base concentration corresponding to  $(C/C_{ox})m \approx 4 \times 10^{-6}$ .

experimental points fall roughly between these two curves. Two features of Fig. 6 should be noted in passing. First, the theoretical curves begin to deviate from the linear dependence on square-root of time and at longer diffusion times this deviation becomes even more marked. And second, for  $(R/m)$  values in this range the junction depth-time relationship is not very sensitive to  $(R/m)$ .

Now according to Sah, Sello, and Tremere (21)  $R$  is very nearly 3 at temperatures of 1100° and 1150°, but for an unspecified amount of phosphorus in the oxide. A value of  $R = 3$  at 1175°C would, therefore, seem reasonable and hence, using the value of  $m = 0.3$ , quoted above

$$R/m = 10$$

The experimental points plotted in Fig. 6 suggest that  $(R/m)$  is a little larger than this, say about 15, but the nature of the comparison is such that this discrepancy is hardly significant, and the experimental data can be considered consistent with the model. Thurston, Tsai, and Kang (11) report, however, that  $R$  is rather sensitive to the amount of phosphorus in the oxide and also possibly, depending on the actual concentration, on temperature. In the present experiments the oxide contained about 5 w/o (weight per cent) of phosphorus and from the data of Thurston *et al.* a value in the region of 5 would be appropriate for  $R$  at 1175°C, whence

$$R/m \approx 16$$

This agrees rather well with the experimental results of this paper although it must be pointed out that according to ref. (11) much larger values of  $R$ , and hence  $R/m$ , are possible. Thus, the value of  $(R/m) = 10$  would seem to represent a lower limiting value, and without knowing precisely what is the appropriate concentration of phosphorus in the oxide a more definite estimate cannot be made.

The experimental surface concentrations for the same samples are plotted, again in dimensionless form, in Fig. 3. As anticipated earlier, these samples, like those of ref. (15), showed a "spike" in the phosphorus concentration at the surface; this spike was neglected in arriving at the measured surface concentrations plotted in Fig. 3. The experimental points show about the right time dependence for a value of  $(R/m)$  in the range 10 to 20 implied by the results of Fig. 6 and tentatively suggested by the data discussed above. In magnitude, however, the points are somewhat lower than expected. The reasons for this are almost certainly connected with the formation of the spike for, as already shown, the removal of a fraction of the flux at the interface would have the effect of lowering the theoretical curves of Fig. 3. Qualitatively such an adjustment would bring the experimental points into better agreement with the predictions.

Finally, it should be pointed out that the trend of the experimental results presented in Fig. 3 and 6 lead one to expect that the concentration profiles in the silicon should be nearly Gaussian, especially at the longer diffusion times. As was mentioned early in this paper this is not unexpected, and the profile shape resulting from anodic oxide diffusion sources is examined in ref. (14).

### Conclusions

The solution of the two-phase diffusion problem given in this paper, exact where the diffusion coefficients are independent of concentration and out-diffusion can be neglected, may be approximately applicable to the more complex practical situation for diffusion from doped (anodic) oxides on silicon. For the samples discussed in this paper, nonprotected oxide sources diffused in a sealed tube at 1175°C, there appears to be an intermediate range of diffusion time (i.e., 1½ hr to perhaps 15 or 16 hr) in which the assumption of no-flow across the oxide-ambient interface is reasonably justified. Under these conditions sat-

atisfactory agreement is found between the predictions of the model and measured parameters such as the junction depth. In the particular samples studied here the concentration profile in the silicon is expected to be nearly Gaussian, especially at the longer diffusion times. A Gaussian profile is not always to be expected, however, and the theoretical model shows that the important quantity is the diffusion length  $\sqrt{D_1 t}$ , in the oxide. When the diffusion length is small compared with the thickness of the oxide (i.e., short diffusion times) an ERFC profile will result.

#### Acknowledgments

This work was carried out while the authors were members of the Westinghouse Research Laboratories, Pittsburgh; they are indebted to the company for providing facilities, and to several of their former colleagues for cooperation and assistance during all phases of the work. Particular thanks are due to Miss Freedman and Mr. Heath of the Mathematics Department for programming and computing the diffusion equation. Dr. O'Keefe was responsible for the out-diffusion experiment mentioned in the text and Mr. Roney assisted with the other experiments.

Manuscript received Aug. 30, 1967; revised manuscript received ca. Dec. 12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Close-Spaced Growth of Degenerate P-Type GaAs, GaP, and Ga(As<sub>x</sub>, P<sub>1-x</sub>) by ZnCl<sub>2</sub> Transport for Tunnel Diodes

P-A. Hoss,<sup>\*1</sup> L. A. Murray, and J. J. Rivera<sup>2</sup>

*Electronic Components and Devices, Radio Corporation of America, Somerville, New Jersey*

#### ABSTRACT

A close-spaced growth system is described in which zinc chloride is used as both the transport agent and the doping source to grow GaAs, GaP, and Ga(As<sub>x</sub>, P<sub>1-x</sub>) epitaxial layers on GaAs substrates. Uniform transport and doping is obtained by situating resistively heated molten zinc chloride on both sides of the inductively heated close-space furnace. Degenerate GaAs layers with areas of 10 cm<sup>2</sup>, thicknesses of 1 mm, and reproducible doping levels of 5 x 10<sup>19</sup> cm<sup>-3</sup> were used to produce up to 1600-amp tunnel diodes.

In the development of high current tunnel diodes uniformly doped wafers of degenerate GaAs 8-12 cm<sup>2</sup> in area are needed. Melt grown crystals do not show sufficient reproducibility of doping or adequate uniformity in these dimensions. The close-spaced growth of epitaxial GaAs has been discussed by a number of authors (1-5). Using H<sub>2</sub>O or HCl as the transport agent this method has produced rapid growth rates (circa 1 mm/hr). A close-spaced inductive furnace (6) has the ability to accept the 10 cm<sup>2</sup> undoped GaAs substrates for epitaxial growth. In these systems doping was achieved by incorporation of n-type dopants such as Se, S, and Te in the source material. Our attempts to grow p-type GaAs using zinc in this manner resulted in n-type layers and loss of the "volatile" zinc to the hydrogen ambient. This paper discusses a new open-tube method of uniformly introducing zinc chloride vapor into the close-spaced furnace for the

p-type epitaxial growth of GaAs, GaP, and their alloys on undoped GaAs substrates, and the use of grown GaAs and Ga(As<sub>0.8</sub>P<sub>0.2</sub>) in making tunnel diodes.

#### Apparatus

The apparatus used is shown diagrammatically in Fig. 1. The close-spaced radio frequency induction furnace (6) is composed of two series-connected, flat-wound copper coils geometrically parallel, as shown. These are powered by a 10 kw generator either at 450 kc, or at 3 Mc. The coils couple to a pair of carbon susceptors placed in a quartz reaction tube of 4.3 x 1.3 cm<sup>2</sup> cross section. The susceptors heat the source and substrate, which are themselves separated by 1 mm thick molybdenum spacers. The required source-substrate temperature difference is obtained by mechanically moving the pair of RF coils vertically toward or away from the pair of susceptors. Temperatures are monitored by means of electrically isolated molybdenum sheathed thermocouples imbedded in the susceptors. One thermocouple electronically main-

Fig. 1. Close space RF furnace with resistively heated side furnaces and temperature profile at start of growth.

tains the substrate susceptor to within  $1^{\circ}\text{C}$  of the growth temperature by controlling the RF generator with a differential amplifier, magnetic amplifier and saturable reactor series. At low hydrogen flows the source susceptor tracks to within  $2^{\circ}\text{C}$  of the temperature required. At each end, the rectangular quartz tube is depressed 1 cm to form 4 cm x 2 cm boats to contain the zinc chloride. Into the side of each boat a thin tube is fused so that its tip is surrounded by the liquid zinc chloride at operating temperatures. The tubes accept thermocouples which electronically control the cylindrical resistance furnace around each boat to within  $4^{\circ}\text{C}$  of its desired temperature. All furnaces can be reproducibly located such that the temperature gradient along the tube is maintained from run to run. Uniformity of the susceptors to within  $2^{\circ}\text{C}$  is periodically checked with a pyrometer. The temperature profile shown in Fig. 1 was obtained by inserting a molybdenum sheathed thermocouple from each end and profiling the running furnaces with the susceptors at equal temperature in nitrogen, but without the source and substrate present. The sharp temperature change in the region between the susceptor and the ambient nitrogen is probably due in part to heat conduction along the 60 mil OD molybdenum sheath. The sheath is grounded, eliminating RF pick-up in the thermocouple circuits as checked by rapid turn off and on of the RF generator at operating power. Furthermore, molybdenum appears inert to the reaction atmosphere.

### Procedure

The GaAs substrates are melt grown, undoped, and angle-cut  $2\text{--}3^{\circ}\text{C}$  off the (111) plane to give up to  $10\text{ cm}^2$  in area. Growth takes place on the chemically polished  $(\bar{1}\bar{1}\bar{1})$  plane. The back (111) side has been previously coated with  $\text{SiO}_2$  from the thermal decomposition of ethyl orthosilicate to reduce decomposition of the backs during the growth of 1 mm layers.

The GaAs and GaP sources were single-crystal or polycrystalline undoped wafers 1-2 mm thick. The  $\text{Ga}(\text{As}_x, \text{P}_{1-x})$  sources were wafers of pressed and sintered mixtures of pure GaAs and GaP powders. X-ray diffraction from copper radiation is used to measure the alloy composition with change in d-spacing. The (111) plane was used for sintered powders and the (444) plane for single crystals.

Zinc chloride has been shown capable of transporting GaAs (8) in a closed-tube system and the effectiveness of zinc as a p-dopant for GaAs is known. Zinc chloride was found well suited for close-spaced transport when treated to reduce its moisture content. CP zinc chloride, as purchased, is stored at  $140^{\circ}\text{C}$  under mechanical vacuum of  $30\text{--}50\mu$ . It is loaded while still warm, and just prior to the run the zinc chloride and susceptors-substrate-source assembly are held at  $300^{\circ}\text{C}$  in flowing hydrogen for 5 min. This

bakeout virtually eliminates hillocks on the epitaxial layers, possibly caused by gallium oxide inclusions.

After bakeout the hydrogen flow is adjusted to  $10\text{--}30\text{ cm}^3/\text{min}$  through the  $4.3 \times 1.3\text{ cm}^2$  rectangular tube cross section of which  $2.4\text{ cm}^2$  is occupied by the susceptors-source-substrate cross section. The GaAs source is then heated to  $840^{\circ}\text{C}$  with GaAs substrate  $10^{\circ}\text{--}20^{\circ}$  higher to etch off some of the substrate. Simultaneously the zinc chloride is heated to approximately  $430^{\circ}\text{C}$ . After etching the temperature is inverted, with the source held at  $840^{\circ}$  and the substrate at  $800^{\circ}\text{C}$ . For the growth of  $\text{Ga}(\text{As}_x, \text{P}_{1-x})$  with  $0 < x \leq 1$  the source is held at  $950^{\circ}$  and the substrate at  $910^{\circ}\text{C}$ .

### Experimental Results

The growth rates and resistivity of GaAs and GaP grown by close-spaced transport depend on the temperature of the zinc chloride, the hydrogen flow, the source and substrate temperatures, and the spacing between them. The system has been operated at no hydrogen flow, but the flow range of  $10\text{--}30\text{ cc/min}$  resulted in a reduction of hillocks on the surface. At these low hydrogen flows the zinc chloride still achieves near saturation, based on growth rate and doping level comparisons with no flow. The GaAs substrate temperature of  $800^{\circ}\text{C}$  for GaAs growth and  $910^{\circ}\text{C}$  for GaP and phosphide-arsenide alloys were found high enough to give satisfactory growth with no tendency to polycrystallinity. The source temperature  $40^{\circ}$  higher was picked to achieve growth rates in the range of  $100\ \mu/\text{hr}$  under the condition of growth for thick layers for tunnel diodes. While not studied in detail, the growth rate can be halved to doubled by reducing or increasing the temperature of the source, with little effect on this high doping level. The observed change in growth rate of GaAs with change in the zinc chloride temperature is shown in Fig. 2. Thickness was measured by a micrometer before and after the run. A  $5000\text{\AA}$  silicon dioxide layer deposited from the thermal decomposition of ethylorthosilicate eliminates back etching of the substrate during growth and the thicknesses measured agree well with measurements between the top of the layer and the substrate where the spacers had prevented growth. The observed change in doping level with changes in zinc chloride temperature was also studied for GaAs, as seen in Fig. 3.

Carrier concentrations are determined by the plasma resonance technique (7). This method gives zinc concentrations in GaAs reproducible to about 3% by IR reflectance in the  $2 \times 10^{19}$  to  $9 \times 10^{19}$  carriers/ $\text{cm}^3$  range. Since the plasma resonance measurement covers a circle about 4 mm in diameter, this method is also used to measure the doping uniformity of layers. An

Fig. 2. GaAs growth rate as a function of zinc chloride temperature

Fig. 3. GaAs doping level as a function of zinc chloride temperature

Fig. 4. Doping variation across a large area GaAs grown layer

example of the high degree of doping uniformity obtainable is shown in Fig. 4, as measured along a 28 mm line of a 32 x 22 mm wafer. The run-to-run reproducibility of zinc doping GaAs was checked out on 19 consecutive runs with temperature and flow settings unchanged. The minimum wavelengths as read by plasma resonance and the equivalent carrier concentrations are shown in Table I. The average is  $5.5 \times 10^{19}$  carriers/cm<sup>3</sup> and the average deviation 13%. The Hall mobilities of the GaAs layers varied from 40 to 50 cm<sup>2</sup>/v-sec in the zinc concentration of 3 to 5 x

**Tunnel Diode Fabrication**

Epitaxial layers 0.6 to 1.0 mm thick with concentrations of 5 to 6 x 10<sup>19</sup> carriers/cm<sup>3</sup> were used to fabricate tunnel diodes. A contact is placed on the top grown (111) surface by lapping it flat, coating with sintered gold, nickel plating the gold, and evaporating another sintered gold layer. The wafer is then reversed and the original GaAs substrate, on the (111) side, lapped off and the wafer polished to a final thickness of 0.4-0.5 mm. A tin-lead dot about 6 cm<sup>2</sup> in area is then alloyed into the (111) surface to form the junction and top contact. The diode is then soldered to its package with Au-Ga-Zn alloy and tested. Figure 5 shows the current voltage trace of such a tunnel diode. Electrical characteristics are as follows:  $I_P = 1640$  amp;  $V_P = 0.21$ v;  $V_F = 1.3$ v;  $I_V = 60$  amp;  $V_V = 0.64$ v.

Smaller tunnel diodes were similarly fabricated from Ga(As<sub>0.8</sub>P<sub>0.2</sub>) wafers.  $I_P/I_V$  ratios up to 30:1 were achieved.

**Discussion**

The authors' previous experience has shown the need for low carrier gas flows if uniformity of growth is to be maintained in close-spaced transport and the reactants kept between the source of substrate. For tunnel diodes where a high doping level is also required, the use of a zinc chloride source on each side allows for low flows without sacrificing doping uniformity. Since the growth rate and doping level were found reproducibly dependent on the zinc chloride temperature, the temperature of the liquid zinc chloride must control the partial pressure of the zinc chloride in the high-temperature region of the furnace. The growth rate can be adjusted independently by means of the source and substrate temperatures.

## The Effects of Growth Rate on the Thermoelectric Properties of $\text{Bi}_2\text{Te}_3\text{-Sb}_2\text{Te}_3\text{-Sb}_2\text{Se}_3$ Pseudoternary Alloys

W. M. Yim and E. V. Fitzke

RCA Laboratories, Princeton, New Jersey

### ABSTRACT

The effects of growth rate on the thermoelectric properties of n- and p-type  $\text{Bi}_2\text{Te}_3\text{-Sb}_2\text{Te}_3\text{-Sb}_2\text{Se}_3$  pseudoternary alloys have been investigated and correlated with microstructures. The results show that higher values of the figure of merit ( $Z$ ) are invariably associated with lower growth rates and hence greater homogeneity. For both n- and p-type alloys, the improvement in  $Z$  was as large as 50% when the growth rate was reduced from about 6 to 0.6 cm/hr. However, the growth-rate dependence of individual thermoelectric parameters was not the same for both alloys. For the n-type alloy, which is a single-phase alloy, slow growth rates resulted in an increase in the Seebeck coefficient, and a decrease both in the lattice thermal conductivity and electrical resistivity. For the p-type alloy, the variations with growth rate in the Seebeck coefficient and, to a lesser extent, in the lattice thermal conductivity were similar to those for the n-type alloy. However, its electrical resistivity increased with decreasing growth rates, and this was shown to be associated with the presence of a Te-rich second phase in the p-type alloy. Consistent with this interpretation are the results of an annealing study of these alloys.

The figure of merit of a thermoelectric material is often lowered by the presence of compositional and microstructural inhomogeneities in the material (1). These inhomogeneities are, in large part, related to growth conditions used for the material's preparation. Although the importance of optimum growth condition is generally recognized, only a few detailed studies (2) have been made in the past to elucidate the role of growth variables on the thermoelectric properties.

In this paper, we shall present the results obtained in a study of the effects of various growth rates on the thermoelectric properties of n- and p-type  $\text{Bi}_2\text{Te}_3\text{-Sb}_2\text{Te}_3\text{-Sb}_2\text{Se}_3$  pseudoternary alloys (3) grown by the Bridgman technique. The presentation of the results will include the metallographic observation of microstructures, and the dependence on growth rate of the Seebeck coefficient, electrical resistivity, and thermal conductivity at room temperature. Included also in this paper are the results of the effects of annealing at 390°C on the room temperature thermoelectric properties of these alloys.

It will be shown that lower growth rates result in better homogeneity and higher figures of merit for both n- and p-type alloys. However, the growth-rate dependence of their individual thermoelectric parameters is not the same, and this difference will be related to the difference in the microstructure of n- and p-type alloys, in particular, to the presence of a second phase in the latter alloy. These results will be corroborated by the annealing study.

### Experimental Procedure

An n-type composition  $(\text{Bi}_2\text{Te}_3)_{75}(\text{Sb}_2\text{Te}_3)_{20}(\text{Sb}_2\text{Se}_3)_5$  doped with 0.16 w/o (weight per cent)  $\text{SbI}_3$ , and a p-type composition  $(\text{Sb}_2\text{Te}_3)_{70}(\text{Bi}_2\text{Te}_3)_{25}(\text{Sb}_2\text{Se}_3)_5$

Key words: thermoelectric alloys;  $\text{Bi}_2\text{Te}_3\text{-Sb}_2\text{Te}_3\text{-Sb}_2\text{Se}_3$  alloys; microstructures; thermoelectric properties; effects of growth rate; effects of annealing.

containing 2 w/o excess Te were used for the present study.<sup>1</sup>

In the preparation of the alloys, high-purity (99.999%) component elements were used, and these were obtained from the American Smelting and Refining Company. The alloys were grown by a vertical Bridgman method with freezing rates ranging from 0.24 to 7.6 cm/hr but under a constant temperature gradient of  $\sim 25^\circ\text{C}/\text{cm}$  in the melt near the freezing interface. The resulting ingots, 0.7 cm in diameter and 18 cm long, consisted of coarse grains, whose cleavage characteristics suggested a preferred orientation with their (111) cleavage planes generally aligned with the long axis of the ingots, and this was particularly true for slowly grown ingots.

The metallographic observation of microstructure was made on sections cut perpendicular to the long axis of the ingots. The etchant used for the n-type material was 20%  $\text{HNO}_3$  in  $\text{H}_2\text{O}$ , and that for the p-type material was 1  $\text{HNO}_3\text{-2 HCl-2}$  saturated  $\text{K}_2\text{S}_2\text{O}_8$  in  $\text{H}_2\text{O}$ .

The measurements of electrical resistivity  $\rho$ , Seebeck coefficient  $Q$ , and thermal conductivity  $\kappa$  were made on short cylinders, 0.7 cm diameter and about 0.7 cm long. The electrical or temperature gradient was applied in the direction of the axis of the cylinder, which was the growth direction of the ingot and, as a result of the preferred growth, this direction coincided approximately with a direction perpendicular to the [111] trigonal axis of the crystallites. The mea-

<sup>1</sup>All compositions are in mole per cent unless otherwise specified, and they represent starting compositions. It should be noted that the above compositions do not correspond to the alloys of the highest figures of merit found in the pseudoternary system. The best n-type alloy is  $\text{SbI}_3$ -doped  $(\text{Bi}_2\text{Te}_3)_{90}(\text{Sb}_2\text{Te}_3)_5(\text{Sb}_2\text{Se}_3)_5$ , and the best p-type alloy is excess Te-doped  $(\text{Sb}_2\text{Te}_3)_{72}(\text{Bi}_2\text{Te}_3)_{25}(\text{Sb}_2\text{Se}_3)_3$ , having room temperature figures of merit  $3.2 \times 10^{-3}$  and  $3.4 \times 10^{-3}$  deg<sup>-1</sup>, respectively (3). Nevertheless, the results presented in this paper are representative of n-type materials in the  $\text{Bi}_2\text{Te}_3$ -rich end and p-type materials in the  $\text{Sb}_2\text{Te}_3$ -rich region of the pseudoternary alloys.

surement techniques have been given in detail in previous papers (3, 4). The measurements of these individual thermoelectric parameters provided a direct determination of the materials figure of merit,  $Z = Q^2/\kappa \cdot \rho$ .

A selected group of n- and p-type specimens was annealed in a partial pressure of Ar at 390°C for a duration as long as 1000 hr. The annealing temperature chosen was, as will be shown later, slightly lower than the melting point of a second phase present in the p-type material. The thermoelectric properties of each specimen were measured at room temperature before and after the annealing treatment. In addition, room temperature Hall coefficients were measured on a few representative slow-grown samples to study the effect of annealing on the carrier concentration and mobility. Hall specimens were prepared by cleaving the bulk material, and had typical dimensions of 7x2x0.3 mm. The direction of magnetic field was perpendicular to, and the current was parallel to, the cleavage plane.

In all measurements, specimens were taken from approximately the same location of ingots, ~ 6 cm from the first portion to freeze.

### Effects of Growth Rate

**Microstructure.**—The compound semiconductors  $\text{Bi}_2\text{Te}_3$ ,  $\text{Sb}_2\text{Te}_3$ , and  $\text{Sb}_2\text{Se}_3$  form pseudoternary solid-solution alloys over a wide range of compositions except in the neighborhood of large  $\text{Sb}_2\text{Se}_3$  concentrations (5). The phase diagrams of  $\text{Bi}_2\text{Te}_3$ - $\text{Sb}_2\text{Te}_3$  (6) and  $\text{Bi}_2\text{Te}_3$ - $\text{Sb}_2\text{Se}_3$  (7) show that the equilibrium distribution coefficient of  $\text{Sb}_2\text{Te}_3$  in  $\text{Bi}_2\text{Te}_3$  and that of  $\text{Sb}_2\text{Se}_3$  in  $\text{Bi}_2\text{Te}_3$  are nearly equal to unity. Therefore, the present materials, when undoped, are pseudoternary alloys of approximately uniform compositions along the length of ingots. For the n-type alloy used in the present study, the amount of  $\text{SbI}_3$  added was within its solubility limit of about 0.2 w/o in the  $\text{Bi}_2\text{Te}_3$ -rich pseudoternary alloys; hence, the present n-type alloy is a single-phase material. The distribution of the dopant appeared generally uniform, as inferred from a straight resistance-scan trace along the ingot except for the first and last 2-cm portions to freeze. For the present p-type alloy, the Te addition exceeded the solubility limit of about 0.2 w/o and therefore the p-type alloy is a two-phase material. Although the equilibrium distribution coefficient of Te in the  $\text{Sb}_2\text{Te}_3$ -rich pseudoternary alloys is less than one, the distribution of second phase was fairly uniform along the ingot except again near the first and last portions to freeze.

In Fig. 1, microstructures of fast-grown, n- and p-type alloys (a and c) are compared with those of slow-grown alloys (b and d). It is clearly seen that at the slow growth rates one obtains an improvement in the microstructural homogeneity.

**(N-type alloy).**—The n-type alloy, when slowly grown (~ 0.6 cm/hr), is a homogeneous material of large grain size, as evident from typical cleavage cracks running obliquely through the middle of Fig. 1(b). These cracks were introduced during polishing in one grain, and the dark area at the top of the photomicrograph is a portion of another grain. By contrast, the fast-grown (~ 4 cm/hr) n-type alloy consists of a lamellar structure, as shown in Fig. 1(a). These are probably the regions of severely varying composition, but are to be distinguished from second phase such as that present in the p-type alloy [Fig. 1(c) and 1(d)].

The lamellar structure is probably associated with constitutional supercooling (8). During growth of multicomponent alloys under a constant temperature gradient, unless the growth rate is sufficiently slow, constitutional supercooling would occur with ensuing compositional segregation. This appears to be the case for the fast-grown n-type alloy shown in Fig. 1(a). By using a slow growth rate, the constitutional super-

Fig. 1. Growth rate ( $R$ ) dependence of microstructures on n-type  $\text{SbI}_3$ -doped  $(\text{Bi}_2\text{Te}_3)_{75}(\text{Sb}_2\text{Te}_3)_{20}(\text{Sb}_2\text{Se}_3)_5$  and p-type excess Te-doped  $(\text{Sb}_2\text{Te}_3)_{70}(\text{Bi}_2\text{Te}_3)_{25}(\text{Sb}_2\text{Se}_3)_5$  alloys: (a) fast-grown n-type,  $R = 3.8$  cm/hr,  $Z = 1.4 \times 10^{-3}$  deg $^{-1}$ ; (b) slow-grown n-type,  $R = 0.57$  cm/hr,  $Z = 2.1 \times 10^{-3}$  deg $^{-1}$ ; (c) fast-grown p-type,  $R = 7.6$  cm/hr,  $Z = 2.2 \times 10^{-3}$  deg $^{-1}$ , and (d) slow-grown p-type,  $R = 0.64$  cm/hr,  $Z = 3.1 \times 10^{-3}$  deg $^{-1}$ . All taken on ingot cross sections.

cooling was avoided, as in Fig. 1(b). The effect on microstructure of different temperature gradients with a constant growth rate was not investigated. However, the effect of increasing the temperature gradient would be, as is well known (8), essentially similar to that of lowering the growth rate.

**(P-type alloy).**—The p-type alloy is, as stated above, a two-phase material consisting of a pseudoternary  $\text{Sb}_2\text{Te}_3$ - $\text{Bi}_2\text{Te}_3$ - $\text{Sb}_2\text{Se}_3$  solid-solution matrix and a second phase, which appears as lamellae on an etched cross section. An electron-probe analysis showed that the second phase was composed of approximately 90 a/o (atomic per cent) Te with small amounts of Bi, Sb, and Se. The melting point of this second phase was found by DTA to be about 415°C, as compared with ~ 450°C for pure Te. From these observations, it appears that the second phase is a eutectic rich in Te. It is interesting in this connection to note that the second phase, whether it resulted from the excess addition of Te or Se, melted at about the same temperature. This shows that in both cases the second phase is similar in composition, indicating that Se preferentially enters into solid solution, and rejects from it the Te-rich second phase (3, 4).

There is a marked difference in the microstructure, especially in the second phase, between fast- and slow-grown p-type alloys. At a growth rate of about 8 cm/hr, the second phase appears as thick lamellae along cleavage planes and grain boundaries, as in Fig. 1(c). At a much lower growth rate of 0.6 cm/hr, the second phase precipitates as thin discontinuous lamellae dispersed in the matrix, as in Fig. 1(d).

**Thermoelectric properties.**—The growth-rate dependence of the thermoelectric properties at 300°K of n- and p-type pseudoternary alloys is shown in Fig. 2(a) (Seebeck coefficient  $Q$ ), 2(b) (electrical resistivity  $\rho$ ), 2(c) (measured total thermal conductivity  $\kappa_{\text{total}}$ , and lattice thermal conductivity  $\kappa_{\text{ph}}$ ), and 2(d) (figure of merit  $Z$ ). The lattice thermal conductivity was obtained from the measured total thermal conductivity by using the relation,  $\kappa_{\text{total}} = \kappa_{\text{el}} + \kappa_{\text{ph}}$  where  $\kappa_{\text{el}}$  is the electronic thermal conductivity and no ambipolar contribution was assumed. The electronic contribution was calculated from the Wiedemann-Franz relation,

Fig. 2. Growth-rate dependence of thermoelectric properties at 300°K of n-type  $Sb_{13}$ -doped  $(Bi_2Te_3)_{75}(Sb_2Te_3)_{20}(Sb_2Se_3)_5$  and p-type excess Te-doped  $(Sb_2Te_3)_{70}(Sb_2Te_3)_{25}(Sb_2Se_3)_5$  alloys: (a) The Seebeck coefficient ( $Q$ ), (b) electrical resistivity ( $\rho$ ), (c) total thermal conductivity ( $\kappa_{total}$ ) and lattice thermal conductivity ( $\kappa_{ph}$ ); and (d) figure of merit ( $Z$ ).

for which the Lorentz number corresponded to the simple case of acoustical lattice scattering and non-degeneracy,  $2(k/e)^2$ , where  $k$  is the Boltzmann constant and  $e$  is the electronic charge.

For both the n- and p-type alloys,  $Q$  increases, and  $\kappa_{total}$  and  $\kappa_{ph}$  decrease, with decreasing growth rate  $R$ . The variations in  $\rho$  with  $R$  are, however, not the same for both materials:  $\rho$  of the n-type decreases, while that of the p-type alloy increases, with decreasing  $R$ .

In general, in a given material where doping impurities are fully ionized, one would expect the electrical resistivity to decrease as the material becomes more homogeneous. The change in  $\rho$  of the n-type alloy [Fig. 2(b)] shows this to be the case, since a greater inhomogeneity is associated with a slower growth rate, as shown by the microstructure in Fig. 1(b). However, the observed change in  $\rho$  of the p-type alloy cannot be explained on the basis of homogeneity alone.

It has been shown (3) that Te acts as a donor in the p-type alloy, and therefore the Te atoms in solid solution would raise the electrical resistivity of the p-type matrix by compensation. However, it is not the resistivity of the matrix that alone is responsible for the  $\rho$  of the bulk. A single-phase p-type alloy having the same major composition as the present one, when doped with a maximum soluble amount of Te of about 0.2 w/o, showed only a slight increase in  $\rho$  to  $7.5 \times 10^{-4}$  ohm-cm from the undoped value of  $6.5 \times 10^{-4}$  ohm-cm. With further additions of Te, the second phase started to precipitate, but the bulk  $\rho$  increased regularly with corresponding increase in  $Q$  up to an onset of the intrinsic conduction. Thus, the Te-rich second phase was essential in controlling the resistivity of the p-type alloy.<sup>2</sup>

The second phase at slow growth rates appears as thin, discontinuous lamellae [Fig. 1(d)] as contrasted to thick, continuous lamellae [Fig. 1(c)] at fast growth rates. While no simple explanation is available, it may be that the higher  $\rho$  for the slowly grown p-type alloy is due to the discontinuous nature of the second phase, in addition to a larger Te concentration in the matrix because of more time available for the solution of Te atoms. This is corroborated by annealing results, the discussion of which will follow shortly.

The present result on the growth-rate dependence of  $\rho$  of the p-type alloy is in disagreement with the result of Cosgrove *et al.* (2), who reported that the resistivity of a p-type material decreased with decreasing growth rate. The composition of their p-type

alloy was  $BiSbTe_3$  doped with 0.56 w/o Se or, in the pseudoternary notation, the material corresponded approximately to a solid solution of  $(Bi_2Te_3)_{50}(Sb_2Te_3)_{48}(Sb_2Se_3)_2$  containing 1 w/o excess Te, most of which would appear as a second phase. Because of this difference in the alloy composition, a direct comparison of the previous and the present results is difficult to make.

Cosgrove *et al.* (2) did not report the presence of a second phase, but they did detect n-type regions in the p-type matrix by thermal probing. It is possible that the n-type regions were of a similar nature to the Te-rich second phase, although in the present work the relatively small dimensions of the second phase rendered the thermal-probe technique unsuccessful.

The increase in  $Q$  for the p-type alloy with decreasing  $R$  is to be expected [Fig. 2(a)], since in an extrinsic semiconductor the Seebeck coefficient is approximately proportional to  $\ln \rho$ . Thus, the increase in  $Q$  for the p-type alloy can be accounted for by the corresponding increase in  $\rho$ . For the n-type alloy, the observed variation in  $Q$  with  $R$  is contrary to what one would expect from the change in  $\rho$ . It was first pointed out by Airapetians (1) that compositional inhomogeneities can substantially reduce the Seebeck coefficient and, at the same time, increase the thermal conductivity of a thermoelectric material by "circulating currents." As a consequence, the inhomogeneities lead to a lower figure of merit for the material. The increase in  $Q$  of the n-type alloy, in spite of a decrease in  $\rho$ , may be ascribed to an improvement in the material's homogeneity with decreasing growth rate.

The measured total thermal conductivity, as well as the lattice thermal conductivity, decreased with decreasing growth rate, as shown in Fig. 2(c). For the n-type alloy, the  $\kappa_{ph}$  decreased by about 20% when  $R$  was reduced from 4 to 0.6 cm/hr. By comparison, the  $\kappa_{ph}$  of the p-type alloy decreased only 5% on reducing  $R$  from 8 to 0.6 cm/hr.

Circulating currents tend to enhance heat transport; hence, a material containing second phase may exhibit a higher thermal conductivity than a similar material without the second phase. However, there is an additional effect on heat transport of the second phase, which tends to decrease the thermal conductivity. In a two-phase material, the possibility exists that sub-microscopic precipitates or crystalline defects, such as arrays of dislocations present at the phase boundaries, may cause significantly the scattering of phonons. Thus, the phonon scattering by these defects would modify the extent of increase in the thermal conductivity arising from circulating currents. Since the present two-phase p-type alloy is already imperfect, even when prepared under most ideal conditions [for instance, a dislocation density of  $10^{10} \sim 10^{11}$  cm<sup>-2</sup> (2) would be required to maintain lattice registry between the second phase and matrix], variations in the growth rate would not drastically alter the defect density. The fact that the  $\kappa_{ph}$  of the p-type alloy is nearly independent of  $R$  suggests this may be the case. Therefore, it appears that the contribution of the circulating currents is relatively small for the present materials, especially for the p-type alloy, over the range of growth rates used. The changes in  $\kappa_{ph}$  for the present case are in no way as large (by a factor of two) as those reported by Cosgrove *et al.* (2) for p-type  $BiSbTe_3$  doped with Se.

The changes in  $Q$ ,  $\rho$ , and  $\kappa$  with different growth rates are reflected in the figures of merit, as seen in Fig. 2(d). The figures of merit of the n- and p-type alloys were significantly improved by using slow growth rates: the resulting improvement in  $Z$  for both materials is more than 50%. The factors contributing the most to this improvement are the increase in  $Q$  and the reduction in  $\kappa_{ph}$  for the n-type, and the increase in  $Q^2/\rho$  for the p-type alloy. The results shown in Fig. 2(d) demonstrate clearly the important role of optimum growth conditions in achieving high figures of merit.

<sup>2</sup> The increase in  $\rho$  with increasing excess Te addition may alternatively be explained by the assumption that the second phase depletes the matrix of Bi and Sb (acceptors), and thus causes a decrease in the hole concentration in the material.

## Effects of Annealing

The changes in the room temperature thermoelectric properties of annealed specimens are shown in Fig. 3(a) ( $Q$ ), 3(b) ( $\rho$ ), 3(c) ( $\kappa_{\text{total}}$  and  $\kappa_{\text{ph}}$ ), and 3(d) ( $Z$ ). It is interesting to note that the rate of the changes is generally greater during the first 10-hr than longer-time annealing. As in Fig. 2, the broken curves are for n-type and the full curves are for p-type alloys. For ease of reference, the same symbol for each individual data point was used in Fig. 3 as in Fig. 2. For example, a full circle at zero annealing time in Fig. 3 corresponds to the same p-type alloy grown at 0.6 cm/hr shown by the full circle in Fig. 2. Also included in Fig. 3 (open triangles) are the annealing data of slow-grown, single-phase, undoped, p-type alloy having the same major composition as the Te-doped alloy.

For fast-grown n-type alloy,  $Q$  increased while  $\rho$  and  $\kappa_{\text{ph}}$  decreased; thus,  $Z$  increased with annealing in a manner similar to the effects of decreasing the growth rate. Although no apparent change in microstructure was observed, this improvement must be related to a partial homogenization of segregated structures. As might be expected, the slowly grown n-type alloy showed essentially no change upon annealing in its thermoelectric properties.

For Te-doped p-type material, annealing resulted in an increase in  $Q$  and  $\rho$ , while  $\kappa_{\text{ph}}$  remained unchanged for both the fast- and slow-grown alloys; hence, there was a slight improvement in  $Z$ . These changes in the thermoelectric properties are again reminiscent of the effects of lowering the growth rate.

Since the single-phase, undoped, p-type alloy showed essentially the same properties before and after the annealing, the increase in  $Q$  and  $\rho$  of the Te-doped alloy must have resulted from the presence

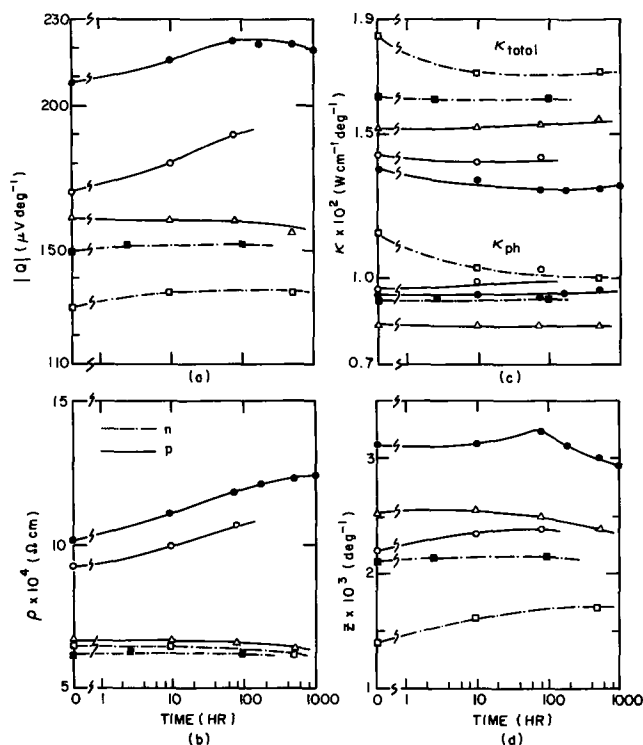

Fig. 3. Variations in thermoelectric properties at 300°K of n-type  $\text{Sb}_{13}$ -doped ( $\text{Bi}_2\text{Te}_3)_{75}(\text{Sb}_2\text{Te}_3)_{20}(\text{Sb}_2\text{Se}_3)_5$ ; p-type undoped, and excess Te-doped ( $\text{Sb}_2\text{Te}_3)_{70}(\text{Bi}_2\text{Te}_3)_{25}(\text{Sb}_2\text{Se}_3)_5$  with annealing time: (a) the Seebeck coefficient ( $Q$ ); (b) electrical resistivity ( $\rho$ ); (c) total thermal conductivity ( $\kappa_{\text{total}}$ ) and lattice thermal conductivity ( $\kappa_{\text{ph}}$ ), and (d) figure of merit ( $Z$ ). ( $\circ$ ) excess Te-doped p-type,  $R = 7.6$  cm/hr; ( $\bullet$ ) excess Te-doped p-type,  $R = 0.64$  cm/hr; ( $\Delta$ ) undoped p-type,  $R = 0.64$  cm/hr; ( $\square$ )  $\text{Sb}_{13}$ -doped n-type,  $R = 3.8$  cm/hr; and ( $\blacksquare$ )  $\text{Sb}_{13}$ -doped n-type,  $R = 0.57$  cm/hr.

Table I. Effect of annealing on room temperature carrier concentration and mobility

	Anneal. time, hr	Carrier conc., $10^{18}/\text{cm}^3$	Mobility, $\text{cm}^2/\text{v} \cdot \text{sec}$
p-type	0	2.3	271
	73	1.9	280
n-type	0	7.0	143
	100	6.8	149

p-type: doped with 2 w/o excess Te, grown at 0.64 cm/hr; n-type: doped with 0.16 w/o  $\text{Sb}_{13}$ , grown at 0.57 cm/hr.

of the Te-rich second phase in the doped alloy. It is most probable that on annealing some re-resolution of Te takes place, which causes a decrease in the hole concentration and results in an increase in  $\rho$  and  $Q$ . The metallographic examination, however, revealed no change in the microstructure after annealing. This is reasonable in view of the following simple argument.

If one assumes that each Te atom acts as a singly ionized donor, and that the hole mobility is independent of annealing, then one can calculate the change in the hole concentration corresponding to the change in  $\rho$ . The number of Te atoms that must dissolve in order to effect the experimentally observed  $\rho$  change, was calculated to be negligibly small as compared with that present in the second phase. Thus, one would not expect to see any change in the structure metallographically. The same conclusion was also arrived at from the calculation of the change in  $Q$  on annealing, with the assumption that  $Q$  is inversely proportional to logarithm of the carrier concentration. A slight decrease in  $Q$  and  $Z$  for the slow-grown p-type alloy beyond 100-hr annealing may be due to evaporation of Te from the specimen, as evidenced sometimes from a thin, shiny film deposit on the inside wall of quartz ampoule.

In a material such as the present p-type alloy, it is difficult to obtain reproducible Hall data because of the presence of second phase. Nevertheless, the data shown in Table I<sup>3</sup> indicate that the changes with annealing in  $Q$  and  $\rho$  of slowly grown p-type alloy were due mostly to a change in the carrier concentration, resulting presumably from the Te re-resolution. For slowly grown n-type alloy, the Hall data show that there was essentially no change in the carrier concentration, nor in the mobility.

## Conclusions

The effects of various growth rates on the thermoelectric properties of n- and p-type  $\text{Bi}_2\text{Te}_3$ - $\text{Sb}_2\text{Te}_3$ - $\text{Sb}_2\text{Se}_3$  pseudoternary alloys have been investigated and correlated with microstructures. The results show that higher values of the figure of merit are invariably associated with lower growth rates and hence greater homogeneity. For both n- and p-type alloys, the improvement in the figure of merit was as large as 50% when the growth rate was reduced from about 6 to 0.6 cm/hr. However, the growth rate dependence of individual thermoelectric parameters was not the same for both alloys.

For the n-type alloy, which is a single-phase material, slow growth rates resulted in an increase in the Seebeck coefficient, and a decrease both in the lattice thermal conductivity and electrical resistivity. These changes are what one would expect from an improvement in the material's homogeneity with decreasing growth rate, since the deleterious effects of circulating currents would diminish as material's homogeneity improves. For the p-type alloy, which is a two-phase material, the variations with growth rate in the Seebeck coefficient and, to a lesser extent, in the lattice thermal conductivity were similar to those in the n-

<sup>3</sup> The carrier concentration was calculated with the assumption of simple spherical band structure, and the mobility reported here is the Hall mobility,  $R_H \cdot \sigma$ , where  $R_H$  is the Hall coefficient and  $\sigma$  is the electrical conductivity.

type alloy. However, slow growth rates resulted in an increase in its electrical resistivity. The resistivity increase in the p-type alloy was interpreted on the basis of Te re-resolution from the Te-rich second phase present in the alloy. Consistent with this interpretation are the results of an annealing study of these alloys. The annealing effects, while less pronounced, were essentially similar to those brought about by variations in the growth rate.

#### Acknowledgments

The authors are grateful to E. J. Stofko and T. V. Pruss for their valuable contributions in materials preparation and thermoelectric measurements. Constructive comments by F. D. Rosi during the course of this work are gratefully acknowledged.

## Technical Note

### Eu<sup>+2</sup> Activation in Some Alkaline Earth Strontium Phosphate Compounds

M. V. Hoffman\*

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio

The fluorescence of divalent europium has received increased attention recently, and a number of phosphors emitting in the blue or ultraviolet region have been described. The efficiency and the narrow spectral distribution of Eu<sup>+2</sup>-activated phosphors make them attractive for use in reprographic and black light applications and for ultraviolet emission in cathode-ray tubes. Nazarova (1) found cathodoluminescence in Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, α and β Sr<sub>2</sub>P<sub>2</sub>O<sub>7</sub> and Sr(PO<sub>3</sub>)<sub>2</sub>, all with Eu<sup>+2</sup> activation. In another group of strontium compounds, Gorbacheva (2) found that Eu<sup>+2</sup> did not enter the β (Sr,Mg)<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> structure completely unless very strong reducing conditions were used, and this gave yellow emission. She also found blue emission with Eu<sup>+2</sup> in SrMg<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>. More recently, Wanmaker and ter Vrugt (3) have reported that divalent europium responds efficiently to ultraviolet excitation in alkaline earth pyrophosphates and showed that the strontium compounds were the most efficient. They described Sr<sub>2</sub>P<sub>2</sub>O<sub>7</sub>:Eu and Sr<sub>0.8</sub>Mg<sub>1.2</sub>P<sub>2</sub>O<sub>7</sub>:Eu and showed that they are efficient phosphors with narrow emission bands.

As pointed out by Wanmaker and ter Vrugt, the Sr compounds are suitable potential host lattices for Eu<sup>+2</sup> activation because of the similarity of ionic radii (Sr<sup>+2</sup> 1.13Å, Eu<sup>+2</sup> 1.17Å). In addition to a site for Eu<sup>+2</sup> substitution, the host lattice should have chemical stability in the nonoxidizing atmospheres required to place Eu in the site as a divalent cation and also the absence of a site or structure which will hold Eu in its preferred trivalent state.

A group of compounds which illustrate these requirements are found in the ternary systems SrO-MgO-P<sub>2</sub>O<sub>5</sub> and SrO-ZnO-P<sub>2</sub>O<sub>5</sub>, and these were exam-

ined with Eu<sup>+2</sup> activation. The orthophosphate joins of these systems have been described previously by Sarver, Hoffman, and Hummel (4). The compounds on these joins are the true ternary orthophosphates, SrMg<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub> and SrZn<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>, and the stabilized high-temperature forms, or β form of Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>, which are found only in the ternary region. These systems also contain the compounds SrMgP<sub>2</sub>O<sub>7</sub>, Mg<sub>3</sub>Sr<sub>2</sub>P<sub>4</sub>O<sub>15</sub>, and SrZnP<sub>2</sub>O<sub>7</sub>. The compatibility triangles are shown in Fig. 1 and 2. No solid solutions were found except in the β orthophosphate regions.

Fig. 1. Compatibility triangles in part of SrO-MgO-P<sub>2</sub>O<sub>5</sub> system

\* Electrochemical Society Active Member.

Fig. 2. Compatibility triangles in part of SrO-ZnO-P<sub>2</sub>O<sub>5</sub> system

The x-ray diffraction data for these compounds are shown in the Appendix.

#### Phosphor Preparation

The starting materials used in these experiments were SrHPO<sub>4</sub>, SrCO<sub>3</sub>, MgNH<sub>4</sub>PO<sub>4</sub>·H<sub>2</sub>O, MgCO<sub>3</sub>, ZnO, (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub>, and Eu<sub>2</sub>O<sub>3</sub>, all of purity normally used in phosphor manufacture. The europium was used either as the oxide or coprecipitated with the strontium compounds. The materials were mixed dry and fired in air at temperatures of from 900° to 1100°C, depending on the composition used. Samples containing a large amount of (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub> were fired initially at 550°C for several hours, milled, and then refired at a higher temperature. The final firing was in a flowing nonoxidizing atmosphere, usually a mixture of less than 1% H<sub>2</sub> in N<sub>2</sub>. Other atmospheres such as mixture of CO and CO<sub>2</sub> can also be used satisfactorily.

#### Measurements

The identifications of these compounds and their determination when present as minor, second phases in the various phosphor preparations were made by x-ray diffraction, using the General Electric XRD-5 with CuK<sub>α</sub> radiation. The emission spectra were obtained with a corrected, direct recording spectrometer with a grating monochromator (5). The excitation response between 120 and 300 nm was determined with a vacuum monochromator and is relative to sodium salicylate. The reflectance spectra in this region were determined on the same instrument and are relative to CaF<sub>2</sub>. This standard is used because it has a higher reflectivity in the ultraviolet than MgO and also is more stable with time. The method used to measure the excitation and reflectance below 300 nm has been described by Johnson (6).

The reflectance measurements in the visible and near ultraviolet regions were made on a Cary 14 spectrophotometer and are also relative to CaF<sub>2</sub>. In the Cary 14, monochromatic light is directed on to the sample, and the photocell detects all wavelengths coming from the sample; i.e., reflected light of the incident wavelength and also any fluorescence emitted by the sample, if it is excited by the incident light. The instrument is modified to measure reflectance of materials fluorescing in the visible by the insertion of a Corning 7-54 filter between the sample and the detector when measuring in the ultraviolet region. Fluorescence in the ultraviolet is transmitted by the 7-54 filter and is recorded as a rise in the reflectance curve at the exciting wavelengths. The Cary 14 is extremely sensitive in this region and can be used to detect weak ultraviolet fluorescence. With phosphors as efficient as those reported here, the interference of the fluorescence is too large to obtain meaningful reflectance

Table I. Summary of fluorescence spectra

Compound	Emission peak 254 nm excitation nm	Half width nm	Relative peak height
SrMgP <sub>2</sub> O <sub>7</sub> :0.02Eu	393	26	100
αSr <sub>3</sub> (PO <sub>4</sub> ) <sub>2</sub> :0.01Eu	405	43	60
αSr <sub>2</sub> P <sub>2</sub> O <sub>7</sub> :0.18Eu	415	40	47
Sr <sub>3</sub> P <sub>4</sub> O <sub>13</sub> :0.02Eu	415	60	20
SrMg <sub>2</sub> (PO <sub>4</sub> ) <sub>2</sub> :0.02Eu	410	47	18
Mg <sub>3</sub> Sr <sub>2</sub> P <sub>4</sub> O <sub>15</sub> :0.02Eu	440	—	5

curves below 400 nm. The instrument, as modified by the insertion of the 7-54 filter, was used to determine the presence or absence of ultraviolet fluorescence, and to give a qualitative measure of the excitation.

#### Results

The incorporation of Eu<sup>+2</sup> is possible in all of the strontium compounds in these systems, resulting in strong absorption bands in the ultraviolet region. The emission and excitation spectra are dependent on the composition and structure of the host lattice. Table I summarizes the fluorescence spectra found for the more efficient phosphors in these systems.

Of the orthophosphate compounds, only αSr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup> is efficient. Nazarova (1) reported an emission peak at 425 nm under cathode-ray excitation. We measured the emission at 405 nm under 254 nm excitation. The SrMg<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub> compound is much less efficient, peaks at 410 nm, and is excited by radiation below 260 nm. The spectral distribution curves of these two phosphors are shown in Fig. 3. The compound, Mg<sub>3</sub>Sr<sub>2</sub>P<sub>4</sub>O<sub>15</sub>, is the least efficient and peaks at 440 nm, with the major excitation below 250 nm.

The SrZn<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub> and SrZnP<sub>2</sub>O<sub>7</sub> compounds are strongly absorbing with Eu<sup>+2</sup> present, but have no visible or ultraviolet fluorescence. The reflectance curves show no evidence of ultraviolet emission under any excitation, Fig. 4. Measuring the reflectance and excitation of SrZn<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu between 140 and 300 nm with the vacuum monochromator also showed no emission and 75-85% absorption in this region.

The substitution of Eu in the β(SrMg)<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub> compound gave both blue and red emission from the two valence states of Eu and showed Eu<sup>+3</sup> absorption lines, even when fired in an atmosphere of 5% H<sub>2</sub> in N<sub>2</sub>.

The β structure is stabilized by the incorporation of a divalent cation such as Mg, Ca, Zn, or Cd in the orthophosphate stoichiometry (4) and should be expected to accept Eu<sup>+2</sup> without difficulty in the Sr site. The β structure, however, can also be stabilized by a trivalent cation, such as Al<sup>+3</sup>, and this stoichiometry falls on the Sr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>-AlPO<sub>4</sub> join, resulting in a de-

Fig. 3. Spectral distribution, 2537Å excitation: curve 1, SrMgP<sub>2</sub>O<sub>7</sub>:0.02Eu<sup>+2</sup>; curve 2, SrMg<sub>2</sub>(PO<sub>4</sub>)<sub>2</sub>:Eu<sup>+2</sup>; curve 3, MgWO<sub>4</sub>; curve 4, αSr<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>:0.01Eu.

Fig. 4. Diffuse reflectance curves,  $\text{SrZnP}_2\text{O}_7:0.01\text{Eu}^{+2}$  and  $\text{SrZn}_2(\text{PO}_4)_2:0.01\text{Eu}^{+2}$ .

fect structure (7). The substitution of  $\text{YPO}_4$  also forms a compound with an x-ray diffraction pattern very similar to Al-stabilized  $\beta$   $\text{Sr}_3(\text{PO}_4)_2$  and may also be the  $\beta$  form. The presence of both blue and red fluorescence suggests that Eu has substituted for  $\text{Sr}^{+2}$  and is also present as  $\text{Eu}^{+3}$ , plus a cation vacancy. Both types of substitution may be present in the same structure, but more likely, the presence of  $\text{Eu}^{+3}$  has moved the composition into a two-phase region of  $\beta$   $(\text{Sr},\text{Mg})_3(\text{PO}_4)_2$  and a  $\beta$ -type structure stabilized with  $\text{Eu}^{+3}$ .

The ternary pyrophosphate  $\text{SrMgP}_2\text{O}_7$  is the most efficient phosphor found in these systems, as shown in Table I. The compatibility relationships show that this compound does not accept  $\text{Mg}_2\text{P}_2\text{O}_7$  or  $\text{Sr}_2\text{P}_2\text{O}_7$  in solid solution, i.e., compositions on the join on either side of  $\text{SrMgP}_2\text{O}_7$  will be two-phase material. The luminescent data and the x-ray diffraction pattern given in ref. (3) for the composition  $\text{Sr}_{0.8}\text{Mg}_{1.2}\text{P}_2\text{O}_7:\text{Eu}$  reflect the presence of more than one phase. The inclusion of  $\text{Mg}_2\text{P}_2\text{O}_7$  with  $\text{SrMgP}_2\text{O}_7$  has no effect on the  $\text{Eu}^{+2}$  emission other than a decrease of the measured intensity due to dilution with an inert material. Composition high in  $\text{Sr}_2\text{P}_2\text{O}_7$ , however, affect the emission and absorption much more strongly than the relative intensities of the two phosphors would indicate.  $\alpha\text{Sr}_2\text{P}_2\text{O}_7$  accepts considerable  $\text{Eu}_2\text{P}_2\text{O}_7$  in solid solution and reaches its peak fluorescence intensity at compositions between  $\text{Sr}_{1.9}\text{Eu}_{0.1}\text{P}_2\text{O}_7$  and  $\text{Sr}_{1.8}\text{Eu}_{0.2}\text{P}_2\text{O}_7$ , or about five to ten times the amount found to be optimum in other  $\text{Eu}^{+2}$ -activated phosphors. When mixtures containing  $\text{Sr}_2\text{P}_2\text{O}_7$  and  $\text{SrMgP}_2\text{O}_7$  are prepared with  $\text{Eu}^{+2}$ ,  $\text{Sr}_2\text{P}_2\text{O}_7$  preferentially accepts the activator, and the emission of  $\text{Sr}_2\text{P}_2\text{O}_7:\text{Eu}^{+2}$  at 415 nm is present in much greater proportion than the compound itself.

The peak fluorescence intensity in the ternary pyrophosphate is found between the composition  $\text{Sr}_{0.99}\text{Eu}_{0.01}\text{MgP}_2\text{O}_7$  and  $\text{Sr}_{0.90}\text{Eu}_{0.10}\text{MgP}_2\text{O}_7$ , with almost constant intensity between  $\text{Sr}_{0.99}\text{Eu}_{0.01}\text{MgP}_2\text{O}_7$  and  $\text{Sr}_{0.95}\text{Eu}_{0.05}\text{MgP}_2\text{O}_7$ . This phosphor peaks at 393 nm under long and short ultraviolet and under cathode-ray excitation. The reflectance curve from the Cary 14 shows considerable emission under 360 nm excitation and strong fluorescence below 325 nm. The true excitation and reflectance curves in the region from 140 to 300 nm are shown in Fig. 5.

The response to excitation between 120 and 300 nm was compared to sodium salicylate, which is constant between the region of 230 to 330 nm, and has a quan-

Fig. 5.  $\text{SrMgP}_2\text{O}_7:0.02\text{Eu}$  phosphor:  $\Delta$  excitation relative to  $\text{NaC}_7\text{H}_5\text{O} = 1$ ;  $\circ$  reflectance relative to  $\text{CaF}_2 = 1$ .

Fig. 6. Relative intensity of 393 nm peak for cation substitution in  $\text{SrMgP}_2\text{O}_7:0.02\text{Eu}^{+2}$ .

tum yield of 64% (8, 9). From this comparison,  $\text{SrMgP}_2\text{O}_7:\text{Eu}$  is almost constant over the range 220-300 nm and has a quantum yield of 90-95%.

#### Cation Substitution

$\text{SrMgP}_2\text{O}_7$  has two sites for cation substitutions, and a wide range of solid solutions are possible. Complete solid solution is probably between  $\text{SrMgP}_2\text{O}_7$  and  $\text{BaMgP}_2\text{O}_7$  and between  $\text{SrMgP}_2\text{O}_7$  and  $\text{SrZnP}_2\text{O}_7$ . Partial substitution of Ca for Sr can be made although the analogous compound  $\text{CaMgP}_2\text{O}_7$  does not exist. The effect on the  $\text{Eu}^{+2}$  emission was measured for substitutions of these cations, and the changes in peak height of the 393 nm emission are shown in Fig. 6. At least 20 mole % of Ba can be substituted without an appreciable change in the peak intensity. With 40% substitution, the brightness is decreased only about 10%, but the compound with complete substitution,  $\text{BaMgP}_2\text{O}_7:\text{Eu}$ , emits at 400 nm, with about 10% of the efficiency of the  $\text{SrMgP}_2\text{O}_7$  analogue. With the substitution of  $\text{Ca}^{+2}$ , a smaller cation, the intensity is decreased and the emission peak is shifted to longer wavelengths (Fig. 7). Substitutions of 10% Zn for Mg changed the absorption edge of the lattice to 390 nm, and the intensity of the emission decreased by about 50%.

#### Acknowledgments

The author would like to thank Dr. R. L. Brown, T. E. Lusk and B. Walsh for the emission and excitation data. The samples were prepared and measured by R. P. Kattler.

## ABSTRACT

Physical-chemical studies of the electrolyte system KOH-ZnO in the range 30-46% aqueous KOH are described. Vapor pressures at 100°-145°C were obtained in sealed bombs equipped with gauges. Electrical conductivities of samples were measured at 10°, 25°, and 55°C. ZnO solubilities over the range 10°-145°C were determined by analysis of KOH solutions saturated with ZnO; a special solubility apparatus was constructed to obtain samples at temperatures above 100°C.

The aim of this study was to obtain fundamental physical-chemical data for the KOH-ZnO electrolyte system, for use in the development of heat-sterilizable silver-zinc cells. The region of interest for this application included electrolyte concentrations of 35, 40, and 45% KOH, sterilization temperatures of 125°, 135°, and 145°C, and operating temperatures in the range of 10°-55°C.

Vapor pressures of aqueous KOH above 100°C have been previously obtained by extrapolation of data taken below 100°C (1) or by comparison with a reference liquid (2). Electrical conductivities have been reported for KOH solutions at several temperatures by Klochko and Godneva (3), and for ZnO-saturated KOH at 25°C by Dirkse (4). Solubility of ZnO in KOH has been studied by Dirkse for the range -30° to 44°C (4).

In the present work, the following are included: (I) Direct measurements of the vapor pressure of 30-46% KOH solutions in the temperature range of 100°C to 145°C. (II) Conductivity data at 10°, 25°, and 55°C for 35-46% KOH solutions containing varying levels of dissolved ZnO from zero concentration to saturation. (III) Studies of ZnO solubility in 35-46% KOH for several temperatures in the range of 10°-145°C.

In general, reagent grade ZnO powder was dissolved in KOH solutions of various concentrations to make electrolytes for these measurements. Analysis for ZnO content was made by titrating  $Zn^{++}$  with 0.1M EDTA to the xylene orange endpoint (pH 5.0-5.5), and for KOH by titrating  $K^+$  with sodium tetraphenylborate solution using an amperometric endpoint detection. Limits of experimental error were  $\pm 0.05\%$  ZnO and  $\pm 0.25\%$  KOH. Individual experimental details will be given in the respective sections to follow.

## Vapor Pressure

Vapor pressures were measured in sealed nickel bombs heated in an oil bath. These bombs were constructed from 2.5 in. diameter nickel pipe nipples, 8 in. long, and nickel pipe couplings. Both items were cut in half and a round, nickel plate heliarc welded to all cut surfaces, thereby making two bombs with caps. Pressures were read on 3 in. dial ammonia gauges with 0-100 psig range. These were connected to the cap through  $\frac{1}{4}$  in. stainless steel fittings and tubing. The parts were assembled using Teflon pipe tape which helped to seal and prevent galling. The oil baths were Blue M, Model MOD-115A, which operated over the range 0-180°C and maintained temperature to within  $\pm 0.5^\circ C$ . The "oil" used was Blue M High Temperature Ucon Fluid.

Key Words: dissolution rate, ZnO in aq. KOH; electrical conductivity, aq. KOH and aq. ZnO-KOH; potassium hydroxide, aq. electrolytes; silver-zinc cells, heat sterilizable; solubility, ZnO in aq. KOH; vapor pressure, aq. KOH; zinc oxide, in aq. KOH.

Initial experiments showed that aqueous KOH, directly in contact with nickel, yielded the same pressure at the elevated temperatures as when contained in a Teflon or polypropylene liner. Pressures in the sealed bomb were read directly in psig and corrected for increase in pressure of entrapped air with temperature. Minor corrections were also applied for expansion of electrolyte and for change of solution concentration due to transfer of water to the vapor phase. Figure 1 presents an Othmer-type plot (5) for vapor pressure of KOH solutions at sterilization temperatures. This plot also includes values obtained from the International Critical Tables (1) for temperatures of 100°C and below.

The Othmer method presupposes constancy of the ratio of molar latent heats of the liquid under study and a reference liquid, according to the equation

$$\log P = (L/L') \log P' + C$$

where  $P$  and  $P'$  are the vapor pressures of the liquid being studied (KOH solution) and the reference liquid ( $H_2O$ ),  $L$  and  $L'$  are their molar latent heats, and  $C$  is an integration constant. The data show that the Othmer treatment of vapor pressure for this system is valid up to and including the highest sterilization temperature.

Experiments with KOH-ZnO solutions yielded no consistent pattern of vapor pressure vs. ZnO concentration at the sterilization temperatures. In fact, within limits of experimental error ( $\pm 0.5^\circ C$ ;  $\pm 0.25\%$  KOH;  $\pm 15$  mm Hg) there was no effect of ZnO dissolution on the vapor pressures of the KOH solutions.

## Conductivity

Electrical conductivities of aqueous KOH and KOH-ZnO solutions were measured using a 50 ml conduc-

Fig. 1. Othmer-type plot; vapor pressure of KOH solutions

Fig. 2. Conductivity of KOH solutions

Fig. 3. Conductivity of KOH-ZnO solutions

tivity cell and a Wayne-Kerr Universal Bridge with low impedance adaptor. The cell was immersed in a temperature-controlled water bath until the resistance for a given electrolyte at a given temperature became constant. Calibration and cell-constant determination were periodically checked using a 1 demal KCl standard solution.

Conductivities of pure KOH solutions at three temperatures are plotted in Fig. 2, which includes data for 25°C from Klochko and Godneva (3). Figure 3 gives data on KOH-ZnO conductivities for the same temperatures. Each line of Fig. 3 begins with the conductivity of pure KOH of a given concentration; the conductivity then decreases slightly with increasing addition of ZnO (expressed as final weight per cent ZnO in the given initial KOH solution). A large number of data points were determined for 40% KOH at 25°C to indicate the experimental accuracy of the measurements. Conductivity points from the data of Dirkse (4) are included for ZnO-saturated solutions at 25°C.

#### Solubility

Preliminary experiments for determining the rate of ZnO dissolution in KOH at sterilization temperatures were run in the sealed nickel bombs, or in similar bombs of stainless steel when magnetic stirring was to be used. In the latter case, the bombs contained Teflon inserts to prevent corrosion of the stainless steel by the hot caustic solutions.

The dissolution of ZnO into aqueous KOH at 145°C as a function of time is plotted in Fig. 4. For each run of this experiment, sufficient ZnO powder was added to 100 ml of a given KOH concentration to yield 8% ZnO in the final solution if all were to dissolve. No stirring was employed; samples for analysis were siphoned from the supernatant solution after the bombs were allowed to cool to room temperature. Dissolution of ZnO in the electrolyte under these conditions increased with time and with KOH concentration. However, in similar experiments with stirring during the heating period, the time dependence was not present and all solutions appeared to be saturated with ZnO at room temperature, even after short heating times. Furthermore, even when samples were unstirred dur-

Fig. 4. Dissolution of ZnO in KOH at 145°C

ing sterilization, a simple physical mixing of the electrolyte and undissolved ZnO followed by a centrifugation of this mixture yielded solutions which were saturated with ZnO to the same level as those which had been stirred for the whole time. These room temperature solubility values, which agreed with those obtained by dissolution of excess ZnO in KOH at 25°C with stirring, are given in Table I.

The above experiments indicated that the rate of ZnO dissolution in KOH is rapid when stirring is employed, but is strongly time dependent in unstirred systems in which diffusion of the soluble species away from the solid-electrolyte interface is a significant factor. A further experiment was devised to confirm this point. Eight 75 ml samples of 40% KOH, containing varying quantities of ZnO powder, were shaken for one minute each at 25°C and then immediately centrifuged and the solutions analyzed. The results are plotted in Fig. 5, in which "ZnO mixed with KOH" signifies sufficient ZnO to yield the final % ZnO indicated if all were to dissolve. The actual amount of ZnO dissolved for a given amount present increases linearly at low ZnO and levels off with increasing excess ZnO as saturation is approached.

In many of the dissolution rate experiments, Tyndall effect observations showed that colloidal dispersion accompanied the dissolution of ZnO. By comparing analyses of clear saturated solutions with those of saturated solutions having heavy Tyndall effects, it was determined that the amount of ZnO in colloidal form was very small and could be neglected in comparison to the amount in solution.

The following conclusions were reached as a result of the dissolution rate experiments:

1. Dissolution of ZnO powder in KOH is rapid when stirring or mixing is used.
2. Dissolution may be slow in unstirred solution due to (a) small quantity of ZnO surface exposed to electrolyte, and (b) limited diffusion of dissolved species away from the solid-liquid interface.
3. The diffusion-limited nature of the dissolution of ZnO in aqueous KOH, and the resulting stratification effect in unstirred electrolyte, is more pronounced the higher the KOH concentration.
4. Colloidal dispersion may occur when excess ZnO is present; however, the quantity in colloidal form is small compared to that in solution.

Initial experiments for determining equilibrium solubilities were run for the range 10°-95°C. Excess ZnO was added to solutions saturated at room temperature in stoppered flasks. These were immersed in a water-bath at the desired temperature and agitated for two days or longer, then allowed to settle until no Tyndall

Table I. Solubility of ZnO in KOH at 25°C

Initial % KOH	Final % ZnO
46	8.3
40	6.5
35	5.2

Fig. 5. Dissolution of ZnO into 40% KOH at 25°C

effect was observable in the supernatant solution. Samples of the solution were then siphoned for analysis. Results indicated little or no variation of ZnO solubility with temperature, i.e., the quantity of ZnO dissolved in each KOH concentration was the same over the entire temperature range as listed in Table I. To check this further, a plot of literature data [listed as % Zn vs. % K in the equilibrium saturated solutions by Dirkse (4)] was made and is shown in Fig. 6. The solid line is drawn for the 25°C data; ZnO solubility increases with KOH concentration along this smooth curve up to about 36% K (corresponding to about 52% KOH), then decreases rapidly with increasing KOH concentration above this point. The data for other temperatures fall along this curve, but the "critical region" of KOH concentration differs for each temperature, as indicated by the broken lines in Fig. 6. For the range of KOH concentration of interest in the present studies, viz. 35-45% initial KOH (or about 23-30% K in the final saturated solution), Fig. 6 suggests that ZnO solubility is temperature independent or very nearly so for all temperatures above 0°C.

In order to ascertain whether the temperature invariance of ZnO solubility in aqueous KOH extends up to sterilization temperatures, a special solubility apparatus was constructed as illustrated in Fig. 7. It consisted of two sealed stainless steel bombs with Teflon liners, connected by a nickel siphon tube for isolating and transferring a small sample of saturated

Fig. 6. Composition of saturated KOH-ZnO solutions

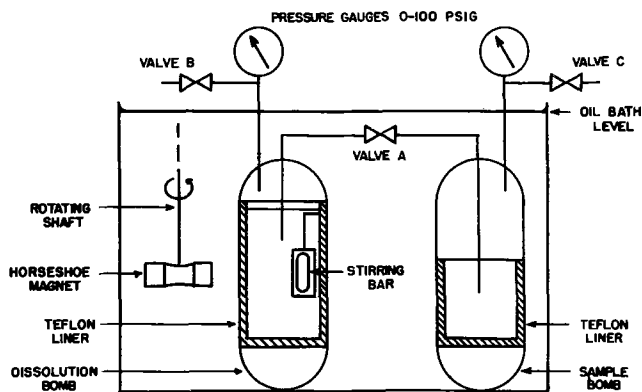

Fig. 7. Schematic of solubility apparatus

Fig. 8. Composition of saturated KOH-ZnO solutions

solution. Valves and fittings were Monel, and gaskets were Teflon. For a given solubility determination, KOH saturated with ZnO at room temperature was placed together with excess ZnO into the dissolution bomb. The apparatus was then assembled in sealed condition with all valves closed, and brought up to temperature in the oil bath. The solution was stirred at least 48 hr to assure attainment of equilibrium, using a magnetic stirrer suspended by silver wire and activated by a rotating horseshoe magnet external to the bomb. After allowing the excess suspended ZnO to settle for a minimum of 48 hr, a valve "A" was opened and a sample of the saturated solution was transferred through the siphon tube; the excess vapor pressure in the dissolution bomb relative to the empty sample bomb was sufficient to accomplish this transfer. When both bombs reached the same pressure, valve "A" was closed; the oil bath was then allowed to cool to room temperature and the sample removed for analysis.

Results of solubility experiments for all temperatures are plotted in Fig. 8. The 25°C curve from Fig. 6 is included in Fig. 8 for comparison. The data from this work confirms that there is little or no temperature dependence of ZnO solubility in aqueous KOH in the range of 35-46% KOH and 10°-145°C.

### Discussion

Baker and Trachtenberg have recently reported conductivity and solubility data for KOH and ZnO-KOH solutions over the temperature range -66° to 36°C (6). These data are in agreement with our results, which are referred to in their article under JPL Contract 951296 (their reference 1). Also described in our original reports are a number of experiments showing the applicability of the fundamental data to sterilizable Ag-Zn cells. The important observations and conclusions of the latter studies are given in the latest contract summary report (7).

The findings of this study suggest a number of possible areas for future investigations which could be of theoretical and practical importance. More sensitive techniques would allow the detection of small changes in vapor pressure of KOH with dissolution of ZnO, which, in turn, could be related to solution activity, etc. Extension of these measurements to low KOH concentrations would also be of interest, especially since a theoretical treatment would be feasible in that region. Finally, diffusion measurements and studies of colloidal properties for this system would be desirable.

### Acknowledgments

The authors wish to express their appreciation to Mr. Ted Heyman for carrying out much of the experimental work. This work was performed for the Jet Propulsion Laboratory, California Institute of Technology, sponsored by the National Aeronautics and Space Administration under Contract NAS7-100.

Manuscript received Oct. 24, 1967; revised manuscript received Feb. 23, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 32.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## ABSTRACT

The rate of adsorption of propane on platinum in 37 m/o HF at 30°C has been measured using single linear voltage sweep techniques as a complement to earlier studies at 90°C. The surface coverage by hydrocarbon species was measured as a function of adsorption time and potential. The rate of adsorption follows Langmuir kinetics with a third-order dependence on free surface. The rate of reaction of the initial adsorbate at 90°C to form a highly electroactive species (type I) was also measured, and found to be proportional to the surface coverage of the initial adsorbate (type II) and the square of the fraction free surface. The subsequent rate of electrochemical oxidation of type I was proportional to the surface coverage of type I and to free surface. Values for the kinetic parameters are reported, and the results are discussed in terms of a proposed mechanism for the over-all oxidation process.

Because of the strong current interest in direct hydrocarbon fuel cells, the study of the kinetics and mechanism of the anodic oxidation of saturated hydrocarbons is of immediate importance.

At present, hydrocarbon fuel cells require the use of platinum as the electrocatalyst in strong acid electrolytes at temperatures above about 90°C (1-8). The choice of the most appropriate acid electrolyte requires that the anion not be specifically adsorbed on the platinum electrocatalyst, since this would block the adsorption of hydrocarbon molecules. This requirement eliminates HCl, HBr, and HI from further consideration. The acid must also be thermally stable and must not react directly with hydrocarbons; this eliminates HNO<sub>3</sub>, concentrated HClO<sub>4</sub>, and H<sub>2</sub>SO<sub>4</sub> (except  $\leq 3N$ ,  $\leq 100^\circ\text{C}$ ) (9). Weak acids must be eliminated because of low conductance and high concentration overvoltages. The final choice seems to be between H<sub>3</sub>PO<sub>4</sub> (4-6) and HF (2, 3, 7, 8) as suitable electrolytes. Some anion of phosphoric acid adsorbs to an appreciable extent on platinum reducing the over-all rate of hydrocarbon oxidation and complicating the study of these processes. On the other hand, the fluoride anion is adsorbed to only a small extent or not at all (10, 11), providing for a maximum extent and rate of hydrocarbon adsorption and electrochemical oxidation.

Because of the above considerations, HF was chosen as the electrolyte for a study of the behavior of hydrocarbons at platinum anodes. Propane was chosen as the saturated hydrocarbon of first interest because it has been shown to react rapidly in fuel cells (1-4, 6-9) and because it is the smallest hydrocarbon molecule containing the characteristic paraffin CH<sub>2</sub> group. In order better to understand the hydrocarbon fuel cell, with

the hope of finding a substitute for platinum, it was decided that a detailed study of the kinetics and mechanism involved in the over-all anodic oxidation process for propane was of interest. It is desirable to study such a complex process by separating it, so far as possible, into the various individual steps which make up the process, starting with the adsorption step, proceeding to surface reactions and finally to the steps which produce carbon dioxide and hydrogen ions.

The adsorption of methane (12) and ethane (13, 14) onto platinum from perchloric acid has been investigated at temperatures below those which correspond to good fuel cell performance. Gilman (13) found that the adsorption process for ethane was second order in free surface, and first order in ethane concentration. The same adsorbates (15), plus propane (15-17) and butane (15) were studied in phosphoric acid, but no kinetic information was obtained because the adsorption process was diffusion-limited. Butane coverage has been measured on platinum electrodes in sulfuric acid (18, 19), but no rate expressions were reported. The adsorption of some unsaturated hydrocarbons such as ethylene (20, 21) and acetylene (21) on platinum has been studied, but the rates were diffusion-limited, so only steady-state coverage information is available.

The first portion of this study showed that the rate of propane adsorption on platinum in hydrofluoric acid at 90°C is consistent with Langmuir kinetics, third order in free surface at both 0.2 and 0.3v vs. a reversible hydrogen electrode in the same electrolyte (rhe) (22). The formation of a highly electroactive species from the initially adsorbed "propane" was also reported (22). This paper extends the adsorption rate studies down to 30°C and provides a kinetic analysis of a surface reaction and the rate-determining electrochemical step in the over-all anodic process.

### Experimental

The electrochemical studies of the rate of propane adsorption and surface reaction were carried out in

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Argonne National Laboratory, Argonne, Illinois.

an all-polytetrafluoroethylene (PTFE) three-compartment electrochemical cell, described in detail in ref. (22). The cell was mounted in a forced convection air thermostat which controlled the air stream temperature to within  $\pm 0.1^\circ\text{C}$ ; control of the electrolyte temperature was better.

The working electrode was a smooth platinum wire 0.146 cm in diameter with an exposed portion 1.034 or 0.960 cm long having a hemispherical end. The surface of the electrode was carefully polished by the procedure given in ref. (22). The "true" surface area of the polished electrode was determined by cathodic hydrogen deposition during a linear cathodic voltage sweep, applied via a potentiostat and function generator. With the assumption that  $220 \mu\text{C}/\text{cm}^2$  is the charge required for the cathodic deposition of hydrogen prior to hydrogen evolution, the true area was found to be  $0.5467 \text{ cm}^2$  for the larger electrode and  $0.474 \text{ cm}^2$  for the smaller one, corresponding to a roughness factor of 1.15.

The highly purified electrolyte solution was 37 m/o HF, prepared from quartz-redistilled water and Mallinckrodt analytical reagent grade 48 w/o HF, in all-PTFE apparatus by the procedure described in ref. (22).

All gases used in the electrochemical apparatus were first saturated with electrolyte solution vapor at the appropriate temperature by passing them through electrolyte-containing bubblers made of Pt and PTFE. The propane was Matheson instrument grade, 99.5% min purity and Phillips research grade, 99.97%; both gave identical results. Argon, 99.998% min. purity, oxygen removed, was used as an inert atmosphere during blank determinations and electrode area measurements.

The electrochemical measurements were performed with a Wenking fast-rise potentiostat, a function generator, a potentiometer, a dual-beam X-Y oscilloscope with differential preamplifiers, and a camera. The wiring diagram and additional details have been presented elsewhere (22).

Before each experiment, the working electrode was given a pretreatment consisting of ten alternate anodic and cathodic potentiostatic pulses of 10-15-sec duration (portion A of the voltage sequence in Fig. 1) in order to bring the electrode to a reproducible condition and prevent the accumulation of hydrogen or oxygen in the vicinity of the electrode. Next, the electrode was protected for the later adsorption step by the rapid formation of a protective oxide layer at 1.6v for 6 sec (portion B of voltage sequence). The potential was then stepped to 1.2v in order to maintain the oxide layer while the appropriate mass transport conditions were established (portion C of voltage sequence). During portion C, propane (or argon) was bubbled over the electrode, with stirring (400 rpm) for 60 sec, after which bubbling was stopped, and stirring was continued for 1 min ( $90^\circ\text{C}$ ) or 2 min ( $30^\circ\text{C}$ ) to sweep any gas bubbles away from the electrode. Finally, the desired mass transport conditions were established: quiescent, propane-saturated electrolyte.

Fig. 1. Voltage sequence for measurement of propane adsorption

The potential of the working electrode was then stepped to the adsorption potential,  $U_a$ , at which the oxide layer was quickly reduced ( $\sim 2 \text{ msec}$ ), and propane was adsorbed for time  $\tau_a$  (portion D of voltage sequence). After time  $\tau_a$  a linear anodic (or cathodic) voltage sweep was applied. The current-voltage trace during the voltage sweep period (see Fig. 1) was photographed from the oscilloscope screen, yielding a permanent record of the current required for the oxidation of the species on the electrode surface (or for the cathodic deposition of hydrogen in the presence of adsorbate). Blank experiments were performed in the presence of argon for use in data reduction. This procedure is explained in more detail in ref. (22) and is similar to that used by Gilman (13) in related investigations.

Various anodic and cathodic sweep experiments were performed as a function of adsorption time  $\tau_a$  (0.01 — 3600 sec), adsorption potential  $U_a$  (0.2 and 0.3v), sweep speed  $dE/dt$  (0.1 — 100 v/sec), and temperature ( $30^\circ$  and  $90^\circ\text{C}$ ). The objective was to determine the rates of propane adsorption and surface reactions, if any, as a function of potential and temperature. The further objective of measuring the rate of anodic oxidation was best achieved by the use of high-area fuel cell electrodes under otherwise similar experimental conditions.

The steady-state anodic oxidation rate for propane was measured at  $90^\circ\text{C}$  as a function of potential by means of an all-PTFE apparatus already described (2,3). These results were used in conjunction with steady-state surface coverages for examination of possible kinetic expressions, as described in a later section of this paper.

### Results and Analysis

As pointed out before (22, 23), it is necessary that the current-voltage trace in the presence of the surface species resulting from propane adsorption be highly reproducible and significantly different from the "blank" trace in the presence of argon. Furthermore, the difference between the traces must be a measure of the amount of material on the electrode surface. This has been shown to be the case for propane on platinum in hydrofluoric acid (22).

A sample trace for propane adsorbed on platinum at 0.3v (vs. r.h.e) in 37 m/o HF at  $30^\circ\text{C}$  for  $\tau_a = 480 \text{ sec}$  is shown in Fig. 2, together with the blank trace in the presence of argon. The difference between the areas under the two traces in the interval between 0.5v and the point where they merge near 1.7v at  $90^\circ\text{C}$  and near 1.8v at  $30^\circ\text{C}$  is called  $Q$ , and has the units of charge (coulombs). This charge can have several components

$$Q = 1.8_{0.5} Q_{\text{HC}} + \Delta Q_{\text{dl}} + \Delta Q_{\text{O}} + Q_{\text{diff}} \quad [1]$$

Fig. 2. Current-voltage traces for 480 sec of propane adsorption on Pt in 37 m/o HF at  $30^\circ\text{C}$  and the corresponding blank trace (argon instead of propane).

Fig. 3. Surface coverage due to propane adsorption at 0.3v, 30°C, as a function of adsorption time.

The value of  $^{1.8}_{0.5}Q_{HC}$ , the charge required to oxidize the hydrocarbon species on the electrode in the interval 0.5-1.8v vs. rHe after adsorption for time  $\tau_a$ , is the desired quantity. It is evaluated by subtracting the three relatively small terms  $\Delta Q_{dl}$ ,  $\Delta Q_0$ , and  $Q_{diff}$  from  $Q$ , and/or performing experiments under conditions where one or more of these correction terms is zero. The term  $\Delta Q_{dl}$  is the change in the charge stored by the double layer as the linear voltage sweep is applied;  $\Delta Q_0$  corresponds to the change in the charge required to oxidize the surface of the electrode to the potential where the traces merge (about 1.7v at 90° and 1.8v at 30°C); and  $Q_{diff}$  accounts for any propane which diffused to the electrode surface from the bulk electrolyte and was oxidized during the anodic sweep, causing an increase in  $Q$ . Proper choice of sweep speeds plays an important part in minimizing the sizes of the correction terms. The method of evaluating  $\Delta Q_{dl}$ ,  $\Delta Q_0$ , and  $Q_{diff}$  is explained in detail in ref. (22). All of the correction terms were small compared to  $Q$ , so that the value of  $^{1.8}_{0.5}Q_{HC}$  could be obtained with good accuracy.

**Propane adsorption at 0.3v, 30°C.**—The conditions of 0.3v and 30°C were chosen for these experiments in order that the present results might be compared to those for 0.3v at 90°C in the same electrolyte on the same electrode (22). Qualitatively, the propane trace of Fig. 2 is significantly different from the corresponding trace for 90°C [Fig. 4, ref. (22)]. The main difference is that only one current peak is observed (near 1.4v) at 30°C while two were observed (near 0.8v and near 1.2v) at 90°C.<sup>4</sup> Because of this difference, no labeling of peaks (type I, type II, etc.) (22) is necessary, but the single peak observed at 30°C is analogous to the type II peak at 90°C.

The single peak at 30°C is analogous to the type II peak at 90°C because of the similarity in peak voltages (1.3 at 90°C vs. 1.4 at 30°C) (22) and because the peak at 30°C can be hydrogenation-desorbed as can the type II peak at 90°C (15, 24). The type I peak at 90°C, by contrast, appears at 0.8v and cannot be hydrogenation-desorbed to a large extent (15, 24, 26). Furthermore, by slowly increasing the temperature and repeating the anodic sweep experiment, the type I peak can be seen to "grow in," while the type II peak remains relatively unchanged (15, 25).

In order to select the appropriate sweep speed range for which  $Q_{diff}$  is negligible, the value of  $Q$  was determined for 0.1, 1, 10, and 100 v/sec at all adsorption times. The values of  $Q$  for each  $\tau_a$  were plotted against sweep speed, and plateaus were found in the range 0.7-20 v/sec, assuring no  $\Delta Q$  or  $Q_{diff}$  contributions in this range. The plateau values of  $Q$  yielded the  $^{1.8}_{0.5}Q_{HC}$  values used in the preparation of the adsorption curve of Fig. 3. The curves of total fractional surface coverage by hydrocarbon species,  $\theta_{HC}$ , and fractional coverage by hydrocarbon species at 1.9v,  $^{1.9}Q_{HC}$  are discussed below. The  $^{1.8}_{0.5}Q_{HC}$  data for the

full time range studied fall far below the amounts permitted by diffusion, hence, the adsorption process is kinetically limited at 30°C. The electrode approaches saturation coverage at  $\tau_a$  of 3600 sec, in contrast with a time of a few hundred seconds obtained at 90°C (22).

It was observed that some of the relatively slowly oxidized adsorbed hydrocarbon species remained on the electrode at potentials above the crossover point in Fig. 2. It was therefore necessary to obtain a measure of the amount of material remaining in order to determine the total surface coverage due to hydrocarbon species. The method previously developed for this purpose (22) depends on the fact that the rate of oxygen evolution at potentials near 1.9v is hindered by the presence of adsorbed species. The fractional decrease in oxygen evolution current was found to be equal to the fractional coverage by slowly (or difficultly) oxidized species:

$$^{1.9}\theta_{HC} = \frac{^{1.9}i_{Ar} - ^{1.9}i_{HC}}{^{1.9}i_{Ar}} \quad [2]$$

where  $^{1.9}i_{Ar}$  is the (oxygen evolution) current at 1.9v with argon present instead of propane (this is the same as  $^{1.9}i_{HC}$  at  $\tau_a = 0$ ), and  $^{1.9}i_{HC}$  is the current at 1.9v in the presence of adsorbed propane, as read from the voltage-sweep oscillogram (e.g., Fig. 2). The voltage 1.9 was chosen because it was found to be in the linear region of the Tafel plots for oxygen evolution. The plateau values of  $^{1.9}\theta_{HC}$  obtained for each  $\tau_a$  as a result of plotting  $^{1.9}\theta_{HC}$  against sweep speed were used to construct the curve shown in Fig. 3. Again, a saturation coverage is approached at 3600 sec.

In order to perform a kinetic analysis for the adsorption rate studies, it is necessary to know the total fractional surface coverage by hydrocarbon species,  $\theta_{HC}$ , as a function of adsorption time. This means that it is necessary to convert the  $^{1.8}_{0.5}Q_{HC}$  and  $^{1.9}\theta_{HC}$  information of Fig. 3 into a plot of  $\theta_{HC}$  vs.  $\tau_a$ . This was accomplished as follows: It is known from previous work on this system (22) that saturation coverage corresponds to a monolayer. Furthermore, the number of electrons (per surface site occupied) required for the oxidation of the more difficultly oxidized species (those still on the surface at 1.9v) is near 4 (21-23) (consistent with about one carbon per Pt site). Values of  $^{1.9}Q_{HC}$  vs.  $\tau_a$  were calculated using the expression

$$^{1.9}Q_{HC} = ^{1.9}n_{HC} ^{1.9}\theta_{HC} Q_{SH} \quad [3]$$

where  $^{1.9}n_{HC}$  is 4 electrons/site occupied and  $Q_{SH}$  is the charge required to deposit a monolayer of hydrogen on the Pt surface (220  $\mu\text{coulombs/true cm}^2$ ). The total charge required to oxidize all of the adsorbed hydrocarbon species on the electrode was calculated as the sum of  $^{1.8}_{0.5}Q_{HC}$  and  $^{1.9}Q_{HC}$ . This value was checked for consistency with the direct observations of  $Q_{HC}$  for higher temperatures. Good agreement was observed:  $Q_{HC, sat} = 850 \mu\text{coulombs/true cm}^2$  at 30°C vs.  $Q_{HC, sat} = 770 \mu\text{coulombs/true cm}^2$  for  $U_a = 0.3v$  and  $Q_{HC, sat} = 1090 \mu\text{coulombs/true cm}^2$  for  $U_a = 0.2v$ , both at 90°C. From the calculated  $Q_{HC}$  values,  $\theta_{HC}$  values were determined using the expression

$$\theta_{HC} = \frac{Q_{HC}}{Q_{HC, sat}} \quad [4]$$

These results were checked for reasonableness by calculating a value for  $n_{HC}$

$$n_{HC} = \frac{^{1.8}_{0.5}Q_{HC}}{\theta_{HC} - ^{1.9}\theta_{HC}} = \frac{^{1.8}_{0.5}Q_{HC}}{^{1.8}_{0.5}\theta_{HC}} \quad [5]$$

The value of  $n_{HC}$  calculated from Eq. [5], using all of the data was 3.77  $e^-/\text{site}$  obscured, in good agreement with the value 3.47 for  $n_{II}$  at 90°C, and a value of 3.71 obtained by Grubb and Lazarus (26) at 60°C in phosphoric acid. These checks do not prove that the  $n$  val-

<sup>4</sup> Additional experiments have shown the 0.8v peak to be absent at 60°C also.

Fig. 4. Langmuir adsorption kinetic plot for the adsorption of propane on Pt in 37 m/o HF at 90°C for 0.2v and 0.3v, and at 30°C for 0.3v (vs. rhe).

ues are absolutely correct, but merely indicate that they are reasonable, and are consistent with the  $1.9\theta_{HC}$  and  $1.8_{0.5}Q_{HC}$  values measured. Furthermore, the assumption that  $\theta_{HC}$  is unity at long times is shown to be reasonable by the value of  $3.77 e^-/\text{site}$  for  $n_{HC}$ .

A plot of the  $\theta_{HC}$  values from Eq. [4] vs.  $\tau_a$  provides all of the information necessary for a kinetic analysis. In keeping with the results obtained for this system at 90°C, a test was made for Langmuir kinetics. The Langmuir rate law may be written as

$$\frac{d\theta_{HC}}{dt} = k_{ads}C_{HC}(1 - \theta_{HC})^m \quad [6]$$

where  $m$  is the order of reaction with respect to free surface and represents the number of surface sites involved in the rate-determining step of the adsorption process. In order to test the applicability of Eq. [6] to the results at 30°C, the following form of Eq. [6] was used

$$\log\left(\frac{d\theta_{HC}}{dt}\right) = \log(k_{ads}C_{HC}) + m \log(1 - \theta_{HC}) \quad [7]$$

A plot of  $\log\left(\frac{d\theta_{HC}}{dt}\right)$  (determined by graphical differentiation) vs.  $\log(1 - \theta_{HC})$  was found to yield a straight line over the full range of experimental values. The value of  $m$ , determined from the slope of the line, was 3.0 just as for 90°C; the value of  $k_{ads}C_{HC}$  was 0.035  $\text{sec}^{-1}$ . Equation [6] was integrated for  $m = 3$ , yielding

$$\theta_F^{-2} - \theta_{F,t_0}^{-2} = 2k_{ads}C_{HC}(t - t_0) \quad [8]$$

where  $\theta_F$  is the fraction of "free" surface, or  $(1 - \theta_{HC})$ . For the present experiments,  $\theta_{F,t_0} = 1$  when  $t_0 = 0$ .

A plot of  $\log\left(\frac{1}{\theta_F^2} - \frac{1}{\theta_{F,t_0}^2}\right)$  vs.  $\log(t - t_0)$  should yield a straight line of unit slope, the intercept of which is  $2k_{ads}C_{HC}$ . This plot, together with the results previously reported for 90°C is shown in Fig. 4. Note that all three lines are straight and have a slope of unity, indicating the applicability of Eq. [6] with  $m = 3$ . The values of  $k_{ads}C_{C_3H_8}$  obtained from Fig. 4 are listed in Table I, together with the measured value of  $C_{C_3H_8}$  at 90°C and an estimated value for 30°C.<sup>5</sup> The values of  $k_{ads}$  in the last column of Table I were obtained by dividing the entries in column 1 by those

<sup>5</sup> The solubility of propane in the HF azeotrope at 30°C was estimated from the measured value at 90°C using the known ratio of solubilities of propane in water and in the HF azeotrope.

Table I. Adsorption rate constants for propane on platinum in hydrofluoric acid azeotrope

$$\frac{d\theta_{HC}}{dt} = k_{ads}C_{C_3H_8}(1 - \theta_{HC})^3$$

Conditions	$U_a$ , volts	$k_{ads}$ , $C_{C_3H_8}$ , $\text{sec}^{-1}$	$C_{C_3H_8}$ , moles/ $\text{cm}^3$	at $p_{C_3H_8}$ , mm Hg	S, m-mol l-atm	$k_{ads}$ , $\text{cm}^3/\text{mole-sec}$

30	0.3	0.035	$5.18 \times 10^{-7}$	742	0.53	$6.6 \times 10^4$

$\Delta H^\ddagger$  for adsorption at 0.3v = 20 kcal/mole.

in column 2. The apparent enthalpy of activation for adsorption at 0.3v was calculated from the last two entries in Table I, and was found to be 20 kcal/mole, a reasonable value for dissociative chemisorption, in which C-H bonds are broken.

Rate of formation of type I by surface reaction at 90°C.—It was found in the earlier portion of this study (22) that at temperatures near 90°C a peak near 0.8v appeared in the anodic sweep oscillogram. This peak (called type I) formed only after a significant fraction of the electrode was covered by adsorbed material (type II). The type I peak has also been observed by other investigators (12-15) and has been found to be only difficultly hydrogenation-desorbed. The results of a number of different indirect observations (12, 14, 16, 22, 24) indicate that the material represented by the type I peak is an oxygenated species, or group of species. The type I material found on Pt in HF at 90°C yielded during its oxidation 3 electrons/Pt site obscured, consistent with the idea of an oxygenated

Because of the fact that the type I peak for Pt exposed to  $C_3H_8$  in HF at 90°C formed after a significant fraction of the surface was covered by type II material (peak at 1.2v), and because the type I material is supposed to be partially oxygenated, one might propose a reaction such as

which corresponds to reactions [16a] and [16b] of ref. (22). If Reaction [9] is a reasonable representation of fact, then the rate expression for the formation of type I material should be

$$\frac{d\theta_I}{dt} = k_I \theta_{II} (1 - \theta_{HC})^{n+m} \quad [10]$$

where  $(1 - \theta_{HC})$  is the fraction of "free" surface, presumably covered by water or some related species (such as OH). The validity of Eq. [10] was tested by making use of  $\theta_{I,0.3}$  [the surface coverage of type I species, evaluated from a cathodic sweep experiment in the range 0.3-0.0v, as explained in ref. (22)],  $\theta_{II,0.3}$  [the surface coverage of type II species, obtained from cathodic sweep experiments in the range 0.3-0.0v, as explained in ref. (22)], and  $\theta_{HC}$  values of Fig. 9, ref. (22) for the preparation of a

plot of  $\log\left(\frac{1}{\theta_{II}} \frac{d\theta_I}{dt}\right)$  vs.  $\log(1 - \theta_{HC})$ . The plot was a straight line over the full range of time for which  $\theta_I$  values were available (0 - 180 sec), indicating that Eq. [10] is valid. The value of  $(n + m)$  obtained from the slope of the line was 2.0. As a final check, a plot of the integral form of Eq. [10] was prepared, as shown

Fig. 5. Test of the integral form of the rate expression for the formation of type I. The slope of the straight line is the rate constant.

in Fig. 5. The slope of the straight line of Fig. 5 yields  $0.099 \text{ sec}^{-1}$  for the value of  $k_1$ . This analysis indicates that the surface reaction by which type I material is formed is second order in free surface and/or  $\text{H}_2\text{O}$  (or OH), and first order in type II.

*Rate of anodic oxidation of type I at 90°C.*—The last step in the over-all oxidation process for propane at potentials below 0.8v is the anodic oxidation of type I to form  $\text{CO}_2$  and  $\text{H}^+$

or

The anodic oxidation of type I is expected to involve one molecule of water and one "molecule" of type I, yielding the rate expression

$$i_1 = N F k_1 \theta_I (1 - \theta_T) \exp\left(\frac{\alpha n F}{RT} \eta\right) \quad [13]$$

In order to determine the applicability of Eq. [13], it is necessary to know the steady-state current density-voltage behavior in the potential range where essentially only type I (of carbonaceous species) is being oxidized (below about 0.8v), and the steady-state surface coverages of type I and total hydrocarbon species.

As discussed in the experimental section above, it was found necessary to observe steady-state current density-voltage characteristics by means of a high-area platinum black electrode, under experimental conditions otherwise identical to those used for the study of the smooth wire electrode at 90°C. The steady-state current density-voltage results are shown in Fig. 6, in Tafel plot form. The data of Fig. 6 are reproducible to within a few per cent in current density at a given potential or less than 10 mv at any current density over the range reported. Data from other electrodes parallel those of Fig. 6, but may be displaced by up to 10 mv. The steepness of the curve at the higher current densities is not related to mass-transport limitations, since electrodes of this type are capable of supporting  $500 \text{ ma/cm}^2$  when operated on propane at higher temperatures (2, 7). As might be expected from the knowledge that the surface coverage of all species is strongly potential-dependent, a straight line was not obtained (Fig. 6). If Eq. [13] is valid, a plot of  $\log\left(\frac{i}{\theta_I(1-\theta_T)}\right)$  vs.  $\eta$  (or  $E_{A-R}$  the voltage of the anode measured against rhe) should yield a

Fig. 6. Tafel plot of the steady-state voltage-current density data from a high-area Pt fuel cell electrode operating on  $\text{C}_3\text{H}_8$  at 90°C in 37 m/o HF.  $E_{A-R}$  is the resistance-free potential of the anode measured against a reversible hydrogen electrode in the same electrolyte.

straight line with a slope of  $(\alpha n F / RT)$ . It should be noted that a portion of the current reported in Fig. 6 is due to the oxidation of hydrogen resulting from the dissociative adsorption of the propane, as well as the hydrogen produced by subsequent dehydrogenation and oxidation steps, but this hydrogen contributes a constant fraction of the total current (8 electrons from hydrogen and 12 from carbon per propane molecule). This fact introduces a multiplicative constant to the right-hand side of Eq. [13]. Another factor to be considered in the test of Eq. [13] is the roughness factor of the high-area electrode, which also enters as a multiplicative constant on the right-hand side of the equation. These considerations make it difficult to determine a value for  $k_i$ , but do not interfere with the establishment of  $\alpha n$ .

The values of  $\theta_I$  and  $(1 - \theta_T)$  for use in Eq. [13] were obtained from the smooth electrode results reported in Fig. 5 of ref. (22) and some additional results. A summary of the surface coverages of all species at  $\tau_a = 300 \text{ sec}$  (essentially steady-state values) (22) is given in Fig. 7. The  $\theta$  values from Fig. 7, together with the steady-state current density-voltage values of Fig. 6 were used to prepare Fig. 8, a test of Eq. [13]. The use of surface coverage values from the smooth electrodes is justified here because of the parallelism in rate and extent of surface coverage by hydrocarbon species for the two types of electrodes (14). The straight line of Fig. 8 indicates the validity of Eq. [13]; the slope corresponds to an  $\alpha n$  value of 0.75. It is reasonable that the rate-determining step involves two electrons (probably the introduction of an oxygen atom to type I to form  $\text{CO}_2$ ), giving  $\alpha = 2$ ,  $n = 0.38$ . The value for  $k_i$  cannot be established because of the uncertainty in the surface roughness of the high-area electrode and the value of  $E_{A-R}$  (the potential of the hydrocarbon anode measured against a reversible hydrogen reference electrode) at which  $\eta$  is zero. If it is desired that  $k_i$  be expressed on the basis of the oxidation of type I only (i.e.,  $N = 3$ ,  $i_1 = 9/20 i$ ) then the value of  $E_{A-R}$  at  $\eta = 0$  must be known for type I. This is an inaccessible value, which prevents the quantitative evaluation of  $k_i$  on the basis of the reversible oxidation potential of type I.

### Discussion

The rate of adsorption of propane on platinum in 37 m/o HF at  $U_a = 0.3\text{v}$  and 30°C is proportional to the third power of the fraction of free surface available for adsorption, in agreement with the results for 90°C at adsorption potentials of 0.3 and 0.2v (vs. rhe). This is consistent with the involvement of three platinum surface sites in the rate-determining step for the

Fig. 7. Surface coverages of hydrogen and hydrocarbon species as a function of adsorption potential at 90°C and 300 sec adsorption time. These are essentially steady-state coverages.

adsorption of propane. It is conceivable that not all three sites are involved directly in the bonding; one or two may be sterically blocked from further participation in the adsorption process. Because of the fact that the Langmuir adsorption rate expression was obeyed over a wide range of surface coverages ( $0 < \theta < 0.95$ ), it is quite probable that the heat of adsorption changes little with surface coverage. The enthalpy of activation for adsorption at 0.3v in the temperature range 30° to 90°C was found to be 20 kcal/mole, consistent with dissociative chemisorption, such as

The adsorbed hydrogen atoms are quickly oxidized at 0.2 and 0.3v; the unbonded M indicates the possibility of sterically blocked surface sites. The rate of adsorption increases with temperature and is higher at 0.3 than at 0.2v. Both of these effects are expected, the former because the adsorption process is dissociative, the latter because the product hydrogen atoms are quickly removed, enhancing the rate of adsorption. The rate constants are summarized in Table I.

After the dissociative chemisorption of propane, the adsorbate probably dissociates further, yielding more hydrogen (which is consumed) and becomes more firmly bonded to the electrode surface. This can cause straining of the carbon-carbon bonds which may result in fragmentation. These processes may be indicated

Fig. 8. Test of Eq. [13] using the current-density voltage data for the over-all rate of oxidation of propane shown in Fig. 6 where the rate-determining step is given by reaction [12], and the surface coverages were taken from Fig. 7. The slope of the straight line corresponds to  $\alpha n = 0.75$ .

schematically as follows

All of these species are considered to be representative of what has been called type II, i.e., the peak near 1.2v at 90°C, and the only peak (at 1.4v) at 30°C. All of the products in reactions [15a], [15b], and [15c] are of the type which can be hydrogenation-desorbed, yielding saturated hydrocarbons. The calculated number of electrons required for oxidation (to  $CO_2$  and  $H^+$ ) of the product species for the above reactions per surface site obscured is: 4.25  $e^-/H$  site for reaction [15b], in good agreement with 4.5  $e^-/H$  site observed for type II at  $U_a = 0.2v$ , 90°C; 3.40  $e^-/H$  site for reaction [15c], compared to 3.47  $e^-/H$  site observed for type II at  $U_a = 0.3v$ , 90°C and 3.77  $e^-/H$  site at  $U_a = 0.3v$ , 30°C. These comparisons serve to indicate that reactions [15a], [15b], and [15c] are reasonable postulates for the identity of the type II material over the range 30°-90°C, and 0.2-0.3v.

Another type of surface reaction occurs at temperatures above about 60°C (15, 25): a partial oxidation, producing a material which is not hydrogenation-desorbed to an appreciable extent, and which is readily oxidized. This material, called type I, is formed at potentials above about 0.15v (22), and causes an anodic peak in the oscillograms at 0.8v at 90°C (22). The charge required for oxidation of the type I material is 2.95  $e^-/H$  site (22), consistent with a stoichiometry such as

which requires 3 electrons per surface site for oxidation to  $\text{CO}_2$  and  $\text{H}^+$ .

As shown above in the Results section, the rate of formation of type I is proportional to the surface coverage of type II and to the square of the fraction free surface. Since type I is a single-carbon species (14, 22, 24) and is singly oxygenated, it is likely that only one water molecule is involved in its formation. It is further likely that an additional "free" surface site is required to accept the hydrogen atoms from type I and  $\text{H}_2\text{O}$  and provide for their conversion to protons. It is therefore suggested that the second order dependence on "free" surface is actually first order in adsorbed  $\text{H}_2\text{O}$  (or OH) and first order in surface available for hydrogen acceptance, corresponding, for example, to the equations

The rate expression for the above processes is

$$\frac{d\theta_I}{dt} = 0.099 \theta_{II} (1 - \theta_{HC})^2 \quad [17]$$

for 0.3v (vs. r.h.e.) at 90°C.

The subsequent oxidation of type I to  $\text{CO}_2$  and  $\text{H}^+$  is a process requiring 3  $\text{e}^-/\text{H}$  site, suggesting reaction [12], and its corresponding rate expression, Eq. [13], which was verified using a high-area electrode

$$i = s N F k_i \theta_I (1 - \theta_T) \exp\left(\frac{\alpha n F}{RT} \eta\right) \quad [18]$$

where  $N = 20$  for the over-all oxidation process for propane,  $s =$  the surface roughness,  $\sim 4000$ ,  $k_i =$  the reaction rate constant for reaction [13],  $\text{sec}^{-1}$ ,  $\alpha = 0.38$ , and  $n = 2$ .

All of the above results and those reported previously (22) suggest an over-all reaction scheme for the anodic oxidation of propane

The type III material is a highly dehydrogenated carbon-rich residue which forms slowly and covers less than 0.1 of the surface at 90°C (22). It can be oxidized to  $\text{CO}_2$  relatively slowly at high potentials ( $>1.8\text{v}$ ) and is generally an undesirable side-product. The desired path, which is the main one for propane at 90°C is the left-hand one. At temperatures below 60°C, the rate of formation of type I is extremely slow; therefore only the adsorption rate was determined at 30°C.

In general, no significant current densities have been measured for saturated hydrocarbons on high-area fuel cell electrodes under conditions where type I does not form at significant rates. It appears that one of the requirements for reasonable performance in fuel cells is a high rate of formation of type I, which can then be oxidized rapidly at acceptable overvoltages. This suggests that the search for more effective electrocatalysts for fuel cells consuming saturated hydrocarbons should concentrate on those materials which catalyze the equivalent of reactions [16a] and [16b] for the hydrocarbon of interest.

### Conclusions

1. Propane is adsorbed on platinum in 37 m/o hydrofluoric acid at a rate which is dependent on potential and surface coverage. The rate law is third order in free surface at 0.2 and 0.3v vs. r.h.e., and at 30° and 90°C. The apparent enthalpy of activation for the adsorption is 20 kcal/mole.

2. A highly electroactive species (type I) is formed from the type II adsorbate at 90°C by reaction with water (or OH). The reaction is first order in adsorbate (type II) and second order in free surface (consistent with first order dependence on water and first order dependence on hydrogen acceptance sites). The rate is a function of temperature and potential.

3. The final current-producing reaction is first order in type I, first order in free surface, and has an  $\alpha n$  value of 0.75 at 90°C. The surface coverage results from measurements on smooth electrodes are compatible with the current-voltage results from high-area electrodes.

4. The results suggest that successful electrocatalysts for the oxidation of saturated hydrocarbons must provide the dual function of promoting the conversion of adsorbed hydrocarbons to type I species, as well as the subsequent conversion of type I to  $\text{CO}_2$ .

### Acknowledgment

It is a pleasure to thank A. D. Tevebaugh for collaboration on the design, construction, and testing of the apparatus, for helpful discussions, and a critical review of the manuscript.

A portion of this work is a part of the program under contracts DA 44-009-AMC-479(T) and DA 44-009-ENG-4909, ARPA order No. 247 with the U. S. Army Mobility Equipment Research and Development Center, Fort Belvoir, Virginia, to develop a technology which will facilitate the design and fabrication of practical military fuel cell power plants for operation on ambient air and hydrocarbon fuels.

Manuscript received Dec. 11, 1967; revised manuscript received Jan. 31, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Growth Characteristics of Iron Oxide Films Generated in Dilute Lithium Hydroxide Solution at 300°C

John B. Moore, Jr.,<sup>1</sup> and Robert L. Jones\*

*Naval Research Laboratory, Washington, D. C.*

### ABSTRACT

In the early stages of iron oxide growth on mild steel in pH 11 LiOH solution at 300°C, the oxide is largely oriented and grows at a rate and with a morphology dependent on the substrate grain orientation. After a certain film thickness is attained, however, the epitaxial oxide growing in the (001) Fe<sub>3</sub>O<sub>4</sub>//(001)α-Fe, [110] Fe<sub>3</sub>O<sub>4</sub>//[100]α-Fe orientation degenerates, leaving in its place a much thinner, fine-grained, randomly oriented "base film" partially covered by large solution-grown Fe<sub>3</sub>O<sub>4</sub> crystals. Experimental evidence indicates that the transformation is induced by stress generated within the epitaxial oxide as the film thickens. The two-phased oxide structure which exists after completion of the epitaxial oxide degeneration persists through oxidation periods of up to at least 300 hr. Observations of its growth behavior lead to the postulation of a growth mechanism in which iron passes through the base film into solution, subsequently to precipitate forming the upper surface crystals. It is shown possible, using this hypothesis, to derive a theoretical rate law which predicts that, in agreement with the experimentally determined corrosion rate data, the corrosion rate should decrease in a logarithmic fashion.

Research initiated by Potter (1) in England and Bloom (2) in the United States has shown that the morphology of iron oxide films generated on steel by attack of high temperature NaOH solution is apparently dependent on the physical system employed. Static corrosion tests at these two laboratories using alkali solutions of similar composition and run at the same temperatures produce oxide films which are chemically the same (Fe<sub>3</sub>O<sub>4</sub>), but structurally different. The Potter films have been examined by electron microscopy (3, 4) and scanning electron microscopy (5) as well as by standard metallographic techniques and it has been established that they have two layers. The inner layer adjacent to the metal is composed of tiny crystallites which come together to form a regular, adherent layer of uniform thickness which, although porous, is nonetheless protective. There is an irregular, poorly adhering, outer layer of much larger

tetrahedral crystals above this; this outer layer is thought to be largely nonprotective. Bloom films, on the other hand, appear to be single-layered, and made up of tightly bound, large Fe<sub>3</sub>O<sub>4</sub> crystals with well developed facets at the oxide/solution interface. These films are less porous and apparently more protective than Potter films. Previous morphological investigations of Bloom-type oxide films have been by metallographic cross-section and light microscopy only, however, and the work reported here, which involves a time sequence study by electron microscopy of the early stages of oxide film growth under Bloom's conditions, was undertaken to provide additional information concerning the physical structure of this type film and to elucidate, as far as possible, the mechanism by which it is generated.

The question as to why one physical form of oxide film or the other should be preferred with a given system has been taken up by Marsh (6) and more recently by Castle and Mann (7). There have also been electron microscopical investigations of the growth of

\* Electrochemical Society Active Member.

<sup>1</sup> Student Summer Trainee. Present address: Chemistry Department, Purdue University, Lafayette, Indiana.

oxide films on stainless steel in high temperature water (8,9) which are of interest in this general problem.

### Experimental

Most of the oxide films examined were formed on the interiors of sealed mild steel capsules filled completely with pH 11 LiOH aqueous solution following the technique devised by Bloom and Krulfeld (10), and heated at 300°C in a circulating air oven. The periods of heating ranged from 30 min to 12 days. A few films were grown on the interior walls of small autoclaves fabricated as described by Potter and Mann (1) using the same alkaline solution and temperature. Heating times in these experiments were generally less than 72 hr.

The capsules were fashioned from mild steel tubing of 0.020 in. wall thickness and 0.25 in. over-all diameter which was found, by analyses, to contain, in per cent, 0.09 C, 0.017 P, 0.032 S, 0.007 N, 0.57 Mn, 0.07 Si, 0.10 Cr, and 0.07 Ni. The autoclaves were made from 2 in. sections of 1 x 0.065 in. cold rolled steel pipe closed at each end with 1 x 0.125 in. caps machined from bar stock. These steels gave under analyses, in per cent, 0.23 C, 0.015 P, 0.038 S, 0.004 N, 0.85 Mn, 0.21 Si, 0.05 Cr and 0.05 Ni and 0.19 C, 0.004 P, 0.033 S, 0.004 N, 0.73 Mn, 0.01 Si, 0.06 Cr, and 0.05 Ni, respectively. The specimens were washed with hot detergent solution, degreased with trichloroethylene, and vacuum annealed at  $10^{-5}$ - $10^{-6}$  mm Hg pressure and 875°C for 1 hr before being cooled and exposed to the atmosphere. This vacuum-anneal pretreatment produces a very thin film of Fe<sub>3</sub>O<sub>4</sub>, which often gives evidence of a high degree of orientation, on the metal surface (11). The annealed specimens were stored in a closed container over anhydrous CaSO<sub>4</sub>.

The LiOH solutions were prepared with reagent grade LiOH and triply distilled water. Lithium hydroxide was chosen as the alkalizing agent in these experiments since Bloom's work has led to the conclusion that LiOH has certain advantages over NaOH and KOH as a boiler water additive (12). Exploratory runs with pH 11 NaOH, however, produced oxide films indistinguishable in the electron microscope from those formed with LiOH solutions, indicating that, with the dilute concentrations and short heating exposures employed here, the cation identity is probably not crucial to the film growth behavior observed.

Sections of oxide for electron microscopical examination were separated from the steel substrate by the iodine-methanol technique (13). When replicas were to be made, the platinum preshadowed carbon replicas of the oxide surface were prepared before the oxide films were stripped from the metal. The composite replica-iron oxide film was then floated on aqueous 20% HF solution which dissolved the oxide, with no visible damage to the replica, in just a few minutes.

Since we wished not only to follow the growth of the oxide film on the capsule wall, but also to determine whether its growth morphology could be related to the oxidation kinetics of the corrosion reaction, corrosion rate data were taken for six capsules in the hydrogen effusion apparatus built by Bloom (10). In this instrument, the corrosion rate is measured by monitoring the hydrogen which diffuses through the capsule wall, that hydrogen having originated in the reaction,  $3\text{Fe} + 4\text{H}_2\text{O} \rightarrow \text{Fe}_3\text{O}_4 + 4\text{H}_2$ . The measurements were made at 300°C using pH 11 LiOH in capsules prepared from the same material and in the same manner as described above.

### Results

An examination of oxide films stripped from the three different steels, that is, from the capsule interiors, and from the caps and walls of the autoclaves, indicates that the oxide morphology and growth pattern is qualitatively the same on all three surfaces, at least over the oxidation periods studied.

Fig. 1. Oxide morphologies developed after 2 hr at 300°C, pH 11 LiOH.

As the oxide film thickens, it becomes more coarsely crystalline, and characteristic morphologies develop on the different substrate grains as shown in Fig. 1. The oxide layer is often well oriented over the surface of an individual metal grain at this stage of film formation, and selected area diffraction from these films will reveal numerous "single crystal" diffraction patterns, of varying degrees of perfection, corresponding to several different oxide orientations. While the oxide in a given orientation does tend to exhibit a unique texture, as Fig. 1 would indicate, these textures do not seem to develop equally well for all orientations, and the establishment of a relationship between a particular oxide morphology and selected area diffraction pattern is difficult, except in one instance: oxide areas which have the distinctive morphology shown in the upper right corner of Fig. 1 always give electron diffraction patterns corresponding to the (001) plane of the spinel crystal structure (Fig. 4a).

Electron diffraction alone is not sufficient to distinguish between Fe<sub>3</sub>O<sub>4</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, or perhaps some cation deficient intermediate, in these circumstances, but, since this oxide exists and grows over several hours in an environment reported to produce Fe<sub>3</sub>O<sub>4</sub>, it is assumed to be Fe<sub>3</sub>O<sub>4</sub> which originally existed on the metal substrate in the epitaxial orientation, (001) Fe<sub>3</sub>O<sub>4</sub>//(001)  $\alpha$ -Fe,  $[\bar{1}\bar{1}0]$  Fe<sub>3</sub>O<sub>4</sub>// $[100]$   $\alpha$ -Fe (14). Bloom et al. (12) have found that LiFe<sub>5</sub>O<sub>8</sub>, which has a spinel structure very similar to Fe<sub>3</sub>O<sub>4</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, can be generated in this system, albeit at somewhat higher LiOH concentrations; this third possibility was ruled out, however, when microanalyses of stripped oxide films failed to show the presence of lithium.

This easily identified (001) oriented oxide, whatever its composition, makes an ideal specimen for following the course of oxide growth, and a study of these areas in oxide films generated with progressively increasing oxidation times (Fig. 2a-h; Fig. 2b and d are at higher magnifications than the rest of the series to show better the fine structure of the oxide film) reveals a most interesting phenomenon. The oxide in the (001) orientation evidently develops at a faster rate than that in other orientations, for areas of (001) oxide crystallites are detectable in films formed with as little as 30 min heating (Fig. 2a and b). It also grows in a different way, thickening in a uniform manner to form a compact, coherent layer while the oxide in non-(001) orientations consists of a thin film and discrete, widely separated larger crystals which appear to be considerably thicker than the film itself (Fig. 2c and d). The (001) epitaxial oxide continues

Fig. 2a

Fig. 2b

Fig. 2c

Fig. 2d

Fig. 2a-d. Time sequence series of electron micrographs showing the iron oxide film at progressive stages of development. The left column shows the oxide after (2a) 30 min and (2c) 2 hr at 300°C, pH 11 LiOH; the right column, replicas of the oxide upper surface at corresponding times.

to thicken with extended capsule heating and, as shown in Fig. 2e and f (6 hr heating), the boundary between the two oxide types becomes quite distinct. At about this point, however, one notices, in scanning across the oxide film, that the relative percentage of the surface area covered by the (001) oxide is definitely reduced, and more so than could be explained by fluctuations between individual specimens. Furthermore, if oxide films from longer heating periods are examined, the (001) oxide morphology is found to be almost completely absent. These facts lead to the conclusion that after a certain limiting thickness is reached, the epitaxial (001) oxide must undergo a transformation, or perhaps more descriptively, a degeneration which removes it from the capsule surface. This conclusion is supported by the appearance of the residual (001) oxide in Fig. 2f and particularly in Fig. 3 where two areas of epitaxially oriented oxide are just being engulfed in the final stages of the transformation.

The manner in which this transformation occurs suggests that it is stress induced and that the process

is initiated only after some minimum amount of stress has been generated within the epitaxial oxide, presumably as a result of the increase in oxide thickness. If selected area diffraction patterns are taken just inside the boundary of a degenerating oxide region and then just outside of it, that is, on an area of the surface which had been previously covered by the oriented oxide, they (Fig. 4a and b, respectively) show that the transformation involves, in addition to a marked decrease in oxide thickness, a decided oriented-to-unoriented transition of the surface oxide. No quantitative value for the epitaxial oxide thickness requisite for the commencement of the transformation process can be given, but the process itself is observed to begin after 2 to 6 hr heating and to be largely completed after 24 hr at temperature.

No other transformations of this nature were discovered when films from periods of heating longer than this were examined; the only visible change in the oxide morphology being a continually increasing coverage of the specimen surface by large, fully faceted crystals (Fig. 2g and h) which have been identified in previous work as  $\text{Fe}_3\text{O}_4$ . One noteworthy finding here, however, was that the thin oxide film next to the metal, the "base" film, which remains visible between the larger crystals, apparently changes little or not at all in thickness as the oxidation periods become longer. This conclusion was reached by comparing the

Fig. 2g

Fig. 2h

Fig. 2e-h. Time sequence series of electron micrographs showing the iron oxide film at progressive stages of development. The left column shows the oxide after (2e) 6 hr and (2g) 96 hr at 300°C, pH 11 LiOH; the right column, replicas of the oxide upper surface at corresponding times.

relative degree of electron transmittancy of base films formed with different heating times as, for example, in Fig. 2e where the time was 6 hr and Fig. 2g where it was 96 hr. While this technique is strictly applicable only for amorphous films, in instances such as this, where the films are composed of small, randomly oriented crystallites and the intensity losses due to diffraction are a direct function of film thickness, a good indication of relative film thicknesses can be obtained from a comparison of transmitted intensities provided, of course, that the electron microscope settings are not changed between specimens.

Replicas of the base film (Fig. 2h) reveal that it has still another distinctive property. After extended periods at 300°C (say, 50 hr and longer), the individual crystallites at the upper surface of this film, which show definite crystallographic forms with shorter heating times, become rounded and pebble-like and occur only over a rather limited size range (approximately 300-500Å). The appearance of the "equilibrium" base film is the same not only over the whole surface of a given specimen, but also between specimens of different steel composition from both the autoclave and capsule systems, indicating that this pebble-like texture is characteristic of the base film.

Fig. 3. Two areas of epitaxial oxide in the final stages of transformation after 6 hr at 300°C, pH 11 LiOH.

Fig. 4. Selected area diffraction patterns from epitaxial (4a, top) and transformed (4b, bottom) oxide areas.

Since the well developed facets of the larger upper crystals are a strong indication that they are formed by precipitation from solution, presumably on top of the base film, several attempts were made to show that there is in fact a polycrystalline layer between these crystals and the metal substrate by mechanically dislodging the crystals in question to reveal the underlying stratum. These upper crystals adhere so tenaciously, however, that if a dislodging force is applied, as by burnishing the oxide film *in situ* on the capsule wall with the end of a wooden rod, they will shear across the main crystal body rather than be dislodged.

The points in Fig. 5 represent the arithmetic mean of corrosion rate data from five capsules (one capsule of the original six leaked). The individual curves all have the same general form and, at 190 hr, they are all within  $\pm 5\%$  of the mean value shown. A logarithmic curve can be fitted to these averaged data points with good precision using the empirical method of Champion and Whyte (15). This fit may not be quite as meaningful as Fig. 5 would lead one to believe, however, for the derived logarithmic equation indicates an oxide film thickness of approximately 1500Å at  $t = 0$ , a value most likely too high by a factor of five or more. On the other hand, it is known that the hydrogen effusion technique employed here tends to give high results at short corrosion times because a certain amount of gas is desorbed from the capsule's exterior as it comes to temperature (10).

### Discussion

Two distinct aspects of oxide film growth in high temperature LiOH solution have been revealed which will, for clarity, be discussed separately. These concern the degeneration of the epitaxially oriented (001) iron oxide, an event occurring in the earlier stages of film formation, and the two-phased, double-layered structural configuration which the oxide film assumes as this process is completed.

*Mechanism of epitaxial oxide transformation.*—In considering possible mechanisms for the epitaxial oxide degeneration, note needs be made of the recent experiments of Grauer and Feitknecht (16). They found that the protectiveness of air-formed oxide films on iron (these were strongly oriented) against attack by chromate solution increased with film thickness up to a certain point, but then decreased drastically. This loss of protective ability was attributed to the appearance of pores or fissures in the oxide film. They observed further that corrosive attack then proceeded in such a way that sections of the original oxide were undermined and displaced from the specimen surface, leaving in their place a very thin, randomly oriented, passive  $\text{Fe}_3\text{O}_4$  film.

A sufficient number of our observations run parallel to those of Grauer and Feitknecht to suggest that we may be observing two different manifestations of one basic phenomenon. We see, for example, electron diffraction patterns (Fig. 6) very much like the one published by these authors to show the degree of orienta-

Fig. 6. Selected area diffraction pattern from an area of nucleating crystallites in an iron oxide film after 30 min at 300°C, pH 11 LiOH.

tion existing in their air-grown films when we examine areas of crystallite nucleation (Fig. 2a) in films grown in our capsules during short (30 min) heating exposures. These patterns are of some interest themselves for, while they resemble the (001) projection of the spinel reciprocal lattice, they cannot be indexed on this basis because of the presence of additional, anomalous diffraction spots, particularly those corresponding to the (311) planes of the spinel lattice. Reports of similar diffraction patterns from oxide films on iron or steel have been made previously and several hypothesis as to the origin of the (311) spots have been advanced (17-20). The one point of agreement seems to be that these patterns are associated with the process of nucleation of oriented oxide crystals on the specimen surface. For our own part, we observe that as the areas of oriented oxide thicken with extended heating, they cease to show this type of pattern, and yield instead the simple (001) spinel pattern (Fig. 4a).

Drawing from this background, we envision the following chronological sequence for the growth and subsequent transformation of epitaxial (001) iron oxide in the Bloom capsule system. A vacuum-anneal pretreatment such as the specimen tubing receives tends to produce an oriented  $\text{Fe}_3\text{O}_4$  film on the iron surface (11); this effect would be especially strong for (001) Fe grains where the favorable epitaxial orientation, (001)  $\text{Fe}_3\text{O}_4$ //(001)  $\alpha$ -Fe,  $[\bar{1}10]$   $\text{Fe}_3\text{O}_4$ // $[100]$   $\alpha$ -Fe, is possible. When the capsules are filled with LiOH solution, some  $\text{Fe}_3\text{O}_4$  may dissolve (21), but since the volume of capsule is small, the dissolution likely does not go to completion. With the commencement of heating, the residual film, still oriented, begins to develop further, with both the rate and morphology of this development dependent on the substrate grain orientation (Fig. 1). The growth rate of (001) iron oxide is apparently higher than that of iron oxide in other orientations (Fig. 2d), and a compact, coherent, and relatively thick layer of oxide soon builds up in this orientation. Stress mounts within this oxide layer as its thickness increases until finally the film fails, producing pores and fissures that permit the LiOH solution access to the underlying metal. Corrosive attack occurs then at the stressed metal/oxide interface so as to cause the oriented oxide to be replaced by a much thinner, finely crystalline, randomly oriented iron oxide film in a manner analogous to that reported by Grauer and Feitknecht. The displaced oxide dissolves, either at the time of displacement or later, since it is in a sealed capsule at high temperature, and then precipitates as secondary crystals on the underlying randomly oriented base film.

While the postulated stress-induced fissures could appear at random sites, e.g., above occlusions, etc., in the epitaxial oxide film, our experimental evidence is that attack usually initiates at the outer perimeter of a (001) epitaxial oxide area and proceeds inward. This is explainable if one assumes that the oxide grows thickest just above the substrate grain boundary, and that fissures would therefore be more likely to appear first in this region. The inward march of the transformation reaction results finally in a total engulfment, or "swallowing up" of the oriented oxide (indicated by arrows) as shown in Fig. 3.

Our electron micrographs also show that an encircling ring of larger crystals, which are apparently reprecipitated  $\text{Fe}_3\text{O}_4$ , is always present about a degenerating (001) oxide region. These secondary crystals arise presumably because the solution in this vicinity is heavily saturated with iron ion species, either from dissolution of the original oxide or fresh corrosive attack on the exposed metal surface, and the freshly formed base film just beyond the epitaxial oxide boundary represents the nearest stable site for nucleation and crystal growth from solution. As the

degenerating oxide recedes across the specimen surface, more or less continuous segments of the encircling ring should be left behind, since these crystals are nonmobile; and, indeed, strands of surface crystals which may be evidence of such a phenomenon are often found, as in the lower portion of Fig. 2e and at the right side of Fig. 3, near the epitaxial oxide boundary. These residual crystal strands might be better delineated and more abundant except for the fact that they are initiated in a supersaturated environment under nonequilibrium conditions and hence likely to be subject to further recrystallization themselves.

*Development of two-phased oxide film.*—The overall appearance of the two-phased film which develops with degeneration of the epitaxial oxide, and the manner in which the base film comes to be more and more covered by large  $\text{Fe}_3\text{O}_4$  crystals as the corrosion reaction progresses, strongly suggest that iron passes through the base film and into solution, subsequently to precipitate on the base film surface. This mechanism for the formation of oxide films on iron in high temperature aqueous media has, in fact, been proposed by Castle and Mann (7), who showed that by varying the factors which control the degree of saturation immediately at the corroding surface, one could apparently grow either Bloom films (no stirring, high saturation) or Potter-Mann films (stirring or iron ion sink, low saturation). If this theory is correct, the large surface crystals, formed by precipitation on a randomly oriented film, should themselves be randomly oriented; our electron micrographs reveal, however, that in certain areas the facets of the individual crystals are well aligned (Fig. 2h). There is no reason to expect crystals precipitating from solution onto a truly polycrystalline, randomly oriented substrate to nucleate and grow with a three-dimensional orientation, and the alignment displayed by these crystals needs explanation if the dissolution-precipitation mechanism is to be considered valid.

A similar type of orientation has been found by Field and Holmes (3) for Potter-Mann films, and they have published a metallographic cross-section micrograph of the oxide film (their Fig. 10) which clearly shows that, in this case, a polycrystalline layer better than  $5\mu$  thick exists between the metal grain and the oriented upper oxide crystal. In a discussion of this phenomenon, these authors pointed out that it seemed to be related to the fact that the specimen had been annealed, since oriented upper crystals occurred only with annealed surfaces and never with abraded surfaces.

A review of our electron micrographs brings forth two possibilities for the origin of the aligned surface crystals observed in our oxide films, neither of which would necessarily preclude the idea that the two-phased film grows primarily through dissolution-precipitation. The areas of crystal alignment are apparently associated with underlying metal grains, since we find instances of abrupt change in the direction of alignment across lines which probably represent the substrate grain boundaries, and different growth patterns are observed, depending on whether the metal grain is (001) or non-(001) oriented.

Many of the tiny crystallites which make up the early, very thin oxide films on non-(001) grains (upper half of Fig. 2b) are aligned, presumably by epitaxial forces. While these oxide films may therefore be considered to be partially epitaxially oriented, the areas of orientation are small and separated from one another, and apparently sufficient stress does not develop, in subsequent thickening of the oxide film, to cause a disorienting transformation in this grouping of oriented crystals. If it happens that the crystal alignment is such that planes giving preferred growth from solution are favorably oriented, then this set of crystals can act as nuclei for the development of

aligned secondary crystals; moreover, since precipitation from solution, under these circumstances, represents a low-stress mode of crystal growth, the precipitated secondary crystals may grow to appreciable size while still maintaining their alignment. It appears then that aligned secondary crystals occur on non-(001) grains because the nucleation sites, rather than being randomly situated, are actually oriented themselves from the very beginning of the growth process.

The initial oxide growth process on (001) substrate grains, on the other hand, is such that stress is produced within the oxide film and a transformation takes place that removes the original oxide, replacing it with a new polycrystalline and randomly oriented film. Can oriented growth of precipitated crystals occur on this surface? There is experimental evidence to indicate that it can. In Fig. 2e, for example, a number of the smaller surface crystals appearing on the freshly formed base film show a simple crystallographic form and a range of size which suggests that they are most likely newly nucleated and growing secondary crystals. Furthermore, the edges of many of these crystals are aligned, providing a clear indication that oriented growth is taking place here. The implications of this finding are uncertain. It may be simply that the transformation does not remove every vestige of orientation in the (001) oxide layer and that some crystallites of the great number constituting the base film remain in register with the substrate and hence with each other. This idea is supported by an examination of the base film diffraction pattern (Fig. 4b) which reveals a slight tendency to residual preferred orientation. Or, it may represent still another instance where an oriented species is observed to nucleate in a previously amorphous or randomly oriented surface film; such observations are not uncommon in gaseous oxidation experiments, having been reported by, among others, Gulbransen for iron oxide films (22), Bartlett for aluminum oxide films (23), etc. Whatever the source of these oriented crystallites, it may be expected that, although they may grow initially by recrystallization within the oxide film, they will eventually switch over to growth from solution and thus lead to the generation of large oriented upper crystals on (001) metal grains.

While these hypothesis may rationalize the presence of oriented secondary crystals in the films studied here, it is not obvious that the same arguments could be applied to explain the appearance of the oriented upper surface crystals found by Field and Holmes (3) where the polycrystalline layer between surface crystal and substrate is fully  $5\mu$  thick. How the surface crystals maintain orientation with the substrate through an intervening layer of such thickness remains a crucial, but unresolved question in the development of theories of oxide film formation in high temperature aqueous solution.

Although none of our conclusions are contingent upon a knowledge of the film structure under the large secondary crystals, it has been tacitly implied in these discussions that as the crystal being formed from solution grows laterally over the base film, the crystallites of this film are not incorporated into the body of the larger crystal, i.e., that a polycrystalline phase remains between the precipitated crystal and the metal below. There is as yet no experimental proof of this; the assumption is made through analogy with the work of the Potter and Mann group who have observed that the upper surface crystals never incorporate the inner polycrystalline layer. Extensions of the upper crystal down into the polycrystalline region are sometimes found however (3) and it may be that the adherence displayed by the secondary crystals in our capsule system results from a mechanical locking-in effect that such extensions would provide.

*Significance of evolved oxide structure.*—Two noteworthy characteristic properties are displayed by the base film once the two-phased structure is fully established: its upper surface takes on a distinctive pebble-like texture, and the film itself comes to a certain limiting thickness beyond which it will not grow. These properties are invariant, as far as can be seen, over the surfaces of the several different specimens examined, and it appears therefore that they are independent of such factors as substrate grain orientation, minor variations in alloy composition, and slight differences in surface pretreatment. Work with anodically passivated metals has shown that noncrystallographic oxide growth such as this occurs when the rate-determining step is diffusion through the passivating oxide film (24). Moreover, it may be noted that while the base film qualities seem unusual at first sight, they are just those that would be expected for an oxide film being simultaneously generated at the oxide/metal interface and dissolved at the oxide/solution interface. The film then would come to a limiting thickness as the rates of the two competing reactions become equal, and its outer surface, which is being continually renewed, would develop a morphology determined predominantly by the dissolution process. Oxide formation at the oxide/metal interface would initially be the faster reaction, but as the oxide film thickens, this reaction, controlled by solid state diffusion of reactants to or from that interface, would slow until its rate just equals that of the dissolution reaction at the oxide surface.

This hypothesis concerning the generation of the base film, which has been developed from observations of the growth behavior of the oxide, turns out to be quite similar to a mechanism of formation for passive oxide films advanced by Vetter (25); he explains the small but constant corrosion current which "passive" films exhibit by proposing that there is dissolution of the passive film, and that the rate of the anodic formation of the passive oxide and of its dissolution become equal at some given (and constant) film thickness. This, and the fact that the passive oxide films isolated by Grauer and Feitknecht (16) show essentially the same characteristics as our base film (they also being finely crystalline, randomly oriented films which remain at apparently constant thickness and show no substrate grain orientation dependence) give reason to believe that what we have described phenomenologically as the base film may actually be a high temperature passive oxide film.

There remains to be considered whether or not the oxide film morphology which has been revealed in this work can be correlated with the kinetic rate data taken during the formation of the film. We see first, from the smoothness of the curve in Fig. 5, that the degeneration of (001) epitaxial oxide either does not entail evolution of appreciable quantities of hydrogen, or takes place over such a small percentage of the specimen surface area that its effect on the over-all corrosion rate is negligible. Second, we note that the curve is logarithmic. Logarithmic reaction rate curves for the water/iron corrosion system have several times in the past been associated with the blocking of pores in the oxide film, so it is of interest to see if evidences of a pore blocking mechanism can be found here. No pores are visible in our electron micrographs, but this, of course, does not preclude the existence of pores smaller than the limit of resolution of the electron microscope (which may be as high as  $50\text{\AA}$  with these specimens), or of pores which follow a tortuous and nondirect route through the film. We can assume though that if there are pores in our oxide films, they are most likely in the base film. There is, however, no indication of any change in this film such as would suggest that pores are being blocked as the reaction progresses, i.e., the base film does not become thicker nor does it become more or less finely

crystalline. The one change that is observed during this period is that the base film is being increasingly covered with thick, adherent  $\text{Fe}_3\text{O}_4$  secondary crystals. Since these crystals are, from every indication, protective, this would suggest that the smooth decrease of the corrosion rate with time occurs not because pores are being blocked within the base film, but because more and more of this reactive film is being covered by shielding  $\text{Fe}_3\text{O}_4$  crystals.

The passing of cations through an oxide film to precipitate as discrete crystals at the solution/oxide surface is formally equivalent to the passing of cationic vacancies in the opposite direction through the film to congregate as cavities at the oxide/metal interface. Furthermore, in both cases, the oxidizing species is forbidden access to the underlying metal at the site of the cavity or crystal, and the effective surface area capable of continuing the corrosion reaction is thus reduced. It is possible therefore to adopt the derivation made for the new logarithmic law which is obeyed when cavities occur at the metal/oxide interface (26), making allowance for the fact that the oxide base film here remains at constant thickness, and show that the logarithmic nature of the corrosion rates observed in these studies can be accounted for in terms of the covering of an underlying oxide film by precipitating crystals, and that the oxide growth morphology and kinetic rate data are, in this sense, mutually consistent.

### Summary

In the growth of oxide films on annealed polycrystalline mild steel in high temperature pH 11 LiOH solution, the initial films tend to be epitaxially related to the substrate grains and to develop characteristic morphologies on the various grain orientations. The (001) oxide morphology is particularly distinctive and it has been possible to follow the growth and subsequent degeneration of this epitaxial species in detail. The degeneration of the (001) oxide begins only after a certain oxide thickness is attained, a fact suggesting that the transformation results from stress generated within the epitaxial oxide as its thickness increases.

The oxide film that exists after the epitaxial oxide has been transformed appears to consist of two layers, first a thin, finely crystalline, randomly oriented base film and above that, an incomplete layer of much larger, thicker crystals which are presumably solution-grown  $\text{Fe}_3\text{O}_4$ . The upper surface of the base film shows a pebble-like texture that is very uniform from point to point on the specimen. This surface is apparently made up of rounded crystallites which are somehow held to a very restricted size range (300-500Å). Furthermore, it appears that the base film comes to and remains at some limiting thickness as the corrosion reaction proceeds. Both of these observations have been interpreted as indicating that the base film is being simultaneously formed at the oxide/metal interface and dissolved at the solution/oxide interface, the film's upper surface texture resulting from the dissolution process and its limiting thickness coming about as the rates of the competing reactions become equal.

All indications are that, once this stage is reached, further film growth occurs by the passage of iron ions through the base film into solution to subsequently precipitate as large  $\text{Fe}_3\text{O}_4$  surface crystals, and the only change detected in the oxide film structure after this is a continually increasing coverage of the base

film by the upper crystal layer. Our corrosion rate data reveal a logarithmic decrease in the oxidation rate over this same time period which suggests that the precipitated crystals are protective and that the corrosion rate decreases as more crystals come down and the remaining area of exposed base film is reduced. This hypothesis is supported by the fact that one can, using the physical model proposed here, derive a theoretical rate equation which indicates that the corrosion rate curve should indeed be logarithmic.

### Acknowledgments

The authors wish to express their appreciation to O. R. Gates who analyzed our specimens, to G. N. Newport and E. D. Osgood who furnished valuable technical assistance, and to Dr. M. C. Bloom who provided many helpful discussions during the course of this work.

Manuscript received Nov. 20, 1967; revised manuscript received ca. Feb. 9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# A Study of Living and Dead Yeast Cells Using Dielectrophoresis

Joe S. Crane and Herbert A. Pohl\*

Department of Physics, Oklahoma State University, Stillwater, Oklahoma

## ABSTRACT

Using a simple new physical technique, dielectrophoresis, living cells can rapidly be distinguished from dead ones, and collected separately. A detailed study using yeast cells is reported here. A comparative study of the dielectrophoresis of aqueous suspensions of living and dead yeast (*Saccharomyces cerevisiae*) was made over a range of frequencies, aqueous conductance, field strength, and time. The amount collected in a given period was observed to increase with field strength and aqueous resistivity except in the highest ranges where a reverse trend occurs. At high field strengths reversal of collection occurs (i.e., dispersion). The frequency responses of living and dead cells are different, enabling remarkably selective collection of living cells from a mixture of living and dead cells. Cells collected in this manner survive.

Dielectrophoresis can be defined as the motion of a neutral particle due to the action of a nonuniform electric field on its permanent or induced dipole moment. In the past, the phenomenon has been applied primarily to inanimate matter (1-5). Recently however, living yeast cells have also been investigated; a qualitative description of their dielectrophoresis was given (6). The present paper describes the more quantitative aspects of yeast cell behavior.

The apparatus used consisted of a pin-plate electrode system, mounted in a shallow cylindrical well which had been cut in a lucite plate. It has been described previously in detail (6). An aqueous suspension of yeast cells was placed in the well and an a-c voltage applied across the electrodes. It was found that the cells migrated towards the pin and collected there in chains parallel to the field lines. The length of these chains, or "yield," was determined microscopically after a given time and was used as a measure of the effectiveness of the field. It was found to be a function of applied voltage, frequency of the applied voltage, suspension resistivity, cell concentration, and time of collection.

The voltages were supplied either by an audio oscillator-amplifier combination or a specially designed 2.55 MHz source. Voltage was measured with a Hewlett Packard Type 410B vacuum tube voltmeter. The suspension resistivity was determined using a parallel plate probe as an arm of a Wheatstone bridge at a frequency of 1 KHz. An auxiliary capacitor was used in parallel with the variable arm of the bridge to improve the null. The resistance thus measured was converted to resistivity by comparison to the corresponding resistance of a 0.01N solution of KCl which has a known resistivity. The optical density of the suspension of cells was measured on a colorimeter, and this in turn was transformed into cell concentration through the use of a conversion curve. The curve was obtained by making a direct, microscopic cell count for various optical densities.

The yeast (*Saccharomyces cerevisiae*) was grown in a fluid peptone-dextrose broth. To prepare a suspension for study, the yeast cells were mixed with deionized water (distilled water passed through an ion exchange resin). The suspension was centrifuged and the supernatant liquid poured off. More deionized water was added, the suspension was mixed thoroughly, and again centrifuged. This washing procedure was continued until the desired specific resistivity was obtained. Dead cells were obtained by autoclaving viable cells and prepared for study by rinsing, etc., as for live cells.

After a suspension with the desired concentration and resistivity had been prepared, 0.060 cc of it was

placed into the electrode well, filling it. With the voltage and frequency preselected, the field was applied across the electrodes for a given length of time. The accompanying graphs (Fig. 1-5) show some typical results.

In general the movement of the cells is not always precisely in the direction of the field lines, as would normally be expected, but instead there is usually some accompanying motion of the liquid. When this motion becomes turbulent, the collected chains can be moved along the pin or even removed from it. This violent action very probably accounts for the drop in collection at high voltages and at high resistivities, shown in Fig. 1 and 2. The peaks that occur in the frequency curves of Fig. 3 are not due to such stirring however, but rather to the changing force on the cells as the frequency is varied.

The most significant point indicated by the data is that shown in Fig. 3. That is, at frequencies about 1 MHz and above, live cells are collected but dead ones are not. In fact dead cells, which had been collected at a lower frequency, were allowed to remain on the pin, and when the 2.55 MHz source was applied, they were immediately expelled from the pin and a clear zone was created around it.

As a visual check of the selectivity at these conditions, a suspension of dead cells was stained with crystal violet and then mixed with an approximately equal concentration of unstained live cells. When the field was applied to this mixture, the live cells collected quite readily but the stained dead cells were virtually unaffected. Under these conditions, dead cells, even if

\* Electrochemical Society Active Member.

Fig. 2. Relative yield of yeast cells collected as a function of suspension resistivity. Live cells collected at 100 kHz and 50 rms volts applied; dead cells collected at 10 kHz and 30 rms volts applied.

Fig. 3. Relative collection of yeast cells as a function of frequency. Voltage applied, 100v rms,  $\rho = 1.3 \times 10^5$  ohm-cm.

hit by live cells travelling toward the electrode, merely ricocheted aside and were not carried on in by the more intense field around the live cells.

A remaining problem with this method of separating cells is that of removing the cells once they have been separated, without remixing them. Since the electrode well is so small, the introduction of an instrument, such as a syringe needle, for extracting the cells causes considerable disturbance of the medium, knocking many of the collected cells off the pin. However, by the careful introduction of a capillary action micropipet, (0.01 cc) the disturbance can be minimized and most of the cells can be satisfactorily removed. An alternate solution to this problem might be a continuous flow process, wherein the suspension moves between the electrodes as part of a continuous stream. Preliminary studies of this method are being made.

There are several interesting observations concerning cell movement which are so far unexplained. One of these is the stirring motion in the system. It usually consists of two circular currents on either side of the pin. Their common current between the pin tip and the plate moves toward the pin in some cases and away from the pin in others. For some conditions, such as high frequency with high resistivity, there may even be no stirring at all. The determining factors are not yet clearly understood.

Another occurrence deserving comment is that some of the cells, having once been attracted toward the pin, will suddenly experience a considerable repulsive force either just prior to or immediately after touching the pin. This occurs while many of the other cells are collecting normally and experiencing no repulsion. Most

Fig. 4. Relative collection of yeast cells as a function of time. Live cells collected at 2.55 MHz, 120 rms volts,  $\rho = 2.2 \times 10^5$  ohm-cm. Dead cells collected at 100 kHz, 30 rms volts,  $\rho = 2.0 \times 10^5$  ohm-cm.

Fig. 5. Relative collection yield of live yeast cells as a function of suspension concentration. Concentration in relative units ( $1.0 \cong 4.6 \times 10^6$  cells/cm<sup>3</sup>). Collection made at 10 kHz, 10 rms volts,  $\rho = 2.0 \times 10^6$  ohm-cm for 2 min at each conc.

of the repulsion occurs at the tip of the pin where the field strength is the greatest which would indicate that there may be some charge transfer taking place.

Finally, at almost any frequency, a few of the collected cells can be seen to be rotating at a few revolutions per second. As the frequency is varied, these cells will stop rotating and others will begin. This is an unexpected result since in a uniform isotropic sphere, an induced dipole in a nonuniform electric field experiences no torque (7). One possible explanation is that the cell rotates as a means of conducting current along its surface (3).

To see if the collected cells were yet viable, the collection was run until complete as evidenced by the lack of free cells in the aqueous regions (about 7-8 min). The collected cells were removed from the pin electrode by the micropipet technique described above. The collected cells bred actively in nutrient agar cultures. We conclude that the dielectrophoretic treatment did not noticeably affect the viability of the yeast cells. Although yeast cells appear to survive readily

the entire history of the separation, it seems very likely that this will not generally be true for all species, for few species are able to withstand prolonged contact with deionized water. One obvious improvement in the technique which is still under study is the use of innocuous solutes such as dextrose, sucrose, glycerine, etc., which can render the deionized medium more satisfactorily isoosmotic to the suspended organisms.

The precise cause of the greater dielectrophoretic response of living cells as compared to dead cells is yet to be learned. It may lie simply in the greater conductiveness or free ion content of the living cells, or it may lie in the more effective double charge layers of the living cells. In our judgment, the latter cause appears more likely to be dominant. It is probable that the sheaths of counter ions in the liquid regions within and without the cells and next layers of their opposites bound more rigidly to cell structures will act as pliable, easily deformed charge clouds, and that these charge clouds readily interact with an external field to produce the high effective polarizabilities of the living cells. The problem is under active investigation. There are, it is recognized, many degrees of "deadness" or "death" recognizable or eventually recognizable in organisms. It is hoped that dielectrophoretic separabil-

ity will help in arriving at sharpened distinctions, not only among degrees of deadness or death, but also between normal and abnormal living cells.

## Some Properties of Electroless Cobalt

Allan S. Frieze,<sup>1</sup> Richard Sard, and Rolf Weil\*

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey

#### ABSTRACT

The nucleation of electroless cobalt deposits, their microstructures and hardnesses, the development of fiber axes and the shape of x-ray diffraction lines, from which information about particle size, lattice-fault densities, and microstrain was obtained, were studied. The results are explained in terms of growth inhibition by codeposited phosphorus. Data obtained from the analysis of x-ray diffraction-line shapes of some cobalt electrodeposits are appended.

Chemically deposited (electroless) cobalt-phosphorus films are of interest primarily because of their magnetic properties. Therefore, the relationships between the magnetic properties and the plating variables (1-7) and, to some extent, the microstructure (1-3), as observed electron microscopically using replicas have been studied previously. However, there has been no study of the structure and properties of Co-P deposits from a metallurgical viewpoint. The purpose of this communication is to report the results of such a study of the nucleation of the deposits, their microstructures and hardnesses as related to their chemical composition, the development of the preferred orientations and the shape of x-ray diffraction lines, which yielded information about microstrains, lattice faulting, and particle size.

#### Experimental Procedure

**Nucleation.**—For the study of the nucleation of cobalt-phosphorus deposits, thin amorphous carbon films served as the substrates. In experiments, which are discussed later, glass and acetate were used as substrates. No difference in the structure of thin deposits was observed when either carbon, glass, or acetate substrates were used. The carbon films were prepared by evaporation on eighth-inch diameter, 200 mesh grids previously covered with a nitrocellulose film,

which had been cast on water. After the carbon evaporation, the plastic film was dissolved. The carbon substrates were sensitized as described by Judge *et al.* (6) and then immersed for various times in baths containing 35 g/l CoSO<sub>4</sub> × 7H<sub>2</sub>O, 35 g/l Na<sub>3</sub>C<sub>6</sub>H<sub>5</sub>O<sub>7</sub> × 2H<sub>2</sub>O, 70 g/l (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, and 5, 10, 25, 40 g/l NaH<sub>2</sub>PO<sub>2</sub> × H<sub>2</sub>O. The pH was adjusted to 8.7 ± 0.15 with NH<sub>4</sub>OH. The baths were operated at 75° and 90°C within 3°C. The deposits on the carbon substrates were examined directly in the electron microscope (Hitachi HU-11) immediately after drying. Transmission microscopy, selected-area and high resolution diffraction were employed.

**Structure of continuous films.**—For the study of the structure of continuous films, glass slides were the substrates. The preplating treatment, the bath compositions, and temperatures were the same as were used for the studies of the nucleation stage on carbon films. By controlling the deposition time, samples varying in thickness from 0.05 to 2μ were obtained. The deposition potential *vs.* a standard calomel electrode was recorded continuously during the plating on the glass substrates. The electrode was connected by means of a glass capillary filled with the plating solution and with the tip about 2 mm from the deposits surface. Initially, as the glass was nonconducting, the potential was zero. As a cobalt layer developed, the potential increased and then leveled off to a constant value, which was reproducible and was therefore considered representative of the plating conditions.

*X-ray diffraction studies.*—The fiber axes of the samples plated on glass were determined by the method of Clark and Simonsen (8). After the fiber axis was identified, the intensity of the x-rays diffracted by the plane normal to it was recorded in some cases with a counter to give a quantitative measure of the degree of preferred orientation.

In addition, four samples about  $1.5\mu$  thick with phosphorus contents of about 1, 2, 3, and 5% were deposited on acetate sheets, which were subsequently removed from the deposit by immersion in methyl-ethyl ketone. These samples were used to determine the microstrains and particle sizes according to the method of Warren and Averbach (9-10). In order to have a sample of sufficient thickness to obtain measurable diffracted intensities from the higher order diffraction lines, which are preferable for the Warren-Averbach method, a ten-layer thick assembly was placed in a special fixture which held them flat.

The Warren-Averbach method of determining the particle size and microstrain has been described in numerous publications. Therefore, only the pertinent parts will be briefly discussed. The diffracted intensity,  $P$ , is measured as a function of the Bragg angle,  $\theta$ , at regular intervals for two or more diffraction lines, preferably multiple orders from the same set of lattice planes. The shape of the broadened peaks as compared to those of an annealed sample is expressed in terms of a Fourier series. The annealed sample corrects for the broadening due to the instrumentation. Thus, the data are in terms of

$$P(\theta) = K \sum_L A_L \exp[-4\pi i L \lambda^{-1} (\sin\theta - \sin\theta_0)] \quad [1]$$

where  $L$  is the distance normal to the reflecting planes,  $A_L$  the Fourier coefficients,  $\lambda$  the wavelength of the x-radiation,  $\theta_0$  the Bragg angle corresponding to the average interplanar spacing, and  $K$  a proportionality constant. It is then assumed that the Fourier coefficients,  $A_L$  are the product of two terms

$$A_L = A_L^{PF} x A_L^S \quad [2]$$

where  $A_L^{PF}$  are the particle-size coefficients and  $A_L^S$  are the microstrain coefficients. It was shown by Warren (10) that only the strain coefficients are a function of the interplanar spacing. If the distribution of microstrains,  $\langle \epsilon \rangle$  is Gaussian, they are related to the Fourier coefficients by

$$\ln A_L^S = -2\pi^2 L^2 \langle \epsilon_L^2 \rangle d^{-2} \quad [3]$$

Therefore, by combining Eq. [2] and [3], the Fourier coefficients,  $A_L$ , are related to the strain by

$$\ln A_L = \ln A_L^{PF} - 2\pi^2 L^2 \langle \epsilon_L^2 \rangle d^{-2} \quad [4]$$

Thus a graph of  $\ln A_L$  vs.  $d^{-2}$  should be a straight line where the intercept is  $\ln A_L^{PF}$  and the slope is proportional to the square of the microstrain,  $\langle \epsilon_L^2 \rangle$ . In order to construct such a graph, the diffraction peaks of at least two sets of lattice planes with different values of  $d$  must be determined. The microstrains and particle dimensions which are determined by this analysis are in the direction perpendicular to the diffracting planes. If the two quantities are isotropic, data from any two or more sets of planes can be used in the analysis. If the particle size and strain vary with crystallographic directions, several orders of diffraction of the same set of planes should be used.

The separation of the broadening due to lattice faults and particle size from the coefficients,  $A_L^{PF}$ , can be performed in hexagonal metals by the following equations (10), which hold for planes with the Miller indices,  $(hkl)$ , as noted:

If  $(h-k) = 3N \pm 1$  and  $l$  is odd,

$$\left[ -\frac{dA_L^{PF}}{dL} \right]_{L=0} = \frac{1}{D} + \frac{|l|d}{c_0^2} (3\alpha + \beta) \quad [5a]$$

If  $(h-k) = 3N \pm 1$  and  $l$  is even,

$$\left[ -\frac{dA_L^{PF}}{dL} \right]_{L=0} = \frac{1}{D} + \frac{|l|d}{c_0^2} (3\alpha + 3\beta) \quad [5b]$$

If  $(h-k) = 3N$ ,

$$\left[ -\frac{dA_L^{PF}}{dL} \right]_{L=0} = \frac{1}{D} \quad [5c]$$

In Eq. [5],  $\alpha$  is the deformation-fault probability,  $\beta$  the growth-fault probability,  $D$  the particle-size dimension, and  $N$  an integer. It can be readily seen that Eq. [5b] and [5c] become identical if  $l$  is zero. As the second-order lines from many planes are often too weak to be usable in the analysis, it is necessary to assume isotropic strains and particle sizes. This assumption has been found (11) to be valid for cobalt powder and should also hold for electrodeposits because of the requirements for continuity in sheet. If isotropic strains and particle sizes are assumed,  $\alpha$  and  $\beta$  can be calculated from first-order lines from planes with the three types of indices set forth in Eq. [5]. Frequently a further assumption is necessary when even the first-order lines which satisfy the condition of Eq. [5b] are too broad. Christian and Swann (12) pointed out that such broadening results if  $\beta$  is large. It must then be assumed that  $\alpha$  is negligible and  $\beta$  is calculated from two sets of diffraction-line data. Then for example, the  $\{10\bar{1}0\}$ - $\{20\bar{2}0\}$  pair can yield data on strain and the actual particle size,  $D$ , as these lines do not broaden due to faulting. The  $\{10\bar{1}1\}$  line can yield a particle-size term with faulting. The faulting probability,  $\beta$ , can then be obtained by substituting the value of  $D$  obtained from the  $\{10\bar{1}0\}$ - $\{20\bar{2}0\}$  pair in Eq. [5a].

The experiments were conducted in a GE XRD6 x-ray-diffraction unit using filtered cobalt radiation. The analysis of the data required some minor alterations from the previously outlined procedure. An annealed cobalt sample invariably contains some face-centered-cubic phase and the faults associated with it. Thus, the diffraction lines from cobalt planes, which broaden due to faults, cannot be used for the determination of the instrumental broadening. Wagner and Aqua (13) suggested that annealed materials with similar absorption characteristics give essentially the same diffraction-peak shape at a given Bragg angle. Copper appeared to be a suitable substitute for annealed cobalt to determine the instrumental-broadening correction. Experiments to show the validity of this substitution are described in the Appendix. Table I shows the copper peaks which were used for the instrumental-broadening correction for the corresponding cobalt lines of the samples under consideration.

The cobalt lines which were used for the calculations of the microstrains were those diffracted by the planes perpendicular to the preferred orientation. The second-order lines of these planes were the only ones sufficiently intense so as to be usable in the analysis. Thus the  $\{0002\}$ - $\{0004\}$  pair was analyzed for the samples with 1% phosphorus which had a  $\langle 0001 \rangle$  fiber axis and the  $\{10\bar{1}0\}$ - $\{20\bar{2}0\}$  pair for the three other samples, which had  $\langle 10\bar{1}0 \rangle$  fiber axes. The  $K_{\alpha 1}$  and  $K_{\alpha 2}$  diffraction peaks were separated analytically by the Rachinger (14) method. The growth-fault probability was

Table I. Copper diffraction peaks used to correct cobalt peaks for instrumental broadening

Copper peak	Cobalt peak
(111)	(0002)
(222)	(0004)
(111)	(10 $\bar{1}$ 0)
(311)	(20 $\bar{2}$ 0)

calculated using the  $\{10\bar{1}1\}$  diffraction line. The microstrains were calculated at  $L = 30\text{\AA}$  for all samples. At smaller values of  $L$ , the Fourier coefficients become inaccurate because they are greatly affected by the background-radiation level, which cannot be selected with great precision.

**Hardness.**—To get an estimate of the hardness, indentations were made on the ten-layer thick composites with a one-gram load in a microhardness tester with a Vickers indenter.

### Results

The study of nucleation of Co-P on the carbon film showed that deposition occurred on the products of the  $\text{SnCl}_2\text{-PdCl}_2$  treatment. The electron-microscope examination of the carbon films which were only sensitized, showed that the products were not uniformly distributed over the surface as seen in Fig. 1a. The initial deposits of Co-P had a similar appearance, as shown in Fig. 1b, thus indicating that Co-P was nucleated on the products of the preplating treatments. As the deposition progressed, the distribution of the Co-P particles became more uniform. The number of particles depended on the plating conditions. Figure 2 shows the structure after 30-sec immersion in the electroless-cobalt solutions. Figure 2a shows the structure which resulted from deposition in the solution containing 10 g/l  $\text{NaH}_2\text{PO}_2 \cdot x\text{H}_2\text{O}$  at  $75^\circ\text{C}$ ; the sample represented by Fig. 2b was plated at  $90^\circ\text{C}$ . More nuclei formed at  $70^\circ\text{C}$  and the particles are smaller. Figures 2c and 2d show the structures developed in a bath containing 40 g/l  $\text{NaH}_2\text{PO}_2 \cdot x\text{H}_2\text{O}$  at  $75^\circ$  and  $90^\circ\text{C}$ , respectively. The number and the size of the particles appear not to have been significantly affected by the tem-

perature and are similar to Fig. 2a. The results from the baths containing 20 g/l  $\text{NaH}_2\text{PO}_2 \cdot x\text{H}_2\text{O}$  were very similar to those shown in Fig. 2c and 2d. Electron diffraction studies of all these samples indicated that

the  $\langle 0001 \rangle$  direction was predominantly perpendicular to the surface. It was also found that palladium particles from the sensitizing treatment tended to have  $\{111\}$  planes parallel to the surface.

After the samples became continuous, they assumed a structure characteristic of the orientation, which in turn was determined by the plating conditions. In the bath containing 5 g/l sodium hypophosphite at  $90^\circ\text{C}$ , the  $\langle 0001 \rangle$  direction continued to be predominantly perpendicular to the surface. The degree of preferred orientation increased with thickness. The degree of preferred orientation became more pronounced the higher the temperature and the lower the hypophosphite content of the baths. The microstructure which developed consisted of relatively large crystallites separated by crevices as shown in Fig. 3. Whenever the phosphorus content of the deposit was below 2%, the structure shown in Fig. 3 occurred. At higher phosphorus contents, in the range of 2 to 5%, an acicular structure shown in Fig. 4 was formed. This structure was associated with a  $\langle 10\bar{1}0 \rangle$  fiber axis.

The thickness at which the change occurred from the  $\langle 0001 \rangle$  axis, which all the initial nuclei possessed, to the  $\langle 10\bar{1}0 \rangle$  preferred orientation which developed in the samples with higher phosphorus contents, was determined from a graph of thickness *vs* the ratio of the diffracted intensity to background of the  $\{0002\}$  and  $\{10\bar{1}0\}$  peaks. The thickness was determined by fluorescent analysis. By taking the ratio of the diffracted intensity to background, a correction for the variation due to thickness was made. In a random co-

Fig. 3. Electron micrograph of replica showing structure associated with  $\langle 0001 \rangle$  fiber axis.

Fig. 4. Electron micrograph of replica showing structure associated with  $\langle 10\bar{1}0 \rangle$  fiber axis.

balt sample, the diffracted intensities from  $\{0002\}$  and  $\{10\bar{1}0\}$  planes are nearly equal. In the cobalt deposits, initially, the  $\{0002\}$  peak was the most intense. At a thickness of about 1000Å, the relative intensity from the two planes was essentially the same. Samples thicker than 1000Å with phosphorus contents above 2% had more intense  $\{10\bar{1}0\}$  lines. Thus, it appears that the change in the fiber axis occurred at about 1000Å. The microstructure as observed by replicas confirmed this result.

The deposition potential of the samples having the structure shown in Fig. 3 varied from 0.78 to 0.83v. The potential decreased with decreasing hypophosphite content of the bath and increasing temperature. The samples which exhibited the structures shown in Fig. 4 were deposited at potentials between 0.85 and 0.88v.

The results of the analysis of the x-ray line shapes by the Warren-Averbach method and the hardness tests are listed in Table II. It is seen that the samples with the  $\langle 0001 \rangle$  fiber axis have a larger particle size, fewer faults, and a lower hardness than those with the other fiber axis. The hardnesses of all samples and the microstrains of deposits with the  $\langle 10\bar{1}0 \rangle$  fiber axis increase with increasing phosphorus content. The particle size appears to remain constant for those samples with the  $\langle 10\bar{1}0 \rangle$  fiber axis. The macrostress as observed from the tendency of the samples to bend, was compressive for all four samples. The samples with the  $\langle 0001 \rangle$  fiber axis were only slightly stressed, whereas the others curled up after removing the substrate.

### Discussion

The nuclei of the products of the sensitizing treatment, in particular those of palladium, were expected according to the Bravais law to form with the closest packed planes,  $\{111\}$  parallel to the surface, as was observed. Cobalt depositing epitaxially on the palladium would then have the  $\{0001\}$  plane parallel to the surface. The observed  $\langle 0001 \rangle$  fiber axis in the nucleation stage probably developed in this way.

The development of a fiber axis characteristic of the plating conditions can be explained by assuming that phosphorus acts as a growth inhibitor. When the phosphorus concentration at the metal-solution interface is low, growth can continue predominantly laterally, i.e., with the  $\langle 0001 \rangle$  direction perpendicular to the surface. Such free growth would lead to the relatively large crystals that were observed. The crevices, seen in Fig. 3, are probably regions of higher phosphorus content, because the structure there resembles that of a deposit with higher phosphorus content. The crevices probably form because the phosphorus content at the metal-solution interface increases as the reduction reaction proceeds. The crevices were observed at thicknesses exceeding 1000Å. Further evidence that a composition difference existed between the crevice regions and the larger crystals was obtained from the fact that on exposure to moisture, corrosion occurred preferentially at the edges of the crevices. It is interesting that the  $\langle 0001 \rangle$  fiber axis and its accompanying microstructure were not observed by Sard, Schwartz, and Weil (15) in cobalt electroplated under a number of different conditions.

Table II. Analysis of x-ray line shapes and hardness tests

Sample No.	Fiber axis	Approximate phosphorus content, %	Particle size, D (Å)	Microstrain, $\langle \epsilon_{0001} \rangle^{1/2}$ (%)	Growth-fault probability, $\beta$	Hardness, kg/mm <sup>2</sup>
1	$\langle 0001 \rangle$	1	200	0.15	0.09	120
2	$\langle 10\bar{1}0 \rangle$	2	100	0.11	0.25	160
3	$\langle 10\bar{1}0 \rangle$	3	100	0.15	0.22	320
4	$\langle 10\bar{1}0 \rangle$	5	100	0.22	0.17	380

According to the theory proposed by Reddy (16), as applied to hexagonal metals, the {0001} plane should tend to be perpendicular to the surface when growth is inhibited. The least inhibited outgrowth (16) should occur when the closest packed direction is perpendicular to the surface, which would lead to a  $\langle 11\bar{2}0 \rangle$  fiber axis. This fiber axis, which was frequently observed in electrodeposited cobalt (15), was not observed in the electroless variety. The  $\langle 10\bar{1}0 \rangle$  direction which also lies in the {0001} plane is not close packed. Therefore, the deposits with the  $\langle 10\bar{1}0 \rangle$  fiber axis can be considered to have experienced a more inhibited outgrowth. The  $\langle 10\bar{1}0 \rangle$  fiber axes were also observed in electrodeposited cobalt (15) and resulted in a similar microstructure to that shown in Fig. 4. The reasons for the relationship between fiber axis and microstructure in cobalt deposits were discussed by Sard, Schwartz, and Weil (15).

The growth-fault probabilities which are listed in Table II are the highest ever reported for cobalt. As the growth-fault probability is the reciprocal of the number of planes between faults, it appears that sample 2 had a fault on the average of every fourth lattice plane. The faulting probability in cold-worked cobalt has been reported to be 0.05 to 0.1 (17). Electrodeposited cobalt, which is discussed in the Appendix to this paper, has maximum values of  $\beta$  of about 0.1 which are about the same as those of the low-phosphorus, electroless deposit. The reason for the high fault densities is apparently connected with the co-deposition of phosphorus. However, the mechanism by which phosphorus causes the faults is as yet unknown.

The particle size of the low-phosphorus sample is about the same as that of electroplated cobalt; the particle sizes of the samples 2, 3, and 4 are smaller. In all instances the particle size determined from the x-ray line-shape analysis is smaller than that observed by transmission electron microscopy of thin foils. The difference, which was discussed by Hofer *et al.* (18), results because the former measurement is the dimension of the coherently diffracting domain which may not appear as a grain in the electron microscope. Except for sample 4, the microstrains are about the same as those measured in electroplated cobalt and are also similar to those observed by Mitra and Halder (19) in cold-worked cobalt. The results of the hardness tests are in accord with the assumption that phosphorus acts as a growth inhibitor. There appeared to be no precipitation hardening as the equilibrium second phase,  $\text{Co}_2\text{P}$  was not observed.

### Conclusions

1. Cobalt-phosphorus deposits are nucleated on the products of the preplating treatments. The size and density of nuclei depends on the temperature of baths with low hypophosphite contents. In baths with higher hypophosphite contents the size and number of nuclei are relatively constant.

2. The initial nuclei which deposited on palladium-activated surfaces appear to have the basal plane of the hexagonal lattice predominantly parallel to the substrate. Samples thicker than about 1000Å assume a fiber axis which depends on the amount of codeposited phosphorus. Phosphorus contents below 2% result in a  $\langle 0001 \rangle$  orientation. When the phosphorus content is between 2 and 5%, a  $\langle 10\bar{1}0 \rangle$  fiber axis is observed.

3. The surface structure of the deposits is determined by the fiber axis. Those deposits with  $\langle 0001 \rangle$  orientations show lateral growth with relatively large grains that are often separated by crevices. An acicular structure is observed when there is a  $\langle 10\bar{1}0 \rangle$  fiber axis.

4. The deposition potential of samples with  $\langle 0001 \rangle$  fiber axes is lower than that with  $\langle 10\bar{1}0 \rangle$ . The struc-

tures can therefore be explained in terms of phosphorus acting as a growth inhibitor.

5. The highest growth-fault density observed in any cobalt sample to date is present in some of those obtained by electroless deposition. The strain, particle size, and hardness results tend to confirm the role of phosphorus as a growth inhibitor.

### Acknowledgments

The study of electroless cobalt was submitted by A. Frieze to the faculty of Stevens Institute of Technology in partial fulfillment of the requirements for the degree of Master of Science (Metallurgy). This work was supported by the International Business Machine Corporation, Poughkeepsie, New York, and their permission to publish it is gratefully acknowledged. The computer program for the evaluation of the Fourier coefficients was supplied by Dr. R. J. DeAngelis, University of Kentucky.

Manuscript received Nov. 29, 1967; revised manuscript received Feb. 12, 1968. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966, as Abstract 117.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX

#### X-ray Line Shape Analysis of Some Cobalt Electrodeposits

A high density of lattice faults was observed by transmission electron microscopy in an earlier study (15) of electroplated cobalt. It was pointed out at that time that the fault density could be determined quantitatively by an analysis of x-ray diffraction profiles. The results of this analysis are reported here.

Five samples were selected from those studied previously (15) for analysis by the Warren-Averbach method, which was discussed in the part of this paper which dealt with electroless cobalt. The first criterion for selecting the specimens was the presence of a measurable diffraction line of the type which is broadened by faulting. Only the samples with the pseudorandomly oriented grains (they were random except that there were relatively few with the basal plane parallel to the substrate) satisfied this condition. Most of the electrodeposits had  $\langle 10\bar{1}0 \rangle$  and  $\langle 11\bar{2}0 \rangle$  fiber axes and hence there were very few grains with the planes of the type which broaden due to faulting, parallel to the surface. Whereas, this condition could be changed by tilting the specimen with respect to the x-ray beam, the broadening which resulted from the altered geometry made the peaks unsatisfactory for quantitative analysis. Of the samples with the pseudorandom structure, those with the broadest diffraction lines were selected.

The diffraction lines of annealed copper filings and those of annealed cobalt which do not broaden due to faulting were used for the instrumental-broadening correction. It was found that both sets of results agreed within experimental error. The results of the Warren-Averbach analysis of the x-ray diffraction lines, together with the plating conditions under which the selected deposits were produced are listed in Table III. The diffraction lines used to obtain the graphs of  $\ln A_L$  vs.  $d^{-2}$  (Eq. [4]) are also listed in Table III. The instrumental-broadening correction in each instance was made with the nearest diffraction line of the annealed copper sample.

As the samples which were selected had the broadest peaks, the particle sizes, fault densities, and strains listed in Table III were probably higher than the average for the cobalt samples of the earlier study (15). The fault density appears to be somewhat higher than that of cold-worked cobalt, but as already pointed out, not as high as that of the electroless variety. The reason for the lower value of the second sample is not known. The fault densities, which indicate a growth fault on the average of every ten to sixteen atom layers, agree with the electron-microscopic observations (20). There is some indication of a larger par-

\* Had face-centered cubic material present.

\*\* pH was 3.5, for all others pH was 2.0

\*\*\* Plated at 60°C, all others plated at room temperature.

particle size for the sample plated at the elevated temperature, as would be expected. No conclusions about the effect of the plating variables are warranted because of the few data available.

The samples marked with an asterisk in Table III were found to have some face-centered-cubic phase present as determined from the presence of the {200} line by x-ray diffraction. It is interesting to note that the fault densities of these samples is not higher than that of the others as would have been expected.

## Electrodeposition of Bright Copper from Copper Sulfate Solutions by Addition of Cyanide Ion

S. Venkatachalam<sup>1</sup> and C. A. Winkler

McGill University, Montreal, Quebec, Canada

#### ABSTRACT

Small concentrations of cyanide ion in copper sulfate solutions, in the presence of either gelatin or cystine, enable the electrodeposition of bright copper, provided the current density is appropriately controlled. Cyanide ion, alone, added to the sulfate solution, causes marked depolarization, and this is strongly accentuated when gelatin or cystine is present. A polarization of about  $240 \pm 10$  mv was associated with maximum brightness of the deposits. Experiments with radioactive cystine and cyanide suggest that a 1:1 complex of the two might be involved in the production of bright deposits. The results seem to be explicable if it is assumed that orientation at the surface is necessary for brightness, and that cyanide ion is capable of acting as an "electron bridge," either alone or in the complex.

The relations between the light-reflecting property, or brightness, the electrolytic polarization, and the structure of an electrolytic deposit have been the subjects of many investigations. In most of the work addition agents, when used, were chosen empirically, since there is still no generally accepted theory to explain the various observations made during the formation of bright electrodeposits. The older theories of

Blum (1) and Bancroft (2), which assume adsorption of brighteners on the cathode, have been further developed by others. Some of these (3-6) have assumed kinetic adsorption on the active centers, while others (7-10) have assumed preferential adsorption on defined faces of the growing microcrystals.

In general, brighteners are not only adsorbed as such on the cathode surface, but may also undergo transformation during electrolysis. The transformation of organic addition agents at the electrode is of particular

\* Electrochemical Society Active Member.

<sup>1</sup> National Research Council of Canada Postdoctoral Fellow.

interest, since the reflectivity of the deposit may then be caused, not by the brighteners initially present, but by the products of their electrochemical reduction or oxidation (11).

Gelatin has been the most commonly used brightener, and the reflectivity of copper deposits in its presence has been studied (3, 12, 13). The behavior in such systems may be markedly altered by the simultaneous presence of halide ion, particularly  $\text{Cl}^-$ , which, in certain ratios to the gelatin, may exert a depolarizing action, or change the brightness of the deposit [e.g., (4)].

Since  $\text{CN}^-$  ion is generally recognized as having some properties similar to the  $\text{Cl}^-$  ion, and since the use of cyanide baths is well known for deposition of several metals, it seemed of interest to investigate the effect of adding  $\text{CN}^-$  to the acid copper sulfate electrolyte generally used for the electrowinning of copper. The studies were extended to include the simple amino acid, cystine, as an addition agent, since it has been found to behave in this capacity in a manner somewhat similar to the more complex gelatin molecule, including similar effect of added  $\text{Cl}^-$  ion (6).

### Experimental

The cell used for the polarization measurements is shown in Fig. 1. It was made of Lucite tubing of 32 mm ID and 155 mm long, cemented into a square anode compartment at the top, in such a way that 2 mm of the tube protruded into the anode compartment. The anode was an annulus of copper, 42 mm ID and 10 mm high, that dipped into electrolyte contained in the channel between the protruding tube and the outer wall of the anode compartment. The copper cathode was bolted to a flange that was cemented to the bottom of the cell, with a butyl-rubber annular gasket between the two to prevent leakage. The total superficial area of cathode exposed to the solution was 8  $\text{cm}^2$ .

Polarization measurements were made with the familiar probe technique and a recording potentiometer. The reflectivity of the plated surface was measured in a parallel beam of light, operated with stabilized line voltage, and projected on to the sample held in a fixed position at  $45^\circ$  to the light beam, in a light-tight box. The reflected light was received on a photocell, the current from which was recorded on a microammeter.

In some experiments, the electrolyte contained  $^{35}\text{S}$ -labelled cystine and  $^{14}\text{C}$ -labelled potassium cyanide. The activity of the plated samples was determined in a windowless  $\beta$ -proportional counter.

A "standard" electrolyte had the composition:  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , 125 g/l (British Drug Houses, A.R. grade);  $\text{H}_2\text{SO}_4$ , 100 g/l (A.R. grade). The water was twice distilled. Copper sulfate from the same manufactured lot, and a constant volume (150 ml) of electrolyte, were used in all experiments, and measurements were all made at  $25^\circ \pm 0.1^\circ\text{C}$ . Before any experiment was made with electrolyte containing an additive, the cathode was cleaned and brought to a

Fig. 1. Diagram of apparatus

"steady-state" surface condition by deposition under rigidly controlled conditions, as described in an earlier publication (12). The additives used, singly or in pairs, included: gelatin,  $\text{CN}^-$  ( $\text{KCN}$ ), cysteine, cystine, methionine,  $\alpha$ -alanine,  $\text{SO}_3^-$  ( $\text{K}_2\text{SO}_3$ ),  $\text{Cl}^-$  ( $\text{KCl}$ ), dithiodiglycolic acid, 2-aminothiazole and  $\text{CNS}^-$  ( $\text{KCNS}$ ).

### Results

**Gelatin with cyanide.**—Addition of various amounts of cyanide ion to the standard electrolyte decreased the polarization from 100 mv ("standard surface" value) to 30 mv (Fig. 2A). In the presence of gelatin, the depolarization by  $\text{CN}^-$  was as much as 200 mv. The cathode deposits showed increasing brightness as the concentration of cyanide ion was decreased. Experiments were therefore made in which the cyanide concentration was kept arbitrarily constant at 0.2 mg/l, and the gelatin concentration was varied from 50 to 200 mg/l. From the results (Fig. 3A), it is apparent that a maximum brightness was attained with about 100 mg/l gelatin, at the C.D. used (2 amp/ $\text{dm}^2$ ).

Experiments were then made in which this maximum gelatin/ $\text{CN}^-$  ratio, i.e., 500/1 was kept constant, while the total amount of the two additives was varied, at current densities in the range 0.5-5 amp/ $\text{dm}^2$ . The maximum brightness then depended on both the amount of the two additives and the current density (Fig. 3B).

**Cystine and related compounds with cyanide.**—Substitution of cystine for gelatin gave the results shown in Fig. 2B and 4A. Cystine behaved in a similar manner to gelatin, but the depolarization due to  $\text{CN}^-$  was less pronounced. As with gelatin, maximum brightness was obtained at a particular ratio of cystine/ $\text{CN}^-$  (roughly 80/1) for a C.D. of 3 amp/ $\text{dm}^2$ .

The effects on reflectivity and polarization of C.D. and  $\text{CN}^-$  concentration, in the presence of cystine, are shown in Fig. 3C and 5A. The close similarity with gelatin +  $\text{CN}^-$  is again apparent; maximum brightness depends on both the ratio of the two additives and the current density.

The effect of  $\text{CN}^-$  was also studied with other compounds that contain the functional groups that are present in cystine, e.g., methionine (an amino acid with a sulfur atom),  $\alpha$ -alanine (an amino acid without a sulfur atom), dithiodiglycolic acid (no amino group, but a -S-S- group). The results are presented in Fig. 2C and 4B. Methionine, like gelatin and cystine, markedly increased the polarization above that of the standard surface;  $\alpha$ -alanine had less effect. Depolarization by  $\text{CN}^-$  was considerably less with these compounds than with gelatin or cystine. The reflectivities of the deposits were not altered by any of these com-

pounds in combination with the  $\text{CN}^-$ . Dithiodiglycolic acid itself behaved as a depolarizer, the values being 45-85 mv at current densities of 1-4 amp/dm<sup>2</sup>, and its behavior was not affected by the presence of  $\text{CN}^-$ . A combination of 20 mg/l methionine, a polarizer like cystine, and 1.4 mg/l dithiodiglycolic acid with 0.2 mg/l of  $\text{CN}^-$  did not alter much either the polarization values or the nature of the deposit (c.f. Table I).

**Cystine with  $\text{SO}_3^-$  and  $\text{Cl}^-$ .**—Sulfite ion is more nucleophilic in a kinetic sense than cyanide ion in reaction with cystine, and like  $\text{CN}^-$ , it is capable of

breaking the -S-S- bond easily (14). However, in the concentration range from 0.2 to 2 mg/l, it was without effect on the nature of the deposit when it was present with cystine (20 mg/l) in the electrolyte. Similar additions of chloride ion, which acts as a depolarizer in the presence of gelatin (4), had no effect on the deposit in the presence of cystine (20 mg/l) other than to cause some depolarization. Similarly, KCNS (0.2 - 0.5 mg/l) and 2-aminothiazole (20 mg/l) were without effect on the deposit, although they possess structures that are somewhat similar to those of the products formed when  $\text{CN}^-$  reacts with cystine (15-18), i.e.,  $\beta$ -thiocyanoalanine (I), 2-aminothiazole-4-carboxylic acid (II) or the equivalent 2-imino-4-thiazolidine carboxylic acid (III).

The data for these several systems are shown in Table I.

**Inclusion of cystine and  $\text{CN}^-$  in the deposit.**—The relative extents to which cystine and  $\text{CN}^-$  were included in the deposit were determined with electrolyte to which had been added cystine with  $^{35}\text{S}$  and  $\text{CN}^-$  with  $^{14}\text{C}$ . The total thickness of copper deposited was kept constant for all the experiments. The results are shown in Fig. 5B.

When cyanide alone was present in the solution, the amount of  $^{14}\text{C}$  included in the deposit remained constant irrespective of the current density. On the other hand, when cystine alone was present, retention of  $^{35}\text{S}$  decreased markedly up to 3 amp/dm<sup>2</sup>, beyond which the value remained constant. Also, when inactive cystine was present in conjunction with active cyanide, the activity of the deposit was rather precisely that corresponding to the inclusion of  $^{35}\text{S}$ , which strongly suggests that each cystine molecule included in the deposit carried with it one  $^{14}\text{CN}^-$  ion.

### Discussion

The results of the present study may be explained if it is assumed that some form of orientation at the surface is essential for brightness. The orientation might, but perhaps need not, correspond to exposure of only one particular crystal plane. That orientation, to produce a surface of relatively constant characteristics, as a condition for brightness is suggested by the almost constant polarization ( $240 \pm 10$  mv), at a C.D. of 2 amp/dm<sup>2</sup>, that characterized deposits of maximum brightness.

The action of gelatin, or cystine, or methionine alone, in increasing the polarization can be explained if it is assumed that these compounds are adsorbed on the active centers, thereby reducing the area of the cath-

Fig. 5. Effect of current density and  $\text{CN}^-$  concentration on the cathode polarization, and the adsorption of  $^{35}\text{S}$  and  $^{14}\text{C}$ , in the presence of cystine. A,  $\circ$  20 mg/l cystine, no  $\text{CN}^-$ ,  $\bullet$  20 mg/l cystine, 0.05 mg/l  $\text{CN}^-$ ,  $\triangle$  20 mg/l cystine, 0.2 mg/l  $\text{CN}^-$ ,  $\blacktriangle$  20 mg/l cystine, 0.5 mg/l  $\text{CN}^-$ ,  $\times$  20 mg/l cystine, 0.8 mg/l  $\text{CN}^-$ ,  $\square$  20 mg/l cystine, 1.0 mg/l  $\text{CN}^-$ ; B,  $\circ$   $\text{CN}^-$  0.3 mg/l,  $^{14}\text{C}$  0.5  $\mu\text{C}/150$  ml,  $\bullet$  cystine 20 mg/l,  $^{35}\text{S}$  0.49  $\mu\text{C}/150$  ml,  $\triangle$  cystine 20 mg/l,  $\text{CN}^-$  0.3 mg/l,  $^{14}\text{C}$  0.5  $\mu\text{C}/150$  ml.

ode at which electron transfer may be readily effected, with a consequent increase in true current density, hence in polarization. On the other hand, the depolarization effect of  $\text{CN}^-$  alone can be explained in the manner suggested by Heyrovsky for the chloride ion (19), i.e., it might decrease the activation energy for the electron transfer by forming an intermediate "complex" of the type, electrode- $\text{CN}^-$ - $\text{Cu}^+$ , in which the cyanide ion acts as an "electron bridge."

While gelatin or cystine might be assumed to act mainly by adsorption at active centers (e.g., peaks), as might be demonstrated by autoradiography (20), it might well be that  $\text{CN}^-$  is adsorbed in a less specific way on the cathode surface. This would mean that,

in the presence of  $\text{CN}^-$ , deposition of metal at the peaks would be mainly through an intermediate complex of the type,  $\text{CN}^-$ -cyst- $\text{Cu}^+$ , while deposition on other parts of the surface would be through a  $\text{CN}^-$  bridge alone, with a smaller activation energy. The  $\text{CN}^-$  ion would then act as a depolarizer both in the absence and in the presence of the organic addition agent, as observed.

Maximum brightness of the deposit, corresponding to maximum orientation of the atoms in the surface, might require an optimal ratio of  $\text{CN}^-$  to cystine (or gelatin) to be present in the cathode film. This would suggest that, as found experimentally, different current densities should be necessary to achieve maximum brightness, corresponding to this particular concentration ratio in the film, as the concentrations of  $\text{CN}^-$  and cystine (or gelatin) are altered in the body of the solution. If the orientation were disturbed by an excess of cystine in the cathode film, a condition that might prevail at low current densities and high cystine to  $\text{CN}^-$  ratio in the solution, a bright deposit would not be obtained. On the other hand, with an excess of  $\text{CN}^-$  in the film, such as might be realized at high current densities and lower cystine to cyanide ion ratios in the solution, the copper ion would deposit directly through the  $\text{CN}^-$  bridge, and a coarser grained, rather than bright deposit, should result. It is also possible that too high current densities would tend to prevent bright deposits by promoting a rate of deposition greater than that with which orientation of the atoms in the deposit can occur.

The composition of a possible complex between cystine (or gelatin) and  $\text{CN}^-$  is suggested by the experiments with  $^{35}\text{S}$ -cystine and  $^{14}\text{CN}^-$ . Since the same activity was obtained, at different current densities, with the active cystine alone as with inactive cystine +  $^{14}\text{CN}^-$ , it would appear that the complex involved in the deposition process contains  $^{35}\text{S}$  and  $^{14}\text{C}$  in a 1:1 ratio, corresponding to a cystine- $\text{CN}^-$  complex of the same ratio.

## Structural Characteristics of the Oxide on the (111) of Copper<sup>1</sup>

J. V. Cathcart\* and G. F. Petersen

*Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee*

### ABSTRACT

Cuprous oxide films, 25 to approximately 500Å thick, formed on the (111) of copper were studied by x-ray, electron microscopic, and ellipsometric techniques. The films were characterized in terms of their surface topography, epitaxial strains, mosaic spread, mosaic size, and their orientation relationships with the substrate metal. The films were demonstrated to contain large numbers of structural defects which could act as paths of easy diffusion, and a correlation was shown to exist between the rate of oxidation of the (111) of copper and the extent of these paths of easy diffusion in the oxide. Estimates were made of the effective grain-boundary width and diffusion coefficient in Cu<sub>2</sub>O, and it was concluded that substantial material transport could occur *via* these paths of easy diffusion.

One of the most notable features of the oxidation of metal single crystals is the marked oxidation rate anisotropy exhibited by these materials including those with cubic crystal structures. A good example of this behavior is furnished by copper (1) which at 250°C shows an order of magnitude difference between the oxidation rates of its most rapidly and most slowly oxidizing orientations. Various authors have suggested that the anisotropy of atomic packing on different crystal planes or the variation of work function with crystal plane might account for the observed results; however, objections can be raised to both these ideas. In recent papers, (2) we pointed to the existence of a correlation between the oxidation rate anisotropy of copper and a corresponding anisotropy of the extent of paths of easy diffusion through the growing oxide films. The present paper is a report of an additional correlation between the rate of oxidation of the (111) of copper and the degree of "lattice disregistry"<sup>2</sup> in the oxide film.

### Experimental Procedures and Results

The copper specimens used in this study were sliced from a 1-in. diameter single-crystal rod at such an angle as to expose a (111) surface. After mechanical polishing through 4/0 grade emery paper, the crystals were electropolished in 60% H<sub>3</sub>PO<sub>4</sub> and washed for 10 min in running distilled water. Just prior to oxidation the specimens were annealed in H<sub>2</sub> for 1 hr at 500°C to reduce the superficial oxide on their surfaces. They were then oxidized in purified oxygen at 200°C and a pressure of approximately 500 Torr. The all-glass apparatus in which the oxidation was carried out was

equipped with optical flats so that a continuous set of oxide thickness measurements could be made with an ellipsometer during the oxidation process.

Twelve specimens were prepared and examined using an x-ray technique developed by Borie and Sparks (3-5). The oxide on all specimens was highly oriented, and the epitaxial relationship between the oxide and metal was the same as that reported by previous authors (6), *viz.*, the (111)<sub>Cu<sub>2</sub>O</sub> || (111)<sub>Cu</sub>. The three <110><sub>Cu</sub> lying in the plane of the metal surface were parallel to the corresponding <110><sub>Cu<sub>2</sub>O</sub> which lie in the plane of the film. There are two ways in which these conditions may be met, thus resulting in twin-related orientations in the oxide. In the first or "parallel" orientation, the oxide and metal lattices are completely parallel to each other. The "antiparallel" orientation may be derived by a 180° rotation of the oxide lattice about its surface normal.

Since the twinning plane in this case is the (111), incoherent twin boundaries with components normal to the film surface must exist within the oxide. These boundaries produce regions of disorder within the oxide lattice and comprise an important fraction of the total "lattice disregistry" within the oxide.

The results of these measurements are summarized in Fig. 1. Nine of the 12 rate curves fell in a scatter band at the top of the graph. The other three specimens exhibited a marked reduction in oxidation rate. A complete rate curve was determined only for one of these three samples, a single thickness measurement being made on each of the others after the completion of oxidation.

The x-ray work revealed that the oxide on the nine specimens whose oxidation rates were essentially the same consisted of approximately equal quantities of parallel and antiparallel orientations. On the slow rate specimens, on the other hand, 78-90% of the oxide was in the antiparallel orientation. The x-ray results thus

<sup>2</sup> The term "oxide lattice disregistry" is used in this paper to mean the disorder existing in the oxide lattice as the result of the presence of dislocation arrays or grain boundaries which can act as paths of easy diffusion.

Fig. 1. Oxidation rate curves for the (111) of copper at 200°C and 500 Torr oxygen. The figures on the graph refer to the percentage of oxide present in the antiparallel orientation.

make it clear that those crystals exhibiting relatively small rates of oxidation were also those for which the extent of incoherent twin boundaries in the oxide was smaller, that is, those films in which a single orientation of the oxide predominated, in this case, the antiparallel orientation.

A trace of  $\text{CCl}_4$  (approximately 1 ppm) was present in the oxidation chamber in at least two of the three slow-rate runs, and this change in the orientation distribution in the oxide was undoubtedly related to the presence of  $\text{CCl}_4$  or some other surface contaminant.

### Discussion

These data along with a few earlier results allow one to construct a model for the oxide film on the (111) of copper. The features of the model may be summarized as follows:

**Surface topography.**—Electron microscope studies of surface replicas and stripped oxide films showed the existence of relatively minor thickness inhomogeneities in the oxide films in the thickness range 100–1000Å for oxidation at approximately 1 atm oxygen and at a temperature of 150°–250°C. Within this thickness range, at least to a first approximation, the films may be treated as a layer of uniform thickness.

**Epitaxial strains.**—With the possible exception of earliest stages of oxidation, the oxide lattice, because of epitaxial forces, is expanded normal to the plane of its surface and compressed in that plane. The x-ray study gave a quantitative expression for these strains in terms of average d-spacing values measured normal to the film surface. The thinnest films (approximately 25Å) were virtually unstrained, their lattice parameter being essentially that of bulk  $\text{Cu}_2\text{O}$ . With increasing thickness, however,  $d_{111}$  increased rapidly and passed through a shallow maximum (2).

**Strain gradient.**—Strain broadening of the (111) and (222) Bragg peaks indicated the existence of a strain gradient within the oxide. In analogy to the previously discussed case of the oxide on the (110) of copper, it was presumed that the strain gradient results from the relief of epitaxial strains within the films through the production of an array of growth dislocations in the films (5).

**Mosaic spread.**—These growth dislocations plus the small misorientations (both tilt and twist) introduced into the oxide during oxidation produce a mosaic structure in the oxide. The mosaic spread, defined in terms of the width at half-maximum intensity of a (111) rocking curve for the films, is smallest for the thinnest films, increasing from a value of 2° at 100Å

to about 7° at 500Å. Dark field electron microscopy of oxide stripped from the (111) indicated an average diameter for the mosaic blocks of 50–100Å.

**Oxide orientations.**—As indicated above, two different, twin-related orientations occurred in the oxide. There are two general ways in which these orientations may be distributed in the film: the orientation of each mosaic block may be fixed by that of the nucleus from which it grows. The oxide would then consist of columns of oxide, some having the parallel, others the antiparallel orientation. This condition, hereafter referred to as “columnar twinning,” is illustrated schematically in Fig. 2a. On the other hand, stacking faults may occur in the oxide causing repeated twinning in each mosaic block. This arrangement we have called “laminar twinning,” and it is shown schematically in Fig. 2b.

At the present time we are able to make only a rather ambiguous choice between these two alternatives. The x-ray results are inconclusive on this point; however, low-pressure oxidation studies by Lawless and Mitchell (7) suggest that the columnar twin model may be more correct. Electron micrographs of specimens oxidized at  $p_{\text{O}_2} = 10\mu$  and 400°C revealed well-formed, three-sided pyramids of oxide on the surfaces of the specimens. Both orientations of the oxide are clearly evident, but each pyramid appears to be almost perfectly formed. Such morphology would be crystallographically impossible if “laminar twinning” occurred.

It is debatable, however, that the results of oxidation at a pressure of 10 $\mu$  can be extrapolated to 1 atm. Thus for the moment no clear answer can be given the question of the precise distribution of the two oxide orientations in  $\text{Cu}_2\text{O}$  films. Whatever this distribution may be, the film will, in any case, be rich in incoherent twin boundaries. Such boundaries are almost as effective as preferred diffusion paths as ordinary high angle grain boundaries (8). Thus the presence of twin-related orientations in the oxide on the (111) automatically leads to the formation of extensive numbers of “paths of easy diffusion” in the oxide films.

**Diffusion effect.**—Crucial to the postulate of the importance of these paths of easy diffusion in the oxide film is the demonstration that the volume of such regions in combination with the appropriate diffusion coefficient is large enough to transport a significant quantity of material through the oxide. No information is available regarding the relative values of the vol-

Fig. 2. Schematic representation of the distribution of twins in the oxide on the (111) of copper.

ume and grain-boundary diffusion coefficients,  $D_v$  and  $D_{gb}$ , respectively for  $\text{Cu}_2\text{O}$ ; however, in general  $D_{gb} \gg D_v$ . For metals, values of  $D_{gb}/D_v$  on the order of  $10^6$  have been reported; e.g., for self-diffusion in silver (9) at  $500^\circ\text{C}$ ,  $D_{gb}/D_v = 4 \times 10^6$ . Similar large values for this ratio have been reported for ionic compounds:  $10^6$  for anion self-diffusion in  $\text{NaCl}$  at  $500^\circ\text{C}$  (10),  $10^2$  for oxygen diffusion in  $\text{Al}_2\text{O}_3$  at  $1500^\circ\text{C}$  (11), and  $10^1$  for Ni in  $\text{MgO}$  at  $1715^\circ\text{C}$  (12). Furthermore, the activation energy for grain-boundary diffusion is generally 1/2 to 2/3 that for volume diffusion (13); thus  $D_{gb}/D_v$  should increase with decreasing temperature. Given the relatively low oxidation temperatures used for our copper specimens, it is reasonable to conclude that for  $\text{Cu}_2\text{O}$  at  $200^\circ\text{C}$ ,  $D_{gb}$  exceeds  $D_v$  by a substantial factor, probably several orders of magnitude.

The second parameter, knowledge of which is needed for our arguments, is the fraction of the total oxide volume associated with the grain boundaries; i.e., the volume fraction of the oxide for which  $D_{gb}$  is the valid diffusion coefficient. Estimates of grain boundary widths,  $\delta$ , given in the literature vary from as low as 5 to  $10^4$  Å with most of the more recent results for ionic compounds favoring comparatively wide grain boundaries. For metals the grain boundaries appear to be very narrow (12), but in ionic compounds the influence of grain boundary may extend large distances into adjacent grains; for example, an effective grain-boundary width of 200 Å was estimated for  $\text{NaCl}$  (10), and, for  $\text{MgO}$  values of  $\delta$  in the range of microns have been reported (12).

As indicated above, the diameter of the mosaic blocks in the (111) oxide films was approximately 100 Å. If the grain-boundary width in  $\text{Cu}_2\text{O}$  films is as high as  $10^2$  or  $10^3$  Å,  $D_{gb}$  will obviously hold for the entire volume of the oxide. On the other hand, if the effective width of the grain boundary is only 10 Å, roughly 20% of the oxide will be associated with grain boundaries. Thus it becomes apparent that grain-boundary diffusion could contribute significantly to material transport through the film for  $D_{gb}/D_v$  as small as 10, and for  $D_{gb}/D_v$  approximately  $10^3$ , grain-boundary diffusion may well be the dominant mechanism for material transport. These conclusions are also consistent with a theoretical analysis by Gibbs (14) of the influence of oxide grain boundaries on diffusion-controlled oxidation.

### Summary

In summary, our x-ray studies of the oxide on the (111) of copper demonstrated that these films con-

tained large numbers of structural defects which may act as paths of easy diffusion. A correlation was shown to exist between the rate of oxidation of the (111) and the extent of these paths of easy diffusion. Finally on the basis of reasonable assumptions concerning grain-boundary widths and diffusion coefficients, it appears that very considerable amounts of material transport could occur across the oxide via these paths of easy diffusion.

### Acknowledgment

The authors wish to thank C. J. Sparks and R. E. Pawel for much valuable assistance and discussion during the course of this research.

Manuscript received Aug. 28, 1967; revised manuscript received ca. Feb. 12, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Electrochemistry of Fused Lithium Perchlorate

Udo Anders and James A. Plambeck\*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

## ABSTRACT

The limiting reactions which occur during electrolysis of fused lithium perchlorate are shown to be  $\text{Li}^+ + e^- \rightarrow \text{Li}^\circ$  and  $\text{ClO}_4^- \rightarrow \frac{1}{2}\text{Cl}_2 + 2\text{O}_2 + e^-$  at the cathode and anode, respectively. The otherwise explosive reaction between the lithium metal generated and the fused perchlorate was prevented by alloying the lithium with silver. A cathodic peak observed at  $-1.5\text{v}$  with respect to a  $\text{Ag(I)/Ag}$  electrode is attributed to the reaction  $\text{ClO}_4^- + 2e^- \rightarrow \text{ClO}_3^- + \text{O}^-$ . Unlike the analogous peak process observed in fused nitrates, the electron:chlorate ratio is not 2:1 even though the expected 2:1 electron:oxide ratio is obtained. This and other behavior is explained on the basis of an oxide and peroxide-catalyzed decomposition of perchlorate and chlorate. Attempts were made to anodize metals into the melt; in no case except silver (for which the expected Nernstian behavior was observed) was this possible, oxide formation being generally observed instead.

While different nitrate melts have received much attention during the past years (1-9) little is known about the electrochemistry of fused perchlorates. Bombi and co-workers (10) established the Nernstian behavior of the  $\text{Ag(I)/Ag}$  electrode in fused  $\text{LiClO}_4$  during a solubility study of silver halides in this melt. Denning and Johnson (11) employed platinum and copper electrodes in fused  $\text{LiClO}_4$ . The copper electrode became coated with oxide as soon as it was inserted into the melt. During cathodic polarization of a platinum electrode, black oxide formation, an increase in the size of this electrode (attributed to  $\text{Li-Pt}$  alloy formation), and gassing were observed. When the current was switched off the material formed at the cathode reacted explosively with the melt.

Apart from the molten state,  $\text{LiClO}_4$  has been the object of studies in organic media. Maki and Geske (12) electrolyzed a 0.1M solution of  $\text{LiClO}_4$  in acetonitrile and obtained from the anode compartment an ESR signal which they assigned for a  $\cdot\text{ClO}_4$  radical. Cauquis and Serve (13) reinvestigated the electrolysis of  $\text{LiClO}_4$  in the different solvent nitromethane and essentially confirmed the earlier results of Maki and Geske.

## Experimental

**Solvent.**—Lithium perchlorate stands out among the perchlorates as being the only one that is stable in the molten state. It melts without decomposition at  $247^\circ\text{C}$  and does not begin to show an appreciable decomposition rate until the temperature is raised over  $400^\circ\text{C}$  (14). All experiments reported in this paper were done at  $260^\circ \pm 10^\circ\text{C}$ .

The  $\text{LiClO}_4$  used was anhydrous reagent grade (Amend Chemical Company). It was dried under high vacuum for 3 days at  $150^\circ\text{C}$ . It was then melted and purged with dry chlorine for 30 min to remove any remaining oxidizable impurities (15); during this time the original dark melt became completely clear. This process was followed by nitrogen purging for 12 hr in order to remove the chlorine from the system. During the experiments nitrogen purging was kept up at a slow rate in order to keep the melt free from traces of water. The initial chloride content was in the range of  $2 \times 10^{-4}$  moles/kg melt. It did not increase to more than  $1 \times 10^{-2}$  moles/kg melt during the time of the investigations, as shown by argentometric titration.

**Apparatus.**—The cell consisted of a Pyrex vessel with 24/40 and 14/20 standard taper joints. Pyrex feed-through tubes to which sintered glass disks of D porosity (Ace Glass Company, Vineland, New Jersey) were fused served as isolation compartments. Holes in the feed-through wall above the melt level

maintained equal pressure between the compartments and cell. The electrodes, each of which was kept in a separate isolation compartment, were silver wires (reference and working electrodes), other metal wires (for anodization studies), and platinum microelectrodes. The heating unit consisted of a heating mantle and a heating tape regulated by variable transformers. For mass spectrometric samples, a Pyrex U-type cell was constructed in which the anode and cathode compartments were separated by a sintered glass disk. The two electrodes were connected to tungsten leads sealed through the compartment tops. The cathode was a massive silver electrode while platinum served as the anode. Tubes leading through liquid nitrogen traps to a vacuum manifold were connected to both electrode compartments.

The voltammetric scans were performed with an Anotrol Model 4100 Potential Controller (Magna Electronics) using a platinum microelectrode, sealed in glass and ground flush, of  $0.9 \text{ mm}^2$  geometrical area. An Anotrol 4510 Scan Unit was used in combination with a EUW-20A (Heath Company) Multispeed Recorder. A Model IV Coulometric Current Source (E. H. Sargent and Company) was used for the anodization of metal electrodes.

**Chemicals.**—The  $\text{Li}_2\text{O}$  (Alfa Inorganics, Inc.),  $\text{Na}_2\text{O}_2$  (calorific grade, Allied Chemical),  $\text{LiClO}_4 \cdot 3\text{H}_2\text{O}$  (reagent grade, G. F. Smith Chemical Company), and  $\text{KOH}$  (analytical grade, British Drug Houses) were used as received. Samples of  $\text{LiNO}_3$  (Alfa Inorganics, Inc.),  $\text{KClO}_3$  (reagent grade, Nichols Chemical Company), and  $\text{KHSO}_4$  (reagent grade, Fisher Scientific) were vacuum-dried over magnesium perchlorate before use. Metal wires were cleaned mechanically and dried with acetone before use.

**Procedure.**—A reference electrode based on the  $\text{Ag(I)/Ag}$  couple (about 0.2M or 0.1M) was generated coulometrically for each experiment, and all potentials in this paper are given with reference to this electrode. Nernstian behavior corresponding to a one-electron change was observed for silver in this solvent on oxidation and reduction, in agreement with the work of Bombi and co-workers (10). Oxide was determined by acidimetric titration of the hydroxide formed after hydrolysis of the contents of a compartment, and chloride was determined by conventional argentometric titration. The method of Chen (16) was used to determine small amounts of  $\text{ClO}_3^-$  in the presence of large amounts of  $\text{ClO}_4^-$ ; the same method indicated the absence of  $\text{ClO}_2^-$  and  $\text{ClO}^-$  in all samples.

## Results and Discussion

Voltammetric scans of the pure  $\text{LiClO}_4$  melt with a platinum microelectrode gave the curve shown in

\* Electrochemical Society Active Member.

Fig. 1. Voltammogram of fused lithium perchlorate. Platinum microelectrode, geometrical area 0.9 mm<sup>2</sup>.

Fig. 1. At the anode the limiting electrode reaction occurs at +1.7v, the rising portion being spread out over approximately 0.3v. The cathodic limiting reaction occurs at -2.7v. There is an additional cathodic peak at -1.5v.

The cathodic limiting reaction is the deposition of lithium metal. Since pure lithium metal reacts explosively with the lithium perchlorate solvent (11) and since cathodic lithium deposition was inevitable during the investigation, it was necessary to reduce the activity of the lithium formed to as low a value as possible. It was found that alloy formation with silver served well for this purpose provided large enough silver electrodes and low enough current densities were used; current densities were approximately 0.1 amp/cm<sup>2</sup> and the total current approximately one meq/cm<sup>2</sup>. This alloy formation reduced but did not completely halt the reaction between lithium and the melt; gentle gas evolution was continuous and the amount of lithium found in the silver was less than that calculated from coulombs passed. Platinum and tungsten electrodes did not show as large a capacity for lithium metal and explosions occurred with both.

The over-all process for the anodic limiting reaction appears to be  $\text{ClO}_4^- \rightarrow 2 \text{O}_2 + \frac{1}{2} \text{Cl}_2 + e^-$ . The slow curvature of the voltammogram as the anodic limiting process begins to occur may indicate an irreversible reaction (17) or other complication. The gases produced at the anode during electrolysis of pure  $\text{LiClO}_4$  in the U-type cell were pumped off under vacuum and trapped with liquid nitrogen. Mass spectrometric analysis on a MS-9 spectrometer (Associated Electrical Industries) showed no fragments containing Cl-O bonds. Only chlorine was detected.

There is a very small but reproducible wave at  $E_{1/2} = -0.5\text{v}$ , which by analogy with nitrate systems (18) is probably due to residual traces of water. Except for this, the only voltammetric feature visible between the anodic and cathodic limiting reactions was a cathodic peak at -1.5v. This appeared similar to the peak observed in fused nitrates. The nitrate peak was interpreted (1, 2, 9) as due to the process  $\text{NO}_3^- + 2e^- \rightarrow \text{NO}_2^- + \text{O}^-$ . In nitrate melts the ratio  $e^-:\text{NO}_2^-:\text{O}^-$  was found to be 2:1:1. In a perchlorate melt the analogous process would be  $\text{ClO}_4^- + 2e^- \rightarrow \text{ClO}_3^- + \text{O}^-$ . When compartments of fused  $\text{LiClO}_4$  were electrolyzed at the peak potential of -1.5v, the  $e^-:\text{O}^-$  ratio found was 2.1, standard deviation 0.2, to one. No reproducible  $e^-:\text{ClO}_3^-$  ratio was observed, although comparison of the IR spectra (Perkin-Elmer 337, Nujol mull) of electrolyzed and unelectrolyzed  $\text{LiClO}_4$  revealed a new band at 970 cm<sup>-1</sup> which (by comparison with a known sample of  $\text{KClO}_3$ ) is due to the  $\text{ClO}_3^-$  ion (19). Chloride ion was also always present as shown by reaction with silver nitrate.

Attempts were made to determine the source of the peak by addition of reagents. Addition of  $\text{H}^+$  (as

$\text{KHSO}_4$ ) or  $\text{OH}^-$  (as  $\text{KOH}$ ) produced no apparent change in the peak. Addition of  $\text{ClO}_3^-$  (as  $\text{KClO}_3$ ) also produced no change in the peak, indicating that it could not be due to the reaction  $\text{ClO}_3^- + 2e^- \rightarrow \text{ClO}_2^- + \text{O}^-$ ; in fact, this reaction does not seem to occur within the decomposition range of the melt. Addition of  $\text{H}_2\text{O}$  (as  $\text{LiClO}_4 \cdot 3\text{H}_2\text{O}$ ) showed a small increase in the peak and violent evolution of a water vapor.

The similarity between the cathodic peak observed in this study and those observed in nitrate melts (1, 9) suggested the possibility of similar thermal equilibria in nitrate and perchlorate melts,  $\text{NO}_3^- \rightleftharpoons \text{NO}_2^- + \frac{1}{2} \text{O}_2$  and  $\text{ClO}_4^- \rightleftharpoons \text{ClO}_3^- + \frac{1}{2} \text{O}_2$ , both producing oxygen. The dissolved oxygen formed might then be the material which undergoes electrochemical reduction,  $\frac{1}{2} \text{O}_2 + 2e^- \rightarrow \text{O}^-$ , explaining the 2:1 electron:oxide ratio. However, although addition of  $\text{NO}_3^-$  (as  $\text{LiNO}_3$ ) increased the cathodic current in the peak region, careful examination indicated that the  $\text{NO}_3^-$  and  $\text{ClO}_4^-$  peaks were different although quite close in potential (Fig. 2), so that they in fact correspond to different processes. These peaks are not, then, due to dissolved oxygen. To prove this, the melt was saturated with dry oxygen gas; this had no effect on the height or position of the peak.

The major difficulty in the assignment of the peak to the  $\text{ClO}_4^- + 2e^- \rightarrow \text{ClO}_3^- + \text{O}^-$  reaction was clearly that no consistent  $e^-:\text{ClO}_3^-$  ratio was found for the electrolysis of fused  $\text{LiClO}_4$ , unlike the nitrate melts in which the expected 2:1 ratio was obtained. Chlorate was always present but generally in amounts less than expected (Table I). Decomposition of the perchlorate solvent would cause inconsistent  $e^-:\text{ClO}_3^-$  ratios as observed, chlorate being an intermediate in the decomposition, and also account for the observed chloride. Since the expected ratio of  $e^-:\text{O}^-$  was ob-

tained, oxide could not be generated or used by this decomposition process; if involved, oxide must act as a catalyst. The gas evolved during electrolysis is therefore the oxygen produced by the oxide-catalyzed decomposition of chlorate and perchlorate to chloride. To test this, O<sup>=</sup> was added (as Li<sub>2</sub>O); obvious decomposition began at once and continued for at least 12 hr. Since the addition of OH<sup>-</sup> (as KOH, which seems highly soluble in fused LiClO<sub>4</sub>) did not induce the catalytic decomposition, water was added (as LiClO<sub>4</sub> · 3H<sub>2</sub>O) to samples in which obvious decomposition was occurring. Gas evolution ceased immediately, as would be expected if the decomposition were oxide-catalyzed; the addition of water would remove the oxide: H<sub>2</sub>O + O<sup>=</sup> → 2OH<sup>-</sup>. Additional evidence for an oxide-catalyzed decomposition is that the freshly generated oxides of magnesium and aluminum produced as discussed below also catalyzed melt decomposition although to a much lesser degree. It is well known that addition of metal oxides produces decomposition of both chlorate and perchlorate melts to chloride (14, 20, 21).

The catalytic decomposition which sets in after the O<sup>=</sup> is formed could occur by the following mechanism

The postulated peroxide intermediate has been found in heated samples of LiClO<sub>4</sub>-Li<sub>2</sub>O by Markowitz and Boryta (14). Addition of peroxide (as Na<sub>2</sub>O<sub>2</sub>) to the LiClO<sub>4</sub> melt induced immediate obvious decomposition as expected. It was also demonstrated that the reaction 4ClO<sub>3</sub><sup>-</sup> → 3ClO<sub>4</sub><sup>-</sup> + Cl<sup>-</sup> does not occur at an appreciable rate in the absence of oxide at this temperature; the addition of 250 mg of KClO<sub>3</sub> to a compartment containing approximately 5g of fused LiClO<sub>4</sub> did not result in any chlorate decomposition at 260°C after 6 hr as shown by analysis.

A peculiarity of fused LiClO<sub>4</sub> is that other than silver no metals could be anodized to form the corresponding ions. The fact that metals cannot be anodized into solution has also been found in the case of the nitrate melts. By addition of transition metal nitrates and chlorides to a nitrate melt a few metal ions could be brought into solution (5). This approach was not possible in fused LiClO<sub>4</sub>; all added transition metal nitrates or chlorides produced oxides immediately. Some of the metal-metal oxide couples are of relatively stable potential; for example Mg/MgO at -2.1v with a fluctuation of 40 mv over a period of hours. Some typical potentials of metals in contact with a LiClO<sub>4</sub> melt are listed in Table II.

Most metals form visible oxide layers with the exception of rhodium, iridium, and platinum which do not appear to form oxide layers even at high current densities. The behavior of the different metals tested is summarized in Table II. The behavior of thallium was

unusual; the area of metal exposed to air formed black oxide as expected, while the area of metal exposed to the melt remained bright. On anodization, thallium was visibly lost from the wire, the surface remaining bright. Nernstian behavior was not observed; the potentials assumed after successive anodizations were stable but no reproducible Nernst slopes could be obtained, values of *n* ranging from 1.6 to 2.9. Analysis of the hydrolyzed melt for thallium (22) gave an e<sup>-</sup>:Tl ratio of about 1:1. This behavior would suggest the formation of a thallium oxide soluble in fused lithium perchlorate.

The reason for this oxide formation with most metals could well be the lower solvation energy of metal ions in fused perchlorates (and presumably also fused nitrates) as compared with fused chlorides (23) in which anodization of many metals is successful. To gain stabilization which is not available from the poorly coordinating perchlorate anion, the metal cation presumably adds oxygen by breaking Cl-O bonds in a neighboring ClO<sub>4</sub><sup>-</sup> anion.

## Mass Spectrometric and Torsion Effusion Studies of the Evaporation of Liquid Selenium

R. Yamdagni and R. F. Porter

*Department of Chemistry, Cornell University, Ithaca, New York*

### ABSTRACT

The composition of selenium vapor evaporating from liquid selenium has been studied mass-spectrometrically using single and double-oven type Knudsen effusion cells. The appearance potentials have been determined for various molecular species ( $\text{Se}_n$ ,  $n = 1$  to 8). The heats of vaporization of  $\text{Se}_2$ ,  $\text{Se}_5$ ,  $\text{Se}_6$ ,  $\text{Se}_7$ , and  $\text{Se}_8$  at 625°K have been obtained and the heat of fusion of selenium has been derived. The average molecular weight of the selenium vapor has been determined from the simultaneous measurements of vapor pressure by Knudsen and torsion effusion methods.

The molecular composition of the gaseous species evaporating from elemental selenium has been a subject of interest for several years. It has been known for some time from vapor density studies (1a-d) that polymeric species are present in the saturated vapor. Mass spectrometric studies of Goldfinger and co-workers (2) indicated that species  $\text{Se}_n$  with  $n$  as high as eight are formed in evaporation. The key problem in interpreting mass spectral data is to analyze the ion current for each species  $\text{Se}_n^+$  with respect to contributions from the simple ionization process

and from ion fragmentation processes that produce  $\text{Se}_n^+$  from a precursor of higher molecular weight than  $\text{Se}_n$ . Recently two papers based on mass spectrometric studies have appeared. Fujisaki (3) studied the evaporation from solid selenium and Berkowitz and Chupka (4) examined the vapor over the solid and liquid.

The work presented in this paper is a result of an experimental program to investigate the evaporation of liquid selenium. Where possible comparison of the results with those of Fujisaki *et al.* (3) and Berkowitz and Chupka (4) will be made.

### Experimental

Mass spectra of selenium vapor effusing from Knudsen-type oven were observed with a 10 in., 60°, direction-focusing mass spectrometer. The procedure is similar to that described in earlier work (5) except for the location of the Knudsen cell with respect to the mass spectrometer. Figure 1 shows the experimental arrangement. Pyrex cells were used for studies up to about 450°C. A few observations with quartz cells were made up to about 800°C, near the normal boiling point of selenium. The cells were heated by a resistance-type furnace that extended about 1 in. over either end of the chamber to provide uniform tem-

peratures. Temperatures were recorded with a chromel-alumel thermocouple. The effusion hole was produced by puncturing the thin glass wall of the cell with a fine tungsten wire (0.008 in. diameter). The opening was checked after the system was under vacuum by applying a "Tesla Coil" discharged near the orifice. For a separate series of experiments the cell was modified by allowing this sample compartment to extend outside the primary heating element. With this arrangement the extension containing a selenium sample could be heated when the main cavity was empty thus permitting independent control of the vapor pressure and vapor temperature (*i.e.*, the double-oven procedure).

In most cases the identification of  $\text{Se}_n^+$  species could be made by comparing the isotope structure observed for each mass grouping with that calculated from the normal isotopic abundances of Se species. For species higher than  $\text{Se}_6^+$ , the isotope structure was not completely resolved but sufficient to ensure identification.

A movable shutter located between the ion source and the cell was used to distinguish ions produced

Fig. 1. Knudsen cell-mass spectrometer assembly

from selenium vapor from those appearing in the background. All ion intensities reported in this paper are those obtained from the shutter effect. Selenium samples (6) with reported purity of 99.999% were used.

### Results

A mass spectrum of the various products evaporated from liquid selenium at 600°K, showing relative ion intensities for species  $\text{Se}^+$  through  $\text{Se}_8^+$  for 75v electron energy is presented in Table I. Higher molecular weight species  $\text{Se}_9^+$  and  $\text{Se}_{10}^+$  were too low in intensity for meaningful comparisons. Appearance potentials for  $\text{Se}_n^+$  are given in Table II. Our results are consistently higher than those observed by Fujisaki *et al.* (3) and by Berkowitz and Chupka (4) but indicated a similar trend in values for  $\text{Se}_2^+$  to  $\text{Se}_8^+$ . At present we do not attach any quantitative significance to the differences in appearance potential values from the three independent determinations. We should note that much of this discrepancy is probably a consequence of variations in methods of determining threshold voltages and methods of voltage calibration. Analysis of ion fragmentation pattern was made from a series of observations of ion intensities as selenium pressure was changed at constant temperature for each ion species. In Fig. 2 we show the change in the  $\text{Se}_2^+/\text{Se}_n^+$  ratio as temperature of the selenium source is changed to effect a change of pressure in the sampling chamber. As the pressure is lowered at constant temperature, the thermodynamic effect is to shift the reaction

to the right. If the pressure is lowered in gradual steps the concentration of molecular species should diminish in the sequence from high values of  $n$  to low values. If an observed ion  $\text{Se}_n^+$  is produced by fragmentation from a molecule of higher molecular weight, the  $\text{Se}_n^+$  should decrease in the same proportion as other ions having the same molecular precursor. We note that as the total pressure decreases  $\text{Se}_8^+$  and  $\text{Se}_7^+$  decrease rapidly but at different rates relative to  $\text{Se}_2^+$  while  $\text{Se}_5^+$  and  $\text{Se}_6^+$  are still observable. We also note that the intensities of  $\text{Se}_3^+$  and  $\text{Se}_4^+$  do not change appreciably relative to that of  $\text{Se}_5^+$  and  $\text{Se}_6^+$ . This suggests a precursor relationship of  $\text{Se}_3^+$  and  $\text{Se}_4^+$  with  $\text{Se}_5^+$  and  $\text{Se}_6^+$ . At very low pressures only  $\text{Se}_2^+$  and  $\text{Se}^+$  could be detected and under no conditions could either  $\text{Se}_3^+$  or  $\text{Se}_4^+$  be detected in the absence of

Fig. 3. Temperature dependence of  $\text{Se}_n^+$  ion intensities

$\text{Se}_5^+$  and  $\text{Se}_6^+$ . Considering the effects with change of pressure and low appearance potentials for  $\text{Se}_2^+$ ,  $\text{Se}_5^+$ ,  $\text{Se}_6^+$ ,  $\text{Se}_7^+$ , and  $\text{Se}_8^+$  relative to  $\text{Se}^+$ ,  $\text{Se}_3^+$ , and  $\text{Se}_4^+$  it is concluded that the former species arise primarily from molecular precursors with corresponding molecular formulas while the latter group is produced in fragmentation processes.

Temperature dependence measurements for  $\text{Se}_n^+$  species are shown in Fig. 3. The Clapeyron equation may be applied directly to the data for  $\text{Se}_2^+$ ,  $\text{Se}_5^+$ ,  $\text{Se}_6^+$ ,  $\text{Se}_7^+$ , and  $\text{Se}_8^+$  since, for these species, we can set the partial pressures of  $\text{Se}_n$  proportional to the ion intensity of  $\text{Se}_n^+$ . From the slopes of the curves we derive heats of vaporization of  $\text{Se}_n(\text{g})$  ( $n = 2, 5, 6, 7$ , and  $8$ ) given in Table III. Berkowitz and Chupka (4) measured the heats of reaction  $m \text{Se}_n(\text{g}) = n \text{Se}_m(\text{g})$ , and from their data we calculated heats of vaporization also listed in Table III.

### Discussion

Several values for the heat of fusion of selenium were calculated from the differences in heats of sublimation reported by Fujisaki *et al.* (3) and heats of vaporization determined in the present work. For these calculations the heat capacity for condensed selenium was taken from the Tables by Stull and Sinke (7) and

<sup>b</sup> Present results, values at  $T_{\text{AV}} = 625^\circ\text{K}$ .

<sup>c</sup> Values at  $T = 490^\circ\text{K}$ .

for  $\text{Se}_5(\text{g})$ ,  $\text{Se}_6(\text{g})$ ,  $\text{Se}_7(\text{g})$ , and  $\text{Se}_8(\text{g})$  were estimated as 25.0, 31.0, 37.0, and 43.0 cal deg<sup>-1</sup>. The average value of  $\Delta H_{\text{fusion}}$  from the four sets of data ( $\text{Se}_5$ ,  $\text{Se}_6$ ,  $\text{Se}_7$ , and  $\text{Se}_8$ ) is  $1.9 \pm 0.2$  kcal/g-atom (Table IV) which is higher than the value of 1.3 kcal/g-atom reported by ref. (7) and is lower than the value of 2.3 kcal/g-atom obtained by ref. (4). The widely divergent values of  $\Delta(\text{Temperature Coefficient})/n$  for Se,  $\text{Se}_2$ ,  $\text{Se}_3$ , and  $\text{Se}_4$  reaffirms the importance of ion fragmentation processes for  $\text{Se}^+$ ,  $\text{Se}_2^+$ ,  $\text{Se}_3^+$ , and  $\text{Se}_4^+$  (at least in solid-vapor equilibrium) while  $\text{Se}_5^+$ ,  $\text{Se}_6^+$ ,  $\text{Se}_7^+$ , and  $\text{Se}_8^+$  arise from direct ionization processes.

Although there is generally good agreement between our measured heats of vaporization of  $\text{Se}_5$ ,  $\text{Se}_6$ ,  $\text{Se}_7$ , and  $\text{Se}_8$  and previously published data, a disagreement exists in the data for  $\text{Se}_2$ . One problem centers about the interpretation of the degree of ion fragmentation to form  $\text{Se}_2^+$  from higher molecular weight precursors in the mass spectrometer. Berkowitz and Chupka (4) concluded that  $\text{Se}_2^+$  arises largely from ion fragmentation processes and that the concentration of  $\text{Se}_2$  in the vapor is quite low. This conclusion was based in part in trying to reconcile the high degree of association of selenium indicated by vapor density experiments (1a-d) with their own mass spectrometric observations. However, taken collectively, the mass spectrometric studies may be interpreted to show that  $\text{Se}_2^+$  observed in the mass spectrum of selenium vapor at temperatures of  $600^\circ\text{K}$  or higher arises largely by simple ionization of  $\text{Se}_2$ . The evidences are as follows:

1. The observed ratios of  $\text{Se}_2^+/\text{Se}_6^+$  and  $\text{Se}_2^+/\text{Se}_5^+$  depend on vapor temperature as shown in Table V. This could not arise if a simple ion-precursor relationship existed between  $\text{Se}_6$  and  $\text{Se}_2$  or between  $\text{Se}_5$  and  $\text{Se}_2$  in the higher temperature experiments. Considering the  $\text{Se}_2^+/\text{Se}_6^+$  and  $\text{Se}_2^+/\text{Se}_5^+$  values of ref. (2) and (3) it can be seen that the contributions made to the  $\text{Se}_2^+$  by  $\text{Se}_6$  and  $\text{Se}_5$  in the present case, cannot be more than 14 and 29%, respectively.

Table V. Ion intensity data pertinent to the formation of  $\text{Se}_2^+$  by ion fragmentation

600	Liquid	2.42	2.65	Present work

Fig. 4. Comparison of appearance potential data for  $\text{Se}_2^+$  obtained from saturated and undersaturated selenium vapor.

2. The appearance potential curve for  $\text{Se}_2^+$  obtained in experiments with the saturated vapor is nearly superimposable on the curve obtained when the system is undersaturated and  $\text{Se}_2$  is the major molecular species (Fig. 4). No structure is evident on the curve to show a break or discontinuity due to onset of a second ionization process. Fujisaki *et al.* (3) noted a break in the appearance potential curve of  $\text{Se}_2^+$  and concluded that even at low temperatures some  $\text{Se}_2$  is observable in the vapor from the solid.

With these considerations we may estimate the heat of formation of  $\text{Se}_2(\text{g})$  by the third-law procedure. In this calculation we assume that  $\text{Se}_2(\text{g})$  constitutes between 10 and 100% of the vapor at  $625^\circ\text{K}$ . Combining entropy and heat capacity data for  $\text{Se}(\text{s},1)$  and  $\text{Se}_2(\text{g})$  [taken from ref. (3) and corrected with our value for  $\Delta H_{\text{fusion}}/T_m$ ] and the vapor pressure data (see Appendix) we obtain the limits in  $\Delta H_{\text{vap}}^\circ$  for  $\text{Se}_2(\text{g})$  of 27.6 to 25.0 kcal/mole at  $625^\circ\text{K}$ . The value of  $\Delta H_{\text{fusion}}/T_m$  given by Berkowitz and Chupka (4) changes these limits to 27.0 to 24.4 kcal/mole, respectively. From these calculations it appears that  $\Delta H_{\text{vap}}^\circ$  of  $\text{Se}_2$  obtained from temperature dependence data is a lower limit. This could happen even if a small fraction of  $\text{Se}_2^+$  was formed by fragmentation of higher molecular species with low temperature coefficients. Therefore, taking both sets of data into account we recommend a value of  $25.5 \pm 2.5$  kcal/mole for  $\Delta H_{\text{vap}}^\circ$  of  $\text{Se}_2(\text{g})$  at  $625^\circ\text{K}$ .

#### APPENDIX

Auxiliary experiments were designed to determine the vapor pressure of selenium in the temperature range overlapping that of mass spectrometric observations. The experimental apparatus is very similar to that described by Lee and Schoonmaker (8). The cell ( $1\frac{1}{4} \times \frac{5}{8} \times \frac{5}{8}$  in.) was made of graphite and had two circular  $\frac{1}{2}$  in. diameter hollow compartments drilled symmetrically on both sides of the suspension axis. The selenium sample was placed in the cell and the compartments were sealed with graphite lids. One effusion hole was located in diagonally opposite walls of each compartment. The holes were tapered off and made conical in shape to make length of channel to radius of hole ratio  $L/r$  negligible. The cell was suspended by a 0.002 in. diameter tungsten wire. The filament and the cell assembly was enclosed inside four molybdenum shields to reduce loss of heat and maintain uniform temperature. The temperature was measured by a chromel-alumel thermocouple placed very near to the cell. The angle of twist of the fiber, produced by

the effusing vapor, was measured by the image of a light spot on a 100 cm circular scale. The image was formed by a small mirror and lens arrangement attached to the suspension system. A permanent C type magnet was used for damping the oscillation of suspension fiber. The entire system was enclosed in a Pyrex bell jar resting on a stainless steel plate. Pressures lower than  $10^{-5}$  mm were maintained inside the bell jar throughout the experiment.

The average molecular weight of vaporizing selenium species was determined from measurements of vapor pressures determined simultaneously by Knudsen and torsion methods as discussed by Searcy and Freeman (9). Pressures in the two cases are given by

$$P_k = W(2\pi RT/M)^{1/2}/k(a_1 + a_2)$$

and

$$P_T = 2D\theta/(q_1a_1 + q_2a_2)f$$

where  $W$  is the rate of effusion in g/sec;  $M$  the molecular weight of effusing species;  $k$  the Clausing factor (taken as unity);  $a_1, a_2$  the area of orifices in square centimeters;  $D$  the torsion constant [determined by the procedure used by ref. (9)];  $\theta$  the angle of twist of the suspension fiber;  $q_1, q_2$  the moment arms in centimeters; and  $f$  the Searcy-Freeman factor (taken as unity).

Results of a series of selenium vapor pressure measurements utilizing the torsion and Knudsen effusion techniques are illustrated graphically in Fig. 5. It was assumed in treating the Knudsen data, only for the purpose of calculations, that Se was the effusing species. Data given in Table VI may be used to calculate, for several temperatures, the average molecular weight ( $M^*$ ) of the vapor from the expression

$$M^*/M_{Se} = (P_k/P_T)^2$$

where  $M_{Se}$  is 78.96.

The temperature dependence data were fitted to a least squares analysis to give

$$\log P_k(\text{atm}) = 7.556 - \frac{6066}{T}$$

$$\log P_T(\text{atm}) = 7.233 - \frac{6093}{T}$$

From these equations we derive at  $T = 510^\circ\text{K}$  an average  $M^*/M_{Se} = 5.6 \pm 0.5$  which compares well with the value of  $5.4 \pm 0.3$  obtained by ref. (1c).

# Measurement of the Gravitational Component of Cell Potential in Molten Salts

Paul Duby\*<sup>1</sup> and Herbert E. Townsend, Jr.\*<sup>2</sup>

University of Pennsylvania, Philadelphia, Pennsylvania

## ABSTRACT

The gravitational component of cell potential has been investigated in a molten salt electrolyte by measuring the emf of a gravity cell in the earth's field. Two silver electrodes were placed at the ends of a 0.5m long tubular cell containing molten silver nitrate. The experiments were carried out by recording the changes of potential difference as changes in height difference between the electrodes were effected by rotating the cell in a vertical plane. An experimental value of  $6.75 \pm 0.05 \mu\text{V}/\text{m}$  was obtained for the gravitational emf per unit height at  $230^\circ\text{C}$  in good agreement with a theoretical result of  $6.78 \mu\text{V}/\text{m}$  as predicted by thermodynamic equations. The emf of a gravity cell has also been measured with a mixture of silver nitrate and silver chloride as the electrolyte. In this case, it is a function of the relative anionic transport numbers of the constituents of the melt and the new experiment is suggested as an alternate method for investigating electrical transport.

When an electrochemical cell consisting of two identical electrodes and an electrolyte is placed in a gravitational field in such a way that the electrodes are at a different level, an electrical potential difference is generated which is the gravitational component of cell potential. This effect was first observed by Colley (1), it was investigated further by Des Coudres (2) at the end of the past century, and it is described in detail by MacInnes (3). More recently, Grinnell and Koenig (4) carried out similar experiments with an improved technique for measuring the potential difference. Their results confirmed the theory and they obtained reliable values for the transport numbers in aqueous solutions of potassium iodide. Des Coudres (5) and Tolman (6) observed a greatly enhanced effect by substituting a centrifugal field of force for the gravitational field. MacInnes and co-workers (7) also carried out an investigation of the effect of centrifugal fields. All these studies, however, concerned aqueous electrolytes.

The purpose of the present investigation is to show that the same effect can be observed in fused salt systems and to determine if the measurement of the electromotive force generated by a gravitational or a centrifugal field can yield some information about transport properties of the melt. As a preliminary step, gravitational cells have been investigated, which consist of silver electrodes in pure silver nitrate or in a mixture of silver nitrate and silver chloride. The present paper is devoted to describing the experimental technique and demonstrating that the measured potential difference is actually the gravitational component of cell potential as predicted by the theoretical equations. This effect will be called gravitational emf or gravity emf.

With mixtures of molten salts, as is the case with aqueous electrolyte solutions, the gravitational emf depends on the transport numbers and partial molar volumes of the various ionic species. In the case of a single molten salt, however, the emf depends solely on the densities of the salt and the electrode. Thus, the magnitude of the emf of a gravitational cell with a single molten salt as the electrolyte can be readily predicted.

Let us consider the simple case of a cell which is made of two metallic electrodes M which behave re-

versibly towards the metallic ion in the molten salt MX, and let there be a level difference  $h_2 - h_1$  between these two electrodes. The free energy of the single molten salt MX, which is assumed to be in thermal and hydrostatic equilibrium, is not a function of the vertical coordinate in a gravitational field since the difference in potential energy is cancelled by the energy difference which results from the difference in hydrostatic pressure. Two metallic electrodes, however, which are located at different levels and which have a density different from that of the melt, are not in thermodynamic equilibrium since the difference between their potential energies does not equal the energy difference associated with the difference in hydrostatic pressure. For example, if the density of the metal is greater than that of the melt, the upper electrode has a greater free energy and it exhibits a negative electrical potential relative to the lower one. Indeed, if the two electrodes are connected by an electronic conductor outside the cell, an electric current flows such that the metal dissolves from the upper electrode and deposits on the lower one.

The mathematical description of this gravitational cell can be approached by two methods. The quasi-equilibrium derivation based on classical thermodynamics was presented by MacInnes (3) while Fitts (8) has shown that the same result is obtained by the nonequilibrium thermodynamics approach, using Onsager's reciprocal relation. For the simple case considered here, the classical approach is simpler, and it has the advantage of being more closely related to the physical picture of the phenomenon.

For the cell consisting of two reversible electrodes of the same metal M at different levels  $h_1$  and  $h_2$  in a single salt MX, which we represent by

the over-all effect of passing an electrical current is the removal of metal from one electrode and the deposition on the other. The displacement of salt, which results from the electrolytic transport, causes no change in the free energy of the system, so that the only contribution to a variation of the free energy is due to the transport of metal. Assuming that the temperature and chemical composition are uniform and constant, the total free energy variation is

$$dG_M = V_M dP + M_M g dh \quad [1]$$

where  $G_M$  is the Gibbs free energy of one gram-equivalent of the metal,  $M_M$  is the equivalent mass,  $V_M$  is

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Henry Krumb School of Mines, Columbia University, New York, N. Y.

<sup>2</sup> Present address: Homer Research Laboratories, Bethlehem Steel Corporation, Bethlehem, Pa.

the equivalent volume,  $P$  is the pressure,  $h$  is the coordinate in the gravitational field, and  $g$  is the local gravitational acceleration.

In a fluid in hydrostatic equilibrium, the pressure gradient is  $dP = -\rho_{MX}gdh$ , where  $\rho_{MX}$  represents the density of the molten salt electrolyte. Equation [1] can be integrated for a finite level difference  $\Delta h = h_2 - h_1$

$$\Delta G_M = (M_M - \rho_{MX}V_M)g \Delta h \quad [2]$$

The equilibrium cell potential  $\Delta E$  is

$$\Delta E = \frac{-1}{F} (M_M - \rho_{MX}V_M)g \Delta h \quad [3]$$

All the parameters in the above equation are well-known, and the value of the emf of a gravitational cell can be predicted for a single fused salt. If the electrolyte is a mixture, however, an additional variation in free energy of the system results from the electrical transport of the various species, and the gravitational emf becomes a function of the transport numbers. If the electrode reaction remains the same and if the single salt is replaced by a mixture of salts  $MX_i$  having a common cation, the passage of electric current causes the migration of anions at different rates and eventually results in a concentration change as observed in the Hittorf-type experiment. This effect can be described by defining the mass transport number  $T_{X_i}$  as the number of gram-equivalents of the ion constituent  $X_i$  which are transported per faraday from anode to cathode during electrolysis. A mass balance shows that, in addition to the transport of one gram-equivalent of metal per faraday from anode to cathode, there is a net transport of  $T_{X_i}$  gram-equivalents of each salt  $MX_i$  in the mixture. The contribution of each of the components of the mixture to the total free energy change  $\Delta G$  is given by a term similar to the right-hand side expression of Eq. [2] multiplied by the corresponding mass transport number.

$$\Delta G = (M_M - \rho_m V_M)g \Delta h + \sum_{i=1}^n T_{X_i}(M_{MX_i} - \bar{V}_{MX_i}\rho_m)g \Delta h \quad [4]$$

where  $\rho_m$  is the density of the mixture,  $M_{MX_i}$  is the equivalent mass of the salt  $MX_i$  and  $\bar{V}_{MX_i}$  is the partial equivalent volume of the salt  $MX_i$ .

The derivation of a similar equation for aqueous electrolytes is given by MacInnes (3). A more sophisticated presentation by Koenig and Grinnell (9) includes a thorough discussion of the assumptions of the quasi-equilibrium approach, as well as the relation between the emf of a gravity cell and the transport parameters from a Hittorf-type experiment.

For the simple case of a mixture of  $AgNO_3$  and  $AgCl$ , the emf of the gravitational cell can be written after some straightforward algebraic substitutions.

$$\Delta E = -\frac{g}{F} (M_{Ag} - \rho_m V_{Ag} + \phi \cdot \tilde{M}) \Delta h \quad [5]$$

where

$$\phi = T_{Cl}N_{AgNO_3} - T_{NO_3}N_{AgCl}$$

$$\tilde{M} = \frac{1}{V_m} (M_{AgCl}\bar{V}_{AgNO_3} - M_{AgNO_3}\bar{V}_{AgCl})$$

$V_m$  is the molar volume of the mixture;  $N_{AgCl}$  and  $N_{AgNO_3}$  are the mole fractions.  $\phi$  is the function introduced by Aziz and Wetmore (10) in order to describe the results of transport experiments in which the concentration change is measured after the passage of a given amount of electricity.

### Experimental

Although the measurement of the gravitational component of cell potential with a molten salt electrolyte

is similar in principle to the measurement with an aqueous electrolyte, the fact that the experiment must be carried out at elevated temperature requires a significantly different technique which is discussed below in some detail.

*Principle of the measurement.*—The importance of separating the effect of the gravitational field from other phenomena and especially the effect of small temperature differences is illustrated by the following comparison. The emf of the gravitational cell, predicted by Eq. [3] for the system silver-silver nitrate at 230°C, equals 6.78  $\mu V/m$  of level difference. The thermal emf of the same system, in contrast, is 330  $\mu V/^\circ C$  (11) at the same temperature. A temperature difference of about  $10^{-3}^\circ C$  between two electrodes placed at one meter level difference would accordingly cause an error of 5% on the value of the gravitational component of cell potential, if an equilibrium measurement were attempted. The construction of a vertical furnace having a 1-meter zone in which the temperature is uniform within  $10^{-3}^\circ C$ , or alternatively, the precise measurement of temperature differences within  $10^{-3}^\circ C$  in order to correct for the thermal emf, are both difficult approaches owing to practical considerations.

It has been found that changes in electromotive forces resulting from changes in an external constraint can be measured in the presence of a much larger thermal emf by recording the electrical response to a sudden variation of the external constraint. This technique was applied successfully to the measurement of a pressure-induced electromotive force of the order of a few microvolts in a similar system (12).

The method of varying the external constraint, used by various investigators for measurements of gravitational emf in aqueous solutions, namely connecting two half-cells by a flexible tube containing the electrolyte and measuring the equilibrium potential difference before and after altering their relative position by a system of ropes and pulleys, is not practical at higher temperature. The technique, which is adopted instead, consists of changing the vertical distance between electrodes at both ends of a salt-filled tube by rotating the whole assembly in a vertical plane. In this manner, only the relative position of the electrodes in the earth's gravitational field is varied very rapidly, while the difference in temperature or surface condition of the electrodes remains unchanged or varies much more slowly.

*Apparatus.*—The cell is represented on Fig. 1. It consists of a 1-in. OD,  $\frac{3}{8}$ -in. ID extruded Teflon tubing threaded at both ends. The electrodes are disks of  $\frac{1}{2}$ -in. diameter machined from high-purity (99.99%) silver, and they are held in position by the Teflon stoppers which thread into the tube and form a salt-tight seal. Teflon was chosen as the container material because such a seal can be easily formed, and the cell can be opened and resealed many times. Teflon is chemically inert and its mechanical properties are adequate up to about 260°C.

The significant features of the furnace are the  $\frac{1}{4}$ -in. wall thickness copper pipe upon which the resistance windings (insulated by several layers of asbestos paper) are wound, and the small, independently controlled windings at both ends which compensate for greater heat losses at those regions. These features are sufficient to provide a region roughly 0.5 meter in length in which the temperature is uniform within  $1.5^\circ C$ , a value found quite adequate for the experiment. A constant-voltage transformer, several autotransformers and an on-off time-proportioning temperature controller are used to regulate the temperature of the furnace within  $\pm 0.25^\circ C$  for durations of several hours. The fairly large heat capacity of the whole furnace further insures that any variation of temperature with time is very slow.

Fig. 1. Cell and furnace for measuring the emf of a gravitational cell. 1, Teflon cell; 2, silver electrodes; 3, molten salt; 4, copper pipe; 5, main resistance winding; 6, end winding; 7, Pyrex tube; 8, spindle and bearing; 9, chromel-alumel thermocouple; 10, tungsten wire; 11, electrode shield.

The furnace is held at the mid-point of its longitudinal axis by a collar which is supported on two bearings, such that the whole assembly can rotate in a vertical plane. A circular index plate has five pairs of holes which, when fitted with  $\frac{1}{2}$ -in. dowells, stop the movement of a manually turned crank at angles of  $30^\circ$ ,  $90^\circ$ ,  $180^\circ$ , and  $270^\circ$  from the horizontal starting position. Thus, by rotating the furnace through angles determined by the placing of pegs in the index plate, quick and well-defined rotations of the cell in a vertical plane result, from which the changes in height difference between the electrodes can be calculated accurately, if their distance is known. Because of the large expansion coefficient of Teflon, this distance was measured for each run by means of two rigid tungsten wires which are soldered into each electrode and extend to the outside of the furnace, supported along their length by an alumina tube.

The tip of a chromel-alumel thermocouple is soldered into each electrode. This has a twofold function of measuring the temperature and providing two alternative leads for measurement of the cell emf. A Keithley model 150A microvoltmeter ( $10^7$  ohms input impedance at  $10 \mu\text{V}$  full-scale sensitivity) amplifies the small emf changes which are then recorded with a strip-chart recorder. The two instruments are calibrated together at the time of the experiment with a Keithley model 260 nV source which remains in series with the cell during both measurement and calibration so as not to change the impedance of the circuit while performing different functions. Although the specified accuracy of the calibrating device is only  $\pm 0.5\%$ , it was compared to a Honeywell model 2768 microvolt potentiometer and found to agree with the more precise instrument within its specified accuracy of  $0.005 \mu\text{V}$ .

**Procedure.**—The electrolyte was prepared by fusing Baker reagent grade  $\text{AgNO}_3$  and holding it for several hours at  $250^\circ\text{C}$  to drive off any residual water. For the mixture, the appropriate amount of Baker reagent grade  $\text{AgCl}$  was added, after weighing in semidarkness. The melt was filtered through medium-porosity fritted glass under a partial vacuum. Filling the cell was found to be critical and extreme care was taken so that no air bubble would be trapped inside the cell.

Prior to actual measurement, the cell and furnace were kept in a horizontal position for several hours until thermal equilibrium was attained. This was necessary for two reasons. First, the mean temperature of the system required time to stabilize, during which temperature changes along the length of the furnace, which were not in phase, produced significant drifting thermal emfs. Second, the temperature profile prior to a measurement had to be adjusted since small temperature gradients in the salt near the electrodes would cause some heat convection and significant and rather fast temperature variations at the electrodes upon rotation of the cell. A similar effect results from the displacement of small solid particles or small gas bubbles in the melt. In addition to the precautions observed in filling the cell, filtering the melt and minimizing temperature gradients, convective effects were decreased by reducing the diameter of the cell immediately in front of the electrode. This was achieved by placing two Teflon disks with two small holes ( $1/20$ -in. diameter) to shield the electrode as shown in Fig. 1.

In general, the potential difference between the two electrodes could be kept to less than  $200 \mu\text{V}$ . This residual difference could easily be cancelled by opposing it by the built-in zero-suppress d-c power supply of the microvoltmeter, and the subsequent measurements of the gravitational emf were made by using one of the more sensitive ranges of the instrument; which in most cases, was  $10 \mu\text{V}$  full scale.

### Results and Discussion

The gravitational emf is a very small effect which must be investigated in the presence of other larger emfs, and it is important to present a method for identifying it without any doubt. Its measurement is based on the observation of the electrical response to a change of the cell position in the earth's gravitational field, and the interpretation of such a signal must be discussed in some detail.

A typical tracing of the actual recorded potential difference between the two electrodes is shown on Fig. 2. During the time preceding point A, the cell remains stationary in its initial position and the cell voltage is essentially constant. During the time interval from A to B, or about 1 sec, the cell is rotated through an angle  $\theta$  to a new position where it is held until time C, or about 3 to 6 sec. Time C and D is spent in rotating the cell back to its original position, where it remains thereafter.

The shape of these recorded signals suggests that they are the sum of three superimposed changes in

Fig. 2. Illustration of gravitational emf measurement by continuous potential recording. From A to B, the cell is rotated  $180^\circ$  from a vertical position; from C to D, it is restored to its initial position. Cell length: 48.16 cm; electrolyte:  $0.88 \text{ AgNO}_3 + 0.12 \text{ AgCl}$ ; temperature:  $230^\circ\text{C}$ .

potential difference. The first effect is due to random electrical noise in the circuit and to slow thermal drifts caused by gradual changes in temperature difference between the two electrodes or at other electrical connections. With good thermal insulation of the system, these drifts are typically less than  $0.1 \mu\text{V}/\text{sec}$ , and they appear linear during the relatively short time of a measurement.

The second contribution to the total signal is attributed to magnetic induction. It is observed during the motion of the furnace from time A to B and C to D, and it is due to induced currents when the loop formed by the cell and its lead wires are rotated in such a manner as to change the net enclosed magnetic flux. The amplitude of this signal and its shape depends on the position of the furnace relative to the magnetic field in the laboratory and the angular velocity of the assembly. It can be minimized by decreasing the area of the loop and by changing its position in the field, but it is difficult to suppress completely.

The third contribution to the composite signal is the gravitational component of cell potential. It should ideally be a square wave if the rotation of the furnace is fast compared to the recorder speed. It can be determined by measuring the vertical difference between two parallel lines drawn through the steady-state portions of the signal, i.e., AD and BC. The potential of the electrode which assumes the higher position after rotation becomes more negative, and this is in qualitative agreement with the physical picture and the equations derived earlier.

Figure 3 is a typical plot of the change in cell potential as a function of the change of the vertical component of electrode separation calculated from the angle of rotation. Each circle encloses the range of three to ten separate measurements. All series of data at a given temperature were found to be linear and to pass through the origin within the experimental uncertainty. The slope of the line corresponds to the gravitational component of cell potential per unit height.

Initially several combinations of cell length and diameter were considered. In general, the same value of the ratio  $\Delta E/\Delta h$  was observed regardless of length or diameter, although the precision of the data was found to improve with increasing length and decreasing diameter. Presumably, the greater effect associated with a longer cell and the decreased convection associated with thinner cells can account for these differences in precision.

The use of a plot of  $\Delta E$  vs.  $\Delta h$  is not the most accurate method for calculating the gravitational emf per unit height. Indeed, for several reasons the measurement of a number of  $180^\circ$  vertical to vertical rotations is preferable and yields a more reliable value. First, the electrical signal is larger, and so is the signal to noise ratio. Second, the rate of change of the

Fig. 3. Measured emf vs. height difference. Cell length: 48.94 cm; electrolyte:  $\text{AgNO}_3$ ; temperature:  $222^\circ\text{C}$ ; slope =  $\Delta E/\Delta h = 6.74 \mu\text{V}/\text{m}$ .

vertical component of electrode separation is minimum at the vertical position and maximum at the horizontal one. Hence, any error due to poor alignment of the angular control device with respect to the true vertical is minimized in measurements involving vertical initial and final positions. Third, the vertical component of separation between the faces of the parallel-aligned electrodes is subject to an uncertainty related to the inside cell diameter, which is also minimum in the vertical position of the cell.

A large number of the  $180^\circ$  vertical to vertical measurements were performed in a temperature range from the melting point of the salt up to about  $260^\circ\text{C}$ . After correction for instrument calibration and cell length, they were fitted to a linear function of temperature by the least squares method. At first, all the measurements were taken into account. Some of the recorded signals, however, were more difficult to read on the chart, as was typically the case when the thermal drift was greater than usual. In order to screen out these readings, in an unbiased fashion, they were disregarded if their difference from the mean exceeded five times the probable error. This criterion corresponds to disregarding data which have a probability less than one chance in one thousand of being valid, assuming a Gaussian distribution. This procedure is rather conservative and the reliability of the experimental technique is evidenced by the fact that it resulted in rejection of less than five per cent of the raw data. Figure 4 represents the measured gravitational emf per unit height as a function of temperature for pure silver nitrate and for a mixture of 12 m/o of silver chloride in silver nitrate. The final best lines are, respectively

for  $\text{AgNO}_3$

$$-\frac{\Delta E}{\Delta h} = 6.75 + 0.15 \times 10^{-3} (t - 200) \quad (\text{st. dev.} = 0.05) \quad [6]$$

for 0.88  $\text{AgNO}_3$  + 0.12  $\text{AgCl}$

$$-\frac{\Delta E}{\Delta h} = 6.73 + 0.47 \times 10^{-3} (t - 200) \quad (\text{st. dev.} = 0.03) \quad [7]$$

where  $t$  is the temperature in  $^\circ\text{C}$ , the emf is in microvolts and the height in meters.

The error resulting from the calibration of the electrical instruments and the error on the length of the cell are both of the order of  $0.005 \mu\text{V}/\text{m}$ , which is small compared to the standard deviation reported above. The latter is accordingly a good estimate of the precision of the final value for the emf per unit height.

The temperature dependence is small, but it is in qualitative agreement with the value obtained by

Fig. 4. Gravitational emf per unit height vs. temperature for pure silver nitrate (a) and for a mixture of silver nitrate and silver chloride (b); — least squares lines through experimental points (Eq. [6] [7]); — — — theoretical line (Eq. [8]).

application of Eq. [3]. Using data from Spooner and Wetmore (13) for the density of silver nitrate, and calculating the equivalent volume of silver from its expansion coefficient (14), the predicted value of the emf per unit height as a function of temperature is

$$-\frac{\Delta E}{\Delta h} = 6.75 + 1.0 \times 10^{-3} (t - 200) \quad [8]$$

This line has also been represented on Fig. 4 and the agreement with our experimental data is well within the range of the precision of the measurement.

In the case of a mixture, Eq. [5] can be used to calculate the transport function  $\phi$ . At 230°C, for instance, using a value of 4.034 g/cm<sup>3</sup> for the density of the mixture, as estimated by extrapolation of higher-temperature data (13), and assuming that the molar volume is a linear function of composition, one gets  $\phi = +0.02$ . The error on  $\phi$ , which corresponds to a standard deviation of 0.03  $\mu$ V/m on the emf per unit height is  $\pm 0.01$ . The errors on the density and partial equivalent volumes should be small in general (0.1%), but they are difficult to estimate here on account of the extrapolation.

The present value of  $\phi$  must be compared with Hill and Wetmore's result  $\phi = +0.05 \pm 0.01$  for the same mixture at 270°C (15),<sup>3</sup> and with  $\phi = -0.02$  which can be computed from data obtained by Monse (16), for 34 m/o AgCl at 250°C. Our result is within the range defined by these two investigations and, notwithstanding the extrapolation of density data, we think it is more reliable. The value of  $\phi = +0.02$  reported here corresponds to a mobility of the chloride ion constituent (relative to silver) equal to 80% of the mobility of the nitrate, and this result is consistent with the fact that, in many fused salt mixtures, the mobilities of like-charged ions are not very different (17).

In conclusion, the excellent agreement of the measured data with the values obtained by a theoretical relation for the pure salt is a definite indication that the observed phenomenon is actually the gravitational component of cell potential. The comparison of our data with other published values of  $\phi$  for a mixture shows that it is possible to obtain some information on the transport numbers by this type of measurement.

It is clear from Eq. [5] that the function  $\phi$  will eventually be calculated by the difference of two quantities which are of similar magnitude: the experimental emf of the gravitational cell and the expression  $(M_M - \rho_m V_M)g/F$ . The relative precision on  $\phi$  will not be very high, but this is due to the fact that  $\phi$  is usually a small quantity which represents the deviation from an ideal situation of equal anion mobilities. As shown by Hill and Wetmore's discussion of their data, the sign and the order of magnitude of  $\phi$  are sufficient to provide some interesting information about the conducting species in the melt.

The use of gravitational cell measurements instead of a Hittorf-type experiment for obtaining values of  $\phi$  offers several advantages. First, and most important, it is an instantaneous equilibrium measurement. The reading itself is carried out in a few seconds, during

which no temperature variation, and especially, no concentration change, can occur. Second, the measurement is rather simple and does not depend upon very accurate chemical analysis.<sup>4</sup> Setting up the experiment requires some care, but most problems were indeed solved and they have been discussed earlier in some detail. The condition, however, for obtaining good transport data is the knowledge, with sufficient accuracy, of the densities of the mixtures and the partial molar volumes in the temperature range. This information is not yet available for the system silver nitrate-silver chloride, but we expect that a more complete study of it will be the subject of a further communication.

#### Acknowledgments

This study is a contribution from the Laboratory for Research on the Structure of Matter, University of Pennsylvania, supported by the Advanced Research Projects Agency, Office of the Secretary of Defense.

Manuscript received Aug. 3, 1967; revised manuscript received ca. Jan. 24, 1968. This paper was presented at the San Francisco Meeting, May 9-13, 1965, as Abstract 100.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

<sup>4</sup>The advantage can be fully appreciated only by a discussion of the errors involved in practice when Hittorf-type experiments are performed with fused salts. As an example, Duke, Laity, and Owens (18) report that, in their investigation of nitrate mixtures, about 90% of their raw data had to be disregarded.

<sup>3</sup>These authors define  $\phi$  as a function of transport fractions which have a sign opposite to that of our mass transport number. In order to get the same sign for the function  $\phi$ , we have interchanged the subscripts 1 and 2 in their expression of  $\phi$ .

## A Study of the Dissipation Factor ( $\tan \delta$ ) of Corrosion Product Films Formed on Aluminum Alloys in Hot Sodium Chloride Solution

W. H. Anthony

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

Electrochemical studies of corroding aluminum surfaces are complicated by the corrosion process itself which continually increases the surface roughness and renders such quantities as capacitance per unit area and corrosion current density virtually indeterminate. The dissipation factor has the advantage that it is area independent because it is proportional to the product of capacitance and resistance whose area dependencies cancel each other out.

Breckenridge (1) recognized that vacancies in an ionic crystal are a source of dielectric loss. McMullen and Pryor (2) created additional point defects in an anodic film on aluminum by raising its temperature and by substituting hydroxyl ions for oxygen ions in the oxide lattice. In both cases, the dielectric loss increased significantly.

Keir, Heine, and Pryor (3) have observed that anodic films on aluminum become more conductive as a result of exposure to sodium chloride solutions. They explained the result by an exchange of chloride ions from the solution for oxygen ions in the oxide lattice. Such areas in the aluminum oxide film containing substantial chloride ions may later become pitting sites due to the increased mobility of aluminum ions through them.

The defect density in an aluminum oxide film may be altered by the introduction of impurity cations resulting from the presence of alloying elements in the aluminum substrate; these defects may in turn affect corrosion processes in a fashion somewhat similar to chloride ions. The present study has as its object the determination of the effect of cation impurities in the surface oxide film resulting from the presence of alloying elements in the metallic substrate on the dissipation factor of corrosion product films and on the corrosion rates of selected commercial aluminum alloys.

### Experimental Procedure and Results

**Bridge measurements.**—The experimental arrangements are shown diagrammatically in Fig. 1. The measuring cell carried a number of masked sheet specimens of the alloys under study immersed in sodium chloride solution at equal distances from each other and from the axis of a large cylindrical aluminum counter electrode.

The samples and the counter electrode were connected to terminals to which the "unknown" leads of a Wayne Kerr B221 transformer ratio arm bridge could be attached. Measurements of the parallel capacitance and the reciprocal of the parallel resistance of the measuring cell were carried out at a frequency of 100 cps. Measurements of the series resistance of the measuring cell were carried out at 10 and 20 kcps, using the Wayne Kerr Q221 low impedance adapter.

The external frequency source used was a General Radio Type 1210-C Unit R.C. oscillator capable of supplying a pure sinusoidal signal from 20–200,000 cps.

The detector used was a General Radio Type 1232-A tuned amplifier and null detector operable over the same frequency range. The signal amplitude passing through the measuring cell was limited to 10 mv peak to peak, and no more than three measurements were carried out during a 12-day run to minimize the somewhat remote possibility of damage to the corrosion films. The amplitude of the signal was monitored by a Type 536 Tektronix cathode-ray oscilloscope.

The following assumptions were made in determining the dissipation factor of the corrosion films on the alloy specimens:

1. The double layer capacitance and the counter electrode capacitance were in series with the specimen capacitance.
2. Both the double layer capacitance and the counter electrode capacitance were so large that their reciprocals could be neglected in the series capacitance formula.
3. The series resistance of the counter electrode was so small that it could be neglected in comparison with the specimen series resistance.
4. The impedance of the measuring cell could be represented by the network shown in Fig. 2. This network has the property of giving a linear plot of series resistance against the reciprocal of the signal frequency if the film impedance is mainly capacitive. Linear plots of this type having a common intercept on the resistance axis were obtained by Young (4) for series resistance measurements on anodic films formed on niobium. Young interpreted the intercept on the resistance axis as a pure solution resistance.
5. It is assumed that a corrosion film on aluminum consists of a thin stratum of oxide between the metal and a much thicker amorphous hydrated layer. The entire dielectric properties reside in this oxide layer, and the amorphous hydrated layer contributes nothing to the dielectric properties. Support for this assumption comes from experiments with boehmite films on aluminum (5) whose thickness computed from their interference colors were of the order of several thou-

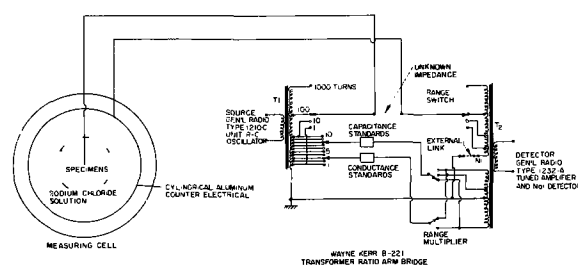

Fig. 1. Arrangements for measuring dissipation factor ( $\tan \delta$ ) of corroding aluminum alloy specimens parallel analog transformer ratio arm bridge.

Fig. 2. Equivalent electrical circuit representing the measuring cell impedance.

sands of angstroms, but whose thickness computed from capacitance bridge measurements were under a hundred angstroms. Obviously, the thick boehmite films contributed nothing to the dielectric properties of the aluminum surface films.

As the measuring frequency was increased, the capacitative path in the film had much lower reactance than the resistive path so that ultimately at infinite frequency the impedance of the measuring cell became simply the pure resistance of the solution in the measuring cell and the access circuitry in agreement with Young. This fact is represented in the diagram by using the symbol  $R_{\infty}$  for the ohmic resistance of the solution plus access circuitry.

The value of  $R_{\infty}$  was thus obtained by extrapolating a plot of the series resistance vs. the reciprocal frequency to a zero value of the reciprocal frequency.

Calculation of the dissipation factor of the corrosion film was then performed by converting the parallel components of the measuring cell impedance to series components by the following formulas

$$C_s = \frac{(1 + \omega^2 C_p^2 R_p^2) C_p}{\omega^2 C_p^2 R_p^2} \quad [1]$$

$$R_s = \frac{R_p}{1 + \omega^2 C_p^2 R_p^2} \quad [2]$$

where  $C_p$  and  $R_p$  are parallel components of the measuring cell impedance and  $C_s$  and  $R_s$  are the corresponding series components.

The  $\tan \delta$  or dissipation factor of the corrosion film was then calculated from the formula

$$\tan \delta = \omega C_s (R_s - R_{\infty}) \quad [3]$$

Various thicknesses of  $4 \times \frac{3}{4}$  in. sheet specimens of alloys under study were masked to expose a  $\frac{1}{2}$  cm<sup>2</sup> window using a polyester backed adhesive tape.

The samples were mounted in the measuring cell with the exposed windows immersed in  $\frac{1}{2}$ M sodium chloride thermostatically controlled at 90°C. The exposed samples and the entire counter electrode assembly were immersed in the solution which was protected from evaporation by means of a layer of molten paraffin. At the end of the experiment, which lasted 13 days, the oxygen content was found to be 2 ppm by a modified Winkler method (6).

**Materials.**—Five commercial alloys, whose analysis is shown in Table I, were selected for study because a considerable amount of information about their susceptibility to corrosion in salt solutions and sea water has been published (7, 8).

**Corrosion tests.**—Duplicate  $1\frac{1}{2} \times 1$  in. sheet samples of the same group of alloys were subjected to corrosion tests; surface pretreatment was as follows: (a) immerse in 5% aqueous sodium hydroxide at 70°C

Fig. 3. Loss tangents of corrosion films on various commercial aluminum alloys exposed to  $\frac{1}{2}$ M sodium chloride at 90°C; oxygen content 2 ppm.

Fig. 4. Corrosion rates of commercial aluminum alloys correlated with loss tangents of corrosion films.

for 1 min; (b) rinse in distilled water; (c) immerse in cold 50% aqueous nitric acid for 10 sec; (d) rinse in distilled water; (e) dry with absorbent paper tissues.

The samples were weighed and then suspended for 60 days in  $\frac{1}{2}$ M sodium chloride at 90°C under a layer of molten paraffin. The oxygen content at the end of the test period was found to be 2 ppm as in the dissipation factor experiments. At the end of the experiment the samples were cleaned in a chromic-phosphoric solution and reweighed.

**Results.**—Figures 3 and 4 show plots of  $\tan \delta$  values vs. time and vs. corrosion weight loss. It is apparent that after an initial higher value,  $\tan \delta$  declines to a value close to its final measured value in 5000 min. There is a very close correlation between the final  $\tan \delta$  value and the weight loss in a fixed time of exposure. It should also be noted that the 5XXX series alloys 5454, 5052 have relatively low corrosion rates compared to alloy 1100 and 6061-T4.

Figure 5 shows a plot of the final  $\tan \delta$  value against the magnesium content of the alloys studied. With the conspicuous exception of alloy 6061 which has a higher copper and silicon content than the 5XXX series alloys, the  $\tan \delta$  value is almost inversely proportional to the magnesium content.

### Discussion

Our observation that 5XXX series alloys have superior corrosion resistance to 6061-T4 in hot aerated brine is corroborated by the work of Bohlmann (7) who found that 5XXX series alloys 5052 and 5454 had superior corrosion resistance to 6061-T4 in circulating

Table I. Elemental composition of commercial aluminum alloys used in the investigation

Alloy	Silicon	Iron	Copper	Manganese	Magnesium	Chromium	Zinc	Titanium
5454-H16	0.11	0.22	0.04	0.84	3.90	0.09	0.02	0.009
5052-O	0.10	0.35	0.05	0.04	2.20	0.17	0.03	0.015
5050-O	0.12	0.48	0.03	0.03	1.53	0.01	0.02	0.018
1100-H14	0.11	0.64	0.12	0.012	0.01	<0.002	<0.01	0.009
6061-T4	0.61	0.43	0.35	0.08	1.10	0.15	0.03	0.021

Fig. 5. Relationship between the magnesium content and the dissipation factor;  $\frac{1}{2}M$  sodium chloride at  $90^{\circ}C$ .

brine at  $300^{\circ}F$  based on weight loss measurements. Summerson, Pryor, Keir, and Hogan (8) measured the pit depth distributions of alloys 5052-H34, 5050-H34, and 6061-T4 after immersion in subtropical sea water. The 5XXX series alloys were found to have fewer and shallower pits in general than alloy 6061-T4.

Our results indicate also that a close relationship exists between the weight loss of aluminum alloys and the dissipation factor of their corrosion product films. We have also suggested that this dissipation factor is proportional to the density of defects in the dielectric layer at the metal interface known as the barrier layer.

### Conclusions

The dissipation factors of corrosion films on commercial aluminum alloys were found to be linearly related to their rates of corrosion in hot sodium chloride solution containing 2 ppm of dissolved oxygen.

5XXX series alloys containing magnesium had corrosion rates and dissipation factors which were inversely proportional to their magnesium content.

Alloy 6061-T4 was found to lose more weight and its corrosion film had a higher dissipation factor than the 5XXX series alloys.

### Acknowledgment

The author wishes to acknowledge the help of Mrs. Catherine Meyer who performed the Bridge measurements and for valuable help and advice from Drs. M. J. Pryor, J. A. Ford, and W. Wolfe, Jr.

Thanks are also made to the Aluminum Division of Olin Mathieson Chemical Corporation for permission to publish this work.

Manuscript received Aug. 10, 1967; revised manuscript received ca. Feb. 23, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Double Layer Capacitance in Aqueous Solution

### III. Polycrystalline Tin

N. A. Hampson and D. Larkin

Chemistry Department, Loughborough University of Technology, Leicestershire, England

Recently differential capacitance measurements at silver(1) and cadmium(2) electrodes have been reported. This note records similar measurements with polycrystalline tin electrodes.

### Experimental

The Schering bridge, electrolytic cell, and purification procedure has been described elsewhere (1, 3). Electrodes ( $7.92 \times 10^{-2}$  cm<sup>2</sup> superficial area) were prepared from 99.999% tin supplied by Johnson Matthey and Company and sheathed in polyethylene (3).

Electrodes were polished mechanically on roughened glass lubricated with water. In most cases electrodes were also electrochemically etched (10 ma/cm<sup>2</sup>, 10% HClO<sub>4</sub>). After washing in double distilled water electrodes were introduced into the electrolytic cell without drying.

Electrolyte pH adjustments were made by the replacement of  $\sim 1/10$ th of the electrolyte by 0.01M HClO<sub>4</sub>.

### Results

Electrometric measurements indicated that outside the potential limits  $\sim -1.6v$  NHE to  $\sim -0.2v$  NHE considerable faradaic current flowed. There was an

almost ideally polarizable region from  $-0.6$  to  $-0.3v$ .

Changes in differential capacitance,  $C_L$ , during the initial stages of electrode/electrolyte contact time were small. Irrespective of electrode pretreatment a 5% reduction in  $C_L$  from the first available value to the stable value after 5 min was typical,  $C_L$  values were stable for at least 24 hr thereafter.

Figure 1 shows typical results of capacitance measurements on stable electrodes. At any potential in the experimental potential range the difference between  $C_L$  values characteristic of etched replicate electrodes was within  $\pm 5\%$  of the mean. Electrodes which had only been mechanically polished had  $C_L$  values  $\sim 25\%$  greater than corresponding etched electrodes.

In neutral solution differential capacitance curves contained a local capacitance maximum at  $-0.75v$ . In acid electrolytes the local maximum occurred at  $\sim 0.6v$  and was not so pronounced. A capacitance minimum occurred at  $\sim -0.4v$  with acid electrolytes which became more pronounced at greater dilution. In the most dilute electrolytes investigated this minimum occurred at  $-0.43 \pm 0.02v$ . The minimum was absent in neutral electrolytes. No hysteresis was observed either in neutral or acid electrolytes. Capacitance curves could be

Fig. 1. Differential capacitance curves for polycrystalline tin in perchlorate electrolytes. 1 kHz; 23°C.  $\blacktriangle$ , 0.1M NaClO<sub>4</sub>, pH, 6.6-7;  $\bullet$ , 0.1M NaClO<sub>4</sub>, pH, 3-3.2;  $\circ$ , 0.007M NaClO<sub>4</sub>, pH, 3-3.3;  $\triangle$ , 0.0007M NaClO<sub>4</sub>, pH, 3-3.2.

traversed indefinitely in either direction without any irreversible changes taking place.

Figure 2 shows the extent of frequency dispersion at an electrolytically etched electrode. The extent of this dispersion was similar with electrodes only mechanically polished.

### Discussion

The differential capacitance curves in both neutral and acid solutions are very similar at negative potentials while at positive potentials marked differences occur. The general tendency of the capacitance at positive potentials in neutral solutions to approach low values is in contrast to the normal behavior of metals at the extremities of their polarizable region where an increase in the differential capacitance is invariably observed, as with tin in acid solutions. This effect is probably due to the formation of an oxide or hydroxide film as the electrode assumes more positive potentials (the hydrogen ions in the acid solution preventing this happening until even more positive potentials are reached). The peak which appears at about  $-0.7v$  in the capacitance curves in neutral solution is probably due to the oxide or hydroxide film developing or being removed (depending on the direction of the potential sweep) giving rise to a pseudo-capacitance similar to those observed when organic compounds are adsorbed on mercury. Increases in the electrolyte resistance were also noted at  $\sim -0.7v$  in neutral solution during potential sweeps which were absent in the acid solutions, such effects are indicative of structural changes in the metal-aqueous solution interphase. In the experimentally polarizable region (zero or very limited d-c flow) the most likely cause is film formation.

The steep rise in  $C_L$  at  $\sim -0.2v$  in acid electrolytes presumably marks the potential at the point of lattice dissolution.

Fig. 2. Dispersion of capacitance with frequency: 0.007M NaClO<sub>4</sub>; pH, 3-3.3; 23°C;  $E_{li}$ ,  $-0.68v$ .

The shapes of the differential capacitance curves in acid electrolytes are similar to those observed with mercury. The capacitance curves form a family which exhibit a minimum. This minimum becomes more pronounced with dilution. These observations indicate that the capacitance curves in acid electrolytes correspond to the tin/electrolyte interphase uncomplicated by adsorption. The capacitance minimum, under these conditions, indicates the potential of zero charge (p.z.c.).<sup>1</sup> If the thermionic work function of tin is taken as 4.1v and that of mercury as 4.5v then the p.z.c. might be expected to be in the region of  $-0.6v$  NHE. The experimental capacitance minimum occurs at  $-0.43 \pm 0.02v$ . This compares well with  $-0.46v$  from capacitance minimum (4) and  $-0.36v$  by dipping (5).

The value of the capacitance obtained in pH  $\sim 3$  solutions are similar to those of mercury under corresponding conditions. Thus it is likely that the true area of the tin electrode is close to the superficial area. [c.f., cadmium (2)]

The small dispersion of frequency is probably explained by a minor degree of surface roughness and heterogeneity as discussed by de Levie (6) and Ramaley and Enke (7).

# Charge-Transfer Complexes and Electrochemical Cells— Coal Batteries

R. A. Friedel

United States Department of the Interior,  
Bureau of Mines, Pittsburgh Coal Research Center, Pittsburgh, Pennsylvania

The discovery that charge-transfer complexes can be used in electrochemical cells has been reported (1, 2). The electrical properties of encapsulated solid-state cells involving various donor substances complexed with iodine and with two other acceptor molecules, tetracyanoethylene (TCNE) and tetracyanoquinodimethane (TCNQ), placed between magnesium and an inert electrode have been described (2). After the initial report on this work (1) it occurred to us that our experience with the charge-transfer complexing ability of coals (3) could possibly be applied to making batteries from coal complexes. Similar batteries were produced from pellets 1 mm thick and 22 mm in diameter of iodine plus various coals mounted between magnesium and copper disks. Open-circuit voltage (ocv) as high as 1.9v and short-circuit current densities (sccd) as high as 14 ma/cm<sup>2</sup> were obtained; also, an anthracite coal was found to produce an ocv of 0.8v and a sccd as high as 50  $\mu$ a/cm<sup>2</sup>. Details will be reported later. The work on coal-iodine and other iodine batteries led us to suspect that: (i) the existence of a charge-transfer complex as such has little to do with the generation of potential and current; (ii) the presence of water is essential to the operation of the batteries; and (iii) water is a reactant, not a catalyst.

On the question of whether a charge-transfer complex is necessary, we found that batteries made from iodine with a variety of coals, ranging from lignite to meta-anthracite, differed only slightly in their electrical characteristics. Also, batteries prepared from pellets of iodine plus clay (kaolinite) and iodine plus paraffin (n-C<sub>20</sub>H<sub>42</sub>) performed just as capably as batteries involving charge-transfer complexes (Table I gives the maximum ocv and sccd for several batteries). In fact, iodine alone between magnesium and platinum or copper electrodes performed very well. Our data indicate that formation of a charge-transfer complex is not necessary for the generation of electric potential and current in iodine batteries. The electron donor in the complex serves essentially as a diluent; thus, the method of preparation of the complex is expected to be unimportant, as Gutman *et al.* reported (2). However, any diluent, including donor substances, can influence the rate at which molecular iodine becomes available for the battery reaction.

Charge-transfer complexes, in themselves, generally do not function as solid-state batteries when placed between appropriate electrodes at room temperature. Tetrachloroquinone ("Chloranil"), or stable com-

plexes made with it, are appropriate examples of inactive components (Table I). It appears that charge-transfer complexes are active battery components only if they contain a moiety that can react with magnesium, such as I<sup>-</sup>, TCNE<sup>-</sup>, and TCNQ<sup>-</sup>.

A variety of batteries have been assembled under dry conditions and operated at 44 to 48% humidity; maximum ocv and sccd values are given in Table I. Most of these batteries were assembled with magnesium and copper electrodes. Platinum in place of copper produces somewhat higher ocv and sccd, but battery operation is similar.

Gutman *et al.* noted the large increase in current when they added large amounts of liquid water to their charge-transfer complexes, but both ocv and sccd decreased drastically in a few minutes. They also noted that the effect of minute amounts of water on cell performance was unknown (2). Tables II-V present ocv and sccd data for iodine batteries, Mg/I<sub>2</sub>/Pt, showing variations with time and the large effect of water. The batteries represented by the data of Table II were prepared under dry conditions and then operated at a humidity of 45%. Table III presents data for a battery prepared under dry conditions and sealed in a 1-liter glass jar containing room air; the amount of water in the 1-liter jar was 0.009g (humidity, 48%). The values of ocv and sccd were measured by means of copper wires sealed into the lid of the desiccator; values are lower than those of Table II because of the lower amount of available water. Table IV represents an operating battery for which 0.02g of water vapor was added to the 1-liter container; both ocv and sccd increased immediately, the more drastic change occurring for the sccd.

Table V demonstrates the striking effect on a battery of removing the source of water completely, by operating an iodine battery in a desiccator. Batteries desiccated include: 1, I<sub>2</sub>; 2, perylene-I<sub>2</sub>; 3 n-C<sub>20</sub>H<sub>42</sub>-I<sub>2</sub>.

\* Similar behavior was observed for Mg/I<sub>2</sub>/Pt.

In some cases batteries prepared in a dry box were placed immediately in a desiccator. Initially, small ocv and scdd were produced, presumably due to traces of water remaining in the dried battery components; then, both ocv and scdd decreased rapidly toward zero. On re-exposure to atmospheric humidity high ocv and scdd were rapidly attained. This cycle was repeated with similar results (Table V). Batteries were also prepared under dry conditions, were exposed

to the atmosphere and permitted to develop high ocv and scdd. Then, desiccation produced the same result as described above. Ocv of zero and scdd as low as  $2 \times 10^{-10}$  amp were measured on desiccated batteries. In all cases after removal from desiccation the batteries immediately developed ocv and scdd, the magnitude of which depended principally on the amount of water (humidity) made available to the battery and, to a less extent, on the age of the battery. Water is absolutely essential to operation of the batteries. The cells studied by Gutman *et al.* were encapsulated (2) but not sealed; water vapor presumably was able to enter their cells.

Water is not merely a catalyst in the battery operation; it participates directly in the battery reaction and is decomposed. We discovered this by collecting gas emitted from shorted batteries placed in closed containers. The gas produced is pure hydrogen. Thus any general equation for the battery reactions must include the decomposition of water.<sup>1</sup> Hydrolysis reaction(s) are apparently involved with the resulting formation of H<sup>+</sup>, followed by  $2\text{H}^+ + 2e \rightarrow \text{H}_2$ . When a battery is shorted in the presence of water vapor the uptake of water is extremely rapid. The electrolyte quickly becomes wet and the evolution of hydrogen becomes rapid. Under low humidity conditions the same reactions are less obvious but undoubtedly occur, including the evolution of hydrogen and rapid absorption of the available water.

<sup>1</sup> We believe that the over-all electrode reaction is essentially

with a theoretical potential of 1.86v. Filter paper soaked with an aqueous solution of molecular iodine and placed between magnesium and platinum electrodes produced the same ocv that were obtained with the iodine batteries.

## On the Activity of Platinum Catalysts in Solution

### III. Facets on Flame-Formed Platinum Spheres

Theodore B. Warner\*

Naval Research Laboratory, Washington, D. C.

In a recent study of factors affecting the activity of platinum electrodes, it was noted that thermal treatments could change this activity markedly (1). Activity was monitored by measuring the rate of the reaction of hydrogen, dissolved in solution and in the electrode, with oxygen present on the surface of the electrode. The thermal treatments involved heating the platinum bead in an H<sub>2</sub>/O<sub>2</sub> flame until it was molten, and then recrystallizing. When the cooling rate through the freezing point was slow, platinum beads had a characteristic appearance, nominally spherical with numerous well-developed flat regions. Such electrodes exhibited relatively high activity compared

with those having more irregular surfaces and fewer or no flat regions.

Many studies using other metals, particularly Ag and Cu, have demonstrated that small spherical single crystals can be formed by recrystallizing the metal under the proper conditions (2, 3). Kaishev and Mutaftshiev (4) formed platinum single crystal spheres by melting and refreezing the ends of previously prepared single-crystal fragments. It appeared probable that the flat regions observed here were crystallographically significant and hence that there might be a correlation between electrode activity for this reaction and degree of crystal perfection. The purpose of this study was to determine whether the flats did have crystallographic significance, and if so, what

\* Electrochemical Society Active Member.

Fig. 1. Flame-formed platinum bead. A regularly arrayed grid has been optically projected onto the surface to reveal facets. Magnification  $\approx 40\times$ . Photograph by A. C. Simon.

crystal faces predominated. This was of interest not only because of the correlation with activity, but because of the very simple procedure by which these spheres could be formed.<sup>1</sup>

### Experimental Results

The platinum bead was examined by optical goniometry; it was mounted in approximately the same position shown in Fig. 1. To obtain better definition of surface details on the bright, reflective bead, the photograph shows the reflection from the bead surface of a grid of regularly spaced lines. Deviations from sphericity are indicated by irregularities in the reflected pattern. The pattern was obtained by mounting the bead in the center of a white, right circular cylinder marked with a black grid of parallel lines. Illumination was projected downward through a translucent planar surface, marked with a lighter rectangular grid, that appears as a bright circle in the photograph. Views of the surface from other angles have appeared elsewhere (5).

The angles between the flat faces were measured using a two-circle optical goniometer constructed according to the design of Barrett and Levenson (6). The poles were plotted on a 20 cm Wulff net graduated at  $2^\circ$  intervals. Goniometer readings were measured to the nearest  $0.5^\circ$  and were precise to  $\pm 0.5^\circ$ . The observed stereographic projection was rotated, using standard techniques (7) to coincide with a standard projection of poles of a cubic crystal and the data are shown in this form in Fig. 2. The solid points are observed poles on the front face of the projection, the open point at A is an observed pole on the rear face, and point B was the surface normal as mounted. Five  $\{111\}$  faces and three  $\{100\}$  faces were observed. The angular distances between all possible pairs of poles were measured using the Wulff net and compared with the angles expected in a perfect cubic crystal (8). The maximum deviation was  $1.7^\circ$ ; the standard deviation of an individual measurement was  $0.87^\circ$ . The  $\{111\}$  faces were all large and of the characteristic lenticular shape clearly visible in Fig. 1. The  $\{100\}$  faces were tiny and of the same shape. Within the precision of the method all of the faces were perfectly flat.

A specific search was made for emerging  $\{110\}$  faces at predicted positions. None was found, although the

<sup>1</sup> They were formed by melting an end of clean 0.030 in. diameter 99.99% pure platinum wire as received, undoubtedly polycrystalline, in a hand oxyhydrogen torch. Temperature was lowered by gradually reducing oxygen content of the flame over a period of 3-5 min.

Fig. 2. Standard (001) stereographic projection of cubic crystal with observed data superimposed at relevant poles. Two poles are plotted at point A, one on the rear face. The surface normal was located at point B.

perfection of the spherical surface would have made identification easy even for a very small face.

The entire surface was repeatedly scanned for faces in other positions, which would be found if the crystal were a twin, or if several interpenetrating crystals were present. No such facets were found. This search was prompted by an anomalous region, visible at the top of the sphere in Fig. 1, that did not have the characteristic shape of an emerging face and was neither flat nor part of the sphere surface. Close microscopic examination showed this to be a tiny dimple, in all probability a shrinkage cavity formed in the last stages of bead solidification.

### Conclusions

The flat regions observed on a platinum sphere formed by melting the end of a wire in an  $H_2/O_2$  flame and slowly cooling the molten bead until resolidified were crystallographically significant. The large facets were  $\{111\}$  faces and the small ones were  $\{100\}$  faces of a platinum single crystal.

### Acknowledgments

The author wishes to thank Jeanne Burbank for suggesting the experimental technique, for making available her goniometer, for numerous helpful discussions concerning goniometry and crystallography, and for a critical reading of the manuscript. He also thanks Sigmund Schuldiner for helpful discussions concerning this work and Albert Simon for devising the technique and obtaining the photographs in Fig. 1.

Manuscript received Feb. 12, 1968.

## Transient Voltage Changes Produced in Corroding Metals and Alloys

Warren P. Iverson<sup>1</sup>

Fort Detrick, Frederick, Maryland

The formation of "hollow whiskers" by the action of slightly acidified potassium ferricyanide and ferrocyanide solutions on metals and alloys (1) appeared to indicate that corroding metals produce bursts of metal ions from various point anodes. Since these bursts of ions appeared to be of a sporadic nature, it seemed possible that there might be transient fluctuations of the electrical charge on the metal. The present communication reports on the detection of such fluctuations in electrical charge.

The circuit shown in Fig. 1 was used. The voltmeter was of the high impedance type (11 megohms) with a chopper stabilized circuit. The electrodes consisted of an inert auxiliary electrode of platinum foil (1 x 4.5 cm) connected to a platinum wire and the test electrode, whose corrosion was to be studied. Various strips of metals and alloys were used as the test electrode. The cell and electrodes were placed in a grounded copper-jacketed chamber to control the temperature and provide a shield from stray currents. The corroding metals or alloys investigated were aluminum, aluminum alloys (2025 and 7075), magnesium ribbon, iron, mild steel (1010), and zinc, and each exhibited voltage fluctuations whose frequency and amplitude depended on the metal being studied. The fluctuations from pure aluminum, the two aluminum alloys, and magnesium were generally extremely rapid (1 to 2 or more per sec) and greater than 100  $\mu\text{V}$  in amplitude. Using a low input impedance audio amplifier with the platinum and the corroding electrode connected directly across the input, a wide range of fluctuations in the audio range could be heard with a loud speaker. Voltage fluctuations from corroding iron, steel, and zinc were slower (1 to 3 or less per 5-min interval) and less in amplitude (<50 or 60  $\mu\text{V}$ ). The fluctuations in the potential appeared to be directly related to the corrosion, because the addition of an inhibitor caused them to disappear. Likewise, a non-corroding metal (platinum) was studied (in this case both electrodes were platinum) no fluctuations were observed. As an example, Fig. 2 shows the voltage fluctuations in a 1010 mild steel coupon partly immersed in distilled water plus 0.1% NaCl and the effect of a corrosion inhibitor, sodium nitrite (2), in causing these fluctuations to disappear. Similar inhibitor effects were observed with aluminum in the presence of nitrates (3).

To account for these voltage fluctuations, it is postulated that they are caused by minute transient changes in the electrical charge on the electrode produced as a result of cathodic and anodic reactions during the corrosion process, the charge at any small interval of time representing the resultant charge of both reactions. The imbalance of charge may also be due to

transient changes in cathodic or anodic areas. If, for example, a corroding metal assumes a temporary increase in negative charge, the electrons would charge the plate of the capacitor in contact with it. An equal or opposite charge would develop on the other plate (flow of electrons away from the plate) thereby causing a difference in measurable potential across the resistance. The electrons might be expected to dissipate through the resistor to the platinum electrode and be removed as a result of reduction of the cations or neutral species in the solution. During a transient decrease in negative charge on the metal and capacitor plate, the flow of electrons would be from the platinum electrode, as a result of oxidation of the anions or neutral species in solution, to the other capacitor plate, again developing a measurable potential across the resistor. If no change in the charge occurs on the test electrode, no measurable potential is developed across the resistor. This is apparently the case for a non-corroding electrode such as platinum or a less noble metal in the presence of an inhibitor for the initial charge on the capacitor soon dissipates, and the measurable potential drops to zero. The time for the voltage developed across the resistor to decrease to zero appears to be directly related to the initial charge in the capacitor and the R.C. time constant and inversely related to the electrolyte concentration.

Investigations of these voltage fluctuations appear to offer much promise for the detection and study of the corrosion process and for the study of corrosion inhibitors. Thus far, these fluctuations give a qualitative "fingerprint" characterization of corrosion processes occurring in different metals and alloys. They also offer a very simple way to detect the efficacy of inhibitors, being able to detect corrosion instantane-

ously. Further analysis of the voltage fluctuations, which is currently underway, will be required to relate them quantitatively to the corrosion rate and to determine the origin of the frequency and amplitude difference that differs with each metal.

## The Direct Observation of Barrier Layers in Porous Anodic Oxide Films

G. C. Wood, J. P. O'Sullivan, and B. Vaszko

*Corrosion Science Division, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England*

Earlier electron microscopical studies (1, 2) indicated that porous anodic oxide films on aluminum contain fine, regular, almost cylindrical pores, penetrating a close-packed hexagonal cellular structure as far as the barrier layer. The electrolyte appeared to determine the pore diameter while the forming voltage decided the barrier layer and cell wall thicknesses, although these features were not observed directly. Subsequently it was suggested (3), without visual evidence, that regular pores do not exist and that current is carried through a hydrogen-bonded structure between submicrocrystallites of anhydrous alumina, the degree of hydration increasing with the distance from the metal. Recent electron microscopy (4), however, supported a fibrous film structure, the fibers being hollow oxide cylinders containing water and anions.

The ability to observe the barrier layer and porous structure in section in some detail would assist considerably in resolving these anomalies. The only known previous attempt (5) led to a postulate that the barrier layer forms, by the interaction of liquid metal and oxygen, to a thickness independent of voltage. The present communication describes the initial results of a direct examination of barrier layer and pore and cell structures for films formed in a phosphoric acid electrolyte at high voltage.

Electropolished 99.99% aluminum specimens were anodized at 85, 100, or 115v for 1 hr in 4, 15, or 25% phosphoric acid at 25°C. Further experiments involved sharply increasing or decreasing the anodizing voltage after 30 min and removing the specimens when various parts on the resulting current/time transient curves had been reached. Films were fractured and di-

rect carbon replicas, shadowed with a platinum/carbon mixture, obtained from the surfaces and sections.

Figure 1a shows a section through the metal and film at the interface and, despite debris, the scalloped film base, cell structure, and pores are clearly visible. In Fig. 1b the film is separated from the metal, but the now classical conception of the film is clearly revealed. Some variation in apparent cell and pore diameters is to be expected, due to the different fracture planes present. Pores can undoubtedly be seen (2) despite statements to the contrary (6). In this particular micrograph they appear at about their "ideal" size, calculated on the assumption that the cell diameter is equal to twice the barrier layer thickness plus the pore diameter (1).

Average film dimensions from a number of such micrographs are shown in Table I. Due to variations in apparent pore diameter next to the barrier layer, the ideal pore diameter has been calculated as described.

Certain general conclusions may be drawn:

1. The classical film model (1, 2) is largely confirmed although the relationships derived (1) may not exactly hold.
2. The barrier layer thickness is proportional to the voltage, the ratio being about 10 Å/v in all cases.
3. The cell size also varies directly with the voltage, although the proportionality constant differs from previously (1).
4. The calculated pore diameter of 570-820Å, which agrees quite closely with the observed values (700-800Å) from Fig. 2, is considerably larger than the 330Å given previously. This was also found for films

Fig. 2. Current density/time curves obtained on (a, top) increasing the voltage from 87 to 117.5v; (b, bottom) decreasing the voltage from 117.5 to 87v.

Table I. Cell, pore, and barrier layer dimensions in anodic films

Voltage	Acid concentration	Barrier layer thickness	A/v	Cell size A	Calculated pore diameter A
	% W/v	A			
87	4	860	9.9	2360	640
103	4	990	9.6	2800	820
117.5	4	1270	10.8	3330	790
87	15	860	9.9	2400	680
87	25	840	9.7	2250	570

formed in sulfuric acid. It should be noted that the previous workers (1) used a method involving a substantial extrapolation from anodizing voltage data and gave no direct measurements.

The size and irregularity of the pores increased as the outer surface was approached. Cells became more fibrous in appearance (4) and pores occasionally merged, divided, or ceased to function. Replicas from the outer film surface gave pore diameters of 600-1400Å for 4% acid, while pores merged for 15% acid and an extremely rough surface with cavities was apparent for 25% acid. This was indicative of pore widening and eventual gross dissolution.

Of particular interest are the results obtained when anodizing was halted, before steady-state conditions had been achieved, after a rapid superimposed voltage increase or decrease. The resulting current-time curves were of the form shown in Fig. 2a and 2b. Increasing the voltage (Fig. 2a) led to a rapid increase in

Fig. 3. Electron micrographs of sections through anodic films formed in 4% w/v phosphoric acid (a, top) 10 min after changing from 87 to 117.5v, showing pore joining and termination; (b, bottom) 13 min after changing from 117.5 to 87v, showing pore branching and incipient pore formation.

barrier layer thickness during the current surge and subsequent decline. Indeed the barrier layer overshot its expected thickness before subsequently thinning to its ideal value. The cell size increased more slowly and reached its expected value without overshooting at about the same time the barrier layer reached its expected thickness. There was some evidence that further thinning of the barrier layer then occurred. During the redevelopment of the cell base pattern certain pores combined and/or ceased to function as current carriers (Fig. 3a), so that the equilibrium number was established.

During the reverse experiment, a recovery period was experienced before the current rose from substantially zero to the steady state value (Fig. 2a). Electron microscopy indicated that barrier layer thinning (probably field-assisted) may have occurred during this period, despite the low current. Again a redistribution of pores and cells was required, in this case an increase in number. Figure 3b shows pores dividing into two and sometimes three branches, although not all the incipient pores continued to function. Presumably there may have been more initial pore branches when the three-dimensional situation is considered. The directional branching must have occurred by field-assisted dissolution in the outer part of the barrier layer, when the voltage was changed. Presumably the local field, temperature, and hydrogen-bonded structure determined which pores persisted. The final pore and cell dimensions after a voltage change appeared partly determined by the pore and cell distribution in the outer film as well as the final anodizing conditions. It is also likely that initial transient period prior to conventional steady-state anodizing has similar influences.

The work, which is continuing, provides strong evidence for certain aspects of the classical geometrical model. However, it must be recognized that prolonged electrolyte action increases porosity and alters the nature of the hydrogen-bonded structure in the outer parts of the film. The pore splitting and merging behavior gives some support to the concept of a transition region in the outer part of the barrier layer and of the porous layer immediately above it exerting some influence.

## Stability of Chemically Deposited Magnetic Thin Films with Time and Temperature

G. Wm. Lawless

Technical Institute, University of Dayton, Dayton, Ohio

Commercial adaptation of chemically deposited magnetic thin films, both hard and soft, seems to be nearing reality. Their suitable magnetic memory characteristics on variety of substrates has been amply demonstrated in numerous references (1-4). However, little seems to have been reported on such potentially troublesome areas as reproducibility, wear characteristics, creep, stress, magnetostriction, and aging, or stability with time and temperature. A study of this last noted property, aging or stability with time and temperature, is reported here.

Low coercive force NiCoP films were deposited from the solution composition as given in Table I. Details of deposition and solution operating characteristics have been previously reported (4), along with deposit composition studies. No analytical data are presented for this initial reporting since only one series of samples was prepared for each temperature level, and film composition would naturally have to be consistent prior to any extended research in this area. However, it may be recorded that past experience indicated that the reported solution, operating at 8.0 pH and 80°, characteristically produces low coercive force NiCoP films of 45-52% Ni, less than 5% P, and balance Co.

The films were deposited to various thicknesses on 5-mil phosphor bronze disks, 1.905 cm in diameter. Film thickness was determined by weight-density measurements with the NiCoP density taken as 8.7

g/cm<sup>3</sup>. All films were anisotropic, and the reported coercive force is taken along the easy axis. They were exposed in a still air atmosphere at temperatures of 25°, 65°, and 100°, periodically removed, cooled, and their magnetic properties evaluated. Relative humidity was not specifically controlled in the ambient environment of the samples, but their containing oven was located in an air-conditioned laboratory wherein the relative humidity variation was probably in the 50-70% range. Of particular interest was the variation in coercive force. Figures 1, 2, and 3 display this variation for samples of comparable thicknesses. One immediately observes that the deposit stability with time (change of coercive force), is a function of both the initial thickness (or initial coercive force) and the ambient temperature. For example, a 2000Å deposit exhibited little change in coercive force after 500 hr at 25°, but at 100° after 500 hr of exposure its coercive force had more than doubled. Similar results were observed for all thicknesses, but the thinner the

Fig. 3. Variation in coercive force

Saturation flux remained unchanged throughout the test period for all samples.

As somewhat of an addendum to this work, the high coercive force chemically deposited Co-P film, previously developed by Fisher and Chilton (1), was also investigated at 100° for a continuous time period of 1100 hr. Approximately 3000Å of the Co-P was applied to a commercially available polyimide film of 2 mil thickness. Four such samples were investigated. Periodic examination of the hysteresis loop of the deposits revealed no change in B-H characteristics over the 1100 hr test period. The coercive force of these test samples was approximately 400 oe in a 1000 oe drive field.

Manuscript received Oct. 11, 1967, revised manuscript received Feb. 6, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

deposit, the more pronounced was the rise in coercive force with time and temperature.

At the exposure temperatures of 25° and 65° the deposits seemed to reach an equilibrium state within 2000 hr, but at 100° exposure the coercive force of all samples (up to 7600Å thickness) continued to increase after 2000 hr.

An interesting stepwise pattern of increasing coercive force was observed on the thinner deposits at 25° exposure, suggesting perhaps a time-temperature equilibrium relationship. But this effect, however real or significant, failed to appear at the higher exposure temperatures.

## DISCUSSION

### SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 114, No. 4, 5, 7, 10, and 12 (April, May, July, October, and December).

#### Solid-State Electrochemical Cells Based on Charge Transfer Complexes

F. Gutmann, A. M. Hermann, and A. Rembaum  
(pp. 323-329, Vol. 114, No. 4)

**Ashok K. Vijh**<sup>1</sup>: The interesting work reported above includes mechanistic conclusions which are not entirely sustained by a further analysis of the experimental results. It is stated that initial discharge of the iodide ions on the magnesium anode is the rate-deter-

<sup>1</sup> Sprague Electric Co., North Adams, Massachusetts.

mining stage (rds) in the over-all reaction. This conclusion is based principally on one piece of experimental evidence, namely, that at low over-voltages, a straight line is obtained between current and voltage and that for a freshly prepared cell, the exchange current density and thence, the stoichiometric number,  $\nu$ , obtained from this straight line has a value approximately equal to two (Fig. 4). The value of  $\nu = 2$  for the electrode reaction reported needs some further discussion and important points are developed below:

1. If the exchange current density,  $i_0$ , obtained by the extrapolation of the Tafel relation from Fig. 3 of the authors (for the freshly prepared cell) is used for the evaluation of  $\nu$  through Eq. [3] of the authors, a value of approximately 12 for the  $\nu$  may be

obtained. This is a frequently used procedure<sup>2</sup> and checks the validity of  $\nu$  obtained solely from the data used in constructing the linear current-potential relation, observed at low over potentials and reported in Fig. 4.

2. If the value of  $\nu$ , for the freshly prepared cell, is obtained by another procedure discussed by Bockris<sup>2</sup> in which transfer coefficients (reported for the present reaction by the above authors in their paper) and thence the Tafel slopes for the anodic and the corresponding cathodic reaction are utilized,  $\nu$  will attain value other than two. This procedure, however, is valid only if both the anodic and the corresponding cathodic reaction have the same mechanism.

3. Again, if the value of  $\nu$  for the freshly prepared cell is estimated by still another procedure, mentioned by Green<sup>3</sup> through the approximate use of data in Fig. 3 and 4 of the authors,  $\nu$  will have a value somewhere between 8 and 12.

4. Adopting the authors' procedure and data for evaluating  $\nu$  for the "aged" cell, a value of  $\nu$  approximately equal to unity may be obtained. It is probably unlikely that an aging period of three days would change the mechanism of the electrode process.

In conclusion, it is believed that it is purely fortuitous that for the particular data (i.e., for the fresh cell) chosen by the authors coupled with the procedure of evaluating  $\nu$  used by them in which both  $i_0$  and  $(d\eta/di)_{i \rightarrow 0}$  (and thence  $\nu$ ) are obtained from the same primary data (Fig. 4, circles), a value of two for the  $\nu$  is obtained. This, however, is quite meager and ambiguous an evidence for proposing reaction mechanism, especially when some degree of corrosion is probably involved as a competing reaction in the present case. The fundamental premise on which the interpretations of the authors are based is that, at higher current densities, the reaction is activation controlled (Fig. 3 and 5). However, a linear potential-log [current] relationship observed over less than half a decade of current densities (Fig. 3) is hardly a "Tafel line" or an evidence for activation control. In Fig. 3, probably a linear relation exists between current and potential (cf. Fig. 7), giving from the slope, the ohmic resistance of the cell. This would imply that the electrode process is probably diffusion-controlled. This suggestion is somewhat emphasized by the theoretically untenable and anomalously high values of the "Tafel Slopes" as deduced from Fig. 3. Again, a substantial accumulation of reaction products on the electrode, as demonstrated by the authors in the present electrode reaction, would rather strongly support a diffusion-controlled mechanism.<sup>4</sup>

### The Alkaline Manganese Dioxide Electrode, I. The Discharge Process

David Boden, C. J. Venuto, D. Wisler, and R. B. Wylie  
(pp. 415-417, Vol. 114, No. 5)

**S. Ghosh**<sup>5</sup>: In ref. (8) of the above paper the authors refer to one of our papers.<sup>6</sup> About our observations on the initial dilation of gamma MnO<sub>2</sub> during the initial stages of this discharge, the possible explanation for this dilation as observed by us was also quoted in the discussion part of this paper. Further, it is emphasized that "this process continues until the lattice is strained to the point at which it becomes unstable and crystallizes to a more stable phase" has been remarked. I would like to refer to my recent publication from the laboratory of Professor Brenet on this particular point.

<sup>2</sup> J. O'M. Bockris and A. K. S. Huq, *Proc. Roy. Soc.*, 237A, 277 (1956); J. O'M. Bockris, in "Modern Aspects of Electrochemistry," Vol. 1, Edited by J. O'M. Bockris and B. E. Conway, Butterworths, London (1954).

<sup>3</sup> M. Green in "Modern Aspects of Electrochemistry," Vol. 2, p. 397, Edited by J. O'M. Bockris, Butterworths, London (1959).

<sup>4</sup> B. E. Conway, "Theory and Principles of Electrode Processes," Ronald Press, New York (1965).

<sup>5</sup> Indian Standards Institution, Manak Bhavan, 9, Bahadur Shah Zafar Marg, New Delhi 1, India.

<sup>6</sup> J. P. Brenet and S. Ghosh, *Electrochim. Acta*, 7, 449 (1962).

Further I would like to refer to one of my publication<sup>7</sup>, wherein I have tried to explain a generalized approach about the mechanism on depolarization of metallic oxides in a cell system. In this paper, I attempted to propose that the "bound water incorporation in the crystal lattice" has a relation with the activity of the nonstoichiometric metallic oxide. The dilation of the crystal lattice has a definite bearing as the pronotonic acidity coupled with hydration is an important factor in determining the polarizability of the compound. I would like to refer to my thesis for my doctorate of science submitted to the University of Strasbourg in December 1966 under the guidance of Professor Brenet, wherein I compared and established different physicochemical techniques like x-ray defraction, electron defraction, magnetic susceptibility, and by chemical analysis about the water incorporation in the crystal lattice of gamma manganese dioxide and alpha and beta lead dioxide. Below are listed a few publications by Professor Brenet which will clarify further the discharge process as we now think for the manganese dioxide.<sup>8,9</sup>

### D. Boden, C. J. Venuto, D. Wisler, and R. B. Wylie:

The authors would like to express their appreciation to Dr. Ghosh for kindly pointing out this additional information. In our work, no attempt was made to determine either the degree of hydration of the crystal lattice or its effect on the electrochemical or crystallographic behavior of the manganese dioxide. The initial part of the discharge, where the lattice dilation occurs, is of great interest and, undoubtedly, further work should be done to determine the nature of the reactions taking place in this region.

### The Role of Hydrogen Peroxide in Oxygen Reduction at Platinum in H<sub>2</sub>SO<sub>4</sub> Solution

A. Damjanovic, M. A. Genshaw, and J. O'M. Bockris  
(pp. 466-472, Vol. 114, No. 5)

**A. L. Juliard**<sup>10</sup> and **C. C. Liang**<sup>11</sup>: We have read with deepest interest this excellent paper showing by the rotating disk-ring method that hydrogen peroxide is not formed as an intermediate in the reduction of oxygen at the platinum electrode in pure sulfuric acid aqueous solution.

However, we are suprised that the authors did not mention in this well documented paper that Liang and Juliard<sup>12</sup> came to the same conclusion using a cyclic-voltammetric method two years earlier.

There is no doubt that the eventual presence of hydrogen peroxide as intermediate can be more sensitively determined by the rotating disk-ring method, than by cyclic-voltammetry. Nevertheless, with the Liang-Juliard technique hydrogen peroxide could be detected if this compound covered more than 1% of the surface of the electrode. Since this was not the case, these authors concluded that the formation of hydrogen peroxide could not be held responsible for the overpotential of reduction of oxygen at platinum in sulfuric acid solutions.

### A. Damjanovic, M. A. Genshaw, and J. O'M. Bockris:

We regret that we did not cite the work of Liang and Juliard in our paper involving the detection of H<sub>2</sub>O<sub>2</sub>. At the time of writing the paper, we did not consider that the potentiodynamic method would have the sensitivity attributed to it.

## Potential of Aluminum in Aqueous Chloride Solutions

T. Hagyard and W. B. Earl (pp. 694-698, Vol. 114, No. 7)

**A. K. Vijh and R. S. Alwitt**<sup>13</sup>: We believe that certain aspects of the above paper need further discussion as some of the conclusions reached by the authors are at variance with our recent work<sup>14</sup> and some previous data.<sup>15, 16</sup> The important points are developed below.

1. These authors have obtained the Tafel plot for the hydrogen evolution reaction (her) (Fig. 6 in the above mentioned paper) by choosing the electrode potential reached at a given current density in a galvanostatic charging curve after 1- $\mu$ sec. This procedure of obtaining a steady-state potential-log (rate) relationship (i.e., the Tafel plot) from a nonsteady-state transient (i.e., the charging curve) at a fixed time is not sound theoretically.<sup>17</sup> However, when initial discharge step is the rate-determining stage with a consequently negligible consumption of charge in the pseudo-Faradaic process, this procedure should give results comparable to those obtained under steady state, especially at higher current densities. However, appreciable discrepancies do arise between our results (obtained by conventional steady-state procedure) (Fig. 1) and those of the present authors for the transfer coefficients,  $\alpha$ , Tafel slopes,  $b$ , constant  $a$  of the Tafel equation and the potential regions for the her in general (Table I). In case of the results shown in Fig. 1, presence of spontaneous surface oxide is thermodynamically impossible.<sup>18</sup> Furthermore, if spon-

Table I.

Parameter	Hagyard and Earl	Vijh <sup>1</sup>
Tafel slope, $b$	$2.3 \times 5 RT/F$	$2.3 \times 2 RT/F$
$\alpha$	0.21	0.51
$a$	-2.21v	-1.012v
Potential region for her	More cathodic than ca.-1.3v	Less cathodic than ca.-1.0v

<sup>1</sup> Our results were obtained over pH range 0.1-4.4 (Fig. 1) and were calculated for pH 3.2 for the pH-dependent quantity,  $a$ , in this table;  $a$  is the constant in the empirical form of the Tafel equation  $\eta = a - b \log i$ .

taneous surface oxide were involved, the discrepancies between the results in Fig. 1 and those of the present authors would be expected in the direction opposite to the one observed<sup>17</sup> e.g., a higher Tafel slope in the presence of oxide. This is because of the kinetic participation of surface oxides in the activation controlled charge transfer event on the electrode, cathode in the present argument.

2. In Fig. 5d of these authors, a cathodic charging curve obtained at very high current density ( $> 7 \times 10^{-1}$  amp  $\cdot$  cm<sup>-2</sup>) is shown to contain some "blips" which have been interpreted as "molecular hydrogen formation of an explosive or chain type." The "blips" probably are vigorous bubble formation and are a usual problem in transients involving high-current densities. Perhaps the authors could explain what they mean by the "explosive" formation of molecular hydrogen.

3. It is stated that the oxide films are formed in aqueous solution, after the first millisecond, due to contamination by dissolved oxygen or impurities. However, a look a Pourbaix's Atlas<sup>18</sup> shows that the presence of oxide on aluminum in the pH range 5-8, approximately, arises due to a spontaneous process since oxide-covered aluminum is the configuration of minimum free energy and hence maximum stability. At the pH used by the authors (pH 3.2), no spontaneous oxide formation should occur, and hence the attempt of the authors to "outrun" the spontaneous, fast, formation of oxide is quite irrelevant. Also, presence or absence of dissolved contaminants is quite secondary as far as spontaneous oxide formation is concerned, and, is not the origin of oxide on aluminum, as these authors seem to assume.

4. It is claimed that no previous data exist either on the her or anodic dissolution on oxide-free aluminum. The authors are apparently unaware of the studies on the her by Pecherskaya and Stender<sup>14</sup> in 2N H<sub>2</sub>SO<sub>4</sub> and by Hickling and Salt in 1N HCl.<sup>15</sup> In these two solutions, existence of spontaneous oxide is thermodynamically impossible (see Pourbaix's Atlas).

5. These authors did not use a Luggin probe between the working and the reference electrode. At higher current densities (ca.  $> 1 \times 10^{-2}$  amp  $\cdot$  cm<sup>-2</sup>) this would tend to introduce significant IR drop, thus introducing unknown errors in the potential values quoted. Also, since anode and cathode have not been separated in the experimental arrangement of these authors, reaction products from the counter electrode would act as depolarizers on the working electrode resulting, again, in unreliable potential values. This criticism is particularly serious in any studies on the her.

6. An important parameter of electrode kinetics, namely, potential of zero charge, has been used in an entirely incorrect sense. It is concluded, by these authors, that the aluminum electrode when dipped in an aqueous solution on open circuit would achieve an initial potential approximately identical with the potential of zero charge for aluminum in that solution (unknown). This misleading statement may be rectified by consulting any of the standard reviews on electrode kinetics.<sup>17</sup>

Fig. 1. Tafel plots for her on oxide-free aluminum in the following acidic solutions (ref. 14): ● 0.2N H<sub>2</sub>SO<sub>4</sub> (pH = 0.94); ○ 0.5N H<sub>2</sub>SO<sub>4</sub> (pH = 0.59); △ 0.86N H<sub>2</sub>SO<sub>4</sub> (pH = 0.37); □ 1.7N H<sub>2</sub>SO<sub>4</sub> (pH = 0.1); × 1N CH<sub>3</sub>COOH (pH = 2.4); ▲ 2N CH<sub>3</sub>COOH + 1N NH<sub>4</sub>COOCH<sub>3</sub> (pH = 4.4); and ■ 2N H<sub>2</sub>SO<sub>4</sub> (pH = 0.04), ref. (15); ● 1N HCl (pH = 0.1), ref. (16).

## Notes:

- (1) Tafel relationships are apparently independent of pH in the range 0.1-0.94. However, scatter in the points makes it difficult to draw any definite conclusions.
- (2) Results in Refs. (15) and (16) are unreliable due to impurities in the solutions etc. (see Ref. 14)

**T. Hagyard and W. B. Earl:** Contrary to the assertion of Vijn and Alwitt, the measurements of potential recorded in our Fig. 6 were not transients but as can be seen from our Fig. 5a the potential reached equilibrium in less than 1 msec. and has been observed to remain substantially unchanged over many seconds. This is clearly stated in our third paragraph and on p. 696 second column.

We cannot be expected to accept the criticism that our results do not agree with their unpublished results without having the opportunity of judging the reliability of their technique. It seems pertinent, however, that the results from the two papers which they quote in their Fig. 1, of which we were well aware, were considered by Bockris [our ref. (5)] and by us to be unreliable because of surface contamination. It is probably not a coincidence that these Tafel lines shown in Fig. 1 as purporting to be for hydrogen discharge on aluminum are almost coincident with the Tafel lines produced by the same authors for hydrogen discharge on iron. Iron is a very common impurity and a negligible amount (about  $10^{-9}$  moles/cm<sup>2</sup>) would suffice for a monolayer on the aluminum surface. The quoted authors did not even pre-electrolyze their solutions.

For conventional over voltage measurements even pre-electrolysis can be effective only if the auxiliary cathode is brought for a long period to a potential at least as negative as that to be reached by the test electrode and then only if the rate of deposition of impurities is greater than their rate of introduction from the anode and all parts. It is our contention that these conditions cannot be met for a reactive metal like aluminum which has a reversible potential around -1.7v. We consider that measurements of hydrogen over voltage on such metals must be carried out in times that are short compared with the time constant for the arrival of a monolayer of impurity atoms from the bulk of the solution. For our experiments A.R KCl was used with Fe = 0.002% max. and the time required for the transport to the electrode surface by molecular diffusion of sufficient ferrous iron to form a monolayer of iron would be 7 sec. if the maximum iron impurity were actually present. Our measurements were made in milliseconds and were thus free from any conceivable effect of impurities in solution. This is one of the main advantages of our method.

If the plots in their Fig. 1 represented a bare aluminum surface then at e.g., -0.5v anodic dissolution of the aluminum would be rapid and add its quota to the cathodic current. From our Fig. 4 a current of 1 a/cm<sup>2</sup> would be contributed from this source and  $10^{-5}$  a/cm<sup>2</sup> (their Fig. 1) from the external current which was presumably what they measured. Obviously the situation was much more complex than they assumed but it can be explained by our more recent work, yet to be published, without contravening the results in our present paper.

The criticism that the Pourbaix diagram for aluminum proves that aluminum oxide cannot exist on the metal at pH 3.2 is invalid and is due to a lack of understanding of the use of such diagrams. The diagram only shows that at equilibrium e.g., at pH 2 and unit aluminum ion concentration, the oxide, if formed, would dissolve to form a solution of the salt. Oxide formation from the metal is accompanied by a very great decrease in free energy and if it occurs faster than dissolution of the oxide in the acid, then oxide will remain on the surface. We have evidence, to be published in due course, that bare aluminum does in fact react chemically with our solutions at pH 3.2 in some 200  $\mu$ s producing an oxide layer of undetermined nature. Slow dissolution of aluminum oxide film in aluminum chloride solutions with the formation of presumably basic salts has been studied by one of us [J. Appl. Chem., 9, 323 (1959)]. The dissolution equilibrium depends on concentration and pH and our use

of pH 3.2 for most of our work was specifically to minimize oxide dissolution and basic salt formation under expected conditions close to the electrode surface.

Their suggestion (2) that the "blips" to which we referred were due to hydrogen bubble formation is hardly consistent with the fact that each "blip" corresponded with the passage of current approximately equal to one atomic layer of hydrogen. Although the point seems to us to be a minor one, we see no reason to retract "explosive" as applied to a surface process taking place, as can be seen dimly in our figure, in about 100  $\mu$ s and possibly involving most of the surface atoms in that time interval.

### A Generalized Expression for the Tafel Slope and the Kinetics of Oxygen Reduction on Noble Metal and Alloys

D. S. Gnanamuthu and J. V. Petrocelli (pp. 1036-1041, Vol. 114, No. 10)

**U. R. Evans**<sup>19</sup>: The new measurements provide welcome positive results, and two negative conclusions are also valuable, since they serve to clear the ground of encumbrances. These are (a) it is not possible to determine reaction mechanisms by means of  $b_c$  and  $i_0$  and (b) there is no apparent relationship of the number of holes in the d-band with the activity in NaOH or with  $b_c$  in H<sub>2</sub>SO<sub>4</sub> and NaOH.

Probably self-polarization, leading to a mixed potential, as envisaged by Hoar<sup>20</sup>, accounts for the failure to realize the reversible potential in absence of external current. But the main cause of the departure from rectilinear relationship between  $\eta$  and  $\log i$  is probably the fact that the cathodic reaction proceeds only on a few small favorable points. The approach resistance to a circular area of radius  $\tau_1$  slightly exceeds

$$\int_{\tau_1}^{\infty} \frac{\omega dr}{2\pi r^2} \quad \text{or} \quad \frac{\omega}{2\pi\tau_1}$$

where  $\omega$  is the specific resistance. If  $\tau_1$  is of atomic dimensions, this may easily exceed any other contribution to polarization and we may expect  $\eta$  to show a rectilinear relation with  $i$ , instead of with  $\log i$ . Such a rectilinear relation has been found for the cathodic reduction of oxygen on iron<sup>21</sup>; also in fuel-cell studies<sup>22</sup>, a long straight limb is often found on plotting  $i$  against  $\eta$ .

Some evidence that the cathodic reaction does occur mainly on isolated spots was provided by early corrosion studies of iron<sup>23</sup>, based on the ferroxyl indicator, although less clear-cut than the evidence that the anodic reaction starts locally and then spreads out. More instructive is the demonstration<sup>24</sup> that, on partly immersed specimens, much of the cathodic reaction occurs on the barely damp zone above the waterline; this entails a large ohmic resistance and would be unthinkable if the whole of the meniscus-zone area was available for the cathodic reduction of oxygen.

The restriction of cathodic reduction to favored spots is a feature of the pseudosplitting mechanism<sup>25</sup>, which explains the established facts better than any of the sixteen rival mechanisms conveniently arranged in Table I. The difficulty of understanding the reduction of O<sub>2</sub> to 2OH<sup>-</sup> (or to H<sub>2</sub>O) has always been that at some stage a splitting of the O<sub>2</sub> molecule would seem to be needed. In the gas-phase this splitting is a rare occurrence, except at high-temperatures, since

it demands 117 kcal. On certain oxide surfaces, the energy demand is much lower: only 23.5 kcal is needed on a  $Cu_2O$  surface, where the affinity between  $Cu_2O$  and the one O atom (giving 2 CuO) allows the other O atom to become free and mobile<sup>26</sup>; this makes splitting an important occurrence at about 200°C, but that mechanism can hardly be in operation in the ordinary corrosion cell. In contrast pseudosplitting can lead to well separated O atoms without any relative movement of the two atoms of the original  $O_2$  molecule. It involves no *ad hoc* assumption, but only the well-recognized fact that hydrogen switching is an easy reaction, being often invoked to explain why the apparent mobility of  $OH^-$  and  $H_3O^+$  ions (which can switch H with a neighboring  $H_2O$  molecule as a Grotthus reaction), is greater than the true mobility of ions which must really thread their way through the crowd; also it explains why acid and alkali, mixed together, immediately neutralize one another.

If an oxygen molecule attaches itself to a surface carrying a carpet of OH groups, (Table I, Stage 1), the switch of hydrogen allows the production of uncovered O atoms at sites which travel about at random (Stages 2, 3, and 4), until at last (Stage 5) a position is reached (perhaps a kink-site where the neighboring OH groups are on the wrong level) less favorable to acquisition of H from a neighboring OH than from a water molecule in the liquid; this requires two electrons and constitutes the essential cathodic reaction

Such a mechanism not only shows why a straight line is obtained on plotting  $E$  against  $i$ , not against  $\log i$ , but also explains the fact that in some cases the current produced is more nearly proportional to  $\sqrt{p}$  than to  $p$  (the oxygen-pressure). For the wandering uncovered O-sites will sometimes meet, producing uncovered pairs which could be in equilibrium with the  $O_2$  of the gas-phase. Early measurements<sup>27</sup> of the corrosion of iron specimens partly immersed in salt solutions showed the corrosion-rate in oxygen to vary between 2.39 and 2.65 times that in air;  $\sqrt{5}$  is 2.23.

The mechanism also explains why efficient fuel cells generally use as electrolyte concentrated alkali or concentrated acid (where an analogous wandering is possible). It is not easy to obtain efficiency with a near-neutral liquid where the necessary chains of OH or  $H_3O$  will rarely occur. Some authorities believe that the failure of fuel cells containing near-neutral liquid is due to rapid changes of pH when current passes;

<sup>26</sup> W. E. Garner, T. J. Gray, and F. S. Stone, *Disc. Faraday Soc.*, **8**, 246 (1950).

<sup>27</sup> U. R. Evans, *J. Chem. Soc.*, 1929, 111.

no doubt that can be a serious cause of polarization, but experiments made with buffer solutions<sup>28</sup> would seem to have been only partly successful. A possible objection to the use of a near-neutral electrolyte is that pseudosplitting will be a rare occurrence, so that instead of

we may often get

where  $O_2H^-$  is the anion of hydrogen peroxide. Now hydrogen peroxide is often detected in the corrosion of zinc and aluminum; the fact that on metals of variable valency it is not detected may be due to its speedy catalytic decomposition on corrosion products. It is also often reported in fuel-cell reactions, but, if formed, is a sign of inefficiency, since the Pourbaix diagram<sup>29</sup> shows that the presence of appreciable  $H_2O_2$  concentration involves a drop in the emf to little more than half the theoretical value. A fuel cell which does not contain corrosive acid or unpleasant alkali would be welcome; but it will call for a mechanism to repress or replace the pseudosplitting mentioned above.

**D. S. Gnanamuthu and J. V. Petrocelli:** We welcome Dr. Evans' discussion and find his proposed mechanism very interesting. Such a mechanism certainly could account for more favorable energetics and deserves serious consideration.

#### Silver Oxide Electrode Processes

T. P. Dirkse, D. DeWit, and R. Shoemaker (pp. 1196-1200, Vol. 114, No. 12)

**J. J. Lander<sup>30</sup>:** The possibility of ion pair formation in concentrated solutions of KOH was suggested based on the following treatment<sup>31</sup> of the data for viscosity<sup>32</sup> and for conductivity<sup>33</sup> of KOH solutions at 25°C in the range 0.6 to 13.4 molar. If it is assumed that conductivity will be a direct function of the concentration and an inverse function of the viscosity and that no other factors are involved, then one may calculate the function  $\eta \lambda / C$  from the measured data to determine its constancy. The accompanying Table I shows the data. The function  $\eta \lambda / C$  is shown to be constant within an average  $\pm 1\%$  over the range 0.6 to 4.0M. Then, as concentration increases, the value of the function decreases, passes through a minimum at about 10M, and rises to the original value at 13.4M. This is interpreted to mean that extent of association is constant in the range 0.6 to 4.0M and that only ionic velocities are changing due to the viscosity increase. The decrease in the value of  $\eta \lambda / C$  above 4.0M could then be due to a greater extent of association (ion

pairing) or decreased ionic velocities due to some cause over and above viscosity, or both. The reason for the minimum and the return to the original value at 13.4M is not clear.

**The Effect of Anodic Films on the Gaseous Oxidation of Tantalum, II. Films Formed in Phosphoric Acid Solutions**

R. E. Pawel (pp. 1222, Vol. 114, No. 12)

**D. A. Vermilyea**<sup>34</sup>: The magnitude of oxygen transport observed in these studies, along with the activation

<sup>34</sup> Research and Development Center, General Electric Co., Schenectady, New York.

energies deduced, allow an estimate of the concentration of defects in anodic films on tantalum. For example, for the 1000Å film formed in Na<sub>2</sub>SO<sub>4</sub> the oxygen flux at 500°C was about  $6 \times 10^{-11}$  gram atoms cm<sup>-2</sup> sec<sup>-1</sup>. The diffusion coefficient should not be much larger than the value obtained from  $D = 10^{-1} \exp(-43000/RT)$ , or about  $10^{-13}$  cm<sup>2</sup> sec<sup>-1</sup>. From the steady state diffusion law the concentration difference across the film is found to be  $6 \cdot 10^{-3}$  moles cm<sup>-3</sup>. Since Ta<sub>2</sub>O<sub>5</sub> itself is present at only  $1.8 \cdot 10^{-2}$  mole cm<sup>-3</sup> the defect concentration is evidently extremely high.

# Anodization of Vanadium in Acetic Acid Solutions

R. G. Keil<sup>1</sup> and R. E. Salomon

Chemistry Department, Temple University of the Commonwealth System of Higher Education,  
Philadelphia, Pennsylvania

## ABSTRACT

Uniform anodic vanadium tetroxide films of controlled thickness have been grown on vanadium in acetic acid-sodium tetraborate solutions containing small quantities of water. The film composition was established using Faraday's law and EPR and ATR spectroscopy. The anode reaction was found to be 100% efficient in the production of vanadium(IV) oxide. The lack of oxygen evolution was attributed to reduced water activity as a result of its interactions with the acetic acid. Information concerning the nature of the film was obtained.

The growth of anodic oxide films on several metals in nonaqueous media has been studied (1,2). The primary reasons for using nonaqueous anodizing solutions are to reduce the fraction of the anodic oxidation product dissolving during film growth (3) and to increase the current efficiency of the film formation process. In some instances, where the oxidation product is readily soluble in an aqueous environment, the use of a nonaqueous media may be the only way to grow an anodic film on that metal in solution (1, 4).

In 1957, Johansen, Adams, and Van Rysselberghe (5) studied the growth of anodic oxide films on a host of metals, including vanadium, in an aqueous boric acid-ammonia solution, pH 8. The study covered only potentials below the oxygen evolution potential using apparent current densities of 0 to 100  $\mu\text{a}/\text{cm}^2$ . For vanadium, a curve characteristic of that obtained for a material in which film growth occurred was not obtained. The authors concluded that for vanadium either an extremely porous film is produced or the oxidation product is rapidly undergoing dissolution. Little else is known about the anodic behavior of vanadium. With aqueous solutions the film tends to go into solution as vanadyl ions when anodization is attempted. Young (6) suggests that anodic films on vanadium might be grown in partly nonaqueous solutions. If an anodic film could be grown on vanadium, determination of the current efficiency of the anode reaction and the effect of repeated film growth upon the metallic substrate surface could be determined owing to the solubility of the vanadium oxides in water (7).

## Experimental

High-purity (99.94%), single-pass zone refined vanadium in both rod ( $\frac{3}{8}$  in. diameter) and foil (0.005 in.) form was purchased from the Materials Research Corporation. According to the supplier, the impurity content was in parts per million: O(200), N(50), H(3), C(150), Fe(50), Ni(10), Mg(5), Si(50), Mn(5), and Mo(50). Glass tubes were sealed to the vanadium metal with epoxy cement. Electrical connection to the external circuit via platinum wire was effected using mercury contacts. Picien wax (mp 80°C) was used as a "stopping off" compound. The molten wax was applied over a 100v anodic film and allowed to solidify gradually. The wax was subsequently removed from the surface of interest by rubbing that surface with a Kimwipe, saturated with toluene.

Prior to film growth the vanadium electrode was abraded, utilizing, first 2/0, then 3/0 and finally 4/0 emery paper. The abrasion was done on a Buehler Ltd. Metallurgical Polishing Wheel. The sample was then etched sparingly (15-30 sec) in a 1:1 water-nitric acid (70% assay) solution. Electrodes etched for long periods, greater than 3 min, showed visual evidence of grain boundary formation. An electrode

with grain boundaries was reabraded. Immediately prior to anodization the electrode was washed, first with absolute alcohol, then with anhydrous acetic acid, and finally with a portion of the anodizing solution. The electrode surface was not allowed to come into direct contact with the atmosphere after the etch step had been completed. Anodic brightening (18-20) of the vanadium metal surface occurred when anodization was attempted in a 95% ethanol-borax solution.

*Apparatus.*—The solvents, glacial acetic acid, ethanol, and glycerol, each containing either borax, sodium acetate, or lithium nitrate were tried as anodizing solutions to determine if they would support the growth of an anodic film on vanadium. Only electrolyte solutions of acetic acid, containing water, supported the growth of an anodic film. Anodic polarization of vanadium in solutions composed of other solvents resulted in dissolution of tetravalent vanadium. An anodizing solution in which a small fraction of the anodic oxidation product underwent dissolution during film growth and in which nonhomogeneous field effects (due to the low conductivity of the solution) were absent was desired. These requirements were met when an acetic acid solution 2.0M in water and 0.020M in  $\text{Na}_2\text{B}_4\text{O}_7$  was used. The conductivity of this solution was 79 micro-(ohm-cm)<sup>-1</sup>. In order that the conductivity of the hygroscopic acetic acid solution would not change significantly during the course of film growth, an anodization cell was constructed which would effectively isolate the anodizing solution from the atmosphere (Fig. 1). For at least 5 min prior to and during film growth the anodizing solution in the cell was purged with nitrogen through a glass frit at a rate sufficient to produce stirring action. The nitrogen was bubbled through traps containing about 100 ml of the anodizing solution prior to and on leaving the anodization cell. The cell was kept in a constant temperature bath. Liquid platinum paint obtained from Englehard Industries, Inc., Liquid Gold Division, was used to make the working cathode and the reference electrodes, as well as the electrical connection for both to the external circuit.

A constant formation current was maintained through the changing resistive load by using a current limiting resistor, together with a gas tube in series with a Keithley Model 241 calibrated high voltage power supply. The current through the circuit was calculated after measuring the potential across a standard resistance with a Leeds and Northrup potentiometer. The potential of the anode with respect to the platinum reference was measured with a Keithley Model 621R electrometer, the output of which was fed into a recorder. Constant current film growth was studied as a function of the apparent current density (100-1014  $\mu\text{a}/\text{cm}^2$ ), electrode separation and temperature (20°-45°C). A Sorensen Nobatron Model 300B power supply was used as a source of voltage for constant voltage film growth. For constant voltage film

Fig. 1. Anodization cell

growth, a small separation (1 mm) was maintained between the vanadium anode and the platinum cathode in order to minimize the solution voltage drop. Films were grown to various formation voltages and then dissolved and analyzed for total vanadium.

**Analytical.**—The amount of vanadium present in a sample was determined using the colorimetric method of Talvite (8) in a slightly modified form. The method involved complexing pentavalent vanadium with 8-hydroxyquinoline in a chloroform medium. The following modifications were incorporated: (a) the film was quantitatively dissolved by immersing the electrode for 200 sec in distilled water (pH 6.6), (b) the vanadium present was oxidized to the pentavalent state with potassium peroxydisulfate, and (c) acetate ion in the sample was destroyed. A 200 sec immersion time was found experimentally to be sufficient to remove completely even the thickest film and make

negligible any contribution due to further oxidation and dissolution of the electrode. Vanadium was not detected after immersing a freshly prepared vanadium electrode in distilled water for 200 sec. The vanadium (IV) ion was oxidized to the pentavalent state with a 1% potassium peroxydisulfate solution. The excess  $S_2O_8^{2-}$  was destroyed by boiling the solution. Acetate ion interfered with the analysis in that it hindered rapid development of the vanadium-8-hydroxyquinoline complex. Therefore, the acetate was destroyed prior to complexing by evaporating a nitric acid solution of the vanadium ion to dryness. Pentavalent vanadium ion was quantitatively extracted from the aqueous phthalate buffered (pH 4.0) solution by complexing it with a 0.5% 8-hydroxyquinoline in a chloroform solution that was free of alcohol. The per cent transmittance was measured at 5500Å in a Beckman DU spectrophotometer. The solution followed Beer's law between 1 and 50  $\mu\text{g}$  of vanadium per milliliter of chloroform solution. The extinction coefficient was  $6.96 \times 10^4 \text{ cm}^3/\mu\text{g}$ .

**Identification of the anodic film.**—A study was made to determine the composition of the anodic film. Since the electrolysis was performed in acetic acid, the possibility existed that the film was vanadyl acetate. X-ray diffraction patterns were obtained to (a) determine whether the film was crystalline, and (b) identify the anodic oxidation product. The diffraction patterns were obtained using a Debye-Hull-Scherrer diffraction camera and a General Electric Model X-RD-6 x-ray diffraction apparatus. Copper  $K\alpha$  radiation was used. The plate voltage on the copper target was 40 kv. The plate current was 20 ma. Copper  $K\beta$  radiation was effectively removed by passing the diffracted radiation through a strip of nickel foil. Samples were usually rotated for periods of 1½ hr while exposed to radiation. Determination of the crystal structure of the anodic film was attempted three ways: (a) scraping a portion of the anodic film and running it in a quartz capillary, (b) *in situ* diffraction of an anodic film on a thin piece of vanadium wire, and (c) *in situ* diffraction of an anodic film on vanadium foil. During sample preparation and irradiation an inert ambient was maintained around the sample by purging a polyethylene bag around the camera with helium. The diffraction results are shown in Table I. Most of the lines were due to the vanadium metal substrate. However, seven very weak lines were obtained for higher formation voltage films which did not match any of the vanadium oxide or oxyhydroxide com-

pounds reported in the literature (9-11). The observed structure is attributed to regions of the film which are in a pseudo-ordered state. The line intensity indicates the structure is short range.

Attenuated Total Reflectance (ATR) spectra of the anodic films were obtained with a Perkin-Elmer Model 337 double beam, recording spectrophotometer in the spectral region 4000 to 400  $\text{cm}^{-1}$ . It was equipped with a Model 12 double beam internal reflection attachment supplied by Wilks Scientific Corporation, South Norwalk, Connecticut. The films were grown to formation voltages between 1 and 75v. On completion of film growth, the film was removed from the anodizing solution in a nitrogen atmosphere, thoroughly wiped with a Kimwipe, and dried in a stream of warm nitrogen. The spectrum was then run using standard procedures (12) on a ThBr-ThI plate (refractive index = 2.5). The complete infrared spectrum of a 50v film between 4000 and 400  $\text{cm}^{-1}$  is shown in Fig. 2. Newly grown anodic films were found to dissolve readily in distilled water. However, if the film was stored for a few days in a nitrogen atmosphere and then immersed in distilled water, it dissolved very slowly. The ATR spectrum of an aged film was found to be featureless (Fig. 3) in the spectral region 4000 to 400  $\text{cm}^{-1}$  with the exception of two bands at 1015 and 975  $\text{cm}^{-1}$ . Comparison of an ATR spectrum of the anodizing solution (Fig. 4) with those of freshly prepared and aged films shows that the structure in Fig. 2, except for the bands at 1015 and 975  $\text{cm}^{-1}$  is due to components of the anodizing solution, principally acetic acid monomer (13) and dimer (14-16), incorporated into the freshly prepared film. For band identification purposes the infrared transmission spectra of the vanadium oxides, obtained from Alpha Inorganics Co., was further substantiated from x-ray diffraction data. Comparison of the spectra shows a good match be-

tween the ATR spectra of the anodic film and the pellet spectra of  $\text{V}_2\text{O}_4$ . An interesting region in the anodic film spectra occurs at frequencies below 975  $\text{cm}^{-1}$  where the continued increase in absorbance of light with wavelength is probably due to absorption by the vanadium metal (12, 17) substrate. A linear increase in film penetration with wavelength is expected.

Electron Paramagnetic Resonance (EPR) spectra of dissolved anodic films contained the well-known signal of the vanadyl ion. A Varian dual-channel paramagnetic resonance spectrophotometer Model 4500 with a  $\text{TE}_{104}$  mode dual cavity was used for the 9.5 kilomegacycles/sec resonance absorption measurements. The magnetic field was controlled by a Fieldial regulator V-FR-2100. 1,1-Diphenylpicrylhydrazyl (DPPH) was used as a standard for "g" measurements as well as an internal standard for determining the concentration of paramagnetic species in a given sample. EPR spectra were obtained for anodic films which were dissolved into an aqueous 0.1M sulfate-bisulfate buffer solution, pH 1.9. The buffer solution was purged with nitrogen for 10 hr to remove all oxygen prior to use. A given film was grown to a desired voltage and on completion of growth the electrode was dried in a nitrogen atmosphere and dissolved in a known volume of buffer solution. A portion of this solution was drawn up by capillary action into each of three capillary tubes and the tubes sealed using a small flame. The solution was kept in the center of the tube until the sealing step had been completed in order to prevent solution evaporation and vanadium oxidation. Standard solutions of vanadyl ion were prepared from vanadyl sulfate,  $\text{VOSO}_4 \cdot x\text{H}_2\text{O}$ . A calibration curve (peak height vs. vanadyl ion concentration) was prepared. The concentration of paramagnetic ions in a sample containing a dissolved anodic film was obtained by comparing the peak height in its EPR spectrum with the calibration curve prepared from the standard vanadyl ion solutions. Knowledge of the volume of buffer used to dissolve the anodic film together with the concentration enable calculation of the total vanadyl ion to be performed. The spectra were identified as those of the vanadyl ion by comparing the g-values obtained from an EPR spectrum of a known vanadyl solution ( $g = 2.0021$ ) with that of the dissolved film. The total amount of vanadyl ion in a given sample was determined as a function of the formation voltage. The dependence was linear. The slope was 0.0178  $\mu\text{moles}$  of vanadyl ion per square centimeter per formation volt.

Fig. 5. Transmission spectra of known vanadium oxides in a KBr matrix between 1100 and 800  $\text{cm}^{-1}$ .

Fig. 6. Constant current growth curves at 25°C for various formation current densities.

**Constant current film growth.**—The growth curves obtained at 25.0°C using various formation current densities and an anode-working cathode separation of 8 mm are shown in Fig. 6. The growth curves obtained when using the painted platinum strip as the reference electrode were identical to those obtained when a saturated calomel Luggin-capillary reference electrode was used. However, the rest potential of the vanadium anode with respect to the platinum strip and the calomel reference electrode was found to be  $-0.12$  and  $0.14$ v, respectively, and invariant with time. Apparently the exchange current density across the platinum strip was sufficient to enable it to assume a stable potential. There are three regions of interest on a given constant current growth curve, *viz.*, (I) the initial transient and film growth below (II) and above (III) the transition point (T.P.). The intersection of an extension of the two straight line portions of the constant current growth curve was designated the transition point. When film growth commenced, the anode potential increased sharply from its zero current value. The initial transient, which was linearly dependent on the growth current density and the anode-cathode separation, was attributed to the ohmic voltage drop across the anodizing solution. The effect of polarization on the double layer, *i.e.*, initial charging of the double layer, was considered minimal. After the initial transient, the potential of the anode slowly increased (region II) in a linear fashion with time due to the growth of the film. Unless the specific resistance of the newly formed layers of the anodic film is changing, the slope of the growth curve is proportional to the rate of film growth. After a time, the slope of the growth curve increased and remained at this higher value (region III) until film breakdown commenced.

The total charge passed to reach the transition point was a function of the apparent current density, increasing linearly with decreasing formation current density. Below  $600 \mu\text{A}/\text{cm}^2$  however, large increases in the charge required to reach the transition point were found. An analysis of the anodizing solution for vanadium showed that vanadium was dissolving during the course of film growth when the potential of the anode was less than the transition potential. The formation voltage was obtained by subtracting the initial transient from the potential of the anode when film growth was stopped. Vanadium was detected colorimetrically in the greenish-blue anodizing solution. The fraction of the anodic oxidation product dissolving decreased with increasing formation current density (Table II). The second linear slope of the con-

\* Anode-working cathode separation, 8 mm.

stant current growth curve (region III) was found to depend linearly on the formation current density (Fig. 7). A determination of the fraction of oxidized vanadium dissolving after the transition point was made. A vanadium electrode was anodized at  $555 \mu\text{A}/\text{cm}^2$  to a formation voltage of 20v. Then the anodization cell was cleaned, fresh anodizing solution added, and the electrode further anodized to a formation voltage of 100v over a period of 15 min. Afterward, the anodizing solution was analyzed for vanadium; however, none was found. Similar results were obtained when the process was repeated using other formation current densities.

The apparent oxidation state of anodically oxidized vanadium, defined as the ratio of the number of Faradays passed to grow the film to the number of moles of vanadium found in the film, was calculated. The average oxidation state of a vanadium ion in the film was  $4.00 \pm 0.06$  (Table III). The apparent oxidation state was neither a function of the formation voltage nor of the formation current density. Gas evolution at the anode was not observed. An anodic film could not be grown at 25.0°C if the formation current density was less than about  $450 \mu\text{A}/\text{cm}^2$ . Below this value the potential of the anode did not increase beyond about 1v. Film growth was found to be increasingly difficult at higher temperatures. In general, the minimal current density required to grow a film increased with increasing temperature. Film growth above 45°C was not possible using a formation current density of  $900 \mu\text{A}/\text{cm}^2$ .

During film growth under constant current conditions, the potential of the anode increased until a certain film thickness was attained. At that potential, film breakdown began. The formation voltage to which a film could be grown before film breakdown occurred was found to depend markedly on the quantity of water in the anodizing solution. Specifically, for sodium borate-acetic acid solutions five and two molar

in water, films could be grown to 25 and 110v, respectively. The dependence of the film breakdown potential on the amount of water in the anodizing solution is quite striking.

**Constant voltage film growth.**—Anodic films were grown under constant voltage conditions to various formation voltages. In all constant voltage work the anode-working cathode separation was 1 mm. A typical constant voltage growth curve is shown in Fig. 8. The initially large current density across the electrode surface as film growth commenced decreased rapidly until it reached a limiting value of  $0.15 \text{ ma}/\text{cm}^2$ . The optical thickness of the film was recorded (Table IV) and the amount of vanadium anodically oxidized in a film of given formation voltage determined colorimetrically. The dependence of the amount of vanadium anodically oxidized on the formation voltage was found. A least squares determination for the linear relationship was found to be  $0.0170 \mu\text{moles}$  of vanadium per square centimeter per formation volt.

### Discussion of Results

**Oxidation state of the vanadium in the film.**—Within experimental error, the apparent oxidation state of the vanadium in the anodic film,  $4.00 \pm 0.06$ , was invariant with the formation voltage and the formation current density. The significance of the result is that the oxidation state of the oxidized vanadium is not a function of the potential of the substrate vanadium. This result sets the maximum oxidation state for the vanadium in the anodic film, but does not identify the film as vanadium (IV) because part of the charge

passed could be producing gas at the anode. Gas evolution at the anode was not observed and as we shall see did not, in fact, occur.

The significance of the EPR results is that the dependence of the amount of vanadyl ion on the formation voltage was experimentally found to be  $0.0178 \mu\text{moles}/\text{cm}^2/\text{formation volt}$  and that this quantity was equal, within experimental error, to the dependence of the total amount of vanadium in the anodic film on the formation voltage, i.e.,  $0.0170 \mu\text{moles}/\text{cm}^2/\text{formation volt}$ . This data, together with the fact that the apparent oxidation state was 4.0, shows the anodization process is 100% efficient in the production of tetravalent vanadium. If the anodic oxidation product were composed of a vanadium(II) species, when dissolved, the vanadium ion would reduce water and go to the trivalent state. Further oxidation, i.e., oxidation of vanadium(III) ion would not be thermodynamically favored in the absence of dissolved oxygen in the solution. Experimentally, an EPR signal was not observed when stock solutions of either pentavalent or trivalent vanadium ion in the buffer solution were treated similarly. The anodic oxidation product was further identified by comparing the transmission spectra of the known vanadium oxides in a KBr matrix with the ATR spectra of anodic films. Comparison showed the anodic film was  $\text{V}_2\text{O}_4$  and that no vanadium(V) oxide was present in the film. The facts that: (a) the anodic film dissolved to form the paramagnetic  $\text{VO}^{2+}$  ion, (b) the ATR spectra of the anodic films matched that of  $\text{V}_2\text{O}_4$ , (c) the apparent oxidation state of the vanadium in the film was 4.0 and invariant with formation voltage, (d) the dependence of the paramagnetic vanadyl ion was equal to the dependence of the total vanadium on formation voltage, and (e) gas evolution at the anode was not observed, permits conclusive identification of the anodic oxidation product as  $\text{V}_2\text{O}_4$ . Oxygen for the anodic film was most likely provided by the water in the anodizing solution because an anodic film could not be formed on the vanadium unless water was present, regardless of the formation current density or the voltage applied to the anode. Lack of oxygen evolution in the acetic acid solutions might be due in part to the low activity of water in the anodizing solutions as a result of strong interactions (25-27) between water and acetate ion. The role of water in the film growth process is under investigation.

The production of vanadium tetroxide as a result of anodic oxidation is not predicted thermodynamically. The available data for vanadium in aqueous media is only approximate when applied to this work. However the  $E_h$ -pH diagram of Pourbaix (28) shows that  $\text{V}_2\text{O}_4$  and  $\text{V}_2\text{O}_3$  are stable in the region of stability of water. The oxidation state which is produced as a result of anodization is dependent on the metal/film interface potential difference (EMF), a parameter which is not measurable in this instance. However, if it were no more than about 0.4v,  $\text{V}_2\text{O}_4$  would be produced.

**Nature of the anodic film.**—The absorption bands in the transmission spectrum of  $\text{V}_2\text{O}_4$  were centered at

1020 and 990  $\text{cm}^{-1}$  while the corresponding bands in the ATR spectra were centered at 1015 and 975  $\text{cm}^{-1}$ . The shift suggests an amorphous film structure. However, in the region of an absorption band the refractive index is not represented well by the Cauchy (21, 22) relationship. Large quantities of electromagnetic energy are dissipated in the vicinity of an absorption band, since a resonance condition exists in which induced dipole moments in the medium are approximately in phase with the electromagnetic field (23). The refractive index of the film was not determined. If the refractive index of the film were close to that of the KRS-5 prism in the region of the absorption, then there is no angle of incidence at which internal reflection can take place and nearly all the energy will pass into the sample. The recorded internal reflection absorption band will be very strong but broadened toward long wavelengths and hence, distorted as compared to that measured by transmission. The degree of crystallinity of the film, therefore, cannot rest solely on the spectral data which is indicative of an amorphous structure. As previously indicated, x-ray diffraction patterns of the anodic films exhibited very weak lines after lengthy exposure to the radiation. These very weak lines also indicate the films are amorphous or very slightly crystalline.

Three pieces of experimental data should now be considered. First, the infrared results (Fig. 2-4) show that the acetic acid, incorporated into the film during film growth, evaporates from the film after a relatively short time. Second, a hump appears on the constant voltage growth curve. Third, the final leakage current density, 0.15  $\text{ma}/\text{cm}^2$ , was 1000 times larger than that found for anodic films formed on some other valve metals (24). The comparative speed with which the acetic acid evaporated suggests it might have been located along channels in the film. The onset of a porous "channel" structure during the early stages of film growth would account for these experimental results.

*Electrochemical kinetic considerations.*—At any time during constant current film growth, the film thickness,  $D_f$ , is given by the expression

$$D_f = D_f^0 + Bt \quad [1]$$

where  $D_f^0$  (cm) is the film thickness prior to anodization (here  $D_f^0 = 0$ ),  $B$  is the film growth rate, in centimeters per second, and  $t$  is the time of film growth. Here  $B$  is given by

$$B = \frac{dD}{dt} = \frac{iM}{nFS} \quad [2]$$

where  $M$  is the molecular weight,  $n$  is the electrode reaction valence,  $S$  is the density of the film, and  $i$  is the apparent formation current density. The film thickness and potential rate of increase is related by

$$\frac{iM}{nFS} = \frac{1}{E} \frac{dV}{dt} \quad [3]$$

where  $E$  is the field strength and  $V$  is the potential of the vanadium electrode with respect to the reference. The film growth rate dependence on the apparent formation current density is plotted in Fig. 7. The

dependence is linear. For constant current growth, a linear dependence of the growth rate on the current density necessitates that the field be constant over the range of current densities investigated. The electrostatic field across the anodic film was calculated for a given growth rate and apparent current density using Eq. [3], and a density of 4.34  $\text{g}/\text{cm}^3$  for the anodic film. The calculated field was constant within experimental error. The average field was  $3.2 \pm 0.2 \times 10^6 \text{v}/\text{cm}$ .

Manuscript received Sept. 28, 1967; revised manuscript received Jan. 16, 1968. This work was done in partial fulfillment of the requirements for the Ph.D. degree at Temple University.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Electric Conduction through Thin Insulating Langmuir Film

Shiro Horiuchi,<sup>1</sup> Jiro Yamaguchi, and Kiyooki Naito

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka, Japan

## ABSTRACT

Electric conduction through calcium stearate Langmuir films of several monomolecular layers has been studied. The devices are prepared by transferring monolayers of stearic acid spread on an aqueous surface to an evaporated tin electrode on a glass substrate and evaporating the upper electrode. Tunnel emission is observed when the aluminum upper electrode is negatively biased and Schottky emission is observed when the lower electrode is negatively biased. The trapezoidal energy barrier model of Simmons adequately accounts for the details of current-voltage-temperature characteristics. The observed barrier height at the stearate and tin interface is 0.8 eV and that at the stearate and aluminum interface is 1.3 eV.

There has been a considerable revival of interest in electrical conduction through thin film insulator, since Mead proposed the "hot" electron devices which operated with hot electrons injected through thin (100Å) insulating film by quantum mechanical tunneling (1).

In order to inject hot electrons with good efficiency and controllability, such a film must be thin, homogeneous, uniform in thickness, and have excellent dielectric properties. Most of experimental studies on the electron transport through thin insulating films sandwiched between metals have been made on oxide grown on base electrode metals because of their uniformity and compactness. Mechanisms such as tunneling (2, 3), Schottky emission (4), field and thermal ionization of traps and impurities (5), etc. have been proposed to explain the observed characteristics.

However, it is known that Langmuir films of certain organic materials behave as good insulators and are easily obtained using the classical process developed by Langmuir and Blodgett (6, 7). It appeared to be an attractive problem to employ these monolayers as an insulating barrier between metal electrodes, because the metal-insulator-metal sandwich would have a definite barrier thickness predicted by the length of a molecule and number of monomolecular layers.

A pioneering and extensive study on Ba and Ca stearate monolayers has been made by Handy and Scala, and their results show promising properties of the Langmuir films as an insulating barrier for the observations of electron tunneling phenomena (8). The metal-insulator-metal sandwich prepared by them exhibited highly nonlinear and thickness-dependent voltage-current characteristics. However, the barrier heights at the electrodes and the explanation of the observed temperature dependence were not given.

It is the purpose of this paper to give details of the voltage and temperature dependences of the current through the calcium stearate monomolecular films sandwiched between aluminum and tin electrodes.

## Experimental Procedures

Metal-insulator-metal structure were fabricated as follows. Monomolecular films were deposited on evaporated tin films on a microscope slide using the Langmuir-Blodgett technique. A 0.005 mol solution of calcium carbonate or barium chloride in deionized water was brought to pH 9 by hydrochloric acid for the flotation medium. Oleic acid was used as the piston oil. Transfer was performed at 0.2-2.0 cm/sec. Counter electrodes of tin or aluminum were used to give junctions in the order of 1 mm<sup>2</sup>.

Capacitance measurement at 1 kc was made on all junctions prior to the V-I characteristic measure-

ment in order to check incompletely insulating junctions which had ohmic characteristics. Capacitance values of good junctions on a slide glass showed fairly good agreement with each other, but the scatter from slide to slide was up by a factor of 2. Capacitance of a junction with 29 layers of monomolecular film was also measured as a function of frequency. It was independent of frequency over the range of 1 kc to 1 Mc. The dielectric constant was calculated from the capacitance using the stearate monomolecular layer thickness of  $\approx 24\text{Å}$ . It was estimated to be 2.5 which is in agreement with bulk value and was used to estimate image potential in the analysis of experimental results.

Current voltage characteristics of the junctions were obtained with d-c voltage at temperatures from 200° to 350°K. When a constant voltage was applied, a large amount of transient current was observed, which decayed approximately in proportion to  $1/t$ . The transient current was proportional to applied voltage, while the steady-state current increased exponentially with increasing voltage. Plots of V-I characteristics were made with the steady state values.

## Results and Discussion

Figure 1 shows a typical result of the V-I characteristics observed in the Al-Ca stearate-Sn junction. When the lower tin metal electrode is negatively biased, the observed current,  $I_1$  is strongly temperature-dependent above 200°K but nearly independent

Fig. 1a. Plot of  $I_1$  and  $I_2$  vs.  $V$  for the Sn-Ca stearate (3 monomolecular layer)-Al junction (with 3 layers of insulating monomolecular film). Black dots and white circles indicate  $I_2$  and  $I_1$ , respectively.

Key words: Conduction through Thin Langmuir films.

Fig. 1b. Plot of  $I_1$  and  $I_2$  vs.  $1/T$  for the Sn-Ca stearate junction

on the temperature below 200°K. In contrast to  $I_1$ , the current  $I_2$  which was observed when the upper aluminum electrode was negatively biased, is independent of temperature in the temperature range studied. Similar characteristics were observed for Al-Ba stearate-Sn junctions. The presence of a temperature-dependent current  $I_1$  and a temperature independent current,  $I_2$  in the same junction suggests that more than one mechanism of electron transfer is operative.

In contrast to these asymmetric junctions, the Sn-Ca stearate-Sn junction showed symmetrical V-I characteristics to the polarity of applied voltage as shown in Fig. 6. The dependence on electrode material suggests that the dominating conduction mechanisms would be barrier limited.

It is well known that the rate limiting mechanism of electron transfer through extremely thin insulating films will be tunneling emission and Schottky emission. Trapezoidal barrier models have been used by Pollack *et al.* to explain the observed V-I characteristics with tunnel and Schottky emissions (9, 10). A similar model is proposed here for the Al-stearate-Sn sandwich system. Simmons has derived the expressions for the thermionic emission (11) and tunnel emission (12) between dissimilar electrodes including the effect of image potential.

The results of Schottky emission can be summarized by the following relations for the trapezoidal barrier shown in Fig. 2.

$$J_1 = AT^2 \exp \left( -\frac{\phi_1}{kT} + \frac{\{14.4[7 + Ks(eV - \Delta\phi)]\}^{1/2}}{kTKs} \right) \quad [1]$$

$$J_2 = AT^2 \exp \left( -\frac{\phi_1}{kT} - \frac{\{14.4[7 + Ks(eV + \Delta\phi)]\}^{1/2}}{kT \cdot Ks} \right) \quad [2]$$

where  $\phi_1$  and  $\phi_2$  are barrier heights between metals and an insulator and  $\Delta\phi_1 = \phi_2 - \phi_1$  ( $\phi_2 > \phi_1$ ),  $s$  is the insulator thickness, and  $K$  is the specific dielectric constant.  $J_1$  and  $J_2$  are the net current flowing in the system when the electrode of lower work function is negatively and positively biased, respectively. From these equations, it is easily seen that Schottky emission will be observed at room temperature when the electrode of the lower barrier height is negatively biased, if the lower barrier height,  $\phi_1$  is 1 eV or less. However, the thermionic emission is hardly observed when the electrode of lower work function is positively biased because the ratio  $J_1/J_2$  is as large as  $10^8$ , if  $\Delta\phi$  is 0.5 eV.

Fig. 2. Trapezoidal energy barrier. Direction of arrows labeled with  $J_1$ ,  $J_2$  indicates that of net electron flow when the lower electrode is negatively and positively biased, respectively.

From the results shown in Fig. 1, only a tunneling process is assumed for  $I_2$ . A Fowler-Nordheim plot of  $I$  at 200°K gave a straight line above  $1/V = 1.2$  ( $v^{-1}$ ). In Fig. 3, a theoretical curve for  $J_2$  obtained by calculation based on Simmons' equations using a dielectric constant of 2.5 is shown together with the experimental values. A reasonable fit can be obtained with the assumed barrier parameters of  $\phi_1 = 0.8$  eV,  $\Delta\phi = 0.5$  eV, and  $s = 23\text{\AA}$ . However, in order to obtain the fit shown here, the effective area of the samples was adjusted to values between  $10^{-8}$  and  $10^{-10}$  of the geometrical area. The assumed barrier heights  $\phi_1 = 0.8$  eV and  $\phi_2 = 1.3$  eV are in good agreement with those obtained from the Schottky plots of  $I_1$  as shown later, but the thickness of barrier for electron tunneling is much smaller than that predicted from the number of transferred layers and estimated from capacitance measurement. The relatively low barrier height of  $\phi_1$  suggests Schottky emission over the barrier. It is considered that the temperature dependence of  $I_1$  shown in Fig. 1b consists of Schottky component  $I^*_1$  and temperature independent component  $I_{10}$ .  $I^*_1$  was obtained by reducing  $I_{10}$ , current values at the lowest temperature from  $I_1$ . Examination of Eq. [1] suggests a plot of  $\ln I^*_1$  vs.  $(eV - \Delta\phi)^{1/2}$  as shown in Fig. 4 with  $\Delta\phi = 0.5$  eV and  $T = 268^\circ\text{K}$ . From the slope and Eq. [1], we obtain  $Ks = 170\text{\AA}$ . The barrier thickness,  $68\text{\AA}$  obtained by dividing  $Ks$  with  $K = 2.5$  is not far from the value,  $75\text{\AA}$  predicted from the number of transferred monomolecular layers.

Fig. 3. Plot of  $I_2$  vs.  $V$  for sample CA-1 at 200°K. Solid curve is a fit of  $I_2$  to Simmons' tunneling equation assuming  $s = 23\text{\AA}$ ,  $K = 2.5$ ,  $\phi_1 = 0.8$  eV, and  $\Delta\phi = 0.5$  eV.

Fig. 4. Plot of  $I_1^*$  vs.  $(eV - \Delta\phi)^{1/2}$  for sample CA-1 at 268°K with  $\Delta\phi = 0.5$  eV.

Equation [1] also suggests the plot of  $\ln(I_1^*/T^2)$  vs.  $1/T$  at constant applied voltage as indicated in Fig. 5. From the slope,  $\phi_1$  is calculated to 0.78 eV by using  $K_s = 170\text{\AA}$ . This value is in good agreement with the value of  $\phi_1$  determined from the voltage dependence of tunnel current  $I_2$ .

In Fig. 6, V-I characteristics and its temperature dependence of the Sn-Ca stearate-Sn junction are shown. A marked difference of the characteristic from that shown in Fig. 1 is the symmetrical characteristic to the polarity of applied voltage. For the case of the Sn-Ca stearate-Sn junction, barrier heights at the metal-stearate interfaces are the same for both the upper and lower electrodes, and a rectangular barrier model will be applicable. By the use of Simmons' tunneling equations for similar electrodes (13), a reasonable fit to the experimental plots is obtained with  $\phi (= \phi_1 = \phi_2) = 0.8$  eV,  $s = 44\text{\AA}$  and  $K = 2.5$ . Barrier height at the Sn-Ca stearate interfaces is in agreement with the corresponding one of the trapezoidal barrier for the Al-stearate-Sn junction. However, analysis of temperature dependent current at higher temperature was not successful. Currents at higher temperature were unstable and could not be used to obtain reliable temperature dependence. A similar analysis to Fig. 5 gave a smaller thermal barrier height of 0.5 eV. These results are summarized in Table I together with the data obtained on the Al-Ba stearate-Sn junction.

Fig. 5. Plot of  $I_1^*/T^2$  vs.  $1/T$  for sample CA-1 at 1.4v

Fig. 6a. Plot of  $I_1$  and  $I_2$  vs.  $V$  for the Sn-Ca stearate-Sn junction. White circles and black dots indicate  $I_1$  and  $I_2$ , respectively. Solid curve in the Fig. 6a is a fit of  $I_2$  to Simmons' equation assuming  $s = 44\text{\AA}$ ,  $K = 2.5$ , and  $\Delta\phi = 0.8$  eV.

Fig. 6b. Plot of  $I_1$  and  $I_2$  vs.  $1/T$  for the Sn-Ca stearate-Sn junction.

Consequently, it has been shown that the temperature and voltage dependence of the current satisfies the Schottky emission mechanism and that the voltage dependence of the low-temperature current is as predicted by tunneling. Barrier heights between the stearate and aluminum and tin obtained by the above analysis are self-consistent and 1.3 and 0.8 eV, respectively.

However, there are two problems remaining in the analysis. One is the difference of barrier thicknesses determined from tunneling current and Schottky current. The other is the barrier height difference of  $\phi_1$  and  $\phi_2$ . As shown in Table I, the barrier thickness obtained from the Schottky current is in reasonable agreement with the value predicted from the number of transferred layers by assuming the length of cal-

Table I. Barrier parameters obtained from analysis based on tunnel and Schottky emission mechanisms

Sample No.	Construction of junction	Number of layers	Predicted thickness of insulator, Å	Tunnel ( $I_2$ )			Schottky ( $I_1^*$ )		
				$\phi_1$ (ev)	$\phi_2$ (ev)	s (Å)	$\phi_1$ (ev)	$\phi_2$ (ev)	s (Å)
CA-1	Sn-Ca stearate-Al	3	71.4	0.8	1.3	23	0.78	1.28	68
BA-3	Sn-Ba stearate-Al	3	71.4	0.8	1.3	22	0.79	1.29	84
C-20	Sn-Ca stearate-Al	4	94.2	0.8	0.8	44	0.5	0.5	—

cium stearate molecule to be 23.8Å (14), while the barrier thickness obtained from the barrier parameters which showed the best fit to the experimental plots of tunneling current disagreed with the former value. This is not surprising. Even for the sample with multistearate layers with which we believe complete coverage has been attained, there will be significant local inhomogeneity in thickness. If there are voids or pin holes in the transferred monolayers, some of them in the outer layers will be filled with metal when the upper electrode is evaporated. Most of the tunneling current will pass through such voids as tunneling emission is more strongly dependent on the barrier thickness than Schottky emission. The fact that the effective area to fit the experimental values of  $I_2$  to the calculated current density is small by a factor of  $10^{-8} \sim 10^{-10}$  seems to support the presence of such conduction patches.

The barrier height determined from the above analysis indicates that the work function of tin is smaller than that of aluminum. This is in contradiction with the values of work functions given by Michaelson (15). However, through use of published values of barrier heights between several kinds of metals and semiconductors, Geppert *et al.* derived preferred values of work functions (16). According to their values, the work function of tin is 0.15 ev lower than that of aluminum, but the difference is not large enough to explain our experimental value, i.e.,  $\Delta\phi = 0.5$  ev.

Another possible cause of the higher barrier height at aluminum electrode is a thin oxide layer at the interface. When tin is coated with calcium or barium stearate, a certain amount of water is entrapped either at the tin surface or in the stearate layers. Deposition

of aluminum forms an active layer which is capable of reacting with trapped water and forming at the aluminum-stearate interface a layer of oxide limited to perhaps one or two atom layers in depth. The aluminum-aluminum oxide barrier is known to be about 1.5 ev, and the effect of image force lowering for such a thin layer would reduce apparent barrier height to the observed value. The barrier diagram for the case would be as shown in Fig. 7 by assuming no trapped charge at the interfaces. However, the current predicted by the model shown in Fig. 7 increases very steeply with increasing voltage, if the thickness of the stearate is assumed to be equal to that obtained from the slope of  $\ln I_1^*$  vs.  $V^{1/2}$ . As a result, conduction patches with thinner effective barrier thickness must be taken into consideration in order to interpret the experimental results. Measurements on the Au-Ca stearate-Sn junctions were tried in order to avoid possible formation of aluminum oxide but were not successful because all the samples prepared showed ohmic characteristics with very small resistance. These problems, therefore, have not been resolved by the present investigation.

#### Acknowledgment

The authors are grateful to Mr. O. Sueta for the set up of the apparatus for layer transfer and the preliminary experimental measurements. The assistance of Mr. O. Furuya is also acknowledged.

# Red Electroluminescent (Zn, Cd)(S, Se)-Type Phosphors

T. Hariu, T. Seki, K. Miyashita, and M. Wada

Department of Electronic Engineering, Tohoku University, Sendai, Japan

## ABSTRACT

Red light emitting electroluminescent phosphors in the (Zn,Cd)(S,Se):Cu system were investigated. The best red electroluminescent phosphor is obtained by firing (0.9Zn,0.1Cd)(0.1S,0.9Se) adding Cu,  $5 \times 10^{-3}$  g-atom/mole and the same coactivator concentration at  $1000^\circ \sim 1100^\circ\text{C}$ . Electroluminescent and photoluminescent properties of phosphors of various composition were interpreted by curves illustrating the energy level variation with composition in solid solution, which is obtained by considering nearest-neighbor effects, and a temperature quenching factor in electroluminescence. From similar considerations, the variation of luminescent properties of phosphors of given composition, containing given luminescent centers, can be predicted, and the critical frequency of excitation when developing electroluminescent phosphors of a given color is presented.

A (Zn,Cd)(S,Se) system as red light emitting electroluminescent (EL) phosphors has been developed for a part of its composition by Palilla and Baid (1), Matsuo *et al.* (2), Mironov and Markovskii (3), and Kolomoitsev *et al.* (4) in the course of our investigation, and earlier by Hegyi *et al.* (5), Larach *et al.* (6), Gelling *et al.* (7), and others, but it seems that a unified discussion on firing condition and EL properties has not been achieved. For example, the optimum firing condition differs from composition to composition, and parameters involved in EL characteristics vary with composition. Thus a question arises, "how shall we expect the possibility of (Zn,Cd)(S,Se) as long wavelength light emitting phosphors?"

Solid solutions have been extensively prepared recently to change energy gap continuously for the purpose of matching the exciting or the emitting energy. In this system, a knowledge about the impurity energy level variation with composition as well as about the energy gap variation is indispensable, for the former is undoubtedly very sensitive to optical and electrical properties.

In this paper we tried to give a systematic discussion on the above problem, and to give basic considerations on the impurity energy level variation in this system in connection with them.

## Phosphor Preparation

The (Zn,Cd)(S,Se) system has two crystal forms, varying with composition and firing temperature. The brightness variation with composition is sometimes referred to as being the difference in crystal form (7-12). Thus this variation, although a little affected by activator and coactivator, is depicted in Fig. 1 with a sample composition which is expected to emit red light, because of its approximately linear variation of band gap and photoluminescent results.

Cu was added in the form of  $\text{CuSO}_4$ , with selected concentrations of 1.2 and  $5 \times 10^{-3}$  g-atom/mole. Cl was mainly used as coactivator in the form of  $\text{NH}_4\text{Cl}$  with the same concentration as Cu and 5 and 10 m/o (mole per cent) respectively. A mixed powder material containing the above impurity was dried and fired in a nonflowing  $\text{N}_2$  atmosphere at  $900^\circ$ ,  $1000^\circ$ , and  $1100^\circ\text{C}$ .

## Results

The peak wavelength of emission spectral distribution of all samples was about  $680 \text{ m}\mu$ . Figure 2 shows the brightness variation with composition. Because firing conditions have different effects on the phosphors with different host crystal compositions, the maximum value of brightness is also plotted (curve B). A dot on the left side is of a sample obtained by two-step firing (13). Also shown are the measured crystal forms. All the samples have nearly equal equivalent lattice constants  $a_H = 3.99$  and  $c_H = 6.51\text{\AA}$ . A

similar tendency of variation in brightness was observed for phosphors of the same composition containing Cu and Mn as activators.

The optimum concentration of Cu is different with composition: a lower concentration ( $1 \times 10^{-3}$  g-atom/mole) for composition near (Zn,Cd)S, but brighter EL phosphor with composition near ZnSe requiring a higher concentration ( $5 \times 10^{-3}$ ). In the latter phosphor, the concentration of coactivator higher than Cu has a minor effect on EL brightness (up to a few per cent) but makes a breakdown at lower voltage. However, in the former the concentration of coactivator higher than Cu ruins EL brightness, but a decrease in the breakdown voltage was not observed. Higher firing temperature ( $1000^\circ \sim 1100^\circ\text{C}$ ) is good for all compositions.

The frequency dependence variation with composition is shown in Fig. 3. Phosphor that contains more Se as host crystal constituent is characterized by a more superlinear dependence.

The luminescence brightness depends on voltage in accordance with the usually observed law [ $B = B_0 \exp(-c/V^{1/2})$ ]. The variation in c-value with composition is shown in Fig. 4, which indicates a smaller c-value for phosphor with composition near ZnSe.

The brightness variation with time is shown in Fig. 5 with composition as a parameter. This indicates that phosphor with composition near (Zn,Cd)S shows a quick decrease with time. The maintenance of the best phosphor in Fig. 2 is shown in Fig. 6. A similar initial increase in brightness shown in this figure was observed in phosphors of all compositions washed in NaCN aqueous solution.

The photoluminescent emission spectra are shown in Fig. 7. Curve A is an emission spectrum at room

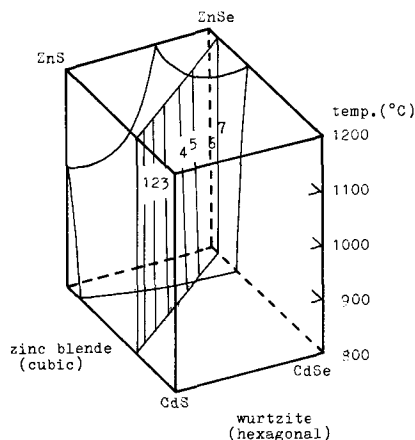

Fig. 1. Crystal structure and investigated composition for red EL phosphor.

Fig. 2. (a, top) Brightness variation with composition; applied voltage 1 kc, 700v; firing temperature 900°C, Cu :  $2 \times 10^{-3}$  g-atom/mole, Cl :  $4 \times 10^{-3}$  g-atom/mole. (b, bottom) Brightness variation with composition (maximum value), applied voltage 1 kc, 700v.

temperature which is common to all compositions with a minor difference. The figure shows that the short wavelength emission band shifts to the shorter wavelength as the composition approaches the ZnSe side.

Figure 8 shows the photoluminescent brightness dependence on temperature, in which it is seen that the luminescence of a phosphor containing more Se was quenched at lower temperature. Phosphors containing a considerable amount of both elements as anion constituent (S and Se) show a slow decay of luminescence with rising temperature, which is not a temperature quenching characteristic of a single band, but a superposed characteristic of some different emission bands characterized by different quenching temperatures. This situation is shown in Fig. 9 using samples of composition No. 5 in Fig. 1, measured with a fixed wavelength scale of the spectrometer.

**Discussion**

*Impurity level variation in solid solution.*—The problem of impurity level variation in (Zn,Cd) (S,Se) solid solution has also been treated by Lehmann (14), based on ionic bonding and the Schoen-Klasen model. The model discussed here is based on the association model, to which were added further aspects relating to impurity level variation.

Fig. 8. Photoluminescent brightness dependence on temperature. Number indicates composition in Fig. 1.

Of the three models for luminescent center; Schoen-Klasen, Lambe-Klick, and association, the last is the most reasonable with  $(\text{Zn,Cd}) (\text{S,Se})$ -type phosphors, for the following reasons:

(A) There are two emission bands (the short and long wavelength band which will be referred to later as band 1 and band 2, respectively) in this type of phosphor activated with Cu and coactivated with halogen or group III elements. The variation in emis-

Fig. 9. Photoluminescent brightness dependence on temperature of composition 5. Wavelength: A-660  $m\mu$ , B-620  $m\mu$ , C-600  $m\mu$ .

sion spectrum with activator and coactivator concentration can be explained by the association model; the lower energy emission band is strong at the activator concentration equal to that of coactivator.

(B) Both emission bands have the same optical quenching spectra, which indicate that the ground states for both bands have the same energy difference from the valence band.

(C) In the EL brightness dependence on voltage [ $B = B_0 \exp(-c/V^{1/2})$ ], both bands have the same  $c$ -value. This fact indicates that excitation energy involved is the same (15)<sup>1</sup>. The latter two discussions have been given by Curie (16).

The basic idea on the impurity level variation is as follows:

*Deep impurity level.*—A wave function of an electron forming a deep impurity level is localized, and in the first approximation the impurity energy level is determined by the impurity ion to which that electron belongs and its nearest neighbors. Thus in the solid solution between crystals to which the same anion belongs, e.g., ZnS and CdS, an energy level of an impurity, a substitute for a cation, does not vary relative to the energy band formed by anions;  $S^{-2}$  in ionic bonding model expressions. On the contrary, if a different anion belongs to this, the situation is different. The impurity level splitting in the latter case was treated by Fonger (17) by using  $\text{Zn}(\text{S,Se})$ .

*Shallow impurity level.*—A wave function of an electron forming a very shallow impurity level is approximated by a hydrogen-like model.

The above ideas lead to a schematic shown in Fig. 10 illustrating the impurity level variation in  $(\text{Zn,Cd}) (\text{S,Se})$  solid solution.

*Discussion of experimental results.*—The energy level variation in the sample composition prepared here is shown in Fig. 11, which is obtained from the vertical section of Fig. 10. The observed variation of emission spectra in Fig. 7 agrees with this; band 1 shifts to a shorter wavelength as the composition approaches ZnSe, while band 2 is almost unvaried.

The variation in quenching characteristics is also explained by the above model, as well as the slow decay in the case of phosphors containing a considerable amount of both anions.

The frequency dependence variation in EL with composition and temperature is explained by considering the temperature quenching factor of EL to be  $[1 + D \exp(-E_c/kT)/f]^{-1}$  (18, 19), ( $E_c$ , the activation energy of temperature quenching),  $E_c$  varying as shown in Fig. 10 and 11.

The variation in emission spectra with frequency and temperature arises from the same effect. That is, at sufficiently low temperature at which quenching oc-

<sup>1</sup> This cannot be a justification of the association model, unless the main excitation is a direct one of luminescent center and not a host excitation.

Fig. 10. Energy level diagram for (Zn, Cd) (S, Se) system

Fig. 11. Schematic energy level diagram for prepared samples

curs in neither band, the emission spectrum variation is not observed except in the change due to cross section of donors, band gap variation, half width variation of emission spectrum, etc. In the temperature region at which quenching occurs, the emission band of the smaller  $E_c$  increases relatively with increasing frequency and falling temperature. Of course, when the emission band which is not due to the delayed recombination, e.g., the Mn band, coexists, the contribution of this band to the emission spectrum variation is to be considered by the same temperature quenching factor as photoluminescence, i.e.,  $[1 + \nu \exp(-E_c/kT)]^{-1}$ . In the latter case the emission spectrum variation with applied voltage is observed to be owing to the differences of the  $c$ -value.

(Zn,Cd)(S,Se) as EL phosphors emitting longer wavelength light.—Red EL phosphors whose composition is near (Zn,Cd)S, made by modified firing technique (20, 13), are superior to those whose composition is near ZnSe, especially under low excitation frequency. The former, however, shows a rapid deterioration, which seems to be due to deep traps because the deteriorated phosphors recover after a day or so without excitation. Further trials, e.g., introducing shallow donors, are expected for improvement.

Under high excitation frequency (a few kilocycles), fairly good red EL phosphors were obtained by using a composition near ZnSe, but the brightness decrease under low frequency excitation is inevitable on account of temperature quenching.

Critical frequencies for application can be determined by defining them as  $f=f_1$  when  $q$  (temperature

Fig. 12. Critical frequencies for application of (Zn, Cd) (S, Se) as EL phosphor. (A) frequency for  $q = 1/2$ , (B) frequency for  $q = 9/10$ .

quenching factor) =  $1/2$  and  $f=f_2$  when  $q \approx 9/10$  [ $(D/f) \exp(-E_c/kT) = 0.1$ ], which are shown in Fig. 12 for room temperature, and  $D=10^8 \text{ sec}^{-1}$  (19), using band 2 (band of higher quenching temperature) and approximating step-like energy level variation with composition by linear variation. This figure indicates the composition to choose of EL phosphors of given color and of given excitation frequency.

#### Acknowledgment

# Fluorescent Properties of Alkaline Earth Aluminates of the Type $MAI_2O_4$ Activated by Divalent Europium

Frank C. Palilla,\* Albert K. Levine,<sup>1</sup> and Maija R. Tomkus

*The Bayside Laboratory, Research Center of  
General Telephone and Electronics Laboratories, Bayside, New York*

## ABSTRACT

The luminescent characteristics of alkaline earth aluminates activated by divalent europium have been investigated. Ultraviolet excitation of these compounds can occur through the host lattice and from the  $4f^7$  ground state to excited states of the  $4f^7$  and  $4f^65d^1$  electronic configurations of divalent europium. The emissions involve  $4f-5d$  transitions as evidenced by the broadness of the spectra, sensitivity to structure, and sensitivity to temperature. Evidence is also presented that the  $Eu^{2+}$  occupies cationic-lattice sites. The performance details of these phosphors in fluorescent lamps are described.

Considerable attention has been devoted recently to the fluorescence of trivalent europium because of the high efficiency of several Eu-activated systems under both cathode ray and ultraviolet excitation and because its relatively simple fluorescence spectrum makes it amenable to theoretical mechanism studies (1). This paper discusses the fluorescence properties of divalent europium with emphasis on its high efficiency as a green and blue emitter when incorporated in certain aluminate lattices. The optical properties of the divalent and trivalent ions of europium differ considerably in several respects, and these differences relate primarily to the degree of interaction with the lattice. Unlike the sharp emission lines obtained from  $Eu^{3+}$ , the emission from  $Eu^{2+}$  is broad and structureless.

Investigations of visible-emitting phosphors based on divalent europium have been reported by a number of workers, dating back to 1934 (2). Attention has also been devoted to the question of the mechanism of the fluorescence process. Freed and Katcoff (3) report that the fluorescence spectrum of  $Eu^{2+}$  in  $EuCl_2$ - $SrCl_2$  solutions consists of broad diffuse bands with an underlying structure that becomes evident at low temperatures. The intense violet-blue fluorescence band which they report has a maximum at 406 nm. Freed and Katcoff furthermore state that the  $Eu^{2+}$  spectrum is particularly sensitive to the crystalline environment. They propose that the principal features of the  $Eu^{2+}$  spectrum are accounted for by the presence, in activated states, of an electron in outer shells (such as  $5d$ ,  $6s$ ,  $6p$ , or the lattice). Butement (4) proposed a similar mechanism for the  $EuCl_2$ - $SrCl_2$  system. The later work of Jenkins and McKeag (5) on europium-activated alkaline earth silicates and the work of McClure and Kiss (6) on rare-earth-activated cubic crystals support this view. Reinfeld and Glasner (7) have recently supplemented the work of previous investigators by a study of the absorption and fluorescence spectra of  $Eu^{+2}$  in alkali halide crystals. The absorption spectrum of  $Eu^{2+}$  contains two broad absorption bands in the ultraviolet, peaking at about 250 and 330 nm, which they too attribute to the  $4f^7 \rightarrow 4f^65d^1$  transition resulting from the splitting of the  $5d$  orbitals by the crystal field. In 1946  $SrAl_2O_4$  was reported as a phosphor host by Froelich (8) who used Mn as an activator. He obtained red fluorescence with long u.v. excitation, but no fluorescence with short u.v. excitation. In 1963 a Belgian patent (9) described broad green emission from this host when activated by europium and synthesized in

a reducing atmosphere. No performance features were discussed, however, nor was a study of the effect of cationic species described.

This paper describes an investigation of the alkaline earth aluminates activated by divalent europium with emphasis on  $SrAl_2O_4:Eu$ . The materials show outstanding response to both long and short u.v. excitation and moderate response to cathode ray excitation. The emission intensity and distribution are shown to be functions of the alkaline earth cationic species. The spectral shifts are attributable to the different crystal field environments of the europium in the various structures obtainable within the  $MO \cdot Al_2O_3$  composition (where  $M = Mg, Ca, Sr, \text{ or } Ba$ ).

## Experimental Procedure

The phosphors are synthesized by dry blending  $MCO_3$  (where  $M = Mg, Ca, Sr, \text{ or } Ba$ ),  $Al_2O_3$ , and  $Eu_2O_3$ , according to the equation

A slight excess of  $Al_2O_3$  is preferable (0.7-0.9 M/Al). A reducing atmosphere of forming gas ( $H_2-N_2$ ),  $H_2$ , or  $NH_3$  is preferred over CO with a firing temperature of  $1200^\circ-1750^\circ C$  for a few hours. When the phosphors are prepared in this manner, a Eu concentration of about 3-5 m/o (mole per cent) for Mg, Sr, and Ba aluminates and 0.1 m/o for  $CaAl_2O_4$  has been found to be optimum, giving products which fluoresce very efficiently under u.v. excitation. X-ray diffraction studies indicate that the major phase present is  $MAI_2O_4$  with some  $Al_2O_3$  in excess. The phosphors tend to decompose in water with a consequent diminution in fluorescence efficiency. X-ray examination shows that one of the decomposition products is  $3MO \cdot Al_2O_3 \cdot 6H_2O$ .

The emission spectra are given in terms of relative energy. This was accomplished by using a NBS 1000w quartz-iodine lamp as an internal reference as described by Avella, Sovers, and Wiggins (10).

## Results and Discussion

The aluminates prepared as described above are well crystallized and the powders produce sharp x-ray patterns. However, the crystalline habit is not well defined. Attempts to obtain uniform particles and a narrow size distribution were unsuccessful. While the structures of Ba and Mg aluminates are known (11), those of Ca and Sr aluminates are still not well characterized (12). The two sites available for incorporating Eu are either the  $Al^{3+}$  sites or the  $M^{2+}$  sites.  $Al^{3+}$  is small (0.50Å) but  $M^{2+}$  ranges in size from 0.65 to 1.35Å. Taking the case of  $Sr^{2+}$ , which is almost

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Richmond College of the City University of New York, Staten Island, New York 10301.

equal in size to  $\text{Eu}^{2+}$  (1.13 to 1.12Å), x-ray diffraction patterns show no crystal lattice distortions supporting the latter site preference ( $\text{Sr}^{2+}$  sites). This, of course, is based on the assumptions that all of the added Eu is incorporated in the crystal lattice and that substitutions up to 8 m/o Eu in a site which would be only slightly distorted by differences in ionic size would show up in the diffraction pattern.

The phosphors, when synthesized in a reducing atmosphere, are greenish in body color. The excitation spectrum of  $\text{SrAl}_2\text{O}_4:\text{Eu}$ , obtained by the method of Eby (13) which corrects for instrumental effects and records excitation spectra in terms of relative efficiency, is presented in Fig. 1. The Mg, Ca, and Ba analogs have closely similar excitation spectra. The strong absorption above 350 nm is consistent with the observed energy level scheme for absorption by  $\text{Eu}^{2+}$  having a  $4f^7$  electronic configuration (14), but the absence of fine structure also indicates absorptions into  $4f^65d^1$  levels which have been lowered by the incorporation of  $\text{Eu}^{2+}$  in a crystalline matrix; the broad absorption that peaks between 240-270 nm is consistent with the energy level scheme for absorption by  $\text{Eu}^{2+}$  having a  $4f^65d^1$  electronic configuration (14); the broad absorption below 200 nm may well represent absorption directly into the host lattice. Since no sharp lines are observed in the emission spectra, the transitions to the ground state must originate in levels of the  $4f^65d^1$  configuration. If absorption occurs into an energy level of the  $4f^7$  configuration above the band or emitting levels of  $4f^65d^1$ , radiationless transition to this latter level occurs prior to the final luminescent transition.

The emission colors range from blue for  $\text{CaAl}_2\text{O}_4:\text{Eu}$  to green for  $\text{SrAl}_2\text{O}_4:\text{Eu}$  with the Mg and Ba analogs peaking at intermediate wavelengths. Figure 2 shows the broad-band character of the emissions, providing evidence that europium is present in the divalent state. The fact that the emissions do not shift in the order of increasing ionic radius of the cation may be due to the different environment about the  $\text{Eu}^{2+}$  in each of the four compounds. The whole spectral range of peaks from 440-520 nm can be obtained by appropriate alkaline earth cationic combinations.

The broadness of the emission band indicates an interaction between the host and the activator which can be attributed to the presence of an excited electron in an outer shell of the  $\text{Eu}^{2+}$  ion. The transitions correspond to  $4f-5d$  transitions. The oscillator strengths of these transitions are orders of magnitude higher than those for the normally weak and shielded  $4f-4f$  transitions of the trivalent Eu ion. The luminescence spectrum of  $\text{Eu}^{2+}$  is also more sensitive to temperature quenching. The luminescence peak of  $\text{SrAl}_2\text{O}_4:\text{Eu}$  at  $-196^\circ\text{C}$  is about 20% more intense than that at room temperature. This result is consistent with the expectation that in luminescent processes involving interaction with the lattice, lattice vibrations which lead to

Fig. 1. Excitation spectrum of  $\text{SrAl}_2\text{O}_4:\text{Eu}$  corrected for instrumental variables.

Fig. 2. Emission spectra of alkaline earth aluminates corrected for instrumental variables.

dissipative interactions are minimized by reduced temperatures. The emission spectrum at liquid  $\text{N}_2$  temperature shows a shoulder on the principal emission, indicating a relatively weak, broad emission band near 450 nm. This does not appear to be lattice emission since no appreciable fluorescence is obtained from the unactivated host material.

Additional evidence that the transitions involved are not confined to the  $4f$  shell of  $\text{Eu}^{2+}$  comes from the excitation spectrum of  $\text{SrAl}_2\text{O}_4:\text{Eu}$ . The feeble excitation band of  $\text{SrAl}_2\text{O}_4$  is broad and peaks at 270 nm; the excitation band of  $\text{SrAl}_2\text{O}_4:\text{Eu}$  is broad and peaks near 350 nm (Fig. 1). The shift in excitation peak indicates that Eu plays the principal role in excitation, while the broadness indicates that this excitation is not restricted to  $4f-4f$  transitions.

Outside of the spectral details described here, there has been little other direct or unambiguous evidence for the presence of divalent europium in this system. A sample of  $\text{SrCl}_2:\text{Eu}$  was prepared, and it was found that the emission consists of a narrow band which peaks at about 410 nm, and which appears to show some structure at liquid  $\text{N}_2$  temperatures. An EPR spectrum, shown in Fig. 3, conclusively established the presence of divalent europium. A similar study was made on  $\text{SrAl}_2\text{O}_4:\text{Eu}$  and  $\text{SrAl}_2\text{O}_4$  and the corresponding traces are shown in Fig. 3b and 3c, respectively. The smeared out band observed in the  $\text{SrAl}_2\text{O}_4:\text{Eu}$  spectrum is real and may be due to  $\text{Eu}^{2+}$ , but the hyperfine structure of  $\text{Eu}^{2+}$  was not observed, even with samples of low activator concentration and more sensitive operating conditions. The hyperfine  $\text{Eu}^{2+}$  structure has, however, been observed with the system  $\text{SrO}\cdot\text{Al}_2\text{O}_3\cdot\text{SiO}_2:\text{Eu}$  (Fig. 3d) which was prepared in an identical manner and which shows the same broad emission characteristics. The inability to observe this ERP structure in  $\text{SrAl}_2\text{O}_4:\text{Eu}$  may be attributed to a site of extremely low symmetry for the  $\text{Eu}^{2+}$ , or even to its presence in more than one site.

It may be significant to note that when the phosphors are prepared in an oxidizing atmosphere, red emission is observed instead of the blue to green emission observed when a reducing atmosphere is used during preparation. It may also be significant that the red and blue to green emission (together with a corresponding

Fig. 3. EPR spectra of (a)  $\text{SrCl}_2:\text{Eu}$ , (b)  $\text{SrO}\cdot\text{Al}_2\text{O}_3:\text{Eu}$ , (c)  $\text{SrO}\cdot\text{Al}_2\text{O}_3$ , and (d)  $\text{SrO}\cdot\text{Al}_2\text{O}_3\cdot\text{SiO}_2:\text{Eu}$ .

white and greenish body color, respectively) is reversible; thus, a phosphor that emits red after refiring in an oxidizing atmosphere will emit green if refired again in a reducing atmosphere. The  $\text{Eu}^{3+}$  emission lines, however, are different depending on whether the phosphor (taking in this case  $\text{SrAl}_2\text{O}_4:\text{Eu}$ ) is fired first in air or first in  $\text{H}_2$  and then air. All the lines present in the latter are also present in the former. The sample fired solely in air, however, has extra emission lines suggesting that the Eu in this case has also been incorporated in a separate phase of  $\text{Al}_2\text{O}_3$  which is present in excess.

Because of their high luminescence efficiency these phosphors are of interest for lighting applications. In this connection it is useful to compare  $\text{SrAl}_2\text{O}_4:\text{Eu}$  with  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  which is commercially used in fluorescent lamps. Both of these phosphors have their emission peak near 520 nm; however, their excitation maxima occur at different wavelengths. At the peak excitation of the aluminate (near 350 nm) the silicate responds only feebly. On the other hand, the intensity of the aluminate emission is 75% of that of the silicate when they are excited at the peak of the latter (254 nm). Additional results were obtained by exciting the phosphors with the total u.v. output of a low-pressure mercury discharge germicidal lamp with dominant emission at 254 nm and a medium pressure S-4 lamp with dominant emission at 365 nm. Brightness readings were obtained by use of a 1P21 photomultiplier in combination with a Wratten 106 filter. The results are presented relative to  $(\text{Zn}_{0.7}\text{Cd}_{0.3})\text{S}:\text{Ag}$ , which also has its emission peak at 520 nm.

	LPMV lamp	MPMV lamp
$(\text{Zn}_{0.7}\text{Cd}_{0.3})\text{S}:\text{Ag}$	100	100
$\text{Zn}_2\text{SiO}_4:\text{Mn}$	310	4
$\text{SrAl}_2\text{O}_4:\text{Eu}$	315	120

In actual fluorescent lamps, where response to the total u.v. radiation from the mercury discharge becomes

significant, the  $\text{SrAl}_2\text{O}_4:\text{Eu}$  exceeds  $\text{Zn}_2\text{SiO}_4:\text{Mn}$  in both lumen output and in maintenance characteristics. For example 40-w lamps containing  $\text{SrAl}_2\text{O}_4:\text{Eu}$  yield 3343 lumens after 117 hr of operation; this level of brightness represents 96.5% of initial lamp output.

The emission of  $\text{SrAl}_2\text{O}_4:\text{Eu}$  is quenched at elevated temperatures. At 300°C the emission intensity is down to about 10% of its room temperature intensity. When the phosphor is allowed to cool, however, the intensity returns to its original level. After prolonged heating at 500°C in air, the reaction is no longer reversible. This is true of all the other alkaline earth aluminates as well.

The phosphors are further characterized by a rapid initial decay followed by a long persistence at a very low light level. Thus the  $\text{SrAl}_2\text{O}_4:\text{Eu}$  phosphor decays to 1/10 of initial brightness in 10  $\mu\text{sec}$  but has a low-level persistence which lasts many seconds. The cathode ray response of the described alkaline earth aluminates is moderate and yields 20-30% of the response from  $(\text{Zn},\text{Cd})\text{S}:\text{Ag}$  cathode ray standards of matching emission color.

#### Acknowledgments

The authors are grateful to J. Ragusin for assistance in the preparation of the samples, to Dr. J. Rosenthal for EPR spectra, to Dr. C. Wiggins for corrected emission spectra, and to Dr. O. Sovers for useful discussions on mechanism. The authors appreciate the assistance of D. Howell in the preparation of this manuscript.

# Anodic Dissolution of Heavily Doped N-Type Ge in Aqueous Solutions

R. Gereth<sup>1</sup> and M. E. Cowher

IBM Watson Research Center, Yorktown Heights, New York

## ABSTRACT

The anodic dissolution of n-type Ge in aqueous solutions is generally assumed to be hole-production-rate limited. Investigations of Ge half-cell reactions, which revealed the significance of the minority carrier density for the dissolution process, have been performed in the past only with lightly doped, n-type Ge electrodes having donor concentrations of less than  $3 \times 10^{16} \text{ cm}^{-3}$ . The present experiments cover the entire resistivity range of available Ge single-crystal material. In the case of heavily doped, n-type Ge with a donor concentration above  $2 \times 10^{18} \text{ cm}^{-3}$ , no evidence of electrolytic current density limitation attributable to a hole deficiency at the semiconductor surface is detected over the voltage range employed between the Ge electrode and the electrolyte. It is suggested that the anodic dissolution of heavily doped, n-type Ge is governed by a conduction band mechanism, *i.e.*,  $\text{Ge} \rightarrow \text{Ge}^{4+} + 4e^-$ , and that, therefore, no holes are required for the dissolution process. This hypothesis is consistent with previous observations that heavily doped, n-type Ge can be electropolished without illumination and with the results of this work showing that the corrosion potential of heavily doped, n-type Ge electrodes cannot be explained on the basis of a minority carrier controlled "quasi-photovoltaic effect."

More than a decade ago Brattain and Garrett (1) published their classical paper, "Experiments on the Interface Between Germanium and an Electrolyte." Following this pioneering work, many other scientists have looked into the dissolution behavior of Ge in aqueous solutions in order to gain new insight into surface effects and to find practical means of preparing mirror-smooth semiconductor surfaces applicable for device fabrication. As a result of these investigations,<sup>2</sup> it is generally assumed that the anodic dissolution of n-type Ge in aqueous solutions requires holes. Consequently, the anodic dissolution of n-type Ge in alkaline solutions is described in the literature (2, 4-7) by the following equation

The parameter  $m$  was found (7) to vary in n-type Ge between 2 and 3.6, depending on the doping level and on the amount of holes available, and to reach 4 for p-type Ge. Equation [1] illustrates that  $m$  holes have to be present for the reaction to occur, while  $(4-m)$  electrons are simultaneously produced. This means that n-type Ge dissolves *via* a combination of valence band and conduction band mechanisms.<sup>3</sup> In accordance with this model it was found, for example, that lightly doped, n-type Ge can be electropolished only if extra holes are supplied by illuminating the Ge wafer with an intense light source (8) and that the corrosion potential of lightly doped, n-type Ge in an alkaline solution containing an oxidizing agent can be explained (6) on the basis of a minority carrier controlled quasi-photovoltaic effect.

On the other hand, it has been stated that heavily doped, n-type Ge can also be electropolished (8) without illumination,<sup>4</sup> a result which is inconsistent with the hypothesis that the hole production is the rate-limiting factor for the anodic dissolution process of n-type Ge (10). In addition, it was recently observed (1) that the corrosion potential  $U_k$  of n-type Ge as a function of hole concentration exhibits an un-

expected extremum, *i.e.*,  $-U_k$  increases with an increase in doping level up to a donor concentration of approximately  $2 \times 10^{17} \text{ cm}^{-3}$  and decreases with an increase in donor concentration beyond this value. For more details see the section on Corrosion Potential  $U_k$  of Ge Electrodes.

It is the purpose of this paper to show that two different mechanisms seem to govern the anodic dissolution behavior of lightly and of heavily doped, n-type Ge. All previous investigations of Ge half-cell reactions, which revealed the significance of holes for the dissolution process of n-type Ge, have been performed only with lightly doped, n-type Ge (1, 4, 5, 7, 12-16) having donor concentrations below  $3 \times 10^{16} \text{ cm}^{-3}$ . The present investigations cover n-type Ge single-crystal material with resistivities ranging from 3 to 0.0008 ohm-cm. Previously reported experiments involving high resistivity, n-type and p-type Ge electrodes have been partly repeated for basis of comparison and will be included in the following sections. Current-voltage characteristics of Ge electrodes immersed in alkaline solutions and alkaline solutions containing an oxidizing agent will be presented. The results of the present experiments suggest that the anodic dissolution of heavily doped, n-type Ge is governed by a conduction band mechanism and that no holes are required for the dissolution process.

## Experimental Arrangement

The simple apparatus used for studying the Ge half-cell reactions in aqueous solutions is illustrated in Fig. 1. The Ge electrode potential was measured against a commercially available saturated calomel reference electrode using a high impedance voltmeter. A platinum foil was used as an auxiliary current electrode. All half-cell measurements were done with the Ge samples in the dark and with the electrolyte covered by a dry  $\text{N}_2$  atmosphere. The Ge wafers were cut from crucible grown crystals and were mechanically lapped on one side and chemically polished (17) on the other. The latter surface was exposed to the electrolyte. A metal film was evaporated on the lapped backside of the wafers and alloyed with the Ge to ensure reliable ohmic contact. Most test samples had (111) oriented surfaces and were doped either with Sb or Ga with the exception of the 0.0008 ohm-cm sample which was doped with As.

<sup>1</sup> Present address: AEG—Telefunken, Hellbronn, Germany.

<sup>2</sup> For a review see Gerischer (2) and Turner (3) and the references given there.

<sup>3</sup> Oxidation in its simplest form can either occur by absorbing a hole,  $\text{A} + \text{p}^+ \rightarrow \text{A}^+$  (valence band mechanism), or by emitting an electron,  $\text{A} \rightarrow \text{A}^+ + e^-$  (conduction band mechanism).

<sup>4</sup> Similar observations (8, 9) have been made during the electropolishing of heavily doped, n-type Si material with resistivities below 0.01 ohm cm.

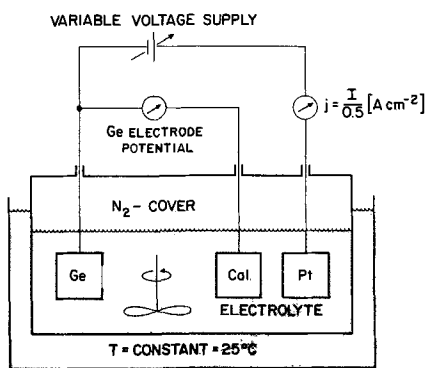

Fig. 1. Corrosion potential apparatus

To facilitate the current-voltage measurements, a special sample fixture was designed which is illustrated in Fig. 2. It consists of two parts: the sample holder and a special measuring jig. The Ge wafers are black-waxed on a hot-plate between two microscope glasses containing circular holes of 0.5 cm<sup>2</sup> area. Due to surface tension a thin film of black wax runs underneath the cover glasses ensuring a tight assembly. The excess black wax in the glass openings can easily be rinsed off using standard organic solvents. By this means, a well-defined area (0.5 cm<sup>2</sup>) of the Ge wafer can then be exposed to the electrolyte. The sample holder is attached to the actual measuring jig by a vacuum-chuck arrangement. A standard o-ring ensures a good seal. This set-up has the advantage that the assembly of the Ge wafer onto the microscope glasses, which play the role of mask and handle, can be performed on a hot-plate away from the rest of the sample fixture. Thus, one sample can be mounted while another is attached to the sample fixture and used for current-voltage measurements. Hence, replacing one sample on the fixture with another takes only a matter of seconds. It just requires releasing the vacuum, taking one sample off, and replacing it with a premounted sample.

### Experimental Results

First, measurements of the corrosion potential  $U_k$  of n-type and p-type Ge will be described. Then the observed current-voltage characteristics of selected Ge electrodes in alkaline solutions with and without an oxidizing agent will be reported. The term "I/V characteristic" will from now on be used to refer to the current-voltage characteristics of the Ge electrodes.

**Corrosion potential  $U_k$  of Ge electrodes.**—Figure 3 shows the results of the  $U_k$  measurements. The corrosion potential was measured potentiometrically vs. a saturated calomel reference electrode. All  $U_k$  values listed in Fig. 3 were measured on Ge electrodes immersed in an electrolyte composed of 0.1M  $K_3[Fe(CN)_6]$ , 0.1N NaOH, and 1.0N  $NaNO_3$ . This elec-

Fig. 2. Sample fixture for electrolytic current-voltage measurements.

Fig. 3. Corrosion potential of Ge electrodes measured at +25°C vs. a saturated calomel reference electrode.

trolyte was chosen because in a similar composition, it had already been studied extensively by other investigations (2). The data for lightly doped, n-type Ge and for p-type Ge agree very well with previously published results (6). However, the linear relation, shown there, between  $U_k$  and the logarithm of the hole concentration does not hold for heavily doped, n-type Ge and an unexpected minimum<sup>5</sup> can be seen in the  $U_k$  vs. hole concentration curve at a donor concentration of approximately  $2 \times 10^{17}$  cm<sup>-3</sup>.

The minimum  $U_k$  value in Fig. 3 is not characteristic for samples with (111) surface orientation. The effect was also observed with (110) and (100) oriented samples and with acid solutions. The individual  $U_k$  readings were extremely stable and could be reproduced within the accuracy of  $\pm 3$  mv over a period of several months. The data shown in Fig. 3 was taken without stirring the electrolyte and at a constant electrolyte temperature of  $25 \pm 0.1^\circ\text{C}$ . The  $U_k$  readings themselves have a temperature sensitivity of, typically, 2 mv/ $^\circ\text{C}$ .

Gerischer and Beck (6) assumed for their model explaining the logarithmic dependence of  $U_k$  on hole concentration that both electrons and holes are required for the anodic dissolution process of n-type Ge. To determine why their hypothesis fails for predicting  $U_k$  of heavily doped, n-type Ge and to understand better the Ge dissolution mechanism, Ge test samples were selected whose  $U_k$  readings fall into areas, left and right, with respect to the minimum  $U_k$  value in Fig. 3. The  $U_k$  value of one test sample coincides very closely with the "minimum  $U_k$  value." The samples are distinguished by circles around the corresponding data points and are comprised of one p-type sample (No. 16); one high resistivity, n-type sample (No. 22); one lightly doped, n-type sample (No. 25); and two heavily doped, n-type samples (No. 26, No. 27). The Ge half-cell reactions of these samples were measured in alkaline solutions with and without an oxidizing agent; the results obtained are presented below.

**I/V characteristics of Ge electrodes.**—Figure 4 shows current-voltage measurements obtained on Ge samples whose resistivities are listed in the upper left corner of the drawing and which were immersed in a 0.1N NaOH solution containing 1.0N  $NaNO_3$ . The current density is plotted vs. electrode potential. Note that the two samples No. 22 and No. 25, both belonging to the group of "lightly doped Ge," exhibit small ( $< 1$  ma/cm<sup>2</sup>) anodic limited current densities, which do not depend on stirring the electrolyte as has been reported previously (2). The I/V characteristic of the most heavily doped n-type sample No. 27 is almost identical with that measured on the p-type electrode. Both

<sup>5</sup> It should be noted that the "minimum" in Fig. 3 actually corresponds to the largest negative corrosion potential value measured.  $U_k$  of Ge is negative with respect to the calomel reference electrode and the ordinate in Fig. 3 is calibrated in the conventional way, with increasing negative mv-values listed from top to bottom.

Fig. 4. Current-voltage characteristics of Ge electrodes immersed in a 0.1N NaOH solution containing 1.0N NaNO<sub>3</sub>.

samples show for Ge electrode potentials between  $-250$  and  $+300$  mv an anodic current plateau much larger in magnitude, however, than that measured for the lightly doped, n-type samples. In addition, this current-density plateau can be drastically increased by stirring the electrolyte or by varying its pH value. This indicates that the current-density plateau is caused by the limited OH ion supply from the electrolyte (5, 16). The stirring action was not uniform in the electrolyte; consequently, fluctuations were encountered when the current-density plateau was reached. For current densities below this value, the current-voltage readings were extremely constant. The renewed current density increase above an electrode potential of approximately  $+0.4$ v is thought to be caused by an increased OH ion supply due to H<sub>2</sub>O electrolysis (14).

To substantiate further the observation that p-type and heavily doped, n-type Ge electrodes show very similar I/V characteristics, the anodic limited current density of the samples was measured for a fixed anodic bias of  $-100$  mv and with no stirring as a function of electrolyte temperature. The results are plotted semi-logarithmically in Fig. 5 vs. the reciprocal electrolyte temperature.

Figure 5 shows that the anodic saturation current density in lightly doped, n-type Ge increased approximately three times for each  $10^\circ$  temperature increment. The heavily doped, n-type Ge electrode behaves exactly like the p-type electrode; both exhibit only a slightly temperature sensitive current density.

The half-cell measurements were extended to a redox system, i.e., an electrolytic cell in which the Ge electrodes are immersed into an alkaline solution containing the oxidizing agent  $K_3[Fe(CN)_6]$  (see Fig. 6). This is the same electrolyte used for measuring the corrosion potentials plotted in Fig. 3. Consequently, the corrosion potentials  $U_k$ , as reported in Fig. 3, are identical with those Ge electrode potentials in Fig. 6 belonging to zero external current. Thus, one can extract  $U_k$  values from I/V measurements via the intersect of the I/V curves with the abscissa. For reasons which will become apparent in the discussion section, it is of great interest to find out how the electrode potentials of the I/V curves in Fig. 6 belonging to zero current density, depend on the concentration of the oxidizing agent in the electrolyte. The experimental answer to this question is given in Fig. 7 and 8 for three selected Ge electrodes. In each case the entire I/V curve was measured for different  $K_3[Fe(CN)_6]$  concentrations (0.005, 0.02, 0.06, and

Fig. 5. Anodic limited current density, measured at a fixed Ge electrode bias of  $+100$  mv vs. the temperature of the electrolyte.

Fig. 6. Current-voltage characteristics of Ge electrodes immersed in a stirred redox-system.

0.1M) in the unstirred electrolyte yielding different  $j_{corr}$  values (0.08, 0.4, 1.5, and 3.0 ma/cm<sup>2</sup>, respectively). However, only the corresponding  $U_k$  vs.  $j_{corr}$  values are plotted in Fig. 7 and 8.

Figures 7 and 8 are arranged by plotting current density semilogarithmically vs. electrode potential. Two kinds of experimental results are shown: solid symbols are used to report the  $U_k$  vs.  $j_{corr}$  studies as outlined above. The open symbols represent regular I/V measurements carried out in an unstirred electrolyte containing 0.1M  $K_3[Fe(CN)_6]$ . This time, however, the Ge dissolution current density rather than the total externally measured current density was plotted.<sup>6</sup> In other words, the open symbols in Fig. 7 and 8 show how the current density through the Ge electrodes increases from the value of the cathodic limited plateau as a function of increasing external electrode potential.

The results from both kinds of measurements can be approximated by one curve for each the p-type and the heavily doped, n-type Ge in Fig. 7. Gerischer and Beck (6) have already reported the same observation for p-type Ge. For the high resistivity n-type Ge,

<sup>6</sup> From the work of Beck and Gerischer (4, 7) one can assume that the externally measured current density represents the difference between the Ge dissolution current density and  $j_{corr}$ .

Fig. 7. Dissolution and corrosion current density as a function of electrode and corrosion potential respectively for p-type and heavily doped, n-type Ge.

Fig. 8. Dissolution and corrosion current density as a function of electrode and corrosion potential, respectively, for lightly doped, n-type Ge.

however, the two current-voltage curves differ drastically (see Fig. 8). For example, at an electrode potential of  $-600$  mv the Ge dissolution current density differs by more than one order of magnitude from the corrosion current density belonging to a  $U_k$  value of  $-600$  mv.

### Discussion

The current density through the Ge electrodes as a function of increasing electrode potential first follows in Fig. 4 and 6 the following pattern: first no Ge dissolution, then an exponential current increase followed by a current plateau, which is hole-diffusion-rate limited for the lightly doped, n-type samples and OH-ion-diffusion-rate limited for both the p-type and the heavily doped, n-type samples. The transition between the exponential branch of the I/V characteristic and the plateau region occurs smoothly. It is, therefore, unlikely that the larger magnitude of the plateau current density in the case of heavily doped n-type Ge is due to additional carriers generated by an avalanche process in the breakdown region of a surface inversion layer (12).

Additional confirmation that the anodic dissolution process of heavily doped, n-type Ge does not depend on the minority carrier density can be gained from the temperature sensitivity of the anodic limited current

density presented in Fig. 5. The strong exponential increase in the anodic limited current density as a function of electrolyte temperature is, for the 3 ohm-cm, n-type Ge electrode quantitatively the same as is known for the temperature dependence of the saturation current in a reversed biased Ge pn junction. Uhler (13) has previously reported the same temperature variation of the anodic-saturation current for the case of a 5.5 ohm-cm, n-type Ge electrode immersed in a 10% KOH solution. These observations suggest that the anodic dissolution current is governed in high resistivity, n-type Ge by the equilibrium concentration of minority carriers, i.e., the concentration of holes. On the other hand, the weak temperature sensitivity in the anodic current-density plateau of p-type and heavily doped, n-type electrodes could be accounted for by an increased OH-ion-diffusion rate from the electrolyte to the semiconductor surface.

The Tafel plots shown in Fig. 7 and 8 substantiate the above described differences in dissolution behavior between heavily and lightly doped Ge. Gerischer (2) has pointed out that p-type Ge behaves exactly like metals under cathodically controlled corrosion conditions. Therefore, the relation between the corrosion potential and the corrosion current density is the same as between electrode potential and the dissolution current density. Compare the location of the solid dots and open circles in Fig. 7. For high resistivity, n-type Ge, however, complication arises by an incomplete balance of minority carrier injection into the electrode surface causing an additional potential drop (6). This explains the fact that, for a given current density, the corrosion potential (solid squares) and the electrode potential (open squares) are widely different in Fig. 8.

In the case of the heavily doped, n-type Ge electrode, one finds no deviation (see open and solid triangles in Fig. 7) from the corrosion behavior known to occur in metals and p-type Ge. This is indicative that the corrosion behavior of heavily doped, n-type Ge is majority carrier controlled.

Gerischer's model (6) explains the corrosion potential of n-type Ge on the basis of two major assumptions, viz., the existence of a surface inversion layer and the importance of both kinds of carriers for the Ge anodic dissolution process. Both assumptions, however, are not valid for the case of heavily doped, n-type Ge. At room temperature, n-type Ge becomes degenerate at a donor concentration of approximately  $2 \times 10^{18} \text{ cm}^{-3}$ , making the existence of a surface inversion layer unlikely for donor concentrations greater than this value. In addition, the experimental results discussed in the previous section have shown that the anodic dissolution of heavily doped, n-type Ge requires only the presence of one kind of carrier, viz., electrons. These considerations suggest that the minimum in the  $U_k$  curve of Fig. 3 is caused by the beginning of a transition region at the end of which n-type Ge becomes degenerate and the mode of anodic dissolution changes from a hole to an electron controlled mechanism. The I/V characteristic of sample No. 25 (0.02 ohm-cm, n-type;  $2 \times 10^{17}$  donors  $\text{cm}^{-3}$ ) shows, in Fig. 4, a barely detectable anodic limited current density ( $< 50 \mu\text{a}/\text{cm}^2$ ), which is hole-diffusion-rate limited. The  $U_k$  of the same sample, however, is not quite as large as expected from an extrapolation of  $U_k$  values measured on more lightly doped, n-type Ge electrodes (see Fig. 3). This is indicative of the beginning of the transition region as defined above. On the other hand, the I/V characteristic of sample No. 26 (0.003 ohm-cm, n-type;  $3.5 \times 10^{18}$  donors  $\text{cm}^{-3}$ ) exhibits in Fig. 4 evidence of an intermediate state. The anodic current plateau is, through this sample, no longer minority carrier-concentration controlled although it is reached at a larger electrode potential than observed for either the p-type or the 0.0008 ohm-cm, n-type electrode. Experiments in which the corrosion potential was used as a tool to measure high surface concentrations ( $C_0 \sim 6 \times 10^{19} \text{ cm}^{-3}$ ) of n-type

diffused Ge layers have shown (11, 19) that the  $U_k$  curve of Fig. 3 can even be linearly extrapolated beyond the data point corresponding to the most heavily doped bulk sample investigated. For example, the above-mentioned diffused n-layer was doped with  $6 \times 10^{19}$  As atoms  $\text{cm}^{-3}$  at the surface according to sheet resistance measurements. This layer showed a corrosion potential of  $-400$  mv immediately after the sample had been immersed in the electrolyte. However, one might speculate that, in the region of extremely high impurity level,  $U_k$  becomes also a function of the specific doping element present.

The results of the present investigations have demonstrated that the anodic dissolution behavior of lightly and heavily doped, n-type Ge is different. Therefore, it seems reasonable to divide the range of n-type Ge material for considering its dissolution behavior into two groups (20), namely, into  $n^-$  and  $n^+$  Ge. The unexpected minimum of  $U_k$  apparent in Fig. 3 for n-type Ge with a donor concentration of  $2 \times 10^{17}$   $\text{cm}^{-3}$  suggests using this donor concentration as a "dividing line" between  $n^-$  and  $n^+$  Ge. For  $n^-$  Ge, the  $m$  values are those reported in the literature (7); for  $n^+$  Ge, however, specifically for degenerately doped Ge with a donor concentration above  $2 \times 10^{18}$   $\text{cm}^{-3}$  at room temperature, an  $m$  value of zero must be postulated because no holes are required for the dissolution process, as shown by the present investigations. This suggests that the dissolution of heavily doped, n-type Ge is given phenomenologically by a conduction band mechanism

Equation [5] states that heavily doped n-type Ge is oxidized by giving off 4 electrons.

It can be speculated that heavily doped, n-type Si might also follow a different dissolution mechanism, i.e., a minority-carrier-concentration independent mechanism in contrast to the data available in the literature for lightly doped, n-type Si. This model might shed some light on the confusion about the anomalous dissolution process in Si.

## Pyrolytic Deposition of Silicon Dioxide in an Evacuated System

J. Oroshnik<sup>1</sup>\* and J. Kraitchman<sup>2</sup>

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

#### ABSTRACT

The formation of silicon dioxide films by the low-temperature (750°C) decomposition of tetraethoxysilane in an evacuated system was studied. The performance of the system was investigated and the film characteristics evaluated. After a simple thermal treatment most of the properties of the deposited oxides were comparable to those of thermally grown oxides.

In the fabrication of semiconductor devices silicon dioxide films are used for a variety of purposes. Various techniques of producing these films have been investigated. While very good quality oxides are produced by the thermal oxidation of silicon, film production by other deposition techniques offers several potential advantages when compared with the thermal

growth of films. Thicker films can be achieved at lower temperatures and in shorter times. The substrate is not consumed during the process. The film can be produced on substrates other than silicon.

One deposition technique that has been investigated involves the pyrolytic decomposition of various silane compounds (1-3). In this technique an open tube system in which a carrier gas is used to bring the silane vapor into the decomposition region was commonly employed. The pyrolytic oxides produced by this technique were reported to have physical and chem-

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Corning Glass Works, Raleigh, North Carolina.

<sup>2</sup> Present address: Glass Research Center, PPG Industries, Pittsburgh, Pennsylvania.

ical properties similar to those of thermally grown oxides. However, recent studies (4) have indicated that there are significant differences between the properties of these pyrolytic oxides and thermal oxides, and for many device applications the quality of these pyrolytic oxides is inferior to those of thermal oxides.

Pyrolytic oxides have also been produced in an evacuated system (5), but no extensive evaluation of the performance of this system or the properties of the oxides have been reported. In this study an evacuated deposition system was used to produce pyrolytic oxides, the performance of the system evaluated, and the properties of the pyrolytic oxides determined.

### Experimental

A schematic diagram of the deposition system is shown in Fig. 1. The central region of the reaction tube was maintained at a temperature of 750°C. Silicon wafers were placed on a 6-in. long quartz boat which was then inserted into the reaction tube. After pumping the system down to a pressure of 15–30 $\mu$ , tetraethoxysilane (tetraethylorthosilicate) vapor was admitted to the system. On completion of a run the vapor flow was stopped, but pumping on the reaction tube was continued for 5 min to remove the remaining vapor and gaseous decomposition products. The reaction tube was then isolated from the cold trap, back-filled with nitrogen, and the samples removed.

To investigate the performance of the system, runs were made in which 1-in. diameter silicon wafers were placed at the ends and in the center of the quartz boat. The boat position was changed from run to run. In some of the runs a needle valve was used to control the rate of delivery of the silane vapor to the reaction tube. At maximum delivery rate (needle valve by-passed) deposition rates of about 300 Å/min were obtained. The results of some typical runs are shown in Fig. 2. The region of most uniform deposition was displaced from the furnace center toward the input end. At the maximum delivery rate the displacement was about 2 in. As would be expected at lower delivery rates, the region of most uniform deposition became broader and was displaced still further toward the input end. However, in all cases the region of uniform deposition was sufficiently broad so that no appreciable variation (less than 50Å) occurred in the oxide thickness on the 1-in. wafers. Multibeam interference measurements on a few samples showed that, for the purposes described above, the oxide thickness could be estimated by comparison of interference colors with a calibrated step gauge constructed of thermally grown oxides on silicon. This rapid and nondestructive comparison technique was used for routine thickness determinations.

### Results

**Etch rate.**—Pyrolytic silicon oxides produced by other techniques have been reported to etch more rapidly than thermal oxides (4). The pyrolytic oxides produced by the vacuum deposition technique used

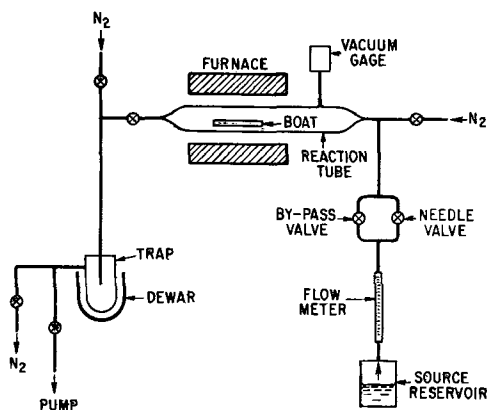

Fig. 1. System used for the deposition of pyrolytic oxides

Fig. 2. Deposition of pyrolytic silicon dioxide. The results illustrated by curves A, B, and C were obtained with the silane vapor delivered at the maximum rate (needle valve by-passed). In the runs illustrated by curves D, E, and F the delivery rate was controlled with a needle valve and monitored with a flow meter. In arbitrary units the flow meter readings were (D) 14.5; (E) 9.8; (F) 5.0.

here were also found to behave in a similar manner. These oxides were observed to etch at the rate of 10–15 Å/sec in P-etch (15 parts of 49% hydrofluoric acid, 10 parts of 70% nitric acid, and 300 parts of water).

It has also been shown that a simple thermal treatment of other pyrolytic oxides increases their density, reduces their etch rate, and improves other properties of these films (4). The oxides produced in this investigation were subjected to a thermal treatment of 10–15 min in wet oxygen (bubbled through water kept at 95°C) at 800°C. The effects of this thermal treatment on vacuum deposited pyrolytic oxides appeared similar to those produced on other pyrolytic oxides. Subsequent to this thermal treatment the densified pyrolytic oxides had etch rates of 2 Å/sec. This value is indistinguishable from that of thermally grown oxides. Thermal treatment with dry oxygen at 800°C for periods as long as 1 hr yielded incompletely densified pyrolytic oxides as evidenced by etch rates of 4 Å/sec and higher.

**Thermal treatment and oxide thickness.**—In earlier work in which pyrolytic oxide films of the order of 1 $\mu$  thick were studied, it was reported that the thickness of the films decreased after thermal treatment (4). In this investigation, films of the order of 0.1 $\mu$  thick have also been studied. Both thickness increases and decreases have been observed following thermal treatment. In particular, films about 0.25 $\mu$  thick exhibited no significant change in thickness after thermal treatment. Thinner films, e.g., about 0.15 $\mu$ , become thicker. Thicker films, e.g., about 0.35 $\mu$ , become thinner.

These observations require no revision of the ideas expressed previously (4) that the film shrinkage is due to densification caused by the thermal treatment. To explain these results it is only necessary to recognize that during the thermal treatment the film simultaneously grows thicker due to thermal oxidation.

The magnitude of these effects can be estimated as follows: The thermal oxidation of silicon can be described by a combination of linear and parabolic rate expressions (6–11). At 800°C in wet oxygen, and for oxides less than 0.5 $\mu$  thick the oxidation behavior is essentially linear and, hence, structural differences between the pyrolytic and thermal oxides would be expected to have a negligible effect on the growth characteristics. We can, therefore, obtain an adequate estimate of the amount of oxide growth that occurs during the thermal treatment by assuming the pre-ex-

Table I. Calculated thickness changes due to thermal treatment

Original thickness, $\mu$	Change in thickness, $\mu$		Net
	Growth <sup>a</sup>	Densification <sup>b</sup>	
0.15	0.010	-0.006	+0.04
0.25	0.010	-0.010	0.00
0.35	0.009	-0.014	-0.05

<sup>a</sup> Calculated using a linear rate constant of 0.05  $\mu$ /hr, a parabolic rate constant of 0.1  $\mu^2$ /hr, and for an oxidation time of 0.25 hr at 800°C in wet oxygen.

<sup>b</sup> Calculated on the basis of a 4% film shrinkage during the thermal treatment.

isting pyrolytic oxide to be equivalent to a thermal oxide of the same thickness.

For these calculations, the linear and parabolic rate constants can be determined with adequate accuracy from available data (7, 12). The results of these calculations are given in the second column of Table I. The last column gives the predicted values due to the combined effects of the growth values in the second column and the shrinkage values in the third column. In agreement with our experimental observations these calculations indicate that a significant increase in the film thickness should be observed only on films thinner than 0.15 $\mu$ , while a significant decrease in film thickness should be observed only on films thicker than 0.35 $\mu$ .

**Masking properties.**—While pyrolytic silicon dioxide was found to be a good diffusion mask for boron and phosphorus, contamination doping from the oxide can be a serious problem. In our initial work using a commercial grade of tetraethoxysilane, calculations made using sheet resistance and junction depth measurements (13) indicated contamination doping levels as high as 10<sup>18</sup> per cc were present in the silicon substrate after diffusion. Subsequent work using a purified form of the silane reduced the contamination level to the order of 10<sup>15</sup> to 10<sup>16</sup> per cc. Although contamination levels of this magnitude are quite acceptable in most instances, there are cases where it would not be satisfactory.

**Optical properties.**—The infrared spectra of the pyrolytically deposited oxides indicated that the amount of water present in the oxides (as evidenced by the O-H stretching band in the 3 $\mu$  region) was not significantly different from that found in thermally grown oxides. The Si-O stretching vibration in the 9 $\mu$  region was found to have its peak at 9.35 $\mu$ . However, after densification the peak shifted to 9.3 $\mu$ . This position is indistinguishable from the position found for this peak in thermally grown oxides.

Ellipsometric measurements on the oxides yielded values of 1.44-1.45 for the refractive index. After densification the measurements yielded values of 1.45-1.46. Thermally grown oxides measured by the same technique were found to have a refractive index of 1.46.

**Electrical properties.**—The electrical resistivity and breakdown strength of the pyrolytic oxides were found to be lower than in thermal oxides; the dielectric constant was higher. However, after thermal treatment the properties of the oxides were not significantly different from those of the thermal oxides. Table II summarizes the various electrical properties

Fig. 3. MOS capacitance-voltage characteristics. Densified pyrolytic oxide 3000 $\text{Å}$  thick on 15 ohm-cm n-type silicon. Voltage is potential of metal contact with respect to silicon substrate. Solid curve, bias swept at normal rate; dashed curve, bias swept very slowly.

of these oxides and some of the other properties discussed previously.

The capacitance-voltage characteristics of metal-oxide-semiconductor (MOS) capacitors fabricated using the pyrolytic oxide were also studied. The small-signal high-frequency (100 kc/sec) capacitance (14, 15) was measured as a function of applied d-c bias. The flat band potential of these capacitors was very large (about -80v), indicating the presence of a high surface state charge density and/or fixed or mobile space charges in the oxide. After densification, the flat band potential was significantly smaller. However, the C-V characteristics then exhibited hysteresis effects. This is illustrated by the curve shown in Fig. 3. When the applied d-c bias is swept at a rate of 0.5-1.0 v/sec, the large hysteresis loop shown by the solid line is obtained. As the sweep rate is reduced, the hysteresis loop narrows as indicated by the dashed line. While it is not clear whether the presence of very mobile ions or other processes are responsible for these effects, it is evident that the MOS characteristics of these pyrolytic oxides are inferior to those of high-quality thermally grown oxides.

### Summary

The deposition of silicon dioxide films by the pyrolytic decomposition of tetraethoxysilane in an evacuated system was investigated. Various performance parameters of the system were studied. Films were deposited at rates as low as 10  $\text{Å}/\text{min}$  and as high as 300  $\text{Å}/\text{min}$ . The oxide films exhibited no significant variation in thickness over a 1-in. diameter wafer.

Various properties such as etch rate, infrared spectra, refractive index, resistivity, breakdown strength, dielectric constant, and capacitance-voltage characteristics of the pyrolytic oxides were measured. While there were a number of significant differences between the properties of these low-temperature pyrolytic oxides and those of thermally grown oxides, most of these differences vanished when the pyrolytic oxides were given a simple thermal treatment.

When subjected to the thermal treatment, thin pyrolytic oxides increased in thickness, while thick pyro-

Table II. Silicon dioxide properties

Oxide	Etch rate (P-etch), $\text{Å}/\text{sec}$	Infrared spectra (Si-O stretching band), $\mu$	Refractive index	Resistivity, ohm-cm	Breakdown strength, v/cm	Dielectric constant
Pyrolytic	10-15	9.35	1.44-1.45	0.01-1 $\times 10^{15}$	4 $\times 10^6$	5.5-6.5
Densified pyrolytic	2	9.3	1.45-1.46	0.1-5 $\times 10^{16}$	5-7 $\times 10^6$	4.0-4.5
Thermal	2	9.3	1.46	0.1-5 $\times 10^{16}$	5-10 $\times 10^6$	3.5-4.0

lytic oxides decreased in thickness. Calculations showed that the observed thickness changes resulting from the thermal treatment could be satisfactorily accounted for by the simultaneous growth of new oxide, plus densification of the pyrolytic oxide.

The thermal treatment was also found to lower the large flat band potential observed on MOS structures fabricated with the pyrolytic oxide to values comparable to those obtained on MOS capacitors fabricated with thermally grown oxides. The magnitude of the hysteresis effects observed in the C-V characteristics of MOS capacitors fabricated using the thermally treated pyrolytic oxide was found to be dependent on the rate at which the bias voltage was swept.

The pyrolytic oxides were also found to have diffusion masking properties comparable to those of thermally grown oxides. When prepared using a purified form of the silane, the contamination levels produced by pyrolytic oxide diffusion masks were reduced to levels of about  $10^{15}$  to  $10^{16}$  per cc.

#### Acknowledgment

The authors wish to thank T. W. O'Keeffe for valuable discussions and assistance in some of the measurements. They are indebted to W. K. Sheets and N. J. Roney for assistance in the experimental work. This work was supported in part by the U. S. Air

Force Avionics Laboratory, Air Force Systems Command, U. S. Air Force.

Manuscript received Sept. 5, 1967; revised manuscript received ca. Feb. 8, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Autodoping of Epitaxial Silicon

W. H. Shepherd

*Fairchild Semiconductor, Research and Development Laboratory, Palo Alto, California*

#### ABSTRACT

It is assumed that autodoping of epitaxial silicon films grown on heavily doped n-type substrates occurs by transfer of the elemental dopant from the backside of the wafer into the gas phase and subsequently into the depositing film. The processes governing the rate of transfer of autodopant into the film are considered and a quantitative relationship derived for the impurity profile in the film. The relationship gives a satisfactory explanation of autodoping from arsenic doped substrates and shows why antimony is so much to be preferred as a substrate dopant.

The resistivity of an epitaxial silicon film is influenced by two principle contamination factors: (a) the dopant transferred from the substrate into the growing film by way of the gas phase, and (b) background contamination from the reactor and impurities introduced with the feed gases. For the great majority of presently required film resistivities background contamination is no problem. Dopant transfer from the substrate, however, or autodoping as it is generally termed, is often a highly important factor determining the choice of substrate dopant and resistivity. There has been some discussion in the literature (1, 2) concerning the manner in which the dopant transfers from substrate to film with the recent consensus being that a significant amount is transferred by way of the gas phase. Joyce (2) has shown that for n-type dopants halide formation is unnecessary since transfer occurs when the substrates are heated in hydrogen alone. This is not surprising since n-type dopants P, As, and Sb are all readily volatile at epitaxial deposition temperatures and need not form halides to enter the gas phase. Furthermore, available thermodynamic data do not support halide transfer mechanisms. Boron is different since its vapor pressure is so low that elemental transfer is negligible. In this case thermodynamic data do support transfer as BCl. The

present paper, however, is concerned specifically only with arsenic autodoping.

In another paper (3) the author presents data on the activity coefficients for n-type dopants in silicon and discusses the mechanisms of deliberate doping. From these considerations it is apparent that arsenic is the best test vehicle for n-type autodoping studies. Antimony has so slight an autodoping effect that it is not normally detectable above background contamination. Phosphorus, under the expected growth conditions, evaporates from the backside of the silicon substrate in dimeric form making analysis of out-diffusion from the silicon complex.

#### Theory

Once deposition begins, the exposed face of the wafer is assumed to be sealed rapidly by the growing film and is not a source of dopant for contamination of the system (4). The back surface of the wafer is uncoated throughout the run and remains a continuing source of autodopant. The qualitative description of the process then is that dopant diffuses from the backside of the wafer in elemental form, mixes, and is diluted in the main gas stream of the reactor and dopes the epitaxial deposit in the usual way.

To obtain a quantitative picture the following assumptions are made:

(A) The dopant evaporates from the back of the wafer in monatomic form, and immediately adjacent to the surface equilibrium exists between the dopant in the gas and in the silicon, i.e., there is no surface barrier to evaporation.

(B) The dopant mixes completely with the main gas stream and remains monatomic.

(C) At the surface of the growing epitaxial layer the dopant is again in equilibrium between gas and solid phases, and the rate of incorporation is not in any way controlled by kinetic processes at the surface.

*Evaporation of dopant from the substrate.*—Since the dopant is in monatomic form in both the gas phase and the solid state, the equilibrium for the dopant in the two phases can be written

$$x_D = \gamma R_s \tag{1}$$

where at an ambient pressure of one atmosphere  $x_D$  is the mole fraction of dopant in the gas phase,  $R_s$  is the mole fraction in the silicon surface, and  $\gamma$  is an activity coefficient dependent only on temperature. If it is assumed that the evaporation is from the front of the wafer rather than the back, the flux of dopant from the gaseous surface region,  $F_D$ , is

$$F_D = \Psi_D \cdot x_D \tag{2}$$

where  $\Psi_D$  is a gaseous transfer coefficient with units of atoms  $\text{cm}^{-2} \text{sec}^{-1}$  (5).

For evaporation from the back of the wafer the rate will be restricted to a degree which is difficult to estimate. For the present this restriction can be represented by a multiplying factor,  $\lambda$ , less than one so that the effective transfer coefficient becomes  $\lambda\Psi_D$ . The flux of dopant from the backside of the wafer is

$$\begin{aligned} F_D &= \lambda\Psi_D\gamma R_s \\ &= \lambda\Psi_D \frac{\gamma C_s}{N} \end{aligned} \tag{3}$$

where  $C_s$  is the concentration of dopant, in atoms  $\text{cm}^{-3}$ , in the silicon surface (backside), and  $N$  is the density of atoms in the silicon lattice, i.e.,  $5 \times 10^{22}$  atoms  $\text{cm}^{-3}$ . Equation [3] states that the flux of dopant is proportional to the surface concentration,  $C_s$ . Under this boundary condition the solution of the problem of diffusion within the substrate is of a well-known form (6) and is

$$F_D = \theta C_B \exp\left(\theta^2 \frac{t}{D}\right) \operatorname{erfc}\left(\theta \frac{\sqrt{t}}{\sqrt{D}}\right) \tag{4}$$

where  $\theta = \lambda\Psi_D\gamma/D$ ,  $t$  is time in seconds, and  $D$  the diffusion coefficient for the dopant in silicon expressed in  $\text{cm}^2 \text{sec}^{-1}$ .  $\theta$  has units of velocity, in this case  $\text{cm sec}^{-1}$ .  $C_B$  is the initial concentration of dopant in the substrate.

*Incorporation of autodopant in the epitaxial film.*—If the total wafer area is  $A \text{ cm}^2$  (counting backside only), the rate of evaporation of autodopant into the reactor gas stream is  $AF_D$  atoms  $\text{sec}^{-1}$ . Hence, for a main stream hydrogen flow rate of  $H$  molecules  $\text{sec}^{-1}$  the mole ratio of autodopant in the stream, assuming complete mixing, is  $AF_D/H$ .

It is assumed that the gaseous dopant in contact with the surface of the growing film is in thermodynamic equilibrium with the impurity component of the crystal the mole fraction of dopant in the gas is, after Eq. [1], equal to  $\gamma R_F = \gamma C_F/N$  where  $R_F$  and  $C_F$  refer to instantaneous atom ratios and concentration of dopant in the surface of the silicon. The mole fraction of autodopant in the gas stream, which for present purposes may be considered as dopant deliberately added to the initial gas stream is  $AF_D/H$ . From previous papers (5, 3) the average flux of dopant from the gas to the wafer surfaces can be written as the difference between the initial bulk concentration and

the equilibrium surface concentration times a transfer coefficient for the dopant. This leads to

$$\text{Dopant Deposition Rate} = \Psi'_D \left( \frac{AF_D}{H} - \frac{\gamma C_F}{N} \right) \tag{5}$$

The transfer coefficient  $\Psi'_D$  is the same one used in Eq. [2] and [3] except that now it is expressed in  $\mu\text{min}^{-1}$  rather than in atoms  $\text{cm}^{-2} \text{sec}^{-1}$ . In making this transformation it must be recognized that since the dopant enters the silicon lattice the atom density of the dopant "film" is that of the parent lattice, i.e.,  $5 \times 10^{22}$  atoms  $\text{cm}^{-3}$ . If the atom fraction of dopant in the film is  $R_F$  and the silicon growth rate is  $G \mu\text{min}^{-1}$  then the rate of deposition of dopant is given by  $GR_F = GC_F/N$ . Equating this with Eq. [5] and rearranging gives

$$C_F = \frac{NA F_D}{H \left( \frac{G'}{\Psi_D} + \gamma \right)} \tag{6}$$

The expression for  $F_D$  (Eq. [4]) can be written

$$F_D = \theta f(t) C_B \tag{7}$$

where  $f(t) = \exp(\theta^2 t/D) \operatorname{erfc}(\theta \sqrt{t}/\sqrt{D})$  is mainly a function of time since  $\theta^2/D$  is not strongly temperature dependent. The temperature dependence of  $\theta$  is due to the activity coefficient  $\gamma$  (Eq. [4]) so that the temperature sensitivity of  $\theta^2/D$  is represented by  $\gamma^2/D$ . Both  $\gamma$  and  $D$  vary with temperature according to the familiar relationship  $\exp(-\Delta H/RT)$ . It is experimentally observed (3) that for arsenic, phosphorus and antimony in silicon  $\Delta H_A \approx \Delta H_D/2$ . Hence  $\theta^2/D$  is temperature insensitive. Substituting for  $F_D$  in Eq. [6], replacing  $H$  with  $H'$  which has practical units of liters  $\text{min}^{-1}$ , and evaluating the numerical factors in  $N$  and  $H$  gives the film/substrate doping ratio as

$$\frac{C_F}{C_B} = \frac{120 A \theta f(t)}{H' \left( \frac{G}{\Psi'_D} + \gamma \right)} \tag{8}$$

For a constant set of growth conditions, the term  $f(t)$  which varies from  $1 \rightarrow 0$  as  $t$  goes from  $0 \rightarrow \infty$  describes the profile in the film. All of the parameters in Eq. [8] are known or can be estimated reasonably well except for  $\lambda$  which has to be established empirically.

In Fig. 1, the function  $\exp x^2 \operatorname{erfc} x$  is plotted against  $x$ . When  $x = \theta(t/D)^{1/2}$  this function is  $f(t)$ . Thus for  $x < 0.1$ ,  $f(t) = 1$ , and for  $x > 1.0$   $f(t) = 1/2x$ .

Putting  $x = \theta(t/D)^{1/2}$  and substituting these approximations into Eq. [8] gives

Fig. 1. Plot of  $f(x) = \exp x^2 \operatorname{erfc} x$  against  $x$

for  $\theta(t/D)^{1/2} < 0.1$

$$C_F = \frac{120 A \theta}{H' \left( \frac{G}{\Psi_D} + \gamma \right)} \quad [9a]$$

for  $\theta(t/D)^{1/2} > 1.0$

$$\frac{C_F}{C_B} = \frac{60 A}{H' \left( \frac{G}{\Psi_D} + \gamma \right)} \cdot (D/t)^{1/2} \quad [9b]$$

From the above relationship we see that initially the level of autodoping is independent of time. During this period the loss of dopant is rate controlled by gas transfer from the wafer surface, and the surface concentration  $C_s$  is not substantially below the bulk concentration  $C_B$ . At longer times when  $C_s \ll C_B$  the condition is reached when dopant evaporates from the surface as fast as it can diffuse there, and solid-state diffusion in the silicon becomes the rate-limiting process. In this condition the autodoping is proportioned to  $t^{-1/2}$ . Approximate calculations show that for arsenic and antimony the time independent phase is so brief that it is not of practical significance.

Since the evaporation of impurity from the back of the wafer is independent of the growth process, at least as far as the model is concerned, the time  $t$  in the above expressions is actually the time of heat-treatment. If the reactor is raised quickly to temperature and deposition is begun immediately, then  $t$  is essentially the growth time. It is more normal, however, to etch the wafers prior to growth; and this is usually carried out at a higher temperature, 1300°C, rather than 1200°C. This can be allowed for by replacing  $t$  in the above relationships by  $(t + t_E)$ , where  $t$  now is the actual growth time and  $t_E$  is an effective pre-heat time at the growth temperature. The value of  $t_E$  is obtained from

$$\{\theta f(t_E)\}_{T_G} = \{\theta f(t_H)\}_{T_H} \quad [10]$$

where  $T_G$  = growth temperature,  $T_H$  = etch temperature, and  $t_H$  = length of etch or preheat cycle.

For the present situation where the etch cycle is 5 min at 1300°C, the growth is at 1200°C, and the dopant is arsenic, it turns out that  $t_E < 1$  min, and in the following analyses it has been ignored.

### Experimental Procedures

All experimental data were obtained using deposition by hydrogen reduction of  $\text{SiCl}_4$  in a conventional horizontal reactor. The arsenic doped substrates had resistivities in the range 0.013-0.015 ohm-cm (i.e.,  $C_B = 1.8 - 2.4 \times 10^{18}$  atoms  $\text{cm}^{-3}$ ) and were approximately 1 in. in diameter. They were prepared for epitaxy by chemical etching. Twenty were used in each run. Also included were two  $p^-$  test chips ( $\sim 80$  ohm-cm) and three 2.0 ohm-cm n-type phosphorus doped test wafers. The  $p^-$  wafers were used to obtain approximate values for the level of autodoping and for the epitaxial thickness from junction depth and V/I measurements. The n-type wafers were for the purpose of comparison with  $n^+$  wafers and for impurity profiling close to the substrate-epitaxial layer interface. Where etching was carried out, HBr was used at a temperature of 1300°C (1200°C optical), the rate of etching was 0.35  $\mu/\text{min}$ , and the time was 5 min. The main  $\text{H}_2$  flow rate was 50 liters/min at room temperature and at atmospheric pressure. All depositions were made at 1200°C (1100°C optical).

Impurity profiles in the epitaxial films were obtained from the capacitance-voltage characteristics of shallow, boron diffused, mesa diodes. The diffused junction depth was  $\sim 1\mu$ , and this is allowed for in all the reported results. Film thicknesses were measured on the  $n^+$  substrates by IR techniques, a correction of  $-1\mu$  being applied in all cases. For lightly doped test

wafers, the thickness was taken from a neighboring  $n^+$  wafer. In some instances the epitaxial layers were thin enough and sufficiently lightly doped for the impurity profiles to be determined into the diffusion tail from the substrate. In these cases the position of the profile relative to the substrate film interface could be established most accurately.

**Results.**—Some general autodoping characteristics observed in the experiments will be summarized before examining the principal features in detail.

1. Analysis of many impurity profiles showed the autodoping to be essentially the same over all wafers within a factor of about two. This indicates a degree of mixing along the reactor length which might seem surprising. However, the tilt of the boat produces a slight suction effect beneath it, and a reverse flow of gas can be observed below the boat when small oxide flakes are present in a deliberately contaminated reactor. This apparently causes substantial mixing of the gases.

2. The level of autodoping is similar on  $n^+$  and  $n$  wafers in the same run. There is, apparently, a slightly lesser effect on  $n$  wafers, but the observed differences are generally within a factor of two between  $n^+$  and  $n$  wafers, and are not very significant. It does, however, correlate with the following observation.

3. There is a trend toward higher autodoping at the edge of  $n^+$  wafers. The variation from center to edge is generally within a factor of two. Because of this, the impurity profiles, when reported for  $n^+$  wafers, have been taken near the center of the wafer.

Figure 2 shows profiles taken on five wafers from a single run. This run included no etch or preheat cycle. All profiles have been adjusted along the distance axis using the outdiffusion tails. The solid line is obtained from the theory in a manner described below.

Figure 3 shows profiles taken on five wafers from a 2-hr run. In this instance the wafers were etched prior to deposition. The first 6-min growth was carried out at 0.75  $\mu/\text{min}$ , and the next 114-min growth at 0.13  $\mu/\text{min}$ . The solid line is from the theory.

The points in Fig. 3 cover part of a growth cycle between 40 and 100 min, while those in Fig. 2 cover the first 15 min. Combining the two sets of data, it should be possible to test Eq. [8] and evaluate the unknown parameter,  $\lambda$  (Eq. [3]).

In Eq. [8],  $\lambda$  appears in  $\theta$  and  $f(t)$ ; all other parameters can be evaluated. The values used for these parameters are:  $C_B = 2 \times 10^{18}$  at.  $\text{cm}^{-3}$ ;  $H' = 50$  liters

Fig. 2. Impurity profiles on epitaxial films grown at 1200°C (corrected) and  $0.55 \mu\text{min}^{-1}$  for 15 min. Substrate doping level,  $C_B = 2 \times 10^{18}$  at.  $\text{cm}^{-3}$ .

Fig. 3. Impurity profiles on epitaxial films grown at 1200°C (corrected) for 6 min at 0.75  $\mu\text{min}^{-1}$  and 114 min at 0.13  $\mu\text{min}^{-1}$ . Wafers were etched for 5 min at 1300°C before deposition. Substrate doping  $C_B = 2 \times 10^{18}$  at.  $\text{cm}^{-3}$ .

$\text{min}^{-1}$ ;  $A = 100 \text{ cm}^2$ ;  $\Psi_D = 1.3 \times 10^{19}$  at.  $\text{cm}^{-2} \text{ sec}^{-1}$ ;  $\Psi'_D = 150 \mu\text{min}^{-1}$ ;  $\gamma = 3.5 \times 10^{-3}$ .

The value of the activity coefficient for As in silicon at 1200°C is taken from previous work (3). The value for the gaseous transfer coefficient for arsenic,  $\Psi_D$ , is taken to be the same as that for  $\text{SiCl}_4$  in the same reactor (5) and is probably uncertain by a factor of two. Using the quantities as defined above, values of  $\theta f(t)$  have been calculated for the data points in Fig. 2 and 3, except for those close to the substrate film interface in Fig. 2. In Fig. 4, values of  $\theta f(t)$  are plotted vs. the corresponding values of  $t^{1/2}$ . The points in the plot should lie on a line corresponding in slope, although not in absolute value, to some portion of the plot in Fig. 1 since the time dependence arises only from  $f(t)$  ( $f(x) = f(t)$  for  $x = \theta\sqrt{t/D}$ ). A reasonable correspondence can be found with the linear portion of Fig. 1 as demonstrated by the solid line in Fig. 4. This means that  $\theta\sqrt{t}/\sqrt{D} > 1.0$ . The actual value of  $\theta$ , and hence  $\lambda$ , can be obtained for the line in Fig. 4 by iteration. Thus,  $\theta f(t) = 1.7 \times 10^{-8}$  for  $t^{1/2} = 1.5 \text{ min}^{1/2}$ . Knowing the diffusion coefficient,  $D$ , for arsenic in silicon ( $D = 2.5 \times 10^{-13} \text{ cm}^2 \text{ sec}^{-1}$  at 1200°C)  $f(t)$  can be calculated for any assumed value of  $\theta$  and for  $t^{1/2} = 1.5$  from Fig. 1 and the product  $\theta f(t)$  then compared with  $1.7 \times 10^{-8}$ . Carrying this process through leads to  $\lambda \approx 0.04$ , i.e., the effective transfer rate by gaseous diffusion from the back surface of a 1-in.

Fig. 4.  $\theta f(t)$  vs.  $t^{1/2}$  for data presented in Fig. 2 and 3

wafer is approximately 1/25 of that from an exposed surface. Values of  $\theta f(t)$  from Fig. 4 were used to calculate the theoretical impurity distributions shown in Fig. 2 and 3.

Using published diffusivities for antimony, values of  $\gamma$  from ref. (3), and  $\lambda = 0.04$ , an autodoping profile for antimony has been calculated and compared with that for arsenic in Fig. 5. The predictions are that, for film thicknesses commonly of interest, antimony is much less of a problem than arsenic. This is in agreement with known facts. Generally, the differences between arsenic and antimony are further magnified by the use of arsenic for high substrate doping levels not attainable with antimony because of its limited solubility.

In the 2-hr slow growth run, Fig. 3, the diode profiling did not reach closer to the substrate than about 9  $\mu$ . To obtain a profile closer to the substrate, one of the 2 ohm-cm n-type wafers was etched in a slow chemical etch to leave, hopefully, about 7-8  $\mu$  of the epitaxial layer. Diodes were made on the remaining film, and an interesting, though in retrospect predictable, effect was observed (2). Two profiles from this wafer are shown in Fig. 6. Both demonstrate a very definite peak in the n-type dopant concentration at what must be the substrate-film interface, since the profiles level off at a concentration close to that ex-

Fig. 5. Comparison of antimony autodoping with that caused by arsenic as estimated using Eq. [8].

Fig. 7. Comparison of impurity profiles of Fig. 6 with Gaussian profile calculated for arsenic "predeposition."

pected for the substrate. This effect can be explained either by the presence of an n-type contaminant on the wafers prior to deposition or to a predeposition with arsenic prior to growth. Such a predeposition can be expected to occur during the preheat cycle, even when etching is taking place, because of the arsenic present in the gas stream, either from evaporation from the substrates or released by the etching process. If this is the correct explanation, the concentration distribution should be close to Gaussian because the length of the growth cycle considerably exceeded that of the preheat cycle and should correspond to that expected for arsenic. To determine the exact profiles, the contribution of the outdiffusion tail from the substrate (phosphorus doped) was first subtracted, assuming the original substrate doping levels of  $2.5 \times 10^{15}$  at.  $\text{cm}^{-3}$  for the upper curve and  $2.0 \times 10^{15}$  for the lower. The data from the two profiles, adjusted so that the maxima of the two curves coincide on the distance

axis, are plotted in Fig. 7. The solid line is a Gaussian profile plotted from the known time and temperature and the diffusivity of arsenic. The fit is excellent.

A consequence of this kind of predeposition is that test wafers of opposite conductivity type to the film being deposited cannot always be used reliably for determining the resistivity of the epitaxial deposit.

### Conclusions

It has been assumed that autodoping is a process involving gaseous transfer of dopant from the backside of the substrate into the epitaxial film. From this premise, a simple theory appears to present a satisfactory explanation of the axial autodoping profiles observed on  $n^+$  arsenic doped wafers.

If the above assumption is correct, sealing of the backside of the substrate wafer with, for example, an  $\text{SiO}_2$  layer should significantly reduce the level of autodoping. Such an effect was clearly established by Joyce *et al.* (2). These authors, in the same paper, also showed that most transfer of substrate dopant to their test wafers occurred during the pregrowth heat-treatment. At this stage, the front surface of the substrate is exposed so that their observation is an expected one. However, pregrowth transfer, except by way of contamination of the reactor, will not influence the doping in the epitaxial film on the  $n^+$  substrates. The effect close to the substrate-film interface on lightly doped test wafers has already been demonstrated.

## Radiotracer Studies of Ion Implanted Profile Build-Up in Silicon Substrates

K. E. Manchester

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

### ABSTRACT

Injection of radiotracer markers at varying fractions of the total implanted dose has provided information on dose dependence of "channeling" in silicon substrates. The implanted profile (total) variation with substrate orientation agrees with that previously reported for electrically active impurities which was determined by junction delineation. Comparison of marker profiles shows a reduction of about 1/10 in impurity ion concentration at three times the depth of the peak of the distribution and about 1/20 the concentration at four times the depth of the peak of the distribution after  $2 \times 10^{13}$  ions/ $\text{cm}^2$  have impinged on the substrate. A greater fall-off in channeled ions is found when the dose was increased to  $5 \times 10^{14}$  ions/ $\text{cm}^2$ .

Doping of semiconductors by injection of impurity ions is an important technique that is being extensively investigated (1). It has been shown that p-n junction properties of implanted structures after a mild thermal treatment are comparable to those of thermally diffused structures (2).

Two important observations one makes when characterizing implanted junctions are: (I) During the anneal which is necessary to optimize and stabilize electrical properties, the p-n junction is observed to move deeper into the substrate. This can be as much as  $0.3\mu$  for an initial depth of  $0.6\mu$ . (II) The depths of

the junctions are much deeper than calculated by existing theory for amorphous solids and they are dependent on substrate orientation.

If this technique is to be used to produce semiconductor devices, it is necessary to characterize the concentration profile of injected ions. To do this, it is necessary to understand the anneal process. The anneal conditions are thermally mild, *i.e.*, 600°C-10 min for phosphorus implanted p-type silicon, and 800°C-15 min for boron implanted n-type silicon. The junction movement suggests either a damage enhanced impurity atom movement or a change in the substitutional/interstitial ratio of injected impurity atoms.

The orientation effect has previously been reported in terms of junction depth as a function of ion energy in the three primary orientations (3). It was found that the deepest junctions for identical implant conditions are found in (110) oriented silicon with depths in the (111) and (100) oriented substrates about equivalent.

The work to be presented here is an investigation of the effect of annealing on implanted profiles and the "channeling" phenomena by a radiotracer technique. The work was initiated by earlier experimental results obtained in this laboratory on profiles of implanted ions by differential sheet conductivity. Integration under the electrical profile accounts for about 80% of the ions striking the sample as measured by beam current.

The experiments to be discussed here were designed to determine the disposition of the remaining 20% of the impinging ions, *i.e.*, are they present as interstitials or have they been lost during the implant, perhaps by sputtering. Unfortunately, this question was not answered; however, valuable information on profile build-up has been derived from our measurements and is discussed herein.

### Experimental

All specimens were implanted with 40 keV  $^{31}\text{P}$  phosphorus ions. A single 40 keV "marker" of approximately  $10^{11}$  ions/cm $^2$  of radioactive  $^{32}\text{P}^+$  was implanted in each specimen after a predetermined number of  $^{31}\text{P}^+$  ions had been implanted. After the marker implantation was complete,  $^{31}\text{P}$  ions were implanted until the total dose of  $5 \times 10^{14}$  ions/cm $^2$  was injected. Three different series were examined in which the implantation sequence was: (a)  $\sim 10^{11}$  ions/cm $^2$   $^{32}\text{P}^+$  followed by  $5 \times 10^{14}$  ions/cm $^2$   $^{31}\text{P}$ ; (b)  $2 \times 10^{13}$  ions/cm $^2$   $^{31}\text{P}^+$  followed by  $\sim 10^{11}$  ions/cm $^2$   $^{32}\text{P}^+$  followed by  $4.8 \times 10^{14}$  ions/cm $^2$   $^{31}\text{P}^+$ ; and (c)  $5 \times 10^{13}$  ions/cm $^2$   $^{31}\text{P}^+$  followed by  $\sim 10^{11}$  ions/cm $^2$   $^{32}\text{P}^+$  followed by  $4.5 \times 10^{14}$  ions/cm $^2$   $^{31}\text{P}^+$ . Handling hazards determined the upper limit of  $^{32}\text{P}^+$ , which could be implanted. It also determined equipment modifications to do the implants.  $^{32}\text{P}$  decays by emission of a 1.7 meV  $\beta$  and has a half life of 14.3 days.

The basic equipment for these experiments was an isotope separator at the Oak Ridge National Laboratory. It is shown schematically in Fig. 1. Ions are generated in the source, accelerated by an electrode system, dispersed according to  $e/m$  by the magnetic field perpendicular to the plane of the beam and impinged on the substrates in the receiver.

The source charge was prepared by irradiating a 2-g sample of red phosphorus with thermal neutrons until 4 Curies of  $^{32}\text{P}$  were produced. The charge was allowed to cool 6 days to reduce short-lived isotope levels to that which could be safely handled.

The source charge container was designed to allow it to be inserted into the source through a vacuum lock and manipulated to break the ampule containing the phosphorus when the charge container was in position.

The receiver was a special design shown in Fig. 2-4. Figure 2 shows the rotatable substrate drum being inserted into the vacuum lock just behind the isolating ball valve. Figure 3 shows the sample drum in position

Fig. 1. Schematic of isotope separator

Fig. 2. Receiver design showing vacuum port for loading sample holder.

in the vacuum system with the index plate removed. During the implantation, the drum is rotated at a fixed speed. Because of the rotary motion, the surfaces of samples are not always normal to the beam, but vary from  $+7^\circ$  to  $-7^\circ$  from the normal. Note the beam entrance slot and the probe just below. Three rows of samples are contained on each drum with twelve samples in each row. Figure 4 shows the index plate in position. Note the double set of indexing slots spaced about 0.8 in. apart in the vertical direction to uncover one row of samples at a time and the probe just below the slot which exposed the sample to the beam. The position of the bottom slot was one mass unit below the upper slot. The purpose of this arrangement was to provide a method of monitoring the  $^{32}\text{P}^+$  beam current by observing the  $^{31}\text{P}^+$  current on the probe. A number of assumptions were involved in this measurement, such as equivalent efficiency of ionization for the two isotopes and also a uniform beam current density across each beam so that the current of  $^{32}\text{P}^+$  ions was the  $^{31}\text{P}^+$  ion current multiplied by the isotope ratio ( $5 \times 10^{-6}$ ). Unfortunately, there were gross errors in these assumptions, which are pointed out in Table I. This table indicates how the row activity varied with position, thus indicating inhomogeneity in the beam. Maximum activity indicated for the middle row is two

Fig. 3. Receiver design showing sample positioning in beam

Fig. 4. Receiver design showing beam current monitoring technique.

orders of magnitude low based on the calculated activity from  $10^{11}$  ions/cm<sup>2</sup>. This discrepancy would not allow a material balance to be made; however, qualitative inspection of profiles provides valuable information.

All samples were implanted with 40 keV ions, both  $^{32}\text{P}^+$  and  $^{31}\text{P}^+$  with all other parameters held constant with the exception of orientation and the fraction of total dose implanted before the marker was injected.

All samples were analyzed in depth by uniformly removing silicon layers of known thickness by the anodic oxidation technique described by Busen and Linzey (4). The activity of each layer was determined by counting the solution of the dissolved oxide. Residual activity was also monitored as a cross check. All count data were corrected for background and also corrected for decay to the time of the implantation.

### Results

In Fig. 5 the influence of the annealing process on impurity movement is shown. Four implantations were made under identical conditions in (100) oriented p-type silicon. Two of these implants were annealed at 600°C for 10 min before profile determination. The other two were processed without thermal treatment. It can be seen that the four sets of data points are fitted by the same curve. It can be concluded that gross diffusion to move the junction  $0.2\mu$  as observed by delineation (5) has not occurred and that this movement is a reflection of a change in the substitutional/interstitial ratio of the injected atoms. Other important features of Fig. 5 are the buried peak which occurs at the depth calculated by theory (6) and the depth at which unit activity occurs.

Figure 6 is the profile of an identical implant in (111) oriented p-type silicon. Here again,  $2 \times 10^{13}/\text{cm}^2$  of  $^{31}\text{P}^+$  were introduced before the tracer marker. This profile is similar in nature to the profile in Fig. 5. Within experimental error, they are the same. Both have unit activity at 3000Å. Here again, notice the peak of the distribution which falls at 500Å in good agreement with Lindhard-Scharff-Schiott theory.

Figure 7 is an identical implant in (110) oriented p-type silicon. Here the "tailing" in the distribution becomes noticeable when compared to the profiles for the (100) and (111) orientations. Unit activity is found 1000Å deeper at 4000Å. The peak is again at 500Å. Comparing the depths for unit activity, it is seen that the depth in the (110) oriented material is 33% deeper than either the (111) or (100) oriented material. This compares favorably with the 31% deeper junction

Fig. 5. Activity profile of  $^{32}\text{P}^+$  marker in (100) silicon injected after  $2 \times 10^{13}/\text{cm}^2$   $^{31}\text{P}^+$  and the effect of annealing.

Fig. 8. Activity profile of  $^{32}\text{P}^+$  marker in (111) silicon injected before  $^{31}\text{P}^+$  dose.

Fig. 7. Activity profile of  $^{32}\text{P}^+$  marker in (110) silicon injected after  $2 \times 10^{13}/\text{cm}^2$   $^{31}\text{P}^+$ .

Fig. 9. Comparison of activity profiles of  $^{32}\text{P}^+$  marker in (111) silicon when injected before and after  $2 \times 10^{13}/\text{cm}^2$   $^{31}\text{P}^+$ .

depth by delineation for 40 keV  $\text{P}^+$  ions in the (110) direction when compared to the other two directions (2).

The profile in Fig. 8 results when the  $^{32}\text{P}^+$  marker is injected first in (111) oriented silicon. Here it is seen that the channeling tail extends deep into the substrate with unit activity occurring almost 2000 Å deeper than previously found when  $2 \times 10^{13}$  ions/ $\text{cm}^2$  of  $^{31}\text{P}^+$  are initially injected. A comparison of the two profiles is shown in Fig. 9 and it can be seen that the fraction of channeling ions or the range of channeling ions has been markedly reduced.

Data for marker profiles injected after  $5 \times 10^{13}$  ions/ $\text{cm}^2$  of  $^{31}\text{P}^+$  indicate a further fall off in channeling; however, this reduction is not as dramatic as the initial one. These data have been obtained from samples with much lower initial activity, thus, the

profiles can only reflect the trend. Figure 10 is a comparison for the (110) direction of implant and Fig. 11 is a comparison for the (100) direction.

### Conclusion

In conclusion, it can be stated that:

1. "Channeling" down an open crystalline direction is definitely concentration dependent. It appears that after  $2 \times 10^{13}$  ions/ $\text{cm}^2$  have been injected either the channels have been blocked by interstitials (either impurity atom or dislodged host atom) or sufficient damage has occurred at the surface to effectively present an amorphous surface to incoming ions.

2. The annealing conditions necessary to restore structure and stabilize electrical properties do not cause a measurable diffusion such as one might conclude from the observed junction movement. The experiments indicate that the injected ion profile is

Fig. 10. Comparison of activity profiles of  $^{32}\text{P}^+$  marker in (110) silicon injected after  $2 \times 10^{13}/\text{cm}^2$  and  $5 \times 10^{13}/\text{cm}^2$   $^{31}\text{P}^+$ .

Fig. 11. Comparison of activity profiles of  $^{32}\text{P}^+$  marker in (100) silicon injected after  $2 \times 10^{13}/\text{cm}^2$  and  $5 \times 10^{13}/\text{cm}^2$   $^{31}\text{P}^+$ .

constant during the annealing process within the error of the experiment. Therefore, the junction movement must result from a change in the substitutional/interstitial ratio for the injected ions.

3. The experimental range for 40 keV phosphorus ions in silicon, which is defined by the location of the buried peak, agrees well with the value calculated by Lindhard's theory for amorphous substrates. This is within reason, since the implantations, which provided the data for the profiles, were made by rotating the samples through an angle of  $\pm 7^\circ$  to the beam direction. Thus, only a small fraction of the incoming ions were injected in a channeling direction. At all other times, the substrate exhibited varying degrees of opaqueness to the ion beam.

## The Influence of Thermal $\text{SiO}_2$ Surface Constitution on the Adherence of Photoresists

Robert O. Lussow

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

#### ABSTRACT

The adherence of certain commercial photoresists with thermal  $\text{SiO}_2$  was found to depend on the surface constitution of the  $\text{SiO}_2$ . Thermal  $\text{SiO}_2$  surfaces were modified to contain: (i) adsorbed molecular water, (ii) appreciable concentration of silanol groups, or (iii) predominantly siloxane structure. The adherence of Kodak photoresists KPR-2, KTFR, and KMER with each of these surface types was evaluated.

In the production of certain microelectronic devices, selected areas of oxidized silicon are protected from chemical etching with photopolymer coatings called photoresists. The etchant removes the oxide layer from the unprotected portion of the surface. The desired

access hole configuration has sides almost perpendicular to the substrate surface. In some cases, however, the etched holes show considerable taper or rounding at the upper edge. Since the etchants normally used do not attack the photoresist, this defect is ascribed to a

failure of the adhesion between the polymer and the oxide. A breakdown of the bonding allows the etchant solution to penetrate the interface between the oxide and photoresist and to attack the originally protected SiO<sub>2</sub> (1).

Attempts to improve the bonding of organic materials to SiO<sub>2</sub> surfaces have centered around the use of surface precoating techniques. The predominant method used, in microelectronics as in other unrelated fields, is based on reacting organohalosilanes with the SiO<sub>2</sub> (2-6). The layer produced serves as the bonding surface for the polymeric material. A recent paper by Bergh (1) has shown that there is a correlation between the water wettability of the SiO<sub>2</sub> surface and the adherence of these surfaces with a commercial photoresist. He found that as the water wettability of the surface increased, the adherence decreased. Bergh concluded that the presence of silanol-type surface groups caused the increase in wettability, with the attendant decrease in adherence. The choice of the organohalosilanes for surface precoatings implicitly supports this conclusion. The work reported here was undertaken to define more clearly the surface structure of thermal SiO<sub>2</sub> and its influence on the adherence of selected photoresists.

### Silicate Composition

SiO<sub>2</sub> is composed of silicon atoms in tetrahedral coordination with oxygen atoms. The surface of an ideal silica surface would be composed of silicon-oxygen or siloxane bridges. Real silica surfaces have been shown to contain outwardly disposed hydroxyl or silanol groups on their surfaces (2, 3, 5, 7, 8).

The surface hydroxyl groups are thermally stable up to temperatures of about 600°C, where sintering begins to occur (9, 10). These silanol-group sites have been shown to be capable of forming coordination or hydrogen-type bonds with molecular water (7-9, 11-13). NMR studies have shown that other surface sites on silica are also capable of forming similar bonds (13). This strongly held water can be removed by heating at high temperatures and using low pressures or long drying times (7, 9, 12). Physically bound water, on the other hand, can be readily removed at moderate temperatures and normal pressures.

### Experimental

**Silicon oxides.**—The surfaces used for these experiments were thin layers of SiO<sub>2</sub> prepared by oxidation of n-type epitaxial silicon. The oxide layers were grown on 1.25-in.-diameter circular silicon slices by thermal oxidation at 970°C in alternating atmospheres of steam and dry oxygen. The resulting oxide layers were about 6000Å thick.

The oxides were cleaned by immersion in hot, concentrated sulfuric and chromic acids, and then rinsed with deionized water. The excess water was blown from the surface and the samples dried for 10 min at 110°C. This was followed by outgassing at 50°C for 30 min in a vacuum oven whose pressure was about 100 milliTorr. The surface condition at this point is referred to as the "initial" condition.

The prepared oxide surfaces were modified by a variety of treatments. Chemical attack by water and acids, and exposure to nitrogen or steam at elevated temperatures were used. The sequence and details of each modification procedure will be discussed below. The modified oxides were subsequently outgassed in a vacuum oven at 50°C for 30 min at about 100 milliTorr pressure.

**Photopolymers.**—Commercial photoresists marketed by the Eastman Kodak Company were used. Three different types were evaluated: (i) Kodak Photo Resist, Type 2 (KPR-2), (ii) Kodak Thin Film Resist (KTFR), and (iii) Kodak Metal Etch Resist (KMER). The processing of the photoresist coatings was done in accordance with the manufacturer's recommendations (14).

**Oxide wettability measurements.**—The wettability of the oxide surfaces was measured by using 4.0 x 10<sup>-6</sup> liter droplets of boiled, 5 x 10<sup>-4</sup> mhos deionized water. The relative wettability of the surfaces was determined by the equilibrium spread size of the water droplets on the respective surfaces. The wettability of each sample is reported as the average diameter, *D<sub>T</sub>*, of four droplets, one placed in each quadrant of the surface. The details of this method have been presented elsewhere (15).

**Evaluation of adherence.**—"Adherence" used in this context is defined as previously discussed by Bergh (1), and was evaluated by the resolution of a pattern etched into the SiO<sub>2</sub> layer. The pattern used for this evaluation was a two-dimensional array of alternating rectangles and circles; approximately 2000 figures were etched into each oxidized silicon slice. The etchant was a hydrofluoric acid solution buffered with ammonium fluoride to attain an etch rate of 1000 Å/min. The quality of the etched patterns was examined microscopically at 100X. Good adherence of the photoresist to the SiO<sub>2</sub> gave patterns with sharp edges; poor adherence was evidenced by color fringes at the periphery of the etched holes, indicating a gradation in oxide thickness. The adhesive quality is reported as the percentage figures in the etched array showing color fringes around their periphery.

### Results and Discussion

The surface structures of a series of thermally oxidized silicon slices were modified by various wet oxidation and hydrolysis techniques. The wettability of these samples was measured before and after the surface treatments and after a subsequent vacuum outgassing. The oxidation and hydrolysis conditions and typical wettability data are summarized in Table I. The surface treatments caused the wettability of all samples to increase. The subsequent vacuum outgassing of the samples treated with H<sub>2</sub>O, HNO<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> reduced their respective wettability to values close to those obtained prior to the surface treatments. For the samples treated with the HF-NH<sub>4</sub>F mixture, the final outgassing reduced the wettability, but the ultimate values were greater than those measured before chemical treatment.

A second series of thermally oxidized silicon slices was subjected to the thermal treatments in air. The water wettability of these samples was measured after heating at each of the temperatures indicated in Table II. The results summarized in Table II show that the wettability increases with temperatures up to 450°C. At 650°C the wettability decreased and did not change further upon heating at 750°C. After the treatment at 750°C, the same samples were heated again at 350°C. This latter treatment increased the wettability to a value consistent with the previous lower temperature data.

Another series of thermally oxidized silicon slices was exposed at 350° and 500°C to flowing nitrogen streams containing varying concentrations of water vapor. Table III shows the water wettability of these

<sup>a</sup> Treated nitrogen streams were preheated to furnace temperature, and then passed over the heated samples.

<sup>b</sup> All samples were cooled to room temperature in dry N<sub>2</sub> at end of treatment.

<sup>c</sup> Saturated by bubbling through 25°C water.

<sup>d</sup> Nitrogen was swept through the vapor phase of a steam generator.

<sup>e</sup> The same samples were used for the 500°C, steam/N<sub>2</sub> and the 750°C, dry N<sub>2</sub> treatments.

samples before treatment, after treatment, and after the final vacuum outgassing. In all cases, the exposure to nitrogen-water vapor at the elevated temperatures increased the wettability. The wettability after exposure was independent of the partial pressure of water vapor at 350°C, but increased with temperature. The wettability after treatment at 500°C showed a very slight increase when the exposure time was raised from 0.5 to 1.0 hr. Vacuum outgassing the treated samples decreased their wettability, but not to the initial values.

Two of the vacuum outgassed samples from the 1.0-hr, steam-nitrogen, 500°C exposure were heat treated for 0.5 hr at 750°C in dry nitrogen. The results of this treatment are also included in Table III. The initial wettability reported for these samples is the final outgassed wettability measured after the 500°C steam-nitrogen exposure. The 750°C heat treatment decreased the water wettability of these surfaces to values lower than those measured on the "initial" samples.

Two methods of sample drying were compared. After the surface treatments previously described, each group of samples was divided into two sets. One set was vacuum outgassed at 50°C, and the second set was desiccated over silica gel for 55 days. The 500°C, steam-nitrogen samples that were desiccated were subsequently vacuum outgassed at 50°C. The water wettability of these surfaces after each drying step is reported in Table IV. The wettability changes with surface treatment were consistent with those reported for the same treatments in Tables I and III. Prolonged desiccation of the prepared samples reduced the wettability to almost the same extent as the vacuum outgassing technique.

<sup>a</sup> Following treatment, the samples were rinsed in flowing DI water for 5 min, blown off with N<sub>2</sub>, and air oven dried 10 min at 110°C.

<sup>b</sup> Samples were cooled to room temperature in dry N<sub>2</sub>.

It is shown by these experiments that the wettability of SiO<sub>2</sub> surfaces can be modified by the treatments and procedures described above: (a) an increase when samples are subjected to wet oxidation and hydrolysis or gas phase oxidation with water vapor, and (b) a partial reversal of increases when the surfaces are vacuum outgassed or desiccated for prolonged periods. In some cases the wettability of the vacuum outgassed surfaces was further reduced by heat treatments at temperatures in excess of 650°C. Comparing the wettability behavior of these samples with the known surface structures of SiO<sub>2</sub>, it is possible to deduce the surface constitution of the modified, thermally oxidized silicon surfaces used in this study.

The increase in water wettability that was reversed by vacuum outgassing or desiccating suggests the presence of strongly adsorbed molecular water. Physically adsorbed water would have been removed by the low temperature oven drying before the wettability measurements. The oxidation conditions used on these samples did not grow a significant amount of additional oxide (16-18). The first step in the oxidation of silicon by water is adsorption of a film of water (19). This mechanism implies that wettability increases that occur after gas phase oxidation should be independent of the partial pressure of water vapor in the gas phase. This was observed with the 350°C gas phase oxidations (Table III). The strongly adsorbed molecular water would be held to the surface by coordination or hydrogen-type bonding. This water was removed at low temperatures at an appreciable rate only when reduced pressures were used.

The wettability changes of the samples treated with the buffered hydrofluoric acid or gas phase oxidations at elevated temperatures were not completely reversed on vacuum outgassing. The permanent increase in wettability is attributed to the formation of additional silanol (Si-OH) groups on the silica surfaces. These are formed by hydrolysis of surface fluoride compounds in the reaction with HF (6, 8), or the thermal oxidation of silicon with water vapor (19). The silanol groups decomposed when heated to temperatures greater than 650°C (Tables II and III), and the elimination of water resulted in a surface comprised of siloxane (Si-O-Si) structure. The variation in initial wettability of the sample surfaces is attributed to variations in the silanol content or in the surface roughness factor (20) produced during the growth of the original oxide layer.

The chemical constitution of these SiO<sub>2</sub> surfaces can be classified into three different types. Type 1 surfaces are those with molecular water strongly bound to the solid. Type 2 surfaces contain an appreciable amount of silanol groups, but no adsorbed molecular water. Type 3 surfaces consist of predominantly siloxane structure with no adsorbed molecular water. These three types are illustrated schematically in Fig. 1.

The influence of these surface structures on adherence with KPR-2 is illustrated in Table V. The surfaces were prepared as described in the table. The same procedure was used on all samples for KPR-2

Fig. 1. Schematic representation of thermal SiO<sub>2</sub> surface structures. (a) Type 1, with adsorbed molecular water; (b) Type 2, containing silanol groups, no adsorbed molecular water; and (c) Type 3, predominantly siloxane structure, no adsorbed molecular water.

processing, etching, and adhesion evaluation. The data of Table V summarize the SiO<sub>2</sub> wettability values after each surface treatment, the surface type of the samples to be etched, and the adhesion performance. Poor adherence resulted when surfaces with the Type 1 structure were used. Both Type-2 and Type-3 surfaces showed good adherence with KPR-2. It should be noted that a high water wettability does not necessarily preclude poor photoresist adherence with the SiO<sub>2</sub> surfaces (6). Samples with wettability as high as  $D_T = 0.19$  in., corresponding to a contact angle of less than 10 arc degrees, show good adherence with KPR-2 if the surface is not of Type 1. This is seen in the data from the samples treated with buffered HF.

Table V. Adhesion of KPR-2 on thermal SiO<sub>2</sub>

Surface treatment <sup>a</sup>	Surface structure	Wettability $D_T$ , in.	Adherence, % defects

Boil, DI H <sub>2</sub> O	Type 1	0.172	KTR	100
Vacuum outgassed <sup>a</sup>	Type 2	0.147	KTR	100
Vacuum outgassed <sup>a</sup>	Type 2	0.146	KTR	100
750°C, N <sub>2</sub> <sup>b</sup>	Type 3	0.111	KTR	0
750°C, N <sub>2</sub> <sup>b</sup>	Type 3	0.109	KTR	0
Boil, DI H <sub>2</sub> O	Type 1	0.152	KMER	0
Boil, DI H <sub>2</sub> O	Type 1	0.159	KMER	0
Vacuum outgassed <sup>a</sup>	Type 2	0.129	KMER	0
Vacuum outgassed <sup>a</sup>	Type 2	0.133	KMER	0
750°C, N <sub>2</sub> <sup>b</sup>	Type 3	0.114	KMER	0
750°C, N <sub>2</sub> <sup>b</sup>	Type 3	0.123	KMER	0

<sup>a</sup> All samples in each series were boiled in DI H<sub>2</sub>O before vacuum outgassing for 30 min at 50°C under 100 milli-Torr pressure.

<sup>b</sup> The samples baked in N<sub>2</sub> at 750°C for 1 hr were first treated as in (a) above.

The adherence of photoresists KTR and KMER to these three surface structures was examined in a similar manner. The evaluation of KTR and KMER adherence is given in Table VI. The data shown are for the surface treatment, surface type, photoresist used, and adherence of each sample. The adherence of KTR was poor on surface Types 1 and 2, but good on surface Type 3. KMER adherence was unaffected by these variations in surface structure.

### Conclusions

Three types of SiO<sub>2</sub> surface structures were deduced from wettability changes caused by various surface treatments. Type 1 surface structures contain a strongly adsorbed layer of molecular water. Type 2 surfaces have a significant amount of silanol groups present, but no adsorbed molecular water. Type 3 surfaces consist of predominantly siloxane structure without adsorbed molecular water. The water wettability alone of these surfaces is not sufficient to predict their adhesion performance. SiO<sub>2</sub> adherence with photoresists is determined by the surface structure of the oxide (which also affects the wettability). Kodak Photo Resist Type 2 does not adhere well to surfaces containing appreciable amounts of adsorbed molecular water, but its adherence is unaffected by silanol or siloxane surface structures. Adsorbed molecular water or silanol surface groups have a detrimental effect on the adherence of Kodak Thin Film Resist. The adherence of Kodak Metal Etch Resist is independent of the SiO<sub>2</sub> surface structures investigated here.

### Acknowledgments

The author wishes to thank Mr. L. H. Wirtz and Miss B. J. Kriscka for assistance in making these measurements, and Dr. H. A. Levine for many helpful discussions.

Manuscript received Oct. 19, 1967; revised manuscript received Feb. 1, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 179.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Geometrical Stability of Shallow Surface Depressions During Growth of (111) and (100) Epitaxial Silicon

C. M. Drum and C. A. Clark

*Bell Telephone Laboratories, Inc., Allentown, Pennsylvania*

### ABSTRACT

The shapes and positions of shallow (500Å) depressions on silicon substrates undergo changes during the growth of epitaxial silicon deposited by the hydrogen reduction of SiCl<sub>4</sub>. Control of this distortion is important for the proper registration of diffusion masks in the fabrication of junction isolated integrated circuits. Data are presented on the shape distortion of surface depressions and the lateral displacements of the edges of these depressions; the effects of surface orientations in the vicinity of (111) and (100), the temperature of the deposition, and the orientation of surface depressions relative to symmetry planes in the lattice are included. Symmetrical displacements of small magnitude (~2.5μ for an 8μ epitaxial layer) can be obtained for one pair of sides of rectangular depressions on surfaces 3° off (111) toward a nearest (110); depressions are obliterated during growth onto surfaces very near (111), and surfaces off (111) toward a nearest (100) produce diffuse, highly distorted figures. For exact (100) surfaces, symmetrical and small displacements can be obtained with both pairs of sides of the rectangular depressions; the sharpness of the boundaries of depressions on (100) surfaces is strongly dependent on the temperature of the epitaxial deposition. Large pits associated with stacking faults on (111) surfaces can be qualitatively understood in terms of distortion of the small groove which occurs at the fault-surface intersection. Generally, knowledge of the anisotropy of the growth rate along with knowledge of the symmetry of the lattice provide a qualitative understanding of the crystallographic dependence of the distortion phenomenon.

During the course of work on the growth of epitaxial silicon for the fabrication of integrated circuits, we have made a study of the geometrical stability of shallow surface depressions during the growth process. The shallow, flat-bottomed depressions were bounded by steps approximately 500Å in height, and it was entirely expected that changes would occur in the shapes and positions of these steps during the growth of epitaxial layers approximately 80,000Å thick (8μ). For example, well known theories of crystal growth include the concept of atoms being incorporated into a growing crystal at favored sites on the surface (1), e.g., monatomic steps or kinks in these steps; thus at low supersaturations, low-indexed surfaces of a crystal could grow by the lateral spreading of these steps. The shallow depressions of interest in the present work had as their boundaries steps several orders of magnitude higher than monatomic steps, thereby exposing some regions with crystallographic orientations different from that of the substrate. Therefore, since the growth rate is known to vary with orientation (2), this provides an additional reason for anticipating that the depressions might undergo changes in shape during growth.

The problem of the stability of the figures arose in the following manner. One method for the fabrication of p-n junction-isolated integrated circuits involves the deposition of n-type epitaxial films onto p-type

substrates. These substrates contain a pattern of highly doped N<sup>+</sup> regions which serve to lower the collector series resistance. Electrical isolation between regions is obtained by diffusing p-type region through the epitaxial layer. The mask for this isolation diffusion must be properly registered, and a sequence of processing steps for accomplishing this is shown in Fig. 1. As indicated on Fig. 1, after the N<sup>+</sup> regions are diffused by standard techniques, the silicon exposed by the windows is re-oxidized thermally. Then, prior to epitaxial growth, all the oxide is removed with HF, leaving shallow depressions in the silicon surface which identify the positions of the N<sup>+</sup> regions. The ideal situation after epitaxial growth is depicted on the left of Fig. 1, in which the depressions after epitaxy faithfully identify the positions of the N<sup>+</sup> buried layers. However, the problem which led to this investigation is illustrated in the section to the right on Fig. 1; namely, the shallow depressions can be laterally displaced during epitaxial growth as drawn. This displacement can in some cases be greater than 25μ and subsequent misalignment of the P<sup>+</sup> isolation diffusion may result in shorting of the P<sup>+</sup> and N<sup>+</sup> regions.

The distortion of the depressions has been found to be strongly dependent on the crystallographic orientation of the surfaces, which is not surprising in light of the known variations in growth rate with orienta-

Fig. 1a. Processing steps for producing shallow depressions at the sites of diffused regions.

Fig. 1b. Cross-sections through substrate (a) and epitaxial surfaces (b), illustrating four cases. 1. Symmetrical distortion, 2. nonsymmetrical distortion without change of size, 3. nonsymmetrical distortion with change of size, 4. obliteration or washout.

tion (2). Throughout this paper, we denote the orientation of the large surface of a slice as being near either the particular (111) plane or the particular (100) plane. Previously, Benjamin and Patzner (3) reported that the pattern distortion was reduced by using slices oriented  $>2^\circ$  off (111), and Boss and Doo (4) reported that it was important to use slices with normals oriented  $3^\circ$  to  $5^\circ$  off [111] toward a nearest  $\langle 110 \rangle$ . This conclusion is generally in agreement with our data contained herein. Boss and Doo mentioned that distortion of depressions 1000 to 2000Å deep can also be minimized with near (111) wafers by reducing the growth rate below  $0.5\mu/\text{min}$ , although they did not specify whether this was accomplished by reducing the temperature or the concentration of reactants. In this connection, it is also noteworthy that Tung (2) has reported that low growth rates, obtained by adjusting the concentration of  $\text{SiCl}_4$ , would yield more perfect surfaces on substrates oriented close to (111); he found that surface pyramids did not grow when the growth rate was less than  $0.4\mu/\text{min}$ , and also that these pyramids did not grow when the substrates were misoriented from (111).

We have found that steps  $\sim 500\text{\AA}$  high generally suffer less change of shape than steps  $1500\text{\AA}$  high, even with properly oriented substrates. In addition, we report a significant influence of the temperature of the

epitaxial deposition, both for near (111) and for (100) surfaces. We have also found that the orientation of the steps relative to mirror planes of symmetry in the lattice is an important variable to consider in producing depressions whose boundaries have symmetrical displacements relative to the edges of the buried layers.

To facilitate later discussion, we define four possible types of distortion, illustrated in Fig. 1b. Cross-sections are drawn to indicate the relative positions of the depressions in the substrate and epitaxial surfaces. The first situation is called "symmetrical distortion," in which case the displacements of the steps are symmetrical about the center. Thus  $\bar{S}_1 = -\bar{S}_2$  in 1 of Fig. 1b. There is no displacement of the center of the figure. The width of the figure may increase or decrease, as shown. The next case is called "nonsymmetrical distortion without change of size." Here there is a net shift of the center of the figure, and the displacement vectors are equal,  $\bar{S}_1 = \bar{S}_2$ . The third case is "nonsymmetrical distortion with change of size," with  $|\bar{S}_1| \neq |\bar{S}_2|$ . The last case illustrates "obliteration" or "washout" of the surface feature.

When considering an entire rectangular depression, the phrase "a pair of sides" will refer to a pair of parallel sides of the rectangle. One pair of sides may in practice become distorted differently from the other pair, so information about both is necessary to completely specify the distortion. We refer to individual surface figures as flat-bottomed depressions or as pits, as appropriate. We use the word *pattern* to denote an array of individual geometrical figures.

### Experimental Details

All of the epitaxial films were grown by the hydrogen reduction of  $\text{SiCl}_4$  at a mole fraction of about 1% unless otherwise stated, and at specified temperatures near  $1200^\circ\text{C}$  with growth rates in the vicinity of  $1\mu/\text{min}$  (5). The substrate slices were placed either directly on the inductively heated susceptor or on a thin quartz wafer on the susceptor. Temperatures were measured by optical pyrometry, correcting for emissivity according to the data of Allen (6). The angular misorientations of the slices from (111) were measured within about 20 min of arc with x-ray goniometry (7), and the directions of the misorientations were determined by Laue back reflection x-ray photographs.

The substrate slices were cut from 4 to 10 ohm-cm, boron-doped ingots. They were mirror polished, cleaned, oxidized at  $1100^\circ\text{C}$ , and antimony was diffused at  $1250^\circ\text{C}$  through windows opened in the oxide by standard photolithography techniques. The last 10 min of the diffusion step was a thermal oxidation with dry oxygen in order to create shallow depressions in the silicon exposed by the windows. Some slices were prepared without the antimony diffusion, i.e., shallow depressions were formed by a short oxidation after windows were opened. Prior to epitaxial growth, all oxide was removed and the surfaces were hydrophobic.

The numerical results herein refer to depressions about  $500\text{\AA}$  deep as measured by interferometry, and to epitaxial thicknesses of about  $3\mu$ . All of the surface observations were made with interference contrast microscopy (8) which provides considerable contrast at steps of small height.

### Distortion and Displacement on Surfaces near (111)

A pattern of circular shallow depressions (Fig. 2a) was used in order to observe the distortion for every possible orientation of steps on a given slice. The circles generally became oval-shaped figures after epitaxial deposition, as shown in Fig. 2b-c. To characterize this change of shape, we define the "shape distortion" to be the difference in the principal diameters of the ovals; some data on the shape distortion as a function of surface orientation and growth tem-

Fig. 2. Undistorted circular depression  $\approx 500\text{\AA}$  deep in silicon substrate (a), and same feature after epitaxial deposition on substrates  $1^\circ$  (b), and  $3^\circ$  off (111) toward a nearest {110} (c). Interference contrast micrographs.

perature are shown in Fig. 3. The general features of the data are the following: (i) there is a discontinuity in the distortion at the exact (111) position, since patterns on surfaces very close to (111) could not be recognized after deposition; (ii) the shape distortion decreased with angular orientation off (111) and was generally lower at higher growth temperatures; and (iii) there was always some measurable distortion.

There are some further details which are important, since there are many ways to misorient a surface off (111). It will become apparent later in this section that symmetry conditions will play a part in determining the most useful way to orient a surface off (111). The exact (111) surface has 3-fold symmetry with three mirror planes in the lattice normal to (111), and this symmetry is reduced with a surface that is slightly off (111). It is possible to retain one of these mirror planes normal to the surface, so that two-fold symmetry is retained. The two ways of doing this are included in the data of Fig. 3, i.e., surfaces  $\theta$  degrees off (111) toward a nearest {100} denoted  $111-\theta^\circ-100$ , and likewise, surfaces off (111) toward a nearest {110}, denoted  $111-\theta^\circ-110$ . From Fig. 3 it is clear that  $111-\theta^\circ-110$  surfaces exhibited lower distortion, less temperature dependence of the distortion and sharper edges. We also experimented with several other ways to orient surfaces off (111), and the results showed the same general decrease in distortion with misorientation. The greatest distortion occurred on  $111-\theta^\circ-100$  surfaces.

A distorted surface pattern should be accompanied by lateral displacement of a step on the epitaxial surface relative to the edge of the buried layer. To measure this displacement, patterns with rectangular features were used; these patterns contained a small alignment feature in the shape of a T, which served as a monitor of the distortion of the surface feature. Figure 4 consists of data on the width of the stem of the T after epitaxial growth plotted against the lateral shift of one side of a depression, as revealed by angle lapping and staining. These points were taken from slices whose orientations ranged from  $\frac{1}{2}^\circ$  to  $4^\circ$  off

Fig. 3. Shape distortion vs. surface orientation near (111)

Fig. 4. Width of a standard surface figure (T) vs. displacement of edge of rectangular figure relative to the edge of the buried layer.

[111] in random directions. As expected, the displacement generally increased with deviations of the width of the stem of the T from its original value. However, a number of points show W close to its original value  $W_0$ , but with a displacement S of approximately  $10\mu$ . These data suggest that an undistorted depression is necessary but not sufficient to ensure that the edges of the depression are precisely ( $\pm 2.5\mu$ ) registered relative to the edges of the buried layer.

According to the data of Fig. 3, the  $111-\theta^\circ-110$  surfaces will provide more control over the shape distortion than the other orientation shown in Fig. 3. We may ask just how small will the lateral displacement be on such a surface, or how precisely can a step be grown relative to the buried layer? It is now clear that the crystallographic orientations play a very important role in the lateral displacement of the depressions, i.e., in the lateral growth at the small steps. Since the original surface feature is symmetrically positioned relative to the buried layer, as drawn in Fig. 1, the ideal situation after epitaxial growth would also be for the figure and buried layer to be symmetrical. To achieve this, opposite sides of a shallow pattern should have identical crystallographic orientations; this will be the case if there is a mirror plane of symmetry in the lattice, normal to the slice and parallel to the edge of the depression.

Fig. 5. Drawing of Laue x-ray pattern from a silicon slice with a  $111\text{-}3^\circ\text{-}110$  surface, and drawing of rectangular surface features with one pair of sides parallel to the mirror plane of symmetry normal to the surface of the slice.

With  $111\text{-}\theta^\circ\text{-}110$  surfaces, as shown in Fig. 5, one orientation of steps in a depression may be aligned parallel to the one mirror plane which is normal to the surface. We experimented with slices oriented  $3^\circ$  off (111) toward a nearest  $\{110\}$ , denoted  $111\text{-}3^\circ\text{-}110$ , and verified that the resultant displacements of the steps parallel to the mirror plane were symmetrical and small ( $\sim 2.5\mu$ ), as shown in Fig. 6. However, other steps in the rectangular figure were not parallel to a mirror plane of symmetry, and the displacements were not symmetrical, as illustrated. A typical value of the maximum displacement for these steps was  $14\mu$  or 1.7 times the epitaxial thickness. In this case the net displacement of the center of the surface figure relative to the buried layer reproducibly occurred in the  $[11\bar{2}]$  direction, using conventional notation (7).

If, with  $111\text{-}3^\circ\text{-}110$  surfaces, the steps were oriented at  $45^\circ$  to those indicated in Fig. 5, we found that sharp figures were grown; however, the displacements were approximately equal to the film thickness but the steps were not symmetrically displaced relative to the buried layer. In this case, neither pair of sides were distorted symmetrically. For reproducible results, it appears necessary to control both the orientation of the pattern and of the slice. One method for routinely accomplishing this is to grind a flat section on the ingot

Fig. 6. Double angle-lap and stain of a slice oriented as in Fig. 5. The displacements were symmetrical for only one pair of sides.

prior to slicing, so that each slice has a  $\{112\}$  flat as shown in Fig. 5. Then the orientation of each slice may be determined by inspection.

#### Patterns on (100) Surfaces

From symmetry considerations, one expects to obtain symmetrical distortion of both pairs of sides of rectangular depressions on exact (100) surfaces. We have experimented with figures whose sides were parallel to the  $\langle 011 \rangle$  directions. Again, it was found that the temperature of deposition had a significant effect on the nature of the distortion, independent of the concentration of  $\text{SiCl}_4$ . At  $1240^\circ\text{C}$ , the resultant depressions had very sharp boundaries and were undistorted. Angle-lapped sections showed that both sets of sides of the depressions were symmetrically shifted by small ( $\sim 2.5\mu$ ) amounts relative to the buried diffusion.

However, at lower temperatures such as  $1215^\circ$  and  $1185^\circ\text{C}$ , much less sharp boundaries resulted. This was an effect of temperature and not an effect of concentration, over the range 0.4 to 1.7 m/o (mole per cent)  $\text{SiCl}_4$ .

These results were obtained on slices with surfaces within 15 min of (100). A complete graph of lateral displacement as a function of orientation off (100) has not been plotted, but a few examples of nonsymmetrical shifts for surfaces  $2^\circ$  off (100) have been observed.

#### Other Effects

Vapor phase HCl etching of silicon is a well established method of final substrate preparation, which generally allows more perfect epitaxial layers to be grown. We found that negligible distortion took place on  $111\text{-}3^\circ\text{-}110$  surfaces during either 1 or 10 min HCl etching at  $1290^\circ\text{C}$  and 1% HCl in  $\text{H}_2$ . Some distortion did result, however, on surfaces closely oriented to (111).

The distortion of depressions does not depend on the presence of a high concentration of dopant; this has been demonstrated by producing shallow patterns in undiffused substrates. The resultant distortions after epitaxial growth showed the same orientation dependence as those on diffused slices. Occasionally the process of antimony diffusion by means of  $\text{Sb}_2\text{O}_3$  in nitrogen produces a rough surface, believed to be associated with precipitation of a second phase. In this event, the boundaries of the diffused regions were "distorted" prior to epitaxial growth, and some distortion after epitaxial growth was thus inevitable.

A few experiments were carried out with deeper ( $1500\text{\AA}$ ) depressions, produced by longer oxidations after diffusion. Their boundaries after epitaxial deposition showed less sharpness than those obtained with  $500\text{\AA}$  depressions, even when other variables such as orientation and growth conditions were identical. Thus, the use of deeper depressions appears to be accompanied by unnecessary complications which do not aid in controlling the distortion phenomenon.

We have no evidence that gas flow conditions have any influence on the distortion. All of the epitaxial layers of this work were grown on horizontally rotating pedestals heated by induction. Several runs were made with a set of identically oriented slices, positioned in a variety of ways on the pedestal; the results showed no effect of the position on the pedestal on the distortion.

#### Effect of Surface Orientations Near (111) on Pits at Stacking Faults

The fact that stacking faults can be detected with interference contrast microscopy on as-grown surfaces of epitaxial silicon (9) indicates that a small surface disturbance occurs at the site of the stacking fault-surface intersection. There are generally two components to this surface irregularity; (i) a well-defined triangular figure (or portions thereof) whose dimensions are directly related to the film thickness, and (ii) a less-sharply defined pit, which can vary

greatly in size and shape. We believe that the origin of these figures is as follows. During growth, there will be a tendency for the surface to become thermodynamically equilibrated since atoms are mobile on the surface; a groove would then form at the intersection of the stacking fault and the surface. This process could be called "stacking-fault grooving," in analogy with the well-known grain boundary grooving which occurs in metals (10). The groove forms so that the energy of the crystal is lowered; at equilibrium, the tension of the stacking fault will be equilibrated by components of the surface tension of the exposed surface at the groove. This grooving would explain the presence of the triangular part of the figure, whose shape will be essentially unaffected by changes in orientation near (111). Next, this groove which is a depression in the surface, will suffer distortion during growth; this distortion is very dependent on surface orientations near (111). Thus the small effect of grooving is enhanced by distortion. In some cases, this distortion-part of the surface figure can be a very large pit, as illustrated in Fig. 7a; the stacking faults at one end of the pit are revealed after a brief Sirtl etch (11) as shown in Fig. 7b. As expected, the largest of these pits occurred on surfaces which gave the greatest distortion, i.e., surfaces off (111) toward a nearest {100}. Also, the various grooves at a single stacking fault triangle became distorted differently, and those grooves which tended to expose regions of exact (111) surfaces became distorted the most. For diffused diodes, some data indicate that these large pits associated with stacking faults have undesirable electrical effects; Orr (12) has measured the reverse voltage at 10  $\mu$ a (breakdown voltage) of diffused diodes on a slice containing large pits at stacking faults. For the particular case he studied, the

results were that diodes with large pits had very low breakdown voltages ( $\sim 10$ v) and diodes without the pits had higher breakdown voltages ( $\sim 60$ v). Further details suggested that low breakdown resulted from a combined effect of the pits and the stacking faults. These very large pits at stacking faults may be eliminated by either reducing the fault density or by using substrates which are oriented off (111) toward a nearest {110}. Also, higher growth temperatures reduce the size of the pits, since the distortion is reduced. Generally, very small pits accompany stacking faults on 111-3°-110 surfaces, as shown in Fig. 7c. Also, no large pits on (100) surfaces have been observed to accompany stacking faults.

### Discussion

It is evident that the distortion is greatly influenced by the crystallographic orientations involved; presumably, an important reason is the anisotropy of the growth rate. A possible qualitative explanation for the temperature dependence of the distortion is a decrease in the anisotropy of the growth rate at higher temperatures. This temperature dependence of the anisotropy has apparently not been studied experimentally, but it is known that many components of the growth process are temperature dependent, e.g., surface diffusion coefficients, nucleation rates, and densities of kink sites.

From experimental data for epitaxial silicon (2), it is known that the growth rate has a cusped minimum at (111) and little or no minimum at (100) or (110). This immediately gives a qualitative understanding of the necessity to orient the surface off the (111) position; since (111) is the slowest growing surface, the growth rate normal to a (111) slice will be very slow compared to the growth of the different crystallographic orientations exposed at the edges of a depression. Thus these figures become obliterated during growth. We have directly observed this process through a microscope equipped with a hot-stage deposition chamber, and the obliteration of figures on surfaces very close to (111) took place quickly, during the first micron of growth. To achieve a higher growth rate normal to the slice, one orients the surface off (111). The choice of the direction off (111) is dictated by experimental data such as that in Fig. 3, together with symmetry considerations.

The observation that some depressions increase their width during growth suggests that preferential etching of material occurs at some steps. It is known (5) that etching of silicon substrates takes place with high (>0.28) mole fractions of  $\text{SiCl}_4$  in  $\text{H}_2$ , and it is generally believed that some etching occurs as a basic part of the growth process at lower concentrations. The present results merely suggest that this etching effect is also dependent on orientation.

This study of the distortion phenomenon has also led to some understanding of the origin of surface topographical defects in general, as illustrated by the example of pits at stacking faults. For a surface free from topographical irregularities, the present results suggest that high temperatures and/or carefully controlled surface orientations are important factors, in addition to the more commonly recognized factors such as substrate perfection and cleanliness.

In conclusion, it appears that knowledge of the epitaxial growth rates as a function of crystallographic orientation, along with knowledge of the symmetry of the lattice are important factors in understanding the distortion in a qualitative manner. Quantitative details on the temperature dependence, the magnitude of the distortion, and the magnitude of the displacements can only be obtained by experiment. In practice, symmetrical and small (approximately  $2.5\mu$ ) displacements can be obtained for both pairs of sides of rectangular depressions on (100) surfaces and for one pair of sides of depressions on 111-3°-110 surfaces.

## Technical Notes

### Scanning Electron Microscopy of Twin Structures in Silicon Web Dendrite Crystals

G. H. Schwuttke and E. K. Brandis

IBM East Fishkill Laboratories, Hopewell Junction, New York

The scanning electron microscope (SEM) has recently been introduced as a new tool to examine and study defects in semiconductor devices (1-3). An outstanding feature of the SEM is its high resolution combined with large depth of focus. More recently the application of the SEM as a refined "probe" has been described (4,5). Specifically, its ability to locate regions of avalanche breakdown in devices has been the subject of several papers (6,7). This note describes the application of the SEM to problems of crystal growth and shows its usefulness for the detection of twin structures in silicon web dendrite crystals.

In general, the detection or location of twins in crystals is relatively easily accomplished through chemical etching. Chemical etching followed by optical inspection is also quite useful for the study of twin structures in semiconductor crystals; however, the interpretation is difficult or sometimes impossible if the twins are spaced as closely as in web dendrite crystals.

Faust and John (8) have shown that the inspection of fractured web crystal surfaces can give reliable information of the true twin structures as long as it is possible to view fractured surfaces directly and the twin spacing is within microscopic resolution.

For submicroscopic twin spacing the electron microscope replication technique has been shown to be very successful and reliable (9). However, this technique is relatively complicated and time consuming.

Such difficulties do not exist for the scanning electron microscope. The electron optics of the SEM provide a large depth of field, many times that of the light microscope. The crystals are inspected directly making cumbersome replication unnecessary. Consequently, the exact surface topography of the crystal is easily explored, and submicron twin lamellae can be detected.

The cleavage planes of silicon are the {111} planes. Skillful cleavage of silicon breaks the crystal on the cleavage planes. This technique works also quite well for thin web and micron web (8). A diagram of the

cleaved section of web dendrite is shown in Fig. 1. The crystallographic indices of the twinned segments are referred to the parent crystal.

For the inspection of such surface structures the SEM is operated in the secondary electron collection mode (4). In this mode of operation the contrast in the SEM topograph depends on the efficiency of secondary electron collection. A (111) cleavage surface appears either bright or dark depending on its position relative to the SEM signal detector. The cleavage plane is bright if secondary electrons are readily collected and the plane appears dark if the position of the signal detector relative to the crystal plane is such that no or fewer electrons are collected (for instance in the shadow side of the plane). From the bright/dark contrast in the SEM topograph the twin structure is easily deduced.

Fig. 1. Diagram of cleaved web dendrite structure

Fig. 2. SEM topograph of cleaved cross section of web dendrite revealing twin structure: (a) (top)  $100\mu$ ; (b) (bottom)  $10\mu$ .

The effect of twin lamellae present in cleaved silicon web dendrite crystals on SEM contrast is shown in Fig. 2a and 2b. Figure 2a is the SEM topograph of the cleaved cross section of such a crystal. Magnification is low, approximately 140X. However, a thin black line indicates the presence of a twin lamellae. This is seen much better at higher magnification. In Fig. 2b, the same crystal area is viewed at a magnification of approximately 2800X. Note the three-dimensional contours displayed in the SEM topograph.

To establish the validity of SEM contrast interpretation SEM topographs of cleaved web dendrites were correlated with electron microscopy results obtained through the replica technique of Stickler (9), specifically developed for the investigation of silicon surfaces. An example of such a correlation is shown in Fig. 3a and 3b. Figure 3a represents the electron transmission micrograph and Fig. 3b is the SEM topograph. The electron micrograph and the SEM micrograph do not show exactly the same area of the web dendrite surface because this is rather difficult to achieve. However, the areas depicted in these two micrographs are located reasonably close to each other and the twin structure is continuous in these areas. The agreement between the two measurements is obvious. Confidence in the SEM method for the inspection of twin structure in web dendrites has been established through numerous measurements.

A systematic investigation of fractured web dendrite crystals by optical and SEM microscopy has shown that optical inspection alone may not always be sufficient to reveal the true twin structure. An example

Fig. 3a. Electron microscope replica of fractured web dendrite crystal showing twin lamellae.

Fig. 3b. SEM micrograph of crystal shown in Fig. 3a

of this is presented in Fig. 4a and 4b. The photomicrograph presented in Fig. 4a is an optical picture of a multiple (submicron) twin structure. The corresponding SEM micrograph is shown in Fig. 4b at a magnification of approximately 7000X. In the optical photomicrograph we recognize only two grooves while in the SEM topograph multiple twinning is clearly evident.

For a quantitative evaluation of SEM pictures the foreshortening of the SEM image as seen on the cathode ray tube must be considered.

#### Acknowledgment

The authors are indebted to Dr. O. C. Wells for his assistance in recording the SEM topographs and also to Mr. D. Cameron and Mrs. F. Ordonez for the skillful electron microscopy. Part of this work was sponsored under Government Contract AF 16(628)-5059.

Manuscript received June 29, 1967; revised manuscript received Feb. 15, 1968. This paper was presented

## Preparation and Properties of Amorphous Germanium Nitride Films

Haruo Nagai and Tatsuya Niimi

*Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan*

Compared to much work on silicon nitride films for passivation of silicon devices, there are only a few reports about the compounds between germanium and nitrogen,  $\text{Ge}_3\text{N}_2$  and  $\text{Ge}_3\text{N}_4$  (1-3).

In this paper a new method of preparation of amorphous germanium nitride film, using the reaction of germanium tetrachloride and ammonia, and some properties of the film are reported.

#### Experimental

The apparatus used for the deposition of the germanium nitride film was similar to an rf-heated silicon epitaxial deposition system widely used, in which the deposition was carried out on a hot substrate crystal placed on a heated molybdenum pedestal held in the center of a vertical fused silica tube. As  $\text{GeCl}_4$  reacts with  $\text{NH}_3$  at room temperature and produces  $\text{Ge}(\text{NH})_2$  and  $\text{NH}_4\text{Cl}$ , the two reactants must be introduced separately onto the hot substrate where the reaction takes place. The vapor of  $\text{GeCl}_4$  was carried into the system by purified hydrogen gas passing over liquid  $\text{GeCl}_4$  stored in an evaporator kept at  $0^\circ\text{C}$ .

The ammonia gas used was of high purity and dried by passing through a KOH column and a cold trap kept at  $-22^\circ\text{C}$  before introduction into the reaction

tube. The substrate surface was (111) single crystal germanium or silicon, mirror polished and etched with CP4. After the temperature of the substrate was raised to the reaction temperature in hydrogen, ammonia and germanium tetrachloride were introduced into the reaction tube.

#### Results

It was possible to form the films in the temperature range from  $400^\circ$  to  $600^\circ\text{C}$ . The deposited films were uniform, transparent, and adherent to the substrates. Above  $600^\circ\text{C}$ , the epitaxial growth of germanium was observed, and below  $400^\circ\text{C}$ , the growth of the film was too slow to be observed. The effect of the substrate temperature on the deposition rate is shown in Fig. 1 for a typical reactant concentration, giving an activation energy of 17 kcal/mole.

When the concentration of  $\text{GeCl}_4$  was varied from 0.1 m/o (mole per cent) to 0.6 m/o, the deposition rates remained almost unchanged, if the reaction temperature and the concentration of  $\text{NH}_3$  were kept constant. The thickness of the film, required for the determination of the deposition rate, was measured by the optical interference technique using mercury light ( $5461\text{\AA}$ ), and, at the same time, the refractive indices of the films were determined to be  $2.06 \pm 0.06$ , which are marked

Fig. 1. Temperature dependence of the deposition rate of the film. Numbers in parentheses are refractive indices.

Fig. 2. Infrared transmission curve for the film on germanium

at several growth points along the experimental curve in Fig. 1. No correlation was found between the value of refractive indices of the films and deposition conditions. The infrared absorption spectra of the films showed the broad band of absorption with a peak between 720 and 750  $\text{cm}^{-1}$ , and qualitatively the peak was found to move toward the lower frequency side at the samples deposited at higher temperatures. In Fig. 2 is shown a typical absorption spectrum taken on a sample having a film of thickness 2870 Å deposited at 600°C on an n-type 40 ohm-cm germanium substrate crystal.

X-ray and electron diffraction show that the films deposited were amorphous. Figure 3 is a typical reflection electron diffraction pattern for the film mentioned in Fig. 2.

It is reported, that above 700°C germanium reacts with ammonia and forms  $\text{Ge}_3\text{N}_4$  crystal which has a mixed structure of  $\alpha$ - and  $\beta$ -phases (4).

The infrared absorption spectrum of the crystal prepared by the above method shows sharp absorption peaks at 770 and 730  $\text{cm}^{-1}$ , the later corresponding to the absorption of  $\alpha$  phase  $\text{Ge}_3\text{N}_4$  crystal (5), and the absorption peaks of the films reported here are near these values. The chemical analyses of the films were not performed, but from these facts, the films deposited were considered to be amorphous  $\text{Ge}_3\text{N}_4$ . Generally the films were slightly soluble in water, con-

Fig. 3. Electron diffraction pattern for the film

Fig. 4. Dependence of the etching rate of the film by 46% HF at 20°C on the deposition temperature. Reactant concentration is the same as the case of Fig. 1.

centrated  $\text{HCl}$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{H}_3\text{PO}_4$ , and  $\text{NaOH}$  solution, but rapidly dissolved in concentrated  $\text{HF}$  and  $\text{HNO}_3$ .

The dissolution rate decreased with the higher growth temperature of the films and Fig. 4 shows an example of the results in 46%  $\text{HF}$  at 20°C. When the film was kept at or above 600°C in hydrogen, the thickness of the film was reduced rapidly, and in  $\text{Ar}$  or  $\text{N}_2$ , the films were decomposed slowly.

The electrical resistivity of the films was very high, ranging from  $10^{14}$  to  $10^{16}$  ohm-cm.

Manuscript received Jan. 29, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Some New Classes of Efficient $\text{Eu}^{2+}$ -Activated Phosphors

G. Blasse, W. L. Wanmaker, and J. W. ter Vrugt

N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

The absorption and fluorescence of the  $\text{Eu}^{2+}$  ion in solids is well known. The fluorescence usually consists of an emission band in the short-wavelength part of the visible region (1). Some of the  $\text{Eu}^{2+}$ -activated alkaline-earth silicates have been reported to show efficient fluorescence (2). Recently the efficient, green fluorescence of  $\text{SrAl}_2\text{O}_4\text{-Eu}^{2+}$  was mentioned in a patent (3). The purpose of this communication is to report on some new classes of efficient  $\text{Eu}^{2+}$ -activated photoluminescent phosphors, whose emission spreads over the region 390-520 nm. More detailed information is published elsewhere (4-6).

Samples were prepared by standard ceramic methods firing in an atmosphere of nitrogen containing 5% of hydrogen. Optical measurements were performed as described before (7). The host lattices involved are the following: (a) alkaline-earth pyrophosphates ( $\text{Me}_2^{2+}\text{P}_2\text{O}_7$ ), (b) alkaline-earth aluminates of the magneto-plumbite type ( $\text{Me}^{2+}\text{Al}_{12}\text{O}_{19}$ ), (c) alkaline-earth magnesium silicates of the types  $\text{Me}_2^{2+}\text{MgSi}_2\text{O}_7$  (e.g., akermannites) and  $\text{Me}_3^{2+}\text{MgSi}_2\text{O}_8$  (merwinites), and (d) alkaline-earth aluminates with tridymite-like structure ( $\text{Me}^{2+}\text{Al}_2\text{O}_4$ ). All these compounds can be easily doped with divalent europium. In this way phosphors are obtained with a high efficiency under 254 and 365 nm excitation. The efficiency for cathode-ray excitation is not so high (although comparable to those of  $\text{Ce}^{3+}$ -activated phosphors). The color of the emission varies from blue to green and depends strongly on the host lattice used and to a lesser extent on the choice of the alkaline earth ion (or the composition of a mixture of alkaline earth ions). It is therefore possible to prepare phosphors with a specific emission peak in the region 390-520 nm by an appropriate choice of the chemical composition of the host lattice.

Table I shows data on the fluorescence of some of the new materials. Figure 1 gives the spectral energy distribution of one example out of every class of the host lattices. The emission region 395-440 nm is covered by the pyrophosphate and aluminate phosphors with general formulas  $\text{Me}_2\text{P}_2\text{O}_7\text{-Eu}$  and  $\text{MeAl}_{12}\text{O}_{19}\text{-Eu}$ , the region 440-475 nm by the silicate phosphors with formula  $\text{Me}_3\text{MgSi}_2\text{O}_8\text{-Eu}$ , the region 440-510 nm by the

Fig. 1. Spectral energy distribution of the emission of: 1.  $\text{Sr}_{10}\text{Mg}_{12}\text{P}_2\text{O}_7\text{-Eu}^{2+}$ , 2.  $\text{BaAl}_{12}\text{O}_{19}\text{-Eu}^{2+}$ , 3.  $\text{Sr}_3\text{MgSi}_2\text{O}_8\text{-Eu}^{2+}$ , 4.  $\text{Ba}_3\text{MgSi}_2\text{O}_7\text{-Eu}^{2+}$  (broken line), and 5.  $\text{BaAl}_2\text{O}_4\text{-Eu}^{2+}$ . 254 nm excitation. Along the ordinate the relative radiant power per constant wavelength interval (I) is plotted.

silicate phosphors with formula  $\text{Me}_2\text{MgSi}_2\text{O}_7\text{-Eu}$ , and the region 500-520 nm by the aluminate phosphors with formula  $\text{MeAl}_2\text{O}_4\text{-Eu}$ . The optimum  $\text{Eu}^{2+}$ -concentration amounts to roughly 2-5 a/o (atom per cent). For further details the reader is referred to other papers (4-6).

Manuscript received Dec. 15, 1967. This paper was presented at the Boston Meeting, May 5-9, 1968, as Abstract 56.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Crystallographic Phase Transformation of Ferric Fluoride

W. J. Croft and M. Kestigian\*

*Sperry Rand Research Center, Sudbury, Massachusetts*

Ferric fluoride ( $\text{FeF}_3$ ) was reported originally to possess the rhombohedral  $\text{AlF}_3$ -type structure (1). More recent work has shown (2, 3) that the structural unit actually is a bimolecular rhombohedral cell (space group  $R\bar{3}c$ ) with the fluorine atoms in slightly distorted hexagonal closest packing. The metal atoms occupy certain octahedral interstices and form a rhombohedrally distorted simple cubic superlattice. The unimolecular rhombohedral pseudocell reported by Hepworth *et al.* (2) has an angle  $\alpha = 88.22^\circ$  which indicates the small degree of distortion from the cube.

Crystals prepared by vapor transport are morphologically orthogonal in outline, appearing as cubes or cubes elongated on one fourfold axis. Examination in plane-polarized light indicates these crystals to be anisotropic and to show extinction at approximately  $45^\circ$  to the elongated (fourfold) axis. Each morphological crystal consists of several units, each of which shows extinction at  $45^\circ$  to the pseudocube [100] edge.

Many of the crystals have a fibrous appearance with the fiber axes at  $45^\circ$  to the elongation direction of the crystal. These fibers extinguish parallel to the polarization directions of the microscope. By tilting various crystals it is observed that the C-axis elongated fibers are clustered in groups or bundles with each bundle having its axis parallel to one of the four  $\langle 111 \rangle$  directions of the pseudocubic form of the crystal.

The present study has also observed crystallographic reflections with  $h + k + l$  odd (superlattice reflection) which Hepworth *et al.* (2) report and cite as evidence of the bimolecular rhombohedral unit cell.

\* Electrochemical Society Active Member.

The crystals were heated on the stage of a polarizing microscope. A Leitz heating stage was used with the sample being held on a transparent, fused quartz plate. The heating chamber was continuously flushed with dry helium which had previously passed through a liquid nitrogen trap. If care was not taken to avoid oxygen, the crystals turned from green to brown when held at temperatures above  $350^\circ$ , indicating that oxidation was taking place. At  $410^\circ\text{C} \pm 5^\circ$  the crystals became isotropic. This is a reasonable transformation although the twinning became much more complex by cycling through this transformation. The room temperature x-ray diffraction pattern reappeared after the heating cycle was complete.

## Conclusion

Crystals of anhydrous ferric fluoride ( $\text{FeF}_3$ ) have been formed by sublimation and grow in the cubic crystallographic symmetry. These crystals have been shown to undergo a phase transformation to a rhombohedral unit cell at  $410^\circ \pm 5^\circ$ . This crystallographic phase transformation prevents the growth of large single crystals by the usual methods.

# The Effect of Moisture on the Aluminum-Silica Reaction

Ronald Silverman

*The Bayside Laboratory, Research Center of  
General Telephone & Electronics Laboratories Incorporated, Bayside, New York*

Considerable interest has been focused recently on the reactivity of aluminum on silica because of the extensive use of these materials in integrated micro-circuit components. Aluminum is used as the contact and conduction metallization, while silica is used as the diffusion mask and insulator. Many investigators have shown that production devices may become degraded during processing and during life as a result of a reaction between aluminum and silica. Working with aluminum heat-treated in contact with thermally grown silica, Lehman (1), Berger (2), and Schnable (3) found that different reaction rates were obtained in various atmospheres. Cratchley and Baker (4), working with silica fibers coated with aluminum, found lower reaction rates than those obtained with the thermal grown silica substrates.

The different reaction rates between Al and  $\text{SiO}_2$  which were observed by the previous investigators may have been due to the variations in the moisture content of the heat-treatment atmosphere and/or the

type of silica substrate. In the present work, the influence of different substrate on the rate of reaction of  $\text{Al/SiO}_2$  composites was studied from  $400^\circ$ - $625^\circ\text{C}$  for 1 to 21 hr. The substrates investigated were as follows: fused silica,  $\text{H}_2\text{O}$  content nil;  $0.5\mu$  thick dry oxygen grown silica films,  $\text{H}_2\text{O}$  content nil; and  $0.5\mu$  thick steam grown silica films,  $\text{H}_2\text{O}$  content 0.1 w/o (5); moisture content of various atmospheres was 1-10,000 ppm  $\text{H}_2\text{O}$ .

Samples were prepared by evaporating 99.999 pure Al at  $10^{-6}$  Torr on to the substrates. Typically  $0.2\mu$  thick films were deposited in a pattern that provided lateral contacts for a four-point resistance determination. The width of the resistance strip was 0.15 cm, and the potential was measured over a distance 0.325 cm. Except for the reduced pressure ( $10^{-6}$  Torr) runs, all samples, at least two for each run, were heat-treated in a  $2\frac{1}{2}$ -in. ID Inconel muffle furnace through which argon, air, hydrogen, nitrogen, or oxygen flowed at the rate of approximately  $10\text{ ft}^3/\text{hr}$ . The dew point

\* Not determined.

of each gas as it entered the furnace was determined, and the ppm H<sub>2</sub>O content was obtained from published dew point vs. moisture content curves. After each treatment the samples were examined visually, and standard x-ray diffraction techniques were used to determine the phases present on reacted fused silica samples. To determine the percentage of the film which had reacted, the electrical resistance after each treatment was measured. An increase in the resistance was attributed to a decrease in the thickness of Al due to reaction with the silica. This appears to be justified since a change in sample color and/or the incidence of a new phase in the x-ray diffraction pattern was observed when a resistance change occurred.

The effect of heat-treatment temperature, atmosphere, and moisture content on the initial ( $R_1$ ) and final ( $R_2$ ) resistance, the percentage of the change in thickness of the reacted film  $(1 - R_1/R_2) 100\%$ , the x-ray phases detected, and the results of visual observations are given in Table I for the 1-hr-treated fused-silica samples. Little or no reaction was detected on samples fired for 1 hr at temperatures up to 575°C (samples 1,4,6,8,11) in any atmosphere. At 600°C, the extent of reaction increased significantly with increased atmospheric moisture for both oxygen-containing and inert atmospheres. The aluminum films were completely reacted in atmospheres containing 6.5 ppm H<sub>2</sub>O (samples 5,7,9) or more, and even in the presence of 2.5 ppm H<sub>2</sub>O, most of the aluminum film (10,12) was consumed. *In vacuo* (2) or in nitrogen (13) containing 1.7 ppm moisture, no reaction was observed. Unexpectedly, the reaction in pure oxygen (14) did not totally consume the Al film, while as little as 6.5 ppm moisture in argon (9) caused complete reaction. The moisture content has a greater effect than the free oxygen in the heat-treatment ambient in influencing the reaction rate. In vacuum (3) at 625°C only a 13% decrease may have been due to slight reaction or to a small amount of evaporation, as evidenced by a slight dulling of the surface.

As expected, all x-ray patterns showed the broad peak, characteristic of amorphous silica. In addition, lines characteristic of Si were found in the x-ray diffraction pattern for several of the reacted films. These films (5,7,9,12) were generally darker (less free Al) than the other films and, as shown earlier, had the greatest resistance. The light-colored film found on the 600°C oxygen treated sample (14) could not be identified with x-ray diffraction analysis.

The magnitude of the resistance, i.e., 4600-5000 ohms, of the completely reacted couples (5,6,9) cannot

be explained on the basis of a continuous Al film; the calculation of the thickness of Al corresponding to this resistance results in the meaningless value of 10<sup>-9</sup> cm. To study this further, resistance measurements of six heavily reacted films were made at +25°, -70°, and -196°C. The resistance in all cases was found to increase with a decrease in temperature and plots (log R vs. 1/T) were straight lines indicative of nonmetallic conduction. The activation energy for the conduction process was calculated to be 0.012 ± 0.004 ev.

The resistance changes for Al films on the three different substrates are tabulated in Table II for 550° and 600°C treatment times from 1 to 21 hr and moisture in the treatment atmosphere from 1 to 10,000 ppm H<sub>2</sub>O. The results showed that there was a small tendency toward greater resistivity change on the steam grown silica samples compared to the fused or the dry-oxygen grown samples. Couples heated at 550°C for 1 hr exhibited no change in resistance regardless of substrate type. However, beyond this period, increases in resistance were found; the rate of change increased with increased moisture in the treatment atmosphere. An abrupt rate increase occurred between 1 and 2.5 ppm H<sub>2</sub>O. In 2.5 ppm H<sub>2</sub>O the Al films were almost totally reacted within 21 hr. In 10,000 ppm H<sub>2</sub>O, total film reaction was obtained between 5 and 21 hr.

At 600°C no reaction was found after the 1-hr treatment in ambients containing 1 ppm H<sub>2</sub>O for all three

\* N<sub>2</sub>, 1 ppm H<sub>2</sub>O; argon, 2.5 ppm H<sub>2</sub>O; air, 10,000 ppm H<sub>2</sub>O; vac, <1 ppm.

substrates. However, between 1 and 5 hr the Al was totally reacted in even these relatively dry atmospheres on all substrates. This is believed to be due to the incidence of the Al-Si eutectic (577°C) which should accelerate the process, as suggested by Cratchley (4).

The results of these experiments suggest that the moisture content of the heat-treatment atmosphere and of the substrates used significantly affected the reaction rate between Al and SiO<sub>2</sub>. These H<sub>2</sub>O contents may have been sufficiently different in the previous investigators work to account for the discrepancies found.

Darkening occurred first at the edges of the film patterns. Therefore, in all probability, an ambient silica-aluminum reaction took place initially. Complete darkening occurred concomitant with a disappearance of elemental aluminum and the growth of a Si phase. It can be deduced that the Al reduced SiO<sub>2</sub> to Si with the formation of an aluminum oxide. The specific oxide could not be identified, since no diffraction patterns characteristic of an Al-oxide were found. The resistance and temperature coefficient of resistance of the completely reacted films indicates that a layer of nonmetallic material was formed. It does not appear

likely that its conduction could be attributed to ionic conduction since the activation energy was too low (6). The type of conduction process involved would have to be determined by other experimentation.

Manuscript received Nov. 6, 1967; revised manuscript received Feb. 29, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of the Electrochemical Society*, Vol. 114, No. 2, 4, and 9 (February, April, and September).

### Travelling Solvent Defects on Silicon Wafers

E. Biedermann (pp. 207-208, Vol. 114, No. 2)

**C. H. L. Goodman**<sup>1</sup>: The defects referred to by Biedermann were in fact discussed six years ago<sup>2</sup> and, as pointed out then, have the same origin as the submelting-point melting patterns on silicon and other materials described still earlier by Pearson and Treuting.<sup>3</sup> In connection with<sup>2</sup> it was later found that the relevant contamination was definitely due to residues left by the water used for washing. These residues could be almost eliminated by using deionized water doubly distilled in a quartz-glass apparatus for the final wash, and preventing this drying freely on the surface of the specimen by wiping the latter clean with hard, ash-free, filter paper.

More recently, at these laboratories, Stewart<sup>4</sup> has developed a Soxhlet isopropyl alcohol washing technique, for gallium arsenide, which completely prevents the development of surface melt patterns, or what Biedermann terms "nails" (we prefer "tadpoles") on heating.

The formation of surface melt patterns should indeed be a general phenomenon with surface-contaminated solids: see for example Danilov's work with silver<sup>5</sup>, Haneman's with InSb<sup>6</sup>, or, for that matter, Stewart's with GaAs.<sup>4</sup>

**E. Biedermann**: I thank Dr. Goodman very much for having drawn my attention to the series of much earlier papers on the submelting point melting patterns on silicon and other materials. No doubt, our

"nails" are physically the same phenomenon. As to the chemical composition of the impurities involved they are, however, clearly of another origin with a much lower melting point of the eutectic pellets. We also observed the "submelting-point globules," but we did not take the trouble to identify their chemical composition, since they do not show up at the common process temperatures of epitaxial growth or diffusion cycles in the usual silicon planar technology.

### Vacuum Thermal Etching of Germanium and Silicon Surfaces

G. J. Russell and D. Haneman (pp. 398-403, Vol. 114, No. 4)

**J. Pfeifer**<sup>7</sup>: In the paper on "Epitaxial Growth of Germanium on Germanium Substrates Cleaned and Heated by Electron Bombardment" published in the *Physica Status Solidi*<sup>8</sup> the electron bombardment on (111) surface of germanium substrates by electron beam of 500 and 1000v was described. In the temperature range of 650°-800°C the morphological properties of the substrate agreed with the observations of Russell and Haneman on (111) Si at 1100°C. With the rise of temperature the average linear dimension of the etch pits increases, whereas their density decreases. The surface microtopography did not change qualitatively almost up to the melting point. In the vicinity of the melting point the surface area of the pits increases in such an extent that the pits are overlapping. The photomicrograph taken by Jona of heat-treated Ge surfaces proves this observation.<sup>9</sup> Even on surfaces on which evaporation was compensated by vapor deposition, no worm-formation could be detected.

Figure 1. displays a Ge surface (111) just below the m.p. The sample was bombarded by electrons of 1000v for 12 min. The surface evaporation was compensated by vapor deposition originating from a separate Ge source. The background vacuum amounted

Fig. 1. Electron bombarded (111) Ge surface in the vicinity of the m.p.

to  $4 \times 10^{-9}$  Torr and even during the electron bombardment the pressure was less than  $1 \times 10^{-7}$  Torr. It might be supposed that the island-like contamination in the interior of the hillocks (Fig. 1a) is some sort of a conglomerate caused by oxide contamination as described by Russell and Haneman in connection with the worm-formation. Figure 1b displays the same sample as Fig. 1a in a smaller magnification, whereas Fig. 1c displays the warmest part of the sample. The melting process, the beginning of which might be observed in Fig. 1a already, produced the drop-like contraction of the hillocks as shown in Fig. 1c.

These results do not seem to support the suggestion according to which the undersaturation might be the only reason for the worm-formation. It is more probable that the topographical conditions in the vicinity of the m.p. are caused by surface contaminations. The contamination of the surface of the sample partly occurs during its chemical preparation. In a vacuum system the samples might be contaminated secondarily by the residual gases and by other heated parts of the work-chamber; in various vacuum systems the heat treated surfaces might be different.

**G. J. Russell and D. Haneman:** The principal point raised by Pfeifer is that triangular etch pits were observed on a heated (111) Ge surface even though some deposition of vapor "from a separate Ge source" was occurring. This is contrasted to the conclusion obtained in the cited paper that worm shaped rather than triangle shaped pits tend to form in the presence of much returning vapor. As detailed in the paper, the amount of such returning vapor, or degree of undersaturation, is a critical factor in determining the shape of the etch pits on vacuum heated (111) Ge surfaces. Pfeifer's findings are not inconsistent with ours provided the return of Ge vapor in her experiments did not compensate the loss beyond the critical amount, i.e., the geometry and temperatures of the two crystals and the other surroundings are of significance in

analyzing the results of such experiments. We stress again the importance of fully detailing the condition of the surroundings of a heated Ge surface in order to properly estimate the degree of undersaturation that is maintained, and hence account for etch figures.

### Activation Energies in the Chemical Etching of Semiconductors in $\text{HNO}_3\text{-HF-CH}_3\text{COOH}$

A. F. Bogenschütz, W. Krusemask, K. H. Löcherer, and W. Musinger (pp. 970-973, Vol. 114, No. 9)

**B. Schwartz and K. L. Lawley**<sup>10</sup>: We find that the interpretation of the data used in Fig. 3 raises some questions in our minds. It has been very well established in the literature<sup>11,12</sup> of the existence of diffusion limitation in the etching of silicon in certain composition regions of this reagent system. However, diffusion limitation in the etching of germanium by this same chemical system has not been so clearly established<sup>13</sup> except, possibly, in very high  $\text{HNO}_3/\text{HF}$  mol ratios.<sup>14</sup>

Many investigators who have studied the etching of semiconductors in this reagent system have found numerous cases where the temperature dependence of the etching rate could be expressed by more than one "apparent" activation energy. Camp<sup>15</sup> did an excellent analysis of this situation to show how one could explain this type of dependence on the basis of sequential controlling mechanisms becoming predominant in different temperature ranges. We believe that such is the case for the germanium data of the author's Fig. 3. We have replotted their data and include, as the solid line (see our Fig. 1), their straight line interpretation. It is our contention that the data are better described by at least two straight lines as shown by the dotted lines on the figure. From a least squares analysis of the data, the temperature dependences appear to be 3.5 and 7.5 kcal/g-mol in the high and low temperature regions, respectively.

In a number of papers on the chemical etching of germanium<sup>15,16</sup>, it was noted that a breaking curve of the shape shown in the accompanying plot, would

Fig. 1. Plot of the logarithm of the etch rate as a function of the reciprocal of the absolute temperature.

have to be described by a reciprocal sum relationship. This mathematical form makes it difficult to extract the true activation energy.

We recommend, therefore, that Messrs. Bogenschütz *et al.*, consider that though the viscosity comparison with etching of silicon may be valid, their analysis of the germanium system is invalid. In addition, we propose that one of the possible explanations for the breaking curve as seen in this work, might be a shift from a physisorption to a chemisorption rate limiting step on the surface and that the temperature dependencies being observed are really related to this mechanism shift.

**A. F. Bogenschütz, W. Krusemark, K. H. Löcherer, and W. Mussinger:** We are pleased to note the interest of B. Schwartz and K. L. Lawley on our experiments and

their interpretation of the results. Although the Si etching system we investigated is not completely identical with the systems quoted by B. Schwartz and K. L. Lawley, an activation energy of the same order of magnitude was found, thus confirming the results of Schwartz and Lawley, and expressing the conclusions in general terms.

For the Ge etching process Schwartz and Lawley suggest a breaking ( $\log R - 1/T$ ) curve. The results published in the literature so far deviate widely from each other. Further clarifying investigations will prove very useful.

Our work was directed principally towards finding a possible relationship between the etching velocity of a system and the viscosity of an etching solution in order to predict the etching behavior of other systems by means of viscosity measurements.

### ABSTRACT

The discharge capacity of sintered silver electrodes in KOH solutions was improved 40-50% when the prior charge was made by a 60 cps asymmetric a.c. composed of two opposing half-wave currents 180° out of phase, rather than a constant charge current, both at the 20-hr rate in 35% KOH at 25°C. Commercial Ag-Zn cells containing similar silver electrodes gave capacity increases of 15-25% under the same conditions. Capacity depended on the proportion of charge and discharge components of the a.c. Capacity improvements were smaller when net charge current was at the 6-hr rate, when charge current was composed of 60 cps half-wave reverse current superimposed on constant charge current, or when the KOH concentration was increased. No significant improvement occurred when the charge with reverse current followed a series of discharges at the 1-hr rate.

An advantage of the silver oxide electrode used in alkaline storage batteries is its ability to be discharged at high current densities. To obtain the full capacity of which the electrode is capable, common practice has been to charge (anodically oxidize) the electrode at a relatively low current density. Previous work at this laboratory has shown that when pulses of charge current are superimposed on a steady charging current, the capacity of the subsequent discharge of a silver electrode can be greater than the capacity obtained by a constant current at the same rate (1). It has also been shown that, when charge current is interrupted periodically throughout a charge, the result can be either increased discharge capacity or faster recharging (2). The present work was undertaken to determine the effects of brief discharge periods during charges. The effects of relatively long discharges will be reported separately.

In the electroplating industry brief current reversal has been used for depolarization and for the periodic reverse current plating process. The effect of superimposing alternating current on direct current has been studied by a large number of investigators. A review of the earlier work was given by Halla (3). Some of the more recent work is covered by Rius *et al.* (4) and the references cited therein. Many of these investigations have dealt with depolarization while gas was being evolved at inert electrodes.

Several reports have been made on effects of charging batteries with an alternating current. The use of a.c. superimposed on direct current for recharging Leclanché primary cells without getting needles of zinc or large amounts of gas was proposed by Beer (5). In a similar way Romanov *et al.* (6) used asymmetric a.c. for charging cells which contained zinc negative electrodes to prevent dendritic zinc from forming and causing damage. Romanov (7) reported several changes after asymmetric a.c. was used for charging pressed silver powder electrodes: the total capacity of the following discharge increased, and the AgO/Ag<sub>2</sub>O potential plateau during discharge was shorter in length and at a lower potential than usual. The electrolyte concentration was not specified. Romanov reported that the use of a constant charge current resulted in AgO that was concentrated at the grid and able to show the AgO potential on discharge, but the use of a.c. resulted in a uniform distribution of AgO throughout the electrode (8). Flerov (9) used sintered silver electrodes in 1.40 sp gr KOH and found

that if a sufficiently large a.c. was superimposed on the steady charging current, the AgO/Ag<sub>2</sub>O discharge potential plateau was eliminated completely, but in contrast to the results of Romanov (7, 8), the total discharge capacity was unchanged. Flerov attributed the lowered discharge potential to diffusion in the solid phase being impeded by cations of alkali metal which had been introduced into the silver oxides during the a-c charge. Rather different results were reported recently for smooth silver electrodes. When an a.c. was superimposed on a constant charging current, the capacity of a smooth silver electrode in 10N KOH was unchanged unless current exceeded a high value that was critical (10). If current during the anodic half-period reached at least 10 ma/cm<sup>2</sup>, then true surface area and discharge capacity of the electrode both increased greatly but the AgO/Ag<sub>2</sub>O discharge potential plateau was not shortened, although this plateau contained an additional plateau if current of the preceding charge exceeded the critical value. The increased capacity was attributed partly to increased surface area and partly to formation of AgO with a different structure than the common AgO.

Thus there is disagreement as to whether or not capacity of a silver electrode can be increased when brief discharge periods occur during a charge, and disagreement as to the causes for the observed changes. The present work describes the results of charging silver electrodes with two types of charge current which had brief periods of current reversal.

### Experimental Procedure

Test cells were made with one of two sizes of sintered silver plaques, depending on the size available when the cells were constructed. The plaques were either 30.5 x 63.5 x 0.8 mm or 41.5 x 38.0 x 0.8 mm. The sintered silver had an average weight of 7.9 or 5.8g, respectively, not including the grid of expanded silver metal. This weight of sintered silver corresponds to a theoretical electrode capacity of 3.9 or 2.9 amp-hr, respectively. The electrodes were wrapped individually with cellulosic separator material, instead of being wrapped in pairs as is the common practice in Ag-Zn cells. The separator was folded around the electrode in such a way that five layers of separator covered both sides of the electrode. The separator was held in place by wrapping with a small Ag wire and was open only at the top of the electrode. The sintered Ag plaques and the separator has been manufactured for use in commercial Ag-Zn storage batteries.

Key words: silver oxide electrode, capacity, charge current, storage batteries.

\* Electrochemical Society Active Member.

The wrapped Ag electrodes were used as both test electrodes and counter electrodes, and were about 2 cm apart in a cell. Each test cell contained one test electrode. Five of the test cells contained one counter electrode and one cell contained two connected in parallel, placed on each side of the test electrode. Microscopic examination of similar Ag electrodes at various states of charge showed that the electrodes were highly porous and, at the 20-hr rate of charge and discharge, having only one side of the electrode face the counter electrode did not favor reaction at that side (11). The test cells contained an excess of either 35% KOH or 50% KOH as the electrolyte and an Ag/Ag<sub>2</sub>O reference electrode. Since a counter electrode was being reduced at the same time as a test electrode was being oxidized, and *vice versa*, little gas was produced in a cell except at the end of charge and discharge. All work was done at  $25^\circ \pm 1^\circ\text{C}$ .

As in the previous work (1, 2) the constant current which resulted in a complete charge or discharge in approximately 20 hr was arbitrarily taken as the standard, or normal, charge and discharge current. Capacity of the test cells decreased during the early charge-discharge cycles and then became relatively constant. After the tenth cycle, the same current was used for the rest of the study of these cells and corrections were not made for deviations in charge or discharge time from 20 hr. Complete normal charges (using the 20-hr rate as defined above) were alternated with complete charges which used one of the reversal conditions. Two types of charge current which had brief periods of current reversal were used. One type was obtained by taking a half-wave rectified current derived from commercial 60 cps alternating current and superimposing this half-wave current in the discharge direction onto a larger constant charge current. The waveform of this current is shown as B in Fig. 1. The second type was obtained by combining two half-wave 60 cps rectified currents which were  $180^\circ$  out of phase and which flowed in opposite directions through resistances of different values (D in Fig. 1). Both of these charge currents were types of 60-cycle asymmetric a.c. with forward components larger than reverse components. Only one set of reversal conditions was used in any given charge.

All charges were continued until oxygen evolution was occurring and potential had stopped changing rapidly. The final charge potential was about 510-530

mv positive to the Ag/Ag<sub>2</sub>O reference electrode when the 20-hr rate of constant charge current was used. Constant current charge input was usually 1 or 2% greater than the capacity of the following discharge. After a charge was finished, a cell was immediately discharged at approximately the 20-hr rate of constant current to a final potential which was 300 mv negative to the Ag/Ag<sub>2</sub>O reference. In a few cases that are specifically noted, a cell was discharged at the 1-hr rate to a final potential which was 500 mv negative.

To minimize variations in cell capacity the discharge capacities of the four normal cycles (20-hr constant current charge and discharge) that were nearest each discharge were averaged. This moving average was then taken as the normal capacity at that particular point in the life of a cell and is the capacity referred to whenever normal capacity is mentioned. The capacity of each discharge was calculated as a per cent of this varying average. Thus, the discharge capacity which followed a charge with current reversals could be compared to a value which was representative of actual cell capacity, regardless of changes in normal capacity over the life of a cell.

Some charges with current reversals which resulted in increased test cell capacity were tried with one model of a commercial Ag-Zn secondary cell. The commercial cells contained either 35 or 45% KOH. Typical electrolyte analysis has been given earlier (2). Each commercial cell had four sintered silver electrodes of the same size as the test electrodes which had a theoretical capacity of 2.9 amp-hr and had five zinc electrodes. The silver electrodes limited cell capacity and gave a theoretical cell capacity of about 11.5 amp-hr, although the nominal rated cell capacity given by the manufacturer was only 5 amp-hr. The Ag-Zn cells were charged individually until cell potentials reached 2.05v. Complete charges at the 20-hr rate of constant current (as defined above) were alternated with charges which had current reversals. The cells were discharged at the 20-hr constant current to 1.10v. Since capacity of these cells varied from one charge-discharge cycle to the next, the 20-hr current was recalculated after each constant current cycle and a different current used for the following cycle whenever actual charge and discharge time had deviated greatly from 20 hr.

## Results

Before any charges with a periodically reversed current were tried, the cells were charged and discharged by the 20-hr constant current until capacity became relatively constant. During the first two charge-discharge cycles of a new test cell, capacity of the electrodes was often as high as 70 to 80% of the capacity theoretically possible for the silver active material. Then capacity decreased until, after 8-10 cycles, it became relatively constant in the range 45-60% of theoretical capacity, usually averaging 50-56% of the theoretical capacity in 35% KOH and about 10% lower in 50% KOH.

Capacity of the commercial Ag-Zn cells also changed with use, but not in the same way as the test cells changed. Thirteen commercial cells were used. Eleven reached a maximum capacity that was 68-79% of the theoretical value, and the other two reached 62 and 64%. The commercial cells which contained 45% KOH always gave the maximum discharge capacity after either the initial or second charge, but the cells which contained 35% KOH did not reach a maximum until charge 5 to 8. After reaching this maximum, the capacity of the commercial Ag-Zn cells gradually declined during the remainder of their lives. Ten of the Ag-Zn cells contained 45% KOH. These cells gave only 4 to 21 (an average of 11) charge-discharge cycles before they developed internal short circuits. A cell was discarded after it developed a noticeable short circuit, as evidenced by unsteady charging potentials and failure to reach 2.05v during charge. The

three commercial Ag-Zn cells, which differed from these ten cells only in the electrolyte concentration of 35% KOH, did not develop noticeable short circuits and were still in good condition when work was completed, after having undergone from 23 to 53 cycles apiece.

Charge acceptance of a silver electrode could be increased over the amount obtained from a constant charge current if the electrode was charged with a constant current which had half-wave rectified 60 cps alternating current superimposed in the discharge direction (B in Fig. 1). When this type of current was used, with net current equivalent in coulombs per unit time to the 20-hr rate of constant charge current, a distinct increase in discharge capacity was obtained from the test cells which contained 35% KOH (Table I). The improvement was insignificant, however, in 50% KOH or when commercial Ag-Zn cells were used (Table I).

Previous work has shown that a charge with half-wave rectified a.c. (C in Fig. 1) can give a greater capacity to a silver oxide electrode than a charge with constant current (2). This work was extended by the use of half-wave rectified 60 cps a.c. in the charge direction which had a smaller half-wave rectified 60 cps a.c. in the discharge direction superimposed on alternate half-cycles (D in Fig. 1). Compared to results when constant current was used for a charge, this asymmetric a.c. gave relatively large capacity increases with the silver electrodes in test cells which contained 35% KOH and gave smaller but definite capacity increases with the commercial Ag-Zn cells (Table II). The effect of varying the a.c. frequency was not studied.

The effective current, when using an asymmetric a.c. derived from commercial a.c., was the numerical value of the constant current which would produce the same quantity of electrochemical products as the asymmetric a.c. The effective current could be calculated by taking the average (arithmetic mean) of the instantaneous a.c. values. The effective current was not the root-mean-square value of the a.c. (the numerical value of a constant current which would produce the same heat or power as the a.c.). It can be shown mathematically that the asymmetric current, obtained by combining two half-wave currents which flowed in opposite directions, had components which reached peak values approximately  $\pi$  times as large as constant currents that were equivalent in cou-

lombs per unit time to these half-wave components (Fig. 1).

Capacity tends to decrease as charge rate increases. Figure 2 shows capacities obtained after complete charges of sintered silver electrodes at various rates of constant current, with the 20-hr rate taken as a reference point. Sixty cps asymmetric a.c. of the type shown as D in Fig. 1 was tried at the 6-hr rate of charge using the test cells (Table III). When the reverse component was low, there was little or no improvement over the capacity obtained following a constant current charge at the 6-hr rate (Fig. 2) or following a charge by a half-wave current at the 6-hr rate (Table III, reverse component 0.0). Capacity of a charge at the 6-hr rate was improved when both components of the asymmetric a.c. were large.

This asymmetric a.c. was used at the 6-hr rate for a few charges of the commercial silver-zinc cells. The results resembled those shown in Table III except that improvement was not as large. For example, three charges at the 6-hr rate which used 6 times the 20-hr rate for the forward component and 3 times for the reverse component gave an average capacity in 35% KOH that was 96% of the normal capacity, while a

constant current at the 6-hr rate gave an average capacity that was 84% of the normal. In 45% KOH capacity was not this large, but showed the same type of improvement. In 45% KOH charges at the 6-hr rate gave an average 81% of normal capacity with the same asymmetric a.c. and 69% of normal with constant charge current.

Potentials of silver electrodes in the test cells are shown in Fig. 3 for a few of the discharges following charges which used 60-cycle asymmetric a.c. at the 20-hr rate. The shape of the first discharge plateau was not completely reproducible. Potential of this plateau was noticeably lower after the forward component of the charge a.c. had been half-wave rectified a.c. than after the forward component had been constant current. The first discharge plateau tended toward lower potentials as the forward and reverse

Solid line, discharge after constant current charge; dash and dot line, after 60 cps half-wave rectified a.c. charge; short dash line, after charge by 60 cps asymmetric a.c. with constant forward component of 3 times the 20-hr rate and half-wave reverse component of 2 times the 20-hr rate; long dash line, after charge by 60 cps asymmetric a.c. with half-wave forward component of 3 times the 20-hr rate and half-wave reverse component of 2 times the 20-hr rate.

components of the previous charge both increased, with net charge current remaining constant. These changes in discharge potentials, following a charge with asymmetric a.c., were observed with commercial silver-zinc cells containing 35 or 45% KOH and with the test cells containing 35% KOH. In 50% KOH, however, the discharge potentials were the same as after a constant current charge.

Interruption of the reverse current component for a few seconds resulted in different charge potentials after current was resumed. The net charge current was increased by interrupting the reverse current component. The net charge current fell back to the normal value after resuming the reverse current, but charging potentials became lower than they were before interruption. This drop in potential was similar to the potential drops observed after pulses of charge current were added to a constant charge current (1). These results suggest that the beneficial results of the two types of charge might be combined, but this was not pursued further.

As already mentioned, cycles with normal charges alternated with cycles having reversals. Sometimes, for no apparent reason, a constant current charge at the 20-hr rate gave a capacity that differed rather widely from the normal capacity. It seemed likely that these differences could be a result of changes that had occurred during the preceding cycle, in which charge current had been reversed. The current composed of two half-wave rectified currents (D in Fig. 1) was the charge current most likely to be followed by a 20-hr constant current charge-discharge cycle which had unusual capacity. There was, nevertheless, no increase or decrease in capacity following a constant current charge which correlated consistently with this or any other of the charges with reversals.

*Discharge rate.*—For the results that have already been given, capacity was measured at the 20-hr discharge rate. There were also three series of charge-discharge cycles in which fully charged silver electrodes were discharged in 35% KOH at the 1-hr rate. Each series consisted of 13-45 consecutive complete discharges at the 1-hr rate following completion of charges at the 20-hr rate. The first discharge at the 1-hr rate gave slightly less capacity than was obtained at the 20-hr discharge rate. As charges at the 20-hr rate and discharges at the 1-hr rate were repeated, discharge capacity gradually increased for 5 or 6 cycles and often exceeded normal capacity. The length of the AgO/Ag<sub>2</sub>O potential plateau decreased during the first few discharges at the 1-hr rate until, finally, the AgO/Ag<sub>2</sub>O potential plateau no longer appeared on discharge. At the same time the Ag/Ag<sub>2</sub>O charge plateau was becoming longer until it reached approximately 1.6 to 2.1 times its normal length, with almost 50% of the charge taking place at the Ag/Ag<sub>2</sub>O plateau. The final potential of the oxygen evolution plateau gradually increased in this period.

After charges at the 20-hr rate and discharges at the 1-hr rate became relatively reproducible, charges were tried under some of the reversal conditions that had proven most beneficial earlier. These conditions no longer increased capacity significantly. For example, the test cells were charged with currents of the types shown in B and D of Fig. 1, having the ratio 3:2 for charge component to discharge component with net charge current equivalent to the 20-hr constant current, but capacity of the subsequent discharge of the test cells at the 1-hr rate was only 100-102% of capacity following a constant current charge.

After resuming the 20-hr discharge rate, it was noted that the electrode had not discharged completely at the 1-hr rate. Ten to 30% additional capacity could be removed at the 20-hr rate following a discharge at the 1-hr rate. Normal cycles revealed several changes from conditions before the series at the 1-hr rate. Capacity had increased 15 to 40%, and the AgO/Ag<sub>2</sub>O

discharge plateau was only 1/3 to 2/3 its normal length. Capacity declined to approximately its former value in 10 cycles. The length of the  $\text{AgO}/\text{Ag}_2\text{O}$  discharge plateau is given in Fig. 4 for normal cycles before and after discharges at the 1-hr rate. As this plateau gradually increased, the amount of charge that took place at the  $\text{Ag}/\text{Ag}_2\text{O}$  plateau gradually decreased back to its former value.

### Discussion

A larger increase in capacity can be obtained from a silver electrode by using an asymmetric a.c. for the charge current than by using the charge methods tried earlier (1, 2). Table II shows that capacities more than 50% larger than normal resulted from charging with a 60 cps asymmetric a.c. composed of two half-wave currents. Capacity increases were smaller, however, when silver electrodes were charged in 35% KOH by an asymmetric a.c. which was obtained by superimposing a half-wave 60 cps current in the discharge direction onto a larger constant charge current (Table I). This difference is not surprising because a half-wave charge current without reversal gave approximately 29% more capacity than a constant charge current (Tables I and II, reverse component 0.0). When forward and reverse half-wave currents were combined, a part of the beneficial effect of reversal was obtained, in addition to the benefit from the rapidly pulsating charge current. Note that the waveform, when a half-wave 60 cps reverse current was superimposed on a constant charge current, was rather different from the waveform of the current obtained by combining two opposing half-wave currents (B and D in Fig. 1). The current reached much larger forward and reverse values for the same net charge current when the two half-wave currents were used.

As a general rule, the capacity of a secondary cell will decrease as charge rate increases. A silver electrode, charged in 35% KOH with constant current at the 6-hr rate, gave a discharge capacity which averaged 83% of the normal capacity (Fig. 2). Previous work has shown that close to 100% of normal capacity could be obtained at the 6-hr rate when a silver electrode was charged with unidirectional current that flowed 1/4 or 1/8 of the time with 60 periods of current flow per second (2). By charging at the 6-hr rate with asymmetric current type D in Fig. 1 which had a sufficiently large reverse component, capacity was obtained which exceeded the normal capacity and was 1/3 greater than the capacity obtained by a constant current at the 6-hr rate (Table

Fig. 4. Per cent of discharge that took place before  $\text{Ag}_2\text{O}/\text{Ag}$  potential was reached after charges at 20-hr rate in 35% KOH at 25°C. Results are given for discharges at the 20-hr rate immediately before (at left) and immediately after (at right) a series of 13 (□), 22 (△) or 45 (○) complete discharges at the 1-hr rate.

III). Although slow charges with this asymmetric a.c. gave a larger capacity than rapid ones, a rapid charge with asymmetric a.c. is valuable if it is important that charge time be small.

After commercial Ag-Zn cells which contained 35% KOH were charged with asymmetric a.c. composed of two half-wave currents, their discharge capacity was markedly larger than the capacity obtained from commercial cells by the other charge methods (Table II). This type of asymmetric a.c. also gave an increased capacity with commercial Ag-Zn cells which contained 45% KOH. Although the capacity increase was relatively small, it was the only time that the commercial Ag-Zn cells which contained 45% KOH showed a definite improvement when charged with periodically varying current. The test cells which contained 50% KOH did not give significantly increased capacity after a charge with either type of asymmetric a.c. This lack of improvement was consistent with the previous results; cells containing 50% KOH never showed the improvement which could be obtained in 35% KOH by charging with a varying current (1, 2).

Compared to a normal charge with constant current, several changes were observed during a charge with asymmetric 60-cycle a.c. The  $\text{Ag}/\text{Ag}_2\text{O}$  potential plateau was shorter than normal for a charge, the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau was longer than normal, and the potential rise to the oxygen evolution plateau was slower than usual. The rapidly fluctuating current was, of course, accompanied by fluctuating cell potentials. As the silver electrode became more completely charged, its potential could exceed the oxygen evolution potential while the charge component of the a.c. reached its maximum value, particularly when a large charge component was used. A part of the current being consumed in gas evolution resulted in a lower current efficiency than the efficiency which was obtained with a constant charge current. The rates of asymmetric a.c. used did not result in a marked increase in cell temperature over the usual warming. One can speculate that charges with asymmetric current could shorten cell life, especially if the components of the current were large with respect to the net effective current. Shorter cell life was not observed, but the experimental method (alternating normal charges with charges having current reversals) would somewhat mask a shortening of life if the harmful effect was weak.

It is believed that the increased capacity that was obtained when the silver electrodes were charged with a 60 cps asymmetric a.c. was mainly the result of the transient high charge currents. The peaks in charge current were closely followed by peaks in potential. When charge potential reached a maximum, there may have been additional oxidation of Ag particles that were already completely surrounded with an oxide coating. Crystal lattice dimensions indicate that there is a large expansion of the crystal as metallic silver is oxidized to  $\text{Ag}_2\text{O}$ . There is only a slight additional increase in volume as  $\text{Ag}_2\text{O}$  is oxidized to  $\text{AgO}$ , but the lattice is distorted as dimensions change in going from face-centered cubic to monoclinic crystals. Microscopic examination of silver electrodes indicated that  $\text{AgO}$  crystals tend to form in larger sizes than do  $\text{Ag}_2\text{O}$  crystals, that during a charge the  $\text{AgO}$  crystals partially or completely fill much of the electrode surface and many internal cavities, and that a thin layer of  $\text{Ag}_2\text{O}$  always separates the  $\text{AgO}$  from the Ag (11). When charge potential reached a maximum, possibly additional  $\text{Ag}_2\text{O}$  formed below the  $\text{AgO}$  coating as oxygen penetrated the coating under the influence of this high potential, and then the  $\text{AgO}$  coating cracked as a result of expansion beneath it. Cracks in the  $\text{AgO}$  coating would allow the electrolyte to penetrate nearer to the metallic silver, and oxidation could continue at lower charge potentials. Another possible, but less likely, factor was that cracking may have resulted from stresses set up by

the rapid formation of oxides when the forward current reached peak values. The reverse current may tend to relieve stresses, however. Although cracking would decrease concentration gradients within the electrode and allow more silver to oxidize, cracking could possibly have the disadvantage of isolating some of the oxidized silver from good electrical contact with the conducting grid.

In addition to the increased capacity, another notable change that was observed following a charge with 60 cps asymmetric a.c. was the tendency for potentials to be lower than usual in the early part of a discharge (Fig. 3). The proportion of the total discharge that took place before potential reached the  $\text{Ag}_2\text{O}/\text{Ag}$  plateau remained approximately the same as it had been following a normal charge. As mentioned earlier, the potential of the initial discharge plateau was lower following a charge with asymmetric a.c. which had large forward and reverse components than it was following a charge at the same net current which had smaller components. These results suggested that if sufficiently large forward and reverse components had been used, the initial potential plateau would disappear, as has been reported to occur (9). Discharges lasted close to 30 hr after the charges which gave greatly increased capacity (Fig. 3) because the discharge current was kept at the 20-hr rate, as defined by capacity following a constant current charge. If a higher discharge rate had been used following the asymmetric a.c. charges which had large components, the initial potential plateau would probably have disappeared at a much lower discharge current than the current required for the plateau to disappear following a normal charge.

Differences in the structure of the charged active material can account for a discharge following an asymmetric a.c. charge having less of an initial potential plateau than a discharge following a constant current charge. Increased concentration gradients of oxygen ions and lowered conductivity could occur in the active material of an electrode with an unusually large proportion of the Ag converted to oxide. Lowered discharge potentials could result from oxygen ions moving through oxide layers that were thicker than usual. Concentration gradients in the electrode would gradually decrease while the AgO coating was being reduced. Conductivity improves after Ag begins to form during a discharge (12). Although the present work has confirmed the report of Romanov that a charge with asymmetric a.c. gave increased capacity (7), the explanation of Romanov for the low initial discharge potential plateau following an asymmetric a.c. charge cannot be accepted (8). Microscopic examination of sintered electrodes during constant current charge and discharge (11) indicated that the reactions did not take place preferentially at the grids as Romanov reported. Perhaps the pressed powder electrodes of Romanov had poorer conductivity than the sintered electrodes used in the present work.

Since current was high for only a fraction of a second during a charge with asymmetric 60-cycle a.c., unduly large concentration gradients did not form in the electrolyte unless large a.c. components were used. Large concentration gradients would form if the current had been kept at its maximum value and would limit the amount of oxidation during a charge. This effect is greatest in very concentrated KOH, where the mobility of the hydroxyl ion becomes most limiting. Therefore, when 60 cps asymmetric a.c. that had large forward and reverse components was used, the charge acceptance was usually poorer in 45% and 50% KOH than it was in 35% KOH for the same current (Tables I and II).

The differences between results with the commercial Ag-Zn cells and the test cells were probably due mainly to different concentration gradients. It is doubtful that the presence or absence of zinc was important because an excess of zinc was present and,

therefore, the silver electrode limited the cell capacity. The commercial cells were tightly packed and had little free electrolyte. This arrangement should result in concentration gradients near the electrode surface being larger in the commercial cells than they were in the test cells at the same current density. Therefore the commercial cells showed less improvement after a charge with reversals than the test cells showed.

It was reported that after a sheet silver electrode had been oxidized by a 50 cps asymmetric current and anodic current density had exceeded a critical value (much higher than the current densities used in the present work with sintered silver electrodes) an x-ray diffraction pattern of the electrode showed a different intensity distribution than was usual for AgO (10). The explanation given was that  $\text{Ag}_2\text{O}_3$  had formed during the anodic pulses at high current density and then decomposed to AgO, and that this AgO had a form imposed by the decomposition of  $\text{Ag}_2\text{O}_3$  rather than by the underlying silver base. It is interesting to note, however, that the x-ray pattern given in (10) resembled rather closely the pattern reported for a tetragonal AgO (13). The tetragonal AgO was reported to be an intermediate phase between  $\text{Ag}_2\text{O}$  and monoclinic AgO when silver metal was oxidized by ozone. Close comparison of the x-ray diffraction patterns could not be made because neither (10) nor (13) gave tabular values for the patterns. Nevertheless one can speculate that perhaps ozone, or some related oxygen species, may be produced at sufficiently high potentials and oxidize metallic silver or  $\text{Ag}_2\text{O}$  to the tetragonal AgO. In the present work, using relatively low currents, potentials were below the value required to produce ozone.

*Discharge rate.*—The lack of improvement when discharges were done at the 1-hr rate was consistent with results reported earlier. After a series of discharges at the 1-hr rate, a silver electrode gave a relatively high per cent of the capacity theoretically possible. Under these conditions a charge with repeated open-circuit periods, which usually resulted in improved capacity, gave only about the same capacity as a constant current charge (2) because the form of silver in the electrode varied with the rate of reduction (14). Fast reduction of the silver oxides resulted in smaller crystals of silver, and rapidly produced silver probably had a larger number of imperfections. These smaller crystals could be charged more readily. Therefore, a charge following several fast discharges can have more capacity than a charge following a slow discharge. The observed gradual increase in capacity during a series of cycles with fast discharges indicated a progressive decrease in particle size of the silver active material. The small particles had a larger surface area, and more  $\text{Ag}_2\text{O}$  formed before charge potential rose to the  $\text{Ag}_2\text{O}/\text{AgO}$  plateau.

The high oxygen evolution potential at the end of a charge, following discharges at the 1-hr rate, indicated that concentration gradients or resistance under these conditions was higher than usual. Higher resistance could result from the finer particles being in poorer contact with each other because a larger than usual proportion of silver had been oxidized. Effects of concentration gradients and resistance become more important at high rates of discharge. The oxide particles were not all reduced before discharge potential dropped to the cutoff value. Capacity was probably limited more by incomplete reduction than by charge acceptance during discharges at the 1-hr rate. It was likely, therefore, that the form of charge current was less important under these conditions than under slow discharge rates. When the slow discharge rate was resumed, particle size increased during the next few cycles, as indicated by the gradually declining capacity and by the potential plateaus gradually recovering their former proportions.

### Conclusions

Charge acceptance was increased markedly, under certain conditions, when current was reversed periodically during a charge. Highest capacity was obtained after a charge by a 60 cps asymmetric a.c. composed of two opposing half-wave rectified currents 180° out of phase, with the reverse component two-thirds as large as the forward component. When test cells containing 35% KOH were charged with this current at the 20-hr rate, one-half more capacity could be obtained than the capacity which resulted from a constant current charge at the same rate. This a.c. used at the 6-hr rate gave one-third more capacity than a constant current at the same rate. When commercial silver-zinc cells containing 35% KOH were charged with this asymmetric a.c., they gave less improvement than the test cells but more capacity than they gave with other charge methods. Improvement decreased with increasing KOH concentration. A discharge following an asymmetric a.c. charge which gave improved capacity showed less AgO/Ag<sub>2</sub>O potential plateau than usual, probably as a result of increased concentration gradients within the electrode. The charges with periodic reversals were not effective in increasing capacity after a series of discharges at the relatively high current of the 1-hr rate. Under these conditions capacity was probably limited more by incomplete reduction during discharge than by charge acceptance.

## Chemical Identification of Adsorbed Species in Fuel Cell Reactions

### I. Propane Oxidation

H. J. Barger, Jr., and M. L. Savitz\*

United States Army Mobility Equipment Research & Development Center, Fort Belvoir, Virginia

#### ABSTRACT

The cathodic desorption products resulting from the reaction of propane at a fuel cell electrode were identified and studied as a function of potential. The ratio of cathodically desorbable material to nondesorbable material was measured at three potentials and compared to similar data obtained for a platinum wire electrode.

Since the demonstration that hydrocarbons oxidize at a fuel cell electrode to give carbon dioxide (1), there has been considerable interest in the elucidation of the over-all reaction mechanism with the hope that the information gained could lead to more reactive and lower cost catalysts. From the work of Gilman (2), Niedrach *et al.* (3), and Brummer *et al.* (4), who used mainly C<sub>2</sub> or C<sub>3</sub> compounds as the reactant, evidence has been obtained for several types of intermediates on the electrode surface. Depending on potential of adsorption, there was a species thought to contain C and H which could be removed by cathodic pulsing, designated CH<sub>α</sub>, another CH material not removed by cathodic treatment which was suggested to be polymeric, CH<sub>β</sub>, and a more highly oxidized substance called O type which was thought to contain at least one C-O bond (4c). Either a flamed platinum wire with a geometrical area of approximately 0.1 cm<sup>2</sup> (2, 4) or 0.20 cm diameter Teflon-bonded platinum black electrode (3) was used in taking these data. Thus, the total amount of adsorbed material was much too small to permit chemical identification of the de-

sorption products. In order to obtain larger amounts of the desorption products, larger electrodes using platinum black catalysts were tried. Grubb (5) found that on cathodic hydrogenation after adsorption at 0.2 and 0.4v, followed by galvanostatic pulsing for 50 min, methane and ethane were obtained in sufficient quantities to be detected by gas chromatography. This is in marked contrast to the work of Shropshire and Horowitz (6) who found only butane starting material after cathodic treatment of their electrode. With these discrepancies in mind, we decided to restudy the cathodic desorption products obtained from the reaction of propane at a fuel cell electrode.

#### Experimental

The cell used in taking the data is shown schematically in Fig. 1.<sup>1</sup> A Teflon o-ring and an electrode backing were placed against the glass cell in circular groove. Against the backing was placed a commercially available American Cyanamid Type LAA-25 electrode consisting of 25 mg/cm<sup>2</sup> platinum black and

<sup>1</sup> Dr. W. T. Grubb, General Electric Company, was very helpful in the initial design of the cell.

\* Electrochemical Society Active Member.

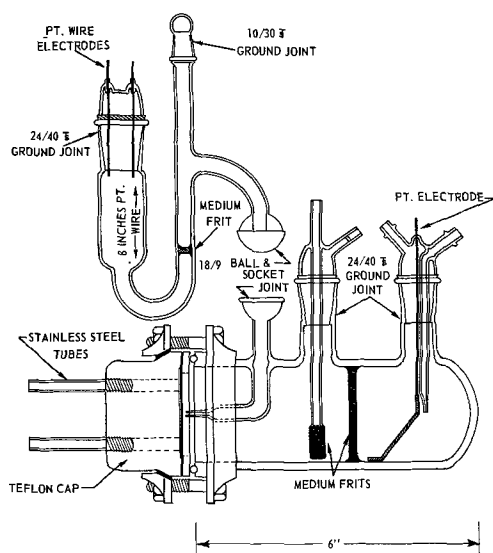

Fig. 1. Schematic diagram of electrochemical cell

25 w/o (weight per cent) Teflon pressed together on a tantalum screen. A Teflon coating on the gas side prevented electrolyte leakage. Immediately behind the electrode was a 1/16-in. gas space milled out of a Teflon block. The potential of the working electrode, active geometric area 20.3 cm<sup>2</sup>, was measured against an autogenous hydrogen electrode (7a) by means of a Luggin capillary fixed 1 mm from the working electrode. The autogenous hydrogen electrode was found to have a potential 40 mv cathodic to the hydrogen electrode in agreement with Giner's results on similar electrodes (7b). All reported potentials are against the autogenous hydrogen electrode. The counter electrode, a 58.2 cm<sup>2</sup> geometric area with a platinum loading of 35 mg/cm<sup>2</sup>, was folded to fit into its compartment which was separated from the working electrode by a glass frit. High-purity helium 99.995% and instrument grade propane 99.5% minimum purity were purchased from the Matheson Company. No organics other than propane could be detected in this gas with the flame ionization detector of the Perkin Elmer 154 D Gas Chromatograph. The electrolyte, 85% H<sub>3</sub>PO<sub>4</sub> Fisher reagent grade, was purified by treatment with 1 volume of hydrogen peroxide for 2 volumes of acid following the procedure of Savitz (8). Untreated electrolyte gave results similar to treated electrolyte. Figure 2 shows the schematic of the circuit used for adsorption and dehydrogenation studies. Potentials were set and controlled by a Wenking 62TRS potentiostat and monitored with a Keithley 610A Electrometer. Two sets of 1.3v batteries were connected in series with the potentiostat through a ten turn potentiometer for manually setting the potential steps used in electrode pretreatment. A model CK 18-3 Kepco power supply was used for anodically and cathodically

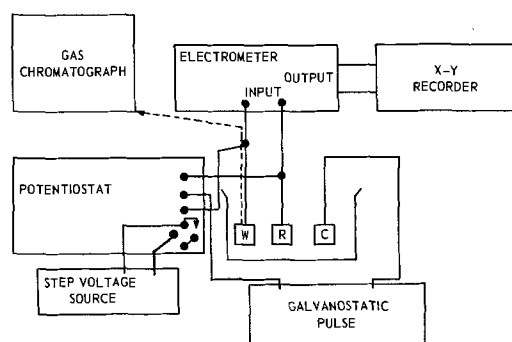

Fig. 2. Circuit diagram for adsorption and dehydrogenation studies.

pulsing the working electrode. Products obtained on cathodic pulse were examined with a Perkin-Elmer 154 D gas chromatograph using a flame ionization detector and a 6 ft Poropak column at 100°C. Product identification was assured by comparison of retention times with Poropak specification literature (9) and with known compounds. Voltage time curves were obtained on a Hewlett-Packard 7000 A X-Y recorder. The cell was maintained at 100°C ± 1 in a Fisher oven.

A typical run using the gas chromatograph would be as follows. First the working electrode was pretreated for the reasons described by Brummer (4a) and Gilman (10). The electrode was held at 1.35v relative to the hydrogen electrode until the current as monitored on the potentiostat no longer changed over a 5-min period. The current at this point was usually between 5 and 20 ma anodic for the total cell, and the time necessary to reach this point was about 3-5 min. Helium which passed over the electrode during this time was stopped, and propane was used instead at a flow rate of 5 to 10 cc/min, the same as for He. Next the potential was lowered to 0.05v by throwing a switch changing the batteries and resistance in series with the potentiostat. There was a lag time of about 20 sec from the time the switch was thrown until the potential reached 0.05v. Again the electrode was held at this potential until the current no longer changed. This usually took about 20 min at which point the cathodic current would be between 150 and 300 ma. Then the working electrode was held at the potential where adsorption was to be studied. When the current no longer changed, often after 45 min (11), the electrode was swept with helium. The current became cathodic or more cathodic depending on potential. During this time the effluent was monitored with the gas chromatograph. After passing helium through the cell for 10 min, a large amount of propane was still being swept from the electrode, but no methane or ethane was observed. A mercury relay, when triggered, switched from the potentiostatic circuit to galvanostatic circuit with which a cathodic current of 1.5 amp was applied to the working electrode. Methane/ethane ratios were found to be independent of the current between 1.5 and 2 amp and whether the pulse was galvanostatic or potentiostatic. The helium effluent was sampled 1½ min after pulsing. This time was very critical if desorption products were to be found. The time reflects the length of the line between the cell and the gas chromatograph and the rate of the helium sweep. Varying amounts of methane and ethane as well as a sizable amount of propane were observed depending on the potential. No normalization of the areas corresponding to methane and ethane concentration was made. The sequence used for gas chromatographic measurements is shown in Fig. 3.

To determine the relative amounts of desorbable and nondesorbable intermediates on the fuel cell electrode, an anodic galvanostatic pulse was used to examine the surface of the electrode. The charging curves were followed with an XY recorder. The electrode was pretreated as above and, when the current no longer changed at the potential being studied, helium was swept through the cell. After a given length of time

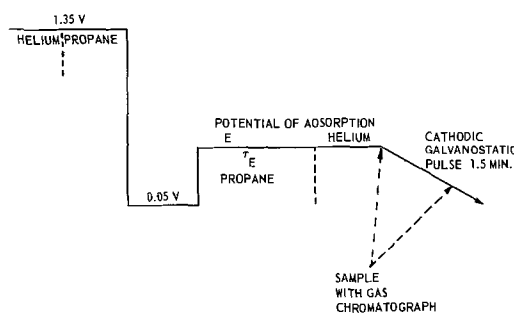

Fig. 3. Potential sequence used in gas chromatographic studies

under helium, the electrode was either anodically pulsed with a galvanostatic current of 2 amp or was potentiostatically lowered to 0.05v for 3 min, after which time the potential was raised back to the original potential of adsorption for 2 min and anodically pulsed as above. Times under helium,  $T$ , were measured exactly and varied to 30 min. A comparison of the background curve, obtained by pretreating and holding the electrode at the potential of interest under helium followed by an anodic pulse, with the curve without the cathodic treatment, gave the amount of charge obtained from the oxidation of all the surface species on the electrode at the time of the pulse. Similarly the anodic charging curve obtained after the cathodic treatment, when compared with the background, gives the amount of charge needed to oxidize the noncathodically desorbable material. The actual charge was obtained by measuring the difference in time between the background charging curve and the anodic charging curve as obtained above at 1.85v and multiplying this value by the current of the galvanostatic pulse. The voltage, 1.85, was chosen because oxygen evolution generally occurred between 1.8 and 1.9v (12). The slopes of the curves in the 1.5-1.9v range were nearly parallel so little error was introduced in picking this value.

Since the working electrodes used here are large and of a complex nature, it was seen that absolute numbers varied from experiment to experiment. However the trends which were observed were real and readily reproducible.

### Results and Discussion

Brummer and Turner (4) have shown that on a platinum wire the absolute amounts of desorbable and nondesorbable intermediates vary with potential. In this work we observe a variance in the composition of the desorbable intermediates as shown by the relative amount of methane compared to ethane seen after a cathodic pulse. The ratio is seen to be very dependent on potential. Propane is not used in this comparison because it is slowly removed from the gas space and the electrode. This propane would be indistinguishable from that resulting from the cathodic hydrogenation of  $C_3$  species on the surface. Undoubtedly the  $C_1$  and  $C_2$  species continue to react while under the long helium sweep, but since there was a large amount of propane on the surface and the current no longer changed, the relative amounts of methane and ethane obtained were felt to be representative of the relative amounts of the species on the surface while propane was passing through the gas space. Although trace amounts of methane and ethane were sometimes observed while sweeping with propane, all were eliminated by sweeping with helium prior to the cathodic pulse. In Fig. 4 there are three voltage regions to be considered. The desorbable  $C_1$  species as measured by the methane is seen to increase from a very small percentage relative to the  $C_2$  species at 0.2-0.3v to approximately one third of the total desorbable  $C_1$ - $C_2$  at 0.35-0.5v and then decreases at higher potentials. Adsorption at open circuit, 0.3-0.35v, gave similar methane-ethane ratios to those obtained on potentiostatic adsorption at 0.3. Since at the low potentials, 0.2 and 0.3v, the relative amounts of the  $C_1$  species is small, these species are probably more reactive than the  $C_2$  species or are incompatible with the surface at these potentials. The possibility that the  $C_1$  intermediates might be dimerizing to give  $C_2$  intermediates is ruled out because no butanes, pentanes, or hexanes were observed on gas chromatographic analysis. These higher molecular weight compounds would have resulted from the interaction of  $C_1$ ,  $C_2$ , or  $C_3$  intermediates.<sup>2</sup> As the voltage is increased to 0.35-0.5v, the

<sup>2</sup> It must be remembered that, when  $C_1$  intermediates are mentioned, methane is not the adsorbed compound in mind. Rather the  $C_1$  species might be thought of as a methine, methylene, or methyl fragment representing three, two, and one bonds between carbon and the surface or a combination of the possibilities. The actual structure of these intermediates is being determined by labelling experiments now in progress.

Fig. 4. Ratio of methane to ethane as a function of potential

amount of methane relative to the ethane increases. At these potentials, there is perhaps enough driving force available for the more reduced  $C_2$  species to contribute to the current. Finally at 0.6 and 0.7v, the methane-ethane ratio decreases. This is hard to rationalize, but might be explained by a change in the platinum surface as suggested by Schuldiner (13). The high dependence of the methane/ethane ratio on potential was demonstrated in another way by adsorbing at 0.7v and lowering the potential to 0.2v while sweeping with helium just prior to the cathodic pulse. On pulsing the methane/ethane ratio for 0.2 was observed. Similarly adsorption at 0.2 and switching to 0.7v prior to pulsing gave results expected for 0.7 not for 0.2.

A galvanostatic anodic pulse with and without prior cathodic treatment after adsorption at a potential was used to differentiate between the amounts of cathodically desorbable and nondesorbable materials. These techniques, used extensively earlier by Brummer and Turner (4c, d) are shown schematically in Fig. 5 and 6. Results, as reflected in the amount of charge obtained, varied markedly depending on the time under helium sweep before the anodic pulse espe-

Fig. 5. Anodic charging curve with cathodic treatment

Fig. 6. Anodic charging curve without cathodic treatment

cially at 0.4v. Thus some of the surface species continued to react under helium at 0.4v so the amount of charge observed after anodic pulse would be smaller than the amount on the electrode when the helium sweep began. To minimize this oxidation, the potential was lowered from 0.4 to 0.2v just prior to sweeping with helium. Less charge was obtained than when the potential was held at 0.4v. It was then observed chromatographically that methane came off the surface in moving the potential from 0.4 to 0.2v. This was shown after all traces of methane and ethane had been removed by helium at 0.4. Again the high dependence of the composition of the desorbable intermediates on potential is demonstrated. The problem of determining the relative amount of desorbable to nondesorbable material at steady state, just prior to He sweep, was solved by sweeping with helium for differing times at the potential of adsorption prior to pulsing and then extrapolating the charge obtained to zero time. As expected from the chromatographic results, the 5-min point was usually off the line because excess propane was still being swept out of the lines, electrode, etc. The extrapolated desorbable/nondesorbable ratios are 3.6, 0.96, 0.44 for 0.2, 0.3, and 0.4v, respectively. Using a smooth platinum wire, Brummer obtained  $CH\alpha/O$  type- $CH\beta$ , ratios for propane of 0.4, 0.4, 0.4, for 0.2, 0.3, and 0.4v (4d) and 1.6, 1.3, 1.2 for hexane (15).<sup>3</sup> At 0.2 and 0.3v where the net current is cathodic, the total amount nondesorbable material does not change with time as evidenced by the zero slope of the time-charge curves (Fig. 7 and 8). However at 0.4v, where there is an anodic current, Fig. 9, nondesorbable material is reacting much faster than the desorbable material (Fig. 10).

These results may be explained by assuming that the oxidation of the nondesorbable species to  $CO_2$  is slow at 0.2 and 0.3v and is replenished by the desorbable intermediates as fast as  $CO_2$  is being formed, keeping the total nondesorbable concentration constant. Another possibility is that the nondesorbable species is changing very slowly, if at all, at 0.2 and 0.3v, and the desorbable intermediates react to give  $CO_2$  by another reaction pathway or come off the electrode as an alkane, alcohol, alkene etc.

<sup>3</sup> There is no evidence presented in this work which indicates the nondesorbable material contains a carbon oxygen bond but this seems to be a reasonable assumption on the basis of Niedrach's work (3).

Fig. 7. Charge vs. time curves for adsorbed species at 0.2v:  $\circ$  = total Q at 0.2v;  $\square$  = nondesorbable at 0.2v;  $\triangle$  = desorbable at 0.2v.

Fig. 8. Charge vs. time curves for adsorbed species at 0.3v:  $\circ$  = total Q at 0.3v;  $\square$  = nondesorbable at 0.3v;  $\triangle$  = desorbable at 0.3v.

Fig. 9. Polarization curve for the LAA-25 electrode on propane

Fig. 10. Charge vs. time curves for adsorbed species at 0.4v:  $\circ$  = total Q at 0.4v;  $\square$  = nondesorbable at 0.4v;  $\triangle$  = desorbable at 0.4v.

### Conclusions

1. The composition of the desorbable species on the surface is highly dependent on potential and changes rapidly when the potential is varied.

2. There is a qualitative similarity between a platinum wire electrode and a fuel cell electrode in that, with propane as a reactant, cathodically desorbable and nondesorbable intermediates are observed. A more detailed comparison shows that the relative amounts of these intermediates differ in the dependence on potential for the two electrodes.

## The Surface Roughening of a Cu-Au Alloy during Electrolytic Dissolution

Howard W. Pickering

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania

### ABSTRACT

During anodic dissolution of Cu 10 a/o (atomic per cent) Au (Cu10Au) alloy the polarization capacity increases with time by a factor of 20 to >100; the factor is higher, the higher the current density in the range investigated (1-5 ma/cm<sup>2</sup>). The polarization capacity can be considered to be approximately proportional to the surface area of the electrode. The capacity and thus the surface area increases by more than an order of magnitude during the first minute of dissolution; further increase proceeds at an ever decreasing rate, so that after about 15 min the surface area no longer changes appreciably with additional amounts of dissolution. A decreasing influence of the time of electrolysis on the magnitude of the surface area is understood in terms of the occurrence of a surface smoothing (aging) process which becomes increasingly more important with increase in the area. Aging is also indicated to occur when the current is interrupted; the capacity decreases sharply at an ever decreasing rate. After 1 hr aging is virtually complete, and the area, although decreased by about a factor of two from that existing just prior to interruption of the current, is still at least 10 times greater than that existing at the start of anodic dissolution. A decrease in surface area after the current is cut off is in accord with the data of Wagner and others for analogous conditions. Extrapolation of the measured capacity to zero time of electrolysis gives an approximation of the double layer capacity for Cu10Au of 30  $\mu\text{f}/\text{cm}^2$ .

In two previous papers (1,2) it was shown that, during anodic dissolution of Cu from Cu-Au alloy at room temperature, Au is not ionized and that enrichment of Au in the alloy occurs. Accordingly Cu diffuses from the bulk alloy toward the alloy-environment interface and Au diffuses in the opposite direction. Volume diffusion in the presence of given supersaturations of mono- and divacancies was analyzed theoretically and concluded to proceed *via* divacancies. For analogous conditions of diffusion Harrison and Wagner (3) have theorized that a plane solid-liquid

interface is not stable. In accord with this result they have observed during preferential dissolution of Cu from solid Cu-Ni alloys in liquid Ag at 1000°C that a highly ragged interface is formed. In particular they have observed wedges filled with liquid metal protruding into the interior of the alloy. Similarly roughening of the surface and penetration of electrolyte into the alloy may be expected when Cu is preferentially dissolved from Cu-Au alloy. Formation of a porous layer during anodic dissolution of Cu-Au has been reported by various authors (4-8); and in one case in-

dividual pores were observed and measured at a few hundred Å diameter by transmission electron microscopy (8). It is the purpose of this paper to obtain a measure of the extent of surface roughening with the help of measurements of the polarization capacity during anodic dissolution of Cu from Cu-Au alloy.

Polarization capacity measurements have been made by Bowden and co-workers (9) for a determination of the roughness of various metallic surfaces. Measurements of this kind have also been used in order to determine the decrease in the true surface area of silver obtained by cathodic reduction of silver chloride by Wagner (10), by Gerischer and Tischer (11), and by Jaenicke and Schilling (12). Measurements may be made with an alternating current in a bridge circuit (11, 12). In particular an alternating current can be superimposed on a predetermined direct current by which the rate of dissolution is determined. For the experimental conditions used by Gerischer *et al.* (11, 12) the measured capacity approximated the differential double layer capacity of the Ag electrode and as such gave a direct measure of its change in surface area with time. The relevant concepts underlying these measurements and those presented in this paper, where in addition one has a faradaic impedance due to the passage of a direct current by which the rate of dissolution of Cu is determined, are contained in the next section.

### General Procedure

Polarization capacity measurements at 24°C were conducted in order to determine approximately the increase in true surface area which occurs when Cu is anodically dissolved from Cu 10 a/o Au (Cu10Au) alloy in 1M H<sub>2</sub>SO<sub>4</sub>. In addition capacity measurements were continued after the current was interrupted in order to examine the possibility that a decrease in true surface area occurs due to the surface migration of atoms and related processes.

*Theory of the capacity measurement.*—The impedance  $Z$  of a circuit between a Cu-Au electrode subject to anodic polarization and a counter electrode comprises the impedance  $Z_1$  of the Cu-Au electrode, the ohmic resistance  $R_e$  of the electrolyte, and the impedance  $Z_2$  of the counter electrode in series

$$Z = Z_1 + R_e + Z_2 \quad [1]$$

In order to simplify the evaluation it is desirable that  $R_e$  and  $Z_2$  be small in comparison to  $Z_1$ . Since  $Z_1$  and  $Z_2$  are inversely proportional to the surface areas of the respective electrodes, it is expedient to make the surface area of the counter electrode much larger than that of the Cu-Au electrode, *e.g.*, one may use a quasi-spherical Cu-Au electrode of radius  $r_1$  of about 0.05 cm surrounded at a distance of about 5 cm by a platinized platinum gauze as the counter electrode. Under these conditions the resistance of the electrolyte is

$$R_e \simeq \frac{1}{4\pi\sigma r_1} \quad [2]$$

where  $\sigma$  is the specific conductivity of the electrolyte, which is supposed to be fairly high so that  $R_e$  is low.

The factors which determine the impedance of an electrode have been discussed by various authors (13-31). For the present investigation, considerable simplification may be introduced. In particular, contributions to  $Z_1$  corresponding to concentration polarization may be considered to be negligible in the case of irreversible dissolution, *i.e.*, when the electrode is at least 0.1v more noble than the equilibrium potential of pure copper in the electrolyte. Also in the case of an alloy from which the less noble component is dissolved, one can neglect differences in the local current density along the outer surface of the electrode in accord with considerations due to Hoar and Agar (32) and to Wagner (33, 34), because the product of the conductivity of the electrolyte and the slope of the po-

tential-current density curve is much greater than the radius of the quasi-spherical electrode.

According to Grahe (19) the impedance  $Z_1$  of the Cu-Au electrode may be represented by a faradaic and a nonfaradaic impedance in parallel. The faradaic impedance comprises an ohmic resistance and a pseudo-capacitance as well. The nonfaradaic impedance is that of the differential double layer capacity  $C_{1d}$ . With increasing frequency of the alternating current the nonfaradaic impedance decreases more and more, whereas the faradaic impedance in parallel remains finite. The over-all impedance  $Z_1$  is equal to the reciprocal of the sum of the admittances in parallel, each of which in turn is equal to the reciprocal of the faradaic and nonfaradaic impedance. Thus, at sufficiently high frequencies,  $Z_1$  becomes practically equal to the nonfaradaic impedance. Representing the impedance of a capacity by an imaginary term, one has

$$Z_1 = -\frac{j}{\omega C_{1d}} \quad [3]$$

where  $j = (-1)^{1/2}$  and  $\omega = 2\pi f$  with  $f$  as the frequency (Hz) of the alternating current. Use of Eq. [3] presupposes conditions where the resistance of the electrolyte in the porous layer of the alloy does not affect the current distribution and does not make a significant contribution to the total impedance.

Substitution of Eq. [2] and [3] in Eq. [1] for  $Z_2 \ll 1$  yields

$$Z = \frac{1}{4\pi\sigma r_1} - \frac{j}{\omega C_{1d}} \quad [4]$$

Equation [4] is the equation for the impedance of a circuit with the ohmic resistance  $R_e = 1/4\pi\sigma r_1$  in series with the differential double layer capacitance  $C_{1d}$  (see Fig. 1 for circuit analog). To test the applicability of Eq. [4] for finite frequencies one may conduct measurements of the real and the imaginary part of the impedance  $Z$  at various frequencies in order to find the frequency above which the real part of  $Z$  is essentially independent of  $\omega$  and the imaginary part is inversely proportional to  $\omega$ .

The differential double layer capacity  $C_{1d}$  is in essence proportional to the true surface area of the Cu-Au electrode. Thus, under conditions where Eq. [4] holds, the imaginary part of the impedance  $Z$  is inversely, and the differential double layer capacity directly, proportional to the true surface area. One has therefore the following relation for the determination of the ratio between the true surface area  $A_1$  of a Cu-Au electrode at time  $t'$  and that at  $t''$

$$\frac{A_1(t'')}{A_1(t')} \simeq \frac{\text{Im } Z_1(t')}{\text{Im } Z_1(t'')} \simeq \frac{C_{1d}(t'')}{C_{1d}(t')} \quad [5]$$

This relation implies that the capacity per unit true surface area is essentially independent of alloy composition and of the true current density. Actually since the capacity per unit true surface area may vary to some extent, Eq. [5] can be used only as an approximation. Nevertheless measurement of the polarization capacity would seem to be an appropriate method for obtaining order-of-magnitude changes in surface area while current is passed. It, unlike other methods such as BET measurements, provides measurement during the experiment itself; hence, changes in surface area which may occur when the current is cut off and spurious contributions which may arise during preparations for using other methods are not part of the measured value.

*Experimental arrangement.*—For measurement of the real and imaginary parts of the impedance of a Cu10Au electrode, the circuit shown schematically in Fig. 1 was used in accord with recommendations made by Gerischer (31). In essence it is a slight modification of the circuit used by Gerischer and Tischer (11)

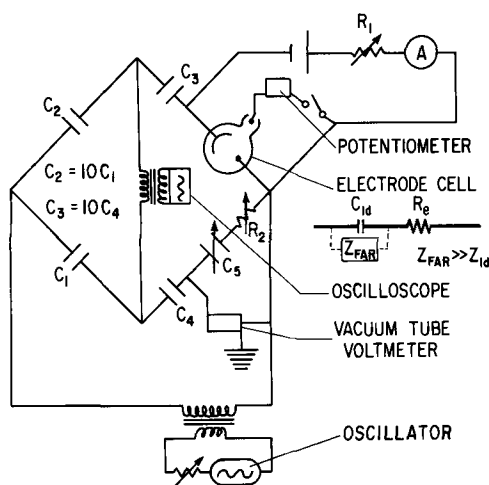

Fig. 1. Circuit for measuring the impedance

for investigations on silver deposits obtained by cathodic reduction of silver chloride. Since the direct current to be applied to the Cu10Au electrode is low, the circuit producing the direct current consists of a battery yielding a rather high voltage of 200v and a variable resistor  $R_1$  in series. Since  $R_1$  is necessarily large the alternating current flows practically only between the test and counter electrodes even without inductances in the d-c circuit as used by Gerischer and Tischer (11). In addition capacitors  $C_3 \approx C_2$  and  $C_4 \approx C_1$  were placed in series with the Cu-Au test electrode and the balancing circuit, respectively. Hence, when the capacitance of the Cu-Au test electrode becomes much larger than  $C_2$  the impedance of the branches containing the test electrode and the balancing elements remains approximately equal to the impedance of their corresponding branches containing the standard capacitors  $C_2$  and  $C_1$ ; otherwise stray impedance would interfere seriously. For this reason, too, the circuit was completely shielded. Capacitances  $C_3$  and  $C_4$  also prevented the flow of direct current from the cell to the other branches of the bridge. Sensitivity remained adequate even at the highest capacity of the Cu-Au electrode, about 50  $\mu\text{f}$ . For  $C_2 = 10 C_1$  and  $C_3 = 10 C_4$ , the double layer capacity  $C_{1d}$  was obtained as  $C_{1d} = 10 C_5$  after the bridge had been balanced. The reference electrode was then switched into the circuit and the potential measured. The circuit was tested and calibrated by making impedance measurements as a function of frequency for capacitors ranging from 0.5 to 50  $\mu\text{f}$  in series with a 7-ohm resistance substituted for the electrode circuit in the unknown branch of the bridge. A Hewlett-Packard 200 CD oscillator provided an alternating current signal over a wide range of frequency. A Tektronix type 543 oscilloscope with a type E amplifier served as the null instrument. The equivalent circuit used for balancing the bridge consisted of Cornell-Dubilier decade capacitors with a range of 0.001-11.111  $\mu\text{f}$  in 0.001  $\mu\text{f}$  increments in series with a General Radio resistor of low inductance rating with a range of 0.1-1000.1 ohm in 0.1 ohm increments. In order to be within the range of a virtually linear relation between current and voltage the root-mean-square amplitude of the a-c voltage across the cell was maintained at 0.003v with the help of a Hewlett-Packard 400D vacuum tube volt meter. A frequency of 30 kHz was chosen for the actual measurements on the basis of preliminary impedance data obtained as a function of frequency on Cu10Au electrodes before and after anodic dissolution, which showed that for this frequency, Eq. [4] was approximately satisfied.

The capacity measurement was made in a Pyrex cell, Fig. 2. A semicylindrical counter electrode made of platinized-platinum gauze was centered 5 cm from a

Fig. 2. Cell used for the polarization capacity measurements

quasi-spherical Cu10Au test electrode with a radius of 0.05 cm. The electrolyte, 1M  $\text{H}_2\text{SO}_4$ , was made from reagent-grade acid and doubly distilled water of conductivity  $3 \times 10^{-7}$  mho-cm $^{-1}$ . Pre-purified He was passed through the solution to eliminate oxygen. The reference cell was a mercury-mercurous sulfate electrode in contact with 1M  $\text{H}_2\text{SO}_4$ . The potentials are reported relative to the standard hydrogen electrode (SHE).

The test electrodes were machined from Cu10Au alloy which had been vacuum-melted from metals of 99.999% Cu and 99.995% Au, homogenized in an evacuated Vycor capsule at 700°C for 4 days, and swaged. They were then sealed with an epoxy cement in finely drawn Pyrex tubes with somewhat less than a hemisphere of surface exposed. A photograph of the electrode at 50X facilitated measurement of its geometrical area. Electrical contact was provided by a copper wire previously soldered to the stem of the electrode which passed along the inside of the tube. Surface roughness resulting from the machining operation was reduced by mechanically polishing to the extent that at 50X the surface had a high gloss and was virtually free of scratches. In order to establish that the high degree of cold work in the specimen did not unduly influence the area increase, a few preliminary runs were made with Cu10Au electrodes which were in the annealed condition (1 hr at 700°C in an evacuated capsule and no mechanical polish). The results for the annealed and for the cold worked samples were not significantly different.

## Results

The capacity measured during anodic dissolution of Cu from Cu10Au increases sharply with time, rising in 10-20 min by a factor of 20 to > 100 depending on the current density. As anodic dissolution continues the capacity eventually levels off and may even decrease. When the current is interrupted the capacity again changes appreciably, decreasing sharply at an initially high but ever decreasing rate. Figure 3 illustrates this behavior for Cu10Au electrodes anodically dissolving at a current density of 1 or 3 ma/cm $^2$ .

From additional capacity data for other current densities it was established that (a) for a given time of electrolysis the capacity is higher the higher the current density and (b) as one proceeds from a current density of 1-5 ma/cm $^2$  the capacity increases to higher and higher values prior to leveling off, with the result that more than a one-hundredfold increase in capacity was measured for Cu10Au electrodes dissolving at 4 or 5 ma/cm $^2$ .

The capacity data appear in Fig. 3 also in terms of the ratio of the measured capacity to the initial capacity,  $C_0$ , where  $C_0$  is obtained by extrapolation to zero time of the capacity measured during anodic dis-

Fig. 3. Capacity measured during anodic dissolution and the ratio of the measured capacity to the initial capacity  $C_0$  for Cu10Au electrodes dissolved in 1M  $H_2SO_4$  at 1 ma/cm<sup>2</sup> (O and □) and 3 ma/cm<sup>2</sup> (Δ).  $C_0$  is obtained by extrapolation to zero time of the capacity measured at the very early stages of dissolution as shown in the insert for the runs at 1 ma/cm<sup>2</sup>. \* indicates the  $C/C_0$  calculated from the BET measurement of area for a Cu10Au electrode which had been dissolved at 1 ma/cm<sup>2</sup> for 8 min.

solution. A reasonably good extrapolation was possible at 1 ma/cm<sup>2</sup> since at very early stages of anodic dissolution a plot of capacity vs. time is nearly linear as may be seen in the insert of Fig. 3. The average initial capacity obtained in this manner from data of several Cu10Au electrodes is  $C_0 \sim 30 \mu f/cm^2$  with a rather poor reproducibility of about  $\pm 50\%$ .

Auxiliary calculations by Wagner (35) show that during the run with the current density  $i = 10^{-3}$  amp/cm<sup>2</sup> the resistance of the electrolyte in the porous zone of the sample was much less than the absolute magnitude of the double layer impedance and, therefore, use of Eq. [3] is justified. Values of  $C_{1d}$  reported for  $i = 3 \cdot 10^{-3}$  amp/cm<sup>2</sup>, however, are somewhat uncertain in view of the contribution of the resistance of the electrolyte in the pores especially at higher depths of penetrations after 5 min. The uncertainty does not seem to be excessive since values of  $C_{1d}$  measured after termination of the run depend only slightly on frequency above 20 kHz (Fig. 5).

Figure 4 shows capacity data for a Cu10Au electrode, where the current of 3 ma/cm<sup>2</sup> was cut off at an early stage of anodic dissolution while the capacity was still rising at a high rate. The decrease in capacity after the current is interrupted occurs mainly

Fig. 4. Capacity of a Cu10Au electrode measured during and after dissolution in 1M  $H_2SO_4$  at 3 ma/cm<sup>2</sup>, illustrating a sharp decrease in capacity when the current is cut off.

within a few minutes; after 1 hr virtually no further change occurs, and the capacity, although decreased by about a factor of two from that existing just prior to cut-off of the current, is still greater by an order of magnitude than at the start of anodic dissolution when the surface was essentially plane.

As standard procedure the capacity and resistance were measured as a function of frequency both before and after anodic dissolution in order to confirm that Eq. [4] was approximately satisfied. These capacity data are shown in Fig. 5 for the electrodes whose capacity during anodic dissolution is reported in Fig. 3; above about 20 kHz the capacity is nearly independent of frequency over a wide range. The resistance behaved similarly, decreasing from a high value at low frequencies to a final value of about 7 ohm for frequencies above 20 kHz.

While current is passing the potential remains fairly constant within  $\pm 20$  mv. After interruption of the current the potential decreases to a less noble value. Potential data obtained during and after anodic dissolution at 1 and 3 ma/cm<sup>2</sup> are shown in Fig. 6.

Discussion

From Eq. [5] and the capacity data the surface area of the Cu10Au electrode is seen to increase by a factor of 20 to  $> 100$  when Cu is anodically dissolved from Cu10Au alloy. On the basis of other investigations (1, 2) which show that anodic dissolution of Cu from Cu-Au alloys occurs via interdiffusion in the alloy, roughening of the surface was to be expected, in accord with theory and experimental data for analogous conditions [Harrison and Wagner (3)].

Fig. 5. Capacity measured before and after dissolution as a function of the frequency of the alternating current for the three Cu10Au electrodes of Fig. 3, illustrating an extended region of frequency over 20 kHz where the capacity is nearly independent of frequency.

Fig. 6. Potential measured during and after dissolution of two Cu10Au electrodes in 1M  $H_2SO_4$  at 1 ma/cm<sup>2</sup> (O) and 3 ma/cm<sup>2</sup> (Δ).

The eventual leveling-off of the capacity suggests that the rate of increase of the surface area decreases until the total area no longer changes appreciably with time even though dissolution of Cu continues. This is understood in terms of an increasing participation of a second process (aging) which tends to reduce the area (35). Initially the surface area increases rapidly, the rate being determined mainly by the rate of Cu dissolution. As dissolution continues and the surface area becomes large, aging becomes more important in determining the net change in surface area; i.e., when roughening has occurred to a considerable extent, there will be significant amounts of Au-rich alloy especially near the original alloy-electrolyte interface where aging may occur in virtually complete absence of Cu dissolution. A net decrease in area in these regions which eventually becomes comparable to the amount of new surface formed near the base of the channels where dissolution of Cu mainly occurs, would explain how a surface area which initially increases sharply finally becomes only a weak function of the time of electrolysis.

When the direct current is cut off and anodic dissolution ceases, the capacity sharply decreases as reported in the data of Fig. 3 and especially 4. The potential also changes appreciably when the current is cut off (Fig. 6). Some data of Bockris and Conway (36) would seem, however, to indicate that the effect of potential on double layer capacity is small for the experimental conditions employed in this investigation. They found that the differential double layer capacity of Cu in 1N H<sub>2</sub>SO<sub>4</sub> becomes a weaker and weaker function of potential as the frequency is increased; at 5 kHz, the highest frequency employed, the differential double layer capacity was virtually independent of potential in the range -100 to 300 mv. Even so, values obtained from Eq. [5] after the current is shut off are somewhat uncertain. A decrease in surface area which occurs after the current is cut off is understandable in terms of continued aging which now proceeds in the complete absence of the metal dissolution and the accompanying formation of new surface.

The occurrence of an aging process is in accord with the data of Wagner (10), of Gerischer and Tischer (11), and of Jaenicke and Schilling (12) for analogous conditions. They observed a decrease in the surface area of silver obtained by cathodic reduction of silver chloride and attributed it to the surface migration of atoms and related processes. Aging during and after anodic dissolution of Cu from Cu-Au alloys may proceed similarly.

The fact that appreciable changes in the surface area may occur when the current is interrupted (as shown in Fig. 3 and 4), shows the desirability of *in situ* measurements of changes of area during anodic dissolution. Measurement of the polarization capacity provides a convenient way to do this especially when only approximate determination of changes in surface area is needed.

It was confirmed by the BET method that the change in surface area may be approximately determined from measurements of the polarization capacity. After dissolution at 1 ma/cm<sup>2</sup> for 8 min the BET area of a Cu<sub>10</sub>Au electrode was found to have increased by about a factor of 25, or something less than twice the increase determined by the polarization capacity (see Fig. 3).<sup>1</sup> Further experimentation is desirable in order to confirm the proposed aging mechanism.

#### Acknowledgment

The author is greatly indebted to Professor Dr. Carl Wagner of the Max-Planck Institut für Physikalische Chemie for suggesting the investigation and making

<sup>1</sup> For comparison of the BET area with the area determined from the capacity, one should note that a decrease in surface area occurs after the current is shut off (i.e., prior to the BET measurement) and that reaction products may remain even after extensive rinsing of the sample. The latter would tend to give a BET area on the high side.

available an unpublished memorandum containing the pertinent theoretical concepts and suggestions on the experimental arrangement. He also gratefully acknowledges helpful discussions with Doctors C. A. Johnson, N. P. Louat, and R. P. Frankenthal, the skillful assistance of Messrs. P. J. Byrne, H. A. Hughes, and E. A. Fischione and the aid of Dr. H. A. Podgurski for the BET area determination, all of this laboratory.

Manuscript received Sept. 5, 1967; revised manuscript Feb. 13, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

# The Oxidation of Niobium in the Temperature Range 450°-720°C

J. S. Sheasby

Faculty of Engineering Science, The University of Western Ontario, London, Ontario, Canada

## ABSTRACT

The oxidation properties of niobium were studied in the temperature range 450°-720°C at oxygen pressures 1-760 Torr. Particular emphasis was placed on correlating the morphology of the reaction products with the oxidation kinetics. During the initial, approximately parabolic oxidation period the scale appears compact, and at the transition from parabolic to linear kinetics the scale blisters and cracks. Scale formed during linear oxidation grows in a series of crude layers. From the relationships determined between the rate of oxidation and the thickness of the oxide layers, it is deduced that the rate of oxidation is controlled at all times by the diffusional properties of the oxide layer in contact with the metal phase. The sensitivity of the rate of oxidation to oxygen pressure is ascribed to the pressure sensitivity of the underlying parabolic rate constant of formation of the niobium pentoxide, and to a lesser extent to changes in the width of the oxide layers with the rate of their formation. The inversion in the temperature coefficient of the oxidation reaction as the temperature is lowered from 625°-600°C is associated with the disappearance of layers of NbO and NbO<sub>2</sub> from the reaction zone and the appearance of a metastable platelet phase.

The oxidation behavior of niobium has been studied by many workers, and the literature was reviewed most recently by Seybolt (1). Niobium exhibits unusual oxidation features, for at each temperature and oxidation pressure the oxidation rate is found to follow a complex series of time laws. This paper describes an investigation into the oxidation behavior of niobium in the temperature range 450°-720°C, at oxygen pressures near atmospheric, for times from 2 min to several hours. At times shorter than this, or for the equivalent oxygen uptake at lower pressures, Hurlen (2) reports that the oxygen rate is time independent. At reaction times longer than several hours a second breakaway reaction has been reported by Kolski (3) and by McLintock and Stringer (4).

The field under study is characterized by a time independent rate (linear reaction rate law), which is usually preceded by a short period of approximately parabolic behavior. The linear reaction rate is pressure-sensitive and also decreases in magnitude as the temperature is increased from 600° to 625°C. The major part of the weight gain is associated with the formation of niobium-pentoxide although oxygen is also consumed by the formation of lower or suboxides and by solution in the metal phase. Whereas there is good agreement between previous studies on the rates of oxidation and types of time laws observed at various oxidation conditions, there is no agreement as to the physical events and the nature of the rate controlling steps associated with each stage. Particular areas of disagreement are: (i) the reaction products formed during parabolic oxidation, and the rate controlling step; (ii) the mechanism of the transition from parabolic to linear oxidation kinetics; (iii) the rate-controlling step during linear oxidation; (iv) the mechanism of the rate inversion at 600°C.

Previous workers (2, 4, 5) have considered the high pressure sensitivity of the oxidation rate and the linear oxidation kinetics indicative of equilibrium oxygen adsorption at an interface, followed by a phase boundary controlled reaction. However, Sheasby, Wallwork, and Smeltzer (6) have recently shown that in the temperature range 720°-825°C the niobium pentoxide scale grows protectively, and that the parabolic rate constant of its formation is pressure sensitive, thus permitting the pressure sensitive linear oxidation kinetics to be rate controlled by a barrier film mech-

anism. This paper describes the results of an investigation into this possibility.

## Experimental

Specimens were cut in the form of squares approximately 1.1 cm<sup>2</sup> from sheet 1 mm thick produced by Fansteel. The specimens were prepared for oxidation by abrasion up to 600 grade silicon carbide paper, followed by electropolishing for 30 sec in a nitric acid -30% hydrofluoric acid electrolyte at 24v using a carbon cathode.

The kinetics of oxidation were examined using a volumetric apparatus. Experimental runs were initiated by admitting oxygen to a specimen brought to temperature under vacuum. Previous estimates of specimen self-heating for this procedure gave an initial rise above the furnace temperature of about 30°C. The specimens then cooled to a steady value in about 4 min to about 2°-3°C above the furnace temperature. For most of the experiments an oxygen pressure of 380 Torr was used, and at this pressure a 1 cm movement of the mercury bead corresponds to an oxygen uptake of approximately  $1.4 \times 10^{-5}$  g/cm<sup>2</sup>. At least two runs were made at each temperature, and the rate constants so determined usually agreed to better than 10%. After oxidation all the specimens were examined metallographically. To obtain minimum loss of oxide the specimens were plunged while still hot into cold-mounting compound.

## Experimental Results

*Kinetic results.*—A series of specimens was oxidized at 380 Torr at approximately 25°C intervals over the temperature range 450°-720°C to a weight gain of about 0.01 g/cm<sup>2</sup>. Further specimens were oxidized as required for specific times, temperatures, and oxygen pressures.

A typical weight gain curve in which initial protective behavior breaks away to a time-independent reaction rate is shown in Fig. 1. A plot of (weight gain)<sup>2</sup> vs. time for the protective period gives a good fit to a straight line intersecting the time axis close to the origin. The weight gain curves for the series of specimens oxidized at 380 Torr were analyzed for values of the reaction rate constants  $Kp_v$  and  $Kl_v$ . Where  $Kp_v$ , the parabolic reaction rate constant, and  $Kl_v$ , the linear reaction rate constant, are defined by

Fig. 1. Oxidation of niobium at 720°C, 750 Torr

the equations

$$w^2 = Kp_v t + a$$

$$w = Kl_v t + b$$

respectively;  $w$  is the weight of oxygen absorbed at time  $t$ , and  $a$  and  $b$  are reaction constants.

It was found that below approximately 610°C the protective period is too short to obtain a parabolic rate constant, and below 550°C, after the initial deviations of approximately 10-min duration, the reaction rate tends to decrease slowly as oxidation proceeds, Fig. 2. This latter behavior has been reported previously by Ayimore *et al.* (7) and by Cox and Johnston (8) and will be discussed later. Values of the linear rate constant  $Kl_v$  agree well with previous investigations (Fig. 3), and in particular a decrease in reaction rate is noted as the oxidation temperature is increased from 600° to 622°C. Values of the parabolic

rate constant  $Kp_v$  are shown in Fig. 4. No other values have been reported for these reaction conditions.

**Metallographic results.**—The principal reaction product in the range 10-760 Torr 450°-720°C is  $\gamma$ -niobium pentoxide as designated by Terao (9). Layers of NbO and NbO<sub>2</sub> are present at the metal surface on specimens reacted above 620°C. Below 600°C these oxides are absent and are replaced by a platelet phase tentatively identified as the suboxide NbO<sub>z</sub> as designated by Norman (10). The appearance or nonappearance of the equilibrium diagram oxides NbO and NbO<sub>2</sub> depends on the time, temperature, and pressure of oxidation, and also on the local radius of curvature of the metal-oxide interface. For instance, as shown in Fig. 5, for a specimen reacted at 626°C in 380 Torr oxygen, NbO and NbO<sub>2</sub> are stable on the main faces of the specimen, but not at the specimen corners. The reaction conditions necessary for the formation of NbO and NbO<sub>2</sub> are the subject of a current study and will be reported later.

In cross section the niobium pentoxide layer tends to be thicker at specimen corners and edges than on the

Fig. 5. Cross section of specimen oxidized at 380 Torr, 626°C for 65 min., showing abnormal edge effect. Magnification A (top) ca. 100X, B (bottom) ca. 525X.

Fig. 6. Cross section of specimen oxidized at 380 Torr, 575°C for 32.5 min, showing normal edge effect. Magnification 125X.

main faces (Fig. 6), thus preventing too literal an interpretation of the reaction rate constants measured by the volumetric apparatus. The niobium-pentoxide layer on all the specimens contains lenticular fissures parallel to the metal surface giving the scale a laminar appearance. When the scale is formed from niobium containing platelets these fissures or pores tend to be aligned, running at an angle of about 60° to the metal surface and occurring in pairs to give a chevron pattern superimposed on the laminations (Fig. 7). This chevron pattern of pores probably has the same origin as the similar structure in tantalum pentoxide scales described and discussed by Stringer (11).

Laminations in niobium pentoxide scale layers formed from NbO and NbO<sub>2</sub> are thicker than those formed from niobium containing platelets. Lowering the oxidation pressure or raising the temperature tends to increase the thickness of these laminations so that above 725°C the oxide is not layered (6). When viewed in polarized light the oxide scales formed at the higher temperatures are seen to be composed of columnar crystals with the long axis normal to the plane of the laminations, Fig. 8d. Similar structures have been observed in scales formed at lower temperatures, but in general the layer widths and oxide grain size are too small to make observation possible. The columnar grains are continuous over many laminations, indicating that when the oxide layered renucleation of oxide crystals was not necessary. In fact, in only rare instances in the several hundred specimens examined, has a structure been observed in which new oxide grains appear to have nucleated beneath a pore.

Several series of specimens were oxidized for various lengths of time at specific temperatures and oxygen pressures. Photomicrographs of one such series oxidized at 720°C in oxygen at 760 Torr for times of 13, 28, 68, and 100 min are shown in Fig. 8 (a-d), and the associated weight gain curve in Fig. 1. The scale is black during the period of the first parabola and in cross section appears compact, Fig. 8a. Deviation from the parabola is accompanied by the appearance of

yellow blisters on the scale, which in cross section are seen to be regions where the scale has become detached from the metal and reacted with oxygen to become stoichiometric, Fig. 8b. It is to be noted that the pores act as barriers to further oxidation, and that until the oxide cracks between the blisters a second layer does not form. Growth of the new coherent layer continues until it in turn blisters, and the cycle repeats. The first two of three layers often form sufficiently in phase to be evident in the kinetic curves. Later, all traces of unevenness are lost and the reaction rate is linear.

Other series reacted at lower temperatures showed similar relationships between the morphology of the reaction product and the associated weight gain curve. However, below 600°C the shortness of the period of initial nonlinear behavior, combined with the uncertainties introduced by the technique of starting the reaction and overheating of the specimen when first introduced to oxygen, prevents quantitative analysis

of either the volumetric or the metallographic measurements.

**Analysis.**—Because of the correlation between the morphology of the oxide scale with the variations in the weight-gain curve it is proposed that this oxidation reaction is an excellent example of the class of oxidation reactions known as “paralinear.” The layered oxide scale emanates from the growth of the oxide to a critical thickness, cracking, and regrowth. Throughout this cycle the rate of reaction is controlled by diffusion across the layer of oxide that is in the process of growing.

The columnar grain structure of the layered oxide indicates that there is no pause in the oxidation reaction associated with the nucleation of new oxide layers. On the other hand, the layer of oxide in contact with the metal phase was not observed to be significantly thicker than the other layers, though cooling cracks make this observation less certain. It follows that the linear oxidation rate  $Kl_o$  should be related by the mean layer width  $W_c$  to the underlying parabolic rate constant  $Kp$  for the reaction (12), according to the equation

$$Kp = Kl_o \times W_c$$

This parabolic rate constant should have the same value as that of the parabolic oxidation at the start of the reaction as measured either by the volumetric apparatus ( $Kp_v$ ) or metallographically. Furthermore, even though the local linear rate constants  $Kl_o$  and lamination thicknesses as determined metallographically can vary from point to point on a specimen, the parabolic rate constant derived using the equation above should have the same value.

Measurements of the width of laminations in the niobium pentoxide scale were made at several points on all specimens. It must be emphasized that particularly at the lower temperatures the scale layers are not clearly defined making it extremely difficult to measure  $W_c$  with any accuracy. Determinations from the specimen shown in Fig. 6 are given in Table I where it can be seen that the derived parabolic rate constants tend to increase as the local linear rate constant increases. The higher values are associated with the curved regions of the specimen and could have been caused by two effects. First, the scale could have cracked closer to the metal at these points, and second, measurements made at 750°C showed that the parabolic rate constant of oxidation on a convex metal surface could be enhanced 30% above that on a flat surface. Apart from sites of more extreme edge oxidation, values of  $Kp$  derived from metallographic measurements taken from around a specimen generally agreed to within 30% of a mean value. The derived parabolic rate constants of all the specimens reacted at 360 Torr as a function of  $(1/T^\circ K)$  are shown in Fig. 4. Two lines can be drawn on this plot, the high-temperature line corresponding to specimens with layers of NbO, and the low-temperature line to specimens with platelets. The data points at about 610°C, between the two lines, were obtained from specimens in which platelets formed initially, and only later in the reaction did a layer of NbO stabilize. In

certain specimens this dual oxidation behavior persisted to the end of the run, Fig. 5, and values of  $Kp$  could be taken corresponding to the two extremes.

### Discussion

From the morphological and kinetic evidence presented the oxidation behavior of niobium in the temperature range 450°–820°C and pressure range 1–760 Torr agrees both qualitatively and quantitatively with a “repeated-parabolic” or “paralinear” scaling model. Differences in scaling behavior as the temperature is lowered are to a large extent caused by a decreased plasticity of the oxide. Above about 750°C the oxide does not layer, and consequently the over-all reaction rate is essentially parabolic (6). At an oxygen pressure of 380 Torr at 720°C the oxide grows protectively to a thickness of about 40 $\mu$ , and as the temperature is lowered to 625°C the protective thickness is reduced to about 13 $\mu$ . Below 600°C, the initial oxide grows to a thickness of only a few microns before failing, possibly because the platelets promote cracking. During this period of oxidation the niobium pentoxide scale layer is growing by a mechanism in which oxygen is the predominate diffusing species. This is evidenced by the sustained appearance of polishing defects from the initial preparation on the free oxide surface. Calculations show that in this phase of the reaction less than 5% of the weight gain of a specimen is associated with oxygen solution in the metal phase and the formation of sub or lower oxides. This value decreases as the reaction proceeds.

After the onset of scale layering the reaction rate is observed to be essentially linear. The excellent agreement between the measured and calculated parabolic rate constants above 625°C, Fig. 4, confirms that the rate of oxidation under these conditions is controlled by the transport properties of the layer of oxide in contact with the metal phase. That is, the linear rate of oxidation is not due to phase boundary control, but is the result of a repeated parabolic process. Below 625°C, such direct confirmation of the oxidation mechanism is not available. However, the correlation of the metallographic observations with inflections in the rate curve, and the analysis of the enhanced oxidation at specimen corners strongly supports the continued operation of a paralinear mechanism. There are no values in the literature with which these calculated parabolic rate constants can be directly compared, although they appear to be approximately one order of magnitude faster than those of Gulbransen and Andrew (13). It is noted that below 625°C the oxides NbO and NbO<sub>2</sub> are not present at the metal oxide interface as required in their description of the oxidation reaction by Cox and Johnston (8), by Inouye (14), and by Blackburn (15).

The initial parabolic rate constants are known to be sensitive to the oxidizing pressure (6). Further, it has been observed both in this study and that of Kofstad and Kjøllesdal (16), that the thickness of scale laminations tends to increase as the oxidation pressure is reduced. Hence the variation of both the linear rate of reaction and the calculated parabolic rate is considered to emanate from these causes and not as a result of phase boundary control.

At temperatures below 550°C, at some time well after breakway, the rates of reaction tend to change slowly to lower values. For example, in Fig. 2B, the rate of reaction of a specimen reacted at 520°C at 380 Torr after 120 min has fallen to 0.6 that of the rate at 20 min. This behavior has been reported previously (7), and was considered to be due to a thickening of the barrier film. This could occur in two ways; the average lamination thickness  $W_c$  could increase, or the lamination thickness could remain constant but the point at which a new lamination forms could move further from the metal-oxide interface. Examination of oxidized specimens showed no evidence of a change in lamination width greater than 0.85, whereas a change of 0.6 is required for the first mechanism. The

second mechanism requires the lamination of oxide adjacent to the specimen to be up to 1.3 times thicker than the average. However, the laminated structure is not sufficiently well defined, particularly near the metal-oxide interface where cooling effects are most disruptive, for such a judgment to be made. An alternative mechanism is proposed by Cox and Johnston (8) to explain this reduction in rate, in which the reaction is partially stifled by restriction of the gas flow due to the growth of the porous outer scale. In growing the porous structure is altered so that the restriction the scale presents to the gas attains a limiting value. Subsequent oxidation would then obey a linear rate law and show an almost linear dependence of the rate on gas pressure. A central feature of their arguments is that the pressure sensitivity of the reaction is a consequence of the porous plug character of the scale, and not due to subsequent phase boundary or transport steps. However, it can be seen in Fig. 2, that oxidation is pressure sensitive from the start of reaction, that is before a porous plug has been formed. Hence it is considered that resistance to oxidation caused by the detached scale laminations is only of secondary importance.

One of the most prominent characteristics of the oxidation behavior of niobium is the decrease in reaction rate of specimens as the temperature is increased from 600°-625°C. This behavior is most evident in the values of the derived parabolic rate constant, where association with the lower temperature line correlates with platelets in the specimen, and association with the high-temperature line correlates with NbO (and probably NbO<sub>2</sub>) at the metal-oxide interface. The platelet phase has been considered in some detail by Cox and Sheasby (17), concluding that the platelets are a metastable phase, and that they form during reaction and not while the specimen is being cooled to room temperature. These conclusions are based on the following arguments.

1. Norman, Kofstad, and Krudtaa (18) noted that platelets only form from supersaturated solutions of oxygen in niobium, and they could not prepare an oxide with the same structure as the platelets by melting together the appropriate quantities of metal and pentoxide.

2. On certain specimens reacted just above 600°C it is possible for platelets to form at one point on a specimen and for layers of NbO and NbO<sub>2</sub> to form at another. The niobium pentoxide scale formed above the platelet phase is always much thicker than that formed above the layers of lower oxides. Typical microhardness traces beneath two such regions are shown in Fig. 9. Theoretical diffusion gradients were

Fig. 9. Microhardness gradients under two different regions of the same specimen.

Fig. 10. Taper section of niobium oxidized at 600°C at an oxygen pressure of 750 Torr for 60 min, showing a band of platelets in the metal phase; taper ratio approx. 10:1. Magnification 250X.

calculated assuming a linear rate of interface motion, varying only the hardness value corresponding to the oxygen concentration at the metal-oxide interface to optimize the fit to the experimental points. As NbO is the stable phase, the hardness of the metal in contact with it, i.e., at zero depth on the broken curve, corresponds to the equilibrium level of saturation of oxygen in niobium. The hardness value under the platelet phase extrapolates to a higher hardness value at the surface, indicating that the metal is supersaturated with oxygen in this region. As platelets are only found within the supersaturated zone they are a metastable phase.

3. Platelets have never been observed beneath a continuous layer of NbO.

4. If platelets are present at the end of oxidation, traces of their previous existence in the metal, as described by Stringer (11) for oxidized tantalum, are observable in the layered niobium-pentoxide. Further, particularly in taper sections, it often appears that the center of single platelets has been consumed by the advancing metal-oxide interface, Fig. 10. It is improbable that platelets nucleating independently during cooling would so often lineup with each other on either side of a region of pentoxide.

The presence of platelets in the reaction zone can therefore be taken as evidence that the metal is supersaturated with oxygen with respect to NbO, the next stable phase on the equilibrium diagram. It follows that in these circumstances the niobium-pentoxide adjacent to the metal phase will be supersaturated with niobium. The oxidation rate has been shown to be controlled by the diffusional properties of the niobium-pentoxide layer in contact with the metal phase. Hence it is proposed that the increase in oxidation rate observed above the platelet phase is due to the enhanced oxygen concentration gradient present in the niobium-pentoxide under these conditions.

## Insulator-Induced Conduction

Jerry M. Cantril and H. A. Pohl\*

*Department of Physics, Oklahoma State University, Stillwater, Oklahoma*

### ABSTRACT

The presence of insulating particles, even those of higher resistivity than the liquid, was found to increase electrical conduction in several dielectrical liquids. We believe this to be a general effect which will occur if the particles have a higher dielectric constant than the liquid. In particular, we observed in several highly purified liquids (C Cl<sub>4</sub> and toluene) that the current conducted across a cylindrical electrode system was considerably enhanced when highly purified solids (*e.g.*, polyvinyl chloride, quartz, or sulfur) were held against the smaller inner electrode by dielectrophoretic force. A theory for the effect is given. It emphasizes the effect of local field concentration (field-focussing) by the particles. This "focussing" of the field in the liquid acts to enhance carrier concentration and conduction since the conduction is in the nonohmic space-charge-limited regime.

Solid particles with a dielectric polarization higher than that of the surrounding liquid medium are pulled dielectrophoretically into regions of highest field strength. This effect has been used to accomplish separations of solid particles in nonuniform electric fields (1-4). The present study has sought to inquire experimentally as to what effect the deposition of solid material might have on electrical conduction through the liquid.

The effects of particles on electrical conduction processes in liquids are as yet incompletely known. Conductive particles such as iron or wet particles such as moist clay are known to play an important role in dielectric breakdown of liquids (6, 7). The role of insulating material particles in conduction in dielectric liquids is less well known, especially at voltages well below breakdown values. Electrophoretic phenomena involving the charging of particles and their subsequent discharge after migration to an electrode are well recognized (6, 7). Kok (6) has expressed the opinion that particles, themselves of an insulating nature, have a negligible effect on current flow in liquid dielectrics and that their effect would be indistinguishable from the background ionic current. Pohl and Schwar (3) have suggested that rotational Brownian motion of suspended particles may enhance current flow by rotationally transporting deposited ions from the medium on the surface of the particles. The effect on conduction due to insulating particles resting at an electrode has not been studied. In the case of purely ohmic conduction one would expect the presence of particles of lower conductivity than the liquid to block current flow. Yet the earlier experiments of Pohl and Schwar had indicated that the opposite might occur, and that the presence of insulating particles could enhance current flow in dielectric liquids. The present work was undertaken to examine more quantitatively the experimental facts and to derive a theoretical understanding of them.

A somewhat distantly related phenomenon is known to occur in glow discharge tubes. When the cathode is entirely covered with a thin film of insulating material

(5) a current increase is observed. The explanation proposed was that a positive space charge was formed either inside or at the surface of the insulating material, the positive charge being supplied by positive ions from the gas plasma in the tube. The resultant high field in the insulating layer pulled electrons through it, some of which are emitted with high velocity into the conducting gas. This effect, as we shall see, is different in an essential way from that which we shall discuss for particles. The particles produce a three-dimensional perturbation in the electric field, the film produces only a one-dimensional one, and different mechanisms are called into play.

The present experiments were conducted with particles held to an electrode in a nonuniform field by the action of dielectrophoretic force. Great care was taken with regard to purity of the liquids and the suspended particles. A combination of exhaustive recycled sorption and electrical de-ionization was used in a sealed test cell to achieve very high purity and a high degree of reproducibility. The experiments, broadly speaking, were done using a slightly modified form of dielectrophoretic technique with cylindrical geometry (1-4). Polyvinyl chloride (PVC), sulfur, and silicon dioxide were used as solids, carbon tetrachloride and carbon tetrachloride-toluene mixtures were used as liquids.

### Experimental

*Test system.*—A schematic diagram of the test system is shown in Fig. 1. The cell was designed so that the purification system was integral with it. The purification system comprised two parts; a sorption bed of 6-12 mesh silica gel in the lefthand chamber of the Pyrex glass cell, and a set of three concentric cylindrical stainless steel electrodes in the righthand chamber. The latter electrodes were connected as shown to a 45v battery. The central chamber served as the test chamber. The sintered glass filter beneath the central test chamber had a maximum pore size of 40-60 $\mu$ , while that under the sorption bed had a maximum pore size of 170-200 $\mu$ . The whole cell was 21.6 cm high and 14.0 cm wide. The chambers were constructed of

\* Electrochemical Society Active Member.

Fig. 1. Schematic diagram of test cell and circuits

35 mm Pyrex glass tubing. The distance from the tops of the filters to the bottoms of the upper two sidearms was 14 cm. Two stirring magnets whose function will be described below sat in the cell. The lower magnet was Teflon encased and was 0.64 cm by 1.92 cm overall. The magnet in the central chamber was Pyrex glass encased and was 0.41 cm by 2.44 cm over-all.

The cell was mounted in a 20 x 44 x 8 cm aluminum box. The box, to complete its shielding function, was fitted with a brass screen door and grounded. The box with its cell enclosed sat in a clear plastic envelope through which passed dry nitrogen to provide a dry inert atmosphere. This assembly was mounted on a magnetic stirrer drive. An aluminum plate was inserted between the stirrer drive and the box to aid dissipation of the heat generated by the stirrer motor. Electrical leads ran from the test cell, through the box wall and the plastic envelope to the test circuit. The entire assembly and test circuit sat in a second shielding cage. The 45v battery was mounted inside the inner shielding box as shown.

The test electrode assembly is shown diagrammatically in Fig. 2. The outer electrode consisted of 2.16 cm ID Pyrex glass tubing provided with an inside transparent conductive tin oxide coating, using the technique of Gomer (8). The stainless steel electrode (which here was never used separately) had an outside diameter of 1.98 cm and an ID of 1.82 cm. The center wire electrode was 22 B. & S. gauge platinum wire, of 0.644 mm diameter. The hollow bolt shaft and nut assembly was used to apply tension to the center wire. The holes and slots in the Teflon spacers allowed the liquid to circulate through the test region during purification.

The test voltages were provided by a bank of Burgess U 320 batteries (nominally 510v each) whose voltages were measured before and after each run with an Aryton Mather Static voltmeter. The current was measured with a Kieithley 610B electrometer. The whole system sat in an electrical cage for shielding and operator safety. The box, cage, and the low side of the electrometer were all at a common ground potential.

**Materials and procedures.**—The solids used were purified PVC, sulfur, and silicon dioxide (quartz). The liquid used for the PVC tests was a mixture of 5.5 to 3 volume ratio of carbon tetrachloride and toluene, chosen to have a density slightly less than that of the powder. Pure carbon tetrachloride alone

Fig. 2. Cross section of test electrode system with views of spacers showing slots and holes for circulation of liquid.

was used for the tests with sulfur and silicon dioxide. The liquid samples used were at least of reagent grade purity. They were stored over solid anhydrous silica gel in a dry box when not in use. The powder samples were stored and dried as a thin layer over anhydrous calcium sulfate for at least one week before use.

The PVC sample, obtained from Bordon Chemical Company, was partially purified by extracting for 12 hr with distilled water to remove impurity salts, then by extracting with reagent grade  $\text{CCl}_4$  for another 12 hr to remove organic impurities. The powder was then dried and sieved to pass 80 mesh screen and stop on 100 mesh screen, then stored in the desiccator. The silicon dioxide was first washed with concentrated HCl, then repeatedly with distilled water, then cp acetone, dried, ground, sized to 80-100 mesh range, and stored dry.

Sulfur was recrystallized 3 times from reagent grade  $\text{CS}_2$ , dried, sized to 80-100 mesh range, and stored dry.

The test cell was loaded by putting the powder sample into the center chamber of the cell, then filling the cell with the desired liquid. After loading and mounting the cell, the lower magnetic stirrer was caused to spin and pump the liquid through the purification loops and test cell. The liquid portion passing through the sorption bed was chemically cleaned. The liquid portion through the ion collector plates was electrically purified by the plating out of the residual ions, in a manner suggested by Streier (9).

Purity was tested periodically by observing the current flow at 300v. The upper (glass-encased) magnet could be selectively activated to follow the larger lower one by running the stirrer drive at low speed. When the desired optimum of purity had been achieved, the liquid was electrically "conditioned" by applying the total voltage of the battery bank across the test system until the current had decreased to an essentially steady value. After conditioning the liquid, a current versus voltage curve was taken while decreasing the voltage in steps. The full voltage was then reapplied and the original curve either rechecked or the powder was caused to be stirred up into the central test chamber by activating the upper stirrer bar. When the powder sample had been pulled dielectrophoretically to the center electrode, another current-voltage curve was taken while again decreasing the voltage in steps as before. On shunting the electrodes, the powder would fall from the center wire allowing the test to be repeated. All results re-

ported here are with the center wire serving as the anode.

Current-voltage readings were taken in the following way. After the attainment of "steady-state" conditions at full voltage as described above, the voltage was decreased in steps by switching out batteries. As each battery was removed and the (reduced) voltage re-applied an initial current peak of temporary nature was observed. Typically a new steady state was reached in 1 hr at each voltage, and the data recorded. The temporary current surge was typically two to four times the final steady-state readings. The instrument error was such as to give a precision of  $\pm 1.2 \times 10^{-13}$  amp.

### Results

A typical set of results is shown in Fig. 3 for a 0.110g sample of 80-100 mesh PVC. After the current-voltage curve for the liquid alone was taken, a second current reading at the highest voltage closely checked the first. (Note the slightly higher circled point at near 5000v.) The powder sample was then stirred up into the test region and allowed to collect at the center wire, then a current-voltage curve obtained with the powder in place on the center electrode. Finally the cell was discharged by shunting, the powder allowed to fall back to the base of the central cell out of the field, full voltage reappplied, and a current reading taken (blacked in circular point near 5000v) on the liquid alone. This reading was typically slightly higher than before on the pure liquid but much lower than with the powder present at the electrode surface. A last point was taken (blacked-in triangle) with the powder again at the electrode surface, completing the proof that the presence of the insulating particles on the electrode did indeed enhance current flow. Closely similar results were obtained in numerous other runs with PVC, sulfur, and  $\text{SiO}_2$ .

The sheath formed at the center wire was observed with a 10 x travelling microscope and had the appearance of villous streamers formed by the powder granules. There was a relatively even vertical distribution of adherence. The maximum sheath diameter was about four times the central wire diameter. The streamers, or "pearl chains" as they have been called arise because of the intensification of the field in the neighborhood of each particle and the resultant dielectrophoretic force between particles along the field lines.

### Discussion

The observed enhancement of current flow caused by the presence of insulating particles cannot be accounted for by the simple argument that the central electrode is just bigger. For an ohmic system the resistance,  $R$ , of a cell with cylindrical electrodes (neg-

lecting end effects) is

$$R = \frac{\rho}{2\pi L} \ln (r_2/r_1)$$

where  $\rho$  is the specific resistivity of the liquid,  $L$  is the cell length, and  $r_2$  and  $r_1$  are the radii of the outer and inner conductors. The current was increased by a factor of about 3 over most of the voltage range when particles were present. To account for such a large factor by enlargement of the central electrode (as if by a conductive layer!) would require the effective diameter of the central electrode to be increased by 10.5 fold. The powders examined were, however, not conductive, but were insulators of a specific resistivity as high as or higher than that of the liquid, and present in a layer such as to be only fourfold greater in diameter than the central wire. Clearly electrode "enlargement" in the simple ohmic sense cannot account for the observed effect.

We suggest instead that the current enhancement by the particles is due to field intensification at their boundaries. In all cases considered here, the particles are of higher dielectric constant than the liquid medium. The particles are pulled dielectrophoretically into the regions of highest field intensity where they tend locally to intensify the field even further. If, for example, the charge carriers originate in the liquid itself by field dissociation (whether of trace impurities or of solvent molecules) then the field enhancement due to the presence of the particles will increase the charge carrier production and, hence, the current (see Fig. 4).

In the following we will find it more convenient to speak of the conductance of the system instead of the total current. Figure 5 shows the conductances of

Fig. 4. Sketch of particle at center electrode showing field intensification.

Fig. 3. Current vs. voltage curves for liquid alone and liquid with 80-100 mesh size PVC.

Fig. 5. Conductance vs. voltage for liquid alone,  $\odot$ ; and that for liquid with 80-100 mesh size PVC,  $\triangle$ .

the system for the 80-100 mesh size PVC run. It is seen that the conductances in both cases are strongly dependent on the applied voltage. To account for the conduction increase we assume a reasonable functional dependence of the conductance of the liquid on the electric field. We then calculate a field enhancement parameter for the case of particles being present. We assume the conductivity  $\sigma_o$  is composed of two terms, a constant term  $\sigma_{oc}$  and a field dependent term  $\sigma(\vec{E})$  where  $\vec{E}$  is the electric field.  $\sigma_{oc}$  may be interpreted as the residual conductivity resulting from impurities and background radiation and/or cosmic radiation. The functional form of  $\sigma(\vec{E})$  is derived by assuming that the energy stored in the field over a distance  $l_o$  aids in the ionization of charge carriers. The conductivity may be written as

$$\sigma(\vec{E}) = qn\mu$$

where  $n$  is the concentration of carriers,  $q$  is the charge of the carrier, and  $\mu$  is the mobility of the carrier in the medium. The field energy over the distance  $l_o$  affecting carrier birth is

$$E = ql_o|\vec{E}|$$

We can now write  $n$  as

$$n = n_o \exp\left(\frac{ql_o|\vec{E}|}{2kT}\right)$$

where  $k$  is Boltzmann's constant and  $T$  is the absolute temperature. The field dependent conductivity can then be written

$$\sigma(\vec{E}) = \sigma_{oo} \exp\left(\frac{ql_o|\vec{E}|}{2kT}\right) \quad [1]$$

where

$$\sigma_{oo} = q\mu n_o$$

We are interested in the region around the center electrode since this is where the particles are deposited and cause the greatest field distortions. In the case of liquid only being in the system, the electric field at the center electrode is

$$\mathcal{E}_o = |\vec{E}| = \frac{V}{r_1 \ln(r_2/r_1)}$$

where  $V$  is the total applied voltage,  $r_1$  is the radius, and  $r_2$  is the inner radius of the outer electrode. Equation [1] may now be written as

$$\sigma(\vec{E}) = \sigma_{oo} \epsilon_o \exp(\alpha_o V)$$

where

$$\alpha_o = \frac{ql_o}{2kT} \frac{1}{r_1 \ln(r_2/r_1)}$$

The total conductivity may now be written as

$$\sigma_o = \sigma_{oc} + \sigma_{oo} \exp(\alpha_o V) \quad [2]$$

The current density is

$$|\vec{j}_o| = \sigma|\vec{E}| = \sigma_{oc}\mathcal{E}_o + \sigma_{oo}\mathcal{E}_o \exp(\alpha_o V)$$

Integrating over the surface area  $S$  of the center electrode we have for the total current

$$\begin{aligned} I_o &= \int_s j_o dS \\ &= \int_s \sigma_{oc}\mathcal{E}_o dS + \int_s \sigma_{oo}\mathcal{E}_o \exp(\alpha_o V) dS \\ &= \sigma_{oc}\mathcal{E}_o S + \sigma_{oo}\mathcal{E}_o \exp(\alpha_o V) S \end{aligned} \quad [3]$$

since  $\sigma_{oc}$ ,  $\epsilon_o$ ,  $\alpha_o$ ,  $V$  and  $\sigma_{oo}$  are constant over the surface. For the conductance  $G_o$  of the system we may now write

$$\begin{aligned} G_o &= I_o/V \\ &= \frac{\sigma_{oc}\mathcal{E}_o S}{V} + \frac{\sigma_{oo}\mathcal{E}_o}{V} \exp(\alpha_o V) S \\ &= G_{oc} + G_{oo} \exp(\alpha_o V) \end{aligned} \quad [4]$$

For the case of particles being present the expression for the total current is similar to [3]

$$I_p = \int_s \sigma_{oc}\mathcal{E}_p dS + \int_s \sigma_{oo}\mathcal{E}_p \exp\left(\frac{ql_o\mathcal{E}_p}{2kT}\right) dS$$

where  $\mathcal{E}_p$  is the electric field at the surface of the center electrode when particles are present. For purposes of convenience we rewrite  $I_p$  as

$$\begin{aligned} I_p &= \sigma_{oc}\mathcal{E}_o \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} dS + \sigma_{oo}\mathcal{E}_o \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} \exp\left(\frac{ql_o\mathcal{E}_o}{2kT} \frac{\mathcal{E}_p}{\mathcal{E}_o}\right) dS \\ &= \sigma_{oc}\mathcal{E}_o \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} dS + \sigma_{oo}\mathcal{E}_o \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} \exp\left(\alpha_o \frac{\mathcal{E}_p}{\mathcal{E}_o} V\right) dS \end{aligned}$$

where the definitions  $\sigma_{oc}$ ,  $\sigma_{oo}$ ,  $\mathcal{E}_o$ , and  $\alpha_o$  are as before. The conductance of system when particles are present may now be written as

$$\begin{aligned} G_p &= I_p/V \\ &= \frac{\sigma_{oc}\mathcal{E}_o}{V} \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} dS + \frac{\sigma_{oo}\mathcal{E}_o}{V} \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} \exp\left(\alpha_o \frac{\mathcal{E}_p}{\mathcal{E}_o} V\right) dS \\ &= G_{pc} + G_{op} \exp(\alpha_p V) \end{aligned} \quad [5]$$

$G_{pc}$ ,  $G_{op}$ , and  $\alpha_p$  are the parameters of the conductance curve when particles are present and may be obtained from the data. The conduction enhancement is characterized by the difference between  $\alpha_o$  and  $\alpha_p$ . We now calculate  $\alpha_p$  knowing  $\alpha_o$ ,  $G_{oo}$ , and  $G_{op}$  and compare this value with the experimental value. Using the second terms on the right-hand sides of Eq. [4] and [5]

$$\alpha_p = \ln \left[ \frac{G_{oo} \int_s \frac{\mathcal{E}_p}{\mathcal{E}_o} \exp\left(\alpha_o \frac{\mathcal{E}_p}{\mathcal{E}_o} V\right) dS}{G_{op} S} \right] \quad [6]$$

For simplicity we now assume an even distribution of identical particles over the surface of the electrode. The surface averaged factor in [6] may then be calculated over an effective area for one particle instead of over the whole electrode surface. The problem remaining is to determine  $\mathcal{E}_p/\mathcal{E}_o$  and the surface of integration. We assumed the solution of the well-known problem of the dielectric sphere in a homogeneous field. For the surface of integration we chose a plane tangent to the sphere and to the electrode surface as shown in Fig. 4. Using these assumptions,  $\mathcal{E}_p/\mathcal{E}_o$  over the surface can be shown to be

$$\begin{aligned} \mathcal{E}_p/\mathcal{E}_o &= \left\{ 1 + 2 \left( \frac{\epsilon_2 - \epsilon_1}{\epsilon_2 + 2\epsilon_1} \right) \left( \frac{a}{r} \right)^3 \left[ 3 \left( \frac{a}{r} \right)^2 - 1 \right] \right. \\ &\quad \left. + \left( \frac{\epsilon_2 - \epsilon_1}{\epsilon_2 + 2\epsilon_1} \right) \left( \frac{a}{r} \right)^6 \left[ 3 \left( \frac{a}{r} \right)^6 + 1 \right] \right\}^{1/2} \end{aligned}$$

where  $\epsilon_2$  and  $\epsilon_1$  are the dielectric constants of the solid and liquid, respectively,  $a$  is the radius of the particle, and  $r$  is the distance from the center of the sphere to a point on the plane.

The calculation for  $\alpha_p$  was carried out for the 80-100 mesh size PVC for a voltage of 5000v. The average particle diameter was taken to be 0.0163 cm, the relative dielectric constants of the liquid and solid to be 2.29 and 12.0, respectively,  $G_{oo}$  to be  $1.19 \times 10^{-16}$  mhos,  $\alpha_o$  to be  $2.91 \times 10^{-4}/v^{-1}$ , and  $G_{cp}$  to be  $3.66 \times 10^{-17}$  mhos. The integration was carried out over a circular area whose radius was twice the radius of the sphere.

With this, it was then possible to obtain the desired result, i.e., an *a priori* evaluation of  $\alpha_p$  by use of Eq. [6].

The value of  $\alpha_p$  obtained by this *a priori* calculation was  $6.2 \times 10^{-4} \text{ volt}^{-1}$ . This value is in rather satisfactory agreement with that found experimentally ( $6.1 \times 10^{-4} \text{ volt}^{-1}$ ). In view of the simplifications used in the calculation, this consonance with experiment lends support to the theory presented. We regard

theory presented as recognizedly a first approximation in interpretation. Further work, both experimental and theoretical is called for.

## Thermodynamic Properties of Molten Mixtures of Nickel Chloride with Some Alkali Halides

Drannan C. Hamby and Allen B. Scott\*

Department of Chemistry, Oregon State University, Corvallis, Oregon

#### ABSTRACT

Thermodynamic properties including the activity coefficient and the partial molar free energy, enthalpy, and entropy of mixing have been determined for the solute  $\text{NiCl}_2$  in the solvents  $\text{KCl}$ ,  $\text{NaCl}$ ,  $\text{LiCl}$ , and 1:1  $\text{NaCl-KCl}$ . The values of the properties were established by measuring the reversible emf of cells of the type

where  $M$  represents an alkali metal cation. Cell emf's were determined over a range of concentration from approximately  $10^{-4}$  to  $4 \times 10^{-1}$  mole fraction of solute and temperatures ranging from the melting points of the solvents to  $900^\circ\text{C}$ . The experimentally determined entropy of mixing has been compared with calculated values based on several microstate models. Reference electrodes of the type

which utilized solid porcelain as a bridge, were immersed in the same melts, and allowed continuous monitoring of chlorine electrode potentials as solute concentration varied.

In a preliminary study of electrode designs the  $\text{AgCl}$  formation cell

was studied as a function of temperature. Several electrode designs were tested for both the chlorine and metal electrodes. The relationship between cell emf and temperature was found to be in agreement with that established by Senderoff and Mellors.

The electrowinning and electrofining of Ni from fused salt baths has received attention in this and other laboratories in recent years (1, 2). This interest has led, in the present case, to a study of several cells of the type

where

$$N = \frac{\text{moles solute}}{\text{moles solvent} + \text{moles solute}}$$

and  $\text{MCl}$  is  $\text{KCl}$ ,  $\text{NaCl}$ , 1:1  $\text{NaCl-KCl}$ , or  $\text{LiCl}$ , for the purpose of establishing cell potentials as a function of both temperature and solute concentration. By utilizing supplementary thermochemical data and making proper choices of standard and reference states, the cell data have been used to calculate solute activity

coefficients as well as partial molar free energies, enthalpies and entropies of mixing of  $\text{NiCl}_2$  in the various solvents. The magnitude of the latter quantity,  $\bar{S}$ , may be predicted theoretically on the basis of various microstate models, and a comparison of theoretically and experimentally derived entropies of mixing has been made.

Reference electrodes of the type

similar to those described by Lamb and Labrie (3) and by Littlewood (4) were placed in the cells described above. The solvent,  $\text{MCl}$ , was always the same on both sides of the membrane. This arrangement allowed measurement of the quantity

$$\Delta E' = E'_{\text{Ag}} - E_{\text{Ag}}$$

\* Electrochemical Society Active Member.

where  $E'_{Ag}$  and  $E_{Ag}$  are emf's for the cell

in the respective cases  $N_{NiCl_2} \neq 0$  and  $N_{NiCl_2} = 0$ . This information is useful in establishing the limits of NiCl<sub>2</sub> concentration over which one may convert potentials measured with the Ag reference electrode to potentials based on the chlorine reference electrode without correcting for junction effects.

The AgCl formation cell

which has received attention in several laboratories, was studied in a preliminary investigation of electrode designs. Of primary interest in this work was the demonstration of chlorine electrode reversibility and the effectiveness of various methods of shielding the metal electrode from direct attack by chlorine.

### Experimental

Two AgCl formation cells and six cells involving NiCl<sub>2</sub> as a solute were tested. These will be referred to as cells A and B and cells I through VI, respectively. Solvents in cells I through VI were KCl, NaCl, 1:1 molar NaCl-KCl, LiCl, LiCl, and KCl, respectively.

The outer cell envelope consisted of two parts, a closed-end Vycor tube and a Pyrex top. The Vycor tube was 64 mm in diameter, 45 cm long, and flanged at the open end; the Pyrex top, also made of 64 mm tubing, had a matching ground flange and tubular openings through which electrodes, a thermocouple, and a sampling tube could be introduced into the cell. When the cell was assembled, the glass flanges were separated by an O ring and clamped together by means of metal clamps. The various cell components, which entered through the cell top, were coupled by means of rubber tubing of appropriate sizes to the tubular openings in the Pyrex top. An inner crucible of Vycor, or Ultra Carbon Company UF-4-S graphite in the case of the AgCl formation cell, was used as the melt container.

Each cell tested utilized two chlorine electrodes, one of each design illustrated in Fig. 1. The graphite rod was 1/4 in. diameter Ultra Carbon Company grade UF-4-S. The porous parts were machined from National Carbon Company, grade 60, porous graphite. The Vycor sheath served to prevent shorting of the electrodes, provided mechanical strength, and defined the path of the Cl<sub>2</sub> into the melt. Air tightness at the top of the sheath was insured by application of a high-melting wax in the liquid state while maintaining a vacuum in the sheath. Pretreatment of the electrodes

consisted of dipping in dilute HF, rinsing, immersion in boiling dilute HCl, rinsing, and then heating to 800°C in Cl<sub>2</sub> for several hours.

Chlorine and HCl gas were Matheson Company "high purity." The gases were passed over Mg(ClO<sub>4</sub>)<sub>2</sub> before entering the cell. The gas delivery system was glass except for a few inches of rubber tubing near the cell top. Chlorine flow was measured by means of a Manostat Corporation, model M9142C flowmeter in the gas line. Gases left the cell through a sulfuric acid trap, the entry tube of which was immersed just below the surface of the acid.

Metal electrodes were 0.020 in. wire obtained from A. D. McKay and described as 99.9+ % pure. The electrodes were cleaned by abrasion with emery paper and wiping with an acetone-dampened cloth. Various designs of Vycor protection tubes for the metal electrodes are shown in Fig. 1. All of the designs were tested in the AgCl formation cell; design D was later utilized for all nickel electrodes. The capillaries were from 0.1 to 0.5 mm in diameter and about 1 cm long. The open ended tube, A, was used only in conjunction with a graphite crucible which provided a shallow well into which the lower end of the tube was received. An atmosphere of dry argon was maintained over the melt inside the Ni electrode protection tubes.

The Ag reference electrodes used in this work utilized a 1/2 in. diameter McDanel porcelain tube as a solid electrolyte. Metallic contact to the silver electrode was made by fusion to platinum inside a small-diameter alumina tube; thus, the silver-air interface was eliminated and electrode stability was improved. An inert atmosphere over the Ag reference electrodes was not found to be necessary.

The salts used in this work were:

AgCl. Mallinckrodt, reagent grade AgCl was oven dried in air and fused under chlorine in the presence of carbon.

NaCl and KCl. Reagent grade materials were further purified by passage through ion exchange columns (5). Before use the salts were vacuum desiccated, oven dried at 120°C in air for many hours, then placed in the cell and gradually heated and melted under continuous chlorine flow in the presence of carbon (6).

LiCl. Reagent grade material was used. Two methods of dehydration were attempted: (a) Cell IV. Aspirator pumping and heating under flowing argon to 400°C, followed by fusion under flowing chlorine in the presence of carbon. (b) Cell V. More extensive vacuum pretreatment consisting of approximately 24 hr at pressures from 0.2 to 0.7 mm Hg combined with intermittent purging of the cell with dry HCl while slowly bringing the cell temperature to 500°C. The salt was then fused under HCl and chlorinated in the presence of carbon.

NiCl<sub>2</sub>. Reagent grade NiCl<sub>2</sub> · 6H<sub>2</sub>O was oven dried in air at 130°C, ground in a porcelain mortar, and subsequently dried for at least 4 hr under anhydrous HCl at 400°C. The salt was transferred to weighing bottles in a glove bag under nitrogen and subsequently stored in a desiccator until used. Transfer to the cell involved brief exposure to the atmosphere.

Electrolytes utilized in the Ag reference electrodes were prepared from the purified NaCl and KCl and from reagent grade LiCl and AgCl. The salts were weighed out in the desired proportions and fused and chlorinated in the presence of carbon for at least one hour. The melts were drawn into clean, dry, Vycor rods from which they were removed as the solid and stored under CCl<sub>4</sub>.

The furnace was a Marshall Company test furnace, 16 in. in length with a 3 in. diameter throat. Power was supplied to the furnace with a West, Model JSB Control. Cell temperatures were determined by means of a calibrated Chromel-Alumel thermocouple housed in a 6 mm Vycor sheath immersed in the melt. The measuring thermocouple was calibrated in freezing

Fig. 1.(a) Chlorine electrode designs; Fig. 1(b) Vycor protection tubes for metal electrodes.

aluminum, supplied by the N.B.S., and by comparison against an L&N Pt, Pt-10% Rh thermocouple, Model 8710-B-K2002. Temperature measurements were observed to vary as much as 3° due to different positioning of the thermocouple in the bath. Since this is estimated to be greater than the degree of uncertainty involved in the calibration the uncertainty in temperature is taken to be  $\pm 3^\circ$ .

Emf measurements were made with a Systems Research Corporation differential voltmeter, Model 5501. This instrument was checked periodically against a laboratory standard Eppley cell.

Thermoelectric effects associated with the electrodes in the absence of electrolyte were determined experimentally *in situ* for each pair of electrodes using powdered graphite as an electrical connection at the hot junction. Thermoelectric potentials developed by various pairs of Ni-to-graphite electrodes differed by  $\pm 2$  mv.
