

# The Effect of Preoxidation and Meniscus Shape on the Hydrogen-Platinum Anode of a Molten-Carbonate Fuel Cell

James T. Cobb, Jr.<sup>1</sup> and Lyle F. Albright

School of Chemical Engineering, Purdue University, Lafayette, Indiana

## ABSTRACT

Electrochemical phenomena in a hydrogen-oxygen fuel cell were studied at 723°K for the three-phase region on smooth platinum anode sheets, partially immersed in a eutectic mixture of lithium, sodium, and potassium carbonates. The meniscus shape varied with the composition of the gas phase and the potential of the anode. A platinum oxide surface was formed on the anode either by a preoxidation technique or by contacting the platinum with gaseous oxygen. A platinized surface, obtained by reduction with hydrogen of this surface, resulted in immediate large increases in current (activation), but the current slowly decreased with time (deactivation). Temporary increases in current were observed as the contact angle suddenly increased as the electrolyte film drained from the anode. The molten-carbonate film, obtained during raising the anode, was apparently relatively impermeable to hydrogen.

The current density at a selected polarization or voltage can be substantially increased through a smooth platinum anode completely submerged in an aqueous electrolyte by preoxidizing the anode surface (1, 2). The platinized surface, produced by the reduction of the oxide layer, slowly "recrystallizes," and the current density decreases toward its value before pre-oxidation. A similar effect is found on a smooth hydrogen-platinum anode partially immersed in an aqueous electrolyte (3).

On a smooth, partially immersed hydrogen-platinum anode, only well-developed menisci (formed by good wetting of the anode by the electrolyte) have been reported. However, evidence exists of variations in the contact angle on several other metal surfaces, partially immersed in aqueous solutions and exposed to various atmospheres and potentials (4-6). Changes in the contact angle have also been observed when the atmosphere was changed around sessile drops of molten sodium disilicate and molten lithium metaborate on smooth platinum surfaces at 1273°K (7, 8).

When a well-developed meniscus is present on an electrode partially immersed in an aqueous electrolyte, a film extends above the meniscus and over 75% of the current results from the transfer of the hydrogen through it (9-11). Migration of hydrogen along the surface of the anode has been shown to be insignificant under these conditions (9, 11). However, the possibility of significant bulk diffusion through the anode material of a high-temperature (723°-973°K) fuel cell has been postulated (12).

The present investigation concerned itself with these phenomena on a platinum anode partially immersed in a eutectic mixture of lithium, sodium, and potassium carbonates at 723°K. The effects of (a) preoxidation, (b) changes in composition of the gas phase, and (c) resistances to hydrogen transfer through an electrolyte film were investigated in regard to the current density through the anode and on the contact angle made by the molten salt with the anode.

**Equipment.**—The fuel cell used is shown schematically in Fig. 1. A 1:1:1 by weight mixture of lithium, sodium, and potassium carbonates (item 1) filled a 2500 ml Vycor beaker (item 2) to a depth of 12.5 cm. The salt was prepurified by melting and skimming the salt, then reducing metallic ions with a magnesium metal strip. An inverted 800 ml glass beaker (item 3) was

immersed approximately 2.5 cm in the salt and served as the fuel chamber. It was supported by three 6 mm glass tubes. Two of these tubes (items 4 and 5) extended to within 2.5 cm of the top of the fuel chamber. One was the gas inlet and the other the gas outlet. A fourth tube, fused shut on the end, contained a chromel-alumel thermocouple, which was placed at the salt surface either just outside the fuel chamber or inside the chamber about 2.5 cm from the anode (item 7).

The glass tube (item 6), which supported the anode, contained a No. 16 B&W gauge Nichrome wire, spot welded to a 12.5 cm length of No. 20 B&W gauge platinum wire, which in turn was spot welded to the anode. The anodes were 4 x 4 cm squares of 0.0125 cm thick platinum sheets. Before use, they were cleaned for a few minutes in cold, concentrated HF. The position of the anode could be altered using a finely adjustable screw support device. Glass tubes and wire connections similar to those of the anode were provided for two platinum-air electrodes (one, the cathode; the other, the reference electrode) (items 8, 9, 10, and 11).

This cell assembly was positioned inside an electric oven (item 12), which had two 6.25 cm square windows, one in the front wall and the other in the back wall. A focused beam of light was directed through the back window. Visual reading of the contact angle allowed only approximate values (0°, 15°, 30°, 60°, and 90°) to be reported. The electric oven was covered with insulation which is not shown in Fig. 1.

Fig. 1. Fuel cell and gas feed system

<sup>1</sup> Present address: U. S. Naval Weapons Center, China Lake, California.

A dry, metered mixture of about 6% CO<sub>2</sub> and 94% air was fed to the cathode and reference electrode through their support tubes (items 10, 11, 13, 14, 15, 16, and 17). Hydrogen, oxygen, nitrogen, carbon dioxide, and mixtures of these gases could be fed to the fuel chamber (items 4, 5, 16, 18, 19, 20, and 21). As a rule, the gas chamber contained about 10% carbon dioxide and 90% hydrogen.

A variable potential was applied to the anode by means of a set of wet cells connected across a voltage divider. The anode potential, with respect to the reference electrode, was measured using a combination of an L&N Type K potentiometer, a Rubicon galvanometer, and an Eppley standard cell. The current passing through the anode was measured using a Triplet Model 630 VOM meter.

*Contact angles and menisci.*—Advancing and receding contact angles are most commonly defined in a system where the entire mass of the liquid is in motion relative to the solid, *i.e.*, a drop of water running down a window pane or an electrode being raised from or lowered into an electrolyte. In the case of the experiments involving a stationary sessile drop or a meniscus on a stationary vertical plate, there was no movement of the bulk liquid with respect to the solid and so there was no classical advancing or receding contact angle. Only increasing or decreasing contact angles (which may have been related to receding and advancing contact angles, respectively) could be observed.

A meniscus whose contact angle is 0° has a film extending above it up the surface of the solid. No three-phase line was present, only a three-phase region at the top of the film. Once a finite contact angle appeared, then a three-phase line became well-defined at the top of the meniscus.

*Effect of atmosphere on contact angle.*—With hydrogen gas above the electrolyte in the beaker (item 3), the contact angle between a partially immersed platinum anode and the electrolyte was approximately 90° at open circuit conditions. The potential was -0.94v. As the hydrogen was replaced with nitrogen, the potential slowly rose, but the contact angle remained constant. After 5 hr the nitrogen was replaced by oxygen. Within several minutes, the potential had risen to a constant value of 0.08v and the contact angle had decreased to about 15°.

*Preoxidation of anode.*—A preoxidation procedure was used in which the anode was maintained briefly at a high potential (0.0-0.3v), and then returned to a lower one (usually -0.5v). Higher currents and changes of the contact angle were observed after preoxidation. Potentiostatic current-voltage curves had characteristics different from those found by Will (13), who did not mention any preoxidation effects. For example, a slightly roughened platinum anode partially immersed in the electrolyte at open circuit had a reference potential of -0.93v and an initial contact angle of about 90°. The potential was then adjusted in steps to -0.8, -0.6, -0.4, -0.2, and 0.0v in two sequences as shown in Fig. 2. The current tended to drop slightly with time after the potential was adjusted upward and to rise slightly with time after the potential was adjusted downward. In each case, the potential was maintained constant for 10 min, and the current was recorded at the end of this time.

When a potential of -0.20v was impressed, the contact angle of the meniscus changed to around 60°; at 0.00v, the angle became 0°. The meniscus height, measured with a cathetometer, was 0.40 cm. As the potential was lowered back to its open-circuit value, the contact angle slowly increased to 60°. After several hours at open circuit, the contact angle had increased to just under 90°. The current was significantly increased after preoxidation at 0.00v, as is seen in the second half of curve 2 of Fig. 2. Such an increase in

Fig. 2. Polarization of a platinum anode showing the effect of preoxidation.

current was also observed in several other current-voltage curves, obtained in a similar manner.

The relationship between the conditions of preoxidation and the increase in activity of the anode following preoxidation was studied. Two series of runs were made with partially immersed anodes, in which the voltage was switched back and forth between -0.50v and 0.10v holding the potential steady at each value for 2 min. This operation was repeated several times and the current at the end of each 2-min interval was recorded, as shown in Fig. 3. Curves 1a and 1b are for a slightly roughened anode; curves 2a and 2b for a smooth one. The (a) portion of each curve indicates the values obtained at -0.50v; the (b) portion shows the data at 0.10v. The contact angle for the first point on the (a) portions was about 90°. For all the other points of the four curves, it was 0°. The current at -0.50v through both anodes increased by a factor of 1.8 in the interval of 2-6 min. This current was somewhat lower at 10 min, then gradually increased for the remainder of the 30-min experiment. At 0.10v, a sharp drop in current through both anodes (curves 1b and 2b) by a factor of about 0.7 was observed between the data points at 4 min and at 8 min. This drop in current was followed by a gradual increase until the very end of the experiment when a second drop in current seemed to be starting.

The rate at which the larger currents, following preoxidation, decreased was found to depend on the conditions of preoxidation. The data for curve 1 of Fig. 4 were obtained at an emergence height of 2.65 cm (*i.e.*, height that the top edge of the anode was above the undisturbed electrolyte surface), beginning with a relatively inactive surface (contact angle about 90°, current 0.71 ma, volts -0.5). Preoxidation was obtained using a potential of 0.10v for 1 min, from -1 to

Fig. 3. Increase in current with time of preoxidation on a platinum anode.

Fig. 4. Deactivation of a platinum anode following preoxidation

0 min on the abscissa (not shown). During this period, the contact angle changed to about  $60^\circ$ . At the end of this 1-min period, the external driving potential was removed temporarily to allow the cell potential to drop to  $-0.50$ v. The external driving potential was then reapplied, and the  $-0.50$ v cell potential was maintained for the next 55 min. The current decreased in general rather steadily during this period from about 1.25 to 0.82 ma. The contact angle remained at  $60^\circ$  during this entire period.

Curve 2 of Fig. 4 describes the behavior of an anode, also at 2.65 cm, which was preoxidized using a higher potential (0.3v for 1 min) then returned to  $-0.50$ v. A minute after preoxidation, the current was 2.0 ma. It decreased rapidly for 5 min, after which it rose slightly for 2 min, then fell rapidly to 1.38 ma at about 10 min after preoxidation. During the first 2 min of this initial 10-min period, the contact angle remained at  $0^\circ$ . For the last 8 min, ripples began to appear at the top of the meniscus. These ripples apparently were caused by the presence along the meniscus top of a number of small regions in which the meniscus was receding. The apparent contact angle increased to perhaps  $10^\circ$  or  $20^\circ$ , and thus a well-defined three-phase line was visible. The ripples were still apparent until 20 min, when the contact angle was around  $30^\circ$ . For the next 10 min, the contact angle continued to increase sporadically along the top of the meniscus. At 30 min, it averaged at about  $60^\circ$ . During this entire 20-min period, the current was generally increasing, although its value fluctuated significantly over short periods of time, as indicated by the data points shown on Fig. 4. Once the contact angle reached  $60^\circ$ , it remained there for the next 60 min. During this period, the current fell with some fluctuations from 1.74 to 0.82 ma.

The general increase in current by a factor of between 1.2 and 1.7 from curve 1 to curve 2 of Fig. 4 is attributed to the increase in the potential of the pre-oxidation process. Apparently the degree of oxidation and possibly the type of oxide on the platinum was different in each case.

Curves 3 and 4 of Fig. 4 and curve 1 of Fig. 5 were obtained on anodes at different emergence heights, which were preoxidized for even longer periods of time (15 min) at 0.30v and then returned to  $-0.50$ v. The generally higher current of curve 4 of Fig. 4 and lower current of curve 1 of Fig. 5 were apparently caused by the difference in the past history of the various portions of the anode surface at the three-phase region in each case. All three curves exhibited a temporary increase in current as rippling became noticeable (see Table I). The data points are not shown in these curves in order to maintain clarity. In general, there were fewer short-term current fluctua-

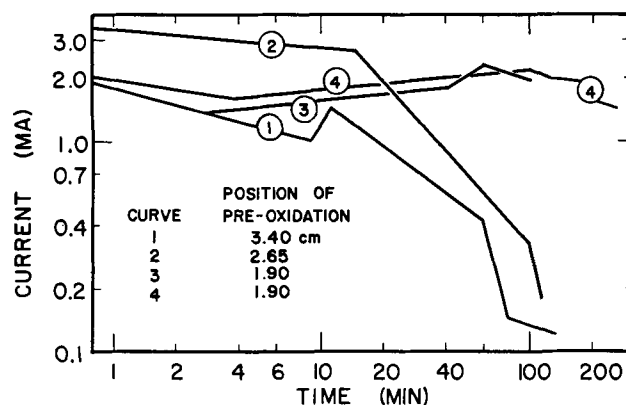

Fig. 5. Deactivation of a platinum anode following preoxidation

tions than observed in curve 2 of Fig. 4. Curves 2 and 4 of Fig. 4 indicate that the rate of deactivation in the time period before ripples appear is a function of the length and potential of preoxidation.

Raising the anode from one partially immersed position to another immediately after preoxidation tended to give immediately higher currents and/or increased currents over relatively long periods of time. The effect of this raising is shown in curves 2, 3, and 4 of Fig. 5. In each case, the anode was raised to an emergence height of 3.4 cm (i.e., to a position where 3.4 cm of the anode was above the undisturbed electrolyte surface) immediately following preoxidation for 15 min at 0.30v. The position of preoxidation is indicated in the legend. After raising, the potential was maintained at  $-0.50$ v, and the current was observed for several hours.

The current increases depended on the distance that the anode was raised (as comparisons of curve 1 of Fig. 5 with curves 2, 3, and 4 indicate). The currents were higher when the anode was raised 0.75 cm as compared to those currents through the stationary anode. For the anodes raised 1.5 cm (curves 3 and 4), the higher currents remained for significantly longer periods of time than those through the stationary anode or through the anode raised 0.75 cm, although during the initial 20 min curves 3 and 4 were below curve 2. The contact angle behavior during the periods covered by each of the curves of Fig. 5 is also shown in Table I. In general, raising the anode after preoxidation lengthened the duration of both the lower contact angles and higher currents.

#### Current Distribution Profile

The current obtained as a function of the emergence height was investigated using an anode which had been preoxidized for 10 min (while completely submerged). Curve 1 of Fig. 6 records the current which was obtained when the anode was raised 0.05 cm every 2 min to an emergence height of 1.15 cm. The top of this anode was not quite horizontal so that its top edge did not rise completely above the level of the undisturbed salt surface until 0.4 cm. The current, which was 0.32 ma at complete submergence, increased very slowly during the initial 0.4 cm to a value of 0.40 ma. The current then increased rapidly for the next 0.6 cm with several small halts before reaching 1.00

Table I. Contact angles during time periods (in minutes) described by various curves of Fig. 4 and 5

Figure	Curve	$0^\circ$	Ripples	$30^\circ$	$60^\circ$	$90^\circ$
4	1					1-55
4	2	1-2	2-20	20-30	30-90	
4	3	1-45	45-130	130-165		
4	4	1-2	2-11	11-20	20-195	
5	1	1-4	5-14	15-23	24-135	
5	2	1-7	8-13	14-24	24-76	80-128
5	3	1-64	70-109			
5	4	1-64	70-174	220-255	267-1485	

Fig. 6. Change in current through a platinum anode being raised and lowered.

cm emergence. Here the current leveled out at about 1.12 ma. The contact angle was  $0^\circ$  during the entire period of raising.

After 4 min at an emergence height of 1.15 cm the anode was slowly lowered to complete submergence, again at 0.05 cm intervals every 2 min. The contact angles at various heights were as follows

1.15 to 1.10 cm—	$0^\circ$
1.05 to 1.00 cm—	$30^\circ$
0.95 to 0.75 cm—	$60^\circ$
0.70 to 0.10 cm—	$90^\circ$

At 0.10 cm the lowest part of the top edge of the anode became completely covered with electrolyte. The upper edge was not completely submerged until  $-0.15$  cm had been reached. The current remained fairly constant at about 1.13 ma during lowering down to 0.50 cm. Only then did the current begin to decrease as lowering continued. The current reached a value of 0.37 ma at  $-0.15$  cm.

A similar procedure was followed using an anode which had been preoxidized, raised, and lowered several times before the data, shown in curve 2 of Fig. 6, were taken. In this case the anode was raised to 1.65 cm and held there for 160 min before lowering was begun. The current during raising was 0.1–0.3 ma smaller than corresponding points on curve 1. The contact angle of the meniscus remained at  $0^\circ$ . During lowering, the current rose slightly and plateaued at about 1.35 ma until a height of 0.65 cm was reached. There the current began to drop. Its values were about 0.10 ma above the corresponding values of curve 1 at positions down to 0.20 cm and then about the same below that point. The contact angle did not rise above  $30^\circ$  during lowering until a height of 0.65 cm was reached. Below 0.65 cm on the lowering portion of the curve, the contact angle rose to around  $60^\circ$ .

## Discussion of Results

### The Platinum Surface

The results of this investigation imply that three basic surface structures were present at various times and positions on the platinum anodes described above. The first of these was smooth platinum covered with sorbed hydrogen (denoted Pt-H) in the potential range  $-1.0$ v to approximately  $-0.30$ v. The second was smooth platinum covered with sorbed oxygen (denoted Pt-O) in the potential range  $-0.20$  to  $0.30$ v. Finally, there was essentially smooth platinum covered by a thin platinized layer (denoted Pt\*) also in the potential range  $-1.0$  to  $-0.30$ v. Such surfaces have been postulated as occurring on platinum surfaces by previous investigators (1, 8, 2). These three surfaces help explain many of the results presented above.

The  $90^\circ$  contact angle on a stationary anode in a hydrogen atmosphere is attributed to the presence of

the Pt-H surface at the three-phase boundary. The  $0^\circ$  contact angle is attributed to the Pt-O surface obtained from a Pt-H surface either by increasing the anode potential or changing the atmosphere to oxygen. The second of these methods shows that the change in contact angle from  $90^\circ$  to  $0^\circ$  is caused by a change in the chemical and physical, but not necessarily electrical, structure of the surface. Chemical changes of the surface affect the roughness (14) and surface tension (15, 8) of the surface. Pask (8) has discussed his results in light of these effects.

When hydrogen replaced oxygen in the atmosphere above the anode, or the potential was reduced below  $-0.20$ v (depending on which method was used to produce the Pt-O surface), the platinum oxide was reduced either directly, by diffusion of hydrogen along the surface or through the anode material, or by a small electrochemical "corrosion-type" cell on the anode surface. The rapid return of the potential to  $-0.50$ v, as noted in Fig. 4 and 5, indicates that the entire Pt-O surface is rapidly reduced. The slow return of the contact angle to high values, in spite of this rapid potential change, supports the hypothesis of the platinized surface (Pt\*). The high degree of roughness, supposedly possessed by such a surface, should be sufficient, according to Johnson and Dettre (14), to maintain a low contact angle.

The activation by preoxidation techniques of a platinum anode for low-temperature cells has previously been reported to be caused by the thin platinum layer of the Pt\* surface (1). However, no mention was made of changes in the meniscus shape as were noted in the present study. Platinized surfaces, however, presumably contain considerably more active catalytic sites than an atomically smooth surface; each site may also be more "active". The slow increase in contact angle, plus the decrease in current following preoxidation, strongly indicate that recrystallization of the platinized surfaces occurs slowly with time to form smooth surfaces again. The observed contact angle on a surface should increase as the surface roughness decreases (15, 14). However, the increase in contact angle will be slower than the roughness decrease, since the electrolyte is receding from the platinum surface (14). Thus, lower currents may be observed at the same contact angle with receding than with advancing menisci.

### The Electrolyte Film

The results of this investigation also imply that any film of molten salt electrolyte above the meniscus region on the electrode is less pervious to transfer of reactants or of products to or from the anode surface than aqueous electrolyte films in low-temperature cells (13). In the present cell, hydrogen as fuel was transferred from the gas phase to the anode; the products, steam and carbon dioxide, were transferred from the anode to the gas phase. Based on molecular size considerations, transfer of the products might be more controlling than the transfer of the small hydrogen molecules.

When an activated anode was raised even relatively slowly, a film of electrolyte was pulled up on the previously submerged portions of the anode. The results of Fig. 6, especially curve 2, show that the presence of this film during raising may cause a current decrease of up to 1 ma from the value observed after the film has drained away. When a film is present, the three-phase region is at the top of this film. The ohmic resistance of the film increases the over-all ohmic resistance of the cell (11), thus lowering the current. There is insufficient transport of reactants or products across the film to counter the removal of the reaction sites to the top of the film.

When a film is present, as is always true to some extent, the resistance to ion transport in this film causes lower potentials toward the top of the film during preoxidation. Thus the upper portions of the anode

should not be as heavily oxidized, and thereafter platinized.

The sudden increase in current on stationary anodes, recorded in curves 2, 3, and 4 of Fig. 4 and in curve 1 of Fig. 5 is attributed to the drop of the three-phase region into the more heavily platinized regions below the top of the original well-developed meniscus. In addition, there was a simultaneous increase in the length of the three-phase region (when rippling appeared.)

Further indication of the nature of the electrolyte film is seen in curves 2, 3, and 4 of Fig. 5. When the anode was raised immediately after preoxidation, the reaction region again remained at a relatively well-defined three-phase region at the top of the film. Very soon (probably fractions of a minute) after preoxidation, this reaction region began to move down, because of film drainage, into a highly-oxidized region on the anode, thus explaining the lack of a sharp, upward increase in the current in these three cases. The fact that a higher initial current was obtained from the anode, which was raised only 0.75 cm, indicated that the film in this case was thick enough to support good currents at a reaction site about 0.35 cm above the top of the meniscus. Only when the anode was raised 1.60 cm after preoxidation did the ionic resistance in the film (mentioned before) lower the initial current. In this case, as the film thinned and drained away, the current slowly increased until the three-phase region reached the top of the meniscus about an hour following preoxidation. The contact angle was also increasing during this time.

When the anode was slowly lowered into the electrolyte and the contact angle of the advancing electrolyte increased up to 30°, the current, as observed in both curves 1 and 2 of Fig. 6, remained constant at its maximum value, or even rose slightly, until an emergence height of 0.50 cm. From this observation, it seems clear that diffusion of hydrogen along the electrolyte/solid interface or through the anode material itself from the Pt-H surface just above the three-phase region is the chief avenue of hydrogen to the reaction site.

Although platinum was the only material used for the anode, it is probable that results similar to those obtained in this investigation might be found with other types of anodes, such as nickel or palladium.

### Conclusions

1. Platinum anodes immersed in a molten carbonate eutectic mixture at 723°K are activated by a preoxi-

dation technique; the platinum surface is first oxidized and then reduced by hydrogen to platinized surfaces. Higher currents are obtained with platinized surfaces.

2. The contact angle between the 723°K molten carbonate eutectic mixture and a stationary, inactive platinum anode is around 90°. During preoxidation it decreases to 0°. The contact angle slowly changes to 90° during deactivation. If the hydrogen atmosphere above a stationary inactive anode is replaced by oxygen, the contact angle again becomes 0° and the height of the meniscus 0.40 cm.

3. At 723°K hydrogen diffuses mainly to the reaction site by a combination of diffusion along the interface of platinum and molten carbonates and/or diffusion through the bulk platinum.

4. Hydrogen apparently does not diffuse in appreciable amounts through the 723°K molten-carbonate film which may be present above the meniscus.

## The Anodic Oxidation of Manganese Oxides in Alkaline Electrolytes

Hong Y. Kang and Charles C. Liang\*

P. R. Mallory & Co., Inc., Laboratory for Physical Science, Burlington, Massachusetts

### ABSTRACT

Manganese dioxide electrodes are discharged in electrolytes of 1M to 10M KOH and immediately reoxidized anodically. The efficiency of the oxidation, determined by chemical analysis as well as subsequent cathodic reduction, is a function of the concentration of KOH and decreases as the KOH concentration increases from 1M to 10M KOH. In 1M KOH, MnO<sub>2</sub> is reduced to a species tentatively identified as an active form of manganese (III) oxide, which can be efficiently reoxidized to MnO<sub>2</sub>. In 10M KOH, however, MnO<sub>2</sub> is reduced first to manganese (III) oxide and subsequently to manganese (II) oxide. This manganese (II) oxide can be recharged only to an inactive form of manganese (III) oxide which is not reoxidized efficiently to MnO<sub>2</sub>.

The cathodic reduction of manganese dioxide in alkaline electrolytes has been investigated by a number of authors (1-5). Kozawa and co-workers (1, 2)

studied the discharge process of electrodeposited manganese dioxide on spectroscopic grade graphite rods in pure KOH solutions in the absence of the zinc electrode. Boden *et al.* (3), Cahoon and Kover (4), and

\* Electrochemical Society Active Member.

Bell and Huber (5) investigated the same process for the pressed  $\text{MnO}_2$ -graphite electrode with and without zinc electrodes present. Kozawa *et al.* (1, 2) observed a two step reduction while other authors (3, 5) observed a three stage reduction in their systems.

The manganese dioxide electrode of rechargeable batteries (6-11) has also received some attention. Koval and Vorobeva (11) studied the anodic oxidation of a mixture of manganese oxide and nickel or iron hydroxide in alkaline electrolytes. They found that the efficiency of the oxidation of the electrode ranged from 6 to 20% and was dependent on the nature of the anion in the manganese salt used for the preparation of the electrode. However, no attempt was made by these authors to analyze and identify the products of the oxidation.

In view of the growing interest in the manganese dioxide-alkaline system in the secondary battery field, it was desirable to investigate the electrochemical behavior of the discharged manganese dioxide electrode. In the present work, electrodeposited manganese dioxide on graphite was first cathodically reduced in pure KOH solutions, then the anodic oxidation of the reduced electrode was studied under various conditions. The presence of a Zn electrode or ZnO in the KOH solution was avoided to eliminate any additional complications in interpreting the data.

### Experimental

**Preparation of the  $\text{MnO}_2$  electrode.**—Manganese dioxide was electrodeposited on 3.2 mm diameter spectroscopic graphite rods (AGKSP). The electrodeposition conditions were similar to those used by Nichols (12). Electrodes were plated at an apparent current density of 2 ma/cm<sup>2</sup> for 1500 sec from a solution containing 50g of  $\text{MnSO}_4 \cdot \text{H}_2\text{O}$  and 65g of  $\text{H}_2\text{SO}_4$  per liter at  $80^\circ \pm 1^\circ\text{C}$ . The electrodeposited manganese dioxide electrodes were washed thoroughly with distilled water and were kept in distilled water for at least 48 hr before use. From the chemical analysis by the method described below,  $6.0 \pm 0.3$  mg of  $\text{MnO}_2$  per electrode were obtained giving  $1.97 \pm 0.02$  for the  $x$  value in  $\text{MnO}_x$ .

**Constant current experiments.**—The manganese dioxide electrodes were discharged and charged in KOH solutions. A platinum wire was used as the counter electrode in an H-cell with a sintered glass frit separating the two compartments. The discharge and charge processes were carried out at room temperature ( $25^\circ \pm 1^\circ\text{C}$ ) at constant current densities supplied by an E/M Model C614 constant current power supply. The working electrode potential during the electrolysis was measured against a Hg/HgO electrode in the same solution as the electrolyte by means of an E-H Model 250 electrometer. The potential-time curves were recorded by a Varian G-14 recorder. All the potentials reported in this paper are referred to the Hg/HgO electrode immersed in KOH of the same concentration as the electrolyte.

**Chemical analyses of the electrodes.**—The oxidation state of manganese on the electrode was determined from the chemical analysis as follows: The sample electrode was put in 50 ml of 6N HCl containing approximately 1g of KI. The HCl solution was well de-aerated in advance by bubbling argon through it. The bubbling was continued until the manganese oxides on the electrode were completely dissolved. The oxidation power of the sample, *i.e.*, the amount of manganese oxides that oxidized iodide was then measured by a titration of the liberated  $\text{I}_2$  with a standard 0.10N  $\text{Na}_2\text{S}_2\text{O}_3$  solution using a microburet. After the titration, the total content of manganese in the solution was determined by the colorimetric analysis of the permanganate produced from the oxidation of  $\text{Mn}^{++}$  by  $\text{KIO}_4$  (13). The  $x$  value in  $\text{MnO}_x$  was calculated

from the total manganese content and the oxidizing power.

**X-ray diffraction.**—The manganese dioxide electrodes which had been subjected to discharge and recharge under various conditions were washed with distilled water until free from hydroxide ion. The electrodes were then dried in a vacuum oven at  $60^\circ\text{--}70^\circ\text{C}$  for about 18 hr prior to the x-ray analyses. Debye-Scherrer x-ray powder photographs of the samples were made using standard techniques (Fe  $K\alpha$  radiation).

### Results and Discussion

Manganese dioxide electrodes were discharged in various KOH solutions at a constant current density to a potential of  $-1.0\text{v}$ , whereupon the current was immediately reversed and the electrodes were charged anodically to various potentials. The current density used in these experiments were ranged from 0.2 to 2 ma/cm<sup>2</sup> of apparent surface area. The electrodes were then removed from the solution, and the oxidation state of manganese on each electrode was determined. The oxidation states of manganese thus determined were compared with those based on the total charge involved in the electrochemical process. Results of these comparisons are shown in Tables I and II. The recharge efficiency, expressed as the fraction of oxidized manganese to the total amount of oxidizable manganese, is also shown in the tables. These results indicate clearly that the rechargeability of the electrode was affected by the concentration of the KOH solution. The higher the concentration of the electrolyte the more difficult it was to reoxidize the electrode to manganese (IV) oxide. It also can be seen from Table II, in the range of current density studied, the general pattern of the electrochemical behavior was not affected by the current density.

It is also noted in Table I that when the manganese dioxide electrode was cathodized to the potential of  $-1.0\text{v}$  the oxidation state of manganese on the electrode or the depth of discharge differed in different KOH solutions. This is in agreement with the observations made by Kozawa and Yeager (1). The reduction of manganese (IV) stopped at manganese (III) when

<sup>1</sup> Calculated on the basis of the total charge involved in discharge and recharge, and the total amount of Mn in the electrode.

<sup>2</sup> Fraction of oxidized manganese to the total amount of oxidizable manganese.

<sup>3</sup> The initial state of the electrode is that obtained by cathodically discharging the original MnO<sub>2</sub> electrode to -1.0v (vs. Hg/HgO) at 1 ma/cm<sup>2</sup> in each KOH solution.

the manganese dioxide electrode was discharged to -1.0v in 1M KOH or to -0.4v in 10M KOH. Further reduction from manganese (III) to manganese (II) occurred when the discharge was carried out in 10M KOH to the potential of -1.0v. It was concluded by these authors (1) that the second step discharge from manganese (III) to manganese (II) occurred through the dissolution of manganese (III) oxide in 10M KOH followed by reduction of Mn(III) in solution to Mn(II) and reprecipitation of manganese (II) in solution to solid manganese (II) oxide. The absence of the second step reduction in dilute KOH solutions was explained as the result of insolubility of manganese (III) oxide in dilute solutions (14).

In addition, the different KOH concentrations resulted in distinctive potential-time curves. This is well illustrated by Fig. 1 where two typical curves, viz., one for 10M and another for 1M KOH, are shown. The dotted lines show the second discharge curves following the anodic oxidation. It is seen that in 10M KOH the recharge curve showed two plateaus whereas in 1M KOH no distinct plateau appeared in the re-

Fig. 1. Potential-time curves of the manganese dioxide electrode at a constant current density of 1 ma/cm<sup>2</sup>; (a) in 10M KOH; (b) in 1M KOH. — First discharge and charge; - - - second discharge.

charge curve. Distinctive characteristics in different KOH solutions can be observed for the second discharge curves also. In 10M KOH the second discharge curve differed pronouncedly from the first discharge curve, indicating that the preceding recharge to the original manganese (IV) state was not efficient. On the other hand, in 1M KOH the second discharge curve was similar to the first one, indicating that the preceding recharge was efficient.

The different behavior patterns of manganese oxides during their anodic oxidation in different KOH solutions may be attributed either to the effect of KOH concentration on the oxidation or to the depth of discharge at the initial point of the anodization. The observations shown in Fig. 2 seem to support the latter case. Figure 2a and 2b show the cases where the re-oxidation of the discharged manganese dioxide electrode was started from the manganese (III) state. Figure 2c shows the recharge curve in 1M KOH when the initial oxidation state of manganese was the manganese (II) state. These time-potential curves clearly indicate that when the recharge following the discharge was carried out in the same solution the KOH concentration affected the anodic oxidation of the discharged manganese dioxide electrode only in that it brought about different depths of discharge. The depth of discharge at the initial point of the anodic oxidation determined the characteristics of the charge process. The chemical analyses of the oxidation states of manganese in these cases (Fig. 2) also supported the conclusion that the depth of discharge was responsible for the different behavior patterns during the anodic oxidation. For instance, when the recharge was started from manganese (II) state, even if it was carried out in 1M KOH (Fig. 2c), the oxidation state of manganese at the end of anodization was about the same as that for the case of 10M KOH.

A necessary consequence of the above conclusion is that the manganese (III) oxide produced from the cathodic reduction of manganese dioxide was more

Fig. 2. Potential-time curves of the MnO<sub>2</sub> electrode at 1 ma/cm<sup>2</sup>; (a) Both discharge and charge in 10M KOH. (b) Discharge in 1M KOH, recharge in 10M KOH. (c) Discharge in 10M KOH, recharge in 1M KOH. — First discharge and charge; - - - second discharge.

active to the anodic reoxidation than the manganese (III) oxide formed by the anodic oxidation of manganese (II) oxide. Indeed either in 10M KOH or in 1M KOH the anodic oxidation beyond manganese (III) oxide was inefficient when the initial material of the oxidation was manganese (II) oxide. While manganese (III) oxide from the cathodic reduction of manganese dioxide was efficiently reoxidized to manganese dioxide in either 10M KOH or 1M KOH.<sup>1</sup>

Attempts to distinguish the two forms of electrochemically different manganese (III) oxide employing the x-ray diffraction technique were not successful because both the samples showed similar x-ray patterns corresponding to  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub>. However, it was also found that both forms of manganese (III) oxide including the originally active one were inactive to the anodic oxidation to manganese dioxide after they were subjected to the washing and drying processes of the sample preparation for the x-ray analysis. Evidently, one or both of the manganese (III) oxides changed in crystal structure during the sample preparation, with a corresponding change in electrochemical behavior. Hence, in the present paper, the differentiation between the two forms of manganese (III) oxide is made primarily on the basis of electrochemical data.

It was proposed by Kozawa *et al.* (1, 2) that the mechanism of the first step discharge of MnO<sub>2.0</sub> to MnO<sub>1.5</sub> is a homogeneous phase reduction and that the product of this step is  $\alpha$ -MnOOH. In the present work it was found that the anodic oxidation was always efficient whenever the preceding discharge of the manganese dioxide electrode was stopped at the point where one could expect  $\alpha$ -MnOOH to be produced. Therefore, it seems logical to conclude that the active manganese (III) oxide which can be efficiently reoxidized to manganese dioxide was  $\alpha$ -MnOOH. Both  $\gamma$ -MnO<sub>2</sub> and  $\alpha$ -MnOOH have the same rhombic crystal structure. And since the mechanism of the cathodic reduction of  $\gamma$ -MnO<sub>2</sub> to  $\alpha$ -MnOOH is a homogeneous phase reaction, it is probable that the anodic oxidation of  $\alpha$ -MnOOH to  $\gamma$ -MnO<sub>2</sub> was a homogeneous phase process also.

The two forms of manganese (III) oxide may differ only in physical properties which lead, *e.g.*, to differences in the contact areas between the depolarizer and the conductor, or in chemical reactivity and identity with its consequences. Differences probably exist between the physical properties of the two forms of the oxide in view of the different paths leading to the two oxides. The active form was produced from  $\gamma$ -MnO<sub>2</sub> through a homogeneous phase reduction, and the inactive form was produced from  $\gamma$ -MnO<sub>2</sub> after it had undergone such processes as (a) a first step reduction, (b) a second step reduction which included (i) dissolution of manganese (III) oxide, (ii) solution reduction, and (iii) reprecipitation of manganese (II), and (c) reoxidation of manganese (II) oxide which may include again dissolution and reprecipitation. These processes most likely resulted in changes in the contact areas between the oxide and the substrate, in the particle size of the oxide, and in the site of deposition of the oxide. However, the electrochemical similarities between the electrodeposited manganese dioxide electrodes and the pressed manganese dioxide-graphite pellet electrodes suggested that these physical conditions alone could not be the decisive cause for the distinctive electrochemical behavior patterns of two forms of manganese (III) oxide.

This leaves the possibility that the two forms of the oxide differed in chemical identity. If this were the case, a possible chemical identity of the inactive form, among others, is  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> according to the x-ray dif-

Fig. 3. Potential-time curves (charge and discharge) at 1 ma/cm<sup>2</sup> in 10M KOH. (a) — Electrodeposited MnO<sub>2</sub> electrode discharged to -1.0v (vs. Hg/HgO); (b) - - - -  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> electrode made from the electrodeposited MnO<sub>2</sub> electrode by discharging it to manganese (II) oxide, then charging it to manganese (III) oxide, and washing and drying; it was identified by x-ray analysis.

fraction patterns discussed in the previous section. The data in Fig. 3 support this conclusion. In this series of experiments, the electrochemical behaviors of the  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> electrode and that of the inactive Mn(III) oxide electrode were compared. The  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> electrode could be prepared according to either of the following procedures.

1. An electrodeposited MnO<sub>2</sub> electrode was cathodized to -1.0v then anodized to 0.2v in 10M KOH. After the electrochemical treatment, the electrode was washed thoroughly and dried at about 60°C.

2. An electrodeposited MnO<sub>2</sub> electrode was cathodized to -1.0v in 10M KOH. The reduced electrode was then taken out of the solution and subjected to air oxidation for at least 8 hr.

Chemical analyses showed that the empirical formula of the manganese oxide in these electrodes was MnO<sub>1.5±0.02</sub> and the x-ray diffraction patterns proved that these were indeed  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> electrodes. The potential-time curves for the anodic oxidation and the subsequent cathodic reduction of the  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> are shown by the dotted curves in Fig. 3. When the electrode was anodized to +0.6v where the evolution of O<sub>2</sub> began to be visible, the oxidation state of manganese was analytically determined as 3.2 ± 0.04. These results clearly indicated that  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> could not be efficiently oxidized to MnO<sub>2</sub> under the experimental conditions. This fact was also shown by the subsequent discharge curve. Most of the discharge process occurred at the potential near -0.4v where MnO<sub>1.5</sub> to MnO took place. When the potential-time curves for the anodization and subsequent cathodization of the Mn(II) oxide electrode (solid line in Fig. 3) were compared with those of the  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> electrode, it revealed that they were superimposable after the Mn(II) oxide electrode reached -0.2v where the manganese oxide became Mn(III) oxide. Based on the similarity of the electrochemical behaviors of these Mn(III) oxides, it is suggested that the manganese (III) oxide produced during the anodic oxidation of manganese (II) oxide in 10M KOH was most likely  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub>. In view of the fact that  $\gamma$ -Mn<sub>2</sub>O<sub>3</sub> and Mn(OH)<sub>2</sub> have different crystal structure and that both Mn(OH)<sub>2</sub> and Mn<sub>2</sub>O<sub>3</sub> dissolve in 10M KOH, the anodic oxidation of the manganese (II) oxide to the manganese (III) oxide probably involved dissolution, solution oxidation, and reprecipitation.

In summary, the electrochemical cycle of reduction-oxidation of the manganese dioxide in 10M KOH is postulated to comprise:

<sup>1</sup> We shall refer the manganese (III) oxide which can be efficiently reoxidized to manganese dioxide as active form and the one which cannot be efficiently reoxidized to manganese dioxide as inactive form. Notice that both of these manganese (III) oxides are active to the cathodic reduction to manganese (II) oxide.

The first step oxidation of  $Mn(OH)_2$  to manganese (III) oxide may involve the dissolution of manganese (II), its solution oxidation to manganese (III) followed by the precipitation of manganese (III). The precipitated form of manganese (III) is thought to be  $\gamma\text{-Mn}_2\text{O}_3$  which is inactive to further oxidation. When the discharge process of  $\gamma\text{-MnO}_2$  is stopped at the end of the first step the reoxidation of the product manganese (III) oxide which is  $\alpha\text{-MnOOH}$  is efficient. Also, once manganese (III) dissolves in KOH solution, reprecipitation to  $\alpha\text{-MnOOH}$  seems to be inhibited.

#### Acknowledgment

The authors wish to express their thanks to Dr. P. Bro and Dr. R. G. Selim for their helpful discussions, to Mr. L. B. Griffiths for the x-ray diffraction measurements, and to Mr. G. H. Boyle for his help in preparing the graphs.

Manuscript received July 19, 1967; revised manuscript received Sept. 5, 1967. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967 as Abstract No. 40.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Chemistry and Crystallography of Basic Antimony Sulfates

H. E. Hintermann\*<sup>1</sup> and C. J. Venuto\*

*ESB Incorporated, The Carl F. Norberg Research Center, Yardley, Pennsylvania*

#### ABSTRACT

The system  $Sb_2O_3\text{-SO}_3\text{-H}_2O$  has been investigated in the  $H_2SO_4$ -molarity range  $0 < M < 12.7$ . Five distinct basic antimony sulfates, previously unreported, have been identified. The chemistry and crystallography of these salts have been established and their ranges of stability in  $H_2SO_4$  determined at room temperature and at the boiling point of the acid. Earlier experimental findings suggesting large amounts of bound crystallization water in these compounds have been disproved.

The ternary system  $Sb_2O_3\text{-SO}_3\text{-H}_2O$  has not been studied extensively. The few reports providing substantial data are those published by Adie (1) in 1890 and more recently by the Russian workers Tananaev and Mizetskaya (2) and Veller and Sobol (3). The results reported on the chemical composition of the basic antimony sulfates are inconsistent and contradictory. The system is of theoretical and practical interest, however, since solutions of antimony or antimony trioxide in sulfuric acid are widely used in analytical procedures and in industry for producing a variety of antimony compounds and more recently in the development of a new battery system (4). This latter application has stimulated a more thorough study of the  $Sb_2O_3\text{-SO}_3\text{-H}_2O$  system at medium and low sulfuric acid concentrations.

The chemical compositions and crystal structures are well established for the two modifications of  $Sb_2O_3$ , i.e., Valentinite (orthorhombic) and Senarmontite (cubic) and for the normal sulfate  $Sb_2(SO_4)_3$  (5, 6). The composition of the basic sulfates, derived from  $Sb_2(SO_4)_3$  as a hydrolysis product or produced by reacting  $Sb_2O_3$  with polyhydrated sulfuric acid,  $H_2SO_4 \cdot x H_2O$ , are uncertain. According to a comprehensive treatise on this subject (7), the normal sulfate  $Sb_2(SO_4)_3$  is obtained in  $H_2SO_4 \cdot 1 H_2O$ . By hydrolyzing this salt in cold water  $2Sb_2O_3 \cdot SO_3$  is formed, by

hydrolyzing it in hot water  $7Sb_2O_3 \cdot 2SO_3$ . In the acid range  $H_2SO_4 \cdot 2H_2O$  (12.3M) to  $H_2SO_4 \cdot 4H_2O$  (8.7M)  $Sb_2O_3 \cdot H_2O$  is said to be formed at room temperature while  $Sb_2O_3$  is formed on heating. Further dilution leads to the precipitation of hydrated antimony trioxide  $Sb_2O_3 \cdot 3H_2O$ .

The Russian investigators (2, 3) obtained an even larger number of basic antimony sulfates by hydrolysis of the  $Sb_2(SO_4)_3$ . At concentrations lower than 8.6-10.7M  $H_2SO_4$ , compounds like  $Sb_2(SO_4)_3 \cdot y H_2O$  are formed at room temperature with  $y$  being 5 or 10, and compounds like  $Sb_2O_3 \cdot x SO_3 \cdot y H_2O$  at 100° and 155°C with  $x/y$  ratios of 2.5/24, 6/23, 20/100, 28/93, and 31/13, respectively.

The primary purpose of the Russian work was the determination of the solubility limits of trivalent antimony in aqueous sulfuric acid of various concentrations, rather than to investigate the composition of the solid phases formed during the reaction. The authors themselves regard the results of the proposed stoichiometry of the reported basic antimony sulfates as only an approximation. Hence not much accurate information exists on the chemical composition of basic antimony sulfates and none on their crystallography.

#### Experimental

The  $Sb_2O_3\text{-SO}_3\text{-H}_2O$  system requires a long time to reach equilibrium condition, i.e., several months at

<sup>1</sup> Present address: Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Suisse.

\* Electrochemical Society Active Member.

room temperature and several days at boiling temperature of the solution. If equilibrium conditions are not attained, mixtures of basic sulfates will result and will make subsequent chemical analyses inaccurate. This is one possible source of error to explain the lack of consistency in the results of previous workers. In addition, once formed, the solid equilibrium reaction product is difficult to isolate from the mother solution in a pure state without further hydrolyzing it or otherwise changing it in the course of the washing procedure. Some workers (1, 3) omit washing the crystalline solid phase with any solvent at all. They attempt to remove the adherent film of mother liquid on the crystal faces by sedimentation, centrifugation, or drying between porous plates. None of these methods is effective enough, and it is obvious that the chemical analyses obtained with these procedures are inaccurate and unreliable.

We found that the high basic sulfates, produced at very low  $H_2SO_4$  concentrations, could be washed effectively with cold water and the medium and lower basic sulfates with absolute methanol, without changing the structural features of these salts. X-ray powder diffraction patterns obtained on the reaction product before and after the washing procedure proved to be a sensitive means of detecting any change in the structure, and thus the chemical composition of the original salt, due to hydrolysis or solvolysis.

The experiments were carried out with reaction mixtures of 10g  $Sb_2O_3$  in 1 liter  $H_2SO_4$  of different concentrations in the molarity range  $0 < M < 12.7$ . To obtain equilibrium conditions, the mixtures were either stored in glass stoppered Pyrex glass bottles at room temperature for 3 to 6 months or heated to the boiling point in Pyrex reaction kettles with reflux condensers for 15 to 25 days. Fisher Certified Analytical Chemicals were used. Prior to use the  $Sb_2O_3$  was dried at  $110^\circ C$  in air for 5 hr. Its x-ray diffraction pattern agreed with that published by ASTM for Senarmontite.

The equilibrium reaction products were filtered through a Gooch crucible of 8-10 $\mu$  pore size. A sample was taken from the still wet residue for x-ray powder diffraction, and some crystals were selected for single crystal analysis for use with a Weissenberg camera. They had a prismatic shape with dimensions of about 0.4 mm in one direction and 0.1 mm in the two others. The powder pattern, obtained on a Norelco diffraction unit using Nickel filtered Copper K  $\alpha$  radiation, served to establish the stability ranges of basic antimony sulfates in sulfuric acid of different molarities at room and boiling temperature of the solutions. It was used further to determine if an equilibrium state actually had been attained and a single pure phase had been formed or if the reaction product consisted of more than one solid phase. Finally, it

served a reference pattern to confirm whether the washing procedure instigated any structural changes of the salt formerly in equilibrium with its solution. Single crystals, representative of each structure type that was stable in a given acid range, were used for microscopical investigations and for the determination of the density by the wet pycnometer method using methyl-benzoate ( $\rho = 4.69 \text{ g/cm}^3$ ) at  $27^\circ C$ . The unit cell dimensions, the space group, the number of asymmetric units per unit cell, and the x-ray reflections for each structure type were established by single crystal x-ray diffraction methods.

The remaining residue was washed either in cold water or absolute methanol while still in the crucible and dried in air. Samples from this product were chemically analyzed. The solvents for  $Sb_2O_3$  found in the literature (1, 8) could not be applied to the basic antimony sulfates. These were neither completely soluble in  $NH_4Cl$ ,  $NH_4NO_3$ , nor in molten  $Na_2CO_3$ . They were soluble in HCl; however, an insoluble basic chloride precipitated simultaneously. Addition of tartaric acid almost completely prevented basic chloride formation. Nevertheless, a slight turbidity of the solution could not be avoided. All basic antimony sulfates investigated were found entirely soluble when heated in a slightly alkaline solution of  $Na_2S$  or  $(NH_4)_2S$ . Acidifying this solution with HCl precipitated antimony as  $Sb_2S_3$  which could be determined gravimetrically as such. The  $SO_4^{=}$  content was determined in the filtrate as  $BaSO_4$ , the water of hydration as the balance. The mean error of determination of Sb and  $SO_4^{=}$  carried out on blanks was smaller than  $\pm 2$  and  $\pm 4\%$ , respectively.

### Results and Discussion

From the unit cell dimensions, space group, number of asymmetric units per unit cell, and the density it was possible to calculate the molecular weight of the compound according to

$$M = \frac{a_o \cdot b_o \cdot c_o \cdot \rho}{z \cdot 1/N}$$

where  $M$  = molecular weight of one asymmetric unit in the unit cell;  $a_o$ ,  $b_o$ ,  $c_o$  = unit cell dimensions in Angstrom units ( $\text{\AA}$ );  $\rho$  = density of the pure phase in  $\text{g/cm}^3$ ;  $N$  = Avogadro's number;  $1/N = 1.6606 \cdot 10^{-24}$  = weight of g in a hypothetical atom of atomic weight 1.000; and  $z$  = number of asymmetric units in the unit cell. Combining these results with those obtained from the chemical analyses, i.e., the Sb/ $SO_3$  ratio of the molecule, the actual chemical formula of the compound could be derived. Thus five distinct basic antimony sulfates were identified in the  $H_2SO_4$  range  $0 < M < 12.7$ . These sulfates are tabulated in Table I together with some crystallographic, chem-

\* A mixture of D and E is formed at  $9.6 < M < 10.2$ .

ical, and physical properties. The stability ranges for the basic antimony sulfates at room temperature and at the boiling point of the acid are reported in Table II.

At boiling temperatures, the basic antimony sulfates form larger crystals and purer reaction products than at room temperature. In the acid range II (Table II) seeds of the structure-type A preferentially formed at room temperature, those of the type B in the boiling acid. Thus the activation energy for the formation of nuclei of the A-type basic sulfate is smaller than for the B-type sulfate at room temperature and *vice versa* at the boiling point of the solutions. A mixture of both salts is formed at intermediate temperatures. Once nuclei of one kind are formed, however, the crystals grow in the crystal habit of the seed, independent of temperature changes that occur during the reaction. Hence the free enthalpy of formation of both salts must be very similar.

The molarity range  $12.7 < M < 15.3$  was not investigated. The normal antimony sulfate Sb<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> was obtained on heating Sb<sub>2</sub>O<sub>3</sub> in an acid 18.7M, *i.e.*, concentrated H<sub>2</sub>SO<sub>4</sub>. No experiments were carried out to hydrolyze this salt in successive steps.

In conclusion, within the sulfuric acid molarity range  $0 < M < 12.7$  none of the five sulfates isolated contains any water of crystallization. This result was

confirmed also by thermal decomposition analysis of these salts at 550°C in a He-stream. The reaction products were Sb<sub>2</sub>O<sub>4</sub>, Sb<sub>2</sub>O<sub>3</sub>, and SO<sub>2</sub> in each instance; no water was found. Earlier experimental findings suggesting large amounts of crystallization water in these sulfates are thus disproved; the water must have been just adsorbed in the form of a sulfuric acid film on the surface of the crystals not properly removed during separation. This is supported by the proposed chemical formulas of the basic antimony sulfates reported by other authors which show that the Sb/SO<sub>3</sub> ratios of compounds obtained in acid concentrations equal to ours are consistently smaller than corresponds to the formulas proposed in this work. This can be explained again in terms of adsorbed layers of dilute H<sub>2</sub>SO<sub>4</sub> at the crystal surfaces of the reaction product.

## The Oxidation of Iron Single Crystals at 350°C

N. Ramasubramanian,<sup>1</sup> P. B. Sewell, and M. Cohen\*

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

#### ABSTRACT

A comparison of the oxidation of (001) and (112) surface single crystals of iron at 350°C and 20 Torr oxygen has been made. The (001) oxidizes more rapidly than the (112). Cubic Fe<sub>2</sub>O<sub>3</sub> persists for a longer time on the (001) than on the (112). The orientation of the underlying magnetite remains constant on both crystals for up to 100 min. With both orientations the α-Fe<sub>2</sub>O<sub>3</sub> starts out as a highly oriented oxide, but on the (112) it becomes randomly oriented at the surface after 50 min. The oxide on the (001) is more firmly adherent than on the (112). In both cases there appears to be an intermediate layer of "γ-Fe<sub>2</sub>O<sub>3</sub>" between the Fe<sub>3</sub>O<sub>4</sub> and α-Fe<sub>2</sub>O<sub>3</sub>. The cross sections of the oxides, as revealed by replica electron microscopy, are different but typical for the two orientations.

A study of the kinetics of oxidation of the various orientations of an iron single crystal in the range of 250°-550°C and 10-760 mm oxygen has been reported by Wagner, Lawless, and Gwathmey (1). The thick-

ening of the oxide was followed by observing the interference colors, a procedure similar to that of Mehl and McCandless in their lower temperature work (2). In the temperature region studied the oxide formed is usually at least two phases, and the interference color method has certain limitations (3, 4).

In this paper the results of some experiments on the oxidations of two single crystals of iron of widely different orientation at 350°C are reported. Weight gains were sufficiently high to measure by microbalance weighing. At this temperature both a cubic oxide and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> are formed, and the amounts of these oxides were measured by a combination of weighing and cathodic reduction. The crystal structure and orientation of the oxides were determined by reflection electron diffraction.

### Experimental

The oxidation apparatus and procedure have been described fully previously (5). All experiments were done at 350°C and a pressure of 20 Torr of oxygen. The specimens were first electropolished (6) and then brought to temperature in a vacuum of 10<sup>-5</sup> to 10<sup>-6</sup> Torr. Blank experiments showed that there was no visible change in the appearance of the specimens nor a measurable weight gain during this period. Oxygen was then admitted rapidly. The experiment was stopped by removing the furnace and cooling the quartz tube with water. Specimens were weighed before and after oxidation on a Mettler microbalance.

The specimens were strain-annealed Ferrovac E<sup>2</sup> single crystals. Two orientations, (001) and (112) were used. Surface areas were approximately 10 cm<sup>2</sup>.

The amount of reducible oxide was measured using the electrolytic reduction method of Oswin and Cohen (7). The solution was 0.15*N* boric acid adjusted to a pH of 7.58 with sodium borate. A current density of approximately 10-11  $\mu$ a cm<sup>-2</sup> was used and potentials are reported *vs.* the saturated calomel electrode. The amount of reducible oxide was determined both by weight loss and by a measurement of Fe<sup>++</sup> in solution.

Reflection electron diffraction was done in a G. E. diffraction apparatus using a camera length of 50 cm and an accelerating voltage of 50 kv. Replicas for electron microscopy were made using the two-stage formvar, platinum-carbon technique.

### Results

The weight gain-time curves are shown in Fig. 1. The total weight gain was determined from the difference in weight before and after oxidation. The reducible oxide was determined both by weight loss due to cathodic reduction and by colorimetric analysis of ferrous iron in solution assuming a cathodic reduction reaction of

These two numbers were then averaged. The magnetite was determined by difference.

It can be seen that both the over-all weight gain and the final rate of oxidation are higher with (001) than the (112) surfaces. In both cases there is a rapid formation of Fe<sub>2</sub>O<sub>3</sub> which then remains fairly constant in amount, while the Fe<sub>3</sub>O<sub>4</sub> increases until both oxides are approximately equal in amount at 100 min. In both cases there is a very rapid weight gain in the first 4 min. After this time the curves are approximately parabolic.

Cathodic reduction curves for the two crystals oxidized for various lengths of time are shown in Fig. 2 and 3. In both cases a definite  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> wave (-300 to -400 mv) is observed with specimens oxidized for less than 100 min. The main Fe<sub>2</sub>O<sub>3</sub> wave is that for  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> at about -600 mv. The final potential drop in all the curves is toward the Fe<sub>3</sub>O<sub>4</sub> potential. This drop is best defined for specimens which have been oxidized for the longer times. The amounts of reducible oxide as determined by both gravimetric and colorimetric analysis and the current efficiency of cathodic reduction are given in Table I.

The specimens were examined by both electron diffraction and electron microscopy after oxidation and

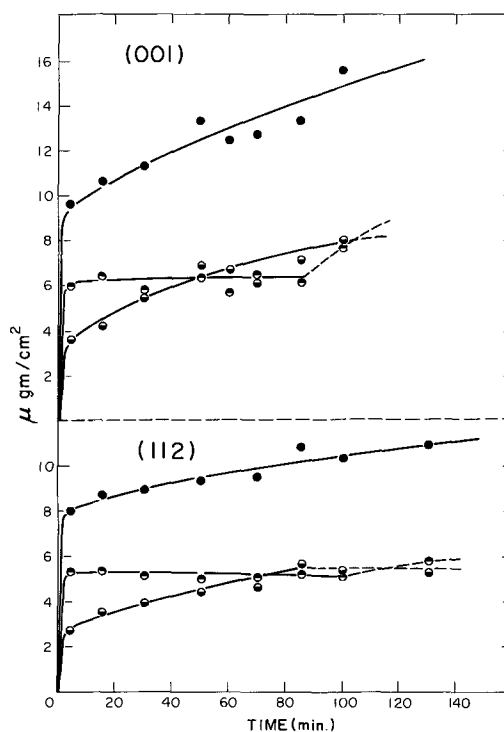

Fig. 1. Weight-gain time curves for the (001) and (112) crystals. ● Total, ○ Fe<sub>3</sub>O<sub>4</sub>, ◐ Fe<sub>2</sub>O<sub>3</sub>.

Fig. 2. Cathodic reduction curves of Fe<sub>2</sub>O<sub>3</sub> on (001) after various oxidation times.

after cathodic reduction to the magnetite, Fig. 4. Once again there was a marked difference in behavior between the two orientations. In the case of the (001) surface there was some evidence for a cubic oxide in the outer layer even after oxidation for 100 min. At 4 min the pattern was predominantly cubic. On the other hand with the (112) crystal the cubic pattern was extremely weak or had disappeared after about 15 min oxidation. Even at 4 min the diffraction pattern was predominantly that of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. In both cases the patterns from the magnetite layers were characteristic of a highly oriented microcrystalline material and were essentially unchanged from 4 to 100 min. The pattern from the outer  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> layer showed evidence of random orientation at longer times of oxidation, particularly with (112) crystals. The relative orientations are the same as those reported previously (8).

The topographical features of the oxides on the two orientations were also markedly different, as shown in Fig. 5 and 6. On the (001) surface the outer layer was essentially smooth at 4 min and there was some

<sup>2</sup> Ferrovac E: C—0.007%, Mn—0.0002, Si—0.0015, Cr—0.0002, Ni—0.0009, Al—0.0005, P—0.003.

Fig. 3. Cathodic reduction curves of  $\text{Fe}_2\text{O}_3$  on (112) after various oxidation times.

roughening at 100 min. The underlying magnetite had a cross-hatch structure, similar to that observed by Laukonis (9) for thick oxide films, from the beginning. On the (112) surface both the outer and inner layers have parallel ridges which seem to become more accentuated with increased time of oxidation. These are similar to the ridges observed by Boggs (10) on some grains of polycrystalline iron oxidized under similar conditions to these. In both cases the thickness of the outer  $\text{Fe}_2\text{O}_3$  layer varied markedly over the surface. This is shown schematically in Fig. 7.

It was noted that the adherence of the underlying magnetite to the metal on the (112) surface was very poor after cathodic reduction of the  $\text{Fe}_2\text{O}_3$ . This led to some stripping of the oxide with the formvar replica. This is shown in Fig. 6 where the darker areas are  $\text{Fe}_3\text{O}_4$ . It can be seen that the oxide has the same structural characteristics as are shown by the replica.

A number of annealing experiments were made in which samples were heated at  $350^\circ\text{C}$  in a vacuum of  $10^{-5}$  Torr after oxidation was completed. There was a marked decrease in the amount of reducible oxide and very little change in the shape of the phase boundaries. Due to the scatter in the measurements no useful kinetic data could be obtained.

### Discussion

The marked effect of crystal orientation on both the over-all reaction rate and the oxide structure which was observed at  $200^\circ$  and  $260^\circ\text{C}$  (11) is even more pronounced at  $350^\circ\text{C}$ . In this work it is also seen that this difference is accompanied by distinct variations in the shape of the oxide-gas interface and the  $\text{Fe}_3\text{O}_4$ - $\text{Fe}_2\text{O}_3$  interface. The oxide on the (112) appears to be less adherent at the metal oxide interfaces than the ox-

Fig. 5. Replicas of outer surface (A) and magnetite surface (B) on (001) crystal after 100 min oxidation.

ide on the (001), particularly after cathodic reduction to the magnetite. Despite these differences the general kinetics is that of very rapid oxidation in the first few minutes followed by essentially parabolic kinetics for the rest of the time. The lack of adhesion on the (112) surface may indicate the formation of voids at the oxide metal interface which, in turn, would decrease the rate of transfer of metal to the oxide and, hence, decrease the oxidation rate. This factor, combined with

Fig. 6. Replica of outer surface (A) and magnetite surface (B) on (112) crystal after 100 min oxidation. Note dark area is transmission through stripped  $\text{Fe}_3\text{O}_4$ .

Fig. 7. Schematic of cross section through the oxides as deduced from electron micrographs, weight gains, and cathodic reduction. The  $\text{Fe}_2\text{O}_3$  layer is "cathodically reducible oxide" and would include the  $\gamma\text{-Fe}_2\text{O}_3$ . A,  $A_1$ , (001)<sub>4</sub> and 100 min; B,  $B_1$ , (112).

the uneven nature of the  $\text{Fe}_3\text{O}_4\text{-Fe}_2\text{O}_3$  boundaries renders a quantitative discussion of the diffusion rates fairly fruitless.

The cathodic reduction curves all show evidence of the presence of  $\gamma\text{-Fe}_2\text{O}_3$  as part of the "reducible oxide." This is probably not on the surface but is present at the  $\text{Fe}_3\text{O}_4\text{-Fe}_2\text{O}_3$  interface as an intermediate phase. The cathodic reduction observation is confirmed by the reflection electron diffraction. Strong spots characteristic of a cubic pattern are observed on the (001) crystal at the end of 4 min and are still discernible after 100 min of oxidation. In contrast to this no diffraction spots belonging to the cubic oxide are observed on the (112) crystal after 15 min of oxidation. This may be due to the outer layer of  $\alpha\text{-Fe}_2\text{O}_3$  on the (112) becoming too thick to allow penetration of the beam to the underlying  $\gamma\text{-Fe}_2\text{O}_3$  or to different shapes of the oxide surface on the two crystals. This difference in shape is observed by replica electron microscopy. The outer layer of oxide on the (001) is smooth, while that on the (112) has a ridgelike structure. The difference in shape of the outer layer results in a difference in penetration of the electron beam to the intermediate cubic oxide. (In the above discussion it should not be assumed that the  $\gamma\text{-Fe}_2\text{O}_3$  is a stoichiometric phase but rather something equivalent to  $\text{Fe}_{3-x}\text{O}_4$  which within some composition range has the electrochemical properties of  $\gamma\text{-Fe}_2\text{O}_3$ .)

The sharp turnover of the weight-gain time curves at around 5 min is probably related to the formation of a continuous outer layer of  $\alpha\text{-Fe}_2\text{O}_3$  of sufficient thickness to lead to a change from an oxidation rate which is controlled by cation diffusion in the cubic oxide to control by anion diffusion in the hexagonal

$\alpha\text{-Fe}_2\text{O}_3$ . As was noted in the results section both the initial and final rates of oxidation are higher on the (001) than on the (112) crystal. This may be related to two factors. First,  $\gamma\text{-Fe}_2\text{O}_3$  is a larger proportion of the reducible oxide on the (001) than on the (112). The  $\alpha\text{-Fe}_2\text{O}_3$  is therefore thinner and the final oxidation rate would be higher. The initially higher oxidation rate is related to the more difficult transformation of cubic oxide to hexagonal oxide on the (001) surface. This was also observed at lower temperatures. The second factor leading to a lowering of rate on the (112) surface is the separation which occurs at the metal-oxide interface. Cation diffusion from the metal surface outward is accompanied by vacancy diffusion toward the metal surface. If the vacancies condense to form voids at the metal surface, separation occurs between the metal and oxide. This has been observed by metallographic techniques for oxidation at higher temperatures (12). It would appear that vacancies can be destroyed at the metal-oxide interface more easily on the (001) crystal than on the (112) crystal. This may be related to the fit of the highly oriented oxide on the metal. The condensation of vacancies to form voids would decrease the oxidation rate by decreasing the effective area of the specimen for cation diffusion. The resultant lowering of the cation flow with the (112) crystal may also result in earlier formation of  $\alpha\text{-Fe}_2\text{O}_3$  as well as recrystallization of the outer  $\alpha\text{-Fe}_2\text{O}_3$  to form polycrystalline oxide. If the final rate of oxidation is controlled by the diffusion of oxygen through the outer  $\alpha\text{-Fe}_2\text{O}_3$ , then the decreased cation flow on the (112) crystal would lead to a smaller oxygen gradient in the oxide and a reduced final rate of oxidation.

The shapes of the  $\text{Fe}_3\text{O}_4\text{-Fe}_2\text{O}_3$  interface appear to be characteristic for the different orientations of underlying iron. Both Laukonis (9) and Boggs (10) have observed similar structures under slightly different conditions of oxidation. The cross-hatch structure of the magnetite surface on the (001) crystal may be related to the method of nucleation or growth of the outer  $\alpha\text{-Fe}_2\text{O}_3$ . Both oxides remain highly oriented even after 100 min of oxidation. The ridgelike structure of both the  $\text{Fe}_3\text{O}_4\text{-Fe}_2\text{O}_3$  interface and the  $\text{Fe}_2\text{O}_3$  surface may be related to the mechanism whereby stress is relieved in the growing oxide film.

With both orientations the combination of the shape of the phase boundaries and the different diffusion mechanisms in the two main oxides make it rather difficult or impossible to calculate diffusion coefficients with the data at hand. The attempt to measure cation diffusion in the magnetite layer by the annealing experiments was unsuccessful due to lack of reproducibility in the measurements.

## The Nucleation, Growth, and Structure of Thin Ni-P Films

J. P. Marton and M. Schlesinger

Department of Physics, University of Western Ontario, London, Ontario, Canada

### ABSTRACT

The nucleation, early growth, and structure of Ni-P on SnCl<sub>2</sub>-PdCl<sub>2</sub> activated dielectric substrates were studied. The SnCl<sub>2</sub>-PdCl<sub>2</sub> treatment was found to provide small catalytic sites on the substrate, serving as the nuclei for Ni-P growth. The average diameter of catalytic sites was estimated to be less than 10Å. The microscopic time rate of Ni-P growth on the nuclei was found to be constant and the growth to be isotropic. The resulting Ni-P deposit in the early stages of growth consists of circular islands. The surface density  $\sigma$  of islands were affected by activation. In later stages of growth, the circular Ni-P islands merged to form a continuous film. The critical film thickness at which continuity is attained is shown to be a function of  $\sigma$ . The structure of as-deposited islands, as well as that of fresh continuous film, was determined by electron diffraction to be liquidlike.

Electroless deposition of nickel on catalytic surfaces due to Brenner and Riddell (1) is well documented (1-4). The chemistry of deposition (4) and some physical properties of electroless nickel (4-6) have been reported. Deposition on dielectric (noncatalytic) surfaces has also been demonstrated (1, 2, 7). A dielectric substrate may be activated (8) by immersion in solutions of SnCl<sub>2</sub> and PdCl<sub>2</sub> for electroless nickel deposition.

Deposits from a number of electroless solutions have been determined (4) to consist of Ni and P, with 2%  $\leq P \leq 12\%$  by weight. Fresh bulk deposits were stated to have either amorphous liquidlike (5) or fine polycrystalline (6) structures. Fresh film deposits were found (9) to be in a liquidlike state. The growth and film geometry of fresh Ni-P deposits have not been reported. Other electroless films (Co-P and Ni-Fe-P) deposited on activated substrates exhibit island-type growth and agglomerated structure. Judge *et al.* (10) found a "hemispherical clumpy growth" of electroless cobalt, and the surface of electroless nickel-iron films was reported by Schmeckenbecher (11) to consist of an "agglomeration of balls." Frieze and Weil (12) reported that nucleation of electroless Co-P films occurred on isolated Pd particles, followed by lateral growth to produce a continuous film.

In our work the nucleation, growth, and structure of electroless Ni-P films on activated substrates were studied. The geometry of films at various stages of growth was determined by transmission electron microscopy and the structure by transmission electron diffraction. Activation of substrates by SnCl<sub>2</sub>-PdCl<sub>2</sub> method results in an island-type growth of Ni-P in the early stage, becoming continuous as the growth proceeds. The surface density of islands and the maximum size of islands varied with the method of activation and the wetting property of substrate surfaces. The structure of individual islands, ranging in size from 200 to 2000Å as well as that of continuous thin films (9), was found to be liquidlike.

### Experimental

Clean substrates of glass, quartz, mica, and Formvar were activated by immersion in activating solutions at room temperature. The variations in activation of

the substrates are shown in Table I. Activated substrates were immersed in electroless nickel solution for Ni-P deposition. The composition of solutions is listed in Table II. Film geometry was not affected by variations in the composition, pH, and temperature of electroless solutions; therefore only one solution of pH = 5.3 was used. Deposition temperature was adjusted to 25° ± 0.5°C, and the time of deposition was varied.

Ni-P was also deposited from the solution on electropolished solid nickel substrates and on microscope slides coated with pure nickel and palladium by vacuum evaporation. These deposits were compared with those grown on SnCl<sub>2</sub>-PdCl<sub>2</sub> activated substrates.

The mass thickness and average thickness of films was determined by weighing and by the Tolansky method (13), respectively. Deposits were prepared for electron microscopy three ways. Self-supporting Ni-P films were floated off the substrates for direct transmission and diffraction measurements; discontinuous deposits were backed by Formvar and then floated off the substrates; shadowed replicas of the surface of deposits were made. Deposits grown on

Table I. Variations in activation of substrates

Method (a)	Dip clean substrates in activating solutions listed in Table II in succession.
Method (b)	Dip clean substrates as in (a) in activating solutions modified by the addition of 10 cc/l isopropyl alcohol.
Method (c)	Dip clean substrates as in (a) in activating solutions modified by the addition of 5 cc/l Kodak "Photo-Flo."

Table II. Composition of solutions used in the experiments

Activating solutions		Electroless solution	
SnCl <sub>2</sub> solution	SnCl <sub>2</sub> 0.1 g/l HCl 0.1 cc/l	Nickel sulphate Sodium hypophosphite Sodium succinate Succinic acid	29 g/l 17 g/l 15 g/l 1.3 g/l
Rinse:	H <sub>2</sub> O at pH = 7	Solution pH	5.3
PdCl <sub>2</sub> solution	PdCl <sub>2</sub> 0.1 g/l HCl 0.1 cc/l	Solution temperature	25°C
Rinse:	H <sub>2</sub> O at pH = 7		

Formvar substrates were left on the substrates and were examined directly.

For transmission and diffraction measurements, a Philips EM75C and an AEI EM6G microscope was used respectively. Both microscopes were operated at 75 kv.

### Results and Discussion

**Nucleation and growth.**—The deposition of Ni-P on all substrates activated by method (a) in Table I, was found to be selective. Deposition appeared to start at certain points on the substrate and continue at those points only. As deposition progressed, islands formed on these nucleation points. If deposition was allowed to proceed, the islands grew in size and eventually merged to form a continuous film. Figure 1 is the transmission image of a typical deposit. Parts of the deposit are islands, other parts are already continuous. In contrast with the island-type growth, deposits that were formed on nickel substrates and on nickel and palladium coated microscope slides were homogeneous and showed no island structure. The image of a shadowed surface replica of such a deposit is reproduced in Fig. 2.

These findings show that the surface of a  $\text{SnCl}_2$ - $\text{PdCl}_2$  treated dielectric substrate is not completely activated. The activation is visualized to produce small catalytic sites dispersed on the surface, serving as the nuclei for Ni-P deposition. The sites are estimated to be less than  $30\text{\AA}$  in diameter, as they cannot be detected in the electron microscope having a point resolution of  $30\text{\AA}$ . A closer estimate of size of the catalytic sites was made indirectly. The diameter  $2r$  of the growing Ni-P islands was measured and was plotted against deposition time. This is shown in Fig. 3. The diameter of catalytic sites was estimated by extrapolation (dotted line), to be less than  $10\text{\AA}$ .

Again from Fig. 3, the microscopic time rate of Ni-P growth  $c$  ( $= dr/dt$ ) is seen to be constant. Also, the geometry of growing islands was observed to be circular in all deposits. These findings imply isotropic growth, and one expects the islands to be half spheres situated base down on the substrate. The circular geometry is shown in Fig. 4 for islands ranging in size from  $200$  to  $2000\text{\AA}$ .

Fig. 1. Electron transmission image of a typical Ni-P deposit on  $\text{SnCl}_2$ - $\text{PdCl}_2$  activated substrate. Parts of the deposit are islands, other parts are continuous.

Fig. 2. Shadowed surface replica of a Ni-P deposit on a solid nickel substrate. Note the absence of islands.

Fig. 3. Plot of diameter  $2r$  of the growing Ni-P islands against time of deposition. Rate of growth  $c = dr/dt$  is constant. Extrapolation (dashed line) at  $t = 0$  gives average size of active sites to be less than  $10\text{\AA}$ .

The number of activation sites per unit surface area  $\sigma$  was found different for different substrates. The value of  $\sigma$  ranged from  $10/\mu^2$  to  $10^4/\mu^2$ . The value of  $\sigma$  was large on substrates with hydrophilic surfaces (i.e., glass), and small on those with hydrophobic surfaces (i.e., Formvar). This is shown in Fig. 5. Figure 5a is the transmission image of sites on glass, and Fig. 5b is the image of sites on Formvar. The respective average values of  $\sigma$  are  $10^4/\mu^2$  and  $10^2/\mu^2$ . It was found possible to decrease the difference in  $\sigma$  between hydrophilic and hydrophobic surfaces by activation method (b) in Table I and to eliminate it by method (c) in Table I. In both cases the small  $\sigma$  increased and the large  $\sigma$  remained constant. Attempts to increase the value of  $\sigma$  beyond  $10^4/\mu^2$  have failed.

Fig. 4. Circular transmission images of islands ranging in size from 200 to 2000Å in four different deposits (a, b, c, d). The islands are visualized to be half spheres situated "base down" on the substrate in all deposits. Fig. 4a. Island size 200Å.

Fig. 4c. Island size 1000Å

Fig. 5. Transmission images of active sites on (a) (top) glass, and (b) (bottom) Formvar substrates made visible by a slight deposit of Ni-P on them. The surface density of sites is  $10^4/\mu^2$  for glass and  $10^2/\mu^2$  for Formvar.

Fig. 6. Transmission images of deposits on substrates with different activation densities: (a) (left)  $10^4/\mu^2$ ; (b) (center)  $10^3/\mu^2$  and (c) (right)  $10^2/\mu^2$ . Note the dependence of film geometry on activation density.

**Film geometry.**—The natural consequence of the variation of  $\sigma$  is a variation in Ni-P film geometry. This is shown in Fig. 6 by the transmission image of three different deposits. The films were deposited on substrates with average  $\sigma$  values of  $10^4/\mu^2$  (Fig. 6a);  $10^3/\mu^2$  (Fig. 6b) and  $10^2/\mu^2$  (Fig. 6c). From the figure it is evident that  $\sigma$  is an important deposition parameter. The quantitative dependence of film growth and geometry on  $\sigma$  may be expressed<sup>1</sup> as

$$d = 2\pi\sigma ct \left( r_0^2 + r_0 ct + \frac{1}{3} c^2 t^2 \right); \quad 0 \leq t \leq (c\sqrt{\sigma\pi})^{-1} \quad [1]$$

and

$$d = 2r_0 (1 + r_0\sqrt{\sigma\pi}) - \frac{1}{3\sqrt{\sigma\pi}} + ct; \quad t \geq (c\sqrt{\sigma\pi})^{-1} \quad [2]$$

where  $d$  is the mass thickness of deposit (volume per unit surface area);  $c$  is the microscopic rate of deposition (increase of local thickness per unit time and/or  $dr/dt$ );  $\sigma$  is the activation surface density (number of active sites per unit surface area);  $2r_0$  is the diameter of active sites; and  $t$  is the time of deposition. Expression [1] describes the growth of discontinuous (island-type) films and the description of growth after continuity is attained is given by expression [2]. Transition from the former to the latter configuration occurs at  $t = (c\sqrt{\sigma\pi})^{-1}$ .

Figure 7a is the plot of expressions [1] and [2] at  $r_0 = 5\text{\AA}$ .<sup>2</sup> The dashed line represents the transition between discontinuous films (below dashed line) and continuous films (above dashed line) and the solid straight line represents a linear ( $d = ct$ ) film growth. In Fig. 7b a comparison is made between the mass thickness of growing deposits and the theoretical curves. Both solid Ni and  $\text{SnCl}_2\text{-PdCl}_2$  activated substrates were used. With  $c = 20 \text{\AA}/\text{min}$   $\sigma$  was found to range between  $10^4/\mu^2$  and  $10/\mu^2$  for the activated substrates.

**"As-deposited" structure.**—The crystal structure of fresh Ni-P deposits has been investigated in the past with somewhat conflicting results. Goldenstein *et al.* (5) determined amorphous liquidlike structure for bulk deposits by x-ray diffraction, and Graham and co-workers (6) found fresh bulk deposits to be polycrystalline by electron diffraction. The present authors (9) showed that continuous, as-deposited thin films of Ni-P are in a liquidlike state. In that work

<sup>1</sup> See Appendix.

<sup>2</sup> The variation of  $r_0$  does not influence the curves appreciably, as  $r_0$  is much smaller than  $ct$  in the range of  $ct$  considered here.

Fig. 7a. Mass thickness  $d$  of Ni-P deposits. Theoretical curves of  $d$  as a function of  $ct$  ( $c$  is rate of deposition,  $t$  is deposition time) for different activation densities  $\sigma$ . Dashed line represents transition between islands and continuous film.

Fig. 7b. Mass thickness  $d$  of Ni-P deposits. Comparison of theoretical curves (a) and experimental values for  $c = 20 \text{\AA}/\text{min}$ . Activation density is seen to range between  $10^4/\mu^2$  and  $10/\mu^2$ .

(9) the temperature dependence of the structure of continuous films was investigated. In the present work the structural nature of as-deposited islands, ranging in size from 200 to 2000Å, as well as that of fresh continuous films of various geometry were studied.

It can be argued that, if the islands in films are single crystals, but are too small to cause proper diffraction, then the same islands grown larger would eventually reveal their crystal identity. If, however, the islands were in a liquidlike state, no size dependency should be detected in the diffraction pattern. From selected area diffraction experiments the latter case was confirmed. Islands whose size ( $2r \approx 2000\text{Å}$ ) was comparable to the effective diameter of the electron beam (8000Å) showed an identical liquidlike structure to those with 200Å diameter. The diffraction pattern of continuous films was also the same. Figure 8 is an example of the diffraction pattern of all our (thin) Ni-P deposits.

The present findings of a liquidlike structure is in apparent contradiction with the results of Graham *et al.* (6); however the difference may be explained by the difference in sample preparation. In their experiments (bulk) deposits were prepared at 90°C for many hours, whereas our (thin) samples were grown at 25°C for only a few minutes.

### Summary

It was shown that electroless deposition of Ni-P on  $\text{SnCl}_2\text{-PdCl}_2$  activated dielectric substrates is selective and that it is homogeneous on continuous catalytic surfaces. The selective deposition is due to selective activation. The  $\text{SnCl}_2\text{-PdCl}_2$  treatment produces catalytic sites on the substrate with less than 10Å diameter. The growth of Ni-P on these sites is isotropic, resulting in a spherical island-type film geometry. The surface density of catalytic sites  $\sigma$  was seen to depend on the substrate material and type of activation, with a maximum value of  $10^4/\mu^2$ . The importance of  $\sigma$  as a deposition parameter was pointed out, and its influence on film growth and geometry was shown quantitatively. Evidence of island growth of different electroless metals (10-12) suggests that the present description of nucleation, growth, and geometry may also be applicable to other electroless films deposited on activated surfaces. The structure of as-deposited Ni-P islands with variable size, as well as that of fresh continuous films, was determined to be liquidlike, and it was concluded that individual islands are not single crystals. Finally, it was suggested that different results on the structure of fresh deposits reported by other workers may have been due to differences in sample preparation.

Fig. 8. Typical diffraction pattern of as-deposited Ni-P islands, and fresh thin Ni-P films (P content of 5 w/o).

### Acknowledgments

The authors wish to acknowledge the valuable assistance of Dr. J. Brown in the diffraction experiments.

The present work is part of a Ph.D. Thesis to be submitted by J. P. Marton to the Graduate Faculty of the University of Western Ontario. Work was supported in part by a Defence Research Board of Canada Grant to Welwyn Canada Limited, London, Ontario, Canada.

Manuscript received July 26, 1967; revised manuscript received Oct. 12, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX

Assume that the small catalytic sites are half spheres with radius  $r_0$ , situated "base-down" on the substrate. Let  $\sigma$  be the number of active half spheres per unit substrate area. Assume that the Ni-P deposition parameters (solution concentration and temperature) are constant in time, and that the density of Ni-P deposit  $\rho$  is constant. Let  $m$  be the mass of the deposit on each active island, and  $r$  be the radius of the growing half sphere. Then  $m = 2/3 \pi (r^3 - r_0^3) \rho$ , and the time rate of change of  $m$  is

$$\frac{dm}{dt} = \frac{dm}{dr} \frac{dr}{dt} = 2\pi\rho r^2 \frac{dr}{dt}$$

Since  $dr/dt = c$ , (c.f. Fig. 3), and  $r = r_0 + ct$  we get

$$dm = 2\pi\rho c (r_0 + ct)^2 dt$$

After integration

$$m = 2\pi\rho ct [r_0^2 + r_0ct + (1/3) c^2t^2]$$

Assuming an average value of  $\sigma$  on the substrate, the total mass  $M$  on the substrate with surface area  $A$  is

$$M = A\sigma 2\pi\rho ct [r_0^2 + r_0ct + (1/3) c^2t^2]$$

With the definition of the mass thickness  $d = M/A\rho$  we get

$$d(t) = 2\pi\sigma ct [r_0^2 + r_0ct + (1/3) c^2t^2] \quad [1]$$

Further assume the islands to form a close packed surface distribution on the substrate. In this configuration each island may occupy a maximum surface area of  $\sigma^{-1}$ . As the islands grow in time the base of each island spreads in the available surface area of  $\sigma^{-1}$ . After a time  $t_0$  the islands touch and begin to form a continuous film whose surface retains the hemispherical features of the islands. At time,  $t_0$ , the area of the base of each hemisphere,  $\pi r^2 \approx \sigma^{-1}$  for large values of  $\sigma$ . Since  $r = r_0 + ct$ ,  $t_0 \approx (c\sqrt{\sigma\pi})^{-1}$  for

small values of  $r_0$ . Relation [1] is therefore valid for times  $0 \leq t \leq (c\sqrt{\sigma\pi})^{-1}$ . For times longer than  $t_0$  the now-continuous film is visualized to grow at a constant macroscopic rate. This growth may be described by

$$d(t) = d(t_0) + c(t-t_0) = 2r_0(1 + r_0\sqrt{\sigma\pi}) - \frac{1}{3\sqrt{\sigma\pi}} + ct \quad [2]$$

$d(t_0)$  having been evaluated by setting  $t = t_0 = (c\sqrt{\sigma\pi})^{-1}$  in Eq. [1]. Combining [1] and [2] the final expression is

$$d(t) = \begin{cases} 2\pi\sigma ct [r_0^2 + r_0ct + (1/3)c^2t^2]; & 0 \leq t < (c\sqrt{\sigma\pi})^{-1} \\ 2r_0(1 + r_0\sqrt{\sigma\pi}) - \frac{1}{3\sqrt{\sigma\pi}} + ct; & t > (c\sqrt{\sigma\pi})^{-1} \end{cases}$$

## The Holmium-Hydrogen System

F. C. Perkins and C. E. Lundin

*Metallurgy Division, Denver Research Institute, University of Denver, Denver, Colorado*

### ABSTRACT

Pressure-temperature-composition data were obtained to study the nature of the holmium-hydrogen system. A Sieverts-type apparatus was employed to perform measurements in the temperature range, 250°-950°C, in the composition range, Ho to HoH<sub>3</sub>, and at pressures from 10<sup>-4</sup> to 630 Torr. The existence of three homogeneous phases was established: holmium solid solution, the dihydride, and the trihydride phases. The limits of hydrogen solid solution in each of the phases were determined from discontinuities in the isothermal plots. Equilibrium plateau decomposition relationships were determined from van't Hoff plots in the two-phase regions

$$\log_{10} p \text{ (Torr)} = -\frac{11,520 \pm 50}{T} + 10.66 \pm 0.05$$

$$\log_{10} p \text{ (Torr)} = -\frac{4080 \pm 50}{T} + 9.12 \pm 0.09$$

The differential heats of reaction in these two regions are,  $\Delta H = -52.7 \pm 0.2$  kcal/mole of H<sub>2</sub> and  $\Delta H = -18.7 \pm 0.2$  kcal/mole of H<sub>2</sub>, respectively. The differential entropies of reaction are,  $\Delta S = -35.6 \pm 0.2$  cal/deg · mole of H<sub>2</sub> and  $\Delta S = -28.6 \pm 0.4$  cal/deg · mole of H<sub>2</sub>, respectively. Relative partial molal and integral thermodynamic quantities were calculated for the system.

The dissociation pressure equation for the holmium solid solution dideuteride plateau region was determined for comparison purposes

$$\log_{10} p \text{ (Torr)} = -\frac{11,420 \pm 60}{T} + 10.70 \pm 0.06$$

The enthalpy of reaction to form the dideuteride phase is  $\Delta H = -52.3 \pm 0.3$  kcal/mole of D<sub>2</sub>, and the entropy of reaction is  $\Delta S = -35.8 \pm 0.3$  cal/deg · mole of D<sub>2</sub>.

Rare-earth metals are characterized by the ability to absorb large quantities of hydrogen and to combine with hydrogen to form hydride phases. Previous investigations concerned with the heavy rare-earth metals at this laboratory defined the systems, erbium-hydrogen (1) and erbium-deuterium (2). The interest in these systems embraced the holmium-hydrogen system as well, because this latter system would be expected from chemical considerations to exhibit hydride phases with characteristics and thermal stabilities similar to the erbium hydrides.

The properties of the rare-earth-metal hydrogen systems have been reviewed in the literature (3-5). The holmium-hydrogen system has been outlined in one previous investigation (6). The present study was undertaken to broaden the temperature and compositional ranges of the above work and to extend the limits of thermodynamic data available for this system.

### Experimental Procedure

The experiments were conducted in a modified Sieverts apparatus. The unit incorporated a mercury diffusion pump for evacuation and a manifold to which were connected a palladium-silver hydrogen thimble,

a gas burette, a mercury manometer, a McLeod gauge (Kontes Glass Company) and a quartz reaction tube for heating to temperatures up to 950°C. High-purity hydrogen was obtained by passing hydrogen through the heated palladium-silver thimble. The 100-ml, precision gas burette was graduated to 0.1 ml divisions. Gas pressures were measured on the manometer to  $\pm 0.5$  Torr and in the McLeod gauge range (10<sup>-4</sup> to 1 Torr) to  $\pm 3\%$ . The quartz reaction tube was heated by a nichrome-wound furnace controlled to a temperature cycle of  $\pm 1^\circ\text{C}$ . Specimen temperatures in the quartz tube were measured independently by means of a chromel-alumel thermocouple located outside and adjacent to the tube at the vicinity of the specimen.

The specimen material was nuclear-grade holmium sponge, 99.9% purity, obtained from the Lunex Company. The large surface area of the sponge and the short diffusion paths permitted the attaining of equilibrium in relatively short periods of time. The typical specimen size was 0.3g.

The specimen of holmium sponge was contained in a tungsten foil boat to prevent contact with the quartz tube. At the beginning of each experiment, the system

with specimen in place was evacuated to less than  $10^{-6}$  Torr and flushed several times with high-purity hydrogen, and finally evacuated again ready for the first gas addition. The specimen was then heated under vacuum to the desired temperature and exposed to a measured batch of hydrogen. After equilibrium was attained (usually in a few hours) the pressure was measured, and the hydrogen composition of the specimen calculated. Successive batches of hydrogen were added until atmospheric pressure was reached. These data were then plotted as an isothermal curve of specimen composition (hydrogen-to-holmium atomic ratio) vs. pressure. Other isotherms were developed in the same manner. Compositions are estimated to be accurate to  $\pm 1\%$ . Preliminary experiments indicated that absorption of hydrogen by the specimen during flushing at room temperature was insignificant and did not change the specimen compositions beyond the limits of error.

The partial-pressure plateaus were determined by cycling suitably hydrided specimens through the temperature ranges of interest. At each temperature, time was permitted for equilibrium to be attained, and the pressure was recorded. The temperatures were cycled both up and down to detect nonequilibrium effects. The logarithm of pressure was plotted against the reciprocal absolute temperature, and the data were treated by a least squares computer analysis to obtain a mathematical van't Hoff relationship.

### Results and Discussion

The holmium-hydrogen system resembles the erbium-hydrogen system, which confirms the tendency for most heavy rare-earth metals to form isomorphous systems when combined with hydrogen. As hydrogen is reacted with holmium the gas is dissolved interstitially in the hexagonal close-packed lattice. On reaching saturation, additional hydrogen reacts with holmium to form the face-centered-cubic, holmium dihydride phase (lattice parameter  $a_0 = 5.165\text{\AA}$ ) (7). A further addition of hydrogen produces the holmium trihydride phase, which has a hexagonal lattice with parameters  $a_0 = 6.308\text{\AA}$ ,  $c_0 = 6.560\text{\AA}$  (8). The dihydride and trihydride phases are not stoichiometric, but exhibit compositional ranges of hydrogen solubility which broaden at high temperatures. The trihydride phase is stable only at relatively low temperatures, tending to decompose to the dihydride at temperatures above  $370^\circ\text{C}$  at atmospheric pressure.

Isothermal curves for the holmium solid solution-dihydride composition range are presented in Fig. 1, and a similar plot for the dihydride-trihydride range is presented in Fig. 2. More than 500 individual data points are represented by these curves. The points are not shown because of the small scale of the plot and the many points involved.

The isotherms can be correlated to the phases and solubility relationships of the holmium-hydrogen phase diagram. For example, as hydrogen initially is taken into solid solution in the holmium metal the gas pressure increases. As the metal becomes saturated, additional hydrogen initiates the formation of the dihydride phase, and the pressure remains constant in the two-phase region. This behavior is in accordance with the phase rule, which dictates that the appearance of a new phase is accompanied by the loss of one degree of freedom. Constant-pressure plateaus were observed at all temperatures investigated. Additions of hydrogen advancing the composition into the single phase dihydride region produce another increase in pressure. Experimental error accounts for the apparent crossing of some isothermal curves in this region. A second two-phase plateau region (Fig. 2) is observed between the dihydride and trihydride single-phase regions at lower temperatures. It is therefore seen that the extremities of the horizontal plateau lines demark the transitions in number

Fig. 1. Family of isotherms in the solid solution-dihydride region of the holmium-hydrogen system.

Fig. 2. Family of isotherms in the dihydride-trihydride region of the holmium-hydrogen system.

of phases and indicate the compositional solid solution limits of hydrogen in the three phases. The solubility limits of the holmium-hydrogen system are listed in Table I.

A log-log plot of composition vs. pressure for the various isotherms in the holmium solid solution region yielded straight lines with slopes approximating 2. This value confirms the validity of Sieverts' law for hydrogen in holmium. Sieverts' law states that the solubility of a diatomic gas in a metal is proportional to the square root of the pressure, implying that the gas is dissolved atomically in the metal.

A total of 78 independent determinations were made to establish dissociation pressures in the metal solid solution-dihydride plateau region as a function of temperature. Specimens were hydrided to 1.0 H/Ho ratio and cycled to temperatures between  $550^\circ$  and  $900^\circ\text{C}$ . Hysteresis effects were absent. The data were treated

Table I. Solubility boundaries in the Ho-H system

Temp, °C	Two-phase region Ho + HoH <sub>2</sub>		Two-phase region HoH <sub>2</sub> + HoH <sub>3</sub>	
	H/Ho	H/Ho	H/Ho	H/Ho
950	0.59	1.20	—	Not stable
900	0.58	1.30	—	Not stable
850	0.56	1.40	—	Not stable
800	0.53	1.50	—	Not stable
750	0.51	1.65	—	Not stable
700	0.48	1.65	—	Not stable
650	0.43	1.80	—	Not stable
600	0.40	1.85	—	Not stable
550	0.40	1.85	—	Not stable
350	—	—	2.21	2.91
325	—	—	2.20	2.95
300	—	—	2.19	2.95
250	—	—	2.17	2.95

by a least-squares computer analysis to describe the best straight line, and the following equation was obtained

$$\log_{10} p \text{ (Torr)} = -\frac{11,520 \pm 50}{T} + 10.66 \pm 0.05$$

where  $p$  = equilibrium hydrogen pressure and  $T$  = absolute temperature, Kelvin.

The plot of the log of plateau equilibrium pressure vs. reciprocal temperature is illustrated in Fig. 3. The slope of the line is related to the enthalpy of the reaction across the plateau region, and the intercept is related to the entropy of the reaction. The values for this plateau region are  $\Delta H = -52.7 \pm 0.2$  kcal/mole of H<sub>2</sub> and  $\Delta S = -35.6 \pm 0.2$  cal/deg · mole of H<sub>2</sub>.

Dissociation pressures of the holmium solid solution-deuteride plateau region were also determined over the same temperature range to detect differences, if any, caused by the isotopic effect. The procedure was the same as described, except deuterium was substituted for the hydrogen. A total of 57 equilibrium pressure points were employed in the least squares analysis, and the resulting equation is presented here

$$\log_{10} p \text{ (Torr)} = -\frac{11,420 \pm 60}{T} + 10.70 \pm 0.06$$

The enthalpy of reaction to form the dideride phase is  $\Delta H = -52.3 \pm 0.3$  kcal/mole of D<sub>2</sub>, and the entropy of reaction is  $\Delta S = -35.8 \pm 0.3$  cal/deg · mole of D<sub>2</sub>. The dissociation pressures for the deuterium plateaus are consistently higher than for the hydrogen system (see the deuterium plateau pressures plotted in Fig. 3). The entropy of reaction for the HoD<sub>2</sub> is slightly more negative than the entropy of reaction for HoH<sub>2</sub>, which is in the right direction on the basis of theoretical considerations (2).

A similar procedure was employed for the analysis of the dihydride-trihydride plateau region. In this in-

Fig. 3. Family of isopleths in the holmium-hydrogen system (included is the plateau isopleth of the holmium-deuterium system).

stance a total of 54 equilibrium pressures were obtained at temperatures between 200° and 350°C. The specimens were initially hydrided to a 2.8 H/Ho composition because the high equilibrium pressures above 300°C depleted the specimen of hydrogen. Specimens not containing an initial excess of hydrogen transformed completely to the dihydride phase at the higher temperatures. Long periods of time were required in order to attain equilibrium at each temperature. In general, the pressure values obtained on heating the specimen to the desired temperature were more reproducible than those obtained by cooling from a higher temperature. The pressures obtained by cooling were erratic and high. A plot of the log of plateau pressure vs. reciprocal temperature was made, and the equation obtained by computer, least-squares analysis is as follows

$$\log_{10} p \text{ (Torr)} = -\frac{4080 \pm 50}{T} + 9.12 \pm 0.09$$

The enthalpy of reaction to form the trihydride phase from the dihydride phase is  $\Delta H = -18.7 \pm 0.2$  kcal/mole of H<sub>2</sub>, and the entropy of reaction is  $\Delta S = -28.6 \pm 0.4$  cal/deg · mole of H<sub>2</sub>.

Data in the metal solid solution region were treated in this same manner. These data are presented in Fig. 3 as a series of isopleths in conjunction with the plateau data. Each solid solution isopleth was fitted by a least-squares, computer program to an equilibrium dissociation pressure equation of the van't Hoff form,  $\log_{10} p = -A/T + B$ . The equation constants,  $A$  and  $B$ , for each of the compositions are tabulated in Table II.

The solution reaction in the metal solid solution is

for which the relative partial molal free energy of solution is

$$\bar{G}_H - \frac{1}{2} G_{\text{H}_2}^0 = RT \ln p^{1/2} \text{H}_2$$

From this relationship, the Gibbs-Helmholtz equation is integrated to provide the van't Hoff form of the dissociation pressure equation

$$\log_{10} p = \frac{-2(\bar{H}_H - \frac{1}{2} H_{\text{H}_2}^0)}{2.303 RT} + \text{constant}$$

The relative partial molal enthalpy and entropy of solution in the holmium solid solution are calculated from the slope and equation constant, respectively. These quantities are tabulated in Table III.

Table II. Equilibrium dissociation pressure equations for the holmium-hydrogen system

Atomic ratio (H/Ho)	Constants in $\log_{10} p \text{ (Torr)} = -A/T + B$	
	A	B
0.10	8,840 ± 240*	6.65 ± 0.24*
0.20	9,430 ± 150	7.72 ± 0.15
0.30	9,830 ± 80	8.52 ± 0.08
0.40	10,330 ± 120	9.31 ± 0.12

\* Extrapolated value.

Table IV. Integral free energies, enthalpies, and entropies of mixing in the holmium-hydrogen system at 650°C

Composition H/Ho ratio	$-\Delta G^M$ (kcal/ g-atom soln)	$-\Delta H^M$ (kcal/ g-atom soln)	$-\Delta S^M$ (cal/ deg · g-atom soln)
0	0	0	0
0.10	1.21	1.73	0.57
0.20	2.09	3.33	1.37
0.30	2.77	4.77	2.17
0.40	3.31	6.09	3.01
0.43*	3.44	6.45	3.26
1.80*	6.05	16.20	10.10

\* Solubility boundaries of the two-phase region,  $\text{Ho}_{0.88} + \text{HoH}_{1.80}$ .

The relative partial molal quantities were used to calculate the integral free energy, entropy, and enthalpy of mixing in the holmium-hydrogen system. The equation for determining the integral enthalpy of mixing per g-atom of solution is

$$\Delta H^M = \frac{1}{1 + n_{\text{H}}/n_{\text{Ho}}} \int_0^{n_{\text{H}}/n_{\text{Ho}}} (\bar{H}_{\text{H}} - \frac{1}{2} \text{H}^{\circ}_{\text{H}_2}) d(n_{\text{H}}/n_{\text{Ho}})$$

The integral entropies and free energies of mixing were obtained in the same manner. A graphical integration was necessary to determine the appropriate thermodynamic quantity for each level of  $n_{\text{H}}/n_{\text{Ho}}$ . Data are presented in Table IV for the temperature 650°C.

#### Acknowledgment

The writers are grateful for the support of the Sandia Corporation, Albuquerque, New Mexico (prime

contractor to the Atomic Energy Commission) in the conduct of this work. Appreciation is expressed for the help of Mr. Russell A. Nye, who served as laboratory technician.

Manuscript received July 27, 1967; revised manuscript received Sept. 14, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Chemistry of Electrical Wire Explosions in Hydrocarbons

Richard L. Johnson and Bernard Siegel

Laboratories Division, Aerospace Corporation, El Segundo, California

#### ABSTRACT

This paper describes the types and extents of high-temperature reactions that can proceed when metals are electrically exploded into atmospheres of various hydrocarbons. Pyrolyses to other hydrocarbons are readily initiated by the electrical wire explosions, forming both equilibrium and nonequilibrium products to relative extents depending on the reaction energetics and kinetics of the individual hydrocarbon reactants. A surprising aspect of these reactions is the extremely high chemical abstraction of the imparted electrical energy. The principal volatile pyrolysis product is always either acetylene or methane. Thermally labile organometallics and metal hydrides do not form in such explosions. However thermally stable metal carbides form readily during wire explosions in highly endothermic unsaturated hydrocarbons, while the saturated hydrocarbons are more inert.

The physical mechanisms of electrical wire explosions have been investigated widely (1), but it is only recently that chemists have begun to investigate the utility of this technique for chemical synthesis (2-5). An electrical wire explosion can be achieved by transferring the stored energy of a bank of capacitors to a metal conductor in a time interval so short that the energy is conserved in the conductor until explosive vaporization or liquefaction results. If the imparted electrical energy exceeds the thermodynamic heat of vaporization, it can be assumed that initially the exploded metal is mainly in the vapor state. In the presence of a surrounding gas of considerably higher total heat capacity the metal vapor will rapidly transfer energy to the surrounding gas. At this point two processes are possible. Either the cooling metal vapor will react chemically with the heated gas to form products containing metal atoms, or the heated gas molecules may react independently of the vapor by undergoing pyrolytic reactions. Al-

ternatively, if the imparted electrical energy is only sufficient to explosively liquefy the metal, one can only observe liquid-gas reactions.

Our laboratory has been engaged in an effort to determine whether conditions can be established for predicting the reaction products of wire explosions in various gases from simple thermodynamic and kinetic factors, and thus to elucidate the scope of this method of synthesizing inorganic and organic compounds. In ref. (2) we showed the effect of reaction energetics on the ultimate yield of products arising from metal explosions in sulfur hexafluoride. In ref. (6) we studied the pyrolysis of methane that is initiated by exploding a number of metals. It was shown that energy is very efficiently transferred from the exploding wire to the surrounding methane molecules, raising portions of these molecules to transient temperatures of 3200°-3500°K. At such temperatures methane is rapidly pyrolyzed to the equilibrium products, acetylene and hydrogen, the predominant volatile products which

we found experimentally. About 70% of the imparted electrical energy was absorbed chemically by the system to effect this pyrolysis. The remaining 30% of the imparted electrical energy was transferred ultimately to the reactor walls and lost to the outside environment. This wastage of energy is believed to have resulted from the rapid temperature quenching that accompanies the endothermic pyrolysis reaction, coupled with the relative inertness of methane at temperatures much below 2500°K.

In the present paper we extend the study of pyrolyses initiated by electrical wire explosions to more reactive hydrocarbons. It was desired to ascertain whether such reactants would lead to the formation of significant amounts of nonequilibrium products in cooler regions of the wire explosion, thus raising the fraction of the imparted electrical energy which is transformed to chemical energy of pyrolysis. Another objective was to ascertain which types of hydrocarbons would react chemically toward the exploding metals, forming products such as metal carbides, organometallics, or metal hydrides; it was shown in ref. (6) that methane is essentially inert in this respect.

### Experimental

**Wire explosions.**—The wire explosions were carried out in a stainless steel bomb shown in Fig. 1. This bomb was machined from a solid block to a wall thickness of  $\frac{1}{4}$  in. to withstand the anticipated shock waves from the exploding wires. The bomb is in two sections so that the wires to be exploded can be mounted conveniently. There are four O-ring seals to keep the bomb vacuum tight. The largest of these O-rings is readily seen on the circumference of the upper section. The other three O-rings, which are not visible, seal between the upper plate surface and the swagelock fittings. The bomb can be evacuated to a pressure of  $2 \times 10^{-5}$  Torr. However, since initial pressures of  $10^{-3}$  Torr produced extraneous gases at levels too low to be observed gas chromatographically within the time limits of our experiments, this level of vacuum was used frequently. Teflon insulators separate the  $\frac{1}{4}$  in. copper pole electrodes from stainless steel parts. Wires to be exploded are fastened to the lower ends of the electrodes by set screws. The distance between electrodes is  $1\frac{1}{2}$  in., and they are positioned to hold the wire  $1\frac{3}{4}$  in. from the top of the cylinder if the wire is placed linearly between the electrodes, the only position used in our experiments. The internal diameter of the bomb is 4 in., and the internal volume is 833 cc. The entire bomb assembly was connected to a vacuum line by a steel ball joint so that the bomb could be filled

with gases and volatile products could subsequently be transferred.

Two electrical discharge systems were used. For those runs in which the delivered electrical input energy was 148 or 466 joules a mechanical Jennings vacuum switch was used to discharge three 14- $\mu$ f capacitors, which were rated for a maximum of 20 kv and connected in parallel. For those runs in which the delivered energy was 2188 joules this capacitor arrangement was discharged by a GE model 7703 ignitron tube. The reported energies are those energies that were actually delivered to the reactor rather than the nominal energies stored in the capacitors. Since a considerable fraction of the nominally stored energy is lost to the external circuitry on discharging the capacitors, it was deemed necessary to determine experimentally the fraction delivered to the exploding wire. This was done by calorimetry.

Wire explosions were carried out as follows. Weighed wires were connected to the electrodes, and the reactor was then sealed and evacuated. The hydrocarbon gas was then introduced to the desired pressure, the valve closed, and the wire exploded by the firing system described above. After firing, the final gas pressure was measured and the volatiles were transferred to a sample bulb for gas chromatographic analysis. The reactor was then opened in a nitrogen atmosphere enclosure for recovery of the nonvolatile products.

The wire masses that had actually been exploded are given in Table I. These masses were determined by weighing the unexploded residues still attached to the electrodes after the wires had been fired. From high-temperature heat capacity data (7,8) we have computed the fractions of exploded wires that were either explosively liquefied or vaporized. For those runs in which 0.3g Pt was exploded, sufficient energy was imparted for vaporization of only 29.4% of the exploded material at an input energy of 466 joules, while the initially exploded Pt was completely liquid at 148 joules. In each of the experiments in which 0.01g Pt or 0.05-0.06g Al were exploded, sufficient energy had been imparted to vaporize the metal fully by a large margin. In the iron explosions there could not have been any appreciable vapor at 466 joules, but sufficient energy had been imparted in the 2188 joule runs for complete vaporization of the iron.

It might be noted that experimentation with explosions of various metals into methane had demonstrated that neither the identity of the metal nor its mass over a wide range of mass ratios affected appreciably the degree of pyrolysis or the ratios of the volatile products (6). Therefore, in studying the pyrolysis reactions of higher hydrocarbons in the present paper it was deemed unnecessary to use mass or identity of the metal as a control factor for pyrolytic reactions. Because we were primarily interested in the chemical reactions resulting from the wire explosion, rather than the electrical explosion itself, the current-time characteristics of the wire explosions were not measured routinely. However there is no question but that explosions did occur. Measurements of the rate of change of current in the conductors being exploded were carried out in this laboratory under conditions somewhat similar to many of the explosions reported herein. These data indicated that current rose to a maximum within several microseconds and then damped out to zero over periods up to 100  $\mu$ sec. Further, examination of the bomb contents after firing of the wire showed that the original wire had disappeared and the metal was found in the form of a fine powder, which was distributed relatively uniformly over all of the walls of the reactor.

**Product analysis.**—Gas chromatographic analysis of the volatiles was made on a dual-column, programmed-temperature instrument with katharometer detection, using a flow rate of 120 ml/min. For earlier runs, hydrocarbons were determined on a 6 ft x  $\frac{1}{4}$  in. column of 120/150 mesh Porapak Q, temperature programmed

<sup>(a)</sup> Unless specified otherwise initial hydrocarbon pressures were in range 400-450 mm.

<sup>(b)</sup> Initial isobutane pressure was 100 mm.

<sup>(c)</sup> All runs except those using input energies of 2188 joules were with Jennings mechanical switch; 2188 joule runs used ignitron switch.

<sup>(d)</sup> Values listed first are for per cent decomposition to volatiles; those given in parentheses are the per cent decomposition to nonvolatile solids.

<sup>(e)</sup> Aggregate of C<sub>4</sub>H<sub>4</sub> + C<sub>4</sub>H<sub>2</sub>.

<sup>(f)</sup> In these runs small amounts of ethylene were not separated from acetylene.

<sup>(g)</sup> The products have been normalized to a scale of 100 for the most prevalent species.

from 50° to 250°C at 4°/min, and hydrogen was determined on a molecular sieve or on a column of coconut charcoal, 6 ft x ¼ in. at 50°C. In later runs all compounds were determined on a 12 ft x ¼ in. Porapak Q column, programmed, after a 4-min delay, at 4°/min from 40° to 250°C. Samples were taken from a glass bulb reservoir through a gas valve with a 5-ml sampling loop. Values reported in Table I are averages of 6 to 12 multiple runs.

In those runs where platinum alkyls were suspected nonvolatile products, the nonvolatile solids were extracted with benzene and the extract tested for a platinum compound. Similarly in the iron-cyclopentadiene explosions, the nonvolatiles were extracted with diethyl ether and the extract tested for ferrocene. Aluminum alkyls are volatile, and these were sought in the Al explosions by mass spectrometric analysis of the volatile products. Carbides were sought by x-ray diffraction. There has never been a reported platinum carbide (9), and x-ray diffraction patterns of our products failed to demonstrate the existence of a platinum carbide in those runs which involved explosions of platinum wires.

The carbon and hydrogen contents of the nonvolatile residues were obtained by the usual combustion procedure, after extraction with organic solvents for those runs in which organometallic products were sought. These residues were not investigated further. Our main purpose in determining the carbon contents was to compute the per cent decomposition of the hydrocarbons to nonvolatile solids for those wire explosions where thermochemical calculations were desired. In those runs where the over-all pyrolysis was very small an experimental uncertainty of several per cent in the gas chromatographic data prevented direct calculation of the yields from data on the lowering of the concentration of the hydrocarbon reactants. The yield of volatile products was obtained by summing carbon atoms from all the volatile product data, and the yield of nonvolatile hydrocarbons (or carbon) was obtained from the carbon content of the residues.

### Results and Discussion

**Hydrocarbon pyrolyses.**—Saturated hydrocarbons higher than methane have increasingly higher rate constants for pyrolytic reactions (10-13). Our prediction that this would lead to more complex pyrolysis products for such hydrocarbons in wire explosions, as compared to methane, with larger proportions of nonequilibrium products and lesser proportions of acetylene, is supported by the product data in Table I.

The pyrolyses of ethane and the butanes resemble that of methane in that much of the acetylene is undoubtedly formed in the 3200°-3500°K temperature range. This temperature range is undoubtedly achieved in a significant portion of the hydrocarbon molecules surrounding the exploding wire as soon as sufficient numbers of molecules abstract energy from the exploded material to reduce the very much higher temperatures that would characterize the previously smaller heated portion. In the case of hydrocarbons higher than methane, further reactions are possible when the temperature falls below even 2000°K, after temperature quenching caused by the endothermicity of acetylene formation and further heat conduction to cold regions of the surrounding gas. At these lower temperatures the speed of the over-all process requires that pyrolyses fall short of equilibrium, and one obtains the nonequilibrium products shown in Table I for the ethane, n-butane, and isobutane reactions.

This additional reactivity at lower temperatures is reflected in the degree to which chemical energy is abstracted from the imparted electrical energy. Whereas the methane pyrolyses carried out at energy levels at 148 to 466 joules waste approximately 30% of the imparted energy, there is essentially no wasted energy in the ethane pyrolysis at 148 joules. From thermochemical data we compute that 110.7% of the imparted energy was transformed into chemical energy of pyrolysis in the ethane run. In view of the 6% uncertainty in calorimetric measurement of the imparted energy to the wire and the experimental uncertainties in the gas chromatographic analyses of products, this is believed to represent essentially complete energy abstraction. There is no conflict between these data and the apparently lower efficiencies of energy abstraction in the methane and ethane runs at 2188 joules. We have observed that the more rapid explosion that accompanies the use of an ignitron firing circuit, rather than a Jennings mechanical switch, leads to a lower degree of energy abstraction with the ignitron system. Because the latter was used in the 2188 joule runs, we compute lower values of 57.3 and 41.6%, respectively, for the degree of energy abstraction in the ethane and methane pyrolyses. However the relative efficiencies of methane and ethane extraction of electrical energy for chemical purposes remain unchanged.

Since saturated hydrocarbons are themselves exothermic, their pyrolysis to acetylene and hydrogen, or even to carbon and hydrogen, is always endothermic.

One would thus expect that the yield of pyrolysis products would be directly proportional to the imparted electrical energies in wire explosions. This is essentially verified by the data for methane and isobutane. At constant pressure, variation of the electrical energy from 148 to 466 joules, a 3.15-fold increase, leads to measured 3.25 and 3.35-fold increases in the yields of volatile products. The data for runs at 2188 joules cannot be compared with these runs because a different firing circuitry was used. Somewhat surprising is the fact that ethylene behaves similarly to the saturated hydrocarbons, both in type of products formed, and in exhibiting a 3.32-fold increase in volatile products when the input energy is increased from 148 to 466 joules. One might expect that ethylene would pyrolyze directly to graphite and hydrogen since the latter reaction is exothermic. Further, the yield of an exothermic reaction should not be directly proportional to the imparted energy.

The explanation for the ethylene data is based on reaction kinetics. It is known that the pyrolysis of ethylene to carbon and hydrogen proceeds through a mechanism that includes Eq. [1] (14); the heats of reaction cited in this paper were computed from

data in ref. (15). The relatively high endothermicity of this step increases the dependence of the type of product formed on the amount of electrical energy imparted to the exploding wire. At lower energy input levels the endothermicity of Eq. [1] reduces the over-all gas temperature to a point where acetylene is kinetically trapped and precludes the exothermic pyrolysis of acetylene to carbon and hydrogen. This should be readily overcome at higher energy levels, as is seen by the data for cyclopentadiene, which is similar to ethylene in the energetics of these pyrolytic reactions. At the higher energy level one obtains a drastically different pyrolysis. The yield approaches completion, unlike any of the pyrolyses of saturated hydrocarbons at such conditions, and the principal volatile hydrocarbon product becomes methane rather than acetylene.

This trend continues in the more highly endothermic alkyne molecules. Comparison of Eq. [1] with Eq. [2] and [3] indicates

a much lesser tendency toward kinetic trapping of acetylene for wire explosions carried out in propyne (allene has very similar energetics), and explains the very high yields of pyrolysis products and volatile product distributions in propyne or allene explosions at lower energy input levels than had been required for comparable pyrolyses of cyclopentadiene. Acetylene, of course, cannot form permanently stable volatile intermediates by endothermic processes and should pyrolyze exothermically at energy input levels even lower than those required for the higher alkynes. Virtually complete pyrolysis of acetylene was observed at the lowest energy input level used in our experiments.

*Metal-hydrocarbon reactions.*—Metal alkyls were not formed by any of the explosions of aluminum or platinum into saturated hydrocarbons. The aluminum alkyls are well-known compounds, and both  $(\text{CH}_3)_4\text{Pt}$  and  $(\text{CH}_3)_6\text{Pt}_2$  have been reported to be reasonably stable compounds (16-19). A qualifying note might be added in regard to the platinum alkyls since doubt has recently been cast on the authenticity of the reported syntheses of these compounds (20). Yet it must be concluded that it appears unlikely that metal alkyls can be prepared by this technique. We

next studied the possible formation of ferrocene by iron wire explosions in cyclopentadiene. This pi-bonded organometallic compound has been reported to have an unusually high thermal stability for this class of compounds since it is not extensively decomposed even at 470°C (21). Yet ferrocene was not formed, at either 466 joules where the over-all reaction of the cyclopentadiene was relatively small or at 2188 joules where the cyclopentadiene reacted extensively.

The difficulty in preparing organometallics by the present technique can be attributed to the limited thermal stabilities of such compounds and the competing pyrolysis reactions of the hydrocarbon reactants. Similar considerations apply to thermally labile hydrides, such as  $\text{AlH}_3$ , which also did not form in these experiments.

On the other hand many metal carbides are extremely stable thermally and should be capable of synthesis by the technique described in the present paper. Although  $\text{Al}_4\text{C}_3$  was not observed in the methane explosion at 2188 joules, this carbide was observed among the products of the aluminum explosions in ethane and isobutane at 2188 joules. This was established by the presence of the x-ray diffraction spectrum characteristic of  $\text{Al}_4\text{C}_3$  in the spectrum of the nonvolatile products of the ethane and isobutane explosions and its absence in the products of the methane explosion. Yet even when  $\text{Al}_4\text{C}_3$  was found among the products of Al explosions in the higher saturated hydrocarbons, the intensities of the Al lines were considerably larger than those of  $\text{Al}_4\text{C}_3$ . Thus the reaction does not go very far toward completion, even at 2188 joules. These results reflect the energetics of Eq. [4] to [6]. Cook and Siegel showed (2) that

for kinetic reasons endothermic reactions in which the metal reacts chemically with the surrounding gas are very inefficient in abstraction of electrical energy in wire explosions. Therefore Eq. [4] could be predicted to proceed to a lesser extent than would Eq. [5] or [6], if all other conditions were equal. Further, the marginal exothermicities of Eq. [5] and [6] would indicate poor yields. On this basis the endothermic unsaturated hydrocarbons should be superior to the exothermic saturated hydrocarbons as reactants leading to metal carbide formation. This is substantiated by the ready formation of  $\text{Fe}_{20}\text{C}_9$  by iron explosions in cyclopentadiene at 2188 joules. Acetylene should be better still, and  $\text{Al}_4\text{C}_3$  was found to be a product of aluminum explosions in acetylene, at energy input levels as low as 148 joules.

*Future studies.*—The application of the exploding wire technique in a small volume bomb is particularly efficacious for the synthesis of transition metal carbides. Cook (22) of this laboratory has expanded on the results of the present study by showing that titanium wire explosions into acetylene diluted with an inert gas can lead to the preparation of TiC samples in high yield and in purity at least equal to 98.6% by weight. The general applicability of the method is indicated by the successful synthesis of  $\text{LaC}_2$ , TiC, ZrC, NbC,  $\text{Nb}_2\text{C}$ ,  $\text{Ta}_2\text{C}$ , MoC,  $\text{Mo}_2\text{C}$ , and  $\text{W}_2\text{C}$ . Although the utility of wire explosions in a small volume bomb for the synthesis of thermally labile compounds appears dim, in view of the results of the present paper, we believe that there is a possible solution to this problem. What is evidently required is the introduction of an additional mode of temperature quenching superimposed on the temperature quenching processes oc-

curing naturally in wire explosions carried out in a limited volume bomb. We are now trying to develop a technique in which the wire explosion is coupled to a device similar to a shock tube. This would provide both extra temperature quenching and longer path lengths at lower temperatures.

#### Acknowledgment

The authors gratefully acknowledge the general laboratory assistance of Miss C. G. Johnson who obtained all the gas chromatography data. Messrs. T. L. North and S. B. Mason assisted with the electrical discharge systems, while S. Hotta, P. Marsh, and E. S. Elliott obtained analytical data.

Manuscript received June 26, 1967; revised manuscript received Sept. 18, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## On the Activity of Platinum Catalysts in Solution

### II. Kinetics of the Pt-O Reaction with Hydrogen and of Pt-H Deposition Using a Double Pulse Technique

Theodore B. Warner\* and Sigmund Schuldiner\*

Naval Research Laboratory, Washington, D. C.

#### ABSTRACT

Surface coverages of oxygen and hydrogen were determined on electrodes of differing activities as a function of time and of voltage in the potential decay curve following an anodic pulse. The electrolyte was 1M H<sub>2</sub>SO<sub>4</sub> containing dissolved hydrogen. No important difference, other than rate, is found in the way Pt-O is removed from surfaces of differing activity; however, a significant difference is noted in the way hydrogen resorbs. The rate of Pt-O removal is of apparent first order in adsorbed oxygen when the initial fraction of the surface covered is about 1.0; it is zero order in adsorbed oxygen and in amount reacted when the initial surface coverage is <0.8. The rate of the decay reaction is probably not limited by mass transport of solution H<sub>2</sub> to the surface, by obstruction of active surface sites by sorbed product molecules, or by slow chemisorption of solution H<sub>2</sub> on the electrode prior to reaction with Pt-O.

In Part I of this series (1) and in a preceding paper (2), the rate of the reaction of oxygen, chemisorbed on smooth platinum, with hydrogen dissolved in 1M H<sub>2</sub>SO<sub>4</sub> and in the Pt derma (the Pt-O/hydrogen reaction) was monitored by observing potential decay on open circuit after an anodic current pulse. The purpose in Part I was to examine how different thermal or chemical treatments affected the intrinsic catalytic activity of smooth platinum, using this reaction rate as a measure of activity. It was found that this intrinsic activity could be modified by several orders of magnitude. The purpose of this work was to determine if surfaces known to have different catalytic

\* Electrochemical Society Active Member.

activities for the Pt-O/hydrogen reaction exhibited significant differences (other than rate) in the way oxygen was removed or hydrogen resorbed.

Breiter (3) has previously studied the chemical reduction of chemisorbed oxygen with H<sub>2</sub>. His results should not be compared directly with these due to important differences in experimental procedure, as previously discussed (2). Sawyer and Seo (4) have also studied this system. Their oxygen generation rates were very low, however, so the electrodes would be presumed to contain some oxygen absorbed in the lattice. The presence of such oxygen affects the hydrogen/oxygen interaction markedly (2). The oxygen

Fig. 1. Double pulse electrode polarization. First pulses (oxidation of  $H_{ad}$  followed by oxidation of  $H_2O$  to  $O_{ad}$ ) are traces 1, 2, and 4; second pulses (oxidation of  $H_2O$  to  $O_{ad}$ ) are traces 3, 5, and 6 taken after reaction ( $Pt-O_{ad} + \text{hydrogen}$ ) times of 10, 6, and 3 msec, respectively, on an electrode with a monolayer decay time of 21 msec. Current density is 2.92 amp/cm<sup>2</sup>.

generation rates used in this work were adjusted such that oxygen was deposited on the platinum surface without concurrent absorption of oxygen into the lattice.

### Experimental

Apparatus and procedures were the same as in Part I except that two precisely spaced galvanostatic pulses were used.<sup>1</sup> A Hewlett-Packard 5214L Electronic Counter (clock rate 100 kc) provided two trigger pulses separated by a time known within 1  $\mu$ sec. These pulses triggered a pulse generator (either an EH Model 132A or an Electropulse 3450D), sending two identical current pulses through the cell. The pulses were adjusted so that the first ended after a known amount, usually one monolayer, of chemisorbed oxygen atoms had been deposited on the electrode (Fig. 1). Current densities were from 2.9 to 4.5 amp/cm<sup>2</sup>.<sup>2</sup>

The anodic charging curves are conceptually divided into the usual regions, called the "H ionization region" and the "O sorption region." In the subsequent decay, the first region is called the "O removal region," and the second the "H deposition region." These regions are diagrammed in Fig. 1a of ref. (2) and they are apparent in Fig. 2 here. In the O removal region, hydrogen is reacting with the oxygen chemisorbed on the electrode. This hydrogen can come from the  $H_2$  dissolved in the bulk of the solution, from  $H_2$  bubbles at the surface and from dermasorbed H (H absorbed in the top 2 or 3 atomic layers of Pt). After a known time into the decay,  $t$ , called at different times either the "reaction time" or the "decay time," the second pulse was triggered to determine how much charge was required to bring Pt-O coverage up to one monolayer. Knowing the initial coverage and this, the amount reacted could be computed. When the voltage decayed below 0.3v, the second pulse gave both the charge required to form the oxygen region and the charge due to oxidation of adsorbed hydrogen.

It was assumed that in the oxygen regions,  $q_0 = q_{\text{measured}} - q_{dl}$ , and in the hydrogen regions,  $q_H =$

<sup>1</sup>Unless otherwise specified, potentials are given vs. the normal hydrogen electrode, all measures of precision are standard deviations of an individual measurement, and electrode areas are "true" (5) areas based on the assumption that  $q_{O+dl} = 456 \mu\text{coul/cm}^2$  when one monolayer of oxygen is deposited at a current density of 3 amp/cm<sup>2</sup>. Precision of an individual area measurement was  $\pm 3.2\%$ .

<sup>2</sup>At these current densities, the IR drop in the solution is a large fraction of the total cell voltage. The IR drop was at times removed from the display by using a Tektronix Type 547 oscilloscope with a Type 1A1 dual trace preamplifier. The rectangular pulse at the generator output was applied to input 1 and appropriately attenuated; the cell voltage was applied to input 2 and the difference signal was displayed.

Fig. 2. Double pulse polarization of electrode on which some hydrogen had resorbed, and typical full decay curve. Pulses are 20  $\mu$ sec/cm and 0.5 v/cm; decay is 50 msec/cm and 0.2 v/cm. Reaction times between pulses were 200, 230, and 260 msec reading from bottom to top on an electrode whose  $t_0$  was 48 msec. Current density is 4.56 amp/cm<sup>2</sup>.

$q_{\text{measured}} - q_{dl}$ . For the first pulse, the significance of the various terms is well understood. For the second pulse, the assumption is made in what follows that all of the charge designated  $q_0$  went to form  $Pt-O_{ad}$  via a net 2-electron oxidation, and all charge designated  $q_H$  went to oxidize  $Pt-H$  to  $H^+$ . The validity of these assumptions will be supported later. The charge due to double layer charging was subtracted from the various  $q_{\text{measured}}$  using previously reported (5) double layer capacitance vs. potential data integrated over the potential region of interest.<sup>3</sup>

The "foot" of each charging curve in Fig. 1 (the horizontal trace to the left of time zero) gives the potential of the electrode prior to each pulse. The first of each pair of pulses started at the normal equilibrium hydrogen potential (0.000v). The foot of the second pulse then defined the potential,  $E(t)$ , in the decay from which the second pulse was taken.

Two bright platinum bead electrodes were used, one with a monolayer decay time,  $t_0$ , of  $47.8 \pm 0.5$  msec, and one with  $t_0$  of  $21.3 \pm 1.5$  msec. The monolayer decay time is the time required for the reduction of a monolayer of chemisorbed oxygen with hydrogen. The electrode areas were about 0.1 cm<sup>2</sup>. For convenience, the more active electrode (activity defined by the rate of the Pt-O/hydrogen reaction) with  $t_0 = 21$  will be termed electrode A, and the less active one, electrode L. It was important to confirm that each measurement of voltage and redeposited charge was made on an electrode whose  $t_0$  was unchanged. This was done by plotting measurements of potential vs. reaction time,  $t$ , from a number of full decay curves taken before, during, and after the double pulse studies, and then comparing these data with the voltage/time information obtained from the foot of the second pulse. The  $t_0$  for the electrodes used did not change during the course of the experiments.

### Results

**Oxygen removal region:  $Pt-O + \text{Hydrogen} = Pt + H_2O$ .**—Voltage-time relation.—To facilitate comparison of results on electrodes with different intrinsic activities, the results for each electrode have been expressed in terms of relative decay times,  $t/t_0$ , where  $t$  is the reaction time, and  $t_0$  the monolayer decay time.

<sup>3</sup>For the second pulse this treatment involved the assumption that  $q_{dl}$  (which includes a contribution from pseudocapacitance near 0.000v) under the nonsteady-state conditions prevailing was not significantly different from that measured in (5). Consideration of the physical situation prevailing shows that this is reasonable; further, the  $q_{dl}$  terms are small compared to total  $q$ .

Fig. 3. Basic decay curve: potential vs. relative decay time

Fig. 4. Fraction of surface covered with  $O_{ad}$  vs. potential during decay. The initial coverages are denoted  $\theta_a$ .

Plots of electrode potential during the decay,  $E(t)$ , vs.  $t/t_0$  (Fig. 3) for data obtained on electrodes with  $t_0 = 21$  and  $48$  msec show no important difference nor are differences noted for the relation between voltage in the decay curve and fraction  $\theta$  of surface covered with oxygen (Fig. 4). It must be kept in mind that the actual times of reaction, however, differed by a factor of 2.2. From repeated measurements on electrodes whose  $t_0$  ranged from 17 to 180 msec, the potential at the end of the decay plateau, at  $t = t_0$  was found to be  $0.283 \pm 0.004v$ .

**Oxygen coverage vs. voltage and time.**—Let  $a$  be the initial oxygen coverage of the electrode in  $\mu\text{coul}/\text{cm}^2$  deposited by the first pulse, and let  $(a-x)$  be the coverage at any later time  $t$ . Let  $q_0$  be the amount of oxygen used in the second pulse to reform one monolayer of  $O_{ad}$ . We assume that  $q_0 + (a-x) = 420 \mu\text{coul}/\text{cm}^2$ ; i.e., the electrode is once again polarized up to the  $O_2$  evolution region when its total oxygen coverage is brought back to one monolayer. The fraction  $\theta$  of the surface covered with oxygen is

$$\theta = \frac{420 - q_0}{420} \quad [1]$$

It is necessary to maintain a clear distinction between  $a$ , the initial concentration in  $\mu\text{coul}/\text{cm}^2$  of oxygen on the surface;  $\theta_a$ , this initial concentration expressed as the fraction of Pt surface sites covered with  $O_{ad}$  ( $\theta_a = a/420 \mu\text{coul}/\text{cm}^2$ ), and  $\theta$ , the fraction of the surface covered with oxygen at time  $t$  after some of the oxygen initially deposited has reacted with hydrogen.

The results in Fig. 5 and 6 show that the relationships between  $\theta$  and  $t/t_0$  for the cases where  $\theta_a \approx 1$  and for  $0.32 \leq \theta_a \leq 0.77$  are quite different. For  $0.32 \leq \theta_a \leq 0.77$ , Fig. 6a shows that the rate of oxygen removal is zero order in the initial concentration  $a$  and in the amount reacted  $x$ . The slopes are independent of  $a$  and average  $700 \mu\text{coul}/\text{cm}^2$ . Converting into units

Fig. 5. Rate of removal of oxygen for case where fraction of surface initially covered is near unity. The symbols have the same meaning as in Fig. 4.

Fig. 6. (a, top) Rate of removal of oxygen for case where fraction of surface covered initially is  $< 0.8$ . The initial coverage  $a$  for each curve is indicated on abscissa below  $t/t_0 \times 100$  values. The origin of each succeeding curve is displaced 10 time units to the right of the preceding curve. The numbers on the curves represent the slopes in  $\mu\text{coul}/\text{cm}^2$ . Fig. 6 (b, bottom) Comparison of cases where  $\theta_a \approx 1$  with ones where  $\theta_a < 0.8$ . The origins for the two curves to the right have been displaced by 40 and 60 ( $t/t_0 \times 100$ ) units.

of  $\theta$ , the rate of oxygen removal is

$$\theta = \theta_a - 1.67 \frac{t}{t_0} \quad [2a]$$

However, for  $0.92 \leq \theta_a \leq 1.03$ , the rate of oxygen re-

removal is given by a first order relation

$$\theta = \exp\left(-k \frac{t}{t_0}\right) \quad [2b]$$

over the range  $1 \leq \theta \leq 0.15$  where  $k$  is the first order rate constant of about 3.2. The curves, plotted separately, show logarithmic relations; the slopes are not considered to be significantly different. (The slopes are strongly dependent on the average values used for  $t_0$  and  $q_0$  monolayer, as well as the extent to which some hydrogen may or may not be oxidized in the oxygen region.)

**Hydrogen redeposition region:**  $\text{Pt} + \text{H} = \text{Pt} - \text{H}$ .—The measured quantities were  $q_{\text{H} + \text{ad}}$ ,  $q_0 + \text{ad}$ ,  $E(t)$ , and time since the end of the first pulse,  $t$ . The time available for hydrogen sorption was taken as  $(t - t_0)$ . Since charging curves at times up to  $t = t_0$  gave little or no indication of any sorbed hydrogen, it was assumed that all hydrogen reaching the electrode up to this time was consumed in reaction with Pt-O, which was known to be present up to  $t = t_0$ . The validity of this assumption is examined in the Discussion Section. After correction for double layer charging, the resulting  $q_{\text{H}}$  vs.  $E(t)$ ,  $q_0$  vs.  $E(t)$ , and  $E(t)$  vs.  $(t - t_0)$  data are shown in Fig. 7 and 8.

### Discussion

**Hydrogen redeposition region.**—The factors that affect rate of potential decay in the Pt-O removal region exert no influence on the rate of potential change in the hydrogen resorption region. However, the amount of hydrogen found sorbed on the electrode after decay to a given potential does vary with the intrinsic activity of the electrode. The more active electrode, A, shows faster hydrogen reappearance in

Fig. 7. Decay potential vs. time allowed for hydrogen resorption

Fig. 8. Amounts of hydrogen found in the hydrogen region, and "oxygen" found in the oxygen region vs. potential attained in decay curve.

the hydrogen ionization region and no excess charge in the oxygen region whereas electrode L shows less  $q_{\text{H}}$  in a given time while the  $q_0$  measured simultaneously is anomalously high. It appears that the over-all rate of the hydrogen resorption is not greatly different in the two cases, but on L considerably more time is required for hydrogen to be sorbed in a form detected below 0.8v in a charging curve. Therefore, on L some hydrogen not yet sorbed in the usual ways is oxidized in the O sorption region, adding to the charge measured there. The slow process impeding hydrogen sorption could be either diffusion to a suitable chemisorption site, sorption of H into the derma, or the act of strong chemisorption itself. An alternate possibility is that it is not the sorption of the hydrogen that governs the potential at which it oxidized, but the kinetics of its subsequent oxidation. Then tiny amounts of unremoved oxygen in the Pt could act as a catalytic poison, impeding the oxidation of hydrogen sorbed near it. It is reasonable that the L electrode would hold oxygen more firmly in the H resorption region just as it did in the O removal region. The fact that oxygen coverage measured on L returns to the normal 1 monolayer at long times assures that no error in electrode area distorts these data.

A very long time, much greater than 10 sec, is required to cover the electrode with full steady-state H coverage, although the equivalent of one monolayer ( $210 \mu\text{coul}/\text{cm}^2$ ) is sorbed in about 0.2 sec on each electrode. This is fully consistent with the view repeatedly expressed by this Laboratory that hydrogen sorbed on the surface is present in various forms, namely, weakly and strongly bonded H and derma-sorbed hydrogen (hydrogen present in the Pt atomic layers just below the surface layer). It is probable that resorption of hydrogen into the derma is the slow process governing uptake of the last portion of the hydrogen sorbed.

The difference between A and L, which affects the rate of Pt-O<sub>ad</sub> reaction with hydrogen, also affects the manner in which hydrogen resorbs on the electrode. It does not, however, affect the  $E(t)$  vs. time relation or the over-all rate of sorption materially.

**Oxygen removal region.**—**Oxygen coverage vs. potential.**—It is apparent from Fig. 3 and 4 that the intrinsic difference between the reaction rates on the two electrodes is removed by normalization, giving voltage/time and oxygen coverage/time behaviors that are essentially the same. The data for  $0.3\text{v} > E(t) > 0.0\text{v}$  (Fig. 4), in which the oxygen coverage of L appears to drop below zero, results from the anomalously high "oxygen" coverages found in the second pulse at certain times (cf. Fig. 8 and discussion in preceding section). It appears that true zero Pt-O coverage may be more closely related to the point of inflection in the decay curve at 0.35v and  $t/t_0 = 0.90$ . Conclusions previously drawn based on comparisons of decay times would not be influenced materially by a 10% change in the decay time used.

**Rate of oxygen removal.**—The rate of oxygen removal was previously (2) shown to be zero order in hydrogen partial pressure (from 1.0 to 0.1 atm), in stirring rate (from quiescent to vigorously gas-stirred), and in amount of oxygen removed from  $\frac{1}{2}$  monolayer to 2 monolayers. Hence, mass transport of solution  $\text{H}_2$  to the surface is not rate-limiting. There is no indication that bare surface must be available for  $\text{H}_2$  to chemisorb prior to reaction with Pt-O, for the integrated rate of removal of oxygen was the same for initial coverages ranging from less than a monolayer to two monolayers (2). In this study the kinetics of the removal were essentially the same for initial coverages of 0.92 and 1.03 monolayer.

The changes observed both in reaction order and in rate when initial Pt-O concentration was less than 0.8 monolayer indicate that the mechanism of the oxygen removal reaction changes. For this reason, the cases

where the initial coverage  $\theta_a$  is less than 0.8 and where it is about 1.0 are discussed separately.

*Case where  $\theta_a < 0.8$ .*—The rate of oxygen removal is independent of  $\theta_a$  and  $x$ . This behavior is to be expected if the surface contains sites with widely differing activities, and if the over-all rate of the reaction  $v_R$  is determined by the rapid rate  $v_R^*$  at relatively few "active sites" that comprise fraction  $l$  of the surface, and that are supplied (rate of surface diffusion  $v_D$ ) as rapidly as necessary from the reservoir of oxygen atoms sorbed on the rest of the surface. Recognizing that in fact there is probably a whole spectrum of sites of differing activity on the surface, we may for simplicity consider the surface to have two kinds of sites, active and inactive (or less active), of fractions  $l$  and  $m$  with the fraction of  $l$  and  $m$  covered with oxygen being  $\theta_l$  and  $\theta_m$ . If  $l$  is quite small, say less than 0.05, and if  $v_D \gg v_R^*$ , then as long as Pt-O is still present on inactive sites,  $l$  remains fully covered until  $\theta_m$  becomes very low. Hence the rate of the reaction of the species on  $l$ , which is the only area catalytically significant, will be zero order in reactant. This model would make reasonable the very wide variations in  $v_R$  that have been observed as a result of thermally annealing or chemically etching the surfaces (1), for if  $l$  is sufficiently small, then addition or subtraction of relatively few active sites can change  $l$  substantially.

For several reasons, it is improbable that active sites are obstructed by product molecules as the reaction proceeds. First, the product will either be  $H_2O$ , the same as the solvent, or, if it is an intermediate, it is likely unstable with a short lifetime. Second, if active sites were obscured, then reaction rate would decrease with amount reacted, contrary to the data in Fig. 6. Finally, when all of the  $O_{ad}$  was reduced, the second charging curve in the O sorption region showed  $q_0 = 420 \mu\text{coul}/\text{cm}^2$ , the amount required for adsorption of 1 monolayer of  $O_{ad}$ . If during decay a significant amount of  $O_{ad}$  were reduced to a product that required only 1 electron per  $O_{ad}$  atom reformed, then recharging to full  $O_{ad}$  coverage would require  $< 420 \mu\text{coul}/\text{cm}^2$ .

*Case where  $\theta_a \approx 1.0$ .*—The rate of oxygen removal was found to be first order in oxygen coverage. The reason for this difference in reaction order and the increase in initial rate at  $a \approx 1.0$  is obscure. It is not the same sort of apparent reaction order change frequently noted in catalytic reactions, where as concentration of the reactant on the active surface increases, the reaction order decreases from unity to zero. Here, in the  $\theta_a < 0.8$  case, the active surface is thought to be fully covered at the lowest initial concentrations used, yet in the  $\theta_a \approx 1$  case the additional adsorbed oxygen somehow causes a change in the reaction order.

Tucker (6) has reported that when oxygen at  $2 \times 10^{-6}$  Torr interacts with Pt at  $400^\circ\text{C}$ , the results may be interpreted in terms of surface Pt atoms being displaced from their normal positions. If the high activity

of the oxygen generated electrochemically in this work is a sufficiently large driving force, then perhaps a related rearrangement occurs here. In such a case, at high coverages the electrode surface would be quite different from that at lower coverages and a different mechanism would be reasonable. It is also conceivable that at very high coverages, additional sites on the surface become catalytically important and hence the initial rate becomes larger. However, it is then not clear why, when coverage has declined to 0.8, the other sites do not control the course of the reaction. In such a case, a zero order reaction rate should be observed for the removal of the remaining oxygen.

### Conclusions

1. This work verifies that in  $H_2$ -saturated solution the time required for potential decay to about 0.300v, after a preceding anodic pulse, is also the time required for removal of the chemisorbed oxygen deposited by that pulse.
2. The rate of removal of  $O_{ad}$  is of apparent first order in adsorbed oxygen when the initial fraction of surface covered is about 1.0; it is zero order in adsorbed oxygen and in amount reacted when the initial fraction of surface covered is  $< 0.8$ . It is zero order in hydrogen partial pressure in both cases.
3. Several alternative rate-determining steps in the decay reaction were considered, one being the rate of surface diffusion of  $O_{ad}$  or  $H_{ad}$  to the active sites, another being the actual rate of reaction at these active sites. The latter is favored as somewhat more probable, for it appears that active sites are involved rather than the whole surface, at least for  $\theta_a < 0.8$ . Steps probably excluded as rate-limiting are: (a) mass transport of solution  $H_2$  to the surface, (b) obstruction of active surface sites by adherent product molecules, (c) chemisorption of solution  $H_2$  on electrode prior to reaction with Pt-O.
4. For electrodes of differing activities, a significant difference is found in the way hydrogen resorbs on recently stripped electrodes; no difference other than rate is found in the way the Pt-O is removed.

## ABSTRACT

EMF measurements were performed at 25°, 30°, and 35°C on the cell

For concentrations up to 0.12M, the activity coefficients at each temperature may be represented satisfactorily by Guggenheim's extension of the Debye-Hückel equation. The partial molal Gibbs free energy, entropy and enthalpy of transfer of LiCl from DMSO to water have been calculated to be  $-4.93$  kcal/mole,  $+24.8$  cal/°K-mole and  $+2.61$  kcal/mole, respectively.

Because of its high dielectric constant and stability, dimethyl sulfoxide has been of interest as an ionizing solvent for some time (Table I). Although the chemistry of the solvent has been the subject of numerous investigations, very few thermodynamic data are available for its solutions. The only thermodynamic data which have been reported for electrolytic solutions in DMSO are some solubilities (1, 2), some acid-base equilibria (3), cryoscopic data on electrolytes in the solvent (4-6), and the heats of solution of several iodides (7). In addition, Cogley and Butler (8) have reported some qualitative thermodynamic results from measurements on the cell to be described below.

The present work is based on EMF measurements on the cell

The paucity of information relevant to the behavior of inorganic salts, and of reactive metals in nonaqueous media, as well as the potential usefulness of the solvent in voltaic cells, and in electrosynthesis, justify this choice. A halide system was chosen because of the low solubility of other salts in the solvent medium for which a reference electrode with a common anion could be found. Previous work in this laboratory established the advantages of the thallium amalgam-thallose chloride reference electrode (9). The nature of the reference electrode restricted the choice of the anion to chlorides and the metal cation to one of those rather high in the oxidation potential series. The lithium electrode was in part selected because of the opportunity to obtain direct thermodynamic measurements on a metal-metal ion couple which, along with the other alkali and alkaline earth metals, reacts spontaneously with most other ionizing solvent media. The potential usefulness of a lithium electrode in galvanic cells was also considered.

## Experimental

The vacuum-tight Pyrex cell constructed for this purpose (Fig. 1) consisted of five approximately 2-cm

diameter tubes arranged in radial positions, each connected to a central tube by 6 mm glass tubing. Reference electrodes and the counter electrodes (Li) were placed in the peripheral compartments, while the central tube served to introduce the solutions. In each experiment, two reference electrodes and three lithium electrodes were used. The cell was designed so that solutions did not come in contact with stopcocks.

The solvent (Matheson, Coleman, and Bell, spectrographic grade) was purified by distillation under reduced pressure at 80°C. The product was found to contain less than 50 ppm water by Karl Fischer titration and had a melting point of 18.58°C.

Lithium chloride (Baker and Adamson) was dried by refluxing thionyl chloride over it for 2 hr. The dried salt was stored in a vacuum desiccator under an atmosphere of dry argon.

The lithium metal (Lithium Corporation of America, 99.9%) was obtained commercially and stored under oil.

Solutions were made either by direct weighing of solute and solvent or by dilution of more concentrated solutions. The solutions were prepared and stored in a glove box under an atmosphere of dry argon. The lithium electrodes were prepared by etching the surface in an HCl solution in DMSO, carefully rinsing with solvent, and then rinsing with a portion of the solution to be used in the cell. The cell was

Fig. 1. Five-compartment cell used for emf measurements

assembled, the solution introduced, and the cell was removed from the glove box and suspended in a grounded water bath. Temperature was controlled within  $\pm 0.01^\circ\text{C}$ .

On each cell the measuring procedure began 15 min after thermal equilibrium at  $25^\circ\text{C}$  had been attained. The measurements were made with an L&N K-3 potentiometer, using carefully calibrated standard cells. The second set of measurements at  $25^\circ\text{C}$  was made 1 hr later and, if there was less than 0.1 mv difference between the readings, the temperature was raised to  $30^\circ$  and  $35^\circ\text{C}$ , respectively, where the measurements were repeated. The temperature was then reduced to  $25^\circ\text{C}$ , and another set of measurements was made. The last measurement at  $25^\circ\text{C}$  always agreed within less than 0.1 mv with the earlier measurements at  $25^\circ$  if the temperature cycle was shorter than 12 hr. The bias potential between the reference electrodes was always less than 0.05 mv and for the lithium electrodes was less than 0.1 mv.

The thallium amalgams used in the present studies were all in the concentration order of  $10^{-2}$  mole fraction thallium. The voltage of the cell [1], was "corrected" to solid thallium metal by using the emf data on thallium amalgam concentration cells of Richards and Daniels (14). The relative potentials of the amalgams employed are given in Tables II, III, and IV.

In Tables V, VI, and VII are given the results of the cell measurements at  $25^\circ$ ,  $30^\circ$ , and  $35^\circ\text{C}$ , respectively. In the first column is given the molality of LiCl in solution. The measured cell voltage,  $E$ , and the amalgam are listed in the second and third columns, respectively. The cell voltage "corrected" to solid thallium,  $E'$ , is given in the fourth column.  $E'$  is related to the standard cell potential and the solution concentration by

$$E' = E^0 - \frac{2RT}{F} \ln m_{\text{LiCl}} \gamma_{\text{LiCl}} \quad [2]$$

where both  $E^0$  and  $\gamma_{\text{LiCl}}$  are unknowns. The usual arbitrary definition is adopted: the activity coefficient of lithium chloride approaches unity as the concentration of lithium chloride approaches zero. The limiting equation proposed by Guggenheim (13) is employed to facilitate extrapolation to infinite dilution, i.e.

$$\ln \gamma_{\text{LiCl}} = -\frac{\alpha z_+ |z_-| I^{1/2}}{1 + I^{1/2}} + 2\beta_{\text{LiCl}} m_{\text{LiCl}} \quad [3]$$

\* Data used in least squares analysis.

Here,  $\alpha$  = Debye-Hückel constant,  $I$  = ionic strength =  $\frac{1}{2} \sum_i z_i^2 m_i$ , and  $\beta_{\text{LiCl}}$  = constant, independent of molality. From [2],

$$E' - \frac{\alpha z_+ |z_-| I^{1/2}}{1 + I^{1/2}} \left( \frac{2RT}{F} \right) + \frac{2RT}{F} \ln m = E^0 = E^0 - \frac{4RT}{F} \beta_{\text{LiCl}} m \quad [4]$$

where Eq. [4] defines  $E^o$ . The function  $E^o$  is listed in the fifth column of Tables V, VI, and VII.

By constructing a plot of  $E^o$  vs.  $m$ , according to Eq. [4], one should obtain a straight line. Extrapolating to  $m \rightarrow 0$ , one can obtain  $E^o$  and then  $\gamma_{\text{LiCl}}$ , for other concentrations at which the cell emf is measured.

$E^o$  is plotted vs. molality in Fig. 2, 3, and 4. The emf-s of the cells were found to be well behaved for concentrated solutions of lithium chloride. As the concentration is decreased, the function  $E^o$  becomes a linear function of molality. The sharp decrease of  $E^o$  at concentrations below  $2 \times 10^{-2}M$  was quite unexpected. This behavior could not be explained by random scatter of data; the decrease persisted at all three temperatures. Several independent sets of solutions, made by both methods, were used, and the data was found to be reproducible and not due to errors in solutions concentration. A reaction in the cell could not have caused this behavior because the cell voltage was constant over the period of the temperature cycle. After 12-hr the lithium electrodes became discolored, and the cell potential began to decrease steadily due to the reaction

The unexpected decrease of  $E^o$  occurred in solutions where the concentration of LiCl was approaching that of TlCl. The solubility product of TlCl in dimethyl sulfoxide is  $5 \times 10^{-7}$  (8). Since TlCl must be kept away from the lithium electrode, where it will react, a concentration gradient of TlCl exists in the cell. The cell potential will be lower than expected when there is diffusion of the sparingly soluble salt from the reference electrode. At higher concentrations of LiCl, it would be expected that the nonuniform concentration distribution would be of no effect, and the effect should become greater as the solution concentration of LiCl decreases. The departure of the potential from

Fig. 2. Extrapolation of emf data to infinite dilution at 25°C.

Fig. 3. Extrapolation of emf data to infinite dilution at 30°C

Fig. 4. Extrapolation of emf data to infinite dilution at 35°C

the linear extension of the line obtained by least squares fit of the data at higher concentrations can be, to a good approximation, explained by quantitative consideration of the effect of diffusion of TlCl (15).

With the foregoing consideration in mind, the extrapolation to infinite dilution was made by fitting a least squares line to the data in the linear region. The results of the data analysis are summarized in Table VIII for the 95% confidence level. From these results were calculated  $\Delta G^o$ ,  $\Delta H^o$ , and  $\Delta S^o$  for the cell reaction. These thermodynamic functions are given in Table IX.

The same calculations may be carried out for aqueous solutions. The quantity  $\Delta \bar{G}^o$  for the transfer at 25°C,

is found to be

$$\Delta \bar{G}^o = -4.93 \text{ kcal/mole}$$

The entropy of transfer at this temperature is calculated to be +24.8 cal/°K-mole, after correcting for the difference in partial molal volume of the two solvents.

Activity coefficients were determined as a function of concentration at the measured temperatures. Activity coefficients obtained from the smoothed data are given in Table X at rounded concentrations.

The behavior of the activity coefficient of LiCl indicates that it is a completely dissociated salt in very dilute solutions. We arrive at this interpretation from the value of  $\beta_{\text{LiCl}}$  which is positive, as in aqueous solutions. In aqueous solutions, a negative value of  $\beta$  is interpreted as an indication of ion pairing (18). Although the magnitude of  $\beta_{\text{LiCl}}$  in dimethyl sulfoxide is larger than in water, we attach less significance to the magnitude than to the sign. Further interpretation

must await further data on other electrolytes in dimethyl sulfoxide.

The activity coefficients from the present study (25°) are consistently higher than those reported by Dunnett and Gasser (18.5°) obtained from freezing point depression studies (4). According to our measurements, correction for temperature would increase the discrepancy. Analysis of the results of Dunnett and Gasser according to the method suggested by Brown and Prue (16)<sup>1</sup> yields a value  $\beta_{\text{LiCl}} = -2.11$ . The reasons for the disagreement with the present study are not understood. It seems possible that traces of water may have caused anomalous freezing point readings in the dilute solutions, those most important for the determination of  $\beta_{\text{LiCl}}$ . Also, the value of the cryoscopic constant (4.36) used by Dunnett and Gasser is subject to question. This value reported by Lindberg, Kenttämää, and Nissema (17) is based on cryoscopic measurements on solutions of benzene in dimethyl sulfoxide, but the most dilute solution used was 0.88M. If one used the cryoscopic constant of Skerlak *et al.* (5), *i.e.*, 3.97, for the above analysis, the value of  $\beta_{\text{LiCl}}$  becomes positive. The value of 3.97 is also consistent with the data of Lindberg *et al.*

According to the present results the free energy and entropy of transfer of LiCl from dimethyl sulfoxide to water are in the direction one would predict from the relative dielectric constant of the two solvents. Calculations of the dielectric constant effect according to the Born equation do not account quantitatively for the free energy and entropy of transfer. Similar conclusions were reached for several other solvents by Strehlow (19). The heat of transfer of LiCl from DMSO to H<sub>2</sub>O is calculated to be +2.61 kcal. This may be compared to the recent measurements of the heats of transfer of several iodides from DMSO to H<sub>2</sub>O (7), for which the heats of transfer, as expected, are larger, in the order of +10 kcal.

## Technical Note

### Effects of Probe Position on Potentiostatic Control during the Breakdown of Passivity

D. C. Mears<sup>1</sup> and G. P. Rothwell

Department of Metallurgy, University of Cambridge, Cambridge, England

The breakdown of passivity of stainless steels with the formation of brightened pits in chloride-containing solutions has received considerable attention since the observations of Brennert(1). More recently, similar breakdown of passivity has been recorded for a wide variety of passive alloys in solutions in which the anion concentration and anode potential are sufficiently high(2). It is of practical interest to assess the natural resting potential of such alloys, and to compare it

with the breakdown potential determined during the measurement of polarization curves in deaerated solutions. If the breakdown potential is considerably higher than the highest natural resting potential of an alloy in a given chloride solution, the alloy is unlikely to undergo chloride breakdown in use in that solution(3). It is essential, however, to know and to control the anode potential precisely during the polarization measurements. We have measured anode potentials simultaneously with two Luggin probes in different positions and find that electrode geometry strongly influences

<sup>1</sup>Present address: Nuffield Department of Orthopaedic Surgery, University of Oxford, Oxford, England.

the potential recorded at different points on the anode. Furthermore, prior to and during breakdown of passivity the electrode potential of the pitting region may fall rapidly to ca. 100 mv more negative than the controlled electrode potential at the passive anode surface.

Electrical analogues have also illustrated these and other problems of electrode geometry(4). Somewhat similar observations have previously been made on the localization of attack on naturally corroding specimens (5-7).

### Electrochemical Experiments

Specimens of stainless steel (18Cr-10Ni-3Mo) and of Vitallium (30Cr-5Mo, bal.Co) were prepared by masking the borders with Picien wax or Lacomit stopping-off lacquer. The anode potential was controlled potentiostatically using a Luggin probe at the center of the specimen. Additional probes were positioned at the masked edge and at the center of the specimen (Fig. 1); the pd between these two saturated calomel reference electrodes was measured using an electronic millivoltmeter. The area of the anode was ca. 1 cm<sup>2</sup>, and that of the concentric cathode ca. 10 cm<sup>2</sup>. Solutions of 0.2M and 1M sodium chloride, and 4M magnesium chloride were deaerated(8) until the specimen potential had fallen below ca. -350 mv(nhe). Potentiostatic anodic polarization curves were then measured in 50 mv, 10 min steps for both alloys, in the three solutions; at each step the pd between the two non-controlling probes was also measured.

While a specimen is passive, the pd between the probes at edge and center is negligible (< 2 mv), except during the current transient after each increase in potential, when the current initially rises, then falls due to film thickening(9), and the pd between the probes may rise to ca. 20 mv (the edge probe being positive), falling rapidly to zero. As the specimen undergoes film breakdown, the transient and steady potential differences between the two probes increase to ca. 100 mv and 40 mv, respectively. Breakdown of passivity, with the formation of hemispherical brightened pits, occurs predominantly at the masked edge of the specimen. As the anode cd increases further the pd between middle and edge probes ceases to rise, and may decrease, falling below zero in many cases. Figure 2 shows a typical polarization curve for Vitallium in 0.2M sodium chloride solution, with a probe pd/potential curve superimposed. For anode potentials below ca. 200 mv, corresponding to passive

Fig. 1. Apparatus for electrochemical experiments

Fig. 2. Anodic polarization curve ( $e/i$ ) and curve for edge/center potential difference ( $e/\Delta e$ ) for Vitallium in 0.2M sodium chloride solution.

current densities of less than 10  $\mu\text{A}/\text{cm}^2$ , the pd between the edge and the middle is negligible. At higher potentials, rapid breakdown occurs with a large increase in current. The pd between edge and middle rises rapidly to ca. 60 mv. At still higher anode potentials, the steady pd decreases rapidly and ultimately changes sign.

The edges of some specimens were coated with Picien wax so that the wax was flush with the face of the specimen. Polarization curves and pd measurements gave results similar to those for earlier experiments.

The above experiments were repeated with the potential of the edge, rather than that of the middle controlled potentiostatically. With specimens at potentials at which they exhibit passive behavior, the pd from middle to edge is negligible. At higher anode potentials chloride breakdown occurs primarily at the center of the specimen. The probe at the middle of the specimen becomes positive to that at the edge by ca. 60 mv.

Anodic polarization curves and pd measurements were repeated in rapidly stirred solutions: breakdown of passivity occurred with random pitting, and the electrode potentials at different points on the anode differed by less than 5 mv.

### Discussion

Potential variations in natural corrosion environments have been measured by previous workers for many different systems. The work of Bianchi(10) deserves particular attention. In the present work, the polarization experiments with measurement of potential variation across the controlled anode show that electrode geometry may strongly influence the observed behavior of specimens under potentiostatic control. For specimens with surface area of ca. 1 cm<sup>2</sup> determinations of the breakdown potential may be in error by  $\pm 50$  mv; for larger specimens, greater error could occur. The site of breakdown may be altered from random pitting to preferential edge attack. Very high rates of flow tend to minimize the effects of electrode geometry and may cause a return to random pitting behavior. These effects may also be minimized when the anode and counter electrode are opposed parallel surfaces of the same extent, such as two plates or two concentric cylinders, with an insulating barrier extending perpendicularly between their ends, as has been suggested by Piontelli(11).

For film growth on a passive metal under potentiostatic conditions, in a cell giving anything other than perfect uniformity of potential, the rate of the anodic

Fig. 3. Potential and current distributions for an electrical analogue of the masked edge on a passive specimen.

process is correspondingly nonuniform. Figure 3 shows the current distribution in an electrical analogue of the masked edge of a passive specimen(4). When the electrode potential, controlled by a probe at the center of the specimen is increased abruptly, the cd at the central region also increases abruptly, then decreases as the passive film thickens. At regions remote from the controlling probe, in which the current distribution leads to current densities higher than those on the bulk of the specimen, the transient cd must also be greater than that near to the probe, although the electrode potential appears to be lower (i.e., potential in the solution more positive), until the equilibrium film thickness has been reached. The transient metal dissolution and film formation processes also occur faster in these regions. This variation in rates of formation may itself lead to structural variations in the film in different regions of the specimen, and to enhanced take-up of aggressive anions into the film, leading ultimately to the observed initial breakdown in these regions. Very high rates of flow of solution then lead to more random attack by increasing the (diffusion controlled) cd near the probe during the transient period, shortening the transient and minimizing differences of potential across the specimen. Similarly, if the controlling probe is placed at the masked edge of the specimen, where the natural current distribution leads to the highest transient current densities, the effect of such transients in determining the site of breakdown is minimized, and random attack is usually observed.

After high potential breakdown of passivity in natural environments, the corrosion process is under cathodic control, and the potential in the pit decreases (b Fig. 4). Consequently, at the lowered mixed potential the pit may be gradually repassivated. If the pit becomes repassivated, the mixed potential may again rise until breakdown of passivity occurs elsewhere on the specimen. Once a pit has formed breakdown in the adjacent area is less likely because of the change in potential distribution. Random breakdown is thus observed in this case.

If the potential is under the control of a cathodic reaction which is not readily polarized, the potential at the pit site falls only slightly after the breakdown of passivity (c Fig. 4), so that adjacent, and ultimately general breakdown can ensue.

For passive specimens under potentiostatic control, with this type of nonuniform current distribution the potentiostat supplies to the center of the specimen the cd required by the anode, and to the edge areas a cd proportionally higher, as dictated by the geometry

Fig. 4. Schematic anodic polarization curves for a typical passive alloy which undergoes high potential breakdown. Curve  $C_1$  represents the behavior of a natural cathode and  $C_2$  that of a less polarizable cathodic reaction. Points  $C_3$ ,  $C_3'$  represent the behavior under potentiostatic control of a system with small pits, and  $C_3$ ,  $C_4$  the behavior of the same system when the pits have become large enough to affect current distribution at the probe.

of the system. When pitting starts, provided that the total current in this area is less than that available in the distribution the pitting can proceed at its limiting cd at the same potential as the bulk of the specimen. However when the pitting area increases so that the current requirement exceeds that available, then the potential and the pitting cd fall so that the total current requirement can be maintained. Thus the electrode potential may fall during pitting to a point such as  $C_3'$  while the bulk of the specimen may be at  $C_3$ . The fact that the film resistance decreases greatly with the onset of pitting may lead to a decreased  $iR$  drop across the film, leading to a still lower measured electrode potential of the metal.

As the pitting area grows larger it may influence the current distribution at the center of the specimen. If this occurs, the pitting current may increase by drawing from the main current distribution, the potentiostat supplying more current as required to maintain the passive potential. Once the pitting current density again reaches the limiting cd, the pitting potential, which is virtually under galvanostatic control, may continue to rise toward  $C_4$ , giving ultimately the observed change in sign of the difference in potential between the pitting and passive regions. We stress therefore that potentiostatic control does not necessarily insure uniformity of potential at the surface of the working electrode.

# Electret Phenomenological Theory Presented in Linear Systems Formalism

Donald E. Tilley

Department of Physics, Collège militaire royal de Saint-Jean, Saint-Jean, Québec, Canada

## ABSTRACT

Standard techniques for the analysis of linear systems are applied to the phenomenological theory of the electret effect, as developed by Wiseman and Feaster and extended by Perlman and Meunier. A generalized electric susceptibility is introduced which allows electret behavior at constant temperature to be characterized by two functions, the impedance and the short-circuit current. Asch's electret theory is shown to be equivalent to the assumption that the generalized susceptibility is an exponential function.

A phenomenological theory of electrets, based on Gross's two-charge theory (1) and the superposition principle used by Wiseman and Feaster (2) as well as by Perlman and Meunier (3), has been given by the author in a previous paper (4) in a form which allows a simple and unified treatment of several electret problems. In the present paper, this theory is reviewed and amplified with the presentation now given using the most familiar tool for the analysis of linear systems, the Laplace transform. Natural generalizations of the electric susceptibility and the dielectric constant are introduced, and the role of these quantities in electret phenomenological theory is emphasized. Finally, it is shown that this theory includes, as a very special case, the electret theory of Asch (5).

### Generalized Electric Susceptibility

The polarization of a dielectric with a time dependent internal electric field  $E(t)$  depends not only on the present value of the field but also on the history of the dielectric. It is convenient to regard the polarization  $P(t)$  as a sum

$$P(t) = P_i(t) + P_s(t) \quad [1]$$

where  $P_i(t)$  is the polarization which responds practically instantaneously to the applied field, and  $P_s(t)$  is the slow response that is determined by fields that have existed at all previous instants up to the time  $t$ . The method of measurement will determine in a given experiment what response should be classified as instantaneous. In any case, in a linear isotropic dielectric the fast response is given by

$$P_i(t) = \chi_i E(t) \quad [2]$$

where  $\chi_i/\epsilon_0$  is the electric susceptibility characterizing the instantaneous response. (MKS units are used throughout this paper.)

The experiments of Wiseman and Feaster (2) and of Perlman and Meunier (3) show that, at constant temperature, the polarization of Carnauba wax is a linear superposition of the contributions furnished by electric fields applied in the past. This superposition principle can be expressed in several different but equivalent ways. The formulation of the superposition principle given in this paper allows the introduction of natural generalizations of the electric susceptibility and the dielectric constant. We assume that the slow polarization response of a dielectric maintained at constant temperature can be characterized by a response function  $\chi_s(t)$  such that a field  $E(t)$  applied between the times  $T$  and  $T + dT$  produces a polarization which, at a later time  $t$ , is  $\chi_s(t-T)E(T)dT$ . The linear superposition of contributions from all previous electric fields gives the polarization

$$P_s(t) = \int_{-\infty}^t \chi_s(t-T)E(T)dT \quad [3]$$

It is assumed that  $\chi_s(t) = 0$  for  $t < 0$  and that  $\chi_s(t) \rightarrow 0$  as  $t \rightarrow \infty$ . The response function  $\chi_s(t)$  is to be determined empirically and is often assumed to be a sum of exponential decays. Equations [1]-[3] yield, for the total polarization, the expression

$$P(t) = \int_{-\infty}^{t+} \chi(t-T)E(T)dT \quad [4]$$

where

$$\chi(t) = \chi_i \delta(t) + \chi_s(t) \quad [5]$$

and  $\delta(t)$  is the Dirac delta function [ $\int_{-\infty}^{+\infty} \delta(t) = 1$

and  $\delta(t) = 0$  for  $t \neq 0$ ]. The relationship between  $\chi(t)$  and the response function  $\pi(t)$  used by previous workers (2, 3) is  $\chi(t) = d\pi/dt$ . In a pioneering paper on dielectric after-effects (6), Gross expressed the after-current as a superposition of contributions from previous voltage changes and used a response function  $\phi(t)$  which is proportional to  $\chi_s(t)$ .

It is the function  $\chi(t)/\epsilon_0$  which merits the name "the generalized electric susceptibility." The corresponding generalized dielectric constant is  $K(t)/\epsilon_0$  where

$$K(t) = \epsilon_0 \delta(t) + \chi(t) \quad [6]$$

as can be seen by examining the relationship between the electric displacement  $D(t)$  and the electric field. The electric displacement is defined by

$$D(t) = \epsilon_0 E(t) + P(t) \quad [7]$$

Now using Eq. [4], [6], and [7] we obtain

$$D(t) = \int_{-\infty}^{t+} K(t-T)E(T)dT \quad [8]$$

which shows that it is the function  $K(t)$  which enables the electric displacement to be expressed as a superposition of contributions from previous electric fields.

The convolution relationships given by Eq. [3], [4], and [8] in the time domain take on a particularly simple form when one takes either the Fourier transform or the two-sided Laplace transform to pass to the domain of complex frequency  $s$ . Since the transform of the convolution of two functions is the product of the transforms, the transform of the polarization is simply the product of the transform of the generalized electric susceptibility with the transform of the electric field.

In initial value problems, it is convenient to use the one-sided Laplace transform with the lower limit 0- (7). Using the bar notation for such transforms we define

$$\bar{E}(s) = \int_{0-}^{\infty} E(t)e^{-st}dt \quad [9]$$

It is necessary to single out the part,  $P_b(t)$ , of the slow polarization response that arises from electric fields which have existed before  $t = 0$ . Equation [3] gives

$$P_b(t) = \int_{-\infty}^{0^-} \chi_s(t-T)E(T)dT \quad [10]$$

Equations [4] and [10] now yield the simple algebraic relation between Laplace transforms

$$\bar{P}(s) = \bar{P}_b(s) + \bar{\chi}(s)\bar{E}(s) \quad [11]$$

and Eq. [5], [6], [8], and [10] give

$$\bar{D}(s) = \bar{P}_b(s) + \bar{K}(s)\bar{E}(s) \quad [12]$$

Equations [11] and [12] show that, in the complex frequency domain, except for the appearance of the term  $P_b(s)$ , the relationship between the fields and the generalized susceptibility and dielectric constant is the same as the relationship in time domain between the fields and the usual susceptibility and dielectric constant when the response is considered to be instantaneous.

#### Electret Impedance

The formalism introduced in the preceding section can be used to present the solution to the electret field equations in the familiar language of circuit analysis. At the interface of an electrode carrying a real surface charge density  $\sigma(t)$  with a dielectric within which there is an electric displacement  $D(t)$ , Gauss's law gives

$$D(t) = \sigma(t) \quad [13]$$

Differentiation of Eq. [13] yields

$$dD(t)/dt = J(t) - cE(t) \quad [14]$$

where  $J(t)$  is the conduction current density within the electrode and  $cE(t)$  is the ohmic conduction current within the dielectric.<sup>1</sup> Taking Laplace transforms we obtain from Eq. [14]

$$s\bar{D}(s) - D(0^-) = \bar{J}(s) - c\bar{E}(s) \quad [15]$$

Using Eq. [12], the solution to Eq. [14] can be written in the transparent and useful form

$$\bar{E}(s) = \bar{z}(s)[\bar{J}(s) - \bar{J}_b(s)] \quad [16]$$

where

$$\bar{z}(s) = 1/[c + s\bar{K}(s)] \quad [17]$$

and

$$\bar{J}_b(s) = s\bar{P}_b(s) - D(0^-) \quad [18]$$

The electret impedance, in the complex frequency domain, is determined by  $\bar{z}(s)$  which is seen to be a simple function of the conductivity  $c$  and the generalized dielectric constant  $\bar{K}(s)$ .

The quantity  $\bar{J}_b(s)$  is the value of  $\bar{J}(s)$  when  $\bar{E}(s) = 0$  and therefore is named the short-circuit current density. All the effects of the past history (at constant temperature) of the dielectric are included in this term. A useful expression for the evaluation of  $\bar{J}_b(s)$  is obtained by using Eq. [1], [2], [7], and [10], together with Eq. [18] to yield

$$\bar{J}_b(s) = s\bar{P}_b(s) - P_b(0^-) - [\epsilon_0 + \chi_i]E(0^-) \quad [19]$$

In Eq. [19], the quantity  $s\bar{P}_b(s) - P_b(0^-)$  is simply the Laplace transform of  $dP_b(t)/dt$ .

Several applications of Eq. [16]-[18] are given in ref. (4). An important special case arises when the generalized susceptibility function is assumed to involve a sum of two exponentials

$$\chi_s(t) = Ae^{-\alpha t} + Be^{-\beta t} \quad [20]$$

<sup>1</sup> It is assumed that the dielectric is homogeneous and that, within the dielectric, the fields  $E$ ,  $D$ ,  $P$  are uniform.

for  $t \geq 0$ . Such a function, with constants  $A$ ,  $B$ ,  $\alpha$ , and  $\beta$  determined empirically, has been found adequate to give good agreement with experimental measurement of the charge decay at constant temperature of Carnauba wax electrets (2-4). For such a  $\chi_s(t)$ , it is easy to give a simple equivalent circuit for a dielectric slab (4).

#### Asch's Theory as a Special Case

Instead of assuming a superposition principle, Asch (5) postulates that the polarization  $P_s(t)$  satisfies the first order linear differential equation

$$dP_s(t)/dt = -\alpha[P_s(t) - kE(t)] \quad [21]$$

with an initial condition,

$$P_s(0) = P_0 \quad [22]$$

It is interesting to notice that Asch's equations, Eq. [21] and [22], are equivalent to a very special case of the general theory developed in this paper, the case where  $\chi_s(t)$  is (for  $t \geq 0$ ) the single exponential function

$$\chi_s(t) = \alpha ke^{-\alpha t} \quad [23]$$

with the initial polarization given by

$$P_b(0) = P_0 \quad [24]$$

In this case Eq. [3] and [10], together with Eq. [23] and [24] yield

$$P_s(t) = e^{-\alpha t} P_0 + \int_0^t k\alpha e^{-\alpha(t-T)} E(T) dT \quad [25]$$

Now using the familiar rules for the differentiation of an integral it is easy to verify that the  $P_s(t)$  given by Eq. [25] is the solution to Asch's Eq. [21] and [22].

In applying his equations to the case of an electret which is polarized at one temperature and then cooled and maintained, for times  $t \geq 0$ , at a constant final temperature, Asch implies that the effect of the temperature change can be described very simply as follows. For a given value of the initial polarization  $P_0$  at the final temperature, the subsequent electret behavior is independent of the temperatures encountered before  $t = 0$  and therefore is the same as if the electret had been maintained always at the final temperature. With this assumption, the polarization  $P_s(t)$  given by Eq. [25] is, for  $t \geq 0$ , the common prediction of both Asch's theory and the special case of the superposition principle, Eq. [3], which arises when  $\chi_s(t)$  is the exponential function given in Eq. [23].

# The Electret Effect in Ice

J. D. Cross

University of Manchester, Institute of Science and Technology, Manchester, England

## ABSTRACT

The electret behavior of polycrystalline and single crystal ice is investigated by means of measurements of the dipole moment of the samples, the currents flowing during charging and discharging, and the potential distribution within the sample. For comparison, measurements are made of the persistent dipole moment of tetradecanol, carboxylic acid C<sub>20</sub>, and paraffin wax. The results show that in these substances the build-up and decay of space charges contribute to the volume polarization.

The electret effect has been mainly studied in complex materials; although such materials have shown the electret effect very strongly their complexity is a severe hindrance to workers hoping to identify the mechanisms of the electret effect. A suitable material for a study of the mechanisms of electret formation should have a known simple structure, the normal conduction processes should be known, and it should be possible to produce samples of high purity in both polycrystalline and single crystal states. All these conditions are fulfilled by ice, and therefore it was chosen as the principal subject for this investigation. To determine the effect of internal structure on the electret effect behavior measurements were also made on samples of 1-tetradecanol, carboxylic acid C<sub>20</sub>, and paraffin wax.

## Experimental Methods

The quantities measured in this investigation were the macroscopic dipole moment of the electrets, the currents flowing during charging and discharging of the electrets, and the potential distribution within the electrets. All samples were disks 12 mm in diameter and 3 mm thick. Polycrystalline samples were made by allowing materials to solidify in a mould. Single ice crystals were grown by a method described by Jaccard (1), and disks were cut from these. All measurements were carried out at a temperature of  $-70^{\circ}\text{C}$  in a nitrogen atmosphere. In all cases the polarizing field was applied for 30 min. The water used had an impurity content of 7 ppm.

*Dipole moment measurements.*—Measurement of the macroscopic dipole moment of an unshielded electret provides a sensitive method of observing changes in the polarization of the electret without the disturbance produced by the removal and replacement of surface electrodes involved in the usual lifted electrode measurements of the surface charge. The dipole moments were measured with a torsion balance similar to that described by Cross and Hart (2).

A schematic diagram of the balance is shown in Fig. 1. The sample, in the form of a disk, is suspended by a gold ribbon between two parallel plates referred to as the field plates. The upper end of the gold ribbon is attached to a torsion head free from backlash. Mirrors  $M_1$  and  $M_2$  are used in conjunction with a lamp and scale to determine the angular position of the sample with respect to the field plates. When the sample holder is clamped the sliding electrodes can be used to apply the required polarizing field; these electrodes are withdrawn when dipole moment measurements are made.

When a potential difference is applied to the field plates the field so produced interacts with the dipole moment of the sample to produce a torque,  $\tau$ , given by  $\tau = \mu \times E$  where  $E$  is the field applied and  $\mu$  is the dipole moment of the sample. By rotating the head of the suspension on opposing torque is applied to the sample to position the axis of the sample at right

angles to the applied field. The field is then reversed, and the suspension is again rotated to position the axis of the sample at right angles to the field. Readings of the torsion head are taken for each field direction. The angular difference between these two readings is twice the angle of twist necessary to counteract the torque due to the field. The dipole moment can be calculated if the torsional properties of the suspension and the field strength are known. The suspension used had a torsion constant of 0.1 dyne cm/radian, the torsion head could be read to 1 min of arc, the applied field was 0.5 esu/cm and therefore dipole moments of approximately  $10^{-4}$  esu could be measured. To study the electret behavior of a material with this balance a sample is prepared in the form of a disk 12 mm in diameter. The sample is fitted into the holder and the sliding electrodes moved to the required position with respect to the sample, and the polarizing field is applied. After a suitable time interval the polarizing field is removed, the sliding electrodes are withdrawn, and the dipole moment is measured as described above.

*Current measurements.*—When a potential difference is applied to electrodes in contact with an electret material a current flows through the circuit. This current decreases with time to a small constant value. If the source of potential difference is removed and electrodes connected together, a current, which decreases with time, flows in the reverse direction.

Fig. 1. Torsion balance

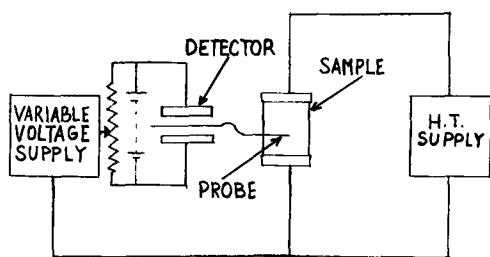

Fig. 2. Schematic diagram of the probe circuit

In this investigation measurements were made of these charging and discharging currents for polycrystalline ice.

**Potential distribution measurements.**—The potential distribution within polycrystalline ice disks, after the application of an electric field by means of electrodes on the surface, was measured by means of three platinum probes inserted at distances of 0.5, 1.3, and 2.5 mm from the cathode. The potential of the probes was determined by a null method. The circuit is shown schematically in Fig. 2. The null detector designed by Hart and Mungall (3) is essentially a robust equivalent of the string electrometer and can easily be constructed to produce a detector with extremely high leakage resistance so that off balance the current drawn by the probe is negligible and at balance there is no current drawn. The sensitivity of the detector was  $\pm 5$ v.

### Results and Discussion

Figure 3 shows the variation of the charging and discharge currents for a sample of ice electrified by applying 3 kv to brass electrodes in contact with the surface. The currents fall off with time reaching almost constant values within 6 min. The total charge liberated on discharging is approximately 150 esu. Figure 4 shows the variation with time of the dipole moment of ice electrified by applying 3 kv to brass electrodes in contact with the sample. The dipole moment corresponds always to a homocharge, the magnitude of which decreases with time. As ice has a low-frequency dielectric constant of approximately 100 the field in the region between an electrode and the sample it is nominally in contact with will be very high, and therefore a considerable amount of charge transfer is to be expected; this may therefore mask any volume effect. To avoid this, samples of ice were electrified by applying a potential difference to electrodes 1 mm from the surface of the samples. Figure 5 shows the dipole moment of ice electrified in this manner as a

Fig. 3. Charge and discharge currents as a function of time for polycrystalline ice electrified between brass electrodes in contact with the surface: applied potential 3 kv.

Fig. 4. Dipole moment as a function of time for polycrystalline ice electrified between brass electrodes in contact with the surface: applied potential 3 kv.

Fig. 5. Dipole moment as a function of time for polycrystalline ice electrified between electrodes 1 mm from the surface: applied potentials 0.5, 1.0, 3.0, 4.0, and 5.0 kv.

function of time after removal of the polarizing field. For applied potentials of 0.5, 1.0, and 3.0 kv the dipole moment corresponds to a volume polarization which decays to zero. For an applied potential of 4 and 5 kv the dipole moment is initially equivalent to a heterocharge, it falls to zero, rises to a maximum value in the opposite direction, and then falls slowly toward zero. This is an electret effect similar to that observed in carnauba wax, the only difference being in time scale. The behavior is explicable in terms of the two-charge theory: ice has a low frequency constant of 100 and therefore with applied potentials of 0.5, 1.0, and 3.0 kv the fields in the air gap between the electrodes and the samples are 2.5, 5.0, and 15 kv/cm, respectively. These fields are too low to cause breakdown in the gap, and therefore no surface charge is deposited, and the dipole moment is due to a heterocharge. With applied potentials of 4 and 5 kv the fields in the air gap are 20 and 25 kv/cm; enhancement by uneven surfaces will produce breakdown, and the observed dipole moment will be the resultant of the volume polarization and a real surface charge.

It should be noted that the dipole moment for samples polarized with "contact" electrodes is approximately one hundred times that for samples electrified with 1 mm air gap. This supports the suggestion that in the case of contact electrodes the high field at the dielectric-electrode interface caused a large transfer of

Fig. 6. Dipole moment as a function of time for single crystal ice electrified between electrodes 1 mm from the surface: applied potentials 2.0 and 4.0 kv.

charge which would have masked the volume polarization present.

Figure 6 shows the dipole moment for single crystal ice electrified between electrodes 1 mm from the surface. The behavior of the single crystal is almost identical to the polycrystalline sample.

The nature of the volume polarization has been a point of dispute in electret studies. The choice lies between a space charge mechanism, a uniform volume polarization, or a combination of the two. All measurements of the internal potential distribution with probes have shown the existence of space charges near the surfaces. X-ray studies of polarized and nonpolarized electrets have failed to show any increased ordering in the polarized electrets. From this evidence it seems that a space charge effect must exist. Objections have been made [Gerson (4)] to the apparent independent decay of a space charge in close proximity with a real surface charge of opposite polarity. This behavior can be explained by a simple model. It is necessary to assume that the surface charges are trapped so that they are not discharged by the approach of a charge carrier forming the space charge, then the situation at the moment the external field is removed is illustrated by Fig. 7. As a simplification the space charges are assumed to exist as a thin uniform layer of charge near each electrode, the charge per unit area being  $Q$ . The trapped surface charge has a density  $\sigma$  per unit area. The electric field at a point in the space charge layer is equal to  $\sigma - Q/KE_0$ , where  $K$  is the dielectric constant of the medium. For  $\sigma > Q$  the surface charge initially predominates, and the internal field holds the space charge to the surface layer. The change in dipole moment is controlled then by the decay rate of the surface charge, the dipole moment reaching zero when  $\sigma = Q$ . This is the behavior shown in Fig. 4 for the sample electrified with electrodes in contact with the sample.

If  $\sigma < Q$  the internal polarization predominates initially, and the internal field results in a migration of the space charge layers to the center of the sample. This migration reduces the contribution of the space charge to the dipole moment, causing the surface

Fig. 7. Schematic diagram of a polarized electret

Fig. 8. Potential distribution within a 3 mm thick sample of polycrystalline ice, 30 min after the application of 1500v to electrodes on the surface.

charge to predominate. The maximum value of the positive dipole moment is reached when the space charges of opposite sign meet. From then on the change in dipole moment is controlled by the decay of surface charge. This is the behavior shown in Fig. 5 and 6 for ice samples electrified between electrodes spaced 1 mm from the surface.

The potential distribution within ice with an applied potential difference of 1.5 kv, measured by the probes, is shown in Fig. 8. The potential distribution shows the existence of a strong positive space charge near the cathode and a very weak negative space charge near the anode. This is to be expected from the theory of electrical conduction in ice proposed by Jaccard (5) in which conduction is attributed to the migration of protons and  $H_3O^+$  ions.

The main experimental evidence against a space charge mechanism is the work by Gross (6) in which measurements were made of the discharge current released when an electret, that had been cooled during polarization, was reheated. The discharge current liberated by sections cut from the electret was found to be independent of the thickness of the sections and of the position in the electret from which the section was taken. This indicated that a uniform polarization was responsible for the current. However, experiments on tetradecanol by Cross and Hart (2) showed that discharge currents are not dependent on internal polarization alone, and the results shown in Fig. 3 and 4 support this view. The surface charge on the ice electret electrified between contact electrodes completely obscures any volume effect and the decay of this major charge concentration must effect the discharge current. Measurements of the discharge current cannot be taken as evidence in favor of a uniform volume polarization unless the contributions of surface effects can be shown to be zero in that experiment.

A uniform volume polarization would arise from a mechanism such as dipole orientation or the short range movements of charges. Such mechanism should be sensitive to the internal structure of the dielectric. To check the dependence of the internal polarization on structure, samples of ice, tetradecanol, carboxylic acid  $C_{20}$ , and paraffin wax were polarized by applying a potential difference of 3 kv to electrodes 1 mm from the surfaces of the samples. The results of these measurements are shown in Fig. 9. All four materials show similar behavior, that is, a slowly diminishing dipole moment corresponding to a volume polarization, yet the structure of the materials differ widely: ice is a purely hydrogen bonded solid. In tetradecanol long hydrogen bonded chains are formed. In carboxy-

Fig. 9. Dipole moment as a function of time for ice, tetradecanol, carboxylic acid C<sub>20</sub>, and paraffin wax, electrified between electrodes 1 mm from the surface. Applied potential 3.0 kv.

lic acid C<sub>20</sub> hydrogen bonded dimmers form and in paraffin as there is no hydrogen bonding.

As the polarization is so little affected by differing structure and crystalline state it is improbable that uniform volume polarization is involved. All dielectrics used in electret studies have a finite electrical conductivity. In any dielectric with a finite electrical conductivity space charges will accumulate near the electrodes applied to the surface if there is any hindrance to the complete discharge of the charge carriers at the electrode. It is impossible to attach removable electrodes to a solid dielectric in such a way that there is perfect electrical contact over the

whole dielectric-electrode interface and, if the surface charge or dipole moment is to be measured, and hence a volume polarization detected, the electrodes must be removable. Therefore in any electret study space charges must accumulate; and in fact whenever they have been directly sought by probe techniques, as in this work and in tetradecanol by Cross and Hart (2) or in carnauba wax [Gemant (7), Antennan (8), Van der Linde (9)], they have been detected.

The conclusion to be drawn is that the persistent volume polarization in electrets must be, at least in part, due to space charges and in simple materials it is wholly due to space charges.

Manuscript received June 29, 1967; revised manuscript received ca. Sept. 27, 1967. This paper was presented at the Electrets Symposium at the Chicago Meeting, Oct. 15-19, 1967, as Abstract 125. This work was supported by a Science Research Council Grant, reference B/SR/4382.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Production and Charge Decay of Film Electrets

Martin M. Perlman<sup>1</sup>

and Cornelis W. Reedyk

*Northern Electric Research and Development Laboratories, Ottawa, Ontario, Canada*

#### ABSTRACT

The object of this work has been to obtain charged dielectric films, electrets, that retain their charge over periods of years when left open circuited. Such films are receiving increasing attention because of their potential use in practical devices such as condenser microphones, electrostatic recorders, air filters, etc. Procedures have been devised to form highly charged thin films and to measure their decay rates. Charge decay comparisons are made among different materials at various temperatures, charged in different ways. A procedure is developed that enables long lifetimes of electrets at room temperature to be predicted by extrapolating short charge decay times at elevated temperatures. A number of materials are identified as suitable for very long-lived electrets.

#### *Production of Electrets with a Large Net Homocharge*

The decay lifetime of the homocharge of an electret is generally much longer than that of the heterocharge. It is desirable therefore to obtain samples with a large net homocharge. The films used in this work vary in thickness between 0.25 and 5 mils. If such a film be charged in the usual way, i.e., by sandwiching between two metal electrodes, applying heat and a field, net heterocharged electrets result. If one attempts to create net homocharged samples by increasing the applied field, the film soon arcs through at a weak point, dust spot, or microscopic inhomogeneity in the surface of the electrodes.

<sup>1</sup> Consultant at Northern Electric Research and Development Laboratories, Ottawa, Ontario, Canada.

Electrets with a large net homocharge may be produced, without arcing, by inserting an appropriate dielectric between metal electrodes and film (1). The dielectric, air gaps, and film then form a 5-layer capacitor, Fig. 1. (The dielectric inserts are metallized on their surfaces remote from the film to eliminate dielectric-electrode air gaps.) The electric fields in the various layers can be determined by applying Maxwell's equations. The expression for the electric fields in the air gaps enables one to explain why electrets with a large net homocharge are obtained using dielectric inserts.

Assuming that the air gaps behave as ideal dielectrics of dielectric constant equal to unity, using the line integral law for electric field, Gauss's law, and

Fig. 1. Five-layer capacitor with dielectric inserts: 1, film; 2, air gaps; 3, inserts; 4, metal electrodes.

the expression connecting electric displacement, field, and polarization, one has (2)

$$E_2 = \frac{V + [d_1(P_1 - \sigma_{r1}) + 2d_3(P_3 - \sigma_{r3})]/\epsilon_0}{d_1 + 2d_2 + 2d_3} \quad [1]$$

where  $E_2$  is the field in the air gaps;  $V$  is the applied charging voltage; subscripts 1, 2, and 3 refer to the film, air gaps, and inserts, respectively;  $d$  is the thickness;  $\sigma_r$  is the real homocharge; and  $P$  is the volume polarization or heterocharge.

At  $t = 0$ , there is no homocharge, i.e.,  $\sigma_{r1} = \sigma_{r3} = 0$ . During charging, the heterocharges  $P_1$  and  $P_3$  increase, and so does the field in the gaps. Eventually, this field will exceed the breakdown strength of the air in the gap, and spray discharges (i.e., homocharge deposition) will occur, increasing  $\sigma_{r1}$  and  $\sigma_{r3}$ . The numerator in Eq. [1] then decreases, and the field in the gap falls to a value below breakdown, quenching the discharges. The heterocharge then continues to increase, and the cycle repeats.

Both heterocharge and homocharge should be present on charging with or without dielectric inserts. However, with inserts, the contribution to the field in the air gap due to the polarization of the inserts relative to that due to polarization of the film is  $2d_3P_3/d_1P_1$ . In these experiments, the latter quantity ranges between 500 and 25, since the insert is 1/16 in. thick, the films are 0.25 to 5 mils thick, and  $P_3$  and  $P_1$  are of the same order. Comparing Eq. [1] with the expression for the field in the air gaps when the inserts are not present (put  $d_3 = 0$  in the numerator of Eq. [1];  $2d_2 + 2d_3$  in the denominator is now the thickness of the air gap), one can see that the gaps will break down many more times during the course of polarization with inserts than without, and one may expect a much larger homocharge in the former case. In Fig. 2, typical voltages across the air gaps are plotted as a function of time in the two cases. Note that the breakdown frequency is much greater in the former case.  $V_0$  is the breakdown voltage of the gaps.

If one attempts to charge an ideal dielectric without inserts,  $d_3 = 0$  in the numerator of Eq. [1], the gap is  $2d_2 + 2d_3$ ,  $\sigma_{r1} = 0$  and  $P_1$  is constant; thus the field in the gap is a constant, and repetitive breakdown cannot occur. With inserts,  $P_3$  varies, and the heterocharge-homocharge cycle takes place. One can of course use a sufficiently high field to create a corona or Townsend discharge and produce homocharge on all films (ideal or not). Charging with inserts produces a large homocharge simultaneous with a volume polarization in nonideal dielectrics, which is desirable for the long-lived electrets considered here.

Most samples were charged with 6 kv applied across the electrodes for 0.5 hr at 120°C. The initial fields were of order 30 kv/cm in the films, 100 kv/cm in the air gaps, and 20 kv/cm in the inserts. Initial charges obtained were about  $5 \times 10^{-8}$  coul/cm<sup>2</sup>. All films were

Fig. 2. Voltage  $V$  across the air gap as a function of time  $t$ ; (a) with inserts (b) with inserts replaced by air gaps.

metallized on one side and stored in microphones, with the charged surface in contact with a metallic backplate. The films were only partially shielded because the average gap between surface and backplate was of the same order as the thickness of the film.

The charges were measured by applying sound pressure to vibrate the film, displaying the output signal on a C.R.O., and applying a d-c bias across the metallized side of the film and backplate sufficient to produce zero output signal (3).

The net surface charge ( $\sigma_r - P_s$ ) and bias  $V_B$  are related by

$$(\sigma_r - P_s) = K\epsilon_0 V_B/d_1 \quad [2]$$

where  $K$  is the dielectric constant of the film, and  $\epsilon_0$  is the permittivity of free space.

#### Typical Homocharged and Heterocharged Film Electrets

All films acquired a large net homocharge when polarized using the inserts; those polarized without the inserts were mainly net heterocharge. Both homocharge and heterocharge were simultaneously present whether samples were charged with inserts or not. This is illustrated in Fig. 3 and 4. In Fig. 3, a 5-mil Mylar sample polarized without inserts had an initial bias of 1200v net heterocharge. (Values stated for the bias  $V_B$  may be converted to net surface charge density,  $\sigma_r - P_s$ , using Eq. [2] with appropriate values for dielectric constant and thickness of the films.) The charge was allowed to decay at room temperature and fell to 200v in about 20 days. The sample was then heated to 80°C to increase the rate of decay. Within 4 hr the net heterocharge decayed to zero and reversed its sign to 48v net homocharge. In Fig. 4, a 5-mil Mylar sample polarized with inserts had an initial bias of 500v net homocharge. The charge was allowed to decay

Fig. 3. Charge decay of a net heterocharged electret (5-mil Mylar charged without inserts).

Fig. 4. Charge decay of a net homocharged electret (5-mil Mylar charged with inserts).

at 80°C. An increase in net homocharge to 750v took place in about 1 hr and then a decay over the next ten days. The initial increase in net homocharge is due to the decay of the heterocharge and is just what one expects if both heterocharge and homocharge are present in a net homocharge sample. The real homocharge in the sample polarized with inserts was at least 15 times greater than in the sample polarized without inserts.

To demonstrate that air breakdown is necessary to produce a homocharge in film electrets, a sample of 0.25-mil Mylar was polarized in a vacuum of  $10^{-5}$  Torr at room temperature. The charge was measured during the polarization process using a dissectible capacitor. A slowly increasing heterocharge was observed over a period of ten days. The sample was then heated and the net heterocharge decayed to zero, rather than reversing the sign of its charge, demonstrating that heterocharge only was present in a vacuum.

The above experiments show that we are dealing with the decay of two coexisting charges, resulting in the decay of a net surface charge, *i.e.*, with a true electret phenomenon in films.

*Charge Decay Comparisons at Various Temperatures*

Charge decay comparisons were made, both at room temperature and at elevated temperature, among many different film materials. The most interesting of the charge decay curves are those of Fig. 5, taken at room temperature. Here, the 1-mil K-1 polycarbonate<sup>2</sup> electret (4) shows no measurable charge decay over a period of 7½ months. These measurements have now been extended. The charge on K-1 polycarbonate shows no measurable decay after 1½ years of storage at room temperature. There are variations of  $\pm 6\%$  in the experimental points about an initial bias of 375v. Figure 6 compares the charge decay of various electret films at 95°C, and Fig. 7 compares K-1 polycarbonate and FEP Teflon<sup>3</sup> at 130°C.

The K-1 polycarbonate electrets are the best of all films tried. They are very long-lived and have the desired mechanical characteristics over a wide temperature range for use in our application, *i.e.*, microphones. Figures 5 and 7 show that whereas K-1 polycarbonate is longer lived than FEP Teflon at room temperature, it is slightly inferior at 130°C. FEP Teflon electrets are the next best choice. They are longer-lived than Mylar<sup>4</sup> and most other films, but tend to flow under stress at elevated temperature.

H-film<sup>5</sup> is poorer than Mylar at room temperature, but better at 95°C. Makrofol KG-polycarbonate<sup>4</sup> and

Fig. 5. Charge decay of various film materials at 25°C

Fig. 6. Charge decay of various film materials at 95°C

Profax<sup>5</sup> form short-lived electrets. Two other films with promising electrical properties are polystyrene<sup>6</sup> and Surlyn.<sup>3</sup> While both have high volume resistivities, they have low service temperatures. Surlyn was longer-lived at room temperature than all other films, with the exception of K-1 polycarbonate. However, its

decay just 10°C above room temperature proved to be more rapid than even that of Mylar.

#### Extrapolation Procedure on Arrhenius Plots

An extrapolation procedure on measurements of short charge decay lifetime at elevated temperature has been developed, which enables a prediction of the long lifetimes at room temperature. In many dielectrics, after decay has taken place for some time, the subsequent decay can be characterized by a single relaxation time  $T_2$ . The dependence of this time on the absolute temperature  $\theta$  is often of the form (5)

$$T_2 = \alpha e^{\epsilon/k\theta} \quad [3]$$

where  $\epsilon$  is an activation energy,  $\alpha$  is constant, and  $k$  is Boltzmann's constant. An "Arrhenius" plot of  $\ln T_2$  vs.  $1/\theta$  usually yields one or more straight lines of different slope. The change in slope takes place at the glass transition temperature.

Figure 8 shows an experimental Arrhenius plot for 1/4-mil Mylar over the temperature range 25°-100°C. Mylar has a glass transition temperature of 80°C. It is amorphous below this temperature and partly crystalline above it. Two straight lines above and below 80°C are evident. Measurements on 1-mil K-1 polycarbonate at 5 different temperatures, and on 1-mil FEP Teflon at 3 temperatures are also plotted in Fig. 8. K-1 polycarbonate is amorphous, and cannot be crystallized at any temperature (6). Thus, hopefully, one straight line can be drawn through the 5 points and extrapolated back to room temperature. This yields a useful life at room temperature in the thousands of years. As stated above, room temperature measurements on the charge of electreted K-1 polycarbonate show no measurable decay over a period of 1½ years. It should also be noted that activation energies may be determined from the slopes of the Arrhenius plots.

#### Parameters Optimizing Lifetime

A theory that relates the net surface charge of electrets to internal field and constants of the material, when the dielectric is polarized at one temperature and decays at another, is not available at present.

Fig. 8. Arrhenius plot of charge decay lifetimes;  $\Delta$ , 0.25 mil Mylar;  $\circ$ , 1 mil K-1 polycarbonate;  $\square$ , 1 mil FEP Teflon.

One can, however, make some guesses as to the parameters that influence lifetime.

The long charge decay lifetimes of net homocharge electrets are due to the presence of two charges of opposite polarity, each of which decays. If both homocharge and heterocharge were to decay at the same rate, the net charge, their difference, would remain constant. Thus comparable rates of decay of homocharge and heterocharge are desirable.

In net homocharge electrets the internal field during decay is in the same direction as that during charging. In general, the volume resistivity must be large ( $> \sim 10^{18}$  ohm-cm) or the homocharge would disappear by conduction in a short time unless the air gaps are zero. The internal field would then be opposite to that during charging, and the decay of the remaining heterocharge would take place in a relatively short time. Since a large resistivity implies a slow rate of decay of the homocharge, one must have a material with a comparable slowly varying polarization, for a long-lived electret.

An imperfectly shielded charged thick sample has a smaller internal field and experimentally, a longer life than a thin sample (2). Crystallinity of the material has an adverse effect on longevity. It may be possible to extend the life of the homocharge by charging under corona at high temperature to produce deep penetration and trapping, and to control the life of the heterocharge by the addition of various ionic impurities to ideal dielectrics.

#### ABSTRACT

A new method of measuring the charge density on a dielectric surface has been developed. An electrode is vibrated in the surface field to produce a signal that is displayed on an oscilloscope, or measured with a VTVM. A bias is then applied across the vibrating and fixed electrodes sufficient to produce zero output signal. The value of this bias and a simple calculation yields the surface charge and its polarity. The method is simple, nondestructive, gives reliable results when compared with other techniques, and has few disadvantages. Measurements may be made at atmospheric pressure without fear of discharges at a wide range of surface-to-electrode gaps. The measurement of the surface charge is independent of circuit parameters.

In 1959, Gubkin *et al.* (1) reviewed various methods of measuring the charge of electrets. This paper outlines the advantages and disadvantages of the various techniques and suggests a new method that is simple and has proven to be reliable.

One of the earliest techniques is that of electrostatic induction, as in Gross (2). The electret is made the dielectric in a dissectible capacitor, whose upper electrode is moveable. To measure the surface charge, the upper electrode is grounded and lowered to induce a charge on it, and then disconnected from ground and raised to transfer this charge to a known capacitor. The voltage across this capacitor is measured and the charge calculated in a simple manner. An inherent disadvantage in the use of the dissectible capacitor is that, except for low surface charge densities, measurements must be made in vacuum to prevent discharges. The discharges in air arise because the field strength in the gap, between the surface of the dielectric and the movable upper electrode, can exceed the breakdown strength of the air, as the electrode is raised for a measurement (3). Another disadvantage is that charges are often generated on contact of the induction electrode and the dielectric (4).

Gubkin (1), Freedman (5), and also Gross (6) have suggested vibrating an electrode or rotating a wafer (10) in the field of the electret, measuring short-circuit alternating current or open-circuit voltage, and relating these quantities to surface charge. While measurements may be conveniently made at atmospheric pressure, ideal short- or open-circuit conditions can never be achieved, and the results must be corrected for circuit parameters.

The charge may of course be determined by applying heat and measuring the resultant thermal depolarization current (9), but this method destroys the sample.

Other methods such as the mechanical displacement of a moveable electrode (1), or the deflection of an electron beam (7) in the field of the electret are cumbersome and have not been widely applied.

#### New Method

In the method suggested here, an electrode is vibrated in the field of the electret to produce a signal that is displayed on an oscilloscope, or measured with a VTVM. A bias is then applied across the vibrating and fixed electrodes (Fig. 1) sufficient to produce zero output signal. The surface charge of the electret is simply related to this bias, the dielectric constant of the sample and its thickness, and is independent of the gap and electrical circuit parameters, as shown below. The polarity of the charge is identical to that of the bias. This method was first used by the authors to study the rate of decay of thin electret films in microphones, as described by Sessler and West (8). Here, an electret film, metallized on one side, was vibrated by sound, and the backplate (electrode) held fixed. The bias was applied as in Fig. 1.

#### Theory

To calculate the electric field in the air gap, apply the line integral law to the two layer capacitor of

Fig. 1. Electrical circuit: 1, vibrating electrode; 2, guardring; 3, air gap  $d_2$ ; 4, dielectric  $d_1$ ,  $K$ ; 5, fixed electrode.

<sup>1</sup> Consultant, Northern Electric Research and Development Laboratories, Ottawa, Ontario, Canada.

Fig. 1, i.e.

$$d_1 E_1 + d_2 E_2 = V \quad [1]$$

where  $d_1$  and  $d_2$  are the thicknesses of sample and gap, respectively,  $E_1$  and  $E_2$  are the electric fields in sample and gap, respectively, and  $V$  is the potential difference between the electrodes. From Gauss's law, one has

$$D_1 - D_2 = \sigma_r \quad [2]$$

where  $D_1$  and  $D_2$  are the electric displacements in sample and gap, respectively, and  $\sigma_r$  is the real charge on the surface of the sample. By definition

$$D_1 = P_1 + \epsilon_0 E_1 \quad [3]$$

where  $P_1$  is the polarization response of the sample to the applied field, and  $\epsilon_0$  is the permittivity of free space. The polarization response  $P_1(t)$  is resolved into two components

$$P_1(t) = P_i(t) + P_s(t) \quad [4]$$

where  $P_s(t)$  is the component that responds slowly to changes in the internal field  $E_1(t)$ , and  $P_i(t)$  is the component that responds practically instantaneously to changes in the internal field and can be characterized by a dielectric constant  $K$ , i.e.

$$P_i(t) = \epsilon_0(K-1)E_1(t) \quad [5]$$

In the air gap,  $P_s(t) = 0$ , and thus combining Eq. [3], [4], and [5] one has

$$D_2 = \epsilon_0 E_2 \quad [6]$$

and

$$D_1 = K \epsilon_0 E_1 + P_s \quad [7]$$

Finally, combining Eq. [1], [2], [6], and [7], the field in the air gap is

$$E_2 = \frac{KV - \left( \frac{\sigma_r - P_s}{\epsilon_0} \right) d_1}{d_1 + Kd_2} \quad [8]$$

where  $(\sigma_r - P_s)$  is the net surface charge density. If now one applies a bias  $V = V_B$  so that  $E_2 = 0$ , Eq. [8] yields

$$(\sigma_r - P_s) = K \epsilon_0 V_B / d_1 \quad [9]$$

Thus the net surface charge of the sample is simply related to the bias that produces zero field in the air gap, and hence zero output signal when the upper electrode is vibrated.<sup>2</sup> The value of the net surface charge, obtained by this method, is also independent of the air gap  $d_2$ . The polarity of the net surface charge (heterocharge or homocharge) is automatically given by the polarity of  $V_B$ .

While the suggested method of measurement is completely independent of the signal voltage and current, it is useful to relate these to surface charge to obtain some idea of the orders of magnitude of the signals involved. Gubkin (1) and Sessler (8) have related the absolute value of the net surface charge to the short-circuit current amplitude and open-circuit voltage amplitude, respectively. The polarity of the charge must be determined independently.

In this paper, a harmonic analysis is made on the electrical mesh of Fig. 1. A general expression is obtained for the output voltage amplitude  $V_o$  in terms of circuit parameters. This result contains Eq. [9] and Gubkin's and Sessler's equations as special cases.

In Fig. 1, applying the principle of continuity at the vibrating electrode, one has

$$I - a \frac{\partial D_2}{\partial t} = 0 \quad [10]$$

where  $I$  is the current in the external circuit and  $a$  is the cross-sectional area of the sample.

<sup>2</sup> It is assumed that during the time the bias is applied the slowly varying polarization  $P_s$  remains constant.

The voltage  $V$  across the electrodes is

$$V = V_B + V_o - V_1 \quad [11]$$

where  $V_1 = IR$  is the voltage drop across resistance  $R$ .

The air gap  $d_2$  is given by

$$d_2 = d_{20} + x \quad [12]$$

where  $d_{20}$  is the equilibrium thickness of the gap and  $x$  is the variation about  $d_{20}$  as the electrode is vibrated.

Combining Eq. [6], [8], [10], [11], and [12], one obtains an equation relating current  $I$  to  $x$ ,  $V$ , and their time derivatives. Assuming that the variables  $x$ ,  $V_o$ ,  $V_1$  can be expanded in a Fourier series, i.e. as

$$A = \frac{1}{2} A_1 e^{j\omega t} + \frac{1}{2} A^* e^{-j\omega t} \quad [13]$$

and keeping only first order terms, one has the following solution for the fundamental frequency mode of operation

$$V_o = (R + 1/j\omega C_o)I + \frac{[V_B - (\sigma_r - P_s) d_1 / (\epsilon_0 K)] C_o v}{j\omega \epsilon_0 a} \quad [14]$$

$C_o$  is the static value of the capacitance of the system, i.e.

$$C_o = \epsilon_0 a / (d_2 + d_1 / K) \quad [15]$$

and

$$v = j\omega \Delta d \quad [16]$$

where  $v$  is the velocity of the vibrating electrode, and  $\Delta d$  is the amplitude of vibration.

There is no output signal under short-circuit or open-circuit conditions when the bias has reduced  $E_2$  to zero so that Eq. [9] applies, since then the coefficient of  $v$  in Eq. [14] is zero. The electromechanical coupling is reduced to zero, and the motion of the system is a function of the mechanical constants only.

Using Eq. [14] with  $R = 0$ ,  $V_o = V_B = 0$ ,  $I = I_o$ , one obtains the following relation between the net surface charge and the short circuit current amplitude  $I_o$ :

$$(\sigma_r - P_s) = (Kd_2/d_1 + 1)^2 d_1 I_o / (Ka\Delta d\omega) \quad [17]$$

This result agrees with Gubkin (1). Combining Eq. [9] and [17]

$$I_o/\Delta d = \epsilon_0 a \omega V_B / (d_2 + d_1/K)^2 \quad [18]$$

Using Eq. [14] with  $I = 0$ ,  $V_B = 0$ , one obtains the following relation between the net surface charge and the open-circuit voltage amplitude  $V_o$ .

$$(\sigma_r - P_s) = - (Kd_2/d_1 + 1) \epsilon_0 V_o / \Delta d \quad [19]$$

This result agrees with Sessler (8).

Combining Eq. [8] or [9] and [19]

$$V_o/\Delta d = E_2 = -V_B / (d_2 + d_1/K) \quad [20]$$

Plots of  $I_o/\Delta d$ ,  $V_o/\Delta d$  vs. gap  $d_2$  using Eq. [18] and [20] are shown in Fig. 2 and 3 for a typical polycarbonate electret film with  $K = 2.9$ ,  $d_1 = 1/4$  mil,  $V_B = 50$  v,  $a = 10$  cm<sup>2</sup>,  $f = 100$  Hz. Note that with gaps ranging from 1 to 4 mm, signals of the order of 1 to 0.3 v/mil of vibration are obtainable.

### Experimental

A preliminary apparatus (Fig. 4) was built to test this idea. It consisted of an electrode made to vibrate by alternating current fed to a solenoid. The assembly was placed over a charged sample that was metallized on one side and provision made to vary the gap  $d_2$ . The electrodes were connected to an oscilloscope, and the bias applied as in Fig. 4. Signals of the order of those predicted were observed. We verified that Eq. [9] is independent of gap (from 0 to 10 mm) and electrical circuit parameters to an accuracy of better than 1%. The charge given by Eq. [9] also agrees with that determined using a dissectible capacitor to bet-

Fig. 2. Short circuit current/amplitude of vibration vs. gap

Fig. 3. Open circuit voltage/amplitude of vibration vs. gap

ter than 1%. A sturdier apparatus is shown in Fig. 5. Here, a motor drives a horizontal rod, eccentrically connected to its shaft. This motion is then translated into a vertical vibration of the upper electrode.

**Conclusions**

A new method of measuring the charge density on a dielectric surface has been developed. The method is simple, nondestructive, gives reliable results when compared with other techniques, and has few disadvantages. A voltage measurement and a simple calculation yield the surface charge and its polarity. Measurements may be made at atmospheric pressure without fear of discharges, at a wide range of gaps, and the surface charge is independent of electrical circuit parameters.

# Preparation and Properties of Vanadium Dioxide Films

J. B. MacChesney, J. F. Potter, and H. J. Guggenheim

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

## ABSTRACT

Phase equilibria of the vanadium-oxygen system have been restudied in the composition range  $\text{VO}_2$ - $\text{V}_2\text{O}_5$  in order to establish the conditions required for stable existence of the  $\text{VO}_2$  phase. Using this knowledge, it was possible to prepare films of  $\text{VO}_2$  exhibiting transition in conductivity between semiconducting and metallic states. Films of  $\text{V}_2\text{O}_5$  were first prepared by vapor deposition of vanadyl trichloride at temperatures below  $127^\circ\text{C}$  in 1 atm of  $\text{CO}_2$ . Reduction of these to  $\text{VO}_2$  was accomplished by heating in controlled atmospheres of appropriate partial oxygen pressure at temperatures between  $500^\circ$  and  $550^\circ\text{C}$ . The resulting thin film ( $0.1$ - $1.0\mu$ ) exhibited a sharp drop (greater than two orders of magnitude) in resistance at the expected transition temperature,  $67^\circ\text{C}$ .

A flurry of interest greeted Morin's discovery in 1959 (1) of unusual semiconducting to metallic transitions in the conductivities of  $\text{VO}_2$ ,  $\text{V}_2\text{O}_3$ , and  $\text{VO}$ . Although, for a time, actively pursued by investigators intent on understanding the mechanism of the conduction anomaly, this interest was largely spent until revived recently. The recent emphasis has been directed toward utilizing this phenomenon in devices. However, difficulties have been encountered in the preparation of the  $\text{VO}_2$  phase in a form applicable to device fabrication. Although methods for the growth of single crystals had been developed (2-4), single crystals were found to be undesirable for this purpose since they tend to disintegrate on cycling through the transition temperature. On the other hand, preparation of dense, sound ceramic bodies has proved difficult (5) due to inability to sinter this oxide by conventional means. Methods for preparing thin films, probably the most desirable form for utilization of  $\text{VO}_2$  in devices, have only recently been reported (6).

In the present work the phase equilibria of the vanadium oxygen system are studied for the range of compositions between  $\text{VO}_2$  and  $\text{V}_2\text{O}_5$ . This knowledge was then utilized to reduce amorphous vanadium pentoxide films to polycrystalline vanadium dioxide films. Resistance measurements of these showed an abrupt change at the appropriate transition temperature which was comparable in magnitude to that of single crystals.

## Experimental Procedures

Although the phase relations of the vanadium oxygen system are generally known (7-10) the conditions of temperature and oxygen partial pressure necessary for the stable existence of vanadium dioxide are uncertain. Since knowledge of these parameters is indispensable to the purpose of this investigation, our first step was to determine representative oxygen isobars for the liquidus region of the diagram  $\text{VO}_2$ - $\text{V}_2\text{O}_5$ . For this study both the quenching technique and weight changes, measured by means of a recording Chevrand thermobalance, were employed. In both cases, controlled atmospheres consisting of carbon dioxide or mixtures of carbon monoxide and carbon dioxide were used. Desired mixtures were obtained using commercially available flowmeters; compositions of these were determined using a gas chromatograph (L&N Chromolax II) which had been calibrated by gas mixtures of known composition. The phase assemblage of each quenched specimen was determined by x-ray diffraction.

Thin films of crystalline  $\text{V}_2\text{O}_5$ , suitable for reduction to  $\text{VO}_2$  were prepared by vapor deposition on polished single crystal sapphire substrates. The apparatus used for deposition is shown in Fig. 1. It consists only of a bell jar with a side arm to permit intro-

duction of  $\text{CO}_2$  and a heater. Vaporization was carried out in 1 atm of  $\text{CO}_2$  by heating  $\text{VOCl}_3$  to near its boiling point while maintaining the substrates at temperatures between  $60^\circ$  and  $120^\circ\text{C}$ . Vaporization was continued until films of desired thickness (approximately  $1\mu$ ) were attained. Subsequent annealing was carried out at temperatures sufficiently below the melting point of  $\text{V}_2\text{O}_5$  to prevent the formation of a liquid phase which would separate into globules on the substrate surface. Resistance measurements of these specimens were made using indium-gallium stripes drawn on their surface as electrodes. These films were further characterized by electron microscopy, and electron and x-ray diffraction.

## Results and Discussion

We should like to preface discussion of our results by a brief description of the phase equilibria of the vanadium oxygen system. It will be appreciated that these can be studied as either a closed or an open system. Most previous studies have been made on the closed system. By this technique various mixtures of vanadium oxides whose total composition is that desired are equilibrated in sealed containers. As such, the amount of oxygen in the container is fixed, and at equilibrium the total composition of the condensed phase or phases will be essentially that of the initial mixture, with only a small pressure of oxygen present in the gas phase filling the volume of the container. Our studies have been made on the open system. Here the total composition of the condensed vanadium oxide phase assemblage changes in response to the oxygen

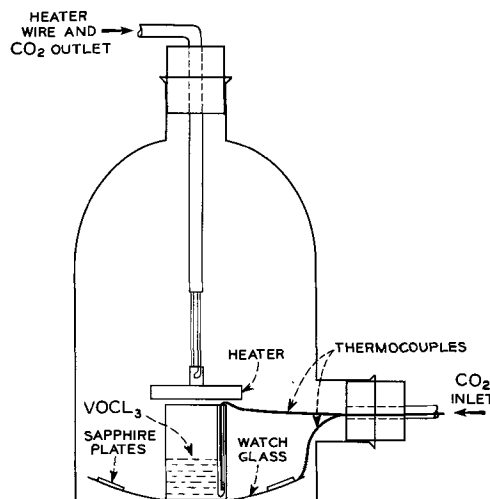

Fig. 1. Experimental apparatus used for deposition of amorphous  $\text{V}_2\text{O}_5$  coatings from  $\text{VOCl}_3$ .

Fig. 2. Phase diagram for vanadium-oxygen system reconstructed from Kachi and Roy (10). Heavy dash-dot lines are oxygen isobars which have been determined for the Liquid + VO<sub>2</sub> and VO<sub>2</sub> + VO<sub>2.17</sub> phase regions. Estimates of the positions of those in adjoining areas of the diagram are shown by light dash-dot lines.

partial pressure of the furnace atmosphere until equilibrium is attained.

Such changes can be visualized by the use of oxygen isobars. These show the change in total composition taking place at fixed partial oxygen pressure in response to changes in temperature. In Fig. 2, a portion of the vanadium-oxygen phase diagram is shown for compositions from VO<sub>2</sub>-V<sub>2</sub>O<sub>5</sub>. The diagram is based on that of Kachi and Roy's (10), but has been modified to show the existence of VO<sub>2.33</sub> (9) and also by the imposition of representative oxygen isobars obtained from the present study. Dashed portions of these show expected trends of such curves in phase regions not extensively studied in the present work.

The significance of these isobars to the present work will become obvious if one recalls the phase rule

$$P + F = C + 2$$

where  $C$  is the number of components of a system,  $F$  is the number of degrees of freedom, and  $P$  represents the number of phases present at equilibrium.

In the present system there are two components, vanadium and oxygen, so that  $P + F = 4$ . First let us consider that portion of the diagram representing a single liquid phase. At equilibrium, in addition to the condensed phase, a gas phase is present containing oxygen at a pressure of 1 atm or less. In this situation, two degrees of freedom remain so that, within limits, both temperature and oxygen partial pressure can be changed without altering the phase assemblage.

But what happens when these limits are exceeded? Specifically, what happens when the temperature or the oxygen pressure is fixed such that the composition of the system is changed so as to cross the liquidus curve separating the liquid phase region from that of crystalline VO<sub>2</sub>? Now three phases are present, and only one degree of freedom remains. In order to maintain two condensed phases (crystalline VO<sub>2</sub> and liquid) in equilibrium, the temperature and oxygen pressure can no longer be independently varied. Instead, VO<sub>2</sub> and liquid are stable only at a single oxygen partial pressure at a single temperature. In practice then, reduction of the oxygen partial pressure at fixed temperature or increasing temperature at fixed oxygen partial pressure will ultimately bring about the complete precipitation of the liquid phase as VO<sub>2</sub>. It can be shown by similar reasoning that VO<sub>2</sub> can be ob-

tained from other crystalline phases in the same manner at lower temperatures.

With this in mind we can simplify the diagram of Fig. 2 to describe more readily the conditions necessary for the stable existence of VO<sub>2</sub> at equilibrium. Since temperature and oxygen pressure are not independently variable when two condensed phases are present, the two-phase region of the diagram of Fig. 2, will become a line on the diagram of  $\log P_{O_2}$  vs.  $10^4/T$  ( $^{\circ}K^{-1}$ ). Such a diagram, Fig. 3, has been constructed from the data of the present study. Here, phase fields of VO<sub>2</sub>-liquid and VO<sub>2</sub>-VO<sub>2.17</sub> are separated by the solid line representing the conditions necessary for the existence of these phases at equilibrium. Dashed lines again are used to represent estimates of conditions giving rise to univariant equilibria involving other vanadium oxide phases.

Before proceeding to describe preparation of films it is important to point out that the oxygen pressures referred to in this discussion are calculated from the standard free energy change for the reaction

An equilibrium constant can be written for this reaction

$$K = \frac{P_{O_2} \cdot P_{CO}^2}{P_{CO_2}^2}$$

from which the oxygen partial pressure is defined by the familiar expression:

$$\begin{aligned} \Delta F^{\circ} &= -RT \ln K \\ &= -RT \ln \left( \frac{P_{CO}^2}{P_{CO_2}^2} \cdot P_{O_2} \right) \end{aligned}$$

In its evaluation, standard free energy values of Coughlin (11) were used, and experimental CO/CO<sub>2</sub> ratios were provided by gas chromatograph readings.

### Preparation of Thin Films

Vapor deposition was attempted using several halide and metallo-organic compounds of vanadium. Among these VOCl<sub>3</sub> (vanadyl trichloride) proved to be satis-

Fig. 3. Diagram of  $\log P_{O_2}$  vs.  $10^4/T^{\circ}K^{-1}$  showing boundary between VO<sub>2</sub>-liquid and VO<sub>2</sub>-VO<sub>2.17</sub> phase fields. Dashed lines are sketched to illustrate positions of phase boundaries of adjacent phases.

factory. Not only is its boiling point low, but also its vapor is decomposed at low temperatures to yield  $V_2O_5$ . We conceive of this decomposition taking place by the reaction

This supposition is strengthened by chromatographic analysis which found phosgene among the effluent gases.

Thin films can be deposited quite rapidly (greater than  $1\mu/hr$ ), even using the rather crude apparatus described which was not intended to optimize the rate. The films produced were amber and transparent. Electron diffraction patterns showed these films to be crystalline  $V_2O_5$ . A typical electron micrograph of the surface (Fig. 4) shows a poorly developed microstructure composed of grains between 0.01 and  $0.1\mu$ .

In reducing these films to  $VO_2$  it was found necessary to remain well below liquidus temperatures. Apparently the liquid oxide phase does not wet the sapphire surface so that the film separated into droplets on the surface whenever reduction was attempted above  $550^\circ C$ . At the same time lowering the annealing temperature very much below this temperature presents a problem. Here, at the relatively high  $CO/CO_2$  ratios needed to accomplish reduction of these films, carbon monoxide will be decomposed to graphite according to the reaction.

Thus there is a lower limit to the temperature range over which reduction can be accomplished using these gas mixtures.

After reduction under the conditions described in Table I, these films were again viewed by electron microscopy. Figure 5 shows a typical surface. Individual crystallites measuring up to  $500\text{\AA}$  can be recognized. The micrograph also shows blistering which is probably caused by release of volatile components during annealing. Talysurf measurements of this film show its thickness to range between 6500 and 9000 $\text{\AA}$ . X-ray diffraction patterns from the surface show the film to be  $VO_2$ . No other phases can be recognized.

Resistance measurements over the range of  $25^\circ$  to approximately  $100^\circ C$  are shown by Fig. 6. Here re-

sistance (ohms/square) is plotted vs. reciprocal temperature ( $10^3/T^\circ K^{-1}$ ). It is to be observed that, on heating to  $65^\circ C$  (2.96 on the reciprocal temperature scale), there is a drop in resistance of more than three orders of magnitude. A hysteresis amounting to between  $7^\circ$  and  $8^\circ C$  is observed in the cooling curve of this figure.

Another experiment which may be of interest to persons concerned with this subject was carried out in conjunction with Rozgonyi and Polito. They prepared polycrystalline  $V_2O_5$  films of 2000 $\text{\AA}$  thickness by oxi-

dizing sputtered vanadium deposits.<sup>1</sup> These were then reduced in mixtures of CO/CO<sub>2</sub> as also described in Table I. Resistance measurements for one such film are shown in Fig. 7. It will be observed that the character of the curves are similar to those shown in the preceding figure. However the transition temperature is slightly higher, 67°C (2.93 on the reciprocal temperature scale). Also it appears that the material behaves as a semiconductor both above and below the transition.

### Discussion

The reader has probably observed that we have taken some pains in our annealing experiments always to approach the  $VO_2$  phase from an oxygen rich composition. This was done to take advantage of the favorable kinetics provided by carrying out the reductions at temperatures only 100°C below the eutectic temperature in the system  $VO_2$ - $V_2O_5$ . This is also thought to provide an additional advantage by retarding the rate at which reduction of  $VO_2$  to phases of lower oxygen content takes place. We have shown in another paper (12) that reduction, even when carried out at oxygen partial pressures appreciably below that in equilibrium with  $VO_2$  phase, can still yield this phase provided that the annealing is not too prolonged.

Another comment on this work concerns the purity of vapor deposited films. After completing the work described above we performed an additional evaporation, employing the same conditions but depositing on a large graphite plate. This provided enough specimen for semiquantitative spectrographic analysis. Results given in Table II show the deposit to be contaminated. These impurities are thought not to be derived from the graphite plate, rather, we think, they result from attack by the vapor species of the nichrome heating elements and its support which were suspended in the bell jar. Obviously this can be eliminated by a different experimental arrangement. However, it is surprising that the properties of these films are not appreciably degraded by high levels of impurities. Although

<sup>1</sup> See "Preparation of Thin Films of Vanadium (Di-, Sesqui-, and Pent-) Oxide" by G. A. Rozgonyi and W. J. Polito, *This Journal*, 115, 56 (1968).

Table II. Impurity levels of vapor deposited thin films

	w/o		w/o
Aluminum	0.X	Copper	0.00X
Iron	0.0X	Titanium	0.00X
Silicon	0.0X	Lead	0.00X
Nickel	0.00X	Magnesium	0.00X low
Tin	0.00X	Manganese	0.000X low

the impurities may contribute to the slight lowering of the transition temperature of the vapor deposited films compared to that of the sputtered vanadium film, and single crystals (1), they have not drastically "smeared" the transition or affected the apparent resistivity of these films.

### Conclusions

Investigation of the phase equilibria of the vanadium-oxygen system has resulted in a further definition of the limits of temperature and oxygen pressure for the stability of the  $VO_2$  phase field. Using these data it was possible to prepare specimens exhibiting a sharp drop in resistivity characteristic of the phase transition between the monoclinic and tetragonal polymorphs of that phase.

Thin films of amorphous  $V_2O_5$  were first prepared on sapphire substrates by vapor deposition. Here,  $VOCl_3$  was vaporized by decomposing  $VOCl_3$  vapor in 1 atm of CO<sub>2</sub> and then converting this to  $VO_2$  by suitable annealing at low oxygen partial pressure. Thin films produced in this manner were shown to have electrical properties typical of the vanadium dioxide and comparable to single crystals of that phase.

### Acknowledgments

The authors are indebted to Miss S. E. Koonce for electron micrographs and to D. L. Nash for spectrographic analysis. They also wish to thank M. D. Rigerink for helpful comments on the text, and to acknowledge useful discussion with W. R. Sinclair, P. J. Fillingham, and G. A. Rozgonyi.

Manuscript received July 25, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract No. 19.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Preparation of Thin Films of Vanadium (Di-, Sesqui-, and Pent-) Oxide

G. A. Rozgonyi and W. J. Polito

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

## ABSTRACT

Polycrystalline thin films of  $V_2O_3$ ,  $VO_2$ , and  $V_2O_5$  have been prepared in the thickness range from 500 to 4000Å. The films are obtained by a post-deposition heat-treatment of sputtered V or V-O films. The quality of the films has been studied by x-ray diffraction techniques and by measuring resistivity as a function of inverse temperature to check the magnitude of the metal to semiconductor transition. Electrically the films compare favorably with bulk crystals, and in addition the films are extremely stable during repeated cycling through the transition temperature.

Since Morin (1) reported on the metal to semiconductor transition in certain oxides there has been considerable interest in the preparation and properties of single crystals of the oxides of vanadium. Vanadium dioxide,  $VO_2$ , which gives rise to a conductivity change of up to  $10^4$  at 338°K has received the most attention (2-7) due to the very convenient transition temperature. However, for fundamental studies and some more restricted device applications vanadium sesquioxide,  $V_2O_3$ , with a conductivity change of greater than  $10^6$  at 168°K, is also of great interest (8-10). A serious problem encountered with both  $V_2O_3$  and  $VO_2$  is a tendency for bulk crystals to fracture. This fracture, plus the need for material in configurations compatible with modern device technology, has stimulated our effort to deposit thin films of the above oxides.

Previous work on thin films has been restricted to the deposition of  $VO_2$  films. The films were obtained either by vapor deposition techniques (11,12) using  $VOCl_3$  or by reactive sputtering of vanadium in argon and oxygen mixtures (13). Since difficulties have been encountered in obtaining consistently reproducible results on these films simple postdeposition annealing of films was attempted. Considerable success was achieved in obtaining uniform large area films of  $V_2O_5$  and  $V_2O_3$ , as well as  $VO_2$ , by choosing a suitable oxidizing or reducing atmosphere while treating sputtered V or V-O films.

## Apparatus and Procedures

Experimentally the vacuum system is identical to that used previously for the sputtering of ZnO (14) with the ZnO cathode replaced by  $V_2O_5$ . However, due to the complexity of the oxidation states of vanadium it was not possible to deposit crystalline films reproducibly and directly, as was accomplished with ZnO. Therefore, postdeposition treatments were devised which recrystallized the films such that their properties were comparable to bulk single crystals. Vanadium films sputtered in conventional bell jar systems were also studied. Substrate materials included single crystal sapphire and amorphous Pyrex glass slides with the best results obtained on the sapphire.

Depending on the oxide desired the films were annealed in the presence of three different flowing gases in three separate open tube furnaces. The gases were water vapor, a mixture of 90%  $N_2$ -10%  $O_2$ , and  $H_2$  which had been bubbled through water. The optimum conditions for obtaining the V-O composition of interest are presented in Table I. No attempt has been made in this study to determine the exact conditions of temperature and oxygen partial pressure necessary for the stable formation of a particular V-O phase. The choice of gas was based simply on its expected oxidizing ( $N_2$ - $O_2$ ,  $H_2O$ ) or reducing ( $H_2$ ) properties.

Attempts at varying the conditions of the wet  $H_2$  treatment to obtain a crystalline phase intermediate to  $V_2O_3$ - $V_2O_5$ , specifically  $VO_2$ , were not successful. This is consistent with the work of Gel'd *et al.* (15) who found that, although  $VO_2$  and  $V_6O_{13}$  were detected during the reduction of powders of  $V_2O_5$  in  $H_2$ , single phases of these compositions could not be formed.<sup>1</sup> In order to obtain  $VO_2$  films the water vapor treatment was used to provide a slightly oxidizing atmosphere for the sputtered V-O films. The exact composition of the thin (500-4000Å), as-sputtered films could not be determined because of the small amount of material and its amorphous nature. However, since they were sputtered in pure argon it is expected that the  $V_2O_5$  cathode material converted to  $V_2O_3 + O_2$  and that the resulting film stoichiometry was of a phase lower in oxygen than  $VO_2$ .

## Results and Discussion

The films were evaluated crystallographically by x-ray powder diffraction techniques and electrically by plotting the resistivity as a function of inverse temperature. A standard four-point probe with 0.010 in. separation was used for the resistivity measurements. Figure 1 shows the  $\rho$  vs.  $1/T$  data for the phases of interest. The metal-to-semiconductor transitions in  $V_2O_3$  and  $VO_2$  films are of the same magnitude as those reported for bulk material (1) and occur at approximately the same temperatures. The semiconductor behavior of  $V_2O_5$  films over the entire temperature range studied is also consistent for that material (2). The width of the hysteresis and the relatively soft behavior at the transition is most likely due to the polycrystalline nature of the films, and the resulting grain boundary effects, although strain introduced at the film-substrate interface, may also be important. Slight chemical inhomogeneities are also possible, and, in certain films, an extra x-ray diffraction line was observed at  $d = 2.25$ . This line could not be unequivocally assigned to any one phase, but it is suspected to be a reflection from  $VO_{1.87}$ . However, the metallic behavior and positive temperature coefficient of resistance in the high temperature regions indicate that the electrical behavior is not seriously effected by extraneous phases. X-ray photographs were taken with Ni filtered  $Cu-K_{\alpha}$  radiation at a fixed beam incidence of  $16^\circ$ , treating the polycrystalline film as if it were a powdered sample. The x-ray results are presented in Table II and compared with the ASTM data for the various phases. The grain size of all films was estimated to be less than 100Å.

The resistance of these films to fracture was checked by cycling the  $VO_2$  samples from room temperature to  $\sim 100^\circ C$  on a hot plate and dipping the  $V_2O_3$  sam-

<sup>1</sup> It should be noted that MacChesney (11) has reduced our  $V_2O_5$  films to  $VO_2$  using a  $CO/CO_2$  reducing atmosphere.

Table I. Optimum conditions for preparation of vanadium oxide films

Desired film	Initial sputtered or recrystallized film	Annealing conditions		
		Atmosphere	Temp, °C	Time, hr
V <sub>2</sub> O <sub>5</sub>	Amorphous V-O or Polycrystalline V	90% N <sub>2</sub> -10% O <sub>2</sub>	500	4
V <sub>2</sub> O <sub>3</sub>	Recrystallized V <sub>2</sub> O <sub>5</sub>	Wet H <sub>2</sub>	550	1
VO <sub>2</sub>	Amorphous V-O Recrystallized V <sub>2</sub> O <sub>5</sub> *	Water vapor	450	4

\* See (11) for details.

ples in and out of liquid nitrogen at least 12 times. The samples would undergo repeated resistance changes of  $>10^3$  ohms for VO<sub>2</sub> and  $>10^7$  ohms for V<sub>2</sub>O<sub>3</sub> as measured with a simple ohmmeter. A point-by-point measurement after the above cycling did not reveal any change in performance.

It has been demonstrated that polycrystalline films of V<sub>2</sub>O<sub>5</sub>, VO<sub>2</sub>, and V<sub>2</sub>O<sub>3</sub> can be prepared by a suitable postdeposition heat-treatment of sputtered V or V-O films. The VO<sub>2</sub> and V<sub>2</sub>O<sub>3</sub> films exhibit metallic-semiconductor behavior characteristic of bulk vanadium oxides with the added feature of stability and resistance to fracture during repeated temperature cycling. It is expected that these films will prove to be reproducible and stable samples for further investigations into the properties of vanadium oxides and the mechanism of the metal-to-semiconductor transition.

# The Measurement of Ionic Mobilities in the Anodic Oxides of Tantalum and Zirconium by a Precision Sectioning Technique

J. L. Whitton<sup>1</sup>

Research Chemistry Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada

## ABSTRACT

The technique of removing thin sections of anodic oxides by vibratory polishing has been used in conjunction with implantation of anion, cation, and inert gas radiotracers to measure the mode of anodic oxide formation on Zr and Ta. The measured transport number for metal during the growth of  $Ta_2O_5$  (0.28) is in good agreement with previous work.  $ZrO_2$  is shown to grow by oxygen migration and preliminary experiments suggest that the process occurs by rapid movement of the oxygen along defects. Comparison of the movement of anion and cation radiotracers with that of an inert gas provides additional evidence that xenon and krypton may be regarded as immobile markers for use in oxidation studies.

The transport mechanism responsible for oxide film growth on metals, i.e., whether growth occurs by metal or oxygen migration or both, can best be measured by the use of inert markers. These markers can be placed initially on, or just beneath the surface of the specimen, and any change in their location, due to subsequent oxidation, is then directly related to the transport mechanism involved.

The best type of marker for thin anodic films is an inert radiotracer injected at a known depth by means of an isotope separator (the conventional embedded Pt wire method is not suitable for oxides of thicknesses less than a few microns). This radiotracer method, using  $^{125}Xe$  as the radioactive marker has been used previously [(1) and references cited therein] to study the anodic oxidation mechanisms of several "valve" metals, including Zr and Ta, the position of the Xe before and after oxidation being determined by  $\beta$ -ray spectroscopy.

A detailed pictorial illustration of the method of obtaining transport numbers from these radiotracer measurements is shown in Fig. 1. The initial location of injected Kr atoms in an oxide layer is shown. In the case where the oxide grows by oxygen migration alone, the marker atoms stay at the same distance from the outer surface; where only metal migration occurs the marker atoms remain at the same distance from the metal-oxide interface; and where a combination of metal-oxygen migration occurs, the marker atoms are buried to an intermediate depth which depends on the ratio of metal to oxygen ion mobility.

As noted in the previous work (1), the ideal marker atoms should be immobile and should not significantly change the properties of the oxide in which they are embedded. Hence, they should be: (i) uncharged, so that no movement occurs due to the applied electric field, (ii) large in size, so that diffusion within the oxide is not a significant factor, and (iii) present in trace amount, so that the macroscopic properties of the oxide remain unaltered. Inert gas isotopes, such as  $^{125}Xe$ ,  $^{133}Xe$ ,  $^{85}Kr$  etc., are expected to fulfill rather closely these requirements of the ideal marker.

Although it is difficult to devise an experiment to show unambiguously that the inert gas markers are or are not immobile, some indication of this can be expected by comparison of the behavior of inert gas atoms with that of anions and cations. This type of experiment can best be performed by injecting two or more radiotracers in the same specimen, then locating simultaneously their positions relative to each

other. The results of such experiments are reported here.

A new method of determining the locations or depth distributions of the radiotracers before and after oxidation has been used. This is a method of precise sectioning using a vibratory polisher which allows layers as thin as 20Å to be removed. As successive layers are removed, the fraction of tracer remaining is determined by measurement of the residual activity, thus providing a direct measure of the location and depth distribution of the markers.

## Experimental Method

The sectioning technique makes use of a commercial vibratory polisher<sup>2</sup> and has been described previously (2). Briefly, the specimens to be sectioned are prepared in the form of right cylinders  $\sim \frac{1}{2}$  in. diameter by  $\sim \frac{3}{4}$  in. long. These have one face mechanically polished on carborundum paper, then on successively finer diamond grit down to 0.25  $\mu m$  before being finally vibratory polished in an aqueous slurry of 0.05  $\mu m$  Linde A  $Al_2O_3$  for 72 hr. It has been shown (2) that this treatment leaves a virtually undeformed mirror-like surface.

The anodic oxide films required for the sectioning procedure were prepared by anodizing vibratory polished surfaces of Ta and Zr at 1 ma/cm<sup>2</sup>, using 0.1M

<sup>2</sup> Syntron Company, Homer City, Pennsylvania.

Fig. 1. A schematic representation of the effect of metal and oxygen migration on the final position of an inert marker in an oxide film.

<sup>1</sup> Present address: Department of Electrical Engineering and Electronics, The University of Liverpool, Liverpool, England.

H<sub>2</sub>SO<sub>4</sub> as the electrolyte for tantalum and saturated ammonium borate for zirconium.

The rate of removal of Ta<sub>2</sub>O<sub>5</sub> and ZrO<sub>2</sub> was calibrated by observing optically the residual oxide thickness after each layer was removed, and plotting this thickness vs. the polishing time. The oxide thicknesses were measured on a u.v. spectrophotometer, using the interference minima-oxide thickness calibration data of Young (3) for Ta<sub>2</sub>O<sub>5</sub> and of Wilkins (4) for ZrO<sub>2</sub>. The rate of removal of Ta<sub>2</sub>O<sub>5</sub> is shown in Fig. 2; the slopes correspond to a rate of 50Å/min of vibratory polishing. The ZrO<sub>2</sub> removal rate (Fig. 3) is not so uniform initially but becomes reasonably constant after the first 100Å. As the removal rate is less than 5 atom layers per minute of vibratory polishing, it is perhaps not too surprising to find that the rate differs somewhat from one experiment to the other. It means,

Fig. 2. Spectrophotometric calibration of sectioning method for Ta<sub>2</sub>O<sub>5</sub>: X, specimen 1; ●, specimen 2.

Fig. 3. Spectrophotometric calibration of sectioning method for ZrO<sub>2</sub>: Δ, X, ●, +, specimens 1, 2, 3, and 4.

however, that a more careful spectrophotometric control is required for ZrO<sub>2</sub> than for Ta<sub>2</sub>O<sub>5</sub>.

The choice of radiotracers was governed by the need to have (i) an anion, a cation, and an inert gas, (ii) such a trio having approximately the same mass so as to have the same initial depth distribution, and (iii) having activities that could be determined independently by a combination of radioactive measuring techniques.

The trio <sup>82</sup>Br, <sup>85</sup>Kr, and <sup>86</sup>Rb fulfill these requirements. Conditions (i) and (ii) are obviously met and condition (iii) also, as <sup>82</sup>Br and <sup>86</sup>Rb emit β<sup>-</sup> particles and gamma rays while <sup>85</sup>Kr is an almost pure β<sup>-</sup> emitter. These properties, therefore, make it possible for the inert gas and the anion or the inert gas and the cation to be injected in the same specimen and the precise location of each isotope determined by a combination of sectioning, measuring the β and γ activities and comparing these measurements to a standard source of each isotope.

In a typical experiment, two specimens of Ta, anodized to 20v in order to form an oxide layer ~ 400Å thick, were used. The Chalk River isotope separator (5) was utilized to inject 30 kev <sup>85</sup>Kr and <sup>86</sup>Rb into one and 30 kev <sup>85</sup>Kr and <sup>82</sup>Br into the second. The depth distributions of these embedded atoms were then measured by removing successive thin layers on the vibratory polisher and using the isotope-selective β- and γ-counting technique to determine at each stage the residual activity of both radiotracers independently.

The anodizing and injection procedure was then repeated but the oxide layer was increased to a total thickness of 1600Å (80v) before the depth distribution was measured. The depth distributions of each isotope were again obtained by β- and γ-counting.

Results and Discussion

The distribution of the three isotopes in Ta<sub>2</sub>O<sub>5</sub> before and after oxide growth is shown in Fig. 4. It is assumed at this point that Kr is a truly immobile marker, so the abscissa scale for the initial distribution (upper scale) has been displaced to make the two Kr peak positions coincide. The fraction of oxide growth by metal migration outward is then immediately seen. Of the extra 1200Å of oxide grown, 340Å are due to metal migrating outwards, and hence 860Å are due to oxygen moving inwards. This gives a transport number for the metal of 0.28 ± 0.03 in good agreement with the previous values of 0.31 ± 0.03 by β-ray spectrometry (1) and of 0.255 ± 0.004 by a chemical stripping method (6).

Fig. 4. Differential distribution of 30 kev <sup>86</sup>Rb, (●), <sup>85</sup>Kr (x) and <sup>82</sup>Br (Δ) in Ta<sub>2</sub>O<sub>5</sub> before (---) and after (—) additional anodizing. The abscissa scale for the initial distribution has been shifted by 340Å (upper scale) in order to make the <sup>85</sup>Kr peak positions coincide.

Fig. 5. Differential distribution of 30 keV  $^{86}\text{Rb}$ , ( $\bullet$ ),  $^{85}\text{Kr}$  ( $\times$ ) and  $^{82}\text{Br}$  ( $\Delta$ ) in  $\text{ZrO}_2$  before (---) and after (—) additional anodizing.

The final locations of  $^{82}\text{Br}$  and  $^{86}\text{Rb}$  indicate that bromine migrates inwards, but with two thirds the mobility of the oxygen, and that the rubidium migrates outwards with two thirds the mobility of the Ta. Qualitatively, this behavior is what would be predicted from simple chemical considerations, *viz.*, that Br migrates as an anion, and Rb as a cation. The broadening of the Br peak may be attributed to the combination of (i) a random walk broadening due to movement of the ions during oxide growth and (ii) the preferential removal of oxide from the edges of the specimen [c.f. ref. (2)].

The location of Kr, Br, and Rb in  $\text{ZrO}_2$  after anodic oxidation is shown in Fig. 5, where again the initial distribution of the three isotopes is shown by the dotted line. In this case the final distribution curves are virtually the same as the initial one (except for a slight broadening), indicating that no new oxide has been formed on the surface, and that therefore all the oxide formation is by oxygen migrating inwards. This is in agreement with the previous work (1).

However, it is interesting to note that although zirconium oxide grows almost completely by oxygen migration, the Br anion does not move appreciably as it does during the growth of tantalum oxide (Fig. 4). This would indicate that in  $\text{ZrO}_2$ , a large monovalent ion such as  $^{82}\text{Br}$  has a negligible mobility compared to the oxygen ion. An alternative possibility is that oxygen movement in  $\text{ZrO}_2$  is by way of holes, grain boundaries, defects, etc. Such a transport mechanism might not be available to the marker atoms because these are embedded uniformly at a depth of about 100 Å in the oxide lattice.

It is known that anodically formed  $\text{Ta}_2\text{O}_5$  is amorphous (7) while  $\text{ZrO}_2$  formed anodically in saturated ammonium borate is crystalline (8) and may contain defects such as holes, cracks, etc. This information strengthens the latter explanation but a more direct method of testing it would be to add  $^{82}\text{Br}$  atoms to the electrolyte and then measure their uptake into a growing  $\text{ZrO}_2$  film, and their final depth distribution within the  $\text{ZrO}_2$  layer.

Preliminary experiments of this type indicate that an appreciable amount of  $^{82}\text{Br}$  does in fact penetrate deeply into the growing  $\text{ZrO}_2$  layer. The measurements were made by first growing a 400 Å (20v) oxide in inactive electrolyte then increasing the oxide thickness to 700 Å (35v) in  $\text{Br}^-$  doped electrolyte. Sectioning and measurement of the residual  $\text{Br}^-$  activity showed that it was distributed throughout the complete oxide, old and freshly formed. The experiment was repeated but in this case the initial undoped oxide was formed to a thickness of 400 Å (20v) then immersed in the  $\text{Br}^-$  doped electrolyte at 10v. Again, on sectioning,

the  $\text{Br}^-$  was found distributed through the oxide. As a control, a 400 Å oxide was formed in inactive electrolyte then immersed in the  $\text{Br}^-$  doped electrolyte with no voltage applied. Sectioning showed that the  $\text{Br}^-$  had not penetrated into the oxide.

These results, together with the observation (Fig. 2) that none of the radiotracers moves appreciably during the anodic formation of  $\text{ZrO}_2$ , suggests that defects, holes, grain boundaries etc. may contribute significantly to the mode of oxygen movement through the growing oxide. This has been postulated previously by Cox and Roy (9) who measured the diffusion of oxygen into growing oxide films of zirconium, and concluded that the measured rates represented diffusion along easy paths which were "probably crystallite boundaries."

Additional evidence that  $\text{ZrO}_2$  grows by oxygen migration was obtained by injecting 30 keV  $^{133}\text{Xe}$  into a 400 Å  $\text{ZrO}_2$  layer, increasing the oxide thickness to 1600 Å and finally injecting 30 keV  $^{125}\text{Xe}$ . The depth distributions of the two Xe isotopes were then measured simultaneously by the sectioning technique and the separation of the gamma ray peaks of  $^{133}\text{Xe}$  (81 keV) and  $^{125}\text{Xe}$  (243 keV). Since the ranges of 30 keV  $^{125}\text{Xe}$  and  $^{133}\text{Xe}$  are virtually the same (10), their final depth distributions in  $\text{ZrO}_2$  should be identical provided that the oxide grows by oxygen migration alone. The results (Fig. 6) illustrate that the  $^{133}\text{Xe}$  and  $^{125}\text{Xe}$  have almost exactly the same location, the extent of metal ion transport, if any, being evidently less than 1%.

### Summary

The comparison of cation and anion movement with the location of krypton in the anodic oxides of tantalum and zirconium, and the measurement of different isotopes of xenon in  $\text{ZrO}_2$  has provided additional evidence that xenon and krypton are immobile markers for use in oxidation studies. The lack of measurable broadening of the krypton distribution tends to confirm this.

The transport number of metal in the anodic oxidation of tantalum has been measured as  $0.28 \pm 0.03$ , in good agreement with other workers' results. The anodic oxidation of zirconium has been shown to proceed almost entirely by oxygen migration, probably by some defect mechanism.

The technique of removing thin sections of anodic oxides by vibratory polishing has been shown to be suitable for the measurement of ionic transport numbers in  $\text{Ta}_2\text{O}_5$  and  $\text{ZrO}_2$ . This type of measurement may in principle be extended to any other metals on which coherent oxides can be formed. A large number of isotopes may be used as radiotracers as shown and, if chosen carefully, may be used simultaneously.

## Property Changes in Pyrolytic Silicon Nitride with Reactant Composition Changes

V. Y. Doo,\* D. R. Kerr,\* and D. R. Nichols<sup>1</sup>

*IBM Components Division, East Fishkill Facility, Hopewell Junction, New York*

**ABSTRACT**

Property changes in pyrolytic silicon nitride were investigated as a function of the reactant composition (silane:ammonia ratio). The potential of developing cracks in films deposited on silicon was greatly reduced by decreasing the ammonia injection rate. However, all films in this work with low ammonia and the films in the previous work with high ammonia were amorphous. Decreasing the ammonia injection rate increases the index of refraction and the electronic leakage while decreasing the dissolution rate (in 48% HF). The deposition rate, the dielectric constant, and the flat-band charge density are not significantly affected by the ammonia injection rate.

In pyrolytic deposition of amorphous silicon nitride films by the reaction of silane and ammonia (1-4), an excess quantity of ammonia is normally injected into the reaction chamber to ensure that the silane will react completely. The properties of the films deposited with silane:ammonia injection ratios in the range of 1:20-40 and under given conditions (temperature, deposition rate, etc.) are essentially the same (1). As the ammonia injection rate is gradually reduced to approach the silane injection rate, the ammonia becomes scarce around a silane molecule. One expects part of the silane to decompose and then be deposited on the substrate without reacting with ammonia, thus causing deficient Si-N bonds in Si<sub>3</sub>N<sub>4</sub> films. In other words, the composition of the silicon nitride films would become silicon rich, thereby affecting the film properties. This paper reports the findings on the property changes of amorphous silicon nitride films as a function of the reactant composition.

**Experimental Procedures**

The amorphous silicon nitride films were prepared by the pyrolytic reaction of silane and ammonia in a hydrogen atmosphere (1-4). The reaction occurred in a fused quartz tube in which a surface treated high-purity graphite susceptor was used to couple with an rf coil placed outside of the quartz tube. The injection rates of silane and hydrogen were maintained at 1 ml min<sup>-1</sup> and 4 liters min<sup>-1</sup>, respectively, throughout this work, while the injection of ammonia was regulated to the predetermined rate.

The substrates were n-type silicon wafers of about 1.5 ohm-cm. The wafers were chemically polished in HF-HNO<sub>3</sub> solution. Prior to deposition, the substrate surface was *in situ* cleaned by heating in hydrogen at about 1225°C. The substrate temperature was then lowered to the predetermined deposition temperature. After the substrate temperature, which varied

from 800° to 1000°C, was stabilized, the deposition of nitride film proceeded.

The film thickness of the amorphous silicon nitride was measured by the interference fringes under sodium light and checked by a Tolansky (5) interferometer. The index of refraction was determined by the differential interfringe spacing method (1) with sodium light ( $\lambda = 5900\text{\AA}$ ) on samples with the nitride films deposited on thermally oxidized silicon substrates. Estimated accuracy is  $\pm 0.05$ .

Electrical properties of the films were investigated using MIS (metal-insulator-silicon) capacitors. After deposition of the silicon nitride films (typically 6000\AA thick), circular aluminum electrodes (20 mil diameter) were evaporated to form the MIS structures. Surface charge was determined from the well-known capacitance-voltage measurement (6,7) using a frequency of 10 kHz. Dielectric constant and electronic leakage measurements were made on the same structures.

**Results and Discussion**

The structure of the pyrolytic silicon nitride films was studied by the transmission electron diffraction and electron microscopy. The results of all the films studied confirmed earlier reports (1) that the films were amorphous. A typically broadly diffused diffraction pattern is shown in Fig. 1. In one sample prepared at 800°C with the silane to ammonia injection, ratio of 1:1, however, a thin layer of fine polycrystallites was detected at the film-substrate interface. Figures 2 and 3 show the transmission electron diffraction and the transmission electron microscopy, respectively, of the polycrystalline material identified as silicon crystallites. The deposit of silicon crystallites may have been caused by the sudden surge of silane at the beginning of deposition. Other samples grown at the same substrate temperature and silane:ammonia ratio with silane injection started 15 sec after ammonia showed no evidence of the presence of polycrystalline silicon.

Fig. 2. Transmission electron diffraction pattern of polycrystalline silicon detected at the interface of silicon nitride-substrate.

Fig. 3. Transmission electron microscopy of the same sample as Fig. 2.

Earlier work (1) reported that cracks are often observed on thick ( $>1\mu$ ) silicon nitride films grown on silicon substrates. The density of cracks increased with increasing film thickness and growth rate ( $>500\text{\AA min}^{-1}$ ). Thick silicon nitride films were grown at a silane:ammonia injection ratio of 1:40. The potential of developing cracks in silicon nitride films (on silicon) is greatly minimized for ratios of 1:1 to 1:5 even though the growth rate is a factor of three greater ( $1500\text{\AA min}^{-1}$ ) as shown in Fig. 4. These results indicate that the composition of the reactants has a profound effect on the stress and strain in the silicon nitride-silicon interface.

The growth rate of the silicon nitride is plotted as a function of the silane to ammonia injection ratio as shown in Fig. 4. Note that at a given deposition temperature, the deposition rate is practically independent of the ammonia injection rate when the silane to ammonia injection ratio is in the range of 1:1 to 1:10. The scattering of results was caused primarily by the experimental error in controlling low injection rates of the reactant gases and the error in thickness measurements.

The index of refraction of the pyrolytic silicon nitride was investigated as a function of the silane to ammonia injection ratio. In general, the index of refraction increases with decreasing ammonia injection rates at all the deposition temperatures (from  $800^\circ$  to  $1000^\circ\text{C}$ ). At the highest ammonia injection rates the refractive index was in the range 2.0-2.1. When the ammonia injection rate equals the silane injection rate, the index of refraction of the amorphous silicon nitride exceeds the index of refraction of the crystalline  $\alpha\text{-Si}_3\text{N}_4$  (RI = 2.1) (8). These results strongly indicate that the composition of the pyrolytically deposited films change gradually toward silicon rich silicon nitride as the ammonia injection rate is reduced to approach the silane injection rate. Since the film structure is amorphous, the excess silicon atoms must be dispersed randomly within the silicon nitride.

The dissolution rate of the silicon nitride in 48% HF (at room temperature) was determined. Figure 5 shows the dissolution rate plotted as a function of the silane to ammonia injection ratio. The dissolution rate of the silicon nitride films grown at a given silane to ammonia injection ratio decreases as expected with increasing deposition temperature. The  $800^\circ\text{C}$  films dissolved much faster than the  $900^\circ$  and  $1000^\circ\text{C}$  films.

Fig. 4. Growth rate vs. silane to ammonia injection ratio

Fig. 5. Dissolution rate in 48% HF vs. silane to ammonia injection ratio. ●, 800°C films; X, 900°C films; ○, 1000°C films.

This suggests that the 800°C films are substantially less tightly bound than the 900° and 1000°C films. The dissolution rate of the films grown at a given temperature decreases with decreasing ammonia injection rate as it approaches the silane injection rate. This can be due to the film composition changing toward the silicon rich silicon nitride.

In all capacitance-voltage measurements a negative bias is required on the aluminum to observe the flat-band capacitance. Flat-band surface charge is defined by  $N_{FB} = C_N V_{FB} / q$  where  $C_N$  is the nitride film capacitance per square centimeter,  $V_{FB}$  is the flat-band bias, and  $q$  is electronic charge. In Fig. 6 the surface charge is plotted vs. silane:ammonia ratio for films deposited at 800°, 900°, and 1000°C. It is seen that the magnitude of  $N_{FB}$  varies with deposition temperature (900°C giving lowest values) but has little dependence on the silane:ammonia ratio. The surface charge has the same sign as that found with thermally grown  $SiO_2$  but is an order of magnitude larger (7). The dielectric constant of the films was obtained by measuring capacitance per square centimeter in the accumulated portion of the C-V characteristic and thickness by the Tolansky technique (5) after etching a step with HF. Uncertainties in the film thickness, electrode area, and capacitance indicate an absolute error in the dielectric constant of, at most, 3%. This permits more accurate dielectric constant measurements than

Fig. 6. Flat-band surface charge from C-V measurements on pyrolytic silicon nitride films deposited on silicon. Measurement frequency is 10 kHz. □, 800°C films; ○, 900°C films; X, 1000°C films.

Fig. 7. Relative dielectric constant of pyrolytic silicon nitride films. Measurements are at 25°C and 10 kHz. Each data point represents an individual wafer. □, 800°C films; ○, 900°C films; X, 1000°C films.

those previously reported (1, 9). Figure 7 shows that the relative dielectric constant (measured at 10 kHz) has little dependence on the deposition temperature or the silane:ammonia ratio and approaches a value of 7.6 as the ammonia fraction increases. Dielectric constant measurements over the range 100 Hz to 1 MHz show no variation with frequency.

At high fields ( $E > 10^6$  V/cm), electronic leakage currents were observed at room temperature in the MIS devices. These currents are characterized as being reproducible between devices on a given wafer, being symmetrical with respect to polarity of the d-c bias, showing no decay with time, and having a nonohmic I-V characteristic. Note that  $\log(I/A)$  is a linear function of the square root of the applied field as shown in Fig. 8 and that doubling the field results in a current increase by several orders of magnitude. Figure 8 also shows a strong dependence of the conductivity on the silane:ammonia ratio. Increasing the ammonia fraction causes a shift of the curve to higher fields with little change of slope. Increasing the ammonia fraction beyond the 1:10 ratio causes very little additional shifting of the characteristic. The slopes of

Fig. 8. Electronic leakage of pyrolytic silicon nitride films deposited at 900°C. Measurements are at 25°C, and the silane:ammonia ratios are given in parentheses on each curve. Theoretical slopes are shown for Schottky barrier injection and Frenkel-Poole emission from traps.

the curves permit a tentative identification of the conduction mechanism. Schottky barrier injection from the electrodes gives a current dependence on the field of  $I \sim \exp(q^3 E / \pi \epsilon)^{1/2} / 2kT$  where  $E$  is the field, and  $\epsilon$  is the optical dielectric constant of the insulator. A Frankel-Poole mechanism (10) in which carriers are emitted from traps in the bulk of the film gives the dependence  $I \sim \exp(q^3 E / \pi \epsilon)^{1/2} / kT$ , which has twice the slope of the Schottky equation. These theoretical slopes are shown in Fig. 8 using a dielectric constant of  $\epsilon/\epsilon_0 = 4$  (refractive index squared) and  $T = 300^\circ\text{K}$ . The slopes of the experimental curves and the symmetry with bias polarity are evidence for the bulk-limited, Frenkel-Poole mechanism. A detailed study of the conduction mechanism is being conducted.

### Conclusion

In the pyrolytic deposition of the amorphous silicon nitride films with the reaction of silane and ammonia, the film property changes were investigated as a function of the reactant composition. The reactant composition was changed by gradually reducing the ammonia injection rate while the silane injection rate was kept constant. The potential of developing cracks in silicon nitride films deposited on silicon substrates is greatly reduced by decreasing the ammonia injection rate to 1-5 times greater than the silane. However, the structure of all films in this work grown with low ammonia and in the previous work (1) with high ammonia ratios is amorphous. The index of refraction increases while the dissolution rate in 48% HF decreases with a decreasing ammonia injection rate. These results indicate that silicon nitride films grown with reduced ammonia (approaching the silane rate) are silicon rich in film composition. The electronic leakage current increases rapidly with decreasing ammonia. The film deposition rate, the dielectric constant, and the flat-band charge density are not significantly affected by the ammonia injection rate.

## Computer Programs for Quantitative and Semiquantitative Analysis with the Electron Microprobe Analyzer

S. S. So and H. R. Potts\*

Systems Development Division, International Business Machines Corporation, Endicott, New York

### ABSTRACT

A description of two FORTRAN IV computer programs is presented to simplify quantitative and semiquantitative analysis with the electron microprobe analyzer. The first program, EPMP1, determines the weight fraction of each element in a specimen from the characteristic x-ray intensity measurements of the specimen and the standards. The second program, EPMP2, calculates the relative characteristic x-ray intensities of all the elements in a specimen by assuming the composition of the specimen to be known. The correction procedure includes dead time correction, one of two background corrections (either constant background or background depending on composition), Philibert's absorption correction modified by Duncumb and Shields, one of three fluorescence corrections (either Birks', Castaing's, or Reed's), and a compound standard correction. The effects of the absorption and the fluorescence of each element in the specimen are easily seen from the output results. Versatility, efficiency, and ease of operation are emphasized in the programs.

Two FORTRAN IV computer programs<sup>1</sup> have been written to facilitate quantitative and semiquantitative analysis with the electron microprobe analyzer. The

\* Present address: IBM, Components Division, East Fishkill, New York.

<sup>1</sup> The program package is available from the IBM Program Information Department, Hawthorne, New York.

first program, EPMP1, calculates the weight fraction of each element in the specimen from the characteristic x-ray intensity measurements of the specimen and the standards. The second program, EPMP2, which is essentially the inverse of the first program, calculates the relative characteristic x-ray intensities of all

the elements in the specimen by assuming the composition of the specimen to be known.

Many correction procedures for electron microprobe analysis are available in literature (1-13). Each procedure has its merits and deficiencies, depending on the system being analyzed. Because of the complex, tedious, and time-consuming process of these correction procedures, computer techniques have been used to make proper correction for a more accurate quantitative analysis (14-18). The present programs include the following corrections: (i) dead time correction, (ii) a background correction (either constant background or background dependent on composition), (iii) Philibert's absorption correction modified by Duncumb and Shields, (iv) Birks', Castaing's, or Reed's fluorescence correction, and (v) a compound standard correction. However, there is no correction provided in the programs for the errors contributed by the following: atomic number effect, fluorescence excitation by the continuum, or contamination of the specimen and the standards.

The programs emphasize versatility and ease of operation. The large combinations of input data indicate the flexibility of the programs; this flexibility allows use of experimental data from various commercial electron microprobes. Codes for the various corrections are provided to eliminate unnecessary input data and computations; these codes thus enhance the efficiency of the programs.

### Theory of Corrections

The theory of electron microprobe analysis is based on relating the weight fraction of an element in a specimen to a ratio. This ratio is defined as the characteristic x-ray intensity generated in the specimen to that generated by a pure standard of the same element under the same experimental conditions. The characteristic x-ray intensity measured by the electron microprobe analyzer is affected by the following: finite resolving time of the detector, background x-ray spectrum, absorption of the emerging characteristics radiation in the specimen, and the fluorescence excitation by the characteristic radiations of other elements in the specimen. The program considers the previous effects in order to have an accurate quantitative analysis.

Due to the finite resolving time of the detector, the measured x-ray intensity,  $I_M$ , is less than true intensity,  $I_T$ . If the dead time,  $DT$ , is known, the program will make a dead time correction for all measured x-ray intensities as given by

$$I_T = \frac{I_M}{1 - I_M \cdot DT \cdot 10^{-6}} \quad [1]$$

where  $DT$  is in microseconds. If no dead time correction is necessary, set  $DT = 0$ , and the program will bypass above calculation.

Two types of background intensity corrections are provided in the program, the constant background and the background depending on the composition. If the continuum x-ray intensity,  $I_B$ , is small compared with the measured characteristic intensity,  $I_T$  (corrected for dead time), a constant background may be used. The corrected x-ray intensity for the  $i^{\text{th}}$  element in a matrix or the  $i^{\text{th}}$  standard element is simply given by

$$\begin{aligned} I_i &= I_T - I_B \\ I_{\text{std}} &= I_{T\text{std}} - I_{B\text{std}} \end{aligned} \quad [2]$$

However, for very small weight fractions (where the characteristic intensity approaches that of the continuum) the background intensity must be measured for each characteristic radiation and for each element in the specimen. Then the background intensity for the  $i^{\text{th}}$  element is given by

$$(I_B)_i = \sum_j W_j I_{ji} \quad [3]$$

where  $W_j$  is the weight fraction of the  $j^{\text{th}}$  element and

$I_{ji}$  is the background intensity of the  $i^{\text{th}}$  element due to the  $j^{\text{th}}$  element. The summation is carried over all the elements in the specimen.

The characteristic radiation is generated beneath the surface of the target and undergoes absorption when it emerges from the target before being detected by the spectrometer. Philibert's absorption correction (4), modified by Duncumb and Shields (11), is used in the program. The true weight fraction of the  $i^{\text{th}}$  element in the specimen, with absorption correction, is given by

$$W_i = I_{\text{rel}} \left[ \frac{F_{\text{std}}(\chi)}{F_i(\chi)} \right] \quad [4]$$

where the relative x-ray intensity,  $I_{\text{rel}}$ , is defined as the ratio of measured characteristic x-ray intensity from the specimen to that of the standard (corrected for dead time and background)

$$I_{\text{rel}} = \frac{I_i}{I_{\text{std}}} \quad [5]$$

and  $F_{\text{std}}(\chi)$  and  $F_i(\chi)$  are the absorption correction factors for the standard and the specimen, respectively. The absorption correction parameter is given by

$$F(\chi) = \frac{1}{\left(1 + \frac{\chi}{\sigma}\right) \left[1 + h \left(1 + \frac{\chi}{\sigma}\right)\right]} \quad [6]$$

where

$$\chi = \text{cosec } \psi \cos \theta \sum_j \mu_{ij} W_j \quad [7]$$

$$h = 1.2 \frac{\sum_j A_j W_j}{\left[\sum_j Z_j W_j\right]^2} \quad [8]$$

$$\sigma = \frac{2.39 \times 10^5}{V^{1.5} - V_c^{1.5}} \quad [9]$$

with  $\mu_{ij}$  as the mass absorption coefficient for characteristic radiation generated from the  $j^{\text{th}}$  element absorbed by the  $i^{\text{th}}$  element,  $\psi$  as x-ray emerging angle with respect to the surface of the target,  $\theta$  as incident electron beam angle with respect to the normal of the target,  $A$  as the atomic weight,  $Z$  as the atomic number,  $V$  as the incident electron beam potential, and  $V_c$  as the critical excitation potential. Note that the parameter  $\chi$  has been modified to account for the inclination of the target to the electron beam.

When the characteristic radiation of the  $j^{\text{th}}$  element is shorter in wavelength than the absorption edge of the  $i^{\text{th}}$  element, it is able to enhance the characteristic radiation of the  $i^{\text{th}}$  element. The true weight fraction of the  $i^{\text{th}}$  element in a specimen, with both absorption and fluorescence corrections, is then given by

$$W_i = I_{\text{rel}} \left[ \frac{F_{\text{std}}(\chi)}{F_i(\chi)} \right] \left[ \frac{1}{1 + K_{fi}} \right] \quad [10]$$

where  $K_f$  is the fluorescence correction factor. Three methods are available in the program to calculate the fluorescence correction parameter,  $K_f$ .

Birks' equation (7) is given by

$$K_{fi} = 0.6 \sum_j E_{ij} W_j \left( \frac{\mu_{ij}}{\mu_j} \right) \left( \frac{V - V_{cj}}{V - V_{ci}} \right)^{1.65} \quad [11]$$

where  $E_{ij}$  is the excitation efficiency of the  $i^{\text{th}}$  element by the characteristic radiation of the  $j^{\text{th}}$  element, and  $\mu_j$  is the mass absorption coefficient of the specimen for characteristic radiation generated from  $j^{\text{th}}$  element.

Castaing's equation (1) is given by

$$\begin{aligned} K_{fi} &= 0.5 \left( \frac{\tau_i - 1}{\tau_i} \right) \sum_{j \neq i} W_j \omega_j(K) \left( \frac{\lambda_j}{\lambda_i} \right) \left( \frac{\mu_{ij}}{\mu_j} \right) \left( \frac{A_i}{A_j} \right) \\ &\quad \cdot \left[ \frac{\ln(1+u)}{u} + \frac{\ln(1+v)}{v} \right] \end{aligned} \quad [12]$$

where

$$u = \left( \frac{\mu_i}{\mu_j} \right) \operatorname{cosec} \psi \quad [13]$$

$$v = \left( \frac{\sigma}{\mu_j} \right) \sec \theta \quad [14]$$

with  $r_i$  as the absorption edge jump ratio (12),  $\omega(K)$  as the K-shell fluorescence yield (19), and  $\lambda$  as the characteristic wavelength.

Reed's equation (9) is a modified form of Castaing's equation; it considers all cases involving K and L characteristic radiations and may be written as

$$K_{fi} = 0.5 P_{mn} \left( \frac{r_i - 1}{r_i} \right) \sum_{j \neq i} W_j \omega_j(K) \left( \frac{U_j - 1}{U_i - 1} \right)^{1.67} \cdot \left( \frac{\mu_{ij}}{\mu_j} \right) \left( \frac{A_i}{A_j} \right) \left[ \frac{\ln(1+u)}{u} + \frac{\ln(1+v)}{v} \right] \quad [15]$$

where  $P_{KK} = P_{LL} = 1$ ,  $P_{KL} = 0.24$ ,  $P_{LK} = 4.2$ , and

$$U_i = \frac{V}{V_{ci}} \quad [16]$$

If a compound of known composition is used as a standard for the  $i^{\text{th}}$  element instead of a pure standard, then the measured x-ray intensity of that element from the compound standard ( $I_{cs}$ ) must be adjusted to be equivalent to the pure standard form ( $I_{std}$ ). Namely,

$$I_{std} = \frac{I_{cs}}{\xi_i} \quad [17]$$

where the compound standard correction factor is calculated from

$$\xi_i = W_i \left[ \frac{F_i(\chi)}{F_{cs}(\chi)} \right] (1 + K_{fcs}) \quad [18]$$

to include both absorption and fluorescence effects of the compound standard.

### Programs

**Quantitative analysis.**—The first program, EPMP1, calculates the weight fraction of each element in the specimen from the characteristic x-ray intensity measurements of the specimen and the standards. Figure 1 outlines the basic operation of EPMP1. Many features are built into the program to handle various situations in data compilation. Any number of problems can be analyzed in the same run of the program by simply stacking each set of input data one after another. The program treats each set of input data as a separate analysis. However, in the analysis of a system of specimens consisting of the same elements but different compositions, the standard intensity measurements may change from one specimen measurement to another because of the stability of the electron microprobe. In this case, the input data for the successive problems may be simplified by the continuation code. Other codes are provided for dead time, background, fluorescence, and compound standard corrections to enhance the efficiency of the program. If any of these corrections are not necessary, then input data is not required for that correction and the program will bypass the execution of that correction. (See List of Input Data.)

The incident electron beam of variable energy may be inclined at any angle with respect to the target. The x-ray emerging angle may be varied from element to element in the specimen. Each element in the specimen has its own compound standard code, so that any number of compound standards may be used as the standard of the specimen. The elements in the specimen may be analyzed in any order. Furthermore, if there is an uncertainty in any of the specimen x-ray intensity measurements, that intensity may be set

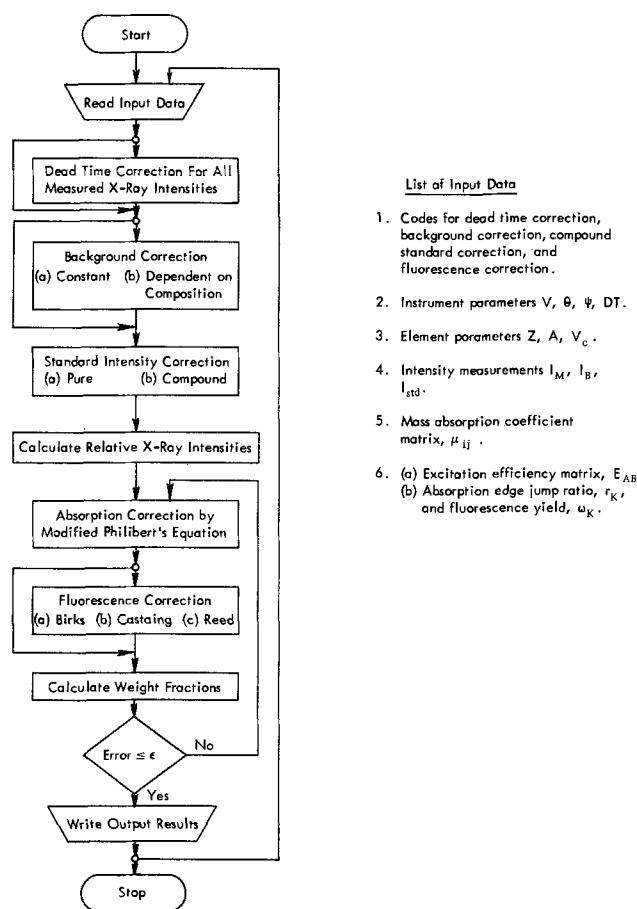

Fig. 1. Flow chart of EPMP1

to zero in the input data. The program will calculate the weight fractions of all other elements in the specimen and will set the remaining weight fraction in the specimen equal to the weight fraction of the uncertain element. This is the only case where the quantitative analysis will yield normalized weight fractions.

Note that the background (dependent on composition), absorption, fluorescence, and compound standard corrections are all dependent on the weight fractions of each element in the specimen. However, these weight fractions are the unknowns of the quantitative analysis. Therefore, the normalized relative x-ray intensities are taken as a first approximation for the weight fractions in calculating the correction terms. This is the only place where any normalization occurs in the iterative approximation. After having made the proper correction, the unnormalized weight fractions obtained from the previous approximation are then used to recalculate the correction terms for the successive approximations. This sets up the iterative procedure which is satisfied by either: (i) the successive approximations of the weight fractions do not change by more than a specified error,  $\epsilon$ , or (ii) the specified number of iterations has been reached. In the latter case, a warning message will be printed out to indicate the slow convergence or the divergence of the iterative steps.

All input data are printed out for easy reference, and they also serve as a record of the problem analyzed. In the output data, the measured relative x-ray intensity and the unnormalized weight fractions (with absorption correction or with both absorption and fluorescence corrections) are printed out. From these values, the effect of the absorption and the fluorescence of each element in the analyzed system is clearly seen. The value of the total unnormalized weight fractions gives an indication of the accuracy of the experimental data.

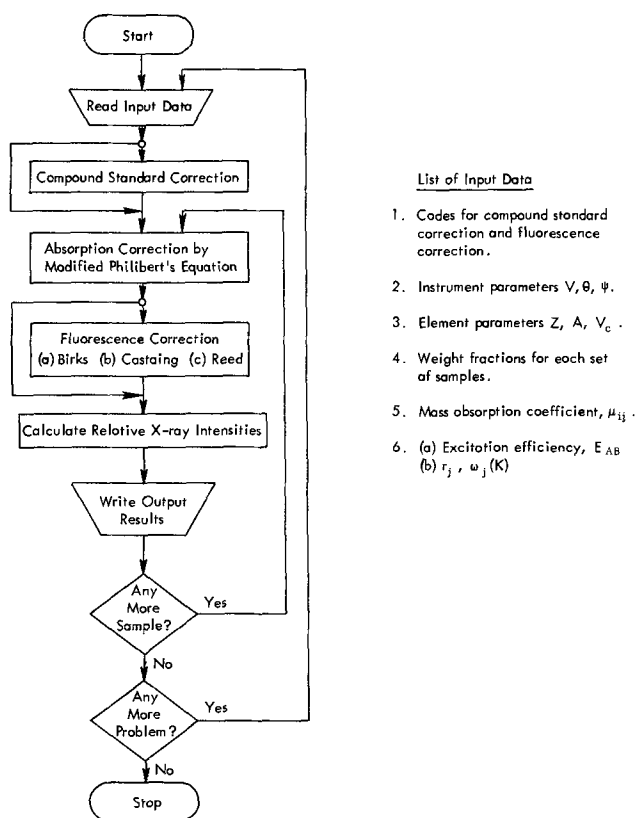

Fig. 2. Flow chart of EPMP2

**Semiquantitative Analysis.**—The second program, EPMP2, is particularly useful in a quick semiquantitative analysis, especially for binary alloys. By assuming various combinations of the weight fractions of a specimen, this program calculates the relative x-ray intensity of each element in the specimen. Figure 2 outlines the basic operation of EPMP2. The correction procedure is the same as the first program, EPMP1 (for the quantitative analysis), except no iterative approximation is necessary since the weight fractions of the specimen are assumed to be known. The calculated results may be plotted on a graph. Then, from the measured relative x-ray intensity (taken with the electron microprobe analyzer), the graph directly gives the weight fraction of that element (Fig. 3). Furthermore, it gives an indication of the degree of accuracy of the x-ray intensity measurements by noting: (i) how near the measured relative intensities approximate a vertical line, or (ii) how close the total measured relative x-ray intensity compared with the total calculated relative x-ray intensity.

### Examples

Table I and Fig. 3 are included to illustrate quantitative and semiquantitative analysis with the electron microprobe analyzer on a system of FeNi alloys over a wide range of compositions. The data<sup>2</sup> used in each alloy correspond to the averaged values of three different locations on the alloy, with ten consecutive measurements over each location. The measured relative intensities (in per cent) of Table I are calculated by Eq. [5].

By assuming various combinations of weight fractions of Fe and Ni, the relative characteristic x-ray intensities are calculated by EPMP2. These results are plotted on a graph as shown in Fig. 3. Using the values of measured, relative, characteristic x-ray intensities from Table I (column 3), Fig. 3 directly yields the weight fractions which are shown in column 4 of

Fig. 3. Calculation of relative x-ray intensity by EPMP2 for FeNi binary alloys.

Table I. This gives a quick semiquantitative analysis of FeNi alloys. If more accurate results are required, the raw data from the electron microprobe analyzer measurements can be fed into EPMP1. Since three methods of fluorescence correction are available in the program, the differences between Birks', Castaing's, and Reed's equations are easily detected by comparing their results as shown in columns 5, 6, and 7 of Table I. The weight fractions of the FeNi alloys were determined by chemical analysis, and listed in column 8 of Table I.

By comparing column 4 of Table I with columns 5, 6, and 7, one can see that the results of EPMP2 are a good approximation to the quantitative analysis. Furthermore, by comparing columns 5, 6, and 7, one should note that the fluorescence corrections by Birks',

9	0.9	0.1	76.07399	9.27002	0.89999	0.10000

\* Modified Philibert's absorption correction and Reed's fluorescence correction.

Castaing's, and Reed's equations differ more significantly for small weight fraction of Fe but tend to agree for larger weight fraction of Fe.

One way to check the accuracy of the iterative approximation of EPMP1 is to use the output from EPMP2 as the input of EPMP1. Then by comparing the output from EPMP1 with the original input to EPMP2, the difference gives a direct indication of the accuracy of the iterative approximation used in EPMP1. Table II illustrates this check with a system of PCu alloys. Nine sets of weight fractions of P and Cu are assumed and used in the input data to EPMP2. The relative characteristic x-ray intensities calculated by EPMP2 are then used as the input data to EPMP1. The weight fractions calculated by EPMP1 may be compared with the original assumed weight fractions. The difference, less than  $\pm 0.03\%$ , is the error of the iterative approximation of EPMP1.

Similarly, the uncertainty in any parameter of the correction procedure may be detected by varying that parameter. By comparing the output results, one gets an indication of the resultant effect on the quantitative analysis due to that particular parameter.

### Conclusions

Two FORTRAN IV computer programs have been used to facilitate quantitative and semi-quantitative analysis with the electron microprobe analyzer. These programs emphasize versatility, efficiency, and ease of operation. A primary advantage of these programs is the freedom of the user to utilize many alternative forms of correction to coincide with the data available. The efficiency of the programs is enhanced by the codes provided, so that unnecessary input data and computations are eliminated. All input data are printed out for easy reference, and they also serve as a record of the problem analyzed. From the output results, the effect of the absorption and the fluorescence of each element in the analyzed system is clearly indicated.

The over-all accuracy of the quantitative and the semiquantitative analysis with the electron microprobe analyzer is still limited by many factors. It not only depends on the system of elements being analyzed, but also depends on the correction procedures, the uncertainty in their parameter values, and the over-all experimental error. As better theories for the electron microprobe analysis are developed, the present programs can be easily modified to give more accurate results.

### Acknowledgments

The authors wish to thank Mr. H. R. MacQueen for experimental data measurements; Metropolitan New York section of The Electron Probe Analysis Society of America for supplying the FeNi specimens and the wet chemistry data on them; and Mr. J. E. Riedy for his assistance in preparing the manuscript.

Manuscript received March 28, 1967; revised manuscript received Sept. 28, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Crystal Growth of a New Laser Material, Fluorapatite

R. Mazelsky,\* R. C. Ohlmann, and K. Steinbruegge

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

### ABSTRACT

Neodymium-doped calcium fluorophosphate is an efficient laser crystal. The growth method, chemistry, spectroscopy, and some pulsed laser results are presented.

The growth of laser technology has resulted in the need for crystals of large size which can perform at higher efficiencies than currently existing materials. A

\* Electrochemical Society Active Member.

material that meets these specifications is neodymium-doped calcium fluorophosphate,  $\text{Ca}_5(\text{PO}_4)_3\text{F}$ . This material doped with manganese and antimony is known to be an efficient phosphor and is, in fact, used in

fluorescent lamps. Johnson (1) has been successful in pulling large crystals of fluorapatite, pure and manganese-doped, from the melt. We have succeeded in preparing crystals by the Czochralski method which, when doped with neodymium, show laser oscillations at low threshold. This paper describes the method and apparatus for growth of the crystals and the pertinent spectroscopic data.

### Experimental

The pulling apparatus was designed such that pull rates between 1 and 40 mm/hr and rotation speeds of 10-110 rpm can be used. The furnace is surrounded by a quartz cylinder attached to the apparatus by means of a neoprene gasket and a brass flange. There are inlet holes for the introduction of appropriate atmospheres and a temperature sensing device. An iridium crucible is used to contain the fluorapatite. Insulation is provided by ½-in. thick zirconia quadrants stacked to form a cylinder. A circular zirconia plate with an access hole caps the furnace and serves as a reflector for minimizing thermal losses from the surface of the melt.

Heating is accomplished using a 30 kw motor-driven 10 kc generator, the a-c power driving water-cooled copper induction coils. It has been found that the lower frequencies give fairly uniform heating even though there are irregularities present in the iridium susceptor. Even with large irregularities no "hot spots" have been observed.

Temperature is controlled by using the output of a sapphire-light-pipe radiomatic detector and feeding it into an L&N Azar recorder controller. The voltage from the recorder controller in association with an L&N current adjusting type relay supplies the input circuit of a Norbatrol linear power controller. The Norbatrol output voltage supplies the necessary field excitation required by the 10 kc generator.

The seed holder consists of a pin vise or a water-cooled copper shaft which is threaded to accommodate a tantalum chuck. The seed is pinned to the tantalum chuck which is then threaded onto the water-cooled shaft such that the seed butts against the shaft. A schematic of the apparatus is shown on Fig. 1.

The fluorapatite crystals are grown in an argon atmosphere. The temperature at the surface of the melt as determined by optical pyrometer readings uncorrected for emissivity is 1705°C during growth. Pull rates of 3-8 mm/hr are used, and the seed crystal is rotated between 30-100 rpm. The melt is quite viscous, and the rapid rotation rate creates a visible swirl pattern on the surface of the melt.

Crystals obtained using rapid pull rates had visible feathery imperfections along the center of the boule. These were described by Johnson (1) as "opalescent inclusions." However, these "feathers" can be minimized or removed by utilizing slower pull rates in the range of 3-5 mm/hr. By using a seed crystal in which the feathers are present, it is possible to propagate these imperfections along the length of the crystal. Rapid changes in the diameter of the growing crystal results in large numbers of these imperfections. Under these conditions the preferred direction for the propagation of imperfections is along the "c" axis of the crystal. It is believed that these imperfections are associated with fluoride vacancies.

Neodymium-doped crystals can be obtained by simple substitution of neodymium for calcium in the melt. Since neodymium is a trivalent ion substituting for divalent calcium, some charge compensation is necessary. There is a self-compensating mechanism by which a fluoride ion may be replaced by an oxide ion. This can also be accomplished by the creation of a vacancy. The chemical formulas for crystals compen-

sated in these ways can be represented by the following

Both mechanisms are possible although it is not clear which predominates during growth.

Calcium fluorophosphate is a complicated chemical system in which it is necessary to consider at least four chemical entities,  $\text{Ca}^{+2}$ ,  $\text{PO}_4^{-3}$ ,  $\text{O}^{=}$ , and  $\text{F}^{-}$ . It is indeed fortuitous that the combination is congruently melting. The substitution of neodymium in the melt is an additional complication. Calcium fluorophosphate is prepared by combining the appropriate weights of  $\text{CaHPO}_4$ ,  $\text{CaCO}_3$ , and  $\text{CaF}_2$ . The substitution of neodymium for calcium can be accomplished by the replacement of any of these compounds with  $\text{Nd}_2\text{O}_3$ . Crystals were grown with  $\text{Nd}_2\text{O}_3$  replacing  $\text{CaCO}_3$ ,  $\text{CaF}_2$ , and combinations of the two. In all cases crystals of fair quality were obtained but they had a pronounced tendency to form color centers under ultraviolet radiation. The problem of color centers in halophosphate crystals has been discussed by Swank (2). Substitution of neodymium can also be accomplished by charge compensation; i.e.,  $\text{Na}^{+1}$ ,  $\text{Nd}^{+3}$  pairs being introduced into the divalent sites. No differences were observed in the Nd emission spectra or in the laser properties, whether the crystals were ion-compensated or allowed to self-compensate.

The segregation coefficient of neodymium in calcium fluorophosphate was determined by x-ray fluorescence analysis. Standard concentrations of neodymium in the host were prepared by solid-state reaction and analyzed. Then small crystals were grown from charges of several concentrations of neodymium varying from 0.5 to 5%. Crystals of the same concentration were pulled at different rates and analyzed to insure that the system was near equilibrium. In each case the mass of the crystals pulled were less than 1% of the total charge. The crystals, ground into powders, were analyzed for neodymium by x-ray fluorescence and compared to the standards. In this manner the concentration of neodymium in the pulled crystal as compared to the melt was determined. A plot of atomic per cent (a/o) neodymium in the melt versus atomic per cent neodym-

Fig. 2. Relative quanta rate of fluorescence of Nd doped  $\text{Ca}_5(\text{PO}_4)_3\text{F}$  at room temperature and 523 nm excitation. Corrected spectrum.

ium in the solid was prepared and a segregation coefficient of 0.52 was determined.

**Optical properties.**—The fluorescence spectrum of  $\text{Nd}^{3+}$  in calcium fluorophosphate at room temperature is shown in Fig. 2. This spectrum has been corrected for sensitivity so that the amplitude is proportional to quanta/sec nm. A larger fraction of the  $\text{Nd}^{3+}$  emission is present in a single line (at 10629 Å) than is found in the  $\text{Nd}^{3+}$  spectra in most other host crystals. The fluorescence decay time of the  $\text{Nd}^{3+}$  fluorescence is 180  $\mu\text{sec}$  at room temperature in a crystal containing 1 a/o neodymium by analysis.

The spectral quantum efficiency, i.e., the number of quanta emitted per unit wavelength interval for each quantum absorbed, particularly at the peak of an emission line, is an important parameter for laser materials. The room temperature line width of the principal line in calcium fluorophosphate is 6 Å, about the same as in yttrium aluminum garnet (YAG). The greater concentration of the emission in a single line in fluorapatite implies a greater spectral quantum efficiency than in YAG for the same over-all efficiency. A direct comparison of a YAG:Nd and fluorapatite:Nd crystal was made by measuring both the amount of energy absorbed and the peak emission intensity for each crystal. It was found that the spectral quantum efficiency at room temperature is  $2 \pm 0.2$

times larger for  $\text{Nd}^{3+}$  in fluorapatite than in YAG for 0.5 a/o Nd in each. This implies that the stimulated emission gain for a given rate of absorbing energy is correspondingly greater for fluorapatite than YAG. The  $\text{Nd}^{3+}$  absorption and excitation spectra are similar for the two materials although fluorapatite has broader absorption bands which are more intense in the visible region of the spectrum. One would expect, therefore, that the threshold for the fluorophosphate should be considerably less than for the same size YAG:Nd rod for the same distributed losses. This has been borne out by laser tests.

Crystals of fluorapatite with 1 a/o neodymium have been fabricated into rods 6.3 mm in diameter and 37 mm long. In the laser testing only a moderately efficient cylindrical pumping cavity was used. A typical rod was excited by a xenon flash lamp with an 800  $\mu\text{sec}$  pulse length. The laser rod had flat polished and parallel ends which were uncoated. Flat external mirrors were used as resonators. The threshold with reflectivities of 99% at one end and 35% at the other was 8 joules, a factor of two lower than YAG:Nd in the same apparatus. The crystal measured appeared of poor optical quality by visual inspection and the loss coefficient was fairly large. However, slope efficiencies in excess of 1% were obtained.

### Conclusion

Fluorapatite is by no means optimized with respect to either crystal quality or doping. However, sufficient data have been obtained to indicate potential superiority with respect to threshold and efficiency over existing crystalline lasers.

## Microscopic Rates of Growth in Single Crystals Pulled from the Melt: Indium Antimonide

August F. Witt\* and Harry C. Gatos\*

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

### ABSTRACT

Vibrations of known frequency introduced into a melt during crystal growth appear as impurity "vibrational" striations in the grown crystal. The growth-characteristics of crystal pulling under rotation (instantaneous microscopic growth rates and growth interface topography) were determined from the spacing and direction of introduced vibrational striations. It was demonstrated that periodic growth rate fluctuations (including local remelting) in the "off-facet" region are associated with rotational crystal pulling in the presence of thermal asymmetry. As a result of local remelting the average microscopic growth rate was shown to be significantly greater than the corresponding pulling rate. "Facet" growth is unaffected by rotation and proceeds at a rate which is identical with the pulling rate, although impurity heterogeneities have been identified in "facet" growth regions.

The effects of growth rates and their variations on crystalline perfection and the distribution of impurities during solidification have been treated extensively

\* Electrochemical Society Active Member.

in a large number of theoretical studies (1-7). The related experimental investigations do not provide the necessary information regarding instantaneous rates of growth and impurity concentrations (8-15). In these

investigations the instantaneous microscopic growth rates could not be directly determined. By necessity, the assumption has been made in some instances that the growth rate is equal to the pulling rate. Very often this assumption is not valid on the microscale. Thus, the formation of impurity striations (rotational and nonrotational) is generally attributed to periodic or random variations of the microscopic growth rate which imply deviations from the pulling rate. The origin of these growth rate fluctuations is attributed to short time temperature variations at the growth interface, caused by rotation of the growing crystal in a thermally asymmetric surrounding (rotational striations) (15), or alternately by random thermal convections due to unavoidable temperature gradients in the system (nonrotational striations) (12).

Recently a technique has been developed (16) which permits the determination of microscopic growth rates and the evaluation of interface morphology with high precision. This technique is presently applied to the investigation of InSb single crystal growth by the Czochralski technique.

### Experimental Procedure

A standard Czochralski crystal puller was modified to permit the introduction of vibrations with controlled and known frequency into the melt during crystal growth (Fig. 1). The incorporation of these vibrations in the form of impurity vibrational striations was achieved by doping the InSb melt with tellurium (15 mg of Te per 50g of InSb). All crystals were grown in a  $\langle 111 \rangle$  B direction (14) and subsequently cut along the growth axis to expose a (211) plane. The cut crystals were then mounted in plastic and polished. The final polish was obtained with a Linde "B" abrasive on a rotating wheel with the polishing direction parallel to that of the growth axis. It was found to be important that alumina abrasive particles be carefully removed from the InSb surface by means of a cotton pad under running water. The InSb crystal while still wet was immersed in a permanganate etchant for 2 min (17). The etched specimens were then rinsed in tap water, washed with soap, and dried in hot air. The etching process revealed impurity heterogeneities including the vibrational stri-

Fig. 1. Schematic representation of crystal growth arrangement

ations as elevations and depressions since the rate of etching is a function of the impurity concentration in the semiconductor. The presence of Te in InSb decreases the rate of etching. The microscopic investigation was performed with an interference contrast microscope (Normarski interferometer).

### Experimental Results and Discussion

*Effects of thermal asymmetry on rotational crystal growth.*—A recent investigation (15) of crystal growth under rotation revealed that in the presence of thermal asymmetry the instantaneous microscopic growth rate should be subject to sinusoidal fluctuations and follow the relationship

$$V = V_0 - \frac{2\pi\Delta TR}{G} \cos 2\pi Rt \quad [1]$$

where  $V$  is the instantaneous rate of growth,  $V_0$  is the pulling rate,  $\Delta T$  is the temperature variation during a  $360^\circ$  seed rotation,  $R$  is the rate of rotation,  $G$  is the temperature gradient in the melt, and  $t$  is the time.

Figure 2 is a section near the periphery of a single crystal which was pulled at a rate of 22 mm/hr and rotated at a rate of 8 rpm. The vibrational frequency was 3.5/sec. The thermal asymmetry was measured by a rotating thermocouple in the melt (without the seed present) at a distance of 6 mm from the rotational axis and was found to be  $1.8^\circ\text{C}$  for a full rotation. It is, of course, expected that the thermal asymmetry during actual growth ( $\Delta T$  in Eq. [1]) is somewhat different from the one measured. The changing spacing of the vibrational striations clearly reveals periodic growth rate changes with a periodicity of  $V_0/R$ . The so-called rotational striations (indicated by arrows) can be clearly identified here as the result of a decreased microscopic growth rate (decreased spacing in vibrational striations) which took place in the "hot" region of the thermally asymmetric melt (15). The actual in-

Fig. 2. Peripheral (off-facet) section of a Te doped InSb single crystal. The variations in the spacing of the vibrational striations reflect fluctuations in the microscopic rate of growth. Rotational striations appear as areas of decreased growth rate (arrows). Pulling rate 22 mm/h; rate of rotation 8 rpm; vibrational frequency 3.5/sec. Magnification ca. 600X.

Fig. 3. Microscopic growth rates of the crystal shown in Fig. 2, as computed from the spacing of the vibrational striations measured at a distance of  $15\mu$  from the actual crystal periphery.

stantaneous growth rates, corresponding to the crystal of Fig. 2, as determined from the spacing of consecutive vibrational striations are seen in Fig. 3. The sinusoidal variations predicted in Eq. [1] are clearly shown. It should be noted that thermal conditions other than those assumed in Eq. [1] and encountered in the case of Fig. 2 can prevail in which case the variations in the microscopic rate of growth are no longer sinusoidal.

The effects of increased thermal asymmetry ( $\Delta T$   $2.4^\circ\text{C}$ ) on the microscopic growth rate during rotational pulling are depicted in Fig. 4. The small increase of  $\Delta T$  from  $1.8^\circ$  to  $2.4^\circ\text{C}$  has resulted in a change of the maximum to minimum growth velocity ratio, within one revolution, from 2.1 (Fig. 3) to 7.4. The small but readily observable change in direction of the vibrational striations in going from the minimum to the maximum spacing reflects a change in the radius of curvature of the growth interface which is greatest in the "hot" region and smallest in the "cold" region during a given revolution. This change corresponds to the continuous relocation of the growth interface which at any point in this "off facet" region (15) is determined by the exact position of the solidification isotherm.

A further increase in thermal asymmetry ( $\Delta T = 2.7^\circ\text{C}$ ) which was brought about by the lateral displacement of the tubular heating element ( $\frac{1}{8}$  in. from its original position) resulted in partial remelting of the grown crystal during rotation as shown in Fig. 5. Such a remelting phenomenon is predicted from Eq. [1] and reflects negative values of the minimum microscopic growth rates. A continuous change in the shape of the growth interface can readily be observed

Fig. 4. InSb single crystal pulled under rotation in the presence of thermal asymmetry. Two rotational striations (arrows) can readily be observed. They reflect the onset of local remelting. Pulling rate 22 mm/hr; rate of rotation 8 rpm; vibrational frequency 8.2/sec. Magnification ca. 1320X.

Fig. 5. Off-facet growth characteristics in InSb pulled under rotation in the presence of pronounced thermal asymmetry. The observed rotational striations are remelt lines which delineate the transitions of high to very low instantaneous growth rates (see text). The change in the direction of the vibrational striations reflects the continuous change of the radius of curvature of the growth interface during rotation. Pulling rate 22 mm/hr; rate of rotation 8 rpm; vibrational frequency 5/sec. Magnification ca. 675X.

here which is more pronounced than in Fig. 2 and 4. During a  $180^\circ$  rotation of the crystal from the hot into the cold region of the melt, the rate of growth increases steadily. This increase is accompanied by a decrease in the radius of curvature of the growth interface and reflects the relocation of the solidification isotherm deeper into the melt. Further rotation by  $180^\circ$  into the original hot region results in a steadily decreasing growth rate which, in turn, corresponds to an upward shift of the solidification isotherm. Concurrently with the growth rate decrease the radius of curvature of the growth interface increases. It can be observed that during this latter  $180^\circ$  rotation remelting takes place, i.e., the microscopic growth rate assumes negative values. Such remelting is a consequence of the fact that the rate at which the crystal is pulled from the melt is less than the rate of upward relocation of the crystal-melt interface. The resulting rotational remelt striation delineates the abrupt transition from a relatively high growth rate to a growth rate which starts at zero and increases steadily to its maximum value at the coldest point in the rotational cycle. It is apparent that for impurities with an equilibrium distribution coefficient  $k_0 < 1$ , the rotational striations constitute regions of decreased impurity concentration.

Single crystal growth in the  $\langle 111 \rangle$  direction generally leads to a more or less extensive facet formation at the growth interface. Figure 6 shows the transition region of a curved, nonsingular growth region (off-facet) to a flat singular facet region, which is reflected in the directional change of the vibrational striations. This transition is characterized by a rather abrupt change of the microscopic growth rate. While the growth rate varies continuously in the "off facet" region it assumes a constant value in the facet region which is identical to that of the macroscopic pulling rate. Obviously variations of the growth rate within

Fig. 6. Transition region of off-facet to facet growth; A facet region, B off facet region. The transition is characterized by the abrupt directional change of the vibrational striations. It can be observed that the instantaneous microscopic rate of growth varies during rotation in the off-facet region and becomes constant in the facet region. Small growth rate variations in the lower part of the facet near the off-facet region are attributed to growth on vicinal planes. Magnification ca. 1250X, oil immersion.

the facet region will result whenever significant temperature changes occur in the melt.

The interaction of remelt rotational striations with the facet results in its abrupt termination; the regrowth immediately following remelting is off facet growth (15). The interference of rotational remelting with the normal facet formation can clearly be observed in Fig. 7. This crystal was pulled at a rate of 35 mm/hr and rotated at a rate of 29 rpm. The frequency of the imposed vibrations was 6/sec. The upper part of the figure shows a section grown in the regular off

Fig. 7. Off-facet, A, and facet, B, region of an InSb single crystal. In the upper part grown under vibration, irregular growth conditions with extensive remelting are observed. Rotation has prevented the normal facet formation. Portions of the suppressed facet can be observed on the extreme left (B). After stopping rotation (lower part) the facet expands and covers the whole field shown. Pulling rate 35 mm/hr; rate of rotation 29 rpm; vibrational frequency 6/sec. Magnification ca. 500X.

Fig. 8. Instantaneous microscopic rates of growth of the crystal shown in Fig. 7 as computed from the spacing of the vibrational striations. The duration of remelting is determined from the number of missing vibrational striations per rotation.

facet mode with the usual microscopic growth rate fluctuations and local remelting. Facet formation can barely be observed in this section since its lateral expansion is depressed by the backmelting process. Upon stopping the rotation (lower part of Fig. 7) the core or facet region expands to the right and the growth rate assumes a constant value identical with the crystal pulling rate (Fig. 8). This experimental result confirms the predicted independent and constant facet growth rate (15).

It can be clearly seen from Fig. 7 and 8 that due to local remelting the actual average microscopic growth rate is significantly greater than the pulling rate.

When, in addition to the controlled vibrations through the crucible, controlled vibrations are simultaneously introduced through the seed, then rather complex interference patterns of vibrational striations are observed in the curved, nonsingular growth sections (Fig. 9). Since this type of vibrational interference pattern is not present in the facet region, it is quite clear that singular and nonsingular planes exhibit basic differences in their growth characteristics.

It is generally assumed that off-facet growth proceeds normal to the interface without substantial kinetic supercooling since nucleation sites are provided by the curved growth interface. "Facet" growth, on the other hand, is believed to require the nucleation of growth steps (kinetic supercooling) which grow at

Fig. 9. Effect of the simultaneous introduction of vibrations through the crucible and the seed holder. The resulting vibrational striations exhibit pronounced interference patterns in the off-facet region. No interference patterns can be observed in the facet region. The frequency of the observed vibrational striations in the facet region shows that the seed vibrations are not incorporated in the form of vibrational striations. Magnification ca. 1000X, oil immersion.

high rates in a lateral direction. The width of individual vibrational lines in the facet region of Fig. 9 corresponds to approximately  $1000\text{\AA}$ . Thus, if facet growth proceeds by actual step growth, then, under the present experimental conditions, the step height cannot exceed  $1000\text{\AA}$  since a height in excess of this value would interfere with the formation of the observed striations. It is apparent that the present technique is uniquely suited for studies of the mechanism of facet growth.

The interference patterns of Fig. 9, which represent localized impurity concentration changes, are not caused by correspondingly localized growth rate fluctuations, since such fluctuations in rate would lead to continuous corrugations at the curved interface. Thus, the observed patterns must be attributed to localized perturbations (in the thickness and/or impurity concentration) of the interfacial boundary layer. Although vibrational interference effects are not observed in the facet region, impurity concentration changes (dark and light regions) under constant microscopic growth rate are observed as shown in Fig. 10. These concentration changes are, thus, most likely due to corresponding concentration changes in the boundary layer.

Impurity concentration changes unrelated to the microscopic growth rate are also shown in the facet region of Fig. 11. In this case controlled vibrations through the seed were intermittently superimposed to the regular vibrations as can readily be seen in the off facet region. The observed concentration changes in the facet region are apparently associated with rotational effects. It is not resolved as yet whether impurity heterogeneities in the facet grown region are due to changes in the thickness, the impurity concentration of the boundary layer, or other effects.

Growth rate fluctuations in a single crystal pulled from the melt without rotation are shown in Fig. 12. The resulting nonrotational heterogeneities are attributed to temperature fluctuations at the growth interface brought about by convective currents (14). From

Fig. 10. Facet region in a single crystal of InSb. The observed dark regions reflect an increased impurity concentration. These impurity concentration changes are not related to growth rate changes since the spacing of vibrational striations remains constant. Magnification ca. 700X.

Fig. 11. Transition region (off-facet to facet) in InSb which was intermittently subjected to crucible and seed vibrations. Pronounced heterogeneities in impurity concentration are observed in the facet region. These heterogeneities exhibit the periodicity of rotation. Magnification ca. 1000X.

Fig. 12. Nonrotational striations in the peripheral part of an InSb single crystal. Note microscopic growth rate changes. Magnification ca. 600X.

the spacing of the vibrational striations (10/sec) and its variation it can be seen that the duration of the growth rate perturbations ranges from a fraction of a second to several seconds. It was generally observed (under the present experimental conditions) that such random growth rate fluctuations are less common in crystals pulled with rotation and could not be observed in crystals pulled under high rotational rates.

#### Summary

Microscopic rates of growth were determined in single crystals pulled from the melt by introducing vibrations of known frequency into the melt containing small amounts of impurity. Such vibrations are incorporated into the growing crystal in the form of vibrational striations. In the investigated system (InSb doped with Te) impurity heterogeneities and superimposed vibrational striations were revealed by means of

a permanganate etchant. The microscopic rates of growth and crystal-melt-interface topography were determined from the spacing and direction of the vibrational striations.

It was shown that off-facet regions (nonsingular, curved interfaces) exhibit constant and periodic growth rate fluctuations during rotational crystal pulling. The extent of the growth rate variations (at constant pulling rate) is a function of the degree of thermal asymmetry in the system. With increasing thermal asymmetry partial remelting results, i.e., the minimum microscopic growth rate assumes negative values during rotation through the hot region of the melt. The so called rotational striations were identified as the result of a decrease in the microscopic growth rate. The extent of the associated variation in impurity concentration is controlled by the rate at which the microscopic growth rate changes. Crystal growth on singular interfaces (facets) was shown to occur at a constant rate, equal to the pulling rate. Impurity heterogeneities were observed in facet regions grown under constant microscopic rate. Their origin is associated with perturbations in the boundary layer conditions.

#### Acknowledgment

This work was supported by the National Science Foundation Grant GK-1653 and by a grant from the Sloan Basic Research Fund administered by M.I.T. The authors wish to express their appreciation to Mr. C. J. Herman and Mr. W. J. Fitzgerald for their skillful laboratory assistance.

Manuscript received Aug. 17, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Deposition of Silicon on Single-Crystal Spinel Substrates

P. H. Robinson\* and D. J. Dumin

RCA Laboratories, Princeton, New Jersey

#### ABSTRACT

Single crystal silicon has been epitaxially grown on (100), (110), and (111) magnesium aluminate spinel. The Hall mobilities of films grown on (111) spinel were higher than similar resistivity films grown on (100) and (110) spinel. Typical values of mobility have been 200 cm<sup>2</sup>/v-sec on 1 μm thick p-type films and 300 cm<sup>2</sup>/v-sec on 15 μm thick p-type films of 0.1 ohm-cm silicon. These mobility values represent 80-100% of the mobility expected on similar resistivity bulk silicon. The autodoping of the films by the substrate was measured and compared with the aluminum autodoping of silicon-on-sapphire films. Silicon grown on spinel was doped about an order of magnitude less than silicon-on-sapphire. The deformation of the film and substrate was found to be anisotropic and the silicon was under a compressive stress of 1-4 · 10<sup>10</sup> dynes/cm<sup>2</sup>.

Recently there has been considerable interest in the growth of silicon films on insulating substrates (1-5). The major portion of this work has been done using either single crystal sapphire or quartz as the substrate material. There have also been reports (6,7) that single crystal magnesium aluminate spinel substrates can be used for the growth of single crystal silicon.

Spinel is a solid solution of MgO and Al<sub>2</sub>O<sub>3</sub> and has a cubic crystal structure with a thermal coefficient of expansion variable with composition but lower than that of sapphire. Spinel is a good insulator which is commercially available in large flame-fusion grown single-crystal boules. This paper will describe the deposition and characterization of single-crystal silicon layers on single-crystal spinel substrates.

#### Physical Properties

The reaction used for the growth of single-crystal silicon films was the pyrolysis of silane diluted in hy-

drogen and has been described in detail (8). Electron diffraction patterns obtained have consistently been those of single-crystal oriented silicon layers and it has been found that the silicon lattice was parallel to the spinel substrate orientation, i.e., (111) silicon parallel to (111) spinel, (110) silicon parallel to (110) spinel, and (100) silicon parallel to (100) spinel, in agreement with previously reported results (6).

Sirtl (9) etching was used to reveal the number of dislocations present in the silicon layers. A typical film grown on (111) spinel and dislocation etched is shown in Fig. 1. The major growth imperfection appears to be stacking faults.

The deformation of silicon films between 2 and 25 μm thick on 0.025 and 0.050 cm thick spinel has been measured using a cross-section microscope. In all cases the deformations were anisotropic and exhibited a maximum deformation in one direction and a minimum deformation perpendicular to this direction. A

\* Electrochemical Society Active Member.

Fig. 1. Dislocation etched 15  $\mu\text{m}$  thick silicon-on-spinel film

typical plot of maximum and minimum deformation of a 5  $\mu\text{m}$  thick silicon film on 0.050 cm thick (111) oriented spinel is shown in Fig. 2. Removal of the silicon by chemical etching restored the spinel to a flat surface. This maximum deformation is about five times as large as the deformation of silicon grown on sapphire (10) and corresponds to a stress in the silicon of  $1.4 \times 10^{10}$  dynes/cm<sup>2</sup>. Measurements of silicon grown on (100) and (110) spinel substrates have yielded similar but smaller anisotropic deformations than (111) spinel. Occasionally the deformation is accompanied by cracking of the spinel substrate as well as the exsolution of  $\alpha\text{-Al}_2\text{O}_3$  from the spinel.

In an attempt to lower the deformation, 0.005 in. stripes spaced 0.050 in. on centers were etched in a 5  $\mu\text{m}$  thick film deposited on (100) spinel. The deformation measured in the direction of the stripes was small; however, the deformation perpendicular to this direction was relatively large. This is a further indication of the anisotropy in the spinel substrates used. Attempts to grow silicon on spinel through holes in a sapphire mask lead to spinel that was cracked along the edge of the deposited line.

#### Electrical Properties

Both p- and n-type silicon films have been grown via the addition of either  $\text{B}_2\text{H}_6$  or  $\text{AsH}_3$  during silicon growth on (100), (110), and (111)  $\text{MgO} \cdot 3.5 \text{Al}_2\text{O}_3$  spinel. Films between 1 and 30  $\mu\text{m}$  thick have been grown. Typical Hall mobilities measured on films 10-15  $\mu\text{m}$  thick are shown in Table I for films grown on different orientations of spinel. The films grown on (111) spinel have consistently had higher mobilities

Fig. 2. Deformation of silicon-on-spinel film: (a) deformation along axis of maximum deformation; (b) deformation along axis of minimum deformation.

Table I. Hall mobility of 10-15  $\mu\text{m}$  thick silicon films grown on spinel

Spinel orientation	Hall mobility (cm <sup>2</sup> /v-sec)	Conductivity type	% of Bulk for same resistivity
(111)	250-330	p-type	80-100
(100)	162-170	p-type	48-58
(110)	50-60	p-type	16-18
(111)	410-645	n-type	53-65

than films grown on either (100) or (110) spinel. The p-type films had higher resistivity than films grown on sapphire under similar growth conditions indicating that aluminum autodoping from the substrate is less severe in silicon grown on spinel than in silicon grown on sapphire (5).

The Hall mobility and resistivity of 1-2  $\mu\text{m}$  thick silicon films grown on (100) and (111) spinel at different growth temperatures were measured and are shown in Fig. 3 and 4. The highest mobility films were grown at temperatures near 1200°C where typical values of 200 cm<sup>2</sup>/v-sec on (111) spinel and 100 cm<sup>2</sup>/v-sec on (100) spinel were obtained on p-type films. Higher Hall mobilities have been measured on thicker films indicating an improvement in silicon structure as the film grows thicker. The increase in Hall mobility with film thickness appears to be a general characteristic of heteroepitaxially grown films (11). The mobility-growth temperature curve was more sharply peaked in (111) silicon films than on (100) silicon films, similar to the behavior of (111) silicon grown on (0001) sapphire and (100) silicon grown on (1102) sapphire (12).

Fig. 3. Hall mobility of silicon films grown on (100) and (111) spinel as a function of growth temperature.

Fig. 4. Resistivity of silicon films grown on (100) and (111) spinel vs. growth temperature.

Fig. 5. Carrier concentration vs. growth temperature

Improvement in silicon crystal quality with increasing film thickness has been directly observed. Silicon films  $15\ \mu\text{m}$  thick grown on (111) spinel were polished at a  $\frac{1}{2}^\circ$  angle to the substrate. Chemical etching of the films indicated a decrease in the incidence of crystal faults as the film became thicker. Defect densities of the order of  $10^8/\text{cm}^2$  have been observed at the surface of  $5\ \mu\text{m}$  thick films.

The carrier concentration of the silicon films, as derived from the Hall data, is plotted in Fig. 5. The substrate autodoping raises the acceptor concentration in films grown at the higher temperatures, an effect previously observed in silicon grown on sapphire (5). At a given growth temperature the acceptor concentration (presumably due to aluminum) in a silicon film grown on spinel is approximately an order of magnitude less than the acceptor concentration in a similar film grown on sapphire. In silicon grown on sapphire the autodoping has been linked with the hydrogen reduction of sapphire releasing aluminum into the film. It is suspected that a similar reaction is releasing aluminum into the silicon films grown on spinel, but the cracking and exsolution of the  $\alpha\text{-Al}_2\text{O}_3$  in spinel at high temperatures have limited the high temperature experiments to determine the source of the acceptors. A comparison between the autodoping found in silicon-on-spinel films and silicon-on-sapphire films is shown in Fig. 6, where the acceptor concentration vs. growth temperature is plotted for  $2\ \mu\text{m}$  thick films grown on both spinel and sapphire.

The activation energy associated with the autodoping process has been determined from plots of accep-

Fig. 6. Comparison of autodoping on silicon films grown epitaxially on sapphire and spinel.

Fig. 7. Diffusion front of phosphorus into p-type silicon-on-spinel as a function of silicon thickness.

tor concentration vs. reciprocal temperature. Activation energies of 170 kcal/mol and 160 kcal/mol on (111) and (100) silicon on spinel have been measured, similar to the activation energies measured in silicon-on-sapphire films.

Diffusion of phosphorus into angle polished surfaces has led to a diffusion profile which was uniform in the thick silicon and a profile that contained diffusion spikes in the thin silicon. A photograph of a phosphorus diffusion front in p-type silicon as a function of film thickness is shown in Fig. 7 where the better quality of the thick film is evident from the sharp diffusion front obtained in the thicker section.

The diode characteristics obtained by phosphorus diffusion into silicon grown on (100) and (111) spinel have been compared with diodes made on similar resistivity bulk silicon. For silicon layers thicker than about  $8\ \mu\text{m}$  the diffusion fronts were sharp and were of the same depth as in bulk silicon. Diode breakdown voltages agreed with those predicted for bulk silicon of similar resistivity (13). The breakdowns were sharp although the reverse currents were larger than predicted (14). This could be due to the low minority carrier lifetime in these films (nano-second range) or due to high field emission in the vicinity of diffusion spikes or precipitates.

All of the work reported in this paper on the growth of silicon on spinel has been with alumina rich spinel having the composition  $\text{MgO}:\text{Al}_2\text{O}_3$ ; 1:3.0-3.5. The major difficulty with the use of alumina rich spinel as a substrate is the exsolution of  $\alpha\text{-Al}_2\text{O}_3$  at dislocations and subgrain boundaries that accompanies high temperature firing of the spinel (15). This weakens the spinel often causing severe cracking of the substrate as well as deterioration of the substrate surface.

Several (111) oriented stoichiometric spinel wafers were polished and fired in hydrogen for times up to 4 hr at  $1400^\circ\text{C}$ . X-ray and microscopic examination of these surfaces after heating showed that no exsolution of  $\alpha\text{-Al}_2\text{O}_3$  had taken place. There was also no evidence of deterioration of the spinel surface or cracking after this heating. A number of polished (111) oriented stoichiometric spinel surfaces were examined by electron diffraction techniques before and after heat treatment in hydrogen. Before heat treatment the mechanically polished stoichiometric spinel surface gave a ring type Laue pattern. Figure 8 shows the electron diffraction pattern indicating poor polycrystalline surface structure representing work damage. After heating in hydrogen at  $1500^\circ\text{C}$  for 1 hr, the surface observed by the electron diffraction pattern is shown in Fig. 9. A much better single crystal spinel surface free of work damage was produced. Microscopic examination of the spinel surface revealed that thermal etching of the spinel was responsible for this change in surface structure.

Fig. 8. Electron diffraction pattern of mechanically polished spinel wafer.

Fig. 9. Electron diffraction pattern of mechanically polished spinel wafer after heating in  $H_2$  at  $1500^\circ C$  for 1 hr.

Work is underway to investigate the electrical properties of silicon on stoichiometric spinel.

#### Summary

The electrical and mechanical properties of silicon grown on excess  $Al_2O_3$  spinel have been measured and compared to silicon films grown epitaxially on sapphire. The films grown on (111) spinel have in general both higher Hall mobilities and less autodoping than similar thickness films grown on ( $\bar{1}\bar{1}02$ ) sapphire. The films on both substrates have a highly reflective surface and in thicknesses less than 4-6  $\mu m$

can be used directly in device processing without the need for mechanical polishing. The temperature at which the highest mobility films were obtained on spinel was about  $50^\circ C$  higher than the temperature at which the highest mobility films were obtained on sapphire (12). Even at the higher growth temperature the autodoping from the substrate is less on the spinel than on the sapphire. Diodes fabricated in the silicon on spinel have yielded sharp reverse breakdown voltages of a value comparable to the breakdown found in bulk silicon.

# Phosphorus Concentration Profile and Phase Segregation in Phosphosilicate Glass on SiO<sub>2</sub> Films

P. F. Schmidt,\* W. van Gelder,\* and J. Drobek

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

## ABSTRACT

The phosphorus distribution in phosphorus diffused SiO<sub>2</sub> films has been determined by means of neutron activation. The general shape of the profile is in good agreement with the results by Fränz *et al.* (4), who used the P<sup>32</sup> isotope. In the phosphosilicate region occasional strong fluctuations of the P concentration were observed, usually accompanied by changes in the etch rate in 0.2N HF opposite to the expected dependence of etch rate on P concentration. The fluctuations were tentatively attributed to phase segregation in the phosphosilicate glass. Confirmation was obtained from related experiments in which polycrystalline films of composition P<sub>2</sub>O<sub>5</sub> x SiO<sub>2</sub> (and possibly P<sub>2</sub>O<sub>5</sub> x 2SiO<sub>2</sub>) were obtained and identified by electron diffraction.

The neutron activation of phosphosilicate layers on SiO<sub>2</sub> films reported here was originally undertaken in order to study the phosphorus distribution for different phosphorus diffusion and subsequent reoxidation conditions. The resulting phosphorus distributions are described.

During the course of this investigation, strong fluctuations of the phosphorus concentration in the glass region as a function of distance into the glass were discovered. It was noticed that these fluctuations often coincided with a trend of the etch rate in 0.2N HF opposite from that expected from the phosphorus concentration: the higher phosphorus concentration often corresponded to a slower etch rate, and vice versa.

These observations could be explained by assuming phase segregation in the glass, with formation of one or more of the compounds occurring in the P<sub>2</sub>O<sub>5</sub>-SiO<sub>2</sub> system according to Tien and Hummel (1), but there was no hard evidence for the correctness of this assumption except for some radioautographs which showed that slow etching regions of the glass contained indeed more phosphorus than the faster etching portions. Audley (2) has reported on the insolubility in HF of a SiO<sub>2</sub> x P<sub>2</sub>O<sub>5</sub> compound. According to Eitel (3) the system SiO<sub>2</sub>-P<sub>2</sub>O<sub>5</sub> is remarkable in that its components and the binary mixtures near them form glasses readily, while the compounds crystallize well.

Independent evidence for the occasional occurrence of a SiO<sub>2</sub>-P<sub>2</sub>O<sub>5</sub> compound in the phosphosilicate glass was obtained when a polycrystalline film, insoluble in HF, was observed to form at the interface between the phosphosilicate glass and a pyrolytic SiO<sub>2</sub> film deposited on top of the glass. Pyrolysis had been carried out at a much lower temperature (850°C) than was used for the original phosphorus diffusion (1040°C).

It was possible to isolate this polycrystalline film, and to identify by electron diffraction alpha-SiO<sub>2</sub> x P<sub>2</sub>O<sub>5</sub> as its main constituent, with possibly some admixture of 2SiO<sub>2</sub> x P<sub>2</sub>O<sub>5</sub>. The surface of the phosphosilicate layer prior to the pyrolytic SiO<sub>2</sub> deposition showed no evidence of compound formation detectable by electron diffraction or etch rate in HF.

Fränz *et al.* (4), who used the P-32 isotope in their study, also report a scatter in the phosphorus profile [Fig. 8b of ref. (4)], which appears to be outside the error of measurement; however, they did not attempt an explanation. If the cause for the fluctuation in phosphorus concentration reported by them is also phase segregation, as appears likely, then their results would indicate that neither neutron activation nor pyrolytic

deposition of SiO<sub>2</sub> are required to trigger the formation of SiO<sub>2</sub> x P<sub>2</sub>O<sub>5</sub> in the phosphosilicate glass.

It is perhaps worth noting in this context that Snow and Deal (5) describe phosphosilicate layers as "behaving as though they had a very slow dipolar polarizability. The 'dipoles' involved may be physical dipoles with a concentration of 10<sup>19</sup> cm<sup>-3</sup>, or they may be small regions of the glass occupying about 6% of the volume which polarize by interfacial polarization."

## Activation Studies

*Method.*—P-type silicon disks after oxidation and phosphorus diffusion, were subjected to neutron activation. The wafers were then etched in dilute HF to remove the oxide in controlled steps of about 100Å, and the phosphorus profile in the oxide was established by measuring the activity remaining on the slice after each etching step. The oxide thickness was measured by means of a spectrophotometer.

As stated above, strong fluctuations in phosphorus concentration were observed in the phosphosilicate region. In order to evaluate the reliability of the tracer data, a knowledge of all possible sources of error is necessary. The experimental technique used is given in the Appendix, together with a brief discussion of the uncertainties accompanying the measured parameters. A full account of the experimental method used for establishing the phosphorus concentration profile in the oxide is given in an extended appendix which is available from the authors on request. It is shown there that the fluctuations of the phosphorus concentration observed in the phosphosilicate region are far outside the error limits.

*Results.*—The over-all diffusion results are summarized in Table I. The thickness of the phosphosilicate glass is defined as that position in the oxide at which the phosphorus concentration drops steeply according to the activity data (see graphs). It can be seen that the phosphorus concentration increases with increasing temperature of diffusion, as expected. Reoxidation in steam under the conditions shown leads to a relatively small increase in glass thickness, to a slight decrease in phosphorus concentration, and to some loss of phosphorus to the ambient (total P/cm<sup>2</sup> of oxide, column 5).

Figures 1 and 2 show two typical phosphorus concentration and etch rate profiles observed in analyzing the samples listed in Table I. The profile shown in Fig. 1 (wafer 30-211), in which phosphorus concentration and etch rate vary in opposite direction at certain positions in the oxide was observed more often than the profile shown in Fig. 2, in which phosphorus concentration and etch rate vary in the same direction. The error bars shown include the contributions

from all known causes. It can be seen that the fluctuations of the phosphorus concentration in Fig. 1 are far outside the errors of measurement.

The low concentration phosphorus tail extending all the way through the oxide and into the silicon substrate<sup>1</sup> is a result of the intense neutron irradiation, and has been described in detail elsewhere (6). An interesting series of autoradiographs is shown in Fig. 3 (wafer 30-223). In addition to the large "diffusion pipe," extending all the way through the oxide, there is a triangular "hot spot," which was initially invisible (a) because it was masked by the high phosphorus concentration of the surface layers. It became visible (b) when 800Å of the oxide had been removed by etching, and then lasted for another 800Å (c) before disappearing again (d); it is thus located in the phosphosilicate glass region (cf. Table I). This triangular spot also showed up optically as a region of increased oxide thickness. If the spot were due just to a higher local concentration of phosphorus (without compound formation), one would expect an increased etch rate and therefore a locally decreased oxide thickness, i.e., the reverse of what is observed. The explanation that adsorption of some kind of protective film had occurred in the area of the triangular spot appears invalid because the oxide thickness in the area of the triangular spot did not remain constant during the series of etching steps from (b) to (c), but decreased

though at a slower rate than the rest of the oxide. Unfortunately, the opportunity was missed to examine this triangular spot by electron diffraction. It will be appreciated that the exposure times in Fig. 3 increased with each etching step, so that features well visible in the long exposure autographs would be swamped in the short exposure pictures. The size of the circular diffusion pipe in radioautographs (c) and (d) is an artifact: the "pipe" has not spread in diameter, but the image of the pipe was badly overexposed at an exposure time adequate for the rest of the wafer. The overexposure caused the diffuse lateral spreading of the image of the pipe. Wafer 30-223 was also the only wafer on which a pipe of such intensity was observed. Densitometric evaluation of the radioautographs taken from other wafers showed that the contribution by pipes is unimportant relative to the phosphorus concentration in the rest of the oxide, at least in the high phosphorus concentration region. In particular, the pipes cannot be held responsible for the fluctuations of phosphorus concentration observed in the phosphosilicate glass region.

The number 30-223 appearing in (d) of Fig. 3 is due to phosphorus decoration of dislocations generated by scribing the Si disk. The decoration disappeared when 1200Å of silicon were removed by anodic oxidation. The lighter periphery of the disks is due to preferential loss of phosphorus from the wafers during neutron irradiation; evaporation of

<sup>1</sup> In addition to some P<sub>2</sub>O<sub>5</sub> "pipes" not present on all wafers.

phosphorus from the center of the disks was suppressed by aluminum spacers inserted between each wafer.

#### Formation of a Polycrystalline Phosphosilicate Film Triggered by Pyrolytic Deposition of $\text{SiO}_2$

**Experimental.**—A number of chemically polished silicon slices, 50 ohm-cm P-type, {111} oriented, diameter 1 in., were oxidized in 100% steam of atmospheric pressure for 1 hr at 1100°C. The resulting oxide thickness was 6800Å, as determined from the wavelength position of the interference fringe minima. The slices were next phosphorus diffused in  $\text{PBr}_3$  at 1040°C for 40 min, resulting in a phosphosilicate glass layer on top of the  $\text{SiO}_2$  film. The total thickness of the dielectric layer after diffusion was 7150Å. The slices were then deposited with  $\text{SiO}_2$  at 850°C from a gas mixture consisting of 0.15%  $\text{SiCl}_4$ , 0.15%  $\text{O}_2$ , and 99.7%  $\text{H}_2$ . The total thickness after deposition of the pyrolytic  $\text{SiO}_2$  was 10,200Å. The slices were then step-etched in P-etch (14), and the remaining thickness of the dielectric layer was measured at various intervals.

Figure 4 shows that the etch rate of the oxide "sandwich" varied with depth as expected. That is, at first the etch rate was fairly constant, then increased steeply in the phosphosilicate glass region, to fall off

Fig. 4. Oxide thickness of sandwich vs. time in P-etch. Thermal  $\text{SiO}_2$ /phosphosilicate glass/pyrolytic  $\text{SiO}_2$ .

\* 3.54 is the highest intensity  $d$ -value of  $2\text{SiO}_2 \times \text{P}_2\text{O}_5$  according to Tien and Hummel (1).

again to a low and constant value when the phosphorus concentration had become negligible.

After 8.5 min of etching, a thin film, apparently insoluble in the P-etch, floated off the surface. This film was removed from the solution and placed into buffered HF<sup>2</sup> for 3 days without dissolving. Transmission electron diffraction showed the film to be  $\alpha\text{-SiO}_2\text{-P}_2\text{O}_5$  (compare below).

No insoluble film was observed when the phosphosilicate layer was etched prior to pyrolytic  $\text{SiO}_2$  deposition. After  $\text{SiO}_2$  deposition, followed by 4 min of etching in P-etch, i.e., still in the deposited  $\text{SiO}_2$  layer, glancing-angle electron diffraction showed some crystallinity, too diffuse for identification (cf. Fig. 4). However, after 7 and 8 min of etching, electron diffraction showed the presence of  $\alpha\text{-SiO}_2\text{-P}_2\text{O}_5$ . This diffraction pattern was distinctly different from the diffuse pattern seen after 4 min of etching. It appears likely that the  $\text{SiO}_2\text{-P}_2\text{O}_5$  crystals induced conversion of  $\text{SiO}_2$  to  $\alpha$ -crystalalite which extended some distance into the pyrolytic  $\text{SiO}_2$ . It is known (7) that  $\text{SiO}_2\text{-P}_2\text{O}_5$  is highly analogous to  $\alpha$ -crystalalite and catalyzes this transformation.

After 8 min of etching there are also indications of the presence of traces of  $2\text{SiO}_2 \times \text{P}_2\text{O}_5$  (presence of the reflection  $d = 3.54\text{Å}$ , cf. Table II), according to the data by Tien and Hummel (1). At 8 min the polycrystalline film was visible under an optical microscope and could be scraped with a sharp needle.

Figures 5, 6, and 7 are a series of pictures of a slice on which the left half lagged 1 min behind in etching time compared to the right hand half. This difference in etching time was brought about by masking the left half, etching the slice for 1 min, and then removing the mask. From then on the left half always lagged behind the right half by 1 min etching time. The pictures were taken under dark field illumination at a magnification of 428x.

Figure 5 shows a polycrystalline film appearing on the right hand side after 8 min of etching, while no crystallinity is yet visible on the left hand side (etched for 7 min). The high intensity light spots on both left and right hand side should be ignored as due to either pin holes or loose particles on the surface.

Figure 6 is taken from the same area of the slice as the right hand side of Fig. 5. It was also etched for 8 min and it shows the film partly scraped by means of a sharp needle.

<sup>2</sup> 40g  $\text{NH}_4\text{F}$ , 15 cc conc HF, 60 cc  $\text{H}_2\text{O}$ .

Fig. 5. Microphotograph of oxide sandwich after etching in P-etch. Right half etched for 8, left half for 7 min. Polycrystalline film visible only on right half.

Fig. 6. Microphotograph of right half of Fig. 5, after scraping with steel needle.

Fig. 7. Microphotograph of oxide sandwich after etching in P-etch. Right half etched for 9, left half for 8 min. Polycrystalline film has lifted from right side, but is visible on left side.

The right hand side of Fig. 7 shows an area that was etched 9 min. The film has completely lifted from this side. A part of the loose film is visible in the lower middle part of the picture. The left side of the

picture shows an area that was etched for 8 min. The polycrystalline film on this side is clearly visible and is identical in appearance with the film in Fig. 6.

#### Identification of the Film as $\alpha$ - $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ by Electron Diffraction

Electron diffraction patterns were obtained both from the isolated film (in transmission) and from the film on the surface (in reflection) after 7-8 min of etching. The patterns taken in transmission were more distinct, and are compared in Table II to the x-ray data by Tien and Hummel (1) for the low-temperature (=  $\alpha$ ) modification of  $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ . The agreement is very satisfactory. The x-ray data contain reflections which do not show up in the electron diffraction pattern because in this latter case the sample is not being rotated so that certain crystal planes do not reflect. The observed reflections, however, match their counterparts in the x-ray data quite closely. The appearance of a reflection at  $d = 3.54\text{\AA}$  may be considered as an indication that traces of  $2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$  are present since this is the strongest reflection of this compound according to Tien and Hummel (1).

#### Discussion

Phase segregation is suggested by the large fluctuations in phosphorus concentration in the phosphosilicate region, and by the often opposing trends of phosphorus concentration and etch rate. The latter relationship is masked to some extent by the strong effect of the neutron irradiation on the etch rate.

The transition from phosphosilicate glass to undoped  $\text{SiO}_2$  extends over 100-200 $\text{\AA}$ . The shape of the diffusion profile in this transition region can be explained on the basis of strongly concentration dependent diffusivity. It was shown by Thurston *et al.* (8) that the diffusivity of phosphorus (pentoxide) in  $\text{SiO}_2$  at lower concentrations than corresponds to the "glass" is strongly concentration dependent and very slow, especially at lower temperatures (below 1200°C). Thus the diffusivity in the phosphosilicate glass region, according to Sah *et al.* (9), is  $2.5 \times 10^{-13} \text{ cm}^2 \text{ sec}^{-1}$  at 1100°C, but only about  $10^{-16} \text{ cm}^2 \text{ sec}^{-1}$  at the same temperature and a concentration of 3%  $\text{P}_2\text{O}_5$  in  $\text{SiO}_2$  according to Thurston *et al.* (8). The fast diffusion in the glass region thus ensures a practically flat concentration profile in the glass up to the point where the phosphorus concentration drops steeply. Reoxidation of the wafers leads to slight penetration of the phosphorus front under the given reoxidation conditions (2-400 $\text{\AA}$ ), a lowering of the maximum phosphorus concentration, and to some loss of phosphorus to the ambient (about 15% of the total originally contained in the oxide after diffusion).

Pyrolytic deposition of  $\text{SiO}_2$  leads occasionally to the formation of a polycrystalline film across the whole surface of the phosphosilicate glass, thus facilitating its detection. The details of this (catalytic) effect have not been established. The main constituent of this film has been unambiguously established as  $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ , possibly with traces of  $2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ . The ratio of  $\text{SiO}_2$  to  $\text{P}_2\text{O}_5$  in the phosphosilicate glass is about 4:1, so that formation of some  $2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$  might be expected. According to Tien and Hummel, the 2:1 compound melts incongruently at 1120°C to a silica-rich liquid and  $\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ . Even though the system in the present case was not heated to 1120°C, the formation of the 1:1 compound was favored.

#### Acknowledgments

The authors wish to thank V. E. Hauser for the deposition of the pyrolytic  $\text{SiO}_2$  films, and D. R. Wonsidler for help with the tracer experiments.

Manuscript received June 5, 1967; revised manuscript received Sept. 27, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## APPENDIX

*Activation Studies, Experimental*

Float-zoned 1.3 ohm-cm P-type silicon, {111} oriented, was used throughout. The wafers were mechanically lapped and polished, and then given a chemical polish to remove surface damage. Average dislocation density of the starting material was  $12,000 \text{ cm}^{-2}$  by Sirtl etch.

Table I lists the wafers according to oxidation and diffusion treatment. Oxidation was carried out in steam, diffusion was from a  $\text{PBr}_3$  source kept at  $30^\circ\text{C}$ , with part of the carrier gas bubbling through the  $\text{PBr}_3$  source. Subsequent to diffusion the wafers were cooled directly to room temperature by pulling from the furnace.

For irradiation, the wafers were wrapped in a special high purity aluminum foil, with high purity aluminum disks inserted between each Si wafer in order to insure uniformity of neutron dose throughout the charge. The wafers were irradiated for seven days at the Brookhaven National Laboratories at a flux of  $1.2 \times 10^{13} \pm 5\%$  thermal and  $1.5 \times 10^{11} \pm 10\%$  fast neutrons  $\text{cm}^{-2} \text{ sec}^{-1}$ , leading to a specific activity of 11.0 Curies per mol of phosphorus. The wafers were not intentionally cooled during neutron irradiation, and the temperature in the aluminum capsule may have risen about  $50^\circ\text{C}$  above the ambient temperature of  $250^\circ\text{C}$  at the place of irradiation.

Subsequent to irradiation the wafers were kept in storage for several weeks to permit decay of the  $\text{Na}^{24}$  beta and gamma activity (from the reaction  $\text{Al}^{27}(\text{n},\alpha)\text{Na}^{24}$ ), of the beta-activity of  $\text{Si}^{31}$  (from the reaction  $\text{Si}^{30}(\text{n},\gamma)\text{Si}^{31}$ ), and of the beta activity of  $\text{Br}^{82}$  (from the reaction  $\text{Br}^{81}(\text{n},\gamma)\text{Br}^{82}$ ). The half-lives of  $\text{Na}^{24}$ ,  $\text{Si}^{31}$ , and  $\text{Br}^{82}$  are 15.05 hr, 2.62 hr, and 35.5 hr., respectively. At the end of the investigation, when the phosphorus activity had already largely decayed, the presence of  $\text{S}^{35}$  could be detected both from its decay rate and its beta-energy spectrum.<sup>3</sup> The  $\text{S}^{35}$  was probably introduced by neutron activation of a chlorine impurity in the  $\text{PBr}_3$  source, by means of the reaction  $\text{Cl}^{35}(\text{n},\text{p})\text{S}^{35}$ .<sup>4</sup> The level of contamination with  $\text{S}^{35}$  was too low to affect the phosphorus determinations. The half-life of  $\text{S}^{35}$  is 86.7 days.

<sup>3</sup>The authors are indebted to J. D. Struthers for these measurements.

<sup>4</sup>Contamination with sulphur cannot be the cause since the observed surface concentrations of  $8 \times 10^{10} \text{ cm}^{-3}$  are above the solid solubility limit for sulphur in silicon (11).

A Nuclear-Chicago gas flow detector, model D47, operated in the Geiger tube mode, in conjunction with a Nuclear-Chicago Decade Scaler, series 8703, was used to determine the activity of the samples. Since this counting system has already 1% loss at 6000 counts/min, suitable aluminum absorbers were placed over the samples. Each time an absorber was removed or exchanged against another absorber, the ratio of the counts under the two conditions was determined. It was thus possible to calculate the counting rate in the most active conditions of the wafers (i.e., before step-wise stripping of the oxide in HF) by using the final counting rate without any absorber (i.e., when most of the activity had been etched away) as the starting point for the calculation. It is felt that no appreciable error was introduced by this procedure, since a sufficient number of counts was taken to reduce the statistical errors to insignificant values.

The detection efficiency of the detector was measured by means of a  $\text{P}^{32}$  simulated source of  $2.8 \times 10^{-5}$  millicuries (supplier: Tracerlab, Waltham, Massachusetts) calibrated against standards of the NBS.

An aluminum holder served to position either the  $\text{P}^{32}$  simulated source or the Si wafers underneath the window of the Geiger tube. Measuring conditions for source and samples were kept as nearly identical as possible. Counts were taken to 10,000 for each point in the high phosphorus concentration region, and to at least 2000 above background in the low phosphorus concentration region of the oxide films.

A Perkin-Elmer model 202 visible-uv spectrophotometer was used to measure the reflectance minima as a function of wavelength (12). Oxide film thicknesses were then calculated by assuming the same refractive index for the phosphorus-doped film as for thermal  $\text{SiO}_2$  films. This involves only a small error, of the order of 1% (4, 13); a more accurate determination of the refractive index would not have been meaningful in view of the continuously changing  $\text{SiO}_2\text{-P}_2\text{O}_5$  composition as a function of film thickness.

Radioautographs were taken with type AA x-ray film because of its sensitivity. It is, however, a double emulsion film and rather coarse grained.

The analysis consisted in principle in measuring the activity of the silicon wafers before and after successive etching of the oxide in dilute HF in order to decrease its thickness in steps of about 100Å each. The oxide from one side of the wafer was removed completely, and the wafer was measured with active side facing the window. After each etching step the oxide thickness was remeasured. On a considerable number of wafers radioautographs were taken before, during, and after stepwise dissolution of the oxide. Controlled etching of the oxide was carried out in 0.2N HF until low phosphorus concentrations were reached and the strength of the etching solution had to be increased in order to have reasonable etch rates. In the phosphosilicate glass region it was not possible to use the so-called "P-Etch" (14) because of the excessively fast etch rate caused by radiation damage to the oxide.<sup>5</sup> It was, however, noticed that the 0.2N HF solution was more sensitive to variations in phosphorus concentration than a 1.0N HF solution, and the latter in turn was more sensitive than the P-Etch. The dissolution of the oxide was usually very uniform, and only occasionally were very weak differences in local interference color detectable by the unaided eye.

The counting rates observed were converted to phosphorus concentrations by means of the relationship

$$A = N \times f \times \sigma \times S \times e^{-\lambda t} \quad [1]$$

where  $A$  is the activity in disintegrations  $\text{sec}^{-1}$  (corrected for the detection efficiency of the system, 13.5%),  $N$  is the number of atoms of  $\text{P}^{31}$  originally present,  $f$  is the thermal neutron flux  $\text{cm}^{-2} \text{ sec}^{-1}$ ,  $\sigma$  is the capture cross section of  $\text{P}^{31}$  for thermal neutrons,  $S$  equals  $1 - e^{-\lambda t}$ ; for  $t$  equals 1 week ( $6.04 \times 10^5 \text{ sec}$ ), and the decay constant  $\lambda$  of  $\text{P}^{32} = 5.6 \times 10^{-7} \text{ sec}^{-1}$ , the saturation factor  $S = 0.28$ . The  $t$  in the exponent in Eq. [1] is the time in seconds elapsed since the end of irradiation.

Equation [1] must in principle be corrected for a

<sup>5</sup>Enhanced by a factor of  $\sim 2$  for pure  $\text{SiO}_2$  and of  $\sim 8$  for phosphosilicate glass compared to the values given in ref. (14).

background activity of  $P^{32}$  introduced by the reaction (15)

However, for phosphorus concentration above  $10^{17} \text{ cm}^{-3}$ , *i.e.*, in the phosphorus concentration range of interest here, this correction may be neglected.

#### Errors

The accuracy of the terms in Eq. [1] determines the precision with which a known disintegration rate can be converted into number of phosphorus atoms. The accuracy with which the disintegration rate is known depends on the knowledge of the collection efficiency of the measuring system. The following assumptions were made concerning these quantities: the slow neutron flux was assumed to be known to  $\pm 5\%$ ; the activation cross section of  $P^{31}$ ,  $0.19 \pm 5.2\%$  barns (16); decay constant of  $P^{32}$ , 14.30 days; accuracy of  $P^{32}$  simulated source,  $\pm 5\%$ ; statistical error inherent in the radioactive decay phenomenon was kept at 1% in the phosphosilicate glass region by taking a sufficiently large number of counts.

The phosphorus concentration profile was obtained by dividing the decrement in phosphorus activity detected on the silicon after each etching step by the thickness of the oxide slice removed. The error due to

statistical fluctuations in counting rate can be kept small, as discussed above, but the determination of the oxide slice thickness introduces a considerable error. The shift in the position of the reflectance minima from one etching step to the next can be measured to about  $\pm 15\text{\AA}$ ; since a single etching step was usually of the order of 200\AA, the error for each individual point in the phosphosilicate glass region due to this source of error is usually about 7.5%.

At the transition from the glass region to the weakly phosphorus-doped  $SiO_2$ , etch rates occasionally dropped to very low values and only 40-50\AA were removed per step. Where the experimental points in the graphs shown are very closely spaced ( $\ll 100\text{\AA}$  apart), only the general trend of the curve, rather than the absolute values of the individual points should be considered; the latter could easily be wrong by a factor of 2. The points outside the phosphosilicate region are shown only for the sake of completeness; they show very strong scatter, as is to be expected for a variety of reasons.

It is estimated that the absolute phosphorus concentrations in the phosphosilicate region are known to better than  $\pm 30\%$ , the relative phosphorus concentrations in the glass region to better than  $\pm 20\%$ , and the relative phosphorus concentrations in the low phosphorus region within a factor of about 2.

## Effects of High Phosphorus Concentration on Diffusion into Silicon

M. C. Duffy,\* F. Barson,\* J. M. Fairfield,\* and G. H. Schwutte

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

#### ABSTRACT

Phosphorus diffusion into silicon has been explored near and above the solubility limit by radiochemical profiling and compared with crystal damage by x-ray diffraction microscopy and Sirtl etch techniques. An apparent diffusion retardation has been found for very high source concentrations that results in a shallowed junction penetration for certain higher surface concentrations. The retardation phenomenon occurs over a narrow range of surface concentrations, within which diffused junctions are nonuniform, or ragged. This effect can be correlated with large amounts of crystal disorder inside the diffused area and dislocation loops outside at the peripheries. These outside loops have been found to degrade transistor gain.

Phosphorus diffusion into silicon has been very important in the semiconductor device industry because of its use in fabricating N-P junctions, especially emitters for N-P-N transistors. Nevertheless, phosphorus diffusion from high concentrations is not well understood and many anomalous effects have been reported (1-6). An additional anomaly not reported previously has been found which manifests itself in an apparent retardation of the phosphorus diffusion under some circumstances when maximum surface concentrations are involved. This anomaly can have serious consequences upon device fabrication.

The effect can best be described by outlining the conditions under which it has arisen in typical transistor fabrication procedures. In our case, phosphorus diffusion is accomplished by a two step process, a deposition and a drive-in cycle. The system and technique are similar to that used by McDonald *et al.* (6). The deposition cycle is 35 min in length at  $970^\circ\text{C}$  with a controlled amount of a phosphorus source in an ambient of nitrogen with about 2% oxygen. The drive-in cycle is 5 min in dry  $O_2$ , 30 min in steam, and 40 min in dry  $O_2$ , also at  $970^\circ\text{C}$ . After deposition only, the diffused junction depth increases with phosphorus source concentration (in the ambient gas) up to a point and, thereafter, remains constant.

Presumably this point corresponds to the solid solubility of phosphorus at the deposition temperature. After the subsequent drive-in cycle, the

junction depth initially increases with phosphorus source concentration as before, but at a certain concentration it decreases sharply as shown in Fig. 1. Also, as illustrated by the photo inserts, there is a concentration range in which the junctions are ragged, which is a serious effect for emitter diffusions. Flat junctions are obtainable above and below this ragged area, which appears to be a transition region.

An understanding of this phenomenon is important for controlling transistor fabrication procedures employing high concentration phosphorus diffusions. Other types of phosphorus diffusion techniques also result in this retardation effect at high concentrations. Furthermore, although flat emitter junctions can be made by employing phosphorus concentrations above the ragged region, certain transistor parameters are influenced and degraded (*e.g.*, gain) when the emitter diffusion is in this retarded region. Therefore, this phenomenon has been investigated with the purpose of understanding the conditions under which it arises. This report describes the investigation and discusses possible mechanisms through which the diffusion retardation and ragged junctions should occur.

#### Experimental Procedure

For this investigation, Czochralski grown silicon wafers (111) oriented and virtually dislocation free were used. They were lapped and chemically polished to remove all surface damage. Phosphorus diffusions

\* Electrochemical Society Active Member.

Fig. 1. Junction depth vs. phosphorus concentration; circles represent data after drive-in cycle. Photo inserts illustrate the junction depth from beveling and staining at representative points.

were done in the manner described in the introduction. Both blanket diffusions over the entire wafers and planar diffusions using standard oxide masking techniques were used; some of the planar structures were emitters of actual N-P-N transistors. Junction depths were measured by standard angle lap and copper staining techniques.

Diffused phosphorus profiles were determined on blanket diffusions by neutron activation analysis techniques similar to that employed by Tannenbaum (1) and Kooi (7). After diffusion, wafers were irradiated with neutrons to produce  $P^{32}$ . The wafers were profiled by anodizing and etching the resultant oxide to remove thin layers of silicon and employing a liquid scintillation radio-assay of the etchants to determine the amount of phosphorus atoms removed in each etching step. In some cases, the wafer itself was counted with a Geiger-Mueller type counter after each step; the two counting techniques agreed well.

The crystallographic damage of the diffused areas was determined by x-ray transmission diffraction microscopy, using the scanning oscillator technique (SOT) to record topographs of entire wafers (8); by transmission electron microscopy (9); and by Sirtl etching (10) of diffused areas. Taking advantage of the nondestructive nature of the first technique, x-ray topographs were made of both blanket and planar diffused wafers after both the deposition and the drive-in cycles. In a few cases, transmission electron microscopy was used to resolve the structure of the crystal disorder revealed by the x-ray topographs (11). Finally, diffused areas were Sirtl etched for 10-15 sec and examined for crystal disorder.

In some cases when the crystal structure around actual devices was examined, transistor gain and  $V_{be}$  were measured and correlated with the crystallographic structure of the phosphorus diffused area. If the base width is narrow compared to carrier diffusion length,  $V_{be}$  at a given low current can be used as a relative measure of total base doping (12). Since the time-temperature cycles of these diffusions were identical and the junction depths similar, small variations in  $V_{be}$  reflect similar variations in effective base width; equal  $V_{be}$ 's indicate equal base widths. For this investigation  $V_{be}$  was used only as a relative measure of effective base width and no attempt was made to relate this factor to transistor gain theoretically.

### Results and Discussion

Figure 2a illustrates the phosphorus profiles prior to drive-in for two concentrations of phosphorus, one above and the other below the ragged region. As might be expected, the profiles are similar and the junction depths are almost equal. Figure 2b shows profiles for two similar wafers after drive-in. In agreement with the junction depth measurements shown in Fig. 1,

Fig. 2. Total phosphorus concentration profiles; (a) after deposition only, (b) after both deposition and drive-in.

the lower surface concentration diffused to a greater depth. Also, the concentration gradient at any depth is steeper for the higher concentration diffusion. Thus, the effective diffusion coefficient for the higher concentration appears to be reduced all along the profile.

The crystal damage in the diffused areas shows a similar relation to the process steps as the diffusion profiles in that anomalous behavior appears after the oxidizing drive-in-cycle on high concentration samples. After deposition only, the x-ray topographs show almost no evidence of dislocations or precipitation even when very high concentrations of phosphorus are used. An example of such a topograph is illustrated in Fig. 3a which shows no contrast indicative of damage. However, after drive-in, wafers deposited with high concentrations of phosphorus (*i.e.*, above the ragged region) reveal much crystal disorder as indicated by the anomalous contrast of Fig. 3b; this is the same wafer shown in Fig. 3a. It was confirmed through electron microscopy that this crystal disorder consists of dislocations and precipitates as illustrated by the electron micrographs, Fig. 3c.<sup>1</sup> On the other hand,

<sup>1</sup> It may seem surprising that no dislocations appear after deposition; however, it is possible that the rather abrupt appearance of the dislocations is the result of a threshold effect activated by the small increase in total concentration and/or an enhancement of crystal energy from the additional heat cycle and surface oxidation of the drive-in. This is supported by Shockley's model which requires a certain minimum impurity concentration for dislocation formation (see H. S. Queisser, *J. Appl. Phys.*, 32, 1776 (1961)).

Fig. 3. X-ray topograph (SOT) and electron micrographs of blanket phosphorus diffused wafer; (a) x-ray topograph after deposition only; (b) x-ray topograph after drive-in; (c) electron micrograph illustrating dislocation networks, taken at the surface, magnification ca. 8000X.

wafers whose deposition phosphorus concentration was below the ragged region are still relatively free of crystal damage after drive-in. Wafers within the ragged region show a varied crystal disorder.

These observations are confirmed by Sirtl etching. After deposition only, the Sirtl etch technique reveals

Fig. 4. Sirtl etch patterns of transistor structures with phosphorus diffused emitters. Note etch pits surrounding emitter area of unit highest phosphorus concentration. Magnification ca. 215X.

little surface structure. After drive-in, there is much crystal disorder for the wafers of higher phosphorus concentration as shown in Fig. 4. For the sample of 500 ppm phosphorus source, there is the beginnings of a "crow's foot" type pattern similar in nature to the slip lines reported by McDonald *et al.* (6) for similar types of phosphorus diffusion. As the concentration increases, the pattern becomes more dense until it resembles a general haze. Note that for the highest concentration there are a large number of etch pits surrounding the emitter. These pits result from dislocation loops that propagate for considerable distances outside of some high concentration phosphorus diffused planar structures. These dislocations have been described previously (13), and have been shown to be distinct from and often in addition to the diffusion induced dislocation networks within the diffused areas.

From the foregoing observation, it appears that the ragged junction area is a transition region in which diffusion induced dislocations and precipitates are forming. In other words, the dislocations, etc. can be directly correlated with retardation of phosphorus diffusion. When these dislocations are uniformly present or absent across a wafer, the junctions are flat. When these dislocations are not uniform, as when the phosphorus concentration is such that dislocations are just beginning to form, the diffused junctions have variable depths; or, they are ragged. This would correspond to the ragged region of Fig. 1.

The crystal damage within the diffused areas, consisting of diffusion induced dislocations and precipitation, was found to extend into the silicon for about 20-25  $\mu$ in. (or about 1/3 junction depth) as determined by combining the x-ray technique with the anodic removal of thin silicon layers. Conversely, the dislocation loops around the edges of the planar structures extend to depths of 0.5 mils (and sometimes more). Thus, the former type of damage would be confined to the emitter of a transistor, whereas the peripheral dislocation loops would extend well through the base. These dislocation loops are correlated with a reduction of transistor gain; a phenomenon presumably due to carrier recombination within the base along the dislocations. For example, consider the two device wafers, of which x-ray topographs are shown in Fig. 5. The phosphorus concentrations are just about the ragged region in both cases (Fig. 1), and all junctions are flat. However, the peripheral dislocation loops around the edges appear on only one of the wafers. Note that the geometry of the units themselves are delineated by the contrast resulting from the macroscopic elastic strains around the phosphorus diffused areas. The average  $V_{be}$  for both was 0.70v ( $\pm 0.005$ ), but the transistor gain (at 2.5 ma) of those without dislocations was  $52 \pm 3$  and of those with dislocations was  $33 \pm 5$ . This phenomenon can also be illustrated by Fig. 6 which plots transistor gain ( $\beta$ ) vs.  $V_{be}$  for units whose phosphorus concentrations in the emitters were both above and below the ragged re-

Fig. 5. X-ray topographs of device structures upon which transistor gain was subsequently measured.  $V_{be} = 0.70$  at  $I_e = 0.5$  ma: (a) devices without peripheral dislocation loops,  $\beta = 52$ ; (b) devices with dislocation loops,  $\beta = 33$ .

Fig. 6. Transistor gain, " $\beta$ " vs.  $V_{be}$  taken at  $I_e = 0.5$  ma for transistor made with high and low phosphorus emitter diffusions.

gion, 8000 ppm and 500 ppm, respectively. Those of higher concentration would have the peripheral dislocation loops but the others would not. It is obvious that the lower phosphorus concentration yields a higher gain for any given  $V_{be}$ .

#### Possible Mechanisms

At this time, it is not possible to establish a firm model to explain the retardation or ragged junction phenomenon; however, several possible contributory mechanisms may be discussed. As indicated above, the formation of dislocations and precipitates at high concentrations of phosphorus appears to correlate directly with the retardation of the phosphorus diffusion. This suggests a possible relation with relief of lattice strain through dislocations. The diffusing phosphorus concentration profile will introduce strains which are counterbalanced by tensile stresses of the silicon covalent bonds in the neighborhood of the profile itself (14). This strain may enhance the diffusion coefficients of the diffusing impurities. For example, Balluffi and Ruoff (15) proposed three possible mechanisms whereby diffusion is enhanced in strained lattices owing to an increased concentration of vacancies. (Phosphorus is generally believed to diffuse by vacancy exchange.) Two of their three mechanisms involve relationships of excess vacancies to moving dislocations, and the third involves merely an increase in vacancy formation rate in the bulk lattice. Now, the formation of high densities of dislocations (or precipitates) may either simply reduce the lattice strain and the strain enhanced diffusion, or it may "anchor" the dislocations at nodal points of the dislocation networks to prevent a dislocation movement. With respect to the latter possibility, Joshi and Wilhelm (9), show the existence of such nodal points in phosphorus diffusion induced dislocation networks and suggested their role in preventing dislocation movement. Thus, the diffusion induced dislocations may nullify a strain enhanced diffusion mechanism, which is operative just below the ragged junction region.

In addition, the diffusion induced dislocations and precipitates may reduce the effective mobility of the diffusing phosphorus atoms by providing precipitation sites for some phosphorus atoms. This possibility was suggested by Lawrence (16) to explain an apparent retarded phosphorus base diffusion of a PNP transistor when high concentrations of phosphorus were used as the base diffusant, and it was further discussed by Joshi and Dash. (17). However, it must be noted from Fig. 2b that the lower phosphorus concentration profile reflects a higher effective diffusion coefficient at depths well below the point at which precipitates cease.

Since high densities of dislocations correspond to the condition of retarded diffusion, any diffusion enhancement due to dislocations, or their formation, is secondary. This is reasonable since these dislocations normally lie perpendicular to the diffusion direction, see Fig. 3c, and are, thus, unlikely to provide preferential diffusion paths. Also, the formation of these dislocations need not produce a large excess of vacancies if their formation mechanism is by slip. Thus, Nicholas' model, whereby the mere formation of dislocations causes very high vacancy concentrations (3), is probably not important in our system.

#### Summary

A retardation effect of phosphorus diffusion at very high concentration is reported. This retardation is phenomenologically related to the formation of diffusion induced dislocations. It is suggested that this relation is through a reduction of strain enhanced diffusion through dislocation formation. However, precipitation at dislocations may also affect the system.

Also reported is the existence of large dislocation loops around planar structures diffused under conditions of retarded phosphorus diffusion. If these dis-

location loops occur around the emitters, they seriously reduce transistor gain.

### Acknowledgments

The authors gratefully acknowledge the help of Dr. B. Masters, under whose direction the radiochemical profiles were obtained, and Mr. B. Medvecky for virtually all of the diffusion work.

Manuscript received June 26, 1967; revised manuscript received Sept. 11, 1967. This paper was presented at the Philadelphia Meeting, Oct. 9-14, 1966, as Abstract 193. Part of this work was supported under AFCRL Contract AF 19(628)-5059, Bedford, Massachusetts.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## D-C Dielectric Breakdown of Amorphous Silicon Dioxide Films at Room Temperature

F. L. Worthing

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

### ABSTRACT

The dielectric breakdown properties of atmospheric pressure steam-grown silicon dioxide films, grown on fresh epitaxial layers with degenerate silicon substrates, were studied at room temperature as a function of d-c voltage, time, polarity, thickness of the oxide, and rate of change of voltage. Contact was made to the oxide by 0.025 in. diameter evaporated gold dots. The observed phenomena were found to depend basically on the polarity of the applied potential. At positive silicon potentials (gold dots negative) dielectric breakdown occurred abruptly with no detectable conduction below breakdown. Positive breakdown is not time dependent and appears to be of the type generally referred to as intrinsic or disruptive breakdown. At negative silicon potentials (gold dots positive) these films exhibited conduction in the nA range and a time dependence of dielectric breakdown. If  $t$  is the time it takes an oxide to breakdown at an applied voltage  $V$ , a linear relationship between  $V$  and  $t^{-1/4}$  is observed over a range of approximately 150v. This is an empirical relationship known as Peek's law.

Several measurements have been found useful for the comparative evaluation of silicon dioxide films developed for device passivation. One of these is dielectric breakdown strength. However, there has frequently been confusion due to discrepancies between values obtained by different methods.

The dielectric breakdown properties of silicon dioxide films were studied at room temperature as a function of d-c voltage, time, polarity, thickness of the oxide, and rate of change of voltage. The films were grown on fresh epitaxial layers of approximately 25 ohm-cm, N-type with 0.01 ohm-cm, N-type silicon substrates. Surface cleaning of the substrates prior to epitaxial deposition consisted of a solvent degrease, a 2-min HF dip, a deionized water rinse, a 15-min soak in HNO<sub>3</sub> at 80°C, and a final deionized water rinse. Oxides were grown directly on the epitaxial layers, without additional cleaning, by heating the silicon substrates in 1050°C steam at atmospheric pressure. Oxide growth time was about 1 hr (depending on the desired oxide thickness) after which the samples were air quenched. Index of refraction for the oxide films was about 1.47.

For the tests about to be described, dielectric breakdown will be arbitrarily defined as occurring at that voltage which is sufficient to produce damage resulting

in a sustained leakage current greater than 1  $\mu$ a as long as the applied voltage is maintained. An order of magnitude change in either direction for this definition would not greatly alter the values of dielectric strength reported here. After-breakdown self-healing is excluded, and a contact dot generally exhibits current greater than 0.1  $\mu$ a at any applied voltage in the same polarity.

### Sample Preparation and Measuring System

The silicon wafers used were 0.250  $\times$  0.420  $\times$  0.015 in. Various samples having oxide thicknesses ranging from 3000 to 10,000Å were used, although the most commonly used oxide thickness was 6000Å. Fifty 0.025 in. diameter gold contact dots 5000Å thick were evaporated on the oxide. The underside of the silicon substrate was electroless nickel plated to make electrical contact with the test stage. Unless otherwise noted, all samples with their contact dots were baked at 400°C for approximately 1 hr in air before breakdown tests were conducted. The gold dots were contacted by a 0.002 in. diameter gold probe.

Test equipment consisted of a Keithley Model 240 regulated high voltage power supply (accuracy  $\pm$ 1%) and a Hewlett-Packard 425A microammeter. Chart recordings were obtained from a Varian strip chart

recorder, Model G-11A, fed from the microammeter. Voltages were measured by a Keithley Model 610A electrometer. The experimental arrangement is shown in Fig. 1. In some cases voltage was applied at a constant rate by means of a motor driven potentiometer.

In defining polarities the convention will be to call the negative polarity that voltage which makes the silicon negative, or gold contact dot positive.

**Results and Discussion**

*Incipient breakdown region.*—Figure 2 shows the current-voltage characteristic of a contact dot for which the voltage was applied as a voltage ramp. The ramp was started from zero and increased at a constant rate of 10 v/min, in the negative direction, that is, with silicon negative. The start of a region which will be referred to as the "incipient breakdown region" is indicated by the increase in conduction at about 280v ( $4.7 \times 10^6$  v/cm). As application of the voltage ramp continued, conduction continued to increase more and more rapidly, until breakdown occurred at 395v ( $6.6 \times 10^6$  v/cm). Figure 3 shows the conduction pattern of a contact dot for which negative potential was again applied as a voltage ramp, increasing at the rate of 10 v/min. This time, however, the ramp was stopped at the very beginning of the "incipient breakdown region." With the resulting fixed voltage of 300v ( $5.0 \times 10^6$  v/cm) maintained on the sample conduction continued to increase, until breakdown occurred 46 min later. It was thus found convenient to define the "incipient breakdown region" as that region where the application of negative potential results in a leakage current sufficiently unstable that, with no further increase in the applied voltage, it will eventually rise continuously until breakdown occurs.

Fig. 1. Experimental arrangement for dielectric breakdown studies, shown for the case of positive silicon potential.

Fig. 2. Current-voltage characteristic of a contact dot for which increasing negative potential was applied to the silicon by means of a voltage ramp generator. Start of the incipient breakdown region is indicated by an increase in conduction at about 280v.

Fig. 3. Conduction pattern of a contact dot for which negative silicon potential was increased to 300v. Conduction continued to increase, with the voltage held constant, until dielectric breakdown occurred in 46 min. Note the appearance of transient current noise pulses, accompanied by visible light flashes, just prior to breakdown.

This is a characteristic feature of the conduction behavior for any fixed negative voltage in or close to the incipient breakdown region; over 100 dielectric breakdown tests were conducted in the manner described using various SiO<sub>2</sub> film samples. Thus the time required for breakdown to occur at the negative polarity is determined by the magnitude of the voltage and its rate of application prior to reaching that magnitude.

If the incipient breakdown region was approached repeatedly by the voltage ramp technique, the current instability started at a somewhat lower voltage each time and eventually breakdown occurred at about 250v ( $4.16 \times 10^6$  v/cm). This is about 150v lower than breakdowns obtained by a single continuous application of the voltage ramp. It thus appears that permanent damage was done each time the incipient breakdown region was approached, even though the current was never allowed to exceed 0.1 na. The phenomenon described here applies only to the case of silicon negative, since the incipient breakdown region is polarity dependent. The effect of lowering the breakdown strength by the previous application of stress has been noted previously by others (1). The foregoing observation would seem also to be in agreement with the theory of a constant volt-time life of insulation (2).

*Time-voltage curves.*—These experimental results show that, with negative voltages applied to the silicon, breakdown of SiO<sub>2</sub> usually is a gradual time dependent process. It is not therefore to be confused with intrinsic breakdown (to be discussed later) which would occur only as a very rapid process and for the most part at considerably higher field strengths.

In Fig. 4 each point represents time to breakdown, at negative silicon potential, for a different contact dot on the same sample. For example, the point indi-

Fig. 4. Dielectric breakdown levels vs. time for negative silicon potential. Point indicated by the arrow was obtained by applying a negative potential of 300v until breakdown occurred in 78 min.

cated by the arrow was obtained by applying full stress at 300v until breakdown occurred in 78 min. ("Full stress" means that full voltage was reached in less than 1 min.) By choosing different test voltages for the various contact dots on a sample a time voltage curve is obtained. These test voltages are shown plotted against linear time. A replot of the same data is shown in Fig. 5 with the linear time scale replaced by a  $t^{-1/4}$  scale, where  $t$  is time to breakdown. The  $t^{-1/4}$  dependence is an empirical relationship known as Peek's law which may be stated as  $V = V_0 + at^{-1/4}$ , where  $V$  is breakdown voltage at any time  $t$ ,  $V_0$  is the infinite-time breakdown, and  $a$  is a constant (3). Materials for which curves obeying this law have been reported in the literature include synthetic plastics, various glasses, porcelain, and mica. (It should be noted, however, that in most of these cases there was no polarity effect, since the same electrodes were used on both sides of the insulator.) Peek's law appears to hold for d.c. only where there is some instability in conduction behavior which causes the current to tend to increase with the voltage held constant. This degradation of the dielectric with time has often been referred to in the literature as "thermal instability," although what actually happens may be gradual chemical or physical deterioration as suggested by Miller (4). The term thermal instability is used here with this qualification. Peek's law is applicable below some potential which is called the intrinsic breakdown level. In Fig. 5 the last two breakdown points, at the extreme right of the figure, fall short of the curve because they are in the intrinsic range which is not time dependent. The intrinsic level for this sample was about 410v. Time-voltage curves, similar to the one shown here, have been obtained for numerous samples with negative potentials applied over the range of 250-450v and at times ranging up to about 22 hr. These curves are reproducible on the same sample. Extrapolation of the curve of Fig. 5 to the intercept at  $t^{-1/4} = 0$  yields an infinite-time breakdown voltage ( $V_0$  of Peek's law) of about 190v ( $3.16 \times 10^6$  v/cm).

Breakdown tests have been performed, using negative potentials, while a sample was held immersed in liquid nitrogen. Negative breakdown was found to be no longer time dependent. This result shows that heating of the stressed area must have some influence on the time dependent type of negative breakdown previously described. At a sufficiently high voltage breakdown occurred instantaneously in a manner similar to that to be described for positive potentials.

**Transient current pulses.**—Rather severe transient current noise pulses are frequently observed in the incipient breakdown region. Such pulses are shown in the chart recording of Fig. 3. A number of workers have reported the unsteady nature of currents just prior to breakdown. O'Dwyer has observed that one of the characteristics of avalanche breakdown in solids

Fig. 5. Replot of the data of Fig. 4 with the linear time scale replaced by a  $t^{-1/4}$  scale, where  $t$  is time to breakdown. The last two breakdown points, at the extreme right of the figure, are not in agreement with Peek's law because they are in the intrinsic range which is not time dependent.

is that prebreakdown current will be very noisy, due to the buildup of avalanches which fail to reach the critical size (5). These pulses are randomly distributed although their magnitude increases with increasing voltage. They may appear with either fixed voltages or with voltage applied by the ramp technique.

**Light emission and surface spots.**—When the pulses described exceed approximately 10 na they are usually accompanied by visible light flashes which occur at various locations over the surface of the gold contact dot. The appearance is that of one or more pin point flashes of blue-white light, when the sample is viewed through a low power microscope in semidarkness. Where such flashes have occurred a change in the surface texture of the gold is usually observed. A portion of the surface of a gold contact dot is shown highly magnified in Fig. 6. The surface spots seen here are burned spots in the gold which indicate the location of previous flash sites. In some instances these spots are observed to have actual holes at their centers. There is evidence that these holes may extend through both the gold contact and the dielectric layer. In this respect they are apparently very similar to the self-healing breakdowns associated with weak spots in the dielectric, as recently reported by Klein and Gafni (6).

A sample on which the oxide under most of the gold contact dots had been broken down was subjected to a 20 to 1 mixture of nitrogen and chlorine gas at 800°C for 30 min (standard for all our chlorine etch studies) after the contact dots had been removed. Etch pits were found where contact dots had been located but not in the 0.024 in. margins between rows of dots.

To check the possibility that potential pinholes of the type discussed by Lopez (7) might be present within the film an ammonium fluoride-hydrofluoric acid etch was then used to reduce the oxide thickness from 6000 to 2500Å. The sample was again subjected to a hot chlorine etch for 30 min. No new etch pits developed in the margins.

As a further check for the possible presence of potential pinholes several samples were exposed to a water-amine-pyrocatechol etching system (8) at 110°C for 6 hr. This treatment removed approximately 1000Å of oxide, and the samples were found to have a negligible pinhole count. From these test results it was concluded that the oxide prior to dot evaporation was relatively free from pinholes or potential pinholes and that the reported light flashes are not caused by pinholes or potential pinholes which are detectable by chlorine or water-amine-pyrocatechol etching (9).

**Discharges.**—An obvious question concerning current pulses and flashes of the type described is whether they might be attributed to some type of discharge phenomena not occurring within the oxide itself. Possibilities include internal discharges (between the gold dot and the  $\text{SiO}_2$  or in minute voids or cavities where the gold makes poor contact with the  $\text{SiO}_2$ ), external or surface discharges (between the edges of

Fig. 6. A portion of the surface of a gold contact dot. Surface spots seen in this figure are burned spots in the gold which indicate the location of previous flash sites. Magnification ca. 100X.

the dot and the neighboring  $\text{SiO}_2$ ), or corona type discharges. Mason has reported that surface discharges are often 10-50 times larger than internal discharges (10).

To determine whether these flashes were occurring in voids, cavities, or areas of poor contact between the gold and the  $\text{SiO}_2$ , the dots on one sample were subjected to rapid heating which caused the formation of many tiny bubbles under each dot. Electric field strengths sufficiently high to cause appearance of the usual flashes were then applied. It was observed that the flashes did not occur under or even near the edges of a bubble.

Next the possibility was investigated that some of these flashes might be the result of surface-type discharges occurring between the gold contact dot and the neighboring oxide. The gold probe was lowered to make contact with a gold contact dot, then paraffin wax was melted over the entire surface of the dot and around the gold probe. It was found that the flashes still occurred with about the same distribution and in the same field strength range. It was further found, however, that negative breakdown was no longer time dependent. Apparently in this case the heat produced when a flash occurred melted some of the adjacent wax which in turn cooled the flash site, thus preventing thermal instability. These results, along with those previously described concerning breakdowns obtained at liquid nitrogen temperature, reinforce speculation that the negative breakdowns observed were the result of thermal instability and were not influenced by external discharge effects.

Further evidence that external discharges need not occur in the range of field strengths observed is found in work done by Austen and Whitehead (11) in which they obtained even higher field strengths in air without encountering discharges. They measured the dielectric breakdown strength of thin sheets of mica at thicknesses of the same order as the  $\text{SiO}_2$  films reported here. Their measurements were made using d-c voltage to obtain field strengths in the range of approximately  $11$  to  $16 \times 10^6$  v/cm. They confirmed the absence of discharges by separate experiments. In later work Plessner has reported similar findings for silica films (12).

**Dielectric breakdown at positive polarities.—Lack of positive conduction.**—Dielectric breakdown at positive potentials (silicon positive) is not time dependent and appears to be of an intrinsic nature, which yields the true dielectric strength of the material itself (13). This lack of time dependence is attributed to the absence of thermal instability, which in turn results from the lack of conduction below breakdown at this polarity.<sup>1</sup> In other words, in the absence of conduction, thermal instability cannot occur. Oxide specimens appear to remain indefinitely stable at positive potentials below their intrinsic dielectric breakdown levels. A typical pattern illustrating the absence of conduction and the lack of time dependence of breakdown with positive silicon potential is shown in Fig. 7. Here the voltage ramp technique was used to apply positive potential at the rate of 10 v/min. Notice the capacitance charging current of about 3 pa which ceased when the ramp was stopped at the 400v level.

This sample was known to have an intrinsic dielectric breakdown of about 410v. However, a potential only 10v below this value could be maintained for over 10 hr with no sign of increased conduction or of breakdown. After this time the voltage ramp was restarted and breakdown occurred, as predicted, at the 410v level ( $\sim 6.8 \times 10^6$  v/cm). Notice the contrast between this behavior and that of the sample shown in Fig. 3.

Conductivity and charge storage experiments, in which asymmetric conduction has been observed in

<sup>1</sup> The lowest current that could be accurately measured was around 2 pa.

Fig. 7. Typical positive conduction pattern illustrating; (a) capacitive charging current of about 3 pa which ceased when the 10 v/min voltage ramp was stopped at the 400v level; (b) pre-breakdown noise pulses; (c) absence of conduction and lack of time dependence with a positive potential of 400v applied to the silicon for over 10 hr; (d) a positive dielectric breakdown level of 410v ( $\sim 6.8 \times 10^6$  v/cm) which was reached when the voltage ramp was restarted.

silica films at low voltage and high temperature, have been reported by (among others): Kerr, Logan, Burkhardt, and Pliskin; Ishikawa, Sasaki, Seki, and Inowaka; and by Yamin and Worthing (14). It was found that rectification occurred and that the conducting direction was with silicon negative, which is in agreement with observations reported here.

#### Voltage ramp technique and transient current pulses.

—Some samples show current pulses in the prebreakdown region with changing positive potential. An example of this may be seen in Fig. 7. Samples which show this effect will often break down about 5-10% below what has been tentatively established (by the application of fixed stresses) as an intrinsic or disruptive breakdown level, if the voltage ramp is allowed to continue.

As previously described for pulses occurring at negative potentials, these current pulses are accompanied by visible light flashes at various locations on the surface of the gold contact dot when they exceed approximately 10 na. If at any time prior to breakdown the voltage ramp is stopped and the resulting fixed voltage maintained on the sample, charging current ceases and breakdown does not occur.

#### Other contact metals and films by other methods.—

The polarity effects and the time dependence of dielectric breakdown reported have been observed for other contact metals such as aluminum and platinum.

The techniques described have been applied to the evaluation of films obtained by other methods on similar substrates.  $\text{SiO}_2$  films obtained by plasma deposition, as reported by Ligenza and Povelonis (15), were tested by the methods described. Some differences in dielectric breakdown and prebreakdown conduction levels were observed, but in general the same basic phenomena as reported for steam-grown  $\text{SiO}_2$  films were found.

**Dielectric strength of atmospheric-pressure steam-grown  $\text{SiO}_2$ .**—Approximately 50 positive dielectric breakdown tests were conducted using various  $\text{SiO}_2$  film samples. Values of intrinsic dielectric strength, derived from the observed positive breakdown potentials, ranged from about  $7 \times 10^6$  v/cm to about  $1 \times 10^7$  v/cm. These values are in general agreement with those reported in the literature for quartz and vitreous silica (16). Positive breakdown values are, in general, highly reproducible for different contact dots on the same sample. A comparison of 12 positive breakdown values, obtained using several different  $\text{SiO}_2$  film sam-

ples, showed an average dielectric strength value of  $7.03 \times 10^6$  v/cm with a standard deviation of  $0.30 \times 10^6$  v/cm. A comparison of dielectric strength values obtained using different area contact dots showed no significant area dependence. No variation in dielectric strength (volts/centimeter) with thickness of the oxide was found over the thickness range used (3000-10,000Å). Since the films were amorphous in structure, no variation of the dielectric strength with thickness was expected from Fröhlich's theory, because the mean-free paths for electrons would be too short (12).

### Summary and Conclusions

Dielectric breakdown and prebreakdown phenomena, for SiO<sub>2</sub> films on silicon, are found to depend primarily on the polarity of the applied potential. This stems from a fundamental difference in the breakdown mechanism involved. At negative silicon polarities dielectric breakdown strength bears a linear relationship to  $t^{-1/4}$ , over a range of approximately 150v, where  $t$  is time for which voltage is applied. This is attributed to conduction and thermal instability. Time-voltage curves form a convenient means for displaying this time dependence at negative potentials.

Dielectric breakdown at fixed positive potentials is not time dependent. Breakdown appears to be of an intrinsic nature which yields the true electric strength of the dielectric independent of time. This is attributed to the lack of conduction below breakdown at positive potentials and the absence of thermal instability, whether due to electrical, thermal, chemical, or other effects. The polarity effects and time dependence of breakdown reported have been observed for other contact metals, such as aluminum and platinum.

In the breakdown experiments reported, which were performed at high voltages and room temperature, it was observed that the conducting direction is with silicon negative.

Conductivity and charge storage experiments have been performed on silica films at low voltage and high temperatures. These have been reported by, among others, Kerr *et al.*, Isikawa *et al.*, and by Yamin and Worthing (14). In these experiments it was also found that rectification occurred and that the conducting direction was with silicon negative.

Light flashes are usually observed at various locations over the surface of the contact dot when transient current noise pulses exceed approximately 10 na. Since both chlorine etch tests and the water-amine-pyrocatechol etching system indicate that the oxides used were initially free of pinholes or potential pinholes, it is concluded that the light flashes are not caused by pinholes which are detectable by these etches.

Values of intrinsic electric strength, derived from observed positive breakdown potentials, range from

about 7 to  $10 \times 10^6$  v/cm. These values are in general agreement with those reported in the literature for quartz and vitreous silica. Positive breakdown values are, in general, highly reproducible for different contact dots on the same sample. No variation in dielectric strength (volts/cm) with thickness of the oxide was found over the thickness range of 3000-10,000Å.

# Mechanism of Branching and Kinking during VLS Crystal Growth

R. S. Wagner and C. J. Doherty

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

## ABSTRACT

The morphology of the solid-liquid interface and the contact angle configuration of the liquid alloy droplet determine the direction of growth of crystals prepared by the vapor-liquid-solid (VLS) technique. There are four different processes by which both growth kinks and branches can be formed. A change in solid-liquid interface shape during VLS caused by a lateral temperature gradient results in the formation of growth kinks. Branches are formed if the alloy droplet ruptures during the kinking sequence. A sudden increase in temperature can cause an unstable contact angle configuration. The alloy droplet may run down the side faces of the growing crystal, leading to the formation of growth kinks or branches. A sudden decrease in temperature may cause "pinching off" of small droplets from the main droplet, giving rise to branches. Finally, the codeposition of liquid-forming impurities may also lead to branch and kink formation. The proposed models have been verified experimentally for VLS growth of silicon and germanium. Crystalline defects, such as dislocations, are not essential for the branching and kinking process. It is shown that "growth shaping" during the VLS process is possible.

Many whisker crystals grown from the vapor contain growth kinks and branches. The accidental attachment of two crystals during growth, which occurs rather frequently, will not be considered in this paper. The morphology of branched and kinked crystals has been studied for germanium (1) and silicon whiskers (2). It has been found that the various segments of these crystals constitute a single crystal. For a kinked germanium crystal, the direction of growth was found to change abruptly from  $[111]$  to  $[\bar{1}\bar{1}\bar{1}]$ . Similarly, a branched silicon whisker with a  $[111]$  main direction was found to be a single crystal, the branch resulting from simultaneous growth in the  $[\bar{1}\bar{1}\bar{1}]$  direction.

Many different theories (3-7) have been proposed to explain branching and kinking during vapor-phase growth of whisker crystals. All theories assume that the whisker crystals grow by the "screw dislocation" mechanism. Branching and kinking are explained by a variation of the dislocation model involving either a climb process of the dislocation at the whisker's tip or nucleation of a branch at a dislocation intersection. However, there is no reported experimental evidence to justify any of the proposed theories. It appears rather that the observation of growth kinking and branching has led many investigators to believe that these changes in growth habit can be attributed to the operation of a screw dislocation mechanism in whisker growth.

It has been shown that the vapor-liquid-solid (VLS) (8-12) mechanism explains many features of the growth of whisker crystals. It is the purpose of this paper to show that branching, kinking, and the growth of curved crystals can also be accounted for by the VLS process. The present work is an outgrowth of an earlier investigation on the controlled growth of silicon crystals in the form of intricate patterns on silicon substrates (10). The crystals shown in Fig. 8 in ref. (10) were grown under nearly isothermal conditions using a resistance heated furnace 10 in. long. Branched or kinked whiskers did not form under these experimental conditions. At this point of the investigation, it was considered worthwhile to take motion pictures during VLS growth. For this objective, the experimental conditions had to be changed drastically. The limited working distance of the microscope required an alteration of the heating system. The resistance furnace was replaced by a 2 in. long graphite tube which served as susceptor inside the reaction tube. A considerable lateral and axial temperature

gradient in the growth zone could not be avoided. Motion pictures of VLS growth clearly showed that very frequently the crystal branched or kinked during growth. In some experiments all the crystals in an array kinked in the same direction, toward the higher temperature region. Because of the small thermal mass of the graphite susceptor, sudden changes in temperature in the growth zone could be obtained by changes in the r-f output of the generator. Such changes, whether intentional or accidental, quite often resulted in branched and kinked whiskers. Similar changes in growth morphology were obtained by sudden changes of the total gas flow through the reaction tube. These observations were studied in detail, and the results are discussed in the following sections.

The proposed models are both simple and unique, and the experimental verification is unequivocal. It will be shown that crystalline defects, such as dislocations, are not essential for the branching and kinking process. We discuss in the first part of the paper the factors which control the direction of growth of silicon crystals grown by VLS. In subsequent sections are described four different processes by which branches and growth kinks can be formed. It is shown that controlled "growth shaping" during whisker growth from the vapor phase is possible.

## Experimental

The experimental procedure for controlled VLS growth of silicon crystals has been reported previously (10). The hydrogen reduction of  $\text{SiCl}_4$  was used as the transport reaction and gold as the liquid-forming impurity. The following experimental parameters were used in this investigation. The mean temperature of crystal growth was  $1000^\circ\text{C}$ . Temperature changes which were introduced intentionally will be discussed in the appropriate sections. A temperature gradient smaller than  $3^\circ\text{C}/\text{cm}$  was used for the isothermal growth experiments. The gradient was increased to over  $40^\circ\text{C}/\text{cm}$  for nonisothermal growth. In some experiments, the gradient was further increased by focussing a high power heat source on the sides of the growing crystals. A total hydrogen flow of 300 cc/min was used with a  $\text{SiCl}_4$ -to-hydrogen mole ratio of 0.02. Preliminary experiments indicated that controlled doping during VLS growth can yield important information about the growth mechanism. It was found that the dopant, introduced in gaseous form, also preferentially enters the liquid alloy droplet at the tip of the growing crystal. Doping therefore results

Fig. 1. Etched section of a [111] silicon crystal doped with phosphorus during isothermal growth. Magnification approximately 50X.

in clearly identifiable impurity striations which are parallel to the solid-liquid (SL) interface. These interface markers, introduced at given time intervals, permit a careful evaluation of interface transitions during branching and kinking. Ten cc/min hydrogen with a mole ratio of 0.0004  $\text{PCl}_3$  was used for the doping experiment. The duration of doping varied from 10 to 30 sec. Doped silicon crystals were sectioned parallel to the growth direction and etched with Sirtl (14) etch for about 1 to 4 min. The maximum diameter of all crystals shown in this paper is about 250-300 $\mu$ . The measured rate of VLS growth was about 1 mm/hr. A high-temperature microscope<sup>1</sup> in conjunction with a movie camera was used to record the growth of individual crystals by time-lapse photography (13). X-ray topographs by the Lang (15) technique were taken on some samples using silver radiation.

**Isothermal VLS growth.**—The majority of silicon crystals prepared by the VLS technique, under isothermal conditions, grew in a [111] direction. It has been proposed (8) that this particular growth direction arises because the solid-liquid interface is a single (111) plane. It has been shown (12) that the interface can be very stable during VLS growth; the stabilizing factor is very likely the interface kinetics. To confirm this point, a number of silicon crystals were doped with phosphorus during isothermal growth. The crystals were subsequently sectioned on a plane parallel to the growth direction and etched as shown in Fig. 1. The pronounced bands indicate the introduction of dopant during growth, whereas the fine bands are produced by fluctuations in growth rate (12). The figure clearly shows that the solid-liquid interface remains stable, parallel to a (111) plane during isothermal VLS growth. It must be concluded that layer growth occurs on this interface; the alloy droplet advances therefore perpendicular to this face in a [111] direction.

It has been reported (12) that the shape of the solid-liquid interface of a [111] crystal is not circular but triangular with rounded corners. Microscopic observation shows that the solid-liquid contact angle along the meniscus of the droplet is nonuniform during growth, being slightly larger at the rounded corners. However, such a contact angle configuration, having threefold symmetry, stabilizes the liquid droplet on the growing crystal. The effect of gravity on the con-

tact angle was found to be negligible. Crystals with diameters ranging from 50 to about 300 $\mu$  were grown in the usual way, vertically upward. Subsequently, the whole growth apparatus was rotated 90°, and the VLS growth continued in a horizontal direction to about 1 cm length. The crystals were afterwards examined in an optical goniometer and found to be straight. Similarly, x-ray reflections obtained with a Weissenberg goniometer showed that the crystals were straight and grew in a [111] direction. It is evident, however, that any force which is strong enough to change the symmetry of the solid-liquid contact angle configuration can influence the direction of growth. Although layer growth still occurs on a (111) plane under isothermal conditions, the resultant growth direction will be controlled by the liquid contact angles.

A suitable combination of interface morphology and liquid contact angle can give rise to growth directions other than [111]. For example, silicon crystals can be grown in a [110] direction as shown in Fig. 2. The doping striations show that the interface consists of two {111} planes forming a ridge configuration. If the crystals are grown at about 1050°C, the prismatic side faces are four {111} planes which are parallel to the [110] growth direction. This configuration leads to a twofold symmetry of the contact angles, stabilizing the droplet on the growing crystals. VLS-grown germanium whiskers are frequently observed with the same [110] morphology. In addition, germanium crystals also grow in the [100] direction (16). In this case, the solid-liquid interface is formed by four {111} planes in the shape of a pyramid. Another morphology has been observed both for germanium and silicon, a twinned crystal growing in a [211] direction. The shape of the interface of these crystals is similar to that one of crystals with a [110] growth direction. However, the angle between the two {111} planes is 141.06° for twinned [211] crystals and 109.48° for [110] crystals, respectively. It can be said in conclusion that the solid-liquid interface is not necessarily perpendicular to the direction of growth. The interface morphology determines the direction of growth, and unidirectional growth is only possible for a stable contact angle configuration. It will be shown in the

Fig. 2. Etched section of a [110] silicon crystal doped with phosphorus during isothermal growth. Magnification approximately 100X.

<sup>1</sup> American Optical long working distance microscope.

following section that a change in interface morphology during VLS growth invariably results in a change in growth direction.

**Nonisothermal growth.**—A model for branching and kinking during nonisothermal VLS growth has been proposed in a previous paper (11). The model is based on the assumption that a lateral temperature gradient can change the morphology of the SL-interface and thereby change the direction of crystal growth. The experimental verification of the proposed mechanism will be discussed in this section. The temperature conditions during VLS growth were changed from isothermal to nonisothermal. Time-lapse photography was used to obtain a permanent record of the growth sequence. The crystals were doped with phosphorus before, during, and after completion of the kinking process. Subsequently, the samples were sectioned, polished, and etched on a plane which is coplanar with the axial directions of the kinked crystal. A typical example of such an experiment is shown in Fig. 3 for a  $[111]$  to  $[\bar{1}\bar{1}\bar{1}]$  kink. In this case the kinking was caused by exposing the right side of the growing crystal to a higher temperature than the left side.

The value of using controlled doping to study successive interface positions is evident. During isothermal conditions, the crystal grew perpendicular to the  $(111)$  plane, as discussed previously. However, the introduction of a lateral temperature gradient caused a change in interface morphology. The  $(\bar{1}\bar{1}\bar{1})$  plane was partly exposed in addition to the original interface. The growth rate perpendicular to the newly formed interface is slower than on the  $(111)$  plane because it is in a region of higher temperature. The new interface grew in area at the expense of the old one until finally the  $(111)$  interface has disappeared. The liquid droplet shifts during this process from the  $(111)$  to the  $(\bar{1}\bar{1}\bar{1})$  interface. Further VLS growth proceeds in the  $[\bar{1}\bar{1}\bar{1}]$  direction. Figure 4 shows an enlargement of a  $(111)$  to  $(\bar{1}\bar{1}\bar{1})$  kink. Note that neither the  $(111)$  nor the  $(\bar{1}\bar{1}\bar{1})$  interface planes deviate from planarity during the kinking process. The macroscopic growth direction gradually changes from  $[111]$  to  $[\bar{1}\bar{1}\bar{1}]$  resulting in the growth of a curved crystal. Figure 5

Fig. 3. Etched section of a  $[111]$  to  $[\bar{1}\bar{1}\bar{1}]$  kinked silicon crystal doped with phosphorus. Magnification approximately 100X.

Fig. 4. Etched section of a  $[111]$  to  $[\bar{1}\bar{1}\bar{1}]$  kink. Magnification approximately 275X.

Fig. 5. Etched section of a  $[110]$  to  $[111]$  kink. Magnification approximately 50X.

shows a section of a crystal with a  $[011]$  to  $[111]$  kink. The  $[011]$  section of the crystal grew with an interface consisting of  $(111)$  and  $(\bar{1}\bar{1}\bar{1})$  planes. Again the SL interface changes in compliance with the proposed model. This sample was grown at a temperature of about  $1050^\circ\text{C}$ . The vapor-solid deposition rate becomes noticeable at this temperature (9, 12). This deposit surrounds the crystal grown by VLS. At even higher temperatures, the concave side of the kink becomes a preferred site for vapor-solid (VS) epitaxy. The true, original shape of the kink will be drastically altered by this deposit.

A small lateral temperature gradient may cause a gradual change in interface morphology. The growth direction will vary over a considerable length of the crystal, resulting in the growth of a curved whisker. Such events have been observed in a few cases. Figure 6 shows a photograph of a crystal curved during VLS growth. The liquid droplet is not supported by a single  $(111)$  interface, but rather extends downwards

Fig. 6. Curved silicon crystal photographed during nonisothermal growth. Magnification approximately 50X.

at the left side of the growing crystal. Again, a VS deposit will obscure the shape of curved crystals. At high temperatures, the deposit ultimately will tend to "straighten" such curved sections, by increasing the diameter of the crystal.

Kinking under the influence of a temperature gradient was observed for over 100 crystals. About 20 crystals were examined for the presence of crystalline defects in the kink region. Lang topographs were taken and sectioned crystals were etched as shown in Fig. 3 and 5. The majority of the samples did not contain any observable defects in the kink region. A few specimens contained islands of Au-Si entrapments which are known to give rise to the generation of defects (12). It must be concluded that crystalline defects, such as dislocations, are not essential for the reported kinking process. Entrapment of liquid alloy may occur during kinking with subsequent formation of defects during cooling.

Figure 7 shows a Lang topograph of a  $[110]$  to  $[11\bar{1}]$  kink. The crystal was grown on an imperfect  $(111)$  substrate. Some dislocations continued to grow from

Fig. 7.  $(111)$  X-ray topograph of a  $[110]$  to  $[11\bar{1}]$  kinked silicon crystal. Magnification approximately 70X.

the substrate into the crystal. All dislocations apparently grew out of the crystal at the lower section. The remainder of the sample, including the kink, is dislocation-free. Note the occurrence of "pendellösung" fringes both in the  $[110]$  and  $[11\bar{1}]$  sections of the crystal. The shapes of the fringes in the two sections are different because the cross section of the crystal is not the same in the two regions. The cross section is diamond-shaped in the  $[110]$  region and hexagonal in the  $[11\bar{1}]$  part. The occurrence of pendellösung fringes in the kink provides additional evidence that defects are not involved in the kinking mechanism.

It is evident from Fig. 4 that the area of the SL interface changes during the kinking process. The area first increases and finally returns to its original value after completion of kinking. The change in interfacial area imposes a constraint on the contact angle of the liquid alloy droplet. The constraint frequently causes rupture of the droplet, thereby giving rise to the formation of branch crystals as shown in Fig. 8. The time-lapse sequence, taken at constant magnification, illustrates four different stages during and after the kinking sequence. The crystal was grown on a  $(111)$  substrate at about  $1050^\circ\text{C}$ . The plane of the photograph is approximately  $(110)$ . Figure 8a shows the trace of the SL interface and the droplet configuration during kinking at a time when the interfacial area is at a maximum. The kinking sequence is almost completed in Fig. 8b. The new  $\{111\}$  interface has increased considerably at the expense of the old interface. A small droplet, indicated by the arrow, has broken away from the main droplet during the transition. Figure 8c shows the interface and droplet configuration after completion of kinking. The small droplet gave rise to the growth of a branch crystal with a  $[111]$  growth direction. A later sequence of growth is shown in Fig. 8d. The effect of VS epitaxy in changing the

Fig. 8. Time-lapse sequence of branching and kinking caused by a lateral temperature gradient. Magnification approximately 120X.

external morphology can be seen at the base region of the small branch crystal by comparison of Fig. 8c and Fig. 8d. Some samples in which branching occurred during the kinking process were examined for perfection, both by x-ray topograph and etching. In most cases the branch and kink were found to be dislocation-free.

Generally, it is rather difficult to control the formation of a desired kink configuration under the influence of a lateral temperature gradient. Kinking can be initiated readily; however, there is little control over the shape of the liquid droplet during the transition process. The orientation of the growing crystal with respect to the isotherm is an important factor, as is evident from Fig. 3. The preferred orientation as indicated in the figure, is that in which only one plane, for example the  $(\bar{1}11)$  plane, is parallel to the isotherm. If the interface transition occurs by exposing two or even three new  $\{111\}$  planes, the droplet invariably ruptures and multiple kinking ("antler" growth) will result. A slow VLS growth rate and a small temperature gradient help to prevent a rapid interface transition which also can cause a rupture of the liquid droplet.

**Sudden increase in temperature.**—It has been shown (10) that the volume of the liquid droplet during VLS growth depends on the deposition temperature. This dependency arises from the liquidus phase relationship of the particular alloy system. This feature has been used to change the diameter of silicon crystals during VLS growth by proper changes of the deposition temperature. It has been noted that such changes must be made gradually in order to avoid instability of the liquid droplet. A sudden increase in temperature, for example, from  $1000^\circ$  to  $1100^\circ\text{C}$  in 10 sec, will usually cause instability. The volume of the droplet will increase by about 13% for such a temperature change. The amount of silicon which is required to satisfy the new phase equilibrium cannot be supplied rapidly enough from the vapor-phase reaction. As a result, the necessary amount will be dissolved from the VLS crystal. The SL interfacial area, however, remains that for the  $1000^\circ\text{C}$  growth condition. As a consequence, the liquid will bulge over the side of the crystal. It will eventually wet the side faces in order to increase the interfacial area and to satisfy a stable contact angle configuration. The individual droplets will cause formation of branch crystals or kinks as VLS growth continues. A typical example of this process is shown in the time-lapse sequence in Fig. 9. Two crystals were initially grown at  $1000^\circ\text{C}$ , then the temperature was rapidly raised to about  $1100^\circ\text{C}$ . Figure 9a shows the droplet configuration during the rise in temperature. The solid-liquid contact angle which is slightly larger than  $90^\circ$  under equilibrium conditions has noticeably increased. In Fig. 9b, taken at maximum temperature, the droplet has increased its contact area by wetting the side faces of the crystal. Subsequently, the temperature was reduced to about  $1000^\circ\text{C}$ . The next two photographs show the resulting growth morphology at different times. The liquid broke up into smaller droplets giving rise to branch growth. Numerous experiments of the kind described in Fig. 9 were performed. It was found that the only important factor is a sufficiently large, rapid increase in temperature. The temperature does not have to be returned to its starting value. A large decrease in temperature after the instability has occurred must be avoided because this may lead to nucleation of silicon crystals in the droplets, resulting in uncontrolled growth (10). The droplet configuration during the rise in temperature was observed visually in some experiments. This provides some control over the resulting droplet configuration. Figure 10 is an etched  $(0\bar{1}1)$  section of a crystal which was kinked by a controlled increase in temperature. Doping was used to

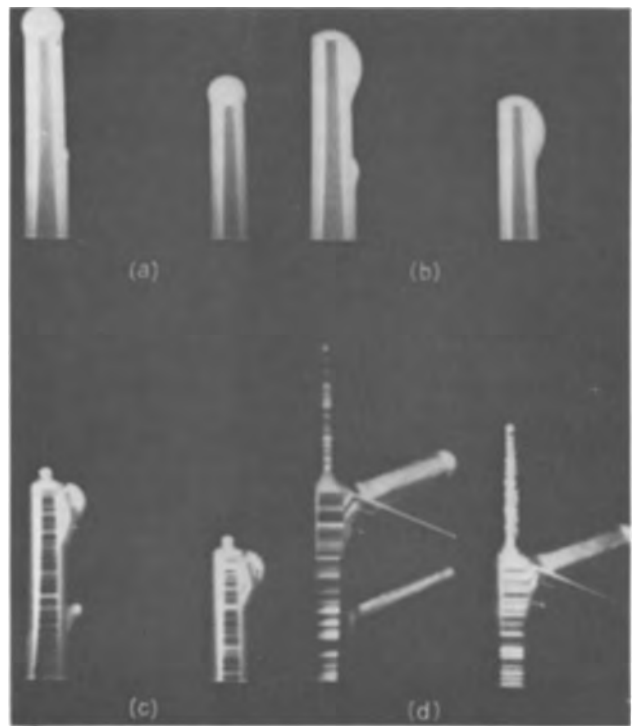

Fig. 9. Time-lapse sequence of kinking and branching caused by a sudden increase in temperature. Magnification approximately 13X.

mark the position of the SL interface during the growth experiment. Before raising the temperature, the droplet was on top of the  $[111]$  crystal which had grown under isothermal condition. The temperature was carefully increased until the droplet was clinging to the side of the crystal near its tip. The doping striations show that a new SL interface configuration was established. The crystal first grew in approximately a  $[011]$  direction and gradually changed to the stable

Fig. 11(a). Photograph of a branched crystal with alloy tips removed by etching. Fig. 11 (b). (111) X-ray topograph showing Au-Si entrapment. Magnification approximately 35X.

[111] direction. No dislocation etch pits could be found on this sample. Six crystals which branched or kinked by the discussed procedure were examined by x-ray topography. Entrapments of Au-Si alloy were found in four samples. Such a topograph and the actual sample are shown in Fig. 11. The hemispherical tips, composed of Au-Si alloy were removed from the crystals by etching. A significant aspect is that the crystallography of the branch and kink crystals is the same as that of the main crystal. Some of the fine crystals which can be seen on the actual sample could not be reproduced properly from the x-ray topograph. An island of Au-Si eutectic is indicated by an arrow. As usual, the inclusion gives rise to formation of defects (12).

**Sudden decrease in temperature.**—This mechanism is basically similar to the one discussed in the previous section. The volume of the liquid droplet decreases if the temperature is lowered during VLS growth. The excess of silicon freezes out of solution, by normal alloy regrowth, in order to establish the equilibrium composition. The solid-liquid contact angle, however, remains essentially constant during the change in temperature. This implies that a reduction in SL interfacial area is required to satisfy the same contact angle configuration. Therefore, a sudden decrease in temperature causes a sudden increase in growth rate because of alloy regrowth and a reduction of the diameter of the growing crystal. Small droplets frequently separate from the meniscus region of the droplet during the transition in volume. These droplets then give rise to formation of branches during subsequent VLS growth. The growth of branch crystals by this process is illustrated by the time-lapse sequence in Fig. 12. The crystal is shown in Fig. 12a during growth at about 1050°C. The temperature was subsequently decreased by 100°C in about 30 sec. Three small droplets were "pinched off" the main droplet during the transition, Fig. 12b. The last figure shows the crystal after continued VLS growth. The three branches grew in the same  $\langle 111 \rangle$  direction, although inclined to the [111] direction of the main crystal.

It has been found in many experiments that this process of branch formation can be initiated easily by a sudden drop in deposition temperature. However, there is little control over the number of branches formed. The change in temperature must be rapid enough to cause separation of small droplets from the main body of the liquid alloy. A gradual decrease in temperature only causes a reduction in diameter of the growing crystal. The deposition temperature can be gradually raised after completion of branching. However, a sudden large reduction in temperature must be avoided because this may result in nucleation of sil-

Fig. 12. Time-lapse sequence of branching caused by a sudden decrease in temperature. Magnification approximately 35X.

icon crystals in the liquid alloy. Such a large reduction may lead to uncontrolled VLS growth as shown in another paper (10).

The most common direction of the side branches is  $\langle 111 \rangle$ . The  $\langle 110 \rangle$  direction has been observed in a few cases. The diameters of the branches are usually small compared to the diameter of the main crystal. X-ray topography and etching studies indicate that the majority of the crystals are dislocation-free.

**Codeposition of liquid-forming impurities.**—The most likely process of branch and kink formation during vapor phase growth is due to codeposition of impurities. Impurities which satisfy the criteria for VLS growth may condense on an already grown whisker crystal. The transport can occur by a chemical reaction, for example, by disproportionation, or simply by an evaporation and condensation process. Such an impurity transport frequently has been observed during whisker growth of silicon or germanium using either a closed or a dynamic system. Each alloy droplet formed by this means may give rise to VLS growth of a branch crystal. The original crystal serves as substrate material. It should be emphasized that only extremely small amounts of impurities are required for this process. For example, a gold-silicon alloy droplet of about 100Å diameter can result in the growth of a silicon whisker a few millimeters long. The final morphology will be altered drastically in most cases because of VS deposition during and after VLS growth.

Many branched and kinked whisker crystals of silicon and of germanium were grown using codeposition of impurities. The experimental conditions for the growth of silicon whiskers have been described previously (2). Similar conditions were used for germanium (16). The formation of branch crystals is initiated by a sudden increase in supersaturation of liquid forming impurities in the growth zone, during or after completion of VLS growth. Numerous new alloy droplets will form and branch growth occurs. The resulting growth morphologies are similar to those in Fig. 3 and Fig. 8 in ref. (2). It is obvious that this process may not be used for controlled growth of branched and kinked crystals.

The mechanism discussed involving the codeposition of impurities probably is the most common cause of uncontrolled VLS growth. It should be noted that careful experimentation with codeposition of impurities originally lead to the discovery of the VLS mechanism (2).

### Summary

The growth direction of silicon crystals prepared by the VLS technique is determined by both the shape

of the solid-liquid interface and the contact angle configuration of the alloy droplet. Unidirectional growth can occur only if these two parameters are kept constant during growth. A necessary condition for unidirectional growth is therefore an isothermal environment. Most crystals grown under this condition grow with a single  $\{111\}$  interface in a  $\langle 111 \rangle$  direction. However, the macroscopic growth direction is not necessarily perpendicular to the growth interface. Specific interface configurations have been found where the interface consists of more than one  $\{111\}$  plane of equal area. These interfaces also form a stable contact angle configuration of the alloy droplet. The resulting growth direction is the vector sum of the individual interface growth directions.

A sufficiently large lateral temperature gradient changes the equilibrium interface, which invariably leads to a change in growth direction. A new stable interface will be formed during growth which is as parallel as possible to the isotherm. While a curved crystal is grown during the interface transition, subsequent growth is again unidirectional. Branches are formed if the alloy droplet ruptures during the kinking sequence. The likelihood of kinking for a given lateral gradient depends on the diameter of the growing crystal. It is the absolute temperature difference across the interface that causes interface transition.

Either a sudden increase or decrease in deposition temperature may introduce instability of the alloy droplet. A sudden rise in temperature causes an unstable contact angle configuration. The droplet may wet the side faces of the crystal to increase the interfacial area. The new droplet configuration results in formation of branches and or kinks. Similarly, a sudden decrease in temperature may cause pinching off of small droplets from the main droplet. These two processes of branching and kinking are more or less independent of the diameter of the growing crystal.

The most common cause of uncontrolled VLS growth of silicon or germanium was found to be the result of codeposition of liquid-forming impurities. The impurities can be transported to the reaction zone by a chemical reaction or by evaporation. Branches are formed when liquid-forming impurities condense on an already grown whisker crystal.

This investigation modifies the usual definition of a branch or kink. The terminology is unambiguous for a single kink, where the liquid droplet did not rupture during the interface transition. It is suggested

that the growth direction which is associated with the main body of the liquid be used as the criterion. If this direction changes during growth, then the crystal is kinked. This is true even if small branch crystals continue to grow in the original growth direction. If the main growth direction remains constant, then any side crystal formed by small droplets is defined as a branch.

In conclusion it is emphasized that the proposed mechanism of unidirectional growth, branching, and kinking is strictly applicable only to whisker crystals grown by the VLS process.

## Diffusion Masking of Silicon Nitride and Silicon Oxynitride Films on Si

F. K. Heumann\* and D. M. Brown

General Electric Research and Development Center, Schenectady, New York

and E. Mets\*

General Electric Semiconductor Products Department, Auburn, New York

#### ABSTRACT

A qualitative study of the masking properties of thin ( $\leq 1500\text{\AA}$ ) silicon nitride and silicon oxynitride films on Si is presented. A range of diffusion conditions was studied for doping sources including B, P, Ga, and As. Silicon nitride was not found to be a diffusion mask for all conditions. Conditions under which it can be expected to mask are specified.

The work of Hu (1) and Doo (2) on the diffusion masking of silicon nitride films on Si showed that very thin layers ( $\leq 1200\text{\AA}$ ) of nitride would mask against B, P, As, and Ga, and might even be utilized as a

\* Electrochemical Society Active Member.

universal diffusion mask, since no masking failures were encountered in their shallow junction diffusion studies. The studies reported here using B, P, As, and Ga diffusion sources were carried out over a wide range of conditions, and although the results do in-

deed indicate that thin ( $\leq 1500\text{\AA}$ ) nitride and oxynitride films will mask for a certain set of diffusion conditions, it becomes clear that silicon nitride cannot be utilized as a universal diffusion mask. Various types of masking failures occur for temperatures and times required for deep junction diffusions.

### Experimental Techniques

Chemically etched 1 ohm-cm Si wafers were coated with nitride or oxynitride films by the pyrolysis of silane and ammonia or silane, ammonia, and nitric oxide at  $1000^\circ\text{C}$ . The volumetric gas ratios used to form these films were: ammonia/silane = 40,000/1 for nitride films and ammonia/silane/nitric oxide = 40,000/1/500 for oxynitride films. No carrier gases were used in either case. Studies of these particular glassy amorphous oxynitride films indicate an equivalent  $\text{SiO}_2$  composition of about 20% (3). The thickness of these films was varied between about 200 and  $2000\text{\AA}$  with a thickness variation over the inner  $3/4$  area of each 2.5 cm diameter wafer of only  $\pm 3\%$ . In some cases, the diffusion studies were carried out using two types of dopant sources: a semisealed quartz box diffusion using dry  $\text{N}_2$  ambient and a glass source containing the dopant element to be studied (phosphosilicate glass or borosilicate glass) and a sealed tube or capsule containing the dopant material (As, P, Ga, B) which after loading, was degassed, evacuated, and back-filled with argon. The results were determined by the following procedure: the nitride film was removed using HF and a thermoelectric probe and surface resistivity measurements were used to indicate whether there was any detectable masking failure, and masked and unmasked portions of the wafer were angle lapped and stained to give junction penetration depths into the Si.

### Results

A general summary of the results of the diffusion experiments using films of  $2000\text{\AA}$  or less are shown in Table I. In some cases, dry thermal oxides were used as control samples. In these instances no masking was evident. It must be pointed out, however, that the masking ability of oxides (and nitrides) are

extremely dependent on the chemical nature of the diffusion conditions. For instance, Thomas *et al.* (4) have shown that very thin oxide films are excellent diffusion masks against B diffusion if the diffusions are carried out under nonglass-forming conditions.

**Boron.**—Amorphous silicon nitride films of thicknesses greater than  $600\text{\AA}$  are excellent masks for temperatures up to  $1250^\circ\text{C}$  for at least 10 hr if the sealed tube system is used. In these cases, the films after diffusion etched at the normal rate of  $150\text{\AA}/\text{min}$  in concentrated 48% HF; however,  $1200^\circ\text{C}$  diffusions for 30 hr resulted in films that would not dissolve in HF even though the films still masked against boron. X-ray diffraction indicated that the films were still amorphous so the original films had not yet converted to the more dense crystalline form. This phenomenon is not understood; perhaps an insoluble B-Si-N compound was formed. Silicon oxynitride films also appear to be suitable B diffusion masks; however, the thickness required for masking is somewhat greater than that for pure nitride. For instance,  $500\text{\AA}$  of oxynitride is not thick enough to mask boron for 4 hr at  $1100^\circ\text{C}$ ;  $1000\text{\AA}$  suffices, however.

In the case of the borosilicate glass box system, it was found that at  $1100^\circ\text{C}$  nitride films of  $500\text{\AA}$  or more mask for at least 5 hr and dissolved at the normal etch rate. However, at  $1200^\circ\text{C}$ , the films failed as diffusion masks and dissolved at about 40 times the normal etch rate. This phenomenon is also not understood, but it suggests that borosilicate-nitride glass can be formed under certain diffusion conditions.

**Phosphorus.**—The results in Table I show that a  $1500\text{\AA}$  thick film of pyrolytic silicon nitride will mask against elemental phosphorus during a sealed tube diffusion at  $1100^\circ\text{C}$  for times up to 10 hr. For 4 hr at  $1200^\circ\text{C}$ ,  $1500\text{\AA}$  is apparently not thick enough, however. Experiments with these particular silicon oxynitride films indicate that  $1500\text{\AA}$  will mask phosphorus for 4 hr at  $1100^\circ\text{C}$ ; thinner films do not mask.

Silicon nitride films do not mask, however, when used in box diffusions where the source is vitrified phosphorous glass. In this case, the films become coated with phosphorus pentoxide or a phosphorous glass during the diffusion experiments and apparently rapidly convert to some kind of  $\text{Si}_3\text{N}_4\text{-P}_2\text{O}_5$  glass as

\* Where mask failure is noted but no masked junction depth is given, masking failure was determined by using a thermoelectric probe.

evidenced by the very rapid etch rate in concentrated HF. The results of a number of box diffusions indicate that  $P_2O_5$  or  $P_2O_3$  glass cannot be used as a diffusion source when thin  $Si_3N_4$  films are used because of the formation of a glass which promotes mask failure. Similar results have been observed by Chu *et al.* (5) using a phosphorus oxytrichloride source.

**Gallium.**—2000Å of thermally grown  $SiO_2$  does not mask Ga. However, 1000Å of  $Si_3N_4$  completely masks Ga at 1100°C for 4 hr. This is also true of the silicon oxynitride film if it is 1500Å thick. The masking ability of the nitride is questionable above 1100°C. For instance, 300Å is not a satisfactory barrier at 1185°C for 15 hr; and as the thickness of the film is increased, cracking of the film occurs at these times and temperatures. Evidence for this problem are the diffusion spikes which occur at localized spots under the film. In one case, the film did not completely etch off in concentrated HF even after many hours. In this instance, a number of rod-shaped purple crystals were observed and identified as  $\alpha-Si_3N_4$ . Apparently the amorphous nitride was partially converted to the more dense crystalline form by the high temperature. This conversion may be catalyzed by gallium. Thus, we see that  $Si_3N_4$  and silicon oxynitride can mask against Ga if the diffusion temperatures are not too high. However, at high temperatures, diffusion spikes appear which are probably caused by the cracking that occurs when the nitride films transform into the crystalline phase; thinner films do not crack, but do not mask either.

**Arsenic.**—As shown in Table I, 1500Å of silicon nitride and oxynitride mask at 1100°C for 4 hr; however, the diffusion depth into the unmasked Si is only 0.6 $\mu$ . On the other hand, sealed tube diffusions at 1200°C for 20 hr showed that 1500Å of  $Si_3N_4$  is not thick enough. Experiments at 1150°C showed that 1000Å masks for 6 hr; however, thicker films or oxynitride films cracked and allowed the As to penetrate these imperfections. When cracking occurred, it also crazed the Si surface.

### Summary

A range of diffusion conditions using thin silicon nitride and silicon oxynitride films as a diffusion barrier against B, P, Ga, and As indicates that thin layers of nitrides are suitable diffusion masks for B if sealed tube diffusions are performed. For example, 1000Å of pure nitride will mask for at least 10 hr at 1250°C. In fact, no masking failure was ever found for these sealed tube diffusions if the film thickness

was at least 1000Å. However, high temperatures and borosilicate glass sources can result in masking failure which may be caused by a film conversion to a borosilicate-nitride glass phase. This behavior is also generally true for phosphorus diffusions; however, in addition, masking failures at high temperatures in the elemental phosphorus sealed tube diffusions did occur. High temperature masking failure for thin films also occurs for sealed tube As diffusions. In the case of Ga, nitrides are much better diffusion masks than oxides, which do not deter this diffusant species at all. However, here again the nitride has a limited application. Although it masks at low diffusion temperatures, high temperature Ga diffusion experiments seem to indicate that the films of thicknesses required for complete masking crack as they change from an amorphous to crystalline phase.

Generally speaking, thin nitride and oxynitride films (thicknesses  $\leq 1500$ Å) can be used as diffusion masks for the times and temperatures suitable for shallow ( $\leq 9\mu$ ) junctions if the proper diffusant sources are used. In these instances, our results generally agree with those of Hu and Doo. Thin film nitride masking and much deeper Si junction depths (30 $\mu$ ) can be attained by using higher temperatures if boron is the diffusant and a sealed tube system is used. Masking of P, As, and Ga and deeper junctions might be obtained by using much thicker films and longer diffusion times, provided of course that the diffusion conditions are such that no catastrophic masking failure (film conversion, cracking) occurs.

## Technical Notes

### Silicon Oxide As An Etching Mask for Silicon Nitride

N. C. Tombs<sup>1</sup> and F. A. Sewell, Jr.

Sperry Rand Research Center, Sudbury, Massachusetts

The use of silicon nitride (1, 2) as a diffusion mask and passivation layer in semiconductor devices involves the etching of defined areas in the nitride. The relatively low etch rate of silicon nitride, compared with silicon oxide, can lead to problems in the securing of

adequate definitions and steep etching angles when using conventional photoresist techniques with hydrofluoric acid etches. Van Gelder and Hauser (3, 4) have described the use of hot phosphoric acid ( $H_3PO_4$ ) as an etch for silicon nitride, in conjunction with a pyrolytically deposited layer of silicon oxide as a mask against the phosphoric acid. Patterns were etched in

<sup>1</sup> Present address: NASA, Electronics Research Center, Cambridge, Massachusetts.

Fig. 1. Test pattern etched through 1500Å thick silicon nitride film using phosphoric acid with silicon oxide mask.

the silicon oxide overlayer using photoresist and hydrofluoric acid etch.

We have successfully utilized an analogous technique, in which the layer of silicon oxide was formed by thermal oxidation of the surface of the silicon nitride. The silicon nitride layer was pyrolytically deposited on a 10-mil silicon substrate to a thickness of 2500Å. The sample was then heated for 8 hr at 1200°C in oxygen. A surface layer of silicon oxide was thereby formed. Infrared absorption measurements revealed the presence of this oxide by an absorption maximum at  $9.2\mu$ . The height of the nitride absorption maximum at  $\sim 11\mu$  was correspondingly decreased, although its wavelength remained unchanged. A test pattern was etched in the oxide layer using the photoresist-buffered HF method. The phosphoric acid etch was prepared by heating 85%  $H_3PO_4$  to 190°C in an open beaker for 2 hr and cooling to 180°-185°C. The sample was immersed in the etch for 10-min periods. After each period it was removed, washed in water, and observed

under the microscope. The interference colors given by the window (nitride) and mask (nitride plus oxide) regions at the different stages are shown below, together with the approximate thickness indicated by the colors. The nitride:oxide etch rate ratio was  $\sim 5:1$ .

Etch time min	Nitride color	(Nitride + Oxide) Å	color	Å
0	gold	2000	violet	2500
10	dark blue	1000	orange-red	2300
20	colorless	<400	orange	2100
30	colorless	0	blue	1500

A test pattern including lines of width  $1\mu$  was used to determine the possibility of etching windows of this width in the nitride. Figure 1 is a photomicrograph of the result obtained in a final nitride thickness of  $\sim 1500\text{Å}$ . Measurements of the width of the windows were made using a filar eyepiece with movable cross-hair, calibrated against a stage micrometer. The results confirmed that the width was close to  $1\mu$ , although the resolution limits make it difficult to give a precise figure. The ultimate limitation in the technique would appear to be the photoresist stage for defining and etching the pattern in the oxide. Advantage can be taken of the fact that the oxide layer ( $\sim 500\text{Å}$ ) is much thinner than the layers normally required for diffusion masking and surface passivation. The photoresist layer likewise can be made thinner, and the pattern definition is thereby improved.

Practical advantages of the technique described include the excellent adherence between the oxide and nitride layers, and the avoidance of porosity or other imperfections in the oxide which might interfere with its effectiveness as an etching mask.

Manuscript received Sept. 25, 1967.

## Defect Structure Model for Wustite

Per Kofstad and A. Zeev Hed

*Metal Science Group, Columbus Laboratories, Battelle Memorial Institute, Columbus, Ohio*

Wustite is a metal-deficient oxide ( $Fe_{1-y}O$ ) (1-9). Its defect structure is commonly interpreted in terms of doubly charged iron ion vacancies (5-9). However, as discussed below such a defect structure model does not give a satisfactory interpretation of the observed behavior, and the purpose of this note is to propose a defect structure model which gives a more consistent interpretation of the experimental results.

The nonstoichiometry as a function of temperature and oxygen pressure has been studied by several investigators (1-4), and the results of the various studies are in good agreement. The results of Vallet and Raccah (3) at 800°-1200°C are shown in Fig. 1.

When assuming small defect concentrations, a defect structure model involving doubly charged iron ion vacancies predicts an oxygen pressure dependence of  $y \propto p_{O_2}^{1/n}$  with  $n = 6$ . As seen in Fig. 1 such a relationship only accounts for the oxygen pressure dependence in the middle of the field, but does not explain the observed behavior over the whole homo-

geneity range. In view of the high defect concentrations in wustite, it would be highly surprising if such a model were applicable; one would rather expect that the activities of all atoms and sites involved in the defect reaction would have to be taken into account.

The assumption of divalent vacancies in wustite also seems doubtful in terms of charge carrier concentrations and their distribution on the iron lattice sites. A neutral iron vacancy consists of a vacant iron site associated with two nearest-neighbor atoms with trapped electron holes (trivalent iron atoms). The ionization of the vacancy essentially represents the transfer of the electron holes away from the neighborhood of the vacant site. When considering that each iron atom on a normal (octahedral) lattice site in  $Fe_{1-y}O$  is surrounded by 12 nearest neighbor iron atoms, it follows that the structure can only contain about 4% of doubly ionized iron vacancies (8%  $Fe^{3+}$  ions on octahedral sites). At higher defect concentrations ( $y > 0.04$ ), the divalent vacancies will have

Fig. 1. Nonstoichiometry in wustite,  $y$  in  $\text{Fe}_{1-y}\text{O}$ , as a function of temperature and partial pressure of oxygen ( $y \propto p_{\text{O}_2}^{1/n}$ ). Experimental results after Vallet and Raccach (3). Broken lines show calculated values for  $y$  if only singly charged complex defects are considered, while solid lines show calculated values when taking into account both singly charged and neutral defects.

$\text{Fe}^{3+}$  ions on neighboring sites, and as such they really represent singly charged vacancies.

Neutron diffraction studies have suggested that for each vacancy which is formed in  $\text{Fe}_{1-y}\text{O}$ , an equal number of iron Frenkel defect pairs are formed in the metal lattice (9). Each defect may on this basis be considered as a complex defect consisting of two iron vacancies associated with an interstitial atom (9). Such a complex defect also results in the same local structure configuration as found in  $\text{Fe}_3\text{O}_4$ .

It is also noteworthy that the heat of formation of the defects in  $\text{Fe}_{1-y}\text{O}$  is negative, *i.e.*, the deviation from stoichiometry at a given oxygen pressure increases with decreasing temperature. In oxides with single, unassociated vacancies the heat of formation is commonly positive (10), and the negative value found for  $\text{Fe}_{1-y}\text{O}$  thus serves as a further indication that defects in this oxide are complex. In  $\text{UO}_{2+x}$ , which also contains complex oxygen defects, the heat of formation of the defects is also negative (11).

From these considerations we conclude that it is highly unlikely that the defects are doubly charged iron ion vacancies. From the available data it seems reasonable to assume that the predominating defects consist of the complex species, *i.e.*, two iron ion vacancies associated with an interstitial iron ion ( $\text{V}_{\text{Fe}}\text{Fe}_i\text{V}_{\text{Fe}}$ ). Proceeding on this basis, we have considered several possible defect structure models, *e.g.*, simultaneous presence of simple vacancies and complex defects, ordering and association of defects, complex defects only, etc., in order to explain the data. In all these alternative models activities or concentrations of all atoms and sites were considered. The model which to us was the most consistent and simple in principle and which gave the best description of the observed behavior is given in the following.

It is assumed that the complex defects, ( $\text{V}_{\text{Fe}}\text{Fe}_i\text{V}_{\text{Fe}}$ ) =  $\text{Fe}_c$ , may be neutral or singly charged. In writing the equations for the formation of these defects, one may write the equations for the formation of a single vacancy and a Frenkel defect pair followed by strong association between these defects. If the association is strong, as is assumed in this case, it is in terms of the law of mass action simpler to consider the complex defect as a unit, and the formation of these complex defects may then be written (13)

$\text{Fe}_c^\times$  and  $\text{Fe}_c'$  are neutral and singly ionized complex

defects, respectively;  $\text{V}_i$  represents an interstitial (tetrahedral) site available for occupancy by the complex defect,  $\text{Fe}_{\text{Fe}}$  is a divalent Fe atom on a normal (octahedral) site,  $\text{Fe}_{\text{Fe}} \cdot e^+$  atom is a Fe atom on an octahedral site with one trapped electron hole (a trivalent iron ion), and  $\text{O}_o$  is an oxygen atom on an oxygen lattice site.

In terms of the law of mass action Eq. [1] and [2] may be written

$$[\text{Fe}_c^\times][\text{O}_o] = K_1[\text{V}_i][\text{Fe}_{\text{Fe}}]p_{\text{O}_2}^{1/2} \quad [3]$$

$$[\text{Fe}_c'][\text{Fe}_{\text{Fe}} \cdot e^+] = K_i[\text{Fe}_c^\times][\text{Fe}_{\text{Fe}}] \\ = K_iK_1[\text{V}_i][\text{Fe}_{\text{Fe}}]^2[\text{O}_o]^{-1}p_{\text{O}_2}^{1/2} \quad [4]$$

where  $K_1$  is the equilibrium constant for the formation of neutral complex species, and  $K_i$  is the equilibrium constant for the first ionization. In terms of single defects,  $K_1$  is a combined value for the formation of the single defects and their association. The electroneutrality conditions require that

$$[\text{Fe}_{\text{Fe}} \cdot e^+] = [\text{Fe}_c'] \quad [5]$$

Expressing the concentrations of the defects in molar fractions,  $y$  is given by

$$y = [\text{Fe}_c^\times] + [\text{Fe}_c'] \quad [6]$$

As oxygen defects are considered to be negligible,  $[\text{O}_o] = 1$ . However, at the high defect concentrations in  $\text{Fe}_{1-y}\text{O}$  activities (or corrections for nonstoichiometry and interactions of defects) for  $[\text{Fe}_{\text{Fe}}]$  and  $[\text{V}_i]$  have to be considered. In this respect,  $[\text{Fe}_{\text{Fe}}]$  is not equal to unity, but part of  $\text{Fe}_{\text{Fe}}$  sites are occupied by electron holes ( $\text{Fe}^{+3}$ -ions on octahedral sites) and part of the  $\text{Fe}_{\text{Fe}}$ -sites are unoccupied due to the formation of the complex defects. When making these corrections, the concentration or activity of  $\text{Fe}_{\text{Fe}}$ -atoms available for the defect formation is given by

$$[\text{Fe}_{\text{Fe}}] = 1 - [\text{Fe}_{\text{Fe}} \cdot e^+] - 2([\text{Fe}_c^\times] + [\text{Fe}_c']) \quad [7]$$

In considering the activity of  $[\text{V}_i]$  a correction must be made for the fact that part of the sites are occupied by the complex defects. In addition, we also propose a correction for defect interaction and suggest that once a tetrahedral site is occupied by a defect, some neighboring sites are blocked for occupancy by additional defects (9). Specifically we propose that each occupied tetrahedral site blocks the six nearest-neighbor tetrahedral sites. The number of tetrahedral interstitial sites is twice that of the octahedral (normal  $\text{Fe}_{\text{Fe}}$ ) sites, and on this basis  $[\text{V}_i]$  is given by

$$[\text{V}_i] = 2 - ([\text{Fe}_c^\times] + [\text{Fe}_c']) \\ - 6([\text{Fe}_c^\times] + [\text{Fe}_c']) = 2 - 7y \quad [8]$$

This proposed blocking mechanism accounts for the marked decrease in the oxygen pressure dependence of  $y$  as the  $\text{FeO}/\text{Fe}_3\text{O}_4$  phase boundary is approached.

By combining Eq. [3]-[8], the value of  $y$  may be expressed as a function of  $p_{\text{O}_2}$  but for the sake of brevity the complicated relationship is not given. The internal consistency of the model is illustrated in Fig. 1, where the solid lines represent calculated values of  $y$  by simultaneous solution of Eq. [3]-[8] for values of the equilibrium constants

$$K_iK_1 = 1.45 \times 10^{-6} \exp(+64,000/RT) \quad [9]$$

$$K_1 = 1.9 \times 10^{-10} \exp(+81,500/RT) \quad [10]$$

$$K_i = 7.65 \times 10^{-4} \exp(-17,500/RT) \quad [11]$$

The stippled lines represent values when only singly charged defects are considered, and the model thus suggests that the neutral defects become increasingly important the lower the temperature. The model suggests an ionization energy of 17.5 kcal/mole or 0.75 eV for the neutral complex defect.

Additional ordering or association of the complex defects is not considered in the model. This may take place, particularly as one approaches the temperature (570°C) at which  $\text{Fe}_{1-y}\text{O}$  becomes unstable or in specimens which are quenched below the decomposi-

tion temperature. However, in terms of the model such additional association is suggested to be of secondary importance in considerations of over-all defect concentrations above 800°C. Only two different states (neutral and singly charged) of the defect are considered, and this does not seem unlikely in view of the fact that the defect concentration only changes by a factor of 3 (from 5 to 15%) when going from the Fe/FeO to the FeO/Fe<sub>3</sub>O<sub>4</sub> phase boundaries.

The electrical conductivity of Fe<sub>1-y</sub>O exhibits the same general oxygen pressure dependence as that for *y* at high temperatures (7, 8). This is also to be expected in terms of the proposed model at temperatures where the singly charged defects predominate. However, under conditions where the neutral vacancies affect the values of *y*, the oxygen pressure dependence of the electrical conductivity ( $\sigma \propto p_{O_2}^{1/n}$ ), should yield somewhat larger values of *n* than that for the deviation from stoichiometry. At the high defect concentrations in Fe<sub>1-y</sub>O the mobility of the charge carriers may also be a function of the defect concentration. In addition, there is evidence that grain boundaries affect the semiconducting properties, as polycrystalline Fe<sub>1-y</sub>O exhibits n-conductivity at the highest defect concentrations, while single crystal oxide remains p-conducting under the same conditions (8).

Kleman (14) has interpreted the results of Vallet and Raccach (Fig. 1) in terms of three separate "phases" within the Fe<sub>1-y</sub>O domain, but no interpretation is given in terms of the defect structure. Carel *et al.*, have later briefly described dilatometric (15) and x-ray diffraction (16) studies on Fe<sub>1-y</sub>O, the results of which are interpreted as a confirmation of the existence of these three phases. The transformations from one phase to another are proposed to reflect second order transitions (15), but no attempt is made to give physical interpretations of the transitions. The possible existence of these three phases reflecting minor changes in the properties is not necessarily at variance with the proposed model. If the transitions are of the second order, this implies that there is no latent heat involved and this, in turn, means that the transitions do not significantly affect thermodynamic properties such as the partial molar heat of dissocia-

tion of oxygen (7) or the heat of formation of the defects. As such the proposed phases are of but minor importance in consideration of the over-all equilibrium defect concentrations and have not at this stage been considered in the above model.

## Luminescence of Dy<sup>3+</sup>-Activated $\beta$ -Ga<sub>2</sub>O<sub>3</sub>

William C. Herbert,<sup>1</sup> Henry B. Minnier, and Jesse J. Brown<sup>2</sup>

Chemical and Metallurgical Division, Sylvania Electric Products, Inc., Towanda, Pennsylvania

Although trivalent dysprosium is a known coactivator or sensitizer in luminescent systems (1), few phosphors of significance are known in which Dy<sup>3+</sup> is the sole activator ion. Jenkins, McKeag, and Ranby (2) have activated various alkaline earth phosphate compounds, most notably Ca<sub>2</sub>P<sub>2</sub>O<sub>7</sub>, with Dy<sup>3+</sup> and made special note of their x-ray and cathode-ray-excited luminescent decay characteristics.

In the present note we describe the photoluminescence of Dy<sup>3+</sup>-activated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>. Although this material is not as efficient as the general class of commercial phosphors, it is one of the brightest Dy<sup>3+</sup>-activated oxide phosphors thus far reported. In addition, the emission of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> : Dy is remarkably similar to that of the standard commercial warm white phosphor, Ca<sub>5</sub>F(PO<sub>4</sub>)<sub>3</sub> : Sb : Mn.

Dy<sup>3+</sup>-activated  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> is prepared by intimately blending the constituent oxides and heat-treating the

mixture in air at 1400°C, for several hours. Dy<sub>2</sub>O<sub>3</sub> additions from 0.5 to 20.0 m/o (mole per cent) were investigated. Maximum photoluminescent brightness was observed in the range 5-10 m/o activator concentration.

Luminescence spectral measurements were obtained using a Perkin-Elmer Model 236 Spectrophotofluorimeter. Emission spectra were recorded in terms of relative energy. Identification of the intense line emissions is accurate to  $\pm 3\text{\AA}$ . C.I.E. chromaticity coordinates were obtained using a Librascope integrator.

The excitation and emission spectra of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> : Dy are shown in Fig. 1. Since no direct absorptions by dysprosium are observed in the excitation spectrum, it must be assumed that the major portion of the energy involved in luminescence arises from the broad host lattice absorptions. These peak at 250 nm and below.

The emission spectrum is dominated by two main groups of lines in the ranges 460-505 and 570-600 nm. A third group of weak lines, not shown in Fig. 1, was

observed between 660 and 690 nm. Several diffuse bands occurring near 435, 450, 540, and 550 nm are believed to be caused by either impurities or host lattice emissions and are not characteristic of Dy<sup>3+</sup> fluorescence.

Table I lists the observed emission lines, their intensities, and most probable ground state for the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>:Dy fluorescence. In Table II the fluores-

Phosphor	Relative peak height	Chromaticity coordinates x	Chromaticity coordinates y	% Total light output
Ca <sub>2</sub> F(PO <sub>4</sub> ) <sub>3</sub> :Sb:Mn (Sylvania No. 4356)	100	0.445	0.420	100
$\beta$ -(Ga <sub>0.95</sub> , Dy <sub>0.05</sub> ) <sub>2</sub> O <sub>3</sub>	495 nm emission	173	0.036	0.422
	588 nm emission	167	0.585	0.415
	Sum of both	—	0.439	0.416

cence of this new phosphor is compared with that of a standard "warm white" halophosphate phosphor, Sylvania Type 4356.

Hund's rule for a 4f<sup>9</sup> electronic configuration predicts that the ground state of Dy<sup>3+</sup> is an inverted <sup>6</sup>H state. The lowest-lying level in this multiplet would be the <sup>6</sup>H<sub>15/2</sub> with 8 doubly degenerate Stark components, the next <sup>6</sup>H<sub>13/2</sub> with 7 components, etc. Dicke and Singh (3) have successfully identified the experimental absorption and fluorescence transitions of DyCl<sub>3</sub> · 6H<sub>2</sub>O in this framework.

An equally successful term assignment of the Dy<sup>3+</sup> transitions in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> (Table I) is not immediately possible. The three observed groups of emission lines at 460-505, 570-600, and 660-690 nm apparently arise from <sup>6</sup>F<sub>11/2</sub> → <sup>6</sup>H<sub>15/2</sub>, <sup>6</sup>H<sub>13/2</sub>, and <sup>6</sup>H<sub>11/2</sub> transitions, respectively. However, in the first group at least 14 lines are observed when one would not expect more than 8 Stark components for a <sup>6</sup>H<sub>15/2</sub> transition; likewise 9 lines are observed for the <sup>6</sup>H<sub>13/2</sub> transition when not more than 7 are predicted. (The lines corresponding to the <sup>6</sup>F<sub>11/2</sub> → <sup>6</sup>H<sub>11/2</sub> transition are too weak and diffuse to be accurately resolved.)

Assuming that all observed fluorescence lines in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>:Dy arise from the <sup>6</sup>F<sub>11/2</sub> level and not higher-lying excited levels, and that Hund's rules are valid for this case, one possible explanation of the extra emission lines is that Dy<sup>3+</sup> occupies two non-equivalent sites in the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> lattice. This would effectively double the number of fluorescence transitions expected experimentally and be much more in line with the observed spectrum. In fact, Geller (4) has established the existence of two different cation sites in the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> crystal structure, one tetrahedrally and one octahedrally coordinated by oxygen.

# Optical Properties by Far Infrared Ellipsometry

Charlie E. Jones and A. Ray Hilton

Texas Instruments Incorporated, Dallas, Texas

The authors recently described (1), an infrared ellipsometer used to measure the thickness of thin silicon and germanium epitaxial layers. The measurement of thin film thickness by ellipsometry requires an accurate knowledge of the optical constants,  $n$  and  $k$ , of the film and substrate at the wavelength of measurement ( $54.6\mu$  in this case). The optical constants  $n$  and  $k$  (real and imaginary parts of the refractive index, respectively) were calculated from an expression given by Lyden (2) for free carrier and lattice absorption in semiconductors. The method was used by the authors in earlier studies (3). The experimental data required for the calculations was supplied from electrical measurements of the semiconductor films and substrates (1). Optical constants can also be calculated directly from ellipsometric measurement of the substrate surface and is the technique commonly used in the visible spectrum range (4). This note presents a comparison of the optical constants obtained on highly doped silicon using ellipsometric measurements to those obtained using the above mentioned techniques. The ellipsometric curves generated for epitaxial layers of undoped silicon on substrates having the different optical constants are presented and compared. Comments are made regarding the fit of experimental data to the various curves.

Four methods have been used to determine  $n$  and  $k$ :

A. Measure the resistivity (probe), determine the number of carriers from a literature curve relating resistivity to carriers (5), and the mobility from a literature curve relating resistivity to mobility (6). Calculate  $n$  and  $k$  from Lyden's expression.

B. Same as A except mobility is calculated from:

$$\text{Mobility} = \frac{6.25 \times 10^{18}}{(\text{number of carriers})(\text{resistivity})}$$

C. Measure the number of carriers and mobility by Hall techniques then proceed with Lyden's expression.

D. Measure, with the infrared ellipsometer, the  $\Delta$  and  $\psi$  value for the substrate and calculate the optical constants from the exact equation given by Winterbottom (7).

Methods A and B depend on resistivity values obtained by the simple probe technique and are therefore not expected to yield as accurate values for optical constants as will method C which utilizes the reliable Hall technique.

The optical constants obtained from each method for a substrate of 0.016 ohm-cm n-type silicon were:

Method	$n$	$k$
A	2.18	2.44
B	2.48	2.18
C	2.21	1.49
D	2.59	1.38

Four curves relating to the ellipsometer parameters  $\Delta$  and  $\psi$  were plotted assuming each of the above optical constants for the substrate and undoped silicon (optical constants  $3.38 - 0.i$ ), as the epitaxial layer. The other parameters of interest are  $\lambda = 54.6\mu$ ; angle of incidence =  $50^\circ$ . These curves are shown in Fig. 1. The arrows on each curve indicate the thickness of the epitaxial layer in microns. The data points (solid dots) are  $\Delta$  and  $\psi$  measurements made on 16 samples of undoped silicon layers deposited on 0.016 ohm-cm n-type silicon. The data points fit best the curve plotted

using the ellipsometrically measured substrate optical constants. The measuring accuracy of the ellipsometer in present form is about  $\pm 3^\circ$  for  $\psi$  and  $\Delta$ . Since in method C the electrical properties were measured to a high degree of reliability, curve C represents the best of the calculated optical constants. Curves A and B can be considered deviations from curve C due to a lack of accuracy in the electrical values obtained by methods A and B. The difference between the optical constants obtained by methods C and D are not due to inaccuracies in the equations relating resistivity and mobility to the optical constants. We have previously shown (1) good agreement between measured and calculated absorption coefficients of 0.01 to 1.0 ohm-cm n-type silicon using these same relationships. The difference probably results from the fact that in method C the resistivity and mobility, used to calculate the optical constants, are values of bulk material while the ellipsometer measures the optical constants of the materials surface.

If ellipsometry is used in the far infrared to measure layer thicknesses ellipsometry should be used for determining the optical constants of the materials in question. It should be noted that by using the  $n$  and  $k$  calculated from the ellipsometric readings and back calculation some insight may be gained as to the accurate electrical characteristics of the surface of the material. This will of course depend on the exactness of the theory relating the electrical and optical properties.

## The Preparation and Examination of PbTe by Transmission Electron Microscopy

E. Levine

*Department of Mechanics, Rutgers—The State University, New Brunswick, New Jersey*

and R. N. Tauber

*Department of Metallurgy and Materials Science and The Materials Research Center, Lehigh University, Bethlehem, Pennsylvania*

The preparation of thin foils of the compound semiconductor PbTe for transmission electron microscopy has not been reported previously. Electron microscopy can be employed in this compound for the study of defects and precipitation effects. The following note describes the preparation technique and some preliminary observations made on thin foils of PbTe.

It has been suggested by various investigators (1-3) that the change of carrier concentration of PbTe on annealing is due to precipitation of Pb or Te from the supersaturated crystal. This is further evidenced by the fact that both the Pb and Te concentration are retrograde in nature (1,2). In this investigation a single crystal of PbTe grown by the Bridgman technique was heat-treated so as to produce precipitation of Pb from the lattice. The procedure was as follows: (a) diffusing the specimens in a Pb-rich atmosphere at 775°C for 28 hr and brine quenching; this produces a maximum Pb-rich PbTe (1, 2). (b) Aging the specimens at 504°C for 25 hr and brine quenching; this should produce precipitates of Pb in the lattice, particularly on dislocation sites (3).

Thin foils of the specimen were prepared for electron microscopy using a combination of mechanical and electropolishing. The specimen was mechanically polished to approximately 200 $\mu$  on various grades of paper with a final polishing on both sides using Linde Gamma AB alumina powder. It was then electropolished using a solution described by Norr (4) which consisted of 20g KOH in 45 ml H<sub>2</sub>O, 35 ml glycerol, 20 ml of ethyl alcohol. The polishing was performed at 4-6v and 0.2 amp/cm<sup>2</sup>. The sample was suspended without any edge masking in the electropolishing solution. Small black dots of apezion wax were placed on opposite sides in the center of the specimen. Accelerated attack occurred in the vicinity of these dots and also around the periphery of the specimen. Polishing was continued until the hole formed under the dots joined up with the peripheral region. Extremely rapid stirring was necessary in order to prevent the build up of a contamination layer.

The PbTe was found to be very brittle before polishing, and considerable care was necessary to avoid shattering. The electropolished thin specimen, however, was found to be very ductile in certain thin regions and could be bent plastically at the edges by 180° and then straightened out again without fracture occurring. This behavior is similar to that found with alkali halide crystals when deformed in a solvent environment (5), i.e., the specimens are notch brittle. The removal of notches or cracks renders the crystal somewhat ductile although even in the thinned specimen cutting with a knife results in brittle fracture along the cleavage planes.

The thinned specimen was examined in a Hitachi Electron Microscope operated at 100 kv. The density of dislocations was found to be quite high and accurate estimates were not possible due to their inhomogeneity. A typical area is shown in Fig. 1. Precipitation was not observed at dislocations as has been previously suggested (3). Arrays of dislocations on their inclined slip planes were observed throughout the foil. Some of these dislocations appeared to be either dipoles or dissociated dislocations (Fig. 2). Stacking fault contrast was not observed between these dislocation pairs. Further contrast experiments on their exact nature are planned for the future. The presence of dissociated dislocations in PbTe has been proposed previously by Rachinger (6).

In the background of Fig. 2 in the neighborhood of the extinction contour many elongated images may be seen which are not visible in the area on the right side of the figure. These images were only visible in the vicinity of an extinction contour and may correspond to an early stage in a precipitation process. The associated diffraction pattern did not show any evidence of such precipitates indicating their volume fraction is small or we are observing a preprecipitation stage of clustering similar to that found in Al-4% Cu alloys (7). Figure 3 is a diffraction pattern of a {100} orientation from a bent portion of the specimen. (The major portion of the thinned specimen was of {112} orientation.) Weak streaking in the <100> directions may be observed which usually

Fig. 1. Dislocation arrays in PbTe

Fig. 2. Possible dipole or dissociated dislocations in PbTe. In the background anomalous images, possibly precipitates, are observed.

Fig. 3.  $\{100\}$  Diffraction pattern of PbTe. Streaks are observed in  $\langle 100 \rangle$  directions indicating either anisotropic expansion coefficient or a strain displacement in this direction.

characterizes the preprecipitation stage in metal systems (7). However, one cannot unambiguously assign these "streamers" to precipitation. Similar streaking has been observed in Ge crystals in the  $\langle 110 \rangle$  directions and their origin is speculative. They may arise from thermal vibrations or anisotropic strain displacements (8). The latter may be created by clustering of atoms. Further work on aging experiments is now in progress to clarify this point.

The dislocations were observed to be quite mobile during observation in the electron microscope. Dislocations in thin foils may move as a result of the stresses set up by the electron beam. That such movement readily occurred is another indication of the possible room temperature ductility of suitably prepared specimens. The movement of dislocations produced a variety of slip trace contrasts as may be seen in Fig. 4 at A and B. The slip trace contrast in some cases rapidly disappeared after a few seconds while other slip traces were of indefinite duration.

Fig. 4. Persistent slip traces due to movement of dislocations while under observation in electron microscope. Slip trace at A clearly visible while that at B is weakly visible.

Slip trace contrast is thought to be due to a surface layer of oxide or other contamination layer on the foil which prevents the slip from penetrating the surface. The observation of the variability of duration and contrasts produced in the same area of the foil suggests that the phenomenon is strongly dependent on the slip vector of the dislocations involved.

Slip trace analysis assuming either  $\{110\}$  or  $\{100\}$  glide planes indicated that dislocations on both planes were capable of movement. Rachinger (6) using trace analysis in bulk specimens observed both glide planes to be operative in PbTe although Buerger (9) had found only evidence of  $\{100\}$  glide plane activity. Evidence of both  $\{110\}$  and  $\{100\}$  glide plane activity had been observed by Seltzer (10) and Matthews *et al.* (11) in PbS. Our observation suggests that PbTe behaves similarly to PbS in that slip (at least in thin films) occurs on both glide planes.

# Formation of Crystalline Films by Laser Evaporation

P. D. Zavitsanos and W. E. Sauer

Space Sciences Laboratory, Missile and Space Division,  
General Electric Company, King of Prussia, Pennsylvania

Vacuum evaporation techniques have been used for the preparation of films of elements and some compounds. When these techniques are applied to compounds or alloys which contain elements of widely different vapor pressures, vapor fractionation takes place to produce films containing an excess of the most volatile component.

A definite improvement was brought about by the "flash" evaporation technique as outlined first by Siegel and Harris (1) and applied in the preparation of compound semiconductor films (2). The "co-evaporation" technique (3-5) also served as an improvement.

Both techniques, however, sometimes suffer from contamination effects due to impurity vapors present in high-temperature furnaces and vacuum atmospheres. Another disadvantage present in the above techniques, as well as in the "sputtering" technique, is the fact that for many materials of interest, amorphous films are produced unless the substrate is independently heated (6, 7).

The evaporation of solids with a pulsed laser beam for the purpose of producing good optical films has been investigated by Smith and Turner (8), and Schwartz (9) with some degree of success. In the present work, the use of a laser beam appears to produce (a) congruent vaporization and films of the same composition as the parent material, and (b) crystalline films without heating the substrate (independently).

## Experimental

The laser used in this investigation was a Lear-Siegler Model H-140Q. It had a maximum output of 10 joules, and a pulse duration of  $5-6 \times 10^{-4}$  sec, and was operated in the burst mode.

The vapor generated by laser evaporation formed a jet, the center of which was always normal to the surface of the source material, independent of the incident angle of the laser beam. For this work, the laser beam entered a glass vacuum system through a glass window and was focused by a 75 mm focal length lens on the surface of the source material at a 45° angle. The source material was mounted (inside the vacuum system) on a holder which could be moved up and down or rotated for focusing or exposure of a new segment of the surface to the beam. Films of Ge and GaAs were prepared by condensing the vapor on various substrates, at room temperature, placed parallel to the specimen 2.5 cm away. Prior to vaporization, the substrates were washed first with acetone and then with ethyl alcohol and air dried at 120°C. Satisfactory films were produced at chamber pressures as high as  $1\mu$ .

For lasers operating in the burst mode, it can be assumed that there is sufficient power density in the beam to raise the surface temperature of the target to its boiling point at a relatively short time compared to the length of the pulse, and the rate of surface recession reaches a steady state rapidly (10). (Time resolved microwave attenuation measurements (11) indicate that this assumption is correct.) If energy losses due to reflection, radiation, conduction through the solid, superheating of solid and gas are negligible, the mass of the generated vapor,  $m$  is given by

$$m = E / [(C\Delta T_1)_{\text{solid}} + \Delta H_f + (C\Delta T_2)_{\text{liquid}} + \Delta H_v]$$

where  $E$  = energy output of laser,  $C$  = specific heat capacity,  $(C\Delta T_1)_{\text{solid}}$  = energy required to heat the solid to its melting point,  $\Delta H_f$  = heat of fusion and or heat of decomposition,  $(C\Delta T_2)_{\text{liquid}}$  = energy required to heat the liquid to its boiling point, and  $\Delta H_v$  = heat of vaporization of liquid at the boiling point. The energy output,  $E$ , used in these experiments was 3 joules per pulse. In the case of Ge and GaAs, the amounts of vapor generated (per pulse) are calculated to be 0.48 and 0.9 mg, respectively.<sup>1</sup>

The deposited area was usually about 3-4 cm<sup>2</sup>, and if the condensation coefficient was unity, the resulting films would have a thickness in the order of 1600-3500Å. Our present estimates, however, (based on optical opacity) indicate that the film thickness (per pulse) was considerably less and of the order of 500-1000Å. In view of the high reflectance of the Ge and GaAs source materials, it is felt that reflection was not negligible and probably was the dominant mechanism of energy loss. The extent of laser energy absorption by the vapor is usually considered to be small at this power level (10) although not proven for our experimental conditions. The resulting deposition rate is extremely high compared to conventional techniques and in the range of  $10^6$  Å/sec. As far as the source temperature is concerned, although it was not measured, by analogy to graphite (13) targets it is felt that it did not exceed the boiling point of the less volatile component by a significant amount. The temperature of the substrates could not have been significantly raised by the laser energy in view of the fact that the substrates were transparent and rather massive (10-15g); even if all the available energy went into heating the substrate, its temperature could not be raised by more than 2°-3°.

## Results

The results which follow were typical of those obtained from measurements on several films (2-3 of each case). Films prepared by laser evaporation were studied by reflection and transmission optical microscopy. Figure 1 shows optical photomicrographs of Ge and GaAs films deposited on glass and sodium chloride substrates. It can be seen that the films are smooth, continuous, and free of "chunks" of materials.

The films were removed from their substrates, and high resolution transmission electron diffraction patterns were obtained using an Hitachi HU-11 electron microscope. Figure 2A is an electron diffraction pattern from a germanium film which had been laser deposited on a glass substrate. Figure 2B is from another germanium film which had been produced by evaporation of the same source material from a resistance heated molybdenum boat. In neither case was the substrate heated by external means. The conventionally

<sup>1</sup> For germanium, the following steps were assumed to lead to vaporization

with  $T_{\text{melting}} = 1210^\circ\text{K}$ ,  $T_{\text{boiling}} = 3100^\circ\text{K}$ ,  $C = 6 \text{ cal} \cdot \text{deg}^{-1} \cdot \text{mole}^{-1}$ ,  $\Delta H_f = 8.83 \text{ kcal} \cdot \text{mole}^{-1}$ , and  $\Delta H_v = 79.1 \text{ kcal} \cdot \text{mole}^{-1}$ . For gallium arsenide, the corresponding gasification processes (12) are

with  $T_{\text{decomposition}} = 1000^\circ\text{K}$ ,  $T_{\text{boiling}}(\text{Ga}) = 2520^\circ\text{K}$ ,  $\Delta H_{\text{decomposition}} = 45 \text{ kcal/mole}(\text{GaAs})$ , and  $\Delta H_v = 61.5 \text{ kcal/mole}(\text{Ga})$ .

Fig. 2. Transmission electron diffraction patterns produced by evaporated germanium films. A(left), laser evaporation; B(right), conventional evaporation.

evaporated film exhibits an amorphous structure which is typical of germanium films condensed on unheated substrates. However, the laser evaporated film exhibits a degree of crystallinity which is typical of films deposited by conventional evaporation onto substrates heated to 300°C or more (7).

In addition to the elemental films, films of GaAs were prepared. The laser evaporation of GaAs was found to proceed congruently. Figure 3A is an electron diffraction pattern produced from a film which had been prepared on a calcium fluoride substrate by

Fig. 3. Transmission electron diffraction patterns produced by evaporated gallium arsenide films. A(left), calcium fluoride substrate; B(right), sodium chloride substrate.

the laser evaporation of gallium arsenide. Figure 3B is from a gallium arsenide film similarly deposited on sodium chloride. The diffraction lines in these two patterns are listed in Table I. Both sets of data are in good agreement with the literature interplanar spacing values for gallium arsenide (14). If the constituents of the deposited film had condensed noncongruently, a second phase would have been present, because of the very limited solubility of gallium and arsenic in gallium arsenide (15). Thus, since all of the diffraction lines could be assigned to gallium arsenide, it was concluded that laser evaporation did produce congruent deposition and crystalline films of gallium arsenide on calcium fluoride and sodium chloride substrates. In the case of laser evaporation (16), coevaporation (4, 16) and sputtering (17) techniques, substrate temperatures of the order of 220°-400°C were required to produce crystalline films of GaAs.

### Discussion

The two most evident features of films prepared by the laser evaporation technique are the congruent deposition of compounds and the degree of film crystallinity achieved on unheated substrates. The reason for congruent evaporation is that conduction of heat away from the focal point and through the solid (target) is a slow process compared to local heating and evaporation. A small volume of material (at the focal point) is raised to a high temperature which is apparently sufficient to produce vapor having the stoichiometry of the target. In a way, this heating process is similar to flash evaporation but more efficient.

The crystallization of the films is probably affected by several factors. The high deposition rates and temperatures would tend to increase the mobility of atoms in the depositing films by providing a high energy environment. Heating of the films (during formation) by reflected laser light (which is preferentially absorbed in the film as compared to the substrate) could also take place and, thus, increase the mobility of the condensing vapor.

## Brief Communications

### Reply to Comments on the Paper "Transport Processes in the Thermal Oxidation of Silicon"

Douglas O. Raleigh

Science Center, North American Rockwell Corporation, Thousand Oaks, California

A recent communication (1) has raised a number of questions concerning my paper "Transport Processes in the Thermal Oxidation of Silicon" (2). Since it is felt that the comments made represent a misunderstanding of the assertions in this paper, a reply was felt necessary.

In a paper in 1962, Jorgenson (3) reported experiments on the effect of an electric field on the thermal oxidation of silicon at elevated temperatures. From the results, he asserted that the normal thermal oxidation process occurred by the diffusion of oxygen ions through the  $\text{SiO}_2$  reaction layer. My own paper was an attempt to clarify the matter of what can be meant by the "effect of an electric field" on a thermal oxidation process. I asserted that an electric field *per se* cannot provide a steady-state driving force for diffusion-controlled thermal oxidation, since the net process involved in normal oxidation is the transport of an electroneutral species (elemental oxygen in the case of  $\text{SiO}_2$ ) through the reaction layer. Accordingly, in examining electric field effects, one must consider the role of the experimental arrangement in altering the nature of the oxidizing system. Specifically, the application of an electric field via ohmic leads provides an external path for electron flow and results in an electrolysis experiment rather than an electric field experiment. Since thermal oxidation by an ionic mechanism involves the transport of both ions and electrons through the oxide layer and electrolysis involves only

ion transport, it is not possible to say *a priori* that an electrolysis experiment proves normal oxidation occurs by an ionic mechanism. It may well be that the electronic conductivity in the oxide is too low to permit more than a minor contribution by an ionic mechanism.

In the recent communication (1), it was said that I asserted the so-called halt voltage is, as a general matter, unrelated to the free energy of formation of the oxide. Reference to an unpublished memo by Wagner was made to show that this is not the case in cells of the type  $\text{Me}|\text{MeO}|\text{O}_2$  with an externally applied voltage. In fact, while I might have made myself clearer, I did not assert this as a general matter, but merely for the cell arrangement Jorgenson (3) employed. In the latter case, a constant current was passed through two conjoined cells  $\text{O}_2|\text{Pt}|\text{SiO}_2|\text{Si}$  and the voltage monitored across each oxide layer. The  $\text{SiO}_2$  in these cells was a growing oxide layer on the surface of an initially clean silicon sample with sputtered platinum electrodes on the two ends. An oxygen atmosphere served for both the normal oxidation and the oxygen electrodes. If the voltage leads across the cells were properly contacted, the cell voltages should have been given by  $V = E \pm iR$ , where  $E$  is the galvanic emf and the sign of the  $iR$  drop depends on the direction of the current.  $E$  is ideally given by  $t_{\text{ions}}\Delta F^\circ_f(\text{SiO}_2)/4F$ , equal to  $t_{\text{ions}}(1.69\text{v})$  at  $850^\circ$ , where  $t_{\text{ions}}$  is the effective ionic transport number in the ox-

ide film. Since the  $iR$  drop would be proportional to the  $\text{SiO}_2$  film thickness, extrapolation of  $V$  vs.  $t$  back to  $t = 0$  should give  $E$ . Instead, all  $V$  vs.  $t$  plots extrapolated back to zero volts, indicating no galvanic emf contribution. As explained in my paper, this would have been the case if the voltage lead to the Si were unprotected from oxidation, since one would then have had an  $\text{O}_2/\text{SiO}_2$  electrode at this site, identical to the main oxide electrode. In this case, one would have been measuring purely  $iR$  drop in the oxide film, which would be unrelated to the free energy of formation of  $\text{SiO}_2$ .<sup>1</sup>

Jorgenson's report of recent galvanic emf data on the cell

is very interesting and may, indeed, indicate both sufficient ionic and electronic conduction in  $\text{SiO}_2$  to support an ionic oxidation mechanism. Caution, however, is required in interpreting the experimental results. It was said that  $p''_{\text{O}_2}$  was 323 Torr and that  $p'_{\text{O}_2}$  was maintained at an ambient value of  $10^{-7}$  Torr by vacuum pumping on the right-hand side of the cell. Ionic transport numbers of 0.40-0.53 were obtained, which were presumably calculated from the galvanic emf via the expression

$$E = t_{\text{ions}} \frac{RT}{4F} \ln \frac{p''_{\text{O}_2}}{p'_{\text{O}_2}}$$

In this, of course, it is important that the ambient value of  $10^{-7}$  Torr for  $p'_{\text{O}_2}$  be also the pressure value inside the sputtered Pt film at the Pt|oxide interface, since it is the latter pressure that determines  $E$ . This is a matter of concern, since oxygen was continually permeating the silica membrane and, indeed, the permeation rate was measured in the same experiment. Jorgenson implied that there was no pressure differential across the Pt, since his measured permeation rates agreed to 10% with those of Norton (4). This, however, is not very convincing, since the permeation rate only depends on  $\Delta p$  and would be essentially the same for any  $p'_{\text{O}_2}$  value small compared that of  $p''_{\text{O}_2}$ . Thus, any of a wide range of  $p'_{\text{O}_2}$  values  $> 10^{-7}$  Torr could have been present at the Pt| $\text{SiO}_2$  interface and would have the effect of lowering the calculated values of the ionic transport number. Experiments with

<sup>1</sup>Note added in proof: Dr. Jorgenson has communicated to the author that he has re-examined his original voltage-time data and finds that it is best fitted to a zero-time intercept not of zero volts, but of 0.61v. If so, this would indicate that there was a galvanic contribution, which should be added to my estimate of the  $iR$  drop. This would yield 1.86v for the predicted halt voltage, in somewhat better agreement with the observed value than my previous estimate.

silica membranes thick enough to retard permeation greatly would be very helpful. Likewise helpful would be the use of a "buffered" oxygen atmosphere, such as a  $\text{CO-CO}_2$  gas mixture, which establishes a low oxygen pressure chemically instead of by evacuation.

Regarding the many small points in my paper which were allegedly incorrect, I can only comment on the two that were actually brought up. Regarding Jorgenson's experiments on the effect of an electric field on the oxidation of zinc (5), I stand corrected in that the author did not assert the results showed diffusion control by oxygen ions, but merely by ions. I must still maintain, however, that the results did not prove diffusion control by ions, but merely showed the presence of some ionic conductivity in the oxide, for the reasons mentioned above and in my original paper. Regarding my model for the stopping voltage, its calculation did not require an assumed value for the ionic transport number, but a value for the ionic conductivity. The latter was obtained from Jorgenson's own data and a value in good agreement with it was obtained from oxygen diffusion data in  $\text{SiO}_2$ . Thus, the original prediction for the stopping voltage remains.

In conclusion, it is felt that the distinction between experiments on the effect of an electric field on thermal oxidation and electrolysis experiments is still an important one. Wagner, in fact, has independently employed the concept of superposed electrolysis to explain oxidation effects in the presence of an external electric field in what I believe is the same unpublished memo to which Jorgenson referred (6). It is felt that this concept provides a rational electrochemical basis for such field effects and clearly indicates their limited relevance in deducing the predominant oxidation mechanism.

Manuscript received Sept. 11, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Application of the Peltier Effect for the Determination of Crystal Growth Rates

Ranjit Singh, August F. Witt,\* and Harry C. Gatos\*

Department of Metallurgy and Center for Materials Science and Engineering,  
Massachusetts Institute of Technology, Cambridge, Massachusetts

A method for the determination of microscopic rates of solidification during crystal growth has been reported recently (1). The method is based on the introduction of relatively high-frequency impurity striations in the growing crystal. Such striations referred to from here on as "rate striations" were induced by establishing controlled low amplitude vibrations of known frequency in the melt during crystal growth. While the exact mechanism responsible for the for-

mation of these striations is as yet not unambiguously determined, it is most likely that they are caused by instantaneous growth rate fluctuations associated with thermal and fluid-dynamic perturbations. It was found that they do not interfere to any detectable extent with the over-all solidification process (2).

The present communication reports on the successful formation of rate striations by employing the Peltier effect. Current pulses of short duration and of the appropriate frequency applied across the crystal-

\* Electrochemical Society Active Member.

Fig. 1. Off-core on-core transition region in a Czochralski grown single crystal of InSb. Rate striations (introduced by employing the Peltier effect) reveal major variations of the microscopic crystal growth rate. Magnification 380X.

melt interface during crystal growth cause corresponding fluctuations in the instantaneous growth rate due to Peltier heating (or cooling). These fluctuations are incorporated in the growing crystal as impurity striations [revealed by polishing and etching (1)] which exhibit the same characteristics as the previously discussed rate striations introduced by vibrations. Like the vibrational striations, the presently reported striations do not effect the over-all crystal growth process and can thus be utilized for the investigation of localized microscopic growth rates and interface morphologies. Instantaneous growth rate changes resulting from Peltier heating (or cooling) have been previously studied extensively in connection with the formation of p-n junctions (3, 4).

In the present study a standard Czochralski pulling system was modified to permit the passage of current pulses across the crystal-melt interface during rotational and nonrotational pulling. A pulse generator in conjunction with a low-frequency current amplifier provided pulses of the desired frequency (5 to 40 cps). With this arrangement it was possible to control the current density and the duration of the current pulses which in turn determine the intensity and width of the induced striations respectively.

Some typical results obtained with Te-doped InSb single crystals are shown in Fig. 1 and 2. Local variations in growth rate within a given single crystal are readily seen in Fig. 1. It is apparent that these variations can be quantitatively evaluated. The constancy of the microscopic growth rate in the "core" of the

Fig. 2. Core region (facet growth) in an InSb single crystal. The microscopic rate of growth as revealed by the rate striations is constant. The alternating light and dark areas indicate impurity concentration changes which are unrelated to the microscopic rate of growth. Magnification 410X.

crystal (2) is seen in Fig. 2. This figure shows also impurity concentration changes (dark and light areas) which obviously do not result from microscopic growth rate changes.

The Peltier effect permits excellent control of the intensity and the width of the induced rate striations. Possible side effects associated with the current transport across the growth interface (mass transport) may limit its usefulness particularly in multicomponent systems.

The detailed nature of the rate striations and their application to the study of solidification processes is being studied in our laboratory.

# Discharge Characteristics of Some Copper Oxide-Magnesium Thermal Cells

Lawrence H. Thaller\*

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

## ABSTRACT

Previously single cells of the system Mg/LiCl-KCl/Cu<sub>2</sub>O were built that had service lives of several days at 425°C. Further studies are conducted to investigate the effect on discharge characteristics, both chemical and electrochemical, of different cell designs. The average rate of self-discharge taking place concurrently with electrochemical discharge at constant load varies from less than one to more than 200 ma. As cell designs are changed to decrease the rates of self-discharge (greater electrode spacings, higher current densities in the electrolyte, and different electrolytes), the over-all cell polarizations increased. The equivalent internal resistance of these cells varies from about 0.2 to about 2 ohms.

Thermal cells are a class of primary electrochemical devices which at room temperatures are inactive. The electrolytes used in these cells are usually mixtures of solid inorganic salts which require the application of heat to melt the electrolyte and thus to activate the cells. For certain applications, these cells have advantages over the more common aqueous or nonaqueous cells (1-3). While in the active state, these cells are not subject to internal chemical reactions of the active materials which lower the output of the cells. A less obvious advantage of a thermal battery is simply the ability of being able to operate at temperatures hundreds of degrees above the operating temperatures of aqueous batteries. It is this latter advantage that this research program is concerned with.

Earlier studies (4) on this system employed magnesium anodes, mixed copper oxide cathodes, and electrolytes of the eutectic mixture of lithium chloride (LiCl) and potassium chloride (KCl). This material when melted (mp, +352°C) has a high specific conductivity ( $K = 1.6 \text{ ohm}^{-1} \text{ cm}^{-1}$  at 450°C) and possesses a high decomposition potential of about 3v. The anode material (Mg) and the cathode material (CuO-Cu<sub>2</sub>O) both have rather high half-cell potentials, low equivalent weights, and were thought to have low solubilities in the electrolyte. The cells discharged in these earlier studies were opened and the contents analyzed quantitatively for products of reaction and unused reactants. Results of a typical analysis are shown in Table I.

The results of Table I show that during the cell discharge magnesium is oxidized to the +2 state and that both the cupric and cuprous oxide are reduced finally to metallic copper. As shown in these earlier studies the open-circuit voltage of these cells at the early stages of discharge are due to magnesium being oxidized to magnesium plus two ion and cuprous ion being reduced to metallic copper.

It was evident from the results of the material balances made on the discharged cells and from the continuous recordings of the cell voltage and cell current taken during the testing of the cells, that self-discharge was a major cause of poor performance. The losses of electrochemical efficiency by internal chemical reactions were of two types. The first type was caused simply by the diffusion of copper ions from the vicinity of the cathode to the magnesium anode. At the anode, the copper ions reacted chemically with the magnesium to form submicron particles of copper. The second type occurred when these small particles of copper suspended in the electrolyte actually formed an electrical short circuit between the anode and either the cell case or the cathode. The former type

affected the cell performance by lowering the yield of current from the cell. The latter type of self-discharge was characterized by erratic voltage and current fluctuations. The object of this research program was to understand and to control the diffusional type of self-discharge and to try to prevent the internal short circuits.

## Experiment

**Electrolytes.**—Mixtures of lithium chloride (LiCl), potassium chloride (KCl), and cesium chloride (CsCl) were used as the electrolytes for these cells. The reagent grade alkali halides were predried at 200°C for several weeks in a drying oven. Three different compositions of electrolyte were used in these studies. They were:

1. 59 m/o (mole per cent) LiCl — 41 m/o KCl
2. 59 m/o LiCl — 20.5 m/o KCl — 20.5 m/o CsCl
3. 59 m/o LiCl — 41 m/o CsCl

The proper proportions of these materials were weighed out in a porcelain crucible. After slowly bringing the ingredients to the melting point, magnesium chips were added in an effort to remove the last traces of water. When all evidence of reaction had ceased, the electrolyte was poured into a waiting cell.

**Sealed cells.**—The cells used in these studies are shown in Fig. 1 and 2. One type had the electrodes arranged in a vertical fashion and will be referred to as the vertical type; the other configuration will be referred to as the horizontal type. Both types of cells had the same nominal inside dimensions of 2.9 cm in diameter by 5.1 cm in height. The material used for the cell case was either commercially pure copper or

nickel. The top assembly of the cell included the lid with the threaded fill tubes and either one or two electrical feedthroughs. The centrally located feedthrough served to insulate the anode from the cell case which was the current collector for the cathode. The other feedthrough was used for the insertion of a thermocouple or a reference electrode.

In all instances, an anode of the desired shape was screwed onto a shaft which extended up through the central feedthrough and was silver soldered onto the top of it. The grade of magnesium used for the anodes is called primary (99.8% Mg). The wire form of cupric oxide was used as the cathode material. The composition of this material varies from batch to batch and with supplier. In general its composition was between 65 and 85 m/o CuO, and the remainder was

Table II. Makeup of a typical open cell

Anode size	12.7-mm diam by 38 mm tall
Anode weight	7.95g (17.5 amp-hr)

cuprous oxide ( $\text{Cu}_2\text{O}$ ). This cathode material was placed either in the bottom of the cell case for horizontal type cells or behind a cylindrical copper screen for the vertical-type cells. Woven glass cloth was used as a separator material in these cells. This tightly woven fabric was manufactured in the form of a continuous cylinder. After being coated with a resin, this material is sold as a flexible electrical insulation. The fabric thickness was about 1 mm. After oxidizing away the resin in a  $500^\circ\text{C}$  furnace, this fiberglass material was suitable for use as a separator in these cells. Its main function was to act as a mechanical barrier through which particles of copper could not form a continuous electronically conducting path. Usually one layer of separator material was placed against the cathode and one layer was placed against the anode.

With all the cell components in the cell, except for the electrolyte, the top assembly was welded onto the cell case. The electrolyte was added to these cells in a furnace which had been preheated to about  $450^\circ\text{C}$ . The final step in the construction was to screw stainless steel screws into the threaded fill tubes and to seal the two together with silver solder.

**Open cells.**—Open cells were used from time to time to perform certain preliminary experiments. These cells employed 20 ml beakers as cell cases and close fitting copper tubes as the cathode current-collectors. These cells used the same anodes, separators, and cathode material as the sealed cells, but were open at the top and thus were exposed to the atmosphere inside the furnace. The spacing between the anode and cathode was provided by the thickness of two layers of glass separator material (approximately 2 mm). A typical makeup of an open cell is shown in Table II.

#### Experimental Setup and Procedure

An unsealed furnace was used for the electrolyte addition step and also for the discharge of the open cells. Figure 3 shows a block diagram of the equipment used for the discharge of the sealed test cells. A fresh cell was wired to the proper leads of the disassembled furnace. The furnace used for heating the sealed cells was pressurized with nitrogen to retard oxidation of the lead wires and cell components during the prolonged exposure to the elevated temperatures. After making the proper exterior electrical

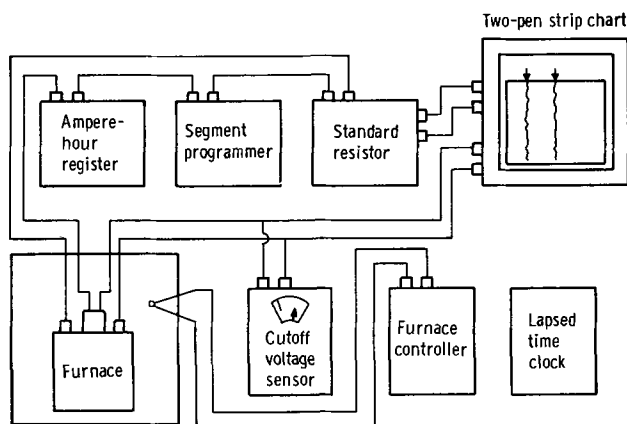

Fig. 3. Block diagram of experimental setup

connections, the furnace as well as the strip chart recorder, were turned on. These test cells had four leads. One positive and one negative wire from the cell went to one pen of a two-pen strip chart recorder. This pen thus recorded the load voltage of the cell while it was under load or the open-circuit voltage of the cell when it was in the no load condition. This same set of wires also went to the cutoff voltage sensor. When the voltage of the cell dropped below a preselected value (cutoff voltage), the sensor would shut off all power to all the equipment.

The other set of wires from the test cell was used to discharge the cell at the proper rate and also to measure the output of the cell in ampere-hours (A-h). One of the wires of this pair went to an electronic counting device. The rate at which this device counted was proportional to the current that passed through the device. The sum of all the counts was thus related to the integral of Idt. This device was in essence an electronic coulometer. From this device, the wire went next to the segment programmer. A complete discharge segment was divided as follows:

- 100-min cell under load  $R_1$
- 10-min cell under load  $R_1 + R_2$
- 10-min cell under no load

This discharge segment was repeated until the cell voltage fell below the cutoff voltage. From the segment programmer, the wire went to a standard resistor. The voltage drop across this resistor was a measure of the current that was flowing through the cell. The current was continuously recorded on the other pen of the strip chart recorder. A lapsed time meter was also used to record the time between the startup of a fresh cell and the termination of the experiment.

After a test had been terminated, the discharged cells were opened, and the unused anode was washed and weighed. The weight loss represented the sum of two different types of reaction. Part of the weight loss was due to electrochemical dissolution and the other was due to chemical dissolution caused by the self-discharge reaction of copper ions with the magnesium. Using the proper conversion factor ( $1\text{g Mg} \equiv 2.20\text{ amp-hr}$ ) these weight losses may be expressed in terms of ampere hours. The total weight loss  $A-h_T$  is then the sum of the weight loss due to electrochemical action  $A-h_{ec}$  and that due to self-discharge  $A-h_{sd}$ . Since the electrochemical output of the cell is measured for each of the cell discharges, all three of these quantities may be determined. By dividing these weight losses by the total lapsed time of the discharge, three average currents were calculated. They were  $I_T$  the total current,  $I_{ec}$  the electrochemical current, and  $I_{sd}$  the self-discharge current. The anode efficiency (AE) is defined as the ratio of the loss of anode weight due to useful electrochemical processes to the total loss of anode weight. For each experiment, the information appearing in Table III was recorded or calculated.

### Results and Discussion

*Determination of optimum amount of electrolyte.*— Since the object of these experiments was the investigation of the discharge characteristics of some com-

pleted cells, preliminary work was necessary to find a suitable group of design parameters from which the cells could be constructed. One of most important parameters was the selection of the amount of electrolyte to be used in the cells. With this particular combination of anode, electrolyte, and cathode, there was no *a priori* reason to believe that the electrolyte would be consumed during the discharge of these cells. Since the earlier studies (4) had shown that the major products of reaction were sparingly soluble MgO and insoluble  $\text{Cu}^0$ , there was no reason to believe the melting point of the electrolyte would be altered during the discharge of the cell. The particles of MgO, however, were held in suspension in the electrolyte and did change its consistency from a free flowing liquid to a semisolid paste.

The role played by the electrolyte in an electrochemical device varies from one system to another. Recent publications indicate that with certain cathode materials the discharge mechanism involves a solid-state electron transfer coupled with the increase of the hydrogen ion content of the solid. This is called the electron-proton mechanism (5), and the electrolyte supplies the protons. When a solid-state electron transfer cannot take place, the solid cathode material must first go into solution. This step is then followed by an electrochemical reduction involving these dissolved species. Although mixed copper oxides are good electronic conductors, lithium ion would not be expected to be able to migrate through the oxide lattice and thus complete an electron-proton type of reaction. Indeed, x-ray analysis of discharged cells showed no evidence of a mixed oxide between copper and lithium. For these reasons, it is felt that in the magnesium-copper oxide cell being studied, copper oxide must first go into solution. The function of the electrolyte, therefore, would be to act as a solvent for the cathode material and also as an accumulator for the products of reaction. The extent to which the cathode material is soluble, therefore, will affect the amount of copper species available both for electrochemical discharge and for transport to the anode.

An open cell was constructed and discharged to find how the over-all polarization was effected by the products of discharge. Using the equivalent circuit concept (6) which assigns an equivalent resistance to the concentration polarization as well as the ohmic resistance of the electrolyte; equivalent cell resistances were plotted as a function of products of reaction in the electrolyte. Figure 5 shows how this over-all equivalent resistance varied as a function of W, the grams of MgO per gram of total electrolyte (Fig. 4). In

Table III. Representative information recorded for each cell

Cell configuration	Horizontal
Anode weight (fresh cell)	5.9g (12.98 amp-hr)
Case material	Nickel
Anode weight (spent cell)	0.52g (1.15 amp-hr)
Electrolyte weight	25g
Separators	1 anode, 1 cathode
Anode to cathode spacing	14 mm
Duration of test	290.8 hr
Anode weight loss	5.38g
Ampere hours delivered	10.90 (amp-hr)
Ampere hours of self-discharge	0.92 (amp-hr)
Electrochemical discharge rate	37.4 ma
Self-discharge rate	3.10 ma
Anode efficiency	92.2%

Fig. 4. Effect of ratio of magnesium oxide to electrolyte on over-all internal resistance.

Fig. 5. Plot of average discharge rate and anode efficiency

this plot, it is seen that the equivalent resistance remains about the same to a  $W$  value of about 28. From information like this, it was decided that about 2g of the LiCl-KCl eutectic were required for every ampere-hour of reaction products. The cells shown in Fig. 1 and 2 use this electrolyte loading factor along with the woven glass fabric separators discussed in the section, Experiment.

**Controlling the self-discharge process.**—The first group of cells to be tested were all alike (class 1-Table IV). They were the vertical type and had copper cases, lids, screens, and shafts. The use of copper throughout was an attempt to eliminate any possible side reactions between the cupric ion and any less noble material of construction to form reducible ions other than copper. Four of these cells were discharged at different average currents. Figure 5 shows the results of this series; the anode efficiencies are plotted against the average current. Here it is seen that although the average electrochemical currents vary over a wide range (43-487 ma), the rate of self-discharge,  $I_{sd}$ , for all these cells is about the same (160-230 ma). From this plot it is seen that at an average electrochemical drain of about 190 ma, the anode efficiency is 50%, or, in other words, the average rate of nonelectrochemical discharge is also 190 ma. This rate is high considering the total capacity of these cells is only about 15 amp-hr.

In all probability, this self-discharge process is caused by the diffusion of copper ions from the vicinity of the cathode to the anode where chemical reaction takes place. This over-all process may be divided into three stages or steps: (i) the solution of the copper ions at the cathode; (ii) the diffusion of the copper ions from the vicinity of the cathode to the anode; and (iii) the reaction of the copper ions with the magnesium anode.

In principle, any one of these three processes could have the slowest rate and thus could control the over-all process. Considering the high temperatures and the large change in free energy (about 40 kcal) for the reaction of copper ions with magnesium metal, the rate of this reaction would be very fast and therefore not rate controlling. Either the rate of solution or the rate of diffusion would control the over-all process.

Table IV. Parameters studied

Cell Class	Type	Distance from anode to cathode, mm	Electrolyte	Separators
1	Vertical	2.0	LiCl-KCl	1 anode, 1 cathode
2	Vertical	5.0	LiCl-KCl	1 anode, 1 cathode
3	Vertical	5.0	LiCl-KCl-CsCl	1 anode, 1 cathode
4	Vertical	5.0	LiCl-CsCl	1 anode, 1 cathode
5	Horizontal	14	LiCl-KCl	1 anode, 2 cathode
6	Horizontal	14	LiCl-CsCl	1 anode, 2 cathode

The basic diffusion equation was used to differentiate between these two processes (solution and diffusion).

$$\text{Rate of diffusion } \frac{dN}{dt} = -DA \frac{dc}{dx}$$

Although the exact applicability of this simple equation to this particular system is not implied, it is instructive to investigate the implications of such an assumption. Fick's first law of diffusion simply states that rate of diffusion  $dN/dt$  is equal to the diffusion coefficient  $D$  of the species that diffuse times the area  $A$  available for diffusion times the concentration gradient  $dc/dx$  of the diffusing species. Several short wide cells were made that contained the same weights of electrode material (same area for dissolution of CuO-Cu<sub>2</sub>O wires) and electrolyte but only had one-half the area available for diffusion between the anode and the cathode. There also was a greater distance between the anode and the cathode. If the rate of self-discharge was controlled by the rate of solution of the copper oxides, these alterations would not be expected to alter the rate of self discharge. Table V shows the results of altering the area for diffusion by a factor of two and decreasing the concentration gradient by a factor of about two.

The fact that the rate of self-discharge was reduced by about a factor of three (although the equation predicted four) makes plausible the conclusion that the factor controlling the self-discharge process was the rate of diffusion of copper ions from the vicinity of the cathode to the anode. Therefore, it should be possible to alter the diffusional characteristics of these cells by any one of the following means:

1. Decrease the area available for diffusion; this can be done, for example, by constructing a short wide cell.
2. Decrease the concentration gradient of the species that diffuse; this may be accomplished by increasing the separation between the two electrodes.
3. Decrease the diffusion coefficient of the species involved in the self-discharge process. Alterations in the ion size and character of the electrolyte might bring this about.
4. Reduce the activity of the ions causing the self-discharge. The formation of complex ions would perform this task.
5. Introduce a separator between the electrodes which would preferentially hinder the passage of the particular ion of interest.

**Studies on alterations of diffusional characteristics.**—The method of data presentation is somewhat different than for other battery studies so it will be explained prior to the discussion of the results of these studies. The anode efficiency as stated earlier may be defined as

$$AE = \frac{I_{ec}}{I_{ec} + I_{sd}}$$

If the assumption is made that the rate of self-discharge,  $I_{sd}$ , of a particular cell configuration and electrolyte is a constant for all rates of electrochemical discharge,  $I_{ec}$ , then a curve may be generated as shown in Fig. 6. Here, it was arbitrarily assumed that  $I_{sd}$

Table V. Self-discharge rates for tall and short cells

Cell	Anode area (for diffusion), cm <sup>2</sup>	Rate of self-discharge, $I_{sd}$ , ma	Average rate of self-discharge, $I_{sd}$ , ma	Self-discharge current per unit area per concentration gradient, $\frac{I_{sd}}{A dc/dx}$
Tall	14.1	160, 160, 205, 235	181	12.8
Short	6.2	40, 51, 63	51	16.7

Fig. 6. Plot of average electrochemical current and anode efficiency. Self-discharge rate, 100 ma.

Fig. 7. Plot of average electrochemical current and anode efficiency.

would be 100 ma. For any assumed  $I_{ec}$ , the anode efficiency can be calculated. For a different assumed  $I_{sd}$ , the curve would be moved up or down, but would maintain the same general shape being asymptotic at zero and 100% anode efficiency. Figure 7 shows a whole family of these curves along with data points for some of the cells run in these studies. It is to be noted that in general the data points for a particular class of cell fall near a line of constant self-discharge, and thus the assumption of constant rates of self-discharge is valid over a wide range of operating conditions. A class of cell is defined as a group of cells having the same electrode spacing, electrolyte, and separator configuration as shown in Table IV. The points near the 200-ma line (class 1) are those seen earlier in Fig. 5. The electrolyte was the eutectic mixture of LiCl-KCl. The points near the 75-ma line are again for vertical type cells but with a greater separation between the anode and the cathode (class 2) (i.e., smaller concentration gradient of the copper ions). With this latter configuration and replacing 50 m/o of the KCl with CsCl, the points fall near the 50-ma line (class 3). The effect of the larger ion size of cesium on the diffusional characteristics is more dramatically shown where all the KCl is replaced with CsCl. The points for these cells of class 4 now fall near the 15-ma line. The eutectic of LiCl-CsCl has about the same composition and melting point as the LiCl-KCl eutectic (mp, 333°C ~ 42.5 m/o LiCl).

For cells of the horizontal type, the same general trend was noticed. When the electrolyte was LiCl-KCl, the rate of self-discharge was about 5 ma for class 5 cells, and when the electrolyte was LiCl-CsCl, the rate was about 3 ma (class 6).

With all these cells, it was found that erratic performance and intermittent short circuits occurred when cells were discharged at average currents less than

about 30 or 40 ma. Figure 7 has a number of points of several classes of cells that are off their respective lines of constant self-discharge. The exact reason for this is not known. At higher values of  $I_{ec}$ , on the other hand, it appears that the cells display a lower value of  $I_{sd}$  than predicted from the curves. This behavior is reasonable since, at the higher rate of electrochemical discharge, the higher concentration polarizations will act to hinder the diffusion of the copper ions from the cathode.

Although it is not obvious from the material presented in Fig. 7, the cells with the lowest rates of self-discharge have the highest over-all equivalent internal resistance. For these cells, a hundredfold decrease in the rate of self-discharge was accompanied by only a tenfold increase in the equivalent internal resistance. In general, the values of the equivalent internal resistance for the horizontal cells was of the order of 2-4 ohms while for the vertical cells it was in the range of 0.2-0.4 ohm. The value of the internal resistance limits the upper value of the current that may be withdrawn from a cell.

Discharge curves of three representative cell classes are shown in Fig. 8 to 10. Figure 8 is the discharge curve of a class 2 cell illustrating the performance over a short discharge time (34 hr) of a cell that used a LiCl-KCl electrolyte. Figure 9 illustrates the performance of a cell (class 3) at a moderate duration discharge (77 hr) using an electrolyte of LiCl-KCl-CsCl. Figure 10 shows the long term (290 hr) operating characteristics of a class 5 cell with a LiCl-CsCl electrolyte. In addition to the open-circuit voltage, the load voltage, and the current, Fig. 10 also has plotted equivalent cell resistance ( $\Delta E/\Delta I$ ) as a function of time to illustrate how this value varies as the cell is discharged. The main point to be noted on these three figures is that abrupt changes in the open-circuit voltage curves occur accompanied with only small and gradual changes in the current and in the voltage under load.

Fig. 8. Discharge curve of vertical cell. Electrolyte, 59 m/o LiCl, 41 m/o KCl; rate of self-discharge, 72 ma; rate of electrochemical discharge, 280 ma.

Fig. 9. Discharge curve of vertical cell. Electrolyte, 59 m/o LiCl, 20.5 m/o KCl, 20.5 m/o CsCl; rate of self-discharge, 41 ma; rate of electrochemical discharge, 132 ma.

Fig. 10. Discharge curve of horizontal cell. Electrolyte, 59 m/o LiCl, 41 m/o CsCl; rate of self-discharge, 3.1 ma; rate of electrochemical discharge, 37.4 ma.

**Explanation of steps in the open-circuit voltage.**—These steps or abrupt changes in the open-circuit voltage may be explained in terms of the following electrochemical model. Assume there are two over-all electrochemical reactions possible (reaction I and II). Over-all reaction I will have an open-circuit voltage  $E_I$  which is greater than  $E_{II}$  by say 100 mv or more. During the initial stages of discharge, the observed open-circuit voltage and the load voltage will be due predominately to the presence of the reactants and the products of reaction I. As the discharge proceeds, there will be fewer type I species, and this reaction may become polarized to the extent that reactants of type II will be discharged concurrently with those of type I. Gradually the proportion of type II species reacting during discharge will become greater until the load voltage will be due predominately to reaction II. However, until almost all the type I reactants have been consumed, the open-circuit voltage will be a consequence of the type I species. Later, of course, the open-circuit voltage will be due predominately to the over-all reaction II. With cells of all classes discharged in these studies, there was at least one abrupt change in the open-circuit voltage during the discharge. The magnitude of these changes ranged from about 50-250 mv.

Figure 11 will illustrate what two successive discharge segment traces look like as the transition (from reaction I to II) is made complete. Figure 11 is based on data from a class 2 cell, and this transition occurred between discharge segments 18 and 19. During the 18th segment, there is an electroactive specie present (type I) that is responsible for the open-circuit voltage, but it is not present in large enough amounts to be able to maintain the higher currents (I drops quickly from 142 to 112 ma). That is, they are subject to extreme concentration polarization. At the 19th segment, this more active specie (type I) has disappeared, and the less active (type II) but more abundant specie is now responsible for both the open-circuit voltage and the load voltage of the cell.

Fig. 11. Variance of current and voltage with time. Sequence of events: starting with constant-load discharge, load is increased for 10 min, then circuit is open for 10 min, after which original load is applied for 100 min and then changes are repeated.

At this time it is not known exactly what this latter over-all electrochemical reaction is. However, x-ray analyses on some cells that had undergone these abrupt changes in open-circuit voltage tended to confirm the contention that a change in over-all reaction had occurred.

**X-ray analysis of the electrolyte after cell discharge.**—The method of analysis was as follows. A discharged horizontal-type cell was opened, and the unused anode was washed and weighed as before. Next, the cell was split down the middle, one-half being placed in a desiccator and the other left out in contact with the moist air. As the materials in the cell picked up hydration water, characteristic colors began to form in horizontal bands in the cathode area. From each of the areas which were made evident by the "wet" half of the cell, x-ray samples were taken from the cell half that had been kept as dry as possible. Figure 12 shows a typical set of results. The existence of the associated compound  $KCl \cdot MgCl_2$  in the anolyte and the presence of  $Li_2O$  in the lower layers of the cathode area are to be noted. The upper area of the cathode area contained  $Cu^0$  and  $MgO$ . The lack of any  $MgO$  in the anolyte is also to be noted. From this set of information, it may be concluded that cations from the anolyte migrate to the catholyte to maintain over-all charge neutrality in these cells. Since the upper portion of the cathodes react first, it may further be deduced that during the latter stages of discharge the lithium ion moves instead of the magnesium ion. The over-all reaction I, therefore, is associated with a reaction that would have  $MgO$  as a product of reaction, such as

whereas reaction II would be associated with a reaction that would have  $Li_2O$  as a product of reaction. One possibility might be

### Conclusions

Long-life high-temperature primary cells can be built that have predictable discharge characteristics. The woven-glass separator material was found to prevent internal short circuits for certain cell configurations. For the cell configurations employed in these studies, the rate-controlling step in the self-discharge process was found to be the rate of diffusion of copper ions from the vicinity of the cathode to the anode. The rate of self-discharge could be considerably reduced by increasing the electrode spacing and by adding CsCl to the electrolyte to reduce ion diffusion rates. The open-circuit voltage of these cells decreased in a stepwise fashion during discharge, with at least two steps observable.

## Cathodic Polarization of the Manganese Dioxide Electrode in Alkaline Electrolytes

A. Kozawa\* and R. A. Powers\*

Consumer Products Division, Research Laboratory, Union Carbide Corporation, Cleveland, Ohio

## ABSTRACT

Polarization of  $\beta$ - and  $\gamma$ - $MnO_2$  is measured at various constant currents in 9M KOH and KOD electrolytes in reduction from  $MnO_2$  to  $Mn(OH)_2$ . Two limiting currents are observed in high-current discharges of  $\gamma$ - $MnO_2$ , one around  $MnO_{1.75}$  and the other after  $MnO_{1.5}$ . The former is attributed to formation of a lower oxide structure on the surface of  $\gamma$ - $MnO_2$  structure. Around  $MnO_{1.9}$ , a Tafel relation is observed for  $\gamma$ - $MnO_2$  and  $i_0$  values are obtained. The polarization is always greater in 9M KOD than in 9M KOH under the same discharge conditions.

In previous work, Kozawa and Yeager (1) found two steps in the cathodic reduction process of  $\gamma$ - $MnO_2$  in alkaline electrolyte; the first step from  $MnO_2$  to  $MnO_{1.5}$  and the second step from  $MnO_{1.5}$  to  $MnO_{1.0}$ . The first step was a homogeneous-phase discharge and the open-circuit potential *vs.*  $x$  value in  $MnO_x$  has been established and its significance was discussed by Kozawa and Powers (2). The second step was a heterogeneous phase discharge, for which a new mechanism was proposed (1) based on the presence of dissolved Mn(III) and Mn(II) ions (3).

The purpose of this work is to investigate the general pattern and magnitude of polarization in the course of cathodic reduction of  $\gamma$ - and  $\beta$ - $MnO_2$  in an alkaline electrolyte in the entire range of the two steps mentioned above. Another purpose is to establish the magnitude of polarization of  $\gamma$ - $MnO_2$  in KOD solutions and compare it to that in KOH solutions.

The nature of the polarization of the first step was studied by Scott (4), and by Kornfeil (5) in ammonium chloride electrolyte, and by Era *et al.* (6) in alkaline electrolyte. These previous studies were mainly based on the analysis of build-up and decay curves in order to test the proton diffusion theory in the solid. No attempt, however, has been made to investigate the steady-state polarization in relation to the stages of the discharge (or  $x$  value in  $MnO_x$ ).

In this investigation, polarization at various constant currents in the course of reduction from  $MnO_{2.0}$  to  $MnO_{1.0}$  was measured in KOH and KOD electrolytes.

## Experimental

**Samples.**—The manganese dioxide powder samples used in this work were electrolytic  $\gamma$ - $MnO_2$ , and  $\beta$ - $MnO_2$  which was prepared from the  $\gamma$ - $MnO_2$  by heating at 400°C for 10 days in air and subsequent washing with 2M  $H_2SO_4$  solution. Details of the physical and chemical properties of these samples are reported in the previous paper (9). The  $\beta$ - $MnO_2$  (III) in this paper was the same as the  $\beta$ - $MnO_2$  (III) in the previous paper (9).

**Discharge cell.**—The discharge cell (Fig. 1) which was used in this work is similar to the previous one

- (9), but modified in order to achieve more homogeneous current-distribution in the cathode mix. One gram of coke, 0.5g of graphite powder, and 50 mg of  $MnO_2$  powder were ground together in a glass mortar for 1 min and transferred into the cell. The mixture was then stirred with 0.35 ml of 9M KOH solution. Two layers of separator paper and a perforated Teflon disk were then placed in the cell and pressed tightly. Electrolyte was added drop by drop at one edge in order to let it soak homogeneously through the mix. Finally the Lucite plug was tightly screwed down and more electrolyte was added from the top.

**Polarization measurements.**—A constant current (1-60 ma) was passed continuously between the  $MnO_2$

cathode and the zinc electrode in the entire course of reduction from  $\text{MnO}_2$  to  $\text{Mn}(\text{OH})_2$ . The IR-free closed circuit voltage (CCV) of the  $\text{MnO}_2$  cathode was measured against a Hg/HgO (9M KOH) reference electrode every 1 ma-hr using a Sargent Model MR recorder or an oscilloscopic method (Fig. 2). A curve of open-circuit voltage (OCV) vs. depth of discharge (ma-hr or  $x$  in  $\text{MnO}_2$ ) has been established for both  $\text{MnO}_2$  samples as reported in a previous paper (9). The potential difference between the IR-free CCV and the OCV was taken as polarization at each stage during the constant-current discharge.

**Electrolytes.**—9M KOH was prepared from reagent grade KOH pellets, and 9M KOD was prepared from 40% KOD in  $\text{D}_2\text{O}$  solution and 99.7%  $\text{D}_2\text{O}$ .

**Errors in the polarization measurements.**—The IR-free CCV shown in Fig. 4, 5, 6, and 8 were obtained by the recorder method in which the circuit was opened for a few seconds while the potential was recorded at a chart speed of 20 ipm. The polarization data in Fig. 7 were measured by the oscilloscopic method (Fig. 2) in which an accurate IR drop was determined from a trace on the screen. A few examples of such a trace are shown in Fig. 3, which also shows typical examples of decay of polarization.

Fig. 3. Oscillographic traces of the current interruption with the circuit shown in Fig. 2. Current is for a single cell containing 50 mg of  $\gamma\text{-MnO}_2$  sample. These traces were obtained at a discharge stage of 1 ma-hr in 9M KOH.

Fig. 4. Constant current polarization of  $\gamma\text{-MnO}_2$ . The currents shown on the curves are for a single cell containing 50 mg  $\gamma\text{-MnO}_2$  sample. The OCV (calc.) was calculated as described previously (2). Curves a and a' are polarization and CCV respectively at 20 ma discharge. Curves c and c' are those at 5 ma discharges.

Fig. 5. Constant current polarization of  $\beta\text{-MnO}_2$  (III). The currents on the curves are for a single cell containing 50 mg  $\beta\text{-MnO}_2$  (III) sample. Curves a and a' are polarization and CCV respectively at 20 ma discharge. Curves c and c' are those at 2.5 ma discharge.

A large portion of the polarization decay may be attributed to the potential change of the R-C network of the carbon materials. The IR drops measured by the oscilloscopic method at various currents for a single cell were proportional to the current. The cell resistance varied from one cell to another in a range of 1.1-3.6 ohms. Table I shows the comparison of the polarization data measured by the two methods. We can see that, at 10 ma or lower currents, the error is less than 10%, but at 20 ma or higher currents, the error is greater than 20%.

Another error which may enter into the polarization measurement, particularly at high current, is due to nonhomogeneous current distribution in the cathode mix caused by the IR drop. In the present mix composition, the volume of the  $\text{MnO}_2$  sample constitutes only 0.5% of the total volume (50 mg  $\text{MnO}_2$  sample in 1.5g of coke and graphite). Error in the polarization value due to the nonhomogeneous current distribution must increase with increasing total current. A qualitative examination was made on this point as follows. Three different amounts of the  $\gamma\text{-MnO}_2$  sample (25, 50,

and 100 mg) were mixed with 1.0g of coke and 0.5g of graphite in the manner described earlier and discharged at the same current density of 0.2 ma/mg of sample (i.e., 5, 10, and 20 ma in total current per cell, respectively). The polarization values for these three cells agreed with each other within the experimental error. This indicated the error due to nonhomogeneous

current distribution may be small except at very high current densities.

When the polarization was measured immediately after packing the cell, the polarization was considerably smaller (about 15-20% smaller than several hours later. This was found to be due to a chemical reduction of MnO<sub>2</sub> by a small amount of reducing substance present in the coke and graphite. The chemical reduction proceeds slowly. We can see this by the decrease in the initial open-circuit potential; it was initially +0.165v vs. Hg/HgO (9M KOH), +0.145 after a few hours, +0.130 after 8-10 hr, and changed very little thereafter. When accurate data are needed, the polarization measurements should be started at least several hours after packing the cell, because the OCV vs.  $x$  value relation was obtained under such a condition. The data of Fig. 4, 5, and 6 were measured 3-4 hr after the packing, and those of Fig. 7 and 8 were measured 8-10 hr after the packing.

## Results

Figures 4 and 5 show polarization (lower part of the figure) and CCV and OCV (upper part) in the entire range of the discharge at various constant currents for  $\gamma$ -MnO<sub>2</sub> and  $\beta$ -MnO<sub>2</sub>(III), respectively. The polarization of  $\gamma$ -MnO<sub>2</sub> initially increases with the depth of discharge to around 2-3 ma-hr (around  $x = 1.9$ ) depending on the current, then remains approximately the same value. The polarization then increases rapidly indicating the presence of limiting  $x$  value around MnO<sub>1.7</sub> depending on the current density. After passing a maximum, the polarization decreases rapidly and reaches a minimum around MnO<sub>1.5</sub> which is the end of the first step. In the second step, from MnO<sub>1.5</sub> to MnO<sub>1.0</sub>, the polarization is at first low and for a while at low currents (below 5 ma) remains approximately constant, then reaches a limiting  $x$  value. These limiting  $x$  values ( $x_1, x_2, \dots, x_8$ ) are summarized in Table II.

The polarization curves of  $\beta$ -MnO<sub>2</sub>(III) looks much different from that of  $\gamma$ -MnO<sub>2</sub> for the first step (MnO<sub>2</sub> to MnO<sub>1.5</sub>), but the polarization curves for the second step are similar in general shape to those for  $\gamma$ -MnO<sub>2</sub>. It was reported in our previous paper (9) that magnitude of polarization of  $\beta$ -MnO<sub>2</sub>(III) is not much different from that of  $\gamma$ -MnO<sub>2</sub> at low current densities (0.05 ~ 0.5 ma/m<sup>2</sup> or below 2 ma/100 mg MnO<sub>2</sub> sam-

ple) in Leclanché electrolytes (5M NH<sub>4</sub>Cl + 2M ZnCl<sub>2</sub> + NH<sub>3</sub>) of pH 5.0 ~ 8.8. However, we can see in Fig. 4 and 5 that the magnitude of polarization of  $\beta$ -MnO<sub>2</sub>(IV) is much greater than that of  $\gamma$ -MnO<sub>2</sub> in 9M KOH particularly at high current densities (2.5 ~ 20 ma per 50 mg MnO<sub>2</sub> sample) in a range of from MnO<sub>2.0</sub> to MnO<sub>1.8</sub> which is important for practical batteries.

Figure 6 shows the comparison of polarization in 9M KOH and 9M KOD at two discharge currents (5 and 20 ma). Polarizations in KOD are greater by about 10-30% than those in KOH, and the limiting  $x$  values (indicated as  $x_D$  and  $x_H$ ) come at an earlier stage in KOD than in KOH. Figure 7 shows polarization ( $\eta_c$ ) vs. logarithm of current at early discharge stages (1, 2, and 3 ma-hr stages) in 9M KOH and 9M KOD. The curves have a straight line portion (at least one decade) and also show a limiting current. The slope of the straight line portion is approximately 130 mv per decade for all the lines. Figure 8 shows polarization vs. logarithm of current in a low current range at the 5 ma-hr discharge stage. These data were obtained in the old cell (containing 100 mg of MnO<sub>2</sub> sample) which was described in a previous paper (9). Even at a low current range, polarization in 9M KOD is greater (by about 10-25%) than in 9M KOH. The slopes of the Tafel lines were 90-92 mv and 35-50 mv per decade for  $\beta$ -MnO<sub>2</sub>(III) and  $\gamma$ -MnO<sub>2</sub>, respectively, and were much smaller than those in Fig. 7.

### Discussion

Among the results obtained in this work, three main points for the first step will be discussed here: the first is the limiting  $x$  value around MnO<sub>1.75</sub>, the second is a sudden decrease of the overpotential after the maximum, and the third is the Tafel relation (Fig. 7) at the early stage of the discharge. Details of the second step (after MnO<sub>1.5</sub>) will be reported in a separate paper.

*Limiting  $x$  value around MnO<sub>1.75</sub>.*—The authors would like to attribute the limiting  $x$  values to the formation of a new lower oxide structure on the surface of the original oxide. It has been pointed out in our previous paper (2) that around the region marked as "lower oxide on the surface" in the upper part of Fig. 4, the OCV deviates considerably from the calculated OCV curve, because the lower oxide structure is formed on the surface of  $\gamma$ -MnO<sub>2</sub> structure and at this stage the whole system cannot be considered as a homogeneous phase (Mn<sup>4+</sup> — Mn<sup>3+</sup> — O = — OH<sup>-</sup> system). We can see in Fig. 4 that as soon as the CCV curves (a' and c') reach the potential of the lower oxide region (-0.12 to -0.16v), the overpotential begins to increase suddenly. This can be seen more clearly in Fig. 6 by the potentials marked as  $E_1$ ,  $E_2$ ,  $E_3$ , and  $E_4$  where the overpotential curve begins to deviate, and the beginnings of the deviation are between -0.115 and -0.160v. This suggests that the determining factor in the formation of the lower oxide structure is not the  $x$  value (or depth of the discharge), but the electrode potential; namely, concentration of [Mn<sup>3+</sup>] on the oxide surface. This lower oxide structure on the surface appears to have extremely high overpotential for the following discharge reaction.

From this discussion we can tentatively conclude that the limiting  $x$  value around MnO<sub>1.75</sub> is probably attributable to the kinetically limited charge transfer process (reaction [1]) on the lower oxide covered surface.

*Overpotential decrease after the maximum.*—The polarization decreases rapidly after the maximum as is seen in Fig. 4. This seems to be due to the beginning of the second step reaction; reduction of dissolved trivalent Mn(III) complex ion (3) to the divalent

state and also reduction of Mn(III) to Mn(II) on the oxide surface. At this stage the potential (CCV) is approaching that of the second step reaction, of which the OCV is -0.385v vs. Hg/HgO (9M KOH); therefore, reaction of the second step reduction is taking place to some extent in addition to the main reaction [1].

This situation can be seen more clearly for  $\beta$ -MnO<sub>2</sub>(III) in Fig. 5. The polarization of  $\beta$ -MnO<sub>2</sub>(III) is much greater than that of  $\gamma$ -MnO<sub>2</sub> in addition to the much lower OCV than that of  $\gamma$ -MnO<sub>2</sub>. Therefore the CCV of  $\beta$ -MnO<sub>2</sub>(III) reaches the second step potential [-0.385v vs. Hg/HgO (9M KOH)] at a very early stage in the discharge and the CCV remains around -0.38v during most of the first step.

The approximate standard potential of the Mn(III)-Mn(II) system in 9M KOH was found to be approximately -0.40v vs. Hg/HgO (9M KOH), as reported previously, based on the polarographic (1) and voltammetric (3) current potential curves in a 9M KOH solution containing Mn(III) and Mn(II) ions.

*Tafel relation at early stages of the discharge.*—The accurate polarization of the reaction [1] at various currents (Fig. 7) was measured only at very early stages of the discharge in order to escape the complications due to both the presence of the lower oxide on the MnO<sub>2</sub> surface and the trivalent manganese reduction. The limiting currents (marked in Fig. 7 as  $i_{L,KOD} = 43$  ma and  $i_{L,KOH} = 62$  ma) cannot be discussed on the basis of pure proton diffusion process, because at the current the polarization (200-250 mv) is high and the CCV is very close to, or already entering into, the potential region of the lower oxide on the MnO<sub>2</sub> surface.

The slopes of these Tafel lines are not far from 120 mv per decade. This can be interpreted that the rate determining step is reaction [1] having  $\alpha$  value of approximately  $\frac{1}{2}$  in the following equation.

$$\eta = \frac{RT}{\alpha nF} \left( \ln \frac{i_0}{i} \right) = a - b \log i \quad [2]$$

The  $i_0$  values were obtained by extrapolation as shown in Fig. 7 for one case. The exchange currents are shown in Table III.

The Tafel slopes in a low current range (Fig. 8) are much smaller than those for the high current ranges (Fig. 7).

When the current values are compared at a constant overpotential for KOH and KOD solutions (in Fig. 7, as indicated by small horizontal arrows), the current ratio  $i_{KOH}:i_{KOD}$  is 1.35-1.55 for the data in Fig. 7. It is interesting to note that the ratio is close to the ratio derived from a simple diffusion rate ratio of deuterium and proton; namely,  $1/\sqrt{H} : 1/\sqrt{D} = 1.41$ .

### Acknowledgment

The authors wish to thank Mr. W. L. Adams, Mrs. H. M. Joseph, and Dr. R. L. Brubaker for their experimental assistance or aid in the preparation of the manuscript, and also thank Professor E. B. Yeager of Western Reserve University and Professor H. A. Laitinen of the University of Illinois for their comments and suggests on this paper.

# Chromium Oxide Scale Growth on Iron-Chromium Alloys

## I. The Influence of Variables on the Oxidation of Fe-28% Cr

G. C. Wood and D. P. Whittle

*Corrosion Science Division, Department of Chemical Engineering,

## ABSTRACT

The oxidation of Fe-28% Cr in oxygen at 800°-1200°C has been studied in detail by thermogravimetric methods, metallography, and electron probe microanalysis. The oxidation rate is critically related to the surface finish and alloy purity but not significantly to variations in specimen size or geometry. Uniform single-layered scales, consisting of Cr<sub>2</sub>O<sub>3</sub> containing a low concentration of dissolved iron, are produced. The oxidation rate shows minor negative deviations from a parabolic law, with an activation energy of  $36 \pm 6$  kcal mole<sup>-1</sup> for the over-all diffusion-controlled process. The deviations from a parabolic law are discussed in light of general oxidation theory and the self-diffusion coefficients of Cr<sup>3+</sup> ions in the scales are derived.

There is considerable general evidence (1-4) that the nature of Cr<sub>2</sub>O<sub>3</sub>-rich scales produced on chromium and iron-chromium alloys depends critically on the alloy purity, heat-treatment, surface finish, and specimen geometry, and on the oxidizing environment and temperature. The present paper presents a study of certain of these features of scale growth on Fe-28% Cr alloys in oxygen, making detailed use of thermogravimetric measurements, metallography, and electron probe microanalysis. In a sequel (5) the influence of the underlying alloy composition on the oxidation behavior is considered more fully.

## Experimental

The compositions of nominally Fe-28% Cr alloys from three different sources, designated A, B, and C, respectively, are given in Table I. All the alloys were produced by vacuum melting and, after appropriate heat-treatments, described in detail elsewhere (6), were cold-rolled to strip 0.04-0.05 cm thick. Alloys A and B were made from the same special Swedish iron base, but purer electrolytic chromium was used for alloy A. The ultrapure alloy C was prepared from zone-refined iron (C 33, N 0.9, H 0.3, Mg 1 ppm) and electrolytic chromium (C 10, H 0.5, Mg 0.5, Al 0.5, Ca 1, Cu 1, O 8, and Se 2 ppm).

Batches of specimens, generally 2.5 x 0.5 x 0.040 cm, were annealed for 5 hr at 1000°C at  $5 \times 10^{-5}$  Torr to remove residual stresses and to give an approximately constant grain size. The latter aim was not fully realized because samples of different purity and chromium content experienced grain growth to varying extents.

The abraded surface used previously (3) was not entirely satisfactory because of residual stresses developed in the surface, incorporated abrasive, and an undefined roughness factor. Consequently, after annealing, each specimen was electropolished (1, 4) immediately prior to use. The electropolishing was per-

formed in a glacial acetic acid/perchloric acid (S.G. 1.72) mixture (20:1 by volume) for 3 min at 0.4-0.8 amp cm<sup>-2</sup>, 10 $\mu$  thus being removed from each alloy surface. Generally, this was followed by a cathodic etch at 10  $\mu$ a cm<sup>-2</sup> in 4N HCl, lasting for 90 sec after the onset of activity (1, 4). The specimen, from which the film left after electropolishing had now been removed (1, 4), was then washed, degreased, dried, and located in the conventional silica spring thermobalance (accuracy of measurement  $\pm 0.05$  mg cm<sup>-2</sup>) for kinetic runs. The whole specimen assembly was sealed into the cold top section of the balance and oxygen was passed for a further hour. At this stage the specimen was rapidly lowered by a winch into a position directly above a Cr<sub>2</sub>O<sub>3</sub>-coated crucible, the furnace already being set at the required temperature. This method was adopted to avoid problems involving pre-oxidation if specimens are brought slowly to temperature *in vacuo*. The first weight gain measurement was made within 2-3 min. At the end of the run the specimen was slowly winched out of the hot zone over a 15-min period and cooled in oxygen.

The oxygen gas had the following analysis: O<sub>2</sub> 99.5%, CO<sub>2</sub> 5 ppm, CO nil, hydrocarbons 10 ppm, H<sub>2</sub> 50 ppm, Ar 0.5%, N<sub>2</sub> trace, H<sub>2</sub>O less than 0.15 g m<sup>-3</sup>. It was further purified by passage at 5 l/hr through a Deoxo cartridge, magnesium perchlorate, and phosphorus pentoxide drying tubes and a concentrated sulfuric acid bubbler. On the exit side a magnesium perchlorate tower and a bubbler minimized back-diffusion. The object of the Cr<sub>2</sub>O<sub>3</sub>-covered crucible was to saturate the atmosphere with the volatile species from Cr<sub>2</sub>O<sub>3</sub>, possibly CrO<sub>3</sub>, so avoiding weight losses from the specimen caused by this process. The furnace temperature was controlled at  $\pm 5^\circ$ C once equilibrium was established.

Conventional metallographic techniques were used to examine the oxidized specimens in plan, or in section after they had been vacuum mounted. A Cam-

bridge MK II "Microscan" instrument operating at 29 kv was used for the electron probe microanalysis. This means that the x-ray source size, producing 95% of the total x-rays generated, was approximately  $1.7\mu$  in the alloy and  $2.5\mu$  in the oxide. The concentration profiles presented represent line scans. Individual points on these profiles indicate where corrections for absorption and fluorescence effects were made, using a computer program, the entire profiles then being adjusted accordingly. Certain compositions were checked by static probe measurements, pure metals being used as standards.

### Results and Interpretation

**Reproducibility and method of presentation.**—The weight gain/time curves for six Fe-27.4% Cr alloy specimens (alloy A) at  $1000^\circ\text{C}$  show the reproducibility of typical runs (Fig. 1). It was difficult to decide whether irregularities in kinetic curves were due to inaccuracies in operating the quartz spring/cathetometer arrangement of the thermobalance or to cracking of the protective oxide at temperature. However, subsequent examination of all specimens in plan and section indicated single-layer scales, so justifying the smooth kinetic curves drawn in Fig. 1.

Reproducibility is seen to be quite good. The largest deviations occurred at low temperatures and short times due to the bigger thermobalance error in measuring small weight gains and to difficulty in fixing zero time for the oxidation run. Substantial deviations were also sometimes seen at  $1200^\circ\text{C}$  [particularly with higher chromium alloys referred to elsewhere (5)] due to irregular scale growth.

**Influence of surface preparation.**—Figure 2 shows that etching after electropolishing considerably reduced the oxidation rate of Fe-27.4% Cr (alloy A) at  $1000^\circ\text{C}$ , there being little significant difference for etching times of 45 and 90 sec, respectively. This effect was also observed at other temperatures.

The oxide grew on all three types of surface at a declining rate, consistent with a small negative deviation from a parabolic growth law, (i.e., in the relationship  $w^n = Kt$ ,  $n$  is slight greater than 2). Etching significantly improved the reproducibility of results. Approximate parabolic rate constants from the first few hours of oxidation were  $3.3$ ,  $1.1$ , and  $1.4 \times 10^{-10} \text{ g}^2 \text{ cm}^{-4} \text{ sec}^{-1}$  for electropolished, 45-sec etched and 90-sec etched batches, respectively. However, all

the rates of oxidation became comparable in the later stages of the runs.

Before oxidation, the electropolished specimens had a specular surface, marred only by a few pits produced during electropolishing by inclusions in the alloy, whereas with the etched alloys the alloy grain boundary structure was delineated but not significantly grooved. Morphologies of scales formed at  $1000^\circ$  and  $1200^\circ\text{C}$  were similar and are described below. However, those formed at  $800^\circ\text{C}$ , and on alloys B and C (which oxidized slower at  $800^\circ$  and  $1000^\circ\text{C}$  as indicated later) showed that the grain boundary pattern persisted in the oxide layer [Fig. 3(a), in the region where scale has not spalled off on cooling]. The alloy grain boundaries appear as ridges in the oxide which, together with Fig. 3(b) which shows the same effect for the under side of the scale, tends to indicate that the scale is thicker at grain boundaries. However, this was never observed in section, perhaps suggesting that the features on one side of the scale are depressions. The individual oxide grains are barely visible at this magnification. Figure 3(c) is typical of all the scale surfaces at  $1000^\circ$  irrespective of the method of surface preparation. The scale is very wrinkled, consistent with substantial scale lifting (shown later to occur on cooling), and the surface has a slightly faceted appearance. Scales formed at  $1200^\circ\text{C}$  were similar except that the emerging scale promontories were not as angular. When the scale was removed mechanically the alloy grain boundaries were still evident but not grooved, Fig. 3(d), and the entire surface was covered by a thin temper-color film. With electropolished surfaces the latter was nonuniform and in places had spalled, revealing specular alloy surface.

Metallographic examination in section always indicated the presence of a single-layer, single-phase oxide, shown later to be  $\text{Cr}_2\text{O}_3$ , containing small quantities of dissolved iron. Scales of this type will subsequently be referred to as ' $\text{Cr}_2\text{O}_3$ ' for convenience. These scales were similar in appearance but different in thickness on the differently finished surfaces at all temperatures. The oxide was relatively uniform in thickness [see Fig. 8(a)-(c)]. In many

cases, the scales had become detached from the substrate and had taken up a wrinkled form at some distance from the alloy. This scale detachment, for both etched and electropolished specimens, occurred on cooling the samples at the end of the runs, because

(A) The oxide could be seen to crack and sometimes fly off the alloy on cooling, generally when the temperature had fallen to 200°-300°C.

(B) There was no gross variation of scale thickness around any cross sections, even at 800°C where possible vapor phase transfer of chromium across closed voids would have been negligible.

(C) The alloy-oxide interface did not contain any massive irregularities, which would have occurred if certain areas had oxidized faster than others.

(D) Scarcely any multilayer 'Cr<sub>2</sub>O<sub>3</sub>' scales were observed. Admittedly the scales could still have detached from the alloy but remained intact around the specimen. This is considered unlikely because specimens where the scale was still fully attached on cooling gave similar growth kinetics.

(E) It is shown later by electron probe microanalysis that the chromium concentration at the edge of the alloy did not vary between regions where the scale was still attached to the alloy and regions where it had separated.

It is thus reasonable to state that an adherent scale similar in appearance to Fig. 8(c) was produced on all specimens at temperature.

The most probable explanation of the enhanced scaling rate on electropolished surfaces is that, under the strongly oxidizing conditions of electropolishing, the initial oxide film formed on the fresh surface contains more Cr<sup>6+</sup> or Cr<sup>4+</sup> ions than usual (7). Each Cr<sup>6+</sup> ion is associated with an extra cation vacancy in the p-type semiconducting oxide postulated, thus permitting a faster cation diffusion rate and con-

sequently a faster scaling rate. After continued scaling, the vacancy concentration diminishes to a level more normal in 'Cr<sub>2</sub>O<sub>3</sub>,' since vacancies are destroyed at the alloy-oxide interface and their rate of production at the oxide-gas interface, by the reaction

(where  $\Box_{\text{Cr}^{3+}}$  is a chromium ion vacancy and  $\oplus$  is an electron hole) is no greater than for any other 'Cr<sub>2</sub>O<sub>3</sub>' scale. Thus the oxidation rate should also decrease and approach that of the etched specimens, as is indeed found (Fig. 2). It is surprising that the effect can persist for so long, considering the thinness of the initial film. There was no evidence of the enhanced scale blistering and layering observed by other workers (1, 4, 7) on pure chromium.

An alternative cause of the increased oxidation rate of electropolished specimens could be that oxide grain boundaries act as short-circuit diffusion pipes (1). One possibility is that on etched specimens the oxide microcrystallites are highly oriented on any particular alloy grain, with negligible mismatch at the microcrystallite boundaries, whereas on electropolished specimens the oxide is randomly oriented, the more highly mismatched boundaries acting as low resistance diffusion paths for ions. Alternatively the initial oxide grain size may simply be greater on etched surfaces than on electropolished surfaces. However, this is the reverse of what would be expected, unless the argument refers merely to the contaminated, air-formed film left after electropolishing or etching, because nucleation is potentially harder on a specular surface. In either explanation the increased oxidation rate may persist because plastic strain of the rapidly formed oxide increases the ionic mobility.

*Influence of specimen geometry.*—Experiments on finely abraded (600 grit) prisms of triangular, rectangular, hexagonal and octagonal section and on cylinders respectively 0.5, 1, and 1.5 cm in diameter, made from Fe-27.4% Cr, (alloy A), displayed few exceptional topographical features after oxidation at 1200°C for 5 or 50 hr. The scale was apparently adherent at temperature, but always tended to flake off on cooling. It was particularly adherent on the cylindrical surfaces and spalled most readily at the ends of prisms where three faces meet. The scale had a slightly more 'sintered' appearance after 50 hr at 1200°C than after 5 hr. It was uniform in section, except for a possible slight thickening at corners accompanied by a rounding of the alloy surface. There was no evidence of even localized scale lifting at temperature.

*Influence of alloy purity.*—Figure 4, depicting the weight gain/time curves at 1000°C for the three purities of nominally 28.0% Cr alloy, shows that the ultrapure alloy C oxidized at a rate similar to the least pure alloy B after about 1.5 hr, but its behavior was nearer that of alloy A in the early stages. The effects persisted for times up to 50 hr. The parabolic rate constants for the first few hours of oxidation are  $1.4 \times 10^{-10}$ ,  $4.7 \times 10^{-11}$ , and  $5.2 \times 10^{-11}$  g<sup>2</sup> cm<sup>-2</sup> sec<sup>-1</sup> for the alloys A, B, and C, respectively. Alloy C obeyed the parabolic law for the entire 5 hr, but the other alloys showed negative deviations.

The alloy grain size decreased in the order C, A, and B because of impurity effects on grain growth, and the number of pits developed during electropolishing increased in this order, but their number was never really significant. The scales on alloys B and C were of comparable thickness and always lifted from the alloy on cooling. However, scales on alloy C tended to crack and fly off the alloy substrate, those on alloy A cracked open but remained on the substrate, and those on alloy B did not appear to alter during this period. Examination in section again revealed a wrinkled single-layer of 'Cr<sub>2</sub>O<sub>3</sub>' of almost uniform

□ Alloy A  
 △ Alloy B  
 ○ Alloy C

thickness, detached from the alloy; the alloy/oxide interface generally remained virtually straight.

In discussing the kinetic measurements, those on alloy C, which is at least 99.997% pure, may be taken as the standard. Possibly with alloy A, which is still quite pure by usual Fe-Cr alloy standards, impurities may enter the scale and increase the cation vacancy concentration. If  $\text{Cr}_2\text{O}_3$  is a metal-deficit p-type semiconductor these would have to be at least quadrivalent (e.g., tungsten and titanium, see Table I). It is doubtful whether carbon is responsible, by producing CO and subsequent scale disruption, particularly as it has been shown (2) that carburization of chromium does not affect its oxidation rate. Presumably the additional impurities present in alloy B cause it to oxidize slower than alloy A (Table I) by a similar mechanism. It is noteworthy that the silicon content (0.08% in B, 0.003% in A) and aluminum content (0.04% in B, 0.008% in A) are significantly higher in B than A, which might affect matters by preferential oxide formation at the alloy/oxide interface or in the internal oxide zone, so reducing the rate of entry of ions into the scale.

Thus there is no simple explanation of the purity effect, and some subtler differences may be involved such as the degree of stress or strain-enhanced ionic lattice diffusion, grain boundary or dislocation pipe diffusion, or the variation in the number of sites for vacancy coalescence both in the alloy and at the alloy/oxide interface. There is no evidence of cracking being relevant in causing the differences in oxidation rate.

*Influence of temperature.*—Most work was carried out on electropolished and etched (90 sec) samples of the relatively pure alloy A, with confirmatory runs on the ultrapure alloy C. Figure 5 shows the temperature-dependence of the oxidation of Fe-27.4% Cr. The absence of discontinuities in the individual growth curves (not shown here), of variations in general or localized scale thickness (nodules), and of multilayering of the ' $\text{Cr}_2\text{O}_3$ ' scales (such layers occupied less than 1% of the specimen sections and then only occurred at 1100° and 1200°C), and information given elsewhere favoring scale attachment at temperature, justify the calculation of parabolic rate constants in all cases. Larger specimens, 3.0 x 1.5 x 0.040 cm, pro-

duced identical kinetic curves and metallographic scale features, but much more of the oxide spalled off completely on cooling. Figure 6(a) and (b) display the (weight gain)<sup>2</sup>/time plots for 50-hr oxidation. At each temperature a curve, slightly concave to the time axis, is evident but generally the deviation from linearity is not sufficient to invalidate the assumption of the parabolic rate law. The deviation is admittedly sometimes more significant after longer times. However, it is important when comparing parabolic rate constants for various sets of oxidizing conditions to use values calculated over corresponding time ranges because the value of each rate constant depends on the 'degree of fit' of the straight line drawn through the experimental points.

The effect of temperature on the scale growth rate is governed by an Arrhenius relationship as shown in Fig. 7, thus,

$$K_p = A \exp(-Q/RT)$$

Fig. 7. Arrhenius plot for the oxidation of Fe-27.4% Cr: □ alloy A; ○ alloy C.

where  $K_p$  is the parabolic rate constant,  $T$  the absolute temperature,  $R$  the gas constant, and  $Q$  the activation energy of the rate-controlling process. The activation energy for the oxidation mechanism, as calculated from the method of least mean squares using a 95% confidence level, was  $36 \pm 6$  kcal mole<sup>-1</sup>. A similar plot for the ultrapure alloy C gave a similar activation energy of  $35 \pm 6$  kcal mole<sup>-1</sup>. Thus, despite the slower scaling rate of the purer alloy C, the same rate-controlling process was apparently involved.

**Metallography of scales in section and electron probe microanalysis.**—All the scales examined were single-layer, single-phase 'Cr<sub>2</sub>O<sub>3</sub>' and, particularly for low temperatures and short times, detached from the alloy on cooling and were left with an undulating profile [Fig. 8(a) and 8(b)]. The oxide formed after 0.5 hr at 1000°C [Fig. 8(a)] is only about 1μ thick and could curl up easily, but after 5 hr it is 4–5μ thick and appears to have cracked in one place. The inner edge of the scale is far longer than the outer edge of the alloy because there is a differential contraction on cooling between oxide and alloy, and it is impossible to match corresponding places along the alloy-oxide interface. There are no gross variations in the oxide thickness around a cross-section, a typical scatter being  $\pm 30\%$ . Also the average scale thickness always corresponds to the thickness computed from the thermogravimetric data within  $\pm 10\%$ , even at 1200°C where any error in fixing zero weight gain for the specimen would be a maximum. Similar behavior persisted for times up to 50 hr.

Figure 8(c) illustrates the somewhat rarer occasions where the oxide remained attached to the alloy on cooling. The oxide is uniformly thick around the whole cross section. Scales such as this support the legitimacy of applying oxidation rate theory to scale growth, particularly since this specimen received the most severe treatment of all specimens, namely, 50 hr at 1200°C. Presumably it did not spall on cooling because of some stress relaxation by scale (or alloy) plastic deformation during the long period at 1200°C, and additionally it would be difficult for such a thick scale to balloon. The pores visible in the oxide, and in Fig. 8(b), are not necessarily genuine and may have been accentuated during metallographic preparation. Similar attached scales were also sometimes observed after shorter oxidation times and at lower oxidation temperatures.

Fig. 8. Cross sections of scales on electropolished and etched Fe-27.4% Cr: (a) 30 min at 1000°C (x830); (b) 5 hr at 1000°C (x830); (c) 50 hr at 1200°C (x415).

When the scale thickness was only of the order of the x-ray source size, a region where the oxide had separated from the alloy was selected for microanalysis, thus avoiding any possibility of iron radiation apparently from the oxide really originating the alloy. Scales generally contained 0.4–5% Fe, but no gradient through them could be measured because the layers were either too thin or contained too low an iron concentration, although more recent evidence suggests it really existed (14).

Figure 9(a), presenting the concentration profiles through scale and adjoining alloy for the Fe-27.4% Cr alloy oxidized at 1200°C for 50 hr, gives an apparently uniform chromium content (63.6%) and iron content (0.4%) across the entire scale section. Repeated determinations on this and similar thick scales always gave low total metal contents (compared with 68.4% Cr for stoichiometric Cr<sub>2</sub>O<sub>3</sub>). The actual interface positions are located at the mid-points of the "inter-faces" measured due to the finite size of the x-ray source. Figure 9(b) gives two traces across sections of a scale formed after 5 hr at 1000°C on Fe-27.4% Cr; the full lines show the concentration profiles across a region where the scale is separated from the alloy by a large void and the broken line where the scale is still attached to the alloy. That the chromium concentration at the alloy/oxide interface is the same in both cases adds support to the idea that scale lifting occurred on cooling because, even if chromium vapor

Fig. 9. Concentration profiles across alloy and scale: (a) Fe-27.4% Cr oxidized for 50 hr at 1200°C, ○ Fe, △ Cr; (b) Fe-27.4% Cr oxidized for 5 hr at 1000°C ○● Fe, △▲ Cr. ——— Scale detached; - - - scale attached.

transport across voids is possible (8), it will not be very significant at this temperature.

### Discussion

*Qualitative considerations of the kinetics and oxide growth mechanism.*—After its rapid establishment,  $\text{Cr}_2\text{O}_3$  containing a low concentration of iron, probably in solid solution, is the only oxide formed, and there are no large compositional changes with time or temperature. It is likely in view of the almost parabolic growth curves that a diffusional mechanism is the rate-controlling factor. At present there are conflicting theories regarding whether  $\text{Cr}^{3+}$  or  $\text{O}^{2-}$  ions have the dominant mobility, but here the more widely accepted cationic mode of transport will be assumed. It is possible that some  $\text{O}^{2-}$  movement occurs, perhaps down grain boundaries or dislocations, but in the absence of evidence this suggestion will be neglected.

There are at least three possible reasons for the small negative deviations from a parabolic growth relationship in the later stages:

(i) Grain growth during oxidation could reduce the number of paths of easy diffusion down grain boundaries, if such ionic transport is significant at this temperature.

(ii) The scales are highly stressed and some plastic flow could occur, possibly enhancing diffusion in the scale. The effect might decrease as the reaction slows and possibly as the iron content of the ' $\text{Cr}_2\text{O}_3$ ' declines.

(iii) The most likely explanation is that the cation vacancies migrating inward through the scale can (a) condense and form pores within the bulk oxide, (b) diffuse to the alloy-oxide interface and condense to form invisible vacancy clusters or visible voids, or (c) diffuse to the alloy/oxide interface and enter the alloy becoming attached to dislocations or inclusions. If voids or pores are formed as in (a) or (b) above, they will tend to obstruct the continued transfer of cations from the alloy to the scale-atmosphere interface. The scale growth is still diffusion-controlled, the effective specimen area simply being decreased. Presumably ionic diffusion around the small voids can occur, thus avoiding uneven scale growth. There is some evidence of pores both in the scales and at the alloy/scale interface, but it cannot definitely be concluded that these are the pores involved.

In the following derivation all the voids are assumed to form and stay at the alloy-oxide interface, although

a similar but not identical result is expected if they are formed within the scale. If  $\phi$  is the effective area of the oxidizing specimen, as indicated above it can be shown that

$$\phi = C \exp(-kt) \quad [1]$$

where  $k$  and  $C$  are constants and depend on the initial conditions. In the early stages of oxidation there are no voids and growth obeys the parabolic law. After a time, the effective area of the oxidizing specimen is reduced to  $\phi$  times its original value; then, the ratio of the experimental weight gain to that calculated from a parabolic relationship (using the  $K_p$  value calculated from the data at early times of oxidation) is equal to  $\phi$ .

The degree of linearity of  $\log \phi$  against  $t$  plots enables the validity of Eq. [1] to be assessed. Most of the kinetic data showed reasonable agreement with the derived equation. Figure 10 shows results for the three metal purities. Alloy C follows the parabolic law over the entire 5 hr of the run; thus  $\phi$  is always equal to 1. Possibly the lack of impurities in the alloy reduces the number of sites available for the condensation of vacancies at the alloy/oxide interface. Also the relatively slow, over-all oxidation rate minimizes the formation of micropores in the bulk oxide. For the impure alloy B there is slight divergence from the parabolic law but this is greater for alloy A. However even here  $\phi$  is still 0.85 after 5 hr (and 0.75 after 50 hr) so the deviation is not great.  $\phi$  and  $\log \phi$  are greater for electropolished than for etched specimens, as expected.

*Quantitative discussion of the oxidation mechanism.*—If reproducible self-diffusion coefficients for  $\text{Cr}^{3+}$  diffusion in  $\text{Cr}_2\text{O}_3$  (preferably scales rather than bulk oxide) were available, it would be most suitable to use them to calculate parabolic rate constants for oxidation to be compared with the present measured values. Figure 11 shows that this is not the case so it appeared more pertinent to adopt the reverse procedure and obtain values of apparent self-diffusion coefficient of  $\text{Cr}^{3+}$  ions in a growing ' $\text{Cr}_2\text{O}_3$ ' scale.

Adaptation of the derivation of Wagner (9) to the case of a single-phase oxide on an iron-chromium alloy (6), in which thermodynamically ideal behavior may be assumed (15), yields

$$K_r = (1 + z) C_{\text{eqCr}^{3+}} \cdot (D^*_{\text{Cr}})_g \left( 1 - \frac{(\pi_{\text{Cr}_2\text{O}_3})^{1/n} \cdot (N_{\text{Cr}})^{3/4n}}{(p_{\text{O}_2})_g^{1/n}} \right) \quad [2]$$

Fig. 10. Influence of alloy purity on  $\phi$  and  $\log \phi$  for the oxidation of Fe-28% Cr alloys at 1000°C: (a)  $\phi/t$  curve; (b)  $\log \phi/t$  curve. □ Alloy A; ○ alloy B.

Fig. 11. Derived values of the self-diffusion coefficient of  $\text{Cr}^{3+}$  ions in  $\text{Cr}_2\text{O}_3$ . — Present work for various values of  $n$ ; ---- ref. (18); - · - · - ref. (17); —●— ref. (11).

where  $K_r$  = the rational rate constant for oxidation, defined as the reaction rate in equivalents per  $\text{cm}^2$  per sec for a scale 1 cm thick;  $z$  = cation valency;  $C_{\text{eqCr}^{3+}}$  = the concentration of  $\text{Cr}^{3+}$  ions in the scale in equivalents per  $\text{cm}^3$ ;  $(D^*_{\text{Cr}})_g$  = the self-diffusion coefficient of  $\text{Cr}^{3+}$  ions in a  $\text{Cr}_2\text{O}_3$  scale in equilibrium with the atmosphere;  $\pi_{\text{Cr}_2\text{O}_3}$  = the dissociation pressure of  $\text{Cr}_2\text{O}_3$ ;  $(N_{\text{Cr}})_m$  = the mole fraction of chromium at the alloy/oxide interface;  $(p_{\text{O}_2})_g$  = the oxygen partial pressure at the atmosphere/oxide interface;  $n$  = an exponent giving the oxygen pressure dependence of the concentrations of cation vacancies  $C_{\square_{\text{Cr}^{3+}}}$  and positive holes  $C_{\oplus}$  thus

$$C_{\square_{\text{Cr}^{3+}}} = 1/3 C_{\oplus} = K(p_{\text{O}_2})^{1/n} \quad [3]$$

where  $K$  is a constant. Theoretically  $n = 5.3$ .

Experimental determinations of the exponent  $n$ , by electrical conductivity measurements on hot sintered  $\text{Cr}_2\text{O}_3$  powder compacts at pressures of  $10^{-2}$  Torr at temperatures up to  $1400^\circ\text{C}$ , gave values varying between 30 (10) and 70 (2,11). Single crystal measurements (12) also predicted virtual independence of oxygen partial pressure, but it was found (13) that the oxidation rate, and also the cationic diffusion rate, varied at pressures of the order of the dissociation pressure of  $\text{Cr}_2\text{O}_3$ , with the  $3/5$ th power of the  $p_{\text{H}_2\text{O}}/p_{\text{H}_2}$  ratio [equivalent to  $(p_{\text{O}_2})^{1/5.3}$ ]. Pressure dependence of defect transport was not observed at higher oxygen pressures, probably due to the saturation of sites available for oxygen adsorption at the growing oxide surface.

Now, the chromium weight fraction never falls below 0.1 after the very early oxidation stages (5), and consequently the mole fraction, which is approximately equal to the weight fraction in this system, always exceeds 0.1.  $K_p$  is not very critically dependent on  $(N_{\text{Cr}})_m$ , so a constant value of 0.1 can be safely employed.

The dissociation pressure of  $\text{Cr}_2\text{O}_3$  has been calculated as a function of temperature (16), and  $K_r$  may be calculated from the  $K_p$  values given earlier. Consequently if assumptions are made about the value of  $n$ , an assessment of  $D^*_{\text{Cr}}$  may be made. Thus, for the formation of  $\text{Cr}_2\text{O}_3$

$$K_r = \frac{1}{2} (K_p/\rho_{\text{Cr}_2\text{O}_3}) (1/g \text{ eqO}_2) \quad [4]$$

where  $\rho_{\text{Cr}_2\text{O}_3}$  = the density of  $\text{Cr}_2\text{O}_3$  (taken as  $5.3 \text{ g cm}^{-3}$ ) and  $g \text{ eqO}_2$  = the gram equivalent of oxygen. Various values of  $n$ , namely 5.3, 30, and 70, were tried.  $C_{\text{eqCr}^{3+}}$  is given by

$$C_{\text{eqCr}^{3+}} = \rho_{\text{Cr}_2\text{O}_3} \cdot 2 z_{\text{Cr}}/M_{\text{Cr}_2\text{O}_3} \quad [5]$$

where  $z_{\text{Cr}}$  is the valency of chromium,  $\rho_{\text{Cr}_2\text{O}_3}$  the density of  $\text{Cr}_2\text{O}_3$  and  $M_{\text{Cr}_2\text{O}_3}$  the g molecular weight of  $\text{Cr}_2\text{O}_3$ . Values of  $K_r$  calculated from Eq. [4] and of  $D^*_{\text{Cr}^{3+}}$  from Eq. [2] are given in Table II. Figure 11 shows a plot of  $\log D^*_{\text{Cr}}$  against  $1/T$  for derived values for Fe-27.4% Cr and also for the measured values for bulk nominally pure  $\text{Cr}_2\text{O}_3$  derived from the literature (11, 17, 18). The pressure dependence of the vacancy concentration, parameter  $n$ , has no effect on the activation energy for self-diffusion at the oxygen pressure employed, nor has it any great influence on the absolute values of  $D^*_{\text{Cr}}$ . Despite the numerous assumptions there is moderate correlation between calculated and observed values. In particular, the results agree well with one set of work at  $1100^\circ\text{C}$ - $1200^\circ\text{C}$  (18) and with another set at  $800^\circ\text{C}$ - $900^\circ\text{C}$  (11). This tends to support the concept of cationic transport as being predominant in ' $\text{Cr}_2\text{O}_3$ ' scales at high temperature. The differences observed could well be related to variations in sample purity which were shown earlier to affect scaling rates substantially and would probably similarly influence behavior in bulk oxides. Also it should be emphasized that the derived values refer to diffusion in a growing scale containing some dissolved iron.

The rational rate constants and values of  $D^*_{\text{Cr}}$  in ' $\text{Cr}_2\text{O}_3$ ' are also given in Table II for scales produced on various other alloys (5), assuming  $n = 5.3$ , and show similar trends.

Any similarity between the activation energy for the oxidation mechanism and for the self-diffusion of  $\text{Cr}^{3+}$  ions in  $\text{Cr}_2\text{O}_3$  would be further evidence of solely  $\text{Cr}^{3+}$  ion motion. Unfortunately the values for bulk  $\text{Cr}_2\text{O}_3$  vary tremendously (11, 17, 18) (Table III). The situation for oxidation activation energies is better, values lying either around  $35 \text{ kcal mole}^{-1}$  or around  $60 \text{ kcal mole}^{-1}$ . In particular, all the low-temperature values approximate to the lower figure. Furthermore, it is shown elsewhere (5) that if temperature ranges where scale cracking are extensive are ignored, all alloys in the range 14-68% Cr gave values which were remarkably close to it too. It is suggested, therefore, that where higher values of activation en-

## Chromium Oxide Scale Growth on Iron-Chromium Alloys

### II. Influence of Alloy Composition

D. P. Whittle and G. C. Wood

Corrosion Science Division, Department of Chemical Engineering,  
University of Manchester Institute of Science and Technology, Manchester, England

#### ABSTRACT

$\text{Cr}_2\text{O}_3$ , containing small quantities of dissolved iron, is the only oxide formed in the oxidation of iron-chromium alloys in the range 22-68% Cr in oxygen at 800°-1200°C; it is also formed, at least initially, on alloys containing 14 and 18% Cr. The oxide growth is diffusion-controlled, with an apparent activation energy of 36 kcal mole<sup>-1</sup>. The increase in oxidation rate with alloy chromium content is slight up to 37% Cr, but becomes more marked with the chromium-rich alloys. Iron only enters the scale during the very early stages of oxidation, so the weight fraction of iron in the oxide decreases with time. Alloy interdiffusion coefficients have been determined from chromium concentration profiles in the underlying alloy. The activation energies for interdiffusion are 51 and 59 kcal mole<sup>-1</sup> for Fe-27% Cr and Fe-59% Cr, respectively, but interdiffusion is much slower for the chromium-rich alloy. The chromium concentration at the alloy/oxide interface, which is determined largely by the ratio of oxidation rate to alloy interdiffusion rate, governs the type of oxide formed if lifting and cracking of the stressed scale occurs. Factors affecting the tendency for scale failure in this way are discussed.

In an earlier paper (1), it was shown that the scales produced on iron-chromium alloys, containing 28-68% Cr, in air at 1100°C were composed of  $\text{Cr}_2\text{O}_3$  containing very small amounts of iron (' $\text{Cr}_2\text{O}_3$ '). There was some evidence that the oxidation rate increased slightly as the alloy chromium content was raised, and it was demonstrated that chromium from the alloy was less readily replenished at the alloy/oxide interface in the chromium-rich alloys.

Detailed data obtained under much more carefully controlled conditions are reported here. Special em-

phasis is placed on the quantitative determination of the variation of scale and alloy composition with time. The study is particularly related to alloys containing 22-68% Cr but formation of ' $\text{Cr}_2\text{O}_3$ ' scales on more dilute alloys is also referred to briefly.

#### Experimental

The chromium and carbon contents of the alloys are listed in Table I. Full details of the compositions of alloys A and B and of the methods of alloy preparation were given previously (1-3). The 59.5 and 68.0% Cr

Table I. Chemical analyses of the iron-chromium alloys (w/o)

Chromium	14.0	18.0	22.9	27.4	28.0	37.4	59.5	68.0
				(A)	(B)			
Carbon	0.006	0.017	0.048	0.006	0.023	0.029	—	—

alloys were prepared from vacuum-melted electrolytic iron and hydrogen-treated electrolytic chromium by arc melting, homogenization, and hot rolling to strip 0.0375 cm thick (4). All the other alloys were produced (1) by vacuum melting, heat-treatment, and cold rolling to 0.04 cm thick strip, using a Swedish iron base and electrolytic chromium, a slightly purer sample of the latter being employed for the 14.0 and 27.4% Cr alloys. The various alloys had impurity levels comparable to those of alloy A (14.0% Cr alloy) and alloy B (18.0, 22.9, and 37.4% Cr alloys) (2).

The specimen preparation, consisting of electropolishing followed by a cathodic etch, was performed exactly as described previously (2). With dilute chromium alloys the specimens were etched immediately on entering the solution, but at intermediate levels the passive state persisted for several seconds before etching commenced. When etching the 59.5 and 68.0% Cr alloys, the HCl had to be carefully deaerated by bubbling nitrogen through the solution, otherwise the specimen remained passive indefinitely.

The oxidation procedure, metallographic methods, and electron probe techniques were conventional (2).

### Results and Interpretation

**Kinetics and metallography.**—Detailed data for Fe-28% Cr of various purities have been given elsewhere (2).

**Oxidation of Fe-59.5% Cr.**—Reasonably blemish-free surfaces were obtained on electropolishing, although there was a greater tendency to pitting than for Fe-27.4% Cr, due either to more critical conditions or to more inclusions in the alloy. On etching, a smaller alloy grain size was revealed.

Figure 1(a) shows the mean short-term weight gain/time plots, whereas for the long-term runs in Fig. 1(b) individual curves are presented because of irregularities observed at 1100° and 1200°C. The sudden increases in weight after 6-hr oxidation were caused by extensive lifting of the protective oxide from the underlying alloy and subsequent scale cracking, allowing rapid oxidation of the bare alloy. Three breaks are observed in the curves at 1200°C but only two at 1100°C. Reproducibility was naturally some-

Fig. 2. Plot of (weight gain)<sup>2</sup>/time for the oxidation of Fe-59.5% Cr. (a) □ 1200°C; △ 1100°C. (b) ○ 1000°C; ■ 900°C; ▲ 800°C.

what poorer than for Fe-27.4% Cr (2) due to this scale cracking.

The (weight gain)<sup>2</sup>/time curves for the first 5 hr of oxidation [Fig. 2(a) and 2(b)] show the usual negative deviation from parabolic behavior [as defined previously (2)] at the lower temperatures. At 1200°C, the increased oxidation produced by scale lifting and cracking causes positive deviations from parabolic behavior, even after 1-hr oxidation. Consequently, there is little merit in extending the parabolic plots to 50 hr. The Arrhenius plot for the data Fe-59.5% Cr in Table II is given in Fig. 3 and yields an apparent activation energy for the oxidation process of  $50 \pm 7$  kcal mole<sup>-1</sup>, using the method of least mean squares and a test for a 95% confidence level. The value is higher than the  $36 \pm 6$  kcal mole<sup>-1</sup> de-

Table II. Comparison of short-term parabolic rate constants for Fe-59.5% Cr and Fe-27.4% Cr at 800°-1200°C (5-hr values)

Temp, °C	Parabolic rate constant, g <sup>2</sup> cm <sup>-4</sup> sec <sup>-1</sup>	
	Fe-59.5% Cr	Fe-27.4% Cr
800	$1.9 \times 10^{-12}$	$1.4 \times 10^{-13}$
900	$1.1 \times 10^{-11}$	$3.7 \times 10^{-13}$
1000	$5.3 \times 10^{-11}$	$1.4 \times 10^{-10}$
1100	$7.0 \times 10^{-10}$	$4.1 \times 10^{-10}$
1200	$1.4 \times 10^{-9}$	$1.2 \times 10^{-9}$

Fig. 3. Arrhenius plot for the oxidation of Fe-59.5% Cr.

duced from similar data (rate constants for 5-hr oxidation) for Fe-27.4% Cr and its accuracy is also reduced, doubtless due to the mild ballooning at the higher temperatures. If the  $K_p$  values for Fe-59.5% Cr at 1100° and 1200°C are ignored because single-layer scales are not formed, the activation energy for oxidation is 35 kcal mole<sup>-1</sup> (dotted curve in Fig. 3), which is much closer to the Fe-27.4% Cr value. Presumably the same rate-controlling mechanism holds in both cases and the difference in the rate constants at 800°-1000°C (Table II) is simply a purity effect (2), which is not understood.

The surface topography of scales was similar to that on Fe-27.4% Cr (2) except that, where the alloy grain structure was replicated, the grain size was smaller. There was no evidence of the oxide wrinkling apparent in section, probably because this was on a fine scale and would not be evident in the oblique illumination of the microscope. At 1000°C the single-layer scale tended to be more flaky than for Fe-27.4% Cr.

At and below 1000°C, the single-layer, single-phase, and approximately uniform scales detached from the alloy on cooling [Fig. 4(a)] and were similar to those on Fe-27.4% Cr. In contrast, Fig. 4(b) displays a multilayered scale after 5 hr at 1200°C. Two major scale layers are visible, but each individual layer appears to contain several minor blisters. Some of the porosity in the layers is probably related to the metallographic preparation. There is the same number of major scale layers around the entire specimen cross section, and the alloy appears to have been attacked relatively uniformly. Probably the scale lifted from the entire alloy surface simultaneously or nearly so, otherwise the breaks would not have been obvious in the kinetic curves. All the specimens oxidized at 1200°C showed scale multilayering, even after only 1-hr oxidation. After 1-, 5-, 10-, and 50-hr oxidation there were, respectively, 2, 2, 3, and 4 major scale layers. These do not exactly correlate with the number of breaks in the kinetic curves. This is not surprising because localized layering would not show up in the kinetics in the early rapid stages of oxidation.

*Influence of alloy chromium content on oxidation rate mainly at 1000°C.*—Figure 5, showing the short-term and long-term kinetic curves for five of the alloys of most comparable purity, indicates that the increase in oxidation rate with alloy chromium content was slight up to 37.4% Cr but became more marked

Fig. 4. Cross sections of scales on Fe-59.5% Cr: (a) 5 hr at 1000°C, magnification ca. 500X; (b) 5 hr at 1200°C, magnification ca. 250X.

Fig. 5. Influence of chromium content on the oxidation of iron-chromium alloys at 1000°C. Inset shows short-term curves.  $\Delta$  Fe-22.9% Cr;  $\square$  Fe-28.0% Cr (alloy B);  $\blacktriangle$  Fe-37.4% Cr;  $\blacksquare$  Fe-59.5% Cr;  $\circ$  Fe-68.0% Cr.

with Fe-59.5% Cr. Fe-68.0% Cr, on the other hand, oxidized much faster during the first 5 hr, but after 50 hr the slopes of the weight gain/time curves are similar for all the alloys. This is not thought to be simply a purity effect because the alloy came from the same source as the Fe-59.5% Cr alloy. The reproducibility of the kinetic curves was roughly comparable for all alloy compositions. Figure 6 indicates a negative deviation from the parabolic oxidation rate law, referred to previously (2).

The parabolic rate constants derived (2) from Fig. 6 are given in Table III and confirm the above trends. Fe-18.0% Cr, which was from the same stock as the 22.9, 28.0, and 37.4% Cr alloys, had only a slightly lower parabolic rate constant. Fe-14.0% Cr and Fe-27.4% Cr, which were made from purer chromium showed comparable rate constants to each other but the values were higher than for the other alloys. All the kinetic curves for all the alloys were smooth at 1000°C, consistent with single-layer scales. Crude estimates of the activation energy of oxidation for Fe-14.0 and Fe-18.0% Cr, where 'Cr<sub>2</sub>O<sub>3</sub>' only was de-

Fig. 6. Plot of  $(\text{weight gain})^2/\text{time}$  for the oxidation of various iron-chromium alloys at  $1000^\circ\text{C}$ .  $\triangle$  Fe-22.9% Cr;  $\square$  Fe-28.0% Cr (alloy B);  $\blacktriangle$  Fe-37.4% Cr;  $\blacksquare$  Fe-59.5% Cr;  $\circ$  Fe-68.0% Cr.

tected, gave  $37 \text{ kcal mole}^{-1}$ , which is close to the values for more chromium-rich alloys.

The external surfaces of scales of comparable thickness appeared the same at 100X magnification on all the alloys, except Fe-68.0% Cr. For thinner scales, there was a difference in grain size of the original alloy, replicated by the scale. Figure 7(a) shows the typical scale structure on Fe-22.9% Cr oxidized for 1 hr at  $1000^\circ\text{C}$ , but after 10-hr oxidation the scale ballooning on cooling is more apparent than usual [Fig. 7(b)]. The tendency of the scale to crack and lift on cooling decreased as the chromium content of the alloy decreased. Thus, it tended to fly off Fe-59.5% Cr and Fe-68.0% Cr, whereas with Fe-37.4% Cr only scale cracking occurred. With the other alloys only scale lifting occurred. Figure 7(c) shows the unusual surface scale morphology for Fe-68.0% Cr after oxidation for 5 hr at  $1000^\circ\text{C}$ . The oxide has a more 'sintered' appearance, and oxide promontories adopt a spheroidal form rather than the angular structure of other scales.

Figure 8(a) and 8(b) are respectively typical examples of nonadherent and adherent single-phase, single-layer ' $\text{Cr}_2\text{O}_3$ ' scales formed on these alloys. The nonadherent scale is very wrinkled, but multilayered scales were never observed. No porosity is apparent even at the alloy-oxide interface. For Fe-22.9% Cr at  $1200^\circ\text{C}$  the scale adhered on cooling [Fig. 8(c)], but the alloy-oxide interface was far more irregular than after oxidation at  $1000^\circ\text{C}$ , or for the more chromium-rich alloys at any temperature. This behavior was even more pronounced for Fe-14.0% Cr and Fe-18.0% Cr and is probably related to plastic deformation of the alloy due to stresses developed in the alloy/scale combination at this elevated temperature, as mentioned later. Over about 1% of the surface of Fe-22.9% Cr at  $1200^\circ\text{C}$ , ballooning occurred in the early stages, there being three layers of scale in places, the two outer layers being extremely thin [Fig. 8(d)]. The pores in these oxides are probably artifacts. Comparable behavior with 14.0 and 18.0% Cr alloys (2), and with abraded Fe-22.9% Cr in air

Table III. Variation of long-term parabolic rate constant with alloy chromium content at  $1000^\circ\text{C}$  (50-hr values)

Alloy, % Cr	Parabolic rate constant, $\text{g}^2 \text{ cm}^{-4} \text{ sec}^{-1}$
14.0	$7.6 \times 10^{-11}$
18.0	$4.3 \times 10^{-11}$
22.9	$5.1 \times 10^{-11}$
27.4 (A)	$1.1 \times 10^{-10}$
28.0 (B)	$5.8 \times 10^{-11}$
37.4	$5.9 \times 10^{-11}$
59.5	$6.8 \times 10^{-11}$
68.0	$1.7 \times 10^{-10}$

Fig. 7. Surface topography of scales under oblique illumination: (a) Fe-22.9% Cr oxidized for 1 hr at  $1000^\circ\text{C}$ , magnification 50X; (b) Fe-22.9% Cr oxidized for 10 hr at  $1000^\circ\text{C}$ , magnification 50X; (c) Fe-68.0% Cr oxidized for 5 hr at  $1000^\circ\text{C}$ , magnification 15X.

at  $1100^\circ\text{C}$  (1), led to breakthrough and stratified iron-rich scale development because, at the time of scale cracking, chromium had not been replenished enough at the alloy/oxide interface to permit fresh ' $\text{Cr}_2\text{O}_3$ ' development.

*Electron probe microanalysis of the oxides.*—Electron probe microanalyses of all the oxide scales are presented in Tables IV-VI. The inaccuracies inherent in this method of analysis, particularly scale thinness and possibly its porosity and difficulties in applying accurate corrections, have resulted in the analyses being low in apparent metal content. Thus, to facilitate comparisons, the analyses have been normalized to a total metal content of 67.6%, this being the figure quoted for slightly nonstoichiometric  $\text{Cr}_2\text{O}_3$  scales (5).

Perusal of Tables IV-VI produces the following general conclusions:

(i) For all the alloys, the percentage of iron in the scale at any given temperature decreases with time. This may be because either the  $\text{Fe}^{2+}$  or  $\text{Fe}^{3+}$  ions are reduced by the chromium to metallic iron or, much more likely, the iron content stays constant and its weight fraction is decreased by the growth of the ' $\text{Cr}_2\text{O}_3$ ' by the addition of chromium only. It is also conceivable that iron ions in the ' $\text{Cr}_2\text{O}_3$ ' can diffuse to the outside of the scale and form a complete thin but undetectable layer there, consistent with the high dissociation pressure of  $\text{Fe}_2\text{O}_3$ . No iron gradients could be detected through the scales. Recent work (22) has detected the outer layer, although this is mainly residual initially nucleated oxide.

(ii) The percentage of iron in the scale decreases as temperature increases for any given oxidation time for Fe-27.4% Cr and Fe-59.5% Cr. This cannot be taken immediately as a genuine trend because the scale thicknesses are vastly different. Thus, dilution of iron in the ' $\text{Cr}_2\text{O}_3$ ' scale occurs to varying extents.

(iii) The percentage of iron in scales of corresponding thickness decreases as the alloy chromium content increases.

*Compositional changes in the underlying alloy during oxidation.*—Only certain of the chromium concentration profiles are presented in the interests of brevity, iron contents obviously following a reverse trend. The abscissas' scales have been selected so that results for various oxidation times are measured from a common interface, namely, the original alloy surface. The position of the actual alloy-oxide interface after a given oxidation time, marked by the start of each

Fig. 8. Cross sections of scales on Fe-22.9% Cr: (a) 1 hr at 1000°C, magnification 1050X; (b) 5 hr at 1000°C, magnification 1400X; (c) 50 hr at 1200°C, magnification 350X; (d) 50 hr at 1200°C, magnification 350X.

profile, is easily computed from a modified form of the parabolic rate law of oxidation written thus

$$d/dt (\Delta x) = \frac{K_c}{\Delta x} \quad [1]$$

where  $\Delta x$  is the location of the alloy-oxide interface measured from the original surface of the alloy after time  $t$ , and  $K_c$  is a modified parabolic rate constant. It may readily be shown that if stoichiometric  $\text{Cr}_2\text{O}_3$  is assumed to form on the alloy surface then

$$K_c = 1/2 K_p \cdot (2A_{\text{Cr}})^2 / (3/2 M_{\text{O}_2} \rho)^2 \quad [2]$$

where  $A_{\text{Cr}}$  is the g atomic weight of chromium,  $M_{\text{O}_2}$  is the g molecular weight of oxygen, and  $\rho$  is the density of the alloy. Thus,  $\Delta x$  can be obtained on integration of Eq. [1].

Detailed profiles were obtained for most of the oxidation specimens previously described, typical results for Fe-27.4% Cr and Fe-59.5% Cr at 800, 1000 and 1200°C being shown in Fig. 9 and 10, respectively. The ends of the profiles mark the position of the inwardly moving alloy/oxide interface with time. Although there are several minor anomalies the following conclusions are possible:

(i) The depth of the chromium-depleted zone (where the alloy chromium content is less than 99% of its original value) increases with time at all temper-

atures and is deeper the higher the temperature and the lower the bulk alloy concentration.

(ii) The chromium content at the alloy-oxide interface rises with oxidation time, although this is not always apparent from short-term runs. Unfortunately this trend cannot be followed experimentally with any great accuracy as both siting and analysis at the interface are difficult. Nevertheless, as is shown elsewhere (6) by theoretical considerations, the measured values are approximately correct.

(iii) The percentage change at any time in chromium concentration at the alloy-oxide interface is greater for Fe-59.5% Cr than for Fe-27.4% Cr. This, together with the smaller depth of depletion, is mainly due to the smaller interdiffusion coefficient in this alloy. The relatively flat chromium profiles immedi-

ately next to the oxide after longer times, again particularly prevalent for Fe-59.5% Cr, are also due to more rapid interdiffusion in the chromium-depleted alloy there.

(iv) The chromium concentrations at the alloy-oxide interface are all in the range 12-18% for Fe-27.4% because the ratio of parabolic rate constant to alloy interdiffusion coefficient is approximately constant in the range 800°-1200°C. The value is more variable for Fe-59.5% Cr at 1200°C, possibly because multilayering is encountered.

(v) For Fe-27.4% Cr and other dilute alloys, where  $D$  is large enough (generally only at 1200°C), zones from the two sides of the oxidizing specimens meet in

the specimen center. This appreciably affects the profiles, so all such results have been omitted.<sup>1</sup>

Fe-28% Cr alloys of different purities (2) showed higher chromium values at the alloy/oxide interface than the Fe-27.4% Cr alloy (A) after oxidation for 5 hr at 1000°C. However, this smaller depletion was simply related to the oxidation rates because the alloy interdiffusion coefficients, as calculated in the Discussion section, showed no significant variation.

Comparison of corresponding profiles is not a simple matter because concentrations at equivalent points along traverses are functions of the alloy interdiffusion coefficient and the oxidation rate as well as other factors. However, the depths of the chromium-depleted

<sup>1</sup> Such behavior essentially produces an alloy more dilute in chromium which could eventually display breakdown.

zones (as defined earlier) at fixed oxidation times are independent of the oxidation rate and are simply related to the alloy interdiffusion coefficient by

$$x_d / (Dt)^{1/2} \approx 2 \quad [3]$$

where  $x_d$  is the depth of the chromium-depleted zone measured (as accurately as microanalysis will permit) from the original alloy surface,  $t$  is the time, and  $D$  is the alloy interdiffusion coefficient, assumed independent of composition in the relevant range. After 1 hr at 1000°C, the depths of the chromium-depleted zones were 33, 28, 27, 13, and 8  $\mu$  for the 22.9, 27.4, 37.4, 68.0, and 59.5% Cr alloys, respectively. The same general order was maintained after longer oxidation times, although there were slight discrepancies with Fe-22.9% Cr. Thus, on a semiquantitative basis there is a minimum interdiffusion rate at about 60% Cr. A further significant feature is that for all the alloys, Fe-14.0% Cr and Fe-18.0% Cr excepted, the chromium concentration at the alloy/oxide interface is never sufficiently low for stratified scale to develop at any stage when cracking is likely to occur.

### Discussion

**Scale compositions.**—The most important conclusion from the scale analyses is that little, if any, iron enters the scale during the later stages of oxidation. If the reduction of the percentage of iron in the scale is simply due to the dilution effect, then the actual amount of iron in the scale will be constant throughout growth. This amount may be calculated as follows.

Let  $M$  be the mass of iron per square centimeter in the thermodynamically unstable film formed on the alloy in the first few minutes (subsequently termed "the initial film") and assume that no further iron enters the scale at longer times.  $M$  g. cm<sup>-2</sup> will then be the actual mass of iron in the scale during the entire oxidation. If  $W$  is the weight fraction of iron in the scale at time  $t$ , then

$$W = M / (\text{Total weight of oxide/cm}^2) \quad [4]$$

The total mass of oxide at time  $t$  follows from the parabolic law and thus

$$W = M (3 M_{O_2}/2) / (K_p \cdot t)^{1/2} \cdot M_{Cr_2O_3} \quad [5]$$

where  $M_{O_2}$  and  $M_{Cr_2O_3}$  are the g. molecular weights of oxygen and Cr<sub>2</sub>O<sub>3</sub>, respectively, and  $K_p$  is the parabolic rate constant measured in terms of mass increase. The weight fraction of iron in the scale is, then, inversely proportional to the square root of the oxidation time.

Unfortunately, the experimental data are not sufficiently accurate to assess the validity of such a law, but it is instructive to calculate and compare the values of  $W$  for the various alloys. Table VII gives the average values for all the data for any set of conditions of temperature and alloy composition.

Before commenting on the trends of  $W$ , some idea of the significance of the term initial film must be presented. The first film produced on iron-chromium alloys entering the hot zone contains mixtures or solid solutions of the component oxides, with iron and chromium present in their alloy proportions or even at this stage with some chromium enrichment (7). In this system, where Fe<sub>2</sub>O<sub>3</sub> and Cr<sub>2</sub>O<sub>3</sub> are isomorphous,

the initial oxide is probably a solid solution, (Fe, Cr)<sub>2</sub>O<sub>3</sub>, although some spinel, Fe Fe<sub>(2-x)</sub>Cr<sub>x</sub>O<sub>4</sub> ( $0 \leq x \leq 2$ ) is also possible. The effective thickness of this initial film depends on the temperature and the oxygen partial pressure, these factors also controlling the extent, if any, of chromium enrichment in the oxide. As soon as the superior affinity of chromium for oxygen becomes predominant, the layers at the base of the film become chromium-rich by the direct formation of 'Cr<sub>2</sub>O<sub>3</sub>' from the oxygen effectively available at the alloy/oxide interface (22). Chromium then continues to enter the scale and the iron present in the initial film is able to distribute itself apparently uniformly through the scale.

For the rapid establishment of a 'Cr<sub>2</sub>O<sub>3</sub>' layer, the 'Cr<sub>2</sub>O<sub>3</sub>' must be formed near the alloy-oxide interface not within the alloy. This implies rapid chromium diffusion to the surface and slow entry of oxygen into the alloy, a condition met by Fe-Cr alloys. For other systems, e.g., Ni-Cr, because chromium diffusion is slower and oxygen solubility apparently greater in the alloy, relatively thick (up to 5  $\mu$  or more) NiO scales are formed on the surface of the comparable alloy before selective chromium oxidation asserts itself (7, 8). Further, since NiO and Cr<sub>2</sub>O<sub>3</sub> are heteromorphous and unable to form solid solutions, and NiCr<sub>2</sub>O<sub>4</sub> formation in this situation is slow, the NiO remains on the surface of the growing Cr<sub>2</sub>O<sub>3</sub>.

By reference to the 1000°C values of  $W$  (Table VII), it is seen, as expected, that there is generally a slight increase in the amount of iron in the initial film as the alloy chromium content is decreased. If it is assumed that the initial film is a mixture of the component oxides in the proportions of iron and chromium in the alloy, then its thickness can be calculated as  $1.2 \times 10^{-2}$  mg cm<sup>-2</sup> (about 250Å) for an oxide of density and metal content corresponding to Cr<sub>2</sub>O<sub>3</sub>.

**Influence of alloy composition on the oxidation rate and scale characteristics.**—Some detailed discussion of the mechanism of 'Cr<sub>2</sub>O<sub>3</sub>' scale formation on iron-chromium alloys has already been given (2). It has been shown here that, neglecting effects due to impurity variations in the starting materials, the rate of oxidation at 1000°C, and probably at other temperatures, only rises slightly (barely within experimental error) with alloy chromium content in the range 18.0-37.4%. Fe-59.5% Cr oxidizes significantly, and Fe-68.0% Cr substantially, faster but these results could again be due to impurities. It was postulated earlier (1) that the observed slight increase in oxidation rate with alloy chromium content is due to iron as Fe<sup>2+</sup> ions decreasing the concentration of cation vacancies and hence the diffusion rate of Cr<sup>3+</sup> ions through the scale. However, it is equally possible for Fe<sup>3+</sup> ions merely to replace Cr<sup>3+</sup> ions in the normal lattice with no resultant effect on oxidation rate according to Wagner-Hauffe valency rules. Nevertheless, the stoichiometry of the resulting Cr<sub>2</sub>O<sub>3</sub>-Fe<sub>2</sub>O<sub>3</sub> solid solution may depend on its exact composition and could vary between metal-deficient p-type for pure Cr<sub>2</sub>O<sub>3</sub> and oxygen-deficient n-type for pure Fe<sub>2</sub>O<sub>3</sub> (23). Thus, in view of the general trend of the higher the alloy chromium content the lower the iron content of the Cr<sub>2</sub>O<sub>3</sub>, the tendency for the oxidation rate to increase with alloy chromium content may be explained because the oxide

Table VII. Calculated values of the weight of iron in the initial film on iron-chromium alloys at 800°-1200°C

		Weight of iron, mg cm <sup>-2</sup>

1000°C		$4.8 \times 10^{-3}$	$12.0 \times 10^{-3}$	$4.4 \times 10^{-3}$	$3.8 \times 10^{-3}$	$3.4 \times 10^{-3}$
						$2.4 \times 10^{-3}$

The value for Fe-14.0% Cr at 1200°C is  $8.8 \times 10^{-3}$  (10-min run only).

with least lattice defects will be 'Cr<sub>2</sub>O<sub>3</sub>' containing a certain relatively low iron concentration. As the variation of the iron content of the 'Cr<sub>2</sub>O<sub>3</sub>' with alloy composition is actually rather small after the initial oxidation stages, little variation of oxidation rate is expected or indeed found.

A similar slight trend would also be expected because, as the bulk alloy chromium concentration is increased, so is the chromium concentration at the alloy/oxide interface. The cation vacancy concentration in the oxide at this interface is thereby decreased, so increasing the vacancy gradient across the scale and therefore the oxidation rate. This effect would only be expected to be small. Previous reports (1) of larger effects of alloy composition on the oxidation rate may have been due to inadequate correlation between kinetic and metallographic data, particularly if scale multilayering occurred.

That the 'Cr<sub>2</sub>O<sub>3</sub>' scales are undoubtedly heavily stressed during formation is deduced from the following observations: (a) the occasional scale ballooning and multilayering at temperature, (b) the formation of a wavy alloy/oxide interface, at least for very pure alloys and lower-chromium alloys at 1200°C. On cooling, additional stressing occurs, as witnessed by: (c) the spalling, sometimes explosive, of parts of the scales on cooling, (d) the tendency of the oxide to wrinkle when released from the constraining influence of the alloy.

The actual oxidation behavior of any specimen depends on the way the stress is developed and relieved by slip, creep, or fracture of the alloy or scale and the extent to which they maintain contact during oxidation or cooling. Such matters are related in a complex way to the specimen geometry, the alloy composition (including phase changes), heat-treatment (degree of cold work and impurity segregation), and surface finish, grain growth, and recrystallization of the alloy and scale, void formation by vacancy coalescence at the alloy/oxide interface, and the oxidation atmosphere and temperature.

It is often stated that stress development due to epitaxial effects and volume changes only occurs when scales grew by the inward movement of O<sup>2-</sup> ions, but this is an oversimplification because stresses undoubtedly develop in all types of oxides. The compressive stress is concentrated in a thin layer immediately adjacent to the alloy and, unless it is relieved by plastic flow of the alloy/film combination, theoretically increases progressively with film thickness until spalling occurs by fracture of the scale from the alloy or of the scale itself. In practice, the stress developed is often not so severe because misfit dislocations are introduced into the oxide at the interface and further stress relief is obtained by slip and climb of dislocations moving away from the surface. Thus, although most of the stress is located near the alloy/oxide interface the entire scale must try to deform to maintain continuity with the core. Therefore, stress of a similar or different sign may be developed in outer parts of the scale and may determine local (*e.g.*, at corners) and to some extent general, scale behavior.

Interface and other stresses are at least partly relieved by slip and creep of the alloy and/or oxide in the appropriate direction. For at least some alloys in the present system, both alloy and scale appear to be deformed, partly explaining the generally maintained adhesion at temperature. Such plastic deformation is most important in the adherent compact oxide supporting the ionic flux building the film, but it should not be neglected elsewhere because specimen continuity depends on deformation of the entire scale.

Behavior on cooling is determined more by thermal contraction characteristics and adhesion, but the former is not very important at temperature, except in the presence of overheating, which should be small here. The stressed oxide may adhere to an alloy in-

definitely, if its cohesion and its adhesion to the alloy are excellent. Adhesion is partly determined by interlocking effects between the alloy and scale, related to surface roughness. However, vacancy coalescence and the nucleation of Kirkendall voids at the alloy/oxide interface weaken adhesion. These phenomena are determined partly by the ability of the alloy (often related to purity) to accept the vacancies diffusing in through the scale. Crack propagation between the alloy and scale, or through the inner barrier layer of oxide, parallel to the alloy/oxide interface, leaving a thin layer of oxide still adherent to the alloy, can also occur.

It is not possible to state exactly which of the above factors is vital in causing failure of 'Cr<sub>2</sub>O<sub>3</sub>' on Fe-Cr alloys. Nevertheless, some pertinent observations may be made.

1. The optimum alloy chromium content for the maintenance of scale adhesion at temperature and the consequent production of uniform single-layer scales was in the range 23-40%, in agreement with indications from previous work (3, 9, 10). With higher chromium concentrations multilayered scales could be obtained, and with low-chromium alloys scale failure was followed by stratified scale development. The influence of alloy chromium content or impurities on the degree of stoichiometry of the scale, the ratio of Cr<sup>3+</sup>/O<sup>2-</sup> ion movement in the oxide, the ability of the alloy to absorb vacancies and the nature of the alloy/oxide interface, and the influence of these factors and the iron content of the scale on the stress development plasticity, and adhesion is unknown.

The plasticity of iron-chromium alloys decreases progressively as alloy chromium content increases at high temperatures. Thus, the optimum chromium content for scale retention at temperature may occur at a composition where the scale and alloy plasticities are just sufficient to relieve the stresses built up in the oxide. At higher chromium levels scale cracking occurs because the alloy cannot yield sufficiently, although it is also possible that the scale (with a lower iron content) is less plastic. There is definite evidence that the alloy can deform with the scale with very pure alloys at high temperature, and with alloys containing 14-23% Cr, producing a highly irregular alloy/oxide interface. It is possible that local scale failure occurs because the alloy can yield easily, but the scale is not sufficiently plastic to bend in the way required. Additionally a greater contribution from O<sup>2-</sup> migration during scale growth might increase the stresses developed here. Experiments with variable specimen geometry also indicated that corners led to scale failure much more readily on Fe-14.0% Cr than with Fe-27.4% Cr. It is not clear how important vacancy coalescence at the alloy/oxide interface was here, but void formation is apparently more likely with the dilute alloy. Scale adhered more readily on abraded Fe-14.0% Cr than annealed alloy at 1200°C, either because scale and alloy interlocking was more complete or because vacancies could more readily enter the alloy.

2. Evidence exists (3) that 'Cr<sub>2</sub>O<sub>3</sub>' grown at 10<sup>-3</sup>-10<sup>-4</sup> Torr was much more uniform, compact, and adherent at temperature, and to a lesser extent on cooling, than scale produced at 1 atm pressure, even though the alloy/oxide interface was much smoother. This tends to indicate that less stress was developed, or even conceivably that the oxide was more plastic, although this is perhaps unlikely because the oxide would be more stoichiometric and contain less iron. However, fewer vacancies would be arriving at the alloy/oxide interface so adhesion could be more readily maintained. Indeed the oxide could still be reasonably heavily stressed, but this would not be evident as long as adherence was maintained.

Adhesion was much more readily lost on cooling, presumably because of the extra stresses induced by

differential thermal contraction between alloy and oxide, lower alloy and oxide plasticity, and thermal shock effects. Adhesion was retained most readily the thicker the scale, presumably because it could not balloon so easily, because more stress had been relieved in the longer oxidation periods when the scale was not growing rapidly, and because it was often formed at higher temperatures, permitting maximum stress relief by plastic deformation. Adhesion on cooling was also better the lower the alloy chromium content, partly due to the superior keying effects of the irregular interface and the other factors mentioned earlier such as the greater alloy plasticity. However, adhesion was also sometimes observed on quite smooth surfaces.

The spalling on cooling was not continuous over the entire surface, but its irregularity did not appear related to any special features such as alloy grain boundaries. Presumably the irregularity does mean that the stresses are not uniformly distributed through the scale or that plastic flow or adhesion is uneven, perhaps due to irregular growth from grain to grain or area to area. There was a greater tendency for spalling on large plane surfaces of specimen than elsewhere, because this approximated more closely to a semi-infinite specimen where cracking by shear failure is more necessary. Scales adhered better at temperature to alloys made from zone-refined metals but spalled off more completely on cooling, indicating that some of the parameters determining the mechanical behavior are purity-dependent.

*Calculation of the interdiffusion coefficient.*—It is possible to calculate interdiffusion coefficients in the underlying alloy from concentration profiles like Fig. 9 and 10. The analysis was not applied to specimens where depleted zones from both sides impinged. Such interdiffusion coefficients, although not fundamental parameters, are important in oxidation problems where concentration changes in the underlying alloy potentially affect the oxidation behavior. Interdiffusion coefficients are composition-dependent, but as derived below can only refer to a small range of chromium concentrations. Thus, the interdiffusion coefficient,  $D$ , is assumed to be independent of alloy composition.

Making the reasonable assumption that only chromium enters the oxide scale, Fick's second law of diffusion may be solved (3) to give the interdiffusion coefficients in the alloy. In order to obtain a complete solution, finite difference techniques have to be employed (6) because the mole fraction of chromium at the alloy/oxide interface  $(N_{Cr})_i$  is an unknown function of time. However, for the present oxidation system, the assumption that  $(N_{Cr})_i$  is independent of time does not produce errors in the interdiffusion coefficients greater than their reproducibility. Thus, the analytical solution (11)

$$\frac{(N_{Cr})_x - (N_{Cr})_i}{(N_{Cr})_b - (N_{Cr})_i} = \frac{\text{erf}[\frac{1}{2}x/(Dt)^{1/2}] - \text{erf}[(\frac{1}{2}K_c/D)^{1/2}]}{\text{erfc}[(\frac{1}{2}K_c/D)^{1/2}]} \quad [6]$$

was used, where  $(N_{Cr})_x$  and  $(N_{Cr})_b$  are the chromium mole fractions at a distance  $x$  from the original alloy surface and in the bulk alloy, respectively, erf denotes the Gaussian error function, erfc, its complement.

Equation [6] enables  $D$  to be computed from the measured values of the other quantities. Initially a crude value of  $D$  is obtained from the depth of the chromium-depleted layer,  $x_d$ . At this depth, Eq. [6] gives

$$\text{erf}[\frac{1}{2}x_d/(Dt)^{1/2}] = 1 \quad [7]$$

from which  $D$  can be obtained by simply plotting  $x_d$  against  $t^{1/2}$  and calculating the gradient of the line.

Fig. 11. Reduced concentration/interdiffusion coefficient plot for specimen of Fe-27.4% Cr oxidized for 50 hr at 800°C. The distances marked on the curves refer to distances from the alloy-oxide interface.

Precise values of  $D$  are then calculated by computing the reduced concentration

$$\frac{(N_{Cr})_x - (N_{Cr})_i}{(N_{Cr})_b - (N_{Cr})_i}$$

as a function of  $x$  and  $t$  for a range of  $D$  values of approximately the same magnitude as the crude  $D$  values. Thus, for each set of oxidizing conditions of alloy chromium content and temperature, a series of curves of reduced concentration against  $D$  at each oxidation time was constructed, e.g., Fig. 11. Values of reduced concentration were also obtained from the experimental concentration profiles, e.g., Fig. 9 and 10, and marked as heavy circles on the constructed curves, Fig. 11. In this way, over a hundred values of  $D$  were obtained for each alloy at each temperature. The arithmetic means of these data are presented in Table VIII, and the coefficients of variation of  $D$ , about 20%, indicate that the assumptions described earlier are not unreasonable.

Close agreement at 1000°C between the present values and values obtained from diffusion data in the literature [calculated (12) from partial chemical diffusivities and self-diffusion coefficients for various alloys assuming ideality in the Fe-Cr system] is indicated in Fig. 12. Thus there is a steady decrease in  $D$  until the value for pure chromium (about  $10^{-13}$  cm<sup>2</sup> sec<sup>-1</sup>) is achieved. It must, of course, be remembered that the  $D$  values refer to a range of chromium concentrations. Arrhenius plots for interdiffusion in Fe-27.4% Cr and Fe-59.5% Cr gave approximate activation energies of 51 and 59 kcal mole<sup>-1</sup>.

Fig. 12. Influence of chromium content on the interdiffusion coefficient of iron-chromium alloys at 1000°C. ○ 13; ▲ 14; △ present work; ■ (15); ▽ (16, 17); ▼ (17-19); ● (20-21); ◇ (18).

The interdiffusion coefficients derived here, although fundamentally less significant, are more meaningful in oxidation studies than the normal diffusion parameters referring to self-diffusion. Concentration gradients always exist in the alloy underlying the scale so what is required is an average over-all value of diffusion rate.

**Significance of the interdiffusion rate in the underlying alloy.**—It has been demonstrated (3) that if the chromium-depleted alloy under a 'Cr<sub>2</sub>O<sub>3</sub>' scale is suddenly exposed to oxygen by scale cracking, it will oxidize in a manner appropriate to its surface chromium content. When this value is below about 13%, 'Cr<sub>2</sub>O<sub>3</sub>' scale is unlikely to re-form and local catastrophic scaling is probable. With the chromium-rich alloys considered here such chromium levels are only likely in the very early stages, making breakthrough improbable (6). Nevertheless, bearing in mind the possible destruction of Cr<sub>2</sub>O<sub>3</sub> scales by complex vanadium-ash-containing environments and subsequent reaction with the alloy, factors affecting the compositional changes in the underlying alloy are worth considering.

The chromium concentration at the alloy-oxide interface depends on: (a) the rate of loss of chromium from the alloy to the scale (measured by  $K_c$ , the modified parabolic rate constant for oxidation); (b) the rate of chromium diffusion to the alloy surface (measured by  $D$ , the interdiffusion coefficient); and (c) the amount of chromium the alloy contained originally (measured by the bulk alloy chromium content).

It has been shown (6) that for this latter factor the percentage of chromium depletion is inversely proportional to the bulk weight fraction of chromium in the alloy. Dependence on the other two factors,  $K_c$  and  $D$ , cannot be given exactly (6), but obviously the greater the value of the ratio ( $K_c/D$ ) the greater will be the percentage of chromium depletion.

Table IX gives the appropriate values of ( $K_c/D$ ) and the reciprocal bulk weight fraction of chromium for the various alloys discussed in the present paper. Thus, the extent of chromium depletion at the alloy/oxide interface is greater for Fe-59.5% Cr than Fe-27.4% Cr, but fortunately the chromium level is still higher so iron-rich scale could not form if the scale cracked.

The situation is complicated in the dilute alloys by  $\alpha/\gamma$  phase changes in the underlying alloy, but the same general principles hold. In all cases the chromium concentration at the alloy/oxide interface drops

# Volume Diffusion During Anodic Dissolution of a Binary Alloy

Howard W. Pickering

*Edgar C. Bain Laboratory for Fundamental Research,  
United States Steel Corporation Research Center, Monroeville, Pennsylvania*

## ABSTRACT

The occurrence of volume diffusion during anodic dissolution of Cu-Au alloys at room temperature is shown again by x-ray and electron diffraction, confirming the result of a previous study. After dissolution the intensity of the diffracted x-rays is increased at Bragg angles,  $\theta$ , corresponding to intermediate Cu-Au compositions. Electron diffraction patterns exhibit new broad diffraction rings corresponding to the formation of intermediate compositions after very early stages of anodic dissolution of about 100 atomic layers of Cu dissolved.

X-ray results of a previous study (1) show that enrichment of Au in Cu-Au alloy occurs during anodic dissolution at room temperature. Accordingly Cu diffuses from the bulk of the alloy toward the surface, and Au diffuses in the opposite direction. Volume diffusion was indicated to be operative via excess divacancies; calculations using the known diffusivity of mono- and divacancies in Cu and Au at room temperature showed that di but not monovacancies have sufficient mobility to enhance interdiffusion of the atoms. Vacancies were concluded to be formed at the surface during anodic dissolution, a consequence of the accumulation of Au on the surface. Furthermore measurements with a rotating disk-ring electrode indicate that ionization of Au does not take place; thus it was concluded that transport of Au does not occur by an ionization and redeposition mechanism. Prior to these results, Graf (2) in 1932 obtained similar, although less conclusive, x-ray diffraction patterns from Cu-Au alloys chemically etched in various aqueous solutions.

It is the purpose of this paper to demonstrate the occurrence of volume diffusion in several Cu-Au alloys during anodic dissolution at room temperature. This is accomplished by x-ray diffraction as previously done for a Cu 10 a/o (atomic per cent) Au (Cu10Au) alloy (1) and by electron diffraction which permits examination at much earlier stages of anodic dissolution. The large difference in atomic sizes makes diffraction techniques particularly useful in this investigation. The occurrence of volume diffusion in a region next to the surface leads to a gradual variation in lattice parameter as a function of distance from the surface, i.e., there results a gradient of the mole fraction of Au between unity and that of the original alloy and of Cu between zero and that of the original alloy. On account of this gradient the diffraction pattern consists of very broad diffraction rings, i.e.,  $\Delta\theta$  of about  $2^\circ$ , with a maximum of the intensity at a certain angle.

The intensity of the x-rays diffracted from regions of variable composition is low in the early stages of dissolution (initially) when the alloy has an essentially plane surface. This is a consequence of the fact that the depth of x-ray penetration is very much greater than the diffusion distance, a few thousand as compared to a few hundred angstroms, respectively (1). At later stages of anodic dissolution, however, the occurrence of severe surface roughening leads to the formation of a porous layer [as much as a 100-fold and more increase in surface area has been found by measurement of the polarization capacity during anodic dissolution of Cu-Au alloys (3)]. Consequently, the thickness of the layer in which compositional differences result is very much greater than the actual

solid-state diffusion distance. Accordingly these regions now can make a significant contribution to the x-ray diffraction pattern. Porous layers have been reported previously for etched Cu-Au alloys on the basis of optical (4-6) and electron (7) metallography. The occurrence of severe surface roughening during anodic dissolution of Cu-Au alloy is in agreement with theory [Harrison and Wagner (8)]: a plane surface is unstable, i.e., perturbations in the surface tend to grow, when preferential dissolution of one component of a binary alloy occurs via interdiffusion of the metals. Conditions are more favorable for obtaining information at an early stage of anodic dissolution with the help of electrons since the depth of penetration of the electrons is of the same order of magnitude as the diffusion distance.

## Experimental

Foils of homogenized (700°C for four days in evacuated quartz capsules, then quenched) Cu1Au, Cu3Au, Cu10Au, and Cu22Au alloys made from metals of 99.999% Cu and 99.995% Au, were prepared by rolling, annealing at 700°C for 1 hr in evacuated quartz capsules and quenching. The foil surfaces were prepared with fine emery and partially lacquered to limit a geometrical area to 5 and 2 cm<sup>2</sup> for x-ray and electron diffraction, respectively. The foil was then inserted vertically in a closed Pyrex cell with a platinum wire counter electrode centered around it. The electrolyte was mainly 1M H<sub>2</sub>SO<sub>4</sub> prepared from reagent-grade acid and doubly distilled water of conductivity  $3 \times 10^{-7}$  ohm<sup>-1</sup> cm<sup>-1</sup>. Before and during the experiment the electrolyte was flushed with He in order to remove oxygen. Current densities of 1 and 5 ma/cm<sup>2</sup> were applied. For these current densities, the potential is in the range where only the anodic dissolution reaction may occur at the Cu-Au electrode. (1, 5, 9).

X-ray diffraction examination of foils mounted in a diffractometer stage was made with nickel-filtered Cu radiation using a Siemens diffraction apparatus. Electron diffraction examination was made in a 50 kv RCA electron microscope modified by removal of the lens between the specimen and the film. For the electron diffraction experiment, prior to anodic dissolution a surgical knife was used for scoring so that a lip was raised on the surface of the foil; this step improved the diffraction patterns.

*X-ray diffraction investigations.*—Broad regions of diffracted intensity, extending approximately from the Bragg angle  $\theta$  characteristic of pure gold to that of the original alloy, were observed after anodic dissolution of the Cu1Au, Cu3Au, Cu5Au, Cu10Au, and Cu22Au alloys in 1M H<sub>2</sub>SO<sub>4</sub>. This agrees with results

previously obtained for Cu<sub>10</sub>Au (1). For example, patterns b of Fig. 1 and 2, corresponding to a relatively early stage of dissolution, contain a broad region of diffracted intensity between the  $2\theta$  positions corresponding to Cu<sub>3</sub>Au and Cu<sub>5</sub>Au, respectively, and pure Au for diffraction of CuK $\alpha$  radiation by {111} planes. Similar results were observed for the first four diffraction planes investigated. The small peak at  $2\theta \approx 38.8^\circ$  in Fig. 1 (most easily seen in pattern a) is due to diffraction of CuK $\beta$  radiation by {111} planes. In Fig. 2 superimposed traces of the x-ray patterns for the different stages of dissolution are substituted for the actual patterns. Broad regions of diffracted intensity are also seen in the x-ray pattern of Fig. 3 which was not obtained directly from the foil itself but rather from particles which had become detached from the Cu<sub>1</sub>Au alloy during anodic dissolution and fell to the bottom of the cell.

At a later stage of dissolution a maximum develops at a  $2\theta$  position corresponding to a Au-rich composition. With further dissolution the maximum shifts toward a certain (higher) gold composition. This is shown for the various alloys in Fig. 4 where the  $2\theta$  position of the maximum is plotted as a function of the dissolution time. Eventually when the specimen is nearly consumed resulting in partial disintegration,

Fig. 1. X-ray diffraction patterns for a Cu<sub>3</sub>Au sheet specimen after various amounts of dissolution at 5 ma/cm<sup>2</sup> in 1M H<sub>2</sub>SO<sub>4</sub>, illustrating a broad region of increased diffracted intensity corresponding to the presence of a composition gradient to the gold-rich side of the original alloy composition. The  $2\theta$  position of pure Au is indicated by the vertical line at  $2\theta = 38.2^\circ$ . (a) prior to anodic dissolution; (b) 3.0 C/cm<sup>2</sup> passed; (c) 6.0 C/cm<sup>2</sup> passed; (d) 24.0 C/cm<sup>2</sup> passed.

Fig. 2. Same as Fig. 1 but for Cu<sub>5</sub>Au. Superimposed traces of the x-ray patterns are substituted for the actual patterns. (a) prior to anodic dissolution; (b) 3.0 C/cm<sup>2</sup> passed; (c) 12.0 C/cm<sup>2</sup> passed; (d) 48.0 C/cm<sup>2</sup> passed; (e) 96.0 C/cm<sup>2</sup> passed.

an appreciable shift of the maxima toward the pure Au composition occurs as seen for the Cu<sub>5</sub>Au alloy in Fig. 2 and 4. Prior to the onset of this final shift in composition the original alloy peaks are already decreased to background intensity.

Figure 4 shows too that for a given current density and time of electrolysis, the position of the maximum is at a lower  $2\theta$  value (corresponding to a greater gold concentration) the higher the gold content of the original alloy. For the most gold-rich alloy, viz., Cu<sub>22</sub>Au, the predominate composition of the reacted region is virtually pure Au after the first several minutes of dissolution. Table I gives the estimated Cu-Au composition corresponding to the position of each maximum after 80 min of dissolution at 5 ma/cm<sup>2</sup>. The composition admittedly has wide error limits. The assignment of a definite composition to the maximum implies only a preponderance of material of this composition with other compositions still present. For this reason the term maximum is used, peak being reserved for profiles corresponding to a single composition. The position of the maximum depends also on the composition of the electrolyte as shown in a previous paper (1); it occurs at a composition less rich in Au for buffered 1N NaCl (pH 5) than for the H<sub>2</sub>SO<sub>4</sub> electrolyte. The influence of current density appears to be slight and within the experimental error (Table I).

As one increases the gold content of the original alloy from 3 to 22 a/o, (a) the intensity of the gold-rich maxima for a given current density and time of electrolysis increases, and (b) the appearance of broad

Fig. 3. X-ray diffraction pattern of particles which became dislodged from a Cu1Au foil specimen during dissolution at 1 ma/cm<sup>2</sup> in oxygen saturated 1.0N CuSO<sub>4</sub> + 0.1N H<sub>2</sub>SO<sub>4</sub> and which fell to the bottom of the cell, illustrating broad regions of increased diffracted intensity at 43 > 2θ > 38.2° and 51 > 2θ > 44.4°, corresponding to diffraction of CuK<sub>α</sub> radiation by {111} and {200} planes, respectively.

Fig. 4. Plot of the 2θ position of the maximum as a function of the dissolution time of the various alloys in 1M H<sub>2</sub>SO<sub>4</sub> at 5 ma/cm<sup>2</sup>.

regions of increased diffracted intensity is detected at an earlier stage of dissolution. These observations might have been predicted on the basis of theoretical considerations (1); for a given current density and time of electrolysis the depth of the interdiffusion zone and the extent of surface roughening may be expected to be greater as the gold content increases.

Optical metallography showed that the final shift of the maximum (e.g., pattern e of Fig. 2) occurs in the absence of original, unreacted alloy. This is seen in Fig. 5, taken of the Cu5Au specimen after 320 min of dissolution at 5 ma/cm<sup>2</sup>. Prior to this final shift of the maximum, unreacted alloy was always observed to be present, e.g., as seen in Fig. 6 for the Cu3Au and Cu22Au specimens after dissolution at 5 ma/cm<sup>2</sup> for 80 min.

In the case of alloys low in Au the reacted layer adheres rather poorly. For Cu1Au alloy, particles are dislodged and may be collected from the bottom of the cell for subsequent diffraction analysis (Fig. 3); the observed dislodging of particles is in accord with industrial experience especially during electrolytic refining of copper containing a small amount of Au.

Table I. Compositions corresponding to the newly formed maxima in the x-ray patterns. These results are for various Cu-Au alloys dissolved mainly in 1M H<sub>2</sub>SO<sub>4</sub> at 5 ma/cm<sup>2</sup> for 80 min

Starting alloy	Position (2θ) of the half-maximum width, in degrees	Estimated compositions†

Fig. 6b. Same as Fig. 6a, but for a Cu22Au foil specimen

Fig. 7. Reflection electron diffraction patterns of Cu<sub>10</sub>Au after anodic dissolution in 1M H<sub>2</sub>SO<sub>4</sub>, illustrating broad lines at gold-rich compositions, in addition to Cu<sub>10</sub>Au alloy lines, in accord with enrichment of Au in the alloy layer immediately next to the alloy-electrolyte interface: (a) prior to anodic dissolution; (b) after 0.10 C/cm<sup>2</sup> passed (1 ma/cm<sup>2</sup> for 100 sec); (c) after 0.14 C/cm<sup>2</sup> passed (20 ma/cm<sup>2</sup> for 7 sec).

ing the very early stages of anodic dissolution. After passage of as little as 0.1 C/cm<sup>2</sup> broad rings corresponding to intermediate Cu-Au compositions appear in the electron diffraction patterns. This is seen in Fig. 7 for Cu<sub>10</sub>Au anodically dissolved in 1M H<sub>2</sub>SO<sub>4</sub>. Similar results were obtained for the other Cu-Au alloys. Passage of 0.1 C/cm<sup>2</sup> corresponds to about 100 atomic layers of dissolved Cu, calculated on the basis of a uniform current density. Actually the current density may be rather nonuniform especially as a result of geometrical and defect inhomogeneities introduced by the surface preparation. Consequently the electron diffraction data at 0.1 C/cm<sup>2</sup> may correspond to somewhat more than 100 atomic layers of Cu dissolved. The data of Fig. 7 and the estimated compositions corresponding to them are tabulated for the first four diffraction planes in Table II. Differences in the 2θ positions of the maxima for different diffraction planes may be due to different depths of penetration, as well as to limited sensitivity in the pattern.

**Electron microprobe investigations.**—Electron microprobe analysis through the cross section of an anodically dissolved Cu<sub>10</sub>Au foil specimen was made in order to determine the gradient of Au and Cu throughout the reacted layer. An over-all increase in

Fig. 8a. Electron microprobe patterns taken through the cross-section of a Cu<sub>10</sub>Au foil specimen after anodic dissolution, illustrating increasing Au contents in the reacted layer as one proceeds outward from the alloy-reacted layer interface. Arrows point out plateaus and maxima presumably resulting from reflection of the beam mainly from particles of remaining, virtually unreacted alloy. As the beam approaches the outer surface of the reacted layer only part of the beam intersects it; consequently the intensity falls off even though the element content may actually increase as in the case of Au in this pattern.

Fig. 8b. Same as Fig. 8a, illustrating decreasing Cu

Au content and decrease in Cu content proceeding outward from the interface between the alloy and the reacted layer were indicated, as shown in Fig. 8. The intensity curves are not smooth but contain plateaus and maxima. These are thought to be due to the presence in the reacted layer of particles of virtually unreacted Cu<sub>10</sub>Au alloy as determined by optical metallography (see for example Fig. 6b); although the effects of porosity in the layer are not known. Porosity may also produce errors in the microprobe determination of concentration.

Table II. Radii of the electron diffraction rings shown in Fig. 7. The value for pure Au is also shown

### Conclusion

The present investigation confirms the result of a previous study (1) that the preferential anodic dissolution of Cu from Cu-Au alloys involves transport of Cu to the surface *via* solid-state diffusion of Cu and Au in the alloy. The use of the diffraction method was definitive in this regard since a spectrum of Cu-Au composition to the gold-rich side of the original Cu-Au composition (as would result during dissolution of Cu *via* volume diffusion) leads to increased diffracted intensity over a broad range of  $2\theta$  between the  $2\theta$  values corresponding to the original alloy composition and pure Au; whereas the formation only of crystals relatively pure in Au [as would result if either of the alternative mechanisms, *viz.*, surface diffusion or ionization-redeposition (1), operates] yields diffracted intensity only at the  $2\theta$  position for pure Au.

### Acknowledgment

The author makes grateful acknowledgment to Dr. Carl Wagner of the Max Planck Institut für Physikalische Chemie who made many suggestions leading to confirmation of the conclusion of a previous joint study (1). Appreciation is also expressed to P. J. Byrne, in particular for his skillful operation of the electron diffraction apparatus, to Messrs. H. Hughes, L. Zwell, and J. Gula, all of this laboratory, for their help with the metallographic, x-ray and electron microprobe investigations, and to Dr. H. Birch of the

Applied Research Laboratory for use of his specially designed electron diffraction apparatus. Helpful comments on the electron microprobe investigation were given by Dr. Th. Hehenkamp of the Institut für Metallforschung, Münster.

Manuscript received Aug. 29, 1967; revised manuscript received Oct. 26, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Oxidation of Lithided Chromium

C. S. Tedmon, Jr.

*University of Denver, Denver, Colorado*

### ABSTRACT

Chromium samples have been electrochemically coated with thin layers of Cr-Li alloy and subsequently oxidized in the temperature range of 1100°-1350°C. Parabolic kinetics were observed in the range of 1100°-1300°C, in both air and dry oxygen. Parabolic rate constants for the Li-coated samples were reduced by nearly one order of magnitude compared with pure chromium samples. Increased spalling resistance and enhanced resistance to nitrification attack were also observed for the Li-coated samples.

In another paper (1), a technique was described for the electrochemical formation of lithium-alloy coatings on a variety of substrate materials. Briefly, the technique involved electrodepositing lithium on cathodic samples, using a molten LiF electrolyte with a carbon anode. Since the process was carried out at temperatures much above the melting point of lithium, the only lithium retained in the sample was that which was present in solid solution or combined as an intermetallic compound with the substrate metal.

Extensive testing was done with chromium samples, and the effects of electrodeposition temperature and time were investigated. Metallographic evidence indicated that the lithium combined with chromium to form what were tentatively identified as a series of intermetallic compounds. Typical microstructures of coated samples are presented in Fig. 1 to 5. It is apparent that the structure of the coating is dependent on both time and temperature of the electrodeposition. In general, the coatings were thin, on the order of 10 $\mu$  in thickness.

It is well known that the presence of lithium in

thermally produced scales on metals which form p-type, semiconducting oxides can be beneficial, producing markedly reduced oxidation rates. This effect, which has been discussed in detail by Haufler (2), has been demonstrated with nickel (3-5), iron (6), chromium (7), and an iron-25% chromium alloy (8). Presumably the Li<sup>+</sup> ions enter the oxide crystal lattice to reduce the cation vacancy concentration and hence decrease cation diffusion. This results in decreased oxidation rates, since the rate-limiting step in the oxidation process for these metals normally depends on cation diffusion.

A principal difficulty in adding lithium to the metals cited above resides in the fact that the melting point of these metals exceeds the boiling point of lithium (1330°C at 1 atm). Consequently, attempts to make direct additions of lithium to the melt frequently result in explosive reactions, and the quantity and distribution of any retained lithium is difficult to control. In order to obtain improved oxidation resistance, it is not necessary that lithium be present uniformly throughout the entire sample; rather, it need only be present near the surface where it can interact with the oxide. Therefore a method of electrochemically pro-

ducing a layer or coating of lithium-containing metal near the sample surface appeared to be a promising means of effecting composition and possibly structure control, and of obtaining improved oxidation resistance.

In the previous paper (1), details of the electrodeposition process and the structural characteristics of the resulting lithium-alloy coated chromium samples were discussed. In this paper, the oxidation behavior of such samples in air and pure oxygen at elevated temperatures is described.

#### Experimental

The samples used in these experiments were made from high-purity, iodide-grade chromium. Prior to the electrodeposition operation, they were ground through No. 4/0 paper, and degreased in toluene and acetone. After electrodeposition, the samples were

Fig. 4. Photomicrograph of a transverse cross section of a chromium sample run at 1000°C in LiF for 120 min. Tapered section,  $\sim 10:1$ . Magnification ca. 50X.

washed to remove any residual adhering LiF, and then again washed with toluene and acetone immediately before insertion in the spring-balance furnace.

Isothermal weight-gain data were obtained using a helical quartz spring. For the size samples used (3-5 cm<sup>2</sup>) the sensitivity was about  $\pm 100$   $\mu$ g. The procedure was to place the sample in the furnace, evacuate the system, and bring the furnace to temperature. The desired atmosphere (either dry O<sub>2</sub> at 100 Torr or dry air at 760 Torr) was introduced and the run was started. Sample temperature was measured with a Pt/Pt-10Rh thermocouple located in an Alundum tube about 0.3 cm from the sample. Temperature control was about  $\pm 5$ C°. When a run was completed, the furnace was shut off and the system evacuated.

Metallographic and x-ray diffraction data were obtained using standard procedures.

#### Results

The structures of samples after electrodeposition, shown in Fig. 1 to 5, are representative of the samples used in the oxidation runs. There was considerable variation in the coating structure, depending on the time and temperature of the electrodeposition process, and consequently a dependence of scaling behavior on the original structure might be expected. All of the samples shown here and used in the oxidation experiments were prepared under conditions of constant current density (0.03 amp/cm<sup>2</sup>).

Kinetic data for oxidation at 1100°, 1200°, and 1300°C are presented in Fig. 6 to 8. The electrodeposition treatment (time and temperature) are indicated for each sample. Note the correspondence between the

Fig. 6. Kinetic weight-gain data for samples oxidized at 1100°C

Fig. 7. Kinetic weight-gain data for samples oxidized at 1200°C

Fig. 8. Kinetic weight-gain data for samples oxidized at 1300°C

samples used in the oxidation runs and the samples shown in Fig. 1 to 5.

An attempt was made to oxidize a sample at 1350°C; however, when the sample was nearly at temperature, it was observed to suddenly start gyrating rapidly in the furnace. The run was terminated, and subsequent examination of the sample showed that the coating had erupted from the surface, causing considerable weight loss. This was apparently caused by rapid and catastrophic volatilization of the lithium from the coating.

The weight-gain data shown in Fig. 6 are from oxidation at 1100°C in dry oxygen of two samples prepared at 900°C for different times. Comparison

with Fig. 1 and 2 indicates that the 360-min sample had a thicker coating than the 10-min sample; furthermore, the coating on the 360-min sample is multi-layered. Oxidation kinetics for the 10-min sample were parabolic throughout the run, whereas the 360-min sample exhibited a region of linear kinetics before conversion to parabolic behavior. Comparison may be made to the oxidation kinetics for high-purity, iodide-grade chromium, shown by the solid line (7). Although the oxidation behavior of chromium is dependent on impurity content, it has been demonstrated (7) that iodide-grade chromium oxidizes at generally slower rates than other commercial grades of chromium.

From the 1200°C data presented in Fig. 7, the beneficial effects of the lithium treatment are obvious. The oxidation rate in dry oxygen is markedly reduced. Similar improvement is seen for oxidation in air. When pure chromium is oxidized in air, in addition to  $\text{Cr}_2\text{O}_3$  formation, there is an additional weight-gain due to the production of  $\text{Cr}_3\text{N}$ . This latter compound forms at the oxide-metal interface and frequently penetrates grain boundaries in the metal. Although the nitride is considered to be unstable with respect to the oxide (9), it is invariably present when pure chromium is oxidized in air. The general phenomena of nitrification of chromium and chromium-based alloys is not well understood and is a problem of current research interest. One aspect of it which does seem clear, however, is that the extent of nitrification is highly sensitive to the structural integrity of the oxide scale. Nitrification appears to be most severe when the scale contains gross defects such as blisters, cracks, and porosity which apparently permit access of air to the metal/oxide interface. This point will be discussed in greater detail in a subsequent section.

Figure 8 presents weight-gain data for samples oxidized in dry oxygen at 1300°C. Again, parabolic kinetics were observed; the improvement brought about by the lithium treatment is apparent. Best results were obtained with the sample which had been run the longest in the LiF, which was also the case with the samples which had been oxidized at 1100°C (Fig. 6). It should also be noted that the 30-min. LiF treated sample oxidized with linear kinetics for about the first 30 min before the transition to parabolic behavior occurred. The scales which formed on the lithium-treated chromium samples were very adherent and nonspalling. This is in marked contrast to the behavior encountered with pure chromium, which spalls very severely when oxidized above about 1000°C.

Parabolic rate constant data for coated samples oxidized at 1100°, 1200°, and 1300°C are presented in Table I; corresponding data for iodide chromium are included for comparison in Table II.

It is readily seen that the coated samples oxidized at considerably slower rates than the iodide chromium. Since lithium is volatile, it is possible that the observed weight-gains may not be representative of only the chromium oxidation reaction, but, rather, might indicate the difference between weight-gain from chromium oxidation and weight-loss from lithium volatilization. There are several reasons why the latter

is probably not the case. First, during the kinetic runs in the range 1100°-1300°C, there was no indication in the furnace tube of the presence of lithium oxide. Second, metallographic observations show that the observed weight-gains are consistent with scale thickness and with the total weight change of the sample. Also, if significant lithium volatilization were occurring, the kinetics would not be parabolic. The effect of volatilization reactions on oxidation kinetics of chromium-based alloys has been previously discussed (10).

Metallographic analysis of oxidized samples disclosed several important features. One of the most interesting is the observation that the metal/oxide interface was very irregular, with the oxide essentially interlocked with the metal. An example of this is shown in Fig. 9, which is a micrograph of a sample which had been given a lithium treatment at 1100°C for 120 min prior to oxidation at 1200°C for 30 hr. In addition to the irregular appearance of the interface, there is metal entrapped in the scale. The general appearance of the latter is characteristic of subscale formation. The scale is quite dense.

Specimens oxidized at 1100° and 1300°C resulted in structures quite similar to that shown in Fig. 9. X-ray diffraction results indicated the scales were  $\text{Cr}_2\text{O}_3$ , with lattice parameters essentially equivalent to those of pure  $\text{Cr}_2\text{O}_3$ .

Figure 10 presents a micrograph from a sample oxidized for about 130 hr in air at 1100°C. This sample had been treated for 120 min at 1100°C in LiF prior to oxidation. The oxide/metal interface is again rather irregular. In addition to the  $\text{Cr}_2\text{O}_3$ , there is a small amount of  $\text{Cr}_2\text{N}$  present. The extent of nitrification, however, is greatly reduced compared with that forming on pure chromium (11).

### Discussion

The presence of lithium in the chromium samples has three beneficial effects, *viz.*, it promotes slow oxidation rates, increases spalling resistance, and enhances resistance to nitrification attack during air oxidation.

The decreased oxidation rates arising from the presence of the lithium can be accounted for by the Verwey-Hauffe mechanism, wherein  $\text{Li}^+$  ions sub-

Fig. 9. Photomicrograph of a transverse cross section of a sample treated in LiF at 1100°C for 120 min, followed by oxidation at 1200°C. Magnification ca. 550X.

Fig. 10. Photomicrograph of a transverse cross section of a sample treated in LiF for 120 min at 1100°C, followed by oxidation at 1100°C in air. Magnification ca. 550X.

stitute in the cation sublattice of the  $\text{Cr}_2\text{O}_3$ , thereby reducing the  $\text{Cr}^{+3}$  vacancy concentration. It is reasonably well established that the oxidation rates of alloys which form  $\text{Cr}_2\text{O}_3$  protective scales is primarily controlled by cation diffusion (7, 11-13), and thus a decrease in the cation vacancy concentration results in slower diffusion rates and hence decreased oxidation rates. Supporting this model are the results of Hagel (14), who found that the electronic conductivity of  $\text{Cr}_2\text{O}_3$  is increased by doping with  $\text{Li}_2\text{O}$ .

The increased spalling resistance probably arises from the irregular boundary at the metal/oxide interface, such as shown in Fig. 9 and 10. The irregular boundary would tend to "key" the oxide in place. The irregular interface is a consequence of what appears to be subscale formation, probably caused by composition inhomogeneities in the lithium alloy layer. Although x-ray diffraction studies identified only  $\text{Cr}_2\text{O}_3$ , there is the possibility that more than one oxide may be involved in this scale and sub-scale, such as  $\text{LiCrO}_2$ ,  $\text{Li}_2\text{CrO}_4$ , or  $\text{Li}_2\text{Cr}_2\text{O}_7$ . Of these,  $\text{LiCrO}_2$  is the most stable (15, 16). That the latter was not found by x-ray diffraction implies that if it exists in the scale, it probably is there in concentrations of less than about 5%.

The origin of this enhanced resistance to nitrification of these alloys on exposure to air is not completely understood. It has been suggested that the mechanisms of nitride formation in Cr-rich alloys requires the presence of gross structural defects in the oxide scale, such as cracks and blisters, which permit access of air to the metal. Presumably if these defects were absent, then the nitride would not form. Therefore it might be expected that since the oxide scales formed on samples in these experiments were adherent and well-bonded to the metal, air was denied access to the metal/oxide interface and only the oxide was formed. Tentative support for this argument is presented in Fig. 11, which is a micrograph of a sample that was treated in the LiF for 120 min at 1100°C, and subsequently oxidized at 1200°C in air. Although the sample was generally free from nitride, there were several regions where it did form, which combined with blisters in the scale, as shown. It is evident from the data presented in Fig. 7 that some amount of nitride formed. The presence of the lithium, although beneficial, does not completely prevent nitrification.

### Conclusions

1. Samples of iodide chromium have been alloyed with lithium by electrochemical reaction in molten LiF.
2. The oxidation behavior of these samples was investigated in the range of 1100°-1350°C; parabolic kinetics were observed in both air and dry oxygen.
3. The lithium alloying had three significant beneficial effects: (a) it resulted in markedly reduced

Fig. 11. Photomicrograph of a sample treated in LiF at 1100°C for 100 min, followed by oxidation at 1200°C in air. Magnification ca. 550X.

oxidation rates, (b) improved resistance to spalling, and (c) increased resistance to nitride formation during air oxidation.

#### Acknowledgments

The authors wish to extend their appreciation to the Metallography Unit of the General Electric Research and Development Center for their excellent services. The advice and counsel of Dr. N. C. Cook throughout this project is appreciated.

Manuscript received Sept. 18, 1967; revised manuscript received Nov. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

#### ABSTRACT

Lithium-rich coatings have been successfully produced on platinum, silver, copper, and chromium samples by electrode position from molten LiF, using a graphite anode. Coatings may also have been made on nickel samples, although the data are less definitive. The coatings produced on copper and silver appear to be solid solutions of lithium with the sample metal, whereas the coatings on platinum and chromium are probably intermetallic compounds. Extensive testing at constant current density was carried out with chromium samples at temperatures between 900° and 1100°C, for deposition times varying from 10 to 360 min. Coating thickness and morphology was found to be time and temperature dependent. Generally low coulombic efficiencies were observed, and it is postulated that diffusion of lithium into the sample is rate-controlling. Possible electrode reactions are discussed.

Electrochemical methods for the deposition of various metals from molten halide salts have been known for many years. Some of the more important procedures have been discussed in a review on molten salt electrochemistry by Reddy (1). The deposition of metals from molten fluoride salts has been an especially active area in recent years. Senderoff *et al.* (2-6) have described methods for the electrodeposition of coherent, dense, and pure deposits of refractory metals, including niobium, tantalum, zirconium, chromium, molybdenum, tungsten, hafnium, and vanadium.

In their experiments, the electrolytes were usually eutectic mixtures of alkali fluoride salts, containing small amounts [e.g., ~10 w/o (weight percent)] of refractory metal fluoride salts, such as NbF<sub>5</sub> and K<sub>2</sub>TaF<sub>7</sub>, in the cases of deposition of niobium and tantalum, respectively. In general, soluble anodes were used, and they were able to produce electrodeposits on a variety of substrates.

In contrast to the methods of Senderoff and Mellors are the techniques developed by Cook (7-10) for the electrodeposition of silicon, boron, chromium, and beryllium from molten fluoride electrolytes. Whereas Senderoff and Mellors essentially produced electro-

\* Electrochemical Society Active Member.

plates of pure metal on the substrate, the metals Cook deposited reacted with the substrate to produce compounds or alloys. This mode of deposit was probably due to several factors, particularly the low current densities and relatively high temperatures at which Cook carried out his processes. Both effects would encourage interdiffusion between the substrate and the deposited metal, leading to the formation of alloy coatings. In fact, Cook has implied (7-10) that the rate of deposition in his processes was controlled essentially by solid-state diffusion rates in the substrate or reaction layer. Thus, for example, when electrodepositing silicon on molybdenum,  $\text{MoSi}_2$  was the principal product, with lesser amounts of  $\text{Mo}_3\text{Si}$  and  $\text{Mo}_5\text{Si}_3$  being present (9). When depositing chromium on mild steel, solid solution single-phase Fe-Cr alloys were formed (10). The electrolytes used by Cook were alkali-fluoride salt mixtures, usually of eutectic composition; consumable anodes were employed. Unlike the methods of Senderoff and Mellors, the techniques developed by Cook were highly sensitive to the nature of the substrate. Electrodeposits could be made on a wide variety of metals, but since compounds or alloys were always formed between the substrate and the element being deposited, plating characteristics varied with each kind of substrate.

Molten alkali fluorides possess several unique properties that make them advantageous for use as electrolytes in electroplating in preference to other halide salts. One of the more significant characteristics is the ability of molten fluorides to flux and dissolve oxides. Consequently, when a substrate metal is introduced into the molten salt bath, any residual oxide scale or film is quickly dissolved, leaving a clean metal surface exposed to the electrolyte. This will help promote mass transport across the surface. In addition, alkali fluorides are in general stable to higher temperatures and less hygroscopic than other alkali-halide electrolytes.

Because of the success in electrodeposition of various metals from molten alkali-fluoride salt baths as described above, it was decided that the feasibility of electrodepositing on certain structural metal substrates using a molten lithium-fluoride electrolyte should be investigated. Since the melting point of lithium fluoride ( $845^\circ\text{C}$ ) is much higher than that of lithium ( $183^\circ\text{C}$ ), appreciable deposits of pure metallic lithium would not be expected on the sample surface. Rather, it would be expected that the lithium retained in the sample would be present as an alloying species, either in solid solution, or as a compound. Excess lithium which might be deposited would either dissolve into the molten salt or migrate away as a second phase in the salt mixture.

There are a number of incentives for developing a process for the electrodeposition of lithium on base metals at elevated temperatures. High-temperature electrodeposition is a possible technique for producing alloys, or at least lithium-alloy coatings on certain metals that cannot be prepared by more conventional methods.

One particular application is in the area of oxidation-resistant materials. It is well-known that the oxidation resistance of certain metals can be improved by either alloying with lithium or by oxidizing the metal surface in an atmosphere containing lithium (11-15). Consequently, the notion of electrochemically producing a layer of lithium-containing metal near the surface of the sample appeared promising.

It was decided to study the electrodeposition of lithium on a number of metals, including some whose solubility for lithium was known to be relatively high, such as copper and silver (16). In addition, it was desired to attempt electrodeposition on metals for which the solubility of lithium is either unknown, such as in platinum, or else believed to be quite small, such as in the case of nickel or chromium (17).

Fig. 1. Schematic diagram of molten fluoride electrodeposition apparatus.

### Experimental

**Sample preparation.**—High-purity sample metals were used throughout the investigation, *viz.*, “thermocouple”-grade platinum, iodide-chromium, carbonyl-nickel, OFHC copper, and 99.99% pure silver. The samples were usually in the form of thin plates, about  $1 \times 2 \times 0.05$  cm, although in the case of platinum, wire of 0.15 cm diameter was used. All samples were abraded through No. 4/O metallographic paper and were rinsed in toluene and acetone prior to the electrodeposition treatment.

**Electrodeposition cell.**—The lithium-fluoride electrolyte was contained in an Inconel vessel which was about 12.7 cm in diameter and 46 cm long. The Inconel vessel was situated inside a multiple-winding furnace which could heat the electrolyte to  $1200^\circ\text{C}$  (Fig. 1). Suitable covers for the vessel were made so that an inert atmosphere could be maintained over the salt. Initially, argon was used; later, forming gas (90%  $\text{N}_2 + 10\% \text{H}_2$ ) was found to be more convenient.

The anode was spectroscopic-grade graphite, which was further purified by a bake-out treatment at  $2300^\circ\text{C}$  for about 15 min.

The lithium fluoride was obtained from the American Potash and Chemical Corporation and was claimed to be about 99.9 w/o pure. As has been reported (2-10), the purity of the electrolyte salt is an extremely important factor in determining the quality and success of the electrodeposition method. In an effort to purify the salt further, two procedures were carried out. First, the salt was vacuum-melted and held above its melting point in vacuum for several hours to drive out volatile impurities. Subsequently, cleanup runs were carried out, in which sheet samples of iron and nickel, having large surface areas, were placed in the cells as cathodes. Current was applied through the cell in an effort to plate out metallic impurities. The composition of the salt after these runs is presented in Table I.

**Mass-spectrometric analyses.**—Standard analytical procedures proved to be unreliable and inadequate for the determination of the small amounts of lithium

present in most of the samples, and a mass-spectrometric method was found to be the most satisfactory. Samples were sent to the Technology Division of the GCA Corporation, Bedford, Massachusetts, for the analysis. The lithium concentration in the sample as a function of distance from the surface was determined in the following manner. A sharply focussed beam of ionized argon was directed onto the sample surface, which locally vaporized a small volume of material from the sample. Because of the fine focussing of the ion beam, the volume of vaporized material was on the order of a few cubic microns. The vaporized species were then analyzed with a mass-spectrometer. By repeated bombardment of the ion beam, composition as a function of distance from the specimen surface could be determined. With the use of suitable standards, the sputter-ion yield for the various elements of interest can be determined, and conversion of intensity data to composition may be made.

*Auxiliary measurement.*—Standard metallographic and x-ray diffraction procedures were employed to study the structures of the electrodeposited coatings. Because these coatings were usually very thin, tapered sections were used in metallography. Microhardness measurements were also made on certain selected samples.

### Results and Discussion

*General observations.*—Electrochemically deposited lithium-alloy coatings were successfully produced on silver, copper, platinum, chromium, and perhaps nickel. The solubility of lithium in silver and copper is probably much larger than for the others, and it is not unexpected that the lithium-alloy coatings in the former were found to be thicker than in the last two. In general, however, coulombic efficiencies were low. For the conditions employed, this suggests that the rate-limiting step is the diffusion of lithium into the sample, rather than the transport of lithium through the electrolyte to the sample. Presumably excess lithium arriving at the sample faster than it can be assimilated would dissolve into the molten LiF, in which it has a solubility of about 2 m/o (mole per cent) metal at 1000°C (18).

Table II presents a summary of operating data and results for a number of different samples. It is interesting to note that the highest coulombic efficiency was obtained on the platinum sample. Silver samples (not listed in Table II) also had high efficiencies; however, since the liquidus temperature at the silver-rich side of the Ag-Li phase diagram decreases rapidly with increasing lithium content, melting of the sample usually occurred for deposition at temperatures as low as 900°C. Consequently, quantitative deposition data for the silver samples could not be obtained.

\* Not determined.

The potential difference between anode and cathode was usually observed to decrease with increasing temperature, which is the expected trend. Since part of the voltage drop between the anode and cathode includes IR losses in the leads, care must be taken in interpreting the potential data. However, since the electrical leads were of essentially constant geometry in all of the runs, variation of the IR losses from run to run, and with temperature, will be small, so that most of the temperature variation in the electrical potential can be attributed to either the electrolyte and/or interface reactions such as solution of lithium into the sample.

Loss of carbon from the anode was observed below the saltline. It was not possible to relate quantitatively the loss of carbon to operating conditions, since adherence of the LiF to the anode, after removal from the bath, precluded accurate weight-loss measurements. The solubility of carbon in molten LiF is believed to be very small (19). The anode reaction is probably

and the cathode reaction would be of the form

where  $n = x + y$ . Because free energies for solution of lithium in either the sample or the electrolyte are not known, open-circuit potentials for the net reaction were not calculated.

*Platinum sample.*—Figure 2 is a micrograph of the platinum sample which is listed in Table II. There is a very clear and well-defined interface between the lithium diffusion zone and the interior of the platinum. Irregularities along this interface are magnified by the 8:1 taper on the sample. The true thickness of the coating is estimated to be about 40-50 $\mu$ . Microhardness data for the platinum sample are presented in Fig. 3. Although there is some scatter in the data obtained on the coating, it is apparent that there is a very pronounced hardening effect due to the presence of the lithium. Also, the hardening effect is clearly limited to the coating, with a sharp discontinuity in hardness occurring at the boundary. The hardness of

Fig. 2. Photomicrograph (8:1 taper section) of a platinum sample held at 1000°C for 20 min. Magnification 60X.

Fig. 3. Microhardness traverse across same platinum sample shown in Fig. 2.

the interior of the sample decreases to a value of 100 KHN at a distance of about  $50\mu$  from the surface. The hardness of the coating appears to be essentially constant. This fact, together with the metallographic observation of the sharp boundary, suggests that coating has a constant composition as would be found for a single intermetallic compound. If the coating were a solid solution of lithium in platinum, a composition gradient in the coating would be expected, which would result in a corresponding hardness gradient. Also, there would not be a sharp interface between the coating and the interior of the sample. The region of the sample extending inward from the coating may be a solid solution of lithium and platinum, since the hardness decreases from about 100 KHN at  $50\mu$  from the surface to 84 KHN at a 0.4 mm depth. The identity of the surface compound is unknown, although the compound  $\text{LiPt}_2$  has been reported in the literature (20). X-ray diffraction patterns were obtained, but could not be indexed. Spectrographic analysis of the sample showed lithium to be present; quantitative analysis was not possible.

**Copper sample.**—Figure 4 is a photomicrograph of a copper sample which had been run for 6 hr at  $900^\circ\text{C}$ . The thickness of the outer zone is about  $200\text{--}250\mu$ . The structure of that zone suggests that the material was molten at some point during treatment. Spectrographic analyses of copper samples showed lithium present, but the concentration was not determined. According to the work of Klemm and Volavsek (21), there is a substantial solid solubility of lithium in copper, which increases with decreasing temperature. At  $900^\circ\text{C}$ , the

Fig. 4. Photomicrograph (10:1 taper section) of a copper sample which had been run for 6 hr at  $900^\circ\text{C}$ . Sample appearance suggests that partial melting had occurred. Magnification ca. 40X.

solidus composition is about 7 a/o lithium. If melting occurred, then presumably the composition of the solidified material must be at least the solidus composition, i.e., about 20 a/o Li.

Microhardness tests on copper samples disclosed a hardness maximum near the edge, with hardness decreasing towards the sample interior, indicating solid-solution hardening of the copper by lithium. Hardness values near the sample surface were about KHN 68-70 (10g load); in the center of the sample, KHN 45-50.

**Nickel samples.**—The solubility of lithium in nickel is not known, but our results indicate it is quite low. Figure 5 is a photomicrograph of a sample of nickel run at  $900^\circ\text{C}$  for 6 hr. The diffusion zone is thin; the sample is mounted with a 10:1 taper in the picture, so the actual thickness is about  $1.0\text{--}1.5\mu$ . Spectrographic analysis did not show lithium to be present; however, with the thin coating on the sample, the negative result is not necessarily conclusive. It is quite possible, however, that lithium is not present in the sample, and the coating is due to deposition of some impurity from the salt. In any case, the morphology of the structure is suggestive of a compound rather than a solid solution.

**Chromium samples.**—The most extensive testing program was carried out with chromium samples. In addition to studying the electrochemical deposition process, the oxidation behavior of coated samples was investigated in detail. The results of that study are discussed elsewhere (22). Operating data for one set of experiments are presented in Table II, in which the effects of deposition time and electrolyte temperature were studied. Several points should be noted. It is apparent that coulombic efficiencies were the greatest for the shortest deposition times, and in general decreased with increasing time, as shown in Fig. 6. Since lithium is being supplied to the sample at a constant rate isothermally, this indicates that it is being taken into the sample at a continually decreasing rate. If the rate of solution of lithium into the sample is controlled by solid-state diffusion, and if the activity of lithium at the electrolyte/sample interface remains constant throughout the operation, then the rate of solution of lithium into the sample would decrease parabolically with time.

There was no strong correlation between coulombic efficiency and electrolyte temperature. The effects of deposition time and electrolyte temperature on the resultant lithium-containing coatings on chromium samples are summarized in Table III. In additional experiments, samples were immersed in the electrolyte for various times and at different temperatures, with no applied potential. None of these samples showed any weight change, and they did not have any surface coating, but remained bright, thus demonstrating that lithium was introduced into the specimen only under the influence of an applied external potential.

Fig. 5. Photomicrograph of a (10:1 taper section) nickel sample which was run at  $900^\circ\text{C}$  for 6 hr. Magnification ca. 200X.

Fig. 6. Coulombic efficiency vs. time for chromium samples run at 900°, 1000°, and 1100°C.

It would be expected that the thickness of a coating ought to increase with increasing time at constant temperature. For samples run for 360 min at 900° and 1000°C, that was not the case, as indicated in Table III. There is, of course, some uncertainty in determining coating thickness metallographically from taper sections, but the data are estimated to be accurate to within  $\pm 4\mu$ . Consequently it may be that the growth rate after 120 min is negligible.

Photomicrographs of some of the more interesting coating structures are shown in Fig. 7-9. Figure 7 presents a sequence of structures that were developed on chromium samples which had been treated at 900°C for varying lengths of time. Some of the samples were electroplated with nickel prior to metallographic preparation, in order to preserve edge detail. It appears that the number of layers in the coatings increases with increasing time at temperature. As is seen from the data in Table III, this was a general trend, although it was more pronounced with samples run at 900°C than with the 1000° and 1100°C samples. The morphology of the outer layer in both the 120-min sample (Fig. 7c) and the 360-min sample (Fig. 7d) shows a coring effect, suggesting possibly the presence of a molten phase during deposition.

Figure 8a shows the structure of a sample coated at 1000°C for 30 min. Only one layer is present. Samples run for 10 min at 1000°C were quite similar in appearance to this 30-min sample. Figure 8b is a micrograph of a chromium sample run for 120 min at 1000°C. This coating is somewhat thicker than the coating shown in Fig. 8a and consists of two layers. The inner layer in Fig. 8b is similar in appearance to the coat-

ing shown in Fig. 8a, suggesting that it might be the same phase. If that were the case, then the thicker outer layer shown in Fig. 8b would be a more Li-rich phase. Samples run for 360 min at 1000°C had coatings with structures closely resembling those run for 120 min.

The micrographs shown in Fig. 9 present representative structures for samples run at 1100°C for various times. Samples run for 10, 30, and 120 min all had similar coating structures, of which that shown in Fig. 9a for a 120-min sample is typical. When samples were run for 360 min at 1100°C, a different structure resulted, consisting of two layers (Fig. 9b). At higher magnification, there is some resemblance in appearance between the inner layer (Fig. 9c), and the coating produced on samples run for shorter times (Fig. 9a). In Fig. 9c, reaction at the grain-boundaries is evident. The grain-boundary structure shown here is quite similar in appearance to that which was found in Fe-25% Cr-0.5% Li alloys that had been produced by induction melting under argon pressur-

ized to several atmospheres to minimize lithium loss by volatilization (15).

Figure 10 presents some results obtained with the ion bombardment technique for a sample which had been run for 360 min at 1000°C. Standards for determining exactly the sputter-ion yields for lithium and chromium were not available, so exact conversion of the intensity data to compositions is not possible. However, it is estimated the sputter-ion yield for lithium may be as much as 100 times that of chromium (23). If that were the case, then the peak in the curve in Fig. 10. would correspond to a lithium concentration of about 0.5 a/o. The presence of the maximum at a position of about  $2\mu$  below the specimen surface, rather than at the surface, is not understood. It may be artificial, arising from the difficulties inherent in trying to resolve distances less than about  $1-2\mu$  by this technique.

Fig. 10. Relative intensity vs. distance into chromium sample, which had been run for 360 min at 1000°C.

A comparison of the data in Fig. 10 with those listed in Table III shows very good agreement between the depth of reaction observed metallographically and that observed by the mass-spectrometric method. It was stated previously that the existence of well-defined boundaries between the coatings and the substrate, as observed metallographically, implied that the coating was an intermetallic compound, rather than a solid solution of lithium in chromium. The data presented in Fig. 10 do not seem to support that argument. Unfortunately, the coatings on chromium samples were too thin to permit definitive micro-hardness data to be obtained, so the question remains unresolved. What is definitely established by the data shown in Fig. 10 is that lithium is clearly present in the sample to a depth of at least  $18\mu$ .

If it is assumed that the data presented in Fig. 10 are a valid representation of the lithium profile in the sample, then an estimate of a diffusion coefficient for lithium in chromium may be made. Assuming that the diffusion coefficient is independent of composition, and also that the effective surface composition is constant and equal in relative magnitude to the value given by the maximum in Fig. 10, then the following solution to Fick's second law applies

$$c(x, t) = c_0 \left[ 1 - \operatorname{erf} \left( \frac{x}{2\sqrt{Dt}} \right) \right]$$

where  $c(x, t)$  is the relative lithium concentration at any time  $t$  and position  $x$ ,  $c_0$  is the surface composition, and  $D$  is the diffusion coefficient. The term  $\operatorname{erf}$  denotes the error function. Note that it is not necessary to know the absolute concentration; only the composition profile is required. That the above solution to Fick's second law applies to the concentration data presented in Fig. 10 is demonstrated in Fig. 11, which is a probability plot of relative composition vs. the distance-time parameter,  $x/\sqrt{t}$ . If the equation given above is a valid solution to the diffusion equation, a straight line should result. It is clear that a good fit obtains. A value of  $c_0 = 0.52$  was used. For the interdiffusion coefficient of lithium in chromium at  $1000^\circ\text{C}$ , a value of  $D \cong 5 \times 10^{-12} \text{ cm}^2 \text{ sec}^{-1}$  is obtained, which is essentially independent of composition, as indicated by the good linear fit of the data in Fig. 11. Although there are no other data available with which to make a comparison, this value seems reasonable.

Fig. 11. Probability plot of relative lithium concentration vs. the distance time parameter,  $x/\sqrt{t}$ , for a chromium sample which had been run 360 min at  $1000^\circ\text{C}$ .

## Conclusions

1. Lithium-rich coatings have been successfully electrodeposited on Ag, Cu, Pt, Ni, and Cr using a molten LiF electrolyte and a graphite anode. The electrodeposition was carried out in the temperature range of  $900^\circ\text{--}1100^\circ\text{C}$ , for times varying from 10 to 360 min.

2. The coulombic efficiency obtained was dependent on the metal being coated, varying from 100% in the case of Pt to about 1% for Cr and Ni, under certain conditions.

3. The coatings produced on Cu and Ag samples appeared to be solid solutions of Li with the substrate metal.

4. The coatings produced on Pt appeared to be an intermetallic compound, possibly  $\text{LiPt}_2$ .

5. Metallographic data suggested that the coatings produced on chromium samples were intermetallic compounds; however, mass-spectrometric data obtained as a function of distance from the sample surface did not confirm that, showing instead a smooth lithium concentration gradient. The extent of Li penetration in Cr samples, as determined metallographically, was in good agreement with the mass-spectrometric data.

## Acknowledgments

The authors wish to extend their appreciation to W. A. Roman, R. R. Russell, and Mrs. E. M. Raviola for metallographic services, and to N. C. Cook, D. A. Vermilyea, and D. W. White of the General Electric Research and Development Center, and C. J. Rosa of the University of Denver, for critical reviews of the manuscript. The continuing assistance, counsel, and interest of N. C. Cook is gratefully acknowledged.

Manuscript received Sept. 18, 1967; revised manuscript received Nov. 1, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Two Remarks on the Resistive Contribution to Overpotential

Benson R. Sundheim

Department of Chemistry, New York University, Washington Square, New York, New York

### Placement of Reference Electrodes

In order to minimize the contribution of the  $iR$  drop to the apparent overpotential, it is generally thought that it is desirable to place the reference electrode on an isopotential surface near the electrode being studied. That is, the potential drop along the current streamlines traversed in passing from one electrode to the other should be small. It is not always possible to do this efficiently. For example, if the indicator electrode is small, the major part of the  $iR$  drop will occur near the surface end. A reference electrode or Luggin capillary cannot reach closely enough to obviate most of the  $iR$  drop. In other cases, the pressing of the Luggin capillary close to the surface of the indicator electrode gets rid of most of the  $iR$  drop, but because of its geometrical blocking of the electrode reduces the current density in the immediate vicinity of the capillary tip. It is sometimes thought that if the Luggin capillary is close enough to the surface it will correctly represent the overpotential contribution characteristic of the instantaneous state of the electrode with little or no effect from the ohmic potential. That this view is incorrect when activation overpotential is significant can be seen as follows.<sup>1</sup>

We select first an extreme case which displays clearly the essential features of the argument. Referring to Fig. 1, we note that B and C have the same potential (with respect to any reference point). We assume that E and D are the locations of two identical reference electrodes placed so as to measure the potentials of B and C, respectively, with essentially no direct contribution from  $iR$ . We further assume that the electrode in question (B and C) has a characteristic current voltage relation; e.g.,  $E = a - b \ln i$ , so that the overpotential  $\eta$  is some specific function of the current  $i$ . Following the two current loops and applying Kirchoff's law to the circuit we obtain

$$\begin{aligned} i_1 R_1 + \delta E_1 &= i_2 R_2 + \delta E_2 \\ i_1 R_1 - i_2 R_2 &= \eta(i_1) - \eta(i_2) \end{aligned}$$

We assume that the reference electrode measures the potential difference between the electrode and the solution immediately adjacent to this indicator electrode. This quantity will be different because of the different current densities of the two electrodes. Let us assume that  $a = 0.1$ ,  $E = E_0 - b \ln i$ ,  $i_t = i_1 + i_2 = 1$  ma,  $R_1 = 10$  ohms, and  $R_2 = 1000$  ohms. By using these values in the above equations it is found that  $i_1 = 0.894$  ma,  $i_2 = 0.106$  ma, and  $\eta_1 - \eta_2 = 0.0927$  v. Thus the two reference electrodes will differ in their readings by approximately 93 mv. If the total current is reduced to  $1 \mu$ a, then  $\eta_1 - \eta_2 = 0.5$  mv and  $i_1 = 0.502 \mu$ a,  $i_2 = 0.497 \mu$ a.

We note that the relative partition of the current varies with the total current and that the two reference electrodes, both placed so as to obviate  $iR$  drop, give different readings with respect to what is in a sense the same electrode (parts connected by an ideal conductor).

<sup>1</sup> This discussion is not meant to be novel, since the "ohmic drop" is well understood by experienced electrochemists, but rather is intended to correct an all too frequently occurring misunderstanding.

Now let us extend this idea to a more common experimental arrangement. In Fig. 2 the indicator electrode B faces the counter electrode A and the rear surface of B is close to a reference electrode C. It may be (falsely) reasoned that C measures the appropriate potential of B at the current density equal to the net current divided by the total area of both sides. In fact, the situation is analogous to the one previously considered. The two surfaces of B are not equally accessible to current streamlines so that differing current densities combine with differing overpotentials to make the electrode an isopotential surface. (For simplicity, we consider that all parts of the rear are equally accessible and all parts of the front of a uniform but different accessibility.) For example, the resistance along a path from the counter electrode to the indicator electrode may be taken to be 10 ohms and that to the rear as 1000 ohms. Then the argument given above applies. We note that the current density as calculated by dividing the net current by the total area (or by one-half of the total area) does not correspond to the apparent measured overpotential. The extent of the discrepancy depends on the net current and on the details of the correct current-overpotential relationship. For other geometries and resistance distributions the error may be greater or lesser.

Fig. 1. Current paths to two parts of an electrode: A, counter electrode; B, C, opposite sides of indicator electrode; D, E, reference electrodes;  $i_1$ ,  $i_2$ ,  $R_1$ ,  $R_2$ , currents and resistances of the respective paths;  $E_1$ ,  $E_2$ , the activation overpotentials appropriate to the two current densities.

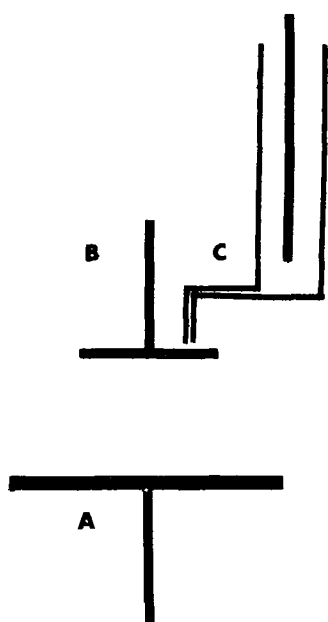

Fig. 2. One method of placing a reference electrode: A, counter electrode; B, indicator electrode; C, reference electrode.

In the case of a plane electrode, against which a Luggin capillary is pressed (Fig. 3), the situation is similar. The presence of the capillary raises the  $iR$  drop on the path to the surface immediately adjacent to the tip so that the current density at that point falls correspondingly. The capillary will then give a true reading of the potential difference between reference electrode and working electrode but at a current density which may be far less than that calculated.

The current distribution in a system without overpotential may be calculated by obtaining the potential from Laplace's equation,  $\nabla^2\phi = 0$ , in the interior of

Fig. 3. Current streamlines near a microelectrode

the solution together with the boundary conditions (electrodes at preassigned potentials), the current being determined by Ohm's law from the potential distribution. In the presence of activation overpotential, the boundary conditions should assign potential drops at the electrode/solution interface which are a given function of the local current density. For an activation controlled reaction in general this leads to a transcendental equation (which, however, is readily solved by computer methods). When concentration overpotential is present the situation is further complicated by the fact that the current distribution changes with time until the steady state is reached.

One means of dealing with the situation experimentally is to make the electrode surface as uniformly accessible as possible and to tolerate an  $iR$  drop which is known. This can be done by the device of placing the reference electrode at a point where it does not interfere significantly with the current streamlines and determining the  $iR$  contribution as outlined below.

#### *Determination of the Resistive Contribution to the Overpotential*

In the study of electrode reactions, substantial currents are sometimes experienced in the course of the study so that contributions to the observed potential from  $iR$  drop are not negligible. The electrode being studied is usually small, may be shielded, or embedded in a cylinder which is being rotated. Thus the placement of the reference electrode can rarely be optimum, that is, the current streamlines proceeding from the counter electrodes to the indicating electrode will lead to a potential distribution and the reference electrode is placed along this potential distribution in such a way that the potential difference between it and the indicator electrode may be considerable.

It is desired to identify this contribution in order that the maximum accuracy may be obtained. Let us assume that a placement of the reference electrode with respect to the indicating electrode has been devised and that the cell is constructed in such a way that the relative positions of the three electrodes are precisely maintained. We now face the problem of evaluating accurately the numerical value of the resistive contribution. It is important to notice that this is not the resistance measured between the reference electrode and the indicating electrode, since this resistance corresponds to the potential difference between the two electrodes for a current distribution which is different from that occurring when the current flows between the indicating and the counter electrode. We proceed as follows: the cell is filled with a solution which is known to behave quite reversibly at the electrodes. We then arrange to apply a signal between the counter electrode and the indicating electrode, the signal being a sinusoidal alternating voltage applied from the signal generator whose peak to peak value is measured as accurately as possible. The potential between the reference electrode and the indicating electrode is now measured as well and compared to that applied between the indicating and counter electrodes. This ratio may be taken at a series of applied frequencies. In the absence of large contributions from shunt capacitance and double layer effects it is expected that the ratio will not be strongly dependent on the frequency. If necessary, it is possible to obtain the ratio at a series of audio frequencies so that, by extrapolating towards zero frequency, the effective d-c resistance can be obtained.

When the cell is now filled with the electrolyte which is to be used in the experiment, the resistance between the working electrode and the indicating electrode is now carefully measured with an alternating current bridge (as a function of frequency if necessary). When the d-c resistance for unpolarized electrodes has been calculated by extrapolation of the a-c value, the effective resistance between the ref-

erence electrode and the indicating electrode is obtained by multiplying this d-c resistance by the limiting value of the ratio obtained above.

This effective resistance can be determined readily with care to four significant figures. (Naturally, double layer corrections, where applicable, would then have to be made.)

When a relationship between the applied potential and the observed current has been obtained, the con-

tribution to the potential arising from  $iR$  drop can be evaluated by simply subtracting from the quantity  $i \times \tau_{\text{eff}}$ , either manually or by appropriate instrumentation.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Brief Communications

### Ion Exchange Membrane Separators for Organic Electrolyte Batteries

A. N. Dey\*

*P. R. Mallory & Co., Inc., Laboratory for Physical Science, Burlington, Massachusetts*

The self-discharge of the nonaqueous Li/CuCl<sub>2</sub> cell has been attributed to the dissolution of the cathode salt in the organic electrolyte (1, 2). The dissolution was caused by the formation of highly soluble chlorocuprate complexes, CuCl<sub>3</sub><sup>-</sup> and CuCl<sub>2</sub><sup>-</sup> (2) which were reduced at the anode. The self-discharge process may be suppressed by a thermodynamic control of the complexation equilibria (1) or by a kinetic control of the rate of reduction or rate of transfer of the oxidant to the anode. We report here on the feasibility of using ion-specific membranes to retard the diffusion of chlorocuprate complexes in organic electrolyte systems.

Data on the behavior of ion exchange membranes or resins in organic solvents like propylene carbonate (PC) and  $\gamma$ -butyrolactone (BL) are scarce. The extent of permselectivity of conventional ion exchange membranes in the above solvents has not yet been established. It has been attempted here to demonstrate the existence of permselectivity of a conventional ion-exchange membrane in BL by studying the transference and self-diffusion properties of the counter ion and co-ions of the membranes.

#### Experimental

**Membrane.**—The ion exchange membrane used was a cation exchange membrane (C-60-81) supplied by American Machine and Foundry Corporation. The membrane was converted into the lithium form by equilibrating with aqueous LiCl solutions for three days with occasional change of solution. The end of conversion was determined by testing aliquots of the LiCl solution for acid. The membrane was superficially dried before use.

**Solutes.**—Anhydrous LiCl, CuCl<sub>2</sub> (Fisher Scientific certified), LiClO<sub>4</sub>, and AgClO<sub>4</sub> (G. Frederick Smith Chemical Company) salts were used as received.

**Transference number.**—The transference number of Li<sup>+</sup> through the cation-exchange membrane (C-60-81) was determined using a cell of the following composition (3).

\* Electrochemical Society Active Member.

The construction of the cell is shown in Fig. 1. The reversible Ag/AgCl electrodes (A) were prepared by pressing thin foils of AgCl on both sides of a silver screen. The electrodes did not show significant polarization at current densities as high as 5 ma/cm<sup>2</sup>. The total capacity of the Ag/AgCl electrode was approximately 100 ma hr. The membrane (B) and the 'O' ring (C) were placed between the two halves of the cell which were clamped together. The 'O' ring provided an adequate seal.

The transference number of Li<sup>+</sup> ion was established by determining the total amount of Cl<sup>-</sup> ion in the anode chamber before and after the passage of the current. The amount of Cl<sup>-</sup> ions in the BL solution was determined by potentiometrically titrating the solutions with standard (0.1(M)) AgClO<sub>4</sub> solutions in BL. The inflexions at the end point were extremely sharp, thus enabling accurate determination of very small concentration changes of the Cl<sup>-</sup> ion.

The procedure was as follows. First, 10 cc of 0.1 (M) LiCl in BL (stock solution) was titrated with standard AgClO<sub>4</sub> solutions in BL. Both anode and cathode compartments of the cell were then filled with 10 cc each of the 0.1(M) LiCl in BL. A current of 0.5 ma (0.25 ma/cm<sup>2</sup>) was passed through the cell for 2 hr.

Fig. 1. The cell for transference number measurement. (A) Ag/AgCl electrode, (B) Cation exchange membrane, (C) 'O' ring.

The solution in the anode compartment was then removed, the compartment rinsed with BL, and the combined solution and rinsings titrated with standard  $\text{AgClO}_4$  solution. The change in  $\text{Cl}^-$  ion in the compartment due to the passage of current was determined from the difference in titration values.

*Diffusion flux.*—The cell used for diffusion flux measurements was identical with that of Fig. 1, except that there were no  $\text{Ag}/\text{AgCl}$  electrodes. The arrangement used to determine the diffusion flux of copper species, e.g.,  $\text{CuCl}_3^-$  through the membrane, was

The diffusion flux of the copper species from the left compartment to the right compartment was determined by following the concentration of copper (polarographically) or  $\text{CuCl}_3^-$  by visual color matching (the solutions of  $\text{CuCl}_3^-$  were highly colored) in the right compartment as a function of time.

The 0.1 (M)  $\text{LiCuCl}_3$  was prepared by taking excess  $\text{CuCl}_2$  in 0.1 (M)  $\text{LiCl}$  in BL. It was shown (2) before that the moles of  $\text{CuCl}_2$  dissolved in BL were roughly equivalent to the moles of  $\text{LiCl}$  present in BL. This was presumed to be due to the formation of highly soluble chlorocuprate complex, e.g.,  $\text{LiCuCl}_3$ .

The arrangement used for determining the diffusion flux of the counter ion,  $\text{Li}^+$ , through the membrane was

The flux of  $\text{Li}^+$  from the left to the right compartment was determined by monitoring the concentrations of lithium in the right compartment by flame photometry (Beckman Du Flame Spectro photometer Model 2400) as a function of time. The  $\text{Ag}^+$  ion was chosen as the cation in the right compartment to avoid interference in flame photometric determination of lithium.

*Sorption measurement.*—Sorption of the copper species by the ion exchange materials was studied by equilibrating known weights of the ion exchange materials with solutions of known concentration of copper in BL and analyzing the solution for the copper after the equilibration. The ion exchange materials used were cation exchange resin, Rexyn (101) and anion exchange resin, Rexyn RG (1) (from Fisher Scientific Co.) and cation exchange membrane C-60-81 and anion exchange membrane A-103-FF (from American Machine & Foundry Corporation). These materials were converted to the  $\text{Li}^+$  and  $\text{Cl}^-$  forms from the  $\text{H}^+$  and  $\text{OH}^-$  forms, respectively, by equilibration with aqueous  $\text{LiCl}$  for one week with occasional change of solution.

The ion exchange materials were weighed after superficial drying. The actual weight of the materials was determined by taking into consideration the amount of water retained according to the manufacturer's specifications. The quantity of the materials used for equilibration with the copper species was such that the total capacity if the ion exchange materials was in excess (approximately ten times) compared to the copper species available in solution. Thus, the presence of small amounts of sorbable copper species could be detected.

The equilibration was carried out by stirring the ion exchange material and the BL solutions of the copper species in a conical flask for three days. No attempt was made to determine the completion of the exchange. The solutions were analyzed for copper polarographically at the beginning and end of the equilibration.

## Results and Discussion

A truly permselective membrane should exclude the co-ions and permit only the counter ions to pass. For a univalent counter ion the transference number through an ideally permselective membrane should be unity. Thus, the determination of the transference number of the counter ion ( $t_+$ ) of an ion exchange membrane gives direct indication of the degree of permselectivity of the membrane.

Considering the cell reaction, it will appear that with electrolysis there will be a decrease in the  $\text{Cl}^-$  ion concentration in the anode compartment. If only the  $\text{Li}^+$  ion is transferred (i.e.,  $t_{\text{Li}^+} = 1$ ), the decrease in  $\text{Cl}^-$  ion will be 1 mole for each faraday. Thus, the transference number for  $\text{Li}^+$  can be determined by using the following relationship

$$t_{\text{Li}^+} = \frac{M_{\text{Cl}^-}^0 - M_{\text{Cl}^-}}{Q} \quad [1]$$

where,  $M_{\text{Cl}^-}^0$  = initial number of moles of  $\text{Cl}^-$  ion in the anode compartment,  $M_{\text{Cl}^-}$  = number of moles of  $\text{Cl}^-$  ion in the anode compartment after passage of  $Q$  faradays of charge. In the above experiments, the total amount of  $\text{Cl}^-$  ion was determined instead of the concentration in order to avoid the errors due to the volume change as a result of electroosmotic solvent transport. The average value of  $t_{\text{Li}^+}$  determined from three experiments was  $0.98 \pm 0.01$ .

The degree of permselectivity  $P$  for an ion exchange membrane can be expressed (4) as

$$P = \frac{t_M - t_S}{1 - t_S} \quad [2]$$

where  $t_M$  = transference number of the univalent counter ion through the membrane and  $t_S$  = transference number of the same ion through the solution. For an ideally permselective membrane  $P \approx 1$ . Using the value of  $t_S$  for  $\text{Li}^+$  as 0.23 [experimental (5) value in  $PC$  is 0.20 and in  $DMF$  is 0.25] and  $t_M$  as 0.98, the degree of permselectivity  $P$  was calculated using Eq. [2]

$$P = 0.97$$

This indicates that a reasonably high degree of permselectivity exists in the nonaqueous system with respect to  $\text{Li}^+$  ion for the cation exchange membrane under consideration.

The results of the sorption measurements are expressed in terms of per cent of initial copper (present in solution) sorbed by the ion-exchange material at the end of the equilibration and are shown in Table I. The results in Table I show that the copper species in solution are preferentially sorbed by the anion exchange materials, thus qualitatively confirming that the copper species in solution are mainly in the anionic ( $\text{CuCl}_3^-$ ) form. The fact that the copper species are preferentially excluded by the cation exchange materials also indicates that the cation exchange mem-

branes could be permselective with respect to the copper species.

Another indication of permselectivity was obtained from the self-diffusion measurements of the  $\text{Li}^+$  ion (counter-ion) and the copper species (co-ion) through a cation exchange membrane (e.g., C-60-81). It can be shown (3) that for a permselective membrane at moderate concentrations of the electrolyte (e.g., less than 1M), the self-diffusion flux of the counter-ions should be considerably greater than the self-diffusion flux of the co-ion. The results of the diffusion flux measurements for the counter ion and the co-ion of the cation exchange membrane C-60-81 in BL are shown in Fig. 2. The diffusion flux of the copper species obtained from the slope of the linear plot was  $2 \cdot 40 \times 10^{-10}$  moles/sec  $\text{cm}^2$ . This flux could be either the diffusion flux of the  $\text{Cl}^-$  ion from the right to the left compartment or the flux of the  $\text{CuCl}_3^-$  ion from the left to the right compartment of a cell, whichever is lower (controlling). It is reasonable to assume from the ion sizes that the self-diffusion flux of the  $\text{CuCl}_3^-$  ion will be lower than that of the  $\text{Cl}^-$  ion as the self-diffusion is mainly dependent on the mobility (3) of the species through the membrane.

The diffusion flux of the counter ion,  $\text{Li}^+$ , obtained from the linear plot was  $3 \cdot 0 \times 10^{-9}$  moles/sec  $\text{cm}^2$ . Again this value represents the diffusion flux of either the  $\text{Ag}^+$  ion or the  $\text{Li}^+$  whichever is controlling. Thus, the comparison between the two values will still be valid. The diffusion of the counter ion is one order of magnitude higher than that of the co-ion. Thus, it is established that ion exchange membranes C-60-81 can be permselective with respect to the dissolved chlorocuprate complex in organic solvents like BL.

The feasibility of retarding the self-discharge of  $\text{CuCl}_2$  cathodes in  $\text{Li}/\text{CuCl}_2$  organic rechargeable systems by using ion exchange membranes is indicated from the above work. Further work in this direction is therefore warranted.

#### Acknowledgment

The author wishes to thank Dr. Per Bro and Dr. J. R. Huff for helpful discussions and Mr. R. W. Holmes for some experimental assistance. Some of this work was carried out under USAMERDC Contract No. DA-44-009-AMC-1537 (T).

Manuscript received Oct. 30, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## On the Role of Lattice Vacancies in Metal Dissolution

D. A. Vermilyea\*

General Electric Research and Development Center, Schenectady, New York

It is usually considered that the dissolution of a clean metal in aqueous solutions takes place by removal of atoms from kink sites in surface steps. The edges of the crystal, as well as screw dislocations, normally provide an abundance of step sources, and under such conditions the driving force at the interface is not great enough to remove atoms from sites other than kink sites.

During corrosion, and especially during stress corrosion, however, a situation which differs in two important respects may be encountered. First, because of the passivity phenomenon the potential may be far more positive than that for the reversible metal-metal ion system. Second, the clean area available for reaction may be minute, especially if this clean area is generated by deformation of the substrate. It is the purpose of this note to consider dissolution when the driving force is high and when no dislocations intersect the bare surface.

Imagine a clean metal surface of arbitrary shape produced, for example, by the emergence of a slip

step on the metal surface and concomitant rupture or drastic thinning of the passive film. The metal will dissolve rapidly because the driving force is high and the surface has high index faces which are stepped. Very shortly, however, the pit will be bounded by low index faces without steps, and rapid dissolution will cease. The surface is now clean but, because there are no kinks, it is unreactive as shown by the following nearest-neighbor calculation.

The activation energy,  $\epsilon$ , for dissolution from a kink site is typically 0.5 ev. An equation valid for high overvoltage is of the type

$$i = zen\nu \exp - (\epsilon - \alpha zF\eta)/kT \quad [1]$$

where  $n$  is the kink density,  $\nu$  the vibration frequency,  $e$  the electronic charge,  $\eta$  the overvoltage, and where the other symbols have the customary meanings. If  $n = 10^{11} \text{ cm}^{-2}$ ,  $\nu = 10^{13} \text{ sec}^{-1}$ ,  $\alpha = 0.5$ , and  $\eta = 0.15\text{v}$ , the current density calculated from this equation for a divalent metal is about 0.3 amp/cm<sup>2</sup> at room temperature, which is plausible. An atom at a kink site on the close packed plane of a face centered cubic metal has

\* Electrochemical Society Active Member.

six nearest neighbor bonds, the strength of each of which is thus  $H_v/6$  where  $H_v$  is the enthalpy of vaporization of the metal. At a site within the close packed plane the atom has nine nearest neighbor bonds, and thus has an additional binding energy of  $H_v/2$ . The activation energy for dissolution would be expected to increase by at least  $H_v/2$ . Using Eq. [1] with  $n = 10^{15} \text{ cm}^{-2}$  then gives for  $H_v = 3.0 \text{ eV}$  a current density of  $10^{-22} \text{ amp/cm}^2$  at  $\eta = 0.15v$ . While this calculation assumes direct transfer at kink sites the same conclusion would be reached if a mechanism involving adsorbed atoms was considered.

The atoms adjacent to a surface vacancy have 8 nearest neighbor bonds, while those near a divacancy have only 7 bonds. The average time required to remove an atom from a vacancy is smaller than from the close packed plane by the factor  $\exp(H_v/6kT)$ , or about  $10^9$  for  $H_v = 3 \text{ eV}$ . At a divacancy the time is  $10^{18}$  times smaller. Suppose the surface has some vacant lattice sites and that the overvoltage is increased until the average time to remove an atom near a vacancy is  $10^2 \text{ sec}$ ; the required overvoltage is about  $0.6v$  for our example. Such an overvoltage would give the negligible current of  $10^{-14} \text{ amp/cm}^2$  from the close packed plane. If there are  $10^{12}$  vacancies per  $\text{cm}^2$ , however, then  $10^{10}$  atoms per  $\text{cm}^2$  would be removed per second near vacancies. Each divacancy created by this process becomes a step nucleus, for the time to remove succeeding atoms from such sites is only  $10^{-7} \text{ sec}$ . A rough estimate of the dissolution current density can be made by noting that  $10^7$  nuclei/ $\text{cm}^2$  would be created in  $10^{-3} \text{ sec}$  and that the steps generated from these nuclei would impinge in about  $10^{-3} \text{ sec}$ . Hence the time to remove an atomic layer would be of the order of  $10^{-3} \text{ sec}$ ; the corresponding current density is  $0.3 \text{ amp/cm}^2$ .

The absolute values obtained in these calculations should not be taken very seriously, and the only point

to be made is that at high overvoltages lattice vacancies may serve as step nuclei. It is also worth noting that divacancies are even more efficient nuclei than are vacancies. If impurities associate with vacancies, then the dissolution of the impurity, which might be more rapid than removal of a solvent atom, can create a divacancy. Conversely, impurities which are more noble could retard step nucleation at a vacancy.

There are two interesting consequences of this possible role of lattice vacancies. The first is that it provides a mechanism for very restricted dissolution during stress corrosion cracking. A slip band may contain many lattice vacancies and be rapidly corroded, while the lattice on each side may be relatively perfect and corrode more slowly. Corrosion tunnels could be formed if the debris was suitably distributed on the slip band. For such a mechanism to be effective it is necessary that steps from dislocation sources be absent or blocked. Steps from sources back along the crack may be blocked by the passive film, but eventually the sides of an advancing crack will encounter other screw dislocations, and it seems that they should be effective step sources. It is not obvious why the crack should not then be rapidly widened; the answer may lie in the mechanism of repassivation, the details of which are poorly understood.

The second consequence is that the injection of vacancies during dissolution of solid solutions appears unlikely. If the overvoltage is raised sufficiently to create vacancies, the vacancies are automatically step sources and have a negligible lifetime.

# "Electrolytic Rectification and Conduction Mechanisms in Anodic Oxide Films"

A Symposium on the "Electrolytic Rectification and Conduction Mechanisms in Anodic Oxide Films" was held at the 131st National Meeting of The Electrochemical Society in Dallas, Texas, May 7-12, 1967. This symposium was sponsored by the Dielectrics and Insulation Division and organized by P. F. Schmidt to bring together the many workers in the field to discuss the current status in this area. Anodic oxides have been used for over fifty years in wet and dry capacitor and rectifier structures, yet concrete mechanisms for asymmetric conduction in these thin dielectric layers have not been completely elucidated. This complexity can be attributed to both the very thin nature (100-5000Å thick) and amorphous state of the oxide which probably lead to the existence of several mechanisms of conduction. These mechanisms have sufficient similar observable conduction characteristics to require extremely careful experimental techniques and diagnostic tests which have not been pursued in all investigations. Moreover, the amorphous state of the oxides, their high impurity content, and the low mobilities of the charge carriers have provided conceptual difficulties since the conventional energy band picture for single crystal or polycrystalline solids may be inadequate for describing transport properties.

Most of the papers presented in this Symposium appear in this issue of the Journal, but for completeness the actual symposium consisted of the following papers:

Both the metal/oxide/electrolyte and the metal/oxide/metal systems were treated. Three papers (Boddy, Hale, and Doremus) tried to approach the subject from a comparative point of view by correlating electrode effects of "bulk" materials with the electrical properties of thin insulating films (by "bulk" is meant  $\gg 1000\text{\AA}$ ). P. J. Boddy presented evidence that the primary step in the mechanism of electronic current flow through semiconducting TiO<sub>2</sub> electrodes, biased anodically in contact with an electrolyte, is electron tunneling from lattice oxide ions at the oxide/electrolyte interface. An interesting and apparently hitherto unexplored effect is the insensitivity of the semiconducting TiO<sub>2</sub> electrode to the kind of ions in the electrolyte, whereas the anodic current density of insulating oxide films appears to be sensitive to the redox potential of the electrolyte.

J. M. Hale treated the insulator/electrolyte system from the theoretical point of view assuming that the oxide is ideally perfect. The predictions of the theory can be checked by means of anthracene electrodes, single crystals of this material being available in good quality. Recent work (Hale, Gerischer) seems to indicate that injection of protons can assist the potential bending inside the solid to the extent that hole injection by the electrolyte becomes possible under conditions where the redox potential of the solution would not suffice by itself.

A group of papers (Doremus, Schmidt, Vermilyea, Michelson) was concerned with the injection and motion of protons in oxide films. R. H. Doremus reviewed the ionic transport and membrane potentials at the interface amorphous oxide/aqueous electrolyte, with emphasis on fused silica for which system the theory is well advanced. The surface hydration and injection of protons into thin anodic oxide films is obviously a closely related subject.

P. F. Schmidt presented evidence that hydration of anodic SiO<sub>2</sub> films is a prerequisite for proton injection, the latter in turn being required to cause appreciable current flow, due either to enhanced field emission or to space charge neutralization of trapped electrons. He also provided a literature review from 1960-1966 of papers dealing directly or indirectly with electronic and/or protonic current flow through oxide films. The paper by D. A. Vermilyea consisted of an analysis of the discrepancies between results obtained from current-voltage and from capacitance-voltage curves on tantalum and niobium pentoxide films. While the evidence for proton injection is very strong, especially when comparing results obtained with H<sub>2</sub>O to those obtained with D<sub>2</sub>O, it appears quite likely that electronic currents are responsible for some of the observed discrepancies.

C. E. Michelson analyzed the current-voltage characteristics of porous Al<sub>2</sub>O<sub>3</sub> films; his model is based on proton transfer in a hydrogen-bonded network assumed to exist in the partially hydrated oxide film.

The substrate metal/oxide interface was the subject of two papers. Ta/Ta<sub>2</sub>O<sub>5</sub> or Nb/Nb<sub>2</sub>O<sub>5</sub> structures show an enhanced conductivity after annealing in air at 300°-500°C, which is apparently due to the gettering of some oxygen from the oxide by the substrate metal. D. M. Smyth and G. A. Shirn treated an exponential conductivity profile in the oxide after annealing, whereas K. Lehovc fitted the data to a model of tunneling from and to states in the oxide. Detailed studies of the interface substrate metal/oxide are clearly very important in understanding the electrical properties of thin oxide films. Studies on double injection and recombination luminescence, in which the injecting properties of the substrate are varied in controlled fashion, would be of considerable interest.

Control of the current flow not by barriers at the interface but by electronic processes in the bulk of the thin film was the topic of papers by T. W. Hickmott and by F. Huber. The paper by Hickmott, who was able to present a fairly detailed energy band picture for anodic Nb<sub>2</sub>O<sub>5</sub>, including an impurity band located 1.2 eV below the oxide conduction band, served to highlight the danger in carrying generalization about any mechanism of electrolytic rectification too far. Clearly the density and location in energy of impurity states will vary from one metal oxide to the next. Hickmott also presented conclusive evidence for double injection in Nb<sub>2</sub>O<sub>5</sub> film, the hole injection being dependent on the work function of the outer metal contact. Hickmott's work raises the interesting question whether the p-i-n junction observed by Huber in anodic oxide films on titanium is due to hole injection

\* These papers appear in this Journal issue.

‡ These papers will be submitted to the Journal.

from the high work function metal contact [as also observed for CdS by Boer and Ward, *Phys. Rev.*, **154**, 757 (1967)], or whether the p-region indeed exists in the outer oxide surface as a consequence of the anodic growth mechanism in the electrolyte used by Huber; the high work function contact metal would then be required only to make ohmic contact to the p-region. The field effect transistor action reported by Huber is certainly of considerable interest.

Evidence for the existence of electrical flaws in thin Ta/Ta<sub>2</sub>O<sub>5</sub> metal structures and the effect of impurity additions to the tantalum substrate on the number and perhaps kind of flaws was presented by N. Schwartz and N. N. Axelrod. Such additions can decrease the number of flaws and thereby also the degree of asymmetry of the electrical properties of the oxide. It is rather surprising that while additions of 10-30 a/o (atom per cent) of such elements as N, O, or C are

required to affect the number of flaws appreciably, as little as 1 a/o of Mo is sufficient for this purpose. Here is clearly a vast and as yet hardly touched field for further material research.

Space charge limited current flow and trap distribution in anodic oxide films on tantalum, as well as drift phenomena on aging which may permit predictions concerning the reliability of devices, was studied by I. M. Walker.

The symposium raised many interesting questions and final answers are still to be sought in many areas. This collection of papers will serve as a current review of the field and hopefully will stimulate further detailed experimental and theoretical work on this subject.

## On the Mechanisms of Electrolytic Rectification

P. F. Schmidt\*

*Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania*

### ABSTRACT

A literature survey of papers dealing with electrolytic rectification and related topics is given for the period 1959-1966. Experiments on current flow in the system n-type Si/SiO<sub>2</sub>/electrolyte are then presented, which indicate the importance of adsorbed water for the electrical properties of this system. The initial increase in conductivity after exposure of the anodic SiO<sub>2</sub> film to water is likely to be of electronic origin. However, protons can be injected at low voltages into the hydrated SiO<sub>2</sub> but not into dry SiO<sub>2</sub>. The injected protons cause a gradual increase of current with time at constant voltage due to enhanced field emission from traps and/or from the cathode. Hydration of the oxide, and its electrical properties, can be reversed by a bake at 150°C in air. Either alkali ions or protons, or both, incorporated into an anodic oxide film by anodization in an incompletely "dry" organic solvent, have a strong effect on lowering the cathodic breakdown voltage at which the current begins to increase with time at constant voltage.

When we first started to concern ourselves with the mechanism of electrolytic rectification, some ten years ago, we approached the problem from the point of view that there ought to be a common cause to the seemingly common phenomenon of oxide covered valve metals passing large currents when biased cathodically in an aqueous electrolyte. The common cause, we presumed, was the penetration of protons into anodic oxide films under cathodic bias in aqueous solution. We, therefore, set forth to prove that no appreciable current would flow in an aprotic solvent like liquid sulfur dioxide in the presence only of large cations like rubidium. This prediction certainly proved correct, but we also came across some unexpected phenomena which we could not explain at the time. We should like to summarize here briefly the main points of that work, published in 1960 with Huber and Schwarz (1), because the results will be of interest in connection with more recent work.

Large alkali ions like K<sup>+</sup> and Rb<sup>+</sup> were found to block the cathodic current very effectively in liquid SO<sub>2</sub>, and up to quite large voltages, whereas small alkali ions like Na<sup>+</sup> and Li<sup>+</sup> pass currents as much as a factor of 10<sup>5</sup> larger at the same applied voltage. Addition of water to the solutions of Rb<sup>+</sup> or K<sup>+</sup> in liquid SO<sub>2</sub> is unimportant, the water apparently freezes out or is complexed without affecting the electrode reaction. At low cathodic voltages, however, the picture was inverted and the larger cations gave somewhat larger currents. Apparently, the large cations are adsorbed to the oxide surface, whereas the small cations are not and must first displace other adsorbed

species under cathodic bias before they can become effective. It was definitely not possible to account for the effect by assuming that Na<sup>+</sup> or Li<sup>+</sup> is able to penetrate into the oxide films, especially in view of the observation that the current in solutions containing a mixture of Rb<sup>+</sup> and Na<sup>+</sup> iodide fluctuated between small and large values. It is difficult to see how the current could decay again once sodium ions have penetrated into the oxide, whereas an explanation is readily available if competing adsorption to the surface of the oxide is held responsible. Vermilyea (2) has since shown for Ta<sub>2</sub>O<sub>5</sub>, one of the oxides studied by Schmidt *et al.* (1), that penetration of sodium ions is not possible even at room temperature. He also showed that Li<sup>+</sup> ions can penetrate from certain non-aqueous solvents but not from aqueous solution where they are apparently too strongly bonded. The same apparently applies to Li<sup>+</sup> in liquid SO<sub>2</sub>, where it is known to be very strongly complexed.

Another remarkable effect was the large activation energy for cathodic current flow in Ta<sub>2</sub>O<sub>5</sub> in the presence of Na<sup>+</sup> and Li<sup>+</sup> ions, *i.e.*, much larger rates coupled with much higher activation energies. Figures 1 and 2 illustrate these points.

The most plausible explanation at the time was that the high local field in the vicinity of a small cation is able to extract electrons from traps in the forbidden gap of the insulator. The inefficiency of the large cations to promote cathodic current flow was attributed to the lower local field strength in their vicinity. A possible alternate explanation arises from the higher deposition potential of the larger alkali ions: an electron arriving at the oxide/electrolyte interface would

Fig. 1. Cathodic current in the system Ta/Ta<sub>2</sub>O<sub>5</sub>/liquid SO<sub>2</sub> as a function of cation size. Ta/Ta<sub>2</sub>O<sub>5</sub> formed to +50v, temperature of measurement -60°C. [Fig. 2 of ref. (1)].

Fig. 2. Apparent activation energies for cathodic current flow in the system Ta/Ta<sub>2</sub>O<sub>5</sub>/liquid SO<sub>2</sub> as a function of cation size. Ta/Ta<sub>2</sub>O<sub>5</sub> formed to +50v, cathodic field strength  $9.0 \times 10^5$  v/cm. [Fig. 7(a) of ref. (1)].

see a higher barrier. Expressing this in another manner: the empty levels of the K<sup>+</sup> and Rb<sup>+</sup> ions in solution may be located above the conduction levels for electrons in the oxide. It is worth noting, however, that the explanation offered for Na<sup>+</sup> and Li<sup>+</sup> ions should still apply because the cathodic current in the case of these ions is many orders of magnitude larger than with high work function metal contacts.

Two other, and apparently contradictory findings concerned the conductivity of thin anodic Al<sub>2</sub>O<sub>3</sub> windows sandwiched between two aqueous electrolyte contacts and the increased conductivity of tantalum pentoxide films with platinum contacts when inserted in a hydrogen atmosphere. It was found that the Al<sub>2</sub>O<sub>3</sub> window passed negligible currents when a bias was applied between the two electrolyte contacts; this observation seemed to negate the penetration of protons into the alumina. The tantalum pentoxide with Pt contacts, on the other hand, showed increased conductivity in a hydrogen atmosphere under cathodic bias, which was largely removed under anodic bias. This experiment clearly pointed toward protonic con-

ductivity. Faced with this discrepancy, we chose not to say much about protons or aqueous contacts in our 1960 paper and limited ourselves mostly to the liquid SO<sub>2</sub> system.

We know now that the two results just quoted are not really as contradictory as they appeared to us at the time, and that it is a gross oversimplification to apply the same criteria to all anodic oxide films irrespective of their chemical composition. We shall hear more about these differences between individual metal oxides during the course of this meeting. It is also worth noting that our 1960 work was carried out exclusively on films 500Å or thicker; we thus missed the pronounced differences in the behavior of films in the 100-300Å range, since then discovered by Vermilyea (2).

In our 1960 paper we included a literature survey in addition to presenting our own work. We shall follow the same course here, taking 1959 as the starting point and in this manner trying to provide continuity of literature coverage.<sup>1</sup>

In this survey we shall include not only studies directly concerned with electrolytic rectification, but also other work which we feel is related to this problem. In doing so a certain arbitrariness of judgment has, of course, been unavoidable. I shall mention only very briefly the fascinating work by Vermilyea, Hickmott, Smyth, and Huber, since we shall have the pleasure of personal presentation by these researchers later in the symposium.

#### New Work since 1959

**Nonuniformity of anodic oxide films.**—The cathodic resistivity of sputtered and then anodized Ta films was shown by Schwartz and Gresh (5) to increase with decreasing size of the metal counter electrode, indicating the existence of "weak spots." The resistivity of the weak spots was shown to be very dependent on the relative humidity under anodic bias, whereas there was little effect of humidity under cathodic bias. The existence of weak spots is also known from the Al/Al<sub>2</sub>O<sub>3</sub>/Al thin film capacitor field, where weak spots can be destructively eliminated by biasing the sandwich into breakdown; the Al top electrode at the breakdown spots is either evaporated or converted to oxide. The emission of lights from "hot spots," as observed, for instance, by Hickmott (68) in his work on negative resistance in metal/oxide/metal sandwiches, is also indicative of "weak spots." One may presume that the occurrence of "weak spots" is related to the intrinsic purity of the substrate and to the perfection of surface treatment prior to anodization. Working with epitaxially deposited silicon films anodized immediately after epitaxy, the author has indeed found it quite difficult to detect weak spots; essentially the whole surface has uniform properties.

**Porosity of anodic oxide films.**—Politycki and Fuchs (6) showed by transmission electron microscopy (TEM) that SiO<sub>2</sub> films grown in N-methylacetamide/KNO<sub>3</sub> solution were free from pores, whereas SiO<sub>2</sub> films grown in aqueous borate solution are quite porous. In fact, the anodization of silicon in aqueous electrolytes bears distinct similarity to the anodization of aluminum in acidic solutions. Claussen and Flower (7) found some pores in SiO<sub>2</sub> grown in N-methylacetamide by means of TEM, but attributed the porosity to insufficient surface preparation. Schmidt *et al.* (8) showed by TEM that SiO<sub>2</sub> films grown in KNO<sub>2</sub>/tetrahydrofurfuryl alcohol (THFA) solution were completely free from pores. Duffek *et al.* (9) compared the "pin-hole" density of thermal and of anodic SiO<sub>2</sub>

<sup>1</sup> In the 1960 survey, reference was inadvertently omitted to the old but probably significant observations by Van Geel (3) that Cu<sub>2</sub>S or CuI pressure contacts to anodic Al<sub>2</sub>O<sub>3</sub> films give cathodic currents of the same magnitude as aqueous electrolytes. The p-i-n junction theory by Sasaki (4) appeared too late for inclusion in the survey, but a reference to a talk by Kobayashi on the same topic was included.

films, grown in a solution of  $\text{KNO}_3$  in ethylene glycol,<sup>2</sup> and found by means of the chlorine etching test that anodic films contained an order of magnitude fewer pin-holes than did the thermal  $\text{SiO}_2$  films.

*Adsorption on and penetration of protons into oxide films.*—The accepted picture of a solid oxide in contact with water is that of a hydration of the outermost or the outer oxide layers, with a certain mobility of protons in this structure. Wei and Bernstein (10) and Feitknecht *et al.* (11) measured the proton diffusivities in  $\text{AlO}(\text{OH})$ ,  $\text{Ni}(\text{OH})_2$ , and  $\text{FeOOH}$ , and found values between  $10^{-19}$  and  $2 \times 10^{-23}$   $\text{cm}^2 \text{sec}^{-1}$ . Onoda and De Bruyn (12) studied the system  $\text{Fe}_2\text{O}_3/\text{H}_2\text{O}$  and showed that a very fast surface reaction was followed by a slow diffusion of protons into a goethite-like interphase separating the bulk oxide from the solution. Proton conductivity in borax was studied by Maricic *et al.* (13) who observed that protonic conduction ceases below  $21^\circ\text{C}$ .

Schwabe (14) measured the release of tritium from alumina films, grown in tritiated solution, when an anodic bias was applied after transfer of the specimen to a nontracer solution. Krembs (15) published similar work on  $\text{Ta}_2\text{O}_5$ . Vermilyea (16) studied in detail the adsorption or desorption of protons on  $\text{Nb}_2\text{O}_5$  and  $\text{Ta}_2\text{O}_5$  films. In a later paper (17) he measured a potential dependent protonic space charge in thin anodic oxide films on Ta, Nb, Ti, W, and Sb, but could not detect the same effect on metals like Al, Zr, or Si; this may be attributable to a much lower mobility of protons in these latter oxides. The proton mobility in  $\text{Ta}_2\text{O}_5$  above  $25^\circ\text{C}$  seems to be indeed unusually large,  $10^{-7}$   $\text{cm}^2/\text{volt sec}$ ; below  $25^\circ\text{C}$  it drops sharply. The room temperature mobility of protons, introduced by electrolysis into vitreous silica, is only  $2.1 \times 10^{-23}$   $\text{cm}^2/\text{volt sec}$ , extrapolating the data by Hetherington *et al.* (18) and using their activation energy of 1.1 ev. [The activation energy for sodium migration in vitreous silica is 1.34 ev according to Owen and Douglas (19).] Hofstein (20) recently observed an extremely fast relaxation process in sodium contaminated thermal  $\text{SiO}_2$  films on silicon, which he attributes to protons. Even the mobility of this very fast species in  $\text{SiO}_2$  films is only  $1.7 \times 10^{-12}$   $\text{cm}^2/\text{volt sec}$  at room temperature, using the activation energy reported by Hofstein (0.68 ev) for the extrapolation. The higher mobility of protons in thermal  $\text{SiO}_2$  films as compared to vitreous silica is perhaps not unreasonable in view of the higher hydroxyl content and possible structural differences of the thermal film. Hofstein's measurements were taken at temperatures above  $27^\circ\text{C}$ . In view of the findings of Maricic *et al.* (13) and of Vermilyea (17) it would be of interest to determine the temperature at which protonic conduction in  $\text{SiO}_2$  ceases. The drift of sodium in thermal  $\text{SiO}_2$  films has, of course, been studied intensively in connection with silicon device work. Snow *et al.* (21) found the activation energy for sodium migration to be approximately the same as in vitreous silica (19). Hofstein (20), however, suggests that the activation energy measured by Snow *et al.* (21) actually applies to the release of the migrating species from a potential well at the outer oxide surface, and not to migration through the bulk of the oxide; the numerical agreement of the activation energy with that measured for sodium in vitreous silica (19) would thus be fortuitous. Yon *et al.* (22) used tracer counting techniques and stepwise dissolution of the oxide to measure the sodium distribution before and after drift. He showed on rather heavily sodium contaminated oxide films that the bulk of the sodium does not redistribute itself significantly during the fast relaxation process reported by Hofstein (20). Kerr (23), on the other hand, using lower levels of contamination and radioautographs in con-

junction with stepwise dissolution of the oxide, finds that all of the sodium reverts to the outer oxide surface.<sup>3</sup> Garino-Canina and Priqueler (24) and Hetherington *et al.* (18) studied the introduction of protons in vitreous silica by high-temperature electrolysis; protonic conductivity of the  $\text{SiO}_2$  is promoted by an aluminum content (or presumably other equivalent defects). Fowkes *et al.* (25) showed that the bulk of tritium incorporated into  $\text{SiO}_2$  by growing  $\text{SiO}_2$  at high temperatures in tritiated water is quite immobile under an applied bias. However, these tritium tracer experiments did not have the same sensitivity as electrical measurements on silicon, and a small fraction of highly mobile protons may have escaped detection. Mitchel and Salomon (26) investigated the permeation of aqueous  $\text{KNO}_3$  solution through anodic  $\text{ZrO}_2$  films, isolated from the substrate by etching in dry chlorine. Significant permeation rates, with an activation energy of 0.74 ev, were observed. The high activation energy, together with the reproducibility of the phenomenon, were considered as evidence that permeation occurs through a network of interstices, rather than through random gross flaws. Free diffusion in water requires activation energies of 0.17–0.22 ev. Dreiner (27) studied the increase in capacitance of anodic  $\text{SiO}_2$  films when in contact with water or a solvent containing water. The rate of capacitance increase obeys a square root of time relationship, with an activation energy 0.66 ev, and could be accelerated by application of a moderate anodic bias. Water is assumed to diffuse into the surface layers of the oxide film where it dissociates to form OH groups which can be acted on by the electric field. Schmidt and Rand (28) investigated the mutual transformation of thermal and anodic  $\text{SiO}_2$  films by anodic or heat-treatment, respectively. The thermal and anodic  $\text{SiO}_2$  films are structurally different, the volume of the anodic  $\text{SiO}_2$  being about 3.8% larger, depending on the electrolyte used. Anodization of thermal  $\text{SiO}_2$  films introduces a hydroxyl band in the IR spectrum of the bulk oxide and increases drastically the insulation resistance of the thermal film. This increase in resistance is probably due only in part to plugging of pin-holes by anodization; generation of deep traps appears to be involved. Ehrenberg *et al.* (29) suggest that OH groups in fused silica provide very deep electron traps. Isaacs and Llewelyn Leach (30) studied the capacitance of a large number of anodized metals by means of a square current pulse technique. They attributed the very large capacitance changes observed under cathodic bias on a number of the transition group metal oxides to reversible chemical reactions occurring within the film.

*Enhanced conductivity in the presence of water.*—The donor action of adsorbed water vapor is well known (31). Thus adsorption of water onto the surface of an insulator or a high resistivity n-type semiconductor can increase the conductivity of the substrate due to the electrons transferred from the adsorbate. This transfer of electrons, of course, causes the appearance of empty levels on the water molecules, and Stutz and De Mars (32) have indeed suggested that hole-type electronic conductivity can occur in layers of water adsorbed onto  $\text{SiO}_2$ . It is, of course, difficult to distinguish between hole conduction in the adsorbed water layer, and electron conduction in the dielectric directly underneath.

A protonic conductivity can arise at adsorbate concentrations such that hydrogen bonded networks exist on the surface of the adsorbent. The elegant work by Eigen and De Maeyer (33) and by Riehl *et al.* (34) on the conductivity of ice leaves no doubt about the reality and importance of this mechanism. It was

<sup>3</sup>Note added in proof: The existence of a fast and of a slow moving Na species, as well as of electrically active and inactive Na in thermal  $\text{SiO}_2$  films seems by now well established, largely due to further work by Hofstein; the same applies to protons in thermal  $\text{SiO}_2$  films (20a).

<sup>2</sup>In the experience of the author, ethylene glycol is not one of the best solvents for the anodization of silicon.

found possible to inject protons into ice by suitable electrodes, to measure space charge limited proton currents, and to observe the trapping of protons at lattice defects, *i.e.*, to establish a full analogy to electronic semiconductors. Gosar (35) actually attributed the proton mobility in ice not to a "hopping process" but to a proton conduction band. It is worth noting that a 1000Å thick film of pure ice with injecting electrodes would pass currents in the milliamperes/square centimeter range under application of a few volts bias. Klotz (36) suggested a mechanism by which hydrogen in a bonded network can transport electrons.

Shockley *et al.* (37) studied quantitatively the charge separation in humid atmosphere on SiO<sub>2</sub> in the fringing field of a p-n junction underneath a SiO<sub>2</sub> film. He was able to show that the electric effects in the silicon observed under these conditions were due to lateral charge motion on the silica surface, as suggested by Atalla *et al.* (38) and not due to charge motion in the oxide perpendicular to the surface. He did not specify the nature of the charge carriers. A phenomenological model of enhanced conductivity due to adsorbed water vapor is due to Rosenberg (39) who showed that there exists an inverse logarithmic relationship between the ratio of the conductivities before and after adsorption and the dielectric constant of the adsorbate/adsorbent complex. The relationship has been shown to hold for a large number of adsorbents and adsorbates. The additional conductivity is ohmic up to the highest field strengths tested (10<sup>5</sup> v/cm). Rosenberg was also able to prove that the conductivity is strictly electronic at low levels of water adsorption, and that protonic conductivity appears only at large percentages of adsorbed water. The increase of conductivity is a d-c or low-frequency phenomenon and disappears at about 10<sup>4</sup> Hz.

Anderson (40) combined infrared measurements with measurements of the conductivity of silica exposed to water vapor at various pressures, and observed enhanced conductivity which he attributed to proton migration on the basis of the conductivities in H<sub>2</sub>O and in D<sub>2</sub>O vapor. He also observed that, while the conductivity of his samples increased with increasing water content, it decreased at constant water content with increasing hydroxyl content (IR evidence). Because of this latter observation he prefers to explain the enhanced conductivity as due to an increase in dielectric constant, as suggested by Rosenberg, rather than on the structural model for protonic conduction in a hydrogen bonded network suggested by E. J. Murphy (41). Anderson's work was done mostly under conditions of high water vapor pressure, so that there exists no discrepancy between his postulate of protonic conductivity and Rosenberg's results.

J. F. Murphy (42) applied the concepts of proton transfer in a hydrogen bonded network to explain the formation and conduction properties of porous Al<sub>2</sub>O<sub>3</sub> films in acidic anodizing media. His model avoids some of the difficulties of earlier theories of porous oxide formation on aluminum (43).

*Injecting contacts and space charge limited currents in solids.*—A great many papers have been published on this subject during the past decade, especially by the group at RCA (44), by Wright in England (45) and by Stöckmann in Germany (46). Double injection of holes and electrons has received particular attention more recently (47), and this work is being extended to electrolyte contacts (48). Mehl *et al.* (49) observed double injection and space charge limited currents for both holes and electrons in anthracene crystals, Van Ruyven and Williams (50) hole injection into n-type ZnS. These findings, as well as the work of Gerischer (51) and of Brattain and Boddy (52) on germanium are of particular interest here because they permit unambiguous determination of the energy

levels in the electrolyte relative to those in the solid and enable prediction whether hole injection by the electrolyte may be expected for a given system. Keating (53) studied hole injection into CdS films by Cu<sub>2</sub>S contacts. This work immediately brings to mind the old experiments by Van Geel on Cu<sub>2</sub>S pressure contacts to anodic Al<sub>2</sub>O<sub>3</sub> films. Lindmayer (54) considered discharge transients from a dielectric sandwiched between metal electrodes. He also observed an inverse time relationship, as did Dreiner (84). In view of what has just been said it is clear that double injection is also a definite possibility if protons can be injected into an oxide film. One would then want to know the efficiencies of the two contacts, potential distribution in the film, mobilities of the species in the film, the capture cross section and trapping probabilities, etc.

*Barrier heights at the metal/oxide interface.*—Barrier heights at the Al<sub>2</sub>O<sub>3</sub> interface have been measured by a number of authors (55) in connection with work on tunnel diode or triode structures. The barrier heights have kept increasing with time, apparently as the purity of the materials and the experimental techniques improved.

Very precise data on the barrier height at the Al/Al<sub>2</sub>O<sub>3</sub> interface have been obtained by Pollack and co-workers (56) who showed that at room temperature both tunnel emission and Schottky emission occurs from the Al substrate of sufficiently thin Al<sub>2</sub>O<sub>3</sub> films, whereas at low temperatures Schottky emission ceases. Williams (57) determined the barrier height for photoemission of electrons from Si into SiO<sub>2</sub>. The work was extended to the Au/SiO<sub>2</sub> barrier by Goodman (58), and very recently to five other metal/SiO<sub>2</sub> barriers (Ag, Al, Cu, Mg, and Ni) by Deal *et al.* (59). Deal *et al.* used both the photoemission threshold and MOS capacitance-voltage measurements for determination of the barrier heights. For the Si/SiO<sub>2</sub> barrier energy, as measured from the silicon valence band, they find 4.35 eV, independent of silicon orientation or type. A barrier of 4.35V is obviously much too high for thermionic emission at room temperature. If appreciable electron emission is nevertheless observed under conditions where the externally applied field is too low to cause a significant tilting of the energy bands, then one must look for mechanisms that could reduce the barrier height. Impurity bands in impure oxides, or migration of small cations like H<sup>+</sup> or Na<sup>+</sup> to the SiO<sub>2</sub>/Si interface are distinct possibilities for lowering of the effective barrier height. Mead (60) drew attention to the fact that a relationship: log current density prop. V<sup>1/2</sup>, may be interpreted as field enhanced thermal excitation of trapped electrons into the conduction band (Poole-Frenkel effect), and that careful measurements are required to distinguish this mechanism of current flow from Schottky emission. Mead's argument, however, that the current through quite thin Ta<sub>2</sub>O<sub>5</sub> films is completely bulk controlled appears somewhat vulnerable in view of his use of the static dielectric constant of Ta<sub>2</sub>O<sub>5</sub> as pointed out also by Goruk, Young, and Zobel (78).<sup>4</sup> Williams (61) investigated the prebreakdown current in CdS, NaCl, and CdF<sub>2</sub>, and found that in all cases the steep rise in current just prior to breakdown must be ascribed to field emission from the electrodes but not to impact ionization. Exclusive control of the current by bulk processes rather than by the electrodes is thus not likely to be the rule in thin metal/oxide/metal sandwiches.

Standley and Maissel (62) published a paper on barriers of various counter electrodes on Ta<sub>2</sub>O<sub>5</sub> thin films (100-200Å). They also observed an effect of a nitrogen content of the Ta substrate on the electrical

<sup>4</sup>Note added in proof: This question has since been clarified by work by Mead *et al.* [J. Appl. Phys., 38, 2384 (1967)], and by J. G. Simmons [Phys. Rev., 155, 657 (1967)]. The papers by J. J. O'Dwyer [J. Appl. Phys., 37, 599 (1966)] and by S. M. Sze [J. Appl. Phys., 38, 2951 (1967)] and by A. K. Jonscher [Thin Solid Films, 1, 213 (1967)] should also be consulted in this context.

properties of the oxide, as studied in more detail by Schwartz *et al.* (63).

*Heat-treatment of anodic oxide films.*—Smyth *et al.* (64) studied the effect of heat-treatment on anodic oxide films on Ta and Nb. They found a permanent conductivity increase at temperatures exceeding 200°C, which they attributed to the gettering of oxygen from the film by the substrate. It would be quite interesting to see the results of photoelectric measurements on such films before and after heat-treatment. Somewhat similar trends, but of course not nearly so pronounced, were observed by Heine and Sperry (65) for oxide films on aluminum. Anodic oxide films (not heat-treated) show a region of uniform resistivity extending through most of their thickness, deviations occurring only directly at the two interfaces. Thermally grown  $\text{Al}_2\text{O}_3$  films on the other hand show a resistivity increasing monotonically from the metal to the outer surface, reflecting the ionic gradients during oxidation.

*Semiconducting anodic oxide films on titanium.*—Huber reported a series of measurements (66) on thin (200–300Å) anodic oxide films on Ti formed in certain electrolytes under conditions of very high current densities. The evaporated Ti films, serving as the anode, may also have been Ta doped, due to the use of a Ta boat during evaporation. The oxide films showed I-V characteristics, capacitances, and photovoltages which are much more suggestive of semiconductor diodes than of insulator films. This appears to be an outstanding example of how much properties can vary from one metal oxide to the other, especially with the transition group metals, and how important impurities and forming conditions can be. Chopra and Bobb (67) also reported on semiconductor-type photovoltages in Nb/Nb<sub>2</sub>O<sub>5</sub> semitransparent metal sandwiches.

*Negative resistances in anodic oxide films.*—Voltage controlled negative resistance (VCNR) in anodic oxide films on a variety of metals, and also in evaporated SiO films, has been studied extensively by Hickmott (68). Very high current densities, up to 34 amp/cm<sup>2</sup>, can be drawn nondestructively through 350Å  $\text{Al}_2\text{O}_3$  films. The true current densities are presumably higher still if one allows for the "bright spots" observed by Hickmott in the light emission from his diodes.

The current controlled negative resistance in Nb/Nb<sub>2</sub>O<sub>5</sub>/metal sandwiches studied by Chopra, (69), Geppert (70), Beam and Armstrong (71), and by Hiatt and Hickmott (72) can be developed also in air. The insulating oxide is "deformed" by forcing a critical current density through it; thermally grown oxides are more easily deformed than anodic oxides. Chopra (69) interprets the phenomenon as avalanche multiplication of carriers in a thin, high field region of the oxide attended by space charge limited flow conditions. The relationship  $I \propto V^n/d^3$  was observed by him both at 77° and at 298°K. Current controlled negative resistance in  $\text{Al}_2\text{O}_3$  was reported recently by Argall (73).

*Conductivity type of anodic oxide films.*—One often finds in the older literature the statement that anodic oxide films are n-type due to an excess of metal at the oxide/metal interface. P-type conductivity at the oxide/electrolyte interface has also been postulated (4). Harrop and Wanklyn (74) measured the conductivity type of anodic oxide films on zirconium produced by anodization in a dilute solution of potassium hydroxide in water, and found p-type conductivity from the sign of the thermoelectric power. Extension of the thermoelectric measurements to other oxide films, and produced in a variety of anodizing solutions, appears desirable.

*Mechanism of anodic oxide growth.*—Implantation of radioactive noble gas ions was used by Davies *et al.* (75) and by Amsel and Samuels (76) to study the

mechanism of anodic oxide growth, whether by cation or anion migration. The general conclusion is that both species are mobile, and that the fraction of current transported by cations or anions is a function of the applied field strength, and probably also of the forming electrolyte. Silicon appears to present a special case, since here only the cation was found to be mobile for the electrolytes and current density ranges investigated (77). The conclusion is based on the use of radioactive phosphorus as a marker, and since the measurements were made at phosphorus concentrations as low as  $10^{18}$  cm<sup>-3</sup>, it does not appear likely that the result is falsified by the phosphorus content of the oxide.

An extensive review of ionic and electronic currents at high fields in anodic oxide film by Goruk, Young, and Zobel (78) has just appeared in Volume 4 of "Modern Aspects of Electrochemistry."

*Stresses in anodic oxide films.*—Strongly stressed films may be expected to crack easily, for instance, when exposed to a strong current pulse; the mechanical condition of the film may therefore be a relevant factor. Stress measurements as a function of polarity of bias, current density during formation, and anodizing medium were reported by Vermilyea (79) and by Bradhurst and Llewelyn Leach (80). Schmidt and Rand (28) showed that no or only weak stresses were present in anodic SiO<sub>2</sub> films grown in relatively concentrated KNO<sub>2</sub>/THFA solution to a thickness of 1400Å. Increased tensile stresses, however, are observed in thicker SiO<sub>2</sub> films (unpublished results), grown in more dilute solution of KNO<sub>2</sub>/THFA.

*Photoeffects in anodic oxide films.*—Lewowski (81) investigated the cathodic light flashes of Al/Al<sub>2</sub>O<sub>3</sub> electrodes under a-c bias. He reported that the cathodic light flash observable in a 1% aqueous solution of oxalic acid is suppressed by the addition of borax to the oxalic acid solution. Ganley (82) repeated these experiments under better controlled conditions (measurement of the potential rather than the cell voltage) and noticed that the oxide became conductive at a small negative potential in the solution containing borax, but showed a high resistance up to large cathodic voltages in the pure oxalic acid solution. The reason for the absence of cathodic electroluminescence in the solution containing oxalic acid plus borax is thus simply the absence of a high electric field across the oxide layer. More interesting than this somewhat trivial explanation is the observation that the addition of borax, which affects the over-all pH of the solution only very little, produces such a pronounced difference in the conductivity of the oxide, at least under a-c bias. Apparently we are here again dealing with a specific sodium ion effect.

Ikonopisov and Nankov (83), who also investigated the cathodic light flashes in oxalic acid, were able to show that the light emission actually continues for tens of minutes under cathodic bias, although at a greatly reduced intensity compared to the first few milliseconds.

Electroluminescence and electron emission from thin metal/oxide/metal sandwiches was studied by Hickmott for a number of systems (68/1965 + 1966/). The threshold for photoconductivity in Nb/Nb<sub>2</sub>O<sub>5</sub>/Au diodes is about 1.2 eV and is attributed to excitation of electrons from an impurity band. The effect of illumination on stored charge from Ta/Ta<sub>2</sub>O<sub>5</sub>/ electrolyte was studied by Dreiner (84). To explain the inverse time law for the residual discharge current, a model is proposed in which a positive space charge in the film, generated during the forming process, gives rise to two opposing electric fields in the oxide.

Chopra (85) described interesting polarity reversals of the integral photovoltage generated by weakly rectifying metal/oxide/metal sandwiches under steady illumination. Chopra assumes the photocurrents to be

generated in the transition regions between the metal contacts and the bulk of the oxide, and explains the polarity reversal as due to the superposition of a fast growing, fast decaying photocurrent with a slow growing, slowly decaying component.

Schuermeyer and Crawford (55) analyze a simple method of separating the opposing photocurrents generated by emission from the metal electrodes into the oxide sandwich. Polack and Morris (86) were able to measure the built-in voltage across a thermally grown  $\text{Al}_2\text{O}_3$  film, predicted by the Mott-Cabrera theory of thin film growth (87), by analyzing the currents through an  $\text{Al}/\text{Al}_2\text{O}_3/\text{Al}$  tunneling structure.

Grove and Snow (88) were able to measure a trap density of  $10^{18} \text{ cm}^{-3}$  at the  $\text{Si}/\text{SiO}_2$  (thermal) interface just inside the  $\text{SiO}_2$  by analysis of the MOS characteristics after irradiation with 35 keV x-rays. Significant differences in the response to ionizing radiation between thermal  $\text{SiO}_2$  films grown in dry oxygen and in steam were noted by Kooi (89).

*Current-time relationship of the cathodic current.*—Van Geel and Pistorius (90) noted that the cathodic current was both a function of the time under forward bias, and of the value of the anodic bias to which the system  $\text{Al}/\text{Al}_2\text{O}_3$  had been last exposed. These experiments were carried out with alternating rectangular voltage pulses of about equal amplitude.

### The $\text{Si}/\text{SiO}_2$ System<sup>5</sup>

I should like to turn now to a description and interpretation of my own experiments on electrolytic rectification, using low resistivity n-type silicon as the substrate. In my 1957 paper with Michel (91) we showed cathodic I-V characteristics as a function of oxide thickness on n-type Si formed in a solution of potassium nitrate in N-methyl acetamide (NMA), the best anodizing medium for silicon known at that time. The purity and crystal perfection of the silicon available in 1957 was quite inferior to the material now available, but even so it was considerably better than the purity of any other valve metal like Ta or Nb available at that time. The curves of cathodic current vs. oxide thickness showed next to no slope, and we concluded at the time that the ability to pass cathodic current in contact with an electrolyte containing protons must be an intrinsic property of the anodic oxide film on silicon. In retrospect, however, the fact that these old experiments were carried out in open beakers becomes of importance since N-methylacetamide is hygroscopic. As we shall see, the presence of water vapor absorbed into the solution must have affected those results.

More recently we have been using a solution of potassium nitrite in tetrahydrofurfuryl alcohol (THFA), which in our experience is a considerably better anodizing medium for silicon than is the  $\text{KNO}_3/\text{NMA}$  solution; we have also taken the necessary precautions to prevent uptake of moisture from the air. Our initial concern was with the phenomenological differences between anodic and thermally grown  $\text{SiO}_2$  films, and we intended to show that the two kinds of films can be mutually transformed into each other by heat-treatment or by anodization, respectively. This work, including the infrared absorption spectra, is reported in the paper with Rand (28). We noticed that anodization of a thermal film caused the appearance of a hydroxyl band in the bulk of the film, but the intensity of this band seemed to vary.

We shall report here on the cathodic current of purely anodic oxide films on Si as a function of forming conditions and of exposure of the  $\text{SiO}_2$  film to liquid water. Concerning thermally grown  $\text{SiO}_2$  films we shall merely state at this time that they block the cathodic current quite well, but that the blocking ability can be increased further by anodization, as one would expect to happen if anodization results in the

plugging of a few pin-holes which the thermal oxide is known to contain. Introduction of trapping centers may also be involved.

### Experimental Techniques

Epitaxial n-type Si of resistivity 0.07 ohm-cm was deposited in a layer  $9\mu$  thick on very low resistivity n-type substrates. The slices were anodized immediately after epitaxial deposition, and great care was taken not to touch the epitaxial surface mechanically before or after anodization. Anodization was to 250v in a solution of  $\text{KNO}_2$  in tetrahydrofurfuryl alcohol (10.8 g/liter) at a current density of  $6 \text{ ma/cm}^2$ ; on reaching 250v, the sample was kept at constant voltage for 24 hr. The leakage current at the end of the anodization was typically  $5 \mu\text{a/cm}^2$  at 250v.

Some oxide was removed in HF from the back surface of the wafer at one edge, and the wafer was clamped in a horizontal position by means of a metal clip. Due to the low resistivity of the substrate, the voltage drop at the contact is negligible for the low currents tested.

The electrolyte contact was established by moving the orifice of a capillary directly in front of the anodized epitaxial surface and pressing a droplet of the liquid out of the capillary until it touched the oxide surface and established electrical contact. It was found of utmost importance not to touch the surface of the oxide with the orifice of the capillary, even though it had been fire-polished. Low cathodic breakdown voltages resulted almost invariably if the tip of the capillary accidentally was made to touch the oxide surface. It is believed that the effect is related to a greater degree of hydration of a mechanically damaged oxide surface. This is in sharp contrast to the behavior of "dry" contacts; even stainless steel points can be used without destroying the blocking ability of the oxide underneath the point.

To investigate this phenomenon somewhat further, an anodized epitaxial surface was subjected to indentations by a Tukon Microhardness Tester, the metal point having been replaced by a Pyrex glass point with a radius of curvature of  $6 \times 10^{-2} \text{ cm}$ . The indentations were carried out with increasing loads in steps of 1, 2, 5, 10, and 50g. A platinum-preshadowed-direct-carbon replica was then taken of the test area, but no structure could be detected below 10g loads. It must be concluded that the aqueous contact is sensitive to mechanical damage to the surface which does not affect dry contacts, and which cannot be detected electronically.

The electrolyte used for testing the cathodic current behavior was concentrated nitric acid, which satisfied the dual requirement of being an ample reservoir of protons, and of not attacking the  $\text{SiO}_2$  film chemically.

### Results

It was found that an oxide grown in a fresh solution of  $\text{KNO}_2$  in THFA blocks the cathodic current very well, and that the current is independent of time up to about 10v applied to  $1500\text{\AA}$  films, i.e., a field strength of about  $7 \times 10^5 \text{ v/cm}$ . The test voltage can often be raised as high as 30v, but in this range of field strengths the current usually begins to become unstable with time, and eventually increases to large values. A typical current density at 10v is  $2 \times 10^{-7} \text{ amp/cm}^2$ . The blocking ability of the oxide and its cathodic breakdown strength are very uniform across the whole epitaxial surface. Most of the current flows through an area only slightly larger than the diameter of the liquid contact. This was established by use of a conductive silver paste guard ring circuit, painted around the periphery of the epitaxial layer. Only when the electrolyte contact was moved very close to the guard ring (approximately a contact diameter, 1 mm, away), did the guard ring circuit begin to draw current comparable in magnitude to the current through

<sup>5</sup> See note added in proof, at end of paper.

the oxide. Figure 3 shows a typical cathodic I-V characteristic.

On the basis of these results we can now assert that there exists no appreciable cathodic conductivity in dry anodic SiO<sub>2</sub> films even when in contact with a protonic electrolyte, but the emphasis is on the word dry.

The infrared spectra of anodic or of anodized thermal SiO<sub>2</sub> films suggested that water can be introduced into the oxide film by anodization under certain conditions, and that this water might have an effect on the electrical properties of the oxide. It has indeed recently been shown by Dreiner (27) that water diffuses into anodic SiO<sub>2</sub> when the film is left in contact with liquid water, or with a solvent containing water. The slow hydration of oxide films on aluminum when in contact with atmospheric moisture has, of course, been known for a long time.

To investigate the effect of water absorption, epitaxial n-type Si wafers which had been anodized and then tested with HNO<sub>3</sub> contacts without driving the test spots into breakdown, were immersed in deionized water at room temperature for 48 hr or more, and were then again tested with the HNO<sub>3</sub> droplet method. Wafers bearing the conductive silver paste guard ring were not immersed in water, but were kept in a container saturated with water vapor at room temperature and with a large droplet of H<sub>2</sub>O placed on the anodized surface inside the guard ring area.

The exposure to liquid water rendered the oxide surface hydrophilic to an extent that the nitric acid from the capillary would spread out over a large and irregularly defined area, so that no measurements could be taken immediately after the exposure to liquid water. It was, however, noticed that large cathodic currents would flow on application of only 1.5v bias. Placing the wafer in the vacuum of a vac-ion pump at  $3 \times 10^{-8}$  Torr at room temperature for 6 hr, however, restored hydrophobicity to the extent that the droplet of HNO<sub>3</sub> from the capillary did not spread much beyond its normal size, and measurements could be taken conveniently. Figure 4 shows that the current compared to the dry condition has increased about a hundredfold, and that the current is now time dependent at much lower voltages than before. Actually, the current in the time independent region is never completely steady but fluctuates about an average value, characteristics of a high field process. The surface after

Fig. 4. Cathodic current in the system n-type Si/hydrated anodic SiO<sub>2</sub>/concentrated nitric acid. Si/SiO<sub>2</sub> formed to + 250v as in Fig. 3, then exposed to liquid H<sub>2</sub>O at room temperature for 48 hr, thereafter dehydrated by keeping in hard vacuum for 6 hr.

hydration was not completely uniform, some spots still showing rather high resistance. Evidently the hydration (and dehydration) process does not occur in uniform fashion, but rather starts at preferred sites.

It should be noted that only the current flowing through the oxide was being measured since the guard ring arrangement was used to obtain the data. It was also noticed during these experiments that the acid on a slightly hydrophilic surface would initially spread out to a larger spot size than usual, but that on application of a cathodic bias the liquid withdrew into the capillary without, of course, losing contact with the oxide. This is the behavior expected for a negatively charged liquid and thus constitutes direct evidence for the transfer of protons to the oxide by adsorption.<sup>6</sup> From the measurements of Parks and De Bruyn (92) it is known that the zero point of charge of SiO<sub>2</sub> in contact with water occurs at a pH of somewhat less than 2. In contact with concentrated nitric acid it is therefore to be expected that the acid will be charged negative with respect to the oxide due to transfer of protons. Protons and hydroxyls are the potential-determining ions for a nonporous SiO<sub>2</sub> film on Si. This observation also rules out the penetration of solution into pores of the oxide film as the mechanism of conduction, at least as far as the Si/SiO<sub>2</sub>/ conc. HNO<sub>3</sub> system is concerned.

Subsequent to testing the water-exposed anodic SiO<sub>2</sub> films with HNO<sub>3</sub> contacts, the wafers were baked in air at 150°C, and were then again tested by the same method. All traces of increased conductivity had disappeared, and the cathodic blocking ability of the oxide was as good or better than before. It was then tried to repeat the cycle, but apparently the heating

<sup>6</sup> It should be noted that the volume of nitric acid displaced on the SiO<sub>2</sub> surface under application of a cathodic bias ( $10^{-3}$ - $10^{-2}$  cm<sup>3</sup>), is several orders of magnitude too large to be explained by electroosmosis through the capillary at the very small currents involved ( $10^{-6}$ - $10^{-5}$  amp), according to the equation  $V = \frac{\epsilon \cdot \zeta \cdot i}{4\pi\eta\lambda}$ , where  $\epsilon$  =

dielectric constant,  $\zeta$  = zeta potential glass/acid,  $i$  = current,  $\eta$  = dynamic viscosity,  $\lambda$  = conductivity of the concentrated acid. It was also noticed that the effect was related to the magnitude of the applied bias (which is dropped almost exclusively across the oxide film) rather than to the magnitude of the current. The system is also different from a simple electroosmotic set-up in that here the area of oxide wetted by the acid changes under application of the bias. The physical parameters involved are the surface areas and surface energies in the system SiO<sub>2</sub>/HNO<sub>3</sub>/air, the ionization of the surface hydroxyl groups, the electrostatic forces, and the hydrostatic pressure of the liquid. The shape of the capillary appears to be critical; with some capillaries the effect could not be observed.

at 150°C had been sufficient to slow down the uptake of water markedly. Warming to 35°C in contact with liquid water for 48 hr was required to restore the "wet" condition of the oxide.

In another experiment an anodized Si wafer, part of which had been exposed to liquid water for 48 hr, was immersed in an acidic gold plating bath and was kept under a cathodic bias of 6v for ½ hr. Gold plating took place only in the area previously exposed to liquid water. While the gold deposit was nonuniform and of low density in the hydrated area, a well-defined continuous gold plate marked the previous periphery of the water droplet used to hydrate the oxide. We do not understand the reason for this latter effect; it may perhaps be related to a different pH at the surface of the water droplet in contact with air, or could be an effect of surface tension at the three phase boundary SiO<sub>2</sub>/H<sub>2</sub>O/air.

In the case of a contact between SiO<sub>2</sub> and concentrated HNO<sub>3</sub>, protons are transferred from the acid to the oxide, setting up a surface dipole which opposes the further entry of protons. When applying a negative bias to the silicon, most of the voltage is dropped across the bulk of the insulator and only a small fraction across the Helmholtz double layer. Penetration of protons is thus reduced until the fraction of voltage dropped across the Helmholtz layer equals the surface dipole due to charge transfer from the liquid to the SiO<sub>2</sub>. Part of the blocking ability of the oxide is thus due to this dipole. If a less acidic electrolyte were used as the contact, the surface dipole would be smaller or, in the case of an electrolyte with pH higher than 2.0 (the isoelectric point of SiO<sub>2</sub>) would even point in the other direction and would favor the injection of protons.

The corresponding experiment was carried out with a solution of potassium nitrate in deionized water, and on a wafer on which the anodic oxide had previously been tested with concentrated HNO<sub>3</sub>, and current blocking to at least 10v applied bias had been observed for every spot tested. In contact with the KNO<sub>3</sub>/H<sub>2</sub>O solution the cathodic breakdown voltage was only 4v initially, but rose slightly from each test spot to the next, apparently reflecting decrease in pH of the liquid at the very tip of the capillary, perhaps due to uptake of CO<sub>2</sub> from the air. It was also noticed that breakdown occurred in a very abrupt fashion; i.e., the current was very small below, and quite large above the breakdown voltage. Breakdown in contact with the concentrated HNO<sub>3</sub> solution is much more gradual, so that a forward I-V characteristic can be plotted in this voltage region, as shown in Fig. 4.

The experiment described is not completely unambiguous because a certain degree of chemical attack on the SiO<sub>2</sub> can occur at higher pH values; in view of the experiments with water soaked anodic SiO<sub>2</sub> films, which regained their blocking ability completely upon heating to 150°C in air, it is felt that the observed phenomena are probably correctly ascribed to charge transfer reactions.

It was stressed before that good blocking ability of anodic SiO<sub>2</sub> films is observed if the oxide is formed in a fresh solution of KNO<sub>2</sub> in THFA. An oxide formed in an "aged" KNO<sub>2</sub>/THFA solution; i.e., one in which several consecutive anodizations have been carried out before, shows a much reduced breakdown voltage. In a particular case tested, the cathodic breakdown voltage in contact with concentrated HNO<sub>3</sub> was only 5v, but extremely uniform across the whole epitaxial surface. From previous anodization with K<sup>42</sup>NO<sub>2</sub> in THFA (72/1965/) it is known that the amount of potassium incorporated into the oxide film increases with each successive anodization and reaches values larger by a factor of 100 compared to a fresh solution. Another possibility is, of course, an increased incorporation of protons with aging of the solution. This would not be unreasonable in view of the measure-

ments by Duffek *et al.* (93) who showed that electrolysis of KNO<sub>3</sub>/NMA solutions produces water by oxidation of the NMA at the Si anode. A similar mechanism may well occur in KNO<sub>2</sub>/THFA solutions. Tracer measurements with T and K<sup>42</sup> are now in preparation to clarify these points. The role of potassium ions or protons in lowering the cathodic breakdown voltage could be related to an enhancement of proton mobility in the oxide, or to enhanced field emission from traps or from the cathode.

#### Discussion

We know now that the ability of SiO<sub>2</sub> to pass cathodic current is strongly dependent on the water content of the oxide, and we must inquire about the role which the water plays in the conduction mechanism. Here we are faced by a dilemma, but it seems that the gradual increase with time of cathodic current in the system n-type Si/SiO<sub>2</sub>(H<sub>2</sub>O)/protonic electrolyte, may well provide a clue to the correct answer. The dilemma we are referring to is the question whether the current is carried by protons, by electrons, or by both.

Actually, a one-carrier proton mechanism in dry SiO<sub>2</sub> can be ruled out just on the basis of the very low mobility of protons in SiO<sub>2</sub>. Even if the room temperature mobilities extrapolated from Hofstein's work (20) are used, by far the highest values reported for protons in SiO<sub>2</sub>, unrealistically large carrier concentrations result in order to satisfy the relationship  $\sigma = n \cdot e \cdot \mu$  at current densities in the ma/cm<sup>2</sup> range. Similarly, a one-carrier electron mechanism is ruled out in view of the blocking behavior of SiO<sub>2</sub> films of the given thickness with metal counter electrodes. Equally impossible is a double-injection mechanism with both types of carriers present in approximately equal concentrations and able to reach the collecting electrode; in this case a very strong dependence on oxide thickness, proportional to 1/d<sup>5</sup>, would be expected, which is clearly not being observed in the case of high forward conductivity. What one has to choose from are therefore two-carrier mechanisms, but with one type of carrier in excess and more mobile than the other.

From the work of Rosenberg (39) it is known that a water content of a dielectric can increase its conductivity by many orders of magnitude. It is also unreasonable to assume that the electronic conductivity of the SiO<sub>2</sub> film has not increased in the presence of the absorbed water. Thus one would not have to postulate a protonic contribution to explain the initial increase in conductivity after exposure to water. The slow increase of current with time of hydrated SiO<sub>2</sub>, however, is difficult to understand if purely electronic conduction were involved. It is known that the conductivity of insulating CdS can be changed in irreversible fashion by application of a critical field strength (94), but the initial increase in conductivity on application of a cathodic bias to hydrated SiO<sub>2</sub> is reversed by simply heating the oxide to 150°C; induced conductivity has been observed in anodic oxide films by Hickmott (68) and by Chopra (69) when a critical current density was forced through the oxide, but the current densities involved were far in excess of the very small currents initially flowing through the hydrated SiO<sub>2</sub> film upon application of a few volts cathodic bias.

Injection of protons accompanying electronic current flow must of necessity result in an increase of current with time. The injected protons will compensate part of the negative space charge in the oxide and increase the current in much the same way as trapped holes increase the gain of secondary photocurrents. In addition, the injected protons can cause enhanced field emission both from traps in the film (Frenkel-Poole mechanism) or from the cathode.

If field emission from the n-type Si into the SiO<sub>2</sub> is the rate-limiting step, as indeed postulated for very

thin (175Å) dry SiO<sub>2</sub> films by Forlani and Minnaja (95), then the bands must be tilted by the same extent to produce the same amount of electron emission for oxide films of different thickness, i.e., the field strength at the contact must be the same. This is not too different from what is actually observed in practice. Essentially the same consideration applies if field emission from traps is the rate-limiting step. Continuous injection of a small proton current would lead to a gradual reduction of the effective barrier height, regardless of whether the barrier at the N-Si/SiO<sub>2</sub> interface or the trap depth is involved, thus causing the slow increase of current with time experimentally observed. When the current density becomes very large, there may, of course, result mechanical damage to the oxide from the evolution of hydrogen gas by recombination of protons and electrons. Proton injection into a completely dry SiO<sub>2</sub> is not readily possible, as we have seen; permeation of water must first generate some kind of hydrogen bonded network along which the protons can migrate. The water thus serves a dual function in SiO<sub>2</sub> films: it increases the electronic conductivity, and it enhances the proton mobility in the oxide. It should perhaps be noted that the electronic conductivity of SiO<sub>2</sub> films, relative to their ionic conductivity, is much better than that of Ta<sub>2</sub>O<sub>5</sub> films, as can be deduced from the fact that the current during formation of Ta<sub>2</sub>O<sub>5</sub> films is nearly 100% ionic, whereas the current during formation of SiO<sub>2</sub> is 96% or more electronic. On the other hand, the mobility of protons in SiO<sub>2</sub> is much lower than in Ta<sub>2</sub>O<sub>5</sub>. Thus the ratios of proton to electron injection under cathodic bias may be considerably different for Ta<sub>2</sub>O<sub>5</sub> and SiO<sub>2</sub> films.

It is possible to substantiate further that the positive carriers injected into the SiO<sub>2</sub> are indeed protons and not holes (an unlikely process anyhow for a material with the forbidden bandwidth of SiO<sub>2</sub>). When biasing the anodized n-side of a p-n junction in silicon cathodically (i.e., in the forward direction) vs. an aqueous electrolyte, while maintaining a reverse bias across the p-n junction, no increase in the reverse current of the junction could be detected, up to the highest current densities tested in the emitter/base circuit. Electron injection by the electrolyte through an anodic oxide on the other hand is readily observed when biasing the anodized p-side of a p-n junction positive vs. the electrolyte. The former experiment is not fully conclusive because the surface recombination velocity at the Si/SiO<sub>2</sub> interface under cathodic current flow should really be known but was not measured in this experiment. In general, however, the surface recombination velocity of silicon is not excessive under a large forward bias, when the Fermi level at the surface is in the vicinity of one of the band edges.

### Conclusions

A literature survey has been given for the period 1959-1966, of papers dealing with electrolytic rectification or related subjects.

It has been shown that the conductivity of anodic SiO<sub>2</sub> increases after exposure to water. This initial increase in conductivity is likely to be electronic rather than protonic in origin. However, protons can be injected into a hydrated SiO<sub>2</sub> film causing an increase of current with time at constant voltage due to space charge neutralization and field emission from traps or from the cathode. Hydration of the oxide can be reversed by a bake at 150°C in air. This bake actually renders the oxide more resistant to hydration than it is immediately after anodization.

Either alkali ions or protons, incorporated into the oxide film by anodization in an incompletely dry organic solvent, have a strong effect on lowering the cathodic breakdown voltage, at which the current begins to increase with time under constant voltage.

### Acknowledgments

The author is indebted to J. D. Ashner for help with many of the experiments. B. F. Howells made the indentation tests and J. Drobek the electron microscopic surface replicas. Stimulating discussions with K. Lehovec and T. W. Hickmott are gratefully acknowledged.

Manuscript received June 15, 1967; revised manuscript received Sept. 15, 1967. This paper was presented at the Anodic Oxides Symposium at the Dallas Meeting, May 7-12, 1967, as Abstract 21.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

Note Added In Proof: Brander, Lamb, and Rundle [*Brit. J. Appl. Phys.*, **18**, 23 (1967)] report on anomalously large space-charge-limited one-carrier electronic flow through SiO<sub>2</sub> thermally grown on Si in low moisture content O<sub>2</sub> and under conditions of high purity of ambient and quartz tube. Provided that the current indeed flows through the conduction band of the oxide, as suggested by the authors, the alignment of the bands in the silicon and in the oxide must be drastically different from the situation investigated in ref. (57) and (58).

Lamb and Rundle [*Brit. J. Appl. Phys.*, **18**, 29 (1967)] describe the reversible switching between a high- and a low-resistance state of Si/SiO<sub>2</sub>/Al structures. The oxide in this case was contaminated with sodium during thermal growth, and the switching action was observed only if the system was subsequently heated in an hydrogen containing atmosphere. This work bears resemblance to the current controlled negative resistance effects observed in Al<sub>2</sub>O<sub>3</sub> and in Nb<sub>2</sub>O<sub>5</sub> (69-73), and also appears to have some bearing on the fast diffusing hydrogen species reported by Hofstein (20).

# Anodic Films, Protons, and Electrolytic Rectification

D. A. Vermilyea\*

General Electric Research and Development Center, Schenectady, New York

## ABSTRACT

Anodic films contain many flaws which for thick films are the sites of electrolytic rectification. For  $Ta_2O_5$  and  $Nb_2O_5$  films below 1000Å in thickness, however, bulk conduction also occurs. For such films the capacitance also increases markedly on polarization in the forward direction (base metal negative). One interpretation of the capacitance changes involves a proton space charge in the film. The relationship between capacitance change and current flow is examined in some detail, and it is shown that there is not a good correlation between the two effects; it therefore appears that two separate phenomena are involved. Possible interpretations are discussed.

During the past several years, the author conducted a number of investigations of various phenomena pertinent to electrolytic rectification. This paper presents a brief summary, some previously unpublished results, and a discussion of problems of interpretation.

### Summary of Previous Studies

**Flaw conduction.**—Anodic barrier films have macroscopic structures ranging from extremely heterogeneous to fairly homogeneous. The substrates on which they are grown are generally neither chemically pure nor geometrically ideal, and film growth on such surfaces results in imperfect films. A study of  $Ta_2O_5$  films revealed the presence of characteristic flaws (1), a schematic drawing of which is shown in Fig. 1. Such flaws resulted from film growth on surfaces which were geometrically irregular or which contained oxides or carbides. There is probably a gap of some kind between the metal surface and the central portion of the flaw. Electronic conduction through thick (>1000Å)  $Ta_2O_5$  films occurs almost exclusively at such flaws (2). The mechanism of such conduction and the entire chemical and physical nature of such flaws are mostly unknown, although some flaws are known to open physically in aqueous solutions. Marked hysteresis of current as a function of voltage has been observed for heavily flawed films, and with gold electrodes the conductivity sometimes increased with decreasing temperature. Such behavior suggests a degenerate semiconductor, but the phenomena are very complicated; probably some electrolysis is also involved. It should be noted that such flaw conduction may involve current densities of many thousands of amperes per square centimeter.

**Bulk conduction.**—Of more interest because potentially some attempts at understanding may be made are results obtained for  $Ta_2O_5$  and  $Nb_2O_5$  films in the thickness range below 1000Å. For such films on reasonably pure smooth substrates bulk conduction predominates. It is believed that  $WO_3$  films also exhibit bulk conduction, while  $ZrO_2$  and  $Al_2O_3$  films conduct only at flaws.

Bulk conduction is not uniform at low fields, some areas conducting much more readily than others. At very high fields, probably approaching  $10^6$  v/cm, the entire surface participates in the conduction process, and the current seems to be more uniform. The potentials

at which the easiest and most difficult paths become active differ by about 1v. There is a strong temperature dependence of conduction, corresponding to activation energies of 0.5-1.0 ev. The current voltage relationships for such films are the same with either aqueous solution contacts or with metal electrodes provided a correction is made for the contact potential. Rectification appears to be determined by the contacts to the film. If a high work function contact is used, the film conducts easily when the base metal is negative. High work function contacts include gold, mercury, and most aqueous solutions. If a low work function electrode is used, conduction may be about equal in both directions or may be slightly higher when the base metal is positive. Low work function electrodes include aluminum, alkali metals dissolved in mercury, and an aqueous solution containing  $Cr(CN)_6^{-3}$  ions. The results of changing the work functions of aqueous solutions indicate that electrons are the predominant charge carriers. Bulk conduction can be increased many orders of magnitude by diffusion of lithium into the film and by a much smaller amount on application of large fields in the forward direction. The presence of liquid water is essential for the latter conductivity increase. Bulk conduction is also sensitive to the forming solution, especially as the film thickness increases. Hydrogen peroxide has a remarkable effect in reducing forward conduction (3); this effect is unstable on continued application of large forward bias. Bulk conduction in thicker films is also a function of the formation rate, temperature, and film history.

The results described for bulk conduction are all consistent with a mechanism in which electrons enter the film at the electrode and move through some kind of states in the film to exit at the other electrode. The substrate-film barriers are low for  $Nb_2O_5$  and  $Ta_2O_5$ , and many contacts give high barriers, so that rectification occurs. If the second contact has a low work function, rectification either does not occur or has a reversed easy flow direction. The effects of forming solution and large forward bias could probably be explained with a suitable distribution of traps. Lithium evidently supplies more electron states in the film and increases the conduction.

**Space charges.**—Prior to the studies of electronic conduction a study was made (4) of capacitance increases accompanying forward bias in aqueous solutions not containing any ready electron acceptors, so that the current flow through the films was small. Under such conditions the electrical capacitance of the film increases markedly, and for  $Nb_2O_5$ , may reach values of the order of  $10^2 \mu F/cm^2$ . The form of the capacitance-voltage relationship is in rough quantitative agreement with a theory involving a space charge within the film. The space charge was thought to be the result of protons evaporating from the surface into the film as the potential was made more nega-

\* Electrochemical Society Active Member.

tive. For thin films, for which equilibrium of the carriers may be assumed, there is no dependence on frequency within the range of 100 cycles to 10 kc, or on temperature between 24° and 75°C. At lower temperature, and for thicker films the capacitance change becomes frequency and temperature dependent as though the mobility of charge carriers was not great enough to allow the equilibrium space charge to develop. Charge carrier mobilities of  $10^{-6}$  to  $10^{-8}$  are consistent with the results. Various experiments were performed in an effort to demonstrate that protons were in fact present in the film, and while all the results are consistent with the proton hypothesis they do not constitute a proof that protons form the space charge.

The evidence adduced in support of proton entry is that slightly different results are obtained with  $D_2O$ , as might be expected from the lower mobility of the deuteron; and that much smaller capacitance changes are observed when mercury, evaporation metal, or nonaqueous solution contacts were used.

One of the reasons for postulating that protons could enter the film was that a study of the double layer at the  $Ta_2O_5$ -solution interface showed convincingly that protons were strongly adsorbed on the interface and that they exchanged rapidly with the solution (5). Presumably they might also be expected to enter the film readily. At that time it was thought that electrolytic rectification occurred only at flaws, so that presumably electrons could only enter the film at scattered sites, while the large values of capacitance attained on negative polarization made it necessary to conclude that the entire surface area was affected. Since the later studies showed that bulk conduction also occurred it is now conceivable that electronic phenomena are responsible for both the conduction and the capacitance change. It is also conceivable, on the other hand, that protons form the space charge and also create the electronic states which allow conduction. The results obtained with lithium add some credence to this suggestion; since lithium enters the film and greatly increases its conductivity could not protons act in the same fashion?

In view of the uncertainty in the interpretations of the observed phenomena it seems worthwhile to compare results for capacitance change and bulk conduction on the same films under similar conditions to see whether any clarification can be achieved.

### Experimental Results

All of the techniques used have already been described (2-4). An important feature of the conduction measurements with aqueous solution contacts is the use of  $Ce^{+4}$  ions as an electron acceptor to preclude control by some slow electrochemical reaction in the solution.

Figures 2 and 3 show data for 350Å  $Nb_2O_5$  films formed at two rates in 0.1M  $HClO_4$  at room temperature. It may be seen that while both slowly formed specimens give higher currents and larger capacitance changes than do the rapidly formed films, the correlation of capacitance change and current is not perfect. Thus samples 1 and 2 give nearly the same C-V curve but very different currents at a given potential, while sample 3 gives a larger current but a smaller capacitance change than does number 4.

Figures 4 and 5 further demonstrate the lack of a detailed correlation between capacitance change and current. In these figures 105Å  $Ta_2O_5$  films formed in dilute and concentrated  $H_2SO_4$  give current-voltage curves which differ relatively little considering the great difference in the nature of the films formed in the two solutions. On the other hand the film formed in dilute  $H_2SO_4$  shows very little capacitance change, while for the other, the capacitance increases by more than an order of magnitude at  $-0.9v$ . The current for the film formed in dilute  $H_2SO_4$  was higher, in contrast to the capacitance change.

Fig. 2. Effect of formation rate on capacitance change. 350Å  $Nb_2O_5$  film formed at 25°C in 0.1M  $HClO_4$ . Specimens 1 and 2 formed in 2 min; samples 3 and 4 in 5 sec.

Fig. 3. Effect of formation rate on current; specimens of Fig. 2

Figures 6 and 7 show that the hysteresis effects associated with electronic current flow and capacitance change also differ. The capacitance is always higher on returning to positive potentials after negative polarization, and stays large to at least  $+1.5$  to  $+2v$ . The current, on the other hand, shows much less hysteresis which is usually of the opposite sign, and the hysteresis loop always closes by about  $+0.5v$ .

For films formed in concentrated solutions irreversible changes occur after negative polarization. Figures 8 and 9 show that sometimes the result of negative polarization may be to change the current-voltage curve and capacitance-voltage curve in opposite directions.

Figures 10 and 11 show data for the same 210Å  $Nb_2O_5$  film tested in mercury (solid lines) and in  $Ce^{+4}$  (circles), the potential scale having been adjusted so that the current-voltage curves coincide. There is a much smaller capacitance increase in the mercury. Note that in the aqueous solutions the presence of  $Ce^{+4}$  does not alter the capacitance-voltage behavior since the same results are obtained in  $HClO_4$  solutions.

### Discussion

It seems clear from the data presented that there is no detailed correlation between current flow and ca-

capacitance change. Perhaps the outstanding example of lack of correlation was published in ref. (2). After alternating current formation, the easy conduction paths are blocked by deposits from the solution, and the current-voltage curve is shifted to more negative potentials. Such films may show very large capacitance changes with negligible current flow even in solutions containing ceric ions. Finally, the current is strongly influenced by temperature over the range  $-73^\circ$  to

$+100^\circ\text{C}$ , while the capacitance change is independent of temperature above some critical temperature.

There are at least two possible interpretations of these results. It could be assumed that electronic phenomena are responsible for both conduction and capacitance change, the conduction occurring through easy paths at somewhat less negative potentials than are required for the capacitance change. At high negative potentials the entire area becomes available for electron conduction, and the capacitance increases because of space charge formation. In order to explain the absence of large electronic currents when metal counter electrodes are used and still allow ready entry of electrons for space charge formation it seems necessary to postulate a large barrier to electron egress at the oxide-solution interface. The absence of large capacitance changes with mercury and nonaqueous contacts is not explained, but there are complications because of contact potential differences and double layer phenomena which may account for such discrepancies.

The alternative explanation is that electrons flow out to carry current and protons flow in to create the space charge. This explanation fits most of the facts, but is somewhat less appealing because of its greater complexity. It might also be argued that more hydrogen than was measured (4) should appear in the metal after prolonged negative polarization. However, it is perhaps easier to imagine a barrier to keep protons from entering the metal than one to keep electrons from tunneling into the mercury, as required by the alternative hypothesis. The question whether protons supply electron states in the oxide appears to be impossible to answer without further information. Suppose that the low capacitance change observed with mercury and with nonaqueous solutions results from a scarcity of protons. It would then be expected that if the current flow depends on protons it would also diminish with dry contacts, but that does not seem to be true. On the other hand, protons may be available at the easy sites even in dry conditions but not generally on the surface.

A final decision between the various possibilities requires more study. The most crucial need is for experiments which would settle conclusively the question of proton motion in the oxide films.

Manuscript received June 15, 1967; revised manuscript received ca. Oct. 3, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 22.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Ionic Transport in Amorphous Oxides

R. H. Doremus

*General Electric Research and Development Center, Schenectady, New York*

## ABSTRACT

To aid in understanding the electrical conductance of amorphous oxide films, some experimental and theoretical results on ionic transport in bulk oxide glasses are reviewed. Results on alkali and hydroxyl ion movement in fused silica are perhaps the most pertinent; results on other glasses help to test theories and to show the effects of additives and hydration of the glass.

The electrical conductivity of amorphous anodic films often involves foreign ions in the films. When the film is formed in aqueous solution these ions are most likely to be hydrogen or hydroxyl. The electrical conductivity of bulk silicate glasses, except for a few special compositions, is controlled by diffusion of ions that are not part of the silicon-oxygen network of the glass. In this paper ionic transport in silicate glasses is reviewed to aid in understanding of ionic motion in amorphous oxide films.

This paper contains sections on the following subjects: structures of silicate glasses and their possible relation to structures of anodic films of other metals; factors that influence the selectivity or binding of small cations in an oxide network, and experiments and theories of transport measurements in silicate glasses that seem to be closest to the situation in anodic films.

### Structure of Amorphous Oxides

The basic building block of silicates is the silicon-oxygen tetrahedron. Each silicon atom is surrounded by four oxygen atoms; the bond distances and angles in this basic unit are very similar within a particular silicate and even from one silicate to another. In fused silica glass ( $\text{SiO}_2$ ) these tetrahedra are attached at their corners. Small displacements from one tetrahedron to another give rise to an amorphous structure that shows no long-range order, but retains the basic silicon oxygen tetrahedron with its usual bond angles and distances.

Zachariasen emphasized that it is this sharing of corners of a tetrahedral or triangular unit that makes an amorphous structure possible (1). As Young (2) has pointed out, Zachariasen included tantalum and niobium pentoxides in his list of probable glass formers, although they had not been made as glasses at that time. One might therefore expect the basic structural unit of amorphous tantalum and niobium oxide films to be oxygen-metal ion tetrahedra that are similar to the phosphorus-oxygen tetrahedra found in amorphous and polymeric phosphates (3). However, there seems to be no direct evidence to support this tetrahedral configuration. In  $\beta\text{-Ta}_2\text{O}_5$  the tantalum seems to be either in the center of a square surrounded by four oxygens, or an octahedron (4). In amorphous aluminum oxide films the aluminum atom may be in a mixture of four and six coordinated states with oxygen; amorphous aluminum oxide is often mixed with crystalline oxide [ref. (2), p. 212ff]. Therefore even the basic structure of various oxide films may be quite different, and it is difficult to know how far one can transpose results on silica to other oxides. Since extensive studies of ionic transport have been made only in silicates, this review is limited to them.

When alkali oxides are melted with silica the viscosity of the melt is greatly reduced, because the silicon-oxygen network is broken up by the formation of, for example,  $\text{SiO-Na}^+$  groups. These alkali ions are much more loosely held in the glass structure so they can easily migrate through it. Therefore when even a

small amount of alkali ion is present in a silicate glass, the electrical conductivity of the glass results entirely from the transport of this ion. This assertion is confirmed by many experiments which show that the alkali ions transport all the electrical current in silicate glasses (5, 6), and that their diffusion is much more rapid than that of other ions in silicate glasses (7). The alkali ions are called "network modifiers"; many other monovalent, divalent, and trivalent ions can act as network breakers or modifiers, but the monovalent are by far the most mobile.

A complication in the structure of silicate glasses is the formation of a second amorphous phase. Most borosilicates, as well as binary sodium and lithium silicate glasses, separate into two phases (8). Most commercial glasses other than borosilicates probably do not separate into two phases, since the presence of many components, especially aluminum, seems to inhibit phase separation. However, this possibility must always be kept in mind when interpreting properties of these glasses.

Hydrated oxides are of particular interest in the study of anodic oxide films, since the latter are usually formed from aqueous solution. However, there seems to be little information on the effect of hydration on the structure of anodic oxide films. When fused silica is treated with water vapor the silicate network is broken and two  $\text{SiOH}$  groups are formed (9, 10). At low water concentrations these groups are isolated from one another, and no molecular water is detectable in the silica (9). There is little known of the structure of silicate glasses extensively hydrated by contact with liquid water. Water slowly dissolves silicates, the rate increasing with increasing temperature (11). There is a gradient of "water" (hydroxyl group) concentration from the surface into the glass interior. With high degrees of hydration the silica becomes like a gel; the equilibrium solubility of liquid water in silica at room temperature apparently has not been measured. In fact it seems likely that the hydrated surface layers of oxides in contact with water are metastable, and given sufficient time the entire sample would dissolve. The rate of dissolution is, of course, a strong function of the composition of the solutions with which it is in contact, and may be very low, so that for practical purposes the hydrated oxides are often stable, although their composition may be slowly changing.

### Ion Selectivity of Oxides

Often it is found that alkali ions do not penetrate into an anodic oxide film from solutions (12), or that certain ions "block" the current in such a film (13). It seems possible that at least some of these phenomena are related to the ion exchange selectivity of the oxides. This selectivity also influences ionic transport in the oxide. Therefore a brief review of factors that determine this selectivity is presented in this section.

The selectivity of hydrated silicate glasses for monovalent ions was studied in detail by Eisenman (14). He found that the selectivity of glass between alkali ions of different sizes was determined by the composition of the glass. For example, glasses containing

silicon as the only network-forming ion showed a strong preference for small ions, particularly hydrogen ions. On the other hand certain sodium aluminosilicate or borosilicate glasses showed a preference for the larger cations, such as potassium, rubidium, and cesium, over sodium or lithium ions. These glasses still preferred hydrogen ions, but much less than the silicates without aluminum or boron. Eisenman related these differences to the structure of the anionic group in the glass. In Fig. 1 are shown his simplified models for the  $\text{SiO}^-$  and  $\text{AlOSi}^-$  groups. In the silicate group the negative charge is concentrated on a single oxygen ion, while in the aluminosilicate group this charge is spread over several oxygen ions. Thus the silicate is more "compact"; it has a higher "field strength" or smaller effective anionic radius. Conversely the aluminosilicate group has a larger effective anionic radius. Therefore the latter group tends to select larger ions from solution, while the silicate group selects smaller ions. Detailed calculations of binding energies relative to the hydration energies in solution illustrate these points (14). Eisenman calculated effective anionic radii of about 0.9 and 2.0 Å for the silicate and aluminosilicate group; these numbers are not exact, but give a rough guide of the relative binding or selecting power of the groups.

The detailed structure of the anionic groups in many hydrated anodic films, such as on tantalum and niobium, is not known, as mentioned earlier, so it does not seem possible to make a direct calculation of their effective anionic radii. However, it is possible to get some idea of these radii from the dissociation behavior of acids containing these anionic groups. For example, Eisenman observed that silicic acid is very weak, while the aluminosilicate group gives a strong acid. He calculated anionic radii close to those of the last paragraph by comparing the dissociation constants of these groups with those of halide acids (14). It is known that niobic and tantalum acids are very weak (15). Also, the first acid dissociation constant of  $\text{Al}(\text{O}-\text{H})_3$  is  $6(10)^{-12}$  (16). Therefore these groups in a hydrated oxide should have small anionic radii and be very selective for small monovalent ions, particularly hydrogen ions. Thus Vermilyea's finding that sodium or lithium ions do not penetrate into tantalum oxide films from aqueous solution (12) is understandable. Vermilyea also found that lithium ions could be introduced into the film from certain nonaqueous solvents (12); in this case the hydrogen ion concentration was apparently so low that some lithium ions were bound to the tantalate groups. It seems possible that other effects of ions on anodic oxide films can be understood in these terms.

Glass-forming ions are sometimes used in the electrolyte in the growth of anodic films, for example, borate ions for films on aluminum. It seems likely that small amounts of these ions are incorporated into the films. They could have a considerable influence on the properties of the films because of their different binding energies with cations, leading to faster diffusion of ions.

Fig. 1. Schematic drawings of  $\text{SiO}$  and  $\text{AlOSi}$  sites using crystal-line ionic radii. Open circles are oxygen ions, solid dot is silicon, finely shaded circle is aluminum ion, shaded cation is sodium, from ref. (14).

### Transport of Ions in Amorphous Oxides

Information about transport of ions is available from both diffusion and electrical conductivity measurements, so it is important to consider the relation between them. In a material in which only one ion is involved in transport, and there is no electronic conduction, the Einstein equation relates the tracer diffusion coefficient  $D$  of this ion to the specific electric conductivity  $\sigma$  of the substance:

$$D = \frac{\sigma RT}{cZ^2F^2} \quad [1]$$

In this equation  $c$  is the concentration of ions,  $Z$  the number of elementary charges on the ion,  $F$  the faraday,  $R$  the gas constant, and  $T$  the absolute temperature. The equation can be derived from strictly kinetic considerations with the assumption that the ionic mobility in the two experiments is the same (7, 17). When this assumption is not valid deviations from Eq. [1] occur, which can often be ascribed to effects of structure or mechanism of transport.

Diffusion coefficients and electrical conductivities in rigid glasses vary exponentially with temperature, so that

$$D = D_0 \exp(-Q_D/RT); \quad \sigma = \sigma_0 \exp(-Q_\sigma/RT) \quad [2]$$

where the pre-exponentials  $D_0$  and  $\sigma_0$  and the activation energies  $Q_D$  and  $Q_\sigma$  are constant with temperature. These quantities are related by Eq. [1]. This equation would indicate a temperature factor  $T$  in one pre-exponential term, but the experiments are not accurate enough to show this dependence. Therefore the activation energies are somewhat different; in the temperature range of interest here  $Q_D$  is about 1 to 2 kcal/mole greater than  $Q_\sigma$ .

As mentioned before, results of transport measurements on amorphous oxides are limited almost entirely to silicates. Extensive measurements for sodium ions in silicates have been made and these are considered first; then results on hydrogen ion transport in silicates are discussed.

*Sodium ions in silicates.*—Tracer diffusion coefficients measured for sodium ions in binary sodium silicate glasses are shown in Fig. 2, taken from Johnson's measurements (7, 18). At lower and higher temperatures Eq. [2] is satisfied, with a region between resulting from the glass transition, in which the structure of the glass is changed by progressive rupturing of the silicon-oxygen network. Attention is here focussed on the lower temperature region where the glass is rigid and has an unchanging structure. The activation energies  $Q_\sigma$  for conductivity in binary sodium silicate

Fig. 2. Tracer diffusion coefficients of sodium in various binary sodium silicate glasses, as measured by Johnson (18).

Fig. 3. Activation energy for electrical conduction in various binary sodium silicate glasses, from ref. (19).

glasses, are shown in Fig. 3 taken from the work of Seddon, Tippett, and Turner (19). Also shown in the figure are results for Vycor (20) and fused silica (21), which contain low concentrations of sodium. These results may not be directly comparable with the others, as mentioned below. The activation energies  $Q_D$  calculated from the tracer diffusion coefficients for sodium silicates in Fig. 1 are not very accurate, but seem to be nearly constant with composition at about 14 kcal/mole. The values of  $D$  calculated from the conductivity and Eq. [1] and those measured directly are different, as shown in Table I. Therefore, Eq. [1] is apparently not valid for these systems. It can be corrected with a factor  $f$

$$D = \frac{f \sigma FT}{cZ^2F^2}$$

Calculated values of  $f$  for binary sodium silicate glasses of different composition are shown in Table I also. These differences between conductivity and tracer diffusion in binary sodium silicates possibly result from phase separation, which is known to occur in these glasses (8).  $f$  Factors in glass have been attributed to a special mechanism of "interstitialcy" diffusion (22, 23), but it seems unlikely that this mechanism can explain the wide variations in  $f$  shown in Table I. Furthermore, an  $f$  of one (Eq. [1] is obeyed) was found for a soda lime glass that was very likely not phase separated (17); there is no reason to expect a different diffusion mechanism for this glass than for the binary sodium silicates. In Vycor glass  $f$  is about one also, while in Pyrex, which contains two phases,  $f$  is about 0.6 (20).

In a hydrated sodium aluminosilicate glass Eisenman (24) found sodium ion mobilities about 1000 times higher than in the dry glass. Apparently hydration changes the mechanism of diffusion.

*Theories and mechanisms.*—The diffusion coefficients of sodium in sodium silicate glasses cannot be described by considering the glass as a viscous liquid. The values calculated from the Stokes-Einstein equation, which describes diffusion in many molecular liquids, are much lower than the measured ones; furthermore, the latter are unrelated to the viscosity of the glass (7). The transport of sodium in these glasses is much more rapid than for the lattice elements

Table I. Diffusion coefficients of sodium in binary sodium silicate glasses at 350°C

	Measured (18)	Calc. (Eq. [1])	
12	7.5	10	0.74
15	11	15	0.74
25	19	33	0.57
36	37	150	0.25

silicon and oxygen (7), so the glass can be treated as a rigid solid in describing diffusion.

A reasonable model for ionic diffusion in silicate glass should therefore be an alkali halide in which the cation diffuses much more rapidly than the anion. In these materials, transport occurs by motion of a structural defect, since direct exchange of two ions is energetically much harder than the motion of defects such as interstitials or vacancies. The same reasoning should apply to ionic diffusion in a glass, except that vacancy diffusion is also unfavorable in them (7), leaving interstitial diffusion as the most likely mechanism. At any temperature there are a certain number of sodium ions that are not in the normal site, but in an "interstitial" site somewhat removed from the normal one. In this formal description a detailed knowledge of the structure of this site is not necessary; in any event it is not known. The fraction  $N$  of the sodium ions that are in these interstitial sites is given by the statistical equation (7, 25, 26)

$$N = \sqrt{p} \exp(-\Delta G_f/RT)$$

where  $\Delta G_f$  is the free energy of formation of the interstitial defect and  $p$  is the number of interstitial sites available to each normal sodium ion.

The diffusion coefficient  $D$  can be described in terms of a random walk of molecules in discrete steps. From the probability of finding a molecule at a certain place after a fixed number of steps

$$D = g \bar{\lambda}^2 \Gamma \quad [3]$$

where  $g$  is a geometrical constant,  $\bar{\lambda}^2$  is the average of the squares of the step lengths, and  $\Gamma$  is the average number of steps made in unit time. The jump rate  $\Gamma_m$  for ionic motion can be calculated from various models; its usual form is (7)

$$\Gamma_m = \nu \exp(\Delta S_m/R - \Delta H_m/RT) \quad [4]$$

where  $\nu$  is the vibration frequency of the diffusing atom, and  $\Delta S_m$  and  $\Delta H_m$  are the entropy and enthalpy of activation for the motion of an atom from one site to another.

In a defect model the jump rate  $\Gamma$  is the product of the number of defects and the probability of jumping given by Eq. [4]. Then from the above equations

$$D = g \bar{\lambda}^2 \sqrt{p} \nu \exp\left[\frac{\Delta S_f/2 + \Delta S_m}{R} - \frac{\Delta H_f/2 + \Delta H_m}{RT}\right] \quad [5]$$

Equation [5] has the form of Eq. [2], with  $Q_D = \Delta H_f/2 + \Delta H_m$  and  $D_0$  a constant. It is difficult to estimate quantitatively the various quantities in Eq. [5]; one can only say that it is consistent with the experimental data.

Some results on the conductivity of sodium silicate glasses in high fields are consistent with some of the assumptions needed to derive Eq. [4] for the jump probability. One assumption is that the ions sit in an energy "well," and to move to a neighboring site the ion must possess the energy to surmount the barrier between sites. If a Boltzmann distribution of energy exists amongst the ions, their jump rate is given by Eq. [4]. When an electric field  $E$  is imposed on them, jumps in one direction become more probable than in the other, giving rise to the following equation for the conductivity (27)

$$\sigma = \frac{cF\lambda\Gamma}{E} \sinh \frac{FE\lambda}{RTg} \quad [6]$$

For low fields  $\sinh X = X$  and Eq [6] becomes

$$\sigma = \frac{cF^2\lambda^2\Gamma}{gRT}$$

which is Eq. [1] and [3] combined. When the fields

are very high, Eq. [6] becomes

$$\sigma = \frac{cF\lambda_1}{E} \exp\left(\frac{FE\lambda_1}{gRT}\right) \quad [7]$$

so that the conductivity depends exponentially upon the field  $E$ . This exponential dependence at high fields has been confirmed for sodium silicate glasses by several authors (28-31); Maurer (29) also found the hyperbolic sine law for intermediate fields. Maurer and Vermeer (31) found the temperature dependence of the pre-exponential and exponential factors of Eq. [7] expected from their low-field results on the same glasses. Maurer calculated jump distances from Eq. [7]; they were high and increased with increasing temperature. However, when these  $\lambda$  values were corrected by using the effective local field  $E_L$  calculated from the Lorentz-Lorenz relation

$$E_L = \left(\frac{\epsilon + 2}{3}\right) E$$

where  $\epsilon$  is the d-c dielectric constant, instead of the external field  $E_0$ , reasonable values of  $\lambda$  (about 5Å) independent of temperature were found. This correction has been questioned (32), but it probably is valid. This distance of 5Å is close to the separation of interstices expected in fused silica (7).

The most important factor in the energy of formation of the interstitial ion is probably the electrostatic energy needed to tear away the cation from its anion. This energy is therefore directly related to the anionic field strength or effective radius discussed in the section on Ionic Selectivity of Oxides. For a particular glass structure this energy should increase as the monovalent cation becomes smaller. The energy for motion of the ion, on the other hand, depends mainly on the energy needed to squeeze through the "doorways" between interstitial sites; this energy should increase with increasing cationic radius. Therefore one might expect a minimum in activation energy and a maximum in diffusion coefficient for ions in glass as their size is increased. Such a maximum is found for ionic diffusion in soda glasses; sodium and lithium ions diffuse most rapidly in these glasses, while hydrogen and potassium ions diffuse more slowly (33).

The effect of the changing structure of the anionic group is shown by Isard's results on the electric conductivity of sodium aluminosilicate glasses (34). The activation energy for conduction, as shown in Fig. 4, decreases as aluminum replaces silicon in the glass

Fig. 4. Activation energy for electrical conduction in various sodium aluminosilicate glasses. Sodium cation fraction held at 0.2, silicon 0.8-X, and aluminum X. From ref. (34).

network, as would be expected from the considerations of the previous paragraph and the section on Ionic Selectivity of Oxides.

The glasses with low sodium ion concentration, Vycor, and fused silica contain some aluminum. It seems likely that the sodium in these glasses is associated with the aluminum, giving aluminosilicate groups, as is the case in quartz (35). Therefore the activation energies for conduction and diffusion of sodium in these glasses may not be directly comparable to those in the binary sodium silicates, because of the probable difference in the anionic group.

*Hydrogen ions in silicates.*—Water diffuses readily into fused silica over a wide range of temperatures. As mentioned before it reacts with the silicon-oxygen network, giving two SiOH groups for each water molecule. The solubility of water in fused silica is proportional to the square root of the water vapor pressure and is little affected by temperature and impurities above about 900°C (10, 36). Below this temperature the solubility is apparently influenced by the thermal history of the silica (10). Roberts and his colleagues studied the diffusion of water into silica over a range of temperatures, and with a variety of techniques (10, 37-39). The diffusion coefficient varied with water concentration; its temperature dependence from 600° to 1200°C was

$$D = 10^{-6} \exp(-18.3/RT)$$

the activation energy being in kilocalories per mole. This equation may be used as a guide for the rate of hydration of fused silica. At 25°C the extrapolated value of  $D$  is  $3.7(10)^{-20}$  cm<sup>2</sup>/sec. This diffusion coefficient implies a very slow rate of hydration of silica at room temperature. For example, the concentration of water is one-tenth that of the surface concentration at distance of 2.7Å in 1 hr and at 72Å in a month.

The reaction of water with alkali silicates involves at least two processes, interdiffusion of hydrogen and alkali ions and dissolution of the silicon-oxygen network (11). The rate of reaction with the network is speeded at higher pH, but the extraction of alkali is slowed because not all the surface sites are occupied by hydrogen ions (see section on Ionic Selectivity of Oxides).

Owen and Douglas concluded that the conductivities of various fused silica samples they examined resulted from sodium ion conduction (21). However, their data, shown in Table II and Fig. 5, show a relation between sodium ion concentration and conductivity only for higher sodium ion concentrations; for lower sodium concentrations no such relation exists. As described below, sodium ions are about 10<sup>4</sup> times as mobile as hydrogen ions in fused silica. Therefore in types OG, OS, and 7940, where the hydrogen ion concentration is about 10<sup>4</sup> times that of sodium, it seems likely that both hydrogen and sodium ions contribute to the conductivity. Furthermore the differences between samples probably reflect the type of site at which these ions are bound. The analyses of the various types of fused silica in Table II are taken from ref. (36), since these should be more accurate than the values given by Owen and Douglas. The higher conductivity of sample OG results from the higher aluminum content of this material, since the monovalent ions are bound less tightly to the aluminosilicate sites (see section on

Table II. Electrical resistivity of fused silicas

Ionic Selectivity of Oxides). The very low conductivity of sample OS results from the low aluminum content of this sample; the diffusing cations are bound more tightly by the silicate groups. This view is further substantiated by some results of Jorgensen and Norton (40) who found a resistivity of  $4.5(10)^8$  ohm-cm at  $1000^\circ$  for Corning 7940 fused silica that had been baked out to remove most of the  $\text{OH}^-$  groups. This is about an order of magnitude higher than the resistivity of the same material before baking out, as shown in Fig. 5.

The temperature dependence of the conductivity of the silicas shown in Fig. 5 cannot be simply explained. The change in activation energy with temperature may result from transport by different species (hydrogen and alkali ions), the presence of different anionic sites (silicate and aluminate), perhaps other impurities, and possibly some electronic conduction. Because of these possibilities the mobility of hydrogen ions in silica at room temperature, which is of interest in the study of anodic films, is uncertain. If all the conductivity of sample OG could be attributed to hydrogen ions at low temperature, their diffusion coefficient would be about  $2(10)^{-24}$   $\text{cm}^2/\text{sec}$  from the data in Fig. 5. This result should probably be considered a maximum.

The motion of hydrogen ions in fused silica in an electrical field was investigated by Garino-Canina and Priquelier (41). They found no appreciable change in a sample of pure fused silica containing  $10^{20}$  hydroxyl groups per  $\text{cm}^3$  after holding at  $1050^\circ\text{C}$  and  $1500$  v/cm up to 300 hr. However, when a similar material containing about  $10^{20}$  aluminum atoms per  $\text{cm}^3$  was electrolyzed, the hydrogen ions moved to the cathode, judging from changes in the infrared absorption of the sample. After 400 hr at  $1050^\circ\text{C}$  and  $1500$  v/cm a sample 2 cm thick showed no more infrared absorption characteristic of hydroxyl groups. These experiments show conclusively that hydrogen ions associated with  $\text{SiOH}$  groups are much less mobile than those with  $\text{SiOAlOH}$  groups. This result is expected from the tighter binding of cations to the  $\text{SiO}^-$  group, as described earlier.

Hetherington, Jack, and Ramsay electrolyzed fused silica in which the current was carried by sodium ions (42). They showed that hydroxyl ions were introduced at the anode from water vapor in the air, and that after a short time the rate of electrolysis was controlled by the mobility of the hydrogen ions, which was about  $10^4$  smaller than for the sodium ions. Their fused silica contained more than enough aluminum to accommodate the monovalent cations. From their data at different temperatures ( $800^\circ$ - $1300^\circ\text{C}$ ) they calculated a resistivity  $\rho$  for the hydroxyl-containing material to be  $\log_{10} \rho = 5.4 + 5400/T$ . This equation gives an activation energy for hydrogen ion conduction of 24.6 kcal/mole, which is almost identical to the

Table III. Diffusion of various species in fused silica

Species	Diffusion coefficient at $1050^\circ\text{C}$ , $\text{cm}^2/\text{sec}$	Activation energy, kcal/mole	Ref.
Sodium ion	$10^{-6}$	24	(42)
Hydrogen ion	$10^{-10}$	24	(42)
Water	$10^{-9}$	18	(10)
Dissolved oxygen	$10^{-8}$	27	(43)
Lattice oxygen	$2(10)^{-11}$	30-80	(44-46)

activation energy for sodium conduction in fused silica and Vycor, mentioned above. This result is not in accord with the description of the paragraphs on Theories and Mechanisms above, where the difference between the mobilities of hydrogen and sodium ions is explained on the effect of binding on the activation energy, so that a higher activation energy for hydrogen ion conduction would be expected. Experiments on the transport of other ions in fused silica are needed to clarify this discrepancy. The value of  $D$  for hydrogen ions in fused silica, extrapolated to room temperature from the data of Hetherington *et al.*, is about  $8.4(10)^{-24}$ , which is not too far from the value calculated above from the conductivity of type OG silica.

The diffusion coefficients of various species in fused silica at  $1050^\circ\text{C}$  are compared in Table III. The diffusion coefficient of sodium was calculated from conductivities in Vycor (20) and fused silica (21) with Eq. [1]. These materials all contained aluminum; without it a lower diffusion coefficient of sodium might be expected. The diffusion of dissolved molecular oxygen was measured by a permeation technique (43), while the diffusion of lattice oxygen was measured by exchange with isotopically enriched oxygen (44-46).

Hydrogen ions apparently occur at several different sites in fused silica. From measurements of hydrogen permeability, Lee concluded that there were a loosely and tightly bound species (47-49). The "loosely bound" hydrogen ions were introduced by reaction with gaseous hydrogen and were easily removed by pumping out. The hydrogen ions introduced during manufacture of the fused silica, and those introduced with water vapor, were more "tightly bound" and could be removed only by long pumping out at high temperature. Hetherington *et al.* found that the hydroxyl groups introduced by electrolysis of fused silica (described above) could not be removed by pumping for long times at high temperatures and so concluded that they were even more stable (42). The results of Lee (49) and Hetherington *et al.* (42, 50) can be combined to describe three types of sites for hydrogen ions in fused silica as follows.

1. Lee's loosely bound hydrogen ions are at reduced  $\text{SiOAlOR}$  groups, where R is some monovalent cation. In the neighborhood of an aluminosilicate group the network links are weaker and, therefore, may be more easily reduced with hydrogen. The resulting hydrogen ion is loosely bound, however, because of the other monovalent cation already present, and is readily removed. Introduction and removal of these sites takes place by diffusion of hydrogen molecules through the glass, and is therefore rapid.

2. Hydrogen ions introduced in manufacture or with water vapor, if the aluminums are already satisfied, form  $\text{SiOH}$  groups. Their introduction and removal takes place by diffusion of water through the silica, which is slow compared to hydrogen diffusion.

3. Hydrogen ions introduced by electrolysis are fixed at aluminosilicate sites. They cannot be removed by pumping out the silica, because they are required for electroneutrality.

In the results described above it was shown from conductivities that hydrogen ions in type 3 sites are much more mobile than those in type 2 sites, even though the latter can be pumped out as water. Thus the terms loosely and tightly bound are misleading. Hydrogen ions in type 1 sites may be more mobile than the others; however, there are no measurements to substantiate this possibility.

The interdiffusion of hydrogen and sodium ions has been studied in a sodium calcium silicate glass (51). The sodium mobility was found to be about 1800 times greater than the hydrogen, supporting the idea of tighter binding and lower mobility for the small hydrogen ion.

Manuscript received May 19, 1967; revised manuscript received Sept. 5, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 23.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Conduction and Stoichiometry in Heat-Treated, Anodic Oxide Films

D. M. Smyth<sup>†</sup> and G. A. Shirn<sup>\*</sup>

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

#### ABSTRACT

The dielectric properties of heat-treated, anodic oxide films on certain valve metals can be explained by an exponential gradient of conductivity which decreases monotonically from the metal-metal oxide interface. Evidence is presented that the activation energy of this conduction process is a function of the conductivity. An analysis of the bias dependence of capacitance is presented which indicates that the donor distribution across the heat-treated oxide also depends exponentially on position. These observations are discussed in terms of specific conduction models.

The dielectric properties of anodic oxide films on tantalum are drastically affected by heat-treatment in air at 300°-500°C. It has been shown that the prop-

erties subsequent to heat-treatment are consistent with there being an exponential gradient of conductivity which decreases monotonically across the oxide from the Ta-Ta<sub>2</sub>O<sub>5</sub> interface (1-4). It has been assumed that the conductivity is related to local deviations from

<sup>†</sup> Electrochemical Society Life Member.

<sup>\*</sup> Electrochemical Society Active Member.

the stoichiometric composition. The conduction is thermally activated, and an activation energy of 0.6 eV has been reported (3). Systematic deviations from this value have been noted, however, and a more detailed analysis of the activation energy of conduction is given in this report.

In addition, analysis of the bias dependence of capacitance according to the Schottky depletion-layer theory (5) sheds some light on the spatial distribution of donors in the oxide (oxygen vacancies).

#### The Activation Energy

It has been shown that the equivalent series capacitance of the heat-treated oxide can be considered to be related to an effective dielectric thickness which is defined as the oxide thickness between the  $Ta_2O_5$ -counterelectrode interface and the intersection of the conductivity profile with a conductivity level designated as  $\sigma_0$  and defined, to a good approximation, as  $\sigma_0 = \omega\epsilon\epsilon_0$  ( $\omega$  is the angular frequency of the bridge signal,  $\epsilon$  is the dielectric constant of the oxide, and  $\epsilon_0$  is the permittivity of free space,  $8.85 \times 10^{-14}$  F/cm). In other words, the effective dielectric thickness is that part of the oxide where  $\sigma < \sigma_0$ . The capacitance is then obtained from this effective dielectric thickness and the parallel plate equation (see Fig. 1). Thus the conductivity profile is obtained from the frequency dependence of capacitance; the reciprocal capacitance defines the position at which the conductivity,  $\sigma$ , equals  $\sigma_0$ , whose value can be calculated from  $\sigma_0 = \omega\epsilon\epsilon_0$ . Plots of log frequency vs.  $1/C_s$  at several temperatures give a family of straight lines which represent the conductivity profiles at those temperatures (see Fig. 2). The activation energy of conduction is obtained from plots of log frequency vs.  $1/T$  taken at constant  $1/C$ , in other words from the temperature dependence of conductivity at a given position in the oxide.

It is possible to create a conductivity profile that has a very distinct demarcation between conducting and insulating oxide. One way in which this can be accomplished is by partial reanodization of a sample previously heat-treated in air or vacuum (heat-treatment in vacuum causes the film to become conducting throughout its entire thickness). During reanodization at or near the original anodization voltage, the conductivity is removed stepwise from the  $Ta_2O_5$ -counterelectrode interface, and a sharp interface between conducting and nonconducting oxide moves gradually through the film toward the underlying tantalum. As shown in Fig. 1, when the reanodization is halted at some intermediate state, the conductivity profile is made up of the original gradient, decreasing into the oxide from the Ta- $Ta_2O_5$  interface to some point

Fig. 1. Schematic representation of the conductivity gradients across heat-treated (solid line) and heat-treated and partially reanodized (dashed line) Ta- $Ta_2O_5$ .

Fig. 2. Conductivity gradients across heat-treated, anodized tantalum. 75v anodization, heat-treated 400°, 30 min in air, Ni dot counterelectrode. Points are from experiment; lines calculated from Eq. [4].

whose location lies closer to the tantalum the more complete the reanodization, where the conductivity abruptly drops to undetectable levels (2). A similar configuration is obtained when samples anodized in concentrated solutions of  $H_3PO_4$  are heat-treated in air. In this case the conductivity profile consists of an inner, shallow gradient near the Ta- $Ta_2O_5$  interface and an outer, very steep gradient. These two gradients correspond to the phosphorus-free and the phosphorus-containing portions of the oxide, respectively (6, 7). When the conductivity distribution lies in a discrete layer, as in the two cases just described, there is a distinct maximum in  $\tan \delta$  as a function of either frequency or temperature (Maxwell-Wagner effect). The temperature dependence of the frequency at which  $\tan \delta$  has its maximum value is another measure of the activation energy of conduction (3).

The experimentally determined activation energies for a variety of samples are listed in Table I. The values 1a and 1b are those described previously (3), and are typical of a large number of samples, all anodized in dilute  $H_2SO_4$  and heated in air. The other values are distinctly smaller, ranging down to 0.44 eV. It is also seen that there is good agreement between the two methods on the same sample (the value of 0.63 eV obtained by the  $\tan \delta$  method for sample 4 is very uncertain because the  $\tan \delta$  maxima were very flat and broad). The different values cannot be correlated with sample preparation since the low values are found for two widely different types.

There is one common aspect of those samples which exhibit anomalously low activation energies; the activation energy was measured for a region of high conductivity compared with the value obtained from

Table I. Activation energy of conduction by two different methods for various sample types

Anodization voltage = 75v and heat-treatment in air at 400° for all samples unless specified otherwise.

the conventional samples. For a normal sample, heat-treated in air,  $E$  is usually measured by taking a cross-section across the  $\log f$  vs.  $1/C$  plots at about  $x = 0.9$  (see Fig. 1 for definition of  $x$ ). At this point the conductivity is two orders of magnitude below that at the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. For all those samples in Table I giving low values of  $E$ , the conductivity gradient is very shallow near the metal so that the experimentally determined  $E$  is characteristic of the conductivity value near the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. This suggests that the activation energy may decrease with increasing conductivity. Such behavior has indeed been observed for a variety of bulk semiconductors, including Ta<sub>2</sub>O<sub>5</sub> and Nb<sub>2</sub>O<sub>5</sub> (8, 9).

As a further check on this behavior, a sample anodized in 8M H<sub>3</sub>PO<sub>4</sub> and heat-treated in air was analyzed in detail. The activation energy measured in the middle of the shallow, inner gradient was 0.52 eV by the  $\log f$  vs.  $1/C$  method (at  $x = 0.775$ ) and 0.49 eV by the  $\tan \delta$  method, whereas the former method gave a value of 0.7-0.8 eV at  $x = 0.63$  which was on the steep outer gradient. The conductivities at these two positions differed by a factor of 70. A careful examination of families of conductivity profiles for several samples has revealed a tendency for the profiles at different temperatures to converge very slightly toward the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. This would represent a decrease in  $E$  with increasing conductivity. The convergence is very small and is not readily apparent since only that portion of the conductivity profile in the range  $0.85 < x < 1.00$  is experimentally accessible.

In the case of a family of simple, exponential conductivity gradients which converge toward the Ta-Ta<sub>2</sub>O<sub>5</sub> interface, and where the temperature dependence of conductivity at each position fits an Arrhenius-type expression

$$E_x = -k \frac{d \ln \sigma_x}{d 1/T} \quad [1]$$

the appropriate analytical expression is

$$\sigma = A e^{-(E_0 - ax)/kT} \quad [2]$$

i.e., there is an apparent linear dependence of activation energy on position in the oxide. It had previously been proposed that

$$\sigma = A_1 e^{a_1 x} e^{-E/kT} \quad [3]$$

where the first exponential term signifies the position dependence of conductivity and the second exponential the temperature dependence (6). The new form is the same except that the slope of the position dependence is now temperature dependent. Figure 2 shows a set of data taken on a sample with a small, electrolessly deposited, nickel electrode (anodization voltage = 75v, heated 30 min at 400°C in air). The symbols represent the experimental points and the lines are calculated from

$$f = A_2 e^{-(E_0 - a_2 1/C)/kT} \quad [4]$$

with  $a_2 = 0.06638$  eV —  $\mu f$ ,  $E_0 = 2.205$  eV, and  $\log A_2 = 15.036$ . The agreement, particularly with respect to the slope which changes by 26% over this temperature range, is excellent. The dashed line is drawn with the same slope as that of the 11.7° data to demonstrate more dramatically the extent of the change in slope.

In Eq. [2] the activation energy is taken as a function of position in the oxide film. Such a direct relationship is, of course, unlikely, and the variation must be in terms of some other parameter which is a function of position. As stated earlier, it is probable that the activation energy is a function of the local conductivity.

#### The Gradient of Stoichiometry

As previously described, the application of an anodic bias (Ta +) to a heat-treated sample results in a

Fig. 3. Effect of d-c bias on the conductivity profile. 100v anodization; standard heat-treatment; measured in 40% H<sub>2</sub>SO<sub>4</sub>. Each bias held 15 min.

temporary reduction of the capacitance (1, 2). The effect is completely reversible up to about one third of the anodization voltage. The effect on the conductivity profile, as determined by the frequency dependence of capacitance, is shown in Fig. 3. The effect of bias is seen to result from the addition of a depletion layer in series with the original dielectric thickness. The depletion layer becomes wider with increasing bias. If this interpretation of the observations is correct, such data can be analyzed by a method derived by Schottky to give the spatial distribution of donors (5). The following section is a description of such an analysis.

According to the Schottky analysis, an increase in bias will result in the depletion of mobile charges (electrons) until a certain total charge has been removed. The thickness of the depletion layer will thus depend on the local density of mobile charges. The depletion layer then contains an equal amount of fixed charges (ionized oxygen vacancies). As long as the applied field is insufficient to move these fixed charges, the effect of bias is reversible.

When a d-c bias is applied to a heat-treated anodic oxide, the capacitance does not adjust quickly to a new stationary value. There is a very rapid change which is immediately followed by a drift whose rate decreases with time. This drift can begin in either direction but will eventually be such as to reduce the effect of bias. An example of such behavior is shown in Fig. 4. The magnitude of the drift can be comparable to the magnitude of the instantaneous change. This drift results in a subsequent history-dependence of the sample which may require several hours to dissipate. As a result, there is a continuous drift of sample prop-

Fig. 4. Time dependence of the effect of bias on capacitance. Same conditions as in Fig. 3.

erties throughout a bias analysis unless several hours of recovery are allowed between each measurement.

In the analysis that follows we have taken the following position. The instantaneous change of capacitance with change of bias represents an immediate electronic response by the system. The subsequent drift is assumed to be a polarization process, perhaps ionic in nature, which is related to the effect of heat-treatment, but is of no consequence to the Schottky analysis. This position is supported by the observation that the instantaneous response is essentially independent of the sample history. A given bias change will result in a given instantaneous change in capacitance,  $C_1 - C_2 = \Delta C$ , even though the actual values of  $C_1$  and  $C_2$  may differ widely, depending on the recent bias history of the sample. The drift with bias must be related to the effects of heat-treatment since its magnitude is far greater than that observed for unheated samples.

In order to obtain the instantaneous capacitance response, the measurements were made with a General Radio Impedance Comparator Type 1605-A in the circuit shown in Fig. 5.  $C_x$  represents the heat-treated sample which could be connected to either of two bias voltages by the switch  $S$ . The bias voltages were supplied by large dry cells and, in each case, the two voltages were shunted by identical, large capacitances ( $C_A = C_B = 686 \mu f$ ) so that the only change in impedance between switch positions was due to  $C_x$ .  $C_d$  and  $R_s$  were respectively a General Radio 1419-A Decade Capacitor plus a Solar Model DK-1 Decade Capacitor, and a ten-turn 500 ohm potentiometer with read-out dial. The former was used to balance the unknown capacitor so that the  $\pm 1\%$  or  $\pm 3\%$  impedance scales could be used. The phase angle was always closely balanced out with  $R_s$ . All measurements were made with a 100 Hz signal.

The procedure was to allow the sample to set for a few minutes at the lower bias to reduce the drift. The impedance difference between  $C_x$  and  $C_d$  was read;  $R_s$  was reduced to the value necessary to balance the phase angle at the higher bias; the bias was switched to the higher value; and the impedance change was read. This procedure was repeated several times between the two biases and the resulting values of  $\Delta(1/C^2)$  were averaged. The scatter was generally within 5%. The setting of  $R_s$  was only a guess for the first cycle, but for subsequent cycles it could be preset to within a phase angle difference of  $\pm 0.0005$  radians. Changes within this range had no significant effect on the impedance. The cycle time had very little effect; a time of 2 min at each bias was used. When the bias was changed there was a flurry of rapid meter fluctuation on the comparator due to charging currents, etc. There was a distinct halt, however, before the slower drift began, and the value at this pause was read visually.

In order to obtain the true, corresponding values of capacitance without drift effects, values of  $C_d$  and  $R_s$

Fig. 5. Diagram of impedance comparator circuit

necessary to give an on-scale impedance reading and a close balance of phase angle were found for the well-rested sample by switching quickly from zero bias to each bias in turn. The sample was rested again and the readings repeated, once at each bias with preset  $C_d$  and  $R_s$ . Each bias was connected for only the 1-2 sec required to obtain the initial response. This technique gave reproducible results, and these values were used to locate the depletion layers in the film.

Reproducible sets of data were obtained for both increasing and decreasing bias, but the two sets differed somewhat since there was more drift after increasing the bias than after decreasing it. The values taken with decreasing bias gave about 20% greater donor concentrations, although the spatial dependence was the same for both sets.

The samples were prepared as described previously (1). The sample area was 18.4 cm<sup>2</sup>, and the measurements were made in an electrolyte of 40% H<sub>2</sub>SO<sub>4</sub>.

The basic expression for the Schottky analysis is

$$\frac{d(1/C^2)}{dV} = \frac{1}{\epsilon\epsilon_0 e N_x} \quad [5]$$

where  $N_x$  is the donor concentration at  $x \propto 1/C$ , and  $e$  is the electronic charge. In the actual evaluation the differential increments were replaced by finite differences.  $N_x$  was plotted as a function of the reciprocal of the capacitance measured for the well-rested sample at the higher bias of each pair.

Figure 6 shows the results obtained from a sample anodized to 150v and then heat-treated at 400° for 30 min in air. The results are plotted as  $\log [\Delta V / \Delta(1/C^2)]$ , which is proportional to  $\log N$ , against the reciprocal capacitance, which is proportional to position in the film. Data obtained for both increasing and decreasing bias are shown. Results are in good agreement with an exponential gradient of donors.

Results from several samples of different thicknesses are shown in Fig. 7. In this case the calculated value of  $N$  is plotted against the normalized distance coordinate,  $x = C_0/C$ , where  $C_0$  represents the capacitance of the entire film without conduction.  $C_0$  has been approximated by the usual parallel plate expression with the thickness taken as  $19.5 \times 10^{-8}$  cm times the anodization voltage, and the dielectric constant as 29 [27.6  $\times$  1.05, which takes into account an irreversible 5% increase in dielectric constant probably caused by slight structural changes in the oxide (1, 2)].  $x = C_0/C = 1.00$  represents the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. The donor distributions shown in Fig. 7 can be approximated by

$$N = 2 \times 10^6 e^{32x}$$

which corresponds to  $\log N_d/N_1 = 14$ , where the sub-

Fig. 6. Schottky plot for 150v anodization, standard heat-treatment.

Fig. 7. Donor distributions for samples of different thickness

scripts  $d$  and  $l$  refer, as usual, to the Ta-Ta<sub>2</sub>O<sub>5</sub> and Ta<sub>2</sub>O<sub>5</sub> electrolyte interfaces, respectively.

For a donor distribution determined solely by interface equilibria during heat-treatment, one would expect the data for the various samples in Fig. 7 to be superimposable. The agreement in slope is very good; the agreement in the  $N$  values is good except for the 150v sample; but there seems to be a slight lateral displacement among the samples. The latter may be largely due to the approximation used to calculate  $C_o$ . The 5% increase in dielectric constant is a typical value which may vary some among different samples. The  $N$  values for the 150v sample are significantly lower than the others. This is partly due to the use of lower bias fields for this sample, 2 – 24% of the anodization voltage as compared with 6 – 33% for the 50v sample. The effect seems too large to be entirely accounted for in this way, however.

The results shown in Fig. 7 extrapolate to about  $2 \times 10^{20}$  donors/cm<sup>3</sup> at the Ta-Ta<sub>2</sub>O<sub>5</sub> interface ( $C_o/C = x = 1$ ). This corresponds to an oxygen vacancy content of about 0.3%, or a composition of Ta<sub>2</sub>O<sub>4.984</sub>. This is a reasonable value for an oxygen deficient transition metal oxide.

### Discussion

A dependence of the activation energy of conduction on the conductivity or on the defect concentration of semiconductors is a well-known phenomenon. As early as 1937, Meyer and Neldel noted that for Fe<sub>2</sub>O<sub>3</sub>, ZnO, UO<sub>2</sub>, and TiO<sub>2</sub>, an expression of the form

$$E \propto -\log \sigma_T \quad [6]$$

is obeyed in the region  $\sigma_{20^\circ} \geq 10^{-2} \text{ ohm}^{-1} \text{ cm}^{-1}$  (10). Such a relation may be expected when a semiconductor obeys an expression of the form

$$\sigma_D = A_D e^{-E_D/kT} \quad [7]$$

where the subscript  $D$  denotes a particular defect concentration, and where the conductivity changes much more rapidly with defect concentration than can be accounted for by the change in the pre-exponential term. It should be noted that this does not represent a direct dependence of the activation energy on the donor or acceptor concentration. Pearson and Bardeen found that for doped silicon

$$E = E_o - cN_A^{1/3} \quad [8]$$

where  $N_A$  is the acceptor concentration (11). More recent work on SnO<sub>2</sub> (12), UO<sub>2</sub> (13), Nb<sub>2</sub>O<sub>5</sub> (9), and Ta<sub>2</sub>O<sub>5</sub> (8) gives indications of activation energies which depend on the conductivity level. Marley and

Fig. 8. Meyer-Neldel relationship between activation energy and conductivity for Nb<sub>2</sub>O<sub>5</sub> (9) and SnO<sub>2</sub> (12).

Dockerty present their results on SnO<sub>2</sub> in terms of the Pearson and Bardeen equation (Eq. [8]); actually their data are in better agreement with the Meyer-Neldel rule (Eq. [6]) as shown in Fig. 8. Janninck and Whitmore have made an extensive study of the conductivity of nonstoichiometric Nb<sub>2</sub>O<sub>5</sub> and find activation energies decreasing from 0.486 to 0.0014 eV with increasing reduction (9). Except for the two samples having the highest activation energies (21 samples in all), where the determination of composition was least certain, their results are in good accord with Meyer-Neldel rule, Fig. 8. [The activation energy for sample 59-39 is listed as 0.0580 eV in the paper by Janninck and Whitmore. It is clearly placed at a much lower value in their plot of  $E$  vs. weight per cent reduction and is listed as 0.00580 eV in Janninck's thesis (14). The latter value is in much better accord with samples of similar composition and is the value used in Fig. 8.] Moreover, the slope of the Meyer-Neldel plot for the data of Janninck and Whitmore and the extrapolated value of the activation energy for the conductivity levels with which we are concerned are similar to the values required to fit the experimental data for heat-treated, anodized tantalum and niobium.

There are several possible interpretations, based on a conductivity-dependent activation energy, for the observed exponential conductivity profile across the heat-treated oxide. First of all, for a system which obeys [6] and [7], we can write

$$-E_D = kT(\ln \sigma_D - \ln A) \quad [9]$$

where  $A$  is taken as constant since strict adherence to [6] requires that  $\sigma_D$  be a function only of  $E$ . Then for the case of an exponential conductivity gradient

$$\sigma = \sigma_1 e^{bx} \quad [10]$$

[9] becomes

$$-E_D = kT(\ln \sigma_1 + bx + \ln A) \quad [11]$$

For  $E_D \equiv E_o$  at  $x = 0$

$$-E_D = -E_o + kTbx = -E_o + ax \quad [12]$$

This gives the observed form of the activation energy, as shown in Eq. [2], and  $kTb$  gives the correct value for  $a$ . Note that the result is independent of the temperature at which the basic observation [10] is made.  $E_o$  can then be calculated if the activation energy is known at any one value of  $x$ . Thus the slope of the profile at one temperature and the activation energy at one position leads to an expression which is in quantitative agreement with the observations at all positions and temperatures. Although this is an interesting arithmetical exercise, it unfortunately tells us very little about the physical nature of the conduction process, and, in fact, assumes a negligible contribution to the slope of the conductivity gradient by the slope of the donor gradient.

The problem can be approached differently with the acceptance of the Schottky analysis which yields an

exponential gradient of donors with  $\log N_d/N_1 \approx 14$ . If these donors are oxygen vacancies and if the conduction results from their partial ionization,

$$V_o^x \rightleftharpoons V_o \cdot + n \quad [13]$$

[Kröger notation (15)], the mass-action expression and the condition for charge neutrality lead to

$$n \propto [V_o^x]^{1/2} K e^{-E_i/2kT} \quad [14]$$

$E_i$  is the ionization energy of the first electron from a neutral oxygen vacancy at a given  $[V_o^x]$ . For constant mobility and introducing the spatial dependence of  $[V_o^x]$  and a position dependent activation energy we can write

$$\sigma = K_1 e^{\beta x} e^{-(E_o - \alpha x)/kT} \quad [15a]$$

$$= K_1 e^{-[E_o/kT - (\alpha/kT + \beta)x]} \quad [15b]$$

This expression differs from [2] in that part of the spatial dependence in the exponent is independent of temperature. In view of the excellent agreement of [2] with experimental results, as shown in Fig. 2, it is clear that not very much of the spacial coefficient can be extracted into a temperature independent term. Table II indicates the relative temperature dependence of  $d \ln \sigma/dx$  [which is proportional to  $d \log f/d(1/C)$ ] for four cases: (i) the experimental results from Fig. 2; (ii) from Eq. [2] in which the slope term is inversely proportional to temperature,  $\beta = 0$ ; (iii) from Eq. [15] with  $\beta$  taken as half of  $d \ln [V_o^x]/dx$  ( $\beta = 16.1$ ) as indicated by [14]; and (iv) from [15] with  $\beta = d \ln [V_o^x]/dx = 32.2$ . The agreement with  $\beta = 16.1$  is not as good as for  $\beta = 0$ , although it would take more extensive data to distinguish decisively between the two cases (moreover, the experimental results are the "raw data" and have not been corrected for the temperature and frequency dependence of the dielectric constant). The calculated results with  $\beta = 32.2$  are more clearly in disagreement with the experimental results.

Two questions may be raised about a model which involves the donor gradient determined by the Schottky analysis. The first question involves the stability of such an extremely steep gradient. Since the heat-treated samples remain unchanged in properties over long periods, the diffusion constant for donors at room temperature must be small enough to support this donor gradient without appreciable diffusion. If one takes an upper limit of a 1Å diffusion length over a time of one year, the diffusion constant must be less than  $10^{-24}$  cm<sup>2</sup>/sec. Multiplying this times the donor concentration gradient for the worst case, i.e., at the Ta-Ta<sub>2</sub>O<sub>5</sub> interface for the thinnest films (about  $10^{27}$  donors/cm<sup>4</sup> for an anodization voltage of 25v), a donor flux of  $10^3$  donors/cm<sup>2</sup> sec is obtained which means that about 10 years would be required to change the donor concentration by 1%. Using the activation energy of 1.95 ev found by Pawel and Campbell for the thermal transport of oxygen through anodic Ta<sub>2</sub>O<sub>5</sub> (16), the diffusion constant at 400° should be greater

than that at 25° by a factor of  $10^{18}$ . Thus if  $10^{-24}$  cm<sup>2</sup>/sec is suitable for a room temperature value, then a value of  $10^{-6}$  cm<sup>2</sup>/sec would be anticipated at 400°. This would correspond to a flux which is far larger than necessary to account for the very short equilibration times observed at 400°. It can be concluded that the donor gradients indicated by the Schottky analysis could be stable at room temperature and still lead to the rapid transport of oxygen observed at moderately elevated temperatures.

The second question concerns the time-constant of the donor levels. Since the bias dependence measurements were taken for the instantaneous response ( $\tau \leq 1$  sec), we must consider whether or not such a response is compatible with the depth of the electronic states in question. The time constant for the emptying of traps of depth  $E_i$  can be written

$$\frac{1}{\tau} \simeq \nu e^{-E_i/kT} \quad [16]$$

where  $\nu$  is generally taken to be the lattice vibration frequency of about  $10^{13}$  sec<sup>-1</sup>. For the conduction model just described,  $E_i$  corresponds to twice the observed activation energy of conduction (Eq. [14]) and thus lies in the range 0.9-1.4 ev for the pertinent region in the film. This would appear to lead to incompatible time constants, but one should consider that the effective trap depth will be reduced by the field according to the Poole-Frenkel effect (17). Equation [16] should be modified to

$$\frac{1}{\tau} = \nu e^{-(E_i/kT - \gamma F^{1/2})} \quad [17]$$

where  $F$  is the applied field and  $\gamma = (q^3/\pi\epsilon\epsilon_0)^{1/2} \cdot 1/kT = 1 - 3 \times 10^{-2}$  (cm/v)<sup>1/2</sup> depending on whether the optical dielectric constant for Ta<sub>2</sub>O<sub>5</sub> ( $\epsilon_r = 4.8$ ) or the dielectric constant for free space ( $\epsilon = 1$ ) is used (18). Since the applied fields lie in the range  $2 \times 10^5$  to  $2 \times 10^6$  v/cm, the Poole-Frenkel correction reduces the calculated time constants to the region of a few seconds for the worst case (highest  $E_i$  and lowest field). This is in accord with the observed response. Some of the observed polarization effects, such as shown in Fig. 4, may arise from the time dependence of the deeper vacancy levels which lie further from the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. As these levels slowly empty, the depletion layer should both widen and move away from the Ta-Ta<sub>2</sub>O<sub>5</sub> interface. This is in the direction of the observed long-term drift.

Three other conduction models might be mentioned which should have very rapid bias-responses. The first two are based on the electron transfer.

going essentially to completion. Conduction could then occur either by a hopping mechanism for cation to cation or by direct ionization to the conduction band from Ta'\_{Ta} (Ta<sup>4+</sup>). For the first case the number of charge carriers would be temperature independent and the observed activation energy would be an activation energy of mobility for the hopping process. This leads to very low mobilities ( $\sim 10^{-8}$  cm<sup>2</sup>/v sec), but these are adequate to give very fast response to a d-c bias because of the short distances and high fields involved. A third possibility would involve partial compensation such that the acceptor concentration is less than  $[V_o]$  but much greater than the concentration of ionized electrons. For the last two possibilities (partial compensation and direct ionization from Ta'\_{Ta}) the ionization energy would correspond to the observed activation energy. For all three models the temperature independent part of the conductivity gradient would correspond to the full Schottky slope ( $\beta = 32.2$ ). These mechanisms are considered unlikely because of the poor agreement for this case shown in Table II.

Table II. Absolute and relative values of the conductivity gradient,

$$d \ln \sigma/dx = \frac{\alpha}{kT} + \beta, \text{ calculated from Eq. [15] for}$$

$$d \ln \sigma/dx = 56.3 \text{ at } 34^\circ \text{ and } E = 0.45 \text{ ev at } x = 1$$

T, °K	$d \ln \sigma/dx$			$(d \ln \sigma/dx)_{284.9^\circ K}$			Observed
	$\beta = 0$	$\beta = 16.1$	$\beta = 32.2$	$\beta = 0$	$\beta = 16.1$	$\beta = 32.2$	
359.0	48.10	50.51	52.83	1.260	1.197	1.101	1.25
348.5	49.53	51.54	53.44	1.223	1.173	1.089	1.21
331.7	52.04	53.33	54.52	1.164	1.134	1.067	1.15
319.8	53.99	54.72	55.35	1.122	1.105	1.051	1.11
307.6	56.12	56.25	56.27	1.080	1.075	1.034	1.10
292.7	58.99	58.30	57.50	1.027	1.037	1.012	1.05
284.9	60.59	60.45	58.19	1.000	1.000	1.000	1.00

In summary, we can propose a detailed model based on acceptance of the donor profile as determined by the Schottky depletion layer analysis. This accounts for slightly more than half of the observed  $\log \sigma_d/\sigma_1 \approx 24$ . Conduction then arises from partial ionization of an electron from the donors (the more weakly bound electron in the case of oxygen vacancies), and the ionization energy corresponds to twice the observed activation energy of conduction. The ionization energy decreases with donor concentration according to the empirical Meyer-Neldel relationship, giving an apparent linear dependence of activation energy on position in the film. The remainder of the slope of the conductivity profile is accounted for by the resulting increased degree of ionization of donors as the Ta-Ta<sub>2</sub>O<sub>5</sub> is approached. This model leads to a space-independent electron mobility of the order of 0.2 cm<sup>2</sup>/v sec.

Manuscript received June 15, 1967; revised manuscript received Aug. 28, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 27.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Impedance for Tunnel Exchange of Electrons Across the Annealed Ta/Ta<sub>2</sub>O<sub>5</sub> Interface

K. Lehovc\*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

#### ABSTRACT

Tunneling of electrons from the tantalum metal into the adjacent oxide is an alternative explanation to a conductivity profile for the observed impedance of annealed Ta/Ta<sub>2</sub>O<sub>5</sub> capacitors as function of frequency, bias voltage, and temperature. The transformation of the Schottky-distribution [ $\partial E/\partial(1/C)^2$  vs.  $(1/C)$ ] into the distribution of recipient sites for tunneling electrons is derived. An explanation for the observed dependence of the activation energy of "conductivity" on position is given. A method is suggested for studying polarization by means of the tunnel impedance.

Smyth and co-workers have analyzed capacitance and loss angle measurements of annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures in terms of an exponential conductivity profile (1-4). This paper shows that a different model, namely, tunneling of electrons from the tantalum metal into the adjacent oxide, may generate an impedance whose frequency dependence is formally identical with that of an exponential conductivity profile. The observed "Schottky profile" (4), while not providing the actual vacancy distribution, can be accounted for by the tunnel model also.

#### Description of the Tunnel Model

The model to be analyzed in what follows considers tunneling of electrons between the tantalum and recipient sites in the adjacent oxide under the stimulus of an applied a-c voltage. The recipient sites are believed to be oxygen vacancies. While no specific distribution for these vacancies needs to be postulated, at least initially, it is reasonable to expect some sort

of decrease of the recipient concentration with distance,  $\delta$ , from the tantalum. To be specific, we shall assume that the recipient sites are electrically neutral if "empty" and become negatively charged, when "occupied" by an electron. Similar arguments could be advanced, however, for recipients which are neutral when occupied and positively charged when empty, and, for the simultaneous presence of two types of recipients, one positively and the other negatively charged.

The fundamental steps of the tunnel exchange of electrons across the Ta/Ta<sub>2</sub>O<sub>5</sub> interface will be discussed using the schematic energy level diagram of Fig. 1. The Fermi level  $\epsilon_F$  in the metal and a recipient state for an electron at the distance  $\delta$  in the oxide have been indicated. At equilibrium, the occupation of this state corresponds to that of a state of the same energy,  $\epsilon^o_T$ , in the metal. When an a-c voltage  $\tilde{E}$  is applied to the oxide, the a-c voltage drop across the distance  $\delta$  is

$$\tilde{V} = \tilde{E}\delta/d \quad [1]$$

Fig. 1. Schematic energy level diagram for the Ta/Ta<sub>2</sub>O<sub>5</sub> interface to explain electron tunnel exchange with a trap of energy  $\epsilon_T$ . Horizontal arrows indicate electron flow; vertical arrows mark modulation of trap energy due to the applied voltage  $\tilde{E}$ . An attenuated wave function for a tunneling electron of energy  $\epsilon$  is shown schematically.

neglecting polarization effects. Accordingly, the receptor state is lifted or lowered with respect to the energy state  $\epsilon_T^0$  in the metal as indicated in Fig. 1. In each instant the electron population tends to equilibrate with that of an equal state in the metal. This causes an outflow of electrons when the energy state is lifted and an inflow of electrons when it is lowered, as indicated by the arrows in the figure. If the electron exchange between the receptor state and the metal is characterized by the time constant  $\tau$ , a phase shift arises between applied voltage  $\tilde{E}$  and the induced current resulting in a lossy capacitive impedance.

The wave function for a conduction electron of the tantalum metal tunneling into the forbidden band of the oxide is exponentially attenuated as shown schematically in Fig. 1. The rate of transition of such an electron to the receptor state is in proportion to the electron density at the position of the receptor state and depends on distance  $\delta$  as  $e^{-2K\delta}$  therefore. Thus, the time constant for the electron exchange between the tantalum metal and the receptor state is of the form

$$\tau = \tau_0 e^{+2K\delta} \quad [2]$$

where  $\tau_0$  is a suitable average over all energies of tunneling electrons and their respective capture cross sections by the recipient state.

In general,  $K$  and  $\tau_0$  will depend (i) on the recipient state, in particular its energy  $\epsilon_T$ , and (ii) on the applied potential  $E$ , which modifies the shape of the barrier through which the electrons tunnel. However, it will be shown later that the expression for the impedance contains the Fermi-factor product  $f(1-f)$ . In the case of a quasicontinuous energy spectrum of traps, the attenuation of this term with energy is much stronger than that arising from the dependence of  $K$  and  $\tau_0$  on  $\epsilon_T$ , so that we may take  $K$  and  $\tau_0$  as the values at the maximum of  $f(1-f)$  over the range  $\epsilon_T$ .

Since tunnel distances are typically only of the order of  $10^{-7}$  cm, and the applied fields are fractions of the formation field, i.e., several  $10^5$  v/cm only, it is unlikely that the deformation of the barrier by the field has an effect of magnitude comparable to that of the field on the Fermi factor.<sup>1</sup> We shall, therefore, consider  $K$  and  $\tau_0$  as empirical constants in this paper, which are the same for all recipient states.

The exponential dependence on distance of the time constant  $\tau$  for tunnel exchange has been pointed out already by Heiman and Warfield (5) who considered tunnel exchange of electrons from the conduction band

<sup>1</sup> Comparing  $\exp(-2K\delta)$  to  $\exp(-qE\delta/kTd)$  and using  $K \approx [2m^*/\hbar^2 (\epsilon_c - \epsilon_T + qE\delta/d)]^{1/2}$ , one realizes that  $\partial K/\partial E \approx q\delta K/2(\epsilon_c - \epsilon_T)d$  is small vs.  $q\delta/kTd$ , for  $K\delta \approx 1$ ,  $(\epsilon_c - \epsilon_T)/q \approx 1$  V and  $qE\delta/d \ll \epsilon_c - \epsilon_T$ .

of a semiconductor into trap levels in an adjacent insulator. The driving force, in their case, was the modulation of the electron density at the surface of the semiconductor by the applied field. In the present case, there is no modulation of the electron concentration in the tantalum metal; rather the "driving force" is the shift of the energy level in the receptor state relative to the Fermi level in the tantalum metal by the applied a-c voltage. The differences between the case of a MOS structure discussed in ref. (5) and the present case of a MOM structure will be discussed in more detail in Appendix I.

For a system of time constant  $\tau$  under the influence of a stimulus of angular frequency  $\omega$ , the case of resonance

$$\omega\tau \approx 1 \quad [3]$$

plays a significant role. Since  $\tau$  varies exponentially with position, according to Eq. [2], we obtain a linear dependence on  $\ln\omega$  for the position  $\delta_0$  where resonance occurs

$$\delta_0 = [2K]^{-1} \cdot [\ln 1/\tau_0 - \ln\omega] \quad [4]$$

It will be shown later that this is the reason for the exponential conductivity profile  $\sigma(\delta^*)$  of Smyth *et al.* (1-4) obtained by plotting a conductivity defined by

$$\sigma = \epsilon\epsilon_0\omega \quad [5]$$

vs. a "distance" defined by

$$\delta^* = d(1 - C_x/C^s) = A\epsilon\epsilon_0(1/C_x - 1/C^s) \quad [6]$$

where  $C_x$  is the ideal oxide capacitance which is related to the oxide thickness  $d$  by

$$C_x = A\epsilon\epsilon_0/d \quad [7]$$

and  $C^s$  is the measured equivalent series capacitance at the frequency  $\omega$ . We have introduced a new symbol  $\delta^*$  rather than the tunnel distance  $\delta$ , since we consider  $\delta^*$  defined by Eq. [6] as an empirical quantity which need not necessarily be equal to the tunnel distance  $\delta_0$  of Eq. [4].

Figure 2 serves to illustrate the origin of the "Schottky profile" according to the tunnel model. The energy levels of recipient states located at different distances  $\delta$  from the tantalum metal are shown: (i) at zero applied bias  $E = 0$ , and (ii) at the anodic bias voltages  $E_1$  and  $E_2$  ( $> E_1$ ). At a frequency  $\omega$  the states communicate with the tantalum metal up to about the distance  $\delta$  for which  $\omega\tau(\delta) \approx 1$ , resulting in the dependence of  $\delta$  on  $\omega$  indicated in the figure.

The energy level of the receptor states is tilted by the angle  $qE/d$  by an applied anodic bias voltage  $E$ .

Fig. 2. Concerning the bias dependence of the tunnel impedance. The tunnel distance at resonance  $\omega\tau \approx 1$  is related to the frequency as noted in the figure on the lower right. Lack of electrons in the metal of energies greater than  $\epsilon_{C0}$  leads to a cut-off distance which depends on bias [ $\delta_1(E_1)$  and  $\delta_2(E_2)$ ].

Fig. 3. Points are experimental conductivity profiles by [5] and [6] according to Smyth and Shirn (4). Theoretical curves by Eq. [43] with parameters of Table I, second column.

In order to understand the origin of the vertical drop of the conductivity profile under bias from which the Schottky plots are derived (4) and which is shown in Fig. 3, let us assume that there are no electrons above a cut-off energy  $\epsilon_{c0}$  in the tantalum metal. This is, of course, a gross oversimplification, introduced here only for the purpose of a simplified explanation of the bias effect. The exact relations will be derived later based on a Fermi distribution. Because of the energy cut-off for electrons, recipient states above the dotted line  $\epsilon_{c0}$  in Fig. 2 cannot exchange electrons with the tantalum metal under an a-c stimulus. The intersects of the energy levels of the recipient states with the cut-off energy correspond to the distances  $\delta_1$  and  $\delta_2$  at the applied d-c bias voltages  $E_1$  and  $E_2$ , respectively. These distances in turn correspond to the cut-off frequencies  $\omega_1$  and  $\omega_2$ , respectively, defined by the relation [4]. At frequencies lower than the cut-off frequency  $\omega_1$ , the tunnel capacitance is independent of frequency since tunneling to the states  $\epsilon > \epsilon_{c0}$  at  $\delta > \delta_1$  is not possible. This leads to the vertical drop-off of the conductivity profile for frequencies  $\omega < \omega_1$  when the bias  $E_1$  is applied. The vertical drop-off of the conductivity profile under bias is illustrated in Fig. 3 using experimental points obtained by Smyth and Shirn (4). The solid lines are theoretical curves according to the tunnel theory, which will be derived later on.

#### Detailed Expressions for the Tunnel Impedance

Designating the density of traps of energy  $\epsilon_T$  by  $n_T$ , i.e., number of traps per unit volume per unit trap energy range, a space charge density

$$\rho = -q \int_{\epsilon_0}^{\epsilon_c} n_T f_T^* \partial \epsilon_T \quad [8]$$

results where  $f_T^*$  is the occupation factor, i.e., the fraction of traps of energy  $\epsilon_T$  which are occupied, and the integration extends over the forbidden band of the oxide. In the case of thermal equilibrium the occupation factor becomes equal to the Fermi factor

$$f_T = [1 + \exp(\epsilon_T - \epsilon_F/kT)]^{-1} \quad [9]$$

However, during nonequilibrium conditions such as the "drift" of the impedance after applying or removing a bias voltage,  $f_T^*$  need not equal  $f_T$ . When applying a small a-c voltage  $\tilde{E}$  to the oxide, the potential  $V(\delta)$  at the position  $\delta$  in the oxide is modulated. This changes the energy of a trap relative to the

Fermi-level  $\epsilon_F$  in the tantalum metal by

$$\epsilon_T - \epsilon_F = \epsilon_T^0 - \epsilon_F - qV(\delta) \quad [10]$$

where  $V(\delta=0) = 0$  has been chosen. The a-c component of [10] (indicated by a wave symbol above the notation) is

$$\tilde{\epsilon}_T = -q\tilde{V} \quad [11]$$

Since the electrons in the traps tend to equilibrate by tunneling with the electrons of the corresponding energy level in the tantalum metal, the modulated trap energy  $\tilde{\epsilon}_T$  induces an alternating charge flow between the trap and the tantalum metal. Thus, the occupation factor  $f_T^*$  contains an a-c component,  $\tilde{f}_T^*$ , generated by the applied a-c voltage  $\tilde{E}$ .

Poisson's equation integrated twice over the oxide provides

$$\tilde{E} = \tilde{V}_{d'} \cdot d + \int_0^d \frac{\tilde{\rho}}{\epsilon \epsilon_0} \delta \partial \delta \quad [12]$$

where  $\tilde{V}_{d'}$  is the field modulation at the electrode at  $\delta = d$ . The second term on the right-hand side is the contribution to the potential from dipoles consisting of the space charge  $\tilde{\rho}$  at  $\delta$  and the opposite charge at the tantalum metal. The field at  $\delta = d$  is related to the charge  $\tilde{Q}_M$  by Gauss' law

$$\tilde{Q}_M = -A\tilde{V}_{d'} \cdot \epsilon \epsilon_0 \quad [13]$$

Inserting the component of [8] which arises from the small a-c modulation into [12] and substituting [13] for  $\tilde{V}_{d'}$ , one obtains the admittance

$$\Sigma = i\omega \tilde{Q}_M / \tilde{E} = i\omega C_x + \Sigma_T \quad [14]$$

where

$$\Sigma_T = i\omega A q^2 \int_0^d \left[ (\delta/d) \cdot (\tilde{V}/\tilde{E}) \cdot \int_{\epsilon_0}^{\epsilon_c} n_T (\tilde{f}_T^* / \epsilon_T) \partial \epsilon_T \right] \partial \delta \quad [15]$$

Evaluation of this integral requires expressions for  $\tilde{V}/\tilde{E}$ ,  $\tilde{f}_T^*/\epsilon_T$  and  $n_T = n_T(\epsilon_T, \delta)$ . To simplify the analysis we shall assume that the a-c space charge  $\int_0^d \tilde{\rho} \partial \delta$  is small compared to  $\epsilon \epsilon_0 \tilde{E}/d$ , so that

$$\tilde{V}/\tilde{E} \approx \delta/d \quad [16]$$

If this assumption is not justified, Poisson's equation must be used to relate  $\tilde{V}/\tilde{E}$  to  $\tilde{\rho}$  and  $\delta$ .

The analysis (to be presented elsewhere) of the tunnel process for electrons between the metal and a single trap level of energy  $\epsilon_T$  in the oxide at the distance  $\delta$  provides

$$\tilde{f}_T^* / \epsilon_T = f_T (1 - f_T) (1 + i\omega \tau_T)^{-1} / kT \quad [17]$$

where  $\tau_T$  is the time constant given by Eq. [2].

The factor  $f_T(1 - f_T)$  in Eq. [17] arises from the fact that a-c exchange of electrons with traps is only possible if the traps are neither completely empty nor completely occupied: In the first case,  $f_T \approx 0$ , emission of electrons is impossible and in the second case,  $f_T \approx 1$ , absorption of electrons is impossible. The occurrence of the factor  $f_T(1 - f_T)$  is well known for other electron transition processes to traps, e.g., transitions between electrons in surface states and those in the conduction band of a semiconductor lead

(6) to a surface state capacitance in proportion to  $f_T(1 - f_T)$ .

In deriving Eq. [17] it was assumed that the traps which participate in the a-c electron exchange with the tantalum metal at the angular frequency  $\omega$  have reached d-c equilibrium with the metal, i.e.,  $f_T^* = f_T$ . During the transient conditions following a switch of d-c bias voltage, when  $f_T^* \neq f_T$ , another contribution to  $\tilde{f}_T^*/\epsilon_T$  may arise in addition to that of Eq. [17] due to the modulation of the attenuation constant  $K$  by the applied field. However, the analysis of transient conditions by means of the tunnel model will not be considered further in this paper.

Inserting [16] and [17] into Eq. [15] and defining

$$\frac{N_T}{1 + i\omega\tau} \equiv \int_{\epsilon_v}^{\epsilon_c} \frac{n_T f_T (1 - f_T)}{1 + i\omega\tau_T} \partial\epsilon_T \quad [18]$$

one obtains

$$\Sigma_T = i\omega A q^2 / kT \cdot \int_0^d (\delta/d)^2 N_T (1 + i\omega\tau)^{-1} \partial\delta \quad [19]$$

Since the experimental data are expressed in terms of a series arrangement  $C^s, R^s$ , we shall transform the parallel conductance  $\Sigma_T$  which shunts the ideal capacitance [7] into a series arrangement (Fig. 4)

$$R^s + [i\omega C^s]^{-1} = [i\omega C_\infty + \Sigma_T]^{-1} \simeq [i\omega C_x]^{-1} + \Sigma_T / (\omega^2 C_x^2) \quad [20]$$

where  $\Sigma_T \ll \omega C_\infty$  has been assumed.

Furthermore, letting

$$\Sigma_T \equiv \omega(\Gamma_T + iC_T) \quad [21]$$

one has

$$\delta^*/d = 1 - C_\infty/C^s \simeq C_T/C_x \quad [22]$$

and

$$\tan \theta \simeq \Gamma_T/C_x \quad [23]$$

#### Comparison of Tunnel Impedance with that of a Conductivity Profile

The impedance resulting from a conductivity profile  $\sigma(\delta^*)$  is

$$R^s + [i\omega C^s]^{-1} = \frac{1}{A} \int_0^d (\sigma + i\omega\epsilon_0)^{-1} \partial d^* \\ = [i\omega C_x]^{-1} - [iA\omega\epsilon_0]^{-1} \cdot \int_0^d (1 + i\omega\epsilon_0/\sigma)^{-1} \partial\delta^* \quad [24]$$

Equation [24] becomes identical to [20] with [19] by the substitutions

$$\delta = \lambda\delta^* \quad [25]$$

with

$$\lambda = \left[ \frac{q^2}{kT\epsilon_0} \frac{N_T}{N_T\delta^2} \right]^{-1} \quad [26]$$

and

$$\epsilon_0/\sigma = \tau \quad [27]$$

The upper limit  $d$  of the integrals in [24] and [19] can safely be replaced by infinity since practically no contributions arise in either integral from the outer oxide region  $\delta \simeq d$ . Equation [27] is satisfied for an

exponential conductivity profile

$$\sigma = \sigma_0 e^{-K\delta^*/d} \quad [28]$$

if we identify

$$\epsilon_0/\sigma_0 = \tau_0 \quad [29]$$

and

$$K\sigma = 2Kd\lambda \quad [30]$$

where  $\tau_0$  and  $K$  are the values in [2].

On the other hand, inserting the tunnel time constant [2] into [19] and using [20] and [6], one obtains [25] as follows: Assume that  $\omega\tau \ll 1$ . Since  $\tau$  varies extremely rapidly with position we may substitute in [19]  $1 + i\omega\tau \simeq 1$  for  $\delta < \delta_0$  and  $1 + i\omega\tau \simeq 0$  for  $\delta > \delta_0$  where  $\delta_0$  is the value defined by [4]. We thus obtain for the capacitive part  $C_T$  of the conductance  $\Sigma_T$

$$C_T \simeq \frac{Aq^2}{kT} \int_0^{\delta_0} (\delta/d)^2 N_T \partial\delta \simeq \frac{Aq^2}{kT} (\delta/d)^2 \bar{N}_T \cdot \delta_0 \quad [31]$$

Equation [25] results from [22] with [26] and [31].

The temperature dependence of the zero bias conductivity profile can be obtained from [22] with [31] and [4]. Smyth *et al.* (4) define the activation energy as

$$U_\sigma = -k \partial \ln \omega / \partial (1/T)_{\delta^* = \text{constant}} \quad [32]$$

Since  $\delta^* = \text{constant}$  implies  $C_T = \text{constant}$ , one has from [31]<sup>2</sup>  $\partial[N_T\delta_0/T]/\partial T^{-1} = 0$ , i.e.,

$$U_\sigma = U_{\tau_0} + 2K\delta[U_{\bar{N}_T} - kT] = U_{\tau_0} + \lambda 2K\delta^*[U_{\bar{N}_T} - kT] \quad [33]$$

where

$$U_{\tau_0} = -k \frac{\partial \ln 1/\tau_0}{\partial 1/T} \quad [34]$$

and

$$U_{\bar{N}_T} = -k \frac{\partial \ln \bar{N}_T}{\partial 1/T} \quad [35]$$

Thus the activation energy of the zero bias "conductivity profile" depends on position as is indeed observed (4).

A dependence of the "conductivity profile" on the bias voltage may arise from the Fermi factor  $f_T$  which enters the definition [18] of  $N_T$ . There is also an influence of the bias voltage on the attenuation "constant"  $K$ , but this effect will be ignored in what follows.

For an energy level sufficiently above the Fermi level that  $\epsilon_T - \epsilon_F \gg kT$  one has  $1 - f_T \simeq 1$ , and

$$f_T \simeq \exp[-(\epsilon_T - \epsilon_F)/kT] = f_T^0 e^{-qpE/kTd} \quad [36]$$

where  $f_T^0 = [f_T]_{E=0}$ . The exponential term containing  $E$  results from the shift of the energy level of the recipient state *vs.* the Fermi level in the metal (see Eq. [10]) and assuming that

$$V = pE\delta/d \quad [37]$$

where  $p \leq 1$  is a factor accounting for the possible presence of polarization.

At this point, detailed assumptions on the energy distribution of the recipient states are required. In the case of a broad energy spectrum of traps overlapping the Fermi energy one has

$$N_T/(1 + i\omega\tau) = n_F \cdot kT/(1 + i\omega\tau_F) \quad [38]$$

with  $\tau_F, n_F$  being the values of  $\tau_T, n_T$  taken at the energy  $\epsilon_T = \epsilon_F$ . Equation [38] results from the sharp attenuation of  $f_T(1 - f_T)$  with energy difference  $\epsilon_T - \epsilon_F$ . This bias dependence of  $\Sigma_T$  is thus expected to be small, resulting only from the dependence of  $n(\epsilon)$  on  $\epsilon$ .

<sup>2</sup> The factor  $(\delta/d)^2$  does not change with temperature if the variation of  $N_T$  with temperature does not depend on position.

Fig. 4. Equivalent series and parallel networks. The network at the right assumes that  $C_T, \Gamma_T \ll C_x$ .

On the other hand, in the case of a single trap level one has

$$N_T \cdot (1 + i\omega\tau)^{-1} = \int n_T \delta \epsilon_T \cdot f_T (1 - f_T) (1 + i\omega\tau)^{-1} \\ \simeq N_T^0 \cdot f_T^0 \exp(-qpE\delta/kTd) (1 + i\omega\tau)^{-1} \quad [39]$$

where [36] has been used and  $N_T^0 = \int n_T \delta \epsilon_T$  is the total recipient concentration.

Inserting [39] into [19] and using [22], one obtains

$$\delta^*/d \equiv 1 - \frac{C_\infty}{C^s} \simeq \frac{C_T}{C_\infty} \\ = \frac{q^2 d}{kT\epsilon\epsilon_0} \int_0^d \frac{(\delta/d)^2 N_T^0 \cdot f_T^0 e^{-qpE\delta/kTd}}{1 + (\omega\tau)^2} \delta \quad [40]$$

This integral becomes nearly independent of  $\omega$  for sufficiently low frequencies that  $qpE\delta_0/kTd \gg 1$ , causing the vertical drop-off of the conductivity profile in Fig. 3 at low frequencies when an anodic bias voltage is applied.

Applying the same considerations which led to [40] to the loss angle, one obtains

$$\tan \theta \simeq \Gamma_T/C \\ = \frac{q^2 d}{kT\epsilon\epsilon_0} \int_0^d \frac{(\delta/d)^2 N_T^0 f_T^0 e^{-qpE\delta/kTd} \omega\tau}{1 + (\omega\tau)^2} \delta \quad [41]$$

which differs from [40] only by the factor  $\omega\tau$  in the integrand.

#### Detailed Analysis for a Special Distribution of Monoenergetic Recipient States

We shall evaluate [40] and [41] for the special case that

$$N_T^0 f_T^0 = N_0/(\delta/d)^2 \quad [42]$$

where  $N_0$  is a constant (independent of position). The inverse  $\delta^2$ -distribution has been chosen since it provides exactly an exponential conductivity profile, as seen readily from the definition of the conductivity profile, [5] with [6], and [22], [31], and [4]. The factor  $d^2$  in [42] has been added for convenience, giving  $N_0$  the dimension of a concentration and is not supposed to indicate explicitly a dependence of the recipient profile on the oxide thickness. Such a dependence need not be specified in what follows; the mathematical analysis applies for  $N_0$  being any arbitrary function of  $d$ . If the recipient distribution  $N_T^0$  were independent of oxide thickness,  $N_0$  would be inversely proportional to  $d^2$ .

With the assumption [42] the product  $N_T^0 f_T^0 (\delta/d)^2$  in the integrand of [40] and [41] becomes equal to the constant  $N_0$ . The expression [40] has been evaluated in approximate form by (i) replacing the upper limit  $d$  by  $\delta_0$  of [4] and (ii) replacing  $1 + (\omega\tau)^2$  by unity. These are the same approximations as have been introduced when deriving [31]. We thus obtain

$$\delta^*/d \simeq \alpha(pE)^{-1} \cdot [1 - e^{-\beta p E \delta_{10} \nu_0 / \nu}] \quad [43]$$

with  $\alpha$ ,  $\beta$ , and  $\nu_0$  the constants listed in Table I. The theoretical curves in Fig. 3 were calculated by [43] for zero polarization, that is,  $p = 1$ , with the values for  $\alpha$ ,  $\beta$ , and  $\nu_0$  of the second column of Table I. These values were chosen to match the intersect ( $\nu_0$ ), and slope ( $\alpha \cdot \beta$ ) of the zero-bias conductivity profile and to fit the 50 Hz point on the curve  $E = 1$  v. The last column of Table I lists numerical values for the constants  $\tau_0$ ,  $N_0$ , and  $K$  obtained from the nu-

merical values for  $\nu_0$ ,  $\alpha$ , and  $\beta$  by the equations listed in column 1. Using these values the parameter  $\lambda = \delta/\delta^* = kT/q\alpha$  becomes 0.054.

The theoretical curves fit the shape of the experimental curves well; however, there is a discrepancy between the bias voltages of the coinciding experimental and theoretical curves for  $E > 1$  v. A possible explanation for this discrepancy is polarization, i.e.,  $p < 1$ , as will be discussed later.

The "Schottky profile" is defined (7) by

$$N_s(\delta^*) = \frac{\partial E}{\partial(1/C^s)^2} [qA^2 \epsilon\epsilon_0]^{-1} = -\frac{\epsilon\epsilon_0}{q} \frac{\partial E}{\partial(\delta^*)^2} \quad [44]$$

Inserting the "cut-off distance"  $\delta^* = d\alpha/(pE)$  of [43] for  $\nu \rightarrow 0$  one obtains

$$N_s(\delta^*) = N_0/[2p(\delta^*/d)^3] \quad [45]$$

where the value for  $\alpha$  listed in Table I has been used. Considering [42] and [45], the charged recipient profile  $N_T f_T^0$  vs.  $\delta/d$  is obtained from the Schottky profile  $N_s$  vs.  $\delta^*/d$  as follows: (i) contract the abscissa by the factor  $\lambda = \delta/\delta^*$ ; (ii) multiply the ordinate  $N_s$  by  $2p(\delta^*/d)^3$  and divide by  $(\delta/d)^2$ , i.e.,

$$N_T^0 f_T^0 \equiv 2N_s \cdot p \cdot (\delta^*/d)\lambda^2 \quad [46]$$

Figure 5 shows an example for such a transformation. The experimental points of  $N_s$  vs.  $\delta^*/d$  are for the sample formed to 100v shown in Fig. 7 of ref. (4). The points  $N_T^0 f_T^0$  vs.  $\delta/d$  were obtained with  $p = 1$  and  $\lambda = 0.05$  and 0.1, respectively. The value  $\lambda = 0.05$  arises from the  $\alpha$ -value of Table I. The origin of the value  $\lambda = 0.1$  will be explained later. The straight line plotted through the  $N_T^0 f_T^0$ -points corresponds to a  $(\delta/d)^{-2}$  dependence which was postulated by us previously to obtain the exponential conductivity profile at zero bias. The line drawn through the  $N_s$  vs.  $\delta^*/d$  points has a slope of  $-3$  as expected from [45].

It should be emphasized that the  $\delta^{-2}$ -dependence of the recipient state concentration was postulated to obtain the observed frequency dependence of the capacitance at zero bias. This space dependence enabled us to predict a  $\delta^{-3}$ -dependence of the Schottky slope which is derived from the bias dependence of the capacitance. The fact that the tunnel theory predicts an observed interrelation between two independent sets of measurements ( $C^s$  vs.  $\omega$  at  $E = 0$ , and  $C^s$  vs.  $E$  at a constant  $\omega$ ) supports our interpretation.

The value

$$N_0 \equiv N_T^0 f_T^0 \cdot (\delta/d)^2 = 2N_s p (\delta^*/d)^3 \quad [47]$$

is independent of the assumptions on  $\lambda$ . From the straight lines plotted in Fig. 5, one obtains  $N_0 = 3 \times$

Fig. 5. Transformation of a Schottky profile  $N_s$  vs.  $\delta^*/d$  taken from Fig. 7, of ref. (4) with a distribution of recipient states,  $N_T^0 f_T^0$  vs.  $\delta/d$ . The straight lines have the slopes  $-2$  and  $-3$ , respectively, expected from [42] and [45]

Table I. Empirical parameters for the theoretical curves of Fig. 3, and corresponding basic quantities

Empirical parameter	Numerical value	Basic quantity
$\nu_0 = (2\pi\tau_0)^{-1}$	$3.10^4 \text{ sec}^{-1}$	$\tau_0 = 5 \times 10^{-6} \text{ sec}$
$\alpha = qd^2 N_0 / \epsilon\epsilon_0$	0.475v	$N_0 = 1.5 \times 10^{18} \text{ cm}^{-3}$
$\beta = 2.3(kT/q \cdot 2Kd)^{-1}$	$0.09\text{v}^{-1}$	$K = 2.5 \times 10^7 \text{ cm}^{-1}$

Fig. 6. Loss angle at different frequencies vs. bias voltage. Experimental points assuming  $\alpha\beta = 50$  and  $K = 2.5 \times 10^7 \text{ cm}^{-1}$ . Theoretical curves by Eq. [41] with [42]. For  $\tau_0 = 5 \times 10^{-6} \text{ sec}$  (Table I),  $u = 0.003$  at 100 Hz, and  $u = 0.3$  at  $10^4 \text{ Hz}$ .

$10^{16} \text{ cm}^{-3}$ . This is twice the value listed in Table I, which was derived from Fig. 4 by [43] with  $p = 1$ .

Figure 6 shows theoretical curves for  $\tan \theta$  calculated by [41] with [42] as a function of bias voltage for the frequencies indicated as parameters and using  $p = 1$ . The pertinent integral listed in the right upper corner of the figure was evaluated numerically using a computer. Experimental points are plotted using the value of  $K$  from Table I, and the slope  $\alpha\beta$  of the semilogarithmic zero bias conductivity profile.

At 100 Hz, one has  $u = \omega\tau_0 = 3 \times 10^{-3}$  using the value for  $\tau_0$  of Table I. In spite of the fact that the sample used for Fig. 6 was not the same as that for Fig. 3 and Table I, the experimental points fit reasonably well except for a discrepancy of the abscissa ( $E$ ) scale similar to that of Fig. 3 and to be discussed later.

### Discussion

It has been shown that a tunneling model based on the relation [2] is capable of accounting for the principal features of impedance measurements (1-4) on annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures without invoking an actual conductivity profile. These features are: (i) the exponential "conductivity profile" defined by [5] and [6] at zero bias (Fig. 3); (ii) the temperature dependence of the zero-bias conductivity profile, showing an activation energy which depends on position (4); (iii) the conductivity profiles under bias voltage showing a cut-off distance at low frequencies (Fig. 3); (iv) the Schottky profile derived from the conductivity profiles under bias voltage (4).

The fact that two physically completely different models, (a) a conductivity distribution extending over several hundreds of angstroms and (b) a tunnel effect through, at most, a few tens of angstroms is capable of explaining the experimental data is not surprising because both models lead to a distribution of time constants, which depend exponentially on distance. The frequency dependence of any system having a distributed time constant spectrum exhibits certain features which are independent of the physical origin of the time constant spectrum.

In order to distinguish between the two models, we need to explore (a) which model accounts more naturally, i.e., with fewer assumptions, for the observed phenomena; (b) which model utilizes numerical values for empirical parameters which are more reasonable, and (c) which model explains experimental features which cannot be explained by the other model.

The conductivity profile involves five empirical parameters: (i) magnitude of conductivity at the metal interface; (ii) slope of the semilogarithmic conductivity profile; (iii) the position independent part of the activation energy of  $\sigma$ ; (iv) the position-dependent part of this activation energy; (v) mobility factor.

The tunnel model also involves five parameters: (i) pre-exponential factor,  $\tau_0$ , of the time constant [2]; (ii) attenuation factor  $K$  of [2]; (iii) activation energy of  $\tau_0$ ; (iv) activation energy of  $\bar{N}_T$ ; (v) constant  $N_0$ .

The conductivity model postulates an exponential distribution of vacancies acting as donors of conduction electrons. The tunnel model postulates an inverse-distance-square profile of recipient sites. The conductivity model postulates a linear dependence of the activation energy defined by [32] for the impurities on position. In contrast, the linear dependence on distance of this activation energy is automatically obtained by the tunnel model [33].

Concerning the numerical values of  $K$ ,  $\bar{U}_{NT}$  and  $N_0$  used for matching the tunnel model to the experimental data:

Simple wave mechanical theory provides  $K \approx 10^8 \text{ cm}^{-1}$  for a barrier 1 eV high, and an electron of free electron mass. The experimental value given in Table I is about four times smaller. This could be attributed formally to a small effective electron mass,  $m^*$ , and/or a low energy barrier,  $\epsilon_c - \epsilon$  in Fig. 1. Indeed, measurements by Mead (8) suggest a low barrier at the Ta/Ta<sub>2</sub>O<sub>5</sub> interface. However, it seems to us more likely that the concept of the potential energy barrier and of the conduction band as shown in Fig. 1 and 2 is not strictly valid for the following reasons:

1. Anodic tantalum oxide is amorphous.
2. The distances involved in tunneling are so small that the discrete atomic structure and image charge potentials should become important.
3. The wave function of a tunneling electron may not be evenly attenuated as shown in Fig. 1, but the attenuation could be arrested in the vicinity of a recipient site, although the tunneling electron may not be trapped at that site. Considering the large concentration of recipient sites, the penetration of a tunneling electron into the oxide could be considerably extended by such an effect.

Comparing [33] with the empirical values of Smyth *et al.* (4), one obtains  $\bar{U}_{NT} \approx 0.055 \text{ eV}$ , i.e., the energy level of the traps lies about  $2kT$  above the Fermi level and  $f_T^0 \approx 0.1$ , accordingly. This is in agreement with  $f_T^0 \ll 1$ , as was postulated to explain the Schottky profile by means of a discrete energy level for traps lying above the Fermi level. With this value for  $f_T^0$  and the  $N_T^0 f_T^0$ -values of Fig. 5 we obtain recipient concentrations in the range of  $10^{21}$  to  $10^{22} \text{ cm}^{-3}$ . Such high concentrations would indicate the presence of a suboxide where a significant fraction of all the atoms can act as recipients. Indeed, suboxides have been observed under more extreme annealing conditions (9). However, at such high concentrations the presence of a single well-defined energy level is unlikely. This aspect of the tunnel model is still unsatisfactory. It is conceivable that [2] with  $\tau_0$  and  $K$  independent of bias needs revision, or else that the profile [39] with [42] on which the detailed comparison is based is not fully adequate.

The tunnel model is capable of describing the bias dependence of the impedance for both anodic and cathodic biases. While no systematic experiments have been made with cathodic bias voltages, the few experimental points in Fig. 6 are in general agreement with the trend of the theoretical curves. Furthermore, Fig. 4 of ref. (4) shows that after returning from an anodic bias to zero bias, the capacitance "overshoots," i.e., the stationary capacitance value at zero bias lies between the value at the anodic bias and that at zero

bias immediately following an anodic bias. In the framework of the tunnel model, this suggests that temporarily a cathodic bias transient is effective, resulting from a positive space charge which has formed in the oxide adjacent to the tantalum during application of the anodic bias voltage. A possible space charge located close to the tantalum decreases the anodic field at the tantalum during the anodic bias by an amount equal to the cathodic field induced by that space charge immediately after switching to zero bias. Thus, in a range of sufficiently small polarization, so that a linear dependence of capacitance on field applies, the capacitance change during the switch of bias should be independent of the amount of polarization, i.e., of the time of application of anodic bias. This has been observed (4). According to this interpretation, we could expect a polarization factor  $p < 1$  in [37], [39], [40], [41], [43], [45], and [46]. This may account for the discrepancy between the applied bias  $E$  of the experimental points in Fig. 3 and 6, and the  $E$  values of the theoretical curves through these points; the actual bias voltages of the experimental points should be replaced by the effective bias voltages  $pE$  which are smaller than  $E$ . For instance, the theoretical bias voltage  $E = 10\text{v}$  in Fig. 3 corresponds to the applied bias  $E \simeq 25\text{v}$ , so that  $p \simeq 0.4$  in this case, provided that  $p = 1$  for the curve  $E = 1\text{v}$  as assumed in deriving  $\beta$ . The experimental points on Fig. 3 have been taken after applying the bias voltage for 15 min (4). Figure 4 of ref. (4) shows that the capacitance change after applying 12v for 1 min is only about  $\frac{3}{4}$  of the instantaneous capacitance change. The suggested polarization factor of about 0.4 for 15 min application of the bias does not seem unreasonable, therefore. Figure 4 of ref. (4) shows that there is already some significant polarization at 1.5v. It may be suspected, therefore, that even at 1v one has  $p < 1$  contrary to the assumptions made in evaluating  $\alpha$  and  $\beta$  from Fig. 3. In this case, the numerical values in the second column of Table I are not  $\alpha$  and  $\beta$ , but  $\alpha/p$  and  $\beta p$ , respectively, where  $p$  is the polarization factor pertaining to 1v. Accordingly,  $\alpha$  would be smaller, and  $\beta$  larger than in the previously assumed case  $p = 1$ . As a consequence,  $\lambda = kT/q\alpha$  would become larger. The value  $\lambda = 0.1$  used in Fig. 5 is based on the assumption that  $p = 0.5$  at 1v.

It is interesting to note that this interpretation, if correct, provides a tool to determine polarization fields at the tantalum interface by means of measuring tunnel impedance. This opens a prospect for the study of residual charge phenomena in metal-insulator structures, comparable to the common use of the depletion capacitance in semiconductor-insulator structures to assess the field at the semiconductor-insulator interface.

The tunneling model discussed here has important implications for the design of capacitors in microcircuits. A prime parameter for comparing the capacitor performance of different materials is the maximum stored energy  $CV^2/2$  per unit volume, which is  $\epsilon\epsilon_0 F_b^2/2$  with  $F_b$  the breakdown field. Since voltages in microcircuits are frequently only of the order of volts, and breakdown fields are of the order of  $10^7$  v/cm, dielectric layers only several tens angstroms wide become of potential interest. Loss mechanisms arising from electrons tunneling several angstroms into the dielectric may thus become quite important.

Pronounced effects such as in annealed Ta/Ta<sub>2</sub>O<sub>5</sub> are unusual. Nevertheless, a significant density of recipient sites may be present in ordinary dielectrics close to a metal electrode, perhaps due to mobile ions in the dielectric which drift toward the boundaries (e.g., Na in SiO<sub>2</sub>)<sup>10</sup> or else due to inherent structural perturbances near the interface of two different materials. Thus, the tunnel model may provide useful information for a much wider range of capacitors and materials than annealed Ta/Ta<sub>2</sub>O<sub>5</sub>.

While the proposed tunnel model may apply to ordinary annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures and perhaps

even to unannealed Ta/Ta<sub>2</sub>O<sub>5</sub> samples, it is unlikely to apply to vacuum annealed Ta/Ta<sub>2</sub>O<sub>5</sub> combinations and certain phosphorus anodized samples where extremely shallow conductivity profiles through a large portion of the oxide have been observed (11, 12). In these cases, the interpretation of the impedance measurements by an ordinary conduction mechanism (1-4, 11, 12) appears to be valid.

### Summary

1. Formulas are derived for the tunneling of electrons from a metal into sites in an adjacent insulator.
2. These equations account qualitatively and quantitatively for the frequency and bias dependencies of annealed Ta/Ta<sub>2</sub>O<sub>5</sub> structures. Thus tunneling is an alternative explanation to that based on a conductivity profile.
3. The distances  $\delta^*$  obtained for the conductivity profile have to be contracted by a factor  $\lambda$  to give the tunnel distances.
4. The vacancy concentration obtained by the Schottky method has to be multiplied by  $2p(\delta^*/d)/i^2$  in order to provide the concentration of recipient sites.
5. In order to arrive at a strictly exponential conductivity profile, an inverse-square-distance distribution of the recipient sites is postulated.
6. The observed dependence of the activation energy of the conductivity profile on position has a natural explanation by the tunnel model.
7. There are indications of space charge polarization affecting the field at the Ta/Ta<sub>2</sub>O<sub>5</sub> interface and thus the tunnel impedance.

### Acknowledgment

The author would like to express his appreciation to D. M. Smyth for making recent experimental results available to him prior to publication and for many stimulating discussions. He would also like to thank R. Linzey for the measurements shown in Fig. 5.

Manuscript received June 15, 1967; revised manuscript received Sept. 6, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 28.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX I

#### Comparison of MOS Tunneling (5) with the MOM Tunneling of This Paper

In the case of a MOS structure, considered in ref. (5), one has

$$\tilde{V}(\delta) = \tilde{\psi}_s + V'd \cdot \delta = \tilde{\psi}_s + (\tilde{E} - \tilde{\psi}_s) \delta/d$$

where  $\psi_s$  is the surface potential of the semiconductor with respect to its bulk. The dominant term on the

right-hand side is  $\tilde{\psi}_s$  so that the variation of charge in the oxide can be treated (5) as a function of the surface potential  $\psi_s$  [viz., Eq. [46], etc., of (5)] or, expressed differently, of the free carrier density at the surface of the semiconductor, which is a well-defined function of  $\psi_s$ . Thus, in a good approximation,  $\tilde{V}(\delta) \simeq \tilde{\psi}_s$ , independent of the tunnel distance  $\delta$ . In other words, the variation of an energy level at the distance  $\delta$  vs. an energy level at  $\delta = 0$ , induced by an a-c field applied at the oxide, can be neglected as a second order effect. On the other hand, this second order effect is the principal effect in our case of a metal-insulator structure, where  $\psi_s = \tilde{\psi}_s = 0$  and  $\tilde{V}$  is in proportion to  $\delta$  [1]. Unlike the case of a semiconductor, the surface potential and the free carrier density at the metal surface are not noticeably varied by the applied field.

The mathematical consequences of this difference between the MOS structure of (5) and the MOM structure are as follows: Our equivalent parallel conductance Eq. [15] with [16] and [17] corresponds to  $i\omega C_{ox} dV_{SS}/d\psi_s$  in (5) with  $dV_{SS}/d\psi_s$  given by their Eq. [64] (see also ref. (13), Eq. [1] and [2]). Several factors in the integrands of Eq. [15] of this paper and of Eq. [64] of (5) can easily be identified with each other, e.g.,  $n_T$  with  $K \cdot g$ ;  $f_T(1 - f_T)/kT$  with  $\partial f/\partial \epsilon_T$ ; and  $(1 + i\omega\tau_T)^{-1}$  with  $[1 + j\omega\tau_C]^{-1}$ . However, our [15] with [16] contains the factor  $(\delta/d)^2$ , which is missing in [64] of (5). This has the following

reason: In our case the "driving force" for the tunneling is the a-c potential variation between surface and recipient state, which accounts for one factor  $\delta/d$  in [16]. The second factor  $\delta/d$  results from the "dipole distance" between the trapped electron and the positive charge left behind on the metal, and the

corresponding change in  $\tilde{V}'_d$  at a given  $\tilde{E}$  as expressed by [12]. The first factor  $\delta/d$  is absent in [64] of (5), since their driving force  $\tilde{\psi}_s$  is independent of  $\delta$ : In the

MOS structures, the tunneling charge  $\tilde{Q}_{SS}$  changes the voltage distribution between depletion layer voltage  $\psi_s$  and oxide voltage by the shift to the bulk side of the depletion layer of the positive charge left behind by a tunneling electron at the semiconductor surface. Since the charge shift across the depletion layer (which, in general, does not occur by tunneling, but by diffusion and field drift) occurs over a larger distance than the tunnel distance, the charge displacement (dipole distance) is much larger in the case of the MOS structure and rather independent of  $\delta$ . As a consequence, much larger charges must tunnel in the case of MOM structures than in MOS structures to obtain impedance effects of comparable magnitude.

In summary, the case of metal-insulator tunneling differs from that of semiconductor-insulator tunneling physically as to the dominant effect, and mathematically by a factor  $(\delta/d)^2 \ll 1$ , occurring in the integrand of the expression for the equivalent parallel conductance.

## Oxygen Evolution on Semiconducting TiO<sub>2</sub>

P. J. Boddy

*Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey*

### ABSTRACT

Semiconducting n-type TiO<sub>2</sub> evolves oxygen under anodic polarization despite the presence of an exhaustion layer. Addition to the solution of species more oxidizable than water causes no increase in current at a given potential, hence electron emission over the surface barrier is unimportant. The data may be interpreted in terms of electron tunneling from oxide ions in the crystal surface as the rate-determining step followed by faster electrochemical processes. Implications for electrolytic rectification are discussed.

The underlying reasons for the phenomenon of electrolytic rectification on anodically formed valve-metal oxide films are still imperfectly understood. Indeed it may well be that no one single cause explains the rectifying behavior in general. Several theories have been suggested in specific cases. Principally, electrolytic rectification has been ascribed to penetration of protons into the films (1), the existence of localized conducting defects in otherwise essentially insulating films (2), and to semiconducting properties (3) including the possible existence of junctions within the films (4).

Many of the pertinent properties of semiconducting films can be more conveniently investigated on massive semiconducting electrodes. By this means processes at the various interfaces (electrolyte/oxide, oxide/metal) may be separately observed. In addition, under appropriate conditions high fields may be applied across a relatively narrow region just within the surface of the oxide, producing a layer devoid of carriers of either sign. In this way fields of quite high magnitude may be conveniently applied across an essentially insulating oxide film of the order of a few thousand angstroms in thickness. Since the field in the bulk of the electrode is negligible, the occurrence of ionic currents through the bulk may be ruled out. The proper choice of an ohmic contact eliminates complicating effects at the oxide/metal interface, hence

the electrolyte/oxide interface, including the high field region just inside the oxide surface, may be investigated directly.

In the course of a series of studies of the electrochemical behavior of semiconducting oxides and mixed oxides [e.g., KTaO<sub>3</sub> (5)] we have had occasion to investigate the rutile form of TiO<sub>2</sub>. The film forming properties of titanium and the high dielectric constant of rutile ( $\epsilon = 89$  along the a-axis, 173 along the c-axis) have led to a good deal of interest in its possible use in electrolytic capacitors. However, some unfavorable features of its electrochemical behavior have prevented its use in this direction.

We believe that our measurements of semiconducting single crystal rutile are relevant to the behavior of anodic TiO<sub>2</sub> films. In addition, our experience with a number of materials leads us to believe that generalizations may be made about the behavior of semiconducting oxides, with appropriate modifications for individual properties, e.g., band gap, carrier densities, crystal structure, etc.

Although, as we will show, n-type semiconducting oxides show rectification behavior when in contact with electrolytes which is in the same sense (anodic direction blocking) as that observed with valve-metal oxides, we most definitely are not implying that electrolytic rectification in general is necessarily due to n-type semiconduction in the oxide films. This, of

course, does not eliminate semiconduction as either a major, or one of several minor contributing factors in specific cases. The object of this paper is to discuss, through the particular example of  $\text{TiO}_2$ , some electrochemical properties of semiconducting oxides, and thus help to clarify ideas which have been proposed relating semiconduction to electrolytic rectification.

### Experimental

Large pieces of single crystal rutile were reduced in hydrogen atmosphere at temperatures in the range  $600^\circ\text{--}700^\circ\text{C}$  for varying times. From these reduced samples electrodes were cut with dimensions about  $6 \times 6 \times 1 \text{ mm}$  with the larger faces perpendicular either to the a- or c-axis. One face was polished through successive grits to  $0.05\mu$  after an ohmic contact (chromium overlaid with gold) had been applied to the opposing face. The electrodes were finally mounted in silicone rubber cement applied so that only the polished face contacted the solution.

The interfacial capacitance was measured, as a function of potential, by means of short duration current pulses (6). Provided the higher values of polarization were not prolonged there was no difference in the capacitance values for increasing and decreasing values of polarization except as mentioned below.

Current-voltage data were measured potentiostatically. Some transient phenomena were observed, the exact nature depending on the donor density and crystal face.

The solutions were not purified in any special way in view of the use of silicone material to mount the electrodes. Most data were taken in neutral buffered phosphate solutions although a few measurements were made at the extremes of the pH range.

The photocurrents due to chopped uv illumination were measured by focussing the light from a mercury arc on to an electrode placed very close to a sapphire window cemented to the side of an electrolytic cell. The a-c voltage across a 10-ohm resistor placed between the electrode and ground was displayed on an oscilloscope and measured as a function of applied voltage.

The transient currents flowing in response to a rectangular anodic voltage pulse were observed with an oscilloscope in a similar manner.

### Results

*Face perpendicular to a-axis.*—Capacitance vs. electrode potential data for two differently doped samples are shown in Fig. 1. Anodic polarization of a wide band-gap n-type semiconductor produces an exhaustion layer devoid of either holes or electrons, this being a direct consequence of the low rates of thermal generation of electron-hole pairs in wide band-gap materials. The exhaustion layer capacitance is generally much smaller than typical values for the Helmholtz layer ( $>20 \mu\text{f cm}^{-2}$ ), hence the measured interfacial capacitance is essentially that of the semicon-

Fig. 1.  $1/C^2$  vs.  $V$  for two samples oriented perpendicular to a-axis.

Fig. 2. Current-voltage behavior of samples from Fig. 1. Note different voltage scale for anodic and cathodic processes.

ductor space charge layer and the applied potential occurs almost entirely within this region. The theory relating capacitance, per unit area,  $C$ , and potential,  $V$ , across an exhaustion layer (7) yields

$$\frac{d(1/C^2)}{dV} = \frac{2}{q\epsilon\epsilon_0 N_D} \quad [1]$$

where  $q$  is the electronic charge,  $\epsilon$  the relative dielectric permittivity, and  $N_D$  the donor density.

Donor densities for the various samples may be easily obtained from the slopes of the plots in Fig. 1 by application of Eq. [1]. The surface field immediately inside the semiconductor,  $F_s$ , is then given by

$$F_s = qN_D/C \quad [2]$$

Anodic current-voltage curves for two differently doped samples are shown in Fig. 2. The large electrode potentials necessary to produce small currents, particularly in the lower doped sample, are very evident. The cathodic i-v curve which is similar for both samples is shown here for comparison although it will not be discussed in detail in this paper. The system shows a considerable degree of rectification (note the different voltage scales for anodic and cathodic processes).

The passage of anodic current requires either injection of electrons or consumption of holes. If electron injection is occurring directly from species in the solution, the current at a given voltage should be increased by the addition of easily oxidizable species to the solution. In fact, the addition of sodium borohydride to the solutions resulted in no increase in current. This result is very similar to that already observed for n-type potassium tantalate electrodes (5). Hence, electron injection from solution species is ruled out. Also the rates of hole generation by thermal processes are too low to be the source of the observed current.

When the data from Fig. 2 are replotted vs. surface field in Fig. 3 a better correlation between the differ-

Fig. 3. Data from Fig. 2 replotted vs. surface field

Fig. 4. Relative photocurrent due to chopped uv light as a function of bias. ( $N_D = 8.5 \times 10^{18} \text{ cm}^{-3}$ ).

ently doped samples is obtained. The charge transport mechanisms which would show such a dependence on surface field are either avalanche multiplication or tunneling.

The occurrence of avalanche multiplication may be checked by observing the current due to injected carriers as a function of bias. The sample of highest doping ( $8.5 \times 10^{18} \text{ cm}^{-3}$ ) was illuminated by chopped uv radiation with energy greater than that of the optical band gap ( $\sim 3.05 \text{ eV}$ ) and the resulting a-c photocurrent observed on an oscilloscope. The relative value as a function of anodic bias is shown in Fig. 4. The range of bias was that covered by the i-V curves in Fig. 2. The lack of increase in the current at high fields ( $50 \text{ V} \approx 5 \times 10^6 \text{ v cm}^{-1}$  for this sample) indicates that avalanche multiplication does not make a major contribution to the anodic current.

When the surface field is sufficiently high, tunneling of electrons may occur from occupied levels at the surface directly into the empty conduction band. The field configuration is shown schematically in Fig. 5. The occupied levels from which tunneling occurs may be either surface states within the forbidden gap or levels at the top of the valence band.

Some further evidence for tunneling from surface levels comes from transient experiments. When a voltage step is applied to the interface it is expected that a transient current will be observed flowing through the external circuit due to the charge stored in the space charge region according to

$$q = \int_{V_0}^V C \cdot dV \quad [3]$$

where  $C$  is a function of  $V$ . On returning the voltage to the original value, an equal and opposite charge would be expected. In practice the transient observed when turning on an anodic voltage exceeds that at turn-off. The magnitude of the difference increases with increase in the voltage step and is plotted in Fig. 6. This result is interpreted in terms of field induced tunneling from surface levels. Since the experiment was carried out at constant pulse width ( $10^{-3} \text{ sec}$ ) the

Fig. 5. Field configuration in an exhaustion layer

Fig. 6. Excess transient at turn-on as a function of surface field. ( $N_D = 8.5 \times 10^{18} \text{ cm}^{-3}$ ).

amount of excess charge is a function of field. At low fields where the barrier to tunneling is wide and thus the tunneling rate is small, very little charge is transported during the time the pulse is on. At higher fields greater amounts of charge should be observed due to the higher tunneling probability. For sufficiently high fields all of the surface levels will be emptied during the pulse and the charge difference should become constant with increasing field. The data in Fig. 6 seem to be approaching a saturation value of  $\approx 10^{14}$  electron charges at high fields.

*Face perpendicular to c-axis.*—The results for this orientation are much more qualitative. The plots of  $(1/C^2)$  vs.  $V$  are strongly nonlinear and are sensitive to bias. Some data for the lower doped of the two samples, which shows this effect to the greatest extent, are shown in Fig. 7. Anodic bias has the effect of increasing the slope of the plots, which indicates a probable decrease in the donor density near the surface. The effect can be reversed by cathodic polarization. The drift of ionized impurities and defects along the c-axis of TiO<sub>2</sub> is known to be very rapid (8). We feel that the donor densities are nonuniform near the surface of samples of this orientation, and are influenced strongly by the surface field. Under these circumstances the surface fields cannot be deduced without determining the distribution profile of the donors.

Current-voltage curves for two samples are shown in Fig. 8. A considerable degree of rectification is still evident although not so marked as with the samples oriented perpendicular to the a-axis which were nominally of approximately the same donor densities. The

Fig. 7.  $1/C^2$  vs.  $V$  for relatively low doped TiO<sub>2</sub> oriented perpendicular to c-axis.  $\circ$ , original condition of electrode;  $\bullet$ , 500  $\mu\text{A}$  for 30 min;  $\triangle$ , 500  $\mu\text{A}$  for 60 min;  $\blacktriangle$ , 500  $\mu\text{A}$  for 150 min.

Fig. 8. Current-voltage behavior of samples oriented perpendicular to *c*-axis.

fact that the bulk dopings were widely different in the two samples was indicated by conductivity measurements made by the four-point probe technique and also by the coloration, the lightly doped being quite clear and the highly doped being strongly blue and almost opaque to visual inspection. However, the similarity in surface doping in the two cases was indicated both by the  $1/C^2$  vs.  $V$  plots at low fields and the  $i$ - $V$  curves which were much more similar for these two samples, than for those oriented perpendicular to the *a*-axis.

### Discussion

**Oxygen evolution.**—At higher current densities the evolution of gas may be observed, and this can only be oxygen for an anodic process in aqueous solutions. It is presumed that oxygen evolution is the only process at all current densities.

The rate-determining step is interpreted as tunneling by electrons from surface levels within the gap or at the valence band edge into the empty conduction band.

The valence band of  $\text{TiO}_2$  consists of overlapping oxygen 2p states. The simplest interpretation of the oxygen evolution reaction is that electrons tunnel from oxygen 2p states at the crystal surface under the influence of the high surface field. This concept is discussed in more detail in our paper on potassium tantalate anodes (5) and will be dealt with only in brief in the present case.

At high values of surface field, where the space charge depth is great, the surface field may be considered constant for some distance into the electrode. In this simplified case the trapezoidal barrier model of Franz (9) may be applied, where the tunneling probability,  $D$ , is given by

$$D = \exp\left(-\frac{4\sqrt{2}(m^*)^{1/2}E^{3/2}}{3\hbar F}\right) \quad (4)$$

$m^*$  being the tunneling effective mass,  $E$  the energy difference between the tunneling level and the top of the barrier, and  $F$  the field.

Calculations based on this model indicate that in order to fit the data it is necessary to postulate a set of states extending into the forbidden gap, distributed exponentially in energy according to

$$N \approx N_0 \exp(-10E) \quad (5)$$

The currents are given by

$$i = \nu \cdot q \cdot \int (N.D.) dE \quad (6)$$

where  $\nu$ , the frequency factor, is taken as  $\sim 10^{13} \text{ sec}^{-1}$ .

The product  $N.D.$  was evaluated as a function of energy for a number of fields and integrated manually. Current densities were then derived from Eq. [6]. A quantitative analysis is made difficult by lack of knowledge of the magnitude of  $m^*$ , but if it is assumed that  $m^* = m_0$ , then a reasonable fit as shown in Fig. 3 may be obtained by assuming a total density of states of  $\sim 10^{14}$  distributed as a delta function at 3.2

ev below the conduction band edge, with an exponential tail on the high energy side as indicated by Eq. [5]. This distribution is consistent with complete emptying of the states in  $10^{-3} \text{ sec}$  at fields  $\geq 5 \times 10^6 \text{ volts cm}^{-1}$  as indicated in the pulse experiments.

We propose that the states in question are oxygen 2p states of surface oxide ions perturbed out of the valence band by termination of the lattice. The assignment of the delta function to 3.2 ev below  $E_C$  is consistent with this since  $E_C - E_V \approx 3.05 \text{ ev}$ .

Electrochemically, the sequence of events is as follows

Subsequent to this rate-determining step, one of several processes may occur

where  $-\text{V}$  is a surface vacancy. Alternatively

or

where  $\text{X}$  is some solution species. Subsequently  $\text{H}_2\text{O}_2$  or  $\text{XO}$  may react to yield  $\text{O}_2$ .

Oxide ion vacancies in  $\text{TiO}_2$  are donors, therefore

will occur rapidly.

Since continuous current may be passed it is necessary to have some means of replenishing the surface states. A likely process is

The net result of Eq. [7], [8], [11], and [12] is the familiar oxygen evolution reaction

The excess transient charge in the voltage pulse experiment is identified with electrons tunneling from surface oxide ions. These electrons are transferred to the conduction band of the oxide and hence are observed in the external circuit.

The process of recharging the states during the off time involves reaction with water molecules in the solution. This process is localized at the oxide/solution interface and hence does not cause current to flow in the external circuit.

The essential novelty of this system is that the barrier to charge transfer lies within the electrode and may be directly perceived through measurements of the dielectric properties of the space charge region, rather than in the Helmholtz region as for metal electrodes. The surface oxide ions correspond to reactive intermediate species in the over-all process of Eq. [13].

**Comments on electrolytic rectification.**—It is clear that rectifying behavior somewhat similar to that exhibited by anodic oxides is observed also on *n*-type semiconducting oxides. We point out in passing that current work on semiconducting tantalum pentoxide shows behavior somewhat similar to that reported here for rutile, although we have not eliminated avalanche breakdown as a possibility in this case.

It might be questioned what comparison there could be between an anodic oxide film a few hundred angstroms in thickness and an electrode  $\sim 1 \text{ mm}$  thick. However, in the semiconductor case we have to be concerned only with the width of the barrier imposed by the space charge region. This, of course, may be much less than the width of the space charge itself. For instance at a field of  $4 \times 10^6 \text{ volts cm}^{-1}$ , the barrier at 3 ev below the conduction band edge is only  $75 \text{ \AA}$ , whereas the total space charge depth is many thousands of angstroms.

It is a natural consequence of the properties of an exhaustion layer that a sample of smaller donor den-

sity requires higher potentials to attain the same surface field. This indicates greater blocking ability for anodic current as the donor density decreases, until, in the limit, the field becomes uniform across the whole width of the electrode (or film, as the case may be).

We find that cathodic current flow occurs very readily in our experiments even for semiconductors of low doping. The flat band potential is approximately  $-0.6\text{v}$  vs. SCE in neutral solutions. At this point no further space charge barrier exists at the oxide/electrolyte interface to cathodic current flow. Provided an ohmic (electron injecting) contact exists at the metal/oxide interface the current is limited only by the conductivity of the film and the barrier in the Helmholtz region, analogous with a metal electrode. Thus, for a hypothetical film with a resistivity of  $10^{10}\text{ ohm-cm}$  and a thickness of  $1000\text{\AA}$ , a cathodic current of  $10^{-6}\text{ amp cm}^{-2}$  involves an ohmic potential drop in the film of only  $0.1\text{v}$ . For rutile, this resistivity corresponds to  $10^9\text{-}10^{10}\text{ donors cm}^{-3}$ , a very low value and pronounced rectification should ensue, extrapolating from the present data.

Some lack of stoichiometry in anodic oxide films would seem to be inevitable, and it is usually very much easier to achieve n-type semiconduction than p-type. It is tempting to consider a slight degree of n-type semiconduction as being an important factor in some cases. There are however some aspects of the experimental observations of electrolytic rectification which are not consistent with a homogeneous n-type film.

Vermilyea (2) has shown that "weak spots" are responsible for much of the cathodic current and has suggested that the film is modified by inclusions originating from the metal. Young (10) is of the opinion that such spots are also responsible for the anodic leakage current. Possibly such spots could be n-type regions in an otherwise insulating, or very slightly n-type, film.

Another problem, less easily disposed of, is the influence of species in solution on the anodic leakage current. Our work on semiconducting oxides has re-

vealed no effect of solution species on anodic current flow in the several cases investigated (KTaO<sub>3</sub>, TiO<sub>2</sub>, Ta<sub>2</sub>O<sub>5</sub>, ZnO). This is presumably a consequence of the relative alignment of energy levels in solution with the band structures of these various oxides. It might be argued that the anodic films are glassy and hence the same band structure picture does not apply. However we find that, at least as far as optical properties are concerned, anodic films of TiO<sub>2</sub> behave similarly to rutile (11). It seems unlikely, although perhaps not impossible, that electron injection could occur into the glassy form but not the single crystal. We rather tend to the view that such direct influence of solution species indicates either fissures through the oxide or some degree of porosity.

## On the Rectification of Anodic Oxide Films of Titanium

Franz Huber\*

Radio Corporation of America, Somerville, New Jersey

#### ABSTRACT

The phenomenon of electrolytic rectification in anodic oxide films has been studied extensively for the valve metal-valve metal oxide-electrolyte system for many years. This paper describes experimental results on the rectification of the electric current in anodic oxide films, especially TiO<sub>2</sub> enclosed between two metallic electrodes. The rectification of the electric current is interpreted on the basis of a p-n junction within these oxide films. In addition, these junctions can exhibit photovoltaic effects and can be used for the fabrication of field effect devices. In these field effect transistors the electrical current flowing between two narrowly spaced electrodes deposited on the oxide surface can be modulated by the application of voltage to the titanium bottom electrode. This experiment shows that a conductive surface layer is adjacent to an insulating layer underneath.

It is a well-known fact that anodically formed oxide films of valve metals (metals such as Ti, Ta, Zr, Al, and Hf) or semiconductors rectify the electric current in a valve metal-valve metal oxide-electrolyte system to a high degree; a number of theories have

been developed to explain this electrolytic rectification (1-3). However, when the electrolyte is replaced by a metallic electrode (preferably applied by vacuum evaporation), the rectification of the electric current disappears in many cases; a large variety of experimental current-voltage characteristics has been observed and reported in the literature. Extremely thin

\* Electrochemical Society Active Member.

oxide films, usually below a thickness of 100Å, exhibit current-voltage characteristics which can be explained by quantum-mechanical tunneling (4, 5).

The rectification of the electric current in thick anodic oxide films (100 to about 5000Å thick) has been interpreted by some investigators to be due to the existence of microfissures in the oxide film (6-9). Undoubtedly, microfissures can exist in anodic oxide films and can be responsible for an increase of conduction or an asymmetry of electric conduction, but many other phenomena of anodic oxide films, such as photo-effects, are explained in a more natural way by the p-n junction theory. For example, increased conduction at localized areas has been observed in Ta<sub>2</sub>O<sub>5</sub> films during plating of silver or copper as counter electrodes. When silver or copper is electrolytically plated at the surface of a thick film of Ta<sub>2</sub>O<sub>5</sub>, the metals are precipitated as fine needles at individual spots on the surface of the oxide, indicating high current flow through small localized areas. This observation is in agreement with experimental results of mercury contacts applied to anodically formed tantalum. Vermilyea (7) found that with tantalum large area mercury contacts rectified, but point contacts did not rectify the electric current. It was concluded that weak spots were responsible for the low cathodic resistance of the large area mercury contacts (8). Anodic oxide films of titanium, however, can be prepared so that electroplating of silver results in a homogeneous and coherent metallic counterelectrode.

On the other hand, anodic oxide films enclosed between two metallic conductors can also be highly insulating. These oxide films can have resistive values of 10<sup>16</sup> ohm-cm and greater (10-12), particularly when the oxide film has been grown at high forming voltages. In these anodic oxide films, the material of the counter electrode can significantly influence the insulation resistance of the oxide layer (13), specifically in the cathodic direction.

A number of investigators believe that the rectification of the electric current in anodic oxide films is basically attributed to the existence of an p-n junction or p-i-n junction within the oxide film (14-23). This interpretation does not exclude the superposition of an electric current flow caused by microfissures that may be present in the oxide film and is independent of whether the counter electrode consists of a metal or of an electrolyte. This interpretation allows a large number of experimental results to be explained by one model. The experiments described in this paper were performed on TiO<sub>2</sub> films, predominantly with metallic electrodes applied to the oxide layer. The experiments support the theory of p-n junction rectification in anodic oxide films.

### Experimental Work

Titanium films have been prepared by evaporation of the metal from a tantalum boat in a vacuum system usually at a pressure of 10<sup>-5</sup> mm Hg. Fast evaporation of the titanium is accomplished by placing the titanium sheet parallel to a flat tantalum boat of about the same ohmic resistance. This arrangement minimizes the amount of gettered gases. A passing electric current simultaneously heats the supporting tantalum boat and the evaporating titanium strip; overheating of the tantalum boat is not necessary. As soon as the titanium ribbon melts due to the direct resistive heating, the liquid metal strip is supported by the flat tantalum boat. A fast evaporation rate can be achieved because the evaporation takes place from a relatively large area (4 cm<sup>2</sup>). Titanium films of several thousand angstroms thickness can be deposited in about 15 sec. At the end of the deposition, the tantalum boat usually breaks after alloying with the liquid titanium. It is suspected that a small amount of tantalum also evaporates and is incorporated into the titanium film. This doping of the anodized TiO<sub>2</sub> film with Ta<sup>5+</sup> ions would lead to increased conduction (analogous to crystalline rutile) (24).

Glass slides have been used as the substrate in most cases during these investigations. However, for the investigation of the piezoelectric effects of these TiO<sub>2</sub> junctions, a flexible substrate consisting of mica or polyethylene has been used. Mechanical stress can then be easily applied by bending the substrate.

In the beginning of the investigations, the titanium films peeled frequently during the anodization process. It was found that excellent adhesion of the titanium film can be accomplished by applying the negative potential to the substrate not only during the glow discharge period in the beginning of the evaporation, but also during evaporation at high vacuum.

The pattern of the titanium films and that of the evaporated counter electrodes is determined by means of mechanical masks. Figure 1 shows 20 test diodes of thin-film TiO<sub>2</sub>.

*Anodic oxidation of titanium.*—The titanium metal was made the anode in an electrolytic cell, and a platinum gauze was used as the cathode. The electrolyte consisted of ethylene glycol, water, and oxalic acid. TiO<sub>2</sub> films with most pronounced rectification of the electric current were formed with an electrolyte consisting of about equal parts per volume of saturated aqueous solution of oxalic acid and ethylene glycol. The influence and importance of the composition of the electrolyte was not investigated further, because satisfactory results were obtained with the electrolyte used. The anodization of the titanium films was performed with the instantaneous application of the full forming voltage from a power source with low impedance, thus allowing the flow of a high initial forming current through the cell. The forming voltage was usually 12v. The thickness of these oxide films was about 1000Å. It is assumed that the high anodization rate is attributable to the large forming current at the beginning of the anodization process and to the electrolyte employed. Higher forming voltages as well as lower current densities for the anodization produce TiO<sub>2</sub> films with less pronounced rectification of the electric current after applying a metallic counter electrode. The reduced rectification ratio is principally created by the increased leakage current in the reverse or anodic direction (titanium positive).

*P-N junction characteristics.*—A number of different materials have been applied as counter electrodes to the TiO<sub>2</sub> layer after anodization. The work function for TiO<sub>2</sub> is reported to be 4.2 ev (25) and, therefore, one group of materials with larger work functions and one group with smaller work functions were selected. Platinum with a work function of 5.3 ev (26), palladium with a work function of 4.99 ev (26), and nickel with a work function of 5.01 ev (26) produce junctions with pronounced rectification of the elec-

Fig. 1. Schematic drawing of thin-film TiO<sub>2</sub> diodes

Fig. 2. Current-voltage characteristics of thin-film  $\text{TiO}_2$  diodes with various counterelectrodes.

tric current, as shown in Fig. 2. Counterelectrodes consisting of low work function materials, such as aluminum, titanium, and indium, block the electric current in anodic and cathodic (reverse and forward) directions. Gold electrodes seem to allow some current flow in cathodic direction. These experimental results imply the existence of a p-n junction within the oxide; therefore a number of additional experiments were performed to prove this assumption. Rectification of the electric current based on a difference of work functions can be excluded because the surface of the semiconducting  $\text{TiO}_2$  would have to be of n-type conduction in order to establish rectification with a platinum or palladium electrode. (The growth mechanism of anodically formed oxide layers opposes the assumption of n-type conductivity of the surface.) Anodic oxidation is a diffusion process in which metal as well as oxygen ions diffuse under the electric field applied across the oxide layer. This diffusion process leads automatically to an excess of metal ions and/or a deficiency of oxygen ions at the valve metal-valve metal oxide interface. On the other hand, an excess of oxygen ions and/or a deficiency of metal ions prevails at the surface of the anodic oxide film. This deviation from stoichiometry of the oxide results in layers of n-type and p-type conductivity, respectively. These findings are in agreement with earlier observations made on anodically-formed  $\text{Al}_2\text{O}_3$  (16-18). The center region of the oxide, according to this model, consists of stoichiometric semiconducting oxide, and the thickness of this i-layer increases with increasing forming voltage. The thicknesses of the surface p-type layer and the inner n-type layer are practically independent of forming voltage and are each about 20-50Å (18).  $\text{TiO}_2$  films anodized to forming voltages higher than 12v show a decrease of conduction in the forward direction. Figure 3 shows the current-voltage characteristics of titanium-titanium dioxide-metal structures of various forming voltages ( $V_f$ ) and various counter electrodes. A diode with a forming voltage of 12v and a counter electrode of palladium has a rectification ratio of  $10^6$ . The series resistance of an enlarged i-layer reduces the forward conduction of the diodes and leads finally to a nonpolar, thin-film capacitor.

For  $\text{Ta}_2\text{O}_5$  films, Sasaki (18) calculated a thickness of 50Å for the surface p-layer. These calculations were based on measurements of the capacitance variation of the  $\text{Ta}_2\text{O}_5$  films (with a forming voltage less than 20v) as a function of bias. For larger forming voltages, the voltage dependence of capacitance becomes less pronounced (19). Schmidt *et al.* (3) claim that the surface barrier can be as thick as 250Å. This claim is based on the fact that the photoeffect in  $\text{Ta}_2\text{O}_5$  and  $\text{Nb}_2\text{O}_5$  films (3000Å thick) disappears after a surface barrier of about 250Å has been removed by chemical etching. Rectification in the  $\text{TiO}_2$  film is eliminated by removing approximately 200Å of the anodically

Fig. 3. Current voltage characteristics of  $\text{TiO}_2$  films as a function of forming voltage and counterelectrodes.

formed  $\text{TiO}_2$  film by chemical etching prior to applying the palladium counterelectrode; a nonohmic symmetrical current-voltage characteristic is obtained. In Fig. 4, the I-V characteristic of a Ti- $\text{TiO}_2$ -Pd diode with the complete oxide film is shown. The nonohmic, but symmetrical characteristic obtained after etching 200Å of the oxide film, prior to the application of the palladium counterelectrode, is also shown in the figure. The application of a large current then destroys the unit completely. The chemical etching does not destroy the oxide film but removes only the top p-layer of the anodic oxide film, as indicated by the resulting I-V characteristic and by the uniformity of the interference color of the remaining oxide film as observed with and without optical magnification. This experiment suggests further that the anodic oxide film consists of layers of different types of conductivities and that the total oxide film does not consist of one type of semiconductor only. Otherwise, if the rectification were due to a work function difference, rectification of the electric current would always be observed with one type of counter electrode material, regardless of the chemical etching of the oxide layer.

In as much as the forming voltage and initial forming current significantly affect the I-V characteristic of a thin-film Ti- $\text{TiO}_2$ -Pd diode, the forming time influences the rectification as well. Figure 5 shows the I-V characteristic of a  $\text{TiO}_2$  layer which has been anodized for 1 and 15 min, respectively. The second characteristic exhibits a very high forward conduction. The interference color of the 1-min anodized film was yellow, while that of the 15-min anodized film was dark blue. Similar I-V characteristics with pronounced rectification of the electric current can be obtained

Fig. 4. Current-voltage characteristics of etched and unetched Ti- $\text{TiO}_2$ -Pd diodes.

Fig. 5. Influence of forming time on forward characteristics of  $\text{TiO}_2$  diodes.

with other valve metal oxides, such as  $\text{Ta}_2\text{O}_5$  or  $\text{HfO}_2$ , as shown in Fig. 6(a) and (b). In this case, the oxide films have been formed in the same way as the  $\text{TiO}_2$  at 12v with high initial forming current, and the electrodes consist of palladium or platinum. It is again true that if larger forming voltages and/or smaller current densities are employed during the anodization process, the rectification becomes less pronounced and nonpolar, thin-film capacitors of tantalum (10) and hafnium (27, 28) with high-performance characteristics are obtained.

Current-voltage characteristics which are similar to those of Zener diodes have also been observed (see Fig. 7) for thin-film  $\text{Ti-TiO}_2\text{-Pd}$  diodes.  $\text{TiO}_2$  layers frequently exhibit this type of conduction. It is assumed that this conduction results from excessive amounts of tantalum incorporated into the titanium films, resulting in the doping of the semiconducting  $\text{TiO}_2$  layer to a higher degree than by the excess of Ti (n-type semiconductor) only.

Plasmionic anodization of titanium has also been studied to some degree. In this process, the oxygen

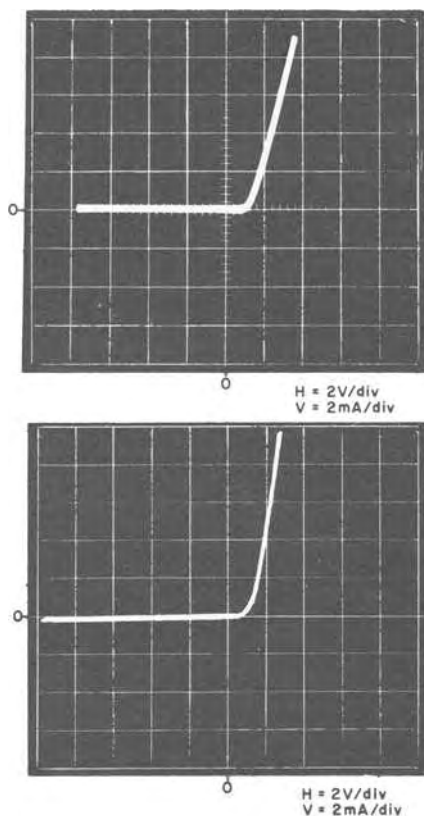

Fig. 6. Current-voltage characteristics of (a) (top) thin-film  $\text{Ta-Ta}_2\text{O}_5\text{-Pd}$  and (b) (bottom) thin-film  $\text{Hf-HfO}_2\text{-Pd}$  diodes.

ions are supplied for the oxide formation by the glow discharge of a partial oxygen atmosphere maintained in the vacuum system. These  $\text{TiO}_2$  films, anodized to 12v, exhibit rectification of the electric current with a smaller ratio of forward to backward current than the "wet" anodized  $\text{TiO}_2$  films. The increased conductivity in the anodic direction is mainly responsible for this observation due to incomplete anodization. The anodization cannot be performed with a high initial forming current; the leakage current at the end of anodization, even after several hours, is several hundred microamperes. Qualitative agreement between wet and plasma anodization can be established and rectification of the electric current can be observed if a large work function material (Pt, Pd) is again employed as a counter electrode. The process, however, is not very useful for quantitative experiments.

The thin-film structure of  $\text{TiO}_2$  diodes is extremely suitable for investigations of piezoelectric effects (29) in p-n junctions of semiconductors. Stress can easily be applied to the junction by bending the diode which is deposited on a flexible substrate (Fig. 8). The p-n junctions are elastically deformed by bending the substrate, either by compression (diode on concave side of substrate) or by tension (diode on convex side of substrate) as shown in Fig. 1. Increasing elastic compression causes a decrease of the junction resistance in forward and backward direction (Fig. 9). These results are in good agreement with similar investigations on shallow p-n junctions in germanium as reported by Rindner (30). In Rindner's experiment, a diamond stylus was pressed onto the semiconductor surface to elastically deform the junctions and decrease the junction resistance. Figure 9 shows the piezoresistive effect for various compression and ten-

Fig. 8. Application of mechanical stress by elastic deformation

Fig. 9. Piezoresistive effect in thin-film p-n junction diodes of semiconducting  $\text{TiO}_2$ .

sion radii of curvature in centimeters. If tension were applied to the thin-film diodes, an effect opposite to that caused by compression takes place on the junction resistance, and the junction resistance increases. At the same time the capacitance of the junction changes by a few per cent with elastic deformation.

Crystallinity of the semiconducting oxide, contact resistance between the crystallites, and piezoresistance of the oxide contribute certainly to the change of the junction resistance of these diodes, but do not explain fully the large changes of junction resistance or the presence of the piezoelectric effect (29).

The voltage dependence of the capacitance has been used previously (18) to determine the thickness of the p-layer and n-layer in anodically formed  $\text{Ta}_2\text{O}_5$  and to calculate the influence of the increase of the space-charge region with increasing forming voltage. Measurements on the voltage dependence of the capacitance in thin-film Ti-TiO<sub>2</sub>-Pd diodes (31) show a decrease of the capacitance with increasing voltage (reverse direction), leading to a linear relationship between voltage and  $1/C^3$  as expected for a linear graded p-n junction (Fig. 10). The slope of the  $1/C^3$ -vs.-voltage curve changes with thickness and with impurity concentration.

In another experiment, two narrowly spaced counter electrodes were applied to the surface of the anodically formed  $\text{TiO}_2$ . The oxide film was again formed by anodization at 12v, and the counter electrodes consist of palladium. The two electrodes, separated by a

Fig. 10. Voltage dependence of capacitance ( $1/C^3$ ) of thin-film Ti-TiO<sub>2</sub>-Pd diodes as a function of reverse bias.

Fig. 11. Transfer characteristics of  $\text{TiO}_2$  unipolar field effect transistor.

gap of 0.001 in., formed the source and drain electrodes of a unipolar field-effect transistor (32). The titanium film acted as the gate electrode. The current flowed in the p-layer from source to drain. Under operating conditions, a reverse bias was applied to the p-n junction by applying the voltage to the titanium film to vary the width of the space-charge region. Figure 11 shows the transfer characteristics of such a device with gate voltages applied in 2-v steps. Transconductance values in the range of 100 microsiemens were obtained. This experiment demonstrates that a conductive surface layer, the conductivity of which can be measured, exists, and this surface layer is adjacent to an insulating layer located underneath.

It is obvious that the performance characteristics of this device have to be improved for practical purposes, but these experiments further support the postulation of the existence of a p-n junction within anodic oxide films of titanium (which were formed in the described way). The effect of current modulation decreases with increasing thickness of the oxide film (higher forming voltages), which is understandable from the point of view of a p-i-n junction model for thicker oxide films.

### Conclusion

The rectification of the electric current in anodic oxide films of titanium has been studied and the experimental results are interpreted on the basis of a p-n junction within the oxide layer. Evaporated electrodes of large work function materials establish ohmic contact to the surface of the anodic oxide layer (p-layer) leading to  $\text{TiO}_2$  diodes. These oxide films are prepared by anodization at 10-15v with high initial forming currents. With increasing forming voltage and thickness of the oxide film, the rectification of the electric current decreases.

The voltage dependence of capacitance, as measured on these junctions, requires a graded p-n junction which is to be expected due to the diffusion process of the oxide formation. Results on piezoresistive and photovoltaic effects of the  $\text{TiO}_2$  films are in agreement with p-n junction theory.

The electric current between two narrowly spaced electrodes deposited on the surface of the oxide film can be modulated by the application of a reverse bias to the junction through the titanium film which acts as the gate electrode. This experiment shows clearly that a conductive surface layer is adjacent to an insulating layer underneath.

If a thin surface layer of about 200Å is removed from the anodic oxide film prior to the application of the electrodes, the rectification of the electric current, as well as the other effects described in this paper, disappear. Preliminary results show that other valve metal oxide films such as  $\text{Ta}_2\text{O}_5$  and  $\text{HfO}_2$  can also exhibit high rectification of the electrical current similar to the  $\text{TiO}_2$  layers.

### Acknowledgment

The author wishes to thank Dr. S. Hofstein of RCA Laboratories for many helpful discussions and for the presentation of the paper at the Dallas Meeting.

Manuscript received June 15, 1967; revised manuscript received Sept. 29, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 30.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Insulator-Electrolyte Interface

J. M. Hale

Cyanamid European Research Institute, Cologne, Geneva, Switzerland

### ABSTRACT

The mechanism of electrolytic rectification would depend on the properties of the insulator-electrolyte interface, if anodic oxide films were sufficiently perfect. These properties are reviewed and a quantitative theoretical interpretation given. Correlations between different experimental measurements and a predictable dependence of observables on controllable parameters should be achieved through use of the equations presented if the metal-insulator-electrolyte structure is responsible for a particular case of electrolytic rectification. Formulas derived after making the assumption that all of the equilibrium potential difference in the insulator-electrolyte interface is located within the solid, seem to be in agreement with experiment. Justification of this approximation is not found in the classical description of the interface, however, since point charged particles are able to approach the hypothetical "surface" without restriction. These formulas would suggest that the layer becomes unrealistically thin at high injection levels. It appears from the solution of a simplified quantum mechanical problem, that electrostatic compression of the real space charge layer might be avoided by "squeezing" of the particles out of the bottom of the potential well.

In order to ascertain the mechanism of conduction and rectification by anodic films, it is useful to know what behavior to expect from the system metal-perfect oxide film-electrolyte. A range of easily applied tests which would detect this structure, if it existed in a particular case, is also useful. The role of flaws might then be clarified.

The oxides of interest are usually insulating, although occasionally semiconducting (1, 2). Several theoretical papers, and a considerable body of experimental works, have been devoted to the study of the semiconductor-electrolyte system (3-13). This paper is concerned with the less well investigated insulator-electrolyte case (14-17). The metal contact will not be considered, though some of the formulas

presented have been derived assuming it to be "blocking."

In support of some of the theoretical findings experimental evidence will be cited gained from an anthracene electrode. This model system differs from an anodic film in its ease of fabrication and reproducibility. Anthracene can be highly purified and is easily shown to be nonporous, a degree of perfection which is difficult, if not impossible, to attain with an anodic film. Once a principle has been verified with a single crystal of anthracene, however, it may be applied with confidence to the anodic film case.

The original proposal that anodic films should show characteristics of a metal-insulator-electrolyte system (18) was at a later date retracted by its author

(19). It has since, however, received some experimental support in studies by Vermilyea (20) and Makrides (21) concerning the variation of forward current with character of a redox system included in the electrolyte. Also the reports of photocurrents, photovoltages, and luminescence can be accommodated into this scheme without the need of introduction of a new mechanism for each phenomenon. At the same time it cannot be claimed that any single picture can fit all of the data recorded in the literature.

The first part of this paper presents a survey of the main tenets of insulator-electrode reactions, together with their current physical interpretations. Then the theory behind one of the familiar approximations made in insulator-electrode theory is submitted to critical examination, namely, that which asserts all of the equilibrium potential difference in the interface to be located inside the solid.

### Properties of the Insulator-Electrolyte Interface

It is well known that a "space charge limited current" can be made to flow through an insulator, provided that one of the contacts to the solid is "ohmic" (22-24). As originally formulated, the theory (22, 26) of this phenomenon required an infinite reservoir of carriers to exist just inside the surface of the solid which could be "drained" by an applied electric field, the magnitude of the current at any particular field being determined only by the rate of penetration of these carriers into the charged solid.

The current in such a model system increases with the applied voltage without limit. Real systems differ from this model, however, partly because of effects originating at the contact. In the insulator-electrolyte system, these differences provide information of importance to electrochemistry (15). We do not discuss the voltage dependence of the current, since this is found to vary strongly with the sample due to "traps" for the carriers inside the solid.

Since there are no intrinsic carriers present in an insulator, the reservoir at the surface must be generated by injection from the ohmic contact; indeed the term ohmic merely describes the type of contact through which charge transfer is possible. Kinetically a dynamic exchange of carriers takes place through the interface, the current in each direction being identical at equilibrium. When the exchange is with a solution of a redox system this current may be called "the exchange current for the redox system at the insulator electrode" without any consequent confusion of terms, since the implication here is quite analogous to its implication at a metal electrode. We shall write the redox reaction in the form

The donor species  $D$  in solution transfers the carrier  $e$  to the solid with formation of the acceptor species  $A$ .

In order that an electrolyte forms an ohmic contact to a solid, there must be a large concentration of carriers in the surface of the solid at equilibrium. The carrier band must therefore be bent at the surface so that it approaches the Fermi level. This is not the only requirement for an injecting contact, however. Application of a potential across the solid removes carriers from the surface layer and hence slows down the capture of carriers by the acceptor species. In the first approximation it does not affect the rate of the donation reaction. Hence the reservoir of carriers will be emptied very quickly by the field unless the rate of replenishment is high so that large rates of drainage can be maintained, that is, the exchange current must be large. The current can become saturated when the voltage becomes high enough to reduce to zero the density of carriers at the surface, so "switching off" the capture reaction. Then the maximum injection current is numerically equal to the exchange current. A limiting diffusion rate of the donor species also leads to current limitation, however. Here, therefore, is a major influence of the interface

upon a current voltage measurement; it leads to current saturation.

These points have been confirmed experimentally, using an anthracene membrane sandwiched between two electrolytes as a model system (16). The passage of continuous hole currents is possible if one of the solutions contains a redox system having a high redox potential, and which has a large exchange current at a metal electrode. This is taken to mean that the very oxidizing electrolytes inject positive holes into the valence band of the insulator until the electrostatic work of injection balances the chemical energy gained in the donation reaction. Evidently the potential in the interface in this condition must be proportional to the standard potential of the redox system,  $D/A$ . The analogous requirements for electron currents, very reducing systems having large exchange currents have also been demonstrated. Recent experiments have indicated the possibility that injection might also be possible from weaker oxidizing agents in the presence of strong acids. This has been interpreted to mean that proton injection into the solid can assist the potential bending due to the oxidant alone, the combined effect being sufficient to create an ohmic contact.

*Theoretical interpretation.*—A quantitative interpretation of these requirements has also been made. For this purpose the donation reaction was assumed to be a member of the simplest class of electron transfer reactions, the so-called "outer sphere" type, having very weak interaction of the orbitals of the solution phase species and the electrode. Extensive theoretical work on such systems has been performed by Marcus (27), who used a quasithermodynamic description of the transition state of the reaction, and by Dogonadze, Chizmadzhev, Chernenko, and Kuznetsov (28) who calculated the quantum mechanical probability of electronic transition under perturbation by a phonon arriving from the solution. These treatments agree that in the first approximation the cross section through the potential energy surface made by the reaction coordinate is parabolic. The reaction coordinate itself may be imagined to be the effective charge on the solution phase species changing gradually from its value in the initial state to its value in the final state. The energy of activation is required to change the configuration of the solvent from equilibrium with the reactants to a compromise configuration in the transition state.

Using these theories and the approximation that all of the potential difference in the interface is located within the solid it is possible to show that the exchange current  $i_0$  for the redox system at the insulator electrode is (15)

$$i_0 = Z F N_c [D] \exp \left\{ - \frac{\lambda}{4RT} [1 + (\Delta - FV)/\lambda]^2 \right\}$$

A formula for  $Z$  was given in the papers by Dogonadze and Chizmadzhev (4); it has the approximate magnitude  $10^7 \text{ cm}^4 \text{ mole}^{-1} \text{ sec}^{-1}$ .  $F$  is the faraday,  $N_c$  the molar density of vacant states in the electrode ( $\sim 10^{-2} \text{ cm}^{-3}$ ),  $[D]$  the concentration (moles  $\text{cm}^{-3}$ ) of the donor species,  $\lambda$  ( $\sim 2 \text{ eV}$ ) the energy scaling parameter for the potential energy parabolas assumed to describe the reaction path (27),  $\Delta$  the gap between the carrier band and the Fermi level in the bulk of the solid, and  $V$  the magnitude of the potential difference at equilibrium between the surface and the bulk of the solid when the activities of  $D$  and  $A$  are equal.  $R$  is the gas constant and  $T$  the absolute temperature. This formula embodies the requirements for an ohmic contact in the following way: In order that  $i_0$  be large, the argument of the exponential factor must be as small as possible, which in turn requires that  $\lambda$  and  $(\Delta - FV)/\lambda$  be small. The first restraint is one which also applies if the redox couple is to have a large  $i_0$  at a metal electrode (29), while the second is true only if  $V$  is made large by the creation of a space charge layer. If only electronic charge separation through the interface is possible, then  $V$  is linearly

related to the redox potential  $E_o$  of D/A as argued above

$$V \simeq E_o - E_{FB}$$

where  $E_{FB}$  is the "flat band potential" of the solid. Then a large magnitude for  $V$  requires that  $E_o$  is well separated from  $E_{FB}$ , which implies a very oxidizing or reducing couple.

If ionic charge separation across the interface is also possible, then a further calculation becomes necessary to deduce the magnitude of  $V$ .

*Simultaneous electronic and ionic charge separation through an interface.*—We retain the model of electron or hole conduction through the insulating layer, but assume that an ion L of the same charge type having a very small mobility in comparison with that of the "carrier," so that the ionic current is much less than electron or hole current, can penetrate the solid to some extent. This increases the charge density in the double layer and hence deepens the potential well for carriers. It is a curiosity that addition of ions, which themselves repel the electronic species, actually leads to an increase in the concentration of the latter. This phenomenon is due to the fact that the partition coefficient for an ion between the two phases fixes the concentration of the ion just inside the solid, in a plane which has the same potential as the solution, while the concentration of carriers is fixed at the other side of the space charge layer, in the bulk of the solid. The concentration of the ion, and that of the carrier, however, have the same functional dependence on the potential at any point in the layer. Hence the increase in potential which accompanies penetration of ions into the solid leads to additional injection of carriers from the solution.

The calculation of  $V$  is made by collecting together equations describing the partition of ions between the phases, the equilibrium between the ions and the molecules of the solid within the solid phase (if one exists), the concentration of carriers, and Poisson's equation describing the space charge layer (30). The first three of these provide an expression for the total charge density at the solid-electrolyte interface in terms of  $V$ , which is precisely the boundary condition needed for solution of Poisson's equation. If  $V \gg 2RT/F$  an approximation can be made which permits the potential to be expressed explicitly in terms of the parameters of interest. This equation is

$$V = V_1 + (2RT/F) \ln \{ \frac{1}{2} [1 + (1 + \beta a_L)^{1/2}] \}$$

where  $a_L$  is the activity in solution of the ions able to penetrate the solid,  $V_1$  is the potential due to the redox system alone (see previous section) at  $a_L = 0$ , and  $\beta$  is a constant specified by

$$\beta = 4z K_p (1 + K) / (\pi N_c v^o) \arccos \{ \exp(-FV_1/2RT) \} \exp [(\Delta - FV_1/2)/RT]$$

$z$  is the valency of the ion,  $K_p$  is the chemical partition coefficient for the ion between the two phases,  $K$  is the equilibrium constant for the "complexing" reaction

where  $M$  is a molecule of the solid,  $v^o$  is the molar volume of the solid, and other symbols have been introduced previously. The complexing equilibrium was included in order that the results might apply to the case of anthracene in contact with strong acids, since it is known that the aromatic hydrocarbons are weakly basic. The magnitude of ionic effects caused by incorporation of ions into the space charge layer depends upon the size of the constant  $\beta$ . If  $a_L \sim \beta^{-1}$  is an attainable activity, then a potential shift, with consequent enhancement of injection current, must accompany increase of ionic activity in solution beyond this point. For  $a_L \ll \beta^{-1}$  the equilibrium potential at the insulating film must be identical to that at a metal (measured against the same reference elec-

trode). For  $a_L \gg \beta^{-1}$ , however, the potential varies with  $a_L$  according to the equation

$$V \propto (RT/F) \ln a_L$$

Experiments designed to check this theory, through measurement of the potential and of the injection current as a function of acidity, are at present in progress in our laboratory. It is certain that effects of acid on injection into anthracene do arise, but as yet we are unable to separate conclusively the effects outlined above from those introduced by varying thicknesses of the anthraquinone film which covers the anthracene surface. Another complicating factor is the variation of the standard potential of many redox systems, which otherwise would be quite suitable, because of complexing effects. Ionic space charges in anodic films have previously been proposed by Vermilyea (31), and by Schmidt (32).

*Photoinjection at the insulator-electrolyte interface.*—Particularly revealing, as a tool for investigation of the properties of the insulator-electrolyte interface is the photocurrent which flows when the insulator is irradiated through the electrolytic contact by strongly absorbed light. There are two principal mechanisms of generation of photoconduction, distinguishable by the relation between the energy of the radiation involved and the energy gap between the valence and conduction bands of the photoconductor. Intrinsic photoconduction can occur when the light is sufficiently energetic to cause direct band to band transitions. This is independent of the nature and polarity of the illuminated contact. Extrinsic photoconduction can occur when the radiation is absorbed to produce electrically neutral, nonconducting states of the crystal ("excitons") which, however, interact with electronic states in the electrolyte. This is likely to happen in a wide variety of materials, including anodic films, yet researches have concentrated on the aromatic hydrocarbons. Naturally these currents are sensitive to the nature and polarity of the electrolyte.

A photocurrent is generated at the anthracene/water ( $O_2$ ) interface, for example, when the solid is irradiated with visible light of energy 3.1 eV (less than the energy of the lowest conducting state at 3.65 eV). Singlet excitons formed in the solid at this wavelength, being electrically neutral, are transported only by diffusion (33, 34). Following a suggestion by Kallmann and Pope (33) we formulate their interaction with a donor species in the electrolyte in the following manner

where  $X$  stands for the exciton.

If  $D$  is an oxidized species, for example, the reaction with the exciton involves an electron transfer from the solid to the solution with release of a hole into the valence band. Thus the process is similar to "dark" injection by an oxidizing medium, but differs in that the electron comes from a state with energy comparable with that of the conduction band, while in the dark case the electron originates from the valence band. A nonradiative mechanism for this reaction does exist, and the process can be very much faster than the dark injection (36).

An interesting point about this system is that at open circuit, when no net current flows through the interface, a steady state exists. The exciton annihilation reaction proceeds with a net formation of carriers, but at the same time the carriers are captured by the acceptor species to fall down to the ground state. One might say, quite correctly, that the photo- and dark-injection reactions are proceeding at the same rate, though in opposite directions (37).

A calculation of the photocurrent requires solutions of the diffusion problem for excitons and the migration problem for carriers, with the kinetic equation for the current through the interface as a common boundary condition. As is the case with dark injection currents, the interface has very little influence on the current-

voltage behavior over most of the range of variation of the current, but it can be responsible for the appearance of saturation at high voltages. This limiting current can be expressed (36)

$$i_{\text{lim}} = i_0 + \mathbf{F} I_0 \left[ (1 + 1/\epsilon_s \sqrt{D_x \tau_x}) (1 + 1/k_f [D] \sqrt{\tau_x/D_x}) \right]^{-1}$$

$i_0$  is the exchange current for the "dark" reaction discussed above.  $I_0$  is the intensity of illumination,  $\epsilon_s$  the extinction coefficient of the solid,  $D_x$  and  $\tau_x$  the diffusion coefficient and lifetime, respectively, of the exciton.  $k_f$ , the heterogeneous rate constant of the photoinjection reaction, is given by

$$k_f = Z \exp \{ -(\lambda/4RT) [1 + (\Delta - \mathbf{F}V - E_x)/\lambda]^2 \}$$

$E_x$  is the energy of the exciton, and  $V$  the potential difference in the interface at equal activities of D and A and in the absence of illumination.

That the photocurrent shows an identical spectral dependence to the light absorption by the solid, because of the influence of  $\epsilon_s$ , has been pointed out previously (34, 38) and is experimentally verifiable for a number of insulators (39). More interesting from the point of view of electrochemistry is the prediction about the variation of the incremental photocurrent,  $i_{\text{lim}} - i_0$ , with the redox potential of the D/A couple, under otherwise identical conditions.

$E_x$  is often so large ( $\sim 3.1$  eV for the first singlet exciton in anthracene) that  $(\Delta - \mathbf{F}V - E_x)/\lambda$  can take the value  $-1$  for a possible choice of  $V$  and  $\lambda$ .  $k_f$ , and therefore the photocurrent, is a maximum under these conditions since the exponential factor becomes unity (40).

This behavior has been checked experimentally at the anthracene membrane. As expected, the photocurrent plotted against redox potential for a series of hole injecting D/A couples (in acid solution) shows a maximum in the region of 1.2V NHE. Knowledge of the positions of the bands, the energy of the exciton, and the value of  $\lambda$  enables the flat band potential of the solid to be calculated from these measurements.

According to this model of the photoinjection process, an increase of the concentration of carriers in the surface must accompany increase of illumination intensity at open circuit. Hence there must be a photopotential developed in the interface. Using the formula

$$V_I = V + (RT/\mathbf{F}) \ln (c_I/c)$$

the subscript I indicating the magnitude of a quantity in the presence of illumination and  $c$  connoting the density of carriers of the surface, together with the formula for  $c_I$  resulting from the earlier calculation, we find an equation which relates the open-circuit photopotential to the total limiting current at the same light intensity:

$$V_I = V + (RT/\mathbf{F}) \ln (i_{\text{lim}}/i_0)$$

This result may be used to estimate the exchange currents,  $i_0$ , of those dark reactions which yield immeasurably small currents in the absence of illumination.

*Double injection and luminescence.*—If the opposite faces of a platelike crystal of an insulator are furnished with contacts ohmic to oppositely charged carriers, then double injection occurs (41). The cancellation of space charge accompanying the superposition of the distributions of electrons and holes within the solid leads to an enhancement of the current over that observed at the same voltage in the single injection case (42-44). The system rectifies, however, Recombination of the oppositely charged carriers in the center of the solid leads to the formation of excitons, some of which decay radiatively giving rise to luminescence.

Electrochemically interesting effects are observed when the injection of one of the carriers becomes interface limited, for the over-all current can increase beyond that level although light output saturates (14).

We have not yet determined the mechanism of transfer of the additional current through the "saturated" contact; this might either be due to the excess carriers of the opposite sign reacting directly with the donors in the electrolyte, or there may be "photoinjection" due to a reaction between excitons and donors at the surface.

#### Distribution of the Space Charge at Equilibrium

In the theoretical description of the properties of the insulator-electrolyte interface, it is often convenient to make the assumption that all of the potential difference generated in the interface by injection is located within the solid. This approximation is known to be reasonable in semiconductors having low carrier densities, and has been justified in that case by means of the formula (4, 13)

$$\frac{V_{S_n}}{V} \approx \left[ \frac{c_{S_d} \epsilon_{S_d}}{c_{S_n} \epsilon_{S_n}} \right]^{1/2}$$

where  $V$  is the total potential difference in the interface and  $V_{S_n}$  the part of that potential across the outer Helmholtz layer;  $c_{S_d}$  and  $\epsilon_{S_d}$  are the concentration of carriers and the dielectric constant of the solid;  $c_{S_n}$  and  $\epsilon_{S_n}$  are the corresponding quantities for the solutions. If  $c_{S_d} \ll c_{S_n}$  for a semiconductor in contact with a reasonably concentrated solution, and  $\epsilon_{S_d} \sim \epsilon_{S_n}$ , then  $V_{S_n} \ll V$ .

In an insulator the carrier density is even smaller than it is in a semiconductor, and hence, at first sight the same approximation appears to be justified. A reexamination of the whole question reveals, however, that the appropriate carrier density to be inserted into the foregoing formula should not be the density in the uncharged solid, but an average density in the space charge layer. This, of course, can be quite different from the bulk value when injection is allowed, so that further consideration becomes necessary. The approximation seems to be satisfactory in practice since it gives formulas in quantitative accord with experiment, but the theoretical explanation for its validity might be different from that applicable to the depletion layer.

*The classical theory.*—The description of the space charge layer provided by classical physics becomes quite untenable at high injection levels. We recall that this theory deals with point charges which experience no net force at equilibrium because an electrical attraction to the layer of counter ions on the outer Helmholtz plane just balances the diffusion force driving the particles down the concentration gradient into the bulk of the solid. Two simultaneous relationships between the particle density  $n$  and the electrostatic potential  $V$  are available, namely the Boltzmann equation

$$n = n(0) \exp [-\mathbf{F}(V - V(0))/RT]$$

and Poisson's equation

$$\frac{d^2V}{dx^2} = -\frac{4\pi n \mathbf{F}}{\epsilon \epsilon_0}$$

which when combined provide an explicit functional dependence for  $n$  or  $V$  on  $x$  the distance into the solid from the interface.  $\epsilon$  is the dielectric constant of the solid, and  $\epsilon_0$  the permittivity of vacuum. For definiteness we choose  $dV/dx = 0$  at  $x = d$ , the "rear" contact to the crystal, which describes a contact establishing the flat band potential at equilibrium. Then charge transfer through that contact is not permitted.

The solution to this problem (26, 45, 46) contains a characteristic length,  $l_c$ , within which significant changes of  $V$  and  $n$  occur. It may be expressed in the form:

$$l_c = \frac{B d}{\sqrt{2} \arccos B} \rightarrow \frac{\sqrt{2} B d}{\pi} \text{ for } V_s \gg \frac{2RT}{\mathbf{F}}$$

Here

$$B = \exp [-\mathbf{F}V_s/2RT]$$

and  $V_s$  is used for the total potential drop within the solid. The startling prediction is made, that if  $V_s = 2v$  so that  $B \sim 4 \cdot 10^{-18}$  at room temperature, then  $l_c < 10^{-18}$  cm. This is a physically unrealistic value. Another manifestation of the same phenomenon becomes evident if the potential difference across the inner Helmholtz layer is calculated. This is

$$V_H = \sqrt{2} \frac{d_H}{l_c} \frac{RT}{F} \frac{\epsilon_s}{\epsilon_H} \sqrt{1 - B^2}$$

Taking  $d_H$ , the thickness of the inner Helmholtz layer, to be 5Å as at a metal, and assuming approximate equality of the dielectric constants of the solid  $\epsilon_s$  and the inner layer  $\epsilon_H$ , we find  $V_H \sim 10^{10}v$  at  $V_s = 2v$ . At first sight the failure of classical physics would not be ascribed to "degeneracy" (the breakdown of Boltzmann statistics), since the usual criterion that the bands should not approach within several  $kT$  of the Fermi level need not be violated, with only  $2v$  of band bending, in the arbitrary wide gap material. It is illuminating to study the simplest theory of a space charge of totally degenerate particles, however, since this does not predict compression of the layer by a field in the same way.

*The totally degenerate space charge layer.*—If the one-electron states for "the particle in a box" are filled up to an energy  $E$ , the density of particles at any point in the box is

$$n = (8\pi/3) (2Em/h^2)^{3/2}$$

$m$  is the mass of the particle and  $h$  Planck's constant. This is called the Thomas-Fermi equation (47, 48). The total energy of any particle in a space charge layer at a point at which the electrostatic potential is  $V$  (consisting of a sum of potential and kinetic energies) is  $ev$ , where  $e$  is the magnitude of the electronic charge. Thus in a "flat bottomed box" the density of particles at the point would be

$$n = (8\pi/3) (2eVm/h^2)^{3/2}$$

Regarding this as a relation between the particle density and the potential at each point in the layer, and assuming Poisson's equation to be valid, a soluble equation in the potential alone may be constructed having the solution

$$V = V_s [1 - (1 + x/l_c)^{-4}]$$

where  $l_c$  is the Thomas-Fermi characteristic length in the layer

$$l_c = (15\epsilon\epsilon_0/8\pi^2 e^2)^{1/2} (h^2/2m)^{3/4} (eV_s)^{-1/4}$$

Evidently  $l_c$  is only weakly dependent on  $V_s$  in this case. At  $V_s = 2v$ , for example,  $l_c \sim 1.2\text{Å}$  if the free electron mass is used for  $m$ .<sup>1</sup> The potential difference across the inner Helmholtz layer is given by

$$V_H = 4 \frac{d_H}{l_c} \cdot V_s \sim 33v \text{ at } V_s = 2v$$

Thus the particles in a degenerate space charge layer, whose density is of the same order of magnitude as the density of allowed eigen states, are unable to approach the surface as closely as do the unrestricted "classical" particles. We are prompted to examine the quantum mechanical problem for the space charge layer, therefore, to enquire whether the densities of states and particles can become comparable.

*The quantum mechanical problem.*—Regarding the layer of ions on the outer Helmholtz plane as the creators of a potential well within which the car-

riers move, we anticipate that the one-electron eigen states will consist of discrete levels with the upper states penetrating deeper into the solid than the lower ones. The separation between these levels, and therefore the density of states will be determined by the width of the well (50). The solid electrolyte interface will represent a nearly vertical potential energy barrier which will reflect the particles incident on the surface, while particles moving in the opposite direction will be confined to the region of the phase boundary by the screened attraction to the ions outside the solid. The well must get narrower as the number of particles in it increases, or synonymously as the total potential difference inside the solid rises.

There is no method of calculating the potential distribution explicitly with this approach. Only a self-consistent procedure would seem to be possible, consisting of alternately solving Schrödinger's equation for the eigen functions using a guessed effective potential well, squaring and adding these to yield the density as a function of position, then solving Poisson's equation for the potential using this estimated density.

We have not carried out this computation. Instead we have sought to gain insight into the behavior to be expected by recalling a much simplified problem originally studied by Dewald (51). This approximates the effective one-electron potential by

$$eV \simeq e\mathcal{E}x \quad x > 0 \\ = \infty \quad x = 0$$

where  $\mathcal{E}$  is a constant field and  $x$  is measured from the interface. Schrödinger's equation is equivalent to Bessel's equation in this case (52). In order to satisfy the condition that the wave function should vanish at  $x = 0$ , the eigen values  $E_n$  must obey the equations

$$-E_n = (3S_n/2)^{2/3} (h^2 e^2 \mathcal{E}^2/8\pi^2 m)^{1/3}$$

where  $S_n$  is a root of the equation

$$J_{1/3}(S) + J_{-1/3}(S) = 0$$

$J_{1/3}$  is the cylinder function of the first kind (52).

Dewald pointed out that, if  $\mathcal{E}$  is given the value  $10^6v \text{ cm}^{-1}$ , then the lowest lying eigen value ( $n = 1$ ) is already 0.17 eV above the bottom of the well, and that the spacing of the first few levels<sup>2</sup> is of the same order of magnitude. At  $\mathcal{E} = 10^7v \text{ cm}^{-1}$  this figure becomes 0.79v. In comparison the zero point energy, and spacing of the lowest energy levels in the free electron band is  $\sim 10^{-15}$  eV. Instead of being distributed over energy as  $E^{1/2}$ , the density of states function within the space charge layer becomes proportional to  $E^{3/2}$ .

Thus, as the potential energy well becomes deeper, tending to confine the particles into a narrower region adjacent to the interface, so the eigen states get squeezed out of the bottom of the well. This is merely an effect of the uncertainty principle, of course, and is a consequence of the wavelike character of the carriers.

We are led, therefore, to distrust any method of calculation of density of particles or of electrostatic potential in a space charge layer, which does not take account of the discreteness of the states occupied by the particles. Both the classical method based upon Boltzmann's equation, and the Thomas-Fermi equation for a degenerate gas, assume a continuous distribution of states over potential energy, and therefore must fail when the potential gradient becomes large. At the same time we can assert that a space charge layer cannot become compressed into a region less than a few angstroms thick. In the absence of quantitative proof we will assume that this is the explanation for the observed sharing of potential between the Helmholtz double layer and the solid in the insulator-electrolyte interface.

<sup>1</sup> In practice the potential varies rapidly within the wavelength of the carrier, inside the space charge layer, so that the use of formulas derived from the flat bottomed box problem is suspect. Swiatecki (49) suggested an improvement to the method which corrects the density for a potential gradient. The numerical integration he recommends shows that this improvement leads to a further expansion of the layer. At  $V_s = 2v$   $V_H$  becomes  $\sim 18v$ .

<sup>2</sup> The levels referred to are for motion in the direction normal to the surface. The spacing of levels for motion in the plane parallel to the surface are unaltered by the field.

Manuscript received June 15, 1967; revised manuscript received Oct. 2, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967 as Abstract 31.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Current-Voltage Characteristics of Porous Anodic Oxides on Aluminum

C. E. Michelson\*

*Finishing and Joining Section, Metals Research Laboratories,  
Olin Mathieson Chemical Corporation, New Haven, Connecticut*

### ABSTRACT

Rapid voltage reduction across porous anodic coatings results in zero current, and a relatively long time is required for recovery to the new equilibrium current. The recovery time is dependent on the voltage change, rate of change, and electrolyte temperature. Capacity measurements show that physical thinning occurs only when current begins to increase late in the recovery period. This behavior appears inconsistent with the conventional pore base dissolution mechanism of porous oxide growth.

Anodic treatment in certain electrolytes, such as sulfuric acid, causes porous coatings to form on aluminum. Other electrolytes, typically boric acid, form nonporous film. Anodizing electrolytes are frequently

classified as dissolving or nondissolving according to their supposed chemical action on the aluminum oxide. This dissolution has been accepted as the direct cause of the pore development and the reason why anodizing does not stop in spite of the films of oxide built up on the metal surface.

\* Electrochemical Society Active Member.

The purpose of this paper is to present some qualitative observations on the dynamic current-voltage characteristics exhibited by porous anodic oxides in the electrolytic cell. These will be discussed in the light of the classical model conceived by Keller, Hunter, and Robinson (1) and the more recent alternative proposed by Murphy and Michelson (2).

## Two Concepts of Structure and Growth of Anodic Films on Aluminum

Before describing the experimental work, two models and mechanisms of oxide growth are reviewed briefly.

### Geometric Pore Model

Keller, Hunter, and Robinson (1) have hypothesized that electrolytic oxidation of aluminum proceeds simultaneously with dissolution of the oxide at selected points. As a result of the dissolution at regularly spaced points a cellular structure arises. Figure 1 illustrates the concept of a hexagonal cell of aluminum oxide containing a star-shaped pore extending from the surface to a point near the metal.

Keller *et al.* call this separation of the pore base from the metal the barrier layer. They have proposed that the barrier layer, cell wall, and pore diameter are related to the anodizing parameters.

On the basis of this model, Hunter and Fowle (3) have concluded that dissolution at the pore base must proceed at a much faster rate than is possible under the usual electrolyte temperature and concentration. The authors hypothesize that the temperature of the pore base must be about 125°C and the acid concentration almost 50% while the bulk electrolyte is operating at 21°C and 15% concentration.

Hunter and Fowle (4) have found that the unit barrier thickness of films formed in sulfuric acid is about constant and close to 10 Å/v. They conclude that voltage and current density affect only the over-all thickness of the coating, not the unit barrier thickness.

### Colloidal Gel Model

The model (Fig. 2) proposed by Murphy and Michelson (2) explicitly considers such important factors as the type of electrolyte, chemical nature of the anodic oxide, and the role of voltage in the growth process. In this model the anodic film is considered to be a duplex in structure. The innermost layer, the barrier, is believed to be largely anhydrous aluminum oxide containing some anions of the electrolyte. Under the influence of the field, aluminum ions move outward from the metal to a region near the outer edge of this layer where the aluminum ions react with the oxygen carrier, probably hydroxyl ions, to form alumi-

Fig. 1. Geometric model of aluminum anodic oxide structure

Fig. 2. Colloidal gel model of aluminum anodic oxide structure

num oxide. The thickness of this barrier layer is determined by the anodizing voltage and it is approximately 10 Å/v applied during anodizing.

The process of converting the newly formed anhydrous oxide proceeds immediately at selected points. The electrolyte and hydroxyl ions moving under the influence of the applied field probably plays an important role in this process of breaking up the continuous anhydrous layer to form discrete particles. These particles finally become the porous layer. The process of conversion from relatively continuous anhydrous layer to an agglomeration of hydrated particles of aluminum oxide is field sensitive. Therefore the field determines the amount of unconverted or barrier layer present at a given time.

The next layer, the outermost layer, is considered to be an agglomeration of submicrocrystalline particles of anhydrous aluminum oxide surrounded by, and held one to another by, submicroscopic regions containing electrolyte anions, water molecules, hydroxyl ions, and hydrogen ions in a relatively complex hydrogen bonded system. The internal surfaces surrounding the submicrocrystallites are considered to be essentially structural features of the outer portion of the anodic films formed in highly acid electrolytes. The pores normal to the metal surface observed by electron microscopy are recognized, but the importance of such pores in the mechanism of film formation is held to be considerably less than in previous models.

The anion of electrolyte plays an important and different role in the colloidal gel model. These anions are oxyanions which can stabilize the surface of the particles of oxide converted from the barrier layer. They adsorb to the surface of the particles as the particles are separated from the barrier layer, and these anions are further capable of forming hydrogen bonded complex containing water, protons, and anions of the electrolyte. It is through this hydrogen-bonded complex surface that ionic conduction occurs. Hydrogen bond shifts between adjacent atoms result in the net transfer of proton and hydroxyl ions in opposing directions at relatively high rates.

The proposed mechanism of anodic coating formation is as follows. Under the influence of the anodizing field, aluminum ions migrate from the metal surface through the barrier layer to the oxygen-rich upper portions of the barrier layer where they react with oxide or hydroxide ion to form essentially anhydrous aluminum oxide. Oxygen containing species (hydroxide ions or water) are brought to the barrier layer by a kind of electrolytic conduction through or along the internal surfaces of the porous layer above the barrier layer. The anodizing field is such that it assists migration of hydroxide and water in the direction of the barrier layer. The hydroxide ion, water, and electrolyte anion which migrate into the barrier layer/porous layer interphase, cause a modification of previously formed barrier layer oxide into a more proton-

ated and hydrous oxide in localized regions, thereby tending to decrease the effective electrical thickness of the layer.

#### Important Differences in the Models

The two models differ in important respects. According to the physical-geometric model, dissolution accounts for the propagation of the pore base. This means that the composition of the porous layer is identical to that of the barrier layer, and it is porous only because it is penetrated by many holes. The colloidal gel model pictures the porous oxide as a "converted" barrier layer consisting of many crystallites, the surfaces of which are highly hydrated and contain anions of the electrolyte. The anion is considered to be important in promoting the formation of the hydrated and hydrogen-bonded surface rather than by promoting the complete dissolution of the oxide at the pore base.

In the case of the geometric model, conduction is assumed to occur by mass transport of electrolyte in and out of the 100Å pores. In the alternative model, it is proposed that site-to-site migration of ions occur in the region near the porous layer interphase.

In the conventional pore model, the applied voltage serves only to move the aluminum ions across the barrier, and the barrier thickness is controlled by the dissolution rate at the pore base. The colloidal gel model assumes that the voltage not only serves to control movement of the aluminum ions across the barrier but, in addition, it plays a role in the conversion of the barrier to the porous layer thereby controlling its thickness. The voltage is also important in the movement of negative ions inward and positive ions outward.

The two models also differ with respect to the events that can be predicted when the voltage is reduced and a new equilibrium attained. In either case, one predicts a drop in current followed by recovery to the new equilibrium value. In the case of the geometric model, dissolution of the barrier would have to occur whereas in the colloidal gel model a conversion of barrier to porous layer would be required to attain the new barrier thickness characteristic of the lower applied voltage.

#### The Recovery Phenomenon

A change in the voltage applied to a sample undergoing anodizing results in a characteristic curve shown in Fig. 3. In this paper we are concerned primarily with the interval between the time voltage is changed and the current attains its new equilibrium value. This is the recovery period. It is convenient to attach symbols to some of the variables in the recovery phenomenon.

- $E_1$ , Higher value of anodic potential applied  
 $E_2$ , Lower value of anodic potential applied

Fig. 3. Characteristic current-voltage relation during recovery period.

$$E_1 - E_2 = \Delta E$$

$I_1$ , Equilibrium current with  $E_1$  applied

$I_2$ , Equilibrium current with  $E_2$  applied

$t_1$ , Time of application of  $E_1$

$t_r$ , Time required for transition from  $I_1$  to  $I_2$

$t_{1/2}$ , Time required for current to recover to  $\frac{1}{2}I_2$

$dE/dt$ , Rate of change between  $E_1$  and  $E_2$

The current recovery phenomenon was examined by the several experimental methods described below.

Anodizing was done in an electrolytic cell and a recorder was used to follow the current transients as the voltage was changed.

#### Experimental

The equipment arrangement used to produce the anodic coatings under controlled conditions is shown in Fig. 4. Power was supplied from a regulated d-c source (Lambda Electronics) of 500 ma capacity and test coupons 2 in. square were used in all tests. By using relatively low currents an excellent control of temperature during anodizing could be achieved. Temperature rise of the electrolyte was held to less than 0.5°C by immersion of the cell in a water bath maintained at 22°C. The electrolyte was stirred during the experiments.

In all experiments the cell current was recorded on a Sargent recorder which placed a resistance of 1 ohm in series with the cell. Voltage changes were made by opening the circuit, readjusting the supply to the new value, then closing the circuit again. Slow changes were made with the "fine" voltage control on the supply.

All aluminum samples (alloys and high-purity metal) were degreased with solvent, chemically brightened, rinsed, and dried with methanol. Electrolytes were made up from chemically pure reagents and demineralized water of less than 1 ppm impurities. Bright platinum cathodes were used in all experiments.

Capacity measurements were made with a General Radio impedance bridge. Measurements were carried out in 15% sulfuric acid using a bright platinum cathode of approximately five times the area of the anode.

#### Results

*Forming and recovery in the same electrolyte.*—Samples of aluminum alloy 1100 were anodized for various times at voltage  $E_1$  to produce coatings of various thicknesses. At the end of each anodizing period the current was suddenly interrupted. With the circuit open the power supply was adjusted to a new value of voltage,  $E_2$ , and the circuit again closed. This voltage change,  $\Delta E = E_1 - E_2$ , always produced a curve of the general shape shown in Fig. 3.

The time of anodizing,  $t_1$ , at voltage  $E_1$  did not produce significant changes in the recovery time,  $t_r$ , provided  $t_1$  was greater than 5 sec. The maximum recovery time was required when  $E_1$  was applied for approximately 1 sec. At times less than 1 sec recovery

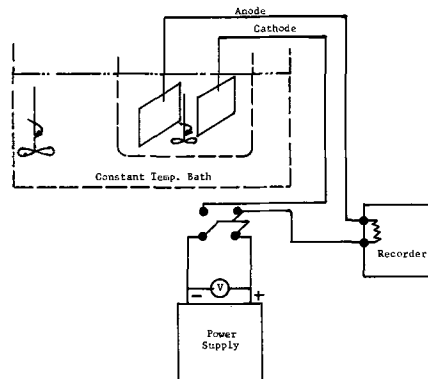

Fig. 4. Basic circuit required for anodizing

Fig. 5. Effect of anodizing time on recovery time (voltage changed from 11 to 8v).

was more rapid. This relation is shown for several alloys in Fig. 5.

Samples anodized for periods as long as 20 min did not exhibit appreciably different recovery characteristics than those anodized at least 5 sec.

Figure 6 shows that recovery time,  $t_r$ , depends on the concentration of the bath. Coatings formed in 30 v/o (volume per cent) sulfuric acid showed recovery in about one fourth the time required at 5% concentration. The displacement of the two curves shows that the recovery time also depends on the magnitude of  $\Delta E$ . An increase in  $\Delta E$  of 1v increased the recovery time approximately tenfold. Figure 7 shows in more detail how the recovery time varies with  $\Delta E$  and  $E_1$ .

As  $E_1$  is increased, with  $\Delta E$  constant, the recovery time is decreased. That is, as the increment of change is moved to higher voltage levels, the recovery period becomes shorter. For example, a change of 4v from 10 to 6 requires about 3 min to recovery whereas a change of 4v from 11 to 7 requires less than 1 min for recovery.

If the experiment is taken to the limiting conditions where  $\Delta E = E_1$ , then  $E_2 = 0$ , the recovery time is measured without voltage applied. The results of such experiments show that the recovery is extremely slow compared with recovery with voltage applied. For example, if a  $\Delta E$  is chosen to give a 2-min recovery time with voltage applied, recovery is found to be incomplete even after standing 20 min without voltage applied. The degree of agitation or thickness of the porous oxide does not affect this result.

Figure 8 is a current recording obtained under conditions where short (1-min) recovery times are involved. The voltage during the recovery period was applied intermittently, and it is proposed that any local heating effects due to current flow would thereby be eliminated and that the oxide-metal-bath temperature should remain fairly close to equilibrium. It is evident that the total time to recover is almost 3 times as long as when voltage is continuously applied.

Fig. 6. Effect of sulfuric acid concentration on recovery time

Fig. 7. Recovery at various levels of applied voltage,  $E_2$  (24°C, 1100 alloy). (Half time, time to one half the equilibrium current, is used because the steep slope of the curve at this point facilitates time measurement.)

Fig. 8. Recovery characteristics using continuous and intermittent voltage application.

*Effect of continuity of voltage change.*—The results reported above were obtained with a discontinuous change from  $E_1$  to  $E_2$ . Completely different characteristics are exhibited if this change is made to occur in a continuous manner. If at the end of time,  $t_1$ , the voltage is slowly and continuously reduced to  $E_2$  by means of the power supply fine voltage control, the recovery time for the current to reach equilibrium is greatly reduced. Figure 9 illustrates this behavior.

Fig. 9. Effect of rate of change of voltage on recovery

*Additional observations of the behavior in the cell.*—A number of experiments were made wherein samples were anodized under one condition and allowed to recover under other conditions. The results showed that, if formation is carried out in an electrolyte of different concentration than the recovery electrolyte, the recovery time is characteristic of the electrolyte used in the formation. That is, samples anodized in 15% sulfuric acid which are then transferred to 30% sulfuric, recover as though they had been allowed to recover in the 15% acid. The same behavior was observed for the reverse order of concentration used in formation and recovery.

Samples anodized at one temperature and allowed to recover at another showed recovery characterized by the temperature of the recovery electrolyte, not the formation electrolyte.

A number of experiments were carried out to determine if recovery could be at least partially induced in a nondissolving system. Samples were anodized in sulfuric acid, transferred to boric acid and held at a potential somewhat less than the potential  $E_2$ . They were then transferred back to the sulfuric acid system for recovery at  $E_2$ . Holding these samples at a potential of about  $E_2$  for periods of 10 min or more in the boric acid reduced the time required for recovery in the sulfuric acid significantly. For example, the time required for recovery at 10v was decreased from 2 min to 1.25 min by holding the sample for 10 min in boric acid at 7v. (The boric acid voltage, 7v, was chosen so as to produce a barrier of about 100Å which is roughly that obtained in sulfuric acid at 10v.)

Finally, capacity measurements were made at various times during the recovery process. The shape of the capacity time curve was nearly identical to that of the current recovery which indicates no appreciable thinning occurs while the current is very low. No doubt capacity changes would occur on prolonged standing with no applied voltage, but during the relatively short times required for recovery with voltage applied this change was not evident.

### Discussion

*Barrier layer adjustments.*—The porous outer layer of anodized aluminum does not contribute significantly to the resistance of the anodizing cell since the resistance does not change significantly as the porous layer thickness increases nearly two orders of magnitude. The electrical behavior of anodized aluminum in the cell must therefore be explained on the basis of changes occurring in the barrier region.

The physical-geometric model postulates dissolution of the barrier layer, thereby permitting continuous growth. The result is the formation of aluminum oxide penetrated by many pores, hence the porous layer. In proposing this simple dissolution theory it was necessary to postulate high temperature and high acid concentration to obtain the high observed rates under normal anodizing voltages.

The experimental evidence given here indicates that dissolution in this simple sense (solution kinetics determined by temperature and concentration) is an unlikely or, at least, incomplete explanation of the changes occurring during current recovery.

When the applied voltage is changed, certain readjustments in the barrier layer are necessary. The barrier layer must satisfy a fixed relation (4) to the anodizing voltage

$$\text{thickness} = (10.5) (\text{anodizing voltage}) \quad [1]$$

The amount by which the barrier thickness must be adjusted, therefore, depends only on the voltage change. If the voltage change is from 14 to 10, then  $\Delta E$  is 4v requiring a thinning of approximately 40Å. Likewise, in going from 10 to 6v, the change is 4v, again equivalent to a change of 40Å in the barrier thickness.

If the process of recovery is one involving a simple temperature dependent dissolution, one would expect that about the same amount of time would be required to dissolve the 40Å in the above example. This follows from the observation that the current drops to 0 in both cases and, accordingly, the temperature at the pore base must drop to that of the body of the solution surrounding the test sample. Since the temperature would be the same in the two cases, the dissolution rate and the time to recovery would be the same in the two examples.

It is an experimental fact, however, that the time required to thin the barrier is dependent on the voltage applied during recovery. For example, Fig. 7 shows that with 8v applied during recovery, it takes about 1½ min to make a 50Å adjustment in the barrier ( $\Delta E = 13-8$ ). On the other hand, when recovery occurs at 6v, it takes nearly 10 min to make a 50Å adjustment ( $\Delta E = 11-6$ ). The times required to thin the barrier 50Å are obviously quite different in the two examples. If no voltage is applied, it was shown that more than 20 min is required to effect recovery.

*Reactions influenced by applied voltage.*—The strong dependence of current recovery on the applied voltage suggests a further look at the voltage dependent reactions in the system. These include the transport of aluminum ions across the barrier, movement of charge species to and away from the barrier-porous interphase, and movement of the barrier into the metal.

It is assumed that the aluminum moves as a charged entity through the barrier under the influence of the applied field. It is unlikely that the barrier contains aluminum and oxygen in stoichiometric amounts, but it is more likely rich in aluminum near the metal. The oxygen-rich portion would be expected near the porous-barrier interphase. The oxygen and aluminum concentration profile probably changes according to the rate at which anodizing proceeds and appears likely to be further from stoichiometric  $Al_2O_3$  at higher anodizing currents.

As aluminum moves from the metal lattice into the barrier, oxygen atoms must move counter to this direction in order to advance the barrier into the metal. Whether or not this movement occurs by individual atom jumps or by movement of the entire lattice is not known. It does seem reasonable, however, to postulate that the lattice at the metal-oxide interface contains many vacancies. It also seems reasonable that the number of such vacancies will depend on the rate of aluminum ion removal from the lattice and the availability of oxygen atoms to fill the vacancies. Again, the vacancies would be expected to increase as the anodizing current is increased. Little is known about the phenomenon of barrier movement, but movement of charged entities into the vacancies would be expected to be dependent on the field.

The third voltage-sensitive reaction involves the movement of charges in the barrier-porous interphase region. It is in this region that reaction occurs between the aluminum ion and the oxygen-containing species and, as a result, protons will accumulate. This accumulation constitutes a space charge which is counter to the applied field, and its magnitude would be expected to depend on the number of atoms entering the reaction. This in turn depends on the anodizing current and the rate at which protons can migrate under the influence of the field.

Therefore, we have a somewhat complex equilibrium condition at any constant current which involves: (i) aluminum ions in transit across the barrier; (ii) oxygen movement into the metal; (iii) a proton space charge density near the outer region of the barrier; and (iv) barrier thickness.

If the voltage is suddenly decreased to a lower value, the system must go through a transition to a new set of equilibrium conditions. This transition would involve thinning of the barrier layer to satisfy the 10Å/v condition, a reduction in the number of aluminum ions

in transit across the barrier, and a lower proton space charge. So little is known about the barrier movement into the metal that no further comment on the rate of this movement can be made.

When the voltage is suddenly interrupted and a lower one reapplied, the accelerating field which appears across the barrier is reduced and the rate at which ions can be moved will also be reduced. In addition, the space charge characteristic of the higher current is present, and it is counter to the field moving the aluminum ions, thereby reducing the net field even more. As a consequence, the migration stops completely, and the current goes essentially to zero leaving the barrier with a space charge, thickness, and stoichiometry characteristic of the current and voltage which was applied just before interruption.

If the oxide is allowed to stand without voltage applied, the space charge and excess aluminum ions in transit must move purely by diffusional processes. Protons can migrate outward or negatively charged ions inward to dissipate the space charge. This could be a relatively slow process since the region of the space charge does not have a highly developed surface area. Rapid site-to-site migration of charge particles is proposed to occur only in the highly porous region which has been converted from the barrier layer.

The redistribution of excess aluminum ions in transit across the barrier could also occur without the influence of an applied field. This process would be expected to be slower under the reduced field, but certainly more rapid than if no voltage whatever is applied.

*Agreement between observations and proposed reactions.*—There is no question that under the influence of an applied field the migration of charged particles is facilitated. The movement of these charged particles would not affect the electrical thickness of the barrier layer as measured by its capacity. The experimental observations indicate that this capacity remains constant during most of the recovery time and only increases when the current begins to increase toward its new equilibrium. The gradual dissipation of the protonic space charge and the redistribution of aluminum ions are two field-sensitive reactions which could account for these experimental observations. One would expect no change in thickness (constant capacity) during this redistribution process and the process should be temperature dependent. This part of the recovery should be attainable in electrolytes such as boric acid, again in agreement with observation. One would not expect the concentration of the recovery electrolyte to exert any marked influence on the redistribution part of the recovery, again in agreement with the experimental observation.

The fact that recovery occurs more rapidly as the recovery voltage is increased is simply a manifestation of the higher fields present. The field during recovery is given by

$$\text{Field (volts/\AA)} = \frac{E_2 \text{ (recovery voltage)}}{E_1 \times 10.5 \text{ (barrier thickness in \AA)}} \quad [2]$$

The recovery voltage,  $E_2$ , can also be expressed in terms of the initial voltage and the voltage change,  $\Delta E$

$$E_2 = E_1 - \Delta E \quad [3]$$

As  $E_2$  is increased,  $E_1$  must increase a like amount to hold  $\Delta E$  constant and the ratio

$$\frac{E_1 - \Delta E}{E_1 \times 10.5} = \text{Field} \quad [4]$$

must also increase.

If the recovery voltage is made sufficiently high, the current can be made to recover very rapidly. Figure 10 illustrates a circuit in which a large series resistance is introduced. The voltage is switched between

Fig. 10. Characteristic recovery with large series cell resistance (square wave voltage cycle is 10 sec).

supplies  $E_1$  and  $E_2$  which are of very high voltage compared to that appearing across the cell. In other words, most of the supply voltage is dropped across the series resistance.

When the circuit is interrupted by a relay and reconnected to the other supply, the cell momentarily sees a very high voltage because the current is low and hence the voltage drop in the series resistance is low. As the current builds up, the drop across the series resistance increases, and consequently the voltage across the cell rapidly and continuously decreases. In effect, this means that the recovery is occurring at a relatively high voltage until the equilibrium current is reached.

If the process is now reversed, that is, the voltage is raised to a higher value, the current will immediately increase. The current transient shows an overshoot before attaining its final equilibrium. This overshoot is understandable because the space charge is not as high as at equilibrium. The barrier oxide is thinner, and the concentration of aluminum ions in transit across the barrier is also lower than at equilibrium for the higher voltage. The net result is a much higher than equilibrium field across the barrier layer which accounts for the momentary high current before equilibrium can be attained.

The dependence of recovery on the rate of voltage change, as illustrated in Fig. 9, also shows that the charge redistribution is a slow process especially at low voltage. It can be seen that reducing the voltage from 11 to 7v in about  $\frac{1}{2}$  sec requires a recovery time of about 40 sec before equilibrium is re-attained. When the same voltage change is made in 2 sec, the recovery is very rapid. If the voltage is changed discontinuously ( $dE/dt$  extremely large), recovery now requires a matter of minutes. This latter observation also indicates the possibility that the discontinuity of the change is an important factor.

### Summary

The current flow during anodizing of aluminum drops to near zero when the voltage applied to the cell is reduced below a critical value. The time required to attain equilibrium current at the reduced voltage is dependent on the voltage change, rate of change, level of reduced voltage, and temperature and concentration of the forming electrolyte.

It is not possible to explain the current recovery on the basis of the simple geometric pore model, but the experimental observations are consistent with the colloidal gel model proposed by Murphy and Michelson.

It is believed that the recovery must be preceded by dissipation of a protonic space charge arising from the reaction between aluminum ions and the ionic oxygen carrier. In addition, it is believed that the stoichiometry of the barrier must be adjusted before the new equilibrium current can be attained. The final

step involved is that of barrier conversion to porous layer to effect the thinning that is observed at the end of the recovery period.

## Information on Anodic Oxides on Valve Metals: Oxide Growth at Constant Rate of Voltage Increase

C. G. Dunn\*

General Electric Research and Development Center, Schenectady, New York

### ABSTRACT

The formation of nonporous anodic oxide films is treated mathematically for the constant rate of voltage increase method to provide a basis for interpreting reanodization current-voltage curves. Illustrative reanodization I-V curves are considered for such initial anodic oxide films as nonporous oxide, porous  $\text{Al}_2\text{O}_3$ , plastically deformed  $\text{Al}_2\text{O}_3$  and  $\text{Ta}_2\text{O}_5$ , and annealed nonporous  $\text{Al}_2\text{O}_3$ . Evidence obtained for pore filling in and the conversion of a porous film into a nonporous film is supported by electron microscopy and thickness measurements. Confirmation of low ductility in  $\text{Al}_2\text{O}_3$  and high ductility in  $\text{Ta}_2\text{O}_5$  is obtained. Information is provided on the restoration of ionic conductivity in  $\text{Al}_2\text{O}_3$ , which is lost by annealing.

Dekker and van Geel (1) obtained information on the porosity and the total thickness of porous anodic oxide films on aluminum from reanodization data. Thus, employing the constant-current method of adding nonporous anodic oxide, they observed an initial rapid rise in voltage, which was ascribed to a filling in of the pores in the initial film and a later slower rise in voltage, which was identified with uniform oxide formation at a rate expected from Faraday's law. In this instance, and in other situations described later, the current density associated with oxide formation is not constant under constant-current reanodization. Some improvement in this respect arises, however, if rate of voltage rise is held constant by a controlled rate of voltage increase. Moreover, the method of holding the rate of voltage increase constant provides more uniform conditions of anodic film formation if many specimens of different (or unknown) surface areas are being compared. Dignam (2) found the "constant rate of voltage increase" or CRVI method both convenient and useful in a study of ionic currents in oxide films on aluminum.

If the anodic film or an outer layer of the film on a valve metal is quite different from the film being formed during reanodization [e.g., the porous layer obtained on tantalum using ultraviolet irradiation and low electric fields (3, 4) is probably in this category (5), and the hydrated oxide produced by a boiling water treatment of aluminum covered with anodic oxide is certainly such a film (6)], certain complications arise making analysis of the reanodization data difficult. In such circumstances more supplementary data than usual are needed for a correct interpretation of CRVI current-voltage data.

In the present paper the illustrations are limited to the oxides; other anodic films including hydrated oxides are beyond the scope of the paper. Equations are given for oxide film formation by the CRVI

method. These include initial steady-state anodization as well as transitions to steady-state conditions on reanodization. Illustrations of current transitions together with interpretations have been selected from such studies as "the nature of porous oxide films," "ductility of nonporous films," and "effect of heat treatment on ionic conduction."

### Theory and Illustrative Results

*Nonporous film formation.*—Consider a flat valve-metal specimen of surface area  $A$  on which a nonporous anodic oxide is growing. At time  $t$  the potential drop across the oxide of thickness  $x$  is  $V_{ox}$ , and across the cell an external electrical circuit is  $V_a$ , with  $V_a$  increasing at a constant rate  $\eta \equiv dV_a/dt$ , where  $\eta$  is a controllable parameter. When the current  $I$  is constant  $dV_a/dt$  and  $dV_{ox}/dt$  are equal. If the Maxwell field strength  $E$  is independent of  $t$  for a given value of  $\eta$ , then

$$dx/dt = (1/E\eta)\eta \quad [1]$$

describes a constant rate of film growth and a steady-state condition. Replacing  $\eta$  by  $dV_a/dt$  gives

$$dx = (1/E\eta) dV_a \quad [2]$$

For a voltage increase of  $\Delta V_a$ , the thickness increase  $\Delta x$  may be measured, and a Maxwell field strength  $E_\eta$  determined since  $\Delta V_{ox} = \Delta V_a$ .

Another equation for  $dx/dt$  is given by Faraday's law as follows

$$dx/dt = \Omega J_{ox} \quad [3]$$

where the constant  $\Omega$  depends on units and is proportional to  $e/\rho$ ,  $e$  is the electrochemical equivalent of the oxide,  $\rho$  is the density of the oxide, and  $J_{ox}$  is the ionic current density associated with oxide formation (at 100% current efficiency  $I/A = J_{ox}$ ). This equation is independent of both  $\eta$  and the steady-state condition. Combining [1] and [3] and solving for  $J_{ox}$  under

\* Electrochemical Society Active Member.

steady-state conditions gives

$$J_{ox} = \eta/\Omega E_{\eta} \quad [4]$$

Now a simple and useful relation between film thickness and capacity holds for the parallel-plate configuration and is

$$A/C_{ox} = \lambda x/\epsilon \quad [5]$$

where  $C_{ox}$  is the capacity,  $\epsilon$  is the dielectric constant, and  $\lambda$  is a numerical factor depending on units. A change in  $x$  equal to  $\Delta x$  produces a change in  $A/C_{ox}$  of  $\Delta(A/C_{ox})$ , which is equal to  $\Delta(A/C)$ , where  $C$  is the measured capacity. In terms of rate of film growth Eq. [5] becomes

$$d(A/C)/dt = (\lambda/\epsilon) dx/dt \quad [6]$$

with  $C$  replacing  $C_{ox}$ . Combining [6] and [1] gives

$$d(A/C)/dt = (\lambda/\epsilon E_{\eta}) \eta \quad [7]$$

If  $\eta$  is replaced by  $dV_a/dt$ , then [7] reduces to

$$d(A/C) = (\lambda/\epsilon E_{\eta}) dV_a \quad [8]$$

which describes how reciprocal capacity varies with voltage at constant  $\eta$ . When  $\epsilon$  is constant, Eq. [8] and [2] are equivalent. (On the other hand, a linear relation between  $A/C$  and  $V_a$ , obtained for example in a sequence involving changes in electrolyte, could also involve discontinuous changes in both  $\epsilon$  and  $E_{\eta}$  with  $\epsilon E_{\eta}$  constant. In such circumstances measured values of  $dx/dt$  would change as  $E_{\eta}$  changed according to Eq. [1], and  $J_{ox}$  would also change unless the ratio  $(dx/dt)/\Omega$  remained constant in Eq. [3].)

The slope  $\lambda/\epsilon E_{\eta}$  in Eq. [8] determines  $\epsilon E_{\eta}$  and depends of course on the rate parameter  $\eta$ . If  $\epsilon$  is known,  $E_{\eta}$  can be calculated from the measured slope.

Considering anodic film growth at 100% coulombic efficiency and constant temperature for simplicity a first approximation between ionic current density and electric field strength (7) may be expressed by

$$J_{ox} = \alpha \exp \beta E \quad [9]$$

where  $\alpha$  and  $\beta$  are constants and  $E \gg 0$  ( $\alpha$  depends strongly on temperature,  $\beta$  depends little on it). If only nonporous film forms along with little or no cation dissolution, these two constants and Eq. [9] summarize the rate effects expected (Eq. [9] applies also to more general situations, including  $E$  varying continuously with time; later considerations will require limited time intervals when  $dE/dt \neq 0$ ). The appropriate parametric expression for calculating  $E$  for given values of  $\eta$  is obtained by combining [9] and [4] and is

$$\Omega E_{\eta} \alpha \exp \beta E_{\eta} = \eta \quad [10]$$

Depending on anode material and electrolyte there are lower limits to the rate of film formation that results only in nonporous oxide. The following application of the above equations to oxide formation on tantalum and on aluminum in terms of specific values of  $\Omega$ ,  $\alpha$ , and  $\beta$  therefore outlines the sort of results expected if nonporous films form at 100% coulombic efficiency and  $Ta^{5+}$  and  $Al^{3+}$  are involved. Table I assembles values of  $\Omega$ ,  $\rho$ ,  $\alpha$ , and  $\beta$  that are used to obtain  $E_{\eta}$  as a function of  $\eta$  from Eq. [10] when  $dx/dt$

Table I. Illustrative values of  $\Omega$  ( $\text{\AA} \text{ sec}^{-1} \text{ ma}^{-1} \text{ cm}^2$ ),  $\rho$  ( $\text{g cm}^{-3}$ ),  $\alpha$  ( $\text{ma cm}^{-2}$ ), and  $\beta$  ( $\text{\AA v}^{-1}$ ) for use with Eq. [3] and [10]. References indicated in parenthesis.

and  $J_{ox}$  are in  $\text{\AA}/\text{sec}$  and  $\text{ma}/\text{cm}^2$ , respectively, in Eq. [3]. Values of  $\alpha$  are taken from current work with  $\eta = \frac{1}{6}$  v/sec and an electrolyte temperature controlled at 27°C; the values are equivalent to selecting 16.0 A/v ( $Ta_2O_5$ ) and 11.7 A/v ( $Al_2O_3$ ) for  $E_{\eta}^{-1}$  in Eq. [1] when  $\eta = \frac{1}{6}$  v/sec.

Results of the calculation of electric field strength as a function of rate of voltage increase are shown in Fig. 1. The variation of  $E_{\eta}$  with  $\log \eta$  is nearly linear (with  $\log J_{ox}$  it is linear according to Eq. [9]); and  $E_{\eta}$  of course changes slowly with  $\eta$ , resulting in  $J_{ox}$  being nearly proportional to  $\eta$  in Eq. [4], or current being roughly proportional to  $dV/dt$  for constant current formation (7). Estimates of  $1/E_{\eta}$  in A/v vs.  $\eta$  are also indicated in the figure.

If cations go into solution during steady-state nonporous film formation, the result is an ionic current density  $J$  which is greater than the current density  $J_{ox}$  for residue oxide

$$J = g J_{ox} \quad [11]$$

where  $g$  is a numerical factor greater than unity. Under this condition it turns out that  $\eta$  in Eq. [10] is multiplied by  $g$ . The actual electric field therefore is the same as the field at 100% efficiency and a rate of  $g\eta$ .

Electronic currents which arise at isolated points or flaws in the oxide have in principle no effect on the electric field in flaw-free areas. Elements of surface area act like parallel electrical circuits in the CRVI method, so isolated electronic currents only produce a higher average current.

Either Eq. [9] or [4] may be used to determine the current density expected for a given value of  $\eta$ . Equation [4] implies that current density depends on both  $\eta$  and  $E_{\eta}$ ; actually  $\eta$  is the only independent parameter. The dependence of  $J_{ox}$  on  $E$  in Eq. [9] is a dependence on  $\eta$  through Eq. [10].

*Reanodization after initial formation to voltage  $V_i$  or to thickness  $x_i$ —"The Current Transition".*—An illustration of anodic oxidation of 99.99% aluminum followed by reanodization is given by the current-voltage curves in Fig. 2. During initial anodization with  $\eta = \frac{1}{6}$  v/sec, the current remained constant.

At 170v the voltage switch was opened, the voltage setting was reduced, and reanodization started at  $\eta = \frac{1}{6}$  v/sec. Essentially no current appeared until the potential drop across the cell was about 150v. The

Fig. 1. Dependence of electric field strength  $E$  or reciprocal field  $E^{-1}$  (at right) on rate of voltage increase  $\eta$  (lower scale v/sec, upper scale v/min) for steady-state oxide formation.

Fig. 2. Steady-state oxide formation at 10 v/min to 170v (at left) followed by reanodization (at right) which produced a sharp current transition with maximum slope at 170v.

current then rose rapidly and leveled off beyond about 195v at the value formerly observed, producing a curve of sigmoidal shape. We call it a current transition.

In the current transition, both oxide thickness and Maxwell field strength vary, *i.e.*,

$$dV_{ox}/dt = E dx/dt + x dE/dt \quad [12]$$

where  $x \cong x_i$ .

Since both the IR drop across "the electrolyte and external electrical circuit" and the cathodic overpotential  $V_c$  increase with increasing current, the rate of voltage increase across the oxide differs from the rate of voltage increase  $dV_a/dt$  (the emf of the oxide reaction  $\xi$  will be taken as a constant). During the current transition, therefore

$$dV_a/dt = dV_{ox}/dt + R dI/dt + dV_c/dt \quad [13]$$

Prior to oxide growth, *i.e.*,  $dx/dt = 0$ , Eq. [12] reduces to  $dE/dt = \eta/x_i$ . A capacitor charging current is involved (see Appendix), but it never increases. In fact, it decreases in the current transition and becomes zero. It also is negligible compared with the oxide forming currents (see Appendix).

Two aspects of the current transition are of principal interest. These are (i) the increase of  $x$  to  $x_i + \delta x$  on reanodization to  $V_i$  and (ii) the slope  $dI/dV$  of the I-V curve at  $V = V_i$ . The current transition occurs over a small voltage range if  $\delta x$  is relatively small or if the slope  $dI/dV$  is large. Both quantities depend explicitly on  $\beta$  in Eq. [9]. They also depend on the so-called constant  $\alpha$  if  $\alpha$  fails to remain constant in the transition. The end of the transition is characterized as steady state with  $I = I_s$ ,  $E = E_s$ ,  $\alpha = \alpha_s$ , etc. Since  $V_{ox}/x$  determines  $E$  at all points of the current transition, both  $V_{ox}$  and  $x$  need to be determined. If the IR drop and the cathode overpotential are negligible, then  $V_{ox} = V_a + \xi$ . The thickness increase may be determined using Faraday's law. Application of Eq. [9] gives

$$(I/I_s) = (\alpha/\alpha_s) \exp \beta E_s [-\delta x/(x_i + \delta x)] \quad [14]$$

for  $x = x_i + \delta x$  and  $V_{ox} = (V_{ox})_i$ . Experimentally, it is found that  $(I/I_s)$  at  $V = V_i$  is close to  $1/2$ . Thus if  $\alpha/\alpha_s$  is constant for a given value of  $E_s$ , then  $\delta x/(x_i + \delta x)$  must be constant for various values of  $x_i$ . This means that  $\delta x$  depends on  $x_i$ . Similarly, the voltage range of the current transition depends on  $x_i$ .

For the current transition in Fig. 2, a calculation gave 0.020 for  $\delta x/(x_i + \delta x)$ ; *i.e.*, the thickness increased 2% on reanodization to  $V_i$ ; it should have increased 1.89% for  $\beta = 430$  A/v and  $\alpha = \alpha_s$ .

The maximum slope  $(dI/dV)_m$  of the current transition occurs near  $V = V_i$  and to a first approximation is

given by

$$(dI/dV)_m \cong I_s \beta / 4x_i \quad [15]$$

if  $d\alpha/dt = 0$ , and if the last two terms in Eq. [12] are negligible. The result expressed in Eq. [15] is essentially independent of  $\eta$ , the rate of reanodization, if  $d\alpha/dt = 0$  (note later comments on  $\alpha$ , however). The maximum slope varies inversely with  $x_i$  as does the maximum slope per unit steady-state current,  $I_s^{-1}(dI/dV)_m$ . A value of this latter term for the curve in Fig. 2 is  $5.1 \times 10^{-2} \text{ v}^{-1}$ . This may be compared with  $5.4 \times 10^{-2}$  for  $\beta/4x_i$  with 430 A/v for  $\beta$  and 1990 Å for  $x_i$ , the 170v film formed at  $\frac{1}{6}$  v/sec.

Transitions of the kind shown in Fig. 2 also occur when reanodization is carried out at a different rate  $\eta'$ . The voltage  $V_i$  for the rate  $\eta$  now becomes  $V_i'$  for the rate  $\eta'$ . From Eq. [2] one obtains  $V_i' = V_i(E\eta'/E\eta)$ . Since the electric field is increased when  $\eta$  is increased (Eq. [9] or Fig. 1), it follows that  $V_i' > V_i$  when  $\eta' > \eta$ .

Application of Faraday's law after reanodization also determines  $V_i'$ . Thus the actual area under the I-V curve to some point  $V$  beyond the current transition is set equal to the area that would be produced at constant current beginning at  $V_i'$  and ending at the same point  $V$ .

Good agreement was obtained experimentally between known values of  $x_i$  or  $V_i$  and values of  $x_i$  determined either by the maximum slope method or by the area under the curve method. Consequently, the reanodization method may be used to determine the thickness of an oxide film. Experimental agreement has also been obtained between reciprocal capacity and voltage for a given value of  $\eta$ , as expressed in Eq. [8], for a sequence of voltage increments involving current transitions when the end of each increment is taken beyond any current transition and anodization is terminated sharply. Smaller transitions occur, however, if voltage is reapplied at the prior terminal voltage during open-circuit advance of voltage.

On the other hand, if the prior voltage is exceeded on open-circuit advance, say by a per cent or two, and this situation is easily obtained during anodization by opening the circuit at voltage  $V_i$  and closing it later at  $V_i + \Delta V$ , one obtains a rapid rise in current and a slow decay to the final steady-state value (an illustration appears later in connection with annealing effects). Such a current transition involves a decreasing electric field during the approach to the steady-state whereas the sigmoidal curve already discussed (Fig. 2) involves only an increasing field.

*Idealized case of two current transitions.*—Consider that a single specimen is covered with oxide, part to a thickness  $x_1$  and the remainder to a thickness  $x_2$ , with  $x_1 < x_2$ . The area of the thinner part is taken as the sum of many separate areas, each having linear dimensions  $l$  such that  $l \gg x_1$  and ionic transport therefore is negligible across boundaries between thin and thick areas. Under these conditions the specimen is equivalent to two flat specimens connected in parallel, one having an area  $A_1$  and oxide thickness  $x_1$  and the other an area  $A_2$  and oxide thickness  $x_2$ . As may be verified experimentally, the I-V curve of such a parallel pair equals the sum of two I-V curves obtained separately; it has a final steady-state current for an area equal to  $A_1 + A_2$  and two current transitions with a constant current between them if  $x_2 - x_1$  is sufficiently large. On the other hand, if  $l \sim x_1$  or  $l \ll x_1$ , as is the case for porous  $\text{Al}_2\text{O}_3$  films for example, the equivalence of two areas in parallel should not be assumed except for determining the total area, the average oxide thickness, and the thickness of the thinner layer.

*Initial porous anodic oxide films.*—Porous films of amorphous  $\text{Al}_2\text{O}_3$  are easily produced anodically on aluminum (7). They consist of a nonporous (barrier)

Fig. 3. Reanodization at 10 v/min of initial porous  $\text{Al}_2\text{O}_3$  film showing two current transitions, the first due to the barrier-layer thickness and the second due to the total thickness of the initial porous film.

layer next to the metal and an outer porous layer adjacent to the electrolyte (13). Porous films of  $\text{Ta}_2\text{O}_5$  may be produced anodically on tantalum using a strong alkaline electrolyte (14). Reanodization under conditions of nonporous film formation often results in an I-V record with two current transitions and an intermediate current plateau as shown in Fig. 3. In other cases, the curve is more complicated.

Regarding the initial oxide for Fig. 3, a porous film was produced on 99.99% Al (with clean surfaces) during anodization to 40v at (5/36) v/min in an aqueous solution of 1% ammonium pentaborate (APB). The average (and nearly constant) current density was  $17.8 \mu\text{a}/\text{cm}^2$ , about a factor of 3.24 higher than the current calculated from Eq. [4] and Fig. 1 for nonporous film formation (similar results were observed for high-purity Al films on glass slides obtained by vacuum vapor deposition). The same electrolyte, 1% APB, however, could be used for reanodization at 10 v/min because only nonporous film forms at this rate and the coulombic efficiency is relatively high.

Analysis of the I-V curve in Fig. 3, along with anodization data, gives the following information: (a) 77v or 900A for the average initial oxide thickness (from the area under the curve); (b) a possible 1710Å average thickness if  $17.8 \mu\text{a}/\text{cm}^2$  for 288 min produced only  $\text{Al}_2\text{O}_3$  film at 100% current efficiency; (c) a current efficiency for forming adherent  $\text{Al}_2\text{O}_3$  of about 53%; (d) 46v or 540A for the barrier-layer thickness from the first current transition (i.e.,  $x_1 \approx 540\text{Å}$ ); (e) a possible outer layer porosity of about 62% if the first current plateau is not high due to  $l \ll x_1$ ; and (f) a possible total film thickness of about 126v or about 1480Å according to the second current transition (however, 1480Å would necessarily be high if 62% porosity is high).

Supplementary data were obtained from appropriate equivalent specimens. Thus, transmission electron micrographs of initial 40v films lifted by the bromine-methanol method (15) revealed a porous structure with a pore density of about  $7 \times 10^{11} \text{cm}^{-2}$ , with pore diameters near 100Å, (i.e.,  $l \sim 100\text{Å}$ ), and with roughly 50% porosity in the outer layer. From 50% porosity, a 540Å barrier-layer thickness, and 900A average thickness one obtains 1260Å as a rough estimate of the initial oxide thickness. Also, a value of 1500Å for the initial oxide thickness was obtained using a Taylor Hobson Talysurf (16) on lifted films (transferred onto glass slides). This number agrees well with 1480Å obtained from Fig. 3, indicating that departure from the  $l \gg x_1$  condition may not involve a large effect. (More data involving thicker porous layers appear to be needed on this point.) Finally, transmission electron micrographs of lifted films after reanodization to the steady-state condition revealed only a nonporous structure and no evidence of the initial porous struc-

Fig. 4. Reanodization of a  $\text{Ta}/\text{Ta}_2\text{O}_5$  specimen with 25v anodic film after a cold-rolling reduction of 56% (solid curve), I-V curve expected for zero ductility (curve A), and I-V curve for uniform oxide thinning (B).

ture. This means that reanodization at the faster rate filled in the pores.

*Plastic deformation of nonporous  $\text{Al}_2\text{O}_3$  and  $\text{Ta}_2\text{O}_5$  films.*—The idealized case of two current transitions discussed previously is well represented by  $\text{Al}_2\text{O}_3$  films, which deform little or not at all during deformation of the substrate aluminum (17,18), because there is a new area with near zero thickness of oxide and a retained old area covered with oxide of the initial thickness. The reanodization method of analysis was applied to cold rolled specimens with either 15 or 100v anodic films. The position of the second current transition was not changed, within experimental error, for reductions in specimen thickness of 20 and 35%. This indicates that the oxide thickness was not changed during substrate deformation.

Anodic  $\text{Ta}_2\text{O}_5$  films on the other hand have relatively high ductility when adherence<sup>1</sup> to the substrate tantalum is strong (7, 18, 19). High ductility is also shown in the present illustration involving a 0.07 mm-thick tantalum strip which was annealed at 2200°C *in vacuo*, anodized to 25v at 10 v/min in 1%  $\text{H}_3\text{PO}_4$ , cold rolled slowly in 12 passes to keep the temperature from rising excessively during a reduction in cross-section area of 56%, cleaned of rolling lubricant, and then reanodized in 1%  $\text{H}_3\text{PO}_4$  at 10 v/min. Figure 4 shows the I-V curve obtained and two fictitious curves marked A and B that were added for comparison. Curve A, with a 25v current transition, is for zero ductility but excellent adherence, i.e.,  $\text{Al}_2\text{O}_3$ -like behavior. Curve B, with a 10.2v transition, is for uniform oxide thinning to an average thickness of the final film (determined from the area under the curve). Within experimental error this average thickness is 56% less than the initial oxide thickness. The large spread in final thickness is due to nonuniform deformation of the relatively large-grained tantalum specimen. This nonuniformity of substrate deformation is passed on to the oxide leading to striking color variations not only among the substrate grains but also within the surface area of individual grains. Such color differences disappear during reanodization.

*Heat-treated nonporous anodic oxide prior to reanodization.*—Dignam (2) found that annealing thin (5v or less) anodic films on aluminum, under conditions producing no crystallization of the amorphous films, completely changed the character of the current transition (or polarization curve) obtained by reanodization. Instead of a sigmoidal curve there were now current peaks.

The present illustrations of this effect of annealing involve thicker films. Thus, in Fig. 5 and 6 are shown reanodization I-V curves for 30 and 120v nonporous

<sup>1</sup> Poor adherence during cold rolling may be overcome, however, using a large reduction (~40%) in the first pass (19).

Fig. 5. Reanodization at 10 v/min of 30v (10 v/min) nonporous  $\text{Al}_2\text{O}_3$  film after a 1-hr anneal at  $300^\circ\text{C}$  in argon.

Fig. 6. Reanodization at 10 v/min of 120v (10 v/min)  $\text{Al}_2\text{O}_3$  film after same 1-hr anneal at  $300^\circ\text{C}$  as in Fig. 5.

$\text{Al}_2\text{O}_3$  films; these were formed at 10 v/min, dried, and annealed at  $300^\circ\text{C}$  for 1 hr in argon. Some 40 and 90v films prepared and annealed in the same manner produced similar current peaks and I-V curves on reanodization at 10 v/min. Unlike unannealed films with a current rise beginning at voltages below  $V_i$  (Fig. 2), all films annealed at  $300^\circ\text{C}$  had the current rise begin at voltage above  $V_i$  (Fig. 5 and 6). These transitions in  $300^\circ\text{C}$  annealed films therefore involve a decreasing electric field. For comparison purposes an example of a decreasing field transition in an unannealed film was obtained as follows. During anodization at 10 v/min, the voltage circuit was opened at 70v and closed 12 sec later at 72v (Fig. 7). The current rose rapidly to a peak value in less than 1 sec, then decayed slowly as the voltage advanced. The steady state was obtained near 83v.

The areas under the curves to steady-state conditions, i.e.,  $I = I_s$  and  $E = E_s$ , were found to be equal within experimental error to those expected for steady-state

Fig. 7. Anodization at 10 v/min except for voltage removal between 70 and 72v to produce a current transition with decreasing electric field.

anodization beyond  $V_i$  to the same termination voltage. This indicates no change in the mass of oxide due to annealing 1 hr at  $300^\circ\text{C}$ . It agrees with the results found by Dignam (2).

A second reanodization of the annealed specimens after completion of the current transition resulted in normal behavior, i.e., sigmoidal curve transitions. The effect produced by annealing on reanodization behavior was therefore removed during reanodization through the transition region. This confirms Dignam's belief that the effect of annealing was reversed by reanodization (see also Discussion comments). The effect of reanodization through part of the transition will be considered later.

For further analysis of the I-V curves of the five films described previously, use is made of five voltage points; these are assembled in Table II in the order of increasing voltage. They are (i)  $V_i$ , the anodization voltage prior to annealing, (ii) 1%  $I_s$ , estimated voltage for a current of 1% of steady-state value, (iii)  $E_m$ , voltage for maximum electric field (a calculated point), (iv)  $I_m$ , maximum current, and (v)  $I_s$ , or the end of the transition. The voltage for maximum field may be obtained from a calculated curve showing  $E$  vs.  $V$ . Since the change in oxide thickness is proportional to the area under the curve, such areas may be used to calculate  $E/E_s$  as a function of voltage when both the IR drop and the cathode overpotential are negligible. Results of such calculations for the 30v and 120v films appear in Fig. 8. The straight lines passing through the point where  $E/E_s = 1$  determine the maximum values of  $d(E/E_s)/dV$  set by the initial oxide thicknesses. The plot of  $E/E_s$  follows these lines as long as the ionic current (and oxide growth) is negligible. Other calculations appear in Table III.

The time intervals given in Table III are determined from increases in voltage at  $\frac{1}{6}$  v/sec between the points listed in Table II. Since  $dE/dt$  varies inversely with initial oxide thickness when the oxide is not growing, an increasing time sequence with increasing  $V_i$ , like column one, is perhaps not unexpected.

Table II. Five voltage points for the transition current curves of four annealed specimens and one (70v) unannealed specimen.  $V_i$  also identifies each specimen

70	—	72 +	72 +	~83

Fig. 8. Calculated curves showing variation of electric field with voltage (or time) in the transition region for 30v (top scale) and 120v (bottom scale) annealed  $\text{Al}_2\text{O}_3$  films; straight lines give curves for no oxide growth.

The time to reach maximum field after the oxide starts to grow should also depend on the rate of increase of the electric field, and it does (column two). The time-voltage sequence in column three involves increasing current but decreasing field (on the average  $E/E_s$  decreases from about 1.13 to 1.07). Column four lists the current rise and for the entire transition are given in columns five and six, respectively. Inspection of the table or a plot of each time sequence against initial anodization voltage shows consistent trends of increasing time with increasing oxide thickness (*i.e.*,  $V_i$ ) except for included points from the unannealed specimen. The long current decay time for the unannealed film does, however, fit into the trend set by the annealed films. A few experiments were therefore made to determine whether the initial part of the reanodization transition played a more significant role in reversing the annealing effect.

Two specimens with 40v films and a 300°C 1-hr anneal in argon were used in the study of reanodization through part of the transition. One involved opening the voltage circuit when the current reached its maximum value during reanodization and the other involved terminating the reanodization when a current about 12% above  $I_s$  was reached during the current rise. Each specimen was reanodized a second time beginning near zero voltage. A sigmoidal curve was obtained for the specimen reanodized to the current peak, thus indicating essentially no residue of the change produced by the anneal. There was a small current peak, however, for the second specimen, indicating incomplete removal of the change produced by the anneal on reanodizing to a point definitely beyond  $E_m$ . Reversal of the annealing changes evidently begins with the ionic current. It probably continues throughout the current rise period since the phenomenon of "rising current with decreasing electric field" occurs here.

Although relatively long periods of time are involved when the current is rising and the electric field is decreasing in the annealed specimens (Table III), much longer periods arise when the reanodization is

done at rates far below 10 v/min in an electrolyte that produces only nonporous film. Thus, reanodization in 0.1% APB at (5/36) v/min of another 40v film annealed 1 hr at 300°C gave a period of 250 sec. In this run the current was greater than the steady-state current for a period of 30 min.

### Discussion

The CRVI and constant current methods of anodization are entirely equivalent at 100% current efficiency of forming adherent oxide, and at less than 100% efficiency they differ only in a minor way unless the efficiency is very low. Equations [1] and [3], therefore, give current density for a given rate of voltage increase and conversely give the rate of voltage increase for a given current density. The results of Fig. 1 also apply for the constant current method if electronic currents are low and the factor  $g$  in Eq. [11] is taken into account for less than 100% ionic current efficiency.

The constant current and CRVI methods appear to be far more different for reanodization experiments. In the constant current method, the current transition shown in Fig. 2 appears as a starting voltage, and the two current transitions shown in Fig. 3 appear as a starting voltage and a break in the rate of voltage rise (1).

The property constant  $\beta$  in Eq. [9] appears explicitly in the maximum slope of the current transition obtained with CRVI reanodization in the presence of an initial anodic oxide film (Eq. [15]). Since  $\beta$  is relatively large,  $(dI/dV)_m$  is also relatively large. This feature provides a simple method of determining the initial oxide thickness. Reanodization studies indicate that this method may also be used in the study of porous oxide films to determine the average oxide thickness, the barrier-layer thickness, and either (a) the total film thickness (and porosity of the outer layer) or (b) an apparent total thickness, which is too large if growth in total thickness occurs prior to the second current transition because of anion transport and favorable geometrical conditions (*i.e.*, pore dimensions near the barrier-layer thickness and considerable porosity in the outer layer). Theoretically an increase in total thickness may arise if anion transport is not small relative to cation transport.<sup>2</sup> The constant current in Fig. 3 following the first current transition, may be interpreted as evidence for cylindrical pores in the outer layer; this interpretation is in agreement with the model of Keller, Hunter, and Robinson (13). The final steady-state current (and particularly the nonporous structure revealed by transmission electron microscopy) confirms the pore filling process described by Dekker and van Geel (1).

A discussion of the significance of "pore formation during slow anodization in 1% ammonium pentaborate" and "pore filling during more rapid reanodization in the same electrolyte" to mechanisms involving ionic current carriers is outside the scope of the present paper.

As in the work of Dignam (2), annealing anodic  $\text{Al}_2\text{O}_3$  films moves the position of maximum slope in the I-V

<sup>2</sup> When the condition  $l \gg x_1$  (which was introduced for the idealized case of two current transitions) is satisfied, no increase in thickness of the thicker areas is expected regardless of the nature of the transport mechanism.

curves to higher voltages. The shape of the I-V curves are of course no longer sigmoidal, and the maximum slope method of determining the initial oxide thickness is no longer valid. The method based on Faraday's law or areas under the curve, however, still applies. No porous films were included in the study of annealing effects. However, it seems reasonable that a shift in position of either "the start of current rise" or "the maximum slope" would occur. Therefore, if annealing has occurred and the annealing effect is present but not allowed for, then an error is expected in the barrier-layer determination by the present CRVI method or the limiting thickness method (20), based on 14 Å/v for Al<sub>2</sub>O<sub>3</sub>.

The lack of a current peak in Fig. 4 may be taken as evidence of no appreciable annealing change due to film heating during the plastic deformation of Ta<sub>2</sub>O<sub>5</sub>. Many light reductions per pass were of course employed and this may have kept the temperature from rising excessively. The contrary experiment of possibly increasing the ionic conductivity of an annealed Ta<sub>2</sub>O<sub>5</sub> film through plastic deformation is suggested on the assumption that annealing removes structure defects (21, 22) and that plastic deformation probably introduces defects.<sup>3</sup>

Vermilyea has shown that annealing is a temperature accelerated process, involving an activation energy (21, 22). Regarding effects of long time at room temperature, limited data for Ta<sub>2</sub>O<sub>5</sub> with three years at room temperature and Al<sub>2</sub>O<sub>3</sub> with several months at room temperature revealed no current peaks for reanodization at 10 v/min. This is not to say that nothing happened but rather that the extent of change must have been small compared with the change produced during 1 hr at 300°C. No attempt was made to enhance low temperature annealing by means of an electric field below the level for ionic conduction, i.e., the field assisted annealing effect reported by Vermilyea (22).

Regarding the effects of annealing on ionic conductivity, free use is made of the ideas advanced by Vermilyea (21, 22), Young (7), and Dignam (2) that the structure of the oxide is altered to some degree by the annealing, which results in a drastic reduction in the number of potential current carriers, and that reanodization reverses this annealing change [in this connection, Vermilyea (23) found that passing constant current until the voltage transient vanished increased the dissolution rate of Ta<sub>2</sub>O<sub>5</sub> in an HF solution from a low "annealed" rate back to the high "as anodized" rate; the reversal by reanodization of x-ray line sharpening produced by annealing (22) was not studied]. Accordingly, it turns out that  $\alpha$  in Eq. [9] for isothermal but not steady-state conditions is a variable parameter and that the value of  $\beta$  determined experimentally depends on how  $\alpha$  varies. However, for a sequence of steady-state measurements, involving currents  $I_1, I_2, I_3, \text{ etc.}$ , or rates  $\eta_1, \eta_2, \eta_3, \text{ etc.}$ , for one temperature the dependence of  $\beta$  on  $\alpha$  tends to be lost. Despite this feature, relationships of the sort given in Fig. 1 for  $\alpha$  and  $\beta$  both constant have value experimentally for steady-state or quasisteady-state conditions.

The Al<sub>2</sub>O<sub>3</sub> films that were annealed for 1 hr at 300°C are apparently unable to attain a quasisteady-state condition even for very low rates of field increase. Perhaps the simplest way to allow for this is to assume that  $\alpha$  in Eq. [9] is now a parameter capable of increasing by several orders of magnitude and  $\beta$  is essentially constant. Thus, under constant voltage and  $E$  nearly constant initially (22, 7) or, as in present experiments with decreasing  $E$ , one may observe a rising current, only because  $\alpha$  is increasing at a rapid rate. In a sense the current depends on both  $\alpha$  and  $E$ , and conversely  $\alpha$  depends on an initial value  $\alpha = \alpha_0$  at  $t = 0$ , with the changes in  $\alpha$  occurring over some time

<sup>3</sup> Along similar lines Bubar and Vermilyea (25) find evidence of enhanced ionic conductivity when plastic deformation and anodization are simultaneous processes.

Fig. 9. Initial portions of I-V curves of Fig. 5 and 6 replotted in terms of  $\log I/I_s$  against reanodization voltage (30v film: top scale; 120v film: bottom scale).

interval  $t$ . Assuming that Eq. [9] gives the amount  $\alpha$  has varied during part of the reversal of the annealed state one writes

$$\alpha/\alpha_0 = (I/I_0) \exp[-8(E - E_0)] \quad [16]$$

with  $\alpha = \alpha_0$  near the beginning of the transition, where  $I = I_0 \neq 0$  and  $E = E_0$ , and  $\alpha = \alpha_s$  at the end of the transition. If  $E_0$  is taken at 1.07  $E_s$  for the present examples of annealing and  $E_m$  at 1.12  $E_s$ , then Eq. [16] gives  $\alpha/\alpha_0 \approx 500$  at the point of maximum field when  $\beta = 430$  Å/v and  $E_s^{-1} = 11.7$  Å/v. At the current peak  $\alpha/\alpha_0 \approx 700$  and at the end of the transition, where  $E_s < E_0$ ,  $\alpha/\alpha_0 = \alpha_s/\alpha_0 \approx 1300$ . These values of  $\alpha/\alpha_0$  suggest that a relatively large change in  $\alpha$  occurs early in the period of rising current.

A plot of  $\log(I/I_s)$  against voltage for the 30v and 120v Al<sub>2</sub>O<sub>3</sub> films is given in Fig. 9 mainly to point out that the curves are nearly linear to points just beyond maximum  $E$ , but the slopes are different. The latter feature is not surprising since the electric field rises more rapidly for the 30v film than for the 120v film. The linear relationship suggests that  $dI/dt$  is proportional to the current. On the other hand, Young (23) reported  $dI/dt$  being proportional to the second power of the current for  $E$  essentially constant. Either relation, however, is consistent with ionic current being responsible for the change in  $\alpha$ .

Reanodization data show that the change in  $\alpha$  produced by annealing may be reversed by a large current in a short time or by a small current in a long time. This suggests that the change in the oxide on reanodization is related to the amount of electric charge passed, a feature noted also by Dignam (24). It is not clear, however, if the amount of charge or extent of oxide growth needed for a given anneal is

independent of oxide thickness or if it increases with oxide thickness (the area under the curve to peak current is considerably larger for the 120v film than for the 30v film, but the ratio is less than the ratio of oxide thickness). This is important if the annealed films are in the same physical state. However, depending on the nature of the annealing change such films may or may not have exactly the same state after a single anneal, which kept annealing variables at a minimum. Thickness might be a factor in the kinetics of the annealing changes. More information on this point would of course be valuable for the purpose of comparing models of ionic conduction, including physical changes produced by annealing and by additional oxide growth after annealing.

### Summary

Holding the rate of voltage increase,  $\eta$ , constant in the formation of an anodic oxide film on a valve metal determines a Maxwell electric field strength  $E_\eta$ . The value of  $E_\eta$  depends on two property parameters  $\alpha$  and  $\beta$ , which appear in the equation  $J = \alpha \exp \beta E$  for isothermal variation of ionic current density with electric field strength. Calculated curves showing the variation of  $E_\eta$  with  $\eta$  are given for  $\text{Al}_2\text{O}_3$  and  $\text{Ta}_2\text{O}_5$  films.

When nonporous  $\text{Al}_2\text{O}_3$  and  $\text{Ta}_2\text{O}_5$  films are reanodized at constant  $\eta$ , relatively sharp current transitions are obtained in the I-V curves due to the relatively large values of  $\beta$ . For initial porous oxide films there are two current transitions; the first transition determines a value for the barrier-layer thickness and the second transition a value for either the total initial oxide thickness or the total thickness attained through growth prior to the second current transition. An example of pore "filling in" by reanodization is given together with supporting electron microscopy and thickness measurements that confirms earlier work by Dekker and van Geel.

Reanodization I-V curves provide a simple method for studying the ductility of nonporous oxide films. Evidence is given for essentially zero ductility in  $\text{Al}_2\text{O}_3$  films and high ductility in  $\text{Ta}_2\text{O}_5$  films, in agreement with published data.

The effect of annealing nonporous  $\text{Al}_2\text{O}_3$  films on the reanodization I-V curves for  $\eta$  constant is studied and discussed in terms of the property parameter  $\alpha$ . Thus, anodic  $\text{Al}_2\text{O}_3$  films formed in the range 30-120v suffer a drastic decrease in  $\alpha$  during a 1-hr anneal at 300°C in argon. Reanodization reverses the annealing effect when a certain amount of new oxide is formed. At fields above steady-state fields, the reversal of  $\alpha$  from a small to a large value is accomplished by a large ionic current in a short time or a small current in a long time.

### Acknowledgments

The author wishes to thank D. A. Vermilyea for discussions on the work and the preparation of the manuscript. Aid was provided by R. R. Russell in the electron microscope studies, and W. R. Reed, Jr. made the Talysurf oxide thickness measurements.

Manuscript received June 14, 1967; revised manuscript received Sept. 6, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 45.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### APPENDIX

*Capacitor charging current.*—Assuming no space charge in the dielectric, Gauss's law gives  $(\lambda 10^3/\epsilon)\sigma$  for the electric field in v/Å, where  $\lambda$  is  $36\pi \times 10^{-3}$  and  $C_{ox}$  in Eq. [5] is in  $\mu\text{F}/\text{cm}^2$  and  $\sigma$  is the charge density ( $\text{mc}/\text{cm}^2$ ) at the metal/oxide interface. Therefore  $dE/dt = (36\pi/\epsilon) d\sigma/dt$ , and  $d\sigma/dt$  is the capacitor charging current density in  $\text{ma}/\text{cm}^2$ . The latter has its maximum value initially when  $dE/dt = \eta/x_i$ . After the current transition,  $J_{ox}$  is constant at its maximum value of  $\eta/\Omega E_\eta$  according to Eq. [4]. Substituting and solving for  $(d\sigma/dt)_m/J_{ox}$  gives  $\Omega \epsilon E_\eta/36\pi x_i$ . For  $\text{Al}_2\text{O}_3$  with  $\epsilon = 8.4$ ,  $E_\eta < 0.1$  v/Å, and  $x_i > 10\text{Å}$  the maximum possible charging current is less than 0.4% of the steady-state current and therefore is usually negligible. Similarly the charge density required for the steady-state field  $E_\eta$  is less than the charge needed to form an angstrom of oxide; it is negligible in the application of Faraday's law.

## Determination of the Etch Rate and the Refractive Index of Silicon Nitride Films with an Ellipsometer

A. N. Saxena\* and O. Tkal

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

The etch rates in concentrated HF (49%) at room temperature and the refractive indices of silicon nitride films prepared by two different methods were determined with an ellipsometer<sup>1</sup> using light of wavelength  $\lambda = 5461\text{\AA}$ . In the first method (1), the silicon nitride film, 5300Å thick, was deposited on 10 ohms-cm, (111), p-type Si using reactive sputtering in N<sub>2</sub>. In the second method (2), the silicon nitride film, 4000Å thick, was deposited on 10 ohms-cm (111), p-type Si using chemical vapor deposition (NH<sub>3</sub> + SiH<sub>4</sub>) in a glow discharge at 400°C. The samples were mounted on the ellipsometer and aligned carefully (3).  $\Delta$  and  $\psi$  were measured at an angle of incidence  $\phi_0 = 70^\circ$ .  $\Delta$  is the change in the difference between the phases of the parallel (p) and the perpendicular (s) components of light on reflection, and  $\tan \psi$  is the factor by which the ratio of the amplitudes of the p and s components changes on reflection. After the initial measurements of ( $\Delta$ ,  $\psi$ ) on the samples, they were etched in concentrated HF at room temperature for 30 sec, rinsed in deionized (D. I.) water and blown dry with N<sub>2</sub> immediately prior to making the next measurement of ( $\Delta$ ,  $\psi$ ). Successive etching in concentrated HF for 30 sec and the measurement of ( $\Delta$ ,  $\psi$ ) were repeated until bare Si surface was reached in the sputtered silicon nitride sample. In the sample in which the silicon nitride film was deposited by chemical vapor deposition in a glow discharge, the etching of the film was stopped around 1700Å due to excessive pinholes appearing in the film.

Figure 1 shows theoretical curves for the variation of  $\Delta$  and  $\psi$  with the film thickness  $d$  as given by the exact equation of ellipsometry (4, 5)

$$\tan \psi e^{i\Delta} = \frac{r_{1p} + r_{2p} e^{-2i\delta}}{1 + r_{1p} r_{2p} e^{-2i\delta}} \cdot \frac{1 + r_{1s} r_{2s} e^{-2i\delta}}{r_{1s} + r_{2s} e^{-2i\delta}} \quad [1]$$

where  $r_1$  and  $r_2$  are the Fresnel reflection coefficients at the ambient-film and the film-substrate interfaces, respectively. Subscripts p and s denote the parallel and the perpendicular (to the plane of incidence) components. Film thickness  $d$  is related to the phase difference  $\delta$  as

$$d = C_{n_1} \delta \quad [2]$$

where

$$C_{n_1} = (\lambda/2\pi) (n_1^2 - n_0^2 \sin^2 \phi_0)^{-1/2} \quad [3]$$

In the derivation of Eq. [1], a discrete interface is assumed between the film of refractive index  $n_1$  and the substrate having the optical constants  $n_2 - ik_2$ . An IBM 360 computer was used to solve Eq. [1] and relate  $\Delta$  and  $\psi$  with ( $n_2 - ik_2$ ),  $n_1$  and  $\delta$ . Figure 2 shows  $C_{n_1}$  vs.  $n_1$  from which the film thicknesses  $d$  can be calculated knowing  $\delta$ . In Fig. 1, theoretical curves are plotted for films having refractive indices  $n_1 = 1.9, 2.0, 2.1, 2.2,$  and  $2.3$  on silicon substrate having  $n_2 = 4.051$  and  $k_2 = 0.027$ . The point 0 in Fig. 1 corresponds to ( $\Delta$ ,  $\psi$ ) for a film-free silicon substrate where  $\Delta = 179.05^\circ$  and  $\psi = 11.77^\circ$ . As the film thickness increases,

the ( $\Delta$ ,  $\psi$ ) point moves counterclockwise on the curve. When  $\delta = \pi$ , the point coincides again with 0 corresponding to  $\delta = 0$ . This is defined as the completion of the zeroth order of film thickness. When the film thickness increases further, the curve is retraced counterclockwise provided, of course,  $n_1$  remains constant. Thus for each "order"  $m$  of thickness, the point 0 is crossed  $m$  times. For a film in the  $m^{\text{th}}$  order, if the measured ( $\Delta$ ,  $\psi$ ) gives  $\delta = x$ , as read from the curve in Fig. 1, then the total film thickness is given by

$$d = (m\pi + x) C_{n_1} \quad [4]$$

Fig. 1. Solid curves show the variation of  $\Delta$  and  $\psi$  with the film thickness  $d$  as given by the exact equation of ellipsometry. Film thickness  $d$  is related to the phase difference  $\delta$  by Eq. [2]. Dashed lines are for constant  $\delta$  indicating its locus when the refractive index of the film  $n_1$  varies. Optical constants of the Si substrate used in the calculation were  $n_2 = 4.051$  and  $k_2 = 0.027$ ; wavelength of light  $\lambda$  was 5461Å, and the angle of incidence  $\phi_0$  was 70°. The experimentally measured ( $\Delta$ ,  $\psi$ ) points as the sputtered silicon nitride film was etched down are plotted in this figure. A heavier dashed line is drawn through the experimental points corresponding approximately to an average value of  $n_1 = 2.06$ .

<sup>1</sup> Gaertner Ellipsometer, Model No. L 119.  
\* Electrochemical Society Active Member.

Fig. 2. Plot of the constant  $C_{n_1}$  vs. refractive index of the film  $n_1$ , as given by Eq. [3].

In Fig. 1, the  $(\Delta, \psi)$  points are plotted, which were measured on the sputtered silicon nitride sample after each successive 30 sec etch in concentrated HF at room temperature. The initial thickness of the film was in the third order, and it was about 5250Å. The data points fit a  $(\Delta, \psi)$  curve for  $n_1 = 2.06$  approximately. Accurate determination of  $n_1$  throughout the film as it is etched down is not possible for the thickness ranges for which  $\delta$  lies approximately between 0 and 20 and between 160 and 180 because the  $(\Delta, \psi)$  curves merge at 0 for various values of  $n_1$ . For each point, the values of  $n_1$  and  $\delta$  were read off from Fig. 1. Using Fig. 2,  $C_{n_1}$  were determined for different values of  $n_1$  and, using Eq. [2], the film thicknesses were calculated.

From these data, the average etch rate for the sputtered silicon nitride film in concentrated HF at room temperature was calculated to be  $291 \pm 16$  Å/min. This is about 50 times the etch rate reported recently by Bean *et al.* (6) who had used Bell No. 2 etch (300 cc  $H_2O + 200g NH_4F + 45$  cc HF).

The average value of the refractive index  $n_1$  of the sputtered silicon nitride film from the above data was found to be  $2.06 \pm 0.03$ . This agrees quite well with the value 2.05 reported by Bean *et al.* (6) It can be concluded from Fig. 1 that the interface between the silicon substrate and the sputtered silicon nitride film is discrete, as expected, because the experimental data points lie on a curve for  $n_1 = 2.06$  as the  $(\Delta, \psi)$  values change when the film is etched down through three orders of film thickness. The refractive index of the sputtered silicon nitride film was also measured with oil immersion technique (7) which gave  $2.1 > n_1 > 2.0$ . This checks fairly well with the average value  $n_1 = 2.06$  determined by the ellipsometric measurements.

Measurements of  $(\Delta, \psi)$  on silicon nitride films deposited by chemical vapor deposition ( $NH_3 + SiH_4$ ) in a glow discharge were also made after successive etching for 30 sec in concentrated HF similar to the procedure described above for the sputtered silicon nitride. Figure 3 shows the data plotted on the theoretical  $(\Delta, \psi)$  curve as in Fig. 1. The film was initially 4000Å thick, and its etching was stopped at a thickness of about 1700Å; no further measurements of  $(\Delta, \psi)$  were made. This was due to the appearance of excessive pinholes in this silicon nitride film. The film thickness  $d$  and the refractive index  $n_1$  for each of the data points were calculated as described above for the sputtered silicon nitride case. The etch rate in concentrated HF for the silicon nitride film deposited by chemical vapor deposition was calculated to be 340 Å/min, however, after a removal of about 1000Å from the top layer, the etch rate increased to 489 Å/min. This increase in the etch rate could be due to the

Fig. 3. This plot is similar to that shown in Fig. 1 except that the experimental  $(\Delta, \psi)$  points are for the silicon nitride film deposited by chemical vapor deposition in a glow discharge. Average refractive index for this film is found to be  $n_1 = 1.98$ .

pinholes in the film. The refractive index of this film remained fairly constant, even after removal of 1000Å from the top layer, and its average value was found to be  $1.98 \pm 0.03$ . Except for a few cases, the data points in Fig. 3 lie fairly well on a curve for  $n_1 = 1.98$  as the  $(\Delta, \psi)$  values change when the film is etched through two orders of film thickness. It can be concluded that the interface between this silicon nitride film and the silicon substrate is also discrete.

#### Acknowledgments

The authors wish to thank G. A. Shirn, A. Janus, and W. Patterson for depositing the silicon nitride films used in this investigation. Helpful discussions with K. M. Busen and M. Ghezzi are appreciated.

Manuscript received July 12, 1967; revised manuscript received Nov. 3, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Zirconium Phosphate Membranes for Intermediate Temperature Fuel Cells

C. Berger\*<sup>1</sup> and M. P. Strier\*

Astropower Laboratory, Advance Systems and Technology, Missile and Space Systems Division,  
Douglas Aircraft Company, Inc., Newport Beach, California

## ABSTRACT

A new type of solid inorganic membrane for intermediate temperature hydrogen-oxygen fuel cell application is described. This is based on zirconium phosphate sintered with the zeolite material "Zeolon-H." The zeolite material contributes to maintenance of water balance in the membrane which is required especially at temperatures above 25°C. Under fuel cell operational conditions, the resistivities of this membrane are at the 20-25 ohm-cm level. Stable fuel cell performance over the temperature range of 25°-151°C was obtained. A maximum performance of 0.790v (64% of the theoretical) at 30 ma/cm<sup>2</sup> was obtained at 130°C.

The principal advantages to be gained from the use of solid membrane electrolytes in fuel cells are compactness, simplicity of design, and minimization of zero gravity limitations. The impetus behind the selection of inorganic membranes in this application is that they are insensitive to oxidation both from a chemical as well as from an electrochemical standpoint, and their dimensional, thermal, and radiation stabilities are high.

Since 1962 this laboratory has been conducting a systematic investigation on cationic inorganic ion exchange membrane materials for fuel cell application. Exploratory work with zeolites demonstrated that they were lacking in both ionic conductivity and mechanical strength (1). Utilization of metallic oxide-phosphoric acid systems, particularly zirconium dioxide, has yielded unique membranes manifesting transverse strength levels of 5000-9000 psi (2a) and resistivities at the 20-25 ohm-cm level (2b).

The original pioneering effort on the use of zirconium phosphate as cation exchange material was performed by Kraus (3), Amphlett (4), and Larsen and Vissers (5). Hamlen (6) studied the conductivity of zirconium phosphate under various conditions of hydration and found that at the highest level of hydration, the mechanism of conductance corresponds to that of an aqueous phase. Hamlen (6) and Dravnieks and Bregman in 1961 and 1962 (7,8) were the first to employ zirconium phosphate membranes in hydrogen-oxygen fuel cells; this was done at ambient temperature. The performances were marginal, and the membranes were weak. More recently, Hamlen and Szymalak (9) have used a specially prepared zirconium phosphate-Teflon matrix with hydrogen and propane fuel cell studies with oxygen over the temperature range 125°-175°C.

Significantly, it has been found in our laboratory that the use of the zeolite material Zeolon-H<sup>2</sup> in these membranes has permitted the maintenance of the water balance at elevated temperatures with resulting stable fuel cell performance. It appears that the water retention action of the zeolite water balancing agent minimizes dehydration at elevated temperatures.

As described by Amphlett (10), zirconium phosphate is ordinarily prepared by two techniques. A salt, such as zirconyl nitrate, is precipitated from acidic solution either by the addition of phosphoric acid or by a soluble phosphate. In the second method, zirconium dioxide is treated directly with phosphoric acid. The nature of the products obtained as far as crystallinity, hydrolytic stability, and ion exchange character is critically dependent on the mode of preparation,

as demonstrated by Amphlett (10) and Clearfield and Stynes (11).

The form of zirconium phosphate obtained by our preparative procedure was found to be amorphous in nature by x-ray analysis (12). The x-ray analysis indicated that the Zeolon-H phase remained intact, indicating no deleterious action by phosphoric acid or the heat imposed during the preparation steps. As pointed out by Clearfield (11), the amorphous form of zirconium phosphate [Zr(HPO<sub>4</sub>)<sub>2</sub> · H<sub>2</sub>O] undergoes hydrolysis in the presence of water, liberating phosphoric acid; however, complete removal of phosphoric acid is not possible without refluxing in alkaline solutions (13). In the type of membranes used in the fuel cell studies described herein, the amount of phosphoric acid lost during fuel cell operation by the end of 300 hr appears to be that which is weakly bonded and in excess of that which reacts with zirconia to form ZrP<sub>2</sub>O<sub>7</sub>.

Herein are presented procedures for preparing inorganic membranes for fuel cell application, together with results of fuel cell behavior over the temperature range of 25°-151°C.

## Experimental

**Membrane preparation.**—The membrane was prepared as a 5.1 cm diameter disk in the following manner: 1000g of cp zirconia and 1000g of 85% phosphoric acid to which were added 200 cc of water were mixed for 20 min in a Waring Blender to a creamy consistency. The blend was poured into a Teflon beaker and dried at 160°C for 18 hr. Then, the dried material was granulated to -16 mesh and calcined at 200°C for 2 hr. A mixture comprised of 1000g of the calcined material, 1000g of 85% phosphoric acid, 600 cc of water, 1000g of Zeolon-H and 60g of Carbowax was ball-milled for 18 hr. Next, the mixture was granulated to -32 + 80 mesh. Then it was pressed at 6.9 x 10<sup>2</sup> kg/cm<sup>2</sup> pressure into a 5.1 cm diameter membrane having a thickness of about 0.7 mm. Finally, the membrane was sintered for 2 hr at 500°C. This comprised the type A membrane.

When it was desired to incorporate platinum black catalyst into the surface of the membrane in efforts to improve fuel cell performance, the following procedure was used. A 20% mixture of platinum black (-350 mesh) with the -32 + 80 mesh zirconium phosphate-Zeolon-H mixture described above was prepared. Then a composite three-layer compression molded membrane was prepared by filling the bottom of the die with this mixture to the extent of 10% by volume, followed by 80% of the original (type A) mixture and, finally, the 10% platinum-containing mixture. The three-layer composite was pressed at 6.9 x 10<sup>2</sup> kg/cm<sup>2</sup> pressure. After pressing, the composite was placed on

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: 13401 Kootenay Drive, Santa Ana, Calif. 92705

<sup>2</sup> Product of the Norton Company, Worcester, Massachusetts.

flat, smooth refractory plates and sintered in air for 2 hr at 500°C. On cooling to room temperature the composite membrane-catalyst wafer was impregnated by being dipped in 85% phosphoric acid for 5 min. The membrane was oven-dried at 120°C for ½ hr and finally sintered at 500°C for 2 hr. This treatment was repeated twice. The platinum impregnated membrane constitutes the type B membrane. Herein, the total weight of platinum black per membrane was of the order of 0.07g, consisting of 2% of the total membrane weight.

**Apparatus and procedure.**—The fuel cell shown in Fig. 1 was used. It was comprised of two covers or outer plates fabricated from "Multimet" metal. An "O" ring was used to maintain electrical insulation between the plates, while an epoxy resin was applied around the pressure annulus to prevent leaks. The electrodes were supported by backup plates as shown in Fig. 2. The design accommodates a 5.1-cm diameter membrane. Free volume space on both the hydrogen and oxygen sides was 9.8 cm<sup>3</sup>. American Cyanamid Type AA-1 gas diffusion electrodes were used throughout this study.

The procedure for assembling the fuel cell fixture was as follows. First, the membrane-catalyst-electrode backup plate wafer was prepared. Before the gas diffusion electrode was placed over the membrane, 0.3g of platinum black powder ( $\leq 325$  mesh) was sprinkled over the membrane surface. Constant pressure was applied within the backup plate, electrode, and membrane arrangement by the use of "C" clamps tightened by means of a torque wrench kept at a constant setting. Then a gas-tight seal was effected between both backup plates by the application of a heat-cured epoxy resin over the periphery of the membrane. The assembled wafer was inserted between the chamber covers and held in place by means of six plastic screws.

Fig. 1. Astropower fuel cell

Fig. 2. Inorganic ion exchange membrane backup plate sandwich

The fuel cell runs were performed at a flow rate of hydrogen of 1-2 cc/min and a flow rate of oxygen of 3-4 cc/min, which afforded optimum performance under these experimental parameters. As all determinations were performed under open-ended conditions, the pressures of the reactant gases could be considered as being at atmospheric. The product water was collected. Calibrated electrical instruments were used for the monitoring of current and voltage characteristics for each test. Most tests were performed with membranes having a thickness in the range of 0.5-1.0 mm.

A-C resistance measurements were performed during the course of fuel cell tests to determine the contribution of ohmic resistance of the membrane to the over-all resistance obtained from the slope of the polarization curve. An a-c signal of 10<sup>4</sup> Hz was superimposed as polarization data were taken so that the d-c polarization and a-c resistance at different external loads could be obtained simultaneously. The a-c resistance was calculated from a-c potentials superimposed across the cell. Potential readings were obtained with a high impedance vacuum tube voltmeter (HP-400 H) having an estimated accuracy to within  $\pm 2\%$ .

### Results and Discussion

**Fuel cell studies.**—Fuel cell test results obtained over the temperature range of 25°-151°C inclusive are summarized in Tables I through III inclusive. In Table I, the results at 25°C indicate that stable continuous operation for 340 hr is possible. Test 7 was performed at a current density of 30 ma/cm<sup>2</sup> during which the voltage output was in the range of 0.450-0.494v. Results of tests performed at 65°C are given in Table II. At

the operational current density of 30 ma/cm<sup>2</sup>, the voltage output is as high as 0.774v (63% of the theoretical value) for the type B membrane. Although both tests 6 and 42 were performed with the same type of membrane, the somewhat higher performance achieved for the former could be attributed to the use of a more porous backup plate offering less resistance for the passage of gases to the gas diffusion electrodes. It is to be noted that there is significantly improved performance at 65° over that at 25°C.

Membrane resistivities determined by the superimposed a-c resistance method are included for tests 81, 83, and 85 in Table III. The highest performance obtained during this study was in test 85. From polarization data for this test, the output voltage at 50 ma/cm<sup>2</sup> was 0.73v (59% efficiency). It appears that fuel cell performance does not change very much over the temperature range of 65°-151°C. From Table III, it is evident that membrane resistivity is unaffected by increasing temperature from 25° to 130°C. A similar situation exists for the zirconium phosphate-Teflon membranes studied by Hamlin and Szymalak (9) over the temperature range of 125°-175°C. Somewhat lower resistivities were attained in the present study. An attempt was made to improve fuel cell performance by the use of moist hydrogen gas. The gas was maintained at relative humidities ranging from 11 to 55% over the temperature range of 98°-126°C. It was found that membrane resistivity and fuel cell performance did not change appreciably during these tests. It appears that the use of zeolite material in the membrane structure is conducive to maintenance of "water balance," as excessive loss of water at elevated temperature would have caused an increase in resistivity. Since in this investigation membrane resistivity has been found to be independent of temperature, it must be concluded that the diminished fuel cell performance observed consistently at ambient temperature is due to inadequate removal of product water from the gas diffusion electrode.

**Hydrolysis studies.**—According to Clearfield (11) there would be justification for considering that the pyrophosphate structure, i.e., ZrP<sub>2</sub>O<sub>7</sub> is obtained by the preparative method described above. On that basis, as well as on the basis of the relative amounts of starting materials employed in the preparation of type A membrane, the following is the assumed composition of the membrane in the dry state: ZrP<sub>2</sub>O<sub>7</sub> 48.8%; H<sub>3</sub>PO<sub>4</sub> 14.5%; Zeolon-H 36.7%. This means that 14.5% of the total dry membrane weight is unreacted phosphoric acid which could be assumed to be weakly bonded in the matrix.

In order to establish the hydrolytic stability of the membrane, the following procedure was used. Type A membrane was exhaustively treated with 0.1N sodium hydroxide solution at 74°C. Treatment was continued until there was no further liberation of phosphoric acid as manifested by potentiometric titration of residual sodium hydroxide with 0.1N hydrochloric acid. This determination indicated an amount of H<sub>3</sub>PO<sub>4</sub> equivalent to 21.9% of the total original dry membrane weight. Assuming that complete hydrolysis of the

ZrP<sub>2</sub>O<sub>7</sub> would have taken place, then an amount of H<sub>3</sub>PO<sub>4</sub> equivalent to 50.6% of the original dry membrane weight would be obtained. Therefore, based on the assumed starting membrane composition indicated above, the exhaustive caustic treatment used herein causes liberation of the unreacted H<sub>3</sub>PO<sub>4</sub> and partial hydrolysis of the ZrP<sub>2</sub>O<sub>7</sub> constituent. Evidence for hydrolyzability of the latter constituent has been presented by Clearfield (11).

The hydrolytic stability of type A and type B membranes under fuel cell operational conditions was determined by analyzing dry membranes which had previously been employed in fuel cell tests by the hot caustic treatment described above. This would yield the total amount of free H<sub>3</sub>PO<sub>4</sub> remaining in the membrane, as well as the H<sub>3</sub>PO<sub>4</sub> derived from the hydrolysis of the ZrP<sub>2</sub>O<sub>7</sub> component remaining in the membrane at the conclusion of the fuel cell test. The results obtained are summarized in Table IV wherein this amount (column 6) is expressed in terms of the percentage of phosphoric acid recovered from the membrane based on the weight of the dry membrane remaining after the fuel cell run. In column 6, the differences in values from that of 21.9% as indicated above for the starting type A membrane show that there is no direct correlation between extent of hydrolysis during fuel cell operation and decrease in performance. Enough acidic component remains in the membrane matrix after 300 hr to permit continuation of significant fuel cell performance.

The results of this investigation show that there must be a sufficiently high concentration of phosphate groups present which are at most only partially leachable as well as an adequate degree of hydration through incorporated zeolite to achieve worthwhile fuel cell performance for as long as 300 hr at temperatures above 25°C.

### Summary and Conclusions

By the reaction of zirconia, phosphoric acid, and the zeolite material, Zeolon-H, under sintering conditions, it was possible to obtain a fuel cell membrane manifesting the following characteristics. These membranes have resistivities of 20-25 ohm-cm under fuel cell operational conditions over the temperature range of 25°-130°C. An optimum performance level of 0.79v at 30 ma/cm<sup>2</sup> was obtained at 130°C. At temperatures below 65°C, the significantly lower performances obtained must be due to inadequate water removal from the cathode, as membrane resistivity is essentially unaffected. The presence of incorporated zeolite material is conducive to maintaining an adequate water balance in the membrane permitting continuous stable operation above 65°C for at least 300 hr.

A gradual loss of that amount of the phosphoric acid which is weakly bonded occurs during the first 300 hr of operation. This does not appear to have a critical controlling effect on fuel cell operation. Fuel cell operation

## The Use of Electrochemical Sectioning in the Study of Diffusion in Tungsten

R. E. Pawel and T. S. Lundy

#### ABSTRACT

A microsectioning technique based on metal anodization and subsequent removal of the anodic oxide film was developed and tested by using it to determine the concentration profiles of  $^{95}\text{Nb}$  in tungsten single crystals after diffusion at 1800°C. The anodization characteristics of tungsten pertinent to quantitative serial sectioning were studied and several techniques for increasing the efficiency of isotope removal during chemical dissolution of the anodic film were tried. The resulting data were highly self-consistent and demonstrate the value of the method in investigating diffusion behavior in tungsten, particularly at low temperatures.

The need for experimental techniques which permit a sensitive and critical examination of extremely steep concentration gradients in solids has increased due to growing interest in the characterization of several aspects of low-temperature diffusion phenomena. When dealing with diffusion at low temperatures, an experiment generally involves not only small diffusion distances, but concentration gradients which may be influenced by the presence of short-circuit paths of various kinds and efficiencies. In addition, diffusion from a free surface has sometimes been observed to result in unusual concentration profiles in the near-surface regions. Since the extraction of the conventional diffusion parameters from experimental data requires fitting the data to a simple, sometimes over-idealized mathematical model, it becomes particularly important that the experimental technique be sufficiently sophisticated to be consistent with the mathematical description. As has been indicated previously (1-3), this problem is magnified for the study of diffusion at low temperatures, and a sectioning method having high resolution is one essential requirement.

The development of microsectioning techniques for the study of concentration gradients has progressed utilizing physical, chemical, and electrochemical means. The electrochemical methods have demonstrated a very high resolution in the few cases where they have been used. Davies and his associates (4, 5) used anodization and chemical stripping techniques to obtain range measurements for heavy ions in aluminum and tungsten. Mortlock (6) recently applied a similar technique, suggested by Whitton and Davies (7), to a tracer diffusion study of near-surface effects in gold single crystals. The present authors have used mechanical stripping of anodic films to study diffusion in tantalum and niobium (1, 8-10). In these investigations, the small section thicknesses of the order of 100Å permitted a quantitative description of the concentration gradients to be made in the region near the surface of the specimen. Diffusion coefficients as small as  $10^{-19}$  cm<sup>2</sup>/sec were determined.

Electrochemically formed films on the "valve" metals generally are of uniform thickness and follow the specimen contours almost exactly. This characteris-

tic offers a potential advantage for diffusion studies which is not always shared by chemical and physical methods of metal removal. The tendency for etching or nonuniform metal removal during chemical dissolution of most metals limits the applicability of this procedure for microsectioning. Similarly, mechanical grinding produces a contour which is generally different on a fine scale from that of the original surface. The size and machining behavior of the abrasive particles must also be considered in determining the limiting sensitivity of this method of sectioning. Particularly in the study of diffusion, the preservation of surface contours during sectioning may be of importance. Although there can be exceptions, the general result of a low resolving power caused by nonuniform metal removal is to flatten the concentration gradient resulting in higher apparent diffusion coefficients.

From the impressive results of range measurements described by McCargo, Davies, and Brown (5) and by Uhler, Domeij, and Borg (11), it appeared that the anodic film-sectioning technique might be applied to the study of diffusion in tungsten much in the same manner as it was applied to tantalum and niobium. In principle, diffusion behavior could then be studied at much lower temperatures than previously possible and short-circuit phenomena (more pronounced at lower temperatures) could be accurately characterized. This paper describes the technique developed for such a study and presents some preliminary measurements on the diffusion of  $^{95}\text{Nb}$  in tungsten in support of its applicability.

### Results and Discussion

**Calibration.**—While tungsten anodizes in a number of electrolytes to form uniform anodic oxide films exhibiting sharp interference colors, it is clear that the characteristics of the process important to a sectioning technique are influenced dramatically by the particular electrolyte and other experimental variables. Pitman and Hamby (12) described many of these characteristics for dilute sulfuric acid electrolytes; McCargo, Davies, and Brown (5) used an electrolyte consisting of 0.4M  $\text{KNO}_3$  and 0.04M  $\text{HNO}_3$ . In the latter work, a film-thickness calibration was obtained by a radiochemical technique and checked by weight-loss measurements after dissolving the films from the anodized specimens.

The experimental procedure and film-thickness calibration utilized in this investigation were established after a series of "screening" tests were performed in various electrolytes. Anodizing characteristics were observed and weight-gain measurements (after anodization) and weight-loss measurements (after film dissolution) were made on tungsten specimens each consisting of electropolished sheets having total surface areas of about 500  $\text{cm}^2$ . By making such a calibration on the basis of both weight-gain and weight-loss values, it was possible to establish the efficiency<sup>1</sup> of film formation for each electrolyte and anodization procedure. For example, while the thickness of anodic oxide formed on tungsten in 0.5%  $\text{Na}_2\text{SO}_4$  to a given voltage was equivalent to that formed in other electrolytes, the efficiency of film formation was much less and more highly dependent on the current density during anodization. At the lowest efficiencies, about 55% at low currents, sufficient tungsten was actually lost to the electrolyte so as to result in a weight loss, rather than a weight gain, during anodization of the specimen. Several dilute acids and solutions of sulfate and nitrate salts were tested at room temperature as possible anodizing electrolytes; solutions exhibiting poor efficiency were characterized by comparatively high decay or leakage currents after full voltage had been applied across the cell.

<sup>1</sup> The efficiency of film formation is defined here as the ratio of the amount of tungsten in the anodic oxide film to the amount actually lost by the specimen during anodization. This value is independent of the "current efficiency" values sometimes used to characterize anodic processes.

Fig. 1. Total amount of tungsten lost by metal specimen during anodization in  $\text{KNO}_3$ - $\text{HNO}_3$  electrolyte.  $\circ$  specimen held at 50v;  $\bullet$  specimen held at 30v.

The electrolyte combination recommended by McCargo, Davies, and Brown (5) was confirmed as a "high-efficiency" electrolyte which was insensitive to minor variations in composition, and this solution (40 g/liter of  $\text{KNO}_3$  plus 2 cc/l of concentrated  $\text{HNO}_3$ ) was used in all work reported in this paper. Efficiencies of film formation of about 99% were observed for this electrolyte when currents during the initial period of anodization were varied from about 0.2-5  $\text{ma}/\text{cm}^2$ . In comparison, the formation efficiency for an anodic film formed in 0.5%  $\text{Na}_2\text{SO}_4$  at 0.5  $\text{ma}/\text{cm}^2$  to 50v was about 88%.

When tungsten specimens were anodized to a given voltage, the films continued to grow after full voltage had been applied across the cell as a function of time as illustrated in Fig. 1. The increase in film thickness, in this case measured as the decrease in weight of the specimen after forming and dissolving the anodic film, is shown to vary linearly with the logarithm of the time. In order to utilize a calibration based on a constant-voltage anodization, a "standard" time of 2 min was arbitrarily chosen so as to limit errors arising from slight differences in the anodization time and procedure. The specimen for calibration was weighed, anodized in the prescribed manner at a given voltage and weighed again. The anodic film was then dissolved in dilute  $\text{NaOH}$  and the specimen reweighed. All weight measurements were made after the specimen had been carefully washed and dried. These measurements appear in columns 2 and 5 of Table I along with the calculated quantities necessary to compare the total amount of tungsten lost by the specimen with the amount that appeared in the anodic oxide film.<sup>2</sup> As these values are nearly identical, all the tungsten is satisfactorily accounted for and thickness-voltage calibrations may be constructed and converted to any basis by simple mass balances.

Figure 2 shows the amount of tungsten removed from the surface of the metal by anodizing to a given voltage. The time dependence taken from Fig. 1 is included in the figure to indicate the extent of the influence of anodization time on such a calibration curve. The corresponding oxide thickness-voltage calibration is presented in Fig. 3. The thickness of the tungsten layer removed may be obtained by multiplying the ordinate values of Fig. 3 by the factor 0.2787A

<sup>2</sup> The anodic oxide formed on tungsten under these conditions was assumed to be  $\text{WO}_3$  with a density of 6.8  $\text{g}/\text{cm}^3$  (12); this value is slightly less than the accepted value for bulk crystalline  $\text{WO}_3$  (7.16  $\text{g}/\text{cm}^3$ ) which is probably due chiefly to structural differences.

of tungsten per angstrom of oxide. The data could be adequately described by two straight lines. Up to 12v, a least-squares analysis yielded

$$T_{\text{WO}_3, \text{Å}} = 23.28 + 20.972v$$

or

$$T_{\text{W, Å}} = 6.49 + 5.845v$$

where  $T_{\text{WO}_3, \text{Å}}$  is the thickness in angstroms of anodic oxide formed,  $T_{\text{W, Å}}$  is the thickness of the tungsten layer consumed by anodizing, and  $v$  is the voltage. Similarly, from 12-70v

$$T_{\text{WO}_3, \text{Å}} = 51.93 + 18.933v$$

or

$$T_{\text{W, Å}} = 14.47 + 5.277v$$

These values are in quite satisfactory agreement with those reported by McCargo *et al.* (5).

While a mechanical stripping technique for anodic films on tungsten [such as that which was used for films on tantalum and niobium (8)] has not yet been found, quantitative separations were achieved simply by dipping the anodized specimen into a dilute (3 g/l)

Fig. 2. Total weight of tungsten lost during constant voltage anodization for 2.0 min in KNO<sub>3</sub>-HNO<sub>3</sub>. Superimposed time scale indicates expected shift for other anodization times.

Fig. 3. Oxide thickness-voltage calibration for tungsten anodized for 2 min at full voltage in KNO<sub>3</sub>-HNO<sub>3</sub> solution. The thickness of the tungsten layer removed by forming this oxide is 0.2787 Å metal per Å oxide (see text).

sodium hydroxide solution for about 1 min. While negligible amounts of the tungsten metal not associated with the oxide were dissolved along with the film, it should be mentioned that the actual dissolution rates of tungsten metal in such environments were observed to be strongly dependent upon the oxygen content of the solution. In a typical solution of NaOH in distilled water at room temperature, tungsten dissolution rates equivalent to about 3 Å/hr were observed after the initial anodic or air-formed film was dissolved. However, if this solution were aerated by bubbling oxygen gas through it for a few minutes, the dissolution rates were observed to increase by more than an order of magnitude. Maximum rates were observed when the bubbler was left in operation while the specimen was immersed, but this additional increase may have been due to stirring or other mechanical effects. The thickness of the air-formed film on tungsten (actually the film formed during our washing and drying procedure, which included a period in a drying oven at 50°C) was determined from these experiments to be approximately 12 Å.

*Diffusion specimens.*—Specimens for the diffusion measurements were prepared as 0.25-in.-diameter cylinders from single-crystal rods of tungsten obtained from Materials Research Corporation. One face of each specimen was prepared metallographically and electropolished in a 130 g/l sodium phosphate solution. The resulting mirrorlike surfaces appeared smooth in the microscope and back-reflection x-ray patterns showed that most surface disturbances were removed during the electropolishing. The axes of the specimens were about 10° from <100>. A thin uniform layer of <sup>95</sup>Nb was deposited on the face by vacuum evaporation of a small quantity of isotope-containing oxalate solution from a hot tungsten filament. The specimens were diffusion-annealed in a tantalum resistance furnace under about 1 atm of high-purity argon. After the annealing treatment, a length of 0.020-in.-Ta wire was securely spot-welded to the back part of the specimen to facilitate handling and to serve as an inert electrical contact during anodization.

The first exploratory experiments on sectioning the diffusion specimens indicated that the minute amount of niobium tracer and accompanying impurities in the diffusion zone had no measureable effect on the characteristics of anodization or subsequent dissolution of the film. In addition, consistent with the high efficiency of film formation, a negligible amount of tracer was observed to be lost to the electrolyte during anodizing. Thus, it appeared that the anodizing technique and calibration presented earlier is applicable to the precision sectioning of tungsten into which small amounts of tracer elements had been diffused.

Shell vials (small test tubes) 15 mm in diameter were used to hold the liquid solution containing the "stripped" metal section. The isotope concentration in each section was then determined in a well-type counter using a NaI(Tl) crystal in conjunction with a single-channel analyzer. Initially, the anodic films were stripped by dipping the specimen into the test tube partially filled with dilute sodium hydroxide. After 1 min, the specimen was raised above the liquid level in the tube and washed with additional solution from a squeeze bottle until the tube was filled to the desired final level. While this procedure seemed to remove the anodic film completely, as was our experience with the films formed on plain tungsten, the erratic behavior of the resulting tracer activity data obtained in this way indicated that the  $^{95}\text{Nb}$  isotope tended to remain on the metal surface as the host oxide dissolved. It appeared that this "left-behind" isotope neither interfered with the anodizing of the tungsten nor was removed into the anodizing electrolyte during the subsequent formation of the film. However, the sporadic removal of portions of this residue into the stripping solution was a serious experimental problem which had to be dealt with in order to utilize the technique efficiently. Until the exact nature of the surface holdup of the tracer is known, this type of experimental difficulty will probably be faced and solved on an individual basis for each isotope.

In order to bring as much as possible of the  $^{95}\text{Nb}$  associated with the anodic oxide layer into the sodium hydroxide stripping solution, we tried several schemes including cathodic stirring,<sup>3</sup> ultrasonic vibration, and gentle swabbing with wet cotton. Each of these procedures by itself improved the consistency of the data; however, it was found that a combination of the last two methods produced results that were most satisfactory. Thus, virtually complete stripping of the  $^{95}\text{Nb}$ -containing tungsten oxide films from the specimens was accomplished in the following manner: a test-tube containing a small wad of cotton packed into its bottom was partially filled with dilute NaOH to which a small amount of detergent had been added. The tube was placed in the tank of an ultrasonic cleaner and the specimen immersed. During the ultrasonic treatment (about 1 min) the specimen was agitated and rubbed gently against the cotton in the bottom of the tube. The specimen was then washed with plain dilute NaOH to fill the tube to the desired level in the manner previously described. The tube was capped and stored for future counting while the anodizing-stripping sequence was repeated until the desired number of "sections" had been obtained.

**Diffusion data.**—As a means to establish the accuracy and the reliability of this method of determining diffusion profiles, the diffusivity of  $^{95}\text{Nb}$  in tungsten at 1800°C was measured several times with the annealing time and section thickness being the principal variables. The experimental procedures were chosen so that the "thin-film" solution to Fick's law for unidirectional diffusion would be applicable to the data. Thus,

$$A_{(x,t)} = \frac{M}{\sqrt{\pi Dt}} \exp\left(-\frac{x^2}{4Dt}\right)$$

where  $A_{(x,t)}$  = the activity (concentration of the isotope) at a distance  $x$  into the specimen at time  $t$ ,  $M$  = the total activity per unit area in the infinitesimally thin isotope layer at  $x = 0$ ,  $t = 0$ , and  $D$  = the diffusion coefficient. Therefore, barring excessive contributions from spurious or secondary mass transport mechanisms, the logarithm of the activity should be a linear function of the square of the penetration distance with the slope of the line being equal to  $-(4Dt)^{-1}$ . The conditions pertinent to this work under which this equation applies have been discussed previously.<sup>1</sup>

<sup>3</sup> Stirring and surface agitation which occurs by gas evolution when a negative potential is applied to the specimen (cathode) in the stripping solution.

Fig. 4. Activity profiles for diffusion of  $^{95}\text{Nb}$  into tungsten single crystals after diffusion for 0.5, 2, and 4 hr at 1800°C.

The concentration profiles of  $^{95}\text{Nb}$  in tungsten single crystals after diffusion for 1/2, 2, and 4 hr at 1800°C are shown in Fig. 4. The specimens were all sectioned by the anodizing-stripping technique utilizing section thicknesses of 100, 250, and 350 Å, respectively. In all three cases the profiles were virtually ideal straight lines from which the diffusion coefficients could be found unambiguously.  $D$  values of 9.65, 9.85, and  $8.95 \times 10^{-15} \text{ cm}^2/\text{sec}$  were determined from the three sets of data indicating a high degree of reproducibility as well as self-consistency for the data. In addition, since different section thicknesses were employed, the data serve as a check on the section thickness calibration and other aspects of the technique as a whole.

These diffusion coefficients agreed well with that determined by a single experiment in which a tungsten specimen was diffusion-annealed for 8 hr at 1800°C and sectioned by the more conventional grinding method. Although in the latter experiment, the penetration profile was obviously not as accurately determined, the agreement provided an additional bit of confidence in the anodizing-stripping procedures. While the data presented in Fig. 4 show substantially ideal penetration behavior, it should also be pointed out that significant deviations from the ideal were observed in these specimens for penetration depths greater than about  $4$  to  $6 \sqrt{Dt}$ . Similar characteristics in the case of low-temperature diffusion in tantalum (1, 9) and niobium (10) single crystals were associated with the contribution made by the relatively low density of various short-circuit diffusion paths to the final mass distribution. Again, this behavior emphasizes the need for high resolution techniques in order to study diffusion phenomena at low temperatures as well as the need to interpret such data with care, even in the case of single-crystal specimens.

### Summary and Conclusions

The applicability of anodic film sectioning techniques to the study of diffusion phenomena in tungsten has been demonstrated. Characteristics of the anodization of tungsten pertinent to sectioning were studied, and a quantitative calibration was determined for a high efficiency electrolyte. Methods for stripping the isotope-containing oxide film from the surface of the specimen were also examined. The propensity of the isotope to remain on the specimen surface during chemical dissolution of the anodic film was counteracted, at least in the case of the  $^{95}\text{Nb}$  isotope, by physical and ultrasonic agitation during the dissolution step.

Concentration profiles for  $^{95}\text{Nb}$  into tungsten single crystals after diffusion for various times at 1800°C were determined by this sectioning technique. The high degree of self-consistency and reproducibility of the data, even when utilizing sectioning thicknesses as small as 100 Å, was encouraging evidence that the method will prove invaluable to low-temperature diffusion investigations in tungsten.

### Acknowledgments

The authors wish to thank R. A. Padgett and J. J. Campbell for their contributions to the experimental work. The assistance of J. V. Cathcart during the course of the investigation is also appreciated. Research was sponsored by the USAEC under contract with the Union Carbide Corporation.

Manuscript received Aug. 31, 1967; revised manuscript received Oct. 25, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Some Aspects of the Parallel Differential Conductance Measured at an Electrode-Electrolyte Interface

H. S. Isaacs\*<sup>1</sup> and J. S. Li. Leach

*Department of Metallurgy, University of Nottingham, Nottingham, England*

### ABSTRACT

Impedance measurements using a square current wave on electrodes of tin, zinc, titanium, chromium, and a uranium alloy show that the measured conductance is related to the measured capacitance and to the Faradaic current through the electrode.

In a previous paper (1) the measured voltage response of oxide-covered metal electrodes to a square current wave was described in terms of an analogue circuit consisting of a resistor and a capacitor in parallel. Particular attention was given to interpreting the values of capacitance observed; in this paper, the other analogue component is considered in detail. The general discussion given here is applicable both to the oxide-covered and oxide-free metals. Although the differential capacitance of electrodes has previously been extensively considered, little attention has been given to the differential conductance. This attitude perhaps stems from investigations of the mercury-electrolyte interface, which is almost ideally polarizable (2), with no resistive component and with a capacitance independent of frequency. The analogue of the solid metal-electrolyte interface (4-6) on the other hand, includes both capacitive and resistive components which are frequency dependent. The frequency dependence has been attributed to the effects of surface roughness (2), but it may also be a characteristic of nonideally polarizable electrodes.

When a potential determining ion is present, the capacity is large and has a maximum at the reversible half wave potential (3, 7). The components of the analogue of the reaction occurring at a mercury-electrolyte interface can be derived from the diffusion characteristics of the potential determining ions and the rate constant for the reaction (3, 8, 9). The analogue of the impedance for the diffusion effects alone is known as the "Warburg impedance" and is frequency dependent. With solid metal-electrolyte systems (6) or when the potential determining ion is specifically adsorbed on mercury (10), the variation with frequency of the analogue is complicated by the

contribution of secondary processes to the Warburg impedance.

Although the effect of reversible adsorption has been considered by a number of authors (9, 11, 12), little attention has been given to the contribution of adsorption processes to the resistive component of the analogue, this often being taken to depend only on the current-voltage characteristics [i.e.,  $(dV/di)$  (9, 13)].

A number of investigators have noted that the impedance of an electrode falls markedly at negative potentials (4, 14, 15) or high current densities (4, 15). A square current wave makes it possible to measure small impedances, and attention is given here to the low impedance measured at negative potentials corresponding to high cathodic current densities.

### Experimental Method

The measuring apparatus has been described previously (1, 14). Basically, the method consists of comparing the voltage change at a point in the solution close to the surface of the test electrode with that of an analogue consisting of a capacitor and a resistor in parallel when a square current wave is applied to each. It is important to note that it is the response of the test electrode and not that of the test cell which is measured. This method has the advantage of eliminating from the measured impedance most of the series resistance associated with the electrolyte (which at times may cause a voltage change of the order of ten times that of the electrode) and all of the impedance of the counter electrode. The residue of the electrolyte resistance can be separated from the electrode impedance as the former gives rise to a voltage change in phase with the applied current wave while the voltage response of the latter shows a phase shift. The use of a square current wave permits the separation of these two components without studying the

\* Electrochemical Society Active Member.

<sup>1</sup> Present address: Metallurgy Department, Brookhaven National Laboratory, Upton, New York.

frequency response. Processes occurring at the electrode having effective time constants (relaxation times) less than one tenth of the period of the square pulse do not influence the results as they also behave effectively as series resistances. By varying the repeat frequency of the square wave these rapid processes may be examined separately.

Many of the difficulties encountered with more conventional measuring methods do not arise with this method, but difficulties occur when the parallel resistive component is very large or very small. In the former case, an almost linear voltage response results and in the latter case, difficulty arises both from the design of the apparatus being sensitive to calibration, and from the very small, highly nonlinear voltage response. Later developments, in particular the mathematical analysis of the voltage response (1) instead of comparison with an analogue have reduced many of the difficulties associated with small resistances.

The square wave of current with a repeat frequency of 400 Hz was passed through an auxiliary electrode and the test electrode to earth. This frequency was chosen as it gave a satisfactory compromise between the conflicting requirements of a large impedance (to get an adequate voltage response) and a parallel resistance which was not too large for the range of the bridge. The a-c voltage response of the test electrode to the square current wave was measured with reference to a silver wire electrode connected to a high impedance amplifier. The d-c potential of the test electrode was controlled with reference to a saturated calomel electrode, by a potentiostat, which included a choke (100 henry) and a variable high resistance ( $5 \times 10^4$  ohm). The choke prevented leakage of the a.c. through the potentiostat, while the resistance damped the response of the potentiostat and prevented the oscillation frequently encountered when using potentiostats with high impedance circuits. The d.c. supplied by the potentiostat was measured with a galvanometer; no d.c. was produced by the bridge. The mean potential of the electrode was measured by a high impedance valve voltmeter ( $10^{13}$  ohm) with reference to a saturated calomel electrode. All the results have been corrected to refer to a standard hydrogen electrode.

Each measurement was made at a fixed potential after which the potential was changed. The measurements required about 10 sec each and were made at varying intervals of potential as shown in the figures. In this way potentiodynamic conditions were approached, but due to the need to balance the bridge at each potential these conditions could not be fully attained.

The purity of the metals used was: tin 99.99%; zinc 99.9%; chromium 99%; titanium 99.99%; uranium 12%; molybdenum 99.95%. The final preparation of the electrodes, with the exception of titanium, was abrasion on 600 grade emery paper. This technique was used, in spite of its disadvantages, because it could be applied to all the metals studied. The reagents for etching and polishing the metals investigated all differ resulting in different undefined surface conditions. The titanium electrode was chemically polished in a solution of 90 cc hydrogen peroxide (10 vols.) and 10 cc 40% hydrofluoric acid.

The solutions were prepared from "Analar" reagents and distilled water and had the oxygen content reduced to a low level by bubbling oxygen-free nitrogen through them. The carbonate solution was 0.1M in sodium carbonate and sodium bicarbonate and had a pH of 9.7. The pH of the 0.5M sodium sulphate solution was increased by the addition of sodium hydroxide.

### Results and Discussion

The variation with potential of the parallel differential conductance of metal electrodes, measured at a square wave repeat frequency of 400 Hz shows a rela-

tion between the conductance and the capacitance usually observed at low current densities and a relation between the conductance and the applied current which is particularly apparent at high currents during the evolution of hydrogen.

Under conditions of concentration polarization the properties of the interface are described by the Warburg impedance which expressed as a parallel network is given by (3)

$$C_p = \frac{1}{2\eta W^{1/2}} \frac{1}{R_p} = \frac{W^{1/2}}{2\eta}$$

where  $\eta$  is a function of the concentration at the electrode-solution interface of the reacting ions in solution and its variation with potential and  $W$  is the angular frequency of the applied sine wave, which, during measurements, is considered constant as a function of potential. These equations depend only on concentration polarization, and it would be expected that the capacitance and conductance would vary with potential in a similar manner. When activation polarization becomes significant, the measured capacitance and conductance would no longer be simply related by the equations given above.

Maxima in both the capacitance and conductance are observed at  $-0.67v E_H$  as the potential of a tin electrode (Fig. 1 and 2) is decreased from a point where an anodic current of about  $2.5 \times 10^{-4}$  amp/cm<sup>2</sup> flows. The potential for zero current is  $-0.64v E_H$ . Similar maxima have been observed for zinc both on decreasing and on increasing the potential (Fig. 3) at potentials close to that for zero current (Fig. 4). The high values of capacitance were observed over a range of 0.15v, which corresponds to that expected on the

Fig. 4. Potential dependence of the current for zinc in a carbonate solution of pH 9.7.

basis of Faradaic admittance. Low values would be expected for the series resistance of the Warburg impedance for a reversible reaction over a range of about 3 units of  $RT/\alpha nF \ln 10$  (3). Taking  $\alpha$ , the distribution coefficient as  $1/2$ ,  $n$ , the number of electrons involved in the reaction as 2, and  $RT/F \ln 10$  as 0.06v at 298°K, the calculated potential range of low resistance is about 0.18v, in good agreement with the observed value.

The conditions for the measurements on tin differ in many respects from those used by Grahame, but the basic phenomenon of concentration polarization is the same, and approximately the same ranges of potential would therefore be expected. The soluble species taking part in the reversible reaction in the experiment on tin were produced during the flow of anodic current. With cathodic currents the concentration of the soluble tin ion falls due to diffusion into the bulk of the solution and deposition on the electrode; on increasing the potential the capacitance maximum and zero polarization current do not occur, as would be expected for a reversible reaction, at exactly the same potential. This difference of 0.03v could also arise from an additional cathodic reaction (*e.g.*, oxygen depolarization) which would shift the zero current to more a positive potential in which case the capacitance maximum would indicate the reversible potential for the reaction of the tin ions, under the conditions of measurement.

The similarity in the potential variation of the conductance and of the capacitance is always marked when the value of the capacitance is high ( $>100 \mu\text{F}/\text{cm}^2$ ) and shows a maximum as a function of potential. This can clearly be seen for tin, zinc and titanium in Fig. 1, 3, and 5. With titanium the high values of capacitance result from a valency change reaction occurring in the surface oxide (1). In this case the variations of the concentration of the reacting species occur in the solid oxide and the potential range over which the high capacitances and conductances are ob-

Fig. 5. Potential dependence of the current and the parallel capacitance and conductance at 400 Hz for titanium in a sulphate solution of pH 14.

served is greater than for reactants dissolved in the liquid phases.

The relation between the capacitance and the conductance is less marked when the value of the capacitance does not vary rapidly with potential, but usually can be discerned. On decreasing the potential below that for the capacitance maximum for tin (Fig. 1) the variation of the conductance and capacitance are similar down to a potential of  $-1.05\text{v } E_H$ . On increasing the potential again the conductance increases more rapidly than the capacitance, but both values decrease again after reaching maxima at a potential of  $-0.55\text{v } E_H$ . The cause of this increase in the conductance on increasing the potential for tin and to a lesser extent for zinc (Fig. 3) after hydrogen has been evolved is not known. The difference between the hysteresis<sup>2</sup> in the conductance and in the capacitance for zinc in the range  $-1.3$  to  $-1.1\text{v } E_H$  is unusual and is an exception to the general observation that the hysteresis for both conductance and capacitance are in the same direction at low current densities. However, the hysteresis is not marked and the differences might arise from instrumental causes. With chromium (Fig. 6) at potentials more positive than  $-1.1\text{v } E_H$  the measured conductance (curve A) and capacitance behave in a similar manner with potential.

The parallel differential conductance of all the metal electrodes tested shows a continuous increase at the more negative potentials, independent of the changes in capacitance. This marked increase in the conductance begins in most cases at a potential close to that at which the current curve shows a change of slope associated with a change in the predominant electrolytic reaction occurring at the electrode-solution interface (16). At potentials more positive than that of the change in slope, the reaction is apparently diffusion controlled; at potentials more negative than the change, the current increases almost exponentially with decreasing potential indicating that an activation controlled reaction, probably hydrogen evolution, predominates.

The similarity between the behavior of the current and conductance as a function of potential change during the evolution of hydrogen may be seen on considering the hysteresis observed in the polarization of

<sup>2</sup> Hysteresis: The difference at a given potential in the values observed on decreasing and increasing the potential.

Fig. 6. Potential dependence of the parallel capacitance and conductance (curve A) at 400 Hz for chromium in a carbonate solution of pH 9.7. The d-c conductance, curve B, is derived from Fig. 7.

metal electrodes. During the evolution of hydrogen, it has been observed that the oxide-covered metals show a larger current on increasing the potential (14, 17, 18) whereas metals which may not be expected to have an oxide film usually show a larger current on decreasing the potential (17, 19).

The current observed on decreasing the potential of a tin electrode (Fig. 2) is larger than that on increasing the potential. This hysteresis is also observed in the conductance (Fig. 1) at potentials below  $-1.1v E_H$ , where the hydrogen evolution reaction occurs. With zinc, the hysteresis in the current (Fig. 4) is again the same as that of the conductance (Fig. 3). Both zinc and tin behave in respect of the hysteresis, as oxide-free metals. Chromium (Fig. 6 and 7), behaves as an oxide-covered metal, judging from the hysteresis in the current and conductance. The type of hysteresis found for a uranium-molybdenum alloy (14), (Fig. 8 and 9) for both current and conductance is also that characteristic of oxide-covered metals.

The results for the conductance of a tin electrode (Fig. 1) give a further indication of a relation between the differential conductance and current. At about  $-1.2v E_H$  on decreasing the potential, the conductance shows a maximum followed by a minimum at  $-1.3v E_H$  which are not reflected in the capacitances at these potentials. The current, however, (Fig. 2) shows a rapid increase at about  $-1.2v E_H$  followed by a concentration controlled reaction at about  $-1.3v E_H$ . If the conductance is given by

$$\frac{1}{R_{dc}} = \frac{1}{\theta} = \frac{di_{dc}}{dE_H} \quad [1]$$

these results would be explained.

Fig. 7. Potential dependence of the current for chromium in a carbonate solution of pH 9.7.

Fig. 8. Potential dependence of the parallel capacitance and conductance at 400 Hz for a uranium-12% molybdenum alloy in a carbonate solution of pH 9.7.

Fig. 9. Potential dependence of the current for a uranium-12% molybdenum alloy in a carbonate solution of pH 9.7.

Assuming that the hydrogen evolution reaction can be described by the Tafel equation

$$E_H = a + b \log i$$

the d-c conductance should be given by

$$\frac{1}{\theta} = \frac{di_{dc}}{dE_H} = \frac{i \cdot \ln 10}{b} \quad [2]$$

The above equation indicates that the d-c conductance is directly proportional to the current when the reaction occurs only under activation control. As the d-c conductance must represent a resistive component of the analogue impedance of the electrode-solution interface, this component should be measurable by a-c impedance measurements, unless relaxation processes occurring at the interface have analogue conductance components comparable to that arising from the direct current.

In Fig. 10 the values of the a-c conductance (Fig. 8) are plotted against the values of the direct polarization current (Fig. 9), both measured at given potentials for a uranium-molybdenum alloy electrode. A straight line is observed at the higher current densities which from the slope ( $b/\ln 10$ ) gives a Tafel slope ( $b$ ) of 0.157. This is close to the value of the Tafel slope calculated for the relevant portion of the curves shown in Fig. 9. The curvature in current plots (Fig. 9) as a function of potential may result from resistance polarization, but this would not be expected to influence the derived value of  $b$ , the Tafel slope, as the resistance affecting the potential measurements appears in the impedance measurements as a series resistance

Fig. 10. Variation of the current and conductance measured at 400 Hz for a uranium-12% molybdenum alloy. The values have been taken from Fig. 8 and 9.

and would not be measured by the techniques employed here.

This method appears attractive for obtaining the Tafel slope, but it is not generally applicable, as the conductance usually includes a component, related to the capacitance, which varies with potential. As the value of  $1/R_p$  usually decreases with decreasing frequency of the applied signal, this method may be applicable at low measuring frequencies.

Figure 6 shows a comparison of a-c (curve A) and d-c (curve B) conductances for chromium. The d-c conductance ( $1/\theta$ ) was determined from the current curve shown in Fig. 7. At low current densities, the d-c resistance is high and orders of magnitude greater than that observed by the a-c measurements, while at the higher current densities (at potentials more negative than  $-1.2v E_H$ ) the a-c and d-c values are similar. No explanation has been found to account for the measured d-c conductances being slightly larger than the measured a-c values, and it is therefore believed that the a-c measurements were slightly in error. The d-c conductance ( $1/\theta$ ) is low at low current densities (Fig. 6) and other processes are taking place at the electrode-solution interface which do not contribute to the direct polarization current. As the current increases,  $1/\theta$  increases, and at high current densities becomes large and contributes significantly to the measured a-c conductance. The contribution to the total conductance of that associated with the polarization current can also be seen for titanium (Fig. 5) at high current densities. At potentials above about  $-1.7v E_H$  the conductance is related to the capacitance while below  $-1.72v E_H$  the conductance increases markedly, independent of the capacitance. This increase is attributed to the contribution of the d-c conductance ( $1/\theta$ ) to the interfacial admittance.

The contribution of  $1/\theta$  is also apparent with applied anodic currents. At potentials more positive than  $-0.8v E_H$  for zinc (Fig. 4) the hysteresis in the anodic current is large. On decreasing the potential the anodic current is larger and a similar behavior is observed with the conductance (Fig. 3). On increasing the potential the conductance is more closely related to the capacity as the contribution associated with the direct polarization current is small due to the high value of  $b$  in the range  $-0.9v E_H$  to  $-0.7v E_H$ . On decreasing the potential the conductance varies in a manner similar to that of the current as the value of  $b$  in this range is now low and the d-c contribution predominates. These measurements indicate that, under anodic currents, the behavior of the measured conductance of an electrode is related to the capacitance at low current densities and/or high values of the Tafel slope while at higher current densities and/or small Tafel slopes, the conductance varies in a manner depending on the polarization current.

Fig. 11. An electrical analogue of the electrode-electrolyte interface.

The impedance of an electrode-electrolyte interface can be represented by the analogue shown in Fig. 11. Here  $C$  represents the capacitance of the electrical double layer which may be assumed to be independent of frequency (3);  $C_1$  represents a capacitance resulting from one or more reversible processes or effective relaxation processes (e.g., adsorption, reversible redox reaction, or a valency change in an oxide), and  $R_1$  a resistance inversely related to the capacitance  $C_1$ ; the resistance  $\theta$  is given by Eq. [1] and results from the polarization current-potential characteristics. This approach has been found to be applicable to all of a wide range of metals measured at a square wave repeat frequency of 400 Hz (20).

The derivation of the frequency dependence of the effective relaxation processes (3) indicates that the capacitance ( $C_1$ ) increases, while the conductance ( $1/R_1$ ) decreases with decreasing frequency. Hence with decreasing frequencies the currents at which  $\theta$  contributes significantly to the impedance decrease, and at low frequencies of measurement it should be possible to obtain information about the polarization characteristics with only very small changes in the electrode potential.

### Summary

The parallel differential conductance measured at 400 Hz at the electrode-electrolyte interface contains two dominant components which are associated with the reactions taking place at the interface. Reversible processes result in a variation in the conductance with potential which is similar to that of the capacitance, while with irreversible reactions controlled only by an activation process, the magnitude of this conductance will be directly proportional to the polarizing current and inversely proportional to the Tafel slope (b) of the activating polarizing process.

## Anodic Processes of Acetate Ion in Methanol and in Glacial Acetic Acid at Various Anode Materials

Norio Sato, Taro Sekine, and Kiichiro Sugino\*

*Department of Applied Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan*

### ABSTRACT

The anodes used in this study were platinum, gold, palladium, lead dioxide, and graphite. The normal Kolbe process, the formation of ethane (and methane) and carbon dioxide, can be realized at a potential higher than 2.0v (vs. SCE) in both methanol and glacial acetic acid. In methanol, only platinum and gold seem to be suitable for realizing the process. In glacial acetic acid, however, all of the anodes except graphite can be used successfully for the same process. Another process, the formation of methyl acetate, occurs in both solvents at graphite in the potential range 1.4-2.0v. A side reaction observed in methanol at palladium, graphite, and lead dioxide was the formation of formaldehyde (and methyl formate in case of lead dioxide) which occurs at potentials as low as 1.2v.

In previous work (1, 2) anodic processes of acetic acid-acetate mixture in aqueous solution were studied first at platinum and then at gold, palladium, lead dioxide,<sup>1</sup> and graphite anodes by carrying out the electrolysis at definite potentials, followed by the accurate determination of the products mainly by gas chromatography.

As shown in the above work, at a platinum anode the stoichiometric formation of ethane and carbon dioxide, the normal Kolbe process, was observed with almost quantitative current efficiency. On the other hand, at gold and palladium anodes, no Kolbe process occurred, and oxygen was evolved with 100% current efficiency. At a lead dioxide anode, the current efficiency for oxygen evolution was reduced to 50%, and no ethane, but carbon dioxide was mainly obtained with a small amount of methanol,<sup>2</sup> formaldehyde etc. At graphite, the current efficiency for the formation of carbon dioxide, methanol,<sup>2</sup> and methyl acetate was 97%. There were also remarkable differences among the potentials at which the reactions occur at these different electrodes. These results suggested that different types of electrode processes were proceeding. In aqueous solution, the existence of OH<sup>-</sup> complicates the mechanism of the "true" Kolbe process which is characterized by the discharge of CH<sub>3</sub>COO<sup>-</sup>.

In the present work, therefore, the same anodic process has been studied in methanol and in glacial acetic acid at various anodes (platinum, gold, palladium, lead dioxide, and graphite), employing similar procedures as those of previous work. In these cases, the influence of OH<sup>-</sup> was eliminated, and the dis-

charge of acetate ion at the anode was more accurately observed.

There are a few papers concerning the electrolysis of acetate in methanol and acetic acid with suggestions about the mechanism of the process involved (4). However most of them have been carried out at a platinum anode. It seems that no systematic investigation of the behavior of various anode materials has yet been made.

filled with methanol or glacial acetic acid saturated with potassium acetate was connected with the cell.

**Electrolyte.**—Mixtures of 1N potassium acetate and 1N glacial acetic acid in methanol or glacial acetic acid saturated with potassium acetate were used for the anolyte and the catholyte. The amount of water in the electrolyte was reduced to 0.1-0.2% except in those experiments to check the influence of water.

**Analysis of the products.**—The main method utilized for the determination of products (Table I) was a gas chromatographic technique previously described (1).

At the same time ordinary analytical procedures were used for the determination and identification of formaldehyde and methyl formate. Formaldehyde was determined as the dimedon derivative gravimetrically. The identification of methyl formate was carried out by hydrolyzing it to formic acid which was obtained as sodium formate, mp 255°C.

### Results and Discussion

**Current density-anode potential curve in methanol.**—In Fig. 2, current density-anode potential curves in methanol at various anode materials are plotted. As shown in Fig. 2, at platinum and gold anodes the curves showed a steep increase of current at around 2.0v (vs. SCE). On the other hand, at lead dioxide anodes a similar steep increase of current was observed at a potential of about 1.2v. At palladium and graphite, although the increase of current first started at 1.2v, the curves tended to approach those obtained at platinum or gold within the range of high current density. It seems that the obvious differences in current-potential curves suggest the particular anodic process in each case.

**Macroelectrolysis in methanol.**—It was confirmed that even at constant anode potential the change of

Fig. 2. Current density vs. anode potential curves in methanol at 20°C. Electrolyte, 1M CH<sub>3</sub>COOH + 1M CH<sub>3</sub>COOK; ● Pt, ○ Au, ▲ Pd, × PbO<sub>2</sub>, and △ graphite.

current density could scarcely be observed during the electrolysis. Therefore, the following experiments were carried out at constant current for the sake of convenience. The results are shown in Table II.

At a platinum electrode (Table II) almost quantitative formation of ethane and carbon dioxide was observed at higher current density (2.8 amp/dm<sup>2</sup>). The amount of methane produced increased with decreasing current density as would be the case for aqueous solutions.

The main process at gold was quite similar to that at platinum. The products were ethane and carbon dioxide although the current efficiency was a little less. That is, even at gold, in the absence of OH<sup>-</sup> ion, the probable process is the discharge of acetate ion at potentials above 2.0v where the normal Kolbe process can occur.

However, in both cases, it should be pointed out that some formaldehyde was found in the product, especially at gold anodes at the lower potentials. Assuming the formation of CH<sub>3</sub>O· at the anode,<sup>3</sup> the formation of formaldehyde may be represented as follows

This side reaction was clearly observed at palladium and at lead dioxide at lower potentials than those at a platinum or gold anode.

At palladium, the products corresponded to the result of a current density-anode potential curve. At the lower potentials (as low as 1.2-1.6v) and the lower current densities, formaldehyde was the main product; whereas, at about 2.0v and at the higher current density (2.8 amp/dm<sup>2</sup>), ethane and carbon dioxide were obtained with 45% current efficiency.

At lead dioxide, it is interesting to note that no carbon dioxide, ethane, or methane were obtained. The main product was found to be methyl formate accompanied by formaldehyde after twice the amount of current in other runs was passed. The process might be as follows, assuming the same CH<sub>3</sub>O· formation as described above

This reaction is characteristic of the lead dioxide anode. The difference in behavior between platinum or gold and lead dioxide led us to suppose that the acetoxy radical was adsorbed by the surface of platinum<sup>4</sup> or gold, but that it was not adsorbed so tightly by the surface of lead dioxide.

To confirm the methoxy radical formation directly, another electrolysis was conducted by adding furane to the electrolyte and using a current density of 2.8

<sup>3</sup>A possible route for the formation of CH<sub>3</sub>O· is the reaction of anodically formed acetoxy radical (and methyl radical) with solvent.

Another possible route for CH<sub>3</sub>O· is as follows

The difficulty in interpreting the latter route is the fact that at platinum or gold there is no increase of current at 1.2v, a potential at which the formation of CH<sub>3</sub>O· may occur at the other three anodes. This led us to support the former route.

Although breaking the O-H bond in methanol by a radical is less favorable than breaking the C-H bond, it becomes conceivable if we consider the fact that, in anodic processes, methanol is attracted to the anode surface (5) and polarized so as to facilitate the fission of its O-H bond.

In contrast, the theory of acetoxy radical stability has gained support from the work of other investigators both in radical reaction (6) and in anodic process of acetate at platinum (7). Additionally, it should be pointed out that the acetoxy radical is formed at a potential far lower than that of the Kolbe reaction at lead dioxide, palladium, and graphite.

<sup>4</sup>According to Conway et al. (8), the acetoxy radical is adsorbed on a platinum anode with its COO group facing the surface; this orientation facilitates the ethane formation on the anode surface. At lead dioxide the same adsorption orientation is difficult due to the nature of the surface which consists entirely of higher oxide; consequently, the acetoxy radical formed can undergo reaction with solvent.

amp/dm<sup>2</sup>. After 4 amp-hr of current were passed, a fraction of bp 150°-157°C was isolated from the anolyte by fractional distillation. This fraction was identified by gas chromatography as 2,5-dimethoxydihydrofuran.

At graphite, the main product was methyl acetate accompanied by formaldehyde and a small amount of hydrocarbons. The formation of methyl acetate may be represented as follows, regardless of the reaction path which will be described later.

No evidence for the formation of ethyleneglycol, succinic acid, or glyoxal could be obtained. This indicated no formation of ·CH<sub>2</sub>OH or ·CH<sub>2</sub>COOH radicals.

The anodic process of acetate in methanol at various anode materials are summarized in Table III.

Since methanol complicates the processes some further experiments were carried out in glacial acetic acid.

*Current density-anode potential curves in glacial acetic acid.*—In Fig. 3, current density-anode potential curves in glacial acetic acid at various anode materials are plotted.

As shown in Fig. 3, with the exception of the case at graphite, the curves showed a steep increase of current at around 2.1v (vs. SCE) at any kind of anode, even at lead dioxide. From these curves similar electrode processes were expected at platinum, gold, palladium, and lead dioxide anodes at potentials more positive than 2.1v.

*Macroelectrolysis in glacial acetic acid.*—According to the information from current density-anode poten-

tial curves the controlled potential electrolyses were carried out at a certain potential with various anode materials. Results are condensed in Table IV.

As shown in Table IV and expected from Fig. 3, very high current efficiencies, more than 90%, were evident at platinum, gold, palladium, and even at lead dioxide anodes for the formation of ethane and carbon dioxide. In these cases there was no distinctive differ-

\* For total products.

ence in the product and its proportion. From the stoichiometric relation between the products in each case, available reaction was supposed to be the normal Kolbe process and simply represented as follows.

That is, even at the surface of lead dioxide, if the radical formed is not removed from the surface, the potential rises above 2.0v and Kolbe products can be obtained just as at other metallic anodes.

In the case at a graphite anode, the amount of hydrocarbon was quite small, and the main product was methyl acetate just as with aqueous or methanolic medium. The current efficiency for methyl acetate reached 95%. Since the formation of ethane or methane was very much lower, it seemed to be better to assume the formation of methyl acetate mainly as the result of decarboxylation from two acetoxy radicals.<sup>5</sup>

At the higher potentials, the following reaction may also be possible.

*Influence of water in glacial acetic acid.*—Further experiments were carried out in glacial acetic acid containing a small amount of water at platinum, gold, and lead dioxide anodes. Current density-anode potential curves for each anode in acetic acid solutions containing 2 and 5% water are shown in Fig. 4.

At platinum and gold a steep current increase was observed at around 2.0v, and no remarkable change could be found from that obtained in glacial acetic acid, except for a little shift of potential to the negative side at gold. On the other hand at lead dioxide, a remarkable difference was seen between the curves in Fig. 3 and those in Fig. 4 on the potentials at which the current flows. Controlled potential electrolyses were then carried out, the results are shown in Table V.

At platinum and gold anodes a high current efficiency was noted except for a small amount of methanol formation at gold even when 5% of water was added in the electrolyte. On the other hand, at lead dioxide the current efficiency for normal Kolbe process was reduced to 6% without agitation and to 0% with agitation even with addition of 2% water. In the last case, the formation of methanol was observed the same as in aqueous solution. It is indeed an anomalous phe-

<sup>5</sup> An alternative route involves the formation of carbonium ion intermediates which can react with acetate ion or acetic acid to give methyl acetate (9). Since normal Kolbe reaction occurs at the other four anodes in glacial acetic acid, this route should be taken into consideration in the case of graphite not only in glacial acetic acid, but also in aqueous or methanolic medium. However, it seems to us that it is indeed platinum rather than graphite at which the formation of CH<sub>3</sub><sup>+</sup> would be possible at the higher potentials.

nomenon and should be clarified by further experiments.<sup>6</sup>

Anyway, the behavior of lead dioxide anode is very interesting as well as that of graphite and further research on these problems will become a key to clarify the Kolbe process.

### Summary and Conclusion

1. In methanol, Kolbe products, ethane (and methane), and carbon dioxide, could be obtained at platinum, gold, and palladium anodes at a potential higher than 2.0v (vs. SCE). A high current efficiency was noted at platinum and even at gold anodes. The formation of formaldehyde due to side reactions was observed in all cases, especially at palladium at lower potentials. At lead dioxide, the whole reaction occurred within the range of 1.2-1.4v, resulting in the formation of methyl formate accompanied by formaldehyde.

2. In glacial acetic acid, Kolbe products formed at platinum, gold, palladium, and lead dioxide anodes at almost the same potentials (above 2.1v) with more than 90% current efficiency. However, when acetic acid containing 2-5% water was used as solvent, a big

<sup>6</sup> The reason is assumed to be that at platinum and even at gold the acetoxy radical, if it is once formed, is adsorbed on the anode surface and undergoes Kolbe reaction; while at lead dioxide, the radical, which is not so tightly adsorbed on the anode as compared with the above cases, can react with water attracted to the lead dioxide surface, resulting in the formation of carbon dioxide and methanol. The possibility of simultaneous electron release from acetate and water cannot be eliminated as a possible mechanism leading to the same products.

Assuming the carbonium ion instead of the radical seems to be more likely to interpret its reaction with water. However, the difficulty in the assumption lies on the fact that, in glacial acetic acid, there is no formation of methyl acetate at lead dioxide.

\* For ethane (and methane) formation.

difference was noticed between lead dioxide and the metallic anodes.

3. At graphite, the main product was methyl acetate in both solvents. The potential for this process was somewhat lower than that of the normal Kolbe process and laid in the range of 1.4–2.0v.

By combining the results obtained herein with those in aqueous solution, the following conclusions are obtained. In water, the formation of Kolbe products occurs only at platinum; in methanol, however, platinum, gold, and even palladium may be used. In glacial acetic acid any insoluble anode seems to serve, but in all cases and in all solvents Kolbe reaction only occurs at a potential higher than 2.0v. The behavior of a graphite anode is the only exception from the above as it is characterized by the formation of methyl acetate in all solvents. In addition, the formation of methanol at graphite and at lead dioxide in aqueous acidic medium is also significant.

# The Reaction of Solvated Electrons at Metal Electrolyte Interfaces

T. Pyle and C. Roberts<sup>1</sup>

Department of Chemistry and Metallurgy, Lanchester College of Technology, Coventry, England

## ABSTRACT

The formation of solvated electrons at metal electrolyte interfaces is discussed. It is suggested that hydrogen molecules may be formed at an interface, without the prior formation of hydrogen atoms, by the reaction

The evolution of hydrogen by this reaction, both electrolytically and spontaneously during the dissolution of a metal, is discussed. For metals which form hydroxides of low solubility, it is proposed that the hydroxyl ions produced by this reaction form a film across the metal surface and that it is the dissolution of this film which determines the characteristics of the hydrogen evolution process. Calculations of the rates of dissolution of iron in reducing acids made on the basis of this model show good agreement with experimentally observed rates. In addition the activation energies for the dissolution of the hydroxide film on iron and mercury, estimated from the dissociation constants of the hydroxides, are 11.4 and 19 kcal/mole, respectively. These values compare favorably with the observed activation energies for the dissolution of iron, 11.5 kcal/mole, and for hydrogen evolution at a mercury surface, 22 kcal/mole.

Conventionally the reaction by which metals evolve hydrogen from aqueous electrolytes is written in several steps which may vary depending on the pH of the electrolyte. For acids the steps most frequently referred to are given below.

For many metals it is reaction [2] that is thought to determine the over-all rate of hydrogen evolution. Indeed Bass (1) has suggested a criterion for the stability of metals in aqueous electrolytes based on the conservation of energy when an electron tunnels from the metal to a hydrogen ion adjacent to the metal. Recently however Walker (2) observed the formation of solvated electrons during the electrolysis of aqueous electrolytes with a silver cathode. The solvated electron is not stable in water and can react to form either hydrogen atoms or molecules by the reactions

While the latter reaction between two negative entities appears unusual, it is well documented and provides an interesting possibility for the formation of hydrogen molecules directly from electrons and water molecules without the prior formation of hydrogen atoms.

The object of this paper is to examine the possible contribution to hydrogen evolution that may be expected from [6] when hydrogen is evolved, either spontaneously or electrolytically, at a metal surface. A model is developed in which the hydroxyl ions that are formed by the reaction are considered to produce a film across the metal surface; it is the dissolution of this film by hydrogen ions that determines the rate of dissolution of the metal and provides the dependence on pH of the stability of metals, and the pH dependence of the current at a mercury electrode in acid/salt mixtures.

## Spontaneous Dissolution of Metals in Aqueous Electrolytes

*Formation of solvated electrons.*—The simplest way in which a metal can dissolve in an electrolyte is for the metal to dissociate into positively charged ions and electrons. The alkali metals are known to dissolve in liquid ammonia (3) in this way, the solvated electrons that are formed are stable, and no further reaction occurs over a period of several days. Walker (4) has suggested that the alkali metals could dissolve in water in a similar manner; the solvated electrons that are formed will dissociate to form hydrogen atoms and hydroxyl ions, reaction [4], or hydrogen molecules and hydroxyl ions, reaction [6]. Because the ratio of the rate constants  $k_6/k_4$  for the reaction is  $> 10^7$ , reaction [6] will be dominant if the concentration of  $e^-_{aq}$  close to the metal surface exceeds  $10^{-7}$  moles/l. Indeed the evolution of nitrogen, rather than hydrogen, when sodium is added to water in which  $N_2O$  is dissolved (5) indicates that it is reaction [6] by which hydrogen is evolved from water rather than reactions [1] to [3].

In order to decide whether or not a metal will dissociate into its ions and electrons when immersed in an electrolyte we shall use a modified form of the criterion proposed by Bass. On this model when the metal is dipped in an electrolyte containing none of the metal ions, ions dissolve from the metal leaving electrons behind and thus charge up the double layer at the interface between the metal and the electrolyte. The field of the double layer will continue to grow until it reaches a value which is sufficient either (a) to permit energy to be conserved in electron transitions to sites in the electrolyte or, (b) to saturate the orientational polarizability of the dielectric, the field strength necessary to accomplish this is  $E \approx 3kT/\mu$  approximately, where  $\mu$  is the dipole moment of the solvent molecule,  $k$  is Boltzmann's constant, and  $T$  the absolute temperature.

Bass showed that metals, which could form hydrogen atoms spontaneously, obeyed the relationship for the work function  $\phi$

$$\phi < (I - W) + 6aekT/\mu \quad [7]$$

where  $I$  is the ionization potential,  $W$  the solvation energy of the hydrogen ion,  $e$  is the charge on the electron, and  $2a$  is the diameter of a water molecule. Inserting values for the constants into [7] Bass showed that there is an upper limit to the work function

$\phi \approx 2.3$  ev above which the metal will apparently be stable in aqueous electrolytes. While this describes satisfactorily the behavior of the alkali metals in water it does not lead to a ready understanding of the pH dependence of the stability of metals such as magnesium and zinc in aqueous electrolytes. However it is possible that the metal could dissociate into metal ions and solvated electrons providing that energy was conserved in the transition of electrons from the metal to the solvent. Because the work done to remove an electron from a metal depends strongly on the distance to which it is removed, a metal will be considered to be unstable if the work done to remove an electron through the double layer to infinity is smaller than the energy gained in solvating the electron at an infinite distance from the metal. This corresponds to the metal dissociating into ions and electrons separated by an infinite distance and on this criterion a metal is unstable if

$$\phi < W_e + 3kTd/\mu \quad [8]$$

where  $d$  the thickness of the double layer is  $\sim(2r_s + r_m)$ ,  $2r_s$  is the diameter of a solvent molecule,  $r_m$  is the radius of a metal ion, and  $W_e$  is the solvation energy of the electron. In liquid ammonia at  $-70^\circ\text{C}$ , where  $d \sim 5\text{\AA}$ ,  $W_e \sim 1.7 \pm 0.4$  ev (3), and  $\mu \sim 1.48 \times 10^{-18}$  esu,  $\phi \leq 2.5 \pm 0.4$  ev, the inequality therefore predicts closely the known behavior of metals in liquid ammonia (3). In water, where  $d \sim 3.8\text{\AA}$ ,  $W_e \sim 1.75$  ev (6), and  $\mu \sim 1.84 \times 10^{-18}$  esu,  $\phi \leq 2.5$  ev which gives essentially the same division of metals into stable and unstable elements as [7] from Bass. However metals with work functions greater than that given by [8] can form solvated electrons close to the metal surface, although these electrons will be effectively locked in the solution unable to diffuse away from the interface into the bulk of the solution. Such metals will be stable and will not react with the solution unless the solvated electrons can be removed continuously. In ammonia, where the decomposition of the solvated electron does not readily occur, further reaction of metals with  $\phi > 2.5$  ev is unlikely to happen under normal conditions. However, in aqueous electrolytes the solvated electron is unstable and consequently the reaction of the metal with the electrolyte can continue. Thus hydrogen molecules may be formed at the interface, by reaction [6], even though it may be energetically unfavorable to form hydrogen atoms on the criterion proposed by Bass. The rate of hydrogen evolution,  $R$ , in moles  $\text{cm}^{-2} \text{sec}^{-1}$  from the reaction of solvated electrons will be given by

$$R = \left[ \sum_{x=0}^{x=\infty} c_x^2 k_6 dx \right] \cdot 10^{-3} \quad [9]$$

where  $c_x$  is the concentration of solvated electrons,  $e_{aq}$ , in moles/l at a distance  $x$  cm from the surface of the metal,  $dx$  is the increment over which  $c_x$  is constant, approximately the diameter of a water molecule, and  $k_6$  is the rate constant for reaction [6]  $\sim 0.5 \times 10^{10}$  ( $\text{M}^{-1} \text{sec}^{-1}$ ) (7). To determine the rate of hydrogen evolution, from the reaction of solvated electrons during dissolution, it is necessary therefore to know the distribution of electrons in the interface.

*Distribution of solvated electrons in the metal-electrolyte interface.*—To become solvated at the interface the electron must be separated from the metal sufficiently to permit it to interact with the water molecules lying adjacent to the surface. We have previously suggested, in a discussion of the activation energy for the solvation of an electron at a metal surface (8), that this position is approximately the radius of a water molecule distant from the surface and is electrically indistinguishable from the metal surface. The concentration of electrons at this point can be obtained therefore by equating the chemical potentials of the electrons in the metal and the solution and is given by

$$c_a = c \exp (\mu_m - \mu_s^0)/kT \quad [10]$$

where  $c_a$  is the concentration of solvated electrons at the inner Helmholtz plane,  $c$  is the concentration of sites,  $\mu_m$  the chemical potential of the electrons in the metal,  $\mu_s^0$  is the standard chemical potential of the electrons at sites in the solution,  $k$  is Boltzmann's constant, and  $T$  the absolute temperature.  $\mu_m - \mu_s^0$  may be calculated as the work done to take a mole of electrons from the metal and solvate them in the solution. Loeb (9) has remarked that close to the metal an electron can be considered to move against a constant field  $e/4x^2_0$  where  $x_0 = e^2/2\phi$ ; it is only at distances larger than  $x_0$  that the electron moves against a mirror image force. For metals such as zinc, magnesium, and iron  $x_0 > a$  the radius of a water molecule and the work done in removing an electron from the metal to a distance  $a$  is  $ae^2/4x^2_0$  ergs. The electron is solvated at this point and the solvation energy regained. Because the dielectric constant of the electrolyte in the double layer is saturated, the solvation energy will be reduced by an amount  $\Delta W$  compared to that in the bulk solution (10).  $\Delta W$  may be calculated by summing the change in the energy stored in a series of concentric shells, of radius  $r$  and thickness  $dr$ , when the dielectric constant is changed from  $\epsilon_1 = 80$  to  $\epsilon_2 = 3$ . The effect will only occur at points in the double layer where the field due to the double layer is greater than that due to the electron, that is for a radius  $r$ , from the electron, greater than  $b$  where  $b$  is given by  $3kT/\mu = e/\epsilon_2 b^2$ . The change in energy stored in a shell of radius  $r$ , thickness  $dr$ , and width  $d$  is  $e^2 d/4r^3 (1/\epsilon_1 - 1/\epsilon_2) dr$ . The total change in energy,  $\Delta W$ , is obtained by summing between  $r = b$  and  $r = \infty$  and is given by

$$\Delta W = \frac{e^2 d}{8b^2} (1/\epsilon_1 - 1/\epsilon_2) \approx -0.11 \text{ ev} \quad [11]$$

The concentration of solvated electrons at the inner Helmholtz plane is given by

$$c_a = c \exp [-ae^2/4x_0^2 - (W_e - \Delta W)]/kT \quad [12]$$

Values of  $c_a/c$  are given in Table I for iron, magnesium, and zinc.

The work required to remove an electron from the surface of magnesium is so small that all the sites adjacent to the surface are occupied. However, because the energy to remove an electron increases rapidly with the distance to which it is taken, the concentration falls by a factor of  $10^{12}$  in the second layer of water molecules for magnesium and  $10^{20}$  for iron and zinc. The very low concentration of solvated electrons, formed in the second layer of water molecules, is in agreement with the criteria we suggested earlier for the stability of metals and indicates that only those electrons formed in the electrolyte directly adjacent to the metal surface can make a significant contribution to hydrogen evolution through reaction [6]. Equation [9] therefore can be written as

$$R = 2ac_a^2 k_6 10^{-3} \quad [13]$$

*Formation and removal of hydroxyl ions at the interface.*—When the solvated electrons react to form hydrogen, the hydroxyl ions that are produced will reduce the number of sites available for the formation of solvated electrons. If the metal forms a soluble hydroxide, the ions will be able to diffuse into the bulk of the solution. However if the metal hydroxide has a limited solubility, the hydroxyl ions will form a film over the metal surface displacing water molecules and reducing the rate of hydrogen evolution. Dissolution

Table I. Values of  $c_a/c$

Metal	$x_0$ (Å)	$\phi$ (ev)	$c_a/c$
Fe	1.4	4.4	$6.15 \times 10^{-6}$
Zn	1.67	4.3	$1.62 \times 10^{-4}$
Mg	2.00	3.6	1

of this film can only occur by the reaction of the hydroxyl ions with hydrogen ions. If the activation energy for the combination of a hydrogen ion with a hydroxyl ion in the film is  $\Delta H$  and the concentration of hydrogen ions in gram ions/liter is  $[H^+]$ , the number of collisions on unit area in unit time which result in the combination of a hydrogen ion and a hydroxyl ion is given by  $N_H$  ( $\text{sec}^{-1} \text{cm}^{-2}$ )

$$N_H = N_{Av}[H^+](kT/2\pi m)^{1/2} 10^{-3} \exp - \Delta H/kT \quad [14]$$

where  $N_{Av}$  is Avogadro's number,  $m$  is the mass of the hydroxonium ion,  $k$  is Boltzmann's constant, and  $T$  is the absolute temperature. If the concentration of water molecules in the surface film is  $c_2$  moles/l, the fraction of the surface covered by the hydroxide film is  $(1 - 0.018c_2)$  and the rate of dissolution of the film,  $R_f$ , in moles  $\text{sec}^{-1} \text{cm}^{-2}$  is

$$R_f = (1 - 0.018c_2)[H^+](kT/2\pi m)^{1/2} 10^{-3} \exp - \Delta H/kT \quad [15]$$

For most reactions, between ions in solution, the rate is controlled by the activation energy required to unsolvate the reacting species. This is not so for the proton, and it will be able to combine with the hydroxyl ion if it is able to provide the energy to cause the dissociation

For magnesium, iron, and zinc we are concerned with the  $II^+$  oxidation state, consequently  $n = 2$ . While the enthalpy of this dissociation is not available, an estimate of the free energy for the dissociation can be obtained from the difference in the free energies of the reactions

the free energies of these reactions can be estimated using the relationship  $\Delta G^\circ = -RT \ln K$ . Because of the spread of the values quoted in Bjerrum, Schwarzenbach, and Sillen (11) an average for both  $K_{s0}$  and  $K_1$  has been taken where

$$\begin{aligned} K_{s0} &= [M^{++}][OH^-]^2 \\ K_1 &= [MOH^+]/[M^{++}][OH^-] \end{aligned}$$

Values for the free energy of dissociation  $\Delta G^\circ$  are given below for magnesium, iron, and zinc in kcal/mole.

The combination of the hydroxyl ions with the hydrogen ions will occur randomly across the surface of the metal, leaving water molecules as defects in the film. Because hydroxides are insoluble, the defects will not remain randomly distributed in the film, but will segregate so that some areas of the metal surface will be covered by the hydroxide while the remaining areas are covered by water molecules. Thus a steady state will be reached between the formation and dissolution of the film. Hydroxyl ions will be formed by the reaction of solvated electrons in the areas covered by the water molecules and will diffuse through the water molecules by proton transfer until they reach the water-hydroxide phase boundary, while water molecules formed in the hydroxide will diffuse in a similar manner, through the hydroxide, parallel to the surface until they also cross the hydroxide-water boundary.

If, in the areas covered by the water, the molecules are considered to be spheres in contact, sites for the solvated electrons will exist at the tricuspoid formed

Table II. Values for free energy of dissociation

Metal	$\log_{10}K_{s0}$	$\log_{10}K_1$	$\Delta G^\circ_{s0}$	$\Delta G^\circ_{K_1}$	$\Delta G^\circ$
Mg	-10.68	2.335	14.61	-3.19	11.4
Fe	-14.15	5.819	19.36	-7.96	11.4
Zn	-16.20	4.757	22.16	-6.51	15.6

Table III. Rates of dissolution of pure metals in reducing acids ( $\text{amp/cm}^2$ ). Calculated from [13] and [15]

Metal	$[H^+]$ (g ions/l)			
	10	1	$10^{-1}$	$10^{-2}$
Mg	$6.3 \times 10^{-2}$	$6.3 \times 10^{-3}$	$6.3 \times 10^{-4}$	$6.3 \times 10^{-5}$
Fe	$3.7 \times 10^{-1}$	$3.3 \times 10^{-1}$	$1.9 \times 10^{-1}$	$4.2 \times 10^{-2}$
Zn	$5.0 \times 10^{-5}$	$5.0 \times 10^{-6}$	$5.0 \times 10^{-7}$	$5.0 \times 10^{-8}$

by three molecules lying in contact with each other and the plane of the surface. The electron will also associate with other molecules lying in the next layer of water molecules, but the concentration of sites,  $c$ , in the layer immediately adjacent to the metal surface will be  $\sim c_2/3$ . Thus for a given pH the value of  $c_2$  can be obtained by equating  $R_f$  to  $2R$  and solving for  $c_2$ . The rate of dissolution can then be obtained from [15] or [13]. Examples of the rates of dissolution of the metals magnesium, iron and zinc are given in Table III for different values of the hydrogen ion concentration.

The predicted rates of dissolution given in Table III indicate the correct order of the reactivities of the metals with reducing acids as it is well known that zinc, in the pure state, dissolves less readily in hydrochloric acids than pure iron. In Fig. 1 experimental rates of the dissolution of pure iron in reducing acids, taken from Bond (12) and Podesta and Arvia (13), are compared to the calculated values over a range of pH. In the pH range 0-3 the agreement between the calculated and observed results is good. From their work Podesta and Arvia also obtained a value of  $11.5 \pm 0.5$  kcal/mole for the activation energy of dissolution of iron in HCl/NaCl mixtures. On the basis of the model that we suggest the removal of the hydroxide film by the reaction

determines the rate of the reaction at values of the  $pH > 1$ . The estimate of the free energy of activation for this reaction, from the dissociation constants of the hydroxide Table II, is 11.4 kcal/mole, a value which is, considering the simplicity of the model, remarkably close to that found by Podesta and Arvia.

It appears therefore that for  $pH > 0$  the model is able to account for the differing reactivities of metals such as sodium, magnesium, iron, and zinc and is able also to predict values of the absolute rates and activation energies for the dissolution of iron in hydrochloric acid that are in close agreement with the experimental results. Because the stability of metals which are capable of displacing hydrogen from aqueous electrolytes appears, on this model, to depend on the formation of an adherent hydroxide film across the metal surface, it is to be expected that any condition which prevents the formation of the film will

Fig. 1. Comparison of calculated and experimental rates of dissolution of iron (300°K).

result in the metal dissolving at a rate independent of pH. It is of interest to note that commercially pure zinc is found to dissolve at similar rates in acids of  $\text{pH} \sim 3$  and alkalies of  $\text{pH} \sim 12$ .

### Electrolytic Evolution of Hydrogen from Aqueous Electrolytes

*Evolution of hydrogen at a mercury surface.*—While experiments of the type performed by Walker (2) have not yet been carried out on a mercury cathode, measurements of the volume of activation for the evolution of hydrogen at a mercury surface led Hills and Kinnibrugh (14) to suggest that the negative volume of activation that was observed must be due to the formation of a solvated electron as the slow step in hydrogen evolution on this metal. This is not the only process which would lead to a negative volume of activation, Hills and Payne (15) have shown that the inclusion of an ion in the double layer leads to an increase in volume. Conversely it is to be expected that for a process in which the removal of an ion from the double layer is rate determining a negative volume of activation would result. If hydrogen is evolved as we suggest, at low current densities the surface will be covered by hydroxide and the reaction

will be the rate-determining step. The combination of a hydroxyl ion and a hydrogen ion in this way will give rise to a negative volume of activation. From the dissociation constants for  $\text{Hg}(\text{OH})_2$  (11),  $\log_{10} K_{s0} = -25.5$  and  $\log_{10} K_1 = 11.5$ , a value for the free energy of dissociation for the reaction

of 19 kcal/mole is obtained. While this is only an approximation to the activation energy for the dissolution of the hydroxide, it is very close to the experimentally observed value of 22 kcal/mole for the activation energy for hydrogen evolution on mercury (16). The observed pH dependence of the current flowing at a mercury electrode (17) would also follow if the dissolution of the hydroxide was the rate-determining step as we suggest.

While the mechanism that we propose appears to be consistent with the behavior of a mercury electrode, it is known that atomic hydrogen is formed on certain electrodes during the cathodic discharge of hydrogen. In particular electrolytically formed hydrogen is found to dissolve in iron and palladium cathodes. It is usually assumed that this must indicate a step of type [2], the combination of an electron and a hydrogen ion, taking place. However it does not preclude the formation of a solvated electron as both reactions [4] and [5] could lead to the formation of atomic hydrogen which, on metals with a high heat of adsorption of hydrogen, will be stabilized despite the criterion proposed by Bass. Thus reactions [2], [4], [5], and [6] can be considered as competing processes, the one which is dominant at a particular time being dependent on the rate constants for the reactions, the concentration of solvated electrons and hydrogen ions in the interface and the heat of adsorption of hydrogen on the metal surface. Any change in any of these factors for a particular metal-electrolyte system would upset the balance between the reactions. In this context it is of interest to note that the adsorption of  $\text{AsH}_3$  and  $\text{H}_2\text{S}$  on an iron surface greatly increases the proportion of electrolytically formed hydrogen that

diffuses into the metal. Presumably the adsorption of these molecules on the surface reduces the mobility of the solvated electrons across the interface and thus reduces the rate of reaction [6].

### Conclusion

The fact that solvated electrons are formed at metal electrolyte interfaces permits the formation of hydrogen molecules, without the prior formation of atomic hydrogen, to be considered. Such a reaction could play a significant role in the hydrogen evolution process at surfaces which do not adsorb hydrogen strongly, and we have shown that a mechanism of hydrogen evolution based on the reaction of solvated electrons is consistent with the known behavior of a mercury cathode. In addition the mechanism permits quantitative predictions to be made concerning the reactivities of metals such as sodium, magnesium, iron, and zinc with liquid ammonia and aqueous electrolytes.

The formation of atomic hydrogen is not entirely prevented, however, even when solvated electrons are formed, but the balance between competing reactions will depend on the concentration of solvated electrons, hydrogen ions, and the heat of adsorption of hydrogen on the metal cathode.

### Acknowledgments

The authors wish to thank Dr. M. E. Foss and Dr. A. J. Richmond for the provision of facilities for this work.

Manuscript received July 24, 1967; revised manuscript received Oct. 26, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Ring-Disk Amperometry: A Study of Indium Dissolution

B. Miller\* and R. E. Visco\*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

## ABSTRACT

By means of the rotating disk-ring electrode technique, the mechanism of the anodic dissolution of indium at a disk in 0.7M HClO<sub>4</sub> at current densities to above 10 ma/cm<sup>2</sup> has been determined to be a rapid one-electron reaction to an In(I) species sufficiently stable to be detected in theoretical amount at the ring. The Tafel behavior of the disk reaction and the anodic and cathodic ring collection efficiencies are in accord with the above; the ring current-potential curves further show that the slowness of the In(I)-In(III) reaction permits the thermodynamically less-favored state to be formed in quantity. Anodic dissolution of indium from amalgams is placed on a consistent basis by a quantitative treatment which takes into account the variable metal activity.

The mechanism of the electrochemical oxidation in acid solution of indium metal and its amalgams has been investigated by several groups of workers using a variety of experimental techniques. Recent studies on indium metal have been reported by Losev (1), Visco (2), Straumanis (3), and Kiss (4). The recent work on amalgams has ranged from studies on very concentrated amalgams by Kozin (5-7) to studies on more dilute amalgams by Losev (8-11), Markovac (12-14), Visco (2,15), and Straumanis (3). In most studies, current-voltage curves, usually under steady-state conditions, were recorded and analyzed. Coulometric studies with subsequent analysis and radiochemical measurements with tagged indium have also been reported (2, 3, 5-7, 9, 10).

A controversy has arisen concerning the existence and role of oxidation states of indium intermediate between zero and three. The evidence that In(I) does exist under most experimental conditions seems overwhelming (1, 2, 4-7, 15-17). The role it plays in the mechanism is yet to be unambiguously established. The species In(II) has not been characterized with certainty. Only one report of its detection exists (17); this, however, rests on an interpretation of the non-ideal behavior of an In(I) disproportionation reaction to give In(0) and In(III). In a similar set of experiments Biedermann and Wallin (16) found no evidence for In(II).

The role played by In(I) in the oxidation of the metal or the amalgam is, as yet, not clear. Losev (1) and Visco (2) have suggested that, as a consequence of successive one-electron unit steps, a finite concentration of In(I) can be built up during anodization both in a reaction layer about the electrode and in the bulk of the solution, reactions [1]-[3]

Straumanis (3), on the other hand, has taken the position that In(0) is quantitatively oxidized to In(III) and any In(I) seen is a consequence of reaction [4]

Alternate schemes have been proposed by Markovac (12-14), based on studies of dilute amalgams, where it is proposed that disproportionation of In(II) could

occur *via* reaction [5]

or that reaction [1] could be slow and rate-controlling.

Based on his studies of concentrated amalgams, Kozin (5-7) has concluded that for current densities up to 100 ma/cm<sup>2</sup> on a 20 a/o (atom per cent) amalgam, indium atoms are oxidized to In(I) via reaction [1], and that In(I) disproportionation is the dominant path to In(III).

To suppose that all of these mechanisms are operative in the redox chemistry of indium, even under the diverse experimental conditions studied, leads to untenable contradictions. We therefore chose to reinvestigate this system using a ring-disk electrode system. This multielectrode configuration operates under well-defined mass transport conditions, and it is also a configuration which allows the simultaneous detection and identification of intermediates (18-20). By monitoring intermediates at the ring for varying disk potentials and/or current densities and by comparing the observed behavior with calculations for the various models, some further understanding of the mechanism can be achieved. Investigations using two working electrodes have been used in previous studies on this system. Losev (1) used a rotating indium disk and a stationary solid indium electrode. Visco (2) used a stationary solid or amalgam electrode and a dropping mercury electrode. Although the results of these experiments are valid, some ambiguity remains because of the lack of controlled mass transport conditions. Kiss (4) has reported the use of an indium disk-indifferent metal ring in a solution containing In(III) in which the ring is employed for the potentiometric detection of disk dissolution products. A negative shift of potential at the indicating ring was qualitatively viewed as evidence for intermediate formation of a lower valent indium state, by comparison to the similar behavior of an iron disk-indifferent ring in ferric solution.

We describe experimental observations of the oxidation of solid and amalgam disk electrodes of indium and compare these results with the several reasonable models already proposed. The results of such a comparison clearly eliminate several schemes and impose certain restrictions on others. Based on these conclusions, a mechanism is proposed which is consistent with results on both solid and liquid electrodes. Further, when due consideration of the activity of indium is made, no difference is seen between the behavior of a solid and an amalgam indium electrode.

## Experimental

Indium electrodes were prepared by plating the metal onto a graphite or an amalgamated gold disk electrode from the indium solution to be studied (5-20 mM

\* Electrochemical Society Active Member.

In(III) in 0.7M HClO<sub>4</sub>) as required during the course of the experiment. For a pure gold surface the hydrogen overvoltage was too low to plate indium *in situ*, and the initial indium coat was deposited from a 20 mM indium perchlorate bath adjusted to approximately pH 2. Three types of disk-ring electrodes were employed: a graphite disk-graphite ring electrode fabricated from General Electric type EC-2 graphite rod, a mercury-coated gold disk-gold ring, and an all-gold split-ring-disk design (21). The gold surfaces were polished using Linde A (0.3 $\mu$ ), and the graphite surface, which contains microvoids due to its finite porosity, was polished on wet twill cloth. On the amalgamated surfaces the mercury layer was reduced in thickness as much as possible by polishing with twill cloth. The graphite and solid gold electrodes had nominally the same dimensions with disk, internal ring, and external ring diameters of 0.187, 0.206, and 0.253 in., respectively. For such geometry the theoretical collection efficiency,  $N_A$ , is 0.34 (22). Experimentally  $N_A$  equals  $(i_r n_d)/i_d n_r$  where  $i_r$  and  $i_d$  are ring current and disk current, respectively, and  $n_d$  and  $n_r$  are the number of electrons transferred in disk and ring reactions.

The range of collection efficiencies observed in our experiments was 0.29 to 0.34. The corresponding diameters for the gold electrode system which was later amalgamated were 0.168, 0.190, and 0.250 in. The calculated collection efficiency for this configuration was 0.40.

The electrode materials were bonded to stainless steel rod and tubing using either conductive-silver epoxy cement or conventional brazing and then machined to match the steel. Assembly of the rod and tube with inner and outer epoxy insulating rings was basically similar to that of Alberty and Bruckenstein (22) except that all contacts were designed for operation with silver-graphite brushes. In the split ring design the completed ring electrode was sawed through at about the 180° points with a 4-mil blade and electrical isolation completed with a 10-mil cut of one section further up the tube. A wire from the separated half-ring was carried up in an outside axial slot machined in the steel tube to a section of the tube which had been isolated from the lower end. Vacuum impregnation with epoxy backfilled the saw cut assuring electrical insulation. Three separate pairs of silver-graphite brushes were used for the split ring electrode.

The tubular electrode passed through a spindle (H. P. Smith Associates, Cheshire, Connecticut) with two nylon collets providing insulation from the metal assembly. The mounted electrode was belt driven from the side through a tachometer and servo-regulated motor system obtained from Electro Devices, Inc., Paterson, New Jersey. Speed regulation over the range employed was  $\pm 0.5\%$ . Exact speed was measured with a photoelectric pick-off and frequency counter (General Radio Company, West Concord, Massachusetts).

Solutions were prepared by anodization of 99.999% indium rod (American Smelting and Refining Company, South Plainfield, New Jersey) to reach the desired concentration. Other chemicals were of reagent grade.

The cylindrically jacketed cell was of approximately 100 ml working volume. Into a standard taper joint in the base of the cell was inserted a Teflon gland through which was mounted a vertical glass bridge ending in a capillary tip under the disk electrode. A fiber-tipped saturated calomel electrode (SCE) completed the reference circuit. Negative tests with silver ion for chloride ion were always obtained after experiments were completed. Potentials are reported vs. SCE. The SCE electrode was determined to be +0.253v vs. a hydrogen electrode in the same solution. A gold wire counter electrode was wrapped around the bridge just above the standard tapered joint, exiting through the gland. Nitrogen was passed

continuously into and over the solution. Experiments were carried out at 23°C.

Measurements were made by means of a locally fabricated three electrode operational amplifier galvanostat-potentiostat to which was added circuitry (21) employing differential amplifiers to operate the ring electrode(s) potentiostatically. Such a configuration required only a single reference electrode and a single counter electrode, as in other designs (23, 24). A controlled potential sweep capability for the ring electrode with an independent choice of disk operating mode (potentiostatic or galvanostatic) was available with the apparatus. The disk current could be linearly scanned while maintaining constant ring potential, for example, to measure collection efficiencies; to examine the current-potential behavior of disk products, the ring potential could be scanned at constant disk current.

According to the display desired, outputs were fed into a Tektronix 564 Storage Oscilloscope equipped with a 3A3 dual differential amplifier (Y<sub>1</sub> and Y<sub>2</sub> axis) and a 2A63 differential amplifier or 3B4 time base (X axis). To regain the higher accuracy inherent in the operational amplifier signals lost in the  $\pm 3\%$  scope display, a Varian F-80 X-Y recorder with a 11  $\times$  17 in. chart was employed. For Tafel measurements a Rubicon 2730 potentiometer served as precision offset to make the 20 mv/in scale of the F-80 accessible. A mercury relay interrupter was used to measure the resistive correction for Tafel data.

## Results

**Indium disk electrode.**—When an indium plate on a graphite or gold disk is made to dissolve anodically in 0.7M HClO<sub>4</sub> under either controlled potential or controlled current conditions, limiting anodic and cathodic currents are found over appropriate potential regions on the ring electrode. The Tafel plot, Fig. 1, of the disk reaction, as obtained from controlled linear current scan experiments, indicates a single 59 mv/decade process (experimental slopes for various runs were 57-62 mv/decade) over the current density range up to at least 50 ma/cm<sup>2</sup>. At this current density a  $\pm 3$  mv variation in disk potential results from a  $\pm 10\%$  uncertainty in the interrupter-determined resistance between reference capillary tip and the disk electrode. In the next current decade, the uncertainty in this resistance precludes a certain assessment of any incipient curvature in the Tafel plot.

A previous potentiometric measurement (2, 15) of the formal potential of the In(0)-In(I) couple in 0.7M HClO<sub>4</sub> with the In(I) concentration estimated polarographically gave a value of -0.388v vs. SCE. Assuming the process yielding the Tafel behavior of Fig. 1 is simply an equilibrium between In(0) and In(I) with subsequent diffusive loss of the In(I) and utilizing the same diffusion coefficient for In(I) as in the

Fig. 1. Curve A, Tafel plot for indium disk at 3000 rpm in 20 mM In(III)-0.7M HClO<sub>4</sub>, corrected for 3.4 ohm resistance; curve B, anodic ring collection efficiency,  $N_A$ , plotted as the ratio to the limiting value, as  $i_d \rightarrow 0 N_A \text{ lim}$ .

polarography with interpolated handbook values for the kinematic viscosity of the solution, a value for the surface concentration of In(I) may be obtained for all currents by means of the Levich equation (25). The calculated value of the conversion factor at 3000 rpm is  $1.36 \text{ (ma/cm}^2\text{) / (millimole/liter)}$ . For the points corresponding to the Tafel line in Fig. 1, insertion in the Nernst equation gives a formal potential of  $-0.40\text{v vs. SCE}$ , in satisfactory agreement with the previous determination. For consistency in subsequent calculations, the value of the formal potential determined in this study with the disk electrode is used.

Substantiating the above assumption that the potential-determining reaction is  $\text{In(0)/In(I)}$  is the rotational speed dependence of the disk potential at constant disk current. On substitution of the surface concentration of In(I) given by the Levich equation, the Nernst equation for the  $\text{In(I)/In(0)}$  couple transforms to

$$E_d = E^{\circ'}_{1/0} + 0.059 \log \frac{i_d}{0.62 D^{2/3} \nu^{-1/6} F A} + 0.059 \log \omega^{-1/2} \quad [6]$$

where  $D$  is the diffusion coefficient of In(I),  $\nu$  the kinematic viscosity,  $F$  Faraday's constant,  $A$  the electrode area, and  $\omega$  the rotational speed. Thus for constant disk current, the disk potential should vary  $59/2 \text{ mv/decade}$  in  $\omega$ . The data for two disk current densities, 1.12 and  $5.62 \text{ ma/cm}^2$ , are shown in Fig. 2. The observed slopes are 27 and  $29 \text{ mv/decade}$   $\omega$ , respectively, in good agreement with the predicted 29.5.

The current-potential behavior of the potentiostatically scanned ring electrode for a fixed anodic current at the disk is shown in Fig. 3. The anodic process exhibits a particularly well-defined limiting-current plateau extending to electrolyte oxidation. The limiting cathodic current region is close to hydrogen evolution on indium and is accordingly less well-defined. The residual current line in Fig. 3 is for a carbon surface. Hydrogen evolution on indium is a slower process than on carbon, and therefore for indium the residual current under the reduction wave can be approximated by a linear extrapolation of the  $+0.3$  to  $-0.5\text{v}$  region on carbon. With proper compensation for residual currents, the anodic to cathodic limiting current ratio is 2 to 1. For the potential sweep in the anodic direction shown in Fig. 3, dissolution of indium from the ring appears to correspond reversibly to the ring reduction process and occurs at potentials consonant with the Tafel behavior seen in Fig. 1. Moreover, indium dissolution at the ring takes place several tenths of a volt lower than the anodic

Fig. 2. Rotation speed vs. disk potential for ● ● ● 1.12  $\text{ma/cm}^2$  and ○ ○ ○ 5.6  $\text{ma/cm}^2$ . Zero volts are  $-570$  and  $-525 \text{ mv vs. SCE}$ , respectively.

Fig. 3. Graphite ring scanned at  $20 \text{ mv/sec}$  from  $+0.4$  to  $-0.85\text{v}$  (solid line) then  $-0.85$  to  $-0.3\text{v}$  (short dashes);  $i_d$   $2.8 \text{ ma/cm}^2$ , rotation speed  $3000 \text{ rpm}$ . Residual current (scan at  $i_d=0$ ) is long-dashed line.

reaction of the disk dissolution product, which at this disk current density for either carbon or gold surfaces does not commence until  $0.0\text{v vs. SCE}$ . It is also to be noted that reduction at the disk of  $20 \text{ mM In(III)}$  in  $0.7\text{M HClO}_4$  does not yield detectable intermediates at the ring in any potential region.

The above behavior implies indium dissolution to be a one-electron reversible process giving In(I), which at the ring can be either reduced by one electron to In(0) or oxidized by two electrons to In(III). To establish this important point definitively, ring current-disk current relationships were examined in two independent ways.

First, the number of electrons involved in the ring reaction was determined by comparing the collection efficiency to that of the known ferro-ferricyanide system. Second, by using a split ring-disk to compare simultaneously the ratio of the anodic ring current to the cathodic ring current as a function of disk current density in a single run, a ratio of electrons was determined.

Results of the first method are collected in Fig. 4. For current densities in the range of curve 1 there is no detectable deviation from linearity of the anodic  $i_{r+}$  vs.  $i_d$ , and the slope obtained is 2.0 times that for the one-electron ferro-ferricyanide couple and the cathodic  $i_{r-}$  (curve 4). The over-all anodic reaction at the ring when indium is being anodized is therefore sensibly only

At current densities higher than about  $3 \text{ ma/cm}^2$  the collection efficiency begins to fall off gradually, but the

Fig. 4. Curves 1-3: ring current-disk current density relation for the conditions  $E_r + 0.8\text{v}$ ,  $20 \text{ mM In(III)}$ ,  $0.7\text{M HClO}_4$ ,  $3000 \text{ rpm}$ ; curve 4: corresponding results for  $E_r -0.6\text{v}$  and  $0.10\text{M Fe(CN)}_6^{4-}$  —  $1\text{M NaOH}$  (disk oxidation, ring reduction).

majority of the indium species detected by the ring appears to be In(I) even up to the 200 ma/cm<sup>2</sup> region. In neither ring-disk current nor Tafel behavior was there any noticeable dependence on current scan direction in the anodic region or on the current sweep rates employed. These curves showed no hysteresis and could be exactly retraced for decreasing current. The  $N_A$  data are also shown on Fig. 1 to relate  $N_A$  to  $E_d$  in the form of the reduced variable  $N_A/N_{A \text{ lim}}$ , where  $N_{A \text{ lim}}$  is the value of  $N_A$  when  $i_d \rightarrow 0$ . For the data plotted  $N_{A \text{ lim}}$  is 0.583/2.

Experimental results for the second method of determining the number of electrons transferred in both ring reactions required the simultaneous measurement of cathodic current on one half-ring,  $i_{r-}$ , and anodic current on the other half ring,  $i_{r+}$ . Oscilloscope traces are shown in Fig. 5. In the  $i_d$  range to 0.5 ma/cm<sup>2</sup> both  $i_{r+}$  and  $i_{r-}$  traces are close to linear and the ratio of the anodic to cathodic slopes as  $i_d \rightarrow 0$  is 2. Even more exact measurements with the higher accuracy of the X-Y recorder, in which  $i_{r+}$  was plotted against  $i_{r-}$ , show that the limiting slopes are in quantitative agreement with a two-electron oxidation and a one-electron reduction, respectively, for the product swept from the disk during dissolution. With half-ring "A" anodic and "B" cathodic, the conditions prevailing in Fig. 5, the slope was 2.30; with connections reversed the slope was 1.64, an average of 1.97. The averaging of the two values eliminates the small geometric differences due to construction which make the collection efficiency of A about 15% larger than that of B. The results of the second method have the considerable advantage of being independent of calibration against a known electrode reaction. The conclusion that the ring reactions involve either one or two electrons assumes only the absence of dimeric (or higher) species such as  $\text{In}_2^{+2}$  as products of the initial disk reaction or their failure to form in transit to the ring. Such an assumption is supported by the Tafel behavior and the essential lack of dependence of ring current on rotational speed for potentials in the linear region of Fig. 4 ( $N_A$  constant  $\pm 3\%$ , 750-6000 rpm at  $i_d = 2.8 \text{ ma/cm}^2$ , see Table I).

To examine the possible origins of a decrease in collection efficiency at high  $i_d$ , the aforementioned rotational speed dependence of  $i_{r+}$  was examined over the current range of interest. The data of Table I, showing the collection efficiencies normalized to the values at 2000 rpm, indicate only a small rotational speed dependence with somewhat lower values at the low speed end at  $>100 \text{ ma/cm}^2$ . The fraction of In(I) lost by a homogeneous reaction in the transit from the disk to the ring must therefore be small. The data

6000	0.98	1.01	0.98

Tabulated values are normalized to the collection efficiency at 2000 rpm for a graphite ring in 20 mM In(III) - 0.7M HClO<sub>4</sub>.

quoted in Fig. 1, 3, and 4, however, are at rotational speeds of 3000 rpm for which minimal homogeneous effects appear to occur. The appreciable drop-off in  $N_A$  occurs in the current density region where the surface concentration of In(I) approaches 0.1M as calculated from the Levich equation (25). The deviation from collection efficiency constancy for the  $\text{Fe}(\text{CN})_6^{-4}$  results is less than 0.5% at 56 ma/cm<sup>2</sup> for 3000 rpm and less than 1% at 80 ma/cm<sup>2</sup> for 5000 rpm.

Another approach to assessing changes in the disk reaction or possible homogeneous reactions at higher currents is to compare the  $i_{r+}$  and  $i_{r-}$  values in this region by the split-ring technique or by measuring the quantities on successive scans at the same ring. The latter tends to cancel changes in transport factors such as eccentricity. A set of successive scans for a single ring is given in Fig. 6. In contrast to the roll-off in  $i_{r+}$ ,  $i_{r-}$  tends to increase; their sum, accounting for three electrons, remains constant. The simplest explanation is that at high anodic currents, disk oxidation to In(II) becomes important. Such a process would account for the increase in  $i_{r-}$  and a compensating decrease in  $i_{r+}$ . Calculated on this basis, the data in Fig. 6 represent a conversion of only about 30% of In(I) to In(II) at the disk even at the highest current densities studied. The corresponding change in the slope of the Tafel plot would therefore be small and within the probable error indicated by the vertical bar drawn on the  $iR$ -free Tafel line near the highest current density in Fig. 1. However, at such high surface concentrations of In(I), the assumption of the absence of migration in the transport from disk to ring may fail. Thus,  $i_{r-}$  should be enhanced by electrical migration of In(I) and  $i_{r+}$  decreased, as is found. In addition, the surface concentrations are proportional to (rotation speed)<sup>-1/2</sup> at a given current, so these postulated field effects are in agreement with the direction of the rotational speed dependence trend ( $N_A$  drops

Fig. 6. Successive runs with graphite electrode at 3000 rpm of  $i_{r+}$  at  $E_r 1.0\text{v}$  and  $i_{r-}$  at  $E_r -0.65\text{v}$  vs.  $i_d$  in 20 mM In(III) - 0.7M HClO<sub>4</sub>. faster at lower speeds, Table I). Hence, interpretation in terms of In(II) formation at the disk remains speculative.

**Indium amalgam disk electrodes.**—A comparison between the electrochemical behavior of a solid indium electrode and an indium amalgam electrode is desirable. Relationships between potentials, indium activities, and the products generated are necessary to determine if a single mechanism is operative for both types of electrodes. These quantities can be determined by using a mercury-coated gold ring disk electrode and then comparing these results to the ones described above for the solid indium electrodes.

Deposition of indium on the disk portion of the electrode allows the *in situ* preparation of amalgams of varying activity. Short deposition time gives a dilute amalgam; continued deposition will eventually give a saturated amalgam [70 m/o (mole per cent)] with an activity of indium equal to that of the solid metal (26). Further deposition will give only solid indium.

The behavior of dilute amalgams, concentrated amalgams, and saturated amalgams with excess solid indium were examined using anodic galvanostatic polarization of the disk. The collection efficiency for In(I), as determined by its oxidation at the ring electrode, was studied as a function of disk currents for several rotational speeds. The potential of the disk electrode,  $E_d$ , was simultaneously monitored. A plot of both disk potential,  $E_d$ , and ring current,  $i_{r+}$ , vs. increasing disk current starting with a saturated amalgam is shown in Fig. 7. Up to a certain level of disk current density, the disk potential and collection efficiency are consistent with the behavior of a solid indium electrode (*vide supra*). However, when the solid phase is exhausted and concentration polarization of the amalgam becomes important, it is observed that the collection efficiency falls quickly to zero. Other experiments of this type have been carried to the point where mercury dissolution commences, and below that potential range, no further electroactive species could be detected at the ring electrode.

The region where indium concentration polarization in the disk becomes significant is one of rapidly changing potential. A more detailed study of this potential region is shown in Fig. 8 where the variation of  $E_d$  and  $i_{r+}$  with time is plotted for a constant  $i_d$ . The data are for a dilute amalgam and show clearly that the quantity of In(I) formed is critically potential-dependent. In Fig. 9  $i_{r+}$  is plotted as a function of  $E_d$  for a constant  $i_d$ . (This run and others at different  $i_d$ 's and rotational speeds are subsequently analyzed in a quantitative kinetic treatment.)

It is possible to calculate what the surface indium activity is at the potential,  $E_{r.o.}$ , where the collection efficiency begins to roll off. Putting both the value of the standard potential for the In(I)/In(0) couple de-

termined above for this medium and the surface concentration of In(I) obtained from the Levich equation for the disk current into the Nernst equation, the log of the indium activity, based on a Henry's law mole fraction scale (26), may be obtained (Table II).<sup>1</sup> The observation by Kozin (7) that In(I) is the sole product formed in amalgam dissolution for amalgams more concentrated than 20 m/o, for which Butler's data (26) show a log activity of  $-0.08$ , is in accord with our experimental observations and the calculation just described, especially considering that the equivalent potential difference between the values is approximately 4 mv.

**Kinetic analysis of amalgam dissolution.**—In order to treat the drop-off in collection efficiency with in-

<sup>1</sup> Activities based on Henry's law (mole fraction scale) may be obtained from activities on a solid indium equals one basis by multiplying them by 21.6.

creasing anodic polarization quantitatively, a kinetic model is necessary. The model chosen has already been given as Eq. [1]-[3], where the rates for the forward and reverse reactions are indicated by the respective  $v$ 's. It is clear from the data of Visco (15) that the homogeneous reaction of In(I) with  $H^+$  is slow. At 20°C in 0.7M  $H^+$ , the half life for the reaction

is 2.2 min. The data presented above on solid disk electrodes for current densities below 2 ma/cm<sup>2</sup> show that In(I) is stable with respect to any homogeneous disproportionation reaction on the time scale of disk-ring transit, as expected from the half-life. Therefore, at low current densities, once In(I) is formed at the interface of a rotating amalgam disk or, for that matter, at any indium anode, it can only be further oxidized heterogeneously to In(II) and/or In(III), or, swept away from the electrode and detected at the ring. Those ions not detected at the ring are then swept to the bulk. Once in the bulk, In(I) ions are slowly oxidized to In(III) by the homogeneous reaction with hydrogen ions, Eq. [8]. If some of the In(I) were oxidized at the amalgam disk, these oxidized species too must either be swept away from the disk, possibly to be detected at the ring or effectively to be lost to the bulk.

In the following derivation certain assumptions are made about the relative rates of the several charge-transfer reactions. It is assumed that the rates  $v_1$  and  $v_{-1}$  are always sufficiently great that reaction [1] is never significantly displaced from equilibrium and therefore the Nernst equation relates the surface activities of In(I) and indium in the amalgam. Kozin (7) has shown this relationship to be true over a wide current density range for the 20 m/o amalgam he studied. The same behavior is seen here in the Tafel plot for a solid indium electrode, Fig. 1.

Of the two charge-transfer reactions remaining, either can be the rate-controlling step. Let us assume, however, that reaction [3] is rate-determining and reaction [2], like [1], is always effectively at equilibrium, although the absence of detectable In(II) indicates that it lies far to the left, making the interfacial concentration of In(II) vanishingly small, at least for the low current density conditions later used to test this model.

Based on the above, the usual steady-state assumption of an equal division of current between successive steps in a sequence of one-electron steps cannot be made for this model. One intermediate, In(I), has a significant interfacial concentration under all conditions, and therefore, as a consequence of the motion of the solution near the interface, some of this species will be swept away from the electrode. The current is still given by

$$i_d/AF = (v_1 - v_{-1}) + (v_2 - v_{-2}) + (v_3 - v_{-3}) \quad [9]$$

The quantity  $(v_1 - v_{-1})$  is greater than  $(v_2 - v_{-2})$  since some of the In(I) is lost from the interface by means of the solution laminar flow. It is possible, however, to relate the rates of the three unit steps by

$$(v_1 - v_{-1}) - m\{\text{In(I)} - \text{In(I)}_{\text{Bulk}}\} = (v_2 - v_{-2}) = (v_3 - v_{-3}) \quad [10]$$

where  $m$  is the mass transport coefficient for a given rotational speed. (Concentrations are to be understood as surface values unless otherwise labeled.) The quantity  $(v_3 - v_{-3})$  may be written as

$$(v_3 - v_{-3}) = k_3 \text{In(II)} \exp(\beta_3 F \Delta\phi/RT) - k_{-3} \text{In(III)} \exp(-\alpha_3 F \Delta\phi/RT) \quad [11]$$

where  $\Delta\phi$  is the potential measured against a standard hydrogen electrode. Substituting [10] and [11] appropriately into [9] gives

$$i_d/FA = 3\{k_3 \text{In(II)} \exp(\beta_3 F \Delta\phi/RT) - k_{-3} \text{In(III)} \exp(-\alpha_3 F \Delta\phi/RT)\} + m\{\text{In(I)} - \text{In(I)}_{\text{Bulk}}\} \quad [12]$$

The reduction of In(III) in strong acids in the absence of any complexing anions such as halide is known to be a highly irreversible process (27-30), and therefore the back reaction (the term involving  $k_{-3}$ ) can be neglected. The bulk concentration of In(I) is always much smaller than the interfacial concentration of this species and the last term in the above equation can be accordingly simplified. Through the Nernst equation a substitution for the In(II) surface concentration in terms of the corresponding quantity for In(I) is possible; the standard potential for this redox couple is then defined as  $E_{O_2/1}$  vs. the standard hydrogen electrode. With this simplification and substitution, Eq. [12] reduces to

$$i_d/FA = 3k_3 \text{In(I)} \exp\left\{(1 + \beta_3) \frac{F \Delta\phi}{RT}\right\} \exp\left\{\frac{-FE_{O_2/1}}{RT}\right\} + m \text{In(I)} \quad [13]$$

In the absence of significant  $iR$  losses for the low disk current densities studied using amalgams, the concentration of In(I) is uniform over the surface of the disk, and  $m$  is therefore given by the Levich equation. The ring current for oxidation of In(I) to In(III) is related to  $m \text{In(I)}$  through the collection efficiency

$$m \text{In(I)} = \frac{i_{r+}}{2FA N_A \text{lim}} = 0.62D^{2/3} \nu^{-1/6} \omega^{1/2} \text{In(I)} \quad [14]$$

Substitution of [14] into [13] gives

$$\frac{i_d - i_{r+}/2N_A \text{lim}}{i_{r+}} = \frac{2.42 k_3 \exp\left\{(1 + \beta_3) \frac{F \Delta\phi}{RT}\right\} \exp\left\{-\frac{FE_{O_2/1}}{RT}\right\}}{N_A \text{lim} D^{2/3} \nu^{-1/6} \omega^{1/2}} \quad [15]$$

A plot of the quantity  $\log\{(i_d - i_{r+}/2N_A \text{lim})/i_{r+}\}$  vs.  $\Delta\phi$  should therefore be linear with a slope of  $(1 + \beta_3)F/2.3RT$ . Such a plot for runs at two rotational speeds and three different disk currents is shown in Fig. 10. The quantity  $2.3RT/(1 + \beta_3)F$  is, for all 6 runs,  $35 \pm 1$  mv, so that  $(1 + \beta_3) = 1.7$ . The potential separation between pairs of lines in Fig. 10 is expected to be  $35 \log(i_{d1}/i_{d2})$  mv. The calculated separation of 10.5 mv may be compared with the observed 11 and 13 mv differences. Losev (11) has measured the

Fig. 10. Experimental test of Eq. [15]; conditions correspond to Table II entries;  $\Delta$  to 1,  $\blacktriangle$  to 2,  $\square$  to 3,  $\blacksquare$  to 4,  $\circ$  to 5 and  $\bullet$  to 6.

Tafel slope for the dissolution of dilute amalgams and obtained a value of 27 mv/decade. Assuming the third electron transfer to be slow, Losev finds  $(2 + \beta_3)$  equal to 59/27 or 2.2. The unit difference between the theoretical quantities results from the fact that Losev measured the oxidation of  $\text{In}(0) \rightarrow \text{In}(\text{III})$  at amalgams of assumed constant surface composition, while Eq. [15] was derived for amalgams of variable composition, where oxidation of  $\text{In}(0)$  to  $\text{In}(\text{I})$  was not accounted for in the exponential but rather in a changing interfacial concentration of  $\text{In}(\text{I})$  as determined by an experimental measurement of the ring current. The latter method appears more likely to represent the actual situation accurately.

### Discussion

The experimental conclusions summarized below warrant the interpretation that, in acidic noncomplexing media as represented by 0.7M  $\text{HClO}_4$ , indium metal at current densities up to at least 10  $\text{ma}/\text{cm}^2$  quantitatively goes into solution in the  $\text{In}(\text{I})$  state. Further,  $\text{In}(\text{I})$  is the major product to above 100  $\text{ma}/\text{cm}^2$ .

(A) The Tafel slope at a rotating disk is 59 mv/decade, in keeping with a reversible one-electron oxidation and diffusive transport of  $\text{In}(\text{I})$  away from the surface.

(B) The product of dissolution may be oxidized in a two-electron step or reduced in a one-electron step, as determined by ring current behavior.

(C) The separation between the dissolution potential of indium metal and the oxidation wave of the dissolution product is compatible with a  $0 \rightarrow 1$  reversible reaction and a slow  $1 \rightarrow 3$  reaction, overcoming the fact that the  $0 \rightarrow 3$  reaction is thermodynamically most favorable.

(D) Neither disproportionation nor homogeneous hydrogen ion reduction of  $\text{In}(\text{I})$  is fast enough to cause measurable loss of this species in transit from ring to disk, as evidenced by the linearity of  $i_r$  vs.  $i_d$  plots and the exact numerical relation of the slope of this plot to that for the known one-electron ferro-ferricyanide couple.

Views of indium dissolution involving one-electron steps have already been mentioned: Visco (2, 15), Losev (1), and Kozin (5, 6, 7). The formation of finite concentrations of  $\text{In}(\text{I})$  is suggested in all these mechanisms; major differences exist on the fate of the species. Losev (1) claims  $\text{ClO}_4^-$  reduction to  $\text{Cl}^-$  provides a path to  $\text{In}(\text{III})$ . However, in this work and in previous results from this laboratory (2, 15), no sign of  $\text{Cl}^-$  formation (silver ion and anodic polarography tests) has been detected. Furthermore, recent ring-disk experiments with added  $\text{Cl}^-$  (31) indicate very significant effects of this ion on the dissolution process itself, effects which were not observed in the present study. The Kozin (7) proposal of disproportionation of  $\text{In}(\text{I})$  as the route to  $\text{In}(\text{III})$  reflects the appearance of indium particles in solution in his experiments. Measurements of the first order  $\text{In}(\text{I}) + \text{H}^+$  reaction rate (15) show no influence of disproportionation up to millimolar initial  $\text{In}(\text{I})$  levels. Since disproportionation must be of higher order in  $\text{In}(\text{I})$ , it is reasonable that this route may become faster than  $\text{H}^+$  reduction at high  $\text{In}(\text{I})$  concentrations. It is to be noted, however, that disproportionation would cause  $i_{r-}$  to fall off at higher anodic disk dissolution currents since neither  $\text{In}(\text{III})$  nor  $\text{In}(0)$  is reduced at the cathodic ring potential of the experiment; this prediction is opposite to the direction found. In the bulk solution, disproportionation may be competitive with  $\text{H}^+$  reduction since they depend on the  $\text{In}(\text{I})$  to  $\text{H}^+$  concentration ratio. Neither reaction is rapid enough, however, to be detected within the transit time of the ring-disk experiments.

The position of Straumanis (3) that  $\text{In}(\text{I})$  is a product only of reaction [4] is clearly contradicted by the present results. The further insistence of Strau-

manis (32) that conclusions of coulometric experiments which indicate lower oxidation states of indium, whether from solid or amalgam dissolution, are due to anode disintegration is sharply disputed, particularly by the fact that  $\text{In}(\text{I})$  is formed most nearly quantitatively at the lowest current densities, an effect exactly opposite to all arguments based on physical disintegration processes. In addition, the ring-disk experiments are not in disagreement with the Straumanis coulometric studies on indium dissolution in acid (3). In those experiments the indium was shorted to a large platinum electrode, effectively potentiostatically controlling the anode at about  $-0.25\text{v}$  on the scale of Fig. 1, or at a sufficiently anodic potential for oxidation to  $\text{In}(\text{III})$  to occur at a dilute amalgam. The appearance of metal particles in solution is also, as noted by Kozin, reasonably a product of  $\text{In}(\text{I})$  formation, not necessarily electrode disintegration.

The process of indium dissolution from an amalgam has been shown to be the same as that at a solid if one takes proper cognizance of the indium activity in the amalgam. With the fixed activity of the solid metal, only increasing the current density can move the anode more positive. With an amalgam, the lowered indium concentration (activity) at the surface in a dilute amalgam or in the concentration polarization of a more concentrated amalgam on anodization has the same effect of a positive shift of potential, but at much lower current densities. The rate of the  $\text{In}(\text{I}) \rightarrow \text{In}(\text{III})$  reaction will then effectively catch up at some moderate current density, and  $\text{In}(\text{I})$  will cease to be detected. Negative results in coulometric tests for the existence of lower valent intermediates, as by Straumanis (3), which are based on dissolution from very dilute amalgams at relatively high anodic overpotentials (33), are thus always to be suspect. When such intermediates can be formed because of kinetic reasons (e.g., a slow further electron transfer step to a higher valence state), these two conditions (dilute amalgams, i.e., a low activity of metal, and high anodic overvoltage) are very unfavorable for their detection. The latter applies to the case at hand; needless to add, the conditions are likewise unfavorable on a direct thermodynamic basis.

The quantitative confirmation of the kinetic model for amalgams has been described above. These ideas also reconcile various literature data about indium dissolution from amalgams. Thus, Straumanis' experiments (3) were with extremely dilute amalgams at high polarizations from which  $n = 3$  is expected. Those of Kozin (7), with 20 m/o and higher amalgams gave  $n = 1$ . Values quoted by Visco (2) of  $1 < n < 3$  were for concentrations yielding a spectrum of indium activities corresponding to the  $i_{r+}$  roll-off region in Fig. 9 and thus an intermediate number.

The views of Markovac (12-14) on the dissolution mechanism of indium have been obtained from experiments on dilute amalgams and fail particularly to take into account the indium activity factors discussed in the above treatment of amalgams. The reversibility of the  $\text{In}(0)$ - $\text{In}(\text{I})$  reaction at both solid and amalgam electrodes and the lack of needing to invoke an  $\text{In}(\text{II})$  disproportionation contradict his various interpretations.

The predictions of the kinetic model for amalgam electrodes are experimentally verified in a region of current densities ( $< 1.5 \text{ ma}/\text{cm}^2$ ) corresponding to the unequivocally clear  $\text{In}(\text{I})$  formation in the Tafel and ring current behavior of the solid, Fig. 1. Experimentally, it is not feasible to carry out the described experiment with amalgam disks at much higher current densities, since the resulting roll-off in potential is too rapid to assure  $i_{r+}$  and  $E_d$  measurements corresponding to the same time scale even at high rotation speeds. The requirement in the model for an amalgam electrode with vanishingly low  $\text{In}(\text{II})$  concentration is satisfied since the  $E_d$  potentials never approach the values that may be suspect with regard

to this assumption at the 100 ma/cm<sup>2</sup> end of the Tafel data on the solid electrodes. Whether an appreciable surface concentration of In(II) can be formed over a narrow potential range at the high current limit of the present Tafel measurements is, as previously discussed, not excluded from the ring current data. This leaves open the question of whether, over some limited potential region, it is possible to remove the second electron (reaction [2]) before the In(I) → In(III) process is sufficiently accelerated to prevent the In(II) concentration from ever becoming significant. Experimentally a nonindium ring must be employed to detect In(I) by its oxidation. Ring current-potential behavior at carbon, mercury, and gold surfaces of this oxidation process does not necessarily characterize quantitatively the behavior of the same reaction at an indium or amalgam disk.

Manuscript received Oct. 6, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Determination of the Composition of Complexes and Their Instability Constants by Calorimetry

### III. The Complex in Fused Sodium Molybdate and Molybdenum Trioxide

Abner Brenner\* and William H. Metzger, Jr.

National Bureau of Standards, Washington, D. C.

#### ABSTRACT

A method of determining the composition of complexes in solution and their instability constants, which is based on the measurement of the partial molal heat effect developed when a small increment of each salt is added in turn to a series of mixtures covering the range of composition from 0 to 100%, has been applied to the molten Na<sub>2</sub>MoO<sub>4</sub>-MoO<sub>3</sub> system at 800°C. The data show that one complex is formed consisting of one molecule of Na<sub>2</sub>MoO<sub>4</sub> and two molecules of MoO<sub>3</sub>. The instability constant is approximately unity, and the complex is between 50% and 75% dissociated.

A general method for determining the composition of complex ions and their instability constants by calorimetry was developed and described in two previous publications. In the first publication (1) the mathematical aspect of the subject was developed, and the method was applied to an aqueous system containing copper cyanide complexes. In the second paper (2) the method was applied to a fused salt system consisting of potassium and cadmium chlorides. This is the

Key words: Complex salts; calorimetry; fused salts; sodium molybdate-molybdenum trioxide system; partial molal heat effect; composition of complex salts.

\* Electrochemical Society Active Member.

third and final paper of the series. It deals with a complex present in the molten sodium molybdate-molybdenum trioxide system.

The laboratory procedure is as follows. Let the two components of the complex be designated by A and B. A series of perhaps 8 or 10 different mixtures of A and B is prepared covering the whole range of composition from pure A to pure B. To a given mixture of approximately 500g is added a small increment of A (a few grams) and the temperature effect measured. Then a small increment of B is added and the temperature effect again measured. The increments should be so

small that they do not change the composition of the mixture by more than 1%. The experimental results are converted into heat changes per mole of A or B added, i.e., into partial molal heat effects (designated as  $\Delta H$ ). These are the amounts of heat that would be evolved if one mole of A or B were added to an infinite amount of mixture. These  $\Delta H$  values are plotted against the composition of the mixtures.

The mathematical derivations in the first paper showed that, if only one complex is present, the curves cross at the stoichiometric composition. This unambiguously determines the composition of the complex even if it is largely dissociated, for example, if the instability constant is unity. The law regarding the heat effects at the stoichiometric composition can be most simply stated in the form:

At the stoichiometric composition, equimolar additions of each component produce equal heat effects.

If the two components form more than one complex, the composition of each can be determined by solving simultaneous equations or by graphical methods.

The instability constant of the complex can be calculated from either the value of the partial molal heat effect or the slope of either curve at the stoichiometric point.

The addition of increments of both A and B is required only when the instability constant is large. If it is of the order of  $10^{-3}$  or smaller, the curves have sharp changes of slopes in the vicinity of the stoichiometric point, and this break in the curve is sufficient to indicate the stoichiometric composition. In this case only one of the constituents needs to be added to the mixture, as was done in the investigation of the copper cyanide complexes (1).

The investigation herein reported was made simply for the purpose of further testing the applicability of the incremental method, and sodium molybdate and molybdenum trioxide were chosen, because they both melt at a high temperature but still within the range of the calorimetric equipment (sodium molybdate,  $687^\circ\text{C}$  and molybdenum trioxide,  $795^\circ\text{C}$ ).

### Experimental

The equipment and technique used were the same as those described in the previous publication (2). The experiments were run at about  $800^\circ\text{C}$ . The increment of sodium molybdate or molybdenum trioxide was contained in a fused silica ampoule which was held in a platinum stirring device immersed in the molten mixture. The ampoule was broken by a tungsten rod while the stirrer was in motion, and the reaction was complete in about 15 sec. The temperature rise was measured with three chromel-alumel thermocouples in series attached to a recorder having a  $100\ \mu\text{v}$  range. The heat capacity of the calorimeter was determined electrically. The tungsten rod used for breaking the silica ampoule was slightly attacked by the mixture. The mixture had a dark color in the molten condition.

### Results

The partial molal heat effects are shown in Fig. 1 by curves 1 and 2. They cross at a point corresponding to a melt containing 66 m/o (mole per cent) of  $\text{MoO}_3$ , which indicates that only one complex is present at  $800^\circ\text{C}$  and that its composition is:  $\text{Na}_2\text{MoO}_4 \cdot 2\text{MoO}_3$ , or  $\text{Na}_2\text{O} \cdot 3\text{MoO}_3$ .

The phase diagram for  $\text{MoO}_3$  and  $\text{Na}_2\text{MoO}_4$  (3) shows very definitely the phase  $\text{Na}_2\text{O} \cdot 2\text{MoO}_3$  melting at  $612^\circ\text{C}$  and the scarcely discernible, incongruently melting compounds  $\text{Na}_2\text{O} \cdot 3\text{MoO}_3$  (melting point  $528^\circ\text{C}$ ) and  $\text{Na}_2\text{O} \cdot 4\text{MoO}_3$  (melting point  $515^\circ\text{C}$ ). The composition of the melt at  $800^\circ\text{C}$ , as shown by the calorimetric method, thus differs from that at  $600^\circ\text{C}$ . Morris, Cook, Sykes, and Templeman (4) measured the densities, molal volumes, and electrical conductivities of the molten mixtures at temperatures above

Fig. 1. Partial molal heat effects produced by the addition of increments of  $\text{Na}_2\text{MoO}_4$  and of  $\text{MoO}_3$  to fused mixtures of the compounds at approximately  $800^\circ\text{C}$ . Curves 1 and 2 are based on experimental results; curves 3 and 4 are calculated on the basis that  $K = 1.0$ , and curves 5 and 6 are calculated on the basis that  $K = 0.01$  for the reaction:  $\text{Na}_2\text{MoO}_4 + 2\text{MoO}_3 \rightleftharpoons \text{Na}_2\text{O} \cdot 3\text{MoO}_3$ . Curves 1, 3, and 5 represent increments of  $\text{MoO}_3$ , and curves 2, 4, and 6 represent increments of  $\text{Na}_2\text{MoO}_4$ .

$800^\circ\text{C}$ . Their data, however, do not indicate the existence of a complex.

### Calculations of the Instability Constant

The instability constant is readily calculated from the value of the partial molal heat effect ( $\Delta H = 4.8$  kcal/mole) at the point of intersection of the curves at the stoichiometric point. The largest value of  $\Delta H$ , at the right-hand end of curve 2, for increments of sodium molybdate is 31.3 kcal/mole, and it will be designated as  $\theta$ . If we assume that the increment of sodium molybdate completely reacts when added to pure  $\text{MoO}_3$ , then  $\theta$  is approximately the heat of reaction for the formation of 1 mole of complex, according to the equation

The ratio,  $\Delta H/\theta$ , represents the fraction of a mole of complex that would be formed if a mole of either  $\text{MoO}_3$  or  $\text{Na}_2\text{MoO}_4$  were to be added to an infinite amount of a mixture. This ratio can also be represented by a partial differential. If  $x$  and  $y$  represent, respectively, the moles of  $\text{MoO}_3$  and  $\text{Na}_2\text{MoO}_4$  used in preparing a given mixture and  $\bar{a}$  represents the moles of complex present in this mixture at equilibrium, then

$$\frac{\Delta H_x}{\theta} = \frac{\partial \bar{a}}{\partial x} = \bar{a}'_x \quad \text{and} \quad \frac{\Delta H_y}{\theta} = \frac{\partial \bar{a}}{\partial y} = \bar{a}'_y$$

At the point of intersection,  $\bar{a}'_x = \bar{a}'_y = \bar{a}'$ .

The equation for calculating  $K$  from  $\bar{a}'$  is

$$K = \frac{4(1 - 3\bar{a}')^3}{3\bar{a}'[3(1 - 2\bar{a}')]^2} \quad \bar{a}' = \frac{4,800}{31,300} = 0.15 \quad [1]$$

This equation is obtained from Eq. 33 of (1), and it gives  $K = 0.33$ . If the calculation were based on the value of  $\Delta H$  at the left side of the curve, then  $\theta = 2 \times 10,600$  kcal and  $\bar{a}' = 4,800/21,200 = 0.23$ . This gives a value of  $K = 0.07$ .

The instability constant can also be obtained from the slope of the curves at the stoichiometric point. A sample calculation is made for curve 1 for  $\text{MoO}_3$ . The quantity required for calculation is  $\bar{a}''_x$ , the second

derivative of the moles of complex,  $\bar{a}$ , formed with respect to  $x$ , moles of  $\text{MoO}_3$

$$\bar{a}''_x = \frac{\partial \bar{a}'_x}{\partial x} = \frac{\frac{\partial}{\partial \theta} \frac{\Delta H_x}{\theta}}{\frac{\partial x}{\partial \theta}} = \frac{1}{\theta} \cdot \frac{\partial \Delta H_x}{\partial x} \quad [2]$$

Since the abscissa represent mole fraction,  $f$ , the slope of the curve is  $(\partial \Delta H_x)/(\partial f)$ , and it must be multiplied by

$$\frac{\partial f}{\partial x} = \frac{y}{(x+y)^2}$$

to give  $(\partial \Delta H_x)/(\partial x)$  (1).

The equation for calculation is

$$K = \frac{2\bar{a}' - 1}{2\bar{a}'} \cdot \left( \frac{\bar{a}'}{3\bar{a}''_x} \right)^3 \quad [3]$$

This equation is derived from Eq. 37 of ref. (1). The slope of the curve,  $(\partial \Delta H_x)/(\partial f)$ , at the stoichiometric point is  $-14.7$  kcal/mole, and  $(\partial \Delta H_x)/(\partial x) = -14.7 \cdot y/(x+y)^2 = -14.7/9 = -1.63$ , if for ease of calculation we let  $y = 1$  and  $x = 2$  at the stoichiometric point. From Eq. [2],  $\bar{a}''_x = \frac{1}{\theta} \cdot \frac{\partial \Delta H_x}{\partial x} = \frac{-1.63}{31.3} = -0.052$

Substitution of  $-0.052$  for  $\bar{a}''_x$  and  $0.15$  for  $\bar{a}'_x$  in Eq. [3], gives

$$K = 2.0$$

A similar calculation can be made for curve 2, which requires finding  $\bar{a}''_y$ . The slope of the curve,  $\partial H/\partial f = 24.7$  kcal/mole.

$$\frac{\partial \Delta H}{\partial y} = \frac{\partial \Delta H}{\partial f} \cdot \frac{\partial f}{\partial y} = \frac{\partial \Delta H}{\partial f} \cdot \frac{-x}{(x+y)^2} = (24.7) \cdot \frac{-2}{9} = -5.5, \text{ if } x = 2 \text{ and } y = 1$$

$$\bar{a}''_y = \frac{1}{\theta} \cdot \frac{\partial \Delta H}{\partial y} = \frac{-5.5}{31.3} = -0.176$$

The formula for computing  $K$  is obtained from Eq. 37 of ref. (1) by interchanging the coefficients for  $x$  and  $y$  in the chemical equation

$$K = \frac{32 \cdot (2\bar{a}' - 1)}{\bar{a}'} \left( \frac{\bar{a}'}{3\bar{a}''_y} \right)^3 = 3.4$$

The values of  $K$  calculated from the slope of the curves do not agree closely with the values of 0.33 and 0.07 calculated from the ordinate of the intersection of the curves. An approximate value of  $K = 1.0$  will be used in the following discussions.

An estimate of the degree of dissociation can be obtained by calculating the heat effect produced by the addition of sufficient components to an infinite amount of mixture of the stoichiometric composition to form one mole of complex. One mole of  $\text{Na}_2\text{MoO}_4$  and two moles of  $\text{MoO}_3$  would have to be added. Since each mole forms 0.15 moles of complex in the stoichiometric mixture the total amount of complex formed would be 0.45 mole. Hence, the complex is 55% dissociated at the stoichiometric point.

According to the derivation given in (1), the values of  $\bar{a}''_x$  and  $\bar{a}''_y$  derived from the slopes of the curves at the stoichiometric point should be inversely proportional to the square of the coefficients of A and B in the balanced equation of their reaction

$$\frac{\bar{a}''_y}{\bar{a}''_x} = \frac{2^2}{1^2} = 4$$

The value of  $\bar{a}''_x$  for the  $\text{MoO}_3$  curve, 1, was  $-0.052$ . The value of  $\bar{a}''_y$  for the  $\text{Na}_2\text{MoO}_4$  curve, 2, was  $-0.176$ . The ratio is 3.4 instead of the theoretical value of 4.

## Discussion

Part of the difficulty in calculating the instability constant comes from the uncertainty in the value of  $\bar{a}'$ , which is determined from the ratio of  $\Delta H$  at the stoichiometric point to the largest value,  $\theta$ . The latter value is not known very exactly when the instability constant is large, for example, near unity. For systems having an instability constant smaller than  $10^{-3}$ , the  $\Delta H$  produced by adding an increment of A to pure B and *vice versa*, should be close to the heat of complete reaction (or a simple fraction of it). In the present example, the  $\Delta H$  for adding an increment of pure  $\text{Na}_2\text{MoO}_4$  to molten  $\text{MoO}_3$  would be the heat of reaction for the formation of a mole of complex (if  $K$  were small), and the  $\Delta H$  obtained by adding  $\text{MoO}_3$  to pure  $\text{Na}_2\text{MoO}_4$  would be exactly half, since only  $1/2$  mole of the complex would be formed per mole of  $\text{MoO}_3$ . However, the ratio between the two partial molal heat effects is very nearly 3 instead of 2. The application of the law of mass action teaches that a reaction is driven toward completion by the presence of an excess of one of the reactants. *A priori*, it might be supposed that a small increment of one reactant added to an infinite quantity of the other would react completely to form the complex. However, that is not generally true, and it was shown in the previous publication (2) that the fraction of conversion of a reactant, A, approaches the limit of  $1/K + 1$ , if one molecule of A is involved in the chemical equation. If  $K = 1$ , as in the  $\text{MoO}_3 - \text{Na}_2\text{MoO}_4$  system, then the largest fraction of conversion of an increment of  $\text{Na}_2\text{MoO}_4$  would be only one-half.

The limit,  $1/K + 1$ , can be derived directly from the expression for the mass action law in terms of mole fraction

$$K = \frac{\left( \frac{y-\bar{a}}{x+y-n\bar{a}} \right) \cdot \left( \frac{x-n\bar{a}}{x+y-n\bar{a}} \right)^n}{\left( \frac{\bar{a}}{x+y-n\bar{a}} \right)} \quad [4]$$

where  $x$  and  $y$  are the moles of reactants initially used to form the mixture and  $\bar{a}$  is the moles of product formed. We seek the value of the ratio  $\bar{a}/y$  as  $y$  and  $\bar{a}$  approach zero, but  $x$  remains appreciable, for example, 1 mole.

$$\frac{(y-\bar{a})}{\bar{a}} = \frac{K(x+y-n\bar{a})^n}{(x-n\bar{a})^n} \quad [5]$$

The limit of this, as  $\bar{a}$  and  $y$  approach zero is

$$\frac{y-\bar{a}}{\bar{a}} = K, \text{ and } \frac{\bar{a}}{y} = \frac{1}{K+1} \quad [6]$$

On the other hand, the limit is different for the reactant, B, which is raised to a power in the mass action equation. In this case, we seek the limit of  $\bar{a}/x$  as  $x$  and  $\bar{a}$  approach zero while  $y$  is held at an appreciable value, such as 1 mole.

Equation [4] may be put in the form

$$\left( \frac{x-n\bar{a}}{x+y-n\bar{a}} \right)^n = \frac{K\bar{a}}{y-\bar{a}}$$

If  $\bar{a}$  and  $x$  are small compared to  $y$ , this reduces to

$$\left( \frac{x-n\bar{a}}{y} \right)^n = \frac{\bar{a}K}{y}$$

$$x = \sqrt[n]{\bar{a}Ky^{n-1} + n\bar{a}}$$

$$\frac{\bar{a}}{x} = \frac{\bar{a}}{\sqrt[n]{\bar{a}Ky^{n-1} + n\bar{a}}}$$

where  $Z$  represents the other multipliers.

$$\frac{\bar{a}}{x} = \frac{1}{Za^{(1-n)/n} + n}$$

As  $\bar{a}$  becomes smaller,  $\bar{a}^{(1-n)/n}$  becomes larger. This is because  $n = 2$  or more and the exponent is negative. Thus, the right side of the equation approaches zero as  $\bar{a}$  becomes smaller and  $\bar{a}/x$  approaches zero.

In Fig. 1, curves 3 and 4 were computed from the law of mass action for the reaction:  $A + 2B \rightarrow C$ , with  $K = 1$  and curves 5 and 6 were computed for  $K = 0.01$ . The ordinates are  $\bar{a}'_x$  and  $\bar{a}'_y x$ . It will be noted that the ordinate of curve 4 approaches the value of  $0.5 = 1/1+1$  whereas, the ordinate of curve 6 approaches the limit of  $0.99 = 1/0.01+1$ . On the basis of curves 3 and 4, the complex would be 75% dissociated at the stoichiometric point.

The limits of curves 3 and 5 approach zero. This prediction of the law of mass action was not verified by the data (curve 1) which we obtained. The authors have no explanation for this discrepancy, but suggest the following two possibilities: that the mass action expression does not hold in an environment consisting of essentially only one of the components, or that a simpler complex, for example,  $\text{Na}_2\text{MoO}_4 \cdot \text{MoO}_3$ , may be formed.

The scale of the ordinate for curves 3 and 4 was chosen so that the curves would intersect at about the same point as the experimental curves. The agreement between the two sets of curves is satisfactory. It may be noted that the ratio of the maximum ordinates for the calculated curves 3 and 4 is about 3, and this matches the ratio obtained experimentally.

### Summary

The calorimetric method of determining the composition of complexes and their instability constants is simple. If only one complex is present, the determination of its composition involves only finding that composition of the mixture of the two constituents, A and B, which gives the same heat effect with small, equimolar additions of A and B. For determining the instability constant, the only other measurement required is the maximum heat effect resulting from the addition of a small sample of A to pure B, or *vice versa*. The ratio of the heat effect at the stoichiometric composition to the maximum heat effect is essentially all that needs to be used in the calculation of the instability constant.

In this and the preceding two papers, we have shown that the calorimetric method gives results even for

systems that are considerably dissociated. This method is of general application, and we are of the opinion that it will yield useful results where other methods are inapplicable or fail. Therefore, we believe that the method warrants further investigation and use.

### APPENDIX

The formulas used for computing curves 3 to 6 are as follows: (They are obtained from Eq. 30 or 31 of reference 1.) Equation 4 is the basic equation.

$$\bar{a}'_x = \frac{\beta}{1+2\beta} \quad [7]$$

$$\bar{a}'_y = \frac{\bar{a}(2\beta+1) - \beta x}{y(2\beta+1)} \quad [8]$$

and

$$\beta = \frac{2\bar{a}^2 K(x+y-2\bar{a})}{(x-2\bar{a})^3} = \frac{2a(y-\bar{a})}{(x-2\bar{a})(x+y-2\bar{a})} \quad [9]$$

The computations are simplified if  $y$  is allowed to have the constant value of unity,  $\bar{a}$  is given various values, and  $x$  is calculated from the equation:

$$x = 2\bar{a} - \frac{y}{1 - \sqrt{\frac{y}{ak} - \frac{1}{k}}} \quad [10]$$

The abscissa is the mole fraction:  $\frac{x}{x+y} = \frac{x}{x+1}$ .

## Digital Computer Treatment of Electrocapillary Data

David M. Mohilner\* and Patricia R. Mohilner

Department of Chemistry, Colorado State University, Fort Collins, Colorado

### ABSTRACT

A digital computer method for the thermodynamic analysis of electrocapillary data has been developed based on least-squares parabolic smoothing and exact cubic fitting of a segment moving along a curve. The accuracy of integration is comparable to that of graphical methods while the accuracy of differentiation is increased to approach that of integration. The speed provided by computer analysis permits continuous monitoring of experimental data without the time-lag associated with graphical techniques.

In the past the thermodynamic analysis of double layer data has involved a tedious, graphical procedure requiring substantially more time than the measurements themselves. Although graphical integration,

used in some parts of the analysis of differential capacitance measurements, can be performed with reasonable accuracy, graphical differentiation, required in any analysis of data from a capillary electrometer as well as in determining surface excesses from dif-

\* Electrochemical Society Active Member.

ferential capacitance measurements, is inherently inaccurate and leads to serious questions in the interpretation of experimental results. In order to provide rapid and accurate assessments of data obtained in electrocapillary and differential capacitance experiments, a series of computer programs have been developed to carry out the thermodynamic analysis digitally without recourse to any graphical techniques.

The resulting computational procedures provide, in addition to vastly increased speed and significant gains in accuracy, a new concept in double layer studies, namely, the ability to operate a meaningful monitor of the electrocapillary data as it is being collected.

In this paper we report on the basic ideas involved in the computer analysis of electrocapillary data with especial reference to the differentiation technique.

Related computational techniques have been reported by Parsons and Zobel (1) and Butler (2) for the integration of differential capacitance curves and by Staicopoulos (3) and Butler (4) for the calculation of interfacial tension from sessile drop measurements. Savitsky and Golay (5) have considered the problems of computer differentiation and smoothing with particular reference to chromatographic data. Recently Parsons (6) and Barradas (7) investigated the problems of differentiation of double layer data by computer techniques.

#### Computational Procedure

All programs have been written in the FORTRAN language. The basic developmental work was done on an IBM 1620 computer while additional work employed IBM 7094 and Control Data Corporation 6400 computers. Graphs were prepared using a Calcomp plotter on-line with an IBM 1620. To prevent serious cumulation of errors, 16 digit precision was used on the 1620 and double precision on the 7094, while normal (14-15 digit) precision was sufficient on the CDC 6400 computer.

#### Sequence of Data Processing

The series of steps required for the thermodynamic analysis of measurements made by capillary electrometer have been applied to the particular case of the adsorption of neutral organic compounds at the mercury-solution interface. The input data include calibration constants and manometer reading—electrode potential pairs for a set of solutions of constant chemical potential (or concentration) of supporting electrolyte and varying chemical potential of organic solute. Digital computation is then utilized to calculate the interfacial tension for each electrode potential at each chemical potential of organic solute, smooth the experimental interfacial tension as a function of both electrode potential and chemical potential of the organic solute, calculate the surface pressure at constant electrode potential,  $\pi$ , and generate the desired partial derivatives of the double layer parameters. The first derivatives of the interfacial tension,  $\gamma$ , give rise to the charge density on the metal,  $q^M$ , and the relative surface excess of the organic solute in the double layer,  $\Gamma_o$ .

$$q^M = - \left( \frac{\partial \gamma}{\partial E^\pm} \right)_{T,p,\mu} \quad [1]$$

$$\Gamma_o = - \left( \frac{\partial \gamma}{\partial \mu_o} \right)_{T,p,\mu',E^\pm} \quad [2]$$

where  $E^\pm$  is the potential of the ideal polarized electrode with respect to an indicator electrode reversible to one of the ions in solution (8),  $\mu_o$  is the chemical potential of the organic solute, the subscripts  $T$ ,  $p$ , and  $\mu$  imply that the temperature, pressure, and composition are held constant while the subscripts  $T$ ,  $p$ ,  $\mu'$ , and  $E^\pm$  imply that temperature, pressure, composition except for the organic solute, and electrode potential are held constant.

A second stage of differentiation, which necessarily includes cumulated errors, may be applied to deter-

mine various cross partial differential coefficients such as the Esin and Markov coefficient,  $(\partial E / \partial \mu_o)_{T,p,q^M,\mu'}$ , or the coefficient which is thermodynamically equal, but opposite in sign,  $(\partial \Gamma / \partial q^M)_{T,p,\mu}$ . These coefficients require that the potential and relative surface excess values be known on the basis of constant charge density on the metal rather than the electrode potential basis provided in the experimental data. Programs have been written to carry out this change in independent electrical variable by digital computation. As a part of the change-of-variable programs, the values of Parsons' auxiliary variable  $\xi$  (9) and of the surface pressure at constant charge density,  $\Phi$ , are also calculated.

#### Differentiation Technique

The method of digital differentiation developed here differs from other systems (5-7) in two significant ways: (a) no attempt is made to fit the entire electrocapillary curve with a higher order polynomial, and (b) there is no restriction on the spacing of potentials or concentrations. Although the exact analytical equation of an electrocapillary curve is not known, it is possible to fit a sufficiently small interval of the curve by a quadratic or cubic equation to a very good approximation. The differentiation technique, then, is based on fitting a moving four-point interval of any curve with an exact cubic equation, as illustrated in Fig. 1 for an enlarged portion of a hypothetical electrocapillary curve. Since the slope of this cubic will best represent the actual data in the central part of the interval, the derivative is calculated from the coefficients  $a$ ,  $b$ ,  $c$ , and  $d$  of this one cubic equation only for the second point of the interval according to

$$q^M = -0.1 (3aE^2 + 2bE + c) \quad [3]$$

where the factor 0.1 arises to give  $q^M$  in microcoulombs/cm<sup>2</sup> when  $\gamma$  is in dynes/cm and  $E$  in volts. To obtain the charge density at the next point, the interval is moved one point along the curve by dropping the first point and adding the next, and the coefficients  $a$ ,  $b$ ,  $c$ , and  $d$  of this new cubic equation are calculated. Thus, with the exception of the leftmost and two rightmost points on any curve, all derivatives are calculated from different cubic fittings of the experimental data. The key subroutines for cubic fitting and calculation of charge density are included in the Appendix.

#### Smoothing and Plotting

The technique of differentiation used here is quite sensitive to experimental errors in the values of interfacial tension. Successful smoothing has been obtained by applying least squares parabolic fitting to moving segments of the electrocapillary curve and calculating the smoothed point only at an internal point in the interval. A discussion of several ways in which moving segments may be selected from a curve is included in the Appendix.

Since the normal tabulated output of digital computation fails to convey a picture of the data as clearly as graphical representation, programs have been developed to utilize a high-speed plotter in conjunction

Fig. 1. Schematic drawing of hypothetical electrocapillary curve showing segment used for fitting and the internal point in that segment at which actual calculation is performed.

Fig. 2

with the computer to provide a more readily grasped presentation of the results of computations.<sup>1</sup>

### Results and Discussion

As a critical test of the validity of the differentiation technique, differential capacitance data were regenerated from Grahame's charge density calculations for 0.1N KCl (10). The points in Fig. 2 are the original differential capacitance measurements and the curve is the computer-calculated differential capacitance using Grahame's integrated data as input to a computer differentiation program. The median error for the computer calculations was 4 parts per thousand. From this example, it can be seen that accurate differentiation of electrocapillary data can be accomplished provided the input data are good.

The computer calculation of charge density from interfacial tension is illustrated in Fig. 3. The small

<sup>1</sup> The Calcomp plotter used in this work actually plots by connecting points by straight line segments. To produce reasonable rounded curves, interpolated points are calculated by moving cubic fittings to provide additional points which the plotter connects by shorter straight line segments.

inflection in the region,  $-0.23$  to  $-0.25$ v, might be ascribed to a property of the electrochemical system, but it is more likely an artifact due to experimental error. When these data were collected (1954), high-speed digital analysis of electrocapillary curves was unavailable, and graphical analyses could not usually be completed in time to permit ready experimental verification of suspect points. The computer techniques described in this paper make it possible for the experimenter to obtain such a charge density curve from raw electrocapillary data within minutes after the measurements are completed.<sup>2</sup> Thus, it is now feasible to use a computer as a continuous monitor of the experimental measurements. Suspect points can thus be located in time to be checked experimentally on the same solution with the same apparatus.

### Computation Time

The speed of digital computation, coupled with the accuracy indicated by Fig. 2, will not only make the experimental work itself the time-limiting factor in electrical double layer studies, but will also, and more significantly, permit much more complete analysis of electrocapillary data. For example, both the Esin and Markov coefficient and its negative, which may be calculated from the relative surface excess and charge density data, may be computed independently to test the internal consistency of the data. Additional cross-partial differential coefficients inherent in the electrocapillary equation may also be calculated as the quality and quantity of experimental data warrant.

As a result of the increased speed and accuracy of thermodynamic analysis it is reasonable to expect fuller exploitation of electrocapillary data, including critical tests of nonthermodynamic relationships such as the Gouy-Chapman-Stern (GCS) theory of the diffuse layer. A program (GCS1) based on the moving cubic fit principle has been written to calculate surface excesses and charge densities for mixed electrolyte solutions of arbitrary composition.

### Experimental Implications

The most striking result of this computer study of electrocapillarity is illustrated in Fig. 4-7. (The straight line segments are apparent in these computer

<sup>2</sup> Naturally the "turn-around" time of the particular computation facility determines the time lag between recording data and obtaining results. The ideal situation would be to have available in the laboratory a remote terminal of a time-sharing computer. Typical turn-around time on the Colorado State University CDC 6400 time-sharing computer without remote terminal is 30 min.

Fig. 4

Fig. 5

Fig. 7

Fig. 6

produced graphs because interpolated data were not used).

These data pertain to the adsorption of pyridine on mercury (12, 13) from 1N KCl. The points in Fig. 4 and 5 are derived from the original interfacial tension measurements by smoothing as a function of electrode potential. The curves connect the corresponding points obtained by two different techniques of smoothing the interfacial tension as a function of the logarithm of the pyridine concentration. In Fig. 4 a moving least-squares parabola was applied to four-point intervals, while in Fig. 5 a single least-squares parabola was used for each complete curve. The curves of Fig. 5 are probably closer to those which would be drawn by the conventional "eyeball" technique. The data smoothed by each procedure were differentiated to produce the relative surface excesses shown in Fig. 6 and 7, respectively. The maximum shown in Fig. 6 would imply a most peculiar behavior of the system, if it were real. The straight lines of Fig. 7 would fit more comfortably into the usual concepts of adsorptive behavior at the metal-solution interface. In fact, these straight lines

have no theoretical significance because they are a necessary mathematical consequence of fitting the entire interfacial tension curve with a parabola and then differentiating it.

The hitherto unnoticed consequence of this analysis of reputable data is that the method of smoothing exerts profound influence on the appearance of the adsorption isotherms. In graphical smoothing, no attempt is usually made to assess the effect of a curve drawn in a slightly different manner so that this effect passed unobserved.

Computer analysis makes it apparent that a decision about the best method of smoothing required more points to be available for the analysis. For meaningful consideration of adsorption in the electrical double layer it is essential to examine data for a large number of concentrations closely spaced along the axis of the logarithm of activity. The number of concentrations to be used should be comparable to the number of potentials now measured for an individual electrocapillary curve.

Until experimental data for systems obtained at closely spaced concentration intervals are available, little can be said about the validity of present reports of relative surface excess data. The reported 10% differences in such values obtained by independent workers in the same laboratory (14), however, can be readily understood in terms of the inaccuracy of graphical differentiation.

#### Differential Capacitance

Computer integration of differential capacitance to obtain charge density by means of the moving cubic fit has been tested using Grahame's differential capacitance data (10) as computer input, and the results are shown in Fig. 8 where the points are the values reported by Grahame and the curve connects the output points from the computer integration. The median error for the computer calculations was less than one part per thousand. In this phase of data analysis the contribution of the computer is speed since graphical integration is recognized as accurate. Applications for the computer in treating differential capacitance measurements in conjunction with the coordinates of the electrocapillary maximum are being developed, since the calculation of relative surface excesses from such data amounts to the analysis of an electrocapillary curve which has been obtained by double integration of the differential capacitance curve. Digital computation can make a significant contribution to the inter-

Fig. 8

comparison of capillary electrometer and differential capacitance measurements, an area of current concern (15).

#### Acknowledgment

The authors wish to express their appreciation to Professor R. G. Barradas of the University of Toronto for making available original experimental electrocapillary data to use in "debugging" the programs. The authors thank the Computer Center of Colorado State University and the Western Data Processing Center for making facilities available. This work was supported by Faculty Research Grants Nos. 311 and 524, Colorado State University.

Manuscript received April 19, 1967; revised manuscript received Oct. 16, 1967. This paper was presented at the Cleveland Meeting, May 1-6, 1966, as Abstract 169.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

#### APPENDIX

The key subroutine, CUBFIT, for calculating the coefficients for each individual cubic equation is presented in Table I. Programs available on request to the authors are described in Table II. Illustrative of differentiation procedures is the subroutine QCAL, to calculate the charge density on the metal, presented in Table III.

Several versions of smoothing programs have been prepared, and work is in progress to determine rational criteria for the concept of "best" smoothing. The routines which have been developed to date are all based on applying a least-squares parabola to segments of the data. The differences in these routines arise in the selection of the segments to be used for any one parabola. The techniques are: (a) calculating one internal point from each least squares parabola obtained for a moving four-point segment, (b) calculating internal points from least squares parabolas based on segments selected by the experimenter who supplies coded designations of the starting point of each interval as input to the program, (c) performing the fitting in (a), testing the curvature of the parabola, and either computing an internal point or extending the interval to five or more points until the curvature is correct, (d) performing the fitting in (a), extending the interval one point at a time until, for each successive fitting, the sum of the squares of the differences between experimental and fitted points fails to decrease.

Preliminary comparisons of differing smoothing techniques did not reveal striking differences in charge density data as a result of the choice of smoothing

## Selective Electroreduction of the Benzene Nucleus

Akira Misono, Tetsuo Osa, Takamichi Yamagishi, and Teruyuki Kodama

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo, Japan

During recent years many studies concerning the electroreduction of aromatic hydrocarbons have been reported (1), but the substrates examined were those with a more anodic reduction potential than benzene. The reduction potential of benzene has been estimated to be about 1v more negative than that of naphthalene from the difference between the electron affinities of the two compounds (2). The polarographic study of electroreduction of benzene has not yet been achieved because solvents, such as acetonitrile, N,N-dimethylformamide or dioxane-water, suitable for the reduction of naphthalene, are decomposed or reduced prior to the reduction of benzene at the potential where the benzene ring may be reduced.

It is well known that alkali metals in liquid ammonia or in low molecular weight amines reduce the benzene nucleus giving dihydro- or tetrahydroproducts (3). Sternberg (4, 5) and Benkeser (6) have reported the reduction of the benzene nucleus by the electrolytic reduction in a solution of ethylenediamine or ethylamine saturated with lithium chloride. Sternberg has also reported the electroreduction of the benzene nucleus in ethanol-hexamethylphosphoramide mixture containing 0.3M lithium chloride (7).

We have been interested in the electroreduction of the benzene nucleus under controlled potential conditions. We have examined the possibility of the above

reaction using many solvents and supporting electrolytes which are supposed to be fairly stable at the potential required to reduce the benzene nucleus, and have obtained unconjugated dienes in good yields in a system of diglyme-water-tetra-n-butylammonium bromide. The cell used was a cylindrical one with a glass filter to separate the catholyte and anolyte. Mercury and platinum were used as cathode and anode, respectively. To a 80 ml solution of diglyme and water was added 12g of tetra-n-butylammonium bromide. The catholyte was prepared by dissolving the substrate (benzene or toluene) in this solution. The anolyte was the solution prepared above. The cathode potential during electrolysis was  $-3.3v$  vs. SCE as indicated in Table I. The cell was constantly cooled by a water bath to keep the temperature at about  $25^{\circ}$ - $30^{\circ}C$ . In the reduction of benzene, the main reduction product was 1,4-dihydrobenzene, and in the case of toluene 2,5-dihydrotoluene was formed predominantly. 1,4-Dihydrobenzene and 2,5-dihydrotoluene were isolated by preparative gas chromatography and identified by IR and NMR absorption spectra (in the NMR spectra, 1,4-dihydrobenzene has absorptions at  $\tau = 7.45$  and  $4.40$  whereas 2,5-dihydrotoluene at  $\tau = 8.35, 7.46, 4.54,$  and  $4.25$ ). The quantitative analyses of the products were performed by the gas chromatographic method. The yield of cyclohexene was small, and 1,2-dihydro-

The last column means the molar percentage of the unconjugated dienes in the monomeric reduction products, and these values nearly represent the selectivity for the formation of the unconjugated dienes.

benzene was either absent or present only in trace amounts. In the case of toluene, three types of tetrahydrotoluene were formed in small amounts, but neither 1,4-dihydrotoluene nor conjugated dienes was observed. Results are summarized in Table I.  $\eta_{1,4DH}$  represents the current efficiency for the formation of unconjugated dienes and  $\eta_{TH}$ , for tetrahydroproducts. In the cases examined, the selectivity for the formation of 1,4-dihydrobenzene or 2,5-dihydrotoluene was higher than that reported by Sternberg who performed the reduction by using lithium chloride in the ethylenediamine solution (4). During electrolysis, bromine formed at the anode diffused through the glass filter to the catholyte thus lowering the current efficiencies. In order to raise the current efficiency, an ion exchange membrane may be used in place of the glass filter so as to prevent the diffusion of bromine to the catholyte.

The electroreduction of the benzene nucleus in our system does not cause the isomerization of unconjugated dienes to conjugated dienes in contrast to the reduction by alkali metal in liquid ammonia or in amine. In the presence of substrate, the cathode potential was nearly the same as that in the absence of substrate at the same current density, and naphthalene was reduced at about 0.5v more anodic potential than that at which the benzene ring was reduced. Based on these results and previously published works (5, 7), we believe that the benzene ring may be reduced by solvated electrons. Detailed results and discussion of

the electroreduction of the benzene ring in this system will be reported in the near future.

Manuscript received June 12, 1967; revised manuscript received Nov. 8, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Contact Electrification of Insulators and Its Relevance to Electrets

D. K. Donald

Research Laboratories, Xerox Corporation, Rochester, New York

## ABSTRACT

Surface charge densities on electrets are frequently measured by means of electrodes which can be lifted from the insulator surface; however, electrification of the surface can occur as a result of this contact between electrode and insulator, and this can be a source of difficulty in interpreting the results. In these experiments, measurements have been made on the contact electrification of paraffin, polystyrene, and polyethylene, among other materials, using mercury as the electrode. In these cases it is found that the contact charge exchange decreases with decreasing contamination of the insulator. Under controlled conditions, equilibrium surface charge densities as low as  $0.003 \text{ nC/cm}^2$  have been observed for paraffin. When the contact event produces both high electric fields and also high local surface potentials, the surface charge causes electrical breakdown during the separation of insulator and electrode. We find that it is useful to "develop" the resulting electrostatic charge distribution by xerographic means. The resultant charge distribution frequently shows the gross patchy structure of Lichtenberg figures previously reported for high voltage discharges to insulators in air.

Studies of contact electrification and of electrets have proceeded separately for some time. It is not clear, however, why they should be handled as two distinct areas of investigation because there are in fact strong similarities in the two areas. Both electret and contact electrification studies usually use very high resistivity materials with long dielectric relaxation times. Therefore it is easy for one in the electret field to see that samples used for contact electrification can be strongly disturbed by frozen-in impurities like those sometimes found in electrets. What can equally well occur in lifted electrode, electret experiments is spontaneous contact-electrification charge on the surface of samples. The discussion that follows centers around these "cross terms" between the two areas.

Lifted electrode experiments (1) are a common tool in observing electrets, but they are also a particular case of contact electrification. Usually the contact is highly patchy between the electrode and the electret. In order to study a better defined contact we have done lifted electrode experiments using liquid mercury as a highly compliant metallic contact. These contacts are without any applied field (in Fig. 1,  $V_B = 0$ ). Nevertheless, surface charge densities above  $16 \text{ nC/cm}^2$  have been recorded on samples of Carnauba wax and  $50 \text{ nC/cm}^2$  recorded on Mylar. The initial charge density may have been higher but in both cases electrical breakdown frequently occurred during contact separation and made the charge non-uniform. At the other extreme we have seen contact charge densities  $< 0.01 \text{ nC/cm}^2$  for other materials.

## Experimental Apparatus

The experimental arrangement uses a mercury bead (2) on a nickel or stainless steel pedestal and a flat insulator sample as a pair forming a triboelectric couple or a contact-electrification couple. The polymer sample is brought near to or contacted with the mercury using a micromanipulator. When the sample and mercury are contacted charge exchange occurs between the sample surface and the mercury. Thus later when the electrode is lifted this charge is observed by the electrometer. Still later the portion of charge which has not leaked away over the insulator is again observed in the electrometer's deflection when the electrode is returned into contact with the sample. For good insulators the charge on lifting and the charge on reconnecting the electrode is the same.

Key words: Contact electricity, Triboelectricity, Electrets, Dielectric phenomena gas breakdown.

For good insulators where the charge decays slowly the surface potential is used as a check on the surface charge density. When the sample and mercury are near one another a bias battery  $V_B$  (Fig. 1) can be used to null the electric field produced between the surface potential  $V_s$  on the polymer sample and the contact potential of the mercury. This method is commonly used in observing work-function differences between metals (3).

For surface potential measurements, the Model 31-V Cary electrometer was used without shunt capacitance ( $C_m$ ) at high sensitivity. A large shunt capacitance ( $C_m = 10^{-9} \text{ F}$ ) was added to the instrument when contact charge was measured.

Both the surface of the mercury and that of the insulator were important in these experiments. The mercury was reagent grade material and either freshly dispensed or aged for several hours in the ambient. By aging the mercury in the ambient the mercury's work-function is shifted, and thereby the character of contact events could be studied in two situations. While we could not control or predict the work-function of the mercury, we could look for differences in contact potential for the mercury in one case *vs.* the other. Polymer samples were also subjected to different surface treatments. The polymer samples were melted in air, "cleaved" with a razor blade or microtome, and were rinsed with solvents. The gas ambients used were laboratory air, dried or moisture-saturated air, argon, and  $\text{CO}_2$  from dry ice. Rough pump vacuum conditions have also been used in the experiments.

The second experimental tool was a special xerographic developer akin to Villarsy's mixture (1788)

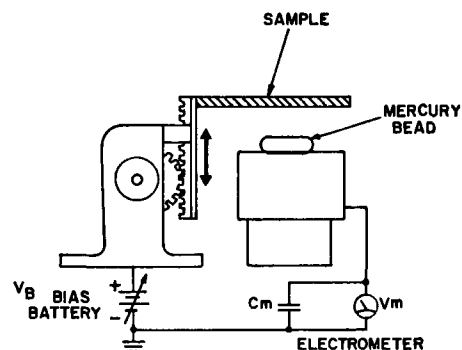

Fig. 1. Contact electrification scheme

Fig. 2. Charge separated by mercury from tetradecanal where the degree of mechanical separation is denoted by "X".

(4) used previously by Woodland and Ziegler (5) as a diagnostic scheme. The developer was dispensed from a "squeeze bottle" as a mixed-powder aerosol. Two Day Glo pigments<sup>1</sup> were used; one color portrays the positively charged areas and the other the negative areas. In this way patchiness could be clearly discerned in the charge patterns resulting from the contact events.

This patchiness indicates that a simple electrometer measurement of charge can be misleading. Indeed, only if the developer shows a uniformly charged spot can the electrometer's reading be taken at face value. On the other hand, highly structured contacts frequently occur. Lichtenberg figures are produced in the events at high levels of surface charge density, and these figures in themselves are a useful guide to the events which occur during contact separation.

### Observations

Figure 2 demonstrates the raw electrometer data for charge exchange in a particular run. The tetradecanol in this run shows contact or separation charging of about  $1/3$  nano-Coloumbs per event, but several other phenomena are evident from the figure as well. The figure shows a residual d-c potential of  $3/4$ v which remained on the tetradecanol after casting. This may be an electret effect produced in casting the film, but it exists on in spite of a conductivity. This conductivity is large enough to produce a dielectric relaxation time of about a minute and a half. With multiple contacts the electrometer shows a large cumulative offset, but as soon as the sample and mercury are left in contact the charge is dissipated in the conductivity of the sample.

With most of the experimental materials the resistivity was very high and a charge once established on a sample did not disappear. However, the charge was hidden from the electrometer when sample and mercury were reconnected, and this formed a convenient base line for the observations. In Fig. 3 the heavy line represents this in-contact state. The electrometer offset produced by separation is indicated schematically by the dots. Incidentally, when the bias battery was changed a corresponding offset occurred in the base line. Such offsets occur for Samples A and E of Fig. 3. Figure 3 also demonstrates how the treatment of the paraffin while it was liquid influenced the charge exchange of the dip-coated paraffin samples. For example, samples B and C in Fig. 3 were made while the liquid was aerated by stirring. These two samples exchanged more charge than the others in the figure, yet they came from the same container of paraffin. The container, incidentally, was of stainless steel, and deep enough to exclude random air from

<sup>1</sup> Every combination of pairs of the Switzer Brothers (Cleveland, Ohio) Day Glo® gave proper two-color images. A 1:1 mixture of lead chromate and xerox toner also worked well.

Fig. 3. Charge separated by mercury from cast paraffins: A, cast from initial melt; B, paddle aerated 5 min following A; C, paddle aerated  $1\frac{1}{2}$  hr following B; D, liquid quiescent in paraffin vapor 2 hr after C; E, liquid quiescent in paraffin vapor 16 hr after D.

the liquid's surface. When glass containers were used the contact charge was always at or above  $0.1$  nC/cm<sup>2</sup>. We blame sodium from the glass for this difference. Paraffin heated for long periods in open air or over-heated for short periods exchanged appreciable charge ( $\sim 1$  nC/cm<sup>2</sup>) with the mercury, but for these samples we also saw evidence of degradation in infrared spectra.

We examined numerous commercial products and films. Our polystyrene Petri dishes, for example, showed no overt charge of the kind reported by Woodland and Ziegler (5) for polystyrene wall tiles, but we could not exclude the possibility of heterocharge covered with counter charge, forming a double layer. Our surface treatments could have left a conducting film on the samples. This may have occurred, but it probably did not. First two-terminal conductivity measurements showed treated surfaces had surface resistivities at or above  $10^{14}$  ohms/square. Second, liquid gallium was contacted to freshly air-dried polystyrene. Charging occurred at many patchy spots on the oxidized gallium's surface and then this structured event was recorded xerographically. Any surface conductivity on the polystyrene must have been small, otherwise the structured charge from the gallium would have been washed out.

We attempted to avoid electret-like histories by preparing our own samples from a conducting state. We relied on the mobility in the liquid to remove gross charged impurities. Dissociated ion pairs were not extracted. In particular, paraffin, octacosane, tetradecanol, polystyrene, polyethylene and Carnauba wax were prepared as solid layers from the melt or extracted from solution and then observed. The range of surface charge densities encountered for several materials is listed in Table I. The lowest charge densities for the top four entries in Table I were associated with improved sample handling and, by inference, greater purity in the samples.

At very low levels of charge ( $< 0.01$  nC/cm<sup>2</sup>) the xerographic developer fails to show any image. As the charge density increases, first circular patches, then structured circular patches can be seen. At moderate charge densities Lichtenberg figures of two colors emerge indicating clearly that there are regions of both positive and negative surface charge density

Table I. Mercury contact charge on samples

Material	Sign	Range of charge density
Paraffin	-	0.003 to 1 nC.cm <sup>2</sup>
Octacosane	-	0.025 to 0.7
Polystyrene	-	0.005 to 10
Polyethylene	-	0.5 to 10
Tetradecanol	±	-1 to +1
Carnauba wax	-	1 to 16
Mylar	-	5 to 50

Fig. 4. Developed xerographic images at different surface charge densities.

on the polymer. At still higher surface charge densities, multiple Lichtenberg figures superimpose on each other forming a welter of radial line segments broken by the wave-like lines of charge deposited in circles. Figure 4 shows sketches of low, moderate, and high levels of surface charge density developed xerographically.

Thus the xerographic developer permits a plan view of the history of a contact separation. The simplicity or complexity of this history occasionally tell the observer about local splotches of impurity, but more frequently indicate that air breakdown must have occurred during separation. In the absence of air breakdown the electrometer observations can be considered reliable. With reference to air breakdown, two parameters are important: Any ground plane influences the nature of the electric fields and therefore the threshold of breakdown. In addition, the absolute pressure influences the nature of the gas discharge through its influence on the mean free path. We have seen both these parameters strongly influence the threshold for formation of Lichtenberg figures. For example, Fig. 4 depicts the behavior of 1-mm thick polystyrene. At this thickness a ground plane behind the polystyrene raised the threshold for Lichtenberg figures from below 5 to 10 nC/cm<sup>2</sup>.

#### Discussion

Our electrometer observations and the xerographic pictures complement each other in this work. Frequently the electrometer observations could be used alone, but at and near the threshold of air breakdown

the xerographic pictures were far more useful than the electrometer's readings. Differential effects due to surface handling were graphically distinguished through the pictures. From our observations we concur with Miller and Murphy (6) that, if ionized impurities can be removed, probably both the electret effects which they saw and the contact electrification reported here will all but disappear, for simple materials such as polystyrene.

It is worth noting that in certain particular cases surface charges produced by simple contact alone can be as large as the electret charge densities observed in the literature. For this to occur both intimate contact and also a strong triboelectric relationship between sample and electrode must obtain. But when an electret is first made and the top electrode is stripped off or when an electret is cut with a knife intimate contact is established.

This work shows again how important careful electrometry (7) and/or high resolution two-dimensional charge patterns are in properly judging air breakdown on electrets. In the author's opinion the xerographic method described here is both simpler and less ambiguous than electrometry in judging the onset of air breakdown in experiments where a worker wishes particularly to exclude air breakdown.

#### Acknowledgment

The author acknowledges the numerous discussions with and the helpful suggestions of P. Keith Watson both during the progress of the work and in the manuscript stage.

# Conduction Properties of Pyrolytic Silicon Nitride Films

J. R. Yeagan<sup>1\*</sup> and H. L. Taylor<sup>†</sup>

Department of Electrical Engineering, The University of Texas, Austin, Texas

## ABSTRACT

Thin film silicon nitride deposited from the reaction of silane and ammonia exhibits reproducible current characteristics at high fields less than breakdown. Conduction behavior with thickness is similar for films from 60 to 1600Å on quartz and silicon substrates. A large temperature dependence, a linear variation of  $\ln I$  with  $V^{1/2}$ , and no electrode dependence indicate thermal emission from the bulk as the dominant injection mechanism at room temperature.

Insulating films conduct a small current before destructive breakdown occurs. The characteristics of this current indicate the reproducibility of the films and help design devices with regard to leakage and breakdown. This paper reports results of a study of the conduction properties of silicon nitride films deposited from the reaction of silane and ammonia.

### Film Deposition

Figure 1 shows the system used for depositing the films. Table I describes the deposition cycle.

The Matheson Company furnishes the semiconductor-grade silane and ammonia. The hydrogen is commercial grade. The quartz reaction chamber with vertical flow uses a resistive-heated graphite substrate holder. After flowing over the heated substrate, the excess gases are burned and vented via a hood. A chromel-alumel thermocouple measures the temperature of the top of the substrate.

Substrates are metal-coated quartz and polished silicon. Metals used for the base contact are Mo, Ni, and Pt. The silicon is 0.01 ohm-cm p-type mechanically polished with a 10-sec etch in 48% HF just before placing in the reaction chamber. Vapor degreasing in trichloroethylene cleans the metals. An electron gun at a pressure of  $10^{-9}$  Torr evaporates the molybdenum. All other metals are evaporated from tungsten filaments at a pressure of  $10^{-6}$  Torr. After film deposition the top electrode of Al or Au is evaporated through a metal mask at  $10^{-6}$  Torr.

A break in the film growth-rate curve shown in Fig. 2 occurs at an ammonia to silane ratio of 7:1. Bean (1) and others attribute this break to the film becoming silicon rich. Deposition temperature is approximately 700°C for all films. An x-ray diffractometer reveals no structure of the films which are transparent and apparently amorphous.

### Thickness Determination

The thickness determination used capacitance measurements and the color of the interference fringes. A value of 2.0 for the index of refraction (1, 2) in the color determination seemed appropriate. The dielectric constant was determined as 5.5 from a series of devices as shown in Fig. 3. The error in thickness from color determination averages out with the several thicknesses and devices used. This value of dielectric constant was used to determine thickness of the very thin films. The capacitance readings are stable to 5 significant figures on metal-nitride-metal devices with zero bias.

### Conduction Properties

Figures 4 and 5 show the conducting properties for a series of MIM and MIS devices with thicknesses ranging from 1600 to 60Å. Curve (a) is from a film on a molybdenum-coated quartz substrate. The rest are from films on 0.01 ohm-cm p-type silicon. The top

electrodes are Al and Au with an area of 1.0 mm<sup>2</sup>. The metal is biased negative for the MIS devices. No difference is observed for the MIM devices when the polarity is reversed; however, on some MIS devices a behavior similar to Fig. 6 is seen. Since the silicon is p-type the difference might be due either to a penetration of the electric field into a surface layer or to hole injection from the semiconductor.

Figures 7 and 8 show the current variation with temperature. Figure 7 is more typical of behavior usually seen. Figure 8 shows two activation energies of 0.72 and 0.11 ev.

The nitride forms uniform pinhole-free films below 100Å as shown by the curves of Fig. 5. The devices usually exhibit "good" electrical characteristics if no defects are observed with a x30 microscope. Contacts to these films are made by lowering a drop of mercury or an indium-gallium paste onto the electrode. This reduces the danger of punching a hole in the very thin films. If pits occur in the silicon substrate the MIS device is usually shorted.

Although no difference in current behavior occurs for the different substrates at the thicker films, several attempts to grow films below 100Å on quartz coated with nickel strips resulted in ohmic characteristics for the nitride. These Ni-nitride-Al devices were not shorted, but exhibited steady capacitance readings which corresponded to film thickness from 49 to 115Å and resistivities of  $10^8$ - $10^{10}$  ohm-cm. The breakdown field on these devices was low ( $\approx 2 \times 10^6$  v/cm) compared to that on the thicker devices ( $1 \times 10^7$  v/cm).

Fig. 10 is a Schottky plot ( $\ln I$  vs.  $V^{1/2}$ ) for curve A of Fig. 4. A straight line curve for this type of plot is characteristic of Schottky emission from the metal electrode into the insulator governed by the equation

$$J = AT^2 e^{-q\phi/kT} e^{[(q^3E/4\pi\kappa\epsilon_0)^{1/2}/kT]} \quad [1]$$

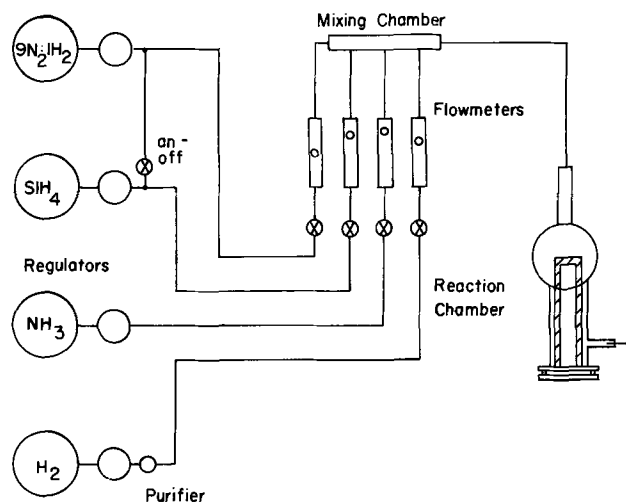

Fig. 1. Deposition system

where  $A = 120 \text{ amp}/(^{\circ}\text{K})^2$ ,  $T = \text{temperature in } ^{\circ}\text{K}$ ,  $q = \text{the electronic charge}$ ,  $K = \text{Boltzmann's constant}$ ,  $\epsilon_0 = \text{the permittivity of free space}$ ,  $\kappa = \text{the relative dielectric constant}$ ,  $E = \text{the electric field}$ , and  $\phi = \text{the barrier the electron sees at the metal-insulator interface}$ .

Closer examination shows that the slope of Fig. 10 is approximately a factor of 2 greater than that predicted from Eq. [1] ( $\kappa = 4.0 - \eta^2$ ). If indeed the electrodes control the current, the barrier ( $\phi$ ) should vary with different metals. From Eq. [1], a variation of only 0.06 eV at room temperature results in a decade difference in current density at equal fields; however, forward and reverse polarity current measurements on MIM devices with the different metal electrodes show little difference.

A bulk or internal Schottky emission (the Poole-Frenkel effect) has been proposed for the mechanism of current injection (3-5).<sup>2</sup> This model assumes that the electrons are thermally emitted from traps leaving a charged site after emission. Frenkel (6) calculates the current expression as

$$\sigma = \sigma_0 e^{q(qE/\pi\kappa\epsilon_0)^{1/2}}/kT \quad [2]$$

At the fields involved in these measurements a straight line results whether current or conductivity is plotted because the exponential term dominates. The main difference between Eq. [1] and [2] is a factor of 2 in the exponent. This difference arises because the barrier lowering is greater for an electron leaving a trap than for emission from a metal surface.

Equation [2] describes the observed behavior of the devices of Fig. 4 and 5 well; however, Fig. 9 shows a

<sup>2</sup>Sze (5) identifies three components of current. He finds that (i) Poole-Frenkel or internal Schottky emission dominates at high temperatures and high fields, (ii) field ionization dominates at high fields and low temperatures, and (iii) at low fields and moderate temperatures the current is dominated by thermal hopping of carriers from one isolated state to another. In general, our data are very similar to Sze's. In fact, the activation energies and barrier heights of Fig. 8 are approximately the same as he reports. However, we do not observe the ohmic current behavior characteristics of the thermal hopping.

Field ionization is characterized by a very small temperature dependence and a linear variation of  $\ln I$  with  $1/V$ . As seen in Fig. 8, the temperature dependence is still quite large for our devices even at lower temperatures. At very high fields ( $> 8 \times 10^6 \text{ v/cm}$ ) the current characteristics do become linear on a Fowler-Nordheim plot ( $\ln I$  vs.  $1/E$ ), however, more work is needed to establish that this is indeed field ionization.

behavior seen on some devices in which the slope is that expected for Schottky emission. The behavior of these devices are quite different from those described above. These devices exhibit slow transient currents

when the bias is increased similar to those observed on SiO<sub>2</sub> (7), and several minutes are sometimes required before the steady-state value is attained. The ammonia to silane ratio for the device of Fig. 10 was 10:1 and quite probably the film was nonstoichiometric with silicon-rich areas in the films. Johansen (8) proposes a model for SiO<sub>x</sub> in which the electrons are emitted from small islands of silicon embedded in the oxide. The behavior is similar to emission from a metal if the islands are larger than the distance from the interface to the position of maximum barrier. This model could explain the data of Fig. 10.

Figure 11 shows the slopes of plots of  $\ln I$  vs.  $V^{1/2}$  as a function of the film thickness. The data divide into two groups. The upper group corresponds to devices with current characteristics similar to Fig 9 and the lower group corresponds to devices similar to Fig. 10. Figure 11 implies that the lower group tends to occur at thicker films and the upper group occurs with thinner films. While this may be true in part, we believe that the film composition is probably the determining factor.

Fig. 11. Variation of slope of  $\ln I$  vs.  $V^{1/2}$  with film thickness

### Discussion

Two types of current behavior have been observed in thin films of silicon nitride. One type tends to occur at fields of  $2 - 9 \times 10^6$  v/cm with steady behavior that follows the Poole-Frenkel model for internal field-assisted thermal emission. Another type seen on some samples exhibits a lower slope on a plot of  $\ln I$  vs.  $V^{1/2}$  and transient effects similar to those observed on  $\text{SiO}_2$ . Different substrates and electrode materials have no observable effects on the current, suggesting that bulk effects control the current. A strong temperature dependence is characteristic of both types.

The nitride forms films below 100Å thickness that exhibit similar current behavior to thicker films indicating that the nitride has fewer pinholes than films of

thermally grown  $\text{SiO}_2$ . This suggests its possible use in tunneling devices.

### Conclusions

Thin films of silicon nitride deposited on substrates of quartz and silicon exhibit a reproducible d-c current component that occurs at high fields but before breakdown. A strong temperature dependence, a linear dependence of  $\ln I$  on  $V^{1/2}$ , and an absence of electrode control indicate that the dominant mechanism at room temperature is thermal emission from the bulk of the nitride.

## Electropolymer Studies, I

### Dielectric Properties of Ionic Membranes

Zeljko Urban

Sea Water Conversion Laboratory, College of Engineering, University of California, Berkeley, California

and Richard A. Wallace

Department of Chemical Engineering, Polytechnic Institute of Brooklyn, New York

### ABSTRACT

The dielectric properties of polystyrenesulfonic acid membranes in their hydrogen form have been studied over the frequency range of  $10^2$ - $10^5$  Hz, with water content and temperature as parameters. Dielectric dispersion is observed for slightly wet sulfonate membranes and is considered to be water-induced. Two distinct membrane hydration stages have been noted at low water contents. Dielectric dispersion processes of the wet ionic membrane in its sodium and potassium forms are also discussed.

Little is known about the influence of absorbed water on dielectric properties of ionic polymer materials. Dickel and Bunzl (1) measured dielectric constants of a variety of sulfonate resins as a function of their water content. They showed that the sorption

process of water in these ionic polymers is not continuous but stepwise. They also found that the hydrogen ion in the hydrated  $-\text{SO}_3^{(-)}\text{H}_3\text{O}^{(+)}$  complex of the sulfonic acid group favors a position closer to the sorbed water rather than to the  $-\text{SO}_3^{(-)}$  group. This

finding supports earlier work of Zundel, Noller, and Schwab (2) who studied hydration stages in sulfonic acid films by means of IR-spectrography.

Kurosaki (3) evaluated the dielectric behavior of sorbed water on silica gel and experimentally showed that three distinct regions of water absorption existed. Invoking Fuoss-Kirkwood theory (4), Kurosaki derived an expression for the differential specific polarization of sorbed water. This expression can be useful in analyzing effect of water on dielectric constant. It should be noted, however, that the values of polarization calculated by Kurosaki's formula are approximate. They are useful when comparing differential specific polarizations of various water-absorption stages.

In this paper we present the dependence of dielectric properties of cationic membranes on their sorbed water content and temperature in the low frequency range. Membrane electrical response characteristics are interpreted in terms of specific polarization and by Cole-Cole analysis.

### Experimental

Polystyrenesulfonic acid membranes were manufactured by Asahi Chemical Company under brand name DK-1. They were converted into the hydrogen form, leached several times with distilled water, and cut into disks. Samples were 2.54 cm in diameter and, on the average, 0.23 mm thick.

Dielectric measurements were made with frequency as a variable and membrane water content and temperature as parameters. Apparatus for the measurements is shown schematically in Fig. 1. G.R. 716-C bridge was used in conjunction with G.R. oscillator, type 1210-C and G.R. 1232-A tuned amplifier as a null-detector. A stainless steel electrode assembly was connected in series with a 1000 pF standard capacitor to the bridge.

Each membrane disk was vacuum dried at 55°C prior to testing. Dielectric tests were carried out in a vacuum oven maintaining temperature within 0.5°C. Membrane weight was measured before and after tests and then averaged. Membrane water content, expressed as molecules of water per equivalent of exchange group  $n$ , is given by

$$n = \frac{(m_w/m_d - 1) 55.5}{Q} \quad [1]$$

where  $Q$  is exchange capacity of the membrane, and  $m_w$  and  $m_d$  are the wet and dried membrane weight, respectively.  $m_d$  was measured after vacuum drying at 70°C for 24 hr. The membrane in this virtually dry condition is referred to as dried. The thickness of membrane disks was measured with Gaertner cathetometer M930 to within 0.001 mm.

Membrane capacitance,  $C$ , and dissipation factor,  $D$ , were measured in the frequency range  $10^2$  through  $10^5$  Hz. Since both  $C$  and  $D$  averaged relatively high, the 1000 pF standard capacitor,  $C_{ST}$ ,  $D_{ST}$ , was added in series with the sample to bring the measured capacitance,  $C_M$ , and dissipation factor,  $D_M$ , to within the measuring range of the bridge. Then the unknown membrane capacitance and dissipation factor were calculated from the values of  $C_M$ ,  $D_M$ ,  $C_{ST}$ , and  $D_{ST}$ .

Fig. 1. Schematic diagram of apparatus to measure the dielectric properties of ion-permeable membranes.

Dielectric constant,  $\epsilon'$ , and loss,  $\epsilon''$ , are computed from membrane capacitance and dissipation factor

$$\epsilon' = \frac{Cd}{\epsilon_r A}; \quad \epsilon'' = D \cdot \epsilon' \quad [2]$$

where:  $\epsilon_r = 8.85 \times 10^{-14}$  F/cm, absolute dielectric constant of vacuum or dry air;  $d$  = distance between electrodes, cm; and  $A$  = electrode area, cm<sup>2</sup>.

Electrode polarization represents a serious error in dielectric measurements especially at low frequencies. In order to record meaningful results, electrode polarization effects must be minimized.

In Fig. 5 is shown the frequency dependence of dielectric loss  $\epsilon''$  for slightly wet ( $n = 1.1$ ) membrane at various temperatures. All four curves display a deviation from a standard bell-shaped  $\epsilon''$  vs. frequency curve. This deviation, due to electrode polarization, seems to occur only at frequencies lower than 2000 Hz. Therefore, it was felt justified to neglect the electrode polarization effect at frequencies higher than 2000 Hz.

Measured values of dielectric constant at frequencies below 2000 Hz were corrected for electrode polarization effects. Cole-Cole circular plots (5) were constructed using the values at frequencies higher than 2000 Hz. Then the values of the static dielectric constant  $\epsilon'_0$  were determined from these plots. Based on this information, membrane dielectric constant values were plotted for frequencies below 2000 Hz, such as shown in Fig. 4.

### Results and Discussion

The sulfonic acid membrane dielectric constant,  $\epsilon'$ , is given in Fig. 2 as a function of water content at 100,000 Hz. This curve illustrates the sorption process of water in the cationic membrane. Similar results were reported by Rosen on effect of water on protein systems (6). Two distinct water-sorption regions are evident. A transition occurs at a water content of  $n \approx 1$ .

Using Kurosaki's Eq. [3] for specific polarization

$$\bar{P}_n = \frac{2\epsilon'^2 + 1}{9\epsilon'^2 \rho} \frac{\partial \epsilon'}{\partial n} \quad [3]$$

where  $\epsilon'$  = measured dielectric constant,  $\rho$  = membrane specific gravity, and  $(\partial \epsilon' / \partial n)$  = variation of dielectric constant with the change of water content, membrane polarizations were calculated. At low water content ( $0 < n < 1$ )  $\bar{P}_n$  is about 0.35. For the higher water content ( $n > 1$ ),  $\bar{P}_n \approx 42$ . This big difference

Fig. 2. Effect of water content on dielectric constant  $\epsilon'$  for sulfonic acid membrane at 100,000 Hz and 20°C.

Fig. 3. Initial hydrations in sulfonic acid membrane

suggests that the sorbed water could cause the membrane to change drastically in its degree of polarizability. Once the water content exceeds the value of  $n \approx 1$  the membrane seems to become highly polarizable.

There is a possible explanation for this abrupt change of specific polarization. In the dried membrane the hydrogen ions are associated with  $-\text{SO}_3^{(-)}$  groups by strong ionic bonds. The whole group  $-\text{SO}_3^{(-)}\text{H}^{(+)}$  is stiff and difficult to polarize. Therefore, the differential specific polarization  $\bar{P}_n$  is rather low.

As the water is sorbed by the membrane the  $-\text{SO}_3^{(-)}\text{H}^{(+)}$  groups hydrate into  $-\text{SO}_3^{(-)}\text{H}_3\text{O}^{(+)}$  ( $n = 1$ ) then  $-\text{SO}_3^{(-)}\text{H}_5\text{O}_2^{(+)}$  ( $n = 2$ ),  $-\text{SO}_3^{(-)}\text{H}_7\text{O}_3^{(+)}$  ( $n = 3$ ), etc. The hydrogen ions begin to dissociate from the  $-\text{SO}_3^{(-)}$  groups and associate with water molecules (1). Now  $-\text{SO}_3^{(-)}$  groups will be coordinated with hydrated hydrogen ions by hydrogen bonding. These bonds confer on hydronium ions a flexibility to move in applied electrical field, enabling them to polarize. Thus the  $\bar{P}_n$  number is high.

Figure 3 illustrates the hydration process in a sulfonic acid membrane. The hydrogen ion is depicted in its preferred position adjacent to the hydrated water (1, 2).

A family of curves representing the relationship of dielectric constant on frequency for slightly wet membrane at various temperatures is shown in Fig. 4. The membrane water content is 4.9% by weight or  $n = 1.1$ . The dashed portions of the curves are corrected for electrode polarization effects as described in experimental section. All four curves display a similar shape. The dielectric constant decreases with increasing frequency passing through a point of inflection. The point of inflection determines the position of characteristic frequency,  $f_c$ . The locations of characteristic frequencies were found by means of Cole-Cole plots. The position of  $f_c$  moves toward higher values as the temperature increases. This shift is probably due to the decrease of membrane microviscosity at higher temperatures.

In Fig. 5 are shown the dielectric loss-frequency curves for the same slightly wet membrane.

Dependence of maximum loss,  $\epsilon''_{\text{max}}$ , on water content at room temperature is shown in Fig. 6. The general trend follows the linear rise of  $\epsilon''_{\text{max}}$  with increasing water content. This seems to suggest that the dielectric absorption in the wet membrane is water-induced. Water-induced dielectric absorption was also

Fig. 4. Frequency dependence of dielectric constant  $\epsilon'$  of slightly wet ( $n=1.1$ ) sulfonic acid membrane at various temperatures. Dashed portions are corrected for electrode polarization effects.

found by other investigators for a series of various polymeric materials (7, 8).

The change of membrane dielectric properties caused by sorbed amounts of water is represented by Cole-Cole plots in Fig. 7. Relatively small amounts of

Fig. 7. Cole-Cole plots for sulfonic acid membrane at 20°C for various water contents.

sorbed water appreciably influence the shape and position of Cole-Cole plots.

Results suggest that the presence of water in sulfonic acid membrane gives rise to a specific, water-induced relaxation process. This process is characterized by high dielectric constant, loss, and dielectric increment,  $\Delta\epsilon'$ . Its characteristic frequency occurs between  $10^3$  and  $10^4$  Hz.

Measurements have also been carried out for the slightly wet sulfonic acid membrane in sodium and potassium forms. From  $\log f_c$ , vs. reciprocal absolute temperature plots, experimental activation energies have been calculated. Typical results are summarized in Table I. For comparison our experimental value for the activation energy of slightly wet membrane in hydrogen form is given.

Table I points out that the activation energy for the membrane in its hydrogen form is about three times smaller than in its sodium or potassium form even though its water content is three times lower. The presence of water within the membrane lowers the

Table I. Activation energies of dielectric dispersion within sulfonic acid membrane in three ionic forms

Ionic form	Water content, moles H <sub>2</sub> O per equivalent	Experimental activation energy, kcal/mole

Potassium	3.1	31.5 ± 10%

energy barrier of the ionic polarization process. In response to an applied electric field, hydrogen ions seemingly polarize an order of magnitude easier than either sodium or potassium ions.

## Direct Observation of Precipitate Phenomena and Dislocations in Annealed CdS:Cu and CdS:Au Single Crystals

Arthur Dreeben\*

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

#### ABSTRACT

The procedure of high-temperature annealing followed by quenching was used to produce significant changes in the microstructures of as-grown CdS:Cu and CdS:Au single crystals. The use of optical microscopy enabled these changes to be directly observed with high resolution. The solubility of copper is retrograde, the maximum being about 0.2 w/o between 475° and 650°C; the maximum solubility of gold is less than 0.03 w/o. Annealing CdS:Cu between 700° and 1100°C causes temperature dependent microchanges that include the formation and growth of precipitates and the generation of dislocations by prismatic punching. In the case of gold, initial precipitates change only when crystals are annealed at or above 900°C. High-temperature precursors of room temperature precipitates are identified from reversible changes in morphology, and unique, high-temperature dislocation structures are observed. Gold also diffuses to the crystal surface where it forms characteristic epitaxial deposits.

This study of the effects of annealing on impurity structures in CdS crystals has a dual purpose. First, treatment of CdS luminescent materials frequently involves heating samples to temperatures of 800°C and higher for various time intervals, after which the material is either slowly cooled or rapidly quenched.

\* Electrochemical Society Active Member.

Although variations in these treatments can produce profound effects in the electrical or luminescent properties of the solids, the accompanying changes in the internal state of the impurities is not always understood.

Second, the detailed behavior of impurities in semiconductors and insulators is a subject of continuing

interest. In semiconductors such as germanium and silicon, donor and acceptor impurities exhibit a retrograde solubility (1) and tend to precipitate out if annealed at temperatures where their solubility is low. Nevertheless, because of their relatively small diffusion constants in these materials, the impurities can be preserved in a metastable state by quenching to room temperature. However, these semiconductors are not transparent to visible light, so that the detailed nature of the precipitate states are often inferred from relatively indirect procedures with only poor definition.

In the case of CdS, direct optical microscopy with high resolution has recently been used to observe decorated dislocations and the morphology and crystallography of precipitate phases in slowly cooled, as-grown crystals (2-5). This highly successful technique has now been employed to view the temperature dependent, transient changes in microstructures that occur when CdS:Cu and CdS:Au single crystals are annealed.

It is found that copper exhibits a retrograde solubility, and that the maximum solubility of copper is greater than gold, 0.2 w/o compared to less than 0.03 w/o. Classical precipitate behavior and morphologies, including formation and dissolution at grain boundaries, conversion of one species into another, and the appearance of new species are clearly observed. Evidence is presented for the generation of dislocations by precipitate particles, and by the mechanism of prismatic punching.

### Experimental

Crystallographically oriented and polished (0001) slices from large vapor grown boules of CdS:Cu and CdS:Au (2-4) were examined for internal microstructures, and photographed under the optical microscope. These crystals were placed in quartz vials that were subsequently evacuated to about  $10^{-6}$  Torr and then filled with purified argon to provide approximately 1 atm pressure at the annealing temperature. The sealed vial was placed in a vertical furnace for the desired length of time after which it was quenched in liquid nitrogen. Some crystals were lightly repolished to remove effects of thermal etching before microscopic examination.

### CdS:Cu Crystals

**Results.**—The internal appearance of the as-grown crystals, as viewed with the optical microscope using transmitted light, was characterized by a polygonal structure as shown in Fig. 1. Chemical analyses of representative crystals showed that they contained 0.05-0.06 w/o Cu, and subsequent analyses after an-

nealing established that no copper was lost during annealing.

The initial microstructure appeared invariant in samples quenched from annealing temperatures lower than 450°C. Treatment at 450°C, however, caused perceptible changes including the elimination of some sub-boundary decoration and a general decrease in precipitate density. Raising the annealing temperature to 475°C appeared to effect complete solution of the precipitate after 45 min. No microstructures, precipitates, boundaries, or other decorations, could be observed even under high power (1050X) magnification. This condition prevailed with no other detectable changes for annealing temperatures up to 650°C, and for prolonged firing times. Above 650°C, however, new precipitate formations occurred in several temperature dependent stages.

The first change, observed in samples annealed at 700°C, was the formation of submicron sized particles distributed almost exclusively along sub-boundaries. The next modification occurred between 700°-800°C in crystals annealed for about 1 hr. It was observed that the particles had grown appreciably to form discrete clusters with an average size of about  $15\mu$ . The clusters were randomly distributed and also arranged linearly along dislocation lines. As seen in Fig. 2, the clusters consist of a dark, circular precipitate with several short radiating arms. The arms themselves are diffusely decorated and often terminate with circular precipitates similar to the central one. Slight additional growth of the system occurred, particularly in the clusters along dislocation lines, when samples were annealed at 850°C for 1 hr, but the configurations were then unaffected by further annealing at the same temperature for up to 5 hr.

A third stage which occurs in some samples after annealing at 900°C for 45 min is marked by a considerable growth of the clusters into asterisk-shaped aggregates up to  $70\mu$  across as shown in Fig. 3. These aggregates are also characterized by a central precipitate with decorated arms. The particular decoration along arm a in Fig. 3B, is characteristic of helical dislocations. Some crystals also had circular loops composed of small precipitates.

The shape itself of the asterisk-like structures, suggests that a particular process may be responsible for their formation in the following manner. After the crystals are annealed at 700°C, the first visible particles appear at boundaries which are well-known preferred sites for precipitation. At higher temperatures, these precipitate particles grow into clusters which then also appear at other sites where nucleation occurs less readily than at boundaries. It is reasonable to assume that these enlarged precipitates cause local strains in the host lattice; generation of dislocations by the process of prismatic punching is one way by which these

strains can be relieved (6). The asterisk shapes, and the appearance of helical dislocations in their arms (as in Fig. 3B) are strong characteristics of this process. It has been recognized in many other crystals (7) containing precipitates that are insoluble at high temperatures, including (Zn,Cd)S:Er (5).

The progressive growth of the asterisk configurations apparently terminates between 900° to 1100°C. After 30 min at the higher temperature, the larger aggregates reformed into discrete precipitates often having a hexagonal morphology and arranged in hexagonal arrays as in Fig. 4. Regions were also observed in which the precipitates were arranged in parallel lines suggestive of slip bands. All of these decorations were further changed by longer annealing at 1100°C. After 5 hr for example, columnar subgrains and low angle boundaries, as shown in Fig. 5, were predominant features; low energy configurations, such as these boundaries, are known to arise during annealing at elevated temperatures (8).

Reheating these crystals to 900°C and then slowly cooling instead of quenching them caused a reversible change in the precipitation to a pattern similar to the original in Fig. 1. In previous work (4), cardioids, dipoles, and other dislocation configurations were observed in slowly cooled as-grown CdS:Cu crystals. It is noteworthy that none of these types were found in any of the quenched crystals. These observations provide evidence that the dislocations seen in the as-grown crystals are probably generated by the second

Fig. 4. (A) and (B) Discrete precipitates, randomly distributed and arrayed in hexagonal formations. Insert in B (1.7X larger) shows hexagonal shape of precipitate itself. All results after 30-min anneal at 1100°C.

Fig. 5. Columnar subgrains in crystal annealed for 5 hr at 1100°C

phase particles as they precipitate from solution when the crystal cools below 475°C.

To establish some limit for the high-temperature solubility, selected crystals with 0.2 and 0.8 w/o Cu were annealed at 650°C and then quenched. In the sample with 0.2 w/o, a very slight precipitate remained visible, whereas a heavy precipitate persisted in the 0.8 w/o sample. At an annealing temperature of 800°C, precipitates remained in both samples. Therefore, copper exhibits a retrograde solubility with a maximum of slightly less than 0.2 w/o occurring in the temperature interval between 475° to 650°C. This is about an order of magnitude greater than the value of 0.02 w/o found in slowly cooled, as-grown crystals (2).

In addition to reduced solubility of the added impurity, two other mechanisms that can account for precipitation in crystals have been pointed out by Black and Jungbluth (9). The first is the formation of

a stable, insoluble compound between the impurity and host. In relation to the present results, it may be pointed out that the existence of a (Cu,Cd)S complex or compound was postulated in connection with experiments on some electroluminescent phosphors (10). However, in the present case, attempts to distinguish different chemical species among the precipitates by microprobe analyses were inconclusive. The second mechanism involves exsolution of residual impurities analogous to the common ion effect that occurs in aqueous chemistry. The low concentration of other impurities in these crystals, however, makes this alternative much less likely.

Another experiment demonstrates that the quenched-in high-temperature solid solutions can be metastable. In the as-grown, polygonized sample shown in Fig. 6A, it has been estimated that the copper concentration at the boundaries is about 0.8 to 1.0 w/o, but that it is only about 0.2 w/o within the grains (4). This sample was annealed at 900°C in a high-pressure bomb under an Ar pressure of 600 psi and then quenched. At that time, microscopic observation showed that all of the precipitates had been eliminated, but that the boundaries were still visible as shown in Fig. 6B. Subsequent reexamination of the sample, which had been aging at room temperature for about one year, revealed that discrete precipitates were again beginning to form at the boundaries as shown in Fig. 6C. During a still later examination, precipitates were also found within grains. It may be pointed out that some influence of pressure on solubility is indicated by the absence of detectable precipitates after the high-pressure anneal, contrasted with only partial solubility in the previously described similar samples, also annealed at 900°C, but under 1 atm pressure.

The CdS:Cu crystals used in these experiments had a very high initial resistivity that did not change detectably in the samples quenched between 475° and 650°C, i.e., those with a maximum amount of copper in solution. This result is consistent with recent conclusions that due to self-compensation (11), p-type conductivity cannot be induced in CdS merely by incorporating acceptor atoms such as copper (2, 12). In experiments on low resistivity CdS:Cu,Cl crystals, Woods (13) reported that copper decorations disappeared, and the resistivity greatly increased when the crystals were rapidly quenched from 700°C. From

this he concluded that a supersaturated concentration of copper acceptors had been quenched in. In that case, however, the copper acted to partially compensate the chloride donors, thereby accounting for the increased resistivity.

### CdS:Au Crystals

In the as-grown samples, the important microfeatures are best observed by viewing the basal (0001) plane. These initial features consist of two types of individual and arrayed precipitate platelets having an extremely regular, hexagonal morphology, together with associated dislocations (3), all of which may be seen later in Fig. 9A. Type I platelets are 2.5-7 $\mu$  across, and are found in clusters or as randomly distributed individuals. They also appear in the highly symmetrical decorations that mark dislocations around type II platelets. The type II are much larger, 160 $\mu$  across, and have a different composition and crystallographic orientation with respect to CdS (3). It is also noteworthy that the hexagonal precipitates are the only ones present in as-grown crystals, and the symmetrical dislocation arrays are observed only in strained regions around the type II hexagons (3). The microscopic changes that occur when the crystals are annealed involve both types of precipitates, and each will be considered separately.

*Results.—Type I precipitates.*—At annealing temperatures below 900°C, no changes could be found in quenched samples. The first change, occurring in crystals heated at 900°C, was an appreciable growth in the size of the platelets from an initial average of 5 $\mu$  to about 9 $\mu$ . A group of three clusters in a crystal are compared before-and-after being heated and quenched, in Fig. 7. It is interesting that neither the general make-up of clusters nor their positions in crystals were appreciably changed. Simultaneously, micron sized particles appeared, often decorating dislocation lines and sub-boundaries not originally present in the as-grown specimens. In addition the particles were found in radially arrayed decorations above (or below) the clusters of enlarged hexagons and individual platelets.

In crystals annealed at 1000°C, further development of the particle network was noted; some hexagons assumed a spherical shape, and large radial decora-

Fig. 7. Clusters of type I hexagonal precipitates in basal plane of CdS:Au crystal: (A) as-grown, (B) after being annealed for 2 hr at 900°C and rapidly quenched. Note identical arrangement of precipitates, but with increased size. Note also new decoration of sub-boundaries in (B).

tions, more clearly defined as asterisk formations, continued to develop locally around cluster and single hexagons. In addition to acting as sources for these localized dislocations, some hexagons also acted as pinning points for line dislocations.

At 1100°C, several additional observations were made. In the midst of the changing microfeatures, original low angle boundaries remained relatively unchanged even after 30 min at temperature. Many hexagon clusters along the boundaries survived the annealing, but many of those within the grains did not. Individual precipitates were still present, but most of these formerly hexagonal species were now spherical. There was an additional and final development of the previously noted dislocations around the remaining clusters, and these features are illustrated in Fig. 8. It can be seen that the asterisk has now been enclosed by a loop with distorted hexagonal symmetry, and that the particles decorating both configurations have become rod-like. Note particularly that these typical arrays are not in the plane of the cluster (3).

The experimental results suggest a possible connection between the rod-like and type I precipitates. It has been shown that the type I hexagons persist and even grow in size when crystals are quenched from 900°C, but that they are replaced by a rod-like species when quenched from 1100°C. On the other hand, however, it was found that upon being slowly cooled from this temperature, many hexagons reform, sometimes with an increase in size, at the same crystal sites they formerly occupied. The before-and-after appearances are very much like those in Fig. 7. Enlarged hexagons are more often found in the interior of crystals while smaller ones are observed nearer the surface.

From these observations together with the well known finding that a rod-like morphology is often adopted by precipitates in an early stage of growth (14), it is reasonable to assume that the rods are early precursors of the type I precipitates. The observed increase in the size of type I hexagons may occur at the expense of smaller ones, perhaps by the process of Ostwald ripening (15) which involves the mobility of precipitate atoms in the "solvent" (CdS) phase, and of the matrix atoms themselves.

The processes that occur during annealing at 1100°C are also affected by time, about 1 hr being required

to establish an apparent steady-state condition with respect to microfeatures. (No additional changes were observed after a 2-hr period.) The notable final characteristics included the destruction of clusters and their dislocation systems, and the development of asterisks quite similar to the CdS:Cu formation shown in Fig. 3. These are believed to arise from the same prismatic punching process previously discussed. Circular loops and spirals were also observed.

The lowest grown-in amount of gold was 0.03 w/o in boules containing only type I precipitates. Even in these samples, however, some kind of precipitate was observed at intermediate annealing temperatures up to 1100°C, showing that the high-temperature solubility of Au in CdS is significantly less than that of Cu. This may be related to the formation of stable high temperature compounds (9) between Au and CdS, and to the larger radius of gold. Evidence for the possible retrograde solubility of gold could not be established in these experiments since the continued presence of precipitates after each annealing step implies that the maximum solubility of gold was always exceeded.

*Type II precipitates.*—Typical localized type II hexagons in as-grown crystals are shown in Fig. 9A, together with their associated dislocation networks decorated with type I precipitates. Figure 9B of the same field but between crossed polarizers, shows the strain birefringence around the giant precipitates, while Fig. 9C illustrates the ultimate situation after annealing at 1050°C for 1 hr destroyed the large hexagons. New dislocation lines, or possibly low angle boundaries can now be seen together with configurations remaining at their original sites. The rate at which this situation is attained depends on time and temperature, but 1050°C was found to be convenient for determining intermediate annealing effects in reasonable time intervals.

It was found that an extensive erosion begins at the centers of the hexagons as shown in Fig. 10, simultaneously with a less rapid over-all reduction in their size. The faster disintegration of the broad face may result from a difference in surface energy between it and the prism planes. Enlarged details of the situation after type II sources are completely removed are shown in Fig. 11.

In this final state, it was observed that the strain birefringence (see Fig. 9B) was still present around the former type II sites, and it is not surprising, therefore, that the decorations seen in Fig. 11 also remain. It will be noted, however, that these decorations are now comprised of particles and rods instead of the

Fig. 8. Decorated dislocation arrays in CdS:Au crystal annealed for 1 hr at 1100°C. Depth of observation in A is 0.24 mm above cluster of type I precipitates in B. Note rod-like decorating species.

original type I hexagons. The possible relationship between these two configurations was discussed earlier. Many dislocation loops, as seen in Fig. 11B were found near the former locations of type II hexagons, but no further study was made of these or other loops pointed out previously.

The difference in size between type I and type II hexagons as effective dislocation sources is noteworthy. In as-grown crystals, no decorations at all were found associated with type I hexagons (3). It will be remembered, however, that in annealed crystals, decorated arrays were observed around individual type I hexagons as small as 9 to 12 $\mu$ , and also around type I clusters 80 $\mu$  in diameter as seen in Fig. 8B. Here, however, the diameter of the generated loop (Fig. 8A) is less than one-half the size typically found with type II hexagons in as-grown crystals (Fig. 9). This kind of decoration was associated with type II precipitates 140-160 $\mu$  across, but was absent when the size was less than 100 $\mu$  (3).

The explanation is believed to be related to the misfit between precipitate and host, and the fact that the two types of hexagons have different compositions and orientations in CdS (3). Apparently the generation of dislocations to relieve the limited strain resulting from the small type I precipitates, can occur only in the more mobile lattice environment at the annealing temperature. In rapidly quenched samples, these dislocations are frozen-in, but the effects are annealed out when the crystals are slowly cooled to room temperature. The greater size of the effective type II hexagons, however, creates a relatively large strain that persists at room temperature not only in as-grown crystals (3), but also in quenched samples, even when the hexagon itself is thermally degraded (Fig. 9C and 11).

The effects of annealing on the type II hexagons were much more rapid when their original locations

were on grown-in dislocation lines. This result is attributed to the well known faster solute diffusion along such dislocation "pipes." Slow cooling of previously annealed specimens in which the hexagons had been destroyed, did not cause them to reprecipitate, in contrast with the type I hexagons. However, there was some preferential particle precipitation around remnants at the type II sites.

In addition to the internal microfeatures described so far, some surface deposits were found on the crystals after annealing steps. The most significant of these was observed after the final annealing treatment at 1050°C for 1 hr and consisted of clusters of individual, truncated hexagonal pyramids. Figure 12 shows a typical example in which the top (in focus) is 54 $\mu$  above the base on the crystal surface.

Chemical analyses for gold showed that as-grown crystals contained about 0.06 w/o, whereas samples annealed and quenched after 1 hr at 1050°C contained only 0.04 w/o. Crystal slices, sectioned to remove any type II precipitates, thus leaving only the small species, also lost some gold, but the surface deposits were not extensive or geometrically defined. The hexagonal morphology of the deposits also reflects the orientation symmetry of type II hexagons which are believed to be gold precipitates (3). It is concluded, therefore, that the pyramids are epitaxial growth forms that result primarily from out-diffusion of the type II precipitates. The diffusion and loss of gold is to be contrasted with the stable behavior of copper in CdS.

#### Summary and Conclusions

The grown-in microstructures in CdS:Cu and CdS:Au single crystals undergo appreciable changes when samples are quenched from elevated annealing temperatures. Copper has a retrograde solubility, and the maximum is estimated to be about 0.2 w/o in the temperature range between 475° and 650°C. Quenching preserves this increased solubility in the solid, but even this greater concentration of acceptor atoms did not cause formation of p-type CdS. The quenched-in solid solution is metastable and reprecipitates when aged at room temperature. Pressure may have an influence on solubility. Evidence has been presented to account for the generation of dislocations by second phase particles and by prismatic punching, to relieve strains at high temperatures.

In contrast to the CdS:Cu crystals, the CdS:Au samples remain unchanged when heated below 900°C. At higher temperatures, however, they undergo remarkable changes involving the growth and eventual reversible deformation of the small (type I) hexagons, and the development of new dislocations and rod-like

Fig. 12. Detail of truncated hexagonal pyramid surface deposits from out-diffusion of gold after annealing a CdS:Au crystal with type II hexagons.

microstructures. The rods are believed to be precursors of the type I precipitates. Giant (type II) hexagons undergo irreversible thermal destruction accompanied by diffusion of Au to the crystal surface where it forms characteristic epitaxial deposits. This loss of Au from CdS is an important difference from the stable behavior of copper. Finally the solubility of Au at high temperatures is apparently less than 0.03 w/o, a much lower value than the estimate for copper.

The results described in this paper demonstrate significant changes in microstructures that occur when slowly cooled, as-grown crystals are subsequently annealed and quenched. It has been seen that the high-temperature precipitate morphology, clusters, asterisks, etc., in crystals quenched from above 650°C, is distinctly different from that in the starting, as-grown crystals. This suggests that the processes for generating these dislocations can operate only at the higher temperatures. It is also possible that the frozen-in structures occur at sites that are available for nucleation only at higher temperatures, and which anneal out on slow cooling.

The appearance and disappearance of directly observable microstructures can serve as guides to the selection of crystal growth conditions that tend to minimize certain imperfections. In addition, the various temperature dependent forms adopted by impurity precipitates, visually demonstrate one of the difficulties in determining solubility and diffusion data in semiconductors, as recently discussed by Woodbury (16). Changes in the solubility of copper, and in dislocation structures are also the kinds of variations that are known to influence some properties of many materials.

It is interesting to speculate, for example, that some recently reported effects of heat-treatments on the conductivity and luminescence of CdS, some of which occur in samples quenched from 500° to 600°C (17-19) may have been influenced by undetected formation of dislocations or changes in solubilities of active impurities. The present finding that copper forms metastable, supersaturated solutions suggests that well-known temporal changes in the photoconductivity of doped CdS could, among other reasons, be connected with gradual reprecipitation of impurities. This work provides new insights into impurity behavior in semiconductors and emphasizes the importance of knowing the thermal history of materials.

#### Acknowledgment

The assistance of W. M. Anderson in the synthesis and preparation of the crystals for examination is

greatly appreciated. M. Fornoff supplied the electron microprobe data, and B. L. Goydich and Mrs. M. Ippolito performed the chemical analyses. The author also wishes to thank M. S. Abrahams for helpful discussions, and L. R. Weisberg and J. Tietjen for critically reviewing the manuscript. The research reported in this paper was sponsored by the Department of Defense, Advanced Research Projects Agency, Materials Science Office, under Contract No. SD-182.

Manuscript received Sept. 29, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Wide Range Measurements of Cathodoluminescence

#### ABSTRACT

Instrumentation is described for determination of the persistence characteristic of a phosphor screen after cathode-ray excitation. Excitation times shorter than 50 nsec are possible. Measurements are made to 0.01% of initial light intensity. Evidence of a "limiting" decay curve for short intense excitations is obtained and possible theoretical implications discussed.

With very few exceptions (1) most studies of phosphor light output under cathode-ray excitation have been confined to a range of two or three decades of intensity or excitation times of the order of microseconds or longer (2-7). Such excitation times are long compared to those of a moving electron beam in a regularly operated cathode-ray tube. The "dwell time,"

i.e., the time for the electron beam to move its own diameter, is frequently less than 20 nsec.

For such short excitation times, it is found that the luminescence decay is more rapid the shorter the excitation time and the higher the beam current density. However, a limiting decay curve is approached at excitation times of 0.2-0.5  $\mu$ sec and current densities of 5-10 ma/cm<sup>2</sup>. For phosphors with power-law decays,

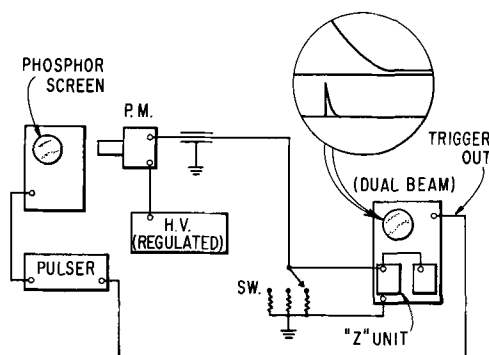

Fig. 1. Instrumentation for observing rise and decay of light from phosphor screen.

it is well known (8) that the decay time<sup>1</sup> after extended excitation (compared to 1  $\mu$ sec) increases, but it has not been as clearly recognized that under these conditions the shape of the decay curve is altered in its very early stages.

To measure less than 0.1% of initial intensity after very short excitation has usually meant construction of highly specialized equipment. With commercially available instruments one can now extend the range of such studies to more than four decades in intensity (from time zero) and to excitation times shorter than 50 nsec.

### Instrumentation, General

The arrangement used is illustrated in the block diagram of Fig. 1. The phosphors studied were incorporated in standard high-speed cathode-ray tubes (CRT's).<sup>2</sup> The CRT was then installed in an appropriate model oscilloscope (which will be called the "exciter" oscilloscope) to take advantage of the input circuitry for producing the necessary beam deflection and hence, phosphor excitation time.

The face of the CRT was covered with an opaque mask near the center of which was a 5 mm diameter hole. The electron beam was focused at a point vertically above the hole (about 2 cm above center in the 3-in. tubes and 3 cm in the 5-in. tubes), but short of the position where beam reflection from the deflecting plates would cause a bright background fluorescence on the screen. A single square pulse was then fed to the vertical deflection plates to pull the beam down to the 5 mm window for the duration of the excitation and then return it to the quiescent position at the top of the screen.<sup>3</sup>

Although a method using beam unblanking and reblanking was experimented with to provide excitation times, it was found to have several disadvantages and to be unable to provide the shortest excitation times required. One advantage of such a method would be elimination of the low level background light present when the deflected beam is not at the center of the screen. Careful study of this problem, however, showed that it can be minimized. Nearly all of what remains is a small constant background at the window contributed by the quiescent off-screen spot. The resulting constant photomultiplier (PM) output provides the reference trace ("zero line") on the output (or "viewing") oscilloscope.

Light output from the screen was picked up by a DuMont 6291 photomultiplier (PM). In the wide range of output current measurements made, regula-

tion and stability of the dynode voltages is extremely important with any PM. After some difficulty with random corona-like noise in various power supplies tried at very low signal levels, the P.D.P.14 model 1565 was found to be most satisfactory.

Dynode biases were provided from a voltage-dividing resistor string. To reduce voltage shifts at the higher multiplier output currents, resistors of higher power and lower resistance ratings than usual were used (20 kohms for cathode to first dynode and 10 kohms for all others). The divider current was nominally 10 ma. With a final dynode (output) current of 1 ma this meant a maximum bias shift on the last stage of 10%. The resultant measured shift in output current linearity was always less than 2%. Since this difficulty arises only in the last one or two stages, the error can be further reduced by providing those biases from separate batteries or well-regulated supplies (9). We found less sensitivity of output pulse voltage to variations in bias current of the last multiplier stage than is predicted by Lush (9).

The sharp rise and fall of the excitation pulses impose minimum bandwidth requirements on the output circuitry. In addition, in order to measure the very lowest light levels, maximum gain of the viewing oscilloscope must be used as well as large load resistors in the PM output. The larger load resistances produce an impedance mismatch with the 170-ohm cable. This, with the input capacitance of the two paralleled plug-in amplifiers (approximately 20 pf each) produces an integrating effect on the signal, resulting in a lowering and rounding of the peak of the output signal when the excitation time is very short. When the user is aware of this it can be allowed for and a proper calibration produced by extrapolation from the case of proper impedance matching.

A diffuser<sup>5</sup> was placed between the screen and the PM to eliminate trouble from variations in sensitivity across the photocathode and to avoid localized overloading of the photocathode. To extend the observed intensities to larger values without overloading the PM, an additional gray filter was used from time to time in front of the photocathode.<sup>6</sup> This filter gave no observable fluorescence to visible light in the region used as was checked by noting no change in shape of persistence curves when the filter was inserted. When employed at all it was used throughout the determination of a complete persistence curve.

### Amplifiers and Viewing Oscilloscopes

The primary reasons for the ability to cover the wide range of intensities were the nonoverloading amplifiers used in the viewing oscilloscope.<sup>7</sup> With such amplifiers and the Dual Beam CRT, it is possible to examine the full persistence signal on one trace and a magnified segment of that signal on the other (Fig. 2). This has the equivalent effect of increasing the available screen height from  $\pm 2$  to  $\pm 2000$  cm, with a smallest measurable signal of 1-2 mm. One thus has an immediate reference check on the initial intensity and a precise determination of the persistence down to less than 0.01% of initial amplitude.

To measure the lowest of these intensities involves very high sensitivities and a need to eliminate all source of noise. Stray daylight (white noise) and light from fluorescent fixtures (white noise plus 120 cycle) are strong sources but easily eliminated. However, 120-cycle noise from pilot lights, cathode heaters, etc., is more troublesome and sometimes cannot be completely eliminated at such low signal levels. As a final step in such elimination the signal trace and the sweep zero line can be triggered successively at the same phase of the residual 120-cycle noise and the difference between the two traces easily measured.

<sup>1</sup> Although susceptible to misinterpretation or mistaken extrapolation, "decay time" as used here will be the time necessary for  $I$  to decrease to  $I_0 e^{-1}$ , conforming to the usage of Leverenz and many others. Various definitions are used by some others, i.e.,  $I/I_0 = e^{-1}$ , 1/2, 1/3, 10%, 1%, etc. A danger in using  $(I/I_0) = e^{-1}$  is that it is not a constant time for any  $(I_2/I_1) = e^{-1}$  (as it is in the case of a pure exponential).

**Time Resolution**

In all cases the response time of the exciter oscilloscope circuitry was much longer than the rise and fall time of the pulser; hence the fall time of the pulse delivered to the deflecting plates was indistinguishable from that of the exciter oscilloscope (Fig. 3). This pulse was in turn clipped optically through use of the mask and aperture. In studying the persistence characteristic of a phosphor one is concerned with the fall time of the exciting pulse, especially when investigating the early stages of the decay.

At the shorter excitation times used it was observed that the buildup and decay of the output light were unchanged whether the beam was constantly on the same crystals or was moved rapidly around on crystals in the window area. Therefore, the fall time of the excitation was governed by the transit time of the spot across the mask edge (0.5 mm maximum diameter for a high current, focused spot). The resulting fall times for the light pulse seen by the multiplier, independent of the buildup and decay of the phosphor output itself, are given in Table I. In cases when the early stages of the persistence characteristic are under careful study and one does not need the dual beam display, System C (Table I) provides greater time

Table I. Time resolution

resolution with a circuitry fall time of 4 nsec. The possible variation of persistence time with beam current density is easily studied by using conditions ranging from high current focused beams to lower current defocused ones. A factor of 3000 in current density is readily available.

**Survey of Experimental Results**

It is well known (8) that the phosphorescent decays of most ZnS phosphors are hyperbolic or power law in form and that the decay characteristic varies with duration of excitation.<sup>8</sup> It is equally well known that the characteristics of some other phosphors are almost completely fitted by exponentials (e.g., CaWO<sub>4</sub>) and are independent of the manner of excitation. A primary reason for the present study of short excitations of power law phosphors was to determine whether there was a fundamental decay (characteristic of the phosphor) which was independent of the duration and intensity of excitation at very short excitations.

In this study a decay curve was found which is characteristic in that it is not affected by decreasing the excitation time to a value below approximately 0.5 μsec. Although, as expected, the latter part of the curve implies a power law ("hyperbolic") decay, the upper part is not fitted by continuation of the same dependence to shorter times, nor does the upper part of the curve appear to be fitted solely by an exponential.

Principal phosphors studied were P 11 (ZnS:Ag,Cl) —(two suppliers), P 22B (ZnS:Ag,Cl), and P 31 (ZnS:Cu,Cl). Experimental results for the P 31 are plotted in Fig. 4. It can be seen that with increasing *t* the curve approaches a straight line on a log *I* vs. log *t* plot and the slope implies an exponent of approximately 1.20 in the relation

$$I(t) \propto t^{-n} \quad \text{for large } t$$

As the duration of excitation is decreased the curve is shifted to shorter and shorter times, approaching a limiting location for excitations of ≤0.5 μsec (checked to excitations of less than 50 nsec) with the slope of the straight portion essentially unchanged.<sup>9</sup> It was found that a similar shift to shorter times was produced with increase in excitation (increase in beam current density) though this effect is less marked for the shorter excitations. This dependence is illustrated in Fig. 5.

In summary, the straight line portion of the decay curve is translated (with apparently unchanged slope)

<sup>8</sup>One exception is ZnS:Mn (no coactivator) where the decay is exponential and independent of the mode of excitation (6,8 p. 256,10).

<sup>9</sup>There may be some indication of a small (possibly within experimental error) systematic change of slope in some cases. If real, it is in the direction of slightly steeper slope for greater duration of excitation.

Fig. 5. Relation between phosphorescence decay and excitation parameters (current density and duration) for a P 31 [ZnS: Cu, (Cl?)] phosphor.

to shorter times by shortened excitation pulses and by increased intensity of excitation, toward a limiting value. This tends to support the concept of a characteristic decay, i.e., traps are occupied in such a short time that no appreciable number have emptied during the exciting period. The "limiting" curves for P 22 and P 11 are shown in Fig. 6.

### Theoretical

If an electron falls into a trap it will escape after a mean lifetime,  $\tau$ . It can then combine with an empty center giving phosphorescence of characteristic lifetime  $\tau$  after the original excitation, provided the probability for the transition to the empty center is large compared to that for escape from the trap. Considering a single level (11 p 150):

$$(dn/n) = -(dt/\tau) \quad \text{and} \quad n = n_0 \exp(-t/\tau)$$

where  $n_0$  is the number of electrons in the level at time zero. If one assumes levels in the band gap and near the conduction band, the lifetime depends on the location,  $E$ , of the level below the conduction band (12, 13)

$$\tau = 1/s \exp(-E/kT) = (1/p)$$

Fig. 6. "Limiting" phosphorescence curves (i.e. for excitations of short duration and high intensity). Samples are P 22B and P 11, left to right, respectively.

where  $p$  is the probability of escape of the trapped electron per second and  $s$ , the absolute rate constant (15), is sometimes called the "attempt-to-escape-frequency" at a given temperature.<sup>10</sup> Since the luminous intensity is proportional to the rate at which the electrons escape, we may write for the single (ith) level

$$I_i = C(dn/dt) = Cn_0s \exp(-E/kT) \exp[-st \exp(-E/kT)]$$

where  $C$  is the light energy produced per electron released.

Let us now consider a distribution density ( $dN/dE$ ) of occupied trapping levels between  $E$  and  $E + dE$ . The number of occupied traps in the interval will be  $dN$ . The total light intensity,  $I$ , from all the levels in a band extending from  $E_s$  (shallow) to  $E_d$  (deep) will be the sum of the  $I_i$ 's for the levels in the band, or

$$I = \int_{E_s}^{E_d} (dN/dE) \{C s \exp(-E/kT) \exp[-st \exp(-E/kT)]\} dE$$

Let us assume a trap density of the form ( $dN/dE$ ) =  $(dN/dE)_s \exp[-\alpha(E - E_s)]$ , i.e., a distribution which at the top of the band of traps is  $(dN/dE)_s$  and diminishes as  $\exp[-\alpha(E - E_s)]$ ...  $E \geq E_s$ . Randall and Wilkins (16) have shown that a distribution of this form for  $E_s = 0$  and  $E_d \rightarrow \infty$  leads to a power law decay of the form:  $I \propto t^{-(\alpha kT + 1)}$ ... for large  $t$ .

To evaluate  $I$  for any  $t$ ,  $E_s$ , and  $E_d$ , we make the substitution:  $\eta = \exp(-E/kT)$ ,  $dE = -kT d\eta/\eta$ ,  $\exp[-\alpha(E - E_s)] = \eta^{+\alpha kT}$

Then:

$$I = C(dN/dE)_s \int_{\eta_s}^{\eta_d} \eta^{+\alpha kT} (-skT) \exp(-st\eta) d\eta$$

Case I: A uniform density of traps, i.e.,  $\alpha = 0$

$$I = (dN/dE)_s (kT/t) [\exp(-st\eta_d) - \exp(-st\eta_s)]$$

$$I(t=0) = I_0 = (dN/dE)_s (skT) (\eta_s - \eta_d) \dots (17)$$

Hence the normalized intensity  $I/I_0$ , or  $I(t)$ , for an initially uniform density of occupied traps is

$$I(t) = [\exp(-st\eta_d) - \exp(-st\eta_s)] / (\eta_s - \eta_d) st$$

When  $E_d \gg E_s$

$$I(t) = [1 - \exp(-st\eta_s)] / st\eta_s$$

and at large  $t$ :  $I(t) \rightarrow 1/(st\eta_s)$

Case II:  $\alpha = (kt)^{-1}$ <sup>11</sup>

$$I(t) = 2 \{ [1 + st \exp(-E_d/kT)] \exp[-st \exp(-E_d/kT)] - [1 + st \exp(-E_s/kT)] \exp[-st \exp(-E_s/kT)] \}$$

$$X \{ [\exp(-2E_s/kT) - \exp(-2E_d/kT)] (st)^2 \}^{-1}$$

For  $E_s = 0$ , and  $E_d \rightarrow \infty$ :  $I(t) = 2 [1 - (1 + st) \exp(-st)] / (st)^2$ . In addition, for  $t \rightarrow \infty$ :  $I(t) \rightarrow 2/(st)^2$ . Note that this shows, as also pointed out by others (18), a  $t^{-2}$  dependence does not necessarily imply a bimolecular process.

In second order kinetics, if the number of excited electrons  $\mathcal{N}$ , is comparable with the number of available centers, the probability for recombination is proportional to  $\mathcal{N}$  and hence  $\mathcal{N}$  decreases hyperbolically with time. The luminescence decay can be written:

$$I/I_0 = 1 / [1 + (I_0 p)^{1/2} t]^2$$

that is, at large  $t$ ,  $I \propto t^{-2}$ . However, the decay is independent of the duration of excitation and also becomes more rapid as the intensity is increased (11, 19). In the present study we do observe a dependence

<sup>10</sup>  $E$  = the minimum energy required to liberate a trapped electron and hence is called the activation energy.

<sup>11</sup> This value of  $\alpha$  is chosen because it is the only other one in the range  $1 \leq n \leq 2$  (or  $0 \leq \alpha \leq 1$ ) for which we have found it possible to perform the integration in closed form and, to our knowledge, the result has not previously been published.

Table II.  $n$  values

Phosphor	Value of $n$
P 22B (ZnS:Ag,Cl)	$1.035 \pm 0.01$
P 11 (ZnS:Ag,Cl)	$1.10 \pm 0.01$
P 31 (ZnS:Cu,Cl)	$1.20 \pm 0.01$

of the decay on duration of excitation. Hence we must conclude either that (a) first order kinetics are dominantly involved or (b) if second order, the two processes involved must have widely different characteristic times since, in that case, the slower process would be the controlling one.

The Modified Bimolecular Decay model (20) (with unequal numbers of electrons and available centers) would not be a possibility since it leads to the prediction of an exponential decay at large  $t$ . If retrapping were involved and considered as a replenishment of the shallower empty traps, the effect on the decay curve after a period greater than a few average lifetimes would be negligible.<sup>12</sup>

Case III:  $0 < \alpha < 1$

Although it was not found possible to secure a closed form for the  $I(t)$  integral in these cases, a numerical integration was performed by computer. Curves were obtained for values of  $n$  ranging from 1.00 to 2.00. It was established that the limiting form at large  $t$  was

$$I(t) = n(st)^{-n} \quad (13)$$

The values of  $n$  found are given in Table II.

The numerical integration curves most nearly matching these experimental results at large  $t$  were plotted and compared with the data. In all cases the calculated curves rose above the experimental points for the smaller values of  $t$  (Fig. 7). It was found that if one added to the calculated  $I(t)$  a pair of appropriately chosen exponential contributions (with lifetimes much shorter than  $\tau$ ) a very much closer fit was obtained (Fig. 7). Such exponential contributions to the emission would be just those produced by pairs of (a) a single short life time originating in the conduction band, (b) one or two very shallow traps, or (c) excited centers. There are five possible pair combinations. The results are consistent with the observed importance of very shallow levels (22-26) and the fast exponential decay observed by others (27). The work of Belikova (22), ZnS:Cu,Cl, and Shionoya (27), self-activated ZnS, show that short excitation times by uv give decay times comparable with those observed in this work.

### Conclusions

One hypothesis can be proposed: in a given material, when shallow traps are more abundant one gets greater relative efficiency and shorter decay<sup>14</sup> (e.g., the P 22B and P 11's studied here are ZnS:Ag, Cl phosphors quite possibly involving different preparation and processing<sup>15</sup>). The P 22B had a higher efficiency and a faster decay (10% point: 7  $\mu$ sec vs. 12.5  $\mu$ sec). The difference is consistent with the supposition that there is a greater density of shallow traps in this P 22B sample than in the P 11's. Such marked effects of preparation and processing on phosphor characteristics strongly underscore the recommendation of Bube (28) and several others that as many different types of measurement as possible should be made on the same sample in order that correlations

<sup>12</sup> Although Garlick and Gibson (21) concluded that retrapping was negligible in the time range 0.01-10 sec, its importance would increase with shorter times as studied here, hence the reason for discussing its possible effect.

<sup>13</sup> Note that in Cases I and II we already had a hint of the factor  $n$  when we obtained  $1/X(st)^{-1}$  and  $2/X(st)^{-2}$ .

<sup>14</sup> By relative efficiency in this context is meant the light output from the phosphor screens of cathode-ray tubes (under the same beam current density and accelerating potential) as recorded photographically.

<sup>15</sup> The effect of preparation and processing on the density and location of shallow traps has been pointed out by others such as Riehl (29) and Bundel (26).

Fig. 7. Comparison of experimental "limiting" phosphorescence data for a P 31 phosphor with (a) calculated curve on basis of assumed trap band density:  $\exp(-0.2E)$ ,  $0 \leq E \leq 15kT$  and (b) calculated curve assuming (a) plus two appropriately weighted, short life time (shallow?) levels.

of such measurements may be made with maximum assurance and reliability.

A summary of the best match to the experimental results is given in Table III. The final equation for total (normalized) intensity is

$$\text{Total } (I/I_0) = XI(t) + Y \exp(-t/\tau_2) + Z \exp(-t/\tau_3)$$

Although, for the P 22B, a weighting of  $X = 0.25$  was tried with resultant values of  $\tau = 3.75$ ,  $Y = 0.30$ ,  $\tau_2 = 0.16$ ,  $Z = 0.45$ , and  $\tau_3 = 0.68$  it was found that the fit was only about half as good as that finally obtained.

From the present work two general conclusions may be drawn for these particular commercial phosphor samples. (a) the luminescence decay at  $t \gg \tau$  is hyperbolic (power law), but (b) in the measurements made (i.e., short duration of cathode-ray excitation) the light sum was primarily from centers of short lifetime and the major part of the light (i.e., that which in our analysis was ascribed to the power law decay) must be due to the emptying of levels shallow compared to those determined by glow curve measurements made above liquid nitrogen temperatures. That the shallow traps yield a light sum comparable to that observed from the more commonly studied peak at about 175°K is indicated in the results of several authors (14, 29-31). Specific shallow traps observed by Riehl (29) were in a ZnS: 0.01% Cu, Cl phosphor. For each of his low-temperature peaks (25° and 50°K) he found concentrations of filled traps comparable with those of the deeper traps usually observed via glow peaks above 100°K. The results of Thoma (32) indicate that the concentration of the additional filled traps at 4.2°K is even larger than that observed for the same phosphors at 80°K.

In the analysis of the data a value of  $\tau$  is obtained and hence a  $p$  in the power law expression. Since  $p = s \exp(-E/kt)$  (the  $E$  being for a single trap or for the top of our assumed band), one must choose a value of  $E$  and then compute the implied  $s$ , or *vice versa*. It is commonly assumed that  $s$  is a constant of the host crystal. If this assumption is made the different values of  $\tau$  (Table III) can be attributed to different locations of the top of the continuous band of filled traps in the

Table III. Constants for best match to experiment (times in  $\mu$ sec)

Phosphor	Trap Band		1st Add'l. Level		2nd Add'l. Level	
	X	$\tau$	Y	$\tau_2$	Z	$\tau_3$
P 22B	0.20	4.7	0.45	0.17	0.35	1.10
P 11	0.20	8.0	0.35	0.27	0.45	2.90
P 31	0.20	16.9	0.35	0.48	0.45	3.30

proposed model. If one chooses three values for  $E$  in the range shown possible by Riehl, an implied value for  $s$  of approximately  $10^6/\text{sec}$  is found. For example,  $E_s = 0.02$  eV for the P 22B yields an  $s$  of  $0.5 \times 10^6/\text{sec}$ . Using this value for  $s$  one gets  $E_s = 0.035$  eV for the P 11 and an  $E_s$  of 0.046 eV for the P 31. If, instead, one takes  $E_s = 0.05$  eV for the P 22B this yields an  $s$  of  $1.6 \times 10^6/\text{sec}$ , in turn implying an  $E_s$  of 0.063 eV for the P 11 and an  $E_s$  of 0.075 eV for the P 31. Because of the difficulty of determining  $s$  with precision, a wide range of possible values may be found in the literature (11, 13, 14, 21, 33). Because of the complexities involved, the possibility that  $s$  may be different for different traps (and hence not a constant of the host crystal) will not be considered here. One of the most recent determinations, by Kröger (33), gives  $s \approx 10^5$  (converted to room temperature) for a ZnS:Cl ("self-activated") phosphor.

In addition to the evidence for the existence of significant shallow traps, it does not seem that the decay times observed can be ascribed to the emptying of those deeper traps indicated by the glow peaks near 175°K. As can be seen in the work of Bube (14), the phosphor was heated slowly (30 sec/°K) for good resolution of peaks, yet there was no substantial shift in the location of the peak. The phosphor was held many minutes in the temperature range 125°-150°K. Thus, one must ascribe a decay time of the order of several minutes to the traps whose thermal emptying contributed to that glow peak. If the 175°K traps were responsible for the phosphorescence seen at room temperature, it can easily be shown that (because of the exponential temperature dependence of trap emptying) the computed  $\tau$  would be more than two orders of magnitude greater than that which is observed.

It appears unlikely that many of the conventionally obtained glow curves indicate the true concentration of shallow traps. Those curves which begin near liquid nitrogen temperature show a significant level of light intensity at their beginning (14, 34, 35). In addition, some authors state that they wait as long as minutes for the initial luminescence to decay before beginning the warming process (36, 37).

#### Acknowledgments

Grateful acknowledgment is made for the original circuit work and associated luminescence measurements made by Mr. Craig J. W. Gunsul. The authors are similarly indebted to Mr. Frank Christiansen and Mr. James Richardson for help in making the persistence measurements and the advice of Dr. Richard Coover in refining programming procedures.

Manuscript received Aug. 24, 1967; revised manuscript received ca. Oct. 5, 1967. This paper was presented at the Cleveland Meeting, May 1-6, 1966, as Abstract 21.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Ellipsometric Investigations of Boron-Rich Layers on Silicon

K. M. Busen,\* W. A. FitzGibbons, and  
W. K. Tsang

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

## ABSTRACT

It is shown that exposure of a silicon substrate to sufficiently high concentrations of diborane results in a surface layer which most likely consists of a silicon-boron phase. This phase, which is controlled by the diborane concentration and the temperature, gives rise to a prediffused layer of boron in the adjacent substrate. Good control of the phase layer affords good control of the prediffused layer. When the phase layer is removed prior to drive-in, optimal control is achieved with respect to the final diffused structure.

The diffusion of impurities in silicon for the processing of electrical components and circuits is determined by the well-known parameters: composition of the gas phase which contains the impurity, time of diffusion, and temperature of the silicon sample. At very high impurity concentrations, a new influential parameter may be introduced by formation of a surface layer whose phase differs from that of the bulk of the sample. Such a layer has been observed by Schmidt and Owen (1). The authors report "the occurrence of a steep spike in the phosphorus concentration at the Si/SiO<sub>2</sub> interface" for samples which were diffused from oxide films on silicon as the impurity carrying source. The nature of the phosphorus layer has been discussed by Kooi (2) who suggests that it may consist of a "Si-P" phase. The investigations described in this article are concerned with samples which were exposed to very high concentrations of diborane gas, and it was concluded that similar to the findings above the formation of a Si-B phase constituting a layer is very likely. It will be shown in this article that under proper conditions such a layer acts as a source for boron diffusion into the adjacent silicon bulk and that control of this layer offers precise control of the diffusion itself.

## Preparation of Samples and Measurements

Silicon slices (1 ohm-cm n-type) were annealed in an ambient of N<sub>2</sub> + O<sub>2</sub> and then were exposed for 5 min at temperatures ranging from 930° to 1100°C to an ambient of N<sub>2</sub> + O<sub>2</sub> + B<sub>2</sub>H<sub>6</sub> (300-1000 ppm) with a total flow of 2 l/min. The O<sub>2</sub> concentration was kept constant at 1% at all times. After diborane exposure, the ambient was changed to an N<sub>2</sub> + O<sub>2</sub> atmosphere again, and heating was continued for 15 min. Glass layers form on the slices during this procedure. The samples thus obtained were subdivided into three groups and, after the samples had been subjected to specific treatments, ellipsometric measurements of the change in the amplitude ratio  $\psi$  and of the relative phase change  $\Delta$  as described by Archer (3) were performed:

(a) The glass layer of samples in this group was removed in small steps by a glass etch. Ellipsometric measurements were taken after each step until  $\psi$  and  $\Delta$  remained constant. The etch consisted of 16 ml conc. HF and 40g NH<sub>4</sub>F dissolved in 100 ml of water (buffered HF).

(b) The glass layer of samples in this group was removed in large steps by another glass etch, which consisted of 1 ml conc. HF diluted in 10 ml H<sub>2</sub>O. Application of the glass etch was terminated when  $\psi$  and  $\Delta$  no longer changed. Then a new etch was applied repeatedly. This etch, which dissolves silicon, consisted of a mixture of HF:HNO<sub>3</sub>:CH<sub>3</sub>COOH =

1:2:6. Subsequent measurements by the ellipsometer showed new changes in  $\psi$  and  $\Delta$ . The etching was terminated when  $\psi$  and  $\Delta$  remained constant again.

(c) This last group was formed by samples which had been reoxidized successively in dry, wet and dry oxygen at 1130°C. The resulting silicon oxide layer was removed in small steps by buffered HF. Ellipsometric measurements were taken after each step until  $\psi$  and  $\Delta$  remained constant.

The results of the ellipsometric measurements are summarized in Fig. 1, where curves I, II, and III are plots of  $\Delta$  vs.  $\psi$  for surfaces as treated according to (a), (b), and (c), respectively.

For reasons to be discussed later, two special samples, A and B, were prepared by exposing silicon slices to an ambient of low and of high B<sub>2</sub>H<sub>6</sub> content, respectively. After removal of the glass,  $\psi$  and  $\Delta$  were determined for each sample. The values were  $\psi_A = 13.27^\circ$ ,  $\Delta_A = 145.65^\circ$  and  $\psi_B = 18.17^\circ$ ,  $\Delta_B = 108.60^\circ$  for sample A and B, respectively. Measurements of the r<sub>p</sub>-component (light vibrating in the plane of incidence after reflection) showed that the intensity of r<sub>p</sub> changed with the angle of incidence and went through a minimum at 76° for sample A, whereas, the intensity of r<sub>p</sub> decreased monotonically with the angle of incidence for sample B.

Fig. 1. Experimental results for samples subjected to specific treatments. Curves I, II, and III refer to measurements on a glass layer, on a phase layer, and on a silicon oxide layer, respectively.

\* Electrochemical Society Active Member.

It will be shown later that silicon slices which are exposed to  $B_2H_6$  concentrations between 300 and 1000 ppm acquire a layer consisting of a silicon-boron phase. This phase is sandwiched between glass and silicon bulk and is insoluble in any glass etch. If one wants to remove the phase layer, one either can use the silicon etch mentioned above or one can apply a two-step process consisting of a 10 min boil in conc.  $HNO_3$  followed by a 30-sec dip in diluted HF. Very thin phase layers dissolve completely after application of the two etching steps, but thicker layers may require repetitions. Since neither step affects the silicon bulk, a selective "phase removal" is possible.

The thickness of the phase layer on sample B was measured by multiple beam interferometry (4) and was found to be  $245 \pm 20 \text{ \AA}$ . This value is representative for the majority of the samples in groups (a) and (b) because these samples and sample B differ only slightly in their measured  $\psi$  and  $\Delta$ . The phase layer on sample A is about  $120 \text{ \AA}$  thick according to investigations by the ellipsometer.

### The Si-B Phase

The ellipsometric measurements are summarized by the curves shown in Fig. 1. In this figure, curve III fits points which refer to some samples in group (c). The curve, when traced in clockwise direction, signifies a sequence of oxide layers whose thickness is decreasing. For a vanishing layer, one theoretically should arrive at  $\psi$  and  $\Delta$  values which are marked by O in Fig. 1. This hardly ever occurs because the silicon surface is always covered by small amounts of residues from etching or other treatments. Archer measured values of  $\psi = 11.80^\circ$  and  $\Delta = 175^\circ$  for a cleanest etched silicon surface. In the present investigation, the end of curve III was found to be at  $\psi_1 = 12.2^\circ$  and  $\Delta_1 = 176.5^\circ$ . The values are close to Archer's values and indicate, therefore, that after removal of the oxide a bare silicon surface was left. According to Fig. 1 of ref. (3), curve III corresponds to an index of refraction of about 1.46.

Curve I goes through points which originate from measurements on samples of the first group. The curve is terminated by the black triangle shown in Fig. 1. The fact that curve I does not end at  $\psi_1$  and  $\Delta_1$  characterizes a surface which is different from a silicon surface. This particular surface seems to be formed by a Si-B phase because: (i) glass etches did not move the end of curve I to  $\psi_1$  and  $\Delta_1$ , and, thus, it is not a glass layer which causes the deviation; (ii)  $V/I$  values measured by the four-probe on phase surfaces were typically around 10 for samples whose phase layers were about  $250 \text{ \AA}$  thick. If the surface belonged to a glass or to an oxide of the same thickness, a  $V/I$  value could not be measured by the four-probe because of the very high resistivity; (iii) phase surfaces of many samples could be converted to silicon surfaces by application of the silicon etch mentioned in (b). This is demonstrated by curve II, which starts at the triangle in Fig. 1 and moves to the black circle in the neighborhood of  $\psi_1$  and  $\Delta_1$ . The triangle represents the average of ellipsometric values which were measured for many phase surfaces and similarly the circle represents the average of values obtained after treatment by the silicon etch.

For sample A, which had a  $120 \text{ \AA}$  thick phase layer, the intensity of the  $r_p$ -component went through a minimum at  $76^\circ$ . Because this angle is identical to the principal angle of  $76^\circ$  for silicon [see, e.g., Ditchburn (5)], it was thought first that this would be indicative of a "silicon-rich" nature of the phase (6). Measurements on anodically oxidized samples (7) having about the same oxide thickness showed, however, that these samples had minima which were close to the  $76^\circ$  angle too. A special method to compute the minima for the oxidized samples as a function of layer thickness (8) led to values which were in good agreement with the measurements. This shows that the observation of

the  $76^\circ$  angle for sample A does not offer enough evidence for the assumption in ref. (6) "... that the reflection comes from a silicon-like surface." The missing minima for sample B and for a sample with a  $250 \text{ \AA}$  thick oxide layer demonstrate, in addition, that no relevant distinction can be made between a phase and an oxide. Sample B was used to determine the refractive index of the phase layer. It was assumed that the layer was sufficiently thin so that no substantial attenuation of the light could take place. Together with the measured thickness of the phase layer the  $\psi$  and  $\Delta$  values give a refractive index of 1.7. Measurements on other phase layers resulted in indices of refraction between 1.6 and 1.7.

### Effect of the Phase Layer on Diffusion

For the following discussion, it is useful to establish some terminology: The term "deposition" refers to a thermal process which results in the formation of two adjacent layers, one being a boron-containing layer intimately associated with the silicon substrate and the other one being a glass layer. A "diffused layer" is the layer which is confined by the silicon surface and the junction which forms by diffusion. "Drive-in" is a process where the boron originating from deposition penetrates further into the silicon bulk by diffusion. A "profile" is the concentration distribution of boron after diffusion. The expression, "control in  $V/I$ ", is related to the differences in  $V/I$  measurements from run to run.

$V/I$  measurements by the four-point probe in combination with the junction depth,  $x_j$ , offer a convenient way to examine the control of diffused layers. For the samples in this investigation it is assumed that the diffused layer is small in comparison with the probe distance, that the surface concentration,  $C_0$ , is much greater than the background concentration of the silicon and that  $x_j$  stays practically constant. Then the average resistivity,  $\bar{\rho}$ , of the layer can be expressed by  $\bar{\rho} = (V/I) 4.53 x_j \rho$  on the other hand, is determined by the diffusion profile as has been shown, e.g., by Busen and Shirn (9). Thus  $V/I$  values can be used as a criterion for diffusion control. During the investigations, junction delineations were performed on various samples. All of these delineations resulted in junction depths which differed by less than  $0.05 \mu$ .

In a number of extra experiments, two sets of samples were subjected to a deposition process. The samples of the first set had a Si-B phase. The second set, which was prepared with a lower  $B_2H_6$  concentration, was free of a phase layer. The samples of each set were then divided into two parts. One part was subjected to phase removal. The other part was left unetched. Finally, all samples were subjected to a drive-in process. The processing steps for this investigation are summarized in Fig. 2. An examination of the samples by  $V/I$  measurements after drive-in led to results which are listed in Table I.

Table I demonstrates that the formation of a phase layer affords a good control of  $V/I$  and that phase removal before drive-in improves the control. When no phase layer is formed, the control becomes poor. Thinner layers, which are not removed prior to drive-in, do not change the control substantially, whereas, thicker layers do. The temperature at which the phase layer is formed during deposition is high enough to cause a diffusion of boron into silicon with the layer acting as a source. In order to distinguish this process from the diffusion which takes place during drive-in, the diffusion into silicon during deposition is called "prediffusion." When the phase layer has been removed, the only remaining boron source for drive-in is the layer which was formed by prediffusion and, consequently, a good control for drive-in is based on a good control of the prediffused layer. Since the prediffused layer originates from the phase layer, the formation and control of the latter layer is an important factor in the control of the "total" diffusion.

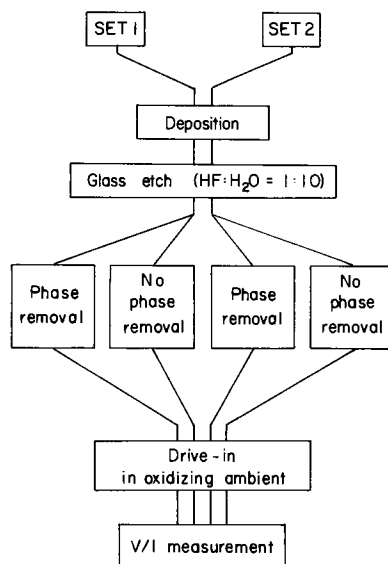

Fig. 2. Processing steps for the investigation of diffusion control. The deposition was for 5 min at 1000°C in an ambient of  $B_2H_6 + N_2 + O_2$ . Set 1,  $B_2H_6$  concentration > 300 ppm; set 2,  $B_2H_6$  concentration < 200 ppm.

The term "total" expresses here the combined action of prediffusion and drive-in diffusion. Experimental evidence shows that the phase layer is controlled by two parameters. The first one is the critical range for the diborane and oxygen concentration and the second one is the temperature control during deposition. In the experiments described here, this control was better than  $\pm 0.5^\circ C$ .

The experimental results, showing good control in the presence of a phase layer, are easily interpreted by the assumption that the amount of boron in the prediffused layer is well controlled by the surface concentration,  $C_0$ , which, in turn, depends on the composition of the Si-B phase according to  $C_0 = k_s C_s$ . In the last equation,  $C_s$  is the concentration of boron in the phase, and  $k_s$  is the distribution coefficient of boron between silicon and the phase. Since  $C_s$  is a function of the temperature only, control of the temperature is synonymous with control of the total diffusion. One of the authors (10) observed in former investigations that a phosphorus-rich layer formed on the surface of silicon slices which had been exposed to sufficiently high  $POCl_3$  concentrations. The necessity to remove this phase for better diffusion control pointed to a model which is very similar to the one described for Si-B in this article.

The foregoing discussion offers an insight into the mechanism of the prediffusion, and Fig. 3 illustrates the relations existing for this kind of diffusion. The figure shows the  $SiO_2-B_2O_3$  glass, which forms during deposition, the phase layer which forms underneath the glass and the silicon substrate with boron prediffused from the phase layer. Boron concentrations are indicated by heavy lines. The concentration distribution of boron after drive-in diffusion is not shown here. For optimal control of the concentration dis-

Fig. 3. Model for prediffusion

tribution in the substrate after drive-in diffusion, the deposition has to be carried out in such a way that the composition of the phase is solely a function of the temperature. The phase layer must be removed after deposition so that a well-controlled prediffusion layer can act as a finite source for subsequent drive-in diffusion. It is of interest to compare the above diffusion mechanism with the mechanism observed by Duffy *et al.* (11). The authors report that their diffusion experiments were carried out "in the concentration region where no insoluble phases form." Therefore, their  $C_0$  was directly "dependent . . . on the  $B_2O_3$  concentration in the glass at the silicon surface," whereas, the  $C_0$  here in Fig. 3 depends on the boron concentration in the phase layer.

Some simple experiments confirmed the expectation that the phase layer grows when the time of deposition increases. Thicker layers normally looked brownish or golden and changed their color on etching. If no action is taken to remove the phase layer after deposition, the supply of boron is unlimited during subsequent drive-in diffusion as long as the layer is only negligibly depleted and consequently a erf-distribution is formed. A severe depletion of the phase during drive-in diffusion, however, would cause a deviation from the erf-distribution. A profile resulting from such a deviation would pose some problems for a mathematical treatment and, therefore, would be unsuitable for device design.

Another problem arises from the observation that the phase layer may not be uniform because of a temperature gradient or of an inhomogeneous gas flow pattern in the furnace tube. This nonuniformity can be observed either on a single sample or among two samples which, for themselves, are uniform. In this case, it is not practical to rely on the phase layer as an additional source during the drive-in process, but it is preferable to remove the layer because then only the very precisely controlled prediffused layer acts as a boron source. For very thin phases (less than 50Å), the drive-in diffusion is not affected very much because the amount of boron is substantially higher in the prediffused layer than in the phase layer.

## ABSTRACT

Beryllium oxide crystals weighing up to 1.3g have been grown hydrothermally with the nutrient temperature at  $530^{\circ} \pm 5^{\circ}\text{C}$  and the growth temperature at  $500^{\circ} \pm 5^{\circ}\text{C}$ . An alkali hydroxide solution of 4N KOH and 0.06N LiOH was used as the hydrothermal solvent. Growth occurred in the vapor phase above the solution. The quality of the seeds used has a major effect on the quality of the crystals grown. The mean growth rate parallel to the c-axis was 0.0026 in./day, but rates of over 0.0056 in. have been measured. The relative growth rates in the various crystallographic directions are

$$[11.0] > [00.1] \sim [00.\bar{1}] > [11.1] > [10.1] > [10.0]$$

The effects of the seed orientation on the quality of the crystals produced are

$$[10.1] \sim [11.1] > [11.0] \sim [10.0] > [00.1] \sim [00.\bar{1}]$$

It is the positive pyramidal termination which is nucleated and grown on the seed.

Beryllium oxide has recently attracted special attention as a ceramic material because, in comparison to alumina which is currently being used, it has a very high melting point, comparable mechanical strength, lower specific gravity, higher electrical resistance particularly at elevated temperatures, and a much greater thermal conductivity. These properties, particularly the latter two, make it unique for heat sink applications in microelectronics, specifically in the area of silicon monolithic integrated circuits. The deposition of a thin semiconductor film on BeO substrates has been achieved (1, 2). The single crystal silicon films were grown from both  $\text{SiCl}_4$  and silane on most of the natural faces of BeO at a substrate temperature of  $1150^{\circ}\text{C}$ . Because of the high deposition temperature, it is necessary that the crystals be of high quality, or they will decrepitate.

Although BeO single crystals have been successfully grown from lithium molybdate fluxes (3-5), the hydrothermal method of crystal growth, which has been successfully applied to the growth of large crystals of quartz, corundum, and other crystals, is potentially capable of growing single crystals of a very refractory oxide at moderate temperatures (6). This enables the growth of more perfect, and strain free crystals than are generally obtained using high temperature methods.

*Previous work.*—Many previous attempts to grow BeO crystals involved either crystallization from molten salts or vapor phase techniques (3-5). In addition, Newkirk and Smith (5) investigated the application of hydrothermal methods to the growth of BeO crystals in both neutral and alkaline environments. In other work, Newkirk (7) has also determined the stability relations for the systems  $\text{BeO-H}_2\text{O}$  and in NaOH solutions with concentrations to 8.02M, as a function of temperature and pressure up to  $600^{\circ}\text{C}$ , and 4100 bars. No noticeable difference was found between the phase diagram for the neutral solutions and that

for NaOH solutions. Newkirk found that the univariant reaction curve passes through the points  $200^{\circ}\text{C}$  at 4100 bars, and  $170^{\circ}\text{C}$  at 300 bars. He also observed that BeO formed in the range  $175^{\circ}$ - $250^{\circ}\text{C}$  was not well developed and possessed a larger unit cell than that normally attributed to BeO. Newkirk and Smith (5) demonstrated that small BeO crystals could be grown hydrothermally in 2.03M NaOH solutions at  $400^{\circ}$ - $425^{\circ}\text{C}$  and 2000 bars. They obtained prismatic crystals 0.125 in. long, which grew in the positive polar direction at a rate of 0.005 in./day.

### Equipment and Materials

*Hydrothermal equipment.*—The hydrothermal equipment used in this work for solubility determinations and preliminary crystal growing runs was two Tem-Pres hydrothermal research units Model HR-1B, fitted with "test tube" type autoclaves fabricated of René or Stellite super alloys. The vessels operating at lower pressures were fitted with cone seals. For the higher pressure range, modified Bridgman-type seals were used. The maximum inside diameter of the test tube-type reactors was 0.5 in.

Three hydrothermal crystal growing systems were used. These were designed to take the Tem-Pres LRA-150 series of autoclaves. The furnaces were Kanthal wound and had two independently controlled temperature zones. Two of these systems had variacs between the control system and the furnace so that the furnace power could be varied to give better control of the temperature gradient in the furnace. The third system incorporated saturable core reactors between the controllers and the furnace. This was particularly useful when small thermal gradients were required. The Tem-Pres LRA-150 autoclaves used were of René and Stellite. The interiors of the vessels were lined with closely fitting silver thimbles. The internal dimensions of the vessels were 1.25 in. diameter and 7.0 in. deep. The seal was of the modified Bridgman type, with one

silver and one brass washer. The inclusion of the brass washer produced a good seal with little distortion of the silver washer. This was particularly important at temperatures above 500°C, because of the plastic flow of silver at the pressures involved.

**Starting materials.**—The manufacturer's batch analysis of the BeO powder used was 99.9%, and the KOH 99.9+%. These were both supplied by the Gallard-Schlesinger Chemical Manufacturing Corporation, Carle Place, New York. Demineralized water from a mixed bed unit was used to prepare solutions. The BeO powder was formed into pellets and fired to about 1400°C by Coors Porcelain Company, Golden, Colorado. The spectrographic analysis of the BeO powder and the pellets made from it are given in Table I. The semiquantitative spectrochemical analyses show that the pellets were contaminated at some stage in the fabrication process. The contamination was, however, not homogeneous. It will be shown later that of the contaminants only SiO<sub>2</sub> is significant in growing crystals of BeO.

### Procedures

The solubility determinations were made on pelletized polycrystalline BeO and on selected single crystals. The solvents used were usually made up as standard solutions from which aliquots were pipetted into noble metal capsules. Where the solubility of the particular compound in water at room temperatures was too low for solutions of the desired strengths to be made up, weighed amounts of the compounds and water were placed in the tube, and the strength of the solutions used at elevated pressures and temperatures calculated from this data. In either case, weighed amounts of BeO and the solvent were sealed in the capsule, which was then placed in the test tube type autoclave and rapidly brought to the required temperature and pressure. The run was usually maintained under these conditions for two days. However, at the higher temperatures and pressures some runs were for a shorter time. In the cases where single crystals of BeO were used in the low temperature range, the period was sometimes extended to five days as a check on equilibrium. The autoclave was quenched and the pressure lowered at the end of the run.<sup>1</sup> The loss in weight of the thoroughly washed and dried pellet was used to calculate the solubility of BeO in the particular solvent in grams of BeO per 100g solvent. When polycrystalline aggregates were used, it was sometimes noticed, particularly in the alkaline solvents, that the pellet recrystallized during the run, and there was nucleation and growth of new BeO crystals. Since it was not practical to collect all the primary crystals quantitatively and at the same time exclude secondary crystals produced during the quench, the run was repeated for a shorter time until the only crystals found were very fine-grained crystals which were presumed to be formed by supersaturation of the solvent with respect to BeO during quenching. In spite of this, it was difficult to prevent recrystallization of BeO in some of the higher temperature runs because of spontaneous nucleation.

<sup>1</sup> Temperatures were lowered to below 100°C in less than 30 sec.

It was, therefore, necessary to use single crystals for these determinations.

The solvents evaluated were 0.1 to 10 normal solutions of H<sub>2</sub>SO<sub>4</sub>, HNO<sub>3</sub>, HCl, HF; 2-8 normal solutions of LiOH, NaOH, KOH, and K<sub>2</sub>CO<sub>3</sub>; 100% Ca(OH)<sub>2</sub>, and the eutectic mixtures in the system Ca(OH)<sub>2</sub>-CaF<sub>2</sub>-CaCO<sub>3</sub>. The lime flux was specifically included in this study because BeO (bromellite) occurs as 1 mm long prismatic crystals in calcite rich rocks from Langban-shyttan, Vermland, Sweden (8), and it was desirable to investigate the use of a solvent which is related to the known geological occurrence of the mineral.

**Culture and preparation of seeds.**—Large high-quality crystals of bromellite (BeO) are not known to occur in nature and so were grown as part of the project. Small seeds 0.1 and 0.2 in. were obtained from runs in sealed 10 mm gold tubes and also from the walls of the LRA-150 vessels in most crystal growth runs. However, because of the mutual interference of the crystals the layer self-nucleated crystals were often of poor quality. This was particularly evident at high temperatures. A 0.0013 in. diameter hole was drilled through the better crystals and a 0.01 in. diameter platinum wire threaded through. These crystals were then suspended in 5 or 10 mm diameter gold tubes. A 4N KOH solution was used as solvent and pelletized BeO as nutrient. These overgrown crystals were further examined and the best ones selected for growth studies. When large enough seed plates of the required orientations were cut from them, the surfaces of these plates were cleaned by boiling in nitric acid.

It was necessary in all cases to determine the quality of the seeds to be used in each run. To do this the opposite faces of the seeds were polished. They were then examined under the binocular and petrographic microscopes. Particular attention was paid to the presence of twinning, inclusions, cracks and strain. A defect which was present in most of the seeds was the ghost boundary of each overgrowth cycle. These boundaries were not well defined when the overgrowth occurred in the lower temperature region of the solubility curve. However, when rapid growth occurred a well-defined junction was observed. Often these contained a small amount of fluid.

**Crystal growth technique.**—The seeds were suspended by platinum wires strung through the holes drilled in them as illustrated in Fig. 1. The autoclaves were divided into two "isothermal" regions by a baffle with a 10% opening. The baffle was held in position by two silver rods joining it to a silver basket at the bottom of the vessel. This basket contained the nutrient material. The thimble lining the autoclave, baffle and basket assembly, and closure plate were all made from silver of the same composition (99.99% pure, supplier's specification).

## Results

**Solubility studies.**—The solubility of BeO in acid solvents ( $\text{H}_2\text{SO}_4$ ,  $\text{HNO}_3$ ,  $\text{HCl}$ , and  $\text{HF}$ ) is dependent on the concentration of the acid used. A syrup was formed in 10N  $\text{H}_2\text{SO}_4$  runs below  $600^\circ \pm 25^\circ\text{C}$ , while in some runs at a somewhat higher temperature both crystals and syrup were obtained. Runs at temperatures of  $1000^\circ\text{C}$  and above gave a most interesting sulfate "glass" of a faint purple to gray color. This "glass" was deliquescent, and on exposure to air it changed to a thick plastic mass. Both the glass and syrup were soluble in water. The glass devitrified on standing at room temperature. Spherulites were present in some of the glasses.

It was established that in acid solutions there was an initial reaction between BeO and the dissolved ions, followed by the decomposition of the product of this reaction to provide BeO nutrient material. The decomposition temperature of these intermediate products varied over wide limits, and in runs with  $\text{HNO}_3$  the nitrate was sometimes found intergrown with BeO. BeO was found to have appreciable solubility in 10N  $\text{H}_2\text{SO}_4$ , but preliminary attempts at crystal growing with this solvent showed that there was a strong tendency for spontaneous nucleation of crystals above the decomposition temperature of beryllium sulfate. This resulted in a mass of fine-grained crystals which did not show any marked tendency to grow as the duration of the runs was increased.

The solubility of BeO in fluxes such as  $\text{Ca}(\text{OH})_2$ , the eutectic mixtures in the system  $\text{Ca}(\text{OH})_2\text{-CaF}_2\text{-CaCO}_2$  and  $\text{CaF}_2$  was very low and only very fine grained BeO was produced. Studies of the solubility of BeO in the alkali solvents  $\text{LiOH}$ ,  $\text{NaOH}$ ,  $\text{KOH}$ , and  $\text{Na}_2\text{CO}_3$  showed that the alkalis had slightly lower solvent power than the acid solvents and (but for  $\text{LiOH}$  and  $\text{Na}_2\text{CO}_3$ ) the crystals grown increased in size with the duration of the run. Figure 2 shows the change in solubility with respect to temperature for some of these solvents at several pressures.

**Growth measurements.**—On the basis of the solubility studies and the quality of the BeO crystals nucleated during these runs, 4N KOH was selected for the growth rate measurements. These data also suggested that the optimum temperature for growth is in the range  $500^\circ\text{-}700^\circ\text{C}$ . The results of these studies are summarized in Table II.

**Some factors influencing crystal quality.**—The determination of the growth rate of the crystals at different temperature conditions using seeds of various orientations served to define closely the best temperature conditions for growth. However, although it

was possible to readily grow BeO crystals weighing over 1g, these were sometimes of poor quality. Evaluations of the various factors involved in these runs served to demonstrate that the major factors affecting the quality of the crystals are (a) quality of the seeds, (b) orientation of the seed used, (c) presence of impurities in the autoclave, (d) too rapid growth rate, and (e) level of the meniscus in the vessel.

Figure 3 illustrates both the effects of seed quality and orientation on the quality of the crystal grown. Defects present in the seed were continued out into the new growth. The effects of seed orientation were also marked. Examination of several overgrown seeds including whole crystals under the microscope showed that the growing area was the positive pyramidal termination. It was this pyramid that was nucleated and subsequently generated the other crystal faces. The (00.1) plane acted as a twin plane. The result was that where the (00.1) was exposed for growth positive pyramids were nucleated there initially and resulted in an area of poor growth. However, since all of these were in the same crystallographic orientation,

Fig. 3. BeO crystals grown from seeds shown in Fig. 1

it was possible for them to heal by lateral growth. Unfortunately, this only occurred when the growth perpendicular to the c-axis was sufficiently fast to keep pace with the growth along the c-axis. Usually the lateral growth was much slower than that along the c-axis and a zone of inclusions occurred parallel to the c-axis. This means that the orientation of the seed must be such that the nucleation on this plane will not cause the crown-type growth which occurs when the (00.1) orientation is exposed for growth. To minimize this, the rate of growth of the seed must be such that few of these positive pyramids are nucleated and these spread out rather than form spires. The use of the [11.0], [11.1], and [10.1] seed plates would seem to encourage this type of growth. The first is not a naturally occurring face, the second occurs very rarely, and the third is a prism face. These seed plates along with others were tested to determine the effects of seed orientation of growth rate and crystal quality. The relative growth rates in the various directions are:

$$[11.0] > [00.1] \sim [00.\bar{1}] > [11.1] > [10.1] \sim [10.0]$$

The effects of the seed orientation on the quality of the crystals produced are:

$$[10.1] \sim [11.1] > [11.0] \sim [10.0] > [00.1] \sim [00.\bar{1}]$$

Impurities like cobalt and lithium affect the morphology of the crystals causing rounding of faces, etc. The effects of silica are not known, but it possibly increases the ease of nucleation of the crystal face. The incorporation of a trace of lithium in the structure minimizes this.

The growth rate of the crystal, particularly in the early stages has a marked effect on crystal quality. Part of the reason for this may be that cutting the crystal creates imperfections, and these become larger and more significant as growth takes place. The surface imperfections on the seed must be removed *in situ* etching followed by an initial period of very slow growth.

The presence of a poor junction between the seed and the overgrowth material has been a major factor in the growth of poor quality crystals because of the concentration of imperfections trapped at the interface. This problem was successfully solved by programming the heating cycle of the vessel. Three heating cycles were studied: (a) rapid heating to temperature, (b) slow heating to temperature, (c) rapid heating to a fixed temperature followed by slow heating. The first procedure gave the poorest junction of overgrowth to the seed and often caused seed dissolution. The second did not improve the quality over the first, but the seed usually remained undissolved. In the third cycle, satisfactory results were obtained by heating the autoclave to  $400^\circ \pm 20^\circ\text{C}$  and maintaining this temperature for 24 hr. The temperature of the autoclave was then raised to the desired value over a 24-hr period, while at the same time a temperature gradient of  $10^\circ\text{C}$  was maintained between the nutrient and growth zones. The autoclave was finally adjusted to the desired operating temperature when the temperature of the nutrient zone was within  $20^\circ\text{C}$  of that desired for the seed zone. This method permitted the dissolving of sufficient material from the seed for it to present a "clean" surface for growth, and so a good junction is possible. The BeO crystals in Fig. 3 were grown using this technique. The nutrient temperature was  $527^\circ\text{C}$  and the seed temperature  $504^\circ\text{C}$ . The stepwise heating cycle outlined above was used. The crystal grown on the [00.1] seed plate was of slightly lower quality, containing a significantly higher dislocation density than the other which was grown on a [10.1] plate. It was observed that the optimum amount of liquid required was such that it was initially below the level of the seeds, and when the vessel was operating, it should be just below the baffle. The level of the liquid inside the vessel during

a run was indicated by the location of the silver dendrites in runs which contained a small amount of oxygen.

**Growth conditions.**—Our experience with growing BeO crystals hydrothermally has established that the best conditions for growth under laboratory conditions are:

Vessel	150 ml autoclave fitted with a silver liner <sup>2</sup>
Solvent	Solution 4N with respect to KOH and 0.06N with respect to LiOH, 65 ml
Wt. nutrient	7g fired BeO pellets
Seeds	High quality BeO seed plates of [10.1] or [11.0] orientation
Baffle opening	10%
Nutrient temperature	$530^\circ\text{C}$
Seed temperature	$500^\circ\text{C}$

To avoid recrystallization of the silver by the KOH solution, the system must be purged of all traces of oxygen. This is easily accomplished by reacting a small piece of pure beryllium metal in the nutrient zone during the run (9).

Figure 3 illustrates the best BeO crystals grown to date, and Table III the purity of some of these crystals. The largest BeO crystal grown to date weighs 1.3g.

### Discussion of Results

One advantage of the hydrothermal method is the fact that the growing crystal is able to reject most of the impurities in the nutrient. Table I shows that the BeO pellets used as nutrient were contaminated with Ca, Mg, Al, and Si during the fabrication process. It is, however, significant that of these only  $\text{Si}^{4+}$  was incorporated in the growing crystal to any extent, and even here it was significantly reduced as compared to the level present in the nutrient. This is important because we have demonstrated that in the production growth of BeO it may not be necessary to use ultra-pure BeO. Experiments with the addition of small amounts of  $\text{Li}^+$  to the growth solution have shown that it is possible to offset the effects of the  $\text{Si}^{4+}$  entering the structure by  $\text{Si}^{4+}$  and  $2\text{Li}^+$  substitute for  $3\text{Be}^{2+}$ . This mechanism permits the filling of all metal ion sites in the structure. However, the amount of LiOH in the solution has to be carefully controlled, otherwise it causes the crystals to grow with curved faces.

One of the unique features of this work is the fact that the crystals are grown in a dense vapor phase above the liquid phase containing the nutrient. A baffle is, however, necessary to separate the vessel into two isothermal zones. The lower nutrient zone contains a

<sup>2</sup> Our experience shows that the design of the pressure vessel and liner affect the convection pattern and temperature profile inside the autoclave.

liquid phase and a vapor phase above it. The upper growth zone contains a vapor phase. The recrystallization process substantially improves the purity and quality of the crystals grown, particularly as the nutrient material has to go from the liquid layer to the vapor layer. It is also important that the meniscus of the liquid not be in contact with the growing crystals, otherwise poor quality crystals result. This may be due to the phase changes in the solution near the growing crystal.

#### Acknowledgments

This work was done as part of a research project on hydrothermal crystal growth sponsored by the U.S. Air Force Materials Laboratory, Wright-Patterson Air Force Base, Ohio. Mr. Paul W. Dimiduk was Project Engineer.

## Growth of Large Single Crystals of Gallium Phosphide from a Stoichiometric Melt

S. E. Blum\* and R. J. Chicotka

IBM Watson Research Center, Yorktown Heights, New York

#### ABSTRACT

A procedure is described for the growth of large single crystals of gallium phosphide. A vertical Bridgman apparatus is employed with a controlled phosphorus pressure source to maintain stoichiometric conditions during freez- ing. The high phosphorus pressure is contained by the use of heavy-walled quartz in the low temperature zone, and by permitting the thin-walled quartz in the hot zone to soften and expand out against a graphite support tube. Crystals doped with both zinc and tellurium have been prepared. The electrical properties of these and "undoped" crystals are presented.

The growth of single crystals of gallium phosphide from a stoichiometric melt is difficult because of the compound's high melting temperature and high dissociation pressure, which are about 1500°C and 35 atm (1), respectively. These extreme conditions impose severe requirements on the usual materials of construction of crystal growing equipment.

The problems that beset crystal growth of GaP from stoichiometric melts have been reviewed by Miller (2) and Shmartsev (3). Generally, such crystal growing operations as pulling, Bridgman growth, or float zoning must be performed in high pressure autoclaves. These are complicated and expensive to construct and only a limited amount of work has been done on such systems. [Frosch (4) described the preparation and floating zone processing of GaP, and Weisberg (5) reported growth in an autoclave crystal puller.]

An appreciably simpler method for high melting high dissociation pressure compounds was developed and described by Fischer (6) for the growth of II-VI compounds. In this method the ingot to be melted and regrown is sealed within a quartz ampoule. The ampoule is in turn held within a close fitting graphite container. On heating the system to the melting point of the compound (ca. 1500°C) the quartz softens and expands against the back-up graphite container which has sufficient strength to contain the pressure. Throughout the remainder of the crystal growth the quartz serves as a semiliquid seal to prevent loss of vapor.

#### Experimental Procedure and Apparatus

A few experiments were sufficient to demonstrate that large grained GaP ingots could not be grown in

the apparatus just described for the following reasons: (i) When GaP alone was loaded into the ampoule it dissociated at the high temperature to an extent determined by the volume of free space that must be filled with vapor, and the gallium-rich liquid that resulted would not crystallize readily as large grains. (ii) When the amount of phosphorus necessary to fill the free space was added to the ampoule to overcome this difficulty, the ampoule frequently ruptured because softening of the quartz ampoule could not be achieved before the phosphorus pressure became too large. This problem was aggravated by the uncertainty in the amount of phosphorus required because of inability to estimate the free volume accurately.

The procedure that we developed consisted of a "two-zone bomb" technique that incorporated both the liquid seal feature employed by Fischer and the controlled condensed phosphorus source of a conventional two-zone Bridgman apparatus.

A general description of the experiment will be given first, followed by details of the apparatus.

*General description.*—A schematic diagram of the apparatus is shown in Fig. 1. Previously synthesized GaP (7) is placed in a cylindrical crucible and sealed with an excess of phosphorus and 100 Torr pressure of argon in the quartz ampoule. The ampoule is placed within the close-fitting graphite tube and held firmly with a graphite screw cap. The tube is now positioned vertically within a resistance furnace-graphite susceptor ensemble. The entire furnace apparatus is housed within a quartz envelope which is capped at both ends. The caps are provided with appropriate feed-throughs to bring power to the resistance furnace and for the control thermocouples. The quartz envelope is evacuated and the system is slowly heated until the

\* Electrochemical Society Active Member.

Fig. 1. Schematic diagram of the apparatus and temperature profile used to grow GaP single crystals.

indicated temperature profile (see Fig. 1) is achieved. The phosphorus overpressure ( $\sim 35$  atm) is maintained during the entire run. Solidification of the ingot is achieved by slowly lowering the temperature of the RF-heated upper zone. Generally, the temperature is lowered to provide a rate of freezing estimated to be between 0.5–1.0 cm/hr.

#### Experimental Details

**Crucible material.**—Boron nitride crucibles were generally used. These are cylindrical in shape with a 45° conical bottom, and are 1.5 cm ID  $\times$  7–15 cm long. They are available as "Boralloy" from High Temperature Materials, Inc. Lowell, Massachusetts. The crucible is cleaned prior to use by white etch ( $3\text{HNO}_3\text{-1HF}$ ). The crucible is supported within the growth ampoule by "Boralloy" tubing not shown in the diagram.

**Quartz ampoule.**—The ampoule is constructed from two sizes of quartz tubing. The upper portion, containing the charge and crucible, is 25 mm OD  $\times$  18 mm ID  $\times$  200 mm long. It is this portion of the ampoule that will be heated to temperatures above the softening point of quartz and must then be supported by the graphite back-up tube. The lower portion of the ampoule is 25 mm OD  $\times$  5 mm ID  $\times$  300 mm. At the temperature of the experiment, this portion of the ampoule remains solid and has sufficient strength to withstand the high internal pressure without the support of the graphite. The greater part of this tube is well below the softening temperature (nominally it is kept below 1100°–1150°C), whereas no portion of the thinner walled section of the ampoule is below 1250°C when the pressure in the system is appreciably elevated, i.e.,  $> 10$  atm.

A quartz wool plug is placed in the lower portion of the ampoule to prevent direct radiation from the crucible onto the condensed phosphorus.

**Graphite bomb.**—The graphite tube is bored so that the quartz ampoule fits snugly. The tube is closed by a graphite screwcap. The lower portion of the tube in the region of the condensed phosphorus is fitted with four thermocouple wells. The tube is 56 cm long over-all.

**Resistance furnace.**—The resistance furnace is tubular and closed at the lower end and serves, in addition to providing heat, to support the graphite tube. It is constructed of solid copper, plated with nickel and gold to lessen oxidation. Inconel-sheathed resistance wire (a product of the Ampere Electronic Corporation) is used as the heating element and it is wound in a spiral groove on the furnace's outer surface. This design was found to be effective in maintaining a shallow temperature gradient in the region of the condensed phosphorus.

**RF heater.**—The crucible portion of the graphite tube is positioned within an insulated susceptor ensemble. This ensemble is a vertical array of tubing (80 mm OD  $\times$  70 mm ID) comprising from top to bottom a 28-cm long graphite susceptor, a 4-cm long alumina spacer (not indicated on the diagram), and a 12.5-cm long lower susceptor. The ensemble is sheathed with graphite wool insulation and held snugly within the quartz envelope. The vertical temperature gradient in the hot zone is achieved by appropriately spacing the turns of the RF work coil. The horizontal temperature gradient in the region of the melt is essentially zero, thereby resulting in a planar liquid-solid interface; the shape of the interface could be delineated from partially solidified ingots whose slow freezing was interrupted by rapid termination.

**Temperature control.**—The temperature of the hot zone is sensed by a commercial thermopile device, using as a light pipe a sapphire rod in a ceramic well within the hot zone (8). The d-c output voltage of the thermopile is used to control the temperature in the conventional way. The temperature of the hot zone is slowly reduced to provide solidification of the melt by the gradient freeze technique.

The temperature of the condensed phosphorus, and hence its pressure, is controlled by thermocouples. Four are used: one for the actual control of the temperature at the condensed phosphorus interface, a second to measure this temperature, and two thermocouples to monitor the ampoule temperature both above and below this point. The temperature of the graphite tube at the phosphorus control point is held to  $\pm 0.1^\circ\text{C}$ . The temperature gradient in this region is about  $1^\circ\text{C}/\text{cm}$ . L&N speedomax H-AZARs with a series 60 CAT unit are used to control the resistance furnace and the Lepel 30 kva generator.

**Argon backfill.**—The ampoule is back-filled with argon at about 100 Torr before sealing. This backfill provides an inert gas pressure of about 1/2 atm during solidification of the GaP. Its purpose is to prevent internal "boiling" of the phosphorus in the melt. Without it, minor fluctuations in temperature can result in phosphorus gas nucleation at the solid-liquid interface and at the crucible-melt interface. These gas pockets remain during solidification and voids are observed in the solid ingot.

#### Experimental Results

Photographs of the starting GaP material and of two different recrystallized ingots are shown in Fig. 2. These photographs are of 1.5 cm diameter wafers cut transverse to the growth direction. The starting material (2a) exhibits the typical polycrystalline growth of synthesized GaP (7). Wafer 2(b) is from a regrown crystal and shows large grain growth; approximately one-half of the wafer is a single grain. This grain pattern remained essentially the same from the 2-cm position to the last-to-freeze portion of the crystal at about 10 cm. Figure 2(c) is of a wafer of our best regrowth. With the exception of a few small grains at the first-to-freeze portion of this ingot, the crystal was entirely single, and weighed 76g. The crystal was

\* The zinc doped sample appears to be nearly degenerate.

tellurium doped at about the 10<sup>18</sup> cm<sup>-3</sup> level. This crystal grew 9° off the <111>.

The electrical properties of several regrown crystals are given in Table I. The starting GaP material used in these regrowths was p-type with net carrier concentrations of about 1 × 10<sup>17</sup> cm<sup>-3</sup>. Regrown crystals, if undoped, are n-type with net carrier concentrations of about 10<sup>17</sup> cm<sup>-3</sup>. The reason for this change in type is, as yet, unproven. Doped crystals have been prepared by adding the dopant, generally zinc or tellurium, directly to the melt.

### Discussion

The procedure described above has consistently produced gallium phosphide ingots that contain single crystal portions that are larger than one quarter of the ingot in cross section and longer than 5 cm. These results, as well as the growth of one completely single crystal ingot, are promising and we believe that the method can be improved to consistently yield ingots that are wholly single. In particular, two modifications are being instituted; these are the substitution of a well shunted resistance furnace for the RF-susceptor unit and provision for seeding the melt. The use of a shunted furnace will provide a better means for tailor-

ing the temperature profile in the melt as well as a better reproducibility of the profile from run to run. The temperature profile is difficult to maintain with the graphite susceptors because they suffer some oxidation at the high operating temperatures. This oxidation alters the temperature profile in an unpredictable way. Seeding of the melt is desirable because it will (i) aid in the control of the growth direction and (ii) prevent supercooling and hence improve control of the rate of solidification of the melt.

### Acknowledgments

The authors are pleased to acknowledge Johannes Grandia and William A. Kahn for aid in the design and construction of the apparatus and Stephen Baliozian for the electrical measurements. Part of this work was supported by the United States Army, Fort Belvoir, Virginia, Contract No. DA-44-009-AMC-1674(X).

Manuscript received Oct. 5, 1967; revised manuscript received Dec. 4, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Electrical Properties of Vapor-Deposited Silicon Nitride and Silicon Oxide Films on Silicon

B. E. Deal,\* P. J. Fleming, and P. L. Castro\*

Research and Development Laboratories, Fairchild Semiconductor, Palo Alto, California

### ABSTRACT

The electrical properties of vapor-deposited silicon nitride and silicon oxide films on silicon have been investigated. The silicon nitride films were produced by the SiCl<sub>4</sub>-NH<sub>3</sub> reaction at 950°C, while the oxides were prepared at 400°C using the SiH<sub>4</sub>-O<sub>2</sub> reaction. The properties were compared with those of thermal oxides prepared in dry O<sub>2</sub> at 1200°C. As contrasted to the thermal oxides, the silicon nitride films are characterized by polarization and room temperature trapping instabilities, relatively high conductance, and high surface state charge densities. The vapor-deposited oxides tend to resemble the nitrides in those properties which are associated with the silicon-dielectric interface, but the bulk properties are more like those of thermal oxides.

For several years, silicon dioxide has been used as a masking and passivating layer over semiconductor devices. For silicon, these films have generally been prepared by the thermal oxidation of the silicon in oxygen or water ambients at temperatures ranging from 900°-1200°C. Other methods of producing passivating layers of silicon dioxide, both on silicon and other semiconductor materials, include pyrolytic decomposition of

\* Electrochemical Society Active Member.

oxysilanes, vapor phase reactions of silicon and oxygen-containing compounds, sputtering, plasma oxidation, and anodization (1, 2). In addition, other dielectrics and glasses have been deposited by sedimentation techniques, either directly on the semiconductor or over a previously formed oxide (3).

In 1965, Sterling and Swann (4) reported a method for depositing films involving chemical reactions in an r.f. discharge. These films included silicon, silicon di-

oxide, and silicon nitride. Shortly after this, Hu (5) and also Doo, Nichols, and Silvey (6) reported the use of vapor-deposited silicon nitride films for passivating silicon devices. Other investigators, such as Tombs *et al.* (7) reported several possible advantages of silicon nitride films as compared to the conventional silicon oxides. One of the most important advantages appeared to be the ability of silicon nitride to mask against diffusing impurities, especially sodium ions. The latter have been a source of considerable difficulty in the fabrication of stable surface-controlled devices (8).

The interest in the use of silicon nitride films as passivating layers over semiconductor devices was considerable.<sup>1</sup> Various deposition methods were reported which included both high-temperature (800°–1200°C) vapor reactions of SiH<sub>4</sub> or SiCl<sub>4</sub> with NH<sub>3</sub> as well as lower temperature sputtering techniques. Two important characteristics of silicon nitride films were emphasized by the various papers. First, it was demonstrated that the structure of amorphous silicon nitride leads to higher density than fused silica, resulting in a lower etch rate, higher refractive index and dielectric constant, and greater masking ability mentioned above. These properties are dependent on the temperature and method of deposition. Second, the silicon nitride-silicon structure gives rise to considerable room temperature electrical instability, other than ion migration, as well as exhibiting a relatively high surface charge, *i.e.*,  $>10^{12}$  cm<sup>-2</sup>.

Because silicon nitride films might offer certain advantages in semiconductor technology, such as enhanced masking of impurities, its electrical properties were studied in further detail. The deposition method used in this investigation was the silicon tetrachloride-ammonia reaction process. Preliminary results concerning etch rates and electrical properties indicated lower temperature depositions would be more satisfactory;<sup>2</sup> therefore, most of the subsequent depositions were carried out at 950°C.

Vapor-deposited silicon oxides were also included in these studies when it was discovered that their interface properties were very similar to those of silicon nitride. They were deposited using the technique involving the oxidation of silane (9). The low temperature required for deposition (~400°C) makes this method attractive for additional passivation of metallized device structures. This type of dielectric might be considered a hybrid between the vapor-deposited nitride and the thermal oxide, since the method of deposition resembles the former while the chemical composition is similar to the thermal SiO<sub>2</sub>. Properties of the two vapor-deposited dielectrics were compared to those of thermal oxide films. Also, properties of silicon nitride and vapor-deposited oxide layers over thermal oxides were determined.

Electrical properties of the above dielectric films on silicon which are reported include dielectric constant, breakdown field, surface charge, surface recombination velocity, work function difference, conductance, polarization, and trapping. The characteristics of these films are compared with one another with particular emphasis being placed on the room temperature instability phenomena.

### Experimental

Silicon used for these studies was in the form of circular slices, 2 cm in diameter, prepared by the Czochralski method. Dislocation count was specified to be less than 100 cm<sup>-2</sup>. Both (111) and (100) surface orientations were used as well as p- and n-type (boron and phosphorus) doping impurities in concentrations of approximately  $1.5 \times 10^{18}$  cm<sup>-3</sup>. After lapping, the

silicon slices were cleaned in organic and inorganic solvents and chemically polished in a 4:10 HF:HNO<sub>3</sub> solution. Final thickness was 150μ.

For those samples involving a thermal oxide, the silicon was oxidized at 1200°C in dry oxygen under conditions described previously (10). The silicon nitride deposition was carried out in a horizontal, r.f. heated quartz reactor. The reactor tube was rectangular in shape, with inside dimensions of 5.0 by 7.5 cm. Hydrogen and ammonia were passed into the reactor along with silicon tetrachloride, the latter titrated at room temperature into the hydrogen stream. The relative flow rates were as follows: H<sub>2</sub> 4 l/min; NH<sub>3</sub> 4 ml/min; SiCl<sub>4</sub> (liquid) 0.2 ml/min (~40 ml/min vapor). As mentioned earlier, all depositions were carried out at 950°C, the deposition rate being approximately 0.12 μ/min.

The vapor-deposited oxide was prepared by the reaction of SiH<sub>4</sub> (diluted in argon) with O<sub>2</sub> at 400°C. The reactants, together with nitrogen as a carrier gas, were directed through a nozzle to the silicon substrates positioned on a hot stage. Flow conditions were as follows: SiH<sub>4</sub> (15%) in argon 0.080 l/min; O<sub>2</sub> 0.085 l/min; N<sub>2</sub> 2.7 l/min. Deposition rate of the oxide was approximately 0.6 μ/min. While this is a relatively rapid deposition, film thickness uniformity was ±2.5% over a major portion of the slice. The nitride uniformity was not quite as good, being about ±7%. Thickness reproducibility from run to run was about ±10% for both types of films.

A number of the electrical evaluations involved MIS (metal-insulator-semiconductor) structures. These were prepared by evaporating aluminum field plates, 375μ diameter, over the dielectric through a mask. Aluminum was also evaporated on the bare, back side of the silicon for contact.

Gate-controlled diodes, used for the surface recombination velocity measurements, were prepared as described in ref. (11). Essentially this structure is a planar diode with an aluminum gate or field plate over the oxidized junction and extending over the substrate region about 125μ. An outside gate is also available for electrically isolating the device from the rest of the semiconductor slice. After preparation of the diffused diodes, the original oxide was stripped in HF and the dielectric to be evaluated (silicon dioxide, silicon nitride over oxide, or silicon nitride) was deposited by the appropriate method. Aluminum contacts and gates were then prepared by conventional metallization and photoresist techniques.

Where low temperature thermal treatments were required, these were accomplished by treatment in nitrogen at 550°C for 2 to 5 min. Various electrical measurements were then carried out as described later in this paper. Thickness measurements were made for all oxidations and nitride depositions using the Tolanski method described earlier (10).

### Results: Physical Properties

It was reported in a number of papers at the Fall 1966 Meeting of the Society in Philadelphia that physical, chemical, and electrical properties of deposited dielectric films depend considerably on deposition conditions, *i.e.*, temperature, composition of reactants, *etc.* For this reason, certain physical properties of the three types of films studied here are listed in Table I. These values will help to characterize the particular films prepared by the process conditions described above. For purposes of this discussion, the formula of the nitride is specified as Si<sub>3</sub>N<sub>4</sub> and that of the vapor deposited oxide as SiO<sub>2</sub>.

Examination of infrared spectra (transmission) of the nitride films indicated a broad absorption peak at 12.0μ; in agreement with the value reported by Hu (5) for films prepared by the SiH<sub>4</sub>-NH<sub>3</sub> reaction deposition. No peaks or shoulders were observed in the 9.2μ range, thus indicating that no Si-O was present. For the vapor deposited oxide, the absorption peak of 9.2μ associated with thermally produced oxides was shifted

<sup>1</sup> It resulted in a special symposium at the Philadelphia Meeting of The Electrochemical Society, Oct. 9-14, 1966, where 24 papers were presented on the subject.

<sup>2</sup> In general, etch rates were slightly higher at lower temperatures. Also, the higher temperature nitrides exhibited very unstable electrical characteristics, *i.e.*, C-V plots could not be made at room temperature as they shifted during the plotting itself.

Table I. Properties of dielectric films on silicon

	Vapor deposited Si <sub>3</sub> N <sub>4</sub>	Thermal SiO <sub>2</sub>	Vapor deposited SiO <sub>2</sub>

\* Oxide etch composition: 1360g NH<sub>4</sub>F; 500 ml HF (49%); 2000 ml H<sub>2</sub>O.

to a higher wavelength (9.7 $\mu$ ), characteristic of less dense, deposited oxides (12).

### Results: Electrical Properties

**Dielectric constant.**—The dielectric constants of silicon nitride films, prepared under the conditions described above, were obtained by measuring the capacitance at 100 kHz of an MIS structure under bias conditions corresponding to strong accumulation of the silicon surface. These values were found to be in the range 4.8–5.8, as compared with 3.85 for thermal oxides. The dielectric constant of the vapor-deposited oxide was 4.5. Goldsmith and Kern (9) report a value of 4.3 for an as-deposited oxide film prepared at 475°C.

**Breakdown field.**—The breakdown field or dielectric strength of silicon nitride films is somewhat difficult to determine due to the high conductance that exists at higher voltages (see later section). However, values were found to be approximately 10<sup>7</sup> v/cm (d.c.). This agrees with findings of Hu (5) and Doo *et al.* (6) and is slightly higher than values found for thermal oxides (9 x 10<sup>6</sup> v/cm) (13). The dielectric strength of vapor-deposited oxides (8.5 x 10<sup>6</sup> v/cm) was found to be very close to that of thermal oxides. These values for vapor-deposited oxides agree with those reported by Goldsmith and Kern (9).

**Surface charge.**—The total charge per unit area  $Q_s'$  induced in the silicon by charges in the dielectric layers was determined from the capacitance-voltage characteristics of MIS structures. This method of charge analysis is described in detail elsewhere (14). Essentially one determines the flatband voltage  $V_{FB}$  of the experimentally measured capacitance-voltage curve. The induced charge  $Q_s'$  is related to  $V_{FB}$  by the expression:

$$Q_s' = (-V_{FB} + \phi_{MS})C_o$$

where  $\phi_{MS}$  is the metal-semiconductor work function difference, and  $C_o$  is the capacitance per unit area of the dielectric layer. For example, for a 0.2 $\mu$  thermal oxide, a flatband voltage of 1v will correspond to 1 x 10<sup>11</sup> electronic charges/cm<sup>2</sup> induced in the silicon if the  $\phi_{MS}$  term is neglected.

Typical C-V plots are shown in Fig. 1 for a silicon nitride film, a vapor-deposited silicon oxide film and a

Fig. 1. Typical capacitance-voltage plots for MIS structures

thermal oxide film on silicon, as well as a double layer of silicon nitride over thermal oxide. Measurements were made at 100 kHz. All structures were prepared using (111), 1.4 x 10<sup>16</sup> cm<sup>-3</sup> p-type silicon substrates and circular (375 $\mu$  diameter) aluminum field plates. After metallization they were annealed at 550°C for 2 min in dry nitrogen. It can be observed from Fig. 1 that the nitride film results in a relatively high surface charge,  $Q_s'/q > 10^{12}$  cm<sup>-2</sup>, compared to 6 x 10<sup>11</sup> cm<sup>-2</sup> for the vapor-deposited oxide and 2 x 10<sup>11</sup> cm<sup>-2</sup> for the thermal oxide. The nitride-over-oxide structure has a charge just slightly higher than that of the plain thermal oxide.

The high charge associated with the nitride-silicon interface appears to be typical (5). It was also found that the vapor-deposited nitride and oxide charges did not vary with silicon orientation. On the other hand, double layers of both nitride over thermal oxide and vapor-deposited oxide over thermal oxide showed the same orientation-dependence of surface charge previously reported by Balk, Burkhardt, and Gregor (15) for thermal oxides on silicon, i.e.,  $Q_s'$  (111) = 2 to 3 times  $Q_s'$  (100). The origin of the charges found in the vapor-deposited oxides and nitrides is not known. While the data reported above indicate they are associated with the dielectric-silicon interface, the lack of orientation dependence would indicate they are not the same as  $Q_{ss}$ , the fixed surface state charge associated with thermally oxidized silicon.  $Q_{ss}$  has been proposed to be due to an excess silicon species from the substrate taking part in the oxidation reaction (16). That no substrate silicon takes part in the reactions involving vapor deposition of silicon nitride and oxide films on silicon has been verified by special weight experiments.

One other observation that may be made regarding the C-V plots of Fig. 1 is the difference in shape between the thermal oxide and the nitride-over-oxide curves. The distortions of the double layer curve, labeled (A), (B), and (D), are probably related to fast surface states, and their significance will be discussed in the next section.

**Surface states and surface recombination velocity.**—The C-V curves of Fig. 1 for the thermal and vapor-deposited oxides are nearly identical in shape to theoretical curves of the same silicon doping and oxide thickness. This implies that over the surface potential range corresponding to the capacitance variation, the fast surface state density is less than 5 x 10<sup>10</sup> cm<sup>-2</sup> (14) for these annealed structures. On the other hand, both the nitride layer and the nitride-over-oxide layer curves show considerable distortion as compared to the theoretical case. This would imply higher densities of fast surface states, especially for the plain nitride film. It should be noted that the curve for the nitride-over-oxide structure after the 550°C annealing treatment is practically identical to that obtained for the thermal oxide alone before annealing. The nitride film evidently prevents the reduction of fast surface states normally occurring during the low-temperature annealing process when aluminum is present over the dielectric (17). Measurements of the surface recombination velocity  $s_o$  were made for these structures. It was found that, while values before annealing varied depending on processing conditions, the values of the thermal oxide, vapor-deposited oxide, and the nitride-over-thermal oxide all were in the range  $s_o = 5$ –10 cm/sec after the annealing treatment. On the other hand, surface recombination velocity values of the nitride film remained high at  $s_o = 200$  cm/sec.

**Work-function effects.**—As mentioned above, the charge induced in the semiconductor of an MIS structure includes a contribution from the metal-semiconductor work function difference,  $\phi_{MS}$ . For most metals in conjunction with thermally oxidized silicon, the value of  $\phi_{MS}$  ranges from +1 to -1v, depending on the metal and silicon doping impurity concentration and type (18). It was found from C-V plots of MIS

structures incorporating either p- or n-type silicon and/or different metal field plates that the  $\phi_{MS}$  values of either silicon nitride or vapor-deposited oxide MIS structures appear to be equal to those previously reported for MOS structures using thermal oxides. It should be noted that while  $\phi_{MS}$  values may be the same, the individual barrier heights at either the Si-dielectric or metal-dielectric interfaces are probably different than the corresponding thermal  $\text{SiO}_2$  values.

**Conductance.**—The current flow through silicon nitride, vapor-deposited oxide, and thermal oxide films was measured using a Keithley Instruments Model 416 Picoammeter. Current was measured as a function of d-c positive and negative bias. The results are shown in Fig. 2, where log current is plotted vs. the square root of voltage of  $0.2\mu$  silicon nitride, vapor-deposited oxide, and thermal oxide films. In addition to the standard nitride used for most of these studies, data are also included in Fig. 2 for a nitride prepared by bubbling  $\text{H}_2$  through  $\text{SiCl}_4$  just to show the effect of processing variables. This film, while exhibiting a higher conductance, etched at the rate of only  $2 \text{ \AA}/\text{sec}$  in concentrated HF.

It can be observed from Fig. 2 that for the same film thickness, the nitride films are the most conductive while the thermal oxide is several orders of magnitude lower in current at a given voltage. The vapor-deposited oxide has a current level near the less-conductive nitride film at lower voltages, but as the voltage increases the current saturates and the characteristic crosses the thermal oxide curve. This observation was quite reproducible for a number of samples of vapor-deposited oxides and occurred for both positive and negative bias.

It can be observed in Fig. 2 that the slopes for the nitride and thermal oxide films, as well as the vapor-deposited oxide at lower voltages, are similar. The data for the nitrides are very similar to those reported by Sze (19). According to Sze, the straight line portion of the plots in Fig. 2 (at least for the nitrides) indicates a bulk-controlled conduction process and is due to field-enhanced emission of trapped electrons into the conduction band of the insulator. This process is called the "internal Schottky" or the Poole-Frenkel effect, and predicts the square root of field-log current density relationship indicated in Fig. 2. This model also predicts a temperature dependence and this was demonstrated by a decrease in conductance at  $-196^\circ\text{C}$  for the silicon nitride films.

It is much less likely that the conductance of thermal oxides would depend on emission of trapped elec-

Fig. 2. Current-voltage relationships for three types of dielectric films on silicon. Data are for negative voltages,  $0.20\mu$  films on  $1.5 \text{ ohm-cm}$  p-type silicon.

trons. This conduction would probably be due to a tunneling mechanism. The latter should be temperature independent and this was found to be the case over the range from  $-196^\circ$  to  $25^\circ\text{C}$ . The results for the vapor deposited oxides are not clear, although it was observed that the current tended to saturate at that voltage where trapping commenced (see later section).

The data shown in Fig. 2 are for negative bias, although the positive values are very similar in all cases. It was found that the measurements could not be switched back and forth between positive and negative bias in the case of nitrides and vapor-deposited oxides without extraneous results being obtained. This was undoubtedly related to the trapping instabilities discussed in a later section. For the same bias, however, measurements could be made from low to high or high to low values of voltage with reproducible results.

**Polarization.**—Preliminary capacitance-voltage measurements of vapor-deposited dielectrics demonstrated certain instabilities that are not typical of MIS structures incorporating clean, thermal oxides. These instabilities are prevalent, even at room temperature, to such a degree that accurate C-V measurements themselves are difficult to obtain. Two distinct types of instability have been distinguished (20-22). They are indicated in Fig. 3 and are denoted as polarization and trapping. The polarization effect characterized in Fig. 3(a) will be discussed first.

The polarization of insulators in MIS devices has been observed in phosphosilicate layers ( $\text{P}_2\text{O}_5$  polarization) (13) and certain vapor-deposited oxides (23). It is characterized by a shift of the C-V plot in the same direction as that caused by ion migration. The amount of displacement will depend on the applied field and its rate increases with temperature. This field effect is demonstrated in Fig. 4 for a  $0.4\mu$  silicon nitride layer over n-type silicon. After subjecting the silicon nitride layer to  $\pm 15$  and  $\pm 30\text{v}$  for 2 min each at  $300^\circ\text{C}$  and then cooling rapidly to room temperature, considerable shifting of the characteristics is observed. The magnitude of the voltage displacement appears to be roughly proportional to the field applied at the elevated temperature. As shown in Fig. 3(a), this polarization may be due to the orientation of dipoles in the silicon nitride layer, similar to that proposed for phosphosilicate layers (13). The field due to these dipoles induces a charge in the silicon which is reflected by a shift in the C-V plot. The effect is thus related to the bulk of the dielectric, not to the interface between the silicon and the silicon nitride. The instability should therefore be present whether or not a thin thermal oxide (which itself does not exhibit

Fig. 3. Two types of proposed mechanisms for charge instabilities of MIS structures incorporating deposited dielectric films on silicon. Also shown in each case is the direction in which the corresponding C-V curve is displaced.

Fig. 4. Example of polarization of silicon nitride layer on silicon due to bias-temperature stress test. Test conditions:  $\pm 15$  and  $30\text{v}$  at  $300^\circ\text{C}$  for 2 min each. [(111)  $1.4 \times 10^{16} \text{ cm}^{-3}$  n-type silicon;  $x_N = 0.40\mu$ .]

polarization) is between the silicon and the nitride layer. This indeed has been found to be the case.

Only a small amount of such polarization (less than  $1\text{v}$  for a  $0.2\mu$  layer) has been observed in the vapor deposited oxides studied in this program and then only at high fields; none in the thermal oxides.

**Trapping.**—A different instability related to silicon nitride films on silicon was first reported by Hu (5). He noted that a displacement along the voltage axis of MIS capacitance-voltage plots occurred at room temperature after application of a negative or positive bias to the field plate. The direction of this displacement was opposite to that caused by ion migration or polarization. Further, this phenomenon occurred only after the applied voltage exceeded some critical threshold voltage or field. Various investigators at the Fall 1966 Meeting of the Society confirmed this effect with values of threshold field ranging over a considerable range. It is generally held that the phenomenon is due to trapping of carriers in the insulator much as described by Heiman and Warfield (24). Accordingly, we shall refer to this effect as the trapping phenomenon. This mechanism is illustrated in Fig. 3b. The application of positive or negative bias to the field plate of an MIS structure would according to this picture bring about trapping of carriers of the opposite polarity in the dielectric near the silicon surface, thus causing the C-V curve to shift in a direction opposite to that in the case of polarization. The trapping effect is thus associated with the silicon-dielectric interface.

Experiments with a typical  $0.2\mu$  silicon nitride layer deposited directly over silicon at  $950^\circ\text{C}$  resulted in room-temperature instabilities as shown in Fig. 5. The original C-V plot of the MIS structure is shown, along with plots obtained after various applied biases. For small applied bias values, either negative or positive, no appreciable displacement of the C-V characteristic is observed. However, at about  $-30\text{v}$  the curve starts to shift in the negative direction and at  $+40\text{v}$  (on a

Fig. 5. Capacitance-voltage plots showing example of room temperature trapping in silicon nitride layer on silicon. [(100)  $1.4 \times 10^{16} \text{ cm}^{-3}$  p-type silicon;  $x_N = 0.21\mu$ .]

separate device from the same run) it shifts in the positive direction. Subsequently, the curves shift about  $8\text{--}10\text{v}$  for each additional  $10\text{v}$  applied, up to  $130\text{v}$  applied bias. Above  $130\text{v}$ , no further displacement in the curves due to trapping is observed. However, at this point, the displacement reverses direction and further small changes in the C-V characteristics are believed to be due to the polarization phenomenon described earlier.

Times of 10 sec were allowed for each bias application. These times appeared to provide a total displacement of at least 90% of that obtained in times up to 30 min for that particular bias.

It was found that exactly the same trapping effect occurs with vapor-deposited oxides on silicon. This phenomenon is similar for various silicon substrates, p-type or n-type, and (111) and (100) orientations. The critical or threshold field is about the same for positive and negative polarities, although that for the negative polarity is generally slightly less. If the displacement  $\Delta V$  of the C-V characteristic is plotted against applied bias, curves of the type shown in Fig. 6 can be obtained. These data are for various silicon nitride and vapor-deposited silicon oxide MIS structures. The dielectric thicknesses are approximately  $0.2\mu$ . It is observed that the positive threshold field for the nitrides is about  $2 \times 10^6 \text{ v/cm}$ , while the vapor-deposited oxide values are about  $4 \times 10^6 \text{ v/cm}$ . Corresponding negative threshold fields are slightly less. The slope of the plots approaches a value of 1.0. Additional experiments for dielectric thicknesses varying from  $0.09$  to  $0.90\mu$  resulted in approximately the same threshold field and slope as in Fig. 6. No such trapping effects could be noted for thermal oxides up to destructive breakdown.

Once the C-V curve has been displaced by a particular amount due to trapping (see Fig. 5), the direction of displacement can be reversed by application of lower voltages of the same polarity or of voltages of the opposite polarity. This process does not appear to be completely reversible but rather is dependent on previous bias history. An example is shown in Fig. 7 for a silicon nitride MIS structure, where voltage displacement  $\Delta V$  is plotted vs. applied bias. It can be seen that the curve obtained by first applying negative bias (dots) can eventually be reached even after first applying positive bias and then negative bias (circles), or vice versa. However, considerable hysteresis is obtained, depending on the magnitude of the initial bias. This hysteresis effect associated with the trapping phenomenon of silicon nitride layers on silicon was previously reported by Hu (5, 20) and by Chu, Szedon and Lee (22). It is also observed for vapor-deposited oxide structures.

Special experiments involving thin thermal oxides under silicon nitride layers resulted in asymmetric trapping characteristics. Nitride layers,  $0.25\mu$  thick,

Fig. 6. Relationship between voltage shift  $\Delta V$  (due to room temperature trapping) and positive applied bias for several MIS structures. Thickness of dielectric films is  $0.20\mu$ .

Fig. 7. Dependence of voltage shift  $\Delta V$  vs. applied bias on previous bias treatment of silicon nitride MIS structure. [(100)  $1.4 \times 10^{16} \text{ cm}^{-3}$  p-type silicon;  $x_N = 0.21\mu$ .]

were deposited over silicon dioxide layers of 60, 290, and 500Å thickness. With increasing oxide thickness the original high charge density induced in the silicon decreased by about an order of magnitude to that of the oxide  $Q_{ss}$  value. Further, the critical or threshold voltage required to initiate trapping increased with thermal oxide thickness. The increase was greater for the negative polarity, in fact trapping under negative bias could no longer be observed for the 500Å oxide samples up to breakdown of the dielectric. These results are indicated in Fig. 8 where the displacement  $\Delta V$  of the C-V curve is plotted vs. applied bias for the series of nitride-over-thermal oxide structures described above. The increase of positive threshold field with thermal oxide thickness is readily apparent. Similar effects are noted for the negative bias curves for 0, 60, and 290Å thermal oxide samples, where trapping occurs. The negative threshold voltages are considerably higher than the corresponding positive bias values, however. Szedon and Chu have reported similar findings for the positive bias polarity case (25). They propose that the increased field required for trapping when a thin oxide is present is due to the fact that the carriers must first tunnel into the conduction band of the oxide and then drift into the nitride before being trapped. The asymmetry found to exist between the positive and negative polarities may simply be due to differences between tunneling probabilities of electrons and holes through the thermal oxide.

Again, results very similar to those obtained for nitride over thermal oxides were obtained for vapor-deposited oxides over thin thermal oxides. The trap-

Fig. 8. Plot of MIS voltage shift  $\Delta V$  (room temperature trapping) vs. applied bias for various thicknesses of thermal oxide under  $0.25\mu$  silicon nitride films. [(111)  $1.4 \times 10^{16} \text{ cm}^{-3}$  p-type silicon.]

Fig. 9. Plot of current vs. voltage in MIS structures for various thicknesses of thermal oxide under silicon nitride layers. Structures are same as in Fig. 8.

ping threshold field increases with thermal oxide thickness, with the increase for negative bias being much greater than for the positive case.

If a thin thermal oxide beneath a vapor-deposited nitride or oxide layer causes an increased threshold field for trapping, then it might be expected that conductance through the double layer structure should be reduced. I-V relationships were determined for the same nitride-thermal oxide samples used for the data given in Fig. 8. The results are shown in Fig. 9. As predicted, the conductance decreases with increasing thermal oxide thickness. Further, the same asymmetry between negative and positive bias is noted, the negative bias conductance being considerably lower at a given voltage.

An over-all comparison between trapping and conduction in the various dielectric structures is shown in Fig. 10. Here the critical field required for trapping is plotted against the field at an arbitrary conduction current density, i.e.,  $\sim 10^{-8} \text{ amp/cm}^2$ . Data are included for various silicon nitride, vapor-deposited oxide, thermal oxide, and double layer structures. The thermal oxides break down before any trapping occurs. The relationship obtained in Fig. 10 indicates that there is a reasonable correlation between the trapping and conduction processes. This probably means that conduction, obeying a bulk-limited process relationship, may be initially limited by the transfer of carriers across the silicon-dielectric interface or

### Summary

The electrical properties of vapor-deposited oxides and nitrides studied in this investigation are tabulated in Table II. Data are also included for thermal SiO<sub>2</sub> as well as a nitride-over-thermal oxide double layer. Electrical properties of vapor-deposited oxide-thermal oxide double layers are quite similar to those of thermal oxides, and, therefore, are not included in the table. The important characteristics of the vapor-deposited nitrides and oxides are summarized as follows.

**Silicon nitride.**—Silicon nitride films have a relatively high surface charge as well as a large density of fast surface states which are both associated with the interface region between the dielectric and the silicon. The fast states are not annealed out by low-temperature annealing processes (with or without the presence of aluminum field plates). The nitride films exhibit two types of electrical instabilities. The first is a temperature dependent bulk polarization, possibly due to the orientation of dipoles under the influence of applied electric fields. The second is a temperature independent interface trapping effect in which carriers from the silicon are trapped in the nitride near the silicon-silicon nitride interface. This trapping requires a certain critical field which is also related to a relatively high, room temperature conductance through the silicon nitride structure.

If a thermal oxide is present between the silicon and the nitride film, then those properties characterized by the silicon-dielectric interface become those normally associated with thermal oxides, i.e., low surface charge densities, no interface trapping, etc. If, however, the thermal oxide is reasonably thin (50-500Å) room temperature trapping and high conductance can occur once a critical field is reached, whereby carriers can tunnel into the conduction band of the oxide and into the nitride. This field is higher for negative gate voltages than for positive voltages.

Silicon nitride films are rather dense, which leads to fairly high dielectric strengths, low etch rates, and excellent masking ability against impurity ion migration.

**Vapor-deposited silicon oxide.**—Many of the electrical properties of vapor-deposited silicon oxide films on silicon, especially those associated with the silicon-dielectric interface, tend to resemble those found for silicon nitride films. This could well be expected since the method of chemical deposition is quite similar. Thus, these low-temperature vapor-deposited oxides exhibit room temperature trapping, higher surface charge densities, and at lower fields tend to have higher conductance than thermal oxides. Further, the introduction of a thermal oxide beneath the vapor-deposited oxide film either eliminates the trapping

instability or causes the threshold field to increase as with the nitrides. The same polarity asymmetry associated with trapping threshold field is also found as with nitride-thermal oxide double layers. The thin thermal oxide beneath the vapor-deposited oxide also reduces the surface charge density and makes it orientation dependent which is not the case for either of the vapor-deposited dielectrics.

Bulk properties of the vapor-deposited oxides tend to resemble thermal oxides. Little polarization has been noted and the conductance is lower than for nitride films at higher fields. However, there is still a relationship between the conductance and the threshold field required for trapping. The vapor-deposited oxides permit fast surface states to be annealed out during low-temperature annealing in the presence of aluminum field plates as is the case for thermal oxides.

Other physical and chemical properties of vapor-deposited oxides, such as density, refractive index, dielectric strength, etch rates, and lack of masking against impurity ion migration are much more related to those of thermal oxides.

### Acknowledgments

The authors wish to thank Maija Sklar, J. Goodell, and M. Barry who provided assistance and advice with certain experimental portions of this investigation. They also greatly appreciate the helpful discussions and suggestions concerning this work which were provided by A. S. Grove, C. A. Mead, and E. H. Snow.

Manuscript received Sept. 11, 1967; revised manuscript received Oct. 17, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## Semiconductor Doping by High Energy 1-2.5 Mev Ion Implantation

### ABSTRACT

The formation of junctions in silicon through the use of mono-energetic ions in the energy range from 1 to 2.5 Mev has been studied. Boron, nitrogen, and phosphorous ions were used. Results are presented on the annealing temperatures required to place these ions in substitutional states and on the distribution of these ions in the host material. A way for localized masking against the ion beam, to obtain planar structures, is also discussed.

The use of ion implantation for doping semiconductors, and especially silicon, has been studied by various workers during recent years. This work can be divided into two broad categories: channeling and nonchanneling (1-4). In the channeling experiments one uses the open channeling directions in the crystalline lattice, as for instance the  $\langle 110 \rangle$  direction for Si, in order to obtain significant penetration of the ions. Most channeling experiments have been carried out with implantation energies in the 10-100 kev range. The channeling mechanism suffers from two disadvantages: the crystal must be very carefully oriented, to within a 1/10 of a degree (5, 6) to obtain repeatable results, and the channels tend to become clogged when deep layers of significant ion concentration are attempted (7). In the nonchanneling work one hopes to minimize channeling and regards the lattice as an amorphous substance for first order theoretical predictions. Although some ions can be expected to be scattered into the channeling directions, their number is small in comparison to the total number of implanted ions (8). The reported work in the nonchanneling area has been done below 500 kev, in which case the peak of the implanted ion distribution is well below  $1\mu$ . Since semiconductor device applications often necessitate deeper junctions, we have undertaken the investigation of ion implantation doping for the energy interval of 1-2.5 Mev. The experiments were conducted with singly charged boron, nitrogen, and phosphorous ions. Initially, some annealing studies to determine necessary annealing temperatures were performed. The emphasis in the study was placed on obtaining distribution profiles for the implanted ions, since these profiles are of prime importance to device design. Other workers in the area have assumed that the ions have a gaussian distribu-

tion about the peak (4). Preliminary experiments indicated that this was not the case in the 1-2.5 Mev range.

To obtain the doping ions, a gas containing the desired ion specie is passed through a thermomechanical leak into a radio frequency activated ion source. A variable voltage probe is used at the top of the source to drive the positive ions into the Van de Graaff accelerator. On emerging from the accelerator tube the ions are allowed to drift into a magnetic analyzing system. Only the desired ion specie, with the desired energy and charge is bent  $90^\circ$  into the exit port. On emerging from the analyzer they are defocused and allowed to drift down a 4-ft tube before hitting the target.  $\text{BF}_3$ ,  $\text{PF}_5$ , and  $\text{N}_2$  have been used as source gases for the boron, phosphorous, and nitrogen ions, respectively. In all cases the implantation target was silicon held at room temperature and oriented within a few degrees to the  $\langle 111 \rangle$  crystalline direction.

When the samples were tested right after the implantation they exhibited a very low conductivity surface layer with no evidence of any type change having occurred. In all cases, evidence of doping by the implanted ions was observed only after annealing at a temperature above  $200^\circ\text{C}$ . The observation of type change after annealing is evidence of the implanted ions having attained substitutional lattice positions (9). Figure 1 shows the annealing data obtained for 2 Mev  $\text{B}^+$  ions that were implanted into 40-50 ohm-cm n-type material in concentrations from  $2 \times 10^{13}$  ions/cm<sup>2</sup> to  $2 \times 10^{16}$  ions/cm<sup>2</sup>. Under these conditions the material is converted to p-type from the surface to a depth of about  $4\mu$ . The samples were implanted over a large area to facilitate sheet resistivity measurements with a resistivity probe having 45-mil probe spacings. The ion beam was not uniform

Fig. 1. Annealing curves for 2 Mev B<sup>+</sup> ion implantations

over this large an area. This is evidenced by the considerable fluctuation in the data points. The samples were annealed for 1 hr at the temperatures corresponding to each data point on the curves. The resistivity is seen to be continually decreasing for all except the lowest concentration implantations. Yet angle lapped and stained bevels taken on higher doped target materials, in which the implanted junctions appear buried, show no measurable increase in the width of the boron implanted p-layers when observed after a 575°C anneal and then viewed again after a 900°C anneal. Figure 2 shows such a comparison. This observation seems to indicate that no additional boron ions have found substitutional sites in the annealing temperature interval from 575° to 900°C. This leads us to speculate that it is the recovery in the mobility with higher anneal temperatures that is responsible for the decreased resistivity.

Table I shows a first order comparison between the total number of implanted ions and the number expected to be in active sites as inferred from the sheet resistivity measurements taken after the 1000°C anneal. Rows 3 and 6 are well within experimental error and thus we conclude that for 2 Mev boron ion implantations as heavy as  $2 \times 10^{16}$  ions/cm<sup>2</sup> there exists approximately a one to one correspondence between the number of implanted ions and the number of impurities that contribute to electrical conductivity.

Profiling of the implantations was accomplished by preparing 100 by 100 mil dice of different resistivities and mounting these into the sample holder as seen in Fig. 3. The samples were then subjected to different total ion doses. Later they were annealed for 1 hr at 700°, angle lapped and stained to allow interferometric measurement of the junctions that resulted from the implanted ions. It should be noted that the dark area on the sample holder is the imprint left by the ion beam, indicating that all four samples were in the center of the beam. Uniformity was further checked by interchanging the sample positions and repeating

Fig. 2. Annealed B<sup>+</sup> implantations into 0.1 ohm-cm n-type targets

Fig. 3. Sample holder

the experiments, in all such cases the results agreed within measurement accuracy.

Figure 4 shows the resulting p-type layers formed by  $4 \times 10^{14}$  ions/cm<sup>2</sup> boron ion implantations at 1¼ Mev and 2½ Mev into n-type silicon varying in resistivity from 18 ohm-cm to 0.01 ohm-cm. Actual depths were measured by a Zeiss interferometer. The measuring accuracy was at least  $\pm \frac{1}{2}$  fringe or approximately  $\pm 0.15 \mu$ . It should be emphasized that the npn structures (buried layers) are formed by just a single processing step, a unique feature of the high energy implantations. When these junction positions are plotted vs. the concentration level of the target materials the implantation profile is obtained. Figure 5 shows these results plotted for a  $10^{13}$  and a  $4 \times 10^{14}$  ions/cm<sup>2</sup> boron implantation at 1¼ and 2 Mev. The

Fig. 5. Distribution curves for B<sup>+</sup> ion implantations annealed at 700°C.

data indicate a tendency for the ions to pile up toward the implantation surface. Only in the case of the 1¼ Mev implantation was a p-region observed in the 0.01 ohm-cm target. It appeared as a very narrow line and thus gave the value of the peak concentration of the implanted ions for that case. In all other cases the peaks are but estimates, and thus are dashed lines on the curves, but the general features of the ion distributions are evident.

Nitrogen was investigated as a possible n-type dopant over the 1 to 2½ Mev range because other n-type dopant ions required higher magnetic field strengths than was available in our analyzing magnet. Nitrogen implanted p-type samples showed n-type layer formation by hot probe conductivity checking as well as by junction staining (10). Low leakage p-n diodes have also been fabricated by nitrogen implantation. Figure 6 shows stains taken after 1-hr anneals at both 700° and 900°C. For nitrogen implantations one observes large junction movement to have occurred between the two annealing conditions. All this movement is toward the implantation direction, so one must postulate that additional impurities have moved into active sites. If some form of enhanced diffusion were responsible for the widening one would expect this to occur equally in both directions. Figure 7 shows a doping profile plot similar to those shown for boron. Although the total number of ions, as found by integrating under the curve, is close

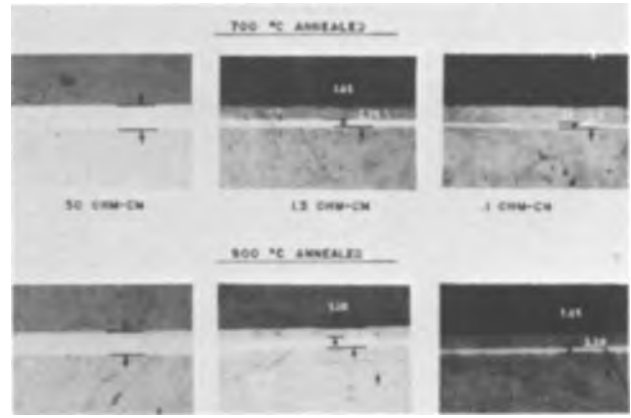

Fig. 6. Profiling samples for n<sup>+</sup> ion implantations, 4 × 10<sup>14</sup> ions/cm<sup>2</sup>.

Fig. 7. Distribution curve for n<sup>+</sup> ion implantation, 2 meV, 4 × 10<sup>14</sup> ions/cm<sup>2</sup>, annealed at 900°C.

to the number of ions implanted, sheet resistivity measurements on low doped background samples show the implanted layer conductivity to be an order of magnitude lower than would be the case for this number of commonly used active donors. Higher temperature anneals begin to increase the resistivity and long anneals at 1200°C can cause the n-layer to disappear, indicating compound formation, such as possibly silicon nitride. Nitrogen doping of silicon by ion implantation provides a first example wherein ion implantation has been used to achieve doping with an element previously considered not feasible for doping. The low conductivity of the nitrogen implanted layer however leaves some doubt to the practicality of using it as a dopant in silicon.

Phosphorous implantations, performed to obtain n-type implanted layers, could only be performed at 1 Mev. Figure 8 shows a plot of the distribution of phosphorous donors as a function of depth after a 1-hr, 700°C anneal; also plotted is a theoretical curve derived from Lindhard's "simple unified range theory" (11). The curves show that close agreement between theory and experiment exists. Yet, again one notes that there is still a tendency for the ions to pile up toward the implantation direction, although markedly less than that observed in the case of boron.

Figure 9 shows the estimates of the depth at which the ion distribution peaks as a function of energy. Since our experimental method actually determines only the limits between which the peaks must be, the error here is larger than the measurement error. The depth of the peaks as calculated from the "simple unified range theory" is also plotted. Good agreement can only be found for phosphorous; the disagreement

Fig. 9. Distribution peaks of implanted impurities

for boron and nitrogen however is not surprising, since discrepancies in the predictions of the theory for collisions where one of the elements has atomic number less than 11 were found by Lindhard when he compared his theoretical predictions to data available to him (11).

In order for the ion implantation method to be practical for electronic applications a convenient masking technique must be available.  $\text{SiO}_2$  has been used by those workers who have been using 500 keV or lower energies. 3 or  $4\mu$  of  $\text{SiO}_2$ , that would be needed for the 2 and 2½ MeV implantations, is rather impractical to work with. Evaporated Au was found to serve well as a mask for the ions. The ions penetrate only 1/3 as deep into Au as they do into silicon. The top of Fig. 10 shows an implantation that was terminated by an evaporated Au mask. Planar passivated junctions can still be obtained by growing a sufficient layer of  $\text{SiO}_2$  over the silicon before the gold evaporation. The implanted ions are attenuated by the  $\text{SiO}_2$  by approximately the same amount as by Si, so that the implantation profile can be determined by just shifting the profile curve to the left a distance corresponding to the thickness of the oxide. An advantage of using such a metal mask is that no ions will be in the passivating  $\text{SiO}_2$  layer as is the case with oxide masked, implanted or diffused structures. The I-V characteristics of a planar diode fabricated by Au masking are shown on the bottom of the figure.

We have shown that 1-2.5 MeV ions of boron, nitrogen, and phosphorous can be used to form p-n junc-

Fig. 10. Au masking for implanted diodes. Top, 2 MeV  $B^+$   $4 \times 10^{14}$  ions/cm<sup>2</sup>, 0.5 ohm-cm n-type target. Bottom,  $B^+$  implanted diode, 2 MeV,  $4 \times 10^{14}$  ions/cm<sup>2</sup>, 0.5 ohm-cm, n-type target.

tions as well as n-p-n or p-n-p buried layers in silicon. Only phosphorous seems to behave according to the predictions of Lindhard's theory; boron and nitrogen differ both in range and variance from the theory. In all cases the distribution of implanted ions was not gaussian about the peak.

### Acknowledgment

The authors would like to acknowledge the invaluable support of W. McLaughlin and J. Lorenzo in performing the laboratory experiments. They also wish to thank L. Lowe and M. Deane for operating the Van de Graaff used for these implantations.

Manuscript received June 19, 1967, revised manuscript received Oct. 20, 1967. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Abstract 97.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

### ABSTRACT

The properties of silicon nitride, oxynitride, and oxide films formed by the pyrolysis of various mixtures of  $\text{SiH}_4$ ,  $\text{NH}_3$ , and  $\text{NO}$  are presented. The variation in physical, optical, and electrical properties of this oxynitride ( $\text{Si}_x\text{O}_y\text{N}_z$ ) series is examined. The electrical and passivation properties of these films on Si are examined and compared with oxides. These electrical data describe the general characteristics of nitride and oxynitride on top of Si and over thin ( $\sim 300\text{\AA}$ ) and thick ( $\sim 1000\text{\AA}$ ) thermal oxide films.

The subject of passivating dielectric films on Si has had a varied history. The early work of Attalla *et al.* (1) showed that Si surfaces could be stabilized by using thermally grown  $\text{SiO}_2$  films. It was found, however, that ionic conduction can occur in  $\text{SiO}_2$  at very low temperatures ( $\sim 150^\circ\text{C}$ ), and these and other experiments subsequently suggested that planar transistor degradation is caused by the accumulation of positive space charge within the oxide (2). Kerr *et al.* (3) showed that this degradation phenomenon could be retarded by formation of phosphosilicate glass before metalization. Subsequently, Snow *et al.* (4) showed that most, if not all, of the positive space charge degradation and low-temperature ionic conduction within the  $\text{SiO}_2$  films was due to alkali ion contamination. Many other workers have subsequently studied the drift effects and stabilization properties of silicate glass films on Si. For example, phosphosilicate glass coatings do not appear to be a stabilization "cure all" judging from the variability of the published results. In fact, the experiments of Snow and Deal (5) suggest that double layer polarization effects will always make this stabilization method less stable than clean oxides covered with high purity metals. Nor does the alkali ion model appear to explain all the various kinds of drift observed by temperature bias experiments. For instance, some types of instability appear to be associated with electrochemical changes of the  $\text{SiO}_2$  at the insulator-Si interface. A recent example of this is the increase in stored positive charge in the oxide that occurs when negative bias is applied to clean MOS samples at elevated temperatures (6).

It is within this historical context that the passivation properties of silicon nitride ( $\text{Si}_3\text{N}_4$ ) and silicon oxynitride ( $\text{Si}_x\text{O}_y\text{N}_z$ ) films must be considered. The early observations about the high chemical stability of this material and the low diffusivity of ions through silicon nitride films has endured. In fact, the low reactivity of silicon nitride to etches has posed a difficulty in pattern forming, which has been successfully overcome by the use of special masking techniques (7-8). The low permeability of nitride to alkali ions (9), oxygen, water vapor (10, 11), and even hydrogen (12) remains one of its most attractive features. On the other hand, the reported electrical qualities of so-called silicon nitride films have been highly variable; and in fact, pyrolytic, glow discharge, and reactively sputtered nitride films appear to be generally inferior to silicon dioxide as insulators.

This work is subdivided into two major sections: the first covers the basic physical properties of pyro-

lytic nitride and oxynitride films; the second section covers their electrical properties on Si and their passivation properties when used to "seal" thermal oxides. The films studied in this investigation were pyrolytically formed; however, comparisons with other types of "nitride" films were made and will be described.

### Experimental Techniques

**Chemistry.**—The reaction kinetics taking place during the pyrolytic formation of  $\text{Si}_3\text{N}_4$  films from gaseous mixtures of  $\text{SiH}_4$  (undiluted) and  $\text{NH}_3$  are obviously quite complicated. Some of the possible reactions that can occur are shown in the free energy of reaction vs. temperature plot of Fig. 1. The direct reaction of silane with ammonia (A) may not be the only primary reaction for the formation of silicon nitride. One must also consider an initial pyrolysis of silane (B) and the reaction of freed Si with ammonia

Fig. 1. Free energy of reaction vs. temperature plot for the possible reactions taking place during the pyrolysis of mixtures of  $\text{SiH}_4$ ,  $\text{NH}_3$ , and  $\text{NO}$ . From JANAF Thermochemical Tables (Dow Chemical Company).

\* Electrochemical Society Active Member.

(C) and the reaction of silane with nitrogen (D) formed by the pyrolysis of ammonia (E). It is quite likely that all the Si released from the rapid pyrolysis of silane is not converted to  $\text{Si}_3\text{N}_4$ , and, as a result, films formed in this manner may contain detectable amounts of excess Si. Inclusion of excess and chemically bonded H is also quite likely, particularly with the use of  $\text{H}_2$  as a carrier gas. In order to minimize these problems, no  $\text{H}_2$  was used, and the  $\text{NH}_3$  to  $\text{SiH}_4$  ratio used was about 40,000:1.

Silicon oxynitride films were formed by introducing NO. In this case, the pyrolytic nitride-forming and oxide-forming reactions (F) are taking place simultaneously.

Figure 2 shows the film growth rates vs.  $1/T$ . Nitride growth rate curves A and B are for a  $\text{SiH}_4$  injection rate of 0.1 ( $\text{NH}_3/\text{SiH}_4 = 40,000$ ) and 0.27 cc/min, respectively. Curve C shows the rate of pyrolytic  $\text{SiO}_2$  growth using  $\text{SiH}_4$  and NO at a NO to  $\text{SiH}_4$  ratio of 800:1 in a  $\text{N}_2$  carrier gas. Notice that in this instance the growth rate saturates with increasing temperature. This is probably due to a premature reaction between  $\text{SiH}_4$  and NO in the gas stream some distance above the heated substrate.

Process control is so important to the interpretation of the results that an extensive coverage of experimental procedure at this point is not thought to be worthwhile. Details of this aspect of the work will therefore be included during the presentation of the results and in the summary where its importance is seen much better in retrospect. Suffice for now that the films used for electrical measurements were all formed on 1 ohm-cm n- and p-type Si and were all about 1500Å thick. The depositions were made on wafers set on a pedestal heated by RF induction. The film thickness variation over the surface of each 2.5 cm diameter wafer was about  $\pm 5\%$  and only  $\pm 3\%$  over a center section, covering about  $3/4$  of the wafer diameter. For the electrical measurements, Al dots 2 mm in diameter were placed on the insulating film by evaporating Al from a W filament through a metal mask. The wafer was not heated during this deposition step. It must be emphasized at this point that the purity of the gases used throughout the process is extremely important. As we will see, many of the previously reported results on silicon nitride films have been anomalous because the experimental system was not "clean."

Fig. 2. Film growth rate curves vs. reciprocal substrate surface temperature. Curves A and B respectively are for a  $\text{SiH}_4$  injection rate of 0.1 cc and 0.27 cc/min into a 4000 cc/min  $\text{NH}_3$  gas flow (activation energy of 23 kcal/mole). Curve C is the rate of  $\text{SiO}_2$  deposition using  $\text{SiH}_4$  and NO for an NO/ $\text{SiH}_4$  ratio of 800 (activation energy of 11 kcal/mole) in an  $\text{N}_2$  carrier gas (50 cc/min NO + 0.06 cc/min.  $\text{SiH}_4$  in 4000 cc/min  $\text{N}_2$ ). Temperatures are uncorrected optical pyrometer readings.

## Results

**Basic physical properties.**—Table I lists the fundamental constants for  $\text{Si}_3\text{N}_4$  and for the series of films formed by varying the amount of injected NO from 0 to 10% (substrate temperature  $\cong 1000^\circ\text{C}$ ). The parameters are as follows: (i) the low-frequency dielectric constant K as determined by measuring MOS accumulation capacity and physical thickness; (ii) the optical index of refraction as found by measuring reflective interference minima at two angles of incidence at an energy of about 2 eV (this method also gives physical thickness); (iii) the density of pyrolytic nitride and oxide films; (iv) the bandgap as defined by the photon energy at which the absorption coefficient is  $100 \text{ cm}^{-1}$ ; (v) the peak of the broad IR absorption band occurring at 8–14 $\mu$  which is produced by some of the Si-N absorption modes; and (vi) the electron affinity of nitride and oxide as determined by the energy difference between the threshold for optical absorption and photoelectric emission.<sup>2</sup> The numbers in the last column labeled est. equivalent %  $\text{SiO}_2$  were found by assuming that each parameter varies linearly between pure nitride and oxide. The range covers the variation in %  $\text{SiO}_2$  as found by using K, n, IR peak, and  $E_G$  as listed in Table I. Plots of any of these parameters vs. injected % NO saturate as the % NO increases. This may also be due to a premature reaction between  $\text{SiH}_4$  and NO in the gas stream above the substrate. The dielectric constant of pure nitride films appears to be about 7.4 while that of the oxynitride decreases continuously from this to about 5.8 for an equivalent  $\text{SiO}_2/\text{Si}_3\text{N}_4$  ratio of 1.0.

X-ray diffraction analysis indicates that the films are completely amorphous in nature. This and the fact that all the parameters in Table I vary smoothly as the NO% varies indicates that these substances are essentially glassy atomic mixtures of Si, N, and O.<sup>3</sup> Furthermore, when oxynitride films are made, the shift in the 11.7 $\mu$  band is quite apparent; however, there is no indication of any oxide absorption at 9.2 $\mu$  that one ordinarily sees when discrete layers of oxide and nitride are deposited on the same wafer. Because of these facts, the equivalent percentage of  $\text{SiO}_2$  quoted in Table I indicates the percentage of bound oxygen. A very small amount of absorption at 3 $\mu$  due to N-H bonds indicates the presence of some excess hydrogen; however, it is not known as yet how this impurity alters the physical properties of these films. No absorption appears at 4.7 $\mu$  unless the ammonia/silane ratio is reduced to about 100. This band has been shown to be due to Si-H bonds (13), and when observable, probably indicates that the films contain excess Si.<sup>4</sup> Of course, the absence of any detectable amounts of absorption at 4.7 $\mu$  does not necessarily indicate that there is no excess Si. Even films prepared using an ammonia/silane ratio of 40,000/1 probably contain small but optically undetectable amounts of Si.

The bandgap and electron affinity measurements make it possible to formulate a basic model for MIS structures using silicon nitride or silicon oxynitride as the dielectric insulating material. Figure 3 com-

<sup>1</sup> A complete absorption curve for silicon nitride was constructed using transmission measurements determined on films of various thicknesses between  $10^2$  and  $2 \times 10^6$  Å. Transmission data were obtained on oxynitride films of 1 $\mu$  thickness. The energy separation of these curves at an absorption coefficient of  $\sim 4 \times 10^4 \text{ cm}^{-1}$  was assumed to be the same as for  $100 \text{ cm}^{-1}$ .

<sup>2</sup> These optical refraction, absorption and photoelectric emission techniques are described by: F. A. Jenkins and H. E. White, "Fundamentals of Optics," p. 255, McGraw Hill Co., N. Y. (1950); E. A. Taft and H. R. Philipp, *J. Phys. Chem. Solids*, 3, 1 (1957).

<sup>3</sup> Therefore, terms like " $\text{Si}_3\text{N}_4$ " and "silicon nitride" mean glassy amorphous substances.

<sup>4</sup> In the case of d-c reactively sputtered films, the effects of excess Si are observable. No 4.7 $\mu$  band is observed if the sputtering is carried out at low voltages (<3 kv) in pure  $\text{N}_2$ . Annealing these films at  $1000^\circ\text{C}$  lowers their conductivity by about 2.5 orders of magnitude and moves the fundamental absorption edge toward shorter wavelengths. This is thought to be caused by the chemical bonding of some of the excess Si with incorporated N. Furthermore, if the sputtering is carried out in a mixture of  $\text{N}_2$  and  $\text{H}_2$ , the 4.7 $\mu$  absorption band occurs and the conductivity is also lowered (13). Other discussions of the 4.7 $\mu$  band can be found in ref. (10) and (14).

Table I. Physical properties of pyroelectric films

	Injected % NO	K	n	$\rho$ (g/cc)	$E_g$ (ev)	IR ( $\mu$ )	X (ev)	Estimated equivalent % $\text{SiO}_2$
Nitride	0.00	$7.4 \pm 0.2$	$2.03 \pm 0.01$	$3.11 \pm 0.07$	4.5	11.7	2.0	0
Oxynitride	0.25	$7.3 \pm 0.1$	$1.98 \pm 0.02$	—	4.7	11.5	—	$7 \pm 2$
Oxynitride	1.25	$7.0 \pm 0.4$	$1.92 \pm 0.01$	—	5.1	11.2	—	$17 \pm 5$
Oxynitride	2.25	$6.7 \pm 0.2$	$1.89 \pm 0.01$	—	5.3	10.9	—	$25 \pm 7$
Oxynitride	5.00	$6.5 \pm 0.1$	$1.79 \pm 0.03$	—	5.6	10.7	—	$34 \pm 8$
Oxynitride	10.00	$5.8 \pm 0.1$	$1.71 \pm 0.03$	—	5.8	10.1	—	$50 \pm 12$

compares the MNS structure with that of the well-known MOS varactor. This energy model shows that the considerably smaller bandgap of  $\text{Si}_3\text{N}_4$  coupled with a larger electron affinity produces much lower potential barriers at each electrode for the MNS structure; furthermore, this model shows that hole injection from the Si into the nitride is more probable than electron injection.

**Etch rates.**—Table II shows how the  $\text{Si}_3\text{N}_4$  etch rate in concentrated HF acid increases as the deposition temperature is decreased below  $1000^\circ\text{C}$ . For temperatures of a  $1000^\circ\text{C}$  and higher, the etch rate is a constant 140  $\text{\AA}/\text{min}$ . The reason for the rapid increase in etch rate for temperatures of preparation below  $1000^\circ\text{C}$  is not known. However, Chu *et al.* (15) have suggested that the increase in etch rate for low deposition temperatures is caused by the decrease in film density. Another point to consider is the increase in H content, as indicated by the increase in absorption at  $3\mu$ , that occurs when the deposition temperature is lowered. Also shown in Table II are the comparative etch rates for the silicon oxynitride series ( $\text{Si}_x\text{O}_y\text{N}_z$ ) formed by varying the amounts of NO injected into the ammonia stream. Here we see a continuous variation starting at 350  $\text{\AA}/\text{min}$  at the 0.25% NO level and increasing to 5000  $\text{\AA}/\text{min}$  at the 10% NO injection level.

Pattern forming is an important aspect of the application of these materials to device making, and Table III shows how one can form patterns in multiple layers of Mo,  $\text{Si}_3\text{N}_4$ , and  $\text{SiO}_2$  in almost any layer order by using the selective etches<sup>5</sup> listed in Table III.

**Electrical properties.**—The reported electrical properties of silicon nitride films deposited on Si show great variance even in their qualitative character. One of the difficulties with this type of investigation is that the so-called nitride films contain undefined and

<sup>5</sup> Holes in  $\text{Si}_3\text{N}_4$  films on Si can also be formed by selective anodization to  $\text{SiO}_2$  followed by etching in "buffered" HF [see ref. (16)].

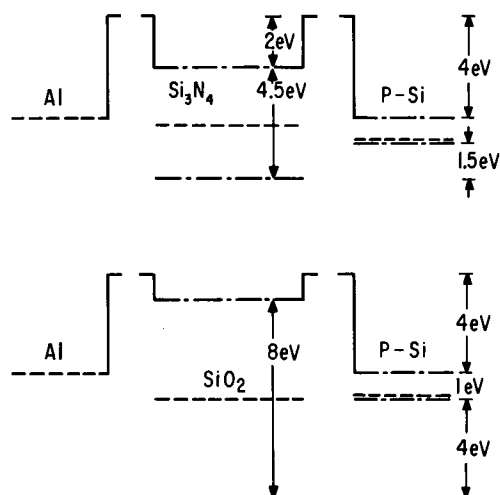

Fig. 3. Basic band models for the formation of rectifying barriers between materials Al,  $\text{Si}_3\text{N}_4$  or  $\text{SiO}_2$  and p-type Si (before contact). - - - represents Fermi levels; - - - represents band edges.

variable quantities of Si, N, H, O and their compounds. Another major difficulty is that these films are generally deposited on top of an undefined Si surface or  $\text{SiO}_2$  boundary layer. For instance, Hu (10) and Doo, Nichols, and Silvey (17) initially reported very high electrical resistivity. More recently, however, Doo and Nichols (18) and Hu, Kerr, and Gregor (19) have investigated the possible causes for the excessive d-c conduction seen in MNS varactors. And indeed, the results of Doo *et al.* (17) appear to have been determined more by the properties of an  $\text{SiO}_2$  film between the Si and nitride film than by the nitride itself.<sup>6</sup> Confusion on whether there is or is not a very thin oxide film underneath the nitride and what the electrical properties of nitride on Si should be still exists.

Such difficulties, among others, led to the early application of nitride films as a final oxide sealant since in this way one can combine the excellent dielectric and controllable interface qualities of  $\text{SiO}_2$  on Si with the chemical inertness and low permeability of nitride. This approach called MNOS will be investigated in a later section. Another approach is to try to combine these properties in a single film by the formation of oxynitride films on Si (20). Because of this subject diversification, three separate subsections are used to

<sup>6</sup> The data in ref. (17) Fig. 8 appear to support this view, since it shows that the dielectric constant for films of 2000 $\text{\AA}$  or less was surprisingly only about 4, and for thicknesses greater than 2000 $\text{\AA}$ , it was only 6.3.

discuss the electrical and passivation properties of these films. The first will deal with nitride and oxynitride films placed directly on Si immediately after reactor etching the Si to insure that all the last vestiges of  $\text{SiO}_2$  are removed from the surface of the Si wafer; the second subsection will show what happens when very thin films ( $\sim 300\text{\AA}$ ) of  $\text{SiO}_2$  are between the nitride film and silicon substrate; and the third will present the results of temperature-bias passivation experiments on composite films composed of about 1200Å of thermally grown oxide covered with thin layers ( $\sim 300\text{\AA}$ ) of nitride or oxynitride (MNOS).

*Silicon nitride and oxynitride films directly on Si.*—

Each of these samples was prepared by the following procedure: (i) the wafer was etched in white etch ( $3\text{HNO}_3:1\text{HF}$ ) and rinsed with distilled  $\text{H}_2\text{O}$ ; (ii) the wafer was placed in the pyrolytic reactor and the reactor was purged with  $\text{N}_2$  and evacuated; (iii) the wafer was heated to  $\sim 1225^\circ\text{C}$  in a flow of purified  $\text{H}_2$  and  $\text{HCl}$  gas was introduced ( $\sim 1\%$   $\text{HCl}$  in  $\text{H}_2$ ) with wafer etching continuing for 3 min; (iv) the system was purged with  $\text{H}_2$  and cooled to  $1000^\circ\text{C}$  at which point the  $\text{NH}_3$  flow was turned on, the  $\text{H}_2$  off, and film deposition was initiated by turning on the  $\text{SiH}_4$  flow.

Before describing the results of the various electrical measurements, let us point out the extreme difficulties in characterizing the exact electrical nature of these films. This is because these pyrolytic nitride films belong to a class of materials which can perhaps be generally described as "leaky insulators with traps." Generally, their characteristics are as follows: Electronic current is strongly time dependent because of space charge and trapping effects. The charge and discharge currents decrease with time in a manner like that of  $\text{SiO}_2$  (21). The electronic currents, besides being strongly time dependent, are also strongly dependent on the polarity of the applied voltage which must be caused by the differences in the potential barriers for hole and electron injection at the Si and Al interfaces. These characteristics together with the poor insulating (especially pure nitride) and trapping effects cause hysteresis in the differential a-c capacitance vs. voltage curves [ $C(V)$ ] as electronic charge is alternately driven in and out of the film by the voltage sweep. The amount of hysteresis of course similarly depends on the magnitude of the voltage excursions and sweep speed. Because of these difficulties, the over-all electrical behavior of these films will be examined and trends in their characteristics will be determined as their chemical nature is changed from pyrolytic nitride to oxynitride and oxide.

Because of the current-time dependence, d-c current vs. field data were taken by waiting one minute after each increase in bias. Log  $i$  vs.  $E$  data for a nitride, oxynitride (10% NO injection), and pyrolytic oxide are compared in Fig. 4. Also shown in Fig. 4 for comparative purposes is the curve given by Hu *et al.* (19) for a RF reactively sputtered nitride which has no polarity dependence and no time dependence, but orders of magnitude higher leakage currents than those of all the pyrolytic films.<sup>8</sup> Notice also that the polarity dependence of nitrides and oxynitrides is the opposite of that of oxide and that the oxynitride has a stronger polarity dependence than the nitride. The polarity dependence shown in Fig. 4 agrees with that predicted by the models of Fig. 3 but does not necessarily prove the correctness of these models. Such a proof is made difficult by the space charge and trapping effects that occur. The initial surge of charge into the film is probably largely controlled by the poten-

<sup>7</sup> The high-purity tank  $\text{H}_2$  was further purified by passing it through a deoxyo unit and two  $\text{LN}_2$  traps in series. Without this precaution, oxide formation would occur in the interval between etching and pyrolytic deposition. The purity of the  $\text{NH}_3$  and  $\text{H}_2$  gases were checked by heating Si wafers for extended times in these gases at  $1000^\circ\text{C}$  and checking for oxide formation.

<sup>8</sup> Current-time dependence of d-c reactively sputtered nitrides increases with annealing and inclusion of  $\text{H}_2$  in the sputtering gas (L. F. Cordes, Private communications).

Fig. 4. Current density vs. field curves of reactively sputtered (19) nitride, and pyrolytic nitride, oxynitride and oxide films on 1 ohm-cm n-type Si. Pyrolytic film data taken after waiting 1 min after each increase in field. (Plus bias means that positive voltage is applied to Al electrode.)

tial barrier heights at the electrodes; however, as the dielectric charging due to trapping continues, the field within the dielectric relaxes near the interface barrier; and hence, the charging currents decrease with time.

The amounts of hysteresis appearing in a  $C(V)$  curve is apparently controlled by the amount of current passing into and through the film and by the amount of charge that is trapped. Measurements of the shifts in flat band voltage are a good measure of this phenomenon and a summary of this behavior for a series of samples is given in Table IV and Fig. 5. Figure 5 shows a typical  $C(V)$  hysteresis loop together with a swept  $I(V)$  curve all taken for the same sweep speed (20 v/sec). Curve 1 is that which occurs if one sweeps negatively from zero, curve 2 returning from negative bias, and curve 3 sweeping negatively but returning from positive bias. If one limits the bias sweep to low but equal and opposite fields, the size of the hysteresis loop, called  $\Delta V_{FB}$  in Fig. 5B, decreases as the oxygen content in the oxynitride series increases. This is shown in Table IV where the third and fourth columns give  $\Delta V_{FB}$  voltages for field sweep limits of  $\pm 4 \times 10^6$  v/cm. Column 3 is for rapid reversal of the sweep direction, and column 4 is for 1-min stops at each end of the sweep limits before reversal. In the fifth column of Table IV,  $\Delta V_{FB}$  voltages are presented for the case when the samples are driven to equal and opposite current levels ( $\pm 2\mu$  amp/cm<sup>2</sup>). In this instance, one uses data such as those shown in Fig. 5A. Very large voltages are required to reach these current levels for the oxynitride films.

\* 20 v/sec sweep. Sweep limits are:  $\pm 4 \times 10^6$  v/cm;  $\pm 4 \times 10^6$  v/cm (1-min stops);  $\pm 2 \times 10^{-6}$  amp/cm<sup>2</sup> for the data in columns 3, 4, and 5, respectively.

Fig. 5.  $I(V)$  and  $C(V)$  curves using a 20 v/sec sweep rate. In Fig. 5A the  $C_0 \frac{dv}{dt}$  signal is nulled out by using a bridge circuit. The data shown are for an oxynitride film ( $\text{SiO}_2/\text{Si}_3\text{N}_4 \sim 1$ ) on 1 ohm-cm n-type Si.

Nevertheless, the films with high oxygen content still produce smaller hysteresis loops.

It is interesting to surmise that the pattern shown by the data in Fig. 4 and 5 and Table IV are controlled by two factors. The increase in band gap with oxygen content which increases the barrier heights at the Si insulator interface and the decrease in the amount of excess Si contained within these films as the NO injection level is increased. Many models have been proposed to explain the various current-voltage characteristics of nitride films. Most of these models are based on mechanisms of carrier excitation from traps within the silicon nitride (19, 22). These models have been tested on samples which exhibit current densities several orders of magnitude higher than those described here [see, e.g., Fig. 4 and ref. (22)]. And indeed, excess Si may be the cause of the carrier traps discussed by Sze (22) and Hu *et al.* (19). Furthermore, Haneta and Nakanuma (23) have shown that hysteresis loops in pyrolytic oxide films are caused by excess Si in the films which occurs when the concentration of the oxidizing gas ( $\text{H}_2\text{O}$ ) is too low.

**Nitride on top of thin thermal oxides.**—An initial layer of thermal oxide makes the electrical situation much more controllable. If the layer is thick enough ( $\sim 200$ – $300\text{\AA}$ ), all traces of the "soft hysteresis" described in the previous section are eliminated because the oxide's insulating properties effectively block the passage of charge into the nitride if the fields are kept low enough. If, however, the field and/or temperature are high enough, charge can be forced through the thin oxide layer into the nitride where some of it becomes trapped. This results in a polarization effect which persists at  $300^\circ\text{K}$ . This effect may have been originally observed by Hu (10) and was ascribed as being a fundamental bulk property of nitride. In our studies, this effect occurs only when a very thin layer of oxide is between the Si and the nitride film. A typical result is described below. The chemically etched Si wafer was placed in the reactor and heated to  $1050^\circ\text{C}$  in  $\text{N}_2$  at which point very dry  $\text{O}_2$  was introduced and the  $\text{N}_2$  flow shut off. After 5 min, the  $\text{N}_2$  flow was reinitiated and the  $\text{O}_2$  shut off.<sup>9</sup> After purging with  $\text{N}_2$ ,  $\text{NH}_3$  was introduced and subsequently followed by  $\text{SiH}_4$  injection and nitride film deposition. A resultant  $C(V)$  curve is shown by curve A of Fig. 6. Originally, the sample has a negative flatband voltage and with equal and opposite voltage sweeps the  $C(V)$

Fig. 6.  $C(V)$  curve showing the lack of hysteresis and room temperature polarization effect (curve B) which occurs when high fields are applied to MIS varactors composed of nitride films ( $\sim 1500\text{\AA}$ ) over a thin ( $\sim 300\text{\AA}$ ) film of thermal oxide.

curve at first looks perfectly normal with no detectable hysteresis for  $\pm 50\text{v}$  sweeps; however, after applying  $+60\text{v}$ , the flatband voltage suddenly moves in the positive direction. With alternate  $\pm 70\text{v}$  sweeps this effect is even more pronounced and ultimately results in a positive flatband voltage as shown by curve B of Fig. 6. This behavior also correlates with the  $I$  vs.  $V$  data for these particular samples. For instance, the high field polarity dependence is that of oxide (plus  $V$  gives larger  $I$  than neg.  $V$ ). At higher temperatures, the oxide can be made to conduct at lower voltages, and if the sample is then cooled with the stress bias still applied, similar polarization effects will occur. The voltages at which this polarization effect occurs are, of course, dependent on the thickness of the underlying oxide.<sup>10</sup> Preliminary stability experiments indicate that the internal field caused by the excess number of electrons trapped within the nitride is not stable; positive flatband voltages produced by high field stressing decrease when the MIS varactor is short circuited at elevated temperatures.

**Thin nitrides on top of thick oxides, MNOS.**—In this final section, the passivation properties of thin nitrides ( $\sim 300\text{\AA}$ ) on top of thick ( $\sim 1200\text{\AA}$ ) thermal oxides (MNOS) will be examined. This section has a very practical orientation since (i) thermal oxides on Si which have excellent dielectric and insulating properties can also be controllably formed with low oxide positive space charge ( $Q_{so}$ ) and negligible fast interface state densities ( $N_{FS}$ ) and (ii) the low permeability of nitride films to alkali ions, water vapor, and hydrogen can be used to passivate and thus preserve the excellent qualities of the underlying oxide. The specialized thermal oxidation and/or annealing methods for attaining the first set of oxide conditions are well known (6, 24–27). The low permeability of silicon nitride to alkali ions and water vapor have also been reported (9–11). It was therefore the purpose of this set of experiments to see what could be attained in terms of stability by this combination, and especially to see what differences might occur if oxynitride films were substituted for nitrides. It was not our purpose to attain low  $Q_{so}$  but only to determine the drift in  $Q_{so}$  during temperature-bias stress conditions. In this instance, the oxide must be thick enough to prevent any of the double layer polarization effects described in the previous section.

All the Al evaporations were made using a W wire filament that contains between 100 and 1000 ppm K. This potassium is ordinarily present in all drawn W wire. The oxides were made by first etching the wafers in white etch and thermally oxidizing them in very dry oxygen ( $< 80$  ppm  $\text{H}_2\text{O}$ ) using an extremely clean RF heated furnace. The oxidation was followed by slow cooling from the oxidation temperature ( $1000^\circ\text{C}$ ). A thin layer (200–400 $\text{\AA}$ ) nitride or oxynitride was

<sup>9</sup> Results in  $300 \pm 20\text{\AA}$  of  $\text{SiO}_2$  as determined by weight using a microbalance (Cahn Instrument Company).

<sup>10</sup> This type of polarization effect has also been investigated by T. L. Chu, J. R. Szecson, and C. H. Lee, *Solid-State Electronics*, 10, 897 (1967).

then pyrolytically deposited at 1000°C on top of this 1200-1500Å oxide film, and temperature-bias experiments were performed using a 25-point probe and an automatically recording  $C(V)$  bridge. A summary of the results of these experiments is shown by a set of representative results in Table V. It must be emphasized at this point that Table V presents a representative "best" set of results. Poorer results occur if the sample's oxide becomes contaminated by improper techniques. The limit of detectable drift in these experiments was  $\Delta Q_{so}/q \approx 10^{10}/\text{cm}^2$ . Each contact of any set deviated only slightly from the average values given in Table V.

Table V presents the following: layer thicknesses in Å, stress temperature in °C, stress time in hours, contact set (5-10 contacts), set bias in volts, and average change in oxide space charge ( $\Delta Q_{so}/q$ ) in units of  $10^{11}/\text{cm}^2$  as determined by the subsequent shift in the room temperature flatband voltage after each stress experiment. (Positive  $\Delta Q_{so}$  corresponds to negative  $C(V)$  shift.) The initial values of  $Q_{so}$  and  $N_{FS}$  (as determined by the shift in the flatband voltage caused by cooling the sample to 78°K) (27) are given in the comment column. Briefly, the results are as follows: (i) as expected, the oxide control sample shows very rapid increases in  $Q_{so}$  with positive bias at 200°C caused by K or Na ion permeation into the oxide; (ii) interface annealing of the type which reduces  $Q_{so}$  can apparently occur even at 200°C as evidenced by the decrease in  $Q_{so}$  with applied negative bias on the MOS control sample. Some further evidence for this is seen in MNOS sample 3 where almost identical decreases in  $Q_{so}$  occurred under negative bias, open, and shorted conditions. (iii) All three MNOS samples have much lower initial  $Q_{so}$  and  $N_{FS}$  values than the dry thermal oxide because of the interface annealing that takes place during the 1000°C pyrolytic deposition of the nitride film and very much better stability for all sets of stress conditions. (iv) No appreciable instability occurs in the MNOS samples for large positive bias even at 250°C except in

MNOS sample 3 which utilizes an oxynitride passivation film of high equivalent  $\text{SiO}_2$  content (see Table I). However, appreciable instability does occur for large negative bias at 250°C. This type of instability, which has already been observed by others using clean MOS structures, is apparently a fundamental and intrinsic property of the  $\text{SiO}_2$ -Si interface.<sup>11</sup> It is thought to be due either to the electrochemical reduction of the  $\text{SiO}_2$  at the  $\text{SiO}_2$ -Si interface or field diffusion of excess Si into the oxide or both. In any case, it is the only type of surface instability that cannot be overcome by any of the presently known oxide passivation schemes.

### Summary

In retrospect, the difficulties of attaining a correct description of the properties of nitride films have been caused by the difficulties encountered in reaching a point at which the processes were clean enough to attain reproducible results. This particular investigation required the fabrication of hundreds of samples before the difficulties could be identified. One example of this occurred when reactor etching was introduced. Previous to reactor etching the dielectric strength of pure nitrides on Si appeared to be exceedingly low ( $\ll 10^6$  v/cm). This was probably caused by pinholes in the nitride under the Al electrode. After reactor etching, all pure nitride films on Si suddenly exhibited high dielectric strength ( $\approx 10^7$  v/cm) and the  $C(V)$  curves had no hysteresis. However, the lack of hysteresis was caused by the fact that thin ( $\sim 100\text{Å}$ ) thermal oxide layers were being formed after reactor etching because the  $\text{H}_2$  used as a carrier gas for the HCl contained some water vapor. The pure nitrides still had as high dielectric strength after the water vapor in the  $\text{H}_2$  was eliminated but now gave the  $C(V)$  curve hysteresis described in the text. A general summary of the results now follows.

The physical properties of glassy-amorphous oxynitride films on Si are strongly dependent on the oxynitride concentration. The details of this variation in going from  $\text{Si}_3\text{N}_4$  to  $\text{SiO}_2$  are shown in the text. These variations in the properties of oxynitride films have also aided the definition of the properties of pure nitride films on Si. For instance, the measurements of band gap and electron affinity have led to a basic model for the nitride-Si contact, which explains, tentatively at least, the polarity dependent leakage and polarization currents. This survey also suggests that

<sup>11</sup> This increase in stored positive charge with negative bias heat treatments was initially reported by Y. Miura and Y. Matukura, *Jap. J. Appl. Phys.*, 5, 180 (1966). The same effect was subsequently reported by A. Goetzberger, Recent News Paper presented at the Cleveland Meeting of the Society, May 1-6 (1966); A. Goetzberger and N. E. Nigh, *Proc. IEEE*, 54, 1454 (1966); and also by Deal *et al.*, ref. (6). For additional details also see Y. Miura and Y. Matukura, *Jap. J. Appl. Phys.*, 6, 582 (1967).

the  $\text{Si}_3\text{N}_4$  trapping centers, which cause the various hysteresis and polarization effects in MNS and MNOS structures, are produced by excess Si in the nitride films.

All the pyrolytic films prepared in the manner described in the text had very high dielectric strength ( $\cong 10^7$  v/cm) as determined by d-c point probe measurements. The variations in leakage and polarization currents for nitrides and oxynitrides had the following general characteristics: (i) for fields between 4 and  $8 \times 10^6$  v/cm, the current varied exponentially with applied voltage; (ii) negative bias (Al negative) currents are higher than those for positive bias; and (iii) the amount of hysteresis in the  $C(V)$  curves decreases as the oxygen content in the film is increased; however, it was never found to be as low as that of oxide. Furthermore, the amount of stored positive charge ( $Q_{so}$ ) in these nitride and oxynitride films on Si as estimated by a flatband voltage for the middle of the hysteresis loop is high ( $1-5 \times 10^{12}/\text{cm}^2$ ).

When thin oxide films ( $\sim 100\text{\AA}$ ) are under nitride films, polarization effects occur when the field is sufficiently high to force electrons through the oxide into the nitride film where it is trapped. Control of Si surface potential and attainment of low stored positive charge and negligible fast interface state densities together with excellent passivation properties can be obtained by covering thicker ( $\sim 1000\text{\AA}$ ) thermal oxide films with thin films ( $\sim 300\text{\AA}$ ) of oxynitride or pure nitride.

# Films of Silicon Nitride-Silicon Dioxide Mixtures

T. L. Chu,<sup>1\*</sup> J. R. Szedon, and C. H. Lee

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

## ABSTRACT

Amorphous films of silicon nitride-silicon dioxide mixtures have been deposited on silicon substrates by the pyrolysis of silane in ammonia-oxygen mixtures in a gas flow system. The properties of these films such as composition, density, dissolution rate, dielectric constant, refractive index, infrared absorption, etc., were determined as a function of the reactant composition. MIS (metal-insulator-silicon) and MIOS (metal-insulator-oxide-silicon) structures were prepared by using silicon nitride-silicon dioxide mixtures as the insulator, and their capacitance-voltage behavior compared with that of MNS (metal-nitride-silicon) and MNOS (metal-nitride-oxide-silicon) structures. Similar to MNS structures, the MIS structures under study are characterized by high charge densities in the silicon-insulator interface region and by the ease of charge transfer across the interface. These effects are considerably reduced in MIOS structures; however, MIOS structures are less stable than MNOS structures under electrical and thermal stresses.

Dielectric films are used for many purposes in semiconductor devices. For most applications, these films should be amorphous in structure to provide uniform properties, impervious to contaminants to minimize instability effects, and compatible with the substrate to yield satisfactory mechanical and electrical characteristics. Films of amorphous silicon dioxide (silica) are the most commonly used dielectric in silicon devices because of the ease of preparation. However, silica is structurally porous; the high permeability of silica films toward impurities and the migration of impurity ions in silica films are undesirable in device applications. On the other hand, amorphous silicon nitride is more dense and therefore more impervious than silica. The density of amorphous silicon nitride is 2.8-3.0 g cm<sup>-3</sup> (1) compared to 2.2 g cm<sup>-3</sup> for thermally grown silica. The ion-migration effect has been shown to be negligible in silicon nitride films even at high temperatures (2). Nevertheless, silicon nitride is not compatible with silicon in properties, and Al-Si<sub>3</sub>N<sub>4</sub>-Si (MNS) structures have been shown to possess inherently unstable charge distribution under the application of large insulator fields ( $\pm 6 \times 10^6$  v/cm) at room temperature (3). Although this instability can be suppressed by using a thin silica interlayer between the silicon and the silicon nitride, the low dissolution rate of silicon nitride films by hydrofluoric acid requires additional masking steps in the photolithographic processes. One may thus deduce that the use of Si<sub>3</sub>N<sub>4</sub> + SiO<sub>2</sub> mixtures optimized with respect to dissolution rate and imperviousness could be a compromise for some applications.

In the present work, a series of films of Si<sub>3</sub>N<sub>4</sub> + SiO<sub>2</sub> mixtures with composition over a wide range were deposited on silicon substrates by the simultaneous nitridation and oxidation of silane in a gas flow system. The properties of these films, such as composition, density, dissolution rate, dielectric constant, refractive index, and infrared absorption, were studied as a function of the reactant composition. A number of capacitor structures Al-(SiO<sub>2</sub> + Si<sub>3</sub>N<sub>4</sub>)-Si and Al-(SiO<sub>2</sub> + Si<sub>3</sub>N<sub>4</sub>) - SiO<sub>2</sub> - Si were prepared, and their electrical characteristics were compared with those of Al-Si<sub>3</sub>N<sub>4</sub>-Si and Al-Si<sub>3</sub>N<sub>4</sub>-SiO<sub>2</sub>-Si structures. The experimental approaches and results are discussed in this paper.

## Films of Si<sub>3</sub>N<sub>4</sub> + SiO<sub>2</sub> Mixtures

Mixtures of silicon nitride and silicon dioxide can be prepared by the reaction of silane with an ammonia-oxygen mixture. These reactions presumably

involve the decomposition of silane and the subsequent nitridation and oxidation of silicon. The over-all reactions are

The equilibrium constants of these reactions in the temperature range 800°-1500°K, calculated from the JANAF thermochemical data (4), are shown in Fig. 1. In the temperature range of interest, 1000°-1200°K, the oxidation of silane is thermochemically more favorable than the nitridation of silane. Furthermore, the rate of the oxidation reaction is also higher than that of the nitridation reaction. Thus, the partial pressure of oxygen in the reactant mixture must be carefully controlled in the preparation of Si<sub>3</sub>N<sub>4</sub> + SiO<sub>2</sub> mixtures.

## Experimental

The deposition of films of Si<sub>3</sub>N<sub>4</sub> + SiO<sub>2</sub> mixtures was carried out in a gas flow system using an apparatus shown schematically in Fig. 2. Appropriate flowmeters and valves were used to control the flow of various reactants, i.e., ammonia, silane, oxygen, and hydrogen chloride. Semiconductor grade silane, anhydrous ammonia of better than 99.99% purity, and oxygen of 99.95% min. purity, all purchased from the Matheson Company, were used without further purification. The reactant mixture of the desired composition was passed through a filter into a fused silica reaction tube of 55 mm ID. Single crystal silicon substrates with main faces of {111} orientation were sup-

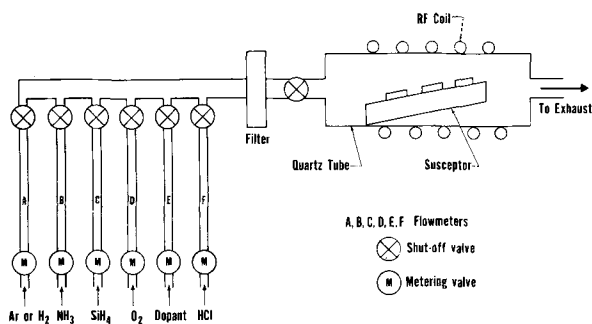

Fig. 2. Schematic diagram of the apparatus for the deposition of silicon nitride—silicon dioxide mixtures.

ported on a silicon-coated susceptor in the reaction tube, and the susceptor was heated externally by an rf generator. The silicon substrates were n-type, 20-50 ohm-cm resistivity and were mechanically lapped and chemically polished in a nitric acid-hydrofluoric acid mixture. In several experiments, the substrate surfaces were etched *in situ* prior to the deposition process by using a hydrogen-hydrogen chloride mixture (5), and approximately  $5\mu$  of silicon was removed from the substrate surface.

The most important variables affecting the deposition rate of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures and their properties are the substrate temperature and the composition and flow rate of the reactant mixture. All deposition experiments in this work were carried out at a substrate temperature of  $900^\circ\text{C}$  using ammonia as the major component in the reactant mixture. The flow rate of ammonia was 40 l/min, the flow rate of silane was 2-10 ml/min, and the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture was 0.5-50. In many cases, a thin silicon dioxide film was deposited on the substrate by the oxidation of silane in an argon atmosphere prior to the deposition of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures.

The thickness, nitrogen and silicon content, density, refractive index, dissolution rate, and infrared absorption of films of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures were determined by techniques used previously in the study of silicon nitride films (1). The analysis of the nitrogen and silicon content was believed to be accurate within  $\pm 0.3\%$ .

#### Results and Discussion

The films of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures deposited on silicon substrates under conditions used in this work were uniform, transparent, and adherent to the substrate. They exhibited no structural features when examined with an optical microscope and were found to be amorphous by electron diffraction examinations. In contrast to silicon nitride films (1), these films were not readily crystallized by electron beam bombardment in an electron microscope.

Since ammonia is present in large excess in all reactant mixtures studied [molar ratio  $\text{NH}_3/(\text{SiH}_4 + \text{O}_2) > 10^3$ ], the properties of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures can be conveniently compared in terms of the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture. In the range of the silane flow rate used in this work, the deposition rate of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures is approximately a linear function of the flow rate of silane. Using silane at a flow rate of 2 ml/min, the deposition rate is about  $0.02 \mu/\text{min}$ , essentially independent of the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture. However, the composition of the deposited film depends strongly on the  $\text{O}_2/\text{SiH}_4$  molar ratio when the reactant mixture is of low  $\text{O}_2/\text{SiH}_4$  molar ratio. Figure 3 shows the mole per cent of silicon nitride in the  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixture as a function of the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture. These mixtures were prepared by using ammonia and silane at flow rates of 40 l/min and 10 ml/min, respectively. As expected, the addition of a small amount of oxygen into the silane-ammonia mixture results in a drastic decrease in the silicon nitride content of the deposit, in spite of the large  $\text{NH}_3/\text{O}_2$  molar

Fig. 3. Composition of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures deposited at  $900^\circ\text{C}$  as a function of  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture. Flow rate of  $\text{NH}_3 = 40$  l/min, flow rate of  $\text{SiH}_4 = 10$  ml/min.

ratio in the reactant mixture. For example, using reactants of molar ratios  $\text{O}_2 : \text{SiH}_4 : \text{NH}_3 = 1 : 2 : 8000$  and  $\text{O}_2 : \text{SiH}_4 : \text{NH}_3 = 2.7 : 2 : 8000$ , the deposit contained 53 and 25% of silicon nitride, respectively. The composition of the deposit levels off as the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant is further increased. Thus, under the conditions used in this work, the control of the composition of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures is more difficult for nitride-rich mixtures than for oxide-rich mixtures.

Similar to the dependence of the composition of the deposited mixtures on the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant other properties of the deposit behave in a similar manner. The density, refractive index, and dissolution rate of the deposit are shown as a function of the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant in Fig. 4, 5, and 6, respectively. A buffer solution consisting of 1:6 49% HF : Saturated  $\text{NH}_4\text{F}$  solution was used as an etchant in the dissolution rate measurements. The samples used for the refractive index and dissolution rate measurements were prepared by using silane at a flow rate of 2 ml/min as compared to 10 ml/min used in the preparation of samples for composition and density determinations. The effect of using lower flow rate of silane on the composition —  $\text{O}_2/\text{SiH}_4$  molar ratio relation shown in Fig.

Fig. 4. Density of  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures deposited at  $900^\circ\text{C}$  as a function of  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant mixture. Flow rate of  $\text{NH}_3 = 40$  l/min, flow rate of  $\text{SiH}_4 = 10$  ml/min.

Fig. 5. Refractive index of  $Si_3N_4 + SiO_2$  mixtures deposited at  $900^\circ C$  as a function of  $O_2/SiH_4$  molar ratio in the reactant mixture. Flow rate of  $NH_3 = 40$  l/min, flow rate of  $SiH_4 = 2$  ml/min.

Fig. 6. Dissolution rate of  $Si_3N_4 + SiO_2$  mixtures in buffered hydrofluoric acid as a function of  $O_2/SiH_4$  molar ratio in the reactant mixture. Deposition temperature =  $900^\circ C$ . Flow rate of  $NH_3 = 40$  l/min, flow rate of  $SiH_4 = 2$  ml/min.

3 is presumably small because of the large excess of ammonia in the reactant.

The infrared absorption spectra of three  $Si_3N_4 + SiO_2$  mixtures prepared by using a silane flow rate of 2 ml/min and  $O_2/SiH_4$  molar ratios of 1, 5, and 50, are shown in Fig. 7. Amorphous silicon nitride shows a broad absorption band at  $830-860\text{ cm}^{-1}$ , characteristic of the stretching of the Si-N bond. This absorption band is shifted toward higher frequencies in  $Si_3N_4 + SiO_2$  mixtures (one of the Si-O stretching bands is at  $1090\text{ cm}^{-1}$ ), and the shift is pronounced even when the  $O_2/SiH_4$  molar ratio is 1. The magnitude of the shift increased with increasing  $O_2/SiH_4$  molar ratio in the reactant.

#### Al-( $Si_3N_4 + SiO_2$ )-Si Capacitors

A number of Al-( $Si_3N_4 + SiO_2$ )-Si, or MIS, capacitors were prepared by depositing  $0.1-0.15\mu$  of the films of  $Si_3N_4 + SiO_2$  mixtures on n-type silicon substrates of 20-40 ohm-cm resistivity, followed by the evaporation of aluminum electrodes of  $3.3 \times 10^{-4}\text{ cm}^2$  area on the insulating films. The capacitors were mounted on TO-5 headers for capacitance measurements at 100 kHz and 1 MHz.

The capacitance of the MIS capacitors measured at 1 MHz was used to determine the relative dielectric constant of the films of  $Si_3N_4 + SiO_2$  mixtures. The results are shown in Fig. 8 as a function of the  $O_2/SiH_4$  molar ratio in the reactant mixture. The film

Fig. 7. Infrared spectral absorbance of films of  $Si_3N_4 + SiO_2$  mixtures deposited on silicon substrates at  $900^\circ C$ .

Fig. 8. Relative dielectric constant (1 MHz) of  $Si_3N_4 + SiO_2$  mixtures deposited at  $900^\circ C$  as a function of  $O_2/SiH_4$  molar ratio in the reactant mixture. Flow rate of  $NH_3 = 40$  l/min, flow rate of  $SiH_4 = 2$  ml/min.

thickness was determined by ellipsometric measurements. As the  $O_2/SiH_4$  molar ratio in the reactant was increased, the dielectric constant of the resulting mixture decreased monotonically from a value of about 9, characteristic of deposited silicon nitride films, toward one of about 4, characteristic of deposited silicon dioxide films. No measurement of dissipation in the insulating films was made, since the dominant loss mechanism in the capacitors was due to the resistance of the silicon substrate.

The capacitance-voltage behavior of MIS capacitors using  $Si_3N_4 + SiO_2$  mixtures as the dielectric is very similar to that of Al- $Si_3N_4$ -Si (MNS) capacitors. The charge density in the Si- $Si_3N_4$  interface region has been deduced from the flat-band voltage of MNS capacitors to be of the order of  $10^{12}$  charges/cm<sup>2</sup>. Fur-

thermore, the interface charge density has been found to vary under large voltage bias ( $\pm 6 \times 10^6$  v/cm of insulator field) at room temperature. This charge instability has been attributed to the charge transfer across the Si- $\text{Si}_3\text{N}_4$  interface with subsequent trapping at sites in the nitride and has been concluded to be a basic property of the MNS capacitors prepared by the chemical deposition technique (3). The effective charge density in Si-( $\text{Si}_3\text{N}_4 + \text{SiO}_2$ ) interface region was also found to be quite high for all the mixtures studied (up to about 80%  $\text{SiO}_2$ ), irrespective of the *in situ* etching of the substrate or other process parameters of the deposition process. Typical values were 1 to  $3 \times 10^{12}$  charges/cm<sup>2</sup>, compared to  $6 \times 10^{11}$  and 1 to  $4 \times 10^{12}$  charges/cm<sup>2</sup>, respectively, in chemically deposited Si- $\text{SiO}_2$  and Si- $\text{Si}_3\text{N}_4$  structures. Since the interface state density in Si-( $\text{Si}_3\text{N}_4 + \text{SiO}_2$ ) structures is independent of the composition of the mixture, these states cannot be directly associated with bulk properties of the dielectrics. The interface charge behavior must be characteristic of silicon-nitrogen bonding at the interface.

Similar to MNS structures, all MIS structures under study exhibited charge instability under large voltage bias at room temperature. This charge instability can be best represented by the flat-band voltage vs. stress voltage loops used for the characterization of MNS structures (3). A polarizing voltage was applied to a MIS at room temperature for about 30 sec, and the flat-band voltage obtained by capacitance-voltage measurements. Results for several MIS structures and an MNS structure are shown in Fig. 9. In all cases, the maximum polarizing voltage used was approximately  $\pm 50$ v. The total flat-band shift for the MNS structure is about 25v. The charge instability in MIS structures is less pronounced. The total flat-band shift for the MIS structures decreases rapidly with increasing  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant. This shift is only 3v or less when the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant exceeds 10.

#### Al-( $\text{Si}_3\text{N}_4 + \text{SiO}_2$ )- $\text{SiO}_2$ -Si Capacitors

The charge instability in MNS structures under large voltage bias at room temperature can be suppressed by using a thin silicon dioxide interlayer between the silicon and the silicon nitride. The same approach was used for MIS capacitors in this study. Approximately 100Å of silicon dioxide was deposited prior to the deposition of the  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixture. The interface charge density in these capacitors was found to be considerably reduced, usually to about  $10^{12}$  charges/cm<sup>2</sup>. When stressed at room temperature under  $\pm 30$ v, the MIOS capacitors (total insulator thickness = 1000-1500Å) also exhibited no measurable instability due to charge transfer or rearrangement (the flat-band voltage changes were less than 0.2v).

To determine the imperviousness of the  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures toward ion migration, the MIOS capacitors were subjected to +20v stress at 200°C for 2 min. The C-V curve was found to shift in voltage in the direction expected from ion migration or

25:1	1450	$1.38 \times 10^6$	$7.2 \times 10^{11}$	5.22
50:1	1440	$1.39 \times 10^6$	$1.5 \times 10^{12}$	10.8

other charge rearrangement in the insulator. Voltage shifts of the C-V curves resulting from the stresses were interpreted, using the insulator capacitance in each case, in terms of the total change in interface charge,  $\Delta N_i$ , at room temperature resulting from positive and negative stresses. Results are shown in Table I. Since differences in film thickness exist among the samples, the ratio of  $\Delta N_i$  to the average stress field,  $E_s$ , was chosen for comparison. The  $\Delta N_i/E_s$  value of the capacitors also increases rapidly with increasing  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant.

#### Summary and Conclusions

Amorphous films of silicon nitride-silicon dioxide mixtures have been deposited on silicon substrates by the pyrolysis of silane in ammonia-oxygen mixtures, using ammonia as the major component in the reactant mixture. Because of the greater reactivity of silane toward oxygen, the partial pressure of oxygen in the reactant must be carefully controlled, particularly at low  $\text{O}_2/\text{SiH}_4$  molar ratios. The  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant must be maintained at  $\frac{1}{2}$  or smaller to obtain  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures containing 50% or more  $\text{Si}_3\text{N}_4$ . When the  $\text{O}_2/\text{SiH}_4$  molar ratio exceeds two, the deposited mixture contains less than 20%  $\text{Si}_3\text{N}_4$  and its composition becomes less sensitive to variations in the reactant composition. Parallel to the change in the composition of the deposit with the  $\text{O}_2/\text{SiH}_4$  molar ratio in the reactant, other properties of the deposit, such as density, dissolution rate, refractive index, infrared absorption, etc., change in a similar manner.

The C-V behavior of MIS capacitors using  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures as the dielectric is very similar to that of MNS capacitors. They are characterized by high interface charge densities, 1 to  $3 \times 10^{12}$  charges/cm<sup>2</sup>, independent of the composition of the  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixtures, or the preparative conditions. They also exhibit charge instability under large voltage bias at room temperature; the instability becoming less pronounced as the silicon dioxide content in the mixture is increased. The high interface charge density and the charge instability in MIS structures can also be reduced by the use of a silicon dioxide interlayer between the silicon and the insulator. However, MIOS capacitors are less stable than MNOS capacitors under electrical and thermal stresses because of the permeability of the  $\text{Si}_3\text{N}_4 + \text{SiO}_2$  mixture toward ion migration.

## Uranium-Uranium Monoarsenide Phase Diagram

Robert Benz and M. C. Tinkle

*Los Alamos Scientific Laboratory of the University of California, Los Alamos, New Mexico*

### ABSTRACT

Uranium-uranium monoarsenide phase boundaries are deduced from thermal analyses and from x-ray diffraction and microscopic analyses of quenched products. The uranium-uranium monoarsenide eutectic occurs at  $1125^\circ \pm 5^\circ\text{C}$  with a composition near pure uranium. Uranium solubility in the UAs phase does not exceed 0.15%. The highest melting point observed with the UAs (+U) phase is  $2705^\circ\text{C}$ .

The phases in the uranium-arsenic system have been reported by Iandelli (1) to be face-centered cubic UAs, body-centered cubic  $\text{U}_3\text{As}_4$ , and tetragonal  $\text{UAs}_2$ . Iandelli found no evidence of formation of solid solutions in preparations that had been heated to temperatures as high as  $900^\circ\text{C}$ . Information on the uranium and UAs phase boundaries at more elevated temperatures is reported below.

### Preparations and Procedure

Preparations with different As/U ratios up to 2 were made by reaction of uranium powder (2) obtained from calcium-reduced metal ( $99.9 \pm 0.1\%$  pure) and arsenic (Johnson, Matthey and Company, Ltd., London, "99.9995%" pure lump arsenic) in a heated ( $400^\circ\text{--}800^\circ\text{C}$ ) silica tube. Phase transitions that occur below  $1000^\circ$  in uranium saturated with arsenic were determined with a resistance furnace and a platinum-rhodium thermocouple for temperature measurement. Higher temperatures were obtained with an induction heater and temperature measurements were made with a calibrated optical pyrometer. The experimental procedures were essentially the same as previously described (3). Lattice parameters were determined from high-angle lines in powder x-ray diffraction pattern photographs obtained with nickel-filtered copper- $\text{K}_\alpha$  radiation. The compositions of the cooled products were determined micrographically by cutting out different phases seen in photomicrographs and weighing. Results are summarized in Fig. 1.

### Results and Discussion

**Uranium phase transitions and the liquidus.**—The solid-solid transitions in arsenic-saturated uranium were obtained by thermal analysis of a single cylinder with the As/U ratio of 0.05. The  $\alpha \rightarrow \beta$  transition initiated at  $665^\circ\text{C}$  and the  $\beta \rightarrow \alpha$  transition initiated at  $642^\circ\text{C}$  at the rate of temperature change of  $5^\circ\text{C}/\text{min}$  indicating an appreciably greater hysteresis than that previously reported (2) for nitrogen-saturated uranium. The  $\beta\text{--}\gamma$  transition occurred at  $775^\circ \pm 3^\circ\text{C}$  on heating and cooling.

The eutectic thermal arrest was determined with an apparatus for measurement of changes in optical emission (4). The arrest occurred  $7^\circ\text{C}$  lower in a specimen with the As/U ratio of 0.5 than in a pure uranium specimen. The melting point of pure uranium has been reported to be  $1132.3^\circ\text{C}$  (5), from which the eutectic temperature of  $1125^\circ \pm 5^\circ\text{C}$  is deduced.

Liquidus compositions as deduced from specimens that had been equilibrated at different temperatures and cooled are plotted in Fig. 1. As shown in Fig. 1,

extrapolation of these data to the uranium melting point and the above described small effect of arsenic on the uranium melting point suggests that the U-UAs eutectic composition is very near pure uranium. X-ray diffraction patterns of powder samples taken from the cooled products in each case contained lines corresponding to the uranium and the UAs phase. Figure 2 is a photomicrograph of a uranium specimen that had been saturated with arsenic at  $1880^\circ\text{C}$  and cooled.

**UAs phase boundaries.**—In order to investigate the uranium-rich UAs phase boundary at approximately 100-degree intervals between  $1600^\circ$  and  $2200^\circ\text{C}$ , reacted powders with an As/U ratio in excess of 1.0 were compacted and heated in a tungsten Knudsen-type crucible *in vacuo*. The period of heating ranged from 30 days at  $1600^\circ\text{C}$  to 7 days at  $1700^\circ\text{C}$  and to successively shorter periods of time at higher temperatures. At first, specimens with the initial As/U ratio of 1.1 were investigated. The phases UAs and  $\text{U}_3\text{As}_4$  were identified in the starting specimens from x-ray diffraction pattern photographs. When heated at selected temperatures between  $1600^\circ\text{C}$  and above, the specimens suffered weight loss by vaporization with preferential loss of arsenic. The cooled products were found to consist of U + UAs phases. Virtually

Fig. 1. Uranium-UAs phase diagram

Fig. 2. Photomicrograph of uranium specimen

Fig. 3. Photomicrograph of a typical product

all the uranium was present at UAs grain boundaries and as irregularly distributed 2- $\mu\text{m}$  inclusions within the UAs grains. The bulk of the uranium in the inclusions was probably present as free uranium in the starting specimen; however, the quantity was too small to be identified from the x-ray diffraction pattern photographs. Samples of the cooled products were subsequently annealed for 1 day at 1100° and at 900°C, cooled, and examined with a microscope for uranium precipitate as evidence for solubility of uranium in the UAs phase. No uranium precipitate could be positively identified and, therefore, the solubility is probably small.

The presence of the uranium particles described as inclusions above made difficult the identification of any small quantities of uranium that might have formed by precipitation as the specimens were cooled. Therefore, the above described experiments were repeated by starting with specimens with which greater care was taken to eliminate free uranium. These specimens were prepared as follows: reacted powder with the As/U ratio of 2.0 was cold pressed, and the excess arsenic was distilled off at 1400°C in an atmosphere of helium until the specimen consisted of a mixture of UAs + U<sub>3</sub>As<sub>4</sub> phases as determined from x-ray diffraction pattern photographs. The previous experiments were then repeated by heating 1.5g cylinders of this material for periods necessary to produce 10-20% weight loss by vaporization. The products that had been heated at temperatures of 1830°C (2 days) or below were found to be porous but single phase UAs with the lattice parameters of  $5.7789 \pm 0.0004\text{\AA}$ . No uranium was detectable with a microscope. Products that had been heated at temperatures of 1900°C (16 hr) and above were found to consist of dense 50- $\mu\text{m}$  UAs grains and of uranium present at the grain boundaries. Some uranium particles, similar to the inclusions described above, were also found in some of the UAs grains located near the surface of the products. The occurrence was, however, appreciably less frequent, supporting the interpretation of their being inclusions. These inclusions may have been formed by decomposition at the surfaces of open pores that subsequently disappeared. The UAs grains in products that had been heated at temperatures near 2200°C contained, in addition, 0.05  $\pm$  0.03 v/o (volume per cent) of uranium as smaller 0.5- $\mu\text{m}$  particles. Figure 3 is a photomicrograph of a typical product. These particles may have formed by precipitation from uranium-rich UAs, but the possibility that they were inclusions at temperature cannot be excluded. From this result and the assumption that the UAs phase as

seen in the microscope is stoichiometric, the solubility of uranium is inferred not to exceed 0.15% below 2200°C corresponding to a solidus with an As/U ratio of not less than 0.998. Based on this result and the results obtained with melting point products described in the next section, the composition range of the uranium-saturated UAs phase is shown in Fig. 1 to be very narrow. In Fig. 1, the solidus is suggested to be weakly retrograde in agreement with the rules for the occurrence of a retrograde solidus as stated by Meijering (6).

In the course of the latter set of experiments, single phase UAs was observed to decompose under steady-state vaporization conditions in a tungsten crucible to liquid uranium at temperatures of  $1865^\circ \pm 60^\circ\text{C}$  and above, but did not decompose at lower temperatures. The analogous UN phase has been reported (2) to decompose to liquid uranium at 1820°C and above. The uncertainties of the two temperatures overlap.

The arsenic-rich UAs phase boundary was investigated by examination of UAs + U<sub>3</sub>As<sub>4</sub> phase mixtures that were heated for different periods of time at selected temperatures ranging from ½ hr at 1400°C to 0.1 min at 1800°C. The mixtures were heated under an atmosphere of helium to reduce the rate of arsenic vaporization. The UAs and U<sub>3</sub>As<sub>4</sub> phases were identified from x-ray diffraction powder patterns as obtained with samples of the porous products. The lattice parameters of the UAs phase were found to be  $5.7783 \pm 0.001\text{\AA}$ , the values of which do not differ significantly from those obtained with uranium-saturated UAs that had been heated to comparable temperatures. These results suggest that any solubility of arsenic in the UAs phase is small. No U<sub>3</sub>As<sub>4</sub> precipitate in the UAs phase was perceptible with a microscope. Corresponding to these results, the arsenic-rich UAs boundary is shown in Fig. 1 to be a vertical line, but the line is broken to indicate (i) an uncertainty due to the rapid rates of vaporization that limited the anneal periods and (ii) an uncertainty in the microscopic examination of the porous products.

**UAs melting points.**—Because arsenic vaporized rapidly and preferentially from UAs at elevated temperatures, melting point compositions could not be controlled at will and the melted products generally consisted of uranium + UAs phases. The melting points were determined by heating cylinders with an initial arsenic:uranium ratio of 1.1 either *in vacuo* or in a helium atmosphere. Those heated *in vacuo* melted at different temperatures between 2200° and 2450°C. The arsenic:uranium ratios in the corresponding products ranged from 0.72 to 0.90. Those heated in a helium

Table I. Analyses of UAs incongruent melting points

Melting point, °C	Atmosphere	Bulk As:U, ±0.05	UAs lattice parameter, ±0.002Å
2705	1 atm. He	0.98	5.774
2695	1 atm. He	0.98	5.777
2640	1 atm. He	0.97	5.775
2560	1 atm. He	0.96	5.776
2500	1 atm. He	0.96	5.777
2486	½ atm. He	0.89	5.775
2412	½ atm. He	0.88	5.776
2370	<i>in vacuo</i>	0.85	5.777

atmosphere melted at temperatures between 2420° and 2705°C and the values of the arsenic:uranium ratios in these products were found to range from 0.89 to 0.98. The highest melting points and the highest arsenic:uranium ratios were obtained with the specimens that were heated in a helium atmosphere. An analogous behavior has been reported for UP when it was melted under similar conditions (7).

Typical melting points are listed in column 1 of Table I. The arsenic:uranium ratios of the products are listed in column 3. As shown in Table I, the temperature at which liquid was observed increases from 2370° to 2705°C as the uranium:arsenic ratio increases from 0.85 to 0.98. Microscopically, the melted products consisted of the phases uranium and UAs with small amounts of UO<sub>2</sub> as impurity. The uranium phase appeared mostly at the UAs grain boundaries indicating that the specimens melted incongruently with an arsenic:uranium ratio of less than 1.0. The specimens that melted at temperatures between 2370° and 2560°C contained a trace of uranium present as small spheroidal particles of uranium within the grains of UAs. These particles were virtually absent in the products

melted above 2600°. Lattice parameters obtained with samples of the cooled products are listed in column 4 of Table I. As seen in Table I, the lattice parameters range in value from 5.774 to 5.777Å with no systematic dependence on thermal history. Differences between these values and the above mentioned values of 5.7783 ± 0.001Å as obtained with UAs heated at lower temperatures may be due to impurities such as carbon, tungsten, and oxygen. From the results obtained with the specimen having the highest melting point, the congruent melting point is estimated to be 2705°C at the arsenic:uranium ratio of 1.00.

## Technical Notes

### Gallium Phosphide: Its Preparation in Bulk Ingot Form

S. E. Blum,\* R. J. Chicotka, and B. K. Bischoff

IBM Watson Research Center, Yorktown Heights, New York

Recent interest in gallium phosphide has made it desirable to obtain relatively large bulk ingots as a material source for both crystal growth and device studies. Reviews of the various methods that have been used are given in the literature by Miller (1) and Shmartsev *et al.* (2). In general, the preparation is complicated by the high melting temperature (~1500°C) and high dissociation pressure (~35 atm) of the compound (3). However, GaP can be prepared from its elements in polycrystalline form quite readily at pressures appreciably below the dissociation pressure. Of the methods described in the above reviews, the vertical Bridgman is the most adaptable to the routine synthesis of GaP.

#### Method of Preparation

Gallium phosphide was prepared from commercially available materials. Both the gallium and red phosphorus were nominally 6-9's quality and were obtained from both domestic and foreign suppliers.<sup>1</sup> The boron nitride ("Boralloy") crucibles (1.5 cm OD x 7 cm long) were produced by High Temperature Mate-

rials, Inc., Lowell, Massachusetts, and were cleaned prior to use with white etch (3 HNO<sub>3</sub>-1 HF).

The apparatus used to synthesize GaP is shown schematically in Fig. 1. It consists of a heavy wall quartz ampoule<sup>2</sup> (18 mm ID x 24 mm OD) within which the gallium charge (30g) and crucible and an excess of phosphorus is sealed *in vacuo*. The ampoule is positioned within a vertical tubular furnace as shown. Synthesis is achieved by heating the gallium inductively while slowly elevating the temperature of the phosphorus, and hence its pressure, until the phosphorus pressure is controlled at ten atmospheres. At this pressure the melt is at about 1500°C and has a composition of about 0.45 atom fraction of phosphorus (4). Solidification can be obtained either by lowering the ampoule and phosphorus temperature control thermocouple simultaneously or by raising the RF coil. Clear, transparent, single phase GaP is obtained at freezing rates of about 1 cm/hr.

Boron nitride was chosen as the crucible material because it has a low emissivity, and therefore overheating and softening of the quartz ampoule is mini-

\* Electrochemical Society Active Member.

<sup>1</sup> 6-9's phosphorus can be obtained from Leico Industries, Inc., New York, N. Y.

<sup>2</sup> Heavy walled quartz ware is available from General Electric, Cleveland, Ohio and from Thermal American Fused Quartz Company, Dover, New Jersey.

Fig. 1. Schematic diagram showing the vertical Bridgman apparatus.

mized. In addition, the GaP does not wet BN appreciably and this facilitates the removal of the ingot. By maintaining sufficient clearance between the crucible and the ampoule (several millimeters) we have been able to synthesize GaP in other crucible materials, e.g., graphite and quartz.

### Results

Gallium phosphide ingots produced by this method are generally completely sound (i.e., free of voids and inclusions) and, if undoped, golden in color. Occasionally, the ingots will have a small region at the first-to-freeze portion of the ingot that is dark and gallium rich. This is sometimes observed at the tail portion as well. In both cases, this is caused by rapid freezing at the front end because of supercooling and, at the tail end of the crystal, because of rapid loss of RF coupling to the melt. However, in most cases when this occurs, no more than about 10% of the crystal is so affected and at least 40g of sound material is obtained in each run.

The gallium phosphide ingots produced are quite polycrystalline. In general, the crystallites are columnar and arrayed with the long axis parallel to the direction of growth. Usually, individual grains are sufficiently large for Hall spiders ( $6 \times 3 \times 1$  mm).

The freezing interface during solidification of the melt is concave toward the solid phase. Such an interface permits growth of crystallites nucleated at the crucible-melt-solid interface. Some attempts were made to alter the shape of this interface by the use of radiation reflectors external to the ampoule. Although the growing interface could be flattened appreciably, it was impossible to do this completely without risking a softening, and hence rupturing, of the quartz ampoule.

Gallium phosphide ingots have been produced in this apparatus over a phosphorus pressure range of 5-25 atm. At pressures below 10 atm, gallium rich material invariably is produced. At the higher pressures, the risk of explosion, due to flaws in the quartz ware, is of course greater. For the purpose of producing GaP at reasonable rates, a phosphorus pressure of ten atmospheres was quite satisfactory. Of about 170 charges prepared at 10 atm, no explosions resulted.

### Electrical Properties and Purity

Gallium phosphide prepared as described above has always yielded p-type material and invariably contains some boron (<10 ppm). Although some variation from ingot to ingot is observed, net carrier concentrations in the low  $10^{17}$  range with room temperature mobilities of about  $115 \text{ cm}^2/\text{v sec}$  are generally

Table I. Electrical properties of synthesized GaP

Crystal	300°K			77°K		
	$\mu, \text{cm}^2/\text{v sec}$	$p, \text{cm}^{-3}$	$\rho, \text{ohm-cm}$	$\mu, \text{cm}^2/\text{v sec}$	$p, \text{cm}^{-3}$	$\rho, \text{ohm-cm}$
143	123	$1.4 \times 10^{17}$	0.35	1110	$4.5 \times 10^{15}$	1.3
145	127	$6.2 \times 10^{16}$	0.79	970	$1.2 \times 10^{15}$	5.5
147	130	$1.2 \times 10^{17}$	0.42	1780	$5.0 \times 10^{15}$	0.75

obtained. Net carrier concentrations of about  $10^{15} \text{ cm}^{-3}$  with mobilities of about  $300 \text{ cm}^2/\text{v sec}$  are typical at 77°K. Gallium phosphide prepared in a graphite crucible yielded semi-insulating material of about  $10^4 \text{ ohm-cm}$ . Material prepared in a quartz crucible was dark and opaque and extremely brittle. Electrical measurements of this ingot could not be made. However, emission spectrographic analysis showed extremely high contamination from the quartz with a silicon content greater than 300 ppm.

Since the impurity content of the GaP is appreciably greater than that of its constituent elements, it is assumed that the major sources of contamination are the quartz ampoule and/or the boron nitride crucible (possibly carbon). Woods and Ainslie (5) have shown in the case of GaAs that the presence of oxygen during synthesis reduces silicon contamination. Cochran and Foster (6) suggested the theoretical possibility of suppressing silicon contamination by using  $\text{Ga}_2\text{O}$  generated by the reaction of gallium and water vapor. Frosch *et al.* (7) demonstrated that the presence of water vapor in GaP vapor transport system effectively reduced the silicon donor concentration. To determine whether or not the same effect could be observed in gallium phosphide, crystals were synthesized in the presence of water vapor (a backfill of 20 mm at room temperature). The electrical properties of three ingots so prepared are shown in Table I.

The most noticeable effect produced by the presence of water vapor during synthesis is the marked increase in the 77°K mobility. This difference is attributed to a decrease in compensation as a result of the decrease in concentration of the minority donor silicon; i.e., the effect of the water is to suppress reaction with either the quartz ampoule or silica in the boron nitride crucible (ca. 50 ppm). The possibility of other reasons for the effect of water cannot be precluded. For example, the reaction of BN with water might form  $\text{B}_2\text{O}_3$  which then acts as a barrier between the crucible and melt.

### Summary

The vertical Bridgman method of synthesis can be easily applied to materials with high melting temperatures and high dissociating pressures. The method described can produce sound gallium phosphide ingots. The presence of water vapor during synthesis and growth produced a marked effect on the 77°K mobility of the crystal. This effect is attributed to a lowering of the silicon concentration.

Manuscript received Oct. 5, 1967; revised manuscript received Nov. 24, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

# Thickness Measurements of Silicon Dioxide Films on Silicon by Infrared Absorption Techniques

J. E. Dial, R. E. Gong, and J. N. Fordemwalt

Microelectronics Division, Philco-Ford Corporation, Santa Clara, California

Infrared techniques have been used previously in the study of silicon dioxide films (1-4). It is well known that silicon dioxide has strong absorption peaks at 9.2 and 21.9 $\mu$  with a weaker peak at 12.1 $\mu$  (5). If radiation of intensity  $I_0$  impinges on a layer of substance of thickness  $d$ , the intensity of the emerging radiation is given by the equation,  $I = I_0 e^{-\epsilon d}$ , known as the Lambert-Bouguer law (6). Lambert-Bouguer's law plots have been made by plotting the optical density of SiO<sub>2</sub> films on Si at 9.2 and 12.1 $\mu$  as a function of thickness. These plots have been found to be linear within experimental error. Thus, infrared absorption may be used as a nondestructive technique for the thickness determination of unknown SiO<sub>2</sub> layers on silicon samples. The 9.2 $\mu$  peak was used for thin films (<10,000Å), whereas the 12.1 $\mu$  micron peak was used for thicker films.

## Experimental

The measurements were made using a Beckman IR-10 spectrophotometer. A simple fixture was fabricated to hold the oxidized silicon wafer. Double beam transmission was used in all cases. The reference beam attenuator was adjusted so that the initial transmission for all samples was the same (nearly 100%) at a wavelength of 5 $\mu$ . This adjustment was necessary to insure adequate response and sensitivity during a scan. The cross-sectional area of the incident beam was 2 cm<sup>2</sup>.

The silicon substrates used were chemically polished Czochralski grown, n-type wafers with 10<sup>15</sup> atoms/cc phosphorus. The wafers were oxidized either in dry oxygen drawn from a liquid oxygen source, or in steam. After the infrared absorption had been measured, the wafers were prepared for interferometer measurement by first etching a step in the oxide down to the silicon and then evaporating 2000Å of aluminum over the step. A Watson multiple-beam interferometer was used to measure the SiO<sub>2</sub> film thickness (7). The thickness measurements made by using the Watson interferometer were calibrated against a Gaertner ellipsometer. The error was found to be less than 2% for measurements between these two methods.

Figure 1 shows a typical IR scan of a wafer with 1470Å of dry oxide on both sides of the wafer. The optical density of the peak was taken as the maximum reading at 9.2 $\mu$  less the reading of the base line at the same wavelength. It was assumed that the thickness of the oxide was the same on both sides of the wafer (since both had received identical treatment), hence,

the thickness value used for the Lambert-Bouguer's law plot for the wafer in Fig. 1 was 2940Å (i.e., 2 x 1470Å). After the thickness had been measured with the Watson interferometer, the aluminum and the SiO<sub>2</sub> were completely stripped from one side, being careful not to damage the oxide on the other side, and the spectrum of the wafer run again. These data were used to construct the Lambert-Bouguer's law plot in Fig. 2 for the 9.2 $\mu$  infrared absorption peak of SiO<sub>2</sub>. The data for oxide on both sides of the wafer are shown as circles whereas triangles represent the data for oxide on one side only.

Figure 3 shows the spectrum of an oxide 16,400Å thick grown in steam. Figure 4 is the Lambert-Bouguer's law plot for thicker oxides based on the 12.1 $\mu$  peak. With thinner steam-grown oxide films, where the 9.2 $\mu$  peak was not totally absorbing, the thicknesses determined using this peak were found to give excellent correlation with the Lambert-Bouguer's law plot generated for dry oxides at 9.2 $\mu$ .

Extrapolation of Fig. 2 and 4 to zero thickness gives zero optical density as anticipated by the method of establishing the base line. The tangent method used compensates for scattering and reflection caused by the surfaces; thus, failure to obtain an optical density of zero for zero thickness would indicate serious problems with the technique.

## Conclusion

From these Lambert-Bouguer's law plots, it appears that infrared absorption may be successfully

Fig. 2. Optical density of dry silicon dioxide vs. film thickness

Fig. 1. Typical infrared absorption spectrum of a 2940Å thick film of SiO<sub>2</sub> on silicon.

Fig. 3. Infrared spectrum of a 16,400Å thick steam-grown SiO<sub>2</sub> film on silicon.

employed as a nondestructive technique for determining the thicknesses of silicon dioxide films. It is felt that the accuracy of these data is limited as much by the Watson interferometer used for the thickness measurements as by the basic infrared equipment and techniques. Limits of error within  $\pm 3\%$  are possible for films from 1000Å to  $3\mu$  thick with this technique. Films as thin as 400Å have been measured with errors of less than 50Å.

## Silver-Manganese Evaporated Ohmic Contacts to p-type Gallium Arsenide

C. J. Nuese and J. J. Gannon

RCA Laboratories, Princeton, New Jersey

As GaAs devices become more sophisticated, the technology of forming low-resistance ohmic contacts to them becomes increasingly important. These contacts can be formed by alloy (1-3), plating (4) liquid regrowth (5), or evaporation (6,7) procedures, each of which has its particular advantages (and disadvantages). However, for many present-day GaAs devices requiring the precise and reproducible location of various geometrical contact patterns, the evaporation of metal through a mask (either an oxide or a metal mask) is particularly desirable. Such an evaporation procedure is even more useful if it is applicable over a wide range of conditions. For n-type GaAs an evaporation procedure using a Au-Ge-Ni alloy (7) has recently been reported.<sup>1</sup>

We report here a Ag-Mn alloy evaporation procedure for p-type single-crystal GaAs which forms low-resistance ohmic contacts over a wide range of temperature and resistivity. The Ag-Mn evaporation provides ohmic contacts to lapped, chemically-polished, or epitaxial as-grown surfaces, and readily supports ultrasonic or thermocompression wire bonding. The contact has a very small penetration depth (no more than a fraction of a micron), and is therefore useful for contacting surfaces adjoining a reasonably shallow junction. The Ag-Mn evaporation procedure is also applicable to p-type GaAs<sub>1-x</sub>P<sub>x</sub> alloys with moderate-to-heavy doping concentrations.

### Procedure

The technique described here is a modification of that used by Schmidt (6) for the evaporation of Ag ohmic contacts on heavily doped GaAs. We have found that Ag evaporated on chemically-polished or as-grown surfaces of lightly doped p-type GaAs ( $p < 10^{18}$  cm<sup>-3</sup>) frequently leads to nonohmic contacts, whereas

<sup>1</sup> In addition, R. H. Cox and H. Strack [*Solid-State Electronics*, **10**, 1213 (1967)] have just reported the evaporation of low-resistance ohmic contacts to GaAs using Ag-In alloys.

### Acknowledgments

The authors are indebted to Mr. D. M. Brettner for his contributions to this paper and to Dr. M. L. Hammond and Mr. M. J. Selser for their assistance in the interpretation of the spectral measurements.

the addition of manganese, an acceptor in GaAs, to the Ag remedies this problem. Because Ag and Mn have vapor pressures of roughly the same magnitude, the Ag-Mn alloy is readily evaporated; however, the replacement of Mn by other frequently used acceptors such as Zn or Cd leads to erratic and irreproducible evaporations because of their high vapor pressures as compared to that of Ag.

Ohmic contacts are formed by evaporating a metal alloy composed of 96 parts by weight of Ag and 4 parts of Mn, both metals having a manufacturer's reported purity of 99.999%. For our particular device applications, the GaAs surface is usually chemically polished on pellow cloth with a dilute sodium hypochlorite solution, or is used in the as-grown condition on vapor-grown epitaxial layers; however, mechanically lapped or polished surfaces have also been contacted with equal success. Following a clean-up bath in dilute HCl and a rinse in distilled water and ethyl alcohol, the wafer is placed on a ceramic heater in a vacuum chamber, and is gradually heated under vacuum ( $10^{-5}$  Torr) to 300°C. The Ag-Mn alloy is then evaporated onto the hot GaAs surface to a thickness of approximately 5000Å. For evaporating a particular array of contacts, a molybdenum mask is placed directly against the GaAs wafer. Finally, the wafer is removed from vacuum and heated to 550°C for 2 min in a hydrogen atmosphere in order to sinter the contacts more thoroughly to the GaAs. It should be noted that the 550°C sintering process is usually not necessary to obtain ohmic contacts; however it does improve the contact adhesion, thereby facilitating ultrasonic wire bonding to the contacts.

### Results

The current-voltage characteristics between a pair of Ag-Mn dots (5 mils in diameter) evaporated on a large variety of single-crystal GaAs wafers with Zn

Fig. 1. I-V characteristics at various ambient temperatures of Ag-Mn contacts evaporated onto a lightly doped ( $1.5 \times 10^{17} \text{ cm}^{-3}$ , Cd) GaAs wafer. The increase in resistivity at  $77^\circ\text{K}$  is due to carrier freeze-out.

or Cd acceptor concentrations between  $1 \times 10^{16} \text{ cm}^{-3}$  and  $1 \times 10^{20} \text{ cm}^{-3}$  have always been linear. Similar ohmic behavior was also found between contacts to a high resistivity (650 ohm-cm, p-type) Mn-doped sample. Ohmic behavior has been obtained for evaporations on {100} and {111} oriented surfaces with no observable distinction between them.

The linearity of these contacts over an extended temperature range is shown in Fig. 1. Here, a pair of the small dots was evaporated onto a Cd-doped GaAs wafer ( $p = 1.5 \times 10^{17} \text{ cm}^{-3}$  at  $300^\circ\text{K}$ ), and the I-V characteristics between the dots were photographed on a curve tracer at several temperatures between  $77^\circ$  and  $800^\circ\text{K}$ . The characteristics of the contacts are clearly linear at each temperature within this range. The increase in the resistance between the dots from a value of 22 ohms at  $300^\circ\text{K}$  to 142 ohms at  $77^\circ\text{K}$  is due primarily to the large increase in the sample resistivity with cooling. Hall measurements on this sample using conventional In-Zn alloyed contacts (8) showed a freeze-out of carriers from  $1.5 \times 10^{17} \text{ cm}^{-3}$  at  $300^\circ\text{K}$  to  $1.6 \times 10^{16} \text{ cm}^{-3}$  at  $77^\circ\text{K}$ , and a corresponding increase in resistivity by a factor of 4 at  $77^\circ\text{K}$ . The gradual increase in total resistance with increasing temperature is probably due mainly to increased sample resistivity.

It is difficult to separate bulk and spreading resistances accurately from the contact resistance, particularly on lightly doped samples. However, with a low-resistivity sample, an upper limit for the contact resistance is conveniently obtained by measuring the total resistance between two contacts to the sample. A total resistance of 0.16 ohms was so obtained between two 5 mil diameter Ag-Mn dots evaporated on a heavily Zn-doped ( $p = 8.5 \times 10^{19} \text{ cm}^{-3}$ ,  $\rho = 1.2 \times 10^{-3} \text{ ohm-cm}$ ) GaAs wafer, thus placing an upper limit of approximately 0.08 ohms on the contact resistance of each Ag-Mn contact. A "specific contact resistance" (contact resistance  $\times$  contact area) of  $1 \times 10^{-5} \text{ ohm-cm}^2$

is thus calculated for these contacts, which is comparable with Schmidt's measurements for Ag contacts to GaAs (6). We should note that these values of contact resistance and specific contact resistance apply only to the particular low-resistivity sample measured here.

The Ag-Mn contacting procedure has been used extensively in the fabrication of GaAs diodes with reasonably shallow p-n junctions (typically  $5\mu$ , but as small as  $1.5\mu$ ) without noticeably degrading device performance. In an attempt to determine the contact penetration depth, an n-type GaAs sample with Ag-Mn contacts was mounted in epoxy and beveled at an angle of  $2^\circ$  to the crystal surface. A variety of chemical etchants were used to delineate any p-n junction bordering a regrown or diffused layer, however to the accuracy of this technique (approximately  $0.2\mu$ ), none was evident. As long as the sintering temperature does not exceed the GaAs-Ag eutectic temperature of approximately  $650^\circ\text{C}$ , no appreciable alloying occurs.

Last, these contacts have also been used extensively to provide ohmic contacts to moderately-doped ( $p > 10^{17} \text{ cm}^{-3}$ ) single-crystal  $\text{GaAs}_{1-x}\text{P}_x$  with  $0 \leq x \leq 0.6$ , and have been used to a lesser extent (but always with success) to heavily doped ( $10^{18} < p < 10^{19} \text{ cm}^{-3}$ )  $\text{GaAs}_{1-x}\text{P}_x$  with  $0.6 \leq x \leq 1.0$ .

### Acknowledgments

The authors wish to thank H. F. Gossenberger for preparing several wafers used in evaluating the contacts. Furthermore they gratefully acknowledge the assistance of H. P. Maruska for performing the Hall measurements, C. W. Benyon for evaluating the wire bonding capabilities, and J. J. Tietjen and L. R. Weisberg for critically reviewing this paper. This research was supported by the Advanced Research Projects Agency, Materials Sciences Office under Contract No. SD-182.

# Measurement of Electrolyte Gradient in an Operating Fuel Cell

M. L. Miller and H. J. Fornasar

Central Research Division, American Cyanamid Company, Stamford, Connecticut

## ABSTRACT

Reference mercury, mercuric oxide electrodes have been developed for monitoring the concentration of potassium hydroxide in hydrogen-oxygen fuel cells operating at 27° and 70°C.

The distribution of electrolyte in the matrix of an operating fuel cell can be measured by imbedding appropriate reference electrodes in various parts of the fuel cell matrix. Knowledge of the concentration distribution in a fuel cell is important for understanding the operation of a cell and for designing fuel cells. Mercury, mercuric oxide electrodes have been shown to be reversible to hydroxyl ions (1, 2) at concentrations less than 0.85M. These electrodes will be useful for measuring the distribution of potassium hydroxide in fuel cells provided the electrodes can be shown to respond to hydroxyl ions at the higher concentrations encountered in an operating fuel cell.

## Experimental

**Fuel cells.**—Two types of hydrogen-oxygen fuel cells were used in the development of reference electrodes. One was a small poly(methylmethacrylate) cell similar to the cell described by Bone (3). A circular area of matrix 2.5 cm in diameter was exposed to gases. This cell was run at room temperature without temperature control, and at 70°C in an air bath. A second cell, which is described in ref. (4), was made from stainless steel plates separated by polytetrafluoroethylene gaskets. The surface of the matrix exposed to gases in this cell was 5.0 x 5.0 cm. The larger cell was heated externally by two electric heaters, and its temperature was regulated by a temperature-control unit connected to a thermocouple within the cell. The pattern of gas flow in each cell was determined by the position of the ports through which gases entered and left the cell. These positions are shown in Fig. 1. The catalytic electrodes were Cyanamid AB1 electrodes (5). The gel membrane was made from crosslinked poly(vinyl alcohol) and contained filler (6). The matrix asbestos was Fuel Cell Asbestos supplied by Johns-Manville.

**Calibration electrodes.**—The ability of mercury, mercuric oxide electrodes to respond to changes in hydroxyl ion concentration at high concentrations of potassium hydroxide was determined in a series of experiments which made use of relatively large electrodes, referred to as "calibration electrodes." The calibration electrodes were made from 2.4 mm diameter glass tubes, one end of which was covered with a poly(vinyl alcohol) membrane (unfilled) which allowed transport of water and ions, but retained solid materials within the tube. A slurry of mercury and mercuric oxide (prepared by triturating with a solution of potassium hydroxide having the concentration of the standard solution in which the electrode was to be used) was placed in the electrode tube together with a platinum wire that had been gold plated and then amalgamated.

Electrodes were made with potassium hydroxide solutions containing 3.25, 4.67, 6.00, 6.56, 7.40, 8.85, and 10.58 moles of potassium hydroxide per kg of water. These electrodes were compared in the cell

at 27° or 70°C. The potential of cell 1 was measured with a Minneapolis Honeywell Potentiometer—Model

2700. The concentration of the reference solution,  $C_1$ , was arbitrarily chosen as 6.56M (6N at 27°). The concentration  $C_2$  ranged from 3.25 to 10.58M. The potentials (in millivolts) of cell 1 at 27° and at 70°C are plotted against  $C_2$  (in molality) in Fig. 2.

**Microelectrodes and matrix assembly.**—The electrodes used to determine the relationship between potential and concentration were not suited for use in an operating fuel cell. Electrodes had to be small enough to insert into a cell without disrupting the gas-tight seal of the gaskets. Gold-plated platinum wires (0.075 mm diameter), amalgamated with mercury to hold the mercury immobile during operation, were used to make these small electrodes. The tip of each amalgamated platinum wire was painted with a slurry of mercuric oxide in a potassium hydroxide solution having the concentration of the solution to be used in the fuel cell (~8M). Laminated matrices (maximum thickness one millimeter) incorporating microelectrodes and gel membranes were assembled as shown in the inserts in Fig. 3. A new set of microelectrodes was used whenever a cell was reassembled. When cells were run at room temperature, polytetrafluoroethylene-coated glass filter sheets (Bel-Art Company, Pequannock, New Jersey) separated the outer reference electrodes from the catalytic electrodes. When cells were run at 70°C with gel membranes, the filter sheets (which decomposed in alkali at high temperatures) were replaced by thin gel membranes. When cells were run at 70°C with Fuel Cell Asbestos the outer reference electrodes were placed in a pocket in the outer layer of asbestos. During assembly, a wick of etched polytetrafluoroethylene felt was inserted in the matrix laminate to serve as a salt bridge. The polytetrafluoroethylene felt (American Felt Company) was etched by treatment with a 10% solution of potassium in liquid ammonia at -50°C. Between measurements the wick was kept dry and covered to prevent carbonate formation. Prior to making a potential

Gas flows: O<sub>2</sub>—21.5 ml/min, H<sub>2</sub>—41.0 ml/min. (B) 5 x 5 cm, 70°C, 100 ma/cm<sup>2</sup>, 0.816v. Gas flows: O<sub>2</sub>—350 ml/min, H<sub>2</sub>—350 ml/min.

measurement the wick was wetted thoroughly with 6.56M potassium hydroxide solution.

The arrangement of a fuel cell containing reference electrodes is shown in Fig. 4. Cells at room temperature, approximately 27°C, were run without temperature control. At 70°C the external reference electrode was held at 27°C and the cell temperature was thermostatically controlled at 70°C. The fuel-cell current was interrupted for approximately 30 sec when the potential was measured. After each potential reading the fuel-cell current was restored and the fuel cell was allowed to re-equilibrate (2-3 min) before proceeding with the next reading. Electrolyte concentrations in the matrix were estimated from measured potentials by the plots in Fig. 2.

**Reliability of the microelectrodes.**—Comparison with calibrating electrodes.—Microelectrodes were placed between asbestos sheets soaked in various concentrations of potassium hydroxide. These sheets were placed in a fuel cell in which no gas was flowing and the potential difference between the microelectrodes in the cell and the large calibrating electrodes outside of the cell was measured. The potential differences

Fig. 4. Assembly for observing potassium hydroxide concentrations in an operating fuel-cell matrix. (A) Section of matrix laminate containing microelectrodes; (B) fuel cell and reference electrodes.

observed in this test at 26° and at 70°C were identical with the potential difference between the large calibrating electrodes shown in Fig. 2.

**Reliability of microelectrodes in an operating fuel cell.**—To determine the reliability of the microelectrodes in an operating fuel cell, it was necessary to find a technique for determining the concentration of potassium hydroxide in the individual layers of the matrix by another method. One method for doing this was to freeze the fuel cell rapidly while running and to separate and titrate individual layers of the frozen matrix. Fuel Cell Asbestos could not be used for this test because the asbestos lacks wet strength. Gel membranes are, however, much stronger than asbestos when saturated with potassium hydroxide solution. Laminates consisting of gel membranes can be frozen, separated and titrated without tearing. In previous work at 27° and 70°C we operated fuel cells containing gel membranes, and fuel cells containing Fuel Cell Asbestos, continuously under constant loads of 55 to 150 ma/cm<sup>2</sup> for periods of 150-200 hr. In these tests the cells containing gel membranes performed exactly the same as the cells containing Fuel Cell Asbestos.

A fuel cell was assembled using a gel matrix which consisted of three layers of gel membrane each approximately 0.4 mm thick. A microelectrode was placed at each interface. The cell was run at constant current for 24 to 48 hr after the microelectrodes indicated that a stable distribution of electrolyte had been established in the cell. Then the cell (while running) was placed in a polyethylene bag and quickly frozen in a dry ice-alcohol mixture. The rapid freezing slowed diffusion of hydroxyl ions and enabled the cell to be disassembled without changing the electrolyte distribution. The laminated gel matrix was separated into layers, the thickness of each layer was measured and the hydroxyl content of each layer was determined by titration. The concentration of potassium hydroxide in each layer was computed by assuming that a section of gel membrane, 5 x 5 x 0.025 cm, after compression and use in a fuel cell, contained 0.03 ml of electrolyte solution. This figure was obtained by titrating a membrane (saturated with 6.56M potassium hydroxide solution) that had been compressed in a fuel cell. Since cells used at 70°C were assembled at room temperature the same figure was used for calculating the volume of electrolyte in membranes used at 70°C. The concentration of electrolyte in the fluid contained in the catalytic electrodes in contact with the membranes was not measured. Figure 3A is a plot of the concentration gradient that was observed after 48 hr in a 2.5 cm diameter cell operated at ambient temperature (~27°C). Figure 3B is a similar plot of the concentration gradient in a 5 x 5 cm cell operated at 70°C. Filled circles represent concentrations mea-

sured with microelectrodes, and crosshatched areas represent concentrations measured by titration. The good agreement between the two types of data attests to the reliability of the microelectrodes at both temperatures.

**Effect of continuous operation in a fuel cell on microelectrodes.**—Two other questions remain to be answered before we can use microelectrodes with confidence to monitor fuel-cell concentrations. These questions are: Does the presence of microelectrodes effect the operation of a fuel cell, and can the microelectrodes withstand continuous exposure to a fuel cell environment? In order to answer these questions a fuel cell containing microelectrodes was run at ambient temperature for 215 hr. During this time the output averaged 0.537v at 100 ma/cm<sup>2</sup>. This is the same performance that we observed with similar fuel cells operating under the same conditions but without microelectrodes. At the end of this test neither the fuel cell nor the microelectrodes showed visible deterioration. Microelectrodes removed from a fuel cell after 200 hr of continuous operation gave correct readings in standard potassium hydroxide solutions.

## Results

**Effect of gas-flow ratios.**—The foregoing experiments establish the reliability of microelectrodes in an operating fuel cell. These electrodes can now be used to measure the effect of operational variables on electrolyte distribution. In the work reported in this paper the electrodes were placed in the center of the matrix. Thus the profile of electrolyte concentrations which we observed is the electrolyte profile in the center of the cell between the catalytic hydrogen and the catalytic oxygen electrodes. The fraction of water removed by the hydrogen (or oxygen) gas streams in an operating fuel cell can be varied by varying the ratio of hydrogen to oxygen in the total gas flow. The data in Fig. 5 show that in a 2.5 cm cell operating at 0.70v with gel matrix, the fraction of water removed by the hydrogen (or oxygen) gas stream is proportional to the percentage of hydrogen (or oxygen) in the total gas flow. The data in Fig. 5 were obtained by passing the emergent gas streams through gas-absorption bottles filled with anhydrous calcium sulfate and weighing the bottles. Before the cell was used for this test it was allowed to operate at a steady rate of 0.70v and 70 ma/cm<sup>2</sup> for 24 hr at a 1:1 (v:v) gas-flow ratio. Then the water collection was started and the gas-flow ratio varied from 3:1 to 1:1 to 1:3 keeping the total gas flow (hydrogen plus

Fig. 5. Percentage of water evaporated by oxygen and hydrogen gas-streams for a 2.5 cm diameter cell at 27°C. Total gas flow 74-83 ml/min, current 70 ma/cm<sup>2</sup>, 0.70v, gel matrix. Arrows indicate scale to be used in reading a particular plot.

oxygen) constant at 74-83 ml/min. In all these tests the amount of water recovered was within 5% of the total water formed.

Figure 6 shows the electrolyte profiles observed under similar conditions in a 2.5 cm diameter cell using Fuel Cell Asbestos at room temperature. Notice that the general character of the profile is the same at the various gas ratios indicating that the transfer of water through the matrix is rapid compared to the changes in other variables that influence the shape of the electrolyte profile.

**Effect of current density.**—The effect of current density on electrolyte was observed in a 5 x 5 cm cell (asbestos matrix) that was run continuously for 348 hr at 70°C. During this time the cell was operated

(A) Gas flows: O<sub>2</sub>—10.5 ml/min, H<sub>2</sub>—73.5 ml/min, 55 ma/cm<sup>2</sup>, 0.550v; (B) gas flows: O<sub>2</sub>—22.5 ml/min, H<sub>2</sub>—67.5 ml/min, 57 ma/cm<sup>2</sup>, 0.568v; (C) gas flows: O<sub>2</sub>—43 ml/min, H<sub>2</sub>—43 ml/min, 64 ma/cm<sup>2</sup>, 0.641v; (D) gas flows: O<sub>2</sub>—60 ml/min, H<sub>2</sub>—30 ml/min, 60 ma/cm<sup>2</sup>, 0.594v. Arrows indicate scale to be used in reading a particular plot.

Fig. 7. Electrolyte profiles in 5 x 5 cm cell after various times of operation at a steady performance. (A) ~27°C, 100 ma/cm<sup>2</sup>, 0.710v; (B) 70°C, 100 ma/cm<sup>2</sup>, 0.810v; (C) 70°C, 100 ma/cm<sup>2</sup>, 0.831v.

for periods of 3 to 4 days at loads ranging from 50 to 150 ma ( $\pm 1$  ma) per  $\text{cm}^2$ . These tests showed that current densities between 50 and 150 ma/ $\text{cm}^2$  have little effect on the shape of the electrolyte profile in the center of this cell.

*Time required to establish a steady-state electrolyte distribution.*—Experiments showed that although a stable operation with respect to current and voltage was established in minutes after start-up of operation, the attainment of a steady state in the electrolyte distribution required between 3 and 6 hr in the 2.5 cm diameter cell at room temperature and approximately the same length of time in the 5 x 5 cm cell at 70°C. However, some other cells which had less uniform gas flow-patterns required as long as 48 hr to reach a steady electrolyte distribution. The time required to attain a steady electrolyte profile and the constancy of the shape of this profile, once attained, is shown by the curves in Fig. 7.

It is evident that the general shape of the concentration profiles in Fig. 3A and 3B is characteristic of the particular cell used and is not radically altered by changes in temperature (Fig. 7), flow rate (Fig. 6), or current density (Fig. 7). The difference in shape of the profiles in Fig. 3A and 3B appears to be related to the difference in gas-flow patterns in the two types of cells. Apparently it will be necessary to measure concentration profiles over the whole face of the exposed matrix, not just through the center, in order to understand the operation of the cell.

### Acknowledgment

The authors wish to thank Dr. R. G. Haldeman and Professor B. E. Conway for advice and encouragement during the course of this work, Mr. J. Skogman for carrying out the water-balance experiments, Dr. K. E. Olsen, Mr. D. Gershberg, and Mrs. D. Bernstein for valuable suggestions in connection with the preparation of the manuscript. They are also indebted to Professor Conway for suggesting the mercury, mercuric oxide electrodes to them.

Manuscript received Sept. 19, 1967; revised manuscript received Nov. 3, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Alkaline Manganese Dioxide Electrode

### II. The Charge Process

David Boden,\* C. J. Venuto,\* D. Wisler, and R. B. Wylie

ESB Incorporated, Research Center, Yardley, Pennsylvania

### ABSTRACT

The reactions occurring during the discharge and charge of manganese dioxide electrodes in 7M KOH are studied by x-ray diffraction and charge and discharge curves. The discharge at first results in the formation of an amorphous oxide by incorporation of protons and electrons into the  $\text{MnO}_2$  lattice. Then the amorphous compound is electroreduced to give  $\text{Mn}_3\text{O}_4$  and finally  $\text{Mn}(\text{OH})_2$  depending on the electrode potential. When electrodes are recharged, the amorphous phase is converted to  $\text{MnO}_2$  whereas the  $\text{Mn}_3\text{O}_4$  remains unchanged in the electrode. It is proposed that on recharge  $\text{Mn}(\text{OH})_2$  is oxidized to  $\text{Mn}_3\text{O}_4$ . The cause of failure of electrodes during cycling seems to be the formation of a film of  $\text{Mn}_3\text{O}_4$  around the electrical contact wire.

The reactions occurring during the discharge of a manganese dioxide electrode in alkaline electrolyte have been investigated by several workers (1-7). However, the charge process, after the electrodes have been discharged, appears not to have been studied. This is of practical importance in understanding the reactions which limit the performance of the rechargeable alkaline manganese dioxide battery.

It is observed in these cells, that if the discharge is limited to a relatively small fraction of the total manganese dioxide capacity, a considerable number of discharge/charge cycles can be obtained, whereas if the cells are deeply discharged, very few cycles are obtainable. At the present time, the source of this restriction is unknown. It was thought desirable, therefore, to investigate the reactions occurring at the manganese dioxide electrode when it is charged after varying degrees of partial discharge.

This paper presents the results of a study whereby x-ray crystallography, chemical analysis, and the analysis of potential-time transients are used to characterize the reactions.

### Experimental

The method of preparation, the size and weight of the electrodes, and the electrolytic cell were identical to those described previously (7). Available oxygen analyses conducted by the arsenious acid method (8) showed the sample of  $\text{MnO}_2$  had an empirical formula of  $\text{MnO}_{1.92}$ , giving the electrodes a calculated capacity of 0.45 amp-hr based on the following reaction

All the discharge and charge operations were carried out at 25°C in 7M KOH solution and the electrode potentials were recorded against a Hg/HgO reference electrode in the same electrolyte using a Texas Instruments Servoriter in conjunction with a Hewlett Packard vacuum tube voltmeter Model 412A.

### X-ray Crystallographic Analyses

Groups of electrodes were discharged at 5 ma  $\cdot$   $\text{cm}^{-2}$  (12.5 ma total) in 7M KOH at 25°C in 0.1C increments of the theoretical capacity (0.1C, 0.2C, 0.3C, etc.). Representative samples were removed from the

cells at each 0.1C increment, crushed, and analyzed with a G. E. XRD-5 x-ray diffractometer using vanadium filtered  $K\alpha$  radiation. Groups of electrodes which had been partially discharged were then charged at 2.5 ma · cm<sup>-2</sup> and samples were analyzed as before at 0.1C charge intervals. For example, a group of electrodes would be discharged to 0.5C with samples being analyzed at 0.9, 0.8, 0.7, 0.6, and 0.5C. The remaining electrodes would then be charged with samples being withdrawn for x-ray analysis at 0.6, 0.7, 0.8, 0.9C, and C. No washing or drying procedures were carried out and all the samples were immediately x-rayed after being covered with a thin film prepared from Duco cement and acetone to prevent possible atmospheric oxidation during the analysis. The  $d$ -values calculated from the x-ray patterns are shown in Table I. For comparison, the ASTM values for the  $d$  values and the relative intensities of the peaks for various manganese oxides are shown in Table II.

The starting material is essentially  $\gamma$ - $MnO_2$  but there appears to be a small amount of  $\beta$ - $MnO_2$  present as indicated by the line at  $d = 3.11\text{\AA}$ . As discharge proceeds the lattice expansion noted previously (7) is again observed and is most clearly seen in the peaks at 2.43 and 2.14 $\text{\AA}$  in the electrode discharged to 0.90 of its calculated capacity ( $MnO_{1.82}$ ). The peak originally appearing at 2.43 $\text{\AA}$  shifts through 2.47, 2.51, and 2.53 $\text{\AA}$  before any new phase is observed, while the peak originally appearing at 2.11 $\text{\AA}$  shifts through 2.14, 2.17, and 2.19 $\text{\AA}$  in the same discharge period. No new compounds are identified in the x-ray pattern until the electrodes have been discharged to 0.5C ( $MnO_{1.46}$ ) at which point  $Mn_3O_4$  is produced. By referring to the x-ray diffraction patterns of Fig. 1, it can be seen that as the discharge proceeds, the x-ray peaks become increasingly less well defined which is characteristic of the take up of protons by the lattice to form an amorphous, strained phase according to

or

At a discharge depth equivalent to 0.50C peaks characteristic of  $Mn_3O_4$  can be seen.

If electrodes which have been reduced in the range of 1.0 to 0.60C are recharged, the original  $\gamma$ - $MnO_2$  structure is regained although there is still evidence of some residual lattice expansion. This is evident from examination of Table I and also from Fig. 2 which shows the x-ray diffraction patterns of an electrode being charged after an initial discharge to 0.6C. Since chemical analyses were not performed on the charged electrodes, the data are given in terms of the fraction

Fig. 3. X-ray diffraction patterns of  $\gamma\text{MnO}_2$  electrodes charging in increments after discharge to 0.0C.

Fig. 4. X-ray diffraction patterns of  $\gamma\text{MnO}_2$  electrodes discharged in increments to  $\text{MnO}_{1.16}$ .

When the fully discharged electrode is charged the  $\text{Mn}(\text{OH})_2$  peaks disappear as shown in Fig. 3 and no new peaks are observed in the x-ray patterns. This indicates that  $\text{Mn}(\text{OH})_2$  is oxidized to either  $\text{Mn}_3\text{O}_4$  or to the amorphous phase noted previously. We think it unlikely that  $\text{Mn}(\text{OH})_2$  can be oxidized to the amorphous phase directly without passing through the lower oxide  $\text{Mn}_3\text{O}_4$ . It is thus probable that  $\text{Mn}(\text{OH})_2$  is oxidized to  $\text{Mn}_3\text{O}_4$  which then remains unchanged. The reaction can probably be written as

#### Discharge and Charge Curves

Four groups of electrodes were discharged and charged as follows: the first group was discharged at  $5 \text{ ma} \cdot \text{cm}^{-2}$  to 0.9C ( $\text{MnO}_{1.82}$ ) and then recharged to 1.0C ( $\text{MnO}_{1.92}$ ) at  $2.5 \text{ ma} \cdot \text{cm}^{-2}$ , the second was discharged to 0.6C ( $\text{MnO}_{1.55}$ ) and recharged, the third to 0.3C ( $\text{MnO}_{1.29}$ ) and recharged, and the fourth to 0.0C ( $\text{MnO}_{1.16}$ ) and recharged. The empirical formulas in parentheses are the experimentally determined values obtained by chemical analysis of the discharged electrodes. The lack of agreement between the calculated and experimental values is due to the low current efficiency towards the end of discharge because of concurrent hydrogen evolution.

These electrodes thus encompassed a range of composition where in the first series only the amorphous phase was present, in the second, amorphous phase plus  $\text{Mn}_3\text{O}_4$ , in the third, amorphous phase plus  $\text{Mn}_3\text{O}_4$  and  $\text{Mn}(\text{OH})_2$ , and in the fourth,  $\text{Mn}_3\text{O}_4$  and  $\text{Mn}(\text{OH})_2$ .

The discharge/charge curves obtained from group one are shown in Fig. 5. The discharge curve proceeds smoothly and the charge curve shows two fairly well defined steps. The first step is attributed to the oxidation of the amorphous compound to  $\text{MnO}_2$ , the quantity of electricity consumed in this reaction almost being equal to that withdrawn during the discharge. The oxidation of the amorphous phase prob-

Fig. 5. Alkaline  $\text{MnO}_2$  electrode discharge-charge potentials at 0.9C.

ably occurs according to the reverse of Eq. [1]. After completion of the first oxidation step, the potential increases rapidly to a well defined plateau at 1.45v. This is probably a mixed potential due to the evolution of oxygen and the oxidation of  $\text{MnO}_2$  to  $\text{K}_2\text{MnO}_4$ . This is supported by the appearance in the electrolyte of a green color due presumably to  $\text{MnO}_4^-$  ions. The charging curves of electrodes in groups 2, 3, and 4 are shown in Fig. 6. The curve of the electrodes discharged to 0.6C again shows two steps and as before, the quantity of electricity consumed in the first step is almost equal to that withdrawn on discharge indicating that, at this point, the electrodes are still chemically reversible. In the electrodes discharged to 0.3C, the existence of highly irreversible  $\text{Mn}_3\text{O}_4$  is evidenced by the rapid increase in polarization at the start of charge. A plateau occurs at 0.65v which most probably corresponds to the oxidation of  $\text{Mn}(\text{OH})_2$  to  $\text{Mn}_3\text{O}_4$ . An inflection is observed after about 8 hr which corresponds to the passage of  $0.050 \text{ amp} \cdot \text{hr}$ . If the reaction is assumed to be identical to Eq. [5], this amount of electricity corresponds to 0.248g of  $\text{Mn}(\text{OH})_2$  or approximately 25% of the electrode weight. A fairly rapid rise in potential then occurs followed by a poorly defined plateau which probably corresponds to the oxidation of the residual amorphous compound to  $\text{MnO}_2$ .

The electrodes of the fourth group contain the same discharge products as those of group three except that

Fig. 6.  $\text{MnO}_2$  potentials during charge

	Discharge to	Charge to
Group 2 ●—●	0.6C	1.0C
Group 3 ▲—▲	0.3C	1.0C
Group 4 □- - -□	0.0	1.0C

Charge current density  $2.5 \text{ ma/cm}^2$ .

the amount of  $Mn(OH)_2$  is now larger and little or no  $MnO_2$  or amorphous phase exists in the electrode. Thus the plateau at 0.65v due to oxidation of  $Mn(OH)_2$  is longer and is followed again by an increase in the potential to the final plateau.

#### Cycling Experiments

A group of electrodes was cycled by discharging at  $5 \text{ ma} \cdot \text{cm}^{-2}$  for 8 hr and charging at  $2.5 \text{ ma} \cdot \text{cm}^{-2}$  for 16 hr. This was equivalent to a cycling between a depth of 1.0C and 0.89C. The potential/time curves of Fig. 7 show that up to 45 cycles, the electrodes cycle with only slight loss in performance. At cycle 63, a large polarization was observed after which the potential was erratic. This was also observed on the charge curve.

The behavior of the electrode suggested that a rapid increase in resistance had occurred at this point. This was thought to be perhaps due to the formation of a film of  $Mn_3O_4$  around the electrical contact wire or the electrode/electrolyte interface. To investigate this, electrodes were prepared containing two electrical contacts; one embedded in the center of the mix and the other tightly wound around the outside. It was thought that if failure was caused by the formation of a layer of  $Mn_3O_4$  around the contact wire, then switching from one contact to the other after failure should restore the performance. These electrodes were cycled between 1.0 and 0.75C using the same conditions as before. The IR drop was determined by use of an interruptor technique employing a Tektronix oscilloscope Model No. 535. The potential time curves are shown in Fig. 8 and the IR measurements in Fig. 9. The electrodes were seen to fail at cycle 9 at which point a high polarization was observed together with an increase in the IR drop. At this point, the current was switched to pass through the other contact. Immediately, the high polarization disappeared and the IR drop fell to that of a fresh electrode. Several additional cycles were obtained before the electrodes failed again.

It is clearly seen that the source of electrode failure is at the  $MnO_2$ /contact wire interface. From the potential of the electrodes, when they fail, it can be concluded that this film is  $Mn_3O_4$ . The magnitude of the IR drop at failure was insufficient to account for the high total polarization observed at this point. Since previous experiments (7) have shown the extremely high irreversibility of  $Mn_3O_4$ , it is not surprising that its precipitation is accompanied by a very large increase in polarization.

A second experiment was conducted using an electrode which, after failure, had a thin concentric layer cut away from the electrode/electrolyte interface and

Fig. 7. Alkaline  $MnO_2$  electrode cycle test. Discharge to 0.89C, C.D.  $5 \text{ ma} \cdot \text{cm}^{-2}$ ; charge to 1.0C + 1% overchg., C.D.  $2.5 \text{ ma} \cdot \text{cm}^{-2}$ .

Fig. 9. Alkaline  $MnO_2$  electrode IR measurements of a double contact electrode, cycling at 0.76C.

then was recycled. This treatment did not reduce the polarization thus indicating once again that the film is formed at the contact/ $MnO_2$  interface.

#### Discussion

The x-ray diffraction data show, as observed before, that in the initial stages of discharge, a lattice expansion occurs with the formation of an amorphous product which cannot be ascribed to any of the well known manganese oxides. This is in agreement with results obtained by Brenet (9) and co-workers in LeClanche cells and appears to be general feature of the discharge of  $MnO_2$  electrodes. No evidence of  $MnO(OH)$  was obtained in contradiction to the results of some other investigations. In the early stages of the discharge, the electrodes are rechargeable as evidenced by the x-ray data and the discharge and charge curves. The charge/discharge reaction can be written as Eq. [2]. At greater depth of discharge, the amorphous phase is reduced to  $Mn_3O_4$  which is evidently not rechargeable and thereafter remains unchanged in the electrode. As the electrode approaches full discharge,  $Mn(OH)_2$  is formed and this is the final product. On recharge,  $Mn(OH)_2$  is observed to disappear from the electrodes as indicated by the disappearance of the  $Mn(OH)_2$  peaks in the x-ray diffraction patterns and the plateau in the charge curves at 0.6v. It is proposed that on recharge,  $Mn(OH)_2$  is oxidized to  $Mn_3O_4$  according to Eq. [5].

On the basis of the x-ray and discharge/charge curve data, one would expect a manganese dioxide electrode in 7M KOH to be rechargeable provided that

the depth of discharge is restricted so that  $Mn_3O_4$  is not formed. This is in fact so, as shown by the data in Fig. 7. However, a gradual deterioration in the performance occurs which allows the electrode potential to fall to the level at which  $Mn_3O_4$  is produced. The IR curves and the data from electrodes containing two contacts show that failure is caused by the precipitation of a film of  $Mn_3O_4$  around the current collector wire.

## ABSTRACT

Single crystals of  $\alpha$ - $Nb_2O_5$  were grown by the Verneuil technique and machined into cylinders. Measurements of electrical conductivity of these specimens as a function of temperature and oxygen pressure were made and compared with similar work by previous investigators. By following the resistance change as a function of time on changing the environmental pressure, determinations of the diffusion coefficient of oxygen were made at varying degrees of nonstoichiometry. Oxygen diffusion coefficients were several hundredfold lower in oxide of large nonstoichiometry. Similar work was performed on  $\gamma$ - $Nb_2O_5$  scales stripped from niobium specimens after oxidation. Although absolute measurements could not be undertaken on these extensively cracked specimens,  $\gamma$ - $Nb_2O_5$  showed similar properties to  $\alpha$ - $Nb_2O_5$ . The relationship is considered of these conclusions to be oxidation behavior of niobium.

In an analysis of the effect of oxygen pressure on the parabolic oxidation rate constants of niobium, Sheasby *et al.* (1) suggested that oxygen diffusion was most rapid in near stoichiometric  $\gamma$ - $Nb_2O_5$ . Other investigators (2-4) have reported in their studies on both  $\alpha$ - and  $\gamma$ - $Nb_2O_5$  that equilibrium was attained far more rapidly in nearly stoichiometric oxide than at larger departures from stoichiometry. As such behavior is not predicted by proposed models of the defect structure of these oxides, the purpose of this investigation was to determine oxygen diffusion constants in  $\alpha$ - and  $\gamma$ - $Nb_2O_5$  at various oxide compositions.

Terao (5) has suggested that the structures of  $\alpha$ - and  $\gamma$ - $Nb_2O_5$  are closely related. The structure of  $\alpha$ - $Nb_2O_5$ , particularly when nonstoichiometric, is not known with certainty (6) but can be indexed by a monoclinic cell (5). Brauer (7) reports a composition range for this phase expressed as  $NbO_x$  where  $2.4 < x < 2.5$ , but Norin and Magneli (8) have identified two compounds  $NbO_{2.46}$  and  $NbO_{2.48}$  in this region. Isopiestic experiments of Blumenthal *et al.* (2) did not indicate the presence of these phases; a value of  $-164$  kcal/mole was determined for the relative partial molar enthalpy of oxygen for the pentoxide phase, its lower stoichiometric limits being  $x = 2.42$  and  $2.44$  at  $1090^\circ$  and  $889^\circ C$ , respectively.

Although the defect structure of  $\gamma$ - $Nb_2O_5$  has not been extensively studied (3), the defect equilibria

describing oxygen deficiency in  $\alpha$ - $Nb_2O_5$  has been studied by several investigators using electrical conductivity and gravimetric techniques (4, 9-14). The majority of investigators agree that in the temperature range  $600^\circ$ - $1400^\circ C$  and pressure range  $1$ - $10^{-6}$  atm the isothermal conductivity is proportional to  $P_{O_2}^{-1/4}$ , and that the conductivity exhibits an exponential temperature dependence with an activation energy of 1.4-1.7 eV (electron volt). These results are interpreted by a defect model involving oxygen vacancies with one trapped electron. At larger departures from stoichiometry at lower oxygen pressures, the picture is less clear. The work of Blumenthal *et al.* (2) suggests no change in defect type, whereas Kofstad and Anderson (14) find that both the isothermal weight change and conductivity of  $\alpha$ - $Nb_2O_5$  are proportional to  $P_{O_2}^{-1/6}$ . These results are interpreted in terms of oxygen ion vacancies without trapped electrons due to a decrease in the ionization energy of electrons from these defects as their concentration increased, in agreement with the work of Jannick and Whitmore (12).

## Experimental

Two sources of reagent grade  $\alpha$ - $Nb_2O_5$  powder and high purity niobium sheet, both 99.5 w/o (weight per cent) pure, were utilized as materials.

Coarse-grained boules of  $\alpha$ - $Nb_2O_5$  were grown by the Verneuil technique using a hydrogen-oxygen flame. The boules were split into individual crystals and these were machined, using an air-abrasive unit, into cylinders approximately 1 mm diameter and 6

<sup>1</sup> Present address: Faculty of Engineering Science, University of Western Ontario, London, Ontario, Canada.  
\* Electrochemical Society Active Member.

mm long, Fig. 1. The [010] monoclinic direction was approximately parallel to the cylinder axis. Polycrystalline plates of  $\gamma\text{-Nb}_2\text{O}_5$  approximately  $1\text{ cm}^2$  and 190 or  $270\mu$  thick, Fig. 2, were obtained by anodically dissolving the metal from specimens oxidized at  $770^\circ\text{C}$ . The oxide was composed of columnar crystals oriented with the [100] tetragonal axis perpendicular to the plane. The oxide plates were extensively cracked and could not be heated above  $750^\circ\text{C}$  without transforming to the alpha modification.

Resistances were measured by two and four point probe direct current techniques. Platinum current and potential leads were wrapped directly on the specimen and contact improved with platinum paint. Four point probe measurements were initially taken; however, the contact resistances were found to be negligible, so many of the experiments were performed using two point contacts. A Keithley 610A electrometer was used as a source of constant current and the potential drop across a specimen was measured either with this instrument, or a Leeds and Northrup Type K3 potentiometer or a Honeywell recorder. Resistances measured in the forward and reverse directions were ohmic within experimental errors of  $\pm 1\%$ .

The diffusion assembly was of a conventional glass design for attaining vacuo of  $10^{-4}$  Torr. Medical grade oxygen, high purity argon, carbon dioxide of 99.95 v/o (volume per cent) purity, and carbon monoxide of 96.6 v/o purity were dried by passage through columns containing phosphorous pentoxide. A specimen was suspended by the electrical leads into the hot zone of a vertically mounted mullite tube heated by an electrical resistance tubular furnace. The temperature was measured with a Pt-Pt 10% Rh thermocouple sited adjacent to the specimen. Pressures in the range  $10^{-3}$ -1 atm were effected statically. To achieve environmental purity in the range  $10^{-3}$ - $10^{-5}$  atm, oxygen was

Fig. 1. Cylindrical crystal of  $\alpha\text{-Nb}_2\text{O}_5$ . Magnification 5X

Fig. 2. Specimen of  $\gamma\text{-Nb}_2\text{O}_5$  stripped from a niobium specimen oxidized at  $760^\circ$  in 1 atm oxygen for 120 min.

continually admitted through a needle valve, the pressure being automatically controlled by magnetic valves in the vacuum line. At oxygen pressures below  $10^{-5}$  atm, flowing atmospheres of either  $\text{CO}/\text{CO}_2$  or  $\text{Ar}/\text{O}_2$  were passed through the reaction tube. The oxygen potentials of these latter atmospheres were measured with a stabilized zirconia galvanic cell placed adjacent to the specimen and controlled by manipulation of needle valves in the gas lines.

To measure the oxygen diffusion constant for  $\alpha\text{-Nb}_2\text{O}_5$ , the specimens were held at a fixed temperature and pressure until the resistance was constant. The pressure was then changed and the variation in the resistance was recorded with time. Specimens were considered as infinite cylinders of radius  $r$  and analyzed using the diffusion equation (15)

$$\frac{C_t - C_f}{C_i - C_f} = \sum_1^{\infty} \frac{4}{\xi_v^2} \exp \left[ -\frac{\xi_v^2 D t}{r^2} \right] \quad [1]$$

$\xi_v$  are the roots of the equation  $J(x) = 0$  where  $J(x)$  is the Bessel function of zero order,  $C_i$ ,  $C_f$ , and  $C_t$  are the initial, final, and value at time  $t$  of the oxide oxygen concentration. These concentrations, in turn, are directly related to the corresponding electrical conductivities. Consequently, this equation was solved for  $Dt/r^2$  for each experimental point on a computer and these values plotted vs. time to obtain the best value of  $D/r^2$ . The oxygen diffusion constant for  $\gamma\text{-Nb}_2\text{O}_5$  was determined under the same experimental conditions and the results analyzed by the diffusion equation for a plate (16).

X-ray diffractometer patterns of powdered oxide were obtained using copper radiation with a nickel filter.

## Results

*Alpha-niobium pentoxide.*—Values of the resistivity at various temperatures of specimens equilibrated with oxygen over the range  $10^{-5}$ -1 atm are shown in Fig. 3. The resistance was proportional to the  $1/4$  power of the pressure. Specimens were also equilibrated with atmospheres of much lower oxygen potentials to  $10^{-16}$  atm. Because of the excessively long equilibration periods of several days, the resistance measurements were not as precise as those at higher pressures. However, the oxygen pressure dependence of the resistance remained within experimental error to the  $1/4$  power, Fig. 4. This relationship was valid for crystals prepared from both stocks of  $\alpha\text{-Nb}_2\text{O}_5$ .

The specific resistances of several specimens prepared from the oxide materials obtained from two sources agreed well and gave a good fit to an Arrhenius plot, Fig. 5. The activation energy was 1.61 eV

Fig. 3. The dependence of the electrical resistivity of  $\alpha\text{-Nb}_2\text{O}_5$  on oxygen pressure over the range  $10^{-5}$  to 1 atm at temperatures of  $927^\circ$ ,  $879^\circ$ ,  $818^\circ$ , and  $725^\circ\text{C}$ .

Fig. 4. The dependence of the electrical resistivity of  $\alpha\text{-Nb}_2\text{O}_5$  on oxygen pressure over the range  $10^{-16}$  to 1 atm at  $909^\circ\text{C}$ .

Fig. 5. Arrhenius plots with determinations for the activation energy for the electrical conductivity of  $\alpha\text{-Nb}_2\text{O}_5$  at 1 atm. The plots 1, 2, and 3 are from references (4), (10), and (3), respectively.

which is to be compared to the value of 1.4-1.65 ev from previous investigators (3,4,10).

The diffusion constant was evaluated from data obtained by changing the pressure over a narrow range and recording the resistance change with time. On plotting  $Dt/r^2$  vs. time as described in the last section to obtain the best value of  $D/r^2$  the linear plots intersected the co-ordinates close to the origin, Fig. 6. However the values of  $D/r^2$  obtained from different determinations under the same experimental conditions varied by as much as a factor of 3. Further difficulty was encountered on raising the pressure to close to atmospheric, e.g., 100-760 Torr, at low temperatures,

Fig. 6. Plots of  $Dt/r^2$  vs. time at  $909^\circ\text{C}$  for  $\alpha\text{-Nb}_2\text{O}_5$  for oxygen pressure changes of 104 to 7.38 Torr, curve 1; 6.28 to 127 Torr, curve 2;  $5.0 \times 10^{-9}$  atm to  $2.5 \times 10^{-15}$  atm, curve 3; and  $2.3 \times 10^{-16}$  to  $1.2 \times 10^{-14}$  atm, curve 4.

when the equilibrium specimen resistance was attained in an unexpectedly short time.

Values for the oxygen diffusion constant at various pressures and temperatures are recorded in Table I. An Arrhenius plot is shown in Fig. 7 of diffusion constant determinations from four specimens. The data points form two bands with the determinations relating to pressure changes in the range  $10^{-5}$ -1 atm being approximately 300 times larger than those made at pressures lower than  $10^{-13}$  atm. The activation energies of 2.2 and 2.3 ev demonstrate that the temperature dependence for diffusion did not change significantly over the investigated pressure range.

A comparison of the powder x-ray diffraction patterns of black nonstoichiometric with white stoichiometric oxide gave an extra line corresponding to  $d = 3.85\text{\AA}$  and  $1.693\text{\AA}$  while the lines at  $d = 2.684\text{\AA}$  and  $1.219\text{\AA}$  were absent, and the line at  $d = 2.070\text{\AA}$  was greatly reduced in intensity.

*Gamma-niobium pentoxide.*—The instability of this oxide imposed restrictions on the system that could be studied. Since the specimens were cracked, no attempt was made to obtain specific resistances. As illustrated in Fig. 8, the resistances of the specimens studied were proportional to the  $0.25 \pm 0.04$  power of the oxygen pressure.

Oxygen diffusion in the oxide as a function of oxygen pressure was determined in the range  $10^{-6}$ -1 atm

Fig. 7. Oxygen diffusion constants from four  $\alpha$ - $\text{Nb}_2\text{O}_5$  specimens as a function of temperature at different pressures. Values in pressure range  $10^{-5}$ -1 atm, curve 1; values in pressure range  $10^{-13}$ - $10^{-16}$  atm, curve 2.

Fig. 8. The dependence of the electrical resistance of a  $\gamma$ - $\text{Nb}_2\text{O}_5$  specimen on oxygen pressure over the range  $10^{-8}$  to 1 atm at  $658^\circ\text{C}$ .

and typical data for plates of thickness,  $a$ , are shown in Fig. 9. Although absolute values of diffusion constants for the cracked specimens could not be obtained, the relative values at different pressures are recorded in Table II. It can be seen that the oxygen diffusivity was insensitive to pressure from  $0.5$ - $10^{-4}$  atm, but decreased rapidly at pressures below this value.

White stoichiometric oxide transformed readily to black nonstoichiometric oxide in an oxygen atmosphere of  $10^{-5}$  atm pressure at  $750^\circ\text{C}$ . The powder x-ray diffraction pattern of the black compared with the white oxide gave extra lines corresponding to  $d =$

Fig. 9. Plots of  $Dt/4a^2$  vs. time at  $628^\circ\text{C}$  for  $\gamma$ - $\text{Nb}_2\text{O}_5$  for oxygen pressure changes of 43 to 96 Torr, curve 1; 160 to 73, curve 2; 1.4 to 2.0, curve 3; and 2.5 to 0.14 Torr, curve 4.

$3.643\text{\AA}$ ,  $3.311\text{\AA}$ , and  $2.971\text{\AA}$  and the lines at  $d = 5.18\text{\AA}$  and  $1.54\text{\AA}$  were absent.

### Discussion

The conductivity of  $\alpha$ - $\text{Nb}_2\text{O}_5$  at pressures in the range  $10^{-5}$ -1 atm was proportional to  $P_{\text{O}_2}^{-1/4}$  in agreement with previous results on polycrystalline specimens (14) but only in partial agreement with those for single crystals. The decreased pressure dependence below  $800^\circ\text{C}$  reported by Chen and Swalin (4) was not observed. Moreover, the conductivity at  $907^\circ\text{C}$  obeyed this pressure relation to  $10^{-16}$  atm whereas a  $P_{\text{O}_2}^{-1/6}$  relation was found for polycrystalline specimens in the pressure range  $10^{-13}$ - $10^{-18}$  atm by Kofstad and Anderson (14).

Arrhenius plots of the specific conductivities from four investigations were illustrated in Fig. 5. The conductivities of polycrystalline material were smaller by an order of magnitude than those for single crystals but the activation energies, irrespective of the type of material, were of the same magnitude 1.4-1.65 ev. Although Chen and Swalin (4) accounted for the high conductivity of their single crystal specimens at temperatures below  $800^\circ\text{C}$  by ionization of impurities, the present results demonstrate that the conductivity is determined entirely by oxide stoichiometry at pressures close to atmospheric over the temperature range  $600^\circ$ - $1400^\circ\text{C}$ . Also, the conductivity experiments demonstrated that the rapidity with which a specimen changed its conductivity was itself a function of the conductivity (stoichiometry). In relating these relaxation periods to the oxygen diffusion constant it was assumed that in the pressure increment under analysis the electron concentration was directly proportional to the oxygen concentration. As it has been shown that the conductivity of  $\text{Nb}_2\text{O}_5$  is proportional to  $\log(P_{\text{O}_2})$  in this study, and that the weight loss of  $\text{Nb}_2\text{O}_5$  is a

function of  $\log(P_{O_2})$ , (2), this assumption is reasonable. The oxygen diffusion constant,  $D$ , so measured is equivalent to the phenomenological diffusion constant defined by Fick's first law.

It will now be demonstrated that the diffusional properties of oxygen in niobium pentoxide cannot be inferred from theory based on ideal solution of point defects exhibiting constant mobility. A  $(P_{O_2})^{-1/4}$  pressure dependence of the electrical conductivity was found over four orders of resistance change, and in agreement with other workers (4, 9, 13) this is interpreted in terms of a vacancy model involving only singly ionized oxygen vacancies. Wagner (17) has shown that for an ionic solid

$$D = \frac{V_m RT}{8F^2 \delta} \frac{K_{ion} K_e}{K_{ion} + K_e} \frac{d \ln(P_{O_2})}{d \ln \delta} \quad [2]$$

where, in this instance,  $K_{ion}$  and  $K_e$  would be the specific conductivities of the singly ionized oxygen vacancies ( $\square\cdot$ ) and electrons (e),  $\delta$  is the oxygen deficit represented by the formula  $Nb_2O_{5-\delta}$ , and  $V_m$  is the molar volume. These conductivities are related to the mobility,  $\mu$ , of charged species by:

$$K_{ion} = \frac{F}{V_m} x_{\square\cdot} \mu_{\square\cdot}$$

and

$$K_e = \frac{F}{V_m} x_e \mu_e \quad [3]$$

where  $x$  represents the atom fraction of the respective point defect.

From the pressure dependence of the resistivity

$$\frac{d \ln P_{O_2}}{d \ln \delta} = -4 \quad [4]$$

If the Nernst-Einstein relation is invoked

$$D_{\square\cdot} = \mu_{\square\cdot} \frac{RT}{F} \quad [5]$$

Substituting Eq. [3], [4], [5] in Eq. [2] and in view of  $K_{ion} \ll K_e$

$$D = \frac{D_{\square\cdot}}{2} \quad [6]$$

According to Eq. [4-6], the magnitude of the oxygen diffusion constant is not dependent on oxygen pressure or oxide stoichiometry providing that the activity coefficient and mobility of vacancies remains constant. In the case of  $\alpha$ - $Nb_2O_5$ , this behavior is valid over the pressure range  $10^{-5}$ -1 atm. It is definitely invalid over the entire investigated pressure range because the values are much smaller at pressures less than  $10^{-14}$  atm (Table I and Fig. 7). A similar behavior was exhibited by  $\gamma$ - $Nb_2O_5$  with the transition to lower values of the diffusion constant occurring at higher pressures. For this oxide modification, the diffusion constant is constant only over the pressure range  $10^{-3}$ -1 atm (Table II).

Knowledge of diffusion in ionic solids is not sufficiently advanced for interpretation of this similar but complex oxygen diffusion behavior for both oxides. With increasing nonstoichiometry the point defects interact giving varying activity coefficients and mobilities. Furthermore, according to Wadsley (6) and Gatehouse and Wadsley (18), removal of oxygen from niobium pentoxide leads to compression of the structure by shear along certain planes, the unit  $ReO_3$  type polyhedra being condensed upon each other. When these shear planes are ordered, a series of related oxides can be recognized as identified by Norin and Magneli (8), and when they are not they are retained in a disordered form difficult to recognize except as a berthollide. Since different x-ray diffraction lines occur and line intensities change when both oxides are changed from small to large nonstoichiometry, it is therefore more reasonable to consider the limiting

rates of oxygen diffusion as the mobilities in particular structures.

Different rates of oxygen diffusion in particular berthollidic structures can account for the unusual oxygen pressure dependence of the parabolic oxidation rates for niobium. When only one ionic species such as oxygen diffuses in an oxide scale over a relatively narrow homogeneity range, the general expression given by Wagner (19) for the parabolic oxidation rate constant may be placed in the form

$$k_r = C_{eq} \int_{a_{O_2}^1}^{a_{O_2}^{11}} \frac{|Z_2|}{Z_1} D_o^* d \ln a_{O_2} \quad [7]$$

Here,  $C_{eq}$  is the oxygen concentration in equivalents per  $cm^3$ ,  $Z_1$  and  $Z_2$  are the valencies of metal and oxygen,  $D_o^*$  is the self-diffusion constant for oxygen, and  $a_o$  is the oxygen activity. The integration would be carried out for the oxygen activity range to the oxide-gas interface from an inner surface of the oxide. Converting  $k_r$  to  $k_p$  ( $cm$  oxide) $^2$ /sec and placing Eq. [7] in differential form

$$D_o^* = \frac{1}{9.21} \frac{d k_p}{d \log P_{O_2}} \quad [8]$$

Figure 1 of ref. (1) shows plots of the parabolic constants for niobium oxidation vs. the logarithm of oxygen pressure over the range  $10^{-3}$ -1 atm at temperatures in the range  $720^\circ$ - $825^\circ C$ . If growth of the oxide scale is governed by volume diffusion, these linear plots demonstrate that the oxygen self-diffusion constant is essentially constant only over a small pressure range wherein the oxide composition remains close to stoichiometry, and that below approximately  $10^{-3}$  atm the oxygen self-diffusion constant has a much smaller value. These and all other available oxidation data (20) for the temperature range  $540^\circ$ - $840^\circ C$  were analyzed according to Eq. [8] and an Arrhenius plot of the diffusion constant is shown in Fig. 10. The self-diffusion constant for oxygen in the  $\gamma$ - $Nb_2O_5$  scale is

$$D_o^* \text{ (cm}^2\text{/sec)} = 1.0 \exp - 42600/RT \quad [9]$$

The self-diffusion constant for oxygen in the essentially stoichiometric oxide is related to the diffusion constant for vacancies by the relation

$$x_o D_o^* \simeq D_o^* \simeq x_{\square} D_{\square} \quad [10]$$

where  $x_o$  and  $x_{\square}$  represent the mole fractions of occupied and vacant oxygen lattice sites. Substituting [6] into [10] gives

$$D_o^* = 2x_{\square} D \quad [11]$$

Fig. 10. Arrhenius plot of the oxygen self-diffusion coefficient for  $\gamma$ - $Nb_2O_5$  calculated from oxidation data for the pressure range  $10^{-3}$  to 1 atm, references (1), (20).

According to Eq. [11] a large decrease in the magnitude of  $D_0^*$  for  $\gamma$ - $\text{Nb}_2\text{O}_5$  at oxygen pressures less than  $10^{-3}$  atm would be primarily caused by the variation in  $D$ . The existence of this variation has been confirmed by the present measurements. Hence, the unusual pressure dependence of the parabolic oxidation kinetics is associated with the formation of a  $\gamma$ - $\text{Nb}_2\text{O}_5$  scale consisting of a series of structures changing with the oxygen potential. These structures would be distinct Magneli phases or blocks of a basic structure joined by regular discontinuities (18). If, as it has been suggested (6), the vacancy concentration in such berthollides is largely independent of composition, the observed decrease in oxygen diffusion rate in  $\gamma$ - $\text{Nb}_2\text{O}_5$  with stoichiometry would be sufficient to account for the decrease in oxidation rate of niobium with oxygen pressure. To determine the validity of these considerations, the self-diffusion coefficient of oxygen in  $\gamma$ - $\text{Nb}_2\text{O}_5$  must be determined as a function of both stoichiometry and structure.

## The Electrochemical Behavior of 4,4'-Azopyridine-1,1'-Dioxide

Joe L. Sadler and Allen J. Bard\*

Department of Chemistry, The University of Texas at Austin, Austin, Texas

#### ABSTRACT

The electroreduction of 4,4'-azobispyridine-1,1'-dioxide (APDO) in dimethylformamide solutions was studied by polarography, cyclic voltammetry, controlled potential coulometry, and electron spin resonance. Voltammetric reduction showed two well-defined, reversible one-electron transfers. Coulometric reduction at a potential corresponding to the plateau of the first wave gave evidence of chemical reactions following the initial electron transfer producing intermediates which were also electroactive at the same potentials. Coulometry at the second wave gave an over-all value of six Faradays per mole for the complete reduction of APDO to the dianion of azopyridine (AP), identified by electrochemical and electron spin resonance techniques. A mechanism for the reduction process consistent with the experimental evidence is presented.

The polarographic behavior of a number of tertiary amine oxides in aqueous systems has been reported (1-9). Kubota and Miyazaki (6a) performed a polarographic study of pyridine N-oxide and its alkyl derivatives followed by a study (6b) of the effect of substituents on the polarographic reduction of pyridine N-oxide derivatives. Recently, Date (7a) reported a thorough polarographic investigation of dimethylaniline N-oxide, followed by an investigation of the relationship between the  $E_{1/2}$  values of a series of similar compounds and the  $\text{pK}_a$ 's of their parent amines (7b). Chambers (8) studied the polarographic and adsorption behavior of dimethyldodecylamine N-oxide and Elving and Warner (9) have reported a study of the polarographic behavior of adenine 1-N-oxide.

In all of the above work, the amine oxide group gives a well-defined, irreversible polarographic wave

between pH values of 1 to 6. Date proposed that the amine oxide group is reduced to the corresponding parent amine in a reaction involving two electrons, the first electron addition being rate controlling. This mechanism agrees quite well with his experimental data and is further supported by Chambers' work on N,N-dimethyldodecylamine N-oxide.

Recently Nasielski and co-workers (10) studied the polarographic reduction of pyridine N-oxide and other heterocyclic N-oxides in DMF solution. They proposed that the reduction involves a single, two-electron wave (composed of reduction to the anion radical, fast protonation, and further reduction, protonation, and dehydration), leading to the free base. We report here a study of the amine oxide 4,4'-azobispyridine-1,1'-dioxide (APDO) in DMF, in which a clear separation of the step leading to formation of the anion radical and to formation of the dianion is obtained.

### Results

Voltammetric methods. The polarographic reduction of APDO,

in a *N,N*-dimethylformamide (DMF) solution containing 0.1 *M* tetra-*n*-butyl-ammonium perchlorate (TBAP) showed two well-defined waves (Fig. 1) with half-wave potentials ( $E_{1/2}$ ) of  $-0.73$  and  $-1.35$  v. vs. an aqueous saturated calomel electrode (SCE). The values of  $E_{3/4} - E_{1/4}$  for the two waves (Tômes criterion for reversibility) 0.06 and 0.07 v, respectively, suggested that the first wave involved a reversible, one-electron reduction and that the second wave may be complicated by a following chemical reaction. The diffusion currents of both waves were directly proportional to the square root of the height of the head of the dropping mercury electrode (dme). The diffusion current constants for the first and second waves were 2.97 and 5.45  $\mu\text{a}\text{-sec}^{1/2}\text{-mM}^{-1}\text{-mg}^{-2/3}$ , respectively.

A cyclic voltammogram of APDO in DMF containing 0.1M TBAP at a hanging mercury drop electrode (hmde) is shown in Fig. 2. At all scan rates employed, the reverse scan clearly shows two anodic peaks, corresponding to the oxidation of APDO monoanion and dianion. The cyclic voltammogram obtained on a planar platinum electrode is illustrated in Fig. 3. The behavior of the first wave is essentially the same as that observed on a hmde; however, the second wave shows a much larger cathodic-to-anodic peak current ratio. Typical results of cyclic voltammetric (linear potential sweep chronoamperometry with reversal) experiments for both a hmde and platinum disk electrode are given in Table I. At both a platinum disk electrode and a hmde, the ratio of the peak current ( $i_{pa}$ ) of the first anodic wave to the peak current of the corresponding cathodic wave ( $i_{pc}$ ) is about 1, as would be expected for the formation of a radical species which is stable during the duration of the measurement. The value of  $E_{pc} - E_{pa}$  for this couple is very

Fig. 1. Polarograms before and after reduction of a 1.32 mM APDO solution in DMF containing 0.1M TBAP at a mercury pool electrode: 1, before reduction; 2, after reduction at  $-1.0$  v vs. SCE.

Fig. 2. Cyclic voltammetry of APDO at a HMDE. The solution contained 0.1M TBAP in DMF and was 1.32 mM in APDO.

Fig. 3. Cyclic voltammetry of APDO at a planar platinum disk electrode. The solution contained 0.1M TBAP in DMF and was 1.32 mM in APDO.

close to the value (0.057v) for a reversible, one-electron reaction.  $E_{pc}$  and  $E_{pa}$  for this couple are independent of scan rate  $v$ , and plots of the current function ( $i_p/v^{1/2}$ ) and  $i_{pa}/i_{pc}$  vs. scan rate [diagnostic criteria given in the work of Nicholson and Shain (11) show this wave to be reversible].

The second reduction wave in cyclic voltammetric experiments utilizing a hmde shows some evidence of a chemical reaction following the reduction to give another electroactive species. The current function decreases about 20% for a 10-fold increase in scan rate, which indicates an ECE-type process (i.e., an electron transfer reaction followed by a chemical reaction generating a species reducible at these potentials). A simple EC process is eliminated, because it is characterized by a change of only 10% in the current function for a 10-fold change in scan rate (11). The anodic-to-cathodic peak current ratios increase with increasing scan rate, as expected for an ECE process.

The results obtained in cyclic voltammetric experiments using a platinum disk electrode also give evidence for the presence of an irreversible chemical reaction following the second charge transfer step. At scan rates up to 657 mv/sec, however, essentially no corresponding anodic wave is seen for the second reduction wave. This suggests that either the following reaction is catalyzed at platinum or perhaps adsorption of the product at mercury occurs. This difference

in behavior at platinum and mercury electrodes was not investigated further.

These results suggest that the following reactions occur during voltammetry

where HS represents any source of protons and APDOH<sup>-</sup> is reducible at the potential of the second wave.

Coulometric experiments at a mercury pool electrode controlled at a potential on the diffusion plateau of both the first (-1.0v) and second (-1.8v) reduction waves were undertaken to study the electrochemical behavior of APDO<sup>-</sup> and APDO<sup>=</sup> and to obtain, via electron spin resonance (esr) techniques, further evidence for the above-postulated mechanism. Reduction of APDO at -1.0v gave values of  $n_{app}$  ranging from 1.40 to 1.92 faradays per mole (Table II). In all experiments the electrolysis current decayed to a value significantly higher than the corresponding background currents. For example, in the case of  $n_{app} = 1.70$ , the current decreased from an initial value of 38 ma to a steady value of 1.4 ma after 30 min, indicating that continued electrolysis does not bring about complete cessation of all reduction reactions. This behavior is indicative of a slow secondary process which produces a product that is electroactive at the same potential. Reversal coulometry at -0.20v vs. SCE gave  $n_{app}$  values for oxidation significantly lower than the corresponding initial reduction  $n_{app}$  values (Table II).

The solution resulting from reduction of APDO at -1.0v vs. SCE was a deep reddish-brown in color and gave an intense esr spectrum of about 75 lines. The spectrum was significantly nonsymmetrical about the center, indicating that the signal obtained was due to a mixture of two or more radical species. The presence of two radical species is also consistent with an ECE mechanism.

### Voltammetry after Reduction

Polarograms for a APDO solution before and after

reduction at -1.0v vs. SCE are shown in Fig. 1. The polarogram for a reduced APDO solution (Fig. 1, curve 2), shows an anodic wave with a large maximum which abruptly drops to near the expected diffusion current value at a potential (-0.68v) near the potential of the electrocapillary maximum for this medium, -0.70v. This behavior is similar to that observed by Santhanam and Bard (12) in their study of 9,10-diphenylanthracene and can probably be attributed to the anodic streaming mechanism proposed by

them. The reduction of APDO<sup>-</sup> to APDO<sup>=</sup> occurs at the same potential as the second polarographic wave in the reduction of APDO (Fig. 1, curve 2). The diffusion current of the second wave is about the same before and after electrolysis at -1.0v. Cyclic voltammetry, utilizing a hmde, on a reduced solution of APDO is shown in Fig. 4, curve 2. The very large anodic current for the oxidation is attributed to the same stirring effect mentioned above. Cyclic voltammetry on a platinum disk electrode does not exhibit this stirring phenomena (Fig. 4, curve 4). The value of  $i_{pc}$  for the first wave at a platinum electrode decreases by about 20% after reduction of APDO at -1.0v (24.5  $\mu A$  before vs. 19.4  $\mu A$  after). Peak potentials ( $E_{pc}$  and  $E_{pa}$ ) for the first reduction step are unchanged.

Further controlled potential reduction of the reduced solution at -1.80v, corresponding to the plateau of the second wave gave an additional 4.1 faradays

Table II. Controlled potential coulometric results<sup>a</sup>

Conc., mM	$n_{app}$		
	Reduction at -1.0v	Oxidation at -0.20v	Reduction at -1.80v
0.90	1.63	—	5.92
1.05	1.92	—	—
1.32	1.92	—	—
1.73	1.40	0.47	—
3.25	1.70	0.70	—
1.05	—	—	5.84

<sup>a</sup> The solution was DMF containing 0.1M TBAP. The cathode was a mercury pool with an approximate area of 12 cm<sup>2</sup> and the anode was platinum wire, isolated by a fine-porosity, sintered glass disk. Potentials given above are vs. SCE. Electrolysis times were 0.5 to 1.5 hr.

Fig. 4. Cyclic voltammetry of APDO on a hmde and platinum disk electrodes at various stages of reduction at a mercury pool working electrode. The solution was 1.73 mM in APDO in DMF containing 0.1M TBAP: 1, C.V. at hmde of original solution; 2, C.V. at hmde after reduction at  $-1.0$  v; 3, C.V. at platinum disk electrode of original solution; 4, C.V. at platinum disk electrode after reduction at  $-1.0$  v; 5, C.V. at a platinum disk electrode after reduction at  $-1.80$  v; 6, C.V. at a platinum disk electrode of an authentic sample of azopyridine in the same medium as described above.

per mole for an over-all value of  $n_{app} = 5.84$ . Cyclic voltammetry, employing a platinum disk electrode, of an APDO solution after complete reduction at  $-1.80$ v, is shown in Fig. 4, curve 5. With the scan initiated in a positive direction from  $-1.80$ v, an oxidation wave occurs at  $-0.76$ v followed, on reversal, by two reduction steps at  $-0.84$  and  $-1.53$ v. These peak potentials are significantly different from those observed for APDO itself.

Reversal coulometry (oxidation) at  $-1.0$ v resulted in no anodic current flow, indicating that the reduced species was not oxidizable at this potential. On changing the potential to  $-0.20$ v, however, this species was oxidized, giving a value of  $n_{app} = 1.44$ . Cyclic voltammetric reduction and oxidation of the species resulting from this oxidation showed waves at the same potentials as those observed for the completely reduced species as noted above; the first charge transfer was apparently reversible with a reduction wave at  $-0.84$ v and was followed by an irreversible reduction with a peak potential of  $-1.53$ v.

Controlled potential electrolysis of this product at a potential corresponding to the first reduction step ( $-1.0$ v) gave a value of  $n_{app} = 1.30$ . The solution was sampled at this stage for esr analysis. The resulting esr spectrum, containing approximately 40 lines, was significantly different from the spectrum of APDO mentioned above.

The most logical product of the complete reduction of APDO, based on the behavior of other amine oxide systems, would involve the 4,4'-azobispyridine (AP) system; hence, the electrochemical behavior of AP was examined. Cyclic voltammetry, employing a platinum disk electrode, of AP is shown in Fig. 4, curve 6. The voltammetric behavior of AP is the same as that of the reduction product of APDO obtained by complete reduction at  $-1.8$ v. Controlled potential electrolysis of AP, using conditions identical to those employed for APDO, was performed at a potential of  $-1.0$ v, which corresponds to the plateau of the first reduction wave. An  $n_{app}$  value of 1.09 electrons per molecule was observed for this reduction. A sample was taken at this stage for esr analysis. The resulting esr spectrum was identical to that obtained from reversal coulometry reported in the previous paragraph.

#### Effect of Proton Donor

To gain some insight into the intermediate steps involved in the reduction of APDO, its electrochemical behavior in the presence of varying amounts of a proton-donating agent was studied. Hydroquinone (HQ), previously employed in a study of 9,10-diphenylanthracene (12) was used as the proton donor. The effect of varying amounts of HQ on the polarographic behavior of APDO is shown in Fig. 5. The first wave is unaffected by increasing concentrations of HQ; however, the second wave is shifted in an anodic direction and the diffusion current is increased as the HQ concentration is increased. The second reduction step changes from near reversible behavior, at zero concentration of HQ ( $E_{3/4} - E_{1/4} = 65$  mv), to completely irreversible character ( $E_{3/4} - E_{1/4} = 150$  mv) in the presence of excess HQ (HQ/APDO ratio = 8.0). The cyclic voltammetric behavior of APDO at a hmde in the presence of HQ is illustrated in Fig. 6. The first reduction step is unaffected by addition of excess HQ with the second reduction showing behavior analogous to that seen in polarography ( $i_{pc}$  increasing and  $E_{pc}$  shifting anodically with increasing HQ concentration). These results suggest that if the chemical reaction following the first reduction step involves protonation, its rate is still negligible during the duration of the voltammetric experiment. However, the rate of the reaction following the second reduction step is increased considerably. Controlled potential electrolysis at  $-0.80$ v was performed on the above-mentioned solution with a resulting  $n_{app}$  of 5.92 electrons, which is the same as the  $n_{app}$  found for the over-all reduction in the absence of proton donor.

Fig. 5. Polarograms for reduction of 1.05 mM APDO in 0.1M TBAP in DMF in the presence of varying amounts of hydroquinone (HQ): 1, no HQ added; 2, HQ concentration is 1.77 mM; 3, HQ concentration is 8.10 mM.

Fig. 6. Cyclic voltammograms for the reduction of 1.05 mM APDO at a hmde in 0.1M TBAP in DMF in the presence of varying amounts of hydroquinone (HQ): 1, no HQ present; 2, 1.77 mM HQ; 3, 8.10 mM HQ.

### Discussion

The mechanism of the electrochemical reduction of APDO is shown in the schematic diagram in Fig. 7. In this diagram electron transfer processes at the electrode are indicated by straight lines (reductions downward and oxidations upward) and chemical reactions are shown as wavy lines. Compounds which are reduction products of APDO are shown as lines below the APDO line; these lines are spaced in increasing numbers of electrons added to the parent molecule. Where the appropriate electrode potentials are known, they are indicated next to the couple. Downward arrows show reduction and upward ones oxidations.

We proposed to explain the experimental results with the following mechanism:

At potentials corresponding to the first wave:

At potentials corresponding to the second wave:

The polarographic and cyclic voltammetric results show that during the small duration of these experiments (3-20 sec), the results can be explained by reactions [1] to [3]. Only a small contribution of the following reactions [9] through [11] is found, resulting in the ECE-type behavior of the second voltammetric wave.

Controlled potential coulometric reduction at a potential corresponding to the plateau of the first wave gives  $n_{\text{app}}$  values significantly greater than one and evidence of production of an electroactive species (current not decaying to the background value). Reversal coulometry (oxidation at the foot of the first wave)

Fig. 7. Schematic diagram of mechanism of the electroreduction of APDO. Electron transfer processes at the electrode are indicated by straight lines (reductions downward and oxidations upward) and chemical reactions by wavy lines. The extent of reduction, in terms of electrons added to APDO, is indicated by the distance down from the APDO line. The potentials at which reactions occur ( $E_{1/2}$ , vs. SCE) are indicated near the appropriate couple, when known. Some qualitative measure of the rates of chemical reactions has been given ("slow" denotes a reaction which does not proceed to an appreciable extent during a time characteristic of voltammetric experiments but is appreciable on the coulometric time scale; "very slow" denotes a reaction which proceeds only partially even in coulometric experiments). — Reduction at  $-1.0\text{v}$ ; ..... oxidation at  $-0.20\text{v}$  following this reduction; - - - - - reduction at  $-1.8\text{v}$ ; -●-●-● oxidation at  $-0.2\text{v}$  following this reduction.

gives a smaller value of  $n_{\text{app}}$ , for example ( $n_{\text{app}}$  reduction = 0.70, Table II). This behavior is ascribed to a

very slow reaction of the anion radical  $\text{APDO}^-$  to form an electroactive species; a protonation reaction to  $\text{APDOH} \cdot$  seems reasonable. Since the first reduction wave of APDO is unaffected by addition of a proton donor, this reaction must be slow, even in the presence of excess hydroquinone. Further reduction and protonation eventually leads to azopyridine (AP), which is reduced at these potentials to the stable anion

radical  $\text{AP}^-$ . Since  $\text{APDOH} \cdot$  is reduced at these potentials in a series of steps involving 4 electrons, only a small amount of reaction of  $\text{APDO}^-$  will give an appreciable contribution to  $n_{\text{app}}$ . For example, the decompo-

sition of about 20% of the  $\text{APDO}^-$  would account for these results. The fact that voltammetry of the reduced solution shows a cathodic peak current, on reversal, of about 80% of the original cathodic peak current, is also in agreement with this mechanism and suggests that some of the intermediates involved in [6] are not oxidizable. Since the second reduction wave is about the same after reduction as in the original solution, reduction of both products and intermediates is suggested. The esr spectra obtained following reduction at potentials of the first wave are probably those of

$\text{APDO}^-$ ,  $\text{AP}^-$  and perhaps some intermediates.

Reduction at a potential on the plateau of the second wave leads in a series of protonation and reduction reactions to  $\text{APH}^-$ , with  $n_{\text{app}} = 6$  (within experimental error). The electrochemical behavior of the solution resulting from this reduction is identical with that obtained from reduction of AP itself.<sup>1</sup> After complete

<sup>1</sup> A complete study of the electrochemistry of azopyridine and other aromatic azocompounds in DMF has been completed (J. Sadler, Ph.D. Dissertation, The University of Texas at Austin, 1967) and has been submitted for publication elsewhere. The behavior of azopyridine shown in the lower part of Fig. 7 has been established in this study.

reduction, oxidation at  $-0.2\text{v}$ , and re-reduction, an esr signal which can unequivocally be ascribed to  $\text{AP}^-$  is obtained, giving further support to this mechanism.

### Experimental

The cell and vacuum line used were essentially the same as reported by Santhanam and Bard (12). DMF purification and storage also followed the procedure outlined there. The filling of the electrochemical cell was accomplished by first evacuating the cell containing the supporting electrolyte and mercury pool, cooling with liquid nitrogen, then distilling DMF under vacuum into the cell. After the distillation had been completed, the cell and contents were allowed to warm to room temperature with continuous evacuation. The cell was then brought to atmospheric pressure by introducing helium through the vacuum line. The helium was obtained from the Matheson Company, LaPorte, Texas. It was passed successively through anhydrous magnesium perchlorate, copper turnings (heated to  $350^\circ\text{C}$ ), activated charcoal cooled to liquid nitrogen temperature, and finally to the cell. A helium blanket over the solution was maintained throughout the experiment. The auxiliary electrode was a platinum wire. The reference electrode was an aqueous SCE connected via an agar plug and sintered glass disk to the test solution. Stirring was by a magnetic stirrer.

The voltammetric experiments were carried out using a multipurpose instrument employing operational amplifier circuitry with three-electrode configuration, similar to those discussed in the literature (13). Controlled potential coulometry was carried out using a previously described apparatus (14).

The APDO was from Aldrich Chemical Company. It was recrystallized twice from absolute ethanol and twice from benzene. The melting point of the resulting product was very sharp at  $236.5^\circ\text{C}$  (decomp.). AP was synthesized by reduction of APDO in ethanol with zinc dust and ammonia. The melting point of the product after recrystallization from petroleum ether, was  $106.5^\circ\text{C}$  as compared to a literature value of  $107^\circ\text{C}$  (15). The TBAP was obtained from Southwestern Analytical Chemicals, Austin, Texas. It was dried in a vacuum oven for 8 hr at  $70^\circ\text{--}80^\circ\text{C}$  and stored in a desiccator until use.

A Varian Associates V-4502 spectrometer employing 100-kc field modulation was used for esr spectroscopy.

### Acknowledgment

The support of this research by the Robert A. Welch Foundation and the National Science Foundation (GP 6688X) is gratefully acknowledged. The authors are indebted to Tom V. Atkinson and Larry O. Wheeler for aid in the esr spectroscopy and to K. S. V. Santhanam for helpful discussions during the work.

Manuscript received July 17, 1967; revised manuscript received ca. Nov. 23, 1967.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1968 JOURNAL.

## The Cu/CuF<sub>2</sub> Couple in Anhydrous Hydrogen Fluoride

Brian Burrows\* and Raymond Jasinski\*

Tyco Laboratories, Inc., Waltham, Massachusetts

### ABSTRACT

The electrochemical behavior of a Cu electrode was investigated in basic, anhydrous HF. Anodization of Cu established the Cu/CuF<sub>2</sub>(s) couple. Micro-polarization and bias tests indicated that this couple was reversible, and its potential vs. an H<sub>2</sub> electrode in the same solution agreed well with that predicted from thermodynamic data. Thus the couple is suitable for use as a reference electrode in basic HF. The formation of a relatively thick, insoluble anodic film at a copper electrode was demonstrated by cyclic voltammetry and chronopotentiometry. Anodic-cathodic cycling of an electrode gave rise to significant roughening of the electrode surface as shown by *i*-E curves, E-t curves, and differential capacitance measurements on cycled electrodes. X-ray analysis of the anodic film confirmed the presence of crystalline copper fluoride. The formation of CuF<sub>2</sub> appears to proceed via dissolution of Cu to form Cu<sup>2+</sup> ions, followed by precipitation of the CuF<sub>2</sub> on the electrode surface. The polarization behavior of Cu electrodes in anhydrous HF solution containing added KF showed that anodic film formation can be approximated by Tafel lines with an apparent exchange current density of about  $3 \times 10^{-6}$  amp/cm<sup>2</sup>. Properties of the anodic film of CuF<sub>2</sub> are quite similar to those observed for noncontinuous anodic films formed in aqueous solutions.

Very little work on the characterization of electrode reactions in anhydrous or aqueous HF has been reported. A small number of potentiometric investiga-

tions have been made (1-3); a brief report on the construction of a rotating nickel electrode for use in anhydrous HF is available (6), and a dropping mercury electrode using a Teflon capillary in aqueous HF

\* Electrochemical Society Active Member.

has also been described (4, 5). The process of electrochemical fluorination of organic compounds has been known for some time (7, 8) and is a commercial operation. Recently, the anodic behavior of metals in HF has been examined, and an attempt was made to find an inert or passive anode at which the mechanisms of electrochemical fluorination could be studied (8). Monel, platinum, and nickel were least reactive; the anodic passivity of nickel in HF was studied in some detail (9).

The Cu/CuF<sub>2</sub>(s) couple has been used as a reference electrode of the second kind in anhydrous HF solutions (2, 3). The electrode was formed by anodizing a Cu plate in HF at +1.0v against a Pt electrode. No direct evidence on the reversibility or composition of the electrode was given. A Hg/Hg<sub>2</sub>F<sub>2</sub>(s) couple has also been used as a reference electrode of the second kind (1, 8, 9). Mention has been made (11) of a direct measurement of the potential of the cell H<sub>2</sub>/HF(KF)/F<sub>2</sub> ( $E = 2.768\text{v}$  at 0°C). It was noted that the fluorine electrode was irreversible.

Cupric fluoride is of interest as a cathode in battery systems using aprotic organic solvents. One method for its preparation is by anodization of copper in anhydrous HF. This paper describes studies of the Cu/CuF<sub>2</sub> electrode and the mechanism of formation of CuF<sub>2</sub> at a copper electrode in basic, anhydrous HF.

### Experimental

Experiments were carried out in a 1M solution of KF in anhydrous HF at 0°C and 25°C. The water content of the HF was nominally 0.04 m/o (mole per cent) corresponding to approximately 0.02M (19).

**Apparatus and procedure.**—A schematic diagram of the apparatus for handling anhydrous HF (Matheson Company, 99.9 m/o) is shown in Fig. 1. B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, and B<sub>4</sub> are Teflon FEP bottles (4 oz capacity). The connecting tubing was of flexible Teflon (0.25 in. ID) and the stopcocks were of polyethylene. Kel-F wax (3M Company) was used to seal all the joints and inlets.

Since the ambient temperature was 25°C, HF was delivered from the cylinder in the gaseous state. Nitrogen was first flushed through the apparatus followed by HF vapor. An ice-bath was then placed around B<sub>1</sub> to condense HF. After about 40 cc of liquid HF had been collected, the ice-bath was removed and placed in position around B<sub>2</sub> (the electrochemical cell with counter, working, and reference electrodes already in position). An incandescent lamp was held under B<sub>1</sub> to warm the HF gently and distill it over to B<sub>2</sub>. A small residual amount of liquid was left in B<sub>1</sub>. An amount of KF (B & A, reagent grade) had previously been added to B<sub>2</sub> so that an ionically conducting solution, approximately ( $\pm 10\%$ ) 1M in KF, would result. It was observed that KF dissolved quite readily in HF with-

Fig. 1. Schematic representation of the apparatus used for handling anhydrous HF. B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, B<sub>4</sub> were Teflon FEP bottles (4 oz capacity). The connecting tubing was flexible Teflon; the stopcocks were polyethylene.

out mechanical stirring. Dry nitrogen was then bubbled through the cell for up to 2 hr until a current-voltage scan at a Cu electrode indicated the absence of impurities (see below).

At the end of an experiment the HF was transferred from B<sub>2</sub> by removing the ice bath, allowing the HF solution to warm up, and applying a gentle vacuum with a water pump. This vaporized the HF into B<sub>4</sub> which contained pellets of KOH. It was possible to remove a working electrode from B<sub>2</sub> during an experiment and replace it with a new one without overly contaminating the HF.

HF vapor could vent through the caustic trap (B<sub>4</sub>) during cell measurements. However, the apparatus did provide a sufficient back pressure to make this leak rate negligible, even at 25°C where the vapor pressure of HF is slightly above 1 atm.

**Electrodes.**—Working electrodes were prepared from sections of electrolytic copper wire 1 mm diameter, covered with shrinkable Teflon (Rayclad Tubes, Inc.) which gave a tight, insulating layer. Sufficient Teflon was removed at the working end of the electrode to expose 1 cm of Cu. The working area (0.33 cm<sup>2</sup>) was cleaned in dilute HNO<sub>3</sub> and washed in distilled water and acetone. The electrodes were placed in the cell (B<sub>2</sub>) through small holes drilled around the lip of the bottle so that a close fit was obtained. The inlet holes were sealed with Kel-F wax. Electrodes of Ag (0.16 cm<sup>2</sup> in area), Pt (0.16 cm<sup>2</sup> in area), and Ni (0.20 cm<sup>2</sup> in area) were prepared similarly. The counter electrode was a coil of Ni wire; a 1 cm square piece of porous copper plaque (Clevite Corporation) was used to form the reference electrode.

The H<sub>2</sub> electrode was of the fuel cell type (15), consisting of Pt black (Engelhard Industries, Inc.) bonded with Teflon and supported on a Pt mesh screen of 2 cm<sup>2</sup> area. This electrode was placed in a Teflon tube (1 cm in diameter) with a hydrophilic porous Teflon frit (Chemplast, Inc.) at one end and held in place with Kel-F wax (3M Company).

**Electrochemical measurements.**—Potentiostatic current-potential curves (cyclic voltammograms) were obtained in the usual manner using a motor-driven, slow-function generator (maximum scan rate 800 mv/min). The output of the function generator was applied to a Wenking potentiostat (Model 61 RS). The i-v curve was recorded on an X-Y recorder (Houston Omnigraphic, Model HR-98T). Since the input impedance of the X-Y recorder was low (0.2 Mohm), a cathode follower was used in the potential-measuring circuit to avoid undue loading of the reference electrode-working electrode cell. The unity-gain follower was constructed from an operational amplifier (Philbrick Researches, Inc., Type P65AU); the input impedance of this device was 33 Mohm. Unless stated otherwise, all i-v curves were obtained using a scan rate of 800 mv/min.

Potential-time curves (chronopotentiograms) were recorded on the same X-Y recorder using the time base. A constant-current power source (Electronic Measurements, Model C623) was used to supply the current at voltages up to 400v.

Steady-state, constant current polarization curves were obtained by recording the change of potential with time on the X-Y recorder with a full scale deflection of 20 sec. The potential assumed a constant value within several seconds and steady-state potential values were read off the plateau. By using relatively short times to measure the activation polarization, convective and concentration polarization effects were minimized.

Micropolarization tests on the Cu plaque were carried out by passing a small constant current and measuring the potential with a differential d-c voltmeter (John Fluke, Model 825A).

The capacity measurements were based on a method in which a triangular wave of 100 cps and an amplitude of 25 mv (i.e., a sweep rate of 5v/sec), biased by

a convenient d-c voltage, was fed into the signal input of the potentiostat (20). The d-c voltage was selected so that Faradaic currents were avoided. The small triangular potential wave (Exact Electronics, Inc., fast function generator, Type 255) was fed via a differential amplifier (Tektronix, Type 2A63 plug-in) into one axis of an oscilloscope (Tektronix, Type 561A). Via another differential amplifier of the same type, the voltage drop across a suitable precision resistor was fed into the other axis of the oscilloscope. The resulting trace on the oscilloscope screen was a rectangular box from which the peak-to-peak current was measured. The differential double layer capacity  $C_{dl}$  was then equal to  $i/2(dE/dt)$ .

**X-ray analysis.**—Qualitative identification of anodic films was obtained from analyses of Debye-Scherrer powder patterns using  $\text{CuK}\alpha$  radiation with a Ni filter at 50 kv and 20 ma. The films were formed on 0.5 mm Cu wire in HF and then exposed to radiation up to 6 hr. The lines arising from Cu were determined during the analysis and eliminated.

### Results and Discussions

The initial studies of the Cu/CuF<sub>2</sub> couple were complicated by the presence of an electroactive impurity. This impurity also reacted at Ag electrodes but not at Pt and Ni. An i-E curve taken at a Cu electrode in impure HF is shown in Fig. 2. The anodic wave beginning at 0 mv (vs. Cu/CuF<sub>2</sub>) was diffusion controlled. After anodization, a black film was present on the Cu electrode; the same film was found on Cu electrodes left in contact with HF for some time. An x-ray analysis of this film showed the pattern of Cu<sub>2</sub>S and possibly CuOH; CuF<sub>2</sub> was not detected.

The impurity was removed by bubbling dry nitrogen (or argon) through the cell for periods of up to several hours. The absence of the impurity was indicated by the disappearance of the diffusion controlled anodic wave and the anodic peak current, as well as the absence of a black film after Cu had been standing in contact with HF. All electrochemical experiments described here were carried out in HF purified by N<sub>2</sub> bubbling.

In an attempt to identify the nature of the impurity, i-E curves were run at Cu electrodes in pure HF after bubbling SO<sub>2</sub> and H<sub>2</sub>S through the solution for about 15 min in separate experiments. Neither of these impurities showed any anodic activity. Bubbling O<sub>2</sub> through the solution also decreased the impurity wave. The presence of dissolved O<sub>2</sub> was detected on a Pt

Fig. 2. Cyclic voltammogram at Cu electrode in impure HF (1M KF) at 0°C. Scan rate was 800 mv/min, and scan was started at 0 mv.

electrode by a reduction wave at +0.5 to +0.6v vs. Cu/CuF<sub>2</sub>. N<sub>2</sub> bubbling removed this reduction wave.

Ag was observed to dissolve anodically in the purified HF and no anodic film was formed. Figure 3 shows a background scan on a platinum electrode in anhydrous HF. The diffusion controlled anodic wave at +1.2 to +1.3v was presumably due to oxidation of traces of water. The limiting cathodic process was H<sub>2</sub> evolution. An order of magnitude calculation can be made of the concentration of water present. Using the equation given by Delahay (24) for the current as a function of potential scan rate with  $\nu = 0.078 \text{ v-sec}^{-1}$ ,  $n = 2$ , and taking  $D = 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$  for the diffusion coefficient of H<sub>2</sub>O in HF, then  $C_{\text{H}_2\text{O}}$  calculates to 0.01M. This is close to the nominal impurity concentration of 0.02M.

As mentioned above, KF was added to HF in order to produce a solution with reasonable conductivity (10). In liquid HF, solutions of the alkali metal fluorides act as bases (10), so that the dissolution of KF may be formally represented as follows

Thus, the solvated fluoride ion acts as a base and its concentration is related to that of solvated protons through

with an equilibrium constant of approximately  $2 \times 10^{-12}$  (10). H<sub>2</sub>O also acts as a base in liquid HF and the following equilibrium is established

with an equilibrium constant of 0.55 (3) at 0°C. Thus all HF<sub>2</sub><sup>-</sup> ion concentrations should include the contribution from the solvolysis of impurity H<sub>2</sub>O according to Eq. [3]. The concentration of H<sub>2</sub>O in HF as taken from the cylinder is nominally 0.02M. Using the approach of Clifford *et al.* (3), the concentration of HF<sub>2</sub><sup>-</sup> contributed from equilibrium [3] was calculated to be 0.01M.

Thus this additional concentration had an insignificant effect on the potential of the Cu/CuF<sub>2</sub> electrode potential in a solution already 1M in HF<sub>2</sub><sup>-</sup> and, for the same reason, a negligible effect on the observed transition times for CuF<sub>2</sub> formation (see below). There may be, however, a specific chemical interaction between CuF<sub>2</sub> and undissociated H<sub>2</sub>O, resulting in a slightly increased solubility of CuF<sub>2</sub>, which would affect transition times. The magnitude of this effect would appear to be negligible since the solubility of CuF<sub>2</sub> in HF (containing about 0.01M H<sub>2</sub>O) at 0°C was found to be less than  $2 \times 10^{-5}\text{M}$  (2). In the presence of 1M KF the solubility of CuF<sub>2</sub> may be even lower.

**Reference electrode.**—Copper electrodes immersed in a 1M solution of KF in HF at 0°C always had low differences (<5 mv) in rest potentials, which differences remained constant. The potential of a fresh Cu

Fig. 3. Cyclic voltammogram at Pt electrode in purified HF (1M KF) at 0°C. Scan rate was 800 mv/min, and scan was started at 0 mv.

electrode placed in solution was less than 5 mv with respect to an electrode which had been immersed for several days. Furthermore, the potentials of fresh or aged electrodes were little different from those of electrodes previously anodized at +200 mv. This behavior suggested that a reversible couple was associated with the Cu electrode in a basic HF solution, namely

To check the reversibility, a polarization test was carried out on a porous Cu electrode (geometric area 2 cm<sup>2</sup>). Small constant currents were passed between the Cu electrode and a Ni counter electrode. The resulting polarization was measured with respect to an unpolarized Cu electrode as shown in Fig. 4. It can be seen that there was no significant hysteresis and only a small displacement of potential when several microamperes were flowing.

It is probable that some CuF<sub>2</sub> was formed at open circuit by corrosion involving trace amounts of reducible impurities in the solvent (12). As will be shown below, the quantity of CuF<sub>2</sub> formed in this manner is small compared with anodically formed CuF<sub>2</sub> at more positive potentials.

The composition of the film formed on copper after repetitive anodization was shown, by x-ray analysis, to be crystalline CuF<sub>2</sub> · 2H<sub>2</sub>O (23). It is probable that CuF<sub>2</sub> formed in the cell hydrolyzed (23) upon exposure to the atmosphere during the x-ray measurements.

The potential of the Cu/CuF<sub>2</sub> couple at 25°C was measured with respect to a hydrogen electrode immersed in the same solution. A Teflon-bonded, high surface area platinum black electrode was introduced into the cell and was separated from the copper electrode and the bulk of the electrolyte by a junction of porous Teflon. The hydrogen electrode was only half immersed in the electrolyte so that a three phase contact could be maintained between the electrode, HF, and hydrogen gas. A flow of H<sub>2</sub> was sustained over the electrode rather than bubbling gas through the electrolyte during the measurements to keep the pressure of hydrogen close to one atmosphere and still avoid significant changes in HF content. The results of three such experiments are shown in Table I; the

potentials were stable within  $\pm 3$  mv for the duration of the experiments (approximately 30 min).

In terms of the self ionization equilibria for HF described above, the half cell reactions are probably as follows

The total cell reaction is thus

with all components in their standard states. Equation [7] assumes that the activity of HF (approximately 50M) in 1M KF equals that of liquid HF. The data of ref. (25) implies that this assumption is valid within the limits quoted in Table I. Although the potentials for each half cell reaction (Eq. [5] and [6]) are dependent on the activity of the HF<sub>2</sub><sup>-</sup>, the total cell potential (Eq. [7]) is independent of this factor because of equilibrium [2].

The theoretical cell potential is also independent of the activity of H<sub>3</sub>O<sup>+</sup> arising from the presence of H<sub>2</sub>O. Thus the two half-cell reactions in a solution containing H<sub>3</sub>O<sup>+</sup> ions are probably [5] and

Adding [5] and [8] together results in the theoretical over-all cell reaction [7], which is independent of the HF<sub>2</sub><sup>-</sup> activity as well as the H<sub>3</sub>O<sup>+</sup> activity because of equilibrium [3]. The standard cell potential at 25°C can be computed from thermodynamic data and a value of +0.27v was obtained in this manner (13, 14) in reasonable agreement with the observed potential. This value at 25°C is in disagreement, however, with that of +0.52v given by Clifford and co-workers (3) for Cu/CuF<sub>2</sub> in HF at 0°C.

**Polarization measurements.**—A cyclic voltammogram for Cu in purified 1M KF-HF is shown in Fig. 5. The scan rate was 800 mv/min, scanning first from 0 to +200 mv vs. a Cu/CuF<sub>2</sub> reference electrode. The current scale in this figure is in terms of ma/cm<sup>2</sup> so that the small currents noted in Fig. 4 are not observable. The form of the curve is substantially different than that of the impure solutions. Apparently only one major process, presumably formation of CuF<sub>2</sub>, is involved.

The i-E curve (Fig. 5) has two principal features: an anodic current peak and a less pronounced cathodic current peak. The anodic peak height was dependent on stirring, scan rate, and number of anodic-cathodic cycles to which the electrode had been subjected. In a quiescent solution the area under the anodic peak (between 0 to 200 mv) and the area under the corresponding cathodic peak (between 0 and -400 mv) was found to be equal at a scan rate of 800 mv/min. In cases when the anodic scan was taken to potentials more positive than +200 mv, the subsequent cathodic area was smaller. This may be attributed to partial dissolution of the film. Such behavior has been observed for anodic films in aqueous solutions (16).

When scan rates much slower than 800 mv/min (160 and 80 mv/min) were used, it was observed that the anodic peak areas were significantly larger than those at 800 mv/min, although the cathodic areas were unchanged. This indicates a loss by convection and diffusion of a soluble intermediate from the vicinity

Fig. 5. Cyclic voltammograms at a Cu electrode in purified HF (1M KF) at 0°C. Scan rate was 800 mv/min, and scans were started at the open-circuit potential, i.e., 0 mv.

of the electrode surface during the formation of the film of  $\text{CuF}_2$ . Similar behavior was observed in the chronopotentiometric experiments (see below).

With each subsequent anodic-cathodic scan, the anodic and cathodic peak heights (and areas) increased, suggesting that the electrode was progressively roughened (Fig. 5). The same behavior was observed with respect to transition times during repetitive constant-current cycling. In 2M KF, the anodic and cathodic peaks were considerably greater, indicating a proportionality between the basicity of the HF solution and the extent of  $\text{CuF}_2$  formation.

A summary of the initial peak areas on fresh Cu electrodes and peak areas after 15 anodic-cathodic cycles in 1M and 2M KF solutions is given in Table II.

From the data in Table II, the initial average film thickness was estimated as  $4 \times 10^{-6}$  cm in 1M KF solution and  $1 \times 10^{-5}$  cm in 2M KF. Alternatively, using the data of Table II, one can estimate an apparent number of molecular layers of  $\text{CuF}_2$  after the method of Hickling and Taylor (18). Thus the initial film thickness in 1M and 2M KF solution was calculated to correspond to 47 and 125 molecular units, respectively. These estimates of molecular units would, in the case of a compact film, correspond to the number of molecular layers. However, the fact that the initial film is as thick as it is suggests that the film has relatively poor protective powers; i.e., the film is noncontinuous or porous. Hackerman, Snavely, and Fiel (8) concluded that Cu was intermediate in its corrosion resistance in HF. They placed Cu between metals such as Ta and Ag which corroded rapidly, and Pt and Ni which were quite stable.

**Differential capacitance measurements.**—Double layer capacitance measurements were made at  $-200$

Table II. Anodic peak areas from i-E curves (scan rate 800 mv/min) recorded at Cu electrodes in HF at 0°C

	Basicity of HF	
	1M KF, mc/cm <sup>2</sup>	2M KF, mc/cm <sup>2</sup>
Initial scan	58	155
15th Cycle	421	531

Table III. Differential double layer capacitance of Cu electrode and charge associated with anodic film formation in HF (1M KF) at 0°C

	C at $-200$ mv ( $\mu\text{f}/\text{cm}^2$ )	Q anodic (mc/cm <sup>2</sup> )	Q <sub>a</sub> /C <sub>dl</sub> (mc/ $\mu\text{f}$ )
1st Cycle	20	58	2.9
2nd Cycle	36	120	3.3
3rd Cycle	105	139	1.3
4th Cycle	138	176	1.3
5th Cycle	167	194	1.2

mv vs.  $\text{Cu}/\text{CuF}_2$  before each anodic potential scan. The results are shown for the first five cycles in Table III, together with the total anodic charge passed to  $+200$  mv (Q anodic) and with the ratio Q anodic/C<sub>dl</sub>. It can be seen that the increase in anodic charge with cycling is primarily due to surface roughening. There is not, however, a direct proportionality between the increase of surface area and the anodic charge.

**Chronopotentiometry.**—A potential-time curve obtained for the formation and discharge of  $\text{CuF}_2$  in 1M KF-HF is shown in Fig. 6 at a current density of 6.7 ma/cm<sup>2</sup> in an unstirred solution. The main feature is the equality of the anodic and cathodic transition times. This implies that an insoluble film is formed on anodization, in agreement with the observations from cyclic voltammetric scans (Fig. 5). These observations also imply that the effect of small amounts of water present (ca. 0.01M) on the anodic formation and cathodic reduction of  $\text{CuF}_2$  was negligible. At lower current densities, it was observed that two poorly defined transition times actually were present on the reduction step. At current densities much higher than 20 ma/cm<sup>2</sup>, the cathodic transition time became too distorted to measure.

The question of diffusion control was checked by observing the effect of stirring ( $\text{N}_2$  bubbling) on the transition times. It was found that stirring increased the transition time for the oxidation step ( $\tau_{\text{ox}}$ ) by about 100% at 15 ma/cm<sup>2</sup>, indicating some form of diffusion control, but  $\tau_{\text{red}}$  was independent of stirring and approximately equal to the  $\tau_{\text{ox}}$  at the same current density in an unstirred solution. This effect of stirring at short transition times is equivalent in terms of convection and diffusion to the effect of using slow scan rates (see below). These effects can be discussed

Fig. 6. Potential-time curve at a Cu electrode in purified HF (1M KF) at 0°C. Current density was 6.7 ma/cm<sup>2</sup>.

in terms of the two possible general mechanisms of CuF<sub>2</sub> film formation.

One mechanism involves the dissolution of Cu to Cu<sup>2+</sup> followed by precipitation of CuF<sub>2</sub> at the electrode surface, *i.e.*

The other mechanism involves the direct formation on the electrode surface of CuF<sub>2</sub>, *via* an adsorbed film of HF<sub>2</sub><sup>-</sup>, *i.e.*
