min). The bulky (20-30g) source heats up more slowly than the seed. At the same time the decomposition pressure of GaAs is nearly ten times greater than that of GaP. Thus, after loading, the seed will soon start to decompose forming gallium on its surface. If the phosphorus pressure is too low, this gallium will not be converted to GaP but will aggregate in small spheres which later may act as centers for unoriented growth when the source comes to temperature and the phosphorus pressure increases. The phosphine used to produce the protective phosphorus pressure was generated by passing wet hydrogen over aluminum phosphide in the same kind of apparatus as used in the synthesis of GaP.

The resistivities of the crystal plates obtained in this study were measured using the Van der Pauw method. Ohmic contacts were made by applying d-c pulses to gallium-wetted gold or tungsten wires resting directly on the etched surface. Etchants recommended by Abrahams and Buiocchi (3) and Richards and Crocker (4), shown by Saul (5) to reveal dislocations, were used on some of the crystals to obtain an estimate of the dislocation density on the (111) phosphorus face, or growth face. The homogeneity of the material was tested by successive lappings followed by resistivity measurements and etch pit counts. Finally, the photoluminescence of the crystal was measured. At liquid nitrogen temperature an u.v. lamp was used to excite red fluorescence which was analyzed and measured with a photomultiplier tube (RCA 7326).

Results and Discussion

Size and quality of crystals.—The GaAs substrates used had a semicircular shape with a diameter of 30 mm. The thickness of the GaP layer was not uniform but decreased going from the center to the long edges, *i.e.*, the edges parallel to the furnace tube. A crystal grown during 60 hr would typically have a maximum thickness of 1 mm. Sometimes a central flat, about 1 cm broad, had developed with irregular terraces leading down towards the edges. A picture of one such crystal is reproduced in Ref. (6).

The etch pit counts for vapor-transported GaP grown directly on the GaAs seeds were found to be of order 10^5 cm^{-2} although a low count of order 10^4 cm^{-2} was sometimes observed. No reduction in this density was achieved by using GaP substrates. Photomicrographs of some typical, etched surfaces are found in Fig. 2(A,B,C). Etch grooves due to stacking faults were observed in a very few crystals.

Table I lists the results of the homogeneity tests. Since the crystals were lapped on the growth face, the properties of the first grown layers were measured last.

Electrical properties.—The Hall mobilities measured for four crystals at room temperature are plotted in Fig. 3 against the Zn partial pressure of the growth ambient. Using interpolated mobility values from this plot, resistivities obtained on a large number of crystals were converted to carrier concentrations. In Fig. 4, the dependence of the carrier concentration on the Zn partial pressure is displayed. At high Zn partial pressures the hole concentration varies as the square root of the Zn pressure. This is the expected behavior for an extrinsic semiconductor for which the fractional ionization of the acceptors is constant. Evidence for such a constant 50% ionization efficiency at room temperature has been given in Ref. (6).

The square root dependence has also been observed by Trumbore (7) over a limited range of concentrations in solution growth of Zn-doped GaP. From Trumbore's data one may calculate the Zn partial pressure over a gallium solution of GaP and Zn from which a crystal with a given Zn concentration can be grown. Thus a crystal containing 1×10^{18} cm^{-3} Zn can be grown at 1040°C from a gallium solution with a Zn concentration of 4×10^{-2} atom per cent. Adopting an activity coefficient of 0.5 for the Zn and a vapor pressure of 2500 Torr one can calculate a partial zinc pressure of 0.5 Torr for this gallium solution. For comparison the water vapor transport system described here required a partial Zn pressure of 0.6 Torr to yield a crystal containing 1×10^{18} cm^{-3} Zn.

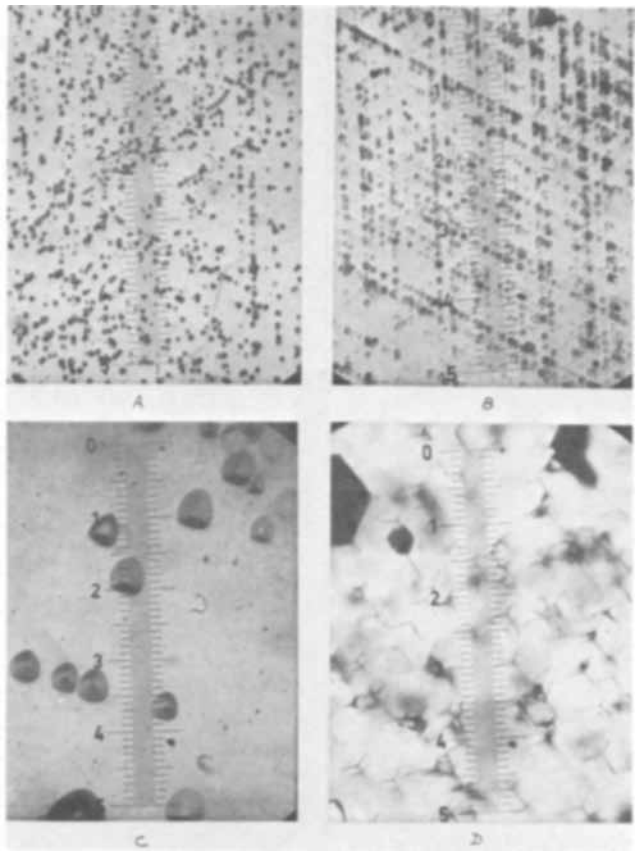

Fig. 2. Etch pits and imperfections on (111) phosphorus faces of vapor-grown GaP crystals. Etch pit density 3×10^5 cm^{-2} (A) and 4×10^5 cm^{-2} (B), one numbered scale unit = 0.15 mm. (C) Etch pits at higher magnification, one numbered scale unit = 0.024 mm. (D) Bulk imperfections, one numbered scale unit = 0.087 mm.

A set of four crystals were selected for surface barrier capacitance measurements and wet chemical analysis. In the latter the zinc was coprecipitated with copper and the precipitate analyzed by x-ray spectroscopy (8). The results are shown in Table II and are plotted in Fig. 4. Due to the fractional ionization of the Zn the total Zn concentration is higher than the hole concentration.

Additional information about impurity concentrations was obtained from spark source mass spectrometry analysis of one sample. The results are summarized in Table III. We note that the concentration of silicon was less than 5×10^{15} cm^{-3}, in agreement with an expected value extrapolated from the data given by Frosch, Thurmond, White, and May (9). Secondly we observe that the concentration of other donors as

Table I

Thickness (mm)	Resistivity (ohm-cm)	Etch pit count (cm^{-2})
Sample No. I		
0.49	0.085	5×10^5
0.42	0.086	6×10^5
0.30	0.083	5×10^5

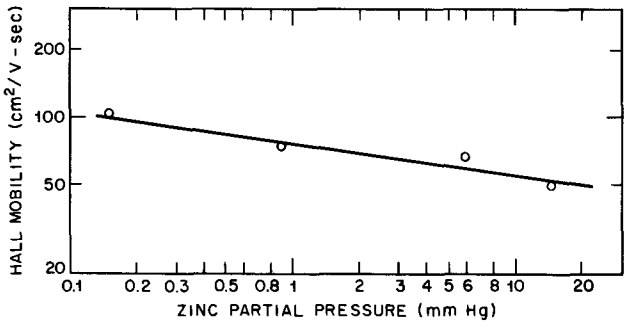

Fig. 3. Room-temperature mobility of Zn-doped, vapor-grown GaP plotted against Zn partial pressure of growth ambient.

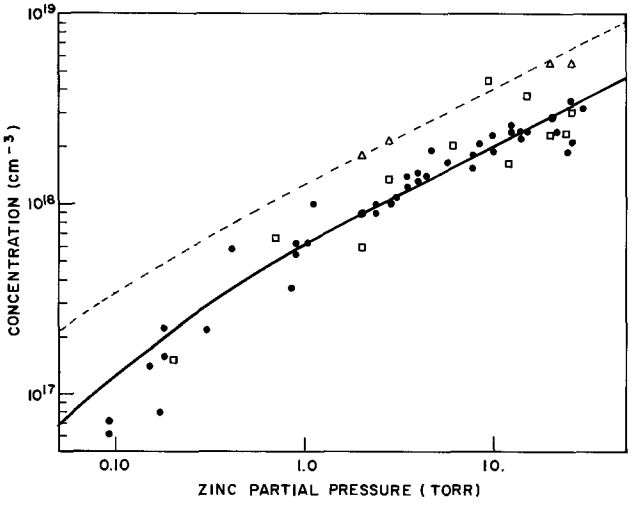

Fig. 4. Carrier and total Zn concentrations as functions of zinc pressure: •, room-temperature carrier concentration from resistivity and Hall data; □, carrier concentration from capacitance measurements (averaged); △, total Zn concentration from wet chemical analysis; ——, calculated room-temperature carrier concentration; - - -, calculated total Zn concentration.

measured by mass spectrometry is small compared to the Zn concentration. This leads us to the conclusion that no significant amount of compensation has occurred. The hole concentration obtained from the resistivities and the interpolated mobilities indicate that the Zn is only about 50% ionized at room temperature. A similar room-temperature ionization efficiency has been measured in Zn-doped, halogen-transported GaP (6).

As shown in Fig. 4 we observe a distinct fall-off in the hole concentration at the lowest Zn partial pressures. This effect may be due to a donor, *e.g.* oxygen, which eludes mass spectrometric analysis or to a transition to intrinsic material at the growth temperature, 1075°C. Recent band gap measurements by M. B. Panish and H. C. Casey (10) indicate that the band gap decreases nonlinearly with temperature and that previous extrapolations to high temperatures have resulted in overestimates of the band gap. Based on the new band gap measurements the intrinsic carrier concentration has been estimated to be 2.6×10^{17} cm^{-3} at 1100°C. Using a value of 3×10^{17} together with the observed room-temperature ionization efficiency of 50% the curves in Fig. 4 were calculated. As can be seen the room-temperature hole concentrations follow this curve quite well. However, the scatter in the data is too large to claim more than qualitative agreement.

If the interpretation of the fall-off in the Zn concentration is correct and the intrinsic carrier concentration is as high as several $\times 10^{17}$ cm^{-3}, the silicon incorporation data of Frosch *et al.* (9) will have to be given a new interpretation. Instead of operating entirely in the extrinsic range as claimed, the authors probably grew silicon-doped crystals in the intrinsic range only. The agreement between the carrier concentration data and the predictions of their model must be considered inconclusive, because of the amphoteric character of the silicon impurity which was ignored in the model. For solution-grown GaAs it has been demonstrated by Rosztoczy (11) that the conductivity type depends on the growth rate and therefore is the result of nonequilibrium growth conditions.

Photoluminescence.—The photoluminescence spectrum of the Zn, oxygen-doped GaP crystals always exhibited two broad bands at 1.84 and 1.96 ev, measured at 77°K. Dean, Frosch, and Henry (2) have shown that 1.96 ev bands are due to Si-Si and Si-S pair recombination. The 1.84 ev band has been shown to consist of two almost overlapping spectra (12). One is due to an exciton bound to a Zn-O complex, while the other arises from pair recombination between a Zn-O complex donor and a Zn acceptor. Thus the presence of oxygen in the crystals was clearly indicated. Due to the large scatter in the photoluminescence data, no correlation of the intensity of the 1.84 ev band with any controllable experimental variables could be established.

Table III. Impurities in sample C from spark source mass spectrometry

Element	atoms/cm³
Carbon	9×10^{16}
Nitrogen	2×10^{16}
Silicon	$<5 \times 10^{15}$
Zinc	3×10^{18}
Arsenic	3×10^{19}
All others	$<3 \times 10^{15}$

Acknowledgments

I am grateful to H. G. White for $N_A - N_D$ measurements and to Miss S. Vincent for the chemical analyses. D. Malm carried out the mass spectrometric analysis. H. C. Montgomery kindly assisted me with the Hall measurements. To C. J. Frosch and F. A. Trumbore and C. D. Thurmond, I owe thanks for helpful discussions.

Manuscript submitted Sept. 12, 1968; revised manuscript received Nov. 18, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Electrical Properties of Silicone Films on Silicon

M. Conti and F. Tegagni

Research and Development Laboratories of S.G.S. SpA., Agrate Brianza, (Milano), Italy

ABSTRACT

The electrical properties of silicone resin films on silicon have been investigated by means of MIS structures. The silicones considered are commercially available methyl phenyl compounds successfully employed in passivating high voltage silicon devices. As contrasted to thermally grown silicon dioxide, well cured silicones feature rather low values of Q_{SS} in the range of few 10^{10} cm^{-2}. However, the surface recombination velocity is appreciably higher, in the range 10-10^2 cm/sec. There is a room temperature trapping instability similar to the one encountered in silicon nitrides. The critical field for the onset of trapping is in the range 0.5-1 x 10^6 v/cm which is significantly lower than that for silicon nitride. The conduction current through the films is a rapidly increasing function of the applied voltage. This behavior is similar to that of silicon nitride although the currents are higher for the same electric fields.

For several years silicone resins and rubbers have been used in passivating silicon devices. Actually, in spite of the many efforts made to establish a suitable planar technology, the best way to obtain high voltage diodes and transistors seems to be silicone passivation. Many publications have been devoted to the chemistry and application of silicones in the electrical industry (1-3). More specifically Kern (4) reported some effects of resin composition on the production of donor or acceptor states at the silicon-silicone interface. The experience gained in developing high voltage devices (up to 1500v) convinced us that some silicone resins should have very good properties such as fixed space charge Q_{ss}, a low density of fast states D_{st}, and low bulk conduction. We also found that the reverse current of relatively large diodes in which the surface contribution was dominant was of the same order of magnitude as in the best passivated planar devices. As a consequence, the contribution of surface recombination had to be essentially the same.

For lack of published data a systematic study of the interface properties of silicone films on silicon was undertaken. Measurements were performed on MSS (Metal Silicone Silicon) capacitors and silicone insulated gate diodes. The capacitors allow the measurement of fixed surface charge density Q_{ss} through CV plots and flatband voltage displacement (5).

Silicone films feature a room temperature trapping instability as encountered in silicon nitride (6); however, the critical field is rather small, in the range of 0.5-1 x 10^6 v/cm. Conduction current through the silicone film was measured through guard ring MSS capacitors. Recombination velocity was examined through the gate diode technique first reported by Grove and Fitzgerald (7).

Final interface properties and, of course, device performance are heavily determined by cure schedule; long cure times result in the best electrical performances.

Experimental

The silicones investigated are commercially available resins especially designed for electrical industry applications. The investigation has been restricted to three types made by different manufacturers, which in the following will be referred to as A, B, and C silicones. They are basically methyl phenyl compounds diluted in xylene or toluene. Type A silicone is a high purity resin which is claimed to be made in glass equipment under carefully controlled laboratory conditions. The high purity is ensured by spectrographic analysis specifications which guard against metal contamination. This compound does not contain any catalyst.

Types B and C are general purpose resins, designated to improve the surface resistivity of insulating materials in electrical circuitry. Type B contains a catalyst, type C does not.

The samples studied were prepared on 10-20 ohm-cm n-type silicon wafers which were first lapped, 30μ etched, polished, and finally 10μ etched to remove most of the mechanically damaged surface.

The wafers were then covered with silicone diluted in toluene to get a sufficiently low viscosity fluid. The wafers were spun up to 4000 rpm on standard resist spinners and then cured. Curing schedule was 2 hr at 65°C, 2 hr at 150°C, and finally from 60 to 200 hr at 220°C. The silicone film thickness was measured by stripping away the silicone in certain areas of the wafer and recording the total height variation between the bare surface and the silicone-coated silicon surface by means of a Talysurf 4 surface inspection test set. The thickness of silicone A samples was typically 1μ $\pm$ 5% and was found to be in agreement with capacity measurements in accumulation situation (see paragraph on fixed surface charge).

In MSS capacitors the central electrode is surrounded by a guard ring electrode which is useful in avoiding surface leakage effects during conduction current measurements. Aluminum thickness was normally 7000Å. In gated diode experiments, silicon dioxide passivated diodes were first obtained by standard planar technology. After having measured the surface recombination velocity, the aluminum and oxide were etched off and the wafers covered by silicones and then cured with the same schedule as with MSS capacitors. To obtain proper gates and contacts, 7000Å aluminum was evaporated and masked.

Most of the measurements refer to silicone A since the reproducibility and the electrical performance of this compound are quite good, whereas B and C materials give high values of Q_{ss} and D_{st}. With type A resin the manufacturer recommends a minimum curing time of 4 hr at 250°C. However, a strong change in characteristics is detectable even after 60 hr. From 100 to 200 hr can be considered as a curing time sufficient to get the complete stabilization of the resin. Figure 1 shows a typical MSS CV plot after 60 hr at 220°C. The transition from accumulation to depletion is quite smooth and is due to a high density of surface states. Figure 2 refers to the same sample after 140 hr (curve a) and 200 hr (curve b) at 220°C. As can be seen, the transition is steeper and the flat-band-voltage is highly reduced. The CV plot depends also on the operating frequency. When the frequency decreases, the flat-band-voltage shifts toward negative gate voltages and at very low frequencies the CV plot features the well-known minimum capacity (7 Hz). Samples cured for 200 hr are significantly similar to those cured for 140 hr, although the longest cures result in a smaller flat-band-voltage spread between 100 kHz and 23 Hz. The density of fast states D_{st} has been computed using the method first reported by Terman (8) and subsequently improved by Berglund (9). At the middle of the energy gap, the state density is rather low, in the range of 10^{10} cm^{-2} ev^{-1}, as can be computed by the low frequency CV plot (80 Hz plot of Fig. 2b).

As the energy is increased toward the conduction band, the state density increases and reaches up to 10^{12} cm^{-2} ev^{-1} in the energy range 0.15-0.30 ev below the conduction band. This can be computed accounting for the flat-band-voltage reduction at 100 kHz and 1 MHz. At such frequencies even the states in the above-mentioned energy interval are not sufficiently fast to follow the surface potential variations (10).

Both silicones B and C feature large and negative flat-band-voltages (see Fig. 3), even when the curing time is increased to 200 hr at 220°C. Furthermore, the transition to the depletion mode is quite smooth.

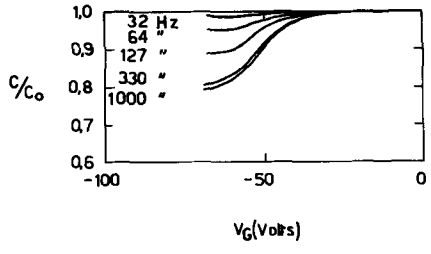

Fig. 1. Type A silicone. CV plots after a 60 hr cure at 220°C

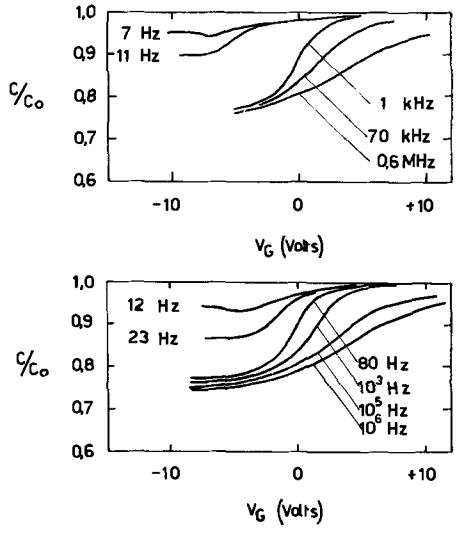

Fig. 2. Type A silicone. CV plots after a 140 hr cure at 220°C (curve a, top) and a 200 hr cure at 220°C (curve b, bottom), silicone thickness 1 μ.

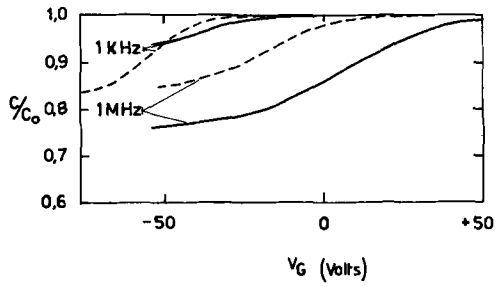

Fig. 3. Typical CV plots of type C (solid lines) and type B silicones (dotted lines).

Trapping effects.—When the electric field is raised above a critical value, the MSS capacitor features a permanent shift in CV characteristics. This instability was previously reported for silicon nitride and is currently ascribed to the trapping of carriers in the dielectric. The critical field strongly depends on the curing schedule. Figure 4 refers to the plot of flat-band-voltage *vs.* bias voltage for a type A-MSS capacitor after 60 hr (dotted line) and after 140 hr (solid line) at 220°C. The additional 80 hr curing time raised the critical field from 5 x 10^5 to 7 x 10^5 v/cm. The sample was given a further 220°C 60 hr curing but no noticeable increase in the trapping field was detected. When bias voltage is changed, a certain time interval is required before the new equilibrium condition is reached. There is a marked difference in the time interval between positive and negative bias of the metal electrode. When the electrode is made positive, the relaxation is controlled by a fast time constant in the range of a few seconds, followed by a much longer one in the range of minutes. When the gate is made negative, there is no fast time constant; the relaxation is controlled by a very long time constant in the range of half an hour. The critical field is strongly dependent on whether measurements are performed in absolute dark or not. Performances so far reported are "dark" performances and a noticeable reduction in the critical field (1-2 x 10^5 v/cm) is obtained when even a small light flux strikes the sample. A light-induced reduction of the trapping field is detectable at wavelengths up to 1.2μ.

Fixed surface charge density Q_{ss}.—As explained in ref. (5), p. 280, the fixed surface charge density Q_{ss} can be computed by the expression

$$Q_{ss}\frac{X_o}{\epsilon_S\epsilon_0} = -V_{FB} + \phi_M - \phi_S$$

where X_o is the silicone thickness, $\epsilon_S = 2.7$ is the silicone dielectric constant, V_{FB} is the low frequency flat-band voltage, ϕ_M and ϕ_S are the metal-silicone and the silicon-silicone barrier heights. The factor

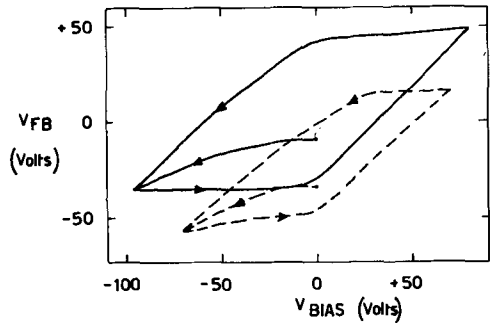

Fig. 4. Dependence of flat-band-voltage on curing conditions of the MSS type A silicone capacitor, with a symmetrical bias stress. Curing time and temperature 60 hr at 220°C (dotted lines) and 140 hr at 220°C (solid lines).

Table I. Fixed surface charge values

Silicone	Cure Time, hr	Cure Temperature, °C	Q_{ss}, cm^{-2}
A	60	220	4-7 × 10^{11}
	140	220	<1 × 10^{11}
	200	220	<3 × 10^{10}
B	Up to 200	220	~10^{12}
C	200	220	~4-10 × 10^{11}

$\epsilon_s\epsilon_0/X_0$ can be quickly obtained from the CV plots when the silicon surface is strongly accumulated (metal electrode heavily positive). In the absence of experimental data for $\phi_M - \phi_S$, the silicon dioxide values have been employed with aluminum against 10 ohm-cm n-type silicon: $\phi_M - \phi_S \simeq -0.4$v (11).

Fixed surface charge values are summarized in Table I.

Surface recombination velocity.—Measurements of the surface recombination velocity were performed by the well established technique of measuring the reverse current of gated diodes as a function of gate voltage. Silicon dioxide passivated diodes were first obtained and measured. The surface recombination velocity S_0 results were typically $S_0 = 10$ cm s^{-1} and Fig. 6 shows a typical plot of reverse current *vs.* gate voltage (dotted line). The aluminum and oxide were etched off, the wafers covered by silicones, and then cured. A typical plot of reverse current *vs.* gate voltage for type A silicone is shown in Fig. 5. As can be seen, the reverse current features the well-known bump when the surface under the gate is depleted. Notice that the gate voltage corresponds to the beginning of depletion in the very low frequency CV plot. The surface recombination velocity as obtained from many measurements resulted in

$$S_0 = 10 - 20 \text{ cm s}^{-1}$$

which is a value not much higher than the best performances measured in annealed oxides (12).

Conduction current.—Guard ring MSS capacitors were employed to measure the conduction current through silicone films. Typical plots at 25°C are reported in Fig. 6.

The conduction performance may be compared with that of silicon nitride which also features a strong dependence on electric field. As reported in ref. (13),

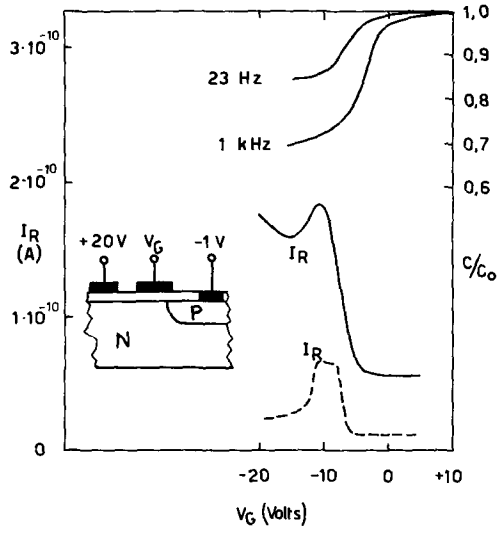

Fig. 5. Reverse current of a silicone insulated gate diode (solid line) as a function of gate voltage V_G. The top curves are CV plots of the gate. Silicon resistivity is 6 ohm-cm and silicone thickness is 1μ (type A). The dotted line plot is the reverse current of the same gated diode when insulated with 0.3μ of thermal silicon dioxide.

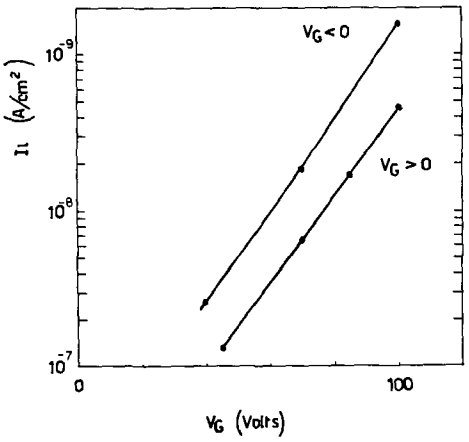

Fig. 6. Current *vs.* applied voltage in 1μ thick type A silicone. Curing time is 140 hr at 220°C.

nitrides are much better as insulators since twice the electric field is required for the same current density. The silicone dielectric strength is strongly dependent on temperature and varies from sample to sample. While at room temperature an electric field up to 10^6 v/cm can be successfully supported, at 90°C few samples survive the electric stresses in excess of 5 x 10^5 v/cm. In measuring conduction currents, the same succession of time constants is found as reported in the section on Trapping effects. This depends obviously on the fact that both conduction current and electric field at the silicone-silicon interface are controlled by the trapping of carriers in the silicone.

Discussion and Conclusions

The silicone-silicon interface properties can be interpreted in terms of the well-established theory currently employed with silicon dioxide (14). Major differences are (*i*) frequency dependent flat-band-voltage, and (*ii*) permanent shift in flat-band-voltage when the critical field is exceeded.

Frequency dependent effects were shown to be due both to fast state density at the silicon dielectric interface (10) and to tunnelling of carriers through the dielectric into dielectric traps (so-called slow states) (15). Although tunnelling effects cannot be entirely excluded, both frequency dependent CV plots and surface recombination measurements can be explained in terms of a proper fast state distribution.

In fact, a low state density at the middle of the energy gap is consistent with a low value of recombination velocity S_0. On the other hand, at zero gate voltage the gated diode reverse current is many times higher than in oxide insulated diodes. This can be explained by the relatively large fast state density far from the middle of the energy gap which has been shown to account for the shift of flat-band-voltage at high frequencies.

Trapping effects in silicones begin at electric fields smaller than in other useful dielectrics. For instance, silicon nitride features critical fields in the range of 2-4 x 10^6 v/cm. From the high voltage device point of view, the room temperature trapping instability is insignificant since the silicone critical field is two or three times higher than the breakdown field of high voltage silicon devices. Actually, in several hundred volt devices, both diodes and transistors, the breakdown field hardly exceeds 2-4 x 10^5 v/cm as opposed to a critical trapping field of 7-10 x 10^5 v/cm. However, as the temperature is raised, the dielectric strength of the silicone film drastically decreases. This is probably the main reason why silicone passivated devices require a significant relaxation in electrical specification as the operating temperature exceeds the 100°-125°C level.

Acknowledgment

Etching Characteristics of Silicon Carbide in Hydrogen

J. M. Harris,* H. C. Gatos,* and A. F. Witt*

Department of Metallurgy and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

It was found that the etching rate of alpha (hexagonal) silicon carbide in hydrogen at high temperatures (above 1550°C) varies with the susceptor material on which the inductively heated silicon carbide rests. Molybdenum exhibits the most pronounced effect increasing the etching rate by about one order of magnitude over that on all other susceptors (W, Nb, Ta, C) employed. Finite etching rates were also observed on α-silicon carbide exposed to inert gas atmospheres at elevated temperatures and were attributed to hydrogen residually present in the susceptors. It was concluded that catalytic action of the susceptor material is involved in the etching process.

It is well known that in the case of silicon, vapor etching prior to vapor growth greatly improves the perfection of the deposited layer (1). However, depending on experimental conditions, vapor etching may compete with the growth process. For example, experiments with silicon carbide in a hydrogen atmosphere have shown that no effective epitaxial growth could be obtained above 1750°C because of the prevailing high etch rates (2-4).

The present experiments were undertaken in connection with our studies on the epitaxial growth of silicon carbide. During these studies it became apparent that the etching rate of α-SiC (hexagonal) in hydrogen is substantially affected by the susceptor material used for induction heating. Temperatures below 1550°C were not considered since the etching rates are very small.

Experimental Procedure

The etching experiments were carried out on α-SiC platelets (0.15 cm^2) of (0001) orientation in a 1.5 in. ID, horizontal, water-cooled, quartz reaction tube. Three different susceptor materials, Ta, C, and SiC-coated carbon were used for inductive heating of the system. Figure 1 (a, b, c) shows schematically the arrangement of the sample and the susceptors. Secondary susceptor strips of Mo, Nb, and W (about 5 cm^2 and 0.5 mm thick) were placed on the primary susceptors as indicated in Fig. 1b.

Etching rates (in microns per hour) were determined from the sample weight changes and of the (0001) area face. Area measurements were made with a planimeter on low magnification (16X) photographs of the samples. The etching rates represent the change in the over-all thickness of the sample. Prior to use the susceptors were etched in a 5:1, conc HF: conc HNO_3 solution; the α-SiC platelets were etched in KOH and cleaned in acetone and then distilled water.

Before introducing the hydrogen the reaction tube was purged with argon or helium while the system was brought up to the desired temperature. The tube was also purged with the inert gas after the termination of the etching experiment to prevent hydrogen embrittlement of the metallic susceptors. The indicated temperatures are uncorrected optical pyrometer readings of the susceptor. All gases employed were >99.999% pure. The experimental results were reproducible to within ± 15%.

Results

Etching in hydrogen.—The results of etching experiments with α-SiC on the various susceptors in a

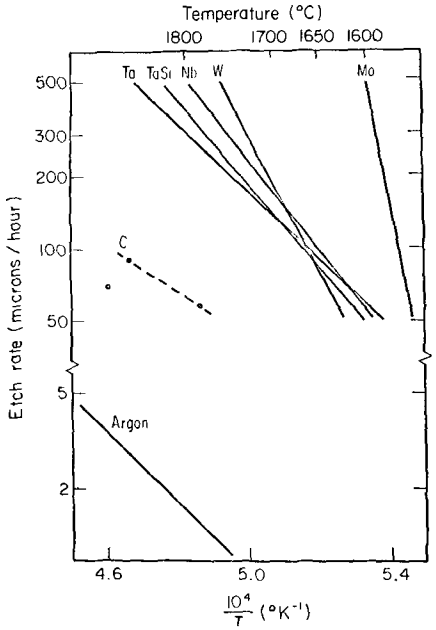

Fig. 2. Effect of susceptor materials on the etching rate of α-SiC in hydrogen. The data obtained with the carbon susceptor are somewhat uncertain because of carbon transfer to the SiC (see text). The published results for SiC decomposition in argon under static conditions are also shown. For clarity the numerous experimental points are omitted. They exhibited a standard deviation less than 5%.

hydrogen atmosphere are presented in Fig. 2. For convenience published results for the etching of α-SiC on tantalum silicide (2,3) and for the α-SiC decomposition in argon (5) are also included. All experiments were performed with a hydrogen flow rate of 2 l/min (measured under atmospheric pressure at room temperature). Those on TaSi had been performed with a flow rate of 2.5 l/min and those in argon had been carried out under static conditions.

The results obtained in the etching experiments on carbon susceptors (Fig. 2) are of limited accuracy due to carbon deposits which could be observed on the SiC surface in contact with the susceptor after etching at high temperatures (>1800°C). Such deposits are apparently the result of carbon transfer from the susceptor to the sample.

Figure 2 shows that the etching rates of α-SiC inductively heated on Ta, TaSi, Nb, and W susceptors in hydrogen are similar. While the apparent activation energies for the etching process on these susceptors (as determined from the slopes of Fig. 2) are not substantially different from that on the carbon susceptor, the corresponding etching rates are considerably higher. In the case of Mo susceptors it is seen that markedly greater etching rates and a stronger temperature dependence prevail.

When carbon susceptors coated with TiC or with Ti-Ta alloy were employed the weight of the α-SiC samples did not change at temperatures up to 1750°C and for etching times up to 20 min. However, a net weight increase was observed after 30 min at 1700°C when a carbon susceptor coated with β-SiC (cubic) was employed. This weight increase was apparently the result of mass transfer of SiC from the susceptor to the sample as a result of the prevailing thermal gradients. Figure 3 shows a typical example of polycrystalline β-SiC deposit on an α-SiC substrate by thermal transport in argon.

The etching rates of the (0001) and (000$\bar{1}$) basal surfaces of α-SiC were studied by masking one of the two with a nonreactive carbon deposit. It was found that the silicon (0001) surface exhibits somewhat higher etching rates than the carbon (000$\bar{1}$) surface. At 1725°C this difference in etching rates was found to be approximately 15%. The etching rates of the basal planes did not significantly change whether or not the surface under investigation was facing the susceptor during etching.

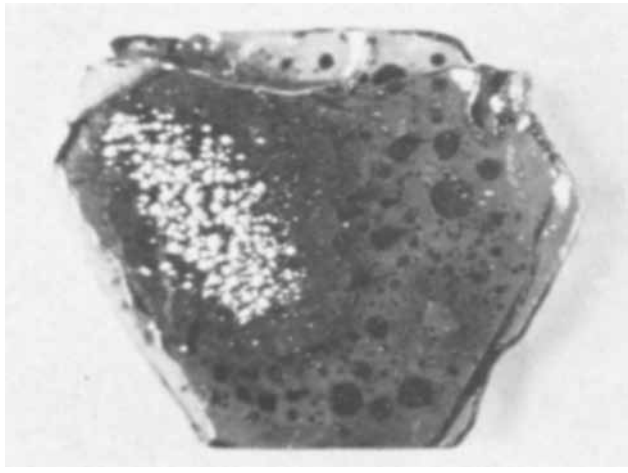

Fig. 3. α-SiC sample after 6 min exposure to argon at 1850°C on a tantalum susceptor. The β-SiC deposit appearing as bright spots is the result of mass transfer from other α-SiC samples simultaneously exposed to the etching conditions. Magnification approx. 6X.

The basal planes were identified by their etching characteristics (6). In hydrogen the carbon surface exhibited well defined dislocation etch pits whereas the silicon surface showed irregular attack and occasional hexagonal pits (see Fig. 4).

Etching in inert gas atmospheres.—Etching experiments were carried out in argon and helium on Ta and Mo susceptors. The results of these experiments are summarized in Fig. 5. It is seen that α-SiC undergoes significant etching when exposed to argon or helium. The etching rate on Mo is considerably higher and exhibits stronger temperature dependence than on Ta susceptors. It is of interest to note that above 1700°C

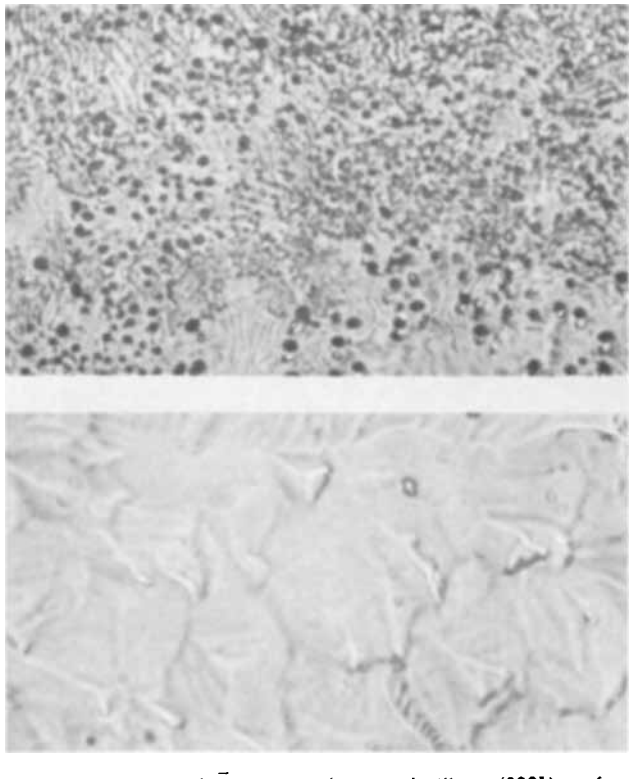

Fig. 4. Carbon (000$\bar{1}$) surface (top) and silicon (0001) surface (bottom) of α-SiC after 20 min exposure to hydrogen at 1650°C on a tantalum susceptor (see text) (100X).

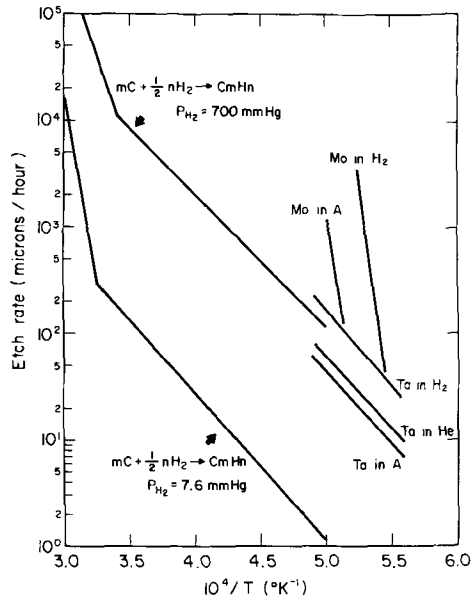

Fig. 5. Etching behavior of α-SiC in argon and helium on tantalum and molybdenum susceptors. The interaction of graphite and hydrogen at high temperatures (7) is also shown (see text).

the etching rate on Mo in an argon atmosphere is higher than on Ta susceptors in hydrogen.

In several experiments it was observed that SiC was deposited in the form of α-SiC from samples at higher temperatures to samples at lower temperatures when several α-SiC samples were exposed simultaneously to argon on Ta susceptors (Fig. 3). Such temperature differences were caused by varying thermal contact of the samples with the susceptor.

Transport experiments in hydrogen.—Etching experiments on Mo susceptors revealed that about 85% of the weight loss of the α-SiC samples could be accounted for by a corresponding weight increase of the Mo susceptor. A chemical analysis of the susceptor after an etching experiment showed that the molar ratio Si/C was now greater than one.

The distribution of the transferred material on the susceptor was investigated by placing SiC samples on Ta susceptors at a fixed distance (3 mm) from the leading and trailing edge of secondary Mo susceptors respectively and exposing them at 1600°C to a hydrogen atmosphere. Figure 6 shows the data of the silicon

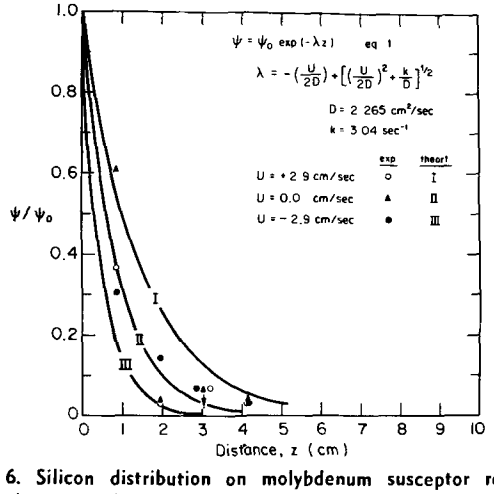

Fig. 6. Silicon distribution on molybdenum susceptor resulting from etching of α-SiC in hydrogen at 1650°C. The normalized concentrations were obtained by extrapolating the data of the chemical analysis to zero distance from the source. Curves I, II, and III represent the concentration profiles based on Eq. [1] (see text).

analyses plotted in normalized concentration *vs.* distance from the source.

If it is assumed that the component distribution in the vapor phase is determined by diffusion from the source in the presence of convection and chemical reaction then the steady state solution of the diffusion equation is (8)

$$\psi = \psi_0 \exp(-\lambda z) \qquad [1]$$

where ψ is the concentration of the component in the vapor phase; $\lambda = (U/2D) + [(U/2D)^2 + (k/D)]^{1/2}$, where D is the diffusion coefficient, U is the gas flow rate, k is an over-all first order rate constant, and z is the distance from the source. When Eq. [1] was applied to the measured distribution of silicon in Mo, the best agreement with the experimental data was obtained for $D_{Si/H_2} = 2.3$ (cm²/sec) and $k = 3.0$ (sec^{-1}). This value for the diffusion constant of silicon in hydrogen at 1600°C appears to be reasonable[1] and is taken as an indication that this mechanism of silicon vapor transfer is plausible under the given conditions.

The results of the above analysis are presented as solid lines in Fig. 6 for the various hydrogen flow rates investigated. No analysis for the carbon data was attempted since the carbon concentrations on the susceptor material were too low to permit an accurate analysis of its distribution.

It was also observed that higher effective etching rates on Ta susceptors occurred when a piece of Mo was placed on the primary susceptor near (but not in contact with) the α-SiC sample. This effect was found to decrease exponentially with distance of separation and became negligible when the distance of the Mo piece was in excess of 15 mm from the sample. At flow rates of 2 l/min such an increase in etching rate was observed on samples placed up or down-stream relative to the Mo piece.

These transport experiments constitute evidence of chemical interaction between the SiC sample and the susceptor. Evidence of chemical interaction was also present whenever etching occurred. At the lower temperatures the susceptor changed color underneath the sample. At higher temperatures the outline of the SiC sample was clearly imprinted on the susceptor by the interaction.

Discussion

It was found that the etching rates of α-SiC in hydrogen, argon, or helium are strongly dependent on the susceptor material on which the samples were inductively heated. It was also found that there was no visible interaction between SiC and the susceptor material unless etching of SiC took place. Apparently during the etching process carbon is removed from SiC as hydrocarbons and the silicon, which forms no stable gaseous compound at these temperatures, reaches the susceptor via surface diffusion or the vapor phase. The experimental results can be accounted for by assuming that a key step in the etching process is the formation of atomic hydrogen which interacts with the SiC to form stable volatile hydrocarbons. On this basis the etching rates should reflect the catalytic effectiveness of the susceptor in forming atomic hydrogen. Consistent with this requirement is the fact that the etching rate of Mo susceptors is much greater than on W susceptors, since it is well known that Mo is more effective than tungsten in converting molecular into atomic hydrogen (10). It should also be noted that the solubility of H_2 is greater in Mo than in W (11). Since the processes considered were not under equilibrium conditions no attempt was made to treat them thermodynamically.

It is not clear at present as to whether the atomic H reacts directly with SiC or with carbon resulting from the decomposition of SiC. It is of interest to note, however, that the reaction rate between graphite and hydrogen (below 2400°C) is directly proportional to the partial pressure of atomic hydrogen (7), and that

[1] A value of $D_{Si/H_2} = 3.2$ cm²/sec for 1100°K was calculated (9) using Chapman-Enskog parameters.

the apparent activation energy for the low temperature hydrogen-carbon reaction is very close to that observed for the etching process on Ta (Fig. 5).

Regarding the observed etching in inert atmospheres, it is believed that it is due in part to residual hydrogen being released from the susceptor upon heating. The materials employed as susceptors are known for dissolving hydrogen which they release slowly at high temperatures (12).

The Effect of Substrate Orientation on the Incorporation of Zinc and Selenium in Vapor-Grown Gallium Phosphide

R. C. Taylor*

International Business Machines Corporation, Research Division, Yorktown Heights, New York

ABSTRACT

Vapor-grown GaP doped with radioactive Zn^{65} and Se^{75} has been prepared by a halogen transport method. The dopant concentration in the crystals ranged from the mid 10^{15} to mid 10^{19} atoms/cm^3. By means of radiotracer and electrical measurements, it was found that the degree of incorporation of the dopant into the growing crystal is dependent on the substrate orientation. Zinc was incorporated into (111)A face growths more readily than into (111)B face growths by a factor of from 12- to 25-fold, depending on zinc concentration in the vapor. Selenium was incorporated into (111)B face growths more readily than into (111)A face growths by a factor of from 4- to 35-fold. Growths on (100) or (110) substrates accepted zinc or selenium dopants to about the same extent as the preferentially doped polar [(111)A or (111)B] face. It was found that selenium had a limit of solubility in an electrically active form of about 4×10^{18} cm^{-3}. The solubility limit for zinc was not reached at 10^{19} cm^{-3}. Studies were also made of undoped and selenium doped growths on higher index orientations. A model is presented to account for the observed orientation effect based on the properties of the (111) double layer.

In earlier publications (1, 2), we reported the effect of substrate orientation on the electrical, optical, and paramagnetic resonance properties of vapor-grown GaP, both undoped and doped with sulfur or selenium. The orientations studied were the polar (111)A (Group III atom) and (111)B (Group V atom) surfaces. It was found that donor impurities were apparently incorporated far more readily into growths on (111)B substrates. Nominally undoped GaP deposited onto (111)B substrates of either GaAs or GaP was n-type and had a resistivity of about 1 ohm-cm, a carrier concentration in the low 10^{16} cm^{-3} range due to a residual sulfur impurity, and a mobility of 170-190 cm^2/v-sec at room temperature. Undoped samples grown on (111)A substrates were high-resistivity (10^3-10^4 ohm-cm) p-type due to a deep acceptor impurity. Growth in sulfur or selenium dopant fluxes sufficient to increase the carrier concentration of (111)B face growths to the low 10^{17} cm^{-3} range increased the resistivity of the still p-type (111)A face growths by two orders of magnitude due to compensation. Similar orientation dependence has also been reported for vapor-grown GaAs (3, 4) and for GaP deposited on GaAs (5).

In the present investigation, in order to gain a more quantitative picture of the magnitude of the effect of substrate orientation on impurity incorporation, radiotracer techniques were employed in conjunction with electrical measurements to determine the true dopant concentrations. Radioactive Se^{75} and Zn^{65} were selected as the dopants so that both donor and acceptor incorporation could be studied. Studies were also extended to the (100) and (110) basic planes with radioactive Zn and Se doping and to higher index planes with no doping and with nonradioactive Se doping.

Experimental

The vapor-grown GaP crystals were prepared by a phosphorous trichloride transport method (1, 6). The apparatus and growth conditions used were the same

* Electrochemical Society Active Member.

as those of Ref. (1). The gallium source temperature was 900°C, the substrate temperature 800°C, and the total hydrogen flow rate was 100 cc/min, of which 50 cc/min passed through the PCl_3 bubbler at −30°C to give a PCl_3 flux of 1.2×10^{-3} moles/hr. In order to employ radioactive species, the H_2Se tank normally used in doping was replaced by hydrogen, and pellets of the radioactive elements were placed in the doping line at the appropriate temperature to attain the desired vapor pressure. When radioactive Zn and Se were in use, 20% of the hydrogen diluent gas was passed over the radioactive material. Depending on the dopant temperature, this resulted in a dopant flux of between 10^{-10} and 10^{-5} moles/hr.

Gallium arsenide substrates were cut from Czochralski pulled crystals. When nominal (111)A and (111)B growths were made, the GaAs substrates were actually oriented 2° off the basic planes. The substrates were mechanically and chemically polished with an H_2SO_4-H_2O_2 etch before introduction into the system. In most cases of (111) growth, A and B oriented substrates were mounted side by side on a vertical holder so that growth occurred on both in the same run.

Average growth rates were 14 μ/hr on (111)A faces, 8 μ/hr on (111)B faces, and 10 μ/hr on (100) and (110) faces. Film thicknesses were approximately 250μ.

After removal of substrates and edge growth, the same section of each GaP growth was used for both radiotracer and electrical measurements. Radiotracer measurements were done by gamma scintillation counting and the Van der Pauw method was used for the electrical measurements. In order to check for doping uniformity through the thickness of the samples, the growths were lapped and remeasured several times. No significant gradients were found.

Results

Zn^{65} and Se^{75} doping of growths on (111)A and (111)B planes.—The results of doping (111)A and (111)B face GaP growths with Zn^{65} and Se^{75} are shown in Tables I and II. The only variable in the growth conditions was the dopant vapor pressure which increases from the top of the tables to the bottom. Each pair of (111)A and (111)B samples was grown in the same run to insure identical conditions. With the exception of 589 and 590, all samples were grown on GaAs substrates. It is clear from both the radiotracer and electrical data that (111)A face growths incorporate Zn far more readily than do (111)B face growths, while the heaviest Se doping is found in samples grown on (111)B faces.

Zinc-doped crystals grown on (111)A faces show a uniform increase in carrier concentration and Zn^{65} concentration as the Zn vapor pressure increases, with a corresponding decrease in resistivity and mobility. Liquid nitrogen electrical data show a carrier freezeout of two orders of magnitude at the low zinc concentrations and no freezeout at the higher concentrations, indicating impurity band conduction at about 10^{18} cm^{-3} (7). The superiority of GaP substrates which was demonstrated in Ref. (1) for n-type samples is shown here for p-type samples by the fact that sample 589 had a liquid nitrogen mobility of 1873 cm^2/v-sec, far higher than any obtained when using GaAs substrates. This is probably due to superior crystal structure of samples grown on GaP substrates.

The properties of Zn-doped crystals grown on (111)B faces show that a very small amount of Zn is taken up on this face, insufficient in fact to compensate the residual background donor impurity in the first five samples. This impurity has been shown by photoluminescence to be sulfur, both by identification of the sulfur exciton line in undoped samples and the zinc-sulfur pair band in Zn-doped samples (1). The amount of sulfur impurity varies with purity of the PCl_3 and in this series of samples is $1\text{-}2 \times 10^{17}$ cm^{-3}, which is the concentration of Zn^{65} required to convert the crystals to p-type.

Selenium-doped crystals grown on (111)A faces show electrical behavior similar to that of the Zn-doped (111)B face growths. As in the Zn case, the lowest doping levels were not sufficient to compensate the carriers of the opposite type that were already present. These growths were high-resistivity p-type, as were undoped samples, until about 10^{16} Se^{75} atoms/cm^3 had been added. [We had previously found about 10^{16} cm^{-3} deep acceptors in (111)A face growths and tentatively identified them as Ga vacancies (2).]

In the more heavily doped (111)B face growths, the Se^{75} concentration and room-temperature carrier con-

centration increase with Se vapor pressure to about 2×10^{18} cm^{-3}. Above this point, Se^{75} concentration continues to rise while the carrier concentration levels off. (A temperature run on one sample showed that $N_d - N_a$ became independent of temperature at 4×10^{18} at about 400°C. This sample had a room-temperature carrier concentration of 2.1×10^{18} and a Se^{75} concentration of 1.3×10^{19} cm^{-3}.) The solubility limit of Se in an electrically active form has been reported by Trumbore (8). Above 4×10^{18} cm^{-3}, Se probably enters the GaP lattice in the form of Se precipitates or neutral complexes such as $V_{Ga}Se_3$ as has been proposed for Se in GaAs (9, 10). It should be remembered that undoped (111)B face growths contain 10^{16}-10^{17} carriers cm^{-3} due to a sulfur impurity so the electrical carrier concentration figures are a sum of the ionized sulfur plus selenium.

The magnitude of the effect of substrate orientation [(111)A and (111)B] on the incorporation of Zn and Se in GaP growths as determined from the radiotracer data is shown in Fig. 1. The ratio of Zn^{65} in GaP grown on a (111)A face to that on a (111)B face is plotted against the Zn^{65} in the (111)A face growths, and the ratio of Se^{75} in (111)B face growths to that in (111)A face growths is plotted against the Se^{75} in the (111)B face growths. It can be seen that, with Zn doping, the orientation effect ratio [Zn on (111)A to Zn on (111)B] increases with decreasing Zn concentration from 12 at 1.4×10^{19} cm^{-3} to 24 at 3.9×10^{17} cm^{-3}. The fact that the highest ratio, 39, does not fall on the line through the other data might be due to the use of GaP substrates for that pair. The concentration dependence of the orientation effect for Se doping is greater than in the Zn case and is in the reverse direction. The ratio increases with increasing Se concentration from 4 at 1.4×10^{16} cm^{-3} to 37 at 3.0×10^{18} cm^{-3}. Points above this concentration are possibly unreliable due to formation of Se precipitates or gallium selenide.

In Fig. 2 and 3, we have plotted the effect of dopant flux on Zn incorporation in GaP grown on (111)A substrates and on Se incorporation in GaP grown on (111)B substrates. The Zn^{65} line in Fig. 2 and the Se^{75} line in Fig. 3 were obtained from samples for which the dopant pellets were weighed before and after the run to determine the number of moles transported and then the resulting Zn^{65} and Se^{75} concentrations were measured in the GaP growths. The carrier concentration lines show the room-temperature carrier concentrations corresponding to the radiotracer concentrations from Tables I and II. In the cases of both Zn^{65} and Se^{75} doping, there is an approximately linear dependence of dopant in the GaP growth on dopant concentration in the vapor. The carrier concentration line in Fig. 3 clearly shows the electrically active solubility limit of Se in the GaP. The corresponding line in Fig. 2 shows that no precipitation or separation of Zn in an inactive form is evident up to a concentration of 10^{19} cm^{-3}.

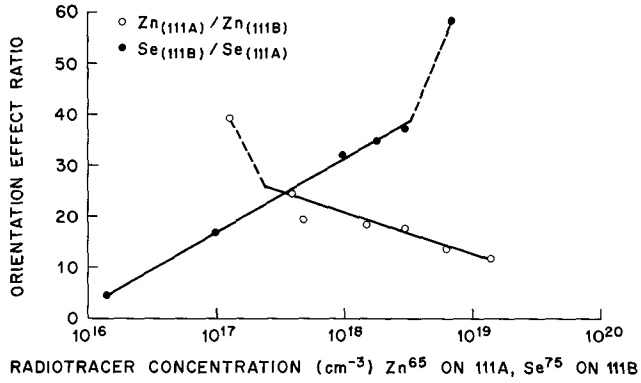

Fig. 1. Concentration dependence of the orientation effect for Zn and Se doping of (111)A and (111)B face GaP growths.

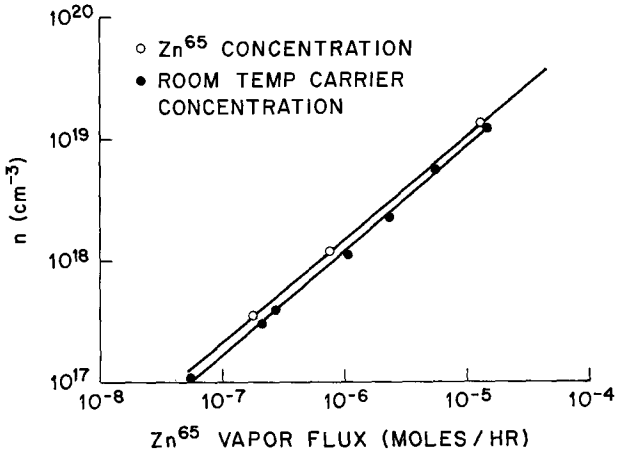

Fig. 2. The effect of zinc vapor flux on Zn^{65} concentration and room-temperature carrier concentration in GaP grown on (111)A substrates.

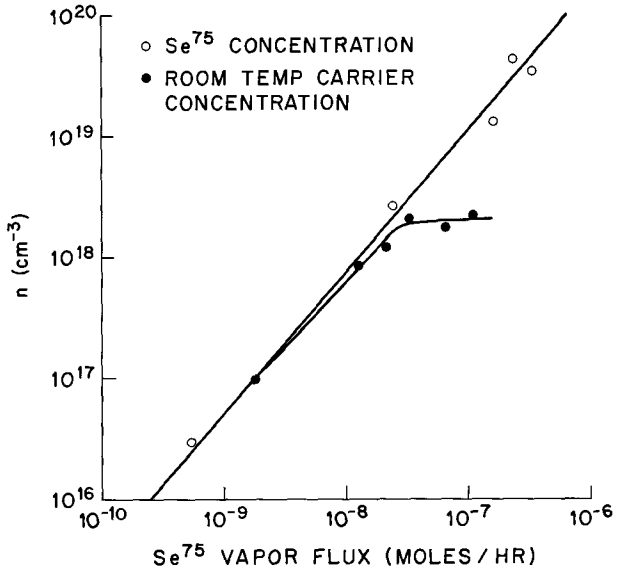

Fig. 3. The effect of selenium vapor flux on Se^{75} concentration and room temperature carrier concentration in GaP grown on (111)B substrates.

Although no runs were actually made in which both Zn and Se were present in the vapor at the same time, an idea of the results may be had by combining the data for Zn and Se doping and assuming no vapor phase interaction between the dopants. The data for Zn and Se doping of both (111)A and (111)B face growths is plotted against dopant flux in Fig. 4. The interesting thing to note is that, in the dopant flux region where the data overlap, the lines for Se doping of a (111)A face growth and Zn doping of a (111)A face growth coincide, and both have the same slope. Thus, while Se prefers (111)B face growths and Zn prefers (111)A face growths, the (111)A face has no preference as to which one it incorporates and is more inert toward both than the (111)B face is to Se. The large effect is that the (111)B face prefers Se to Zn by a factor of 1000. Therefore, when both Se and Zn are present in the vapor in equal concentrations, a (111)A face growth should be compensated and a (111)B face growth should be strongly n-type. These observations might be a fortuitous combination of the orientation effect and dopant distribution coefficients and apply only to the case of Zn and Se under the conditions of these experiments.

There was an interesting effect of Se doping on the growth rates of (111)A and (111)B face growths and on the surface morphology of (111)B face growths.

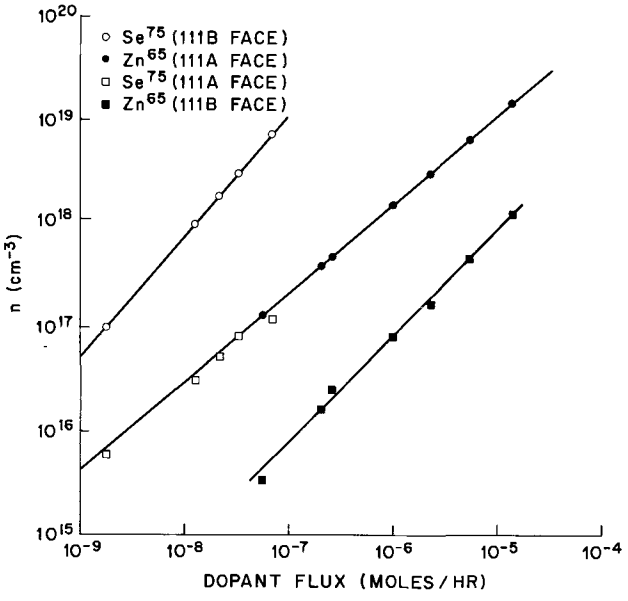

Fig. 4. The effect of dopant flux on Zn^{65} and Se^{75} concentration in GaP crystals grown on (111)A and (111)B substrates.

Zinc doping had no effect on either. When the Se concentration on (111)B face growths reaches the mid 10^{19} cm^{-3} range, the growth rate abruptly changes from the normal 8 μ/hr to about 2 μ/hr. When the concentration on (111)A face growths reaches the mid 10^{18} cm^{-3} range, the rate changes from 14 μ/hr to about 20 μ/hr. This occurs both when the two faces are growing together in the same run or when the two faces are introduced into the system separately. The change on the (111)B face could be due to the formation of selenium precipitates causing strain and impeding normal growth, but there is no apparent reason for the increase in the (111)A growth rate. Such a decrease in growth rate was reported by Hara and Akasaki (11) in sulfur-doped, vapor-grown GaP. However the decrease cannot be due to depletion of GaCl vapor by formation of Ga chalcogenides as they postulated, or the (111)A face growth rate would also decrease. The drop in rate must be associated with changes at the crystal surface. Changes in growth rate and morphology of epitaxial GaAs with doping level have also been reported (12).

The effect of Se concentration on (111)B growth surface morphology is shown in Fig. 5. The greatest change in the surface morphology occurs in the low 10^{18} cm^{-3} range where there is relatively little change in the orientation effect ratio [Se on (111)B to Se on (111)A]. The morphology change is probably associated with the appearance of Se precipitates, and does not occur on (111)A face growths. X-ray studies showed all of these growths to be single crystal.

Zn^{65} and Se^{75} doping of growths on (100) and (110) planes.—Zn^{65} and Se^{75} doped GaP growths were also made on the other two basic orientations, (100) and (110). The results of the radiotracer measurements on Zn-doped samples are given in Table III. The dopant flux for these samples, as determined from the weight loss of the Zn pellet, was 3.6×10^{-7} moles/hr. The values in the table for (111)A and (111)B orientations are those that would be expected from Fig. 1 and 2 for this dopant flux. The Se^{75} radiotracer and electrical results are given in Table IV. The (111)A and (111)B data are for two samples from Table II grown at the same Se pressure. It can be seen that for both Zn and Se doping, the GaP grown on (100) and (110) faces incorporates the dopant to about the same degree as does the GaP grown on the preferentially doped polar face. Zinc is taken up in (100) and (110) growths almost as well as in (111)A growths and the Se uptake in (100) and (110) growths is close

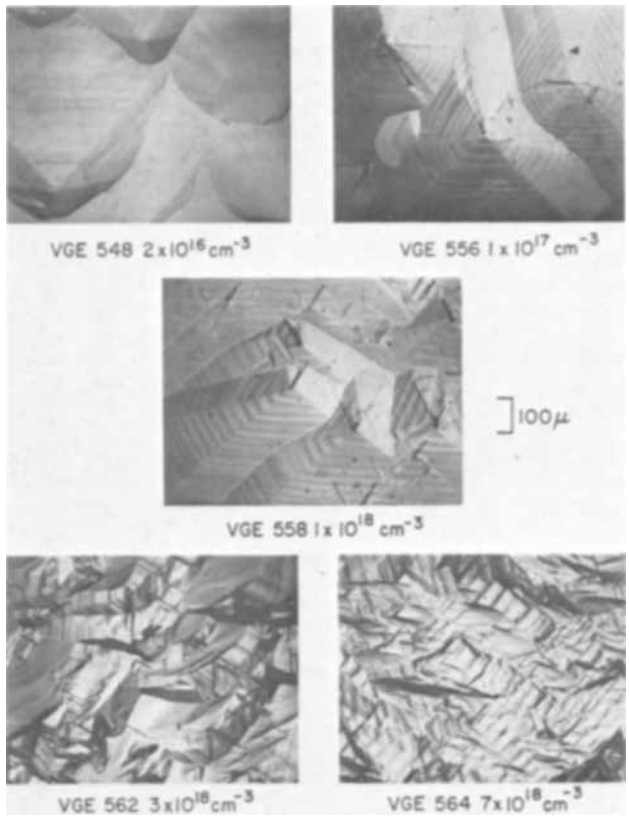

Fig. 5. The effect of selenium concentration on the surface morphology of GaP crystals grown on (111)B substrates.

to that in (111)B growths. The electrical data, while giving the correct relative order of dopant incorporation on the basic planes, do not show the true magnitude of the orientation effect due to varying degrees of compensation. A nominally undoped (110) growth is n-type with a resistivity of 50-100 ohm-cm, a carrier concentration in the low 10^{16} cm^{-3} range, and low mobility. Undoped (100) growths are n-type with a resistivity of 10^3 to 10^4 ohm-cm.

Growth on higher index planes.—In order to see if misorientation from the basic (111) plane had any effect on the anisotropy of impurity incorporation, several higher index planes were studied. The planes were misorientations from the (111) plane in the direction of both the (100) plane [(h11) planes] and the (110) plane [(hh1) planes]. For example, the misorientation in the (100) direction was 5°, 10°, 19.3° [(211) plane], and 29.4° [(311) plane]. Also included was the (310) plane which is a (h10) plane. The complete list of orientations studied is shown in the stereographic triangle of Fig. 6. With the exception of the (100) and (110) planes, both the "A" and "B" faces of each orientation were investigated by slicing the wafers in half, reversing one half, and growing on both halves in the same run. The A and B faces of all the (h11) and (hh1) orientations were distinguishable with a standard $NaOH-H_2O_2$ etch.

In all cases, with the exception of the (100), (110), and (310) planes, there was a pronounced orientation effect on electrical properties of the deposited GaP. All undoped samples grown on "B" faces were n-type with

Table III. Zn^{65} doping of basic planes

Sample No.	Substrate orient.	Zn^{65} (cm^{-3})	$\frac{Zn^{65}_{(111A)}}{Zn^{65}_{(basic)}}$
609	(110)	2.8×10^{17}	2.2

—	(111)A	6.2×10^{17}	1.0
—	(111)B	2.8×10^{16}	22.2

Table IV. Se^{75} doping of basic planes

Sample No.	Substrate orient.	Se^{75} conc (cm^{-3})	$\frac{Se_{(111B)}}{Se_{(basic)}}$	Cond. type	ρ (ohm-cm) RT	n (cm^{-3}) RT	μ (cm^2/v-sec) RT
557	(111)A	5.2×10^{18}	34.7	n	4.0	2.0×10^{16}	78
558	(111)B	1.8×10^{18}	1.0	n	0.057	1.2×10^{18}	90
559	(100)	5.3×10^{17}	3.4	n	0.52	9.9×10^{16}	121
560	(110)	1.6×10^{18}	1.1	n	0.33	4.0×10^{17}	47

resistivities between 0.1 and 10 ohm-cm and carrier concentrations of 2×10^{16} to 4×10^{17} cm^{-3} (depending on the purity of the PCl_3 used). "A" face growths were either p-type or semi-insulating with resistivities of 10^5 ohm-cm and higher. Carrier concentrations, where measurable, were 10^{12} cm^{-3} or less. Similar findings were made by Groves (5) on growths on (211) planes. Properties of undoped growths on (100) and (110) planes were mentioned in the previous section. Growths on both sides of the (310) wafer were n-type with resistivity of about 50 ohm-cm and a carrier concentration in the low 10^{16} cm^{-3} range. Growths were also made on the above orientations using hydrogen selenide doping. No radioactive species were present for a quantitative determination, but electrical measurements showed the persistence of the orientation effect. It is clear therefore that the orientation effect exists on all (h11) and (hh1) planes, and does not exist on (h10) planes. In the absence of radiotracer data, it is difficult to know if there is any diminution of the effect as misorientation from the (111) plane increases.

Surface morphology of growths was significantly affected by misorientation from the (111) plane, and in each (h11) and (hh1) higher index orientation there was a substantial difference between the "A" and "B" morphologies. There was no difference in morphology between growths on the two sides of the (310) plane. Misorientation from the (111) plane had little effect on the growth rates of undoped growths on the "A" and "B" faces.

Discussion

Some of the more striking features about Zn and Se doping of vapor-grown GaP that are brought out by the radiotracer and electrical data are: the linear dependence of dopant concentration in the crystal on dopant flux in the vapor; the opposite direction of the concentration dependence of the orientation effect in the case of Zn and Se; the persistence of the orientation effect on all (h11) and (hh1) planes and the absence of the effect on (h10) planes; the similarity in behavior between the (100) and (110) planes and the preferentially doped polar plane for both Zn and Se doping.

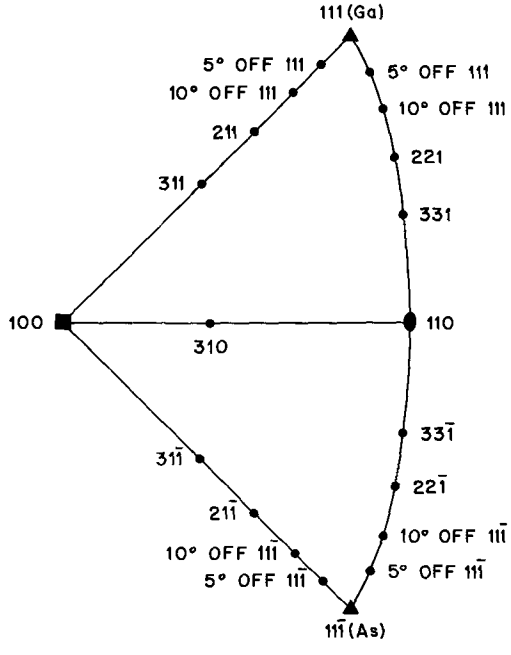

Fig. 6. Stereographic triangle showing the higher index and basic orientations studied in section on *Growth on higher index planes.*

The approximately linear dependence of dopant concentration in the crystal on dopant flux is surprising in that the 800°C growth temperature is well within the extrinsic region for Zn- and Se-doped GaP. According to the model presented by Kroger (13) for equilibrium doping of an extrinsic semiconductor, there should be a square root dependence of ionized acceptor or donor concentration on the vapor concentration of the dopant, and at 800°C all of the zinc and selenium are ionized. A linear dependence should occur only in the intrinsic semiconducting region. Trumbore (8) did find a square root dependence for Zn-doped solution-grown GaP, but a linear dependence for Se-doped material at carrier concentrations where extrinsic behavior was expected. A linear dependence was observed by Luther (14) for Zn-doped, vapor-grown GaP and a linear dependence has been found for Cd-doped, vapor-grown GaP (14, 15). Zinc and Se doping of GaP during vapor growth therefore appears to be a non-equilibrium process.

The direction of the concentration dependence of the Se-doping orientation effect suggests that the effect will disappear when the (111)B growth Se concentration falls to the low 10^{15} cm^{-3} range. It is possible that at such low concentrations the doping becomes an equilibrium process, the deposition being limited only by the input rate of the selenium and independent of the substrate surface. As the selenium pressure increases, the incorporation into the crystal becomes a kinetically controlled process and more and more orientation dependent. Other investigators reporting orientation effects have dealt with concentrations in the range of 10^{17} carriers cm^{-3} and above for donors on (111)B faces (3, 5). There is no obvious explanation for the opposite direction of the concentration dependence of the orientation effect for Zn doping. It is possible that surface nucleation sites become saturated at the higher concentrations so that incorporation on (111)A surfaces is lessened. The effect might also be related to the fact that the diffusion coefficient of Zn is far greater than that of Se in GaP, and that the diffusion coefficient increases with Zn concentration (16). This might allow for redistribution of the Zn in the heavily doped (111)A growths in such a way as to lessen the orientation effect. The approach to equilibrium which might be occurring in Se doping would not be observable with the Zn since higher dopant concentrations are present.

The persistence of the polarity orientation effect through all of the (h11) and (hh1) higher index planes may possibly be explained on the basis of Sangster's model (17). According to this model, all high-index nonbasic orientations are stepped structures consisting of "treads" and "risers" of the basic planes. The (h11) planes are stepped structures consisting of (100) treads and (111) risers and the (hh1) planes are composed of (111) treads and (110) risers. All of these planes can be resolved into stacks of (111) double layers. Thus, aside from the fact that the planes are stepped, they have essentially (111) characteristics and would be

expected to show the polar nature of the basic (111) plane. When h becomes greater than 5 on (h11) planes, the axes become indistinguishable from (100) so that the polarity effect should cease. This has been confirmed in the case of GaAs growth rates by Shaw (18). The (h10) planes *e.g.*, (310) and (210), which are combinations of (100) and (110) planes, are composed of (100) treads and (110) risers and should therefore show no polarity effects.

The behavior of GaP growths on (100) and (110) faces suggests that there is a similar mechanism involved in Zn incorporation on (111)A, (100), and (110) planes and in Se incorporation on (111)B, (100), and (110) planes. The similarity can again be found in Sangster's model of the nucleation and growth process on the basic planes. A Zn atom being incorporated into GaP on a Ga site on a (111)A, (100), or (110) plane will attach itself to two surface P atoms with no increase in dangling surface bonds and no nucleation barrier. In contrast, on a (111)B surface the Zn atom will attach itself to only one surface P atom. It will be loosely held and in the presence of low Zn pressure in the vapor stream might tend to re-evaporate. The analogous situation exists with Se doping. Selenium going onto a P site in GaP will bond to two surface Ga atoms on (111)B, (100), and (110) surfaces, but to only one on a (111)A surface.

Technical Notes

Sparking Voltages Observed on Anodization of Some Valve Metals

R. S. Alwitt* and A. K. Vijh*

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

Wood and Pearson (1) recently presented some experimental results for breakdown voltages of anodic oxide films on valve metals. Breakdown voltage was defined as the voltage at which visible sparking was observed to start or, in the absence of sparking, the steady voltage that was achieved at constant current. We have repeated some of their measurements and extended the work to another electrolyte system. Our results are in general agreement with those of Wood and Pearson except for the case of aluminum. This difference is critical since it weakens a correlation presented by those authors and suggests some other correlations which are presented here.

Wood and Pearson attempted to associate the tendency for breakdown with the type of bonding in the oxide. It is essential to explore such connections between electrical and other properties in order to arrive at a unified theory of the properties of anodic oxides. An important point in their analysis is that a higher melting point corresponds to a greater degree of ionic bonding. However, for at least some of these oxides the dependence of melting point on cohesive forces (2) indicates the opposite, a higher melting point corresponds to a greater degree of covalent bonding. This point will be pursued in the Discussion Section.

Experimental

Foil and wire specimens of aluminum, niobium, tantalum, and zirconium, of the highest purity available, were chemically polished and then anodized at room temperature in either 3% aqueous ammonium tartrate or 39% w/w ammonium pentaborate in ethylene glycol. The anodization current density was 0.5 ma/cm^2 in all cases except for zirconium in ammonium tartrate where 5 ma/cm^2 was used because of the low current efficiency for oxide formation.

Table I. Comparison of sparking voltages in two electrolytes

Metal	Purity, %	Type	Sparking voltage: Glycol borate	Sparking voltage: 3% NH_4 tartrate: Our results	Sparking voltage: 3% NH_4 tartrate: Wood & Pearson	Dielectric constant	$-\Delta H_f$/eq, kcal/eq
Al	99.97	Foil	442		245	8-10	65.3
	99.99	Wire	—	350 (210)	—		
Zr	99.88 + 0.1 Hf	Foil	325 (200)	315 (100)	300	22-25	64.6
Ta	99.9+ (electronic grade)	1 mil Foil	250	275 (205)	195-200	28	50.0
		0.5 mil Foil	—	205			
Nb	(electronic grade)	Foil	215	190	165-190	41	46.3
		Wire	—	170	—		

Notes: 1. Sparking voltage defined as voltage at which sparking began over entire sample surface, accompanied by rapid voltage fluctuations.
2. Voltages in parentheses indicate approximate points where large decrease in dV/dt occurred usually accompanied by gas evolution.

Results

Our observations of anodization and subsequent breakdown were similar to those reported by Wood and Pearson. The notable exception was that we saw sparking with all metals, including aluminum. For aluminum in ammonium tartrate this was achieved by taking great care to eliminate sources of contamination in both the electrolyte and the atmosphere above the solution. Otherwise, no sparking was observed and voltages close to those reported by Wood and Pearson were obtained, with corrosion on the specimen stem at the solution/air interface.

The breakdown voltages we observed are listed in Table I along with values taken from Table III of Wood and Pearson (1). The ranking of metals in both electrolytes was the same, but differed from the results of Wood and Pearson in that the breakdown voltage for aluminum was higher than that for zirconium. For the cases of tantalum and niobium, use of metal obtained from different sources did not affect the ranking.

Discussion

The fact that we observed the same ranking of breakdown voltage in two electrolytes of very different composition makes more tenable the suggestion advanced by Wood and Pearson (1) that sparking breakdown reflects some basic property of the oxides. Certainly this same ranking would not be realized in all electrolytes, probably because of chemical interactions between solute species and oxide. Aluminum is particularly susceptible to such complications. A glycol borate electrolyte was chosen for this study since this system was known to produce an amorphous oxide on aluminum at 100% current efficiency with little incorporation of species from the electrolyte (3). It is believed that under the conditions of these experiments the tartrate electrolyte behaves very much like the glycol borate.

Because of the higher sparking voltage obtained with aluminum, our results offer no correlation with oxide melting point. We do find an inverse correlation between sparking voltage and oxide dielectric constant (1) (Table I), and direct correlation with both a-c resistivity of the oxide (4) and heat of formation per equivalent (5) (Table I).

Since the sparking voltage is a poorly defined property of a complex phenomenon it is difficult to assign a physical significance to these correlations. It has been shown for many compounds, including valve metal oxides, that $-\Delta H_f$/eq. is approximately equal to half the value of the forbidden band gap (5). This suggests a correlation between sparking voltage and band gap which would reflect the often cited (but as yet unproven) electronic nature of the breakdown.

Although a correlation between sparking voltage and melting point is no longer found to exist, the attempt of Wood and Pearson (1) to connect a higher melting point with increased ionic bonding merits further discussion. It has been demonstrated recently (2) that the melting points of these oxides increase systematically with increasing heats of atomization per equivalent (*i.e.*, approximate values of average metal-oxygen bond energies) and not with lattice energies per equivalent. This is illustrated in Fig. 1. Bond energies emphasize the covalent aspects of cohesion whereas lattice energies represent the ionic aspects (2). This indicates that the melting point is largely determined by the covalent part of the bonding. It has been concluded elsewhere (2) that various properties diagnostic of electrical and thermal stability of these oxides are largely influenced by bond energy and not by lattice energy. The dielectric breakdown is probably related to the thermal and electrical stability of these materials.

It is important to emphasize that the ionic component of solid-state cohesion is denoted accurately only by lattice energies. Secondary quantities like melting points and (calculated) per cent ionic character are only crude measures of ionic cohesion in solids and are valid only for extremely ionic compounds, such as fluorides of the alkali and alkaline earth metals.

If per cent ionic character of solids is to be calculated, the criteria of Wells are to be preferred to those of Pauling, since it has been recently pointed out that Pauling's criteria for determining ionicity yield gross overestimates of ionic character when applied to solids (6). Wells' procedure predicts predominantly covalent character for these oxides as indicated by the calculations of Wood and Pearson.

Some recent experiments, modelled after those of Waring and Benjamini on silicon (7), deserve brief mention here since they may stimulate further consideration of the sparking process on valve metals.

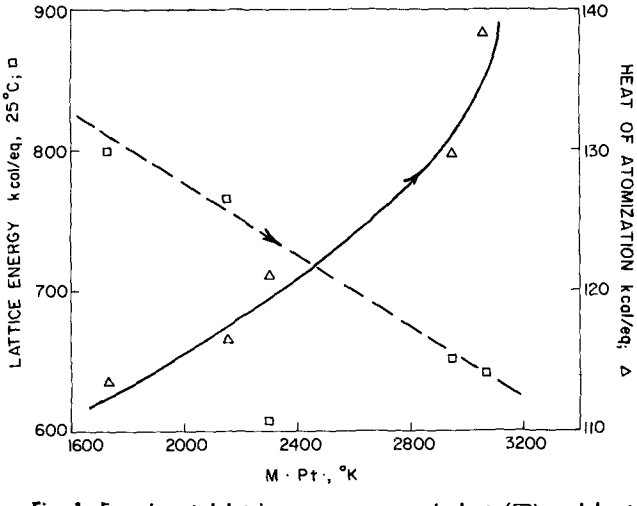

Fig. 1. Experimental lattice energy per equivalent (□) and heat of atomization per equivalent (△) vs. melting point for ZrO_2, HfO_2, Al_2O_3, Ta_2O_5, and Nb_2O_5; for details, see ref. (2).

Waring and Benjamini observed sparking during the anodization of silicon in a solution of KNO_3 in ethylene glycol. To help determine the region in which the sparks were generated they bubbled neon against the silicon wafer. When these bubbles passed near a spark they gave a brilliant red-orange flash characteristic of a neon discharge. From this they concluded that the sparks were associated with a strong field that extended into the solution.

In our experiments on Al, Ta, and Zr anodes in the glycol borate electrolyte the same characteristic neon flashes were observed. On each of these metals, as well as on Si (7), copious gas evolution accompanied sparking. This suggests that sparking may be the electrical discharge through gas generated at the anode surface. When neon becomes mixed with this gas it imparts its characteristic color to the discharge.

However, when the experiment was conducted in the aqueous tartrate electrolyte no red flashes were seen on Nb, Ta, or Zr anodes even though considerable sparking was evident. It was thought significant that in this aqueous solution oxygen is probably the gas generated at the anode, whereas it has been found in our laboratory that the gas generated at Al anodes in the glycol borate electrolyte is a mixture of CO, H_2, and CH_4 (8). Mixtures of neon with each of these three gases were bubbled against Ta anodes in the aqueous tartrate electrolyte, but in no case could a neon discharge be produced.

Thus, when glycol is the electrolyte solvent an effect due to sparking can be detected on the solution side of the oxide/solution interface. In an aqueous electrolyte the same test provides no information. We cannot yet offer an explanation for this.

Acknowledgments

Point Defect Concentrations as an Aid in Calculating Thermodynamic Activities

C. G. Carson, III, W. R. Bitler, and G. Simkovich

Metallurgy Section, Department of Materials Science, The Pennsylvania State University, University Park, Pennsylvania

Since the definition of thermodynamic activity and activity coefficient by Lewis (1), the determination of these quantities has been the concern of many investigators. A large number of experimental methods for determining these quantities have evolved through the years (2). Techniques for subsequent evaluation of activities within multicomponent systems by integration of the Gibbs-Duhem equation also have been advanced considerably during this time (3-6).

During an investigation on the effect of nonhydrostatic stress on the activity of interstitials in solid solution, it was necessary to obtain thermodynamic data on the lithium-tin system. This note deals with a method for deriving such data, which, while based on the familiar concepts of the defect solid state (7), to the writers' knowledge has not been utilized as a means of determining thermodynamic activities. The main purpose of this note is to draw attention to the method outlined as a possible means of obtaining thermodynamic activities in a few selected systems which might prove difficult to measure by other more standard methods (2).

In the following the most important assumption that is made is that the activity coefficients of the charged point defect species remain constant over the range of interest. Such an assumption, often made in defect chemistry studies (8), implies that the defect concentrations fall within the range where Henry's law holds, *i.e.*, the dilute solution range.

Consider first the dissolution of a donor atom, *e.g.*, lithium, into pure elemental semiconductor silicon

$$D_{(g)} = D^+ + n \qquad [1]$$

where D^+ indicates a donor positively charged with respect to the undisturbed lattice and n denotes a quasi-free electron. If the concentrations of these defects are less than the degeneracy limit and the donor is completely ionized, one may apply the mass action principle to Eq. [1] to obtain

$$K_1 = \frac{N_{D^+}{}^{0} N_n{}^{0}}{P_{D(g)}{}^{0}} \qquad [2]$$

where N indicates the concentration of the species, and the superscript zero indicates the selected standard state for the species considered.

We assume that the silicon is doped only with the donor, D, and that the intrinsic concentrations of defects are small in comparison to the donor concentrations. Under these assumptions, electrical neutrality requires

$$N_{D^+}{}^{0} = N_n{}^{0} \qquad [3]$$

so that Eq. [2] may be written

$$K_1 = \frac{(N_{D^+}{}^{0})^2}{P_{D(g)}{}^{0}} = \frac{(N_n{}^{0})^2}{P_{D(g)}{}^{0}} \qquad [4]$$

If we now consider the dissolution into silicon of a donor from a binary or multicomponent alloy, whose components other than the donor are insoluble in silicon, and follow the procedure leading to Eq. [4], we obtain

$$K_1 = \frac{N_{D^+} N_n}{P_{\underline{D}(g)}} = \frac{(N_{D^+})^2}{P_{\underline{D}(g)}} = \frac{(N_n)^2}{P_{\underline{D}(g)}} \qquad [5]$$

where the underscored D indicates the donor in an external solution. Utilizing the definition of the activ-

ity of the i-th species, a_i, as

$$a_i = \frac{P_i}{P_i^\circ} \qquad [6]$$

and equating Eq. [4] and [5] yields, on rearranging

$$a_D = \frac{P_{D(g)}}{P_{D(g)}^\circ} = \left(\frac{N_{D^+}}{N_{D^+}^\circ}\right)^2 = \left(\frac{N_n}{N_n^\circ}\right)^2 \qquad [7]$$

Thus, if the assumptions made in arriving at Eq. [7] are correct, one may obtain the activities of the donor from measurement of the concentration of dissolved donor or the concentration of quasi-free electrons.

To obtain electron concentrations, one may, as one possibility, utilize electrical conductivity (κ) measurements. Since donor doped silicon crystals conduct mainly by the movement of electrons one has

$$\kappa = N_n \mu_n e \qquad [8]$$

where μ_n is the mobility of the electrons and e is the electronic charge. Substitution of Eq. [8] into Eq. [7] gives

$$a_D = \left(\frac{\kappa/\mu_n}{\kappa^\circ/\mu_n^\circ}\right)^2 \qquad [9]$$

Thus, measurement of the electrical conductivity and knowledge of the mobilities, which, it is noted, do change extensively over small concentration ranges (9), permits one to calculate the activity of the donor.

Should the concentration of intrinsic defects and the presence of other doping agents be significant in comparison to that of the donor, then these must also be taken into account.

Let us assume that such is the case and that the doping agent, other than the donor, is an acceptor, A.

The intrinsic equilibrium constant, K_{int}, relating concentrations of defects in silicon may be expressed as (8)

$$K_{int} = N_n N_p \qquad [10]$$

where p indicates a positive hole.

Charge neutrality, in the case where both acceptors and intrinsic defect concentrations are comparable to the donor, is given as

$$N_n + N_{A^-} = N_p + N_{D^+} \qquad [11]$$

where A^- indicates the acceptor, A, substituting for silicon and bearing an effective negative charge in comparison to the undisturbed lattice.

Use of Eq. [10] and [11] permits one to obtain the concentration of electrons as

$$N_n = \frac{N_{D^+} - N_{A^-} + [(N_{A^-} - N_{D^+})^2 + 4K_{int}]^{1/2}}{2} \qquad [12]$$

Once again, utilizing Eq. [2], [5], and [6], one may obtain

$$a_D = \frac{P_{D(g)}}{P_{D(g)}^\circ} = \frac{N_{D^+} N_n}{N_{D^+}^\circ N_n^\circ} \qquad [13]$$

Knowledge of K_{int} and the various defect concentrations permits one to calculate the activities of the donor through use of Eq. [12] and [13].

For example, consider the case of silicon in contact with a Li-Sn alloy melt. The equilibrium concentration of lithium ions in silicon in contact with pure lithium metal has been determined by Reiss *et al.* (10). The solubility of lithium in boron doped silicon in equilibrium with a lithium-tin alloy has been measured by Reiss and Fuller (11). From these data the activities of Li in the external phase, Li-Sn, is calculated utilizing Eq. [13] based on pure lithium as the selected standard state. Table I lists their pertinent data and the calculated activities for $T = 339°C$ with $K_{int} = (5.96 \times 10^{15})^2$ and for $T = 404°C$ with $K_{int} = (2.06 \times 10^{16})^2$.

Activity coefficients for the lithium in the Li-Sn system have also been calculated and are listed in Table I. Extreme negative deviation from Raoultian behavior is noted.

The lithium activities calculated show remarkable constancy considering the wide range of concentrations studied and indeed indicate that the assumptions made in arriving at Eq. [12] and [13] are valid.

It should be noted that at zero acceptor concentrations Eq. [12] reduces to

$$N_n = \frac{N_{D^+} + [N_{D^+}^2 + 4K_{int}]^{1/2}}{2} \qquad [14]$$

so that intrinsic concentrations may be neglected only when

$$N_{D^+}^2 > 4K_{int} \qquad [15]$$

Since information such as mobilities and concentrations of intrinsic defects is well known for the elemental semiconductors silicon and germanium the use of these substances in the method outlined requires the least amount of experimental effort. However, the application of this method to an ionic semiconductor or an ionic compound is also feasible.

Finally, it should be noted that although we have considered electrical conductivities as a means of measuring defect concentrations, any method giving these concentrations may be utilized.

In summary, we have outlined a method for obtaining activities of a component common to two condensed phases. The method utilizes the measurement of point defect concentrations in one of these phases and is based upon dilute solution theory. The method is restrictive but may, on occasion, prove useful in systems where concentrations and mobilities of point defects are well known.

Studies on Chlorate Cell Process

III. Depolarization of Cathodic Hydrogen Evolution in the Bipolar Chlorate Cell Process

Electrochemistry Department, Institute of Chemistry, Technology, and Metallurgy, Beograd, Yugoslavia

ABSTRACT

The cathode process of hydrogen evolution in chlorate cells, including possible depolarization, has not been studied to date. High hydrogen polarization at graphite electrodes delayed the industrial application of bipolar cells for more than 80 years. A new method of depolarization has been developed which consists of depositing on the cathode side of a graphite electrode metallic chromium and/or an addition of small amounts of molybdate. The finely divided cathode molybdenum deposit decreases the cathode polarization for the hydrogen evolution reaction (h.e.r.). The Tafel lines obtained on metallized graphite exhibit nearly the same slopes as the ones for the parent metals, but are shifted to more positive values. This represents a further extension of the methods for depolarized hydrogen cathode evolution with metallized graphite (8, 9).

Bipolar chlorate cells have found recent acceptance in industry because of their high permissible current densities, low potential drops in the electrodes, simple design, and high capacity (1, 2). The bipolar construction of the cell allows copper bus bars and their connections to graphite electrodes to be almost completely eliminated (except for the first and the last electrode connection). Thus, contact resistances are practically avoided. However, the higher the current density, the higher is the electrode polarization, especially at graphite electrodes. The aim of the present paper is to show that depolarization of h.e.r. on graphite can be achieved with a corresponding cell voltage reduction, to match that of iron cathodes, at least.

Some Aspects of the Depolarized Hydrogen Cathode Evolution together with Suppressed Hypochlorite Reduction

There are two possible cathode reactions that could take place inside chlorate cells:

(*a*) Hydrogen evolution (main reaction)
$2H_2O + 2e \rightarrow H_2 + 2OH^-$
(*b*) Reduction of hypochlorite (side reaction)
$ClO^- + H_2O + 2e \rightarrow Cl^- + 2OH^-$

The cathode current losses due to hypochlorite reduction are governed by diffusion of its ions toward the electrode surface and could be suppressed by concentration polarization at a high enough current density (3).

Müller (4) introduced dichromate addition to the electrolyte in the industrial chlorate cell process to suppress cathode hypochlorite reduction and to achieve a suitable *p*H buffering effect as well as iron corrosion inhibition. The chromate action was theoretically explained by the formation of a thin cathode surface layer, probably consisting of chromium oxides, which decreases the effective surface area and hence provides hypochlorite ion concentration polarization and thus prevents its cathodic reduction.

Nagai and Takei (5) reported practically complete suppression of cathodic reduction of hypochlorite ions at chromium-plated 18Cr-8Ni stainless steel. The electrolyte was without added chromate ions, which supported the theory established by Müller (4). However, unplated 18Cr-8Ni stainless steel by itself did not suppress hypochlorite cathode reduction (5).

It is well known that in electrolysis, even from acid solutions, the cathode diffusion layer is alkaline in respect to the bulk solution because of the h.e.r. and metal electrodeposition often is accompanied by hydroxide formation.

Vander Poorten (6) recently examined the reduction of chromic acid in the presence of chloride ions and pointed out by potentiostatic current/potential curves, some sudden transitions before hydrogen evolution, indicating the formation of a resistant layer on the electrode, which was considered as a "cathodic passivation" layer.

Wagner (7) showed theoretically that there exists a critical potential difference across the cathode diffusion boundary layer of the order of, or greater than, $kT/|z_i| \cdot e = 0.025/|z_i|$, (where k is the Boltzmann constant, T temperature in °K, z_i hypochlorite ion valence, or that of another reducible anion, and e the electronic charge), providing the adverse potential gradient for negatively charged hypochlorite ions so that their reduction is effectively suppressed. As long as the current density or potential difference is relatively low, chromate reduction takes place, but it will practically cease after a sufficient cathode layer of chromium oxide is formed. After that all anions, chromate as well as hypochlorite, will be repulsed by an adverse potential gradient. In this manner an effective diaphragm is formed without causing an excessive *IR*-drop or electrode polarization. The theoretical considerations of Wagner (7) are in accordance with results of Maroni *et al.* (10) and Kolthoff and Shams el Din (11).

Maroni *et al.* (10) showed the cathode reduction of hypochlorite to be governed by diffusion in sodium chloride solutions and the electrode potential to be changed to more positive value with sudden chromate addition, which then in a short time decreases to the previous one.

Kolthoff and Shams el Din (11) pointed out the appearance of a strongly adhering monomolecular film consisting of chromium oxide and hydroxide mixture, insoluble and resistant in strong acid solutions.

Effective depolarization of the h.e.r. can be obtained with a number of metals, as shown by Zholudev and Stender (13). However, precious metals are excluded for the present application because of high price and limited availability.

In previous papers, the authors (8, 9) have pointed out that thin cathode deposits of active metal forms of molybdenum or cobalt change the polarization characteristics of graphite for the h.e.r. The Tafel lines obtained on metallized graphite exhibit nearly the same slopes as the ones on molybdenum or cobalt metal, but are shifted to more positive values of potential.

Two methods of depolarization for the h.e.r. in bipolar chlorate cells with graphite electrodes have been

* Electrochemical Society Active Member.

developed. The first one results from an electrolytic chromium deposition over the whole surface of the cathode side of the graphite electrode in sufficient thickness that polarization characteristics similar to those of the deposited metal itself are obtained.

The second one, much simpler, more effective, and more economical, is based on the previously developed method of depolarization of the h.e.r. in mercury cell decomposers (8). This consists of depositing active molybdenum from molybdate in a negligible amount over the graphite cathode surface.

Molybdenum has a double effect: it decreases the polarization for the h.e.r., and it increases the potential gradient in the chromium oxide diaphragm. The latter effect results from the fact that all the current of the h.e.r. is now predominantly concentrated in fewer pores, *i.e.* only those at the bottom of which there are sites of an extremely small amount of molybdenum. The increased potential gradient effectively suppresses further reduction of chromate, molybdate, or hypochlorite in accordance with Wagner's theory (7).

Vanadium could be expected to have a similar effect.

The combination of the two methods seems also to be useful and effective.

Experimental

The effect of the depolarized h.e.r. has been studied by comparing the polarization curves on graphite, iron, 18Cr-8Ni stainless steel, chromium, molybdenum, cobalt, and on molybdenized, chromized, cobaltized, and vanadized surfaces of graphite. Two electrolytes for chlorate production were investigated: 310 gpl sodium chloride at *p*H 6.2 and 8.0, with chromate content of 4.8 gpl. Available chlorine concentrations during investigations were at steady state in respect to *p*H, load, and current density of prepolarization (14), and hence were equal in all measurements.

Cathodic polarization was carried out in an apparatus illustrated in Fig. 1. The intention was to achieve conditions as close as possible to those in industrial electrolytic chlorate production. Special precautions, such as pre-electrolytic purification treatment, were not undertaken since, in the range of current densities (1-300 ma/cm^2) of practical importance, the influence of impurities in reagent-grade sodium chloride solution can be neglected. The apparatus used was of glass-Teflon construction in order to avoid any organic material as impurity. The temperature was kept constant at 40°C ± 0.2°C by means of a water thermostat.

Cathode potentials were measured *vs.* SCE by means of VTVM (*p*H-mv meter type PHM 22R, Radiometer, Copenhagen). The tip of the Luggin capillary was about 0.03-0.05 cm diameter and touched the cathode. The pseudo-ohmic polarization at higher current densities was determined galvanostatically and subtracted from the measured values of potential.

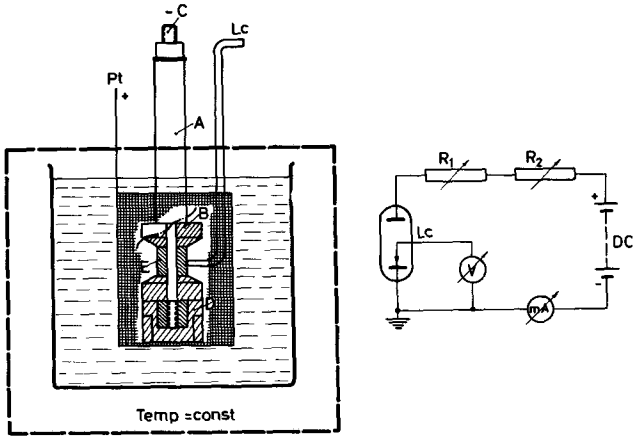

Fig. 1. Apparatus for measurement of hydrogen overpotential on various cathodes: Pt(+), Winkler platinum counterelectrode (anode); E, cathode of various materials; Lc, Luggin capillary; C, cathode connecting screw (nickel); D, Teflon fastener device with nickel nut; A and B, Teflon connections; mA, multirange milliammeter; V, vacuum-tube voltmeter; R_1 and R_2, variable resistors; DC, d-c supply.

Polarization curves were taken in the usual way using platinum counterelectrode and a saturated calomel reference electrode connected *via* a bridge to the Luggin capillary.

The approximate value of the emf of the galvanic cell

$$Pt(Pt)\ H_2/H_3O^+,\ 300\ gpl\ NaCl,\ H_2O//SCE$$

was calculated for *p*H 8.00 and 40°C, and overvoltages were obtained by subtracting this value (740 mv) from measured potentials.

Cathodic polarization of metallic chromium, cobalt, and molybdenum was carried out in the same apparatus as presented in the previous paper (8) since the metal electrodes were in the form of sheet.

The cathodes with exposed apparent surface areas of approximately 1.0 cm^2 (12 mm diameter) for sheet electrodes and 3.0 cm^2 for cylindrical electrodes were prepared as follows.

The molybdenum electrode was made of pure molybdenum sheet received from Climax Molybdenum Company, New York, type TZM [*cf.* (8)]. The electrode was mechanically polished and, after the usual cleaning with detergents, it was cathodically prepolarized in the investigated solution for 2 hr at a current of 100 ma.

The cobalt electrode was formed of electrolytically prepared pure cobalt sheet obtained from International Nickel Limited, London [*cf.* (9)] and prepolarized in the investigated solution, as was the molybdenum electrode.

The chromium electrode was formed of pure chromium sheet also obtained from International Nickel Limited, London, Batch GSKY, prepared electrolytically in the following purity: C, 0.01%; Al, 0.005%; Ni, 0.01/0.02%; Mn, 0.01%; Sn, 0.01/0.02%; Zn, 0.01%; B, 0.001%; Pb, 0.005%; Mo, 0.01%; Mg, 0.001%; Ti, 0.01%; S, 0.002%; Si, 0.01%; P, 0.005%. The electrode was mechanically polished and after proper cleaning with detergents it was cathodically prepolarized, as was the molybdenum one.

The mild steel [*cf.* (8)] and 18Cr-8Ni stainless steel electrodes were formed of technical materials, prepared and prepolarized as above.

Chlorate cell quality graphite blocks of SIGRI Elektrographit, Meitingen, type EKS special grade for chlorate cells, were carefully abraded with No. 600 grit emery cloth and then prepolarized as above.

Molybdenized graphite was obtained by submerging the prepared graphite electrodes in saturated sodium molybdate solution for 1 day, followed by immediate cathode prepolarization in the investigated solution as described for metallic molybdenum.

Cobaltized graphite was prepared by the procedure described in the previous paper (9).

Chromatized graphite was prepared as follows. Graphite blocks of SIGRI, type EKS, were carefully abraded and pretreated as described by Vaasos *et al.* (15), and then a chromium deposit was obtained from tetrachromate baths by the modified Bornhauser method (16). This consists of plating from a bath of chromic oxide (CrO_3) 300 gpl, NaOH 59-60 gpl, H_2SO_4 0.6-0.75 gpl, and ethanol (96%) 1 ml/liter, at a temperature of 16°-22°C and a current density of 150 amp/dm^2. The anode was insoluble Pb90-Sb10 alloy. Prepolarization was carried out as for all other electrodes.

Vanadized graphite was obtained by submerging the prepared graphite electrode in a saturated solution of sodium vanadate for 1 day, followed by immediate cathodic prepolarization in the investigated solution as for the other electrodes.

Polarization curves were also taken for electrodes made of the same graphite and impregnated with lin-

seed oil according to a recently described method (17).

All values presented in this paper refer to the electrolyte with 4.8 gpl of sodium chromate and at pH 8.0. At the pH value of 6.2, the Tafel lines were shifted to more negative values by about 30 mv. The reproducibility of potentials was better in the presence of chromate ions, though the values were practically the same.

Results and Discussion

The Tafel lines obtained for various electrodes are given in Fig. 2, 3, and 4. Reproducibility of the Tafel lines in ascending and descending direction of measurements repeated several times was better than ±10 mv.

The Tafel lines were fitted to the function

$$\eta = a - b \log i = b \log \frac{i_o}{i}$$

by the least-squares method for evaluating the slopes and intercepts (Table I).

Results show that the polarization characteristics of graphite have been changed considerably by depositing very small quantities of metal on its surface. The Tafel lines of metallized graphite for the h.e.r. are shifted to more positive values of potential, even compared to those for the metals themselves, while exhibiting nearly the same slopes.

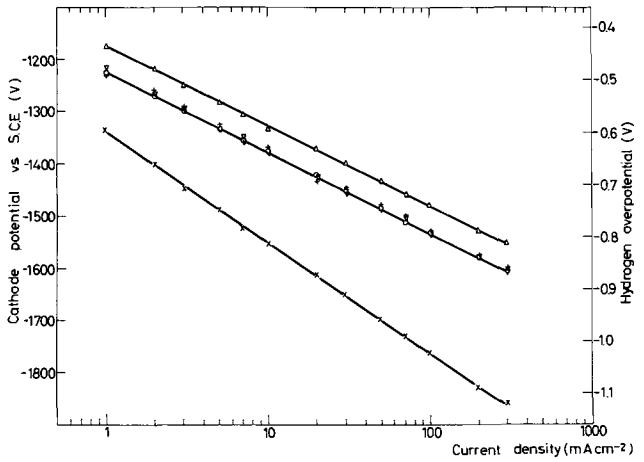

Fig. 4. Tafel plot of experimental results for various cathodes at 40°C: ×, graphite; ▽, 18Cr-8Ni stainless steel; +, chromatized graphite; ○, chromium; △, chromatized and molybdenized graphite.

The chromium deposit of 40-60μ thickness over the graphite surface shifts the Tafel line to values as positive as for 18Cr-8Ni stainless steel or metallic chromium (Fig. 4). To provide additional protection, the strongly adhering deposit of chromium in the chlorate cell process is covered further with chromium oxides obtained by chromate reduction. After anodic graphite is used up during the chlorate cell production, the chromium could be recovered by conventional processing and used once again for deposition on new graphite surfaces. Hence, thin deposits of chromium could substitute for large weights of steel cell body and cathode plates of monopolar cells. The addition of dichromate to the electrolyte is eliminated as are many copper lead-ins and bus bars. Thus, all voltage drops at contacts and through metal are reduced.

As in the previous paper (8), a small addition of molybdate to graphite or the solution completely changes the polarization characteristics of the electrode. Tafel lines for molybdenized graphite are shifted to more positive values and, especially at higher current densities, they are even more positive than for iron. Subsequent addition of molybdate to the investigated chloride solution, *i.e.* over 0.5 gpl, does not fur-

[d] Graphite electrode impregnated in saturated sodium molybdate solution and prepolarized in sodium chloride solution with molybdate ions and without chromate ions.

ther change Tafel lines, which is in accordance with Wagner's theory (7), as well as with the previous paper of the present authors (8). Polarization characteristics of graphite impregnated with linseed oil are also improved by the addition of molybdate to the investigated solution (Fig. 3). The molybdenum deposit is stable as long as it is cathodically protected, but it is renewed in a short time by the next cathodic polarization of the electrode after the electrode has been without load.

The fact that molybdenized graphite exhibits the same slope of the Tafel lines as for the metal itself suggests that there is some metallic form of coating. The observed highly catalytically active black dots probably represent molybdenum oxide reduced to the metal by adsorbed hydrogen atoms. Further cathodic evolution of hydrogen keeps molybdenum in reduced form during the process. Our investigation has shown that the coating is not catalytically active for hydrogen oxidation in fuel cells, as pointed out by Feuillade (18) for molybdenum oxides deposited on carbon. The coating oxidizes if it is not cathodically protected and loses its activity. It needs repeated cathodic polarization to regain its previous activity and Tafel line slope.

An interesting behavior of molybdenized graphite has been observed: the Tafel line was shifted to more positive values of potential if molybdate was added prior or together with chromate (Fig. 3). However, the electrode impregnated in molybdate solution and prepolarized with chromate present in, but molybdate absent from, the sodium chloride solution exhibits an intermediary transition behavior between the two considered cases (Fig. 3).

A chromatized graphite electrode, impregnated in saturated molybdate solution and polarized in the presence of molybdate ions in a chloride solution, exhibits the same behavior as the molybdenized graphite just considered (Fig. 4). Its polarization characteristics are independent of molybdate concentration over 0.5 gpl in solution.

Voltage-current characteristics of a suitably scaled-up bipolar cell (21) for the usual chlorate process conditions as well as for molybdate addition to the electrolyte are presented in Fig. 5, comparing the depolarizing effects achieved under industrial processing conditions.

Addition of molybdate to the investigated electrolyte in the case of metal electrodes (Co, Mo, Fe) does not change their polarization characteristics. However, it has been pointed out that the Tafel line shifts to more positive values of potential for the stainless steel electrode in the presence of molybdate ions in the solution. The appearance of molybdenum black over its exposed surface was also observed. This fact could be of importance for monopolar cells also.

The addition of vanadate was also tried, and its presence exhibits an appreciable depolarization too (Fig. 2).

An investigation was also made of the influence of cobalt coating on the graphite surface, obtained by the described method (9). The effect (Fig. 2) was stronger than with molybdenized graphite as was previously observed in caustic soda solution. However, due to the well-known catalytic effect of cobalt ions (12) on decomposition of hypochlorite, an effective cathode protection of the deposited cobalt should be provided all during the process.

Effect of molybdate on chlorate and hypochlorite stability.—Molybdates, and mainly Mo^{5+} ions, have been used as promoters for the catalytic activity of some other ions such as osmium for chlorate reduction in strong acid solution (19, 20). The catalytic action of molybdate for hydrogen peroxide decomposition is also well known. Therefore, an investigation was made of the effect of molybdate in the chlorate cell process, as well as on hypochlorite and chlorate decomposition.

Sodium molybdate in the amount of 1 gpl, was added separately to hypochlorite and chlorate solutions at pH

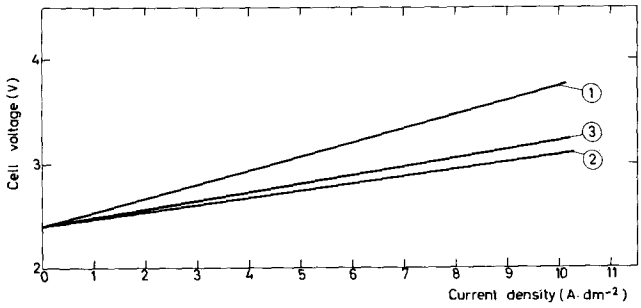

Fig. 5. Voltage-current characteristics of a scaled-up bipolar chlorate cell and the effect of depolarization in industrial process conditions: 1, usual cell conditions (unimpregnated graphite, TUP, Dubrovnik, Yugoslavia); 2, molybdenized graphite as cathode (chromate absent); 3, molybdenized graphite as cathode (dichromate content 4.0 gpl).

8.0 and their concentrations were followed as a function of time at 40°C. During more than 20 hr of investigation, no significant decomposition was observed.

In an apparatus for continuous chlorate production described recently by the authors (21), the influence of 1.0 gpl molybdate on chlorate cell current efficiency was investigated. No significant change in current efficiency was observed for the same pH and under otherwise similar conditions (flow, current density, temperature, concentration) of the process. Apparently the promoting effect of Mo^{5+} ions is possible only under strongly acidic conditions and in the presence of strong reducing or catalyzing agents, which are excluded in the usual industrial electrolytic chlorate process. The Mo^{5+} ions in the chlorate cells exist only inside the strongly alkaline cathode diffusion layer and for a short time, because they are further reduced to metallic molybdenum or an oxide of lower valence at least. Therefore, one could conclude that the small addition of molybdate has no significant influence on current efficiency in the chlorate cell process. The anodic effect is the same as for chromate ions themselves (22).

Miscellaneous observations.—The present methods thus improve the polarization characteristics for the h.e.r. at the graphite electrode by 200-300 mv with the molybdenized surface, more than 500 mv with the cobaltized, and about 150 mv with chromatized graphite.

In conclusion, current flow normal to the exposed graphite side surface for the electrochemical process in bipolar cells provides minimized paths through electrodes and hence enables application of higher current densities with reduced cell voltage. At the same time, small additions of molybdate provide a depolarizing effect for the h.e.r., similar to iron, which allows high current densities for bipolar chlorate cells (Fig. 2).

Therefore, an impregnation of graphite with molybdate is suggested, as well as the addition of 0.1-0.2 gpl to the electrolyte, as a suitable method for continuous cathode depolarization in a bipolar chlorate cell process.

In the previous paper, the authors (21) have pointed out the strong buffering effect of hypochlorous acid-hypochlorite ions just in the pH region providing the maximum conversion rate to chlorate. Thus, an application of the described depolarization methods provides the possibility for reducing dichromate addition, which is important for the chlorate crystallization process.

The methods of depolarization for the h.e.r. described here seem to be very advantageously applicable to all electrolytic processes having graphite or other porous cathodes, such as is the case for water and hydrochloric acid electrolysis, and should lead to lower cell voltages.

Acknowledgments

This work was supported and carried out by the Institute of Chemistry, Technology, and Metallurgy of Beograd, Yugoslavia, and Faculty of Chemical Technology of Split, University of Zagreb, Split, Yugoslavia.

The authors are deeply indebted to Professor Dr. A. R. Despić of Beograd for his personal interest in this work and his contributions to the direct preparation of the paper.

The authors wish also to express their gratitude to all members of the Electrochemistry Department of the Institute for their suggestions and stimulating discussions in connection with the present paper.

Process for Coating Tin-Free Steel with Layers of Metallic Chromium and Chromium Oxide

Nobuo Fukuda, Shigeru Yonezaki, Hajime Nitto, Minoru Kamada, Hidejiro Asano, and Kazukiyo Terayama

Yawata Iron & Steel Company, Limited, Chiyoda-ku, Tokyo, Japan

ABSTRACT

Tin-free coated steels are attracting attention as new container materials. As a result of studies that have been conducted since 1957 on tin-free steel, a double-layered chromium-chromium oxide tin-free coated steel (T.F.S.) has been developed. The properties of T.F.S. are excellent because each layer compensates for the others' deficiencies; namely, pin holes in the chromium are sealed by the chromium oxide and thermal cracking of the oxide layer is minimized by the underlying chromium metal layer. T.F.S. can be produced by a one-step cathodic treatment, using dilute chromic acid solution containing sulfate ion. The thicknesses of each layer may be controlled independently by treating conditions. The manufacturing equipment for this process is similar to that used in the electrotinning process. However, plating bath and tank lining materials must be carefully selected.

A rise in the price of tin due to the shortages and the instability of production, as well as inroads being made by aluminum and plastics producers into the market for container materials, has compelled can manufacturers and steel makers to take greater interest in the development of low-cost steel base container materials, such as tin-free steel (T.F.S.).

Against this background, competition for T.F.S. development is being waged throughout the world, and T.F.S. should soon enter an age of practical application. In anticipation of such a trend, development of T.F.S. was initiated in 1957.

After studying the feasibility of such processes as electrolytic phosphating, nonelectrolytic and electrolytic chromating, nickel and chromium plating, it was concluded that the double-layered T.F.S. consisting of an upper layer of chromium oxide and an underlayer of metallic chromium was most effective.

The chief merit of the double-layered T.F.S. is that the pinholes in the metallic chromium layer are sealed by the chromium oxide layer. Thermal cracking of the chromium oxide layer is minimized by the metallic chromium layer.

If the coating layers are too thin, the corrosion resistance is poor and, if too thick, the lacquer adhesion is poor. After determining the optimum film thickness (*see* Table I) for the most favorable combination of corrosion resistance and lacquer adhesion, commercial production was started on double-layer T.F.S. in 1967 on a unique high-speed production line (maximum 1200 fpm).

The purpose of this report is to describe briefly the production process for T.F.S.

Table I. Quality specification

Item	Coating weight (mg/dm² surface)
Metallic chromium	0.7 ~ 1.5
Chromium oxide	0.3 ~ 0.6

Table II. Comparison of coating film composition with conventional chromium plating and T.F.S. process at same plating conditions (Bath temp: 50°C)

Name of treatment	Concentration of plating solution	Plating condition: Current density, amp/dm²	Plating condition: Plating time, sec	Coating weight: Metallic Cr, mg/dm²	Coating weight: Cr oxide, mg/dm²
Conventional chromium plating	CrO_3:250 g/liter $SO_4^=$:2.5 g/liter	40	3	2.5	0.03
Plating solution for T.F.S. process	CrO_3:45 g/liter $SO_4^=$:0.45 g/liter	40	3	2.6	0.6

Process for Double-Layered T.F.S.

The mechanism of double-layered film deposition.—In conventional chromium plating, a solution containing about 250 g/liter of CrO_3 (chromium trioxide) and about 2.5 g/liter of sulfate ion is used. However, in order to obtain a double-layered T.F.S., in a single step, a solution containing less than 50 g/liter of CrO_3 and a small amount of sulfate ion is used.

Utilizing a solution for a double-layered T.F.S., samples were prepared and compared with samples of the ordinary chromium-plated steel. In both instances, the same current density, plating time, and bath temperature were used. As shown in Table II, the thickness of the chromium on the T.F.S. samples was about the same as that on the samples from the conventional chromium-plating solution, whereas the chromium oxide layer on T.F.S. was several hundred times thicker. Further, the thickness of the chromium oxide film gradually decreased if the samples were immersed in the solution before being dried as shown in Fig. 1.

From the results of these two experiments, it has been concluded that the chromium oxide film is the undissolved residue of intermediate products of reduction produced during chromium plating.

The key problem is how to develop this intermediate product into a double-layered T.F.S. in a single electrolysis step.

Outline of the process.—The new T.F.S. is produced by a process similar to electrotinning as shown in Fig. 2.

The steel base strip is prepared for plating in the same manner as for tinplate. The steel strip is first

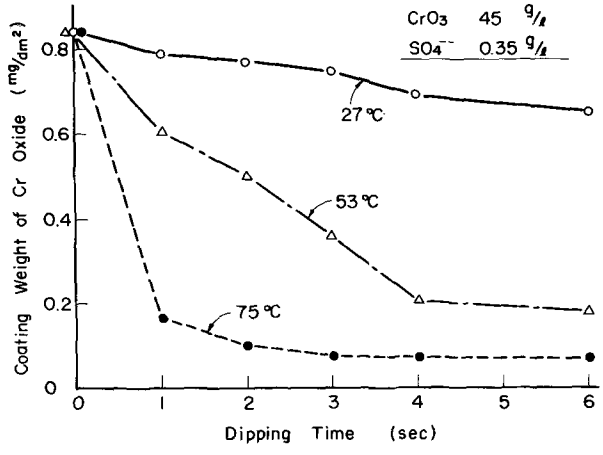

Fig. 1. Influence of dipping time in treating solution on chromium oxide coating weight.

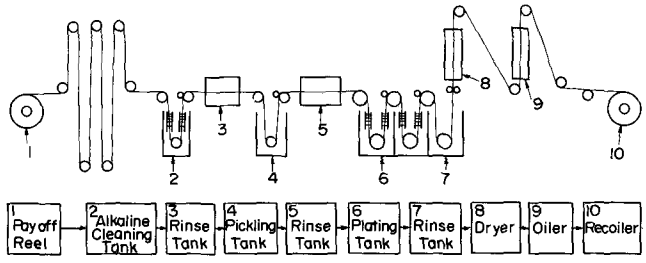

Fig. 2. T.F.S. plating line layout

washed by the alkaline cleaning method to remove completely all stains and oil on the surface. For double-reduced strip, cleaning must be particularly thorough. To obtain optimum surface properties, electrolytic alkaline cleaning is recommended. After rinsing with water, the strip is pickled with sulfuric acid at room temperature. Then the strip is treated cathodically in a plating bath to form a double-layered film on its surface. After removing the strip from the plating solution, it is rinsed in warm water, dried in hot air, and oiled.

Plating solution.—The plating is conducted in solutions having the compositions given in Table III. The fact that this solution is considerably less concentrated than that used for conventional chromium plating, as noted earlier, explains why it is possible to obtain a double-layered film in one-step electrolysis. Other advantages also accrue from use of a weaker solution.

It is cheaper, in the first place, and, even when used in a high-speed line, the drag-out (depletion) of chromic acid is less than that of conventional plating solution, so there is no need to recover CrO_3.

Second, it is less corrosive, having about one fifth of the chromic acid concentration used in conventional plating solutions. Hence, roll and lining materials present less problems.

Third, it is less of a health hazard to plant workers because CrO_3 fumes generated during electrolysis are proportionately weaker than those produced in conventional chromium plating.

Current efficiency for the deposition of metallic chromium and the line speed total current curve.—Unlike the electrotinning or galvanizing processes, the current efficiency of chromium plating varies with the current density and the bath temperature. This process exhibits similar characteristics. Hence, coating weight cannot be kept constant simply and linearly by adjusting current density to line speed if the line speed changes.

Since in chromium plating a drop in current density causes a corresponding drop in current efficiency, it may be necessary to actually increase current density to compensate for a drop in current efficiency when the line slows down. For this reason, the line speed-total current curve does not pass through the zero-point.

The line speed *vs.* total current curve for the new T.F.S. line, depositing 1 mg/dm² of metallic chromium is shown in Fig. 3.

Coating weight control of chromium oxide.—As already indicated, the oxide layer of the film, being an intermediate residue of the plating process, dissolves when reimmersed in the plating solution without electrolytic action. When plating in a vertical tank, it was found that the oxide film dissolved on parts of the strip not facing the anode, (*e.g.*, parts A, B, C, and D in Fig. 4). Thus, in multitank continuous plating, the oxide film is produced and dissolved alternately.

Table III. Plating solution of T.F.S. process

Concentration	CrO_3	<50 g/liter
	$SO_4^=$	<0.5 g/liter
Temperature of plating solution		50° ~ 60°C

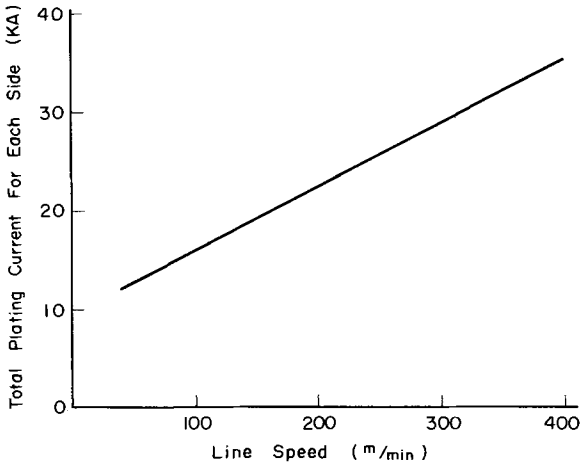

Fig. 3. Total current-line speed curve for 1.0 mg/dm² metallic chromium in actual line (width: 800 mm).

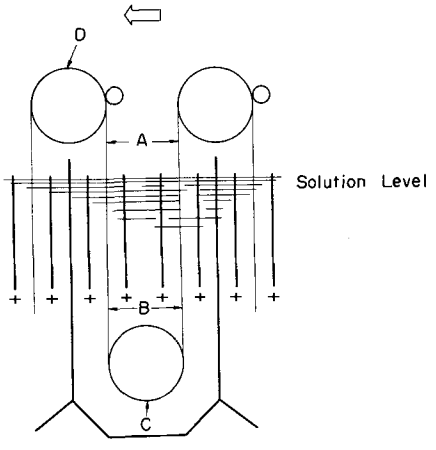

Fig. 4. Cross-sectional view of vertical plating tank

This behavior becomes even more severe at higher bath temperatures.

If electrodeposition and dissolution of chromium oxide occur alternately, the effect of each pass on the deposition of chromium oxide should become greater toward the rear pass. The contribution ratio of each pass to the deposition of chromium oxide was measured in the actual line. It was found that most of the chromium oxide deposits in the last tank as had been anticipated. This shows that, by controlling the current in the last tank, it is possible to control the amount of chromium oxide deposition independently of the amount of metallic chromium deposition. Actually, in this process the amount of chromium oxide deposition is controlled by the current in the last tank and the bath temperature.

Plating Equipment

Since a clean strip surface is also necessary for T.F.S., equipment for pretreatment is essentially the same as for electrotinning:

The pretreating section has an alkaline dunk tank, alkaline scrubber, electrolytic alkaline cleaning tank, pickling tank, and scrubber tank. Tank lining and roll material are also the same as used in electrotinning.

A predip tank, plating tanks, and rinse tanks are used in the plating section, the number of plating tanks depending on how much metallic chromium is to be required, on current capacity, and on line speed.

Vertical plating tanks are best since it has been found that in horizontal plating gas generated during electrolysis produces surface defects on the underside of the strip.

Lead-tin alloy is used for the anode. The space between the anode and strips is 25-40 mm.

The conductor roll is made of copper with a chromium-plated surface similar to that employed in electrotinning. The roll and tank lining material should be selected carefully because chromic acid solution is oxidizing; ordinary rubber, for instance, is corroded by chromic acid and the life of the lining becomes short; moreover, it reacts with chromic acid and increases the Cr^{+++} and sulfate ion in the plating solution. As shown in Fig. 5, increased Cr^{+++} reduces conductivity of the plating solution; sulfate ion increase changes the plating solution and makes operation difficult.

After testing various roll and lining materials, a special resin resistant to chromic acid corrosion was developed as shown in Fig. 6. This material is as easily fabricated into rolls or linings as ordinary rubber, whereas polypropylene and PVC are hard to make and tend to crack with aging.

This new resin has been used with very satisfactory results for hold-down rolls, sink rolls, and linings of plating tanks.

To prevent surface defects caused by plating solution remaining on the strip, a hot water rinse is used. Rinse water is supplied continuously to reduce chromic acid and sulfate ion concentrations, but losses from drag-out are so slight that no attempt is made to recover the chromic acid.

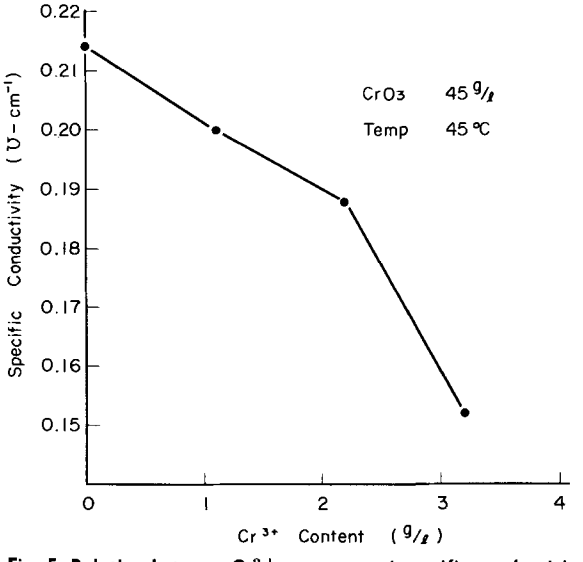

Fig. 5. Relation between Cr^{3+} content and specific conductivity

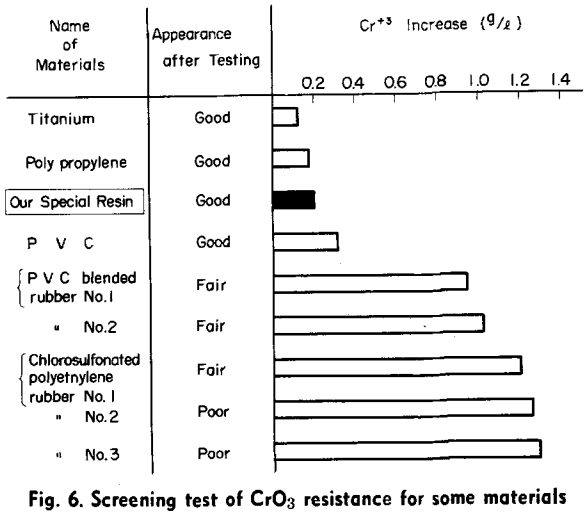

Fig. 6. Screening test of CrO_3 resistance for some materials

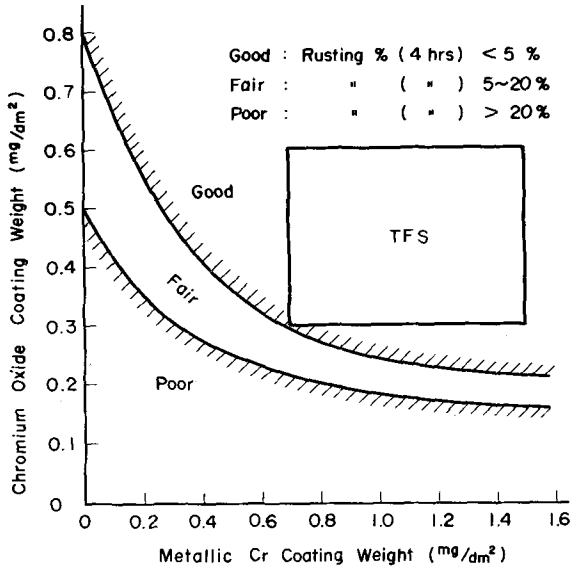

Fig. 7. Relation between salt spray test and coating weight

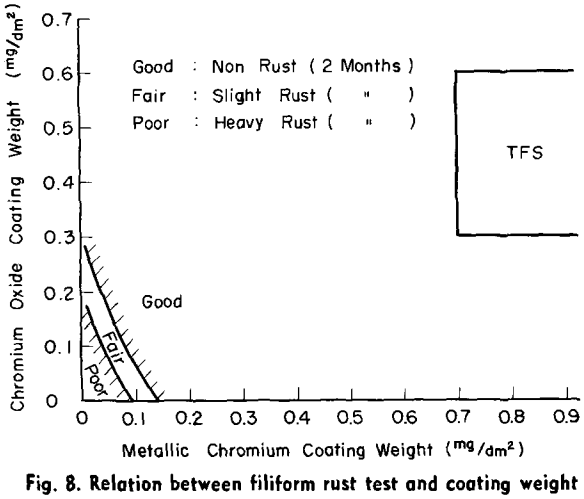

Fig. 8. Relation between filiform rust test and coating weight

The strip is dried by blowing hot air of 150°C on it before it goes through the electrostatic oiler.

Installation of a fume exhauster system is recommended to expel fumes generated during electrolysis.

Quality

The T.F.S. described herein is used for containers of carbonated beverages, beer, and various foodstuffs, also for bottle caps, battery cases, motor oil cans, pails, liquid detergent cans, and PVC laminated sheets.

To find the optimum coating weights of chromium oxide and metallic chromium required to produce adequate levels of corrosion resistance and lacquer adhesion for such a wide range of uses, the following tests were carried out.

Tests for Quality of Coating

Corrosion resistance of an unlacquered sheet.—First, as a general corrosion test, the corrosion resistance of an unlacquered sheet was evaluated by the salt spray method and the relation between the coating weights of each layer of the film and corrosion resistance was examined. As shown in Fig. 7, the coating specification of the T.F.S. was found to be satisfactory.

Filiform rust test.—Filiform rusting after lacquering is very undesirable because it greatly reduces the market value of a canned product.

The relation between each layer of the film and the filiform rusting is shown in Fig. 8. As this figure shows, the double layer of the T.F.S. prevents filiform rusting.

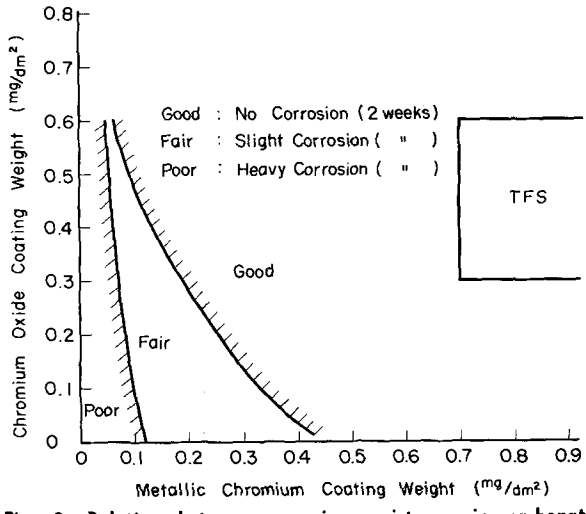

Fig. 9. Relation between corrosion resistance in carbonated beverage and coating weight.

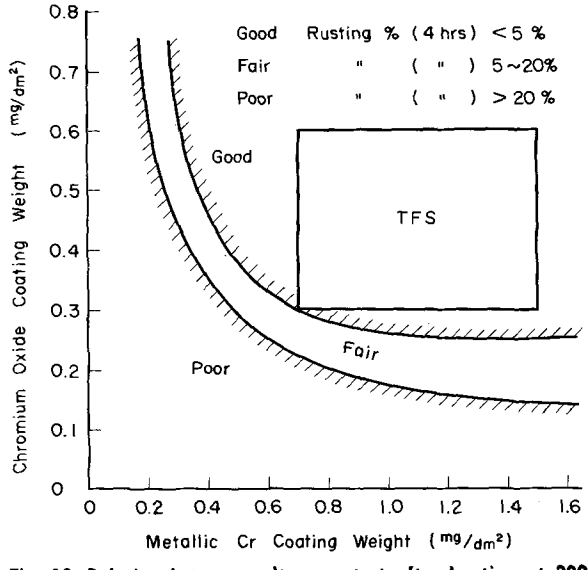

Fig. 10. Relation between salt spray test after heating at 200°C × 10 min and coating weight.

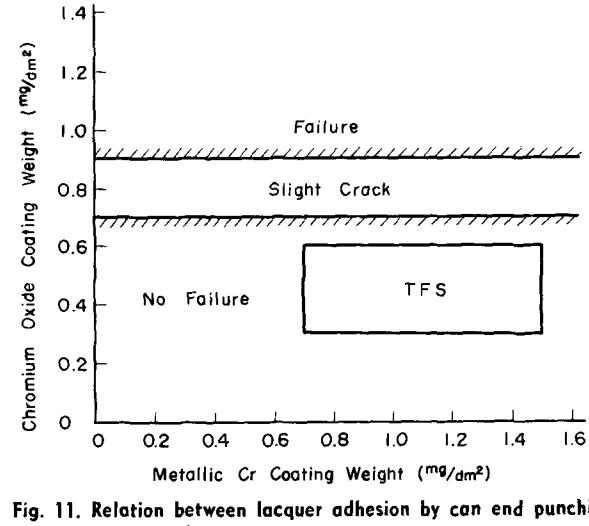

Fig. 11. Relation between lacquer adhesion by can end punching test and coating weight.

Corrosion resistance in carbonated beverage (lacquered sample).—The results of a corrosion test in carbonated beverage are shown in Fig. 9.

As this figure shows, the double layer of the T.F.S. coating insures excellent corrosion resistance in carbonated beverages.

Corrosion resistance after heating.—T.F.S. can be used for the inner surface of an unlacquered can. In this instance, one side of the sheet will be heated prior to fabrication and packing. Accordingly, the corrosion resistance of T.F.S. was examined after heating for 10 min at 200°C by the salt spray test. The results were satisfactory as shown in Fig. 10.

Lacquer adhesion.—The relation between the coating weight and lacquer adhesion of T.F.S. was examined by means of the can and punching test. The results are shown in Fig. 11. As this figure shows, lacquer adhesion deteriorates as the coating weight of oxide chromium exceeds 0.7 mg/dm², keeping in mind that the coating weight of metallic chromium is not related to lacquer adhesion. Also in this test, the specifications of the T.F.S. proved to be satisfactory.

Conclusions

1. The specifications for our T.F.S. are: metallic chromium, 0.7-1.5 mg/dm²; chromium oxide, 0.3-0.6 mg/dm².

If T.F.S. has the above coating weights, it exhibits satisfactory results for such tests as the salt spray test (4 hr), filiform rust test, corrosion test in carbonated beverage, salt spray test after heating, and the lacquer adhesion test by can end punching.

2. A manufacturing process was developed that produces tin-free steel in a one-step electrolytic treatment. Equipment used in this process is also described.

Plating Stresses from Electroless Nickel Deposition on Beryllium

R. M. Shemenski, J. G. Beach,* and R. E. Maringer

Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Commercial electroless nickel coatings on beryllium are shown to produce residual stresses of appreciable magnitude at the coating-substrate interface. A 0.005-in. layer of electroless nickel deposited on one side of a 0.010-in. beryllium strip induced residual compressive stresses in the beryllium substrate as high as 33,000 psi as calculated from the curvature of the plated composite. Evidence is presented to indicate that at least a substantial part of this residual stress is the result of a solid-state reaction and accompanying volume change in the coating during normal stress-relief annealing of the composite near 200°C. This is believed to be an ordering reaction associated with formation of the Ni_3P precipitate phase. The effect of temperature change on the level of induced stress in a nickel-beryllium composite due to a difference in coefficients of thermal expansion was investigated. The net difference in coefficients of thermal expansion increased in the temperature range 25°-50°C to a maximum value of $(\alpha_{Ni} - \alpha_{Be})_T = 1.9 \times 10^{-6}$ to 2.6×10^{-6} $\left(\frac{\text{in./in.}}{\text{°C}}\right)$, and then decreased approximately linearly up to 200°C at a rate of $\sim 6 \times 10^{-9} \left(\frac{\text{in./in.}}{\text{°C}}\right) / \text{°C}$.

Electroless nickel plating is a general term applied to processes based on the controlled, autocatalytic reduction of nickel cations by means of hypophosphite anions on certain catalytic surfaces in the presence of water (1-4). Brenner *et al.* listed the advantages of electroless nickel deposition as (*a*) deposition of uniform thickness in recesses as well as exposed areas, (*b*) no excessive build-up on projections or edges, and (*c*) elimination of the need for electroplating power sources and equipment (1-4). Coatings obtained by the electroless nickel process are typically α-nickel containing 8-10% by weight of phosphorus and minor amounts of other residual elements (5). The structure of electroless nickel deposits has been subject to considerable altercation. Differences in structure, composition, and properties of electroless nickel deposits are attainable, depending on the type of electroless nickel bath and operating parameters for deposition of a specific electroless nickel alloy. Brenner described electroless nickel as "fine-grained coherent deposits with a laminated structure sometimes imposed upon a columnar structure" (1). On the other hand, Gutzeit *et al.* (2, 5) reported that "electroless nickel coatings have the structure of an amorphous solid substance with liquid-like disorder of the atoms," this amorphous character being dependent of the nature of the substrate for deposits up to 0.010 in. in thickness. Goldenstein *et al.* (6) and Ziehlke *et al.* (7) also found catalytic nickel deposits to be amorphous by using x-ray and electron-diffraction techniques. They found that the amorphous structure reverted exothermically to a crystalline phase mixture of Ni + Ni_3P at low temperatures. Graham *et al.* (8, 9), Dixmier and Doi (10), and Randin *et al.* (11) all reported that electroless nickel had a very fine grain size of the order of 10^{-6} cm, and that the as-plated deposit was a supersaturated solid solution of phosphorus in nickel [$Ni_{(P)}$] as a metastable intermediate state between that of a mixture of Ni + P and the equilibrium system of $Ni_{(P)}$ + Ni_3P.

Dixmier and Doi found that this structure was a heavily faulted fcc-hcp structure, with the phosphorus atoms located interstitially in the hcp layers (10). Albert *et al.* showed that the structure was essentially a strained fcc-nickel lattice (12). Apart from these

* Electrochemical Society Active Member.

Corrosion resistance after heating.—T.F.S. can be used for the inner surface of an unlacquered can. In this instance, one side of the sheet will be heated prior to fabrication and packing. Accordingly, the corrosion resistance of T.F.S. was examined after heating for 10 min at 200°C by the salt spray test. The results were satisfactory as shown in Fig. 10.

Lacquer adhesion.—The relation between the coating weight and lacquer adhesion of T.F.S. was examined by means of the can and punching test. The results are shown in Fig. 11. As this figure shows, lacquer adhesion deteriorates as the coating weight of oxide chromium exceeds 0.7 mg/dm², keeping in mind that the coating weight of metallic chromium is not related to lacquer adhesion. Also in this test, the specifications of the T.F.S. proved to be satisfactory.

Conclusions

1. The specifications for our T.F.S. are: metallic chromium, 0.7-1.5 mg/dm²; chromium oxide, 0.3-0.6 mg/dm².

If T.F.S. has the above coating weights, it exhibits satisfactory results for such tests as the salt spray test (4 hr), filiform rust test, corrosion test in carbonated beverage, salt spray test after heating, and the lacquer adhesion test by can end punching.

Plating Stresses from Electroless Nickel Deposition on Beryllium

R. M. Shemenski, J. G. Beach,* and R. E. Maringer

Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Commercial electroless nickel coatings on beryllium are shown to produce residual stresses of appreciable magnitude at the coating-substrate interface. A 0.005-in. layer of electroless nickel deposited on one side of a 0.010-in. beryllium strip induced residual compressive stresses in the beryllium substrate as high as 33,000 psi as calculated from the curvature of the plated composite. Evidence is presented to indicate that at least a substantial part of this residual stress is the result of a solid-state reaction and accompanying volume change in the coating during normal stress-relief annealing of the composite near 200°C. This is believed to be an ordering reaction associated with formation of the Ni_3P precipitate phase. The effect of temperature change on the level of induced stress in a nickel-beryllium composite due to a difference in coefficients of thermal expansion was investigated. The net difference in coefficients of thermal expansion increased in the temperature range 25°-50°C to a maximum value of $(\alpha_{Ni} - \alpha_{Be})_T = 1.9 \times 10^{-6}$ to 2.6×10^{-6} $\left(\frac{\text{in./in.}}{\text{°C}}\right)$, and then decreased approximately linearly up to 200°C at a rate of $\sim 6 \times 10^{-9} \left(\frac{\text{in./in.}}{\text{°C}}\right) / \text{°C}$.

Electroless nickel plating is a general term applied to processes based on the controlled, autocatalytic reduction of nickel cations by means of hypophosphite anions on certain catalytic surfaces in the presence of water (1-4). Brenner *et al.* listed the advantages of electroless nickel deposition as (*a*) deposition of uniform thickness in recesses as well as exposed areas, (*b*) no excessive build-up on projections or edges, and (*c*) elimination of the need for electroplating power sources and equipment (1-4). Coatings obtained by the electroless nickel process are typically α-nickel containing 8-10% by weight of phosphorus and minor amounts of other residual elements (5). The structure of electroless nickel deposits has been subject to considerable altercation. Differences in structure, composition, and properties of electroless nickel deposits are attainable, depending on the type of electroless nickel bath and operating parameters for deposition of a specific electroless nickel alloy. Brenner described electroless nickel as "fine-grained coherent deposits with a laminated structure sometimes imposed upon a columnar structure" (1). On the other hand, Gutzeit *et al.* (2, 5) reported that "electroless nickel coatings have the structure of an amorphous solid substance with liquid-like disorder of the atoms," this amorphous character being dependent of the nature of the substrate for deposits up to 0.010 in. in thickness. Goldenstein *et al.* (6) and Ziehlke *et al.* (7) also found catalytic nickel deposits to be amorphous by using x-ray and electron-diffraction techniques. They found that the amorphous structure reverted exothermically to a crystalline phase mixture of Ni + Ni_3P at low temperatures. Graham *et al.* (8, 9), Dixmier and Doi (10), and Randin *et al.* (11) all reported that electroless nickel had a very fine grain size of the order of 10^{-6} cm, and that the as-plated deposit was a supersaturated solid solution of phosphorus in nickel [$Ni_{(P)}$] as a metastable intermediate state between that of a mixture of Ni + P and the equilibrium system of $Ni_{(P)}$ + Ni_3P.

Dixmier and Doi found that this structure was a heavily faulted fcc-hcp structure, with the phosphorus atoms located interstitially in the hcp layers (10). Albert *et al.* showed that the structure was essentially a strained fcc-nickel lattice (12). Apart from these

* Electrochemical Society Active Member.

differing opinions, there is significant agreement that as-plated electroless nickel is a metastable structure characterized by some degree of atomic disorder which tends toward the equilibrium $Ni_{(P)} + Ni_3P$ structure upon heating. X-ray diffraction studies of nickel phosphide (Ni_3P) indicated that it has a body-centered tetragonal structure ($a = 8.91$Å, $c = 4.39$Å). When precipitated in a parent nickel lattice, it shows a preferred orientation with the {111} planes of fcc nickel parallel to the {110} planes of Ni_3P. Furthermore, the average interatomic distance of 2.6Å on the {110} planes of Ni_3P is very close to the interatomic distance of 2.5Å in Ni. The lattice parameter of electroless nickel is 3.52Å (11). The atomic radii of phosphorus and nickel are 1.28 and 1.24Å, respectively, differing by somewhat more than 3%. From changes in lattice parameter with phosphorus content, it is believed that phosphorus content in a stress-relieved nickel deposit is very low, and, therefore, only a little (if any) phosphorus occupies substitutional or interstitial sites in an α-Ni lattice.

Variations in phosphorus content of electroless nickel deposits have a marked influence on the mechanical properties of the coatings. Abrupt changes in tensile properties at approximately 7% by weight phosphorus (49% by volume Ni_3P) were found to indicate a change from a ductile Ni continuous phase at low phosphorus levels to a brittle Ni_3P matrix at high phosphorus contents (9, 13). The response of electroless nickel to heat treatment also is sensitive to phosphorus content, especially at low temperatures. The hardness of deposits with phosphorus content above 9 w/o (weight per cent) remained practically constant for heat treatments of ~5 hr up to 300°C, whereas the hardness of low-phosphorus deposits increased when heat treated at temperatures above 125°C (13). In the high-phosphorus deposits, Graham *et al.* stated that the very low rate of hardening for heat treatments below 200°C seems to be indicative of the presence of an "activation energy barrier," dependent on phosphorus content, that retards the initial stages of transformation of the supersaturated Ni + P solid solution (9). After heat treatment at 200°C, Graham *et al.* reported an increase in hardness at a decreasing rate with increasing phosphorus content up to 9 w/o (9). Goldenstein *et al.* concluded that no transformations occur at 200°C in electroless nickel containing 7-10 w/o phosphorus since their work showed no increase in hardness for 21 hr at that temperature (6). An initial increase in hardness of Ni + 8-10 w/o P from ~500 DPH to ~600 DPH (Rockwell C-50 to 55) within the first few hours followed by no observed change after 617 additional hours at 200°C was found by Lee (14). Ziehlke *et al.* observed no changes in microstructure for samples (7-10 w/o P) heat treated below 400°C (7). Domnikov stated that a slight increase in the microhardness of electroless nickel deposits (phosphorus content not specified) heat treated at 120°-200°C could be explained by an incomplete formation of the Ni_3P phase (15).

This research was part of a larger program to investigate the production of large precision, diffraction-limited mirrors which require a dimensional instability of $<0.033\lambda$ rms or 2.2×10^{-6} cm in the visible region over a moderate temperature range and for long periods of time. The purpose of this particular study was to investigate the effects of commercially processed electroless nickel deposits on dimensional stability of beryllium substrates by comparing the magnitude of residual plating stresses with the micro-yield strength (*i.e.*, the stress to produce a residual plastic strain of 1×10^{-6}) of beryllium. Response of the $Be\text{-}Ni_{(P)}$ system to thermal excursions from ambient temperature to ~200°C (normal stress-relief annealing temperature for electroless nickel) was analyzed to determine the net variation of coefficients of thermal expansion as well as the effect of temperature on microstructural stability. Differences in coefficients of thermal expansion between substrate and coating of the order of 1×10^{-6}/°C are considered pernicious for diffraction-limited mirrors, but could be accommodated in normal applications.

Experimental Procedure

Preparation of beryllium strips.—A beryllium powder, grade S-200 (Brush Beryllium Co., BeO ~ 1.8%) was hot isostatically pressed into a fully dense rectangular block. The faces of this block were milled to an accurate rectangular geometry and rough slabs 0.075 in. thick by 4.75 in. long by 0.625 in. wide were cut off with a water-cooled cut-off wheel. The slabs were assembled into a package and the ends and sides milled by a carbide end mill at 600 rpm (fine hand feed). The final finish on the sides was made according to the standard practice of taking successively finer cuts of 0.010-0.005-0.002-0.002-0.001 in. in depth. Very fine holes approximately 0.025 in. in diameter were made at one end about 0.25 in. from the edge to facilitate handling during plating. The final cuts on the top and bottom surfaces of the strips were made by using an end mill to remove 0.030 in. at 0.005 in./cut from first one side and then the reverse side, ending with cuts of 0.002 in. in one pass in one direction and 0.001 in. on the return pass on both sides to a thickness of 0.030 in. The final strip size as machined was 4.3 x 0.30 x 0.030 in.

These strips were then chemically polished to remove approximately 0.010 in. from all surfaces in a solution composed of:

H_2SO_4 (95-98%)	47 ml
H_3PO_4 (85-87%)	410 ml
H_2O	130 ml
CrO_3	70g
Temperature	160°-170°F
Removal rate	~0.6-0.8 mil/min

The samples were inspected thoroughly and measured accurately, especially to note any curvature or bow-out of the strip. The final strip dimensions were 4.28 x 0.28 x 0.010 in. Twelve identical strips were prepared in this manner and three strips were sent to each of four commercial plating companies using the "KANIGEN"[1] process to be coated with a 0.005-in. layer of electroless nickel on one side; the reverse side was masked in the usual manner employed by each company. The usual outgassing and/or stress-relieving heat treatment (180° ± 20°C for ~5 hr) for electroless nickel was requested for all strips. An additional specimen (No. D-Jan67), prepared in an identical manner and electroless nickel coated by one of the companies 1 yr earlier, was included in this study in order to determine the effect of shelf life on an electroless nickel deposit.

After the plated strips were returned, all dimensions were measured again. The curvature (ρ) of the coated strips was computed from measurements of total strip bow-out made by using a Gaertner Scientific Corporation optical comparator accurate to ±0.00005 in. and was used to calculate the residual plating stresses. Some uncertainty in the level of plating stresses calculated by using a single ρ for the entire composite would be expected due to edge effects and localized irregular curvatures. By measuring ρ over very short distances along representative strips from each group, a random variation in ρ of ±33% maximum was found. Since ρ enters into the calculations in the denominator of one term, a deviation in ρ would not necessarily affect the calculated stresses proportionately. Calculations showed that ±30% seems to be a reasonable estimate of the maximum variation and the nominal accuracy of the plating stresses reported here should be ~±20%. The bow-out of these strips was measured upon heating and cooling by viewing with the Gaertner comparator through an insulated glass window in a laboratory furnace while

heating to 200°C in ~3 hr and furnace cooling to room temperature in ~20 hr.

Results

The microstructures of the four commercially prepared electroless nickel deposits are shown in Fig. 1. There were slight differences in microstructure reflecting the different plating conditions used by each commercial plater; however, since the resulting microstructures were similar, any effect of plating conditions should be minimal. The thicknesses of nickel coatings deposited by each plater are summarized in Table I. The residual stresses resulting from plating electroless nickel on thin beryllium strips were calculated based on the model shown in Fig. 2; the derivation used in these calculations is given in the Appendix. The magnitudes of the plating stresses in the Be-$Ni_{(P)}$ composites are summarized in Table II. It is seen that the residual plating stresses (σ_{M2A}) are quite significant when compared with the nominal microyield strength of S-200 grade beryllium (~6000 psi). Temperature for electroless nickel deposition is normally about 90°C. A nickel-coated part is usually given a stress-relief aneal at ~190°C or higher for 1 hr/mil of coating thickness. To evaluate the effect of heat treatment on electroless nickel deposited on beryllium, one specimen from Company A (Specimen A-1) was received in the as-plated condition. This sample was bowed considerably less than the two strips plated and stress relieved by Company A. However, after a heat treatment up to 200°C and furnace cooling, the sample showed a curvature quite comparable with the others received from Company A

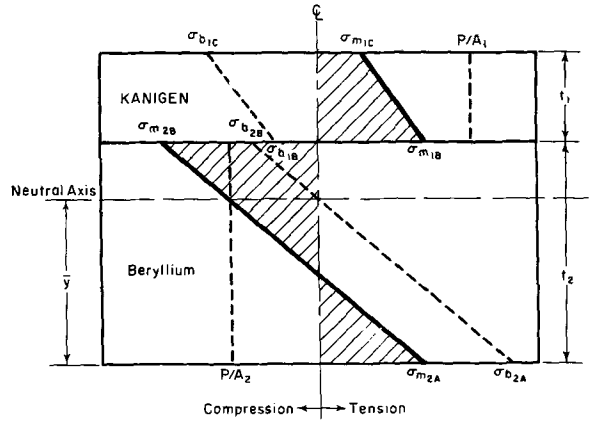

Fig. 2. Schematic representation of typical stress distribution in a cross section of an electroless-nickel-plated beryllium strip.

(see Fig. 3). Another strip (Specimen B-2) initially plated and given a stress-relief anneal by the plater was further heat treated at 240°C for 20 hr. The radius of curvature of this composite decreased from 13.68 to 8.63 in., and the computed maximum fiber stress in the beryllium at the interface ($\sigma_{M_{2B}}$) increased from 19,970 psi (compressive) to 31,670 psi (compressive). The results of the heat treatments are summarized in Table III.

Figure 3 shows the typical response to temperature variations observed for electroless-nickel-coated beryllium strips. The shapes of bow-out *vs.* temperature curves were all quite similar since the rate of change of bow-out with temperature was approximately constant. The only significant difference among all the beryllium strips was the magnitude of initial bow-out; this was reflected by a change in vertical displacement of the curves such as shown in Fig. 3. Strip A-1 (Fig. 3) was tested in the "as-plated" condition; heating to 190°C apparently resulted in a structural change within the $Ni_{(P)}$ layer as indicated by the irreversibility in the heating and cooling curves. Strips A-2 and A-3 were given a stress-relief anneal before testing, and these specimens retraced essentially the same curves upon heating and cooling. These results suggested that a solid-state reaction occurred upon heat treating at ~180°-190°C. This produced a volume change in the electroless-nickel microstructure which was constricted on one side by the beryllium substrate. Hence, an increased curvature of the composite resulted. These tests demonstrated that the $Ni_{(P)}$ deposits are metastable structures and that temperature excursions and/or heat treatments can in fact increase residual stresses which adversely affect dimensional stability. In the absence of structural changes in a coating, a change in curvature with variation in temperature resulted from a temperature dependence of the difference in coefficients of thermal expansion between beryllium and nickel, $\Delta\alpha = (\alpha_{Ni} - \alpha_{Be})_T$. This is seen by the reversibility of the change in bow-out upon heating and cooling observed for the composites. The $\Delta\alpha$ values were calculated by using the radius of curvature of the bowed beryllium-nickel composite as follows (16):

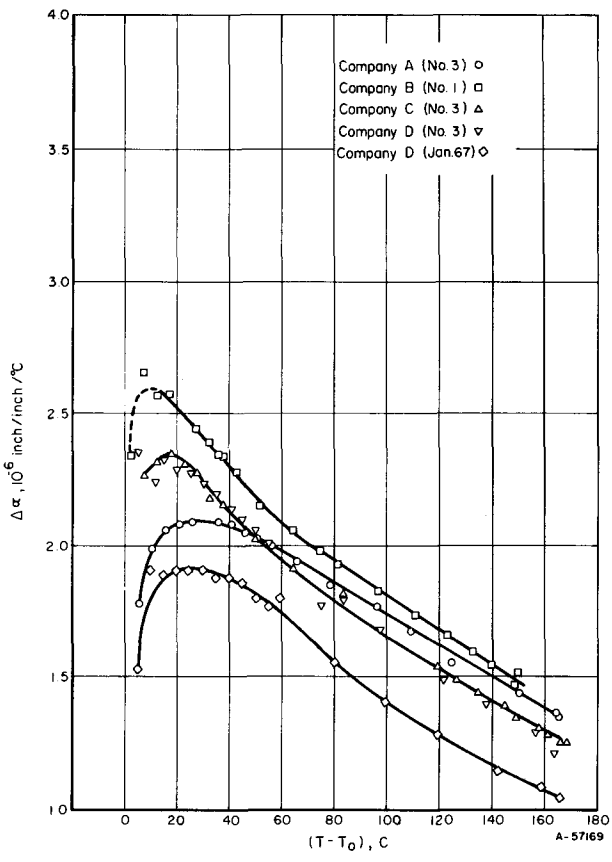

Fig. 4. Variation of the difference in coefficients of thermal expansion between electroless nickel and beryllium with temperature change.

and

$$\rho = \frac{C^2 + 4L^2}{8L} \qquad [2]$$

where ρ is radius of curvature, t is thickness, E is tensile modulus, T is temperature, C is length of bowed-composite, and L is bow-out (*see* Fig. 2). Figure 4 summarizes the variation of $(\alpha_{Ni} - \alpha_{Be})_T$ with change in temperature. The difference in coefficients of thermal expansion initially increased up to a temperature difference of $\Delta T \sim 20°C (T = 25°\text{-}50°C)$, then decreased at an approximately linear rate of

$$\sim 6 \times 10^{-9} \left(\frac{\text{in./in.}}{°C} \right) \Big/ °C$$

up to ~190°C which was the maximum temperature reached in these studies.

Discussion

Since the magnitude of bow-out for the Be-$Ni_{(P)}$ composites was used to calculate residual plating stresses, a thinner substrate allowed greater bending and in fact increased the sensitivity of the stress measurements; however, thin beryllium strips presented some problem in handling during masking, plating, cleaning, etc. Some bending of the strips during handling could have introduced error into the stress calculations. Yet, coated samples from each plating company were very consistent with respect to initial absolute amount of bow-out which suggests that either all strips within each group of three coated specimens were bent the same amount during handling or that the initial bending primarily reflected the specific coating conditions used. This latter explanation is more plausible. Also, the calculations for stress resulting from a difference in coefficients of thermal expansion utilized only the change in bow-out (ΔL) as a function of thermal treatment. Thus, the initial absolute value of bow-out was not a significant factor affecting these calculations and conclusions.

It is recognized that the use of electroless nickel coatings on beryllium will in fact produce deleterious residual stresses within the composite due to such factors as plating stresses, structural instability of the Ni+P lattice, difference in coefficient of thermal expansion, *etc.* Barnes stated that within the present state of technology there exists a necessity for using electroless nickel and that good engineering and process control should mitigate the inherent disadvantages (17). Barnes calculated the stress magnitude for an initially plane, 61-cm-diameter, 5.08-cm-thick, nickel-coated beryllium mirror resulting from a 10°C change in temperature. He reported that the change of stress in the beryllium substrate would be 0.006 ksi (tensile) and, in the nickel layer, 0.70 ksi (compressive). By using bow-out *vs.* temperature data such as shown in Fig. 3, the change in deflection (bow-out) with temperature can be approximated for two ranges of temperature as follows:

$$(T = 0 \text{ to } 100°C) \frac{\Delta L}{\Delta T} \sim 0.38 \text{ mil/°C}$$

$$(T = 100° \text{ to } 200°C) \frac{\Delta L}{\Delta T} \sim 0.2 \text{ mil/°C} \qquad [3]$$

Table IV summarizes the effect of a change in deflection resulting from a given thermal treatment on maximum fiber stresses at a Be-$Ni_{(P)}$ interface. From these data and by using the relationships given in Eq. [3], a change in temperature of 10°C would be expected to change the stress levels in a beryllium substrate and electroless-nickel layer by the following amounts:

Whereas the change in compressive stress in an electroless-nickel deposit for a 10°C temperature is in fair agreement with Barnes (17), the residual stress change in a beryllium substrate differs greatly. This difference can be rationalized by considering the derivations used to calculate stress levels. Barnes used a plate model with strain depending only on the temperature change, ignoring any stress relief by bending. A Beam model was used in the present study and stress levels were deflection governed (*see* Appendix) with deformation a function of the relative elastic moduli and thicknesses of a beryllium substrate and the nickel layer. The important difference between these two approaches is that the present study recognized the influence of volume changes of the nickel layer as a determinant of imposed stress. Barnes assumed that since plating is done at 80°-100°C, a stress-free layer is deposited and that subsequent cooling to room temperature produces some stresses in the composite (temperature-governed). This was, indeed, observed here. However, he further assumed that significant stress relief may occur at the 190°C anneal commonly given to electroless-nickel deposits, whereas it was shown that this treatment causes finite volume changes in the Ni+P metastable structure, thereby increasing the magnitude of the residual stresses in the Be-$Ni_{(P)}$ composite.

It is well substantiated in the literature that no precipitation of Ni_3P occurs at temperatures below 200°C. Contraction of a metastable Ni+P lattice detected in this study by a change in curvature upon heating to 200°C is most probably a transformation of the electroless-nickel lattice from a structure of relative disorder to one of higher order. This is likely to be an ordering of nickel and phosphorus atoms in the first stage of forming a Guinier-Preston type of zone. It is evident that more information is needed about the behavior of electroless nickel, not only to define the as-plated structure but also to study the precipitation kinetics and the relative interplay of volume effects and temperature response ($\Delta\alpha$) of an electroless-nickel-coated/metallic substrate composite.

For most applications of electroless nickel, residual stresses of the order found above can be tolerated; however, for diffraction-limited precision optical surfaces, these stresses may produce unacceptable distortions.

Summary

1. Electroless-nickel deposition on beryllium results in a significant level of residual stress within a composite due to both volume effects and temperature response.

2. Upon heating to temperatures below 200°C, a contraction in the metastable Ni+P structure results, presumably from a transformation to a more ordered lattice, probably the first stage in development of G-P zones. This leads to high stresses in the electroless-nickel deposit and its substrate.

3. Temperature-imposed stresses in Be-$Ni_{(P)}$ composites result from a difference in coefficients of thermal expansion. This difference $(\alpha_{Ni} - \alpha_{Be})_T$ increases in the range 25°-50°C and then decreases approximately linearly at a rate of $\sim 6 \times 10^{-9}\left(\frac{\text{in./in.}}{^\circ\text{C}}\right)/^\circ$C.

4. The temperature response of electroless-nickel-plated beryllium was independent of commercial plater and reproducible upon repeated thermal cycling after any volume effects were stabilized.

5. Stresses at the interface of a Be-$Ni_{(P)}$ composite after plating at ~ 90°C and cooling to ambient temperature in the order of 2000-5000 psi can be expected to increase after a stress relief anneal to 10,000-15,000 psi due to volume effects.

APPENDIX

Calculation of Residual Stresses

Procedures and formulas adapted from (a) S. Timoshenko, "Strength of Materials," pp. 217-219, P. Van Nostrand Co., (b) Albert G. H. Dietz, "Engineering Laminates," p. 354, John Wiley & Sons, New York (1949).

From Dietz: $\delta = \Delta\alpha\Delta T = f(\rho, E_1, E_2, t_1, t_2)$

$$\text{(from Fig. A-1)}\quad P/A = \frac{E\delta L}{L}$$

Assume: coating and strip are the same length (L); then Fig. A-2 is equivalent to Fig. A-1, resulting in the appearance of a net moment as shown in Fig. A-2.

$$M = \frac{EI}{\rho}$$

$$I = \frac{bt^3}{12}$$

$$\frac{PL}{A_1E_1} + \frac{PL}{A_2E_2} = \delta L \qquad [A\text{-}1]$$

$$P\left(\frac{1}{A_1E_1} + \frac{1}{A_2E_2}\right) = \frac{\delta L}{L} \qquad [A\text{-}2]$$

$$P\left(\frac{bt_2E_2 + bt_1E_1}{b^2t_1E_1t_2E_2}\right) = \frac{\delta L}{L} \qquad [A\text{-}3]$$

$$P = \frac{\delta L}{L}\left(\frac{bt_1t_2E_1E_2}{t_1E_1 + t_2E_2}\right) \qquad [A\text{-}4]$$

$$\sigma_{m2} = -\frac{P}{A_2} + \frac{t_2E_2}{2\rho} \qquad [A\text{-}5]$$

$$\sigma_{m1} = +\frac{P}{A_2} - \frac{t_1E_1}{2\rho}$$

Equation [A-5] does not consider the neutral axis; therefore, construct a beam of one material to replace the composite having the same stiffness (AE) and dimensions (b, t_1, t_2) but an irregular cross section (Fig. A-3).

Equivalent stiffness

$$A_1{}^1E_2 = A_1E_1$$

$$E_2b\left(\frac{E_1}{E_2}\right)t_1 = bE_1t_1$$

$$I_y = \frac{bt_2^3}{12} + A_1{}^1d_2{}^2 + \frac{b\left(\frac{E_1}{E_2}\right)t_1^3}{12} + A_1{}^2d_1{}^2 \qquad [A\text{-}6]$$

$$\bar{y}\left(bt_2 + b\frac{E_1}{E_2}t_1\right) = bt_2\frac{t_2}{2} + \left(\frac{E_1}{E_2}\right)bt_1\left(t_2 + \frac{t_1}{2}\right) \qquad [A\text{-}7]$$

$$\bar{y} = \frac{\frac{t_2^2}{2} + \left(\frac{E_1}{E_2}\right)\left[t_1t_2 + \frac{t_1^2}{2}\right]}{t_2 + (E_1/E_2)t_1} \qquad [A\text{-}8]$$

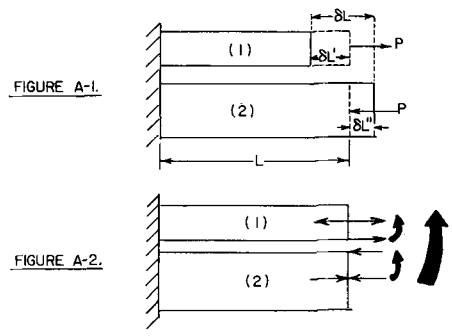

FIGURE A-1.

FIGURE A-2.

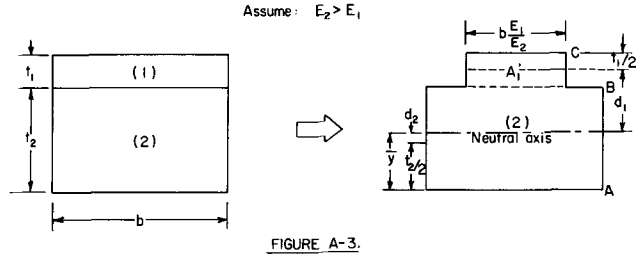

FIGURE A-3.

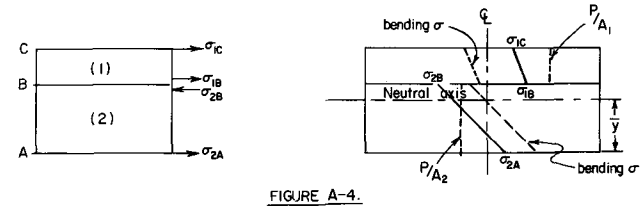

FIGURE A-4.

$$\bar{y} = \frac{\frac{t_2^2}{2} + \left(\frac{E_1}{E_2}\right)\frac{t_1^2}{2} + \left(\frac{E_1}{E_2}\right)t_1t_2}{t_2 + (E_1/E_2)\,t_1} \qquad [A\text{-}9]$$

$$d_2 = \bar{y} - \frac{t_2}{2} = \frac{\left(\frac{E_1}{E_2}\right)t_1^2 + \left(\frac{E_1}{E_2}\right)t_1t_2}{2t_2 + 2t_1(E_1/E_2)} \qquad [A\text{-}10]$$

$$d_1 = \left(t_2 + \frac{t_1}{2}\right) - \bar{y} = \frac{t_2^2 + t_1t_2}{2t_2 + 2t_1\,(E_1/E_2)} \qquad [A\text{-}11]$$

$$I = \frac{bt_2^3}{12} + bt_2\left[\frac{(E_1/E_2)t_1^2 + (E_1/E_2)t_1t_2}{2t_2 + 2t_1\,(E_1E_2)}\right]^2 + \frac{b(E_1/E_2)t_1^3}{12} + (E_1/E_2)\,bt_1\left[\frac{t_2^2 + t_1t_2}{2t_2 + 2t_1\,(E_1/E_2)}\right]^2 \qquad [A\text{-}12]$$

Let:

$$e = \frac{E_1}{E_2}$$

$$I = \frac{b}{4}\left\{\frac{t_2^3 + et_1^3}{3} + \left[\frac{e^2t_1^4t_2 + 2et_1^3t_2^2 + e^2t_1^2t_2^3 + et_1t_2^4 + 2et_1^2t_2^3 + et_1^3t_2^2}{t_2^2 + 2et_1t_2 + e^2t_1^2}\right]\right\} \qquad [A\text{-}13]$$

$$P = \frac{E_2b}{2\rho(t_1 + t_2)}\left\{\frac{t_2^3 + et_1^3}{3} + \left[\frac{et_1t_2(et_1^3 + 2et_1^2t_2 + et_1t_2^2 + t_2^3 + 2t_1t_2^2 + t_1^2t_2)}{t_2^2 + 2et_1t_2 + e^2t_1^2}\right]\right\} \qquad [A\text{-}14]$$

$$P = \frac{E_2b}{2\rho(t_1 + t_2)}\left\{\frac{t_2^3 + (E_1/E_2)t_1^3}{3} + \left[\frac{(E_1/E_2)t_1t_2\{(E_1/E_2)t_1^3 + t_1^2t_2(2(E_1/E_2) + 1) + t_1t_2^2[2 + (E_1/E_2)] + t_2^3\}}{t_2^2 + 2(E_1/E_2)t_1t_2 + (E_1/E_2)^2t_1^2}\right]\right\} \qquad [A\text{-}15]$$

The Infrared Interference Method of Measuring Epitaxial Layer Thickness

P. A. Schumann, Jr.*

International Business Machines Corporation, Components Division, East Fishkill Laboratory, Hopewell Junction, New York

ABSTRACT

The infrared interference method of measuring the layer thickness of silicon layers deposited on heavily doped substrates of the same type is a well-known technique. The correction factors and theoretical models in existence are discussed and their limits of application defined. It is shown that, for most cases, it is not necessary to correct for the profile of impurities in the epitaxial layer due to out-diffusion and autodoping. A new method of calculating the thickness from the interference maxima and minima is presented which includes the phase shift and wave-length dependence of the reflection at the layer-substrate interface. It is shown that, with a spectrophotometer capable of scanning the wave-length range 2.5-50μ, layer thicknesses to 0.8μ can be measured. Comparisons are made between this technique, a stain technique, and the spreading resistance technique for N/N$^+$ and P/P$^+$ silicon with layer thicknesses from 1.5 to 16μ. The precision of the infrared interference technique is quoted and correlation curves between the techniques are presented.

The infrared interference method of measuring the thickness of epitaxial layers deposited on highly doped substrates of the same conductivity type is accepted as a precise and useful technique. It has primarily been used on silicon but some use has been made on germanium. The technique was introduced by Spitzer and Tanenbaum (1) in 1961. Later that same year, Grochowski and Pliskin (2) described improved measurement techniques and compared the infrared interference technique with a stain technique. Albert and Combs (3) discussed the technique, again comparing it with a stain. They developed fringe charts and pointed out that as the reflectivity of the layer-substrate interface was changing with wave length, the positions of the maxima and minima must be determined by the envelope technique. Several of the preceding papers discussed the conditions necessary for interference fringes to be observed. It was pointed out by Schumann, Phillips, and Olshefski (4) that the phase shift on reflection at the layer-substrate interface was a function of wave length and must be accounted for in calculating the thickness. These phase shifts were tabulated (5, 6) and have been used successfully for routine measurement. Two papers (7, 8) were published on the effects of the impurity profile due to out-diffusion and autodoping in the epitaxial layer on the reflection spectra of N/N$^+$ silicon wafers. Abe and Kato (7) describe the reflection in terms of a multilayered step function approximation to a complimentary error function profile. Sato, Ishikawa, and Sagawara (8) developed an effective index of refraction of the layer which accounts for the same type of profile. It is shown in this paper that it is not necessary to account for the impurity profile in the epitaxial layer if errors ranging up to 4% in thickness can be tolerated, provided the wave-length dependence of the phase shift and reflectivity of the layer-substrate interface are incorporated in the calculations.

The precision of the technique is perhaps the best of any of the commonly used semiconductor materials measurements. The multilaboratory three sigma precision of the technique as determined by the ASTM (9) using phase shift corrections and the average of all peaks and valleys obtained for N/N$^+$ silicon layers greater than 5μ is $\pm$ (0.005t + 0.25μ) and for the P/P$^+$ silicon layers is $\pm$ (0.025t + 0.25μ) where t is the thickness of the layer to be measured in microns. For this paper, measurements on three wafers with thicknesses of 2, 4, and 8μ were made with a Perkin-Elmer

* Electrochemical Society Active Member.

621 spectrophotometer over a period of 3 weeks to determine single instrument precision. The reading of the position of a single peak or valley resulted in a standard deviated (pooled) of 0.72%. Thickness obtained from a single peak or valley using the new corrections contained in this report had a standard deviation of 0.82%. In previously published work (2, 3), the technique was compared with various staining procedures but no firm correlation curve was ever established.

The spreading resistance technique (10, 11) of measuring impurity profiles in epitaxial layers is well suited for comparison with the infrared interference technique. The impurity profile thus determined can be compared with the thickness obtained with the infrared interference technique.

Theory

For the reflection from the step function system shown in Fig. 1, neglecting polarization effects which will be small if the angle of incidence is equal to or less than 30°

$$R = \frac{r_1^2 + r_2^2 - 2r_1r_2 \cos(\delta - \phi)}{1 + r_1^2r_2^2 - 2r_1r_2 \cos(\delta - \phi)}$$

where

$$r_1^2 = \left(\frac{n_1 - n_0}{n_1 + n_0}\right)^2, \quad r_2^2 = \frac{(n_2 - n_1)^2 + k_2^2}{(n_2 + n_1)^2 + k_2^2};$$

$$\delta = \frac{4\pi n_1 h}{\lambda}\left(1 - \frac{n_0^2}{n_1^2}\right) \sin^2 \phi_0$$

and

$$\phi = \tan^{-1}\left(\frac{2n_1k_2}{n_1^2 - n_2^2 - k_2^2}\right)$$

where

- n_i is the index of refraction
- k_i is the extinction coefficient
- R is the reflectivity of the layer-substrate system
- r_1^2 is the reflectivity of the air-layer interface
- r_2^2 is the reflectivity of the layer-substrate interface
- θ is the phase shift on reflection at the layer-substrate interface
- ϕ is the angle of incidence
- λ is the wave length in vacuum

The factors n_i and k_i are associated with the real and complex part of the complex index of refraction, $n^* = n - ik$. Polarization effects can be neglected in this case because, at 30° angle of incidence, the error in reflectivity between r_1^2 and an expression including polarization is less than 1% at $\lambda = 50$ μm. Due to the high index of refraction of the epitaxial layer, the angle of incidence at the layer-substrate interface has a maximum of 8° with a 30° angle of incidence at the air-layer interface. The error in r_2^2 is then much less than 1%. Both errors are much less than that at $\lambda = 2$ μm.

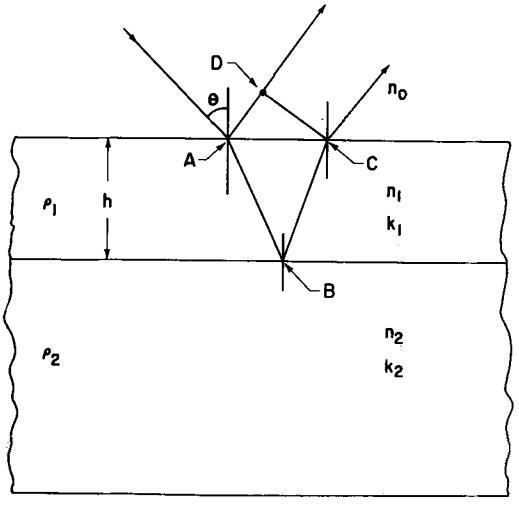

Fig. 1. Basic geometry of infrared interference technique

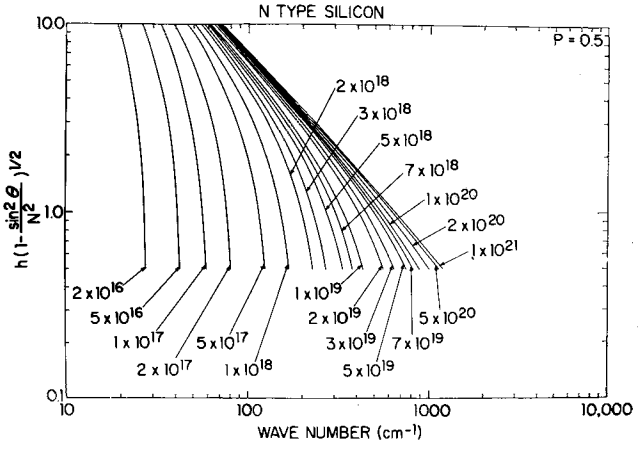

Fig. 2. Sample of thickness charts for N-type silicon. Normalized thickness is plotted as a function of the position of the minima, $P = 1/2$, for various substrate impurity concentrations.

The value of R was numerically calculated and the positions of the maxima and minima determined. This was performed on an IBM 7094 computer using the theory for the optical constants described earlier (4, 12) and produced a series of graphs (13) similar to Fig. 2.[1] The approximate order is usually known, but if not it may be calculated from

$$P_{k+m} = \frac{m\nu_{k+m}}{u_{k+m} - \nu_R} + \frac{1}{2} - \frac{\theta_k u_{k+m} - \theta_{k+m} u_k}{2\pi(\nu_{k+m} - u_k)}$$

where

- P_{k+m} is the order of the $k + m$'th fringe,
- u_i is the wavenumber of the i'th fringe
- θ_i is the phase shift at the layer-substrate interface for u_i

These charts then make it possible to find the thickness of the epitaxial layer without any calculations for the various orders. They include the phase shift corrections, and since they are the position of the actual maxima or minima as observed they preclude the use of the envelope tangent method. The difference between this technique and the phase shift correction scheme will be greatest for very thin layers. Figure 3 shows a calculated reflectivity for an N/N$^+$ structure with a layer thickness of 0.5μ. The position of the maxima is quite different from the tangent point of the envelope curve which is also calculated.

The phase shift corrections apply a correction of about +8% and the charts about +6% to the uncorrected thickness values for thicknesses between 1 and 10μ. For this comparison the phase shift and uncorrected thicknesses were calculated from

$$t_{k+m} = \left(P_{k+m} - \frac{1}{2} + \frac{\theta_{k+m}}{2\pi}\right) \frac{1}{2\nu_{k+m}\,[n_1^2 - \sin^2\phi_0]^{1/2}}$$

[1] Note: A complete set of curves is available from the author on request.

Table I. Comparison of infrared interference with various techniques to measure epitaxial thickness showing correlation equations and experimental error of fit of correlation curve

Treatment @1200°C	T1 t_s	T1 t_{IR}	T1 t_{SRP}	T1 t_{SRS}	T1 t_{SRHP}	T2 t_s	T2 t_{IR}	T2 t_{SRP}	T2 t_{SRS}	T2 t_{SRHP}	T3 t_s	T3 t_{IR}	T3 t_{SRP}	T3 t_{SRS}	T3 t_{SRHP}
None	4.75	4.91	5.3	4.9	4.8	6.9	7.30	7.3	7.2	7.1	0.78	1.17	1.32	0.97	0.85
30 min	4.42	4.85	5.3	4.6	4.5	6.5	7.19	7.4	6.7	6.5	0.63	1.21	1.32	0.74	0.65
60 min	—	4.82	5.4	4.2	4.1	—	7.03	7.3	6.3	6.0	—	—	—	—	—
90 min	—	4.72	5.0	4.1	4.1	—	—	—	—	—	—	—	—	—	—
Maximum charge (per cent)	—	3.9	7.4	16.3	14.6	—	3.9	1.3	12.5	15.5	19.3	3.3	0	23.7	23.5

For the uncorrected case θ_{k+m} was assumed to be zero. In all cases, the thickness was obtained for all the maxima and minima observed, and averaged. As many as 12 orders were observed in some cases. The variance of all the thickness values was calculated about the mean and averaged over all the wafers measured. The square root of the average variance is a measure of the consistency of the technique and was 9.2% uncorrected, 5.1% phase shift corrected, and 3.6% chart corrected.

Comparison with Stain and Spreading Resistance

The wafers measured by the infrared interference technique were beveled at a shallow angle and spreading resistance profiles were made. The bevels were later stained with a silver stain (14) whose composition was: 100 ml 48% HF, 2 ml HNO_3, and 1 ml $AgNO_3$ sol.

The silver nitrate solution was composed of 2g $AgNO_3$ in 100 ml H_2O. The stain was developed with illumination and observed under low magnification. As soon as bubbles began to appear, the stain was quenched with water. The thickness thus read is labeled t_S.

The spreading resistance profiles were made by the technique described earlier (11). A sample profile is shown in Fig. 4. Several techniques were used to determine the thickness from the profile. It is clear because it is a profile that there is no definite demarcation of thickness. The slope method used the intersection of the tangent of the downward portion of the profile and the tangent line to the peak value, labeled t_{SRS}. The thickness of maximum impurity concentration is labeled t_{SRP}, and the thickness of half the maximum impurity concentration, t_{SRHP}. These thickness values along with those determined by the infrared interference method are shown in Fig. 4 for that sample. The general relationships between these thickness values and the rms per cent error of the fit of the correlation curves which was obtained by a least squares technique are given in Table I. The best agreement from 1 to 10μ is with the spreading resistance peak technique, as the infrared interference technique indicates a thickness slightly less than the peak concentration.

All wafers studied in this report were grown in a horizontal epitaxial reactor by the hydrogen reduction of $SiCl_4$ at 1210°C with a 2-min postdeposition bake in hydrogen at the deposition temperature.

The half peak technique should be the most accurate indication of the metallurgical interface. The stain technique seems to indicate a position on the profile below the peak. The spreading resistance slope technique and the stain indicate almost the same thickness.

Effect of Altered Profile

Three of the wafers grown by the standard epitaxial process were subjected to various heat treatments in order to alter the impurity profile in the layer. These layers had nominal thickness of 1.77, 4.91, and 7.3μ before heat treatment. The same stain, infrared, and spreading resistance techniques were used to determine thickness. The uncorrected spreading resistance profiles are shown in Fig. 5, 6, and 7. It is apparent from these that the impurity profile was altered significantly by the heat treatments. Table II lists the results obtained by the various thickness methods described. Figure 8 is a plot of the per cent change in thickness from the untreated case as a function of the heat treatment time averaged over all the wafers. The infrared interference technique of measuring the thickness is much less sensitive to changes in the impurity profile than all of the other techniques except the spreading resistance peak method.

The stain technique was not able to resolve those layers which were heat treated more than 30 min. The stain region was too broad and shaded. With the exception of the data point at 60 min, the infrared and spreading resistance values track very well. In all cases, the spreading resistance slope and spreading resistance half-peak values were comparable.

Conclusions

Several conclusions can be drawn regarding N/N+ and P/P+ epitaxial silicon from the data presented in this paper:

1. The infrared interference method measured the location in depth of a point on the impurity profile which is close to the maximum impurity concentration. The measured thickness decreases as the profile becomes less abrupt.

Table II. Comparison of various techniques to measure epitaxial layer thickness as a function of heat treatment to alter profiles

Technique	Correlation equation with infrared influence	RMS error of fit, %
Stain	$t_{IR} = 1.054\, t_s + 0.196$	10.1
Spreading resistance slope	$t_{IR} = 1.018\, t_{SRS} + 0.272$	6.6
Spreading resistance peak	$t_{IR} = 0.936\, t_{SRP} + 0.058$	7.5
Spreading resistance half peak	$t_{IR} = 1.022\, t_{SRHP} + 0.327$	7.0

2. The stain method measures a position on the steep portion of the impurity profile which is approximately that given by the spreading resistance slope technique.

3. The infrared interference technique as practiced in this paper is relatively independent of the shape of the impurity profile and thus for the variations in profiles normally encountered it is not necessary to incorporate additional profile corrections. For the drastically altered profiles a maximum change of 4% in thickness was measured.

4. Both the single-instrument and multilaboratory precisions are good for the infrared interference technique as practiced in this paper.

5. The lower limit of measurable thickness is 0.8 μm if a 4% error can be tolerated. Thinner layers can be measured but the effects of the profile become more important.

Acknowledgments

The author would like to acknowledge the experimental assistance of Mr. C. P. Schneider who made the measurements reported. He would also like to thank Mr. C. M. Sakkas for programming the IBM 7094 computer to perform the calculations.

Manuscript submitted April 29, 1968; revised manuscript received ca. Nov. 30, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 82.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Preparation and Properties of Epitaxial Gallium Arsenide

M. Maruyama, S. Kikuchi, and O. Mizuno

Central Research Laboratories, Nippon Electric Company, Limited, Kawasaki, Japan

ABSTRACT

High-purity epitaxial layers of n-type gallium arsenide have been grown by vapor deposition, using the reaction of arsenic trichloride with gallium. The purity of the layers was significantly increased when nominal 99.9999+% arsenic trichloride was substituted for nominal 99.999+% material. When the less-pure arsenic trichloride was used, there was a systematic variation in the electrical properties of layers grown in successive runs with the same gallium source. Resistivity and Hall coefficient measurements were made between 300° and 4.2°K. The maximum electron Hall mobilities were 9180, 164,000, and 175,000 cm^2/v-sec at 300°, 77°, and 50°K, respectively. No impurity band conduction was observed even at 4.2°K in pure samples.

Recent work on GaAs (1-4) has indicated that vapor phase epitaxial growth using the reaction (5) of arsenic trichloride with gallium is an excellent method to prepare high-purity and high-mobility gallium arsenide. We have used the method and obtained layers with maximum electron Hall mobility up to 175,000 cm^2/v-sec and room-temperature mobility up to 9180 cm^2/v-sec, carrier concentrations usually being in the range 1 x 10^{14}-4 x 10^{14} cm^{-3}. It is the purpose of this report to describe the preparation and electrical properties of high-purity gallium arsenide epitaxial layers grown from the vapor phase by using the reaction of arsenic trichloride with gallium.

Growth Procedure and Electrical Measurements

Starting materials were gallium (Eagle-Picher Industries 99.99999%), arsenic trichloride (Mining and Chemical Products 99.999% and Mitsubishi Metal Mining Company 99.9999%), and palladium-diffused hydrogen.

The substrates were Cr-doped semi-insulating GaAs (room-temperature resistivity $> 10^8$ ohm-cm) prepared by horizontal boat growth and cut in the (100) plane. The wafers with mirrorlike surfaces were obtained by lapping with Carborundum and mechanical polishing with diamond paste on a rotating pad. They were degreased in boiling trichloroethylene three times and stored in ethyl alcohol. They were lightly etched with the solution of $3H_2SO_4 + H_2O_2 + H_2O$ and finally washed in deionized water before use.

A two-zone furnace was used for this work. The reaction tube, substrate holder, gallium boat, and $AsCl_3$ bubbler were made of high-purity quartz. The dimensions of the reaction tube were about 1m in length and 37 mm ID. Gas supply tubing and valves were made of stainless steel. The quartz parts were cleaned with *aqua regia* and rinsed with deionized water.

The epitaxial process was as follows. Twenty-five grams of gallium were put in the first zone of the reaction tube. The reaction tube was flushed with hydrogen and the furnace was turned on. Both zones were set at 850°C. When the furnace was heated up to the operating temperature, hydrogen was bubbled at a rate of 300 cc/min through the $AsCl_3$ held at 25°C for 1 hr and gallium was completely saturated with arsenic. After the saturation was achieved, the reaction tube was flushed with hydrogen and the furnace was cooled to room temperature. Then the substrate was put in the second zone. The reaction tube was again flushed with hydrogen and the furnace was turned on. The temperatures were held at 850°C for the source gallium and at 730°-750°C for the substrate. The temperature gradient in the vicinity of the substrate was 10°C/cm. The flow rate of the hydrogen gas saturated with $AsCl_3$ at 0°C in the bubbler was about 300 cc/min, corresponding to about 5 x 10^{-5} moles/min of $AsCl_3$. The growth rate was about 15 μ/hr.

The Hall coefficient R_H and resistivity ρ were measured from 300° to 4.2°K on bridge-shaped samples formed by etching. The carrier concentration n was calculated from the relation $n = 1/R_H e$, where R_H is the value measured at 6000 gauss. The electron Hall mobility was calculated from the Hall coefficient measured in low magnetic field (650 gauss).

The donor concentration N_D, acceptor concentration N_A, and donor ionization energy E_D were estimated from R_H *vs.* T curves, using the relation (6)

$$\frac{n(N_A + n)}{(N_D - N_A - n)} = \frac{N_C}{D} \exp\left(-\frac{E_D}{kT}\right)$$

where D is the degeneracy of the donor level, T the absolute temperature, and N_C the effective density of states in the conduction band, given by

$$N_C = 2\left(\frac{2\pi m^* kT}{h^2}\right)^{3/2}$$

where m^* is the density of states effective mass of the electrons. In the present calculation, the values $m^* = 0.0072\ m_e$ (7) and $D = 2$ were used.

Dislocations were revealed on the (111) gallium plane by chemical etching with the solution (8) $3HNO_3 + 4H_2O$. The dislocation density in the layer 5-10μ apart from the epitaxial-substrate interface was less than that in the substrate by a factor of 1-2 as reported previously (9). The dislocation density in the substrate was about 10^3-10^4 cm^{-2}.

Results and Discussion

The epitaxial layers grown in initial experiments exhibited considerable scatter in their electrical properties, with n varying from 10^{13} to 10^{15} cm^{-3} and μ_H at room temperature varying from 1000 to 7000 cm^2/v-sec. This scatter resulted from the presence of leaks in the growth apparatus, and may have been due to contamination by O_2 or H_2O. It was eliminated by using

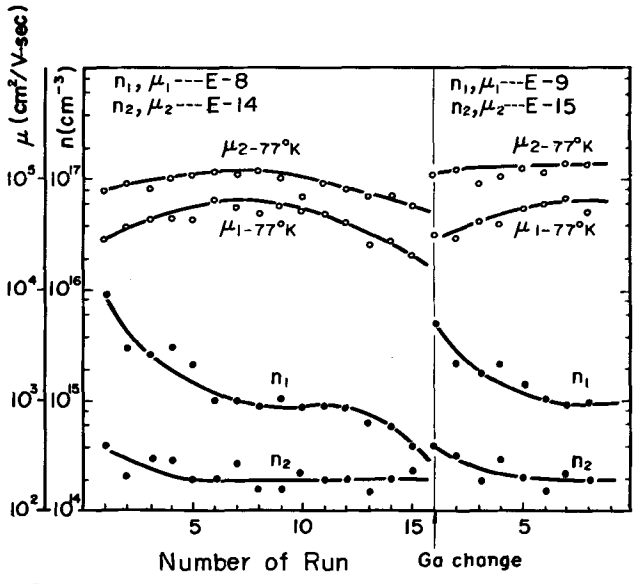

Fig. 1. Variation in the electrical properties of epitaxial layers formed in successive runs of a reaction series. The curves labeled n_1 and μ_1 show the carrier concentrations and the electron Hall mobilities in series E-8 and E-9. The curves labeled n_2 and μ_2 show those quantities in series E-14 and E-15.

apparatus which could be evacuated to pressures of the order of 10^{-4} Torr. All the epitaxial layers described in the rest of this paper were grown with the leak-free apparatus.

Figure 1 shows the electrical properties of the layers grown in successive runs of four reaction series, E-8, E-9, E-14, and E-15. The nominal purity of the $AsCl_3$ used was 99.999+% in series E-8 and E-9, and 99.9999+% in series E-14 and E-15. Each series consisted of about 20 runs with a single gallium source. The source was changed between series E-8 and E-9, and between series E-14 and E-15. The thickness of the growth layers is about 15μ. In Fig. 1, n_1 designates the carrier concentrations at 300°K and $\mu_{1\text{-}77°K}$ designates the electron Hall mobilities at 77°K for the layers prepared in series E-8 and E-9, while n_2 and $\mu_{2\text{-}77°K}$ indicate the corresponding quantities for series E-14 and E-15.

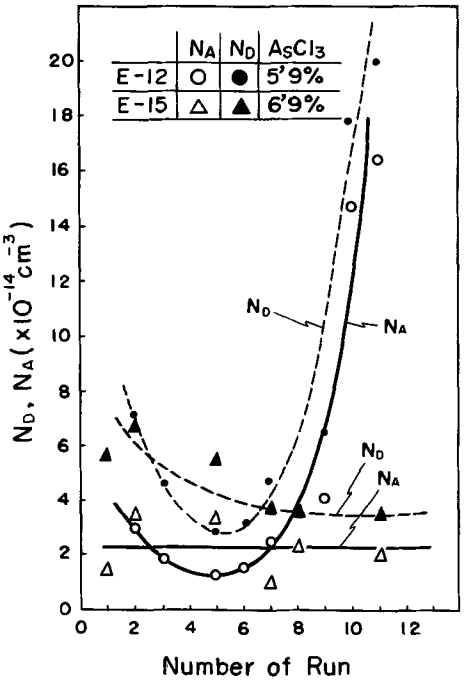

Fig. 2. Variation in the acceptor and donor impurity concentrations obtained in successive runs of two reaction series.

In the first half of series E-8, the electron Hall mobilities at 77°K, $\mu_{1\text{-}77°K}$, increase to a maximum value, while those at 300°K are essentially constant. After the weight of source gallium decreases to about half its original value, n_1 and μ_1 decrease markedly. When the source gallium is replaced by a fresh one (*i.e.*, E-8 → E-9), n_1 and μ_1 recover the original values of the first half of series E-8. In the latter half of series E-8, it was observed that the acceptor concentration N_A increased clearly in successive runs. In some series, the layers were converted from n-type to p-type by con-

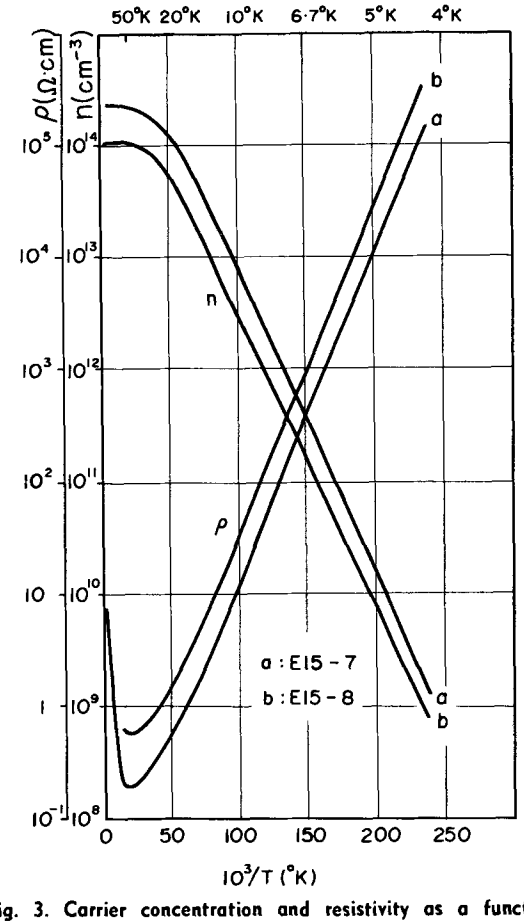

Fig. 3. Carrier concentration and resistivity as a function of temperature in n-type epitaxial GaAs.

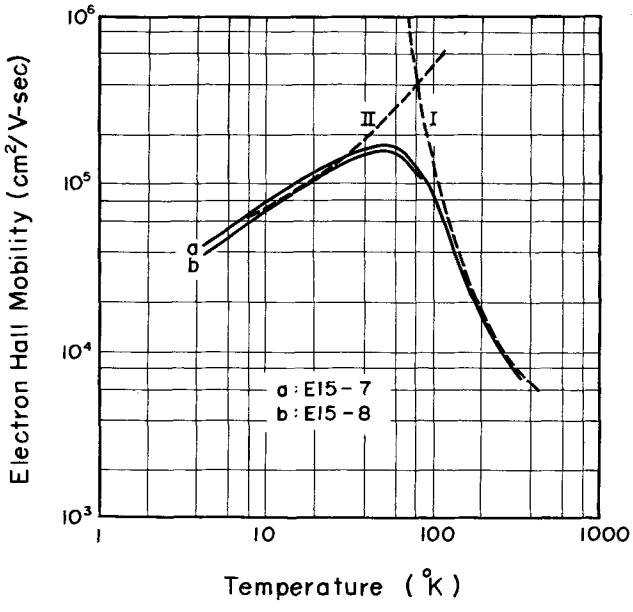

Fig. 4. Mobility as a function of temperature in n-type epitaxial GaAs.

Table I. Properties of high-purity n-type epitaxial GaAs

Sample	$N_D - N_A$ (cm^{-3})	N_D (cm^{-3})	N_A (cm^{-3})	E_D (ev)	μ (cm^2/v-sec) 300°K	77°K	peak (50°K)
15-7	2.6×10^{14}	3.6×10^{14}	1.0×10^{14}	0.0048	8.580	164.000	175.000
15-8	1.2×10^{14}	3.6×10^{14}	2.4×10^{14}	0.0047	9.180	153.000	162.000
15-11	1.6×10^{14}	3.5×10^{14}	1.9×10^{14}	0.0046	8.400	150.000	160.000

tamination with acceptor impurities. When high-purity $AsCl_3$ (99.9999+%) was used, however, no appreciable contamination was observed (*see* the curves for E-14 and E-15). In order to clarify the situation, the calculated values of the acceptor and donor concentrations are plotted in Fig. 2 against the run number for series E-12 and E-15. The same purity $AsCl_3$ was used in series E-12 as in series E-8. It is clearly seen that no appreciable change in N_D and N_A occurred when 99.9999+% $AsCl_3$ was used, in contrast to the case for 99.999+%. From these results, it may be concluded that in the initial runs of a series the source gallium acts as a getter for the acceptor and donor impurities in the $AsCl_3$, but eventually it becomes saturated and is no longer an effective getter. The decrease in N_D and N_A observed in the initial runs of each series must be due to the depletion of impurities from the walls of the reaction tube or from other static parts of the system.

Typical curves for the temperature dependence of ρ, n, and μ_H for high-purity specimens are shown in Fig. 3 and 4. No impurity band conduction is observed even at 4.2°K in pure samples. The most important scattering mechanism between 300° and 100°K seems to be polar optical-mode scattering. Curve I in Fig. 4, computed from the theory (10) for this type of scattering, agrees well with the experimental results. Ionized impurity scattering is dominant below 50°K. Curve II was calculated from the Brooks-Herring theory (11) using the data for sample E15-7. The difference between the theory and experimental results may be due to the difference between zero-field Hall mobility and drift mobility. The highest Hall mobility of 175,000 cm^2/v-sec at 50°K was observed for this sample, in which $N_D = 3.6 \times 10^{14}$ cm^{-3} and $N_A = 1.0 \times 10^{14}$ cm^{-3}. Values of N_D, N_A, E_D, and μ_H obtained for typical samples are given in Table I. For sample E15-7, the mobility at 77°K (164,000 cm^2/v-sec) was decreased to 143,000 cm^2/v-sec when calculated from the high field Hall coefficient.

The dependence of the donor ionization energy on donor concentration is shown in Fig. 5. The value of E_D extrapolated to infinite dilution is approximately 0.005 ev, which is consistent with the previous data (3).

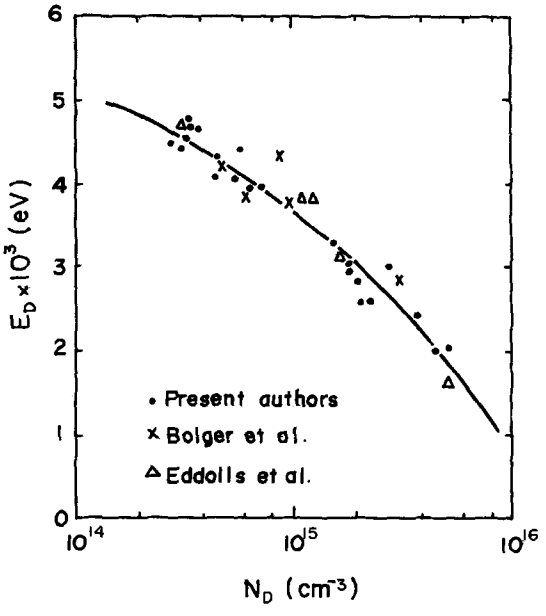

Fig. 5. Dependence of donor ionization energy upon donor concentration.

Acknowledgments

It is a pleasure to thank Drs. Y. Sasaki, S. Asanabe, T. Okada, and Y. Matsukura for useful advice, and Messrs. H. Iwasaki and Y. Kuwano for assistance in the measurements of electrical properties.

Manuscript submitted July 5, 1968; revised manuscript received Nov. 18, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 62.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Algorithms for the Vapor Pressure of Water Over Aqueous Solutions of Salt and Caustic Soda

R. B. MacMullin

R. B. MacMullin Associates, Niagara Falls, New York

ABSTRACT

Incidental to development of a digital computer program for the performance of electrolytic chlor-alkali cells is the necessity of general formulas for calculating the vapor pressure of the aqueous solutions used for the electrolytes. This paper offers algorithms for vapor pressure of pure water, pure NaCl solutions, pure NaOH solutions, and aqueous solutions containing both NaCl and NaOH, within the range of conditions usually encountered in commercial cells of both the mercury and the diaphragm type.

Incidental to development of a digital computer program for the performance of electrolytic chlor-alkali cells is the necessity of a general formula for calculating the vapor pressure of the aqueous solutions used for the electrolytes. The electrolytes usually encountered are:

	Diaphragm cell	Mercury cell
Anolyte	NaCl, >20%, 90°-100°C	NaCl >20%, 50°-90°C
Catholyte	NaOH, 10-14%, 93°-103°C NaCl, 14-20%, 93°-103°C	NaOH, 30-60%, 70°-120°C

The algorithms[1] which follow cover a range of conditions which include the above ranges of interest.

I. Vapor pressure of pure water over the range 10°-150°C.

II. Vapor pressure lowering due to the dissolved NaCl over the range 3M to saturation, and 30°-110°C.

III. Vapor pressure lowering due to the dissolved NaOH: (*a*) over the range 0-12.5M, 20°-110°C, (*b*) over the range 12.5-25M, 20°-110°C.

IV. Combinations of II and III(*a*).

In this paper, temperature is expressed °C; concentration, as Molality (g.f.w./kg H_2O); M for NaCl, N for NaOH; vapor pressure, as Torr (mm Hg).

Vapor Pressure of Pure Water

The steam tables of Keenan and Keyes (1) are based on two formulas taken from the paper by Smith, Keyes, and Gerry (2). The second formula covering the range 10°-150°C is the simpler of the two:

$$\log_{10}\frac{p_c}{p} = \frac{x}{T}\left[\frac{a + bx + cx^3}{1 + dx}\right] \qquad [1]$$

p = vapor pressure in int atm
p_c = critical pressure, 218.167 int atm
T = degrees Kelvin, t°C + 273.16
T_c = critical temperature, 647.27°K
x = $T_c - T$
a = 3.2437814
b = 5.86826×10^{-3}
c = 1.1702379×10^{-8}
d = 2.1878462×10^{-3}

Expressing p as Torr and t as °C, the above formula reduces to the following, which are programmed in sequence:

$$374.11 - t = x \qquad [2]$$

$$\text{antilog}_{10}\left(5.219603 - \frac{x}{t + 273.16}\left[\frac{a + bx + cx^3}{1 + dx}\right]\right) = p_o \qquad [3]$$

This formula reproduces published tables for the vapor pressure of water to within ± 0.02 Torr.

[1] Here used as the art of reducing data involving three or more variables to a single algebraic equation for computer use.

Vapor Pressure Lowering in Pure Salt Solutions

Source of data: International Critical Tables (3), Vol. III, p. 370.

The fractional lowering of vapor pressure due to the solute (in this case NaCl) is expressed

$$R = \frac{(p_o - p)}{p_o M} = \frac{\Delta p}{p_o M} \qquad [4]$$

Since the concentration of NaCl in the table is expressed as w/o (weight per cent), the Molality is

$$M = \frac{\text{w/o NaCl}}{\text{w/o } H_2O} \div 0.0584428$$

Values of 100 R were calculated for each of the data points given in the ICT table quoted above. In Fig. 1, 100 R *vs.* t is plotted for the various concentrations, and R appears to be a linear function of t. In Fig. 2, 100 R *vs.* M. is plotted for the various temperatures, and above 3 M, R appears to be a linear function of M. The lines appear to intersect at the point 100 R = 3.5 at M = 3.0. That is, above 3 M, R may be expressed as follows:

$$R = (M - 3)\ (0.0019772 - 0.00001193\ t) + 0.035 \qquad [5]$$

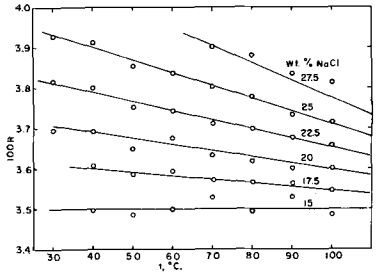

Fig. 1. Vapor pressure lowering, pure aqueous NaCl. Range 15% NaCl to saturation; 40°-110°C.

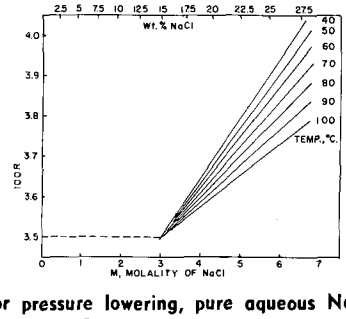

Fig. 2. Vapor pressure lowering, pure aqueous NaCl. Range, 3M to saturation; 40°-110°C.

Since $p = p_o - RMp_o = (1 - RM)p_o$

$$p^+ = [1 - ((M^+ - 3)(1.9772 \times 10^{-3} - 1.193 \times 10^{-5} t^+) + 0.035)\, M^+]\, p_o^+ \quad [6]$$

where the superscripts indicate conditions applicable to the anolyte.

The above formula reproduces most of the data in the ICT tables, at concentrations above 15 w/o NaCl and temperatures from 40° to 110°C, to an accuracy of about ± 0.5 Torr. Several random inconsistencies in the ICT data are apparent.

Below 15 w/o NaCl, it will generally be sufficiently accurate for most purposes, to take $R = 0.035$ at any temperature. For the anolyte problem, the concentration will nearly always be above 15% NaCl, where the sophisticated formula above applies.

Vapor Pressure Lowering in Pure Caustic Soda Solutions

Source of data: International Critical Tables (3), Vol. III, p. 370.

The fractional lowering of vapor pressure due to the solute (in this case NaOH) is expressed

$$R = \frac{\Delta p}{p_o N}$$

Since concentration of NaOH in the ICT table is expressed as C = g NaOH/100g H_2O

$$N = \frac{C}{3.99971} = \text{g.f.w./kg } H_2O$$

100 R has been calculated for all data points given in the ICT table up to $C = 120$ (55% NaOH), at 20°, 40°, 60°, 80°, and 100°C. In Fig. 3, 100 R *vs.* N is plotted for various values of constant t, and one notes that 100 R goes through a maximum at about N = 12.5 Molal.

Case A.—Concentrations < 12.5 Molal (33 w/o of NaOH). In Fig. 4, 100 R *vs.* t is plotted at various values of N. At each value of N, R appears to be a linear function of t. The lines appear to intersect at a common point, 100 $R = 3.17$, $t = 174$°C.

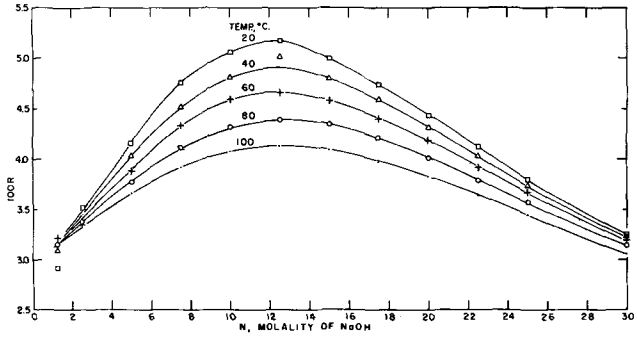

Fig. 3. Vapor pressure lowering, pure aqueous NaOH. Range, 0-30 Molal; 20°-100°C.

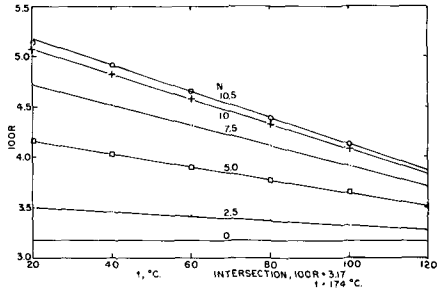

Fig. 4. Vapor pressure lowering, pure aqueous NaOH. Range, 0-12.5 Molal NaOH; 40°-110°C.

Calling the slope of these lines $-dR/dt = m$,

$$R = 0.0317 - m(t - 174)$$

or

$$R = 0.0317 + m(174 - t)$$

The slope of each line was then measured, as per the table which follows:

Molality, N	Slope 100 m $-\Delta$ 100 $R/\Delta t$
0	0
2.5	0.00214
5	0.00636
7.5	0.01000
10	0.01227
12.5	0.01299

In Fig. 5, the negative of the slope, 100 m is plotted against Molality. The curve appears to be close to a quadratic with a maximum at N = 12.5. However, at lower concentration the curve reverses, as shown. A suitable curve fit is obtained by assuming a polynomial of the form

$$m = a + bN + cN^2 + d/N \quad [8]$$

Solving this polynomial for the data given, the following constants are formed

$$a = -8.6715 \times 10^{-5}$$
$$b = 3.368 \times 10^{-5}$$
$$c = -1.354 \times 10^{-6}$$
$$d = 7.88 \times 10^{-5}$$

Hence,

$$R = 0.03170 + (174 - t)(a + bN + cN^2 + d/N) \quad [9]$$

and

$$\Delta p = [(0.03170 + (174 - t)(a + bN + cN^2 + d/N)]N p_o \quad [10]$$

and

$$p = (1 - RN)\, p_o = \{1 + [(t - 174)(a + bN + cN^2 + d/N) - 0.03170]N\} p_o \quad [11]$$

The curves shown in Fig. 3, up to N = 12.5, are actually a plot of Eq. [11]. All the data points fall on these curves, except two, and these are believed to be errors or misprints in the data tabulated in ICT.

Case B.—N >12.5 (33% NaOH) to N = 30 (55% NaOH). Applicable to caustic made in decomposer of a mercury cell.

In Fig. 6, 100 R *vs.* t is plotted at various values of N. At each value of N, within the temperature range of 60°-110°C, R appears to be a linear function of t. The lines appear to intersect at a common point, 100 $R = 2.83$, $t = 198$°C.

Calling the slope of these lines $-dR/dt = m$,

$$R = 0.0283 + m\,(198 - t) \quad [12]$$

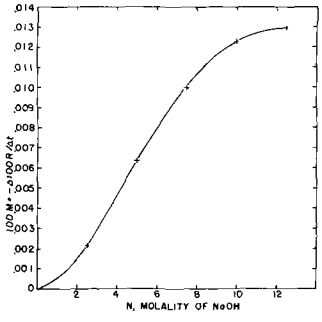

Fig. 5. Temperature coefficient of 100 R for pure NaOH. Range, 0-12.5 Molal NaOH; 40°-110°C.

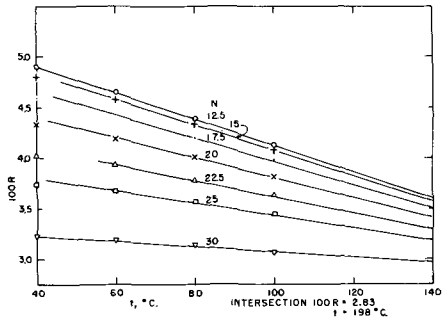

Fig. 6. Vapor pressure lowering, pure aqueous NaOH. Range, 12.5-30 Molal NaOH; 40°-110°C.

The slope of each line was then measured, as per the table which follows

Molality, N	Slope 100 m $-\Delta$ 100 $R/\Delta t$
12.5	0.01319
15	0.01268
17.5	0.01160
20	0.00990
22.5	0.00804
25	0.00616
30	0.00254

In Fig. 7 the negative of the slope 100 m is plotted against Molality. The curve shows a maximum at N = 12.5. As before, a suitable curve fit is obtained by assuming a polynomial of the form

$$m = a' + b'N + c'N^2 + d'/N \quad [13]$$

Solving this polynomial for the data given, the following constants are found

$$a' = 6.2066 \times 10^{-4}$$
$$b' = -2.3155 \times 10^{-5}$$
$$c' = 2.1860 \times 10^{-7}$$
$$d' = -2.920 \times 10^{-3}$$

Hence,

$$R = 0.0283 + (198 - t)(a' + b'N + c'N^2 + d'/N) \quad [14]$$

$$\Delta p = [0.0283 + (198 - t)(a' + b'N + c'N^2 + d'/N)]N\,p_o \quad [15]$$

$$p = (1 - RN)p_o = \{1 + [(t - 198)(a' + b'N + c'N^2 + d'/N) - 0.0283]N\}p_o \quad [16]$$

The curves shown in Fig. 3, from N = 12.5 to N = 30, are actually a plot of Eq. [16]. These curves fit the data from the ICT table very well.

Vapor Pressure Lowering in Diaphragm Cell Liquor

Let Δp_M be the vapor pressure lowering due to the NaCl

Δp_N be the vapor pressure lowering due to the NaOH

$$p^- = p_o^- - \Delta p_M^- - \Delta p_N^- \quad [17]$$

where the minus superscripts refer to the catholyte at t^- °C.

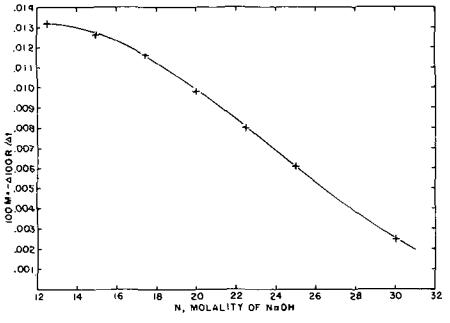

Fig. 7. Temperature coefficient of 100 R for pure NaOH. Range, 12.5-30 Molal NaOH; 40°-110°C.

For the usual cell liquor composition range, M^- will be >3 Molal and N^- <12.5 Molal. The assumption is now made that the Δp_M^- and Δp_N^- are additive, as indicated from Eq. [17].

From II

$$\Delta p_M^- = [(M^- - 3)(0.0019772 - 0.00001193\,t^-) + 0.035]M^-\,p_o \quad [18]$$

From IIIA

$$\Delta p_N^- = [0.03170 + (174 - t^-)(a + bN^- + c(N^-)^2 + d/N^-)]N^-\,p_o \quad [19]$$

$$p^- = \{1 - [(M^- - 3)(0.0019772 - 0.00001193\,t^-) + 0.035]M^- - [(174 - t^-)(a + bN^- + c(N^-)^2 + d/N^-) + 0.0317]N^-\}p_o^- \quad [20]$$

Defining the fractional decomposition of salt in one pass through the diaphragm cell as D, then

$$\frac{N^-}{M^-} = \frac{D}{1 - D} \quad [21]$$

so that, if D is known, there is only one concentration variable, either N^- or M^-.

It is also worth noting that, in a diaphragm cell, the catholyte temperature is always greater than the anolyte temperature. For Hooker cells at rated load, $t^- - t^+$ = approx 3°C.

Example

Figure 8 shows the calculated vapor pressure of diaphragm cell liquor at various concentrations of NaOH and salt decomposition within the range of interest, for a typical temperature of 100°C. Since the solubility of NaCl in NaOH solutions is limited, the saturation line is shown. Only that portion of the plot lying above the saturation line is valid.

Comparison of calculated vapor pressure along the saturation line with experimental data indicates an accuracy within 3%. This is sufficiently good for most engineering purposes. Greater accuracy would require taking into account the interaction between NaCl and NaOH; that is, the slight departure from the assumption that the vapor pressure lowerings of the two solutes are additive.

Programming

For input to a digital computer, the equations can be simplified. The format will depend on the computer used and its program logic. For example, for the Mathatron 8-48 (Mathatronics Division of Barry Wright Corporation, Waltham, Massachusetts),

Eq. [3]

$$c \cdot x \cdot x + b)\,x + a)\,x \div (t + 273.16) \div (1 + d \cdot x) - 5.219603)\,(-1) = \log p_o, \text{antilog} = p_o$$

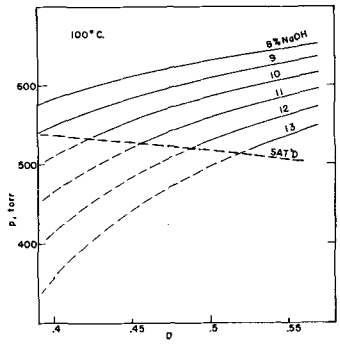

Fig. 8. Vapor pressure of catholyte from a diaphragm cell vs. salt decomposition. Ordinate, Torr. Abscissa, fractional decomposition D. Heavy dashed line shows saturation with NaCl. Valid values of composition and vapor pressure lie above this line.

Eq. [6]

$$1.9772 \cdot 10^{-3} - 1.193 \cdot 10^{-5} \cdot t^{+}) \ (3 - M^{+}) - 0.035) \ M^{+} + 1) \ p_o = p^{+}$$

Eq. [11]

$$cN + b) \ N + a + d \div N) \ (t - 174) - 0.0317) \ N + 1) \ p_o = p$$

Eq. [16]

$$c'N + b') \ N + a' + d' \div N) \ (t - 198) - 0.0283) \ N + 1) \ p_o = p$$

Eq. [20]

$$c \cdot N^{-} + b) \ N^{-} + a + d \div N^{-}) \ (t^{-} - 174) - 0.0317) N^{-} + ((3 - M^{-}) \ (1.9772 \cdot 10^{-3} - 1.193 \cdot 10^{-5} \cdot t^{-}) - 0.035) \ M^{-} + 1) \ p_o = p^{-}$$

Manuscript submitted Oct. 22, 1968; revised manuscript received Dec. 6, 1968. This paper was presented at the Tripartite meeting of the A.I.Ch.E., Montreal, Sept. 25, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Erratum

There was an error in the paper "Accommodation of Lattice Mismatch at Heterojunctions" by R. S. Mroczkowski, A. F. Witt, and H. C. Gatos, **115**, 750 (1968) which was published in the July 1968 issue of the Journal (**115**, 750-752).

In considering the theoretical dislocation density required for the accommodation of an abrupt lattice mismatch in single crystal growth ($\Delta = Sa_o^2/\delta$), inadvertently, the lattice translation in the $a_{(110)}$ direction in the zinc-blende lattice was taken as $a_{(110)} = \sqrt{2}a_o$ instead of $a_{(110)} = \frac{1}{\sqrt{2}} a_o$; the theoretical dislocation density is smaller by a factor of 2 than that indicated in the article. Consequently, a comparison with the experimentally observed dislocation density suggests that part of the lattice mismatch is accommodated by strain. In the light of the present correction, the results seem to confirm the validity of the Van der Merve model.

The authors are grateful to Dr. G. O. Krause, of Texas Instruments, Inc., for bringing this error to their attention.

Cathodic Discharge of Nickel Sulfide in a Propylene Carbonate-$LiClO_4$ Electrolyte

Raymond Jasinski* and Brian Burrows*

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

A preliminary evaluation was made of the cathodic discharge of nickel sulfides in $LiClO_4$-propylene carbonate electrolyte. Theoretical energy densities of approximately 400-700 whr/lb are calculated, depending on the choice of the specific nickel sulfide. The nickel sulfides tested had solubilities $<10^{-4}$M in the charged and partially discharged state. High coulombic efficiencies (>50%) were achieved at 1 ma/cm^2. A discharge of 10 ma/cm^2 could be sustained, but at a lower efficiency. The discharge plateau is between 1.8 and 1.4v.

The performances of the most nonaqueous batteries are limited by the positive electrode (1). Positive electrodes with acceptable electrochemical performance have high solubilities and, hence, poor shelf life. Apparently most materials investigated to date, *e.g.*, CuCl, AgCl, CuF_2, must first dissolve in order to discharge (2). However, the metal ions, once in solution, can also reach the negative electrode, generally lithium, and discharge chemically. Problems arising from excessive solubility are particularly insidious in the case of metal chlorides since one of the discharge products, Cl^-, causes further dissolution of the positive plate material (3).

A possible solution of the problems presented by high solubility is to prevent migration of metal ions to the negative electrode with separator membranes. This approach is being studied (4); it presents its own problems in achieving membrane perfection and stability and low ohmic losses. An alternative approach is to employ insoluble plate materials, preferably of good electrical conductivity. This alternative has been the guiding principle behind the work described below.

Transition metal sulfides are particularly insoluble materials in aqueous solutions. In the absence of complex ion formation it was thought likely that these compounds would also be insoluble in aprotic, organic solvents.

The experiments described below on nickel sulfide imply that this material is (*i*) electrochemically active, (*ii*) chemically stable.

The term "nickel sulfide" is actually a generic one. Six stable, crystallographically defined sulfides exist (5): Ni_3S_2, Ni_6S_5, Ni_7S_6, NiS, Ni_3S_4, and NiS_2.

The equivalent weight and energy density of this series of compounds varies as shown in Table I. It was assumed that the reaction products were Li_2S and nickel metal. Li_2S is apparently insoluble in the electrolyte; quantitative data are not available. The higher energy density of the Li/NiS_2 couple reflects the discharge of the $(S\text{-}S)^=$ ion as well as the reduction of divalent nickel.

Clearly the use of materials with high sulfur content provides for high energy densities, approaching that of the Li/CuF_2 couple (740 whr/lb). However, a high energy density is not the only criterion for selecting a positive plate material. A suitable compound must (*a*) be electrochemically active, (*b*) be relatively insoluble, (*c*) not show undesirable side reactions, *e.g.*, electrolyte decomposition and/or formation of soluble intermediates, and (*d*) be compatible with a lightweight electrode structure, *i.e.*, not require large amounts of conducting binder.

Apparatus and Procedure

All electrochemical measurements were carried out in a recirculating argon atmosphere dry box (Vacuum Atmospheres Corporation). The electrolyte was 1M $LiClO_4$ in propylene carbonate (PC). Chronopotentiograms were recorded on an X-Y recorder (Houston Omnigraphic, model HR-98T). To avoid loading of the reference electrode-working electrode cell, a unity-gain voltage follower, constructed from an operational amplifier (Philbrick, type P65AU) was used in the potential measuring circuit. Current was supplied by a constant current power supply (Electronic Measurements, model C633).

Experiments were performed in a three-compartment cell. The working electrode, in the middle compartment, was separated from the counter electrode by a glass frit and from the reference electrode by a Luggin capillary.

In all experiments, the reference electrode was the Li/Li^+ couple (6), formed by immersing a Li rod in PC/$LiClO_4$ (1M) solution. Initially, the counter electrode was a Pt foil. In later experiments, the Pt was replaced by a Li rod to avoid solvent decomposition.

The sulfide electrodes were prepared by mixing the powder with approximately 10% graphite and pressing the mixture between folded, expanded-nickel metal, spot-welded to nickel wire. The sulfides apparently occluded only small amounts of water during pressing in air, since there was only slight evolution of hydrogen in the potential region for water reduction. The coulombic efficiencies were not markedly different when water was rigorously excluded from the system. Electrode thickness was approximately 30 mil.

No attempt was made to optimize material purity or electrode structure in this preliminary survey. The nickel sulfides were prepared as described below and their composition was confirmed by x-ray diffraction.

NiS was formed by reacting 1.5M $NiCl_2 \cdot 6\ H_2O$ with 0.5M $(NH_4)_2S$. The precipitate was washed thoroughly with water, heated at 120°C under N_2, and then transferred to the dry box.

The same procedure was followed for NiS_2 using 0.5M $NiCl_2 \cdot 6\ H_2O$ and 1.5M $(NH_4)_2S$.

Ni_3S_2 was prepared by the reduction of anhydrous $NiSO_4$ by hydrogen at 300°C (7).

Washing of the NiS and NiS_2 precipitates was critical. Discharge of NiS_2 which had not been washed

Table I. Equivalent weight of Li/Ni sulfide couples

Compound	Equivalent weight, g*	Energy density**
Ni_3S_2	67	388

thoroughly resulted in the formation of a black-brown film in the working electrode compartment. When this cell was removed from the dry box there was a strong odor of H_2S from it. Thoroughly washed NiS_2 does not produce a film or odor.

Qualitative resistivity measurements were made on pressed disks of the nickel sulfides. NiS and NiS_2 were insulators; Ni_3S_2 powder was an electrical conductor. However, the powder, as prepared, contained from 1 to 5% metallic nickel.

Results and Discussion

Discharge behavior.—Half-cell discharge curves of Ni_3S_2, NiS, and NiS_2 are shown in Fig. 1 at 10 ma/cm^2 and in Fig. 2 at 1 ma/cm^2. The theoretical capacity was computed on the basis of complete reduction to metal and sulfide ion. The performance of CuF_2 electrodes, prepared in a similar manner, is also shown in the figures for comparison purposes. It is apparent that the performance of CuF_2 in this configuration is not as good as that of the nickel sulfides. Note, however, the effect of added conductive binder (Fig. 1 *vs.* Fig. 2). Complete utilization of CuF_2 would produce 0.54 amp hr/g CuF_2; complete utilization of Ni_3S_2 would produce 0.46 amp hr/g.

The amounts of graphite binder used for the sulfides are listed in the figures. Since the Ni_3S_2 powder is an electronic conductor, it would be expected that little binder should be needed. Since the conductivities of discharge intermediates, if any, are not known, graphite was added as a precautionary measure.

All discharge curves show an initial section of high potential and short duration which may arise from an impurity, such as sulfur. Figure 1 shows that the discharge curve for a sulfur-carbon electrode falls approximately in the high potential section of the sulfide discharges. Thus, if sulfur is present in the electrode, it probably discharges above 2v (*vs.* Li/Li^+).

The discharge of sulfur at 10 ma/cm^2 is shown in more detail in Fig. 3. After about 1.6% of the material had discharged (2.4v), a yellow-brown substance moved off the electrode into the electrolyte. In view of the electrochemical behavior of sulfur in other

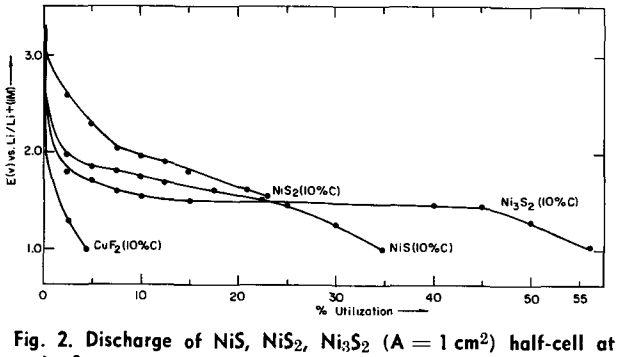

Fig. 2. Discharge of NiS, NiS_2, Ni_3S_2 (A = 1 cm^2) half-cell at 1 ma/cm^2.

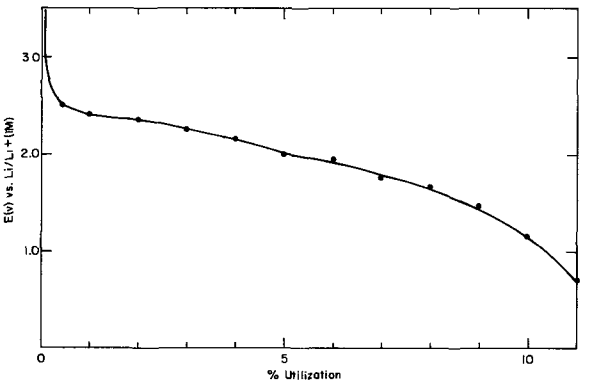

Fig. 3. Discharge of S —50%C (A = 1 cm^2) at 10 ma/cm^2

electrolytes, it is likely that this material is a polysulfide.

In order to explore further the origin of the high potential portion of the nickel sulfide curves, the electrodes were partially discharged and then allowed to return to open circuit for 30 min. If an active impurity were present, it should be eventually consumed and an open-circuit characteristic of the sulfide should be reached. The assumption here is that the presence of partially discharged nickel sulfide will not affect the open-circuit potential of the bulk of the electrode material. The data obtained for Ni_3S_2 and NiS are shown in Fig. 4 where the open-circuit potentials are plotted against the per cent charge delivered at 5 ma/cm^2. The times on open circuit are listed in the figure. A plateau in potential is reached between 1.6 to 1.8v *vs.* Li/Li^+.

The rapid decay in open-circuit potential of the Ni_3S_2 electrode (0-2% discharge) is also consistent with the hypothesis that an impurity is involved. The data for NiS could be interpreted as a larger amount of impurity. Since NiS was precipitated from aqueous solution, some free sulfur is to be expected via the air oxidation of sulfide ion.

Shelf life.—A few qualitative tests were made of nickel sulfide stability in 1M $LiClO_4$/PC electrolyte. Powdered NiS was equilibrated in solution overnight. Supernatent was withdrawn, diluted 1:1 with distilled water, and tested for soluble nickel with dimethylglyoxime (DMG). The test was negative.

A 10^{-4}M $NiCl_2$ solution was used as a control. The addition of DMG to an aqueous solution produced a pink coloration. Diluting the solution 1:1 with $LiClO_4$/PC diminished the intensity considerably. However, some coloration was still visible. The original negative test thus implies that the solubility of NiS in $LiClO_4$/PC is less than 10^{-4}M.

The same test was applied to a partially discharged NiS electrode. The result was also negative, implying that the discharge intermediates, if any, are also insoluble.

A further solubility test consisted of suspending for two days a cleaned lithium rod in solution equilibrated with and containing powdered nickel sulfide. No de-

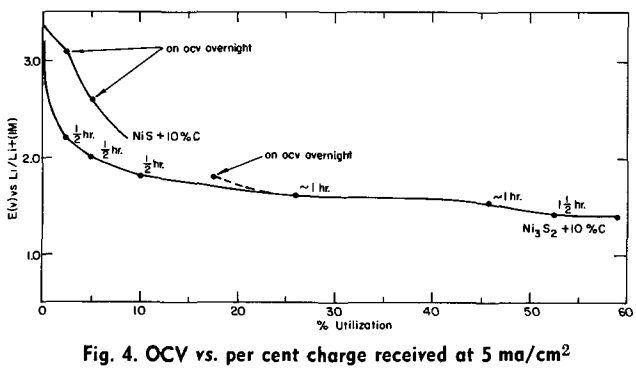

Fig. 4. OCV *vs.* per cent charge received at 5 ma/cm^2

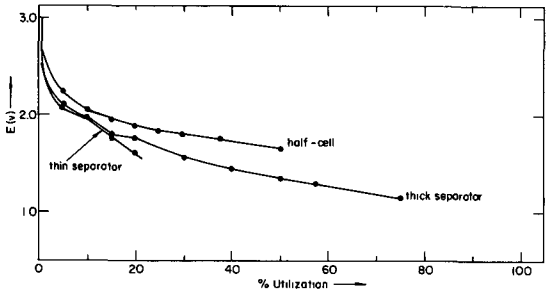

Fig. 5. Discharge of NiS/Li cell at 1 ma/cm^2

posit was noted on the electrode. Finally, a number of electrodes were discharged with interruptions overnight with no adverse effects. A complete cell (see below) was subjected to interrupted discharge, also with no adverse effects. Although further work remains to be done on this subject, it appears that nickel sulfide positives have greater stability than copper halide electrodes. It is important to consider the solubility of the discharge intermediates as well as of the starting plate material, particularly for battery applications which involve large discharge times.

Cell testing.—Because the nickel sulfides discharged well in the half cell, a prototype battery was assembled. The nickel sulfide (NiS) electrode, 2 x 2.5 cm, served as the battery positive electrode. The separator material was glass-fiber filter paper (about 12 mil thick). The plates were held together by small tabs of lithium ribbon, insulated from the positive by the separator, and were immersed in 60 cc of PC/$LiClO_4$ (1M). Comparative discharge curves for the half cell and full cell are shown in Fig. 5. The battery performed well although at a slightly lower potential than the half cell. A thinner separator (¼ thickness) did not seem to improve the discharge of the battery to any extent in this configuration.

Conclusions.—Nickel sulfides can be discharged at high utilization in 1M $LiClO_4$/PC at current densities between 1 and 10 ma/cm^2, *e.g.*, routinely efficiencies greater than 60% are achieved with Ni_3S_2. The discharges of NiS and NiS_2 are more affected by the electrode structure. A single discharge plateau was observed in all the tests conducted. Nickel sulfides have low solubility in the solvent tested ($<10^{-4}$) and, hence, should have a long shelf life. Depending on the specific sulfide chosen, the theoretical energy density may be of the same order as for most metal halides.

Acknowledgment

The authors wish to acknowledge the assistance of Mrs. Susan Kirkland in carrying out the laboratory work as well as the support of the U.S. Navy Air Systems Command under Contract No. N-000-19-68-C-0402.

Manuscript submitted Oct. 14, 1968; revised manuscript received Nov. 22, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Oxidation of Iron-Carbon Alloys at 500°C

W. E. Boggs,* and R. H. Kachik

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

When iron is oxidized at 500°C in oxygen at 10 Torr, blisters develop in the scale. This does not occur when the iron is oxidized at 500°C in oxygen at 700 Torr, nor when the iron contains carbon as a cementite precipitate. It appears that the iron oxide scale blisters if cation vacancies can accumulate at the oxide-metal interface. The higher oxygen pressure inhibits scale blistering by promoting more rapid formation of the outer layer of Fe_2O_3, which lowers the rate of vacancy formation and accumulation. The presence of carbon in the substrate inhibits scale blistering by providing additional vacancy sinks, thereby largely preventing the accumulation of vacancies at the oxide-metal interface.

When the iron-carbon alloys are oxidized at 500°C in oxygen at 10 Torr, a decarburized zone appears in the alloy substrate near the oxide-metal interface. This means that, under the experimental conditions, the rate of diffusion of carbon from the alloy substrate exceeds the rate of diffusion of iron into the scale. Decarburization does not occur when the alloy is oxidized at 500°C in oxygen at 700 Torr. This effect of oxygen pressure can be explained if it is assumed that at 10 Torr, carbon oxides are formed at the oxide-metal interface and escape through pores in the scale. At the higher pressure, oxygen enters the pores and is incorporated into the scale, thereby blocking the pores and preventing the escape of carbon oxides.

The results of several investigations of the oxidation of iron-carbon alloys at temperatures above 700°C have appeared in the literature (1-8). Three iron oxide phases, FeO, Fe_3O_4, and Fe_2O_3 are stable in this temperature range, and the reactions between carbon and the oxides are favored thermodynamically. The published information is not directly applicable to the present study, which was conducted at temperatures up to 500°C at which only two oxide phases, Fe_3O_4 and Fe_2O_3, are stable, and at which the reactions between carbon and these oxides are not favored thermodynamically.

* Electrochemical Society Active Member.

Wagner *et al.* (9) have published a general qualitative discussion of the oxidation of metal-carbon alloys. They discussed two general reaction sequences: (*i*) diffusion of carbon to the metal-scale interface, where it reacts with the scale to produce gaseous carbon oxides which may accumulate and cause rupture of the scale, and (*ii*) diffusion of carbon through the scale to react with oxygen at the scale-gas interface. The second sequence would allow decarburization to take place without scale rupture. The possibility of the diffusion of the gases produced in the first sequence through the scale without rupture was not discussed.

Engell (7) oxidized Fe-carbon alloys in air and in CO-CO_2 mixtures over the temperature range 750°-1050°C and found that the specimens oxidized in air decarburized without scale rupture. Chemical analysis of the scale, largely FeO, showed that the solubility of carbon in the scale was so low (0.003%) that transport of carbon (Wagner's second sequence) through the scale was not likely. Therefore, since blistering was not observed, Engell proposed that pores present in the scales on iron-carbon alloys permitted the effusion of the carbon oxides. He further proposed that the pores offered a constant resistance to gas flow at all times such that oxygen could not be transported directly from the gas phase to the metal surface, but rather reacted with CO within the pore to produce CO_2, some of which then reacted with carbon arriving at the base of the pore to produce more CO.

Billings and Smeltzer (8) studied the oxidation of iron-carbon alloys at 800°-950°C in CO-CO_2 atmospheres, conditions under which FeO is the only iron oxide formed. Their conclusions were that, under their experimental conditions, iron oxidation took place in the early stages at random nucleation sites on the surface, and decarburization (and carbon oxidation) took place concurrently at active sites in the areas of exposed iron between the iron oxide nuclei. They argued that a competition occurred between the iron oxidation and the carbon oxidation processes for available adsorbed oxygen. Evidence was presented that as iron oxidation progressed and the surface coverage by FeO became more nearly complete, the decarburization reaction was "stifled" to a large extent. The stifling of direct decarburization by scale growth was accompanied by the onset of partial diffusion control of decarburization as carbon or carbon oxides moved outward through pores between the impinging FeO crystallites. It should be noted that the reduction of FeO by carbon is thermodynamically favored by about 7.7 kcal at 950°C. Thus, it appears likely that CO forms at the Fe-FeO interface and that the carbon, in that form, moves outward through pores in the FeO scale under the experimental conditions of Engell (6, 7) and of Billings and Smeltzer (8).

Although the information cited in the literature is not directly applicable to the present study because of the differences in experimental conditions, the concepts are useful in helping to explain the observed phenomena.

Materials and Experimental Work

An aluminum-deoxidized iron base and five iron-carbon alloys were prepared by vacuum melting. The compositions of these alloys are listed in Table I. The material was hot-rolled to ¼-in. thick plates then trimmed and surface-ground to remove scale and surface defects. The alloys were then cold-rolled into sheet 0.006-0.012 in. thick. The cold-rolled sheet was cut into 2- by 5-cm specimens, which were electropolished in a 15% perchloric-85% glacial acetic acid electrolyte, washed, and vacuum annealed 4 hr at 950°C. After slow cooling (2°C/min) to room temperature in vacuum, the specimens were again electropolished and washed, and then were inserted in the microbalance system. After treatment in hydrogen at a pressure of 10 Torr for 1 hr at 400°C and evacuation for 40 min, the oxidation experiments were begun with adjustment of the specimen temperature and the introduction of oxygen at the required pressure (10).

Table I. Analysis of iron-carbon alloys

Alloy	Composition, %								
	C	Mn	P	S	Si	Cu	Ni	Cr	Al

Results and Discussion

Oxidation of iron at 500°C.—The weight gain *vs.* time curves for the oxidation of the iron base at 500°C and an oxygen partial pressure of 10 Torr are characterized by alternating periods of high and low oxidation rate, Fig. 1. These changes in oxidation rate are associated with scale blistering cycles. It is believed that the blisters in the scale are initiated by vacancy rafts that form under the oxides as vacancies accumulate at the oxide-metal interface. The oxide phase that forms first when iron begins to oxidize under the experimental conditions is Fe_3O_4. This oxide is a cation-deficit p-type semiconductor. The incorporation of oxygen into the Fe_3O_4 lattice produces cation vacancies that move inward through the oxide toward the oxide-metal interface, as iron ions move outward toward the oxide-oxygen interface (10). As iron ions cross over from the metal into the oxide they leave behind at the interface the vacancies which can then, according to Evans (11), accumulate at the oxide-metal interface to form cavities, pass into the metal and react with a vacancy sink such as a dislocation, or pass through the metal (if sheet) and join a cavity in the far side.

The number of vacancy sinks available in a well-annealed metal should be constant at constant temperature. Therefore, the rate of vacancy annihilation at a given temperature should be constant or slowly decrease as the available vacancy sinks are consumed. If the rate of arrival of the vacancies at the oxide-metal interface is higher than the annihilation rate, vacancies will tend to accumulate at the oxide-metal interface and cause the oxide to lose contact with the metal (12). Vermilyea (13) has pointed out that an oxide such as Fe_3O_4, which grows by cation diffusion, will be relatively unstrained, since each new layer is formed at the oxide-gas interface and need only fit the preceding layer. Accordingly, the Fe_3O_4 layer probably is relatively unstrained at the time of separation. However, once contact is lost between the oxide and the metal, iron ions cease to diffuse through the oxide, and the oxide then reacts with ad-

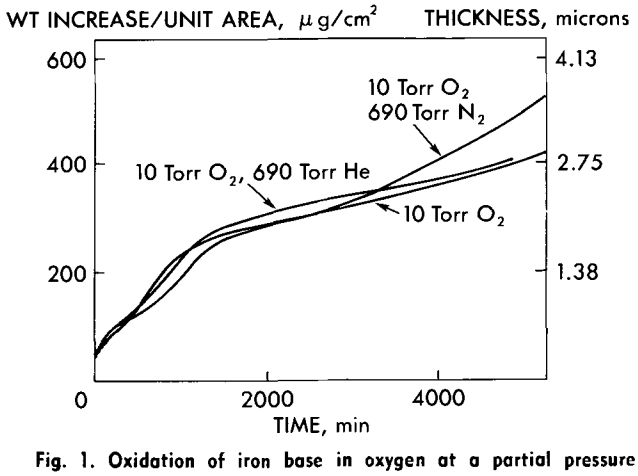

Fig. 1. Oxidation of iron base in oxygen at a partial pressure of 10 Torr.

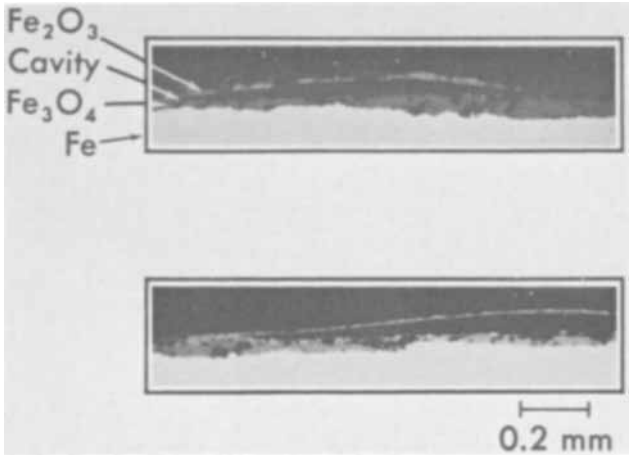

Fig. 2. Oxide blisters formed on iron base at 500°C in oxygen at a partial pressure of 10 Torr. Conditions: top, 500°C, 10 Torr O_2, 690 Torr N_2, 5600 min., bottom, 500°C, 10 Torr O_2, 690 Torr He, 4200 min.

ditional oxygen to become Fe_2O_3. Since Fe_2O_3 grows inward by anion diffusion and has a 2% greater volume than Fe_3O_4 (14), stresses are developed in the oxide, causing it to arch away from the iron substrate in the areas of separation and form the observed blisters, Fig. 2. (On cooling at the termination of an experiment, the difference between the thermal contraction of the oxide and that of the metal causes additional arching of the blister caps.) Eventually, the blister cap cracks and allows oxygen to leak into the cavity, thereby initiating a fresh oxide layer on the exposed metal surface.

The data obtained from the oxidation of the iron base at 500°C and a higher oxygen pressure, 700 Torr, conformed to a smooth, nearly parabolic, curve and there was no evidence of blistering in cross sections of the resulting scale, Fig. 3.

Specimens were oxidized in mixtures of an inert gas such as nitrogen, helium, or argon at a pressure of 690 Torr and oxygen at a pressure of 10 Torr to determine if the observed effect of pressure was the result of squashing of the oxide into the metal at the higher total pressure, 700 Torr. As is shown in Fig. 1 the weight gain curves were similar to those obtained in pure oxygen. Blisters were observed in the scale. Thus, it does not appear that the increase in oxidation rate observed in oxygen at a pressure of 700 Torr can be explained as squashing of the oxide.

The oxide films formed in 1 min and 25 sec at 500°C in oxygen at pressures of 10 and 700 Torr were examined using a polarizing microscope. (The anisotropic phase, Fe_2O_3, is visible under polarized light, whereas the isotropic phase, Fe_3O_4, is dark.) It appeared that the outer, Fe_2O_3 layer, was more complete on the oxide formed at 700 Torr than it was on the oxide formed at 10 Torr. This observation suggests the following mechanism to explain the difference in oxidation behavior observed at the two oxygen pressures. As long as Fe_3O_4 is exposed to gaseous oxygen, cation vacancies are generated at a high rate, diffuse through the scale, and accumulate at the oxide-metal interface, as was discussed in detail above. However, as the surface of the Fe_3O_4 becomes completely covered with a layer of Fe_2O_3, the rate of formation of cation vacancies is drastically reduced and vacancies arriving at the oxide-metal interface can be annihilated at vacancy sinks before they can accumulate. Thus, the oxide formed at 500°C and 700 Torr remains in contact with the metal and thickens more or less continuously under diffusion control.

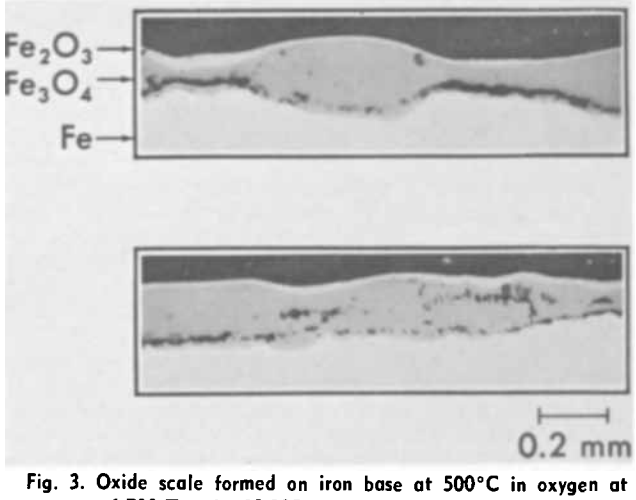

Fig. 3. Oxide scale formed on iron base at 500°C in oxygen at a pressure of 700 Torr for 11,325 min.

Oxidation of iron-carbon alloys at 500°C.—The effect of carbon concentration on the oxidation kinetics at 10 Torr and at 500°C is shown in Fig. 4. The oxidation rate of the iron-carbon alloys was much higher than that of the iron base under these conditions. The effect of carbon concentration on the oxidation kinetics at 700 Torr is shown in Fig. 5. The oxidation rate of the iron-carbon alloys was initially higher than that of the iron base but became lower as the oxidation progressed. The plots of weight gain *vs.* time obtained from the oxidation of the iron-carbon alloys at both oxygen pressures conformed to smooth curves and no evidence of blistering was found in cross sections of the resulting oxide scale, Fig. 6. The data presented in Fig. 4 and 5 show that the over-all scaling rate of the iron-carbon alloys was not increased appreciably at 500°C by increasing the oxygen pressure from 10 to 700 Torr.

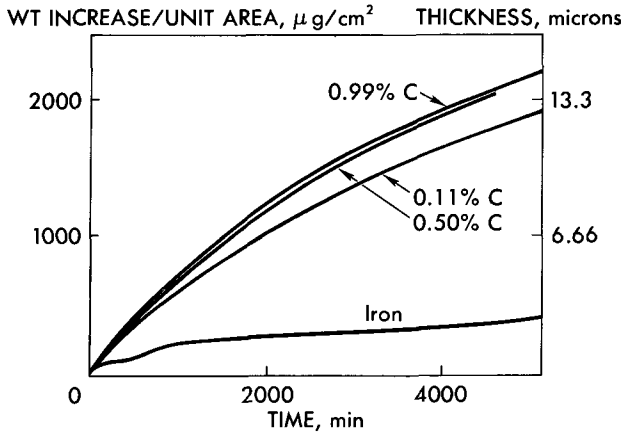

Fig. 4. Effect of carbon concentration on the oxidation of iron-carbon alloys at 500°C in oxygen at 10 Torr.

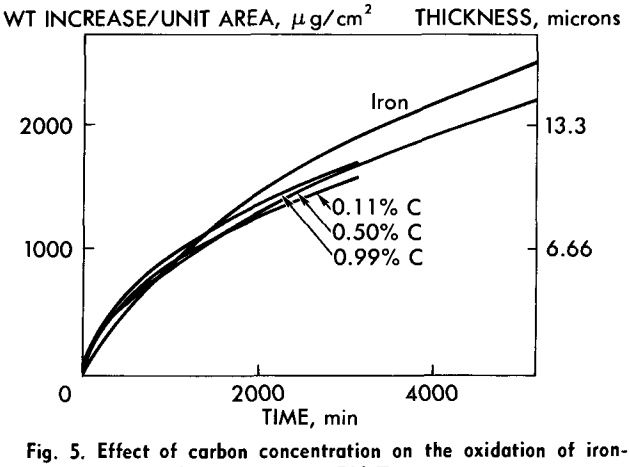

Fig. 5. Effect of carbon concentration on the oxidation of iron-carbon alloys at 500°C in oxygen at 700 Torr.

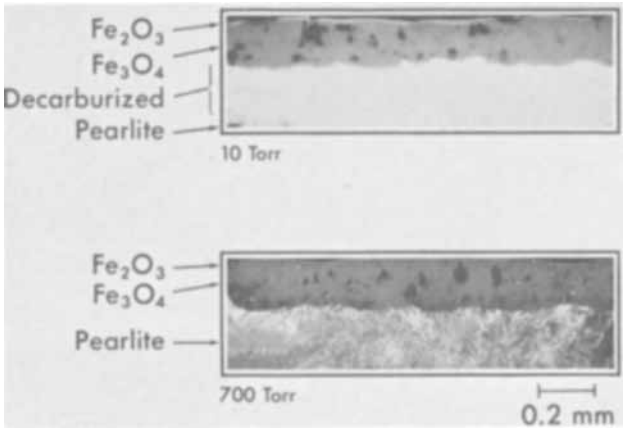

Fig. 6. Effect of oxygen pressure on the decarburization of the iron-0.99% carbon alloy in 5600 min at 500°C.

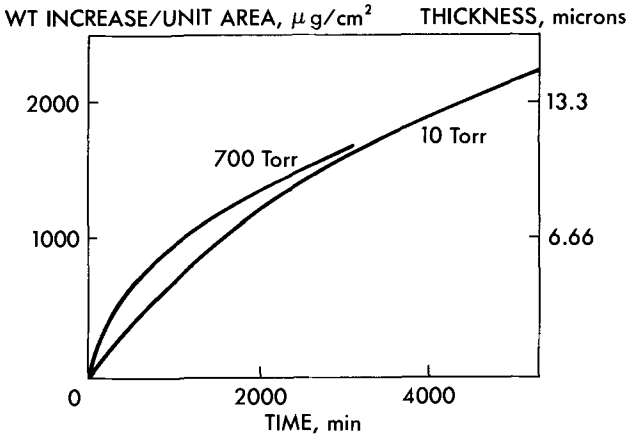

Fig. 7. Effect of oxygen pressure on the oxidation of the iron-0.99% carbon alloy at 500°C.

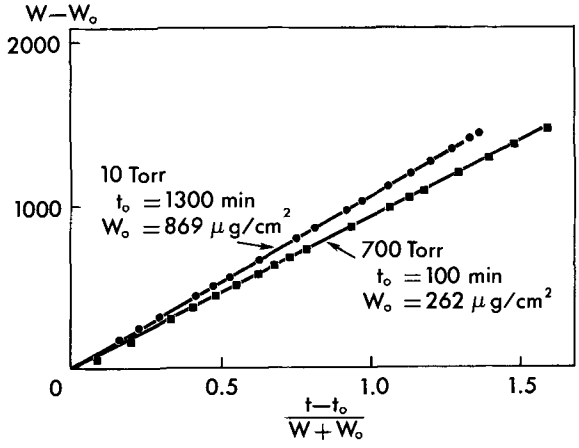

Fig. 8. Parabolic plots of the oxidation of the iron-0.99% carbon alloy at 500°C.

The freedom from scale blistering at 10 Torr exhibited by the iron-carbon alloys, in contrast to the iron base, is believed to be due to a greater number of vacancy sinks (dislocations) generated in the substrate by the precipitation of cementite during specimen preparation and by the subsequent volume decrease associated with decarburization. The vacancy annihilation rate will, therefore, be higher so that there is less tendency for vacancies to accumulate, and the scale will remain in better contact with the metal during the early stages of oxidation than is the case with the oxidation of pure iron. Caplan (12) has shown that cold-worked iron specimens exhibit higher oxidation rates than do well-annealed iron specimens. He has also observed that separations occur between the oxide and the metal with well-annealed material, but not with cold-worked material. He concludes that cold work prevents oxide separation, and thereby increases the oxidation rate, by providing additional sinks for the cation vacancies arriving at the Fe-Fe_3O_4 interface and thus preventing vacancy accumulation. According to Caplan, the cold work is effective, in spite of the annealing that begins as soon as the specimen is heated for oxidation, because extra vacancy sinks are required only at the beginning when the reaction rate is greatest and the vacancy flux a maximum.

The slight increase in initial oxidation rate with increasing carbon concentration can also be explained on this basis. Any slight vacancy accumulation that might occur at the lower carbon concentrations would tend to throttle the flow of iron through the scale to support the oxidation reaction; but at the higher carbon concentrations, enough vacancy sinks are available to annihilate all of the vacancies reaching the oxide-metal interface.

The oxidation of the iron-carbon alloys at an oxygen pressure of 10 Torr is accompanied by decarburization of the substrate. As the oxidation proceeds, a decarburized zone develops in the substrate at the oxide-metal interface and the pearlitic zone retreats toward the center of the specimen, Fig. 6, top. The phenomenon of decarburization below the oxide-metal interface will occur only when the rate of diffusion of carbon in the metal at a given temperature exceeds the rate of diffusion of iron into the scale (15).

In contrast, no decarburized zone appears when the alloy is oxidized at 700 Torr, Fig. 6, bottom. This difference is evident not only in the micrographs of cross sections of specimens oxidized at the two oxygen pressures, but also in the kinetic data, Fig. 7. The weight gain observed in the oxidation of the iron-0.99% carbon alloy at 10 Torr was lower than that observed in the oxidation of the same alloy at 700 Torr by the weight of carbon evolved at the lower oxygen pressure. Parabolic plots of those data are shown in Fig. 8. At 700 Torr the weight-gain data began to exhibit parabolic behavior after about 100 min. In contrast, at 10 Torr the weight gain data began to exhibit parabolic behavior after about 1300 min. The weight gain observed in the oxidation of this alloy at 10 Torr was the net result of the weight gain resulting from the oxidation of iron and weight loss resulting from the simultaneous decarburization.

The effect of oxygen pressure persists even after the experimental conditions have been altered. In a series of experiments with the iron-0.5 carbon alloy, oxidation was begun at 700 Torr and then after 5 min, 100 min, or 1000 min the oxygen pressure was reduced to 10 Torr and the reaction allowed to continue until the total time was 5600 min. Changing the oxygen pressure after 1000 min had little effect on the kinetic data. The specimen oxidized for 1000 min at 700 Torr did not decarburize when the oxygen pressure was reduced; some decarburization occurred in the specimen oxidized for 100 min at 700°C, and normal decarburization was observed in the specimen oxidized for only 5 min at 700 Torr before the pressure reduction, Fig. 9.

Another example of the persistence of the effect of oxygen pressure during scale growth on the subsequent behavior of the oxide is that oxide formed at 10 Torr can be reduced by internal carbon, whereas the oxide formed at 700 Torr cannot be similarly reduced. Specimens of the iron-0.50% carbon alloy were oxidized at 500°C and oxygen pressures of 10 or 700 Torr for 4000 min to produce fairly thick and adherent scales. At the end of this time, the oxygen was removed and the specimens were then allowed to anneal in vacuum for 4400 min at 500°C. A loss in weight was observed for the specimen oxidized at 10 Torr, whereas the weight of the specimen oxidized at 700 Torr remained constant. When the oxide scales produced in

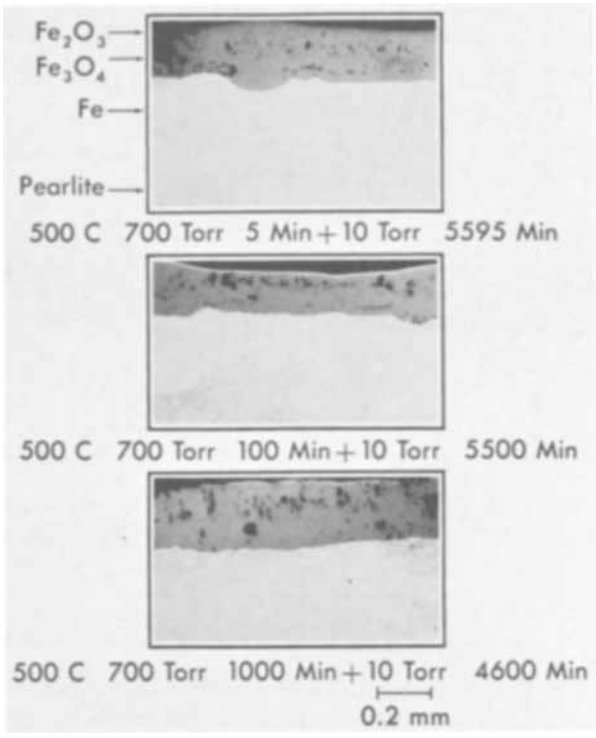

Fig. 9. Sections showing the effect of scale formed on the iron-0.50% carbon alloy at 700 Torr on the subsequent decarburization at 10 Torr.

these two experiments were examined in cross section, it was found that a zone of iron particles, resulting from the reduction of Fe_3O_4 by carbon, had developed near the oxide-metal interface of the specimen oxidized at 10 Torr, Fig. 10. No similar oxide reduction was observed in the specimen oxidized at 700 Torr. The reduction of Fe_3O_4 by carbon is not thermodynamically favored at 500°C. However, it appears that the reduction is permitted by the removal of the gaseous reaction product, CO.

The fact that CO rather than CO_2 was evolved during the vacuum reduction of the oxide was demonstrated by the following experiment: a specimen of the iron-0.11% carbon alloy was oxidized at 350°C in oxygen at 10 Torr for 60 min in the microbalance to form an oxide film containing 64 μg of oxygen. This

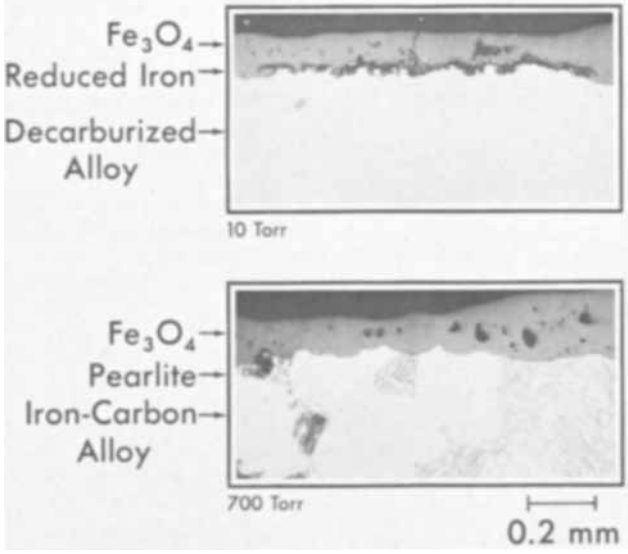

Fig. 10. Scale formed on the iron-0.50% carbon alloy in 4000 min at 10 Torr and 500°C is partially reduced by carbon during a 4400 min vacuum anneal at 500°C. The scale formed at 700 Torr is not similarly reduced during vacuum annealing.

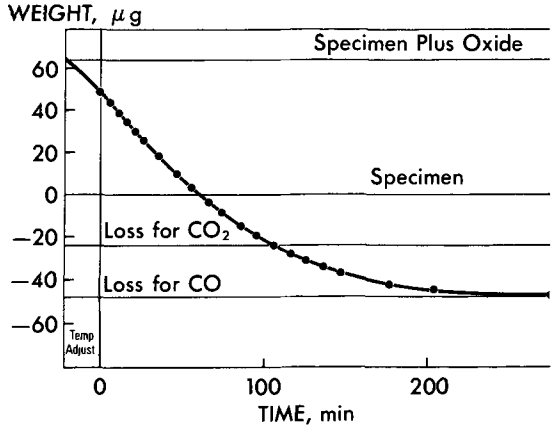

Fig. 11. Vacuum reduction of the oxide formed on the iron-0.11% carbon alloy in 60 min at 350°C in oxygen at 10 Torr.

oxide film was then completely reduced by vacuum annealing at 500°C for 1185 min. The weight losses to be expected from the evolution as CO or CO_2 were calculated from the known weight of the oxide and the amount of carbon required for the reduction. Under the experimental conditions, twice as much carbon would be required to reduce the oxide if CO were the gas evolved than would be required if CO_2 were evolved. As is shown in Fig. 11, the observed weight loss demonstrated that the gaseous reaction product of the vacuum reduction was CO.

A specimen of the iron-0.99% carbon alloy was oxidized at 10 Torr and the gas evolved was trapped in a liquid-nitrogen-cooled finger and determined volumetrically. The iron oxide scale was then completely reduced in hydrogen in order to determine by difference the amount of carbon evolved during the oxidation. The weight of the carbon, trapped as CO_2, amounted to 97.2% of the weight of carbon evolved during the oxidation.

An iron-0.50% carbon alloy specimen was oxidized at 500°C in a gas mixture consisting of helium at a partial pressure of 690 Torr (added first) and oxygen at a partial pressure of 10 Torr. Decarburization of the iron substrate was observed under these conditions in about the same amount as had been observed when the alloy was oxidized in pure oxygen at a pressure of 10 Torr. Thus, the oxygen partial pressure rather than the total gas pressure controls the decarburization process.

In view of the foregoing experimental observations, the most attractive explanation of the pressure dependence of the decarburization involves pores through the oxide that remain open to permit the escape of CO or CO_2 at an external oxygen pressure of 10 Torr but quickly become blocked to prevent decarburization at an oxygen pressure of 700 Torr. In the earliest stages of oxidation, adsorbed oxygen can react with carbon at the alloy surface in the areas between expanding iron oxide nuclei to produce CO. Since, under the experimental conditions, the iron oxide nuclei grow together to form an iron oxide film in a few seconds, the observed amount of decarburization cannot be explained by this direct reaction between carbon and oxygen.

The continuation of decarburization after the formation of an iron oxide film at an oxygen pressure of 10 Torr could be explained by carbon moving through the oxide layer and being emitted into the atmosphere as a gaseous reaction product, CO or CO_2. However, the transport of carbon through the iron oxide film by solid-state diffusion appears unlikely because of the low solubility of carbon in the oxide and because it is difficult to explain the effect of oxygen pressure on the decarburization if the reaction between carbon and oxygen takes place on the outer surface of the oxide. Therefore, it appears that the carbon is oxidized at the oxide-metal interface and that the resulting

gaseous reaction products escape into the atmosphere through pores or faults in the oxide layer.

Thus, it is believed that pores remain in the grain boundaries when iron oxide nuclei grow together. As the oxide thickens at 10 Torr, oxygen entering a pore reacts with CO flowing up from the oxide-metal interface to form CO_2. Some of this CO_2 diffuses back to the base of the pore where it reacts with carbon to produce CO. In this way, a CO-CO_2 atmosphere of low oxidizing potential is maintained within the pore, inhibiting the growth of iron oxide on the pore walls.

However, when the external oxygen pressure is 700 Torr, oxygen enters the pores faster than CO is produced so that the oxidizing potential of the pore atmosphere is much higher. The excess oxygen is incorporated into the iron oxide lattice in the pore walls. Thus, the pores close quickly at the higher oxygen pressure, blocking the escape of gaseous carbon oxides and thereby stopping further decarburization of the alloy substrate.

Except for the direct reaction of oxygen with carbon, none of the possible reactions that could produce gaseous carbon oxides at the oxide-metal interface are favored thermodynamically at 500°C. Thus, the reaction can proceed only if the reaction product can escape from the site of the reaction. When the escape paths are blocked, the reaction stops.

The mechanism for the preferential oxidation of carbon with CO_2 to produce CO at the base of the pore is not clear. Theoretically, under the experimental conditions, the oxidation of iron by CO_2 is slightly favored over the oxidation of carbon by CO_2. Thus, the iron at the base of the pores should be covered with a thin iron oxide layer through which the carbon must pass as it escapes from the iron substrate. The reasons why this thin oxide film does not grow and quickly block the decarburization have not been resolved.

If the proposed mechanism for decarburization of the iron substrate through an oxide scale is valid, it appears that, even at the lower oxygen pressure, the pores should eventually close as the concentration of CO in the pore atmosphere decreases because of the increasing length of the pore and the increasing length of the diffusion paths from the source of the carbon (the Fe_3C phase deep in the iron substrate) to the oxide-metal interface. The kinetic data presented in Fig. 7 for the oxidation of the iron-carbon alloys at oxygen pressures of 10 and 700 Torr tend to support this hypothesis. The rate of oxidation at both pressures is probably quite similar but the decarburization reaction at 10 Torr results in a lower rate of weight increase. After 2000 to 3000 min, the weight-gain rates are similar, which indicates that the decarburization reaction has probably stopped. Furthermore, samples oxidized for extended periods at 10 Torr still have Fe_3C platelets below a decarburized layer despite the fact that decarburization at the early rates should have completely eliminated the carbon. Thus, some mechanism, such as eventual pore closure, evidently exists.

Surface-area measurements by the B.E.T. method using xenon were made on specimens of the iron-0.99% carbon alloy that had been oxidized for 1000 min at 500°C in oxygen at pressures of 10 and 700 Torr, respectively. The oxide formed at 10 Torr had 8 times the surface area of the oxide formed at 700 Torr, presumably because of the surface area of the pores. Unfortunately, the slow evolution of CO from the specimen oxidized at 10 Torr prevented establishment of the adsorption-desorption isotherms with sufficient accuracy for pore-size estimations.

An additional experiment was devised to demonstrate differences in porosity in the scales formed at the two oxygen pressures. Representative specimens of the iron-0.5% carbon alloy were oxidized at 500°C for 3900 min. After this period of time, the temperature was decreased to 350°C and held for 2 hr. The iron diffusion rate outward through the Fe_3O_4 was considerably reduced at the lower tempearture. Consequently, oxygen penetrating through the pores in the oxide was able to convert the oxide in the pore walls to Fe_2O_3 and thereby decorate the pore walls for identification in the metallographic cross sections. The results of these experiments are shown in Fig. 12. Considerable porosity was evident in the scale formed at 10 Torr, but only slight oxygen penetration was observed in the scale formed at 700 Torr.

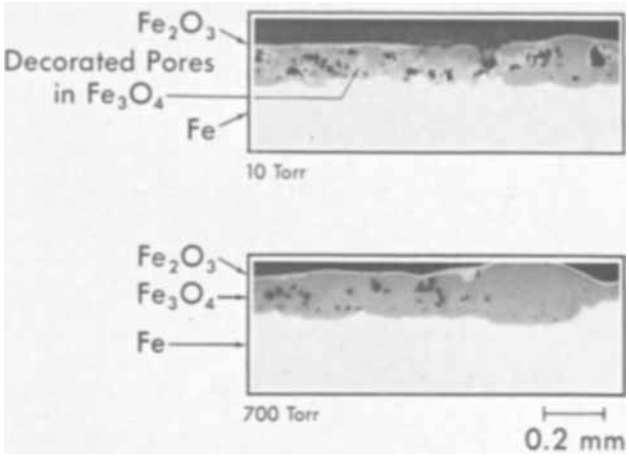

Fig. 12. Effect of oxidizing conditions (oxygen pressure) on the porosity of the scale formed on the iron-0.50% carbon alloy. Specimens first oxidized for 3900 min at 500°C and then 120 min at 350°C.

The distribution of the Fe_2O_3 in these sections suggests that the Fe_3O_4 layer is much less compact than the Fe_2O_3 layer. Most of the pores appear to be concentrated in the lower two-thirds of the Fe_3O_4, and connections between these and the outer layer are relatively rare. Thus, it appears that pore closure occurs near the outer surface of the scale as required for the proposed mechanism for decarburization.

Summary

The oxidation of an iron base and a series of iron-carbon alloys at 500°C in oxygen at pressures of 10 and 700 Torr has been studied in detail. Reasonable explanations have been developed for the various phenomena observed in connection with these oxidation experiments.

Blisters grow in the scale formed on the iron base during oxidation at 10 Torr. It appears that iron-ion vacancies diffuse through the scale and accumulate at the oxide-metal interface at a faster rate than they can be annihilated at vacancy sinks existing in the metal substrate. This causes separation to occur between the oxide and the metal. Subsequent conversion of the Fe_3O_4 to Fe_2O_3 in the scale over the separation introduces strain, which causes the separated area to bow up away from the metal and form the blister. When cracks develop in the blister cap, gaseous oxygen enters the cavity, forming a new oxide layer on the exposed metal, and the process repeats.

Blistering is not observed when the iron base is oxidized at 500°C in oxygen at a pressure of 700 Torr. It appears that the outer phase of the scale, Fe_2O_3, nucleates and grows laterally to form a continuous layer more rapidly at 700 Torr than at 10 Torr. The formation of a continuous layer of Fe_2O_3 reduces the rate of formation of iron-ion vacancies so that those vacancies arriving at the oxide-metal interface can be annihilated at vacancy sinks in the metal and thus do not accumulate at the interface to cause the oxide-metal separations that result in oxide blisters.

The presence of cementite, Fe_3C, in the substrate also tends to prevent the formation of oxide blisters even when these alloys are oxidzed at 500°C in oxygen at a pressure of 10 Torr. It appears that additional vacancy sinks generated by the precipitation of cementite

during specimen preparation and by the volume decrease associated with decarburization increase the vacancy annihilation rate and thus prevent the formation of the oxide-metal separations that occur in the oxidation of iron under similar conditions.

It has also been observed that the iron-carbon alloys decarburize when oxidized at 500°C in oxygen at 10 Torr, but do not decarburize when oxidized at 500°C in oxygen at 700 Torr. This effect of oxygen pressure can be explained if it is assumed that pores develop as the iron and carbon are competitively oxidized, starting with a clean metal surface. Initially, carbon is oxidized and escapes into the atmosphere from sites in the areas between iron oxide nuclei. As the nuclei grow together and the iron oxide thickens, pores or faults are left at the oxide grain boundaries. Carbon from the substrate reacts with CO_2 in the pore atmosphere to form CO. Thus, the pores provide paths for the escape of carbon oxides into the atmosphere. When the external oxygen pressure is 10 Torr, oxygen entering the pores reacts with CO to form CO_2. This mechanism maintains a CO-CO_2 atmosphere of low oxygen activity within the pores, keeping them open.

However, at the higher pressure, 700 Torr, oxygen is able to enter the pores and be incorporated in the iron-oxide lattice. This causes the growth of fresh oxide in the pores, blocking them and preventing the escape of carbon oxides. Since none of the reactions that could oxidize carbon at or near the oxide-metal interface are thermodynamically favored at 500°C, escape of carbon oxides is necesary in order for the reaction equilibrium to be shifted in the direction of carbon oxidation. Thus, once the pores are blocked, carbon oxides cannot escape, and the decarburization reaction stops.

Acknowledgment

The authors gratefully acknowledge the surface area measurements by Dr. Harry Podgurski and Frank N. Davis of the U. S. Steel Fundamental Research Laboratory. The authors also acknowledge the helpful discussions of Dr. Donald Caplan of the Canadian National Research Council and Professor Dr. Hans-J. Engell of the Max-Planck-Institut für Metallforschung.

Polarographic Measurement of the Reaction between o-Chlorobenzalmalononitrile and 2-Diethylaminoethyl Mercaptan (DEAEM)

Pascal A. Tarantino* and Samuel Sass

Research Laboratories, Edgewood Arsenal, Maryland

ABSTRACT

Controlled-potential and first derivative polarography were found to be effective for determining the kinetics of reaction of two electroactive compounds in nonaqueous and partially aqueous media. The mechanism and rate of reaction of o-chlorobenzalmalononitrile with 2-diethylaminoethyl mercaptan were found to be dependent on the relative concentration of the reactants, the solvent medium and temperature. A rapid-scan polarograph with a trielectrode system was used for most of this study.

The purpose of this study was to determine the electrochemical properties (polarography) of o-chlorobenzalmalononitrile (CS) and related compounds in several media and in the presence of a rapidly reacting nucleophile. Since CS is a potent irritant and has been used successfully for riot control, it could be used as a standard of comparison with related compounds. This information could be useful both from the standpoint of analytical methodology and for obtaining a better understanding of structure-activity relationships.

The polarographic reduction of benzalmalononitrile in Prideaux and Ward buffers, pH 4-8.9, with 30% alcohol is reported by Bargain and Delepine (1): in acid media there occurs a single two-electron wave, and in basic media, two waves, each corresponding to one-electron addition. In dimethylformamide (2) benzalmalononitrile gives only one wave with a one-electron addition, indicating the formation of a free

* Electrochemical Society Active Member.

radical. The influence of proton donors (benzoic acid and phenol) in dimethylformamide for this compound (3) has also been reported: with phenol, two reduction waves occur; and when benzoic acid is used, three distinct waves are formed.

Holmes *et al.* reported on the spectral (4) and polarographic analysis (5) of some benzalmalononitriles and related compounds, and on their rates of reaction with potassium cyanide (6), n-butanethiol, and n-butylamine (7), including also a theory for the action of benzalmalononitriles on nerve endings.

Sass *et al.* (8) reported on attempts to utilize aliphatic mercaptan as a reagent for the volumetric analysis of CS and related compounds. This study indicated that more than one thiol adduct could be obtained with CS, depending on the medium and the pH. Under conditions in which a second thiol adduct was obtained, one thiol group was readily removed by titration with iodine.

The work described in the present report represents a study of the polarographic characteristics of CS under conditions that had not been described previously, nor had an aminomercaptan been used heretofore for reaction studies.

Experimental

Reagents.—Preparation of DEAEM.—The free base mercaptan was isolated from the hydrochloride salt, purchased from Evans Chemetics, Inc. The salt was neutralized with a methanol solution of sodium methoxide, decanted from the sodium chloride precipitate, and fractionally distilled in vacuo. The collected DEAEM showed a purity of 99.85%, as indicated by iodine titration.

CS.—A CS sample of 99.5% purity was obtained by recrystallization from an ethanol-water solution, washed with water, and dried *in vacuo*. The white crystalline material melted at 96°C. The purity was determined by volumetric titration (8).

Solvents.—Reagent grade anhydrous methanol and acetone were used with no further purification. The water content for both of these solvents was less than 0.05%. Practical grade acetonitrile was purified by refluxing for 3 hr over phosphorus pentoxide, decanted, distilled, refluxed over potassium carbonate, decanted, and redistilled. The solvent, stored in an amber bottle, contained less than 0.05% water and did not reduce iodine.

Electrolytes.—Lithium nitrate and tetrabutylammonium perchlorate (Bu_4NClO_4) were used as electrolytes. Lithium nitrate, B and A Standard of Purity, was used with no further purification. Tetrabutylammonium perchlorate was prepared from the corresponding bromide salt (9).

Purging gas.—Prepurified nitrogen was used for purging electrolytic solutions before and during the recording of all polarograms and rate studies.

Apparatus.—Polarograph.—A modified version of the ORNL Controlled Potential and Derivative DC Polarograph (10) was used. The new polarograph (ORNL-Q-1988-FES), which is capable of doing rapid regular and first and second derivative d-c polarography,[1] was constructed in our laboratory. It permits a fast scan of the polarograms up to 3 v/min, which was found to be very convenient for reaction-rate study.

Polarographic cell.—A trielectrode cell was all-glass constructed to accommodate a nitrogen gas purger and a three-electrode system. The polarizable electrode was a Smolar type DME with a drop-time (t) of 0.5 sec., a flow rate (m) of 3.85 mg/sec and $m^{2/3}t^{1/6} = 2.18$ $mg^{2/3}/sec^{1/2}$. The reference electrode was an aqueous Ag/AgCl (saturated) system bridged to the test solution by a saturated KCl solution, a 4% KNO_3 agar plug and a sintered glass disk. The counter electrode was a spiral of platinum wire (18 gauge) isolated from the test solution by a 7 mm porous tip Vycor tube filled with the electrolyte used in the cell.

Procedures.—All polarographic work for calibration and rate study was conducted at 25°C by using a water-jacketed cell and a circulating bath with temperature control.

Calibration.—The method of standard addition was used for all calibration at 25°C. The electrolyte (20 ml of 0.1M $LiNO_3$ or Bu_4NClO_4) was placed in the electrolytic cell and purged for 5 min. A given volume of the standard was added, and the purging of the cell solution continued for 1 min longer. The nitrogen purge was diverted to the solution surface, and polarograms were recorded at a scan rate of 1.5 v/min, or as otherwise indicated.

Rate procedures.—The reaction rate between CS and DEAEM was investigated in the solvents listed above. The rates were measured at 25°C under different concentrations of reactants in 20 ml of electrolyte.

A 20-ml volume of electrolyte was placed in the electrolytic cell, purged for 5 min, and the residual current recorded. DEAEM, from a freshly prepared standard, was added to the cell solution to correspond to 1 mM; the system was purged for 1 min, and the purge was diverted to the surface of the solution. After the DEAEM polarogram was recorded, the applied voltage was set on the flat portion of the DEAEM anodic limiting current, and the time-sweep circuit of the recorder was closed to coincide with the addition of CS, and purging was maintained for 30 sec to insure uniform mixing of the solution. The gas purge was diverted to the surface of the solution mixture, and the consumption of the DEAEM was recorded using the preset time-sweep. The monitoring of the rate was continued until the rate curve indicated a 70% consumption of DEAEM.

For cases where both reactants were monitored, derivative polarography was used at a scan rate of 3 v/min. The sequence of preparing the reaction mixture was the same as that described above. The derivative polarograms recorded the DEAEM oxidation peak and the CS reduction peak in about 30 sec. Consecutive derivative polarograms were recorded at time intervals, depending on the speed of the reaction.

Results and Interpretation

Polarography of DEAEM.—The selection of DEAEM as a reactant was based essentially on the desire to more closely approximate thiol associated with amine as in protein (*i.e.*, the cysteine group). Preliminary studies with cysteine indicated that it would be difficult to handle because of instability in any but acidic media. Tests with alkanethiols such as n-pentyl mercaptan showed that, in the absence of added base, the compounds are not polarographically active in the media employed here.

Polarography of DEAEM in various solvents.—DEAEM was calibrated in four different electrolytic media: anhydrous methanol, 50% aqueous methanol, anhydrous acetone containing 0.1M $LiNO_3$, and anhydrous acetonitrile with 0.1M Bu_4NClO_4. Normal and derivative polarography were determined for the calibrations in anhydrous methanol. The other solvents were submitted to only normal polarography.

DEAEM in anhydrous methanol has two waves: one anodic at —0.438v and one cathodic at —0.960v. The first is the oxidation of the thiol, and the second is due to the reduction of the disulfide. The wave and the peak heights are both linear with concentration for the anodic and cathodic diffusion current. The normal and first derivative data for this compound are given in Table I.

The polarograms for DEAEM in 50% aqueous methanol are well defined. The anodic (—0.452v) and the

$I = u\,A/C \cdot m^{2/3}t^{1/6}$ and $I' = I$/min.

cathodic (−0.735v) half-wave potentials are constant with increasing concentration; the diffusion current constants are −0.69 and 0.07, respectively. There is very good linearity for both waves with concentration.

The polarographic results for DEAEM in acetone and in acetonitrile are almost identical. The only difference is in the shape of the waves; that in acetonitrile is fairly well defined, and the wave in acetone becomes irregular with increase in concentration. The half-wave potentials are −0.468v and −0.461v for DEAEM in acetone and acetonitrile, respectively. The diffusion current constant is the same for both solvents, about −1.93.

Tautomeric forms of DEAEM.—The anodic diffusion current constant of DEAEM, as indicated by data in Table II, is dependent on the degree of hydrolytic character and on the polarity of the solvent. This current change could be due to several factors such as viscosity and polarity of the solvent, and charge of the electroactive material (11). The pKa for triethylamine and DEAEM in aqueous methanol at 25°C is 9.4 and 7.3, respectively. The lower pKa for DEAEM indicates a less basic amine. These results could indicate the presence of DEAEM in two tautomeric forms:

$$Et_2NCH_2CH_2SH \rightleftharpoons Et_2\overset{\oplus}{\underset{H}{N}}CH_2CH_2S^{\ominus}$$

The formation constant of the charged molecule (or zwitterion) is dependent on the polarity of the medium. The zwitterionic nature for analogous compounds has been shown for 8-mercaptoquinoline and 3 mercaptopyridine (12). In another study (13), the actual percentage of 8-mercaptoquinoline in the zwitterionic form was measured in different solvents (water, 97%; ethanol, 1.3%, acetonitrile, 0.5%; acetone, 0.14%; and ethyl ether, 10^{-5}%). The percentage of DEAEM in the zwitterionic form is probably much greater since it is generally known that aliphatic amines are more basic than the corresponding heterocyclic type.

0.1	−12.5	0.5	96
3.0	−12.0	2.0	86
5.0	−11.0	3.6	75
7.0	−10.0	4.9	67
16.0	−8.0	5.5	59
32.0	−0.2	13.3	2

Note: At 0.1 hr the indicated quantity of RSSR, based on its own wave, was of the order of 4%; after 32 hr it was at a level of approximately 98%.

Stability of DEAEM.—Once the DEAEM standard in methanol is placed in a purged electrolyte, consecutive polarograms with time indicate no change in either the anodic or the cathodic wave. However, the stock standard solution, 0.1M DEAEM, changes with time. The data given in Table III indicate that, for this solution, the anodic wave decreases and the cathodic wave increases with time of standing. Although there is no 1:2 correlation between the drop in the anodic wave and the rise of the cathodic wave, it is evident that DEAEM is being converted to its corresponding disulfide (14). According to this time-stability study, the DEAEM standard solution should be used for no more than 5 hr.

Effect of water on the diffusion current of DEAEM.—Four DEAEM standard solutions were prepared, each containing the same concentration (5 mM) in 100%, 90%, 80%, and 50% methanol with 0.1M $LiNO_3$ electrolyte. It was found that the anodic diffusion current decreases with increasing quantities of water present in the electrolyte. The cathodic wave showed some increase. This decrease in height of the anodic wave is probably due to diffusion effects produced by the increasing viscosity or change in dielectric of the methanol-water solution. The data are shown in Table IV.

Polarography of o-chlorobenzalmalononitrile (CS).—CS was the most readily available irritant at the time of this study. Its biological effectiveness had been tested on both animal and man and information made available on some of its chemical reactivity. Under these circumstances, the selection of this compound as a standard of comparison could prove useful for obtaining a better understanding of structure-activity relationships.

Polarography of CS in various solvents.—The calibration of CS was performed in the same media and under the same polarographic conditions as those used for DEAEM.

In anhydrous methanol, CS was calibrated by both normal and derivative polarography. The two cathodic wave heights and derivative peaks of CS are linear with concentration. The half-wave potentials and the maximum derivative peaks are constant for the first wave and peak; but for the second, there is a shift toward a more negative potential with increasing concentration. The average half-wave potentials for the first and the second cathodic waves are −0.896v and −1.635v, and the voltage peaks (Ep) are −0.909v and −1.703v. A summary of this data is shown in Table V.

In 50% methanol a polarogram of CS produces two waves; the first is a wave (—0.79v) having a maximum which can be suppressed with one drop of 1% Titron X-100. With time there occurs a decrease of the CS first wave and a corresponding increase of the second wave (—1.3v). The over-all height of the first and the second wave remains constant. Since this electrolyte contains 50% water, hydrolysis of CS is undoubtedly occurring.

$$ArCH=C(CN)_2 \overset{H_2O}{\rightleftharpoons} ArCHO + CH_2(CN)_2$$

In this experiment an equilibrium was reached at the end of 40 min. A polarogram of o-chlorobenzaldehyde, run under identical conditions, gave a half-wave potential at —1.30v. The fact that the half-wave potential for the known sample of o-chlorobenzaldehyde was identical to the second wave for CS in 50% aqueous methanol was a proof that CS had hydrolyzed.

Polarograms of CS in acetone give only one wave (—0.924v) with a diffusion current constant equal to 4.7. There is an increasing linear deviation at concentration greater than 3 mM.

CS in acetonitrile exhibits two waves, one at —0.941v and the other at —1.766v. The diffusion current constant for the first wave is 4.2 and for the second wave, 0.6. The diffusion current for the first wave has very good linearity with concentration. The second wave is linear up to 2 mM, beyond which it is not reproducible.

Comparison of the polarography of o-chlorobenzaldehyde with that of CS.— o-Chlorobenzaldehyde, which is both an intermediate and a hydrolysis product of CS, was polarographed using the same solvent systems as those described previously. Malononitrile, the other intermediate and also a hydrolysis product, showed no wave in these media. The purpose of these polarograms was to assign a half-wave potential to the aldehyde should it appear during subsequent reaction studies. The polarographic data obtained on o-chlorobenzaldehyde are shown in Table VI. Data cited previously for CS are repeated for comparison.

Polarography of the formation of CS from its intermediates.—In order to confirm the stability of benzalmalononitriles and the dependability of the rate measurement in the electrolyte used for making all standard solutions (0.1M $LiNO_3$ in anhydrous methanol), an experiment was devised employing polarography to follow the formation of CS from its intermediates:

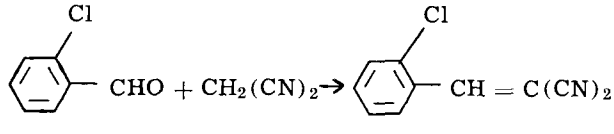

Table VI. Comparison of o-chlorobenzaldehyde with CS in the same electrolytic media

Electrolyte	o-Chlorobenzaldehyde $-E_{1/2}$, v	o-Chlorobenzaldehyde I	CS $-E_{1/2}$, v	CS I
0.1M $LiNO_3$, CH_3OH	1.355	1.15	0.895/1.635	2.48/1.47
0.1M $LiNO_3$, 50% CH_3OH	1.300	1.88	0.790/1.315	1.47/0.23
0.1M $LiNO_3$, $(CH_3)_2CO$	1.405	1.51	0.924/none	4.67/—
0.1M Bu_4NClO_4 CH_3CN	1.605	1.19	0.941/1.766	4.21/0.55

From this information it was intended to prove that the reaction was irreversible and that clear waves could be obtained. The half-wave potentials for the three compounds involved in the above reaction are: CS, —0.896v and —1.635v; malononitrile, inactive; o-chlorobenzaldehyde, —1.355v.

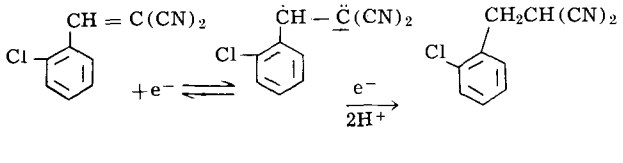
An equimolar mixture of o-chlorobenzaldehyde and malononitrile was polarographed in 0.1M $LiNO_3$, anhydrous methanol. The polarogram, run immediately after mixing, gave only the half-wave potential of the aldehyde. Subsequent polarograms indicated a slow decrease of the aldehyde wave. The solution was left overnight and polarographed again, 24 hr later. By this time the aldehyde wave had completely disappeared and new waves, characteristic of CS, were observed. Calculation, based on diffusion current, indicated a 98% conversion to CS. In a parallel experiment, o-chlorobenzaldehyde and malononitrile were reacted in the same manner. Results from a volumetric titration for CS (8) indicated the same order of conversion to compound.

Electrode processes of DEAEM and CS in methanol. —*DEAEM.*—The aminothiol, when first distilled and polarographed, shows only an anodic wave, that at —0.44v. With aging, the clear, concentrated aminothiol changes to an amber color. Polarograms of the aged aminothiol show, in addition to the anodic wave which is characteristic of the thiol group, a cathodic wave of a much lower current intensity occurs at —0.96v. The magnitude of the cathodic wave is less than 5% of the anodic wave. The second wave is due to a disulfide reduction. The electrode reaction of the aminothiol is not a direct oxidation of mercaptan but, instead, an indirect oxidation of mercury with the formation of mercurous mercaptide (14):

$$Et_2NCH_2CH_2SH + Hg \rightleftharpoons H^+ + Et_2NCH_2CH_2SHg + e$$

Consequently, the anodic current being measured is the oxidation of mercury which is directly related to the mercaptan concentration.

CS.—Normal polarograms of CS give two cathodic waves, the first is well defined and reversible while the second is drawn out and irreversible. The current temperature coefficients for the first and second waves are 2.0 and 2.4% per degree, respectively. The current and the square root of the mercury height gives a linear relationship for both waves. The polarographic wave equation (15) plots of the first CS wave are linear and the n-value averaged to one electron. The reversibility of the first cathodic wave is indicated by the excellent symmetry at its first derivative peak (16) and the linearity of the log-plots mentioned above. Coulometric studies of CS confirmed a one-electron reduction for the first wave; the second wave occurs too close to the background discharge for accurate coulometric determination, but indications are that it is also a one-electron process. Based on these results the following electrode processes are postulated for CS:



The diffusion current constant (I) of the first CS wave is 2.48 and that for the one-electron process of acetophenone in the same electrolyte is 2.43.

Polarographic reaction rates of CS and DEAEM.—A preliminary investigation of the reaction between CS and DEAEM indicated that when CS is in excess, the decrease in DEAEM content follows a pseudo first-order reaction. When the quantity of DEAEM is equivalent to or is in excess of CS, the reaction is significantly more complex. In the latter case, the CS concentration-time curve shows three slopes: the first, a rapid initial drop which could be indicative of a prior equilibrium, and the other two represent the formation of the mono- and di-adducts of CS-DEAEM. In an attempt to further resolve the formation of two different adducts, the interaction of CS was studied in greater depth.

Reaction rate study of CS with DEAEM.—The derivative polarographic technique was found to be very convenient for monitoring simultaneously the DEAEM (—0.45v) and the CS (—0.92v) derivative peak heights when utilizing a fast scan of 3 v/min (Fig. 1). Both reactant peaks decrease in height, as represented by recordings which occur less than 20 sec apart. A new peak appears at —1.7v and varies as the reaction proceeds; this peak is apparently characteristic of a reaction intermediate and end product, but it could not be quantitated. Plots made of the respective quantity of reactants consumed allowed the determination of reaction rate with respect to each component. These reaction-process curves (Fig. 2, 3, and 4) could be used to determine the nature of the product on an empirical basis at a given time. In the following experiments the rates were measured for four different ratio conditions of the reactants in 20 ml of methanol.

The progress of the reaction at a ratio of CS/DEAEM, 1:1 (20:20 μmoles) is shown in Fig. 2. The initial drop in CS is significantly greater than that of DEAEM. As the reaction proceeds, the curves cross at a point equivalent to a 1:1 reaction (mono-adduct). The continued consumption of DEAEM to approximately 65% of reaction while CS equilibrates at approximately 50% might be explained as the formation of some di-adduct (CS·2RSH).

At a ratio of CS/DEAEM, 2:1 (20:10 μmole) the initial CS drop exceeds that of DEAEM. As the reaction approaches completion, the consumption of reactants becomes equivalent, indicating a 1:1 reaction (CS·RSH, mono-adduct). This experiment is illustrated in Fig. 3.

Experiments in which the excess of DEAEM over CS was run as 2.5:1 (50:20 μmole) and 5:1 (50:10

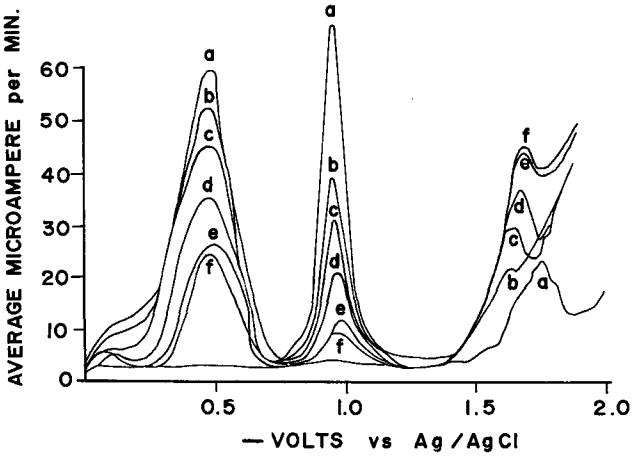


Fig. 1. Derivative reaction rate of 50 μmoles DEAEM with 20 μmoles CS (scan rate 3000 mv/min; Smoler 0.5 sec DME; electrolyte 0.1M $LiNO_3$ methanol; reaction time: a = initial, b = 3.5 min, c = 9.0 min, d = 24 min, e = 73 min, f = 182 min).

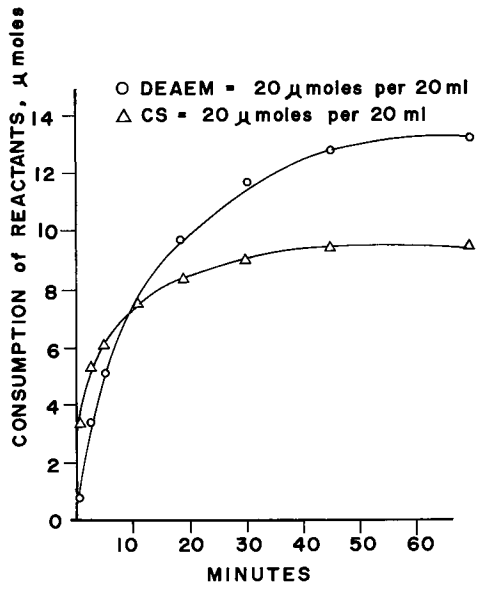

Fig. 2. Consumption of DEAEM and CS during reaction at a molar ratio of 1:1.

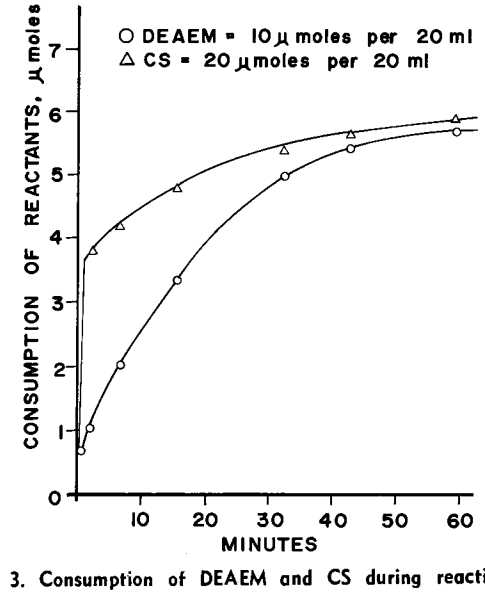

Fig. 3. Consumption of DEAEM and CS during reaction at a molar ratio of 1:2.

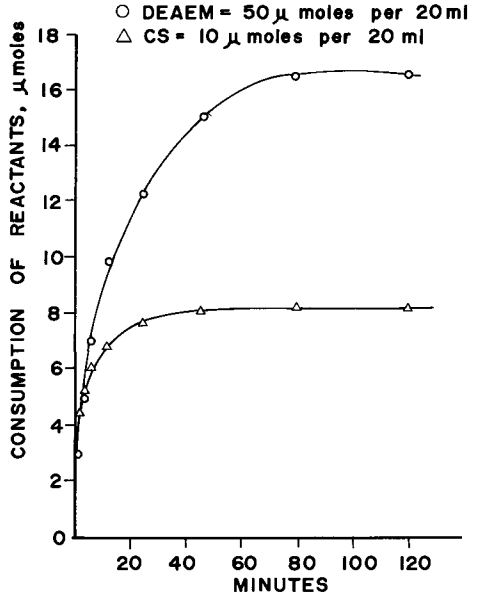

Fig. 4. Consumption of DEAEM and CS during reaction at a molar ratio of 5:1.

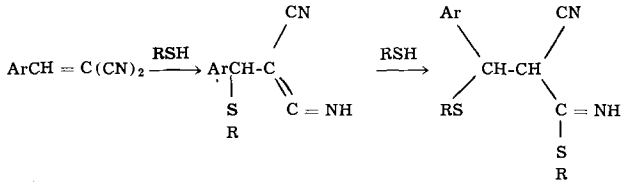
μmole) also showed the faster initial drop for CS over that of DEAEM. As the reaction progressed, there was an intersection of the reactant curves that was approximately equivalent to mono-adduct formation. Beyond this point the relative consumption of the components was reversed. At equilibrium or completion of reaction, the ratio of the components consumed was DEAEM/CS, 2:1, indicating the di-adduct (CS·2DEAEM).



These two experiments, where DEAEM was in excess, also prove that no more than two equivalents of mercaptan are involved in the reaction. The consumption of the reactants for the 5:1 ratio is illustrated in Fig. 4. The structure of the mono-adduct given in the above equation could be explained by the qualitative behavior of the peak at −1.7v; it increases during the formation of the mono-adduct; levels off for some time; and, during the formation of the di-adduct, a slow decrease of this peak takes place.

Table VII summarizes the ratio of reactants (DEAEM/CS) initially mixed and that consumed against time. The tabulated results reflect the same trend as the reaction-progress curves explained above. When CS is in excess, the ratio of reactants represented by the product is one, while at equimolar quantities, the ratio of reactants (DEAEM/CS) is greater than one. The latter result indicates that a mixture of products is being formed. With an excess of DEAEM, the ratio of reactants in the product approaches two, which shows definitely that the di-adduct, $(DEAEM)_2CS$, is the end product.

Reaction rate of CS with DEAEM under varying concentration conditions.—For purposes of reactivity screening, it was found that a ratio of CS to DEAEM of 5:1 could produce the best comparative results, especially when monitored on the basis of mercaptan consumed. Under this condition, only the formation of the mono-adduct is being measured, thus precluding the complexities involved when mixed products are obtained. When CS was maintained in excess from 2:1 and higher, no indication of product other than the mono-adduct was found during a 2-hr rate study.

Millimolarity mixtures of CS and DEAEM in the ratio of 1:1 to 20:1 were polarographed against time at 25°C in 20 ml of anhydrous methanol (0.1M $LiNO_3$). Semilog plots of unreacted mercaptan were made against time on multiple separate determinations for each ratio of reactant. The half-reaction times showed a reproducibility within 3% for the reactants ratio of 3:1 and higher; for ratios of 2:1 and lower, the reproducibility was within 10%. As the ratio of reactants is increased by increasing the concentration of CS, the half-reaction time decreases rapidly at first; when ratios of 5:1 and greater are used, it approaches a constant value.

When the ratio is maintained at 5:1 and the concentration of both reactants is increased, the half-reaction time is decreased. Thus, on the basis of these results, it is imperative that both the ratio and the concentration of the reactants be maintained constant when the reactivity of different analogs and homologs is to be compared. The results showing specific rate constants and half-reaction times *vs.* ratio of reactants and millimolarity are shown in Table VIII.

Reaction rates were determined at 5:1 ratio (CS/DEAEM) in different solvents to determine the effect of solvent on rate. The electrolytes used were 0.1M $LiNO_3$ for 50% methanol, anhydrous methanol, and anhydrous acetone; and 0.1M Bu_4NClO_4 for anhydrous acetonitrile. It was found that the half-reaction times increased in this order: 50% methanol (1 min), anhydrous methanol (6 min), acetonitrile (10 min), and acetone (30 min). The selection of anhydrous methanol as a convenient solvent for screening studies was based on its reasonable half-reaction time, as well as on those criteria discussed previously.

Temperature effect on reaction rate of CS with DEAEM.—The influence of temperature on reaction rates of CS with DEAEM was studied in the range of 15°-40°C. Rates were measured in triplicate for each 5°C increment. The ratio of the reactants was maintained at 5:1 (CS/DEAEM, 5 mM: 1 mM). The DEAEM concentration-time data for these reaction rates were treated as two alternative types of reaction: pseudo first-order and reversible pseudo first-order (Table IX).

(*a*) First order reaction and rate equation: With an excess of CS, DEAEM reacts as designated by DEAEM $\xrightarrow{CS}$ CS·DEAEM. If the initial concentration and the concentration at time, t, of DEAEM are represented by A_o and A, respectively, the integrated rate equation (17) for the reaction is $\ln A = \ln A_o - kt$. A plot of $\ln A/A_o$ *vs.* t should be linear and its slope equal to the first-order rate constant. Experimental results have shown that a plot of the rate data using the above

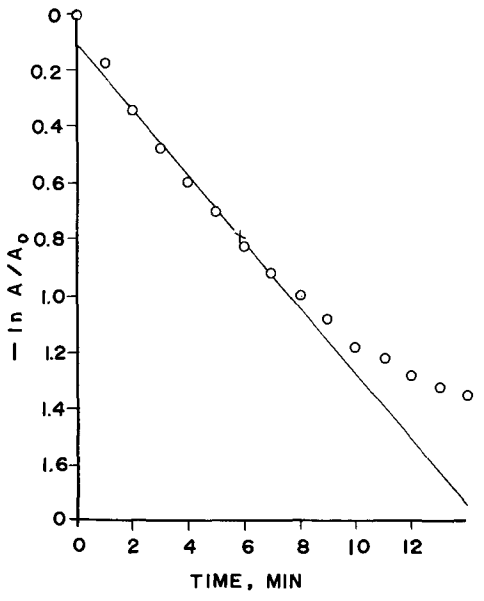

Fig. 5. First order reaction of CS with DEAEM (5:1) at 25°C; $k = 0.1171$ min^{-1} ($t_{1/2} = 5.92$ min).

first-order rate equation gives some deviation at the beginning of the reaction, and a greater deviation close to the end of the reaction (Fig. 5). This observation plus the fact that the isolated mono-adduct, CS·DEAEM, indicated dissociation to the original reactants (when a dilute solution of this product was polarographed with time) lead to the conclusion that the reaction is reversible and the reversible first-order rate equation should be used.

(b) Reversible first-order reaction and rate equation: The reversible reaction of DEAEM with an excess of CS is given by

$$\text{DEAEM} \underset{k_b}{\overset{\text{CS},\ k_f}{\rightleftharpoons}} \text{CS} \cdot \text{DEAEM}$$

The reversible first-order rate equation (18) representing the above reaction is

$$-dA/dt = (k_f + K_b)\,A - k_b A_o \qquad [1]$$

A and A_o were defined above; k_f is the forward rate constant and k_b is the backward (or reverse) rate constant. The integrated form of Eq. [1] is

$$\ln \frac{k_f A_o}{(k_f + k_b)\,A - k_b A_o} = (k_f + k_b)t \qquad [2]$$

The rate constants in Eq. [1] or [2] can be solved readily by the use of an analog computer. If the reaction of CS with DEAEM is permitted to approach equilibrium and A_e is the equilibrium DEAEM concentration, then $dA/dt = 0$ and Eq. [1] becomes

$$(k_f + k_b)\,A_e = k_b A_o \qquad [3]$$

Substitution of Eq. [3] into [2] gives

$$\ln \left(\frac{A_o - A_e}{A - A_e} \right) = (k_f + k_b)t \qquad [4]$$

The slope of this equation is equal to the sum of the forward and reverse rate constants. This slope together with Eq. [3] makes possible the calculation for k_f and k_b. A plot of Eq. [4], using the same concentration-time data which was used for the simple first-order equation, gives excellent linearity for almost the entire reaction with some deviation only after equilibrium of the reaction is reached (Fig. 6).

(c) Arrhenius temperature dependence of rate constants: The reproducibility of the rate constants, for

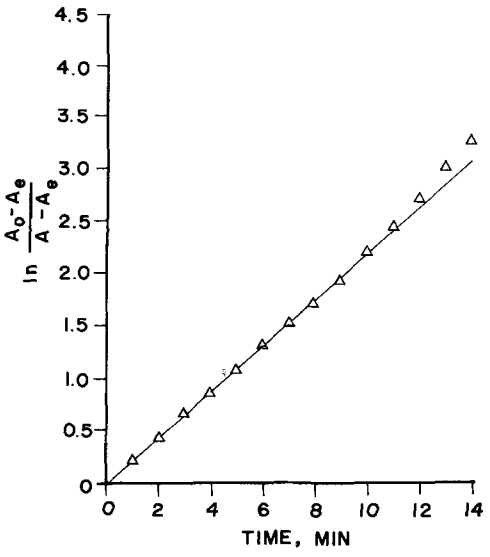

Fig. 6. Reversible first order reaction of CS with DEAEM (5:1) at 25°C, $k_f = 0.1676$ min^{-1} and $k_b = 0.0502$ min^{-1}.

each of the temperature increments, was of the order of 1% for the simple first-order k; for the reversible first-order, the forward rate constant (k_f) was of the order of 7%. The average rate constant for each isotherm (Table IX) was used to calculate $t_{1/2}$'s for the simple and complex (reversible) reaction. For the case of the reversible reaction, the formation constant, K, of the reaction was calculated from the ratio of the forward and reverse reaction constant, k_f/k_b. The average rate constants for the various temperatures given in Table X were used to make two separate Arrhenius plots by using the following equation (19)

$$\ln k = \ln A - \frac{E_a}{RT}$$

The activation energy, E_a, was obtained by equating $-E_a/R$ to the slope of the respective plots (Fig. 7). The value of the universal gas constant, R, is 1.987 cal/mole/degree. The activation energies for the simple and reversible reaction were 13.9 and 11.6 kcal/mole, respectively.

Discussion

The purpose of this investigation was to develop a procedure for a subsequent screening study of the re-

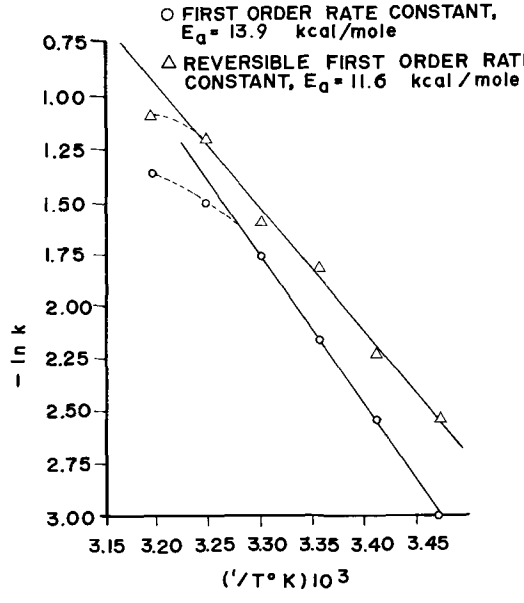

Fig. 7. Arrhenius plot for reaction of CS with DEAEM

activity of benzalmalononitriles and related irritants with a mercaptan. The principal requirements were to select a hydroxylic solvent as close as possible to water and a mercaptan to simulate the protein-thiol present *in vivo*. These requirements were approximated by the use of methanol as the solvent and DEAEM as the mercaptan.

CS and DEAEM were each found to be polarographically active in methanol, acetonitrile, and acetone. Both compounds were found to show linearity for diffusion current *vs.* concentration in the above solvents. The basic reaction being followed was the same regardless of the solvent, with the exception of 50% methanol where hydrolysis was noted. The speed of reaction between CS and DEAEM varies considerably with the polarity of the solvent in the following order: 50% methanol > methanol > acetonitrile > acetone. The magnitude of the zwitterionic form of DEAEM in the above solvents decreases in the same order. The charged aminomercaptan appears to have a major controlling effect on the reaction rate.

The type of reaction occurring was found to depend on the ratio of the starting materials. Thus, in the attempt to elucidate the reaction mechanism between CS and DEAEM, the ratio of initial concentration had to be considered.

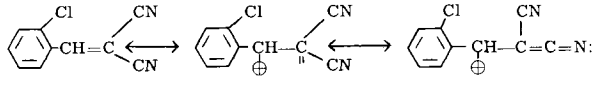
CS can add one or two molecules of DEAEM, depending on the relative concentration of the participating reactants. Polarographic rate studies have confirmed the following results:

(*A*) When CS is in excess, the observed rates demonstrate the addition of one molecule of DEAEM based on the thiol consumed.

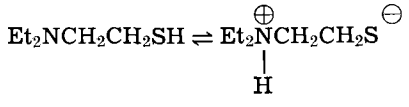
(*B*) When CS and DEAEM are present in equimolar quantities, rates have shown the establishment of an equilibrium for the mono-thiol addition and a subsequent addition to a site other than the CS α-β double bond.

(*C*) When DEAEM is in excess, the decrease of CS concentration *vs.* time shows three distinctly different slopes (rates). The first one of which could be indicative of the rapid formation of a prior equilibrium; the second, a moderately fast mono-thiol addition; and the third, a comparatively slow, second thiol addition to CS.

Based on the above discussion, a reaction mechanism can be illustrated to explain the mono- and di-addition of DEAEM to CS. The presence of nitrile groups in CS, due to their strong electronegativity effect, makes the α-β double bond in CS highly active and extremely susceptible to nucleophilic attack. The resonance of CS may be represented by the following three structures

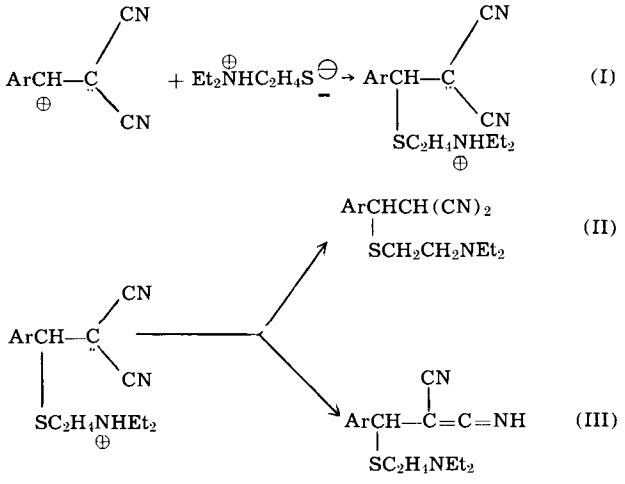


The aminomercaptan, DEAEM, due to its basic nitrogen, exists practically all in its zwitterionic form in polar solvents, and partially in semipolar solvents. In methanol, the following equilibrium exists

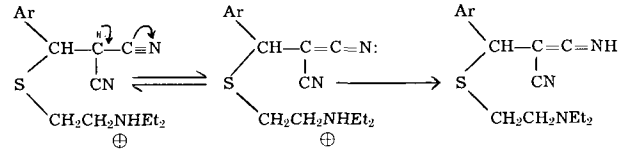


The zwitterion, being a stronger nucleophile, is probably the form of the thiol which takes part in the reaction with CS in methanol as a solvent.

By using the above resonance of CS and the ionic form of DEAEM, the mono- and di-adduct formations can be illustrated as follows

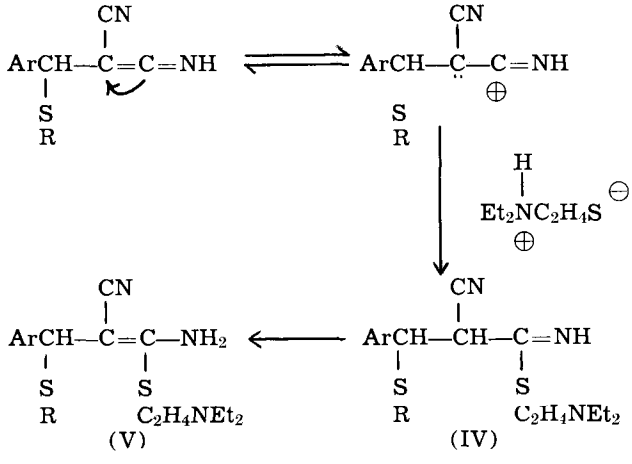


Polarographic indications were that structure (III) occurs in the mono-addition since there is an increase of a new reduction peak at −1.7v. This peak, although not too well defined, can be due only to the reduction of a newly formed conjugated system. The latter system can be initiated only by the free electrons on the alpha carbon in resonance with one of the nitrile groups



and subsequently stabilized to the imine form by the quaternary nitrogen proton.

The second addition of thiol is possible for structure (III) and not for structure (II). The addition of a second thiol was observed in the rates at equimolar concentration of the reactants, and more definitely as the mercaptan concentration was increased. Under these conditions, at equilibrium the consumption of DEAEM and CS agree with the stoichiometry of CS(DEAEM)$_2$. Thus, the second addition could go through the following steps:



The products (II) or (III) and (V) have been isolated. Their elemental analysis did agree with CS(DEAEM) and CS(DEAEM)$_2$, respectively.

The mono-adduct (III) was a brown oil. The isolated di-adduct was a white solid (mp 82°-84°C) whose IR and NMR spectra conform with structure (V). The imino form represented by structure (IV) is assumed to have existed prior to the end product (V).

The effect of temperature on the reaction rate constants with DEAEM gave excellent linearity between 15°-40°C, which is a good indication of the validity of the reaction rates. The calculated activation energy

was 13.9 kcal/mole for the simple reaction, and 11.9 kcal/mole for the reversible reaction.

Conclusions

A method employing controlled-potential dc polarography was developed for determining the rates of reaction of CS (o-chlorobenzalmalononitrile) and its analogs and homologs with a selected nucleophile, DEAEM (2-diethylaminoethyl mercaptan). Both the irritant and the nucleophile are electrochemically active; and, with derivative polarography, it is possible to measure almost simultaneously the disappearance of the two components during reaction. The developed method employs methanol as the solvent with lithium nitrate as added electrolyte, and a trielectrode system consisting of a rapid dropping-mercury electrode, a Ag/AgCl reference, and a platinum counter electrode.

The products obtained on the reaction of CS and DEAEM were found to be dependent on the concentration of the reactants. Based on rate curves, a 1:1 reactant mixture produces, initially, a monothioether (CS·DEAEM) through addition to the α-β double bond on CS. With CS in excess, the same product is formed. When DEAEM is in excess, a dithioether results, with addition first at the β carbon and then at a nitrile carbon, CS·$(DEAEM)_2$.

At a 5:1 ratio of CS to mercaptan, the half-reaction times in various solvents increased in the following order: aqueous methanol (1 min), methanol (6 min), acetonitrile (10 min), and acetone (30 min).

Manuscript received June 26, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 208.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Combined Adsorption of Cadmium(II) and Thiosulfate on Mercury

Donald J. Barclay and Fred C. Anson*

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California

ABSTRACT

The combined adsorption of thiosulfate and Cd(II) on mercury, as measured by chronocoulometry, is reported. It is concluded, primarily on the basis of the relationship between the amount of adsorbed thiosulfate and adsorbed Cd(II), that the reaction leading to the thiosulfate induced adsorption of Cd(II) is

$$[S_2O_3^{2-}]_{ads} + CdS_2O_3 \rightleftharpoons [Cd(S_2O_3)_2^{2-}]_{ads}$$

Data is also given on the adsorption of thiosulfate from cadmium-free solutions.

In a previous paper (1) we suggested that the mechanism by which specifically adsorbed and complex-forming anions induce adsorption of white metal cations on mercury involves an interaction between the adsorbed anions and an uncharged metal-anion complex to produce the adsorbed surface species. The inducing anions include iodide (1, 2), bromide (1, 2), chloride (2), and thiocyanate (2, 3, 4). In all previous studies, only the cation adsorption was measured because the concentrations of inducing anions required to produce significant adsorption of cations were too large to permit the application of the convenient chronocoulometric technique (5). For the measurement of the anion adsorption this difficulty is essentially eliminated in solutions of Cd(II) and thiosulfate because substantial Cd(II) adsorption is induced by thiosulfate concentrations in the millimolar range. We therefore studied this system with the chronocoulometric technique in the expectation that simultaneous determination of the adsorption of both cadmium and thiosulfate would enable the composition of the adsorbing species to be identified. The results indicate that, as is true in halide-induced adsorption, the uncharged complex, CdS_2O_3, is the adsorbing species.

The adsorption of thiosulfate on mercury has not previously been studied, but on the basis of a recent classification of anion adsorbability (6) which suggests that soft bases [in Pearson's (7) sense] are strongly adsorbed on positively charged mercury, it seemed reasonable to expect strong specific adsorp-

* Electrochemical Society Active Member.

tion of the thiosulfate anion. The anodic oxidation of mercury in the presence of thiosulfate proceeds according to Eq. [1] (8)

$$Hg + 2\,S_2O_3^{2-} \rightleftarrows Hg(S_2O_3)_2^{2-} + 2\,e \qquad [1]$$

which was the basis of the chronocoulometric determination of the adsorbed thiosulfate. The amount of adsorbed Cd(II) was similarly determined by the procedure previously employed (1).

The adsorption of zinc(II) from thiosulfate solutions and Cd(II) from sulfate solutions was also searched for. In both cases, the adsorption, if any, was less than 0.5 $\mu C/cm^2$.

Experimental

Cadmium adsorption.—The amount of adsorbed Cd(II) was determined by double potential step chronocoulometry with procedures and apparatus that have been previously described (9). The electrode potential was stepped from various initial potentials, E_i to −1000 mv *vs.* S.C.E. where the reduction of Cd(II) is diffusion controlled, and then back to E_i. Adequate time was allowed to elapse following the second potential step to ensure that the thiosulfate adsorption had reached equilibrium before any data points were taken. At the lowest concentrations of thiosulfate employed (1 mM) 5 msec were required. A 20 sec waiting period at E_i after the creation of each new mercury drop electrode was adequate to assure initial adsorption equilibrium.

Thiosulfate adsorption.—Preliminary experiments to determine the amount of adsorbed thiosulfate by double potential step chronocoulometry indicated that the product of the electrode reaction, $Hg(S_2O_3)_2^{2-}$, was also strongly adsorbed, so the correct double layer charging correction could not be obtained in the usual way. The tactic developed in previous chronocoulometric studies with analogous systems (10, 11) was therefore employed to determine the amount of adsorbed thiosulfate: Three single potential step chronocoulometric experiments were performed. First, the electrode was potentiostated at −1000 mv *vs.* S.C.E. where it could reasonably be assumed that no thiosulfate was adsorbed at the low concentrations employed (5 mM or less). The potential was stepped to +150 mv and the resulting charge flow was measured. Least-squares analysis of the charge-time data yielded an intercept equal to the difference in charge on the electrode between −1000 mv and +150 mv, $\Delta Q(-1000 \rightarrow 150)$. The charge on the electrode at +150 mv would be expected to decrease with time until the surface became saturated with adsorbed $Hg(S_2O_3)_2^{2-}$. To overcome this possible source of error no data points at +150 mv were included in the least-squares analysis until enough $Hg_2(S_2O_3)_2^{2-}$ to cover the surface had been generated.

Next, the potential was stepped from −1000 mv to E_i, where thiosulfate was adsorbed, but no electrode reaction proceeds. The resulting step-change in charge gave the difference in the charge on the electrode between −1000 mv and E_i, $\Delta Q(-1000 \rightarrow E_i)$. Finally, the potential was stepped from E_i to +150 and the charge-time data analyzed to give an intercept, I, corresponding to the amount of thiosulfate adsorbed at E_i plus the difference in charge on the electrode between E_i and +150 mv

$$I = F\Gamma_{S_2O_3} + \Delta Q(E_i \rightarrow 150) \qquad [2]$$

From the results of these three experiments the thiosulfate adsorption could be calculated according to Eq. [3]

$$F\Gamma_{S_2O_3} = I - \Delta Q(E_i \rightarrow 150) =$$

$$I - [\Delta Q(-1000 \rightarrow 150) - \Delta Q(-1000 \rightarrow E_i)] \qquad [3]$$

When both thiosulfate and Cd(II) were present the procedure just described could not be used because there is no potential where thiosulfate adsorption can be eliminated before cadmium reduction commences. The appropriate double layer charging corrections in this case were obtained from the double potential step experiments used to measure the cadmium adsorption in which the potential was stepped from E_i to −1000 and back to E_i. These experiments yielded values of $\Delta Q(E_i \rightarrow -1000)_{Cd}$ corresponding to the difference in the charge on the electrode at E_i and −1000 in the presence of adsorbed Cd(II). These values of $\Delta Q(E_i \rightarrow -1000)_{Cd} = -\Delta Q(-1000 \rightarrow E_i)_{Cd}$ were substituted for the last term in Eq. [3] to calculate $F\Gamma_{S_2O_3}$. Reaction [1] proceeds at the diffusion limited rate at +150 mv even in the presence of Cd(II) because the stability of the $Hg(S_2O_3)_2^{2-}$ complex is much greater than the Cd(II)-$S_2O_3^{2-}$ complexes.

The hanging mercury drop electrode was the standard commercially available type (Brinkman Instruments) modified to provide better electrical contact (12).

Reagent grade chemicals [KNO_3, $Na_2S_2O_3$, and $Cd(NO_3)_2$] were used without further purification but thiosulfate solutions were prepared frequently and stored in dark bottles. The ionic strength of all solutions was maintained at unity with potassium nitrate and most experiments were performed at room temperature (25° ± 2°C); the experiments at lower temperatures were performed with the cell immersed in a slurry of ice in a sodium nitrate solution. Solutions were deoxygenated with prepurified nitrogen which was passed through copper turnings at 400°C, a trap maintained at −70°C, and triply distilled water. Triply distilled water was used to prepare all solutions. Potentials are reported in mv *vs.* S.C.E.

Results and Discussion

Adsorption of thiosulfate.—The charge due to adsorbed thiosulfate is plotted as a function of potential in Fig. 1, for 1, 2, 3, and 5 mM concentrations of thiosulfate. Higher concentrations were not used because the uncompensated resistance in the cell seriously degraded the quality of the data above 5 mM. (Typical indications of the presence of errors attributable to uncompensated resistance are intercepts of charge *vs.* $t^{1/2}$ plots that suggest "negative adsorption" or current transients that contain kinks or plateaus instead of a smooth monotonic decay.) The values of $q_{S_2O_3}$ in Fig. 1 could be reproduced within a range of *ca.* ±2 $\mu C/cm^2$.

Inasmuch as this is the first quantitative data on thiosulfate adsorption it is of interest to compare the adsorption of this anion with that of iodide and thiocyanate. In Fig. 2, the charge due to adsorbed

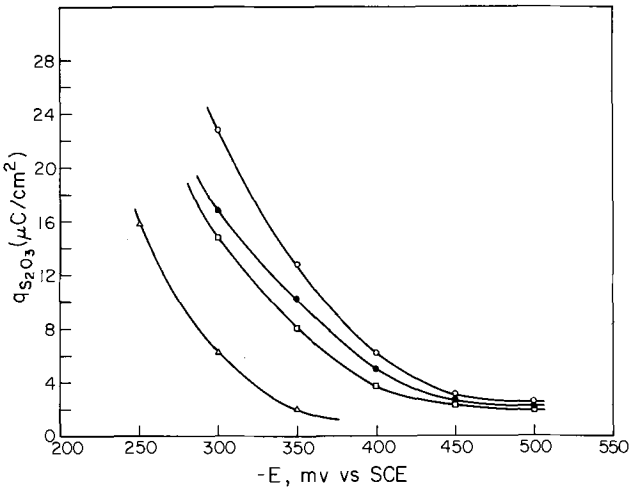

Fig. 1. Dependence of $q_{S_2O_3}$ on E_i. Thiosulfate concentration, mM; Δ, 1.0, □, 2.0; ●, 3.0; ○, 5.0. Each point is the average of several replicate experiments. At more negative potentials than those shown $q_{S_2O_3}$ decreases to values smaller than the experimental reproducibility (~ 0.5 $\mu C/cm^2$).

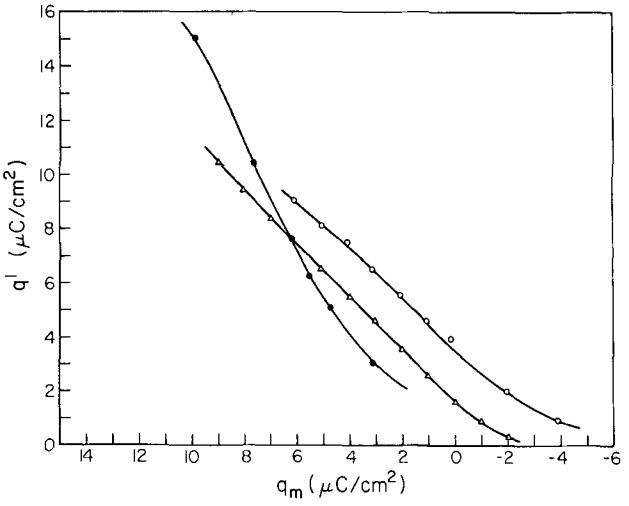

Fig. 2. Comparison of q' (charge due to specifically adsorbed anion) as a function of electrode charge for 4 mM I^- (○), 6 mM NCS^- (△), and 3 mM $S_2O_3^{2-}$ (●). q_m for $S_2O_3^{2-}$ was obtained from chronocoulometric data as described in (1).

anions is plotted *vs.* electrode charge for 4 mM iodide (13), 6 mM thiocyanate (14), and 3 mM thiosulfate. These plots are not strictly comparable because of the concentration differences and because our results were obtained in the presence of 1M potassium nitrate. However, these factors will probably not affect the significant feature of this comparison which is that the adsorption of thiosulfate increases more rapidly with increasing electrode charge than does that of iodide or thiocyanate. The slope $(\partial q_{S_2O_3}/\partial q_m)$, on the linear part of the plot is approximately 2 compared with about 1 for the corresponding iodide and thiocyanate plots. This difference presumably reflects the two-fold greater charge on the adsorbing thiosulfate anion.

The potential at the point of zero charge for a 0.1M solution of sodium thiosulfate (no KNO_3 added) is -540 ± 15 mv as determined by measuring the charge flowing into a d.m.e. (15). This rather negative value suggests that the specific adsorption of the thiosulfate anion is quite strong.

Adsorption of cadmium.—The adsorption of Cd(II) from solutions of varying thiosulfate concentration was determined as a function of potential. The limits on the initial potential, E_i, were set on the anodic side by mercury oxidation and on the cathodic side by the reduction of Cd(II). Figure 3 gives the variation of

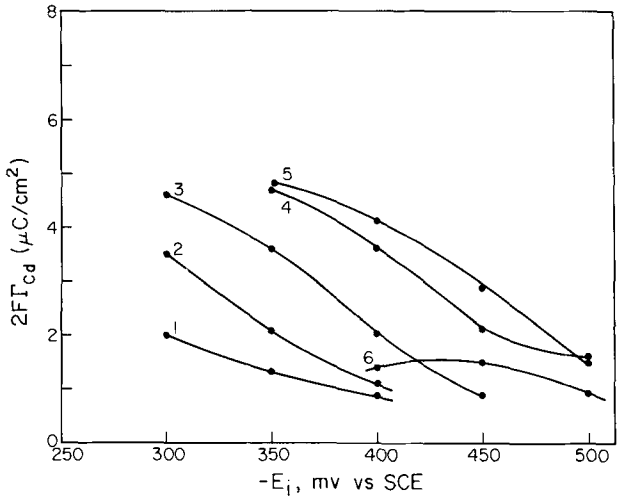

Fig. 3. Potential dependence of Cd(II) adsorption induced by thiosulfate. Cadmium concentration = 0.5 mM. Thiosulfate concentration: 1. 2 mM; 2. 3 mM; 3. 5 mM; 4. 10 mM; 5. 25 mM; 6. 100 mM.

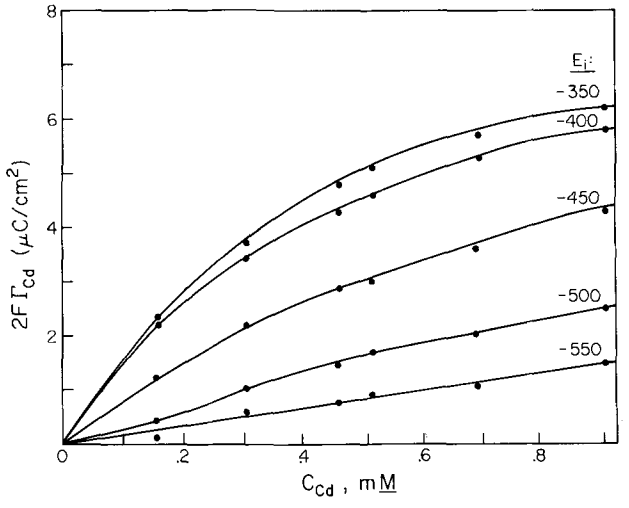

Fig. 4. Dependence of $2F\Gamma_{Cd}$ on Cd(II) concentration in 25 mM $S_2O_3^{2-}$ at various potentials.

$2F\Gamma_{Cd}$ with E_i for concentrations of thiosulfate between 2 and 100 mM and at a Cd(II) concentration of 0.5 mM. Figure 4 is a plot of $2F\Gamma_{Cd}$ *vs.* the Cd(II) concentration in 25 mM thiosulfate where the Cd(II) adsorption was greatest.

Noteworthy points from Fig. 3 are that very low thiosulfate concentrations are adequate to induce the adsorption of Cd(II) and that the maximum adsorption occurs at a thiosulfate concentration of only about 25 mM; with 100 mM thiosulfate the adsorption is quite low, and at higher concentrations it is essentially absent. The strong potential dependence of the adsorption indicates that, as is true with iodide and bromide (1), and thiocyanate (3), specific adsorption of the inducing anion is required for the cation adsorption to occur. Taken together these observations are compatible with the adsorption of a cadmium-thiosulfate complex species by attachment of the complex to a specifically adsorbed thiosulfate anion.

By suitable analysis of double potential step chronocoulometric data (5) any change in the charge on the electrode produced by the adsorption can be determined. For cadmium in thiosulfate solutions the charge changes were very small [*e.g.*, $\Delta Q < 0.3$ $\mu C/cm^2$ when 4.7 $\mu C/cm^2$ of Cd(II) is adsorbed] which suggests that the adsorbing species is not highly charged.

Adsorption of thiosulfate in the presence of Cd(II).—Since both free thiosulfate anions and a cadmium thiosulfate complex appear to be adsorbed from cadmium-thiosulfate solutions, the sum of the two will comprise the values of $\Gamma_{S_2O_3}$ resulting from the chronocoulometric experiments in these solutions (Γ is in moles/cm²)

$$(\Gamma_{S_2O_3})_{total} = \Gamma_{S_2O_3}^{anion} + x\Gamma_{Cd(S_2O_3)_x} \qquad [4]$$

The data in Table I show how $(\Gamma_{S_2O_3})_{total}$ varies as the Cd(II) concentration is increased in 1 mM and 3 mM $Na_2S_2O_3$ solutions. At first, $(\Gamma_{S_2O_3})_{total}$ increases with the Cd(II) concentration, clearly demonstrating that the adsorbing Cd(II) brings additional thiosulfate with it to the electrode surface. However, at the highest Cd(II) concentration (10 mM) $(\Gamma_{S_2O_3})_{total}$ drops well below the value prevailing before any cadmium was added. This behavior results from the fact that with 10 mM Cd(II) a large portion of the total thiosulfate present is converted to the CdS_2O_3 complex leaving a concentration of free thiosulfate which corresponds to a much lower value of $\Gamma_{S_2O_3}^{anion}$. Since this term is the dominant contributor to $(\Gamma_{S_2O_3})_{total}$, the value of the latter decreases accordingly. In short, the decrease in $\Gamma_{S_2O_3}^{anion}$ produced by lowering the free thiosulfate concentration is greater than the increase in $\Gamma_{Cd(S_2O_3)_x}$ resulting from the higher concentration of CdS_2O_3.

1.0	7.0	1.75	13.7	9.9	3.6	2.3
10.0[a]	3.3	—	10.2	6.6	—	—

[a] $\Delta Q(-1000 \rightarrow E_i)$ could not be evaluated as described in the Experimental Section at this concentration of Cd(II). Instead the difference in $\Gamma_{S_2O_3}$ between E_i and −500 was measured, and by estimating $\Gamma_{S_2O_3}$ at −500 from the calculated concentration of uncomplexed thiosulfate, $\Gamma_{S_2O_3}$ at E_i was evaluated. The error in this procedure will not be large as the adsorption of thiosulfate and Cd(II) at −500 is small.

Data such as those in Table I provide the information needed to deduce the average composition of the cadmium-thiosulfate complex, $Cd(S_2O_3)_x^{2-2x}$ that is adsorbed. When Cd(II) is added to an initially cadmium-free thiosulfate solution the resulting change in $(\Gamma_{S_2O_3})_{total}$ should be given by Eq. [5]

$$\Delta(\Gamma_{S_2O_3})_{total} = \Delta\Gamma_{S_2O_3}^{anion} + x\Gamma_{Cd(S_2O_3)_x} \qquad [5]$$

where Δ signifies the difference between the value obtained after the addition of Cd(II) and the value in the absence of cadmium. $\Delta(\Gamma_{S_2O_3})_{total}$ is obtained directly from the two anodic chronocoulometric experiments based on reaction [1]. $\Gamma_{Cd(S_2O_3)_x}$ is obtained from a cathodic double potential step chronocoulometric experiment in which the Cd(II) is reduced. $\Delta\Gamma_{S_2O_3}^{anion}$ cannot be obtained directly. It was evaluated from the appropriate constant potential adsorption isotherm measured in cadmium-free thiosulfate solutions and the bulk concentration of thiosulfate anion in the cadmium-thiosulfate solutions calculated from the formation constants of the cadmium-thiosulfate complexes (16). This method of evaluating $\Delta\Gamma_{S_2O_3}^{anion}$ assumes that the adsorption isotherm for thiosulfate anion adsorption will remain unchanged in the presence of 3-4 μC/cm² of adsorbed Cd(II). This approximation seems reasonable because almost no change in the charge on the electrode is produced by the adsorption of this amount of Cd(II). The values of x that result from this analysis are given in Table II. The fact that they are close to unity indicates that the predominant adsorbed species is CdS_2O_3 although the experimental uncertainty in the measured adsorptions limits the strength of this conclusion.

Adsorption induced by adsorbed anions.—It has been previously proposed (1) that the mechanism by which specifically adsorbed anions induce the adsorption of white metal cations involves bond formation between adsorbed anions and a metal cation-anion complex. In the particular case of Cd(II) adsorption from iodide solutions the adsorption process was described by a reaction such as

Table II. Average composition of the adsorbed cadmium-thiosulfate complex, $Cd(S_2O_3)_x^{2-2x}$

$\Delta\Gamma_i = \Gamma_i$ with Cd(II) − Γ_i without Cd(II).

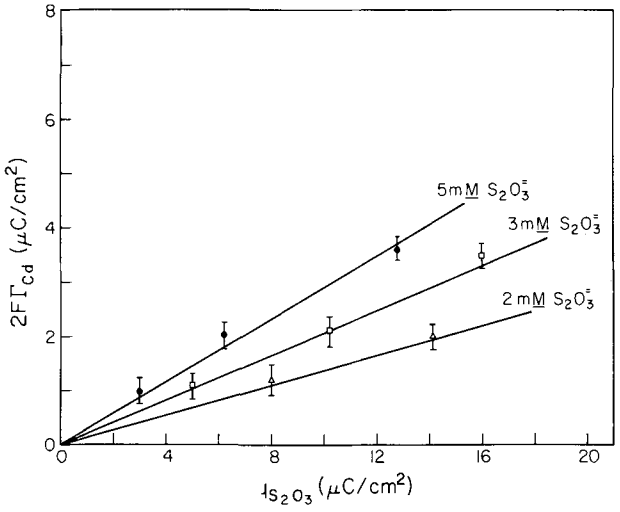

Fig. 5. Correlation between $q_{S_2O_3}$ and $2F\Gamma_{Cd}$ in 2, 3, and 5 mM $S_2O_3^{2-}$. Concentration of Cd(II) was 0.5 mM.

$$(I^-)_{ads} + CdI_2 \rightarrow (I - CdI_2)_{ads} \qquad [6]$$

Evidence to support this proposal included a close correlation between the amount of Cd(II) adsorbed and the quantity of specifically adsorbed anions on the electrode. The same kind of correlation obtains in cadmium-thiosulfate solutions, as is shown in Fig. 5. This figure contains plots of $2F\Gamma_{Cd}$ *vs.* the charge due to adsorbed thiosulfate anions for three different thiosulfate solutions. The plotted values of $q_{S_2O_3}$ are the chronocoulometric values of adsorbed thiosulfate in cadmium-free solutions less a small correction to take account of the decrease in the bulk concentration of free thiosulfate produced by the addition of Cd(II). The linearity of these plots at such low values of $q_{S_2O_3}$ and the fact that all the lines extrapolate to the origin is strong evidence in favor of an adsorption process involving association between adsorbed thiosulfate anions and a Cd(II) complex.

Additional evidence in support of this conclusion comes from experiments testing the effect of temperature on the adsorption. Table III compares the values of $2F\Gamma_{Cd}$ obtained at several thiosulfate concentrations at 25° and 0°C. The uniformly greater Cd(II) adsorption at the lower temperature parallels a greater adsorption of $S_2O_3^{2-}$ at 0°C as measured, at the lower thiosulfate concentration, by anodic chronocoulometry (Table III). The equilibrium constants for the formation of cadmium thiosulfate complexes show temperature dependences too small to account for the increased adsorption on this basis (16). The simplest ex-

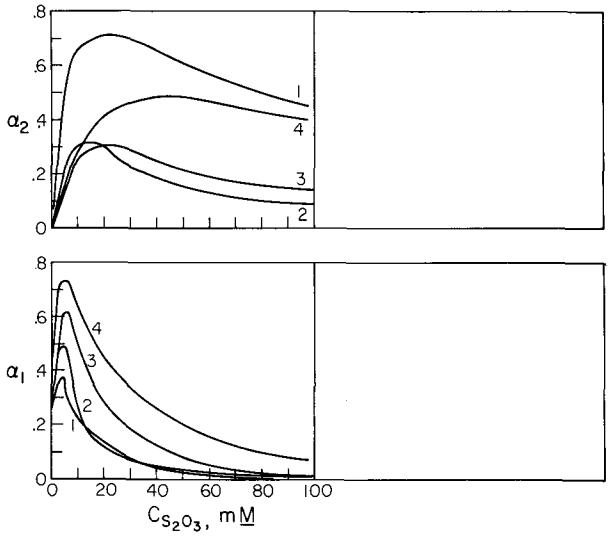

Fig. 6. α_1 and α_2 (the fraction of cadmium present as the mono- and bis-complex) as a function of thiosulfate concentration. There is only fair agreement among the reported values of the cadmium-thiosulfate complex formation constants. Four different sets were employed [1. ref. (17); 2 and 3, ref. (18); 4, ref. (19)] and all lead to the same qualitative deductions about the preponderant species at each thiosulfate concentration.

planation, and the one we prefer, is that the increased adsorption of $S_2O_3^{2-}$ induces increased adsorption of the CdS_2O_3 complex because the adsorption involves bond formation between these two species.

It has been argued previously (1) that reliable information on the composition of adsorbing complexes may be obtained from the dependence of the metal adsorption on the bulk concentration of the complex-forming anion only when the adsorption is evaluated at constant values of adsorbed anion. Unfortunately, the lack of data on thiosulfate adsorption at concentrations above 5 mM prevented the appropriate analysis in this case. However, the fractions of Cd(II) present as the mono- and bis-thiosulfato complexes were computed from some of the reported stability constants and the results are summarized in Fig. 6. The concentration of $Cd(S_2O_3)_2^{2-}$ turns out to be about the same in 5 mM $S_2O_3^{2-}$ as it is in 100 mM $S_2O_3^{2-}$. Since $q_{S_2O_3}$ is much greater at the higher $S_2O_3^{2-}$ concentration, one might expect considerably greater adsorption of Cd(II) at the higher $S_2O_3^{2-}$ concentration if $Cd(S_2O_3)_2^{2-}$ were the adsorbing species. In fact, $2F\Gamma_{Cd(S_2O_3)_x}$ is much greater in 5 mM than in 100 mM thiosulfate even though $q_{S_2O_3}$ is greater at the higher thiosulfate concentration (Fig. 3). This fact is more compatible with the adsorption of the uncharged complex, CdS_2O_3, as was proposed above on other grounds.

Because thiosulfate is an ambidentate anion the site of the proposed bonding between an adsorbed thiosulfate anion and the adsorbing Cd(II)-thiosulfate complex is not obvious. Attachment to one of the oxygen atoms of the adsorbed thiosulfate (which is almost certainly adsorbed via the outer sulfur atom) would appear to be sterically preferable. Nevertheless, a case can be made for the proposition that the same outer sulfur atom which binds the adsorbed thiosulfate ion to the electrode serves as the site of attachment to the electrode surface of the Cd(II) in the adsorbing complex: No adsorption of Zn(II) from thiosulfate media could be detected ($\Gamma < 0.5$ $\mu C/cm^2$) under the same conditions that produced substantial adsorption of Cd(II), *i.e.*, significant adsorption of thiosulfate on the electrode and substantial concentrations of ZnS_2O_3 or $Zn(S_2O_3)_2^{2-}$ in the solution. Since Zn^{2+} is a harder cation than Cd^{2+} (7) it would be expected to have a stronger affinity than Cd^{2+} for the available oxygen atoms in adsorbed thiosulfate anions. The failure of adsorbed thiosulfate to induce any adsorption of Zn(II) thus suggests that attachment through oxygen is not the mechanism by which thiosulfate induces the adsorption of Cd(II).

A related experimental result is the lack of adsorption of Cd(II) from sulfate electrolytes in which $CdSO_4$ is formed and substantial sulfate anion adsorption can be achieved at high positive charges on the electrode. The soft Cd(II) does not avail itself of the opportunity to adsorb via the hard oxygen atoms in the adsorbed sulfate.

The bonding of the Cd(II) in CdS_2O_3 molecules to the sulfur atom of a sulfur-bonded, adsorbed thiosulfate anion poses greater steric difficulties than were encountered in the corresponding iodide-induced adsorption of Cd(II) (1). This difference may account for the lower values of Γ_{Cd} resulting from thiosulfate-induced adsorption even though the Cd(II)-thiosulfate complexes have the higher formation constants.

Theoretical Analysis of Mixed Potentials

David Gray[1] and Allen Cahill

Department of Chemistry, The University of Mississippi, University, Mississippi

ABSTRACT

A mathematical treatment of mixed potential generation is developed from basic electrochemical theories, such that the relationships between rest, mixed, and Nernst potentials are evident. Various approximations of the general mixed potential equations are also developed and discussed.

Single Process Electrode Kinetics

For a simple electrode reaction

$$Ox + ne = R \qquad [1]$$

where Ox is the oxidized species and R is the reduced species. Where the actual charge-transfer valence, z, is equal to the net electrode reaction valence, n, the following may be used

$$i = i^\circ \left[e^{-\alpha \frac{zF}{RT}\eta} - e^{(1-\alpha)\frac{zF}{RT}\eta} \right] \qquad [2]$$

where i is the net current density (often referred to simply as the net current), i° is the exchange current density, α is the transfer coefficient corresponding to the cathodic process, $\mathbf{F}$ is the Faraday, R is the gas constant (different from R used in reaction [1]), T is the temperature in °K, and η is the overvoltage defined as

$$\eta = E - E^{eq} \qquad [3]$$

where E is the applied potential and E^{eq} is the Nernst (equilibrium) potential (1, 2). By the American conventions, i will be positive and η will be negative for a net cathodic process, and i will be negative and η will be positive for a net anodic process.

When diffusion processes are important in reaction [1], Eq. [2] may be rewritten as

$$i = i^\circ \left[\left(1 - \frac{i}{i_c^d}\right) e^{-\alpha \frac{zF}{RT}\eta} - \left(1 - \frac{i}{i_a^d}\right) e^{(1-\alpha)\frac{zF}{RT}\eta} \right] \qquad [4]$$

where i_i^d is the limiting diffusion current density of either the cathodic or the anodic process.

Since the exchange current density, i°, of an electrode reaction is a function of the activities of the reacting species, Delahay and Berzins (3) have introduced the following equation

$$i^\circ = z\mathbf{F}k^\circ a_{ox}^{1-\alpha} a_r^{\alpha} \qquad (n = z) \qquad [5]$$

where k° is the heterogeneous rate constant for electrode reaction [1] and a_i is the activity of the oxidized or reduced species. By defining the standard exchange current density, $i^{\circ\circ}$, as

$$i^{\circ\circ} = z\mathbf{F}k^\circ \qquad \left(\text{or } \frac{z\mathbf{F}k^\circ}{1000}\right) \qquad [6]$$

Spiro (4) has rewritten Eq. [5] as

$$i^\circ = i^{\circ\circ} a_{ox}^{1-\alpha} a_r^{\alpha} \qquad (n = z) \qquad [7]$$

Generally, Eq. [5] and [7] are written with concentrations substituted for activities. This substitution probably causes a large part of the differences in k° and $i^{\circ\circ}$ values as determined by different workers for the same electrode reaction (4).

More complex electrode reactions like

$$pOx + ne = qR \qquad (n \neq z) \qquad [8]$$

where the charge-transfer reaction may occur more than once for the net reaction to occur once have also been considered (1, 5) in evaluating the activity dependence of the exchange current density. For this complex case Eq. [7] may be rewritten as

$$i^\circ = i^{\circ\circ} a_{ox}^{(1-\alpha)\frac{z}{n}p} a_r^{\alpha\frac{z}{n}q} \qquad [9]$$

Equation [9] is often written employing a stoichiometric number, ν, which is the number of times the rate determining step must occur for the net reaction to occur once. The terms, n, z, and ν may be related by

$$\frac{n}{\nu} = z \qquad [10]$$

Mixed Potentials—General

When an electrode is immersed in a solution, there are numerous electrochemical processes which may occur. If one of these processes has a high relative exchange current density to the other possible processes, then it will dominate all processes and the electrode will measure the equilibrium potential of that process, which is calculated by the Nernst equation. When this happens, the electrode is said to be reversible with respect to that particular process. In fact, a practical criterion for reversibility is that the Nernst equation be obeyed. It is important to emphasize that many of the potentials given in standard electrode potential tables are values obtained from thermodynamic data rather than from electromotive force data and caution must be exercised in using them to predict electrode behavior. These values can only be used for electrochemical purposes when the process of interest is kinetically dominating all the other processes which can occur; in other words, when its i° value is considerably higher than the i° values for all the other possible processes.

It is evident that zero net current to an electrode does not necessarily correspond to equilibrium conditions at the electrode when more than one reaction is taking place at the electrode. For the net current to be zero it is only necessary for the sum of the total cathodic currents and the total anodic currents to be zero; that is, the total rate of reductions must equal the total rate of oxidations.

If two or more processes are competitively occurring at the same electrode and at zero net current, a net chemical change or reaction is generally proceeding and the net cathodic and anodic reactions are coupled and they must proceed at the same net rate ($i = i_c + i_a = 0$), and at the same potential, which will be different from the equilibrium potential for any of the processes. This potential is called the mixed potential, and the electrode is called a mixed or polyelectrode. The classic example of mixed potential generation is electrolytic corrosion; that is, when an electrode reacts with the solution in which it is immersed under zero

[1] Present address: Lockheed-Georgia Company, Marietta, Georgia.

net current conditions and at a rest potential which does not appear to be related to the equilibrium potential of the electrode metal or the solution.

The essential idea of mixed potential generation was anticipated by Frumkin (6), Hammett and Lorch (7), and Bronsted and Kane (8) in research on the dissolution rate of sodium amalgam. The classic paper of Wagner and Traud (9) demonstrated that the general behavior of a mixed potential can be explained by the "principle of superpositioning of partial current-voltage curves" of each process involved in the net electrode reaction. Wagner and Traud were aware of the fact (10, 11) that the partial current-voltage curves as well as the mixed potential values must be determined in similar environments. Vetter (12) has pointed out that the mixed potentials, as well as the current-voltage curves, depend greatly on the surface characteristics of the electrode, while the Nernst potentials are independent of the surface properties as shown by Fig. 1. It should also be noted that the partial current-voltage curves are also dependent on the activities of the process components. This is often ignored in graphical determinations of mixed potentials.

The graphical method for determining mixed potentials was initially developed by Wagner and Traud (9). In general, the mixed potential is evaluated by plotting the appropriate partial current-voltage curves as in Fig. 2. The mixed potential, E_m, is the potential at which the net cathodic current for one of the two processes is equal in magnitude to the net anodic current for the other process. In this simple case of two electrode processes, the mixed potential will correspond to two different overvoltages, $\eta_c = E_m - E_2^{eq}$ and $\eta_a = E_m - E_1^{eq}$, where $\eta_c < 0$ and is cathodic and $\eta_a > 0$ and is anodic. The dashed line in Fig. 2 is the over-all current-voltage curve for the mixed electrode. The E_m value will tend toward the E^{eq} value for the process with the highest i° value and it will always be between the equilibrium potentials of the two competing processes. In many cases the cathodic and anodic currents are plotted without regard to sign as in Fig. 3, where the mixed potential is determined by the point of intersection of the partial current-voltage curves. Since mixed potentials are involved in corrosion phenomena, the cathodic current (and also the magnitude of the anodic current) associated with the mixed potential is often referred to as the corrosion current, i_{cor}. The graphical method of evaluating mixed potentials has been expanded for complex systems. Of particular note is the work of Tomashov (13), Hoare (14), and Stern and co-workers (15-17). Hoare (14), and Conway and Bourgault (18) have demonstrated the generation of mixed potentials in systems involving chemisorbed oxygen. Polarographic analysis of mixed potentials has been performed by Kolthoff and Miller (19), and Milicevic (20). Vetter's recent book (12) contains an excellent review of mixed potentials and their importance in interpreting electrolytic corrosion.

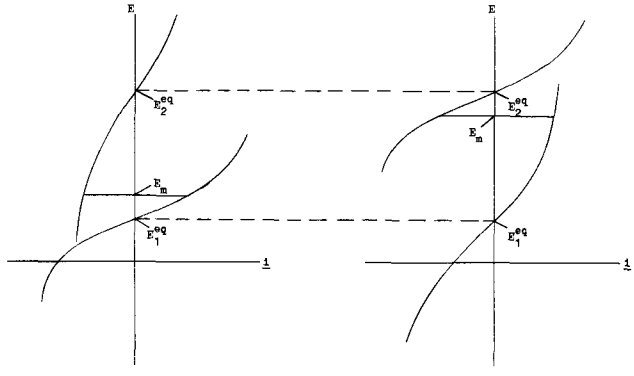

Fig. 1. Dependence of the mixed potential on the relative positions of the partial current-voltage curves.

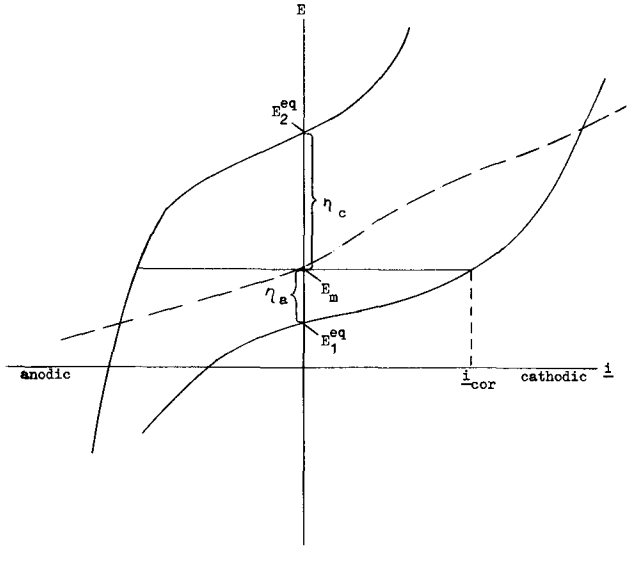

Fig. 2. Graphical determination of a mixed potential generated at a mixed electrode by the coupling of two electrode processes.

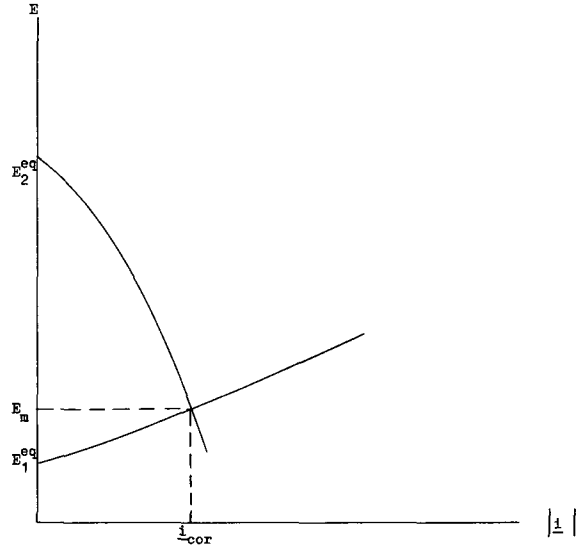

Fig. 3. Graphical determination of a mixed potential generated at a mixed electrode by the coupling of two electrode processes when the cathodic and anodic current densities are taken as absolute values.

Mixed Potentials—Mathematical

If x simultaneous electrode processes

$$\begin{aligned} &Ox_1 + n_1e = R_1 \\ &\vdots \\ &Ox_i + n_ie = R_i \qquad (n_i = z_i) \\ &\vdots \\ &Ox_x + n_xe = R_x \end{aligned} \qquad [11]$$

are occurring at the same electrode and at zero net current to the electrode then one may write for each process

$$\begin{aligned} &\eta_1 = E_m - E_1^{eq} \\ &\vdots \\ &\eta_i = E_m - E_i^{eq} \\ &\vdots \\ &\eta_x = E_m - E_x^{eq} \end{aligned} \qquad [12]$$

where η_i is the overvoltage for the i^{th} process, E_m is the mixed or rest potential of the electrode, and E_i^{eq} is the Nernst potential for the i^{th} process which can be written as

$$E_1^{eq} = E_1^{o} + \frac{RT}{n_1\mathbf{F}} \ln \frac{a_{ox1}}{a_{r1}}$$

$$\vdots$$

$$E_i^{eq} = E_i^{o} + \frac{RT}{n_i\mathbf{F}} \ln \frac{a_{oxi}}{a_{ri}} \qquad (n_i = z_i)$$

$$\vdots$$

$$E_x^{eq} = E_x^{o} + \frac{RT}{n_x\mathbf{F}} \ln \frac{a_{oxx}}{a_{rx}} \qquad [13]$$

where E_i^{o} is the standard electrode potential for the i^{th} electrode process. Each process will be proceeding at a rate which can be expressed by the net current for that process.

$$i_1 = i_1^{o} \left\{ e^{-\alpha_1 \frac{z_1\mathbf{F}}{RT}(E_m - E_1^{eq})} - e^{(1-\alpha_1)\frac{z_1\mathbf{F}}{RT}(E_m - E_1^{eq})} \right\}$$

$$\vdots$$

$$i_i = i_i^{o} \left\{ e^{-\alpha_i \frac{z_i\mathbf{F}}{RT}(E_m - E_i^{eq})} - e^{(1-\alpha_i)\frac{z_i\mathbf{F}}{RT}(E_m - E_i^{eq})} \right\} \qquad [14]$$

$$\vdots$$

$$i_x = i_x^{o} \left\{ e^{-\alpha_x \frac{z_x\mathbf{F}}{RT}(E_m - E_x^{eq})} - e^{(1-\alpha_x)\frac{z_x\mathbf{F}}{RT}(E_m - E_x^{eq})} \right\}$$

The only condition that has been set is that the total net current is zero. Therefore, one may write

$$i_{total} = i_1 + i_2 + \ldots + i_i + \ldots + i_x = \sum_{i=1}^{x} i_i = 0 \qquad [15]$$

It is important to emphasize that it is not necessary to specify which processes are over-all cathodic and which are over-all anodic. If a process is over-all cathodic, then the $(E_m - E_i^{eq})$ terms in Eq. [14] will be negative and the net current for that process, i_i, will be positive, and if a process is over-all anodic, then the $(E_m - E_i^{eq})$ terms will be positive and the net current for that process will be negative.

From Eq. [15] one may write that

$$\sum_{i=1}^{x} i_i = 0 = \sum_{i=1}^{x} i_i^{o} \left\{ e^{-\alpha_i \frac{z_i\mathbf{F}}{RT}(E_m - E_i^{eq})} - e^{(1-\alpha_i)\frac{z_i\mathbf{F}}{RT}(E_m - E_i^{eq})} \right\} \qquad [16]$$

which can be rearranged to

$$\sum_{i=1}^{x} i_i^{o}\, e^{-\alpha_i \frac{z_i\mathbf{F}}{RT}E_m}\, e^{\alpha_i \frac{z_i\mathbf{F}}{RT}E_i^{eq}} = \sum_{i=1}^{x} i_i^{o}\, e^{(1-\alpha_i)\frac{z_i\mathbf{F}}{RT}E_m}\, e^{-(1-\alpha_i)\frac{z_i\mathbf{F}}{RT}E_i^{eq}} \qquad [17]$$

In systems in which the following two conditions exist

$$\alpha_1 = \alpha_2 = \ldots = \alpha_i = \ldots = \alpha_x = \alpha \qquad [18]$$

$$z_1 = z_2 = \ldots = z_i = \ldots = z_x = z \qquad [19]$$

Eq. [17] reduces to

$$e^{-\alpha\frac{z\mathbf{F}}{RT}E_m} \sum_{i=1}^{x} i_i^{o}\, e^{\alpha\frac{z\mathbf{F}}{RT}E_i^{eq}} = e^{(1-\alpha)\frac{z\mathbf{F}}{RT}E_m} \sum_{i=1}^{x} i_i^{o}\, e^{-(1-\alpha)\frac{z\mathbf{F}}{RT}E_i^{eq}} \qquad [20]$$

These two conditions are not very harsh since in most electrode processes z is one and α is one-half. Condition [19] also requires that all the n_i values are equal to z since in this treatment n_i is assumed to be equal to z_i in Eq. [11].

Thus, the mixed potential for x simultaneous processes occurring at the same electrode under conditions [18] and [19] is given by

$$E_m = \frac{RT}{z\mathbf{F}} \ln \frac{\sum_{i=1}^{x} i_i^{o}\, e^{\alpha\frac{z\mathbf{F}}{RT}E_i^{eq}}}{\sum_{i=1}^{x} i_i^{o}\, e^{-(1-\alpha)\frac{z\mathbf{F}}{RT}E_i^{eq}}} \qquad [21]$$

Schneider and Schlegelmilch (21) and Kortüm (22) have derived the following equation for a mixed potential involving two electrode processes occurring at the same electrode with $\alpha = \frac{1}{2}$.

$$E_m = \frac{RT}{z\mathbf{F}} \ln \left\{ \frac{i_1^{o}\, e^{\frac{z\mathbf{F}}{2RT}E_1^{eq}} + i_2^{o}\, e^{\frac{z\mathbf{F}}{2RT}E_2^{eq}}}{i_1^{o}\, e^{-\frac{z\mathbf{F}}{2RT}E_1^{eq}} + i_2^{o}\, e^{-\frac{z\mathbf{F}}{2RT}E_2^{eq}}} \right\} \qquad [22]$$

Obviously Eq. [22] can be obtained from Eq. [21] by setting $x = 2$ and $\alpha = \frac{1}{2}$.

If one electrode process is dominating all the other processes, then the electrode should be reversible to that particular process. From Eq. [21] one can see that if one electrode process is dominant then

$$E_m = E_i^{eq} \qquad [23]$$

where E_i^{eq} is the Nernst potential for the dominant electrode process.

If the complete system of x electrode processes is at equilibrium, then the mixed potential will be given by any of the x Nernst potentials.

Since the Nernst equation is only applicable when both the net current is zero and either one electrode process is kinetically dominating all other possible electrode processes or the system is at equilibrium, Eq. [21] is a more general equation than the Nernst equation. However, it must be remembered that in Eq. [21] both the i_i^{o} value and, of course, the E_i^{eq} value are also dependent on the activities of the electrode process components. Since mixed potential generation implies that a net chemical reaction is proceeding, the values for i_i^{o} and E_i^{eq} will be constantly changing until equilibrium is attained. (If a passive film forms on the electrode then the rate of the coupled electrode processes may become so slow that i_i^{o} and E_i^{eq} will not change noticeably over long periods of time.)

Equation [21] can be written in a more elegant form employing standard exchange current densities and standard electrode potentials by noting that for each electrode process [11] there corresponds the following relationships (refer to Eq. [7])

$$i_1^{o} = i_1^{oo}\, a_{ox1}^{1-\alpha}\, a_{r1}^{\alpha}$$

$$\vdots$$

$$i_i^{o} = i_i^{oo}\, a_{oxi}^{1-\alpha}\, a_{ri}^{\alpha}$$

$$\vdots$$

$$i_x^{o} = i_x^{oo}\, a_{oxx}^{1-\alpha}\, a_{rx}^{\alpha} \qquad [24]$$

Substituting Eq. [13] and [24] into Eq. [21] yields

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{i=1}^{x} i_i^{\circ\circ} a_{oxi} e^{\alpha \frac{zF}{RT} E_i^{\circ}}}{\sum_{i=1}^{x} i_i^{\circ\circ} a_{ri} e^{-(1-\alpha)\frac{zF}{RT} E_i^{\circ}}} \quad [25]$$

Now, if one electrode process is kinetically dominating all the other possible processes, Eq. [25] will give

$$E_m = E_i^{\circ} + \frac{RT}{zF} \ln \frac{a_{oxi}}{a_{ri}} \qquad (z = n) \quad [26]$$

which is the Nernst equation for the dominant electrode process.

Equation [25] is preferred over Eq. [21] since each exponential term in Eq. [25] has to be evaluated only once and Eq. [25] is written in a form which emphasizes the fact that the activity of each species is constantly changing until equilibrium is attained. Equations [21] and [25] also serve to answer questions such as the type raised by Lingane (23) concerning the role of the Pt^{++}/Pt electrode reaction in setting up a hydrogen electrode on platinum. These equations demonstrate that all processes which can occur at an electrode can be taken into consideration when evaluating the rest potential of the electrode. If one process kinetically dominates all the other processes, either because of its high relative $i^{\circ\circ}$ value or because of its high relative activity values, then the rest potential will correspond to the Nernst potential of that process and the electrode can be said to be reversible to that process. If two or more electrode processes are competitively occurring simultaneously at the electrode, then the rest potential will correspond to the mixed potential as determined by either Eq. [21] or Eq. [25].

The overvoltage equations [14] are written for pure charge-transfer rate control. When diffusion processes are significant, Eq. [21] and [25] can be rewritten as (refer to Eq. [4])

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{i=1}^{x} \left(1 - \frac{i_i}{i_{ci}^{d}}\right) i_i^{\circ} e^{\alpha \frac{zF}{RT} E_i^{eq}}}{\sum_{i=1}^{x} \left(1 - \frac{i_i}{i_{ai}^{d}}\right) i_i^{\circ} e^{-(1-\alpha)\frac{zF}{RT} E_i^{eq}}} \quad [27]$$

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{i=1}^{x} \left(1 - \frac{i_i}{i_{ci}^{d}}\right) i_i^{\circ\circ} a_{oxi} e^{\alpha \frac{zF}{RT} E_i^{\circ}}}{\sum_{i=1}^{x} \left(1 - \frac{i_i}{i_{ai}^{d}}\right) i_i^{\circ\circ} a_{ri} e^{-(1-\alpha)\frac{zF}{RT} E_i^{\circ}}} \quad [28]$$

where i_i is the net current for the i^{th} process and i_i^{d} is the limiting cathodic or anodic diffusion current for the i^{th} process. The value for i_i can be calculated as long as a_{oxi} and a_{ri} can be either measured or calculated since the partial current for the i^{th} process is related to the rate of change of the species activities for that process. Of course, these two equations become less reliable as the diffusion processes become stronger.

For more complex electrode reactions, where $z \neq n_i$ and under conditions [18] and [19]

$$\begin{aligned} &p_1 Ox_1 + n_1 e = q_1 R_1 \\ &\cdot \\ &\cdot \\ &p_i Ox_i + n_i e = q_i R_i \qquad (z \neq n_i) \\ &\cdot \\ &\cdot \\ &p_x Ox_x + n_x e = q_x R_x \end{aligned} \quad [29]$$

the exchange current densities for each process can be related by Eq. [9] such that for the i^{th} process

$$i_i^{\circ} = i_i^{\circ\circ} a_{oxj}^{(1-\alpha)\frac{z}{n_i} p_i} a_{rj}^{\alpha \frac{z}{n_i} q_i} \quad [30]$$

Substituting Eq. [30] and the Nernst equation for the i^{th} process (refer to Eq. [13] noting that $n_i \neq z$) into Eq. [21] results in

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{i=1}^{x} i_i^{\circ\circ} a_{oxi}^{\frac{z}{n_i} p_i} e^{\alpha \frac{zF}{RT} E_i^{\circ}}}{\sum_{i=1}^{x} i_i^{\circ\circ} a_{ri}^{\frac{z}{n_i} q_i} e^{-(1-\alpha)\frac{zF}{RT} E_i^{\circ}}} \quad [31]$$

An equation involving both Eq. [21] and Eq. [25] would be very useful when one or more of the x *simultaneous electrode processes occurs* by an unknown mechanism, specifically by an unknown charge-transfer step. In this case, each term in Eq. [25] which involves an unknown mechanism may be replaced by the corresponding term from Eq. [21]. However, reliable data must be available for the exchange current density of the substituted process and, of course, this process must be independent of the other electrode processes. This method would be very useful in systems where complex electrode reactions (*i.e.*, the hydrogen or oxygen electrode reaction) have to be considered.

Approximations of the Mixed Potential Equations

Approximations similar to those made in current-overvoltage studies (1, 12) involving one process may also be made in mixed potential studies involving x simultaneous electrode processes at zero net current.

If the following is true for all the simultaneous processes

$$|E_m - E_i^{eq}| < 0.02 \text{ volt} \qquad \text{(case 1)} \quad [32]$$

and if conditions [18] and [19] are obeyed, provided α is approximately one-half (1), then Eq. [16] may be replaced by

$$E_m = \frac{\sum_{i=1}^{x} i_i^{\circ} E_i^{eq}}{\sum_{i=1}^{x} i_i^{\circ}} \quad [33]$$

by using the approximation $e^x = 1 + x$.

Case 2 corresponds to the familiar Tafel approximation. It is important to note that the statement

$$|E_m - E_i^{eq}| > 0.05 \text{ volt} \qquad \text{(case 2)} \quad [34]$$

must be true for all of the simultaneous electrode processes which are under consideration. The fundamental drawback in this approximation is that before one can write a general mixed potential equation, one must be able to specify which processes are cathodic and which are anodic. For the over-all cathodic processes, the $(E_m - E_i^{eq})$ terms are negative and from Eq. [14] one can write that

$$i_j = i_j^{\circ} e^{-\alpha \frac{zF}{RT} (E_m - E_j^{eq})} \qquad \text{(cathodic)} \quad [35]$$

For the over-all anodic processes, the $(E_m - E_i^{eq})$ terms are positive and from Eq. [14] one can write that

$$i_k = -i_k^{\circ} e^{(1-\alpha)\frac{zF}{RT} (E_m - E_k^{eq})} \qquad \text{(anodic)} \quad [36]$$

Conditions [18] and [19] are followed and since no net current flows the following can be written

$$\sum_{j}^{r} i_j + \sum_{k}^{s} i_k = 0 = \sum_{i}^{x} i_i \qquad [37]$$

where

$$j \neq k \qquad [38]$$

$$r + s = x \qquad [39]$$

From Eq. [37] one obtains

$$\sum_{j}^{r} i_j^\circ \, e^{-\alpha \frac{zF}{RT}(E_m - E_j^{eq})} = \sum_{k}^{s} i_k^\circ \, e^{(1-\alpha)\frac{zF}{RT}(E_m - E_k^{eq})} \qquad [40]$$

Rearranging Eq. [40] yields

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{j}^{r} i_j^\circ \, e^{\alpha \frac{zF}{RT} E_j^{eq}}}{\sum_{k}^{s} i_k^\circ \, e^{-(1-\alpha)\frac{zF}{RT} E_k^{eq}}} \qquad [41]$$

Equation [41] can be rewritten as

$$E_m = \frac{RT}{zF} \ln \frac{\sum_{j}^{r} i_j^{\circ\circ} \, a_{oxj} \, e^{\alpha \frac{zF}{RT} E_j^{\circ}}}{\sum_{k}^{s} i_k^{\circ\circ} \, a_{rk} \, e^{-(1-\alpha)\frac{zF}{RT} E_k^{\circ}}} \qquad [42]$$

If only two simultaneous processes need to be considered under condition [34] and obviously one is over-all cathodic and the other is over-all anodic, the following equation may be written without conditions [18] and [19]

$$E_m = \frac{\alpha_c z_c E_c^{eq} + (1-\alpha_a) z_a E_a^{eq} + \frac{RT}{F} \ln \frac{i_c^\circ}{i_a^\circ}}{\alpha_c z_c + (1-\alpha_a) z_a} \qquad [43]$$

This equation has been given previously by Schneider and Schlegelmilch (21).

Introducing condition [19] into Eq. [43] yields

$$E_m = \frac{\alpha_c E_c^{eq} + (1-\alpha_a) E_a^{eq} + \frac{RT}{zF} \ln \frac{i_c^\circ}{i_a^\circ}}{\alpha_c + (1-\alpha_a)} \qquad [44]$$

Now, introducing condition [18] into Eq. [44] gives

$$E_m = \alpha(E_c^{eq} - E_a^{eq}) + E_a^{eq} + \frac{RT}{zF} \ln \frac{i_c^\circ}{i_a^\circ} \qquad [45]$$

and if α is equal to one-half, Eq. [45] may be written as

$$E_m = \tfrac{1}{2}(E_c^{eq} + E_a^{eq}) + \frac{RT}{zF} \ln \frac{i_c^\circ}{i_a^\circ} \qquad [46]$$

Acknowledgments

The author is indebted to Professor P. Delahay for his instructive comments and to Dr. Andrew Stefani for his interest in publishing this work. This paper is based on part of a dissertation submitted by one of the authors (D.G.) in partial fulfillment of the requirements for a Ph.D. degree.

Manuscript received Dec. 13, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

ABSTRACT

Experimental studies were made of the effect of self-complexation on the cathodic deposition of zinc onto an inert substrate in 0.1-3.0M $ZnCl_2$ solutions with and without a supporting electrolyte. The effect of the self-complexation reactions was accounted for by the use of the apparent transference number of the zinc ion in Sand's equation and a diffusion coefficient of 1.7×10^{-5} cm^2/sec at 25°C. The equations of Morris and Lingane provided a good estimate of the influence of the supporting electrolyte.

The deposition of a metal from a solution of one of its salts in the absence of a supporting electrolyte is accompanied by the depletion of ionic species at the electrode, and the attendant IR drop may be sufficiently large to obscure the potential jumps associated with the onset of other electrode reactions. Chronopotentiometric equations are available (1) for simple reaction systems in fully supporting, partly supporting, and nonsupporting electrolytes, but no treatment has been presented for the partially self-supporting system which results when self-complexation occurs.

Solutions of zinc chloride contain anionic zinc species (2) whose concentration increases when the zinc chloride concentration increases. This is indicated by the transference number of the zinc ion that changes from positive values in dilute zinc chloride solutions to negative values in solutions more concentrated than about two molar (3). The disproportionation of the zinc complexes would be expected to occur sufficiently fast to eliminate any kinetic terms in the chronopotentiometric equations. However, the complexes might be expected to act as a supporting electrolyte, and they might reduce the effective zinc ion concentration at the cathode due to the migration of anionic zinc species.

The purpose of the study was to investigate the self-supporting phenomenon in zinc chloride solutions and to obtain a quantitative description of the self-supporting effect.

Experimental Techniques

Zinc chloride solutions were prepared from analytical grade reagents, and the concentration of the stock solutions was determined with calibrated hydrometers. It is known that zinc chloride solutions undergo hydrolysis with the formation of precipitates (4). When they occurred, they were dissolved by the addition of sufficient $HClO_4$ just to clear the solutions. The supporting effect of the $HClO_4$ is considered in the section on Experimental Results.

A schematic diagram of the cell is shown in Fig. 1. Particular care was exercised in the design of the cell to achieve a uniform current distribution on the cathode. The latter consisted of a circular platinum disk with a diameter of 0.81 cm. It was mounted horizontally at the bottom of a cylindrical cavity with an inner diameter equal to the diameter of the cathode. The cavity was 1.3 cm deep. The zinc counter electrode was located about 3 cm away from the cathode, and it had a diameter of 4 cm. Visual inspection of the zinc deposits on the cathode indicated that a uniform current distribution prevailed under all the conditions of the reported experiments. A reference electrode of zinc was mounted flush with the cavity wall, Fig. 1, and it was located about 0.1 cm away from the cathode.

Conventional circuitry was used for the chronopotentiometric measurements with pulses derived from a 240v stack of lead-acid batteries. An Ebert Electronics, model HD-4, mercury switch gave fast and clean switching at all the currents used. The maximum change in the current during any one pulse was 2.3%, attributable to the changing resistance of the cell during the pulse. The currents were measured with an accuracy of 0.5% with a Greibach model 700 ammeter. A battery derived bias voltage was used in series with the zinc reference electrode to position the pulse suitably on the Tektronix Model 555 CRO screen. The voltage difference between the working electrode and the biased reference electrode was fed to the oscilloscope through a Tektronix Type O preamplifier. IR drops of about 6v and less were encountered, depending on the current densities and solutions used. The traces were recorded photographically, and the time scale of the CRO was calibrated with a Servomex wave form generator, model LF141.

The solutions were deaerated with nitrogen, and a nitrogen blanket was maintained over the solutions. The platinum electrode was restored after every pulse by the anodic dissolution of the zinc to the point of incipient oxygen/chlorine evolution, after which the solution was purged with nitrogen. The restored electrodes were smooth and shiny and they were considered satisfactory for continued use. Anodic currents above about 200 ma/cm^2 resulted in discernible interferences in the subsequent cathodic traces, and, accordingly, this current density was not exceeded during the zinc dissolutions.

The transition times were taken at the point of inflection of the voltage-time curves, and the experiments were restricted to transition times of 5 sec and less to avoid convective disturbances. Because of the

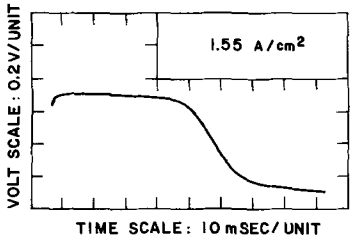

Fig. 2. Chronopotentiogram of 0.6M $ZnCl_2$ in 2.0M $LiClO_4$ at pH 4.9.

high zinc chloride concentrations this necessitated the use of current densities as high as 4.64 amp/cm². The high current densities led to a significant heating of the electrolyte, particularly at the cathode in the absence of a supporting electrolyte, and although the cell was maintained at 25° ± 0.1°C, it is known that higher temperatures occurred during the zinc depositions.

Experimental Results

In the presence of the supporting electrolyte a well-defined voltage step was noted for the transition from zinc deposition to hydrogen evolution on platinum, Fig. 2. In the absence of the supporting electrolyte, however, the depletion of ionic species at the electrode caused a large potential drop that obscured the transition point progressively at the higher current densities for the concentrated $ZnCl_2$ solutions, Fig. 3. An unequivocal transition point could not be defined above 3.0M $ZnCl_2$. A distinguishing feature of the pretransition potential drop that may be seen in Fig. 3 was the change of its time derivative from negative to positive values with an increase in the current density. Although the shape of the transition regions varied noticeably between the runs they did not influence the observed transition times.

The first phase of the experimental work was concerned with the question of the rate-controlling step in the deposition of zinc from the zinc chloride solutions. The known occurrence of anionic zinc species in concentrated zinc chloride solutions (2) suggested the possibility that even if Zn^{+2} could be reduced without kinetic complications at the currents used, the reduction of the chloride complexes might proceed via their dissociation to Zn^{+2}, and the rate of the dissociation reaction might be rate controlling. Delahay (5) showed that a slow reaction step preceding the chronopotentiometric reduction of metal ion complexes should cause $(it^{1/2}/C)$ to decrease with an increase in the current density. No such current dependency was observed in any of the solutions whether a supporting electrolyte was used or not. For example, an $(it^{1/2}/C)$ value of 813 amp $sec^{1/2}$ cm/mole was found for a 2.0M $ZnCl_2$ solution at pH 5.2 with a standard deviation of 3.7% at current densities between 1.17 and 4.64 amp/cm². Since the concentration of the complexes would be expected to depend on the pH of the zinc chloride solutions, the possibility existed that kinetic effects might occur over a limited pH range. $(it^{1/2}/C)$ was found to be independent of the current density in the pH range of interest, pH 3.0 to pH 5.5. Furthermore, $(it^{1/2}/C)$ was independent of the pH in the same pH range. Thus, at pH 4.9 a 0.4M $ZnCl_2$ solution had an $(it^{1/2}/C)$ value of 1006 amp $sec^{1/2}$ cm/mole with a standard deviation of 3.7% over the current density range of 0.19 to 1.94 amp/cm². A 1.0M $ZnCl_2$ solution had an $(it^{1/2}/C)$ value of 1000 amp $sec^{1/2}$ cm/mole with a standard deviation of 8.9% over the pH range of pH 3.0 and pH 5.5.

The absence of a current density effect on the transition time parameter confirmed the absence of convective effects as well. If convection had been present $(it^{1/2}/C)$ should have increased with a decrease in the current density at low current densities. Since convective effects would change $(it^{1/2}/C)$ in the same sense as would kinetic effects, a mutual cancellation of the two effects was precluded. Convective effects were observed for transition times in excess of about 5 sec, but no data are reported for such long transition times.

The preliminary observations indicated that the chronopotentiometric measurements could be made without any kinetic complications, and any effects noted for the influence of the solution parameters on $(it^{1/2}/C)$ should be attributable, therefore, to their influence on the mass transfer process itself.

The transference number of the zinc ion changes from 0.33 in a 0.5M $ZnCl_2$ solution to −0.02 in 2.0M $ZnCl_2$ (3). This indicates that the anionic complexes of the zinc ion become increasingly significant for $ZnCl_2$ concentrations above 0.5M, and if any self-supporting effects were to be present, they would be expected in the more concentrated solutions.

The nature of the $(it^{1/2}/C)$ changes to be expected was ascertained by observing the effect of $LiClO_4$ on the transition time parameter. In a 2.0M solution $(it^{1/2}/C)$ remained constant at 610 amp $sec^{1/2}$ cm/mole with a standard deviation of 8.3% for $ZnCl_2$ concentrations between 0.1 and 3.0M. A decrease in the concentration of the supporting electrolyte from 2.0 to 0.0M $LiClO_4$ led to an increase of $(it^{1/2}/C)$ from 580 to 1070 amp $sec^{1/2}$ cm/mole in a 1.0M $ZnCl_2$ solution, Fig. 4, with a standard deviation of 64.1 amp $sec^{1/2}$ cm/mole about the hand-fitted curve shown in the figure. Therefore, if a self-supporting effect were present, it would cause a decrease of $(it^{1/2}/C)$ with an increase in the $ZnCl_2$ concentration for concentrations greater than about 0.5M $ZnCl_2$ in the absence of $LiClO_4$.

The effect of the $ZnCl_2$ concentration on $(it^{1/2}/C)$ is shown in Fig. 5 for a solution containing no $LiClO_4$ at a constant pH of 4.9. A curve representing the mean value of $(it^{1/2}/C)$ was drawn by trial and error and it gave values of 1120 amp $sec^{1/2}$ cm/mole for the very

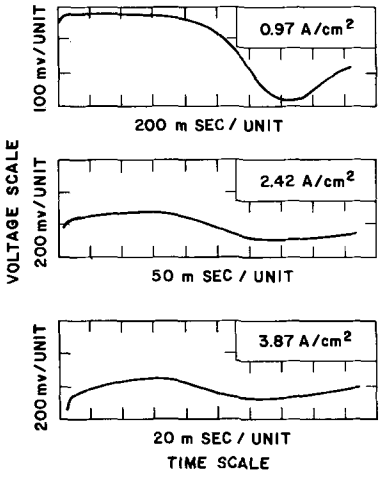

Fig. 3. Chronopotentiograms of 1.0M $ZnCl_2$ at pH 4.9 and various current densities.

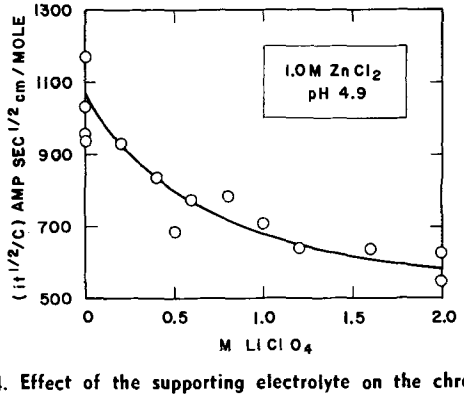

Fig. 4. Effect of the supporting electrolyte on the chronopotentiometric constant.

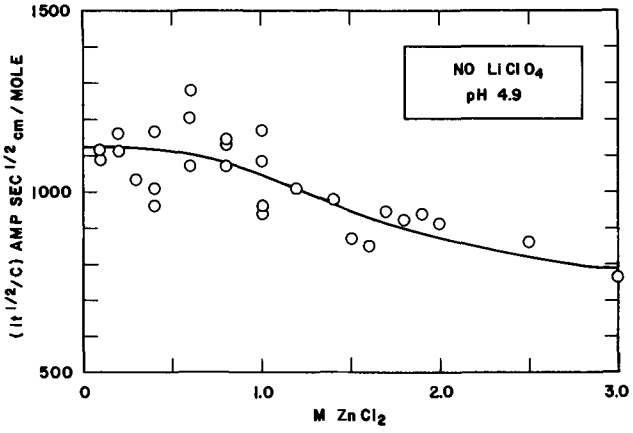

Fig. 5. Self supporting effect in $ZnCl_2$ solutions at pH 4.9

dilute $ZnCl_2$ solutions and 790 amp $sec^{1/2}$ cm/mole for the 3.0M $ZnCl_2$ solution. The standard deviation about the curve shown in Fig. 5 was 80.3 amp $sec^{1/2}$ cm/mole. A considerable scatter was observed for $ZnCl_2$ concentrations of 1.0M and less, and in that region the standard deviation was 93.5 amp $sec^{1/2}$ cm/mole. In the higher concentration range the standard deviation was 48.2 amp $sec^{1/2}$ cm/mole. Within the limitations of these standard deviations the $(it^{1/2}/C)$ values appeared to remain nearly constant for $ZnCl_2$ concentrations below 0.5M, and at higher concentrations it decreased with an increase in the $ZnCl_2$ concentration. Thus, the effect of the complexation reactions was qualitatively equivalent to the use of a supporting electrolyte.

Since $HClO_4$ had been added to maintain a constant pH of 4.9 consideration had to be given to the effect of the $HClO_4$ as a supporting electrolyte. The greatest amount of $HClO_4$ added was 0.73 cm^3 1.0M $HClO_4$ to 200 cm^3 of a 0.1M $ZnCl_2$ solution. It was found (see the following section) that the equations of Morris and Lingane (1) gave a good estimate of the effect of the supporting electrolyte, and, using their equations, it was calculated that the change in $(it^{1/2}/C)$ attributable to the $HClO_4$ would be 4.6% or less.

A series of $ZnCl_2$ solutions were prepared with a minimal amount of $HClO_4$, just sufficient to prevent the precipitation of insoluble hydrolysis products of $ZnCl_2$ and the $(it^{1/2}/C)$ values shown in Fig. 6 were obtained. The same general effect of the $ZnCl_2$ concentration was observed as for the pH 4.9 solutions, except that $(it^{1/2}/C)$ decreased continuously from an extrapolated value of 1300 amp $sec^{1/2}$ cm/mole at a vanishing $ZnCl_2$ concentration. In the higher concentration range, the $(it^{1/2}/C)$ values agreed reasonably well. The minimal $HClO_4$ solution data extrapolated to an $(it^{1/2}/C)$ value of 840 amp $sec^{1/2}$ cm/mole for a 3.0M $ZnCl_2$ solution which may be compared with 790 amp $sec^{1/2}$ cm/mole for the pH 4.9 solution. The data had a standard deviation of 50.8 amp $sec^{1/2}$ cm/mole about the hand-fitted curve shown in Fig. 6.

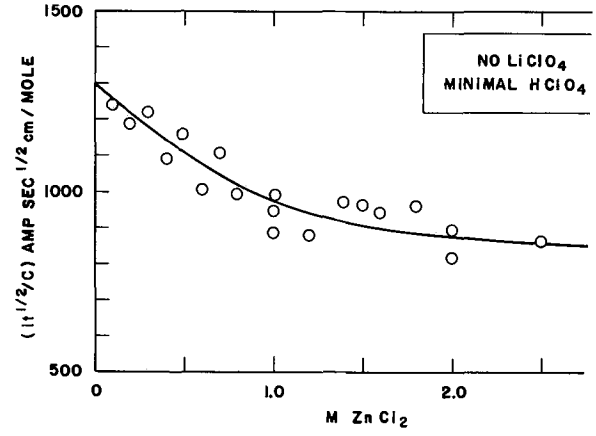

Fig. 6. Self supporting effect in the minimal $HClO_4$ solutions

Several measurements were made with a mercury electrode in the same cell to check for possible surface kinetic and surface roughness effects (the surface area would change during zinc deposition on platinum but not on mercury). An $(it^{1/2}/C)$ value of 593 amp $sec^{1/2}$ cm/mole with a standard deviation of 64 amp $sec^{1/2}$ cm/mole was found for $ZnCl_2$ concentrations below 1.0M $ZnCl_2$ in 2.0M $LiClO_4$ in good agreement with the results for the platinum electrode under the same conditions, *viz.*, 610 amp $sec^{1/2}$ cm/mole. In the absence of a supporting electrolyte the mercury surface changed its shape and size to such an extent on the application of the pulse that well-defined transition times were not obtained.

Discussion

The experimental results established that the deposition of zinc from the zinc chloride solutions was mass transfer controlled, and the chronopotentiometric behavior of the system could be discussed, therefore, in terms of its diffusional and chemical equilibrium characteristics.

Two circumstances impeded an adequate analysis of the diffusion process. The diffusion coefficient used in the chronopotentiometric equations represented an average value obtained by an unknown averaging process, and it was a composite coefficient in the sense that several species contributed to the process which were present in concentration ratios which changed in the gradient region. Furthermore, the diffusion layer became depleted in ionic species and an appreciable ohmic heating of the electrolyte occurred during the diffusion process. Because of these factors the diffusion coefficients calculated from the experimental data are of an heuristic nature.

Case I. Self supporting $ZnCl_2$ *solutions.*—The principal objective of the study was the investigation of the self-supporting effect attributable to the complexation equilibria in the zinc chloride solutions in the absence of an added supporting electrolyte and the search for a quantitative description of the effect. We consider first the experimental $(it^{1/2}/C)$ values extrapolated to a vanishing zinc chloride concentration where ideal solution behavior would be expected and the pertinent Sand equation should apply:

$$(it^{1/2}/C) = \mathbf{F}(\pi D_s)^{1/2}\,(1 - T_+)^{-1}$$

$\mathbf{F}$ = Faraday's constant
T_+ = Transference number of zinc ion
D_s = Diffusion coefficient of zinc chloride

Using the extrapolated, experimental $(it^{1/2}/C)$ values and the reported transference number of the zinc cation of 0.39 (3), the following diffusion coefficients were calculated:

$ZnCl_2$ solution	$(it^{1/2}/C)$ amp $sec^{1/2}$ cm/mole	D_s cm^2/sec
Constant pH 4.9	1120	1.56×10^{-5}
Minimal $HClO_4$	1300	2.15×10^{-5}

These values may be compared with a diffusion coefficient of 1.25×10^{-5} cm^2/sec calculated from the equivalent conductivity of the zinc and chloride ions tabulated by Conway (6). The values agreed well, considering the complexity of the zinc chloride solutions.

The next question concerned the self-supporting effect. The experiments with $LiClO_4$ as a supporting electrolyte had shown that it caused a decrease in $(it^{1/2}/C)$. An analogous effect was observed in the absence of $LiClO_4$ by increasing the zinc chloride concentration in the range where complexation occurred. The transference number of the zinc ion provided a measure of the extent of the complexation reactions, and it was thought that the use of the concentration

dependent transference number in Sand's equation might describe the behavior of the system. In particular, since the diffusion process occurred across an appreciable concentration gradient, the mean transference numbers were used to calculate the diffusion coefficients below from the experimental $(it^{1/2}/C)$ values:

$ZnCl_2$ moles/liter	T_+ mean	pH 4.9 solution $(it^{1/2}/C)$ amp $sec^{1/2}$ cm/mole	pH 4.9 solution D_s cm^2/sec	Minimal $HClO_4$ solution $(it^{1/2}/C)$ amp $sec^{1/2}$ cm/mole	Minimal $HClO_4$ solution D_s cm^2/sec
0.0	0.39	1120	1.56×10^{-6}	1300	2.15×10^{-5}
0.5	0.37	1110	1.65×10^{-6}	1110	1.65×10^{-5}
1.0	0.31	1050	1.80×10^{-5}	970	1.31×10^{-5}
1.5	0.24	950	1.78×10^{-6}	910	1.60×10^{-6}
2.0	0.19	870	1.69×10^{-5}	875	1.70×10^{-5}

The mean value of the diffusion coefficient for each of the two solutions was 1.7×10^{-5} cm^2/sec. In the pH 4.9 solution it remained approximately constant over the entire concentration range whereas it decreased first and then increased as the concentration increased in the minimal $HClO_4$ solution.

The behavior of the experimental D_s values may be contrasted with the expectations for the diffusion coefficient of zinc chloride. The viscosity of zinc chloride solutions increases uniformly by about 30% (7) over the same concentration range, and the activity corrections to the diffusion coefficient calculated from the data in the literature (8) would predict a decrease of D_s between 0 and 1 mole/liter and an increase between 1 and 2 mole/liter. Combining the viscosity and activity corrections, the diffusion coefficient would be expected to decrease about 40% between 0 and 1 mole/liter and increase about 10% between 1 and 2 mole/liter. Qualitatively, this agreed with the behavior observed in the minimal $HClO_4$ solution, but the pH 4.9 solution gave a contrary behavior. The standard deviations of the $(it^{1/2}/C)$ data would give D_s deviations of about 10 and 16% for the minimal $HClO_4$ and the pH 4.9 solutions, respectively, which suggested that the observed D_s patterns might reflect reproducible characteristics of the two solutions. However, in view of the complexity of the diffusion process, we do not attach any fundamental significance to the observed behavior as yet beyond observing that the assumption of a constant diffusion coefficient of 1.7×10^{-5} cm^2/sec provided a reasonably good description of the self supporting effect when the concentration dependent transference number of the zinc ion was used in Sand's equation.

Case II. $ZnCl_2$ *in a supporting electrolyte.*—It was established that the self supporting electrolyte effect in the zinc chloride solutions was analogous to the effect of an added supporting electrolyte, but although the effect could be described formally by the use of the apparent transference number of the zinc ion, it left open the question of how to describe explicitly the effect of a supporting electrolyte. The data obtained in the 2.0M $LiClO_4$ solutions at various $ZnCl_2$ concentrations and in the 1.0M $ZnCl_2$ solutions at various $LiClO_4$ concentrations were used to examine this question.

The 2.0M $LiClO_4$ solutions of zinc chloride may be considered to have been fully supporting at the lower zinc chloride concentrations and the use of Sand's equation for the case of a supporting electrolyte would be justified. The experimental $(it^{1/2}/C)$ value of 610 amp $sec^{1/2}$ cm/mole gave a zinc ion diffusion coefficient of 1.27×10^{-5} cm^2/sec which may be compared with the value of 0.71×10^{-5} cm^2/sec calculated from the equivalent conductivity of the zinc ion at infinite dilution. The agreement appears to be reasonable, but a detailed comparison of the two values will not be pursued. Instead, we focus attention on the changes caused by the supporting electrolyte.

The most complete description available of the effect of a supporting electrolyte is that given by Morris and Lingane (1). The values of $(it^{1/2}/C)$ calculated from their equations [29], [30], and [31] are given below where the equivalent conductivities tabulated by Conway (6) were used.

Molar ratio* $LiClO_4/ZnCl_2$	$(it^{1/2}/C)_{calc}$ amp $sec^{1/2}$ cm/mole	$\left[(it^{1/2}/C)\left(\frac{n_c}{n_0}\right)^{1/2}\right]_{exp}$ amp $sec^{1/2}$ cm/mole	Ratio
0.5	888	950	1.07
1.0	791	817	1.03
1.5	732	748	1.02
2.0	692	729	1.05

* 1.0M $ZnCl_2$.
n_c = viscosity of $LiClO_4$-$ZnCl_2$ solution; n_0 = viscosity of water at the same temperature.

No corrections were introduced for the concentration dependence of the transference number of the zinc ion since the same zinc chloride concentration was used in all the solutions. Since the equations of Morris and Lingane contained no viscosity terms we used experimental viscosity values to adjust the observed $(it^{1/2}/C)$ values to a common basis with the calculated $(it^{1/2}/C)$ values, it being assumed that the product of the diffusion coefficient and the viscosity of a solution would remain constant. A common anion was assumed by Morris and Lingane in the derivation of their equations, and we modified the terms pertaining to the common anion by the use of the mean diffusion coefficient of the chloride and perchlorate ions weighted by their respective formal concentrations. No activity corrections were available, and, therefore, a comparison of the numerical values of $(it^{1/2}/C)$ was not attempted. However, their relative change may be compared as a function of the concentration of the supporting electrolyte.

It may be seen that the equations of Morris and Lingane provided a very good estimate of the effect of the supporting electrolyte on the transition time for the zinc deposition process. The changes in $(it^{1/2}/C)$ were predicted within approximately 5%. Since a meaningful basis existed for the comparison of the changes in $(it^{1/2}/C)$ it was considered that the good agreement resided in the adequacy of the description rather than in fortuity. However, data on other electrolyte systems would be needed to confirm the general applicability of the equations of Morris and Lingane to concentrated solutions of a reducible ion in the presence of a supporting electrolyte.

Conclusions

The complexation reactions in concentrated zinc chloride solutions gave rise to a decrease of $(it^{1/2}/C)$ with an increase in the zinc chloride concentration in the absence of a supporting electrolyte. The changes in the chronopotentiometric constant were analogous to the effect of an added supporting electrolyte, and they were considered to be, tentatively, the result of a self supporting effect attributable to the presence of the complexes in the concentrated solutions.

The self supporting effect could be predicted reasonably well from Sand's equation for the chronopotentiometric constant in the absence of a supporting electrolyte, using a diffusion coefficient of 1.7×10^{-5} cm^2/sec, provided the concentration dependent, apparent transference number of the zinc ion was used to account for the complexation reactions.

The changes in the chronopotentiometric constant attributable to the presence of a supporting electrolyte were predicted quantitatively by the equations of Morris and Lingane.

Technical Notes

The Anodic Oxidation of CO on Nickel Sulfide in Base

Raymond Jasinski*

Tyco Laboratories, Inc., Waltham, Massachusetts

A number of papers have appeared in recent years on the anodic oxidation of carbon monoxide in basic solutions, *e.g.*, (1-4). Electrochemical oxidation of CO is catalyzed by a variety of metals. However, the rest potentials reported have been significantly more positive than the calculated, thermodynamic value, —0.39v (*vs.* a reversible hydrogen electrode in the same solution), for the reaction

$$CO + 4\,OH^- \rightarrow CO_3^= + 2H_2O + 2e^- \qquad [1]$$

For example, the rest potential for CO on platinum at 23°C has been quoted (2) at +50 mv *vs.* RHE in 1*N* KOH and + 83 mv in 6*N* KOH. In acid the thermodynamic value is —0.105v *vs.* a reversible H_2/H^+ electrode in the same solution.

Recently (2), it has been suggested that the discharge mechanism for CO on platinum, as well as on Raney nickel, takes place according to the following scheme

$$CO + 2\,OH^- \rightarrow CO_3^= + 2H_{ads} \qquad [2]$$

$$2H_{ads} + 2\,OH^- \rightarrow 2H_2O + 2e^- \qquad [3]$$

In effect, the carbon monoxide electrode behaves as a hydrogen electrode operating at low partial pressures of H_2. Alternatively, it has been suggested (4) that CO is first chemically converted to formate ion on Raney nickel, maintaining the same oxidation state, and then to carbonate ion by electrochemical oxidation.

This paper describes the anodic discharge of CO in 6*N* KOH on the compound Ni_3S_2. The equilibrium potentials at 25° and 75°C are negative with respect to the H_2/OH^- electrode in the same solution, although still somewhat more positive than the thermodynamic $CO/CO_3^=$ potential.

Experimental

Ni_3S_2 was prepared from $NiSO_4$ as follows (5): hydrated $NiSO_4$ was dried by programmed heating (<25°C/hr) under a stream of N_2. At 300°C, the temperature and flow of N_2 were kept constant for at least 20 hr to insure thorough drying. When drying was complete, $NiSO_4$ was reduced by H_2 for another day. The principal product was Ni_3S_2, as confirmed by x-ray diffraction measurements. Qualitative measurements on a pressed disk of this material indicate that it is an electronic conductor. However, some metallic nickel was present.

After preparation, the powder was mixed with a Teflon emulsion (~30%) and formed into an electrode in the usual manner (6). The catalyst loadings were variable (see below); no attempt was made to optimize electrode structure for these preliminary experiments.

Electrode testing was carried out in 6*N* KOH in the "floating electrode assembly" (7). Potential measurements were carried out *vs.* a "Dynamic Hydrogen Electrode" (8), calibrated against a commercial platinum electrode under hydrogen in the same solution and at the temperature of operation. Reference electrode stability in the presence and absence of CO was confirmed by periodic checks with a commercial calomel electrode. All potentials are given *vs.* the reversible hydrogen electrode (RHE) in the same solution.

The test electrode (a 1 cm^2 disk) was held at selected potentials with a Wenking potentiostat. Unless otherwise noted, curent readings were taken after steady state had been reached, generally 10-15 min.

A freshly prepared electrode, when first assembled, exhibits a gradually decaying cathodic current below +400 mv, independent of the gas phase (N_2, CO, H_2). After 1-2 hr this current is negligible (<0.01 ma/cm^2). Presumably this current represents the reduction of surface oxide formed during electrode preparation. All data were obtained after this conditioning procedure.

Results

The electrode was first scanned under an atmosphere of N_2. Anodic corrosion current was not observed below +330 mv at 75°C. Hydrogen bubbles are observed to form on the electrode at negative potentials. Under O_2, the electrode is apparently diffusion limited in the same potential range for the cathodic reduction of this gas. Anodic current could not be generated below +330 mv with hydrogen as the fuel; nor could current be generated from methanol, formic acid, or ammonia. However, significant current was sustained when carbon monoxide was present in the gas phase. The actual value of the current was influenced by the catalyst loading and by minor variations in the electrode preparative procedure.

A steady state voltage-current plot for a Ni_3S_2 electrode (20 mg/cm^2) under CO and under H_2 at 75°C is shown in Fig. 1. Figure 2 shows similar data for another Ni_3S_2 electrode (30 mg/cm^2) operated at 25°C. The maximum performance obtained at 75°C has been with an electrode containing 30 mg/cm^2 of catalyst, *i.e.*, 80 ma/cm^2 at +200 mv RHE.

The question arises, of course, whether this electrochemical activity is due to the catalytic oxidation of CO or represents CO-induced corrosion of the electrode material, possibly according to the following sequence

* Electrochemical Society Active Member.

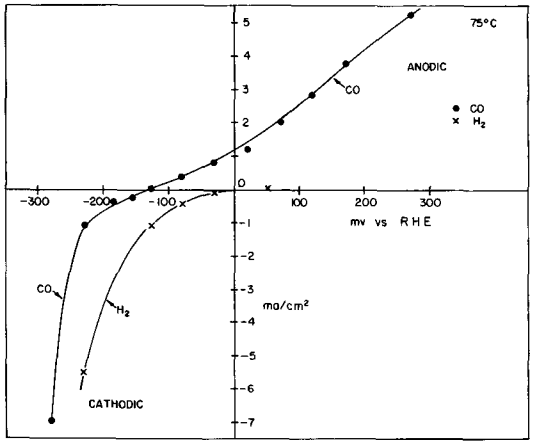

Fig. 1. Steady state voltage current plot for Ni_3S_2 electrode (20 mg/cm^2) under CO and under H_2 at 75°C.

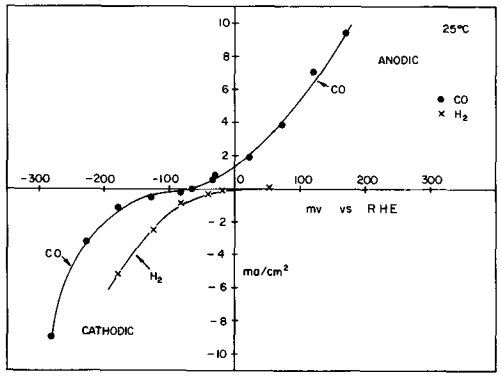

Fig. 2. Steady state voltage current plot for Ni_3S_2 electrode (30 mg/cm^2) under CO and under H_2 at 25°C.

$$Ni_3S_2 + 4CO \rightarrow 3Ni(CO)_4 + 2S^{=} - 4e \quad [4]$$

$$S^{=} + 8\,OH^{-} \rightarrow SO_4^{=} + 4H_2O + 6e^{-} \quad [5]$$

Ignoring Eq. [4], approximately 96 coulombs would result from the oxidation of 30 mg of Ni_3S_2. An experiment was therefore run in which this electrode was held at +100 mv (RHE) and the current followed with time. These data are shown in Fig. 3. There is a gradual improvement in performance (part of the conditioning effect mentioned above) with the current leveling out at ~42 ma/cm^2. The total charge passed was about 430 coulombs, well in excess of that required by Eq. [5]. Furthermore, the electrode was completely intact at the end of the experiment.

Discussion

Ni_3S_2 is stable in 6*N* KOH below +330 mv at 75°C. In this voltage region, Ni_3S_2 will catalyze, at room temperature and at 75°C, the anodic oxidation of carbon monoxide, but not of H_2, NH_3, methanol, or formate ion. This selectivity implies that the mechanism of oxidation does not involve formate ion or gaseous H_2 as intermediates. The reaction product was assumed to be carbonate ion, although this has not yet been confirmed by chemical analysis.

In all experiments with CO as the fuel, equilibrium potentials were more negative than the reversible H_2 electrode in the same solution, as well as the values published for CO on Raney nickel and on platinum (2). At 75°C the equilibrium potential was —180 mv (RHE); at 25°C, —60 mv (RHE).

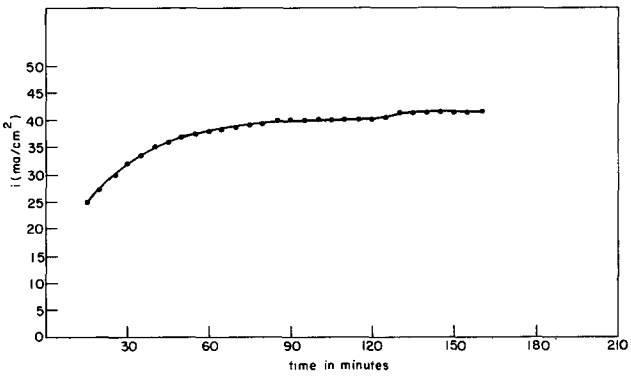

Fig. 3. Current vs. time at +100 mv for CO on Ni_3S_2

Judging from Fig. 1 and 2, the cathodic evolution of H_2 is most likely repressed by the presence of CO; gas bubbles were not observed above —100 mv on the electrode. Because of the negative equilibrium potential and suppression of H_2 evolution, it is unlikely that the anodic oxidation mechanism proceeds through H_{ads} (Eq. [2] and [3]). Detailed mechanistic studies are required to rigorously substantiate this point.

By the use of high catalyst loadings (≧30 mg/cm^2), significant current densities can be obtained, *e.g.*, 80 ma/cm^2 at +200 mv RHE. It is to be expected that optimization of electrode design and the use of higher operating temperatures would further improve performance.

The use of this catalyst in a fuel cell is, of course, obvious. It is suggested, because of the selectivity of Ni_3S_2 to CO in the presence of H_2, that this catalyst could also be used to remove, electrochemically, CO from H_2-CO mixtures. Preliminary experiments indicate that, at a constant potential, the current sustained by this electrode is proportional to the concentration of CO in the gas phase. This also suggests the use of Ni_3S_2 as the basis of a detector for CO in the H_2, N_2, or other "inert" gases.

Preliminary tests were also carried out with an electrolyte one molar in K_2CO_3 and in $KHCO_3$. Performance was poor at 75°C, *e.g.*, 0.1 ma/cm^2 at +180 mv.

^{22}Na and ^{14}C Diffusion in a Mixture of Li/Na/KCO_3

R. L. Frederick and E. L. Williams

Fundamental Research, Owens-Illinois Technical Center, Toledo, Ohio

A eutectic ternary mixture of Li_2CO_3, Na_2CO_3, and K_2CO_3 can be formed which will melt around 400°C. As reported by Janz *et al.* (1-3), the eutectic mixture contains Li_2CO_3, Na_2CO_3, and K_2CO_3 in molar ratios of 43.5:31.5:25.0. A similar ratio of 44:30:26 was reported by Rolin *et al.* (4).

A melting temperature of 400°C is 325° to 490°C lower than the melting temperature of the salts in the pure state. Melting temperatures of 500°-600°C make the alkali carbonate mixtures attractive as an electrolyte in high temperature fuel cells. Transport studies in various alkali carbonate melts have been made by Janz *et al.* (2, 5, 6) and by Spedding and Mills (7, 8), but to our knowledge no diffusion measurements have been made in the alkali carbonates below the melting temperature. In the study reported here, the diffusion of Na^+ and $CO_3^=$ ions was measured in a mixture of lithium, sodium, and potassium carbonates near the eutectic mixture by a sectioning technique employing ^{22}Na and ^{14}C tracers. Also, the electric conductivity of this carbonate mixture was measured.

Procedure

Analytical reagent grade chemicals were used to prepare the carbonate mixture which contained Li_2CO_3, Na_2CO_3, and K_2CO_3 in a molar ratio of 41:37:22, respectively. This mixture melts approximately 150°C higher than the true eutectic mixture. The appropriate quantities of raw chemicals for the mixture were melted first at 700° in an alumina crucible and then individual specimens of 1 cm in diameter and approximately 1 cm in thickness were prepared by melting 3-4g of the carbonate mixture in a small zirconia crucible, again at 700°C. Both meltings, as well as the diffusion anneals, were in a CO_2 atmosphere to prevent decomposition of the carbonate. On one surface of each specimen a thin layer of the radioactive isotope was formed by allowing to dry 8-10 drops of an alcohol solution containing the isotope. The ^{14}C isotope was in the form of Na_2CO_3, while the ^{22}Na isotope was in the form of NaCl. The activity of the layer was normally greater than 10,000 counts/min.

For the diffusion to take place, the sample pellets were heat treated in an electric resistance furnace controlled to ±2.0°C of the desired temperature from 18 to 113 hr, depending on the temperature. After the diffusion anneal, the pellets were sectioned and the activity of each section was determined as previously described (9), with the addition that precautions were taken during the sectioning to minimize the absorption of water from the atmosphere. The activity of the sections containing the ^{22}Na isotope was counted by a Nuclear-Chicago single-channel gamma ray spectrometer (Analyzer/Scaler Model 8725 and Scintillation Detector Model DS202V). The activity of the sections containing the ^{14}C isotope was counted by a Nuclear-Chicago liquid scintillation counter (Unilux Model 6850). For the liquid scintillation counting each section was washed off the abrasive paper of the sectioning machine by distilled water into a scintillation counting vial filled with Cab-O-Sil "O."[1] The purpose (10) of the Cab-O-Sil "O" was to keep any precipitates which may form suspended throughout the mixture. To this mixture was added 18 ml of scintillation fluid, which consists of 1-4 dioxane as the solvent and 70 g/liter naphthalene, 4 g/liter of 2,5-diphenyloxazole, 0.1 g/liter of 1,4-bis[2-(5-phenyloxazole)] as solutes. The total volume of the contents of each vial was 23-25 ml.

[1] Cabot Corporation, Boston, Massachusetts.

The electrical conductivity of the carbonate mixture was measured on one of the pellets placed between a silver electrode and a nickel electrode. At temperatures below 275°C, d-c measurements were made with a Tullamore Electrometer (Model VTE-2). At temperatures between 250°-325°C, the resistance was measured by an a-c method with a General Radio Impedance Bridge (Type 1650-A) at 1000 Hz.

Results

In the study reported here, the radioactive isotope diffuses from a thin film into a solid of essentially "infinite" length. Thus, the distribution of the tracer in the solid can be described by the equation

$$A_i = A_0/\sqrt{\pi Dt}\,\exp X_i^2/4Dt \qquad [1]$$

where A_i is the activity concentration of section i at distance X_i from the surface, t is the time of diffusion, A_0 the activity originally at $X_i = 0$, $t = 0$, and D the diffusion coefficient. Thus, plotting A_i *vs.* X_i^2 results in a straight line in which D can be evaluated from the slope.

The results of the tracer diffusion measurements are listed in Table I as the Na^+ and $CO_3^=$ ion diffusion coefficients. It is assumed that the measure of the ^{22}Na and ^{14}C isotope diffusion is in reality a measure of the sodium and carbonate ion diffusion, respectively: that is, there is little or no isotope effect and the ^{14}C is in the $CO_3^=$ ion form. Plots of the diffusion coefficients for each ion *vs.* reciprocal temperature as shown in Fig. 1 reveal a good fit with a straight line and thus is in accordance with the simple Arrhenius equation

$$D = D_0 \exp(-E_a/RT)\ \text{cm}^2/\text{sec} \qquad [2]$$

where D_0 is the frequency factor, E_a is the activation energy, R is the gas constant, and T is the absolute temperature. The values of D_0 and E_a, including the estimated probable error, were evaluated and for the temperature range of 200°-400°C are

For Na^+

$$D_0 = 2.4 \pm 0.4 \times 10^{-3}\ \text{cm}^2/\text{sec} \qquad E_a = 13.0 \pm 0.3\ \text{kcal/mole}$$

For $CO_3^=$

$$D_0 = 1.1 \pm 0.4 \times 10^{-3}\ \text{cm}^2/\text{sec} \qquad E_a = 13.2 \pm 0.3\ \text{kcal/mole}$$

These values were calculated by a least squares treatment of the data.

The values of D_0 and E_a reported here are very similar in magnitude to those reported by Spedding and Mills (7) for Na^+ and $CO_3^=$ diffusion in Li/Na/

Table I. Tracer diffusion in Li/Na/KCO_3 mixture (41:37:22 mole per cent)

Temperature, °C	Diffusion coefficient (cm²/sec) Na^+	Diffusion coefficient (cm²/sec) $CO_3^=$
160	7.0×10^{-9}	—
200	1.9×10^{-9}	7.8×10^{-10}
225	3.0×10^{-9}	—

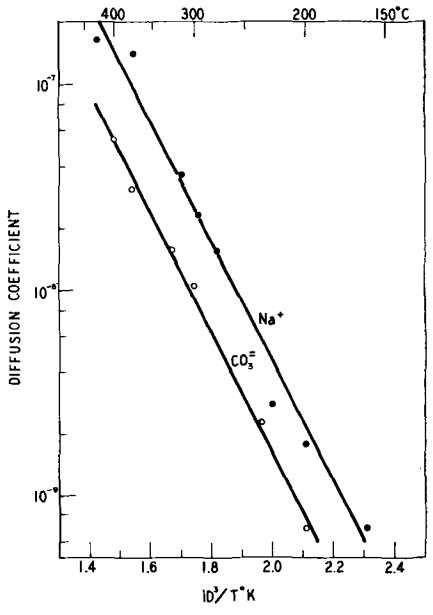

Fig. 1. Diffusion coefficients of both the Na^+ and $CO_3^=$ in the carbonate mixture plotted against reciprocal absolute temperature.

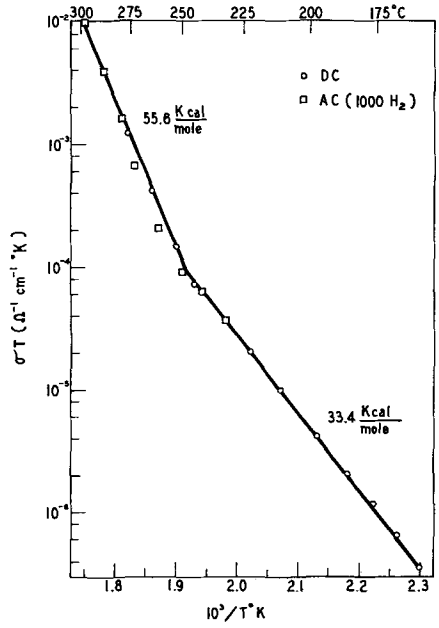

Fig. 2. Electrical conductivity of the carbonate mixture in the temperature range of 150°-300°C plotted as conductivity times temperature vs. reciprocal absolute temperature.

KCO_3 eutectic melt of 43.5:31.5:25.0 mole per cent. Their values for the activation energy are 11.0 and 10.1 kcal/mole for the Na^+ and $CO_3^=$, respectively, and are only slightly lower than those reported here. The largest difference is in the D_0 value for the Na^+. They reported 8.1 x 10^{-3} cm^2/sec for D_0, which is more than three times the value of 2.4 x 10^{-3} cm^2/sec reported here for sodium diffusion in the solid.

The electrical conductivity of the material is shown in Fig. 2. The slope of the best fit straight line to the data corresponds to an activation energy of 33.4 kcal/mole at the lower temperatures and 55.6 kcal/mole at the higher temperatures. The explanation for the change in energies is not known, but it should be noted that both of these energy values are much higher than the activation energies found for the Na^+ and the $CO_3^=$ ions by the tracer measurements.

Acknowledgment

Grateful acknowledgment is made to our colleagues at the Owens-Illinois Technical Center for their helpful comments and discussions.

Brief Communication

Answer to "The Uhlig Defect Model of Oxidation Kinetics" by A. T. Fromhold, Jr.

H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

In the above paper (1), Fromhold criticizes my theory of initial oxidation kinetics first published in 1956 (2) and which was extended to interpret data obtained in my laboratory by MacNairn (2), Pickett and MacNairn (3), and Nwoko (4) on thin-film oxidation behavior of Cu, Ni, and Zn, respectively. Some of the matters discussed by Fromhold repeat his earlier criticisms which were answered in ref. (4) and hence there is no need to repeat the answers here.

By and large, it can be said in summarizing the discussion that Fromhold starts out with different as-

* Electrochemical Society Active Member.

sumptions than mine and reaches different conclusions. The final criterion, of course, of which set of assumptions is better must rest on the accord which is reached with the experimental facts. No theory can hope to survive which is based solely on philosophic speculations and which nowhere along the line makes contact with reality.

Examining some of the details, it should first be made clear that there is usually more than one solution to any differential equation, and the corresponding choice of variables and boundary conditions is arbitrary. The only requirements are that the latter must be self-consistent and that the final solution must have physical significance. I believe that these requirements are adequately met in my solution of the Poisson equation.

Fromhold, using his own particular assumptions, calculates the contribution of the negative space charge layer in zinc oxide to the potential at the metal surface showing that the contribution amounts to only 5.4×10^{-3}v. He concludes that "the space charge for all practical purposes provides an insignificant attenuation of the current." However, using my assumptions instead (2), the analogous calculation for a ZnO film 50Å thick on Zn containing a density n of trapped electrons equal to 0.24×10^{18}/cm^3 is given by $\frac{4\pi ne}{\epsilon}(ly - y^2/2)$ where y is the thickness of oxide, ϵ is the dielectric constant of ZnO (10), e is the charge on the electron (4.8×10^{-10} esu) and l, equal to 1.3×10^{-5} cm, is the theoretically maximum attainable thickness of constant space charge density oxide. The value of l under the above-stated conditions is obtained from the empirical oxidation rate constant k_0 (17/2.3A) equal to $\frac{\epsilon kT}{4\pi ne^2 l}$. The resultant calculated potential is 0.13v which is a substantial contribution satisfactorily accounting for the observed decrease of electron transfer and corresponding slow-down of the oxidation rate after Zn is exposed 140 min to O_2 at 206°C.

The observed change to a higher reaction rate subsequent to the initial reaction rate, giving rise to an observed two-stage logarithmic kinetics, we have ascribed to dissociation of trapped charge at a critical oxide thickness L. Reduced space charge density accounts for a lower retarding potential at the metal surface for electron transfer per unit increase of oxide thickness. The objection is raised that such an abrupt change is "non physical" and out of accord with Boltzmann statistics. But obviously the transition to second-stage kinetics is only abrupt in a relative sense. If more experimental points were obtained in the region of transition, it is expected that the change in growth of oxide would occur over a narrow range of oxide thickness rather than at a single value. Nevertheless, the average value of oxide thickness marking the transition is sufficiently sharp both on examining the experimental data and from the consequences of theory to allow a single oxide thickness to be designated. Further refinements would undoubtedly define a narrow range of oxide thickness instead. This detail has no consequence with regard to the validity of the theory.

In chemical kinetics, when a given reaction results from several concurrent reactions, the standard procedure is to consider that the slowest reaction of the group is the one that limits the over-all reaction. In the thin-film oxidation process, I have considered electron transfer to be the slow process determining the over-all oxidation rate. This does not mean that I have negligently omitted consideration of ion migration, but only that ion migration is a fast process in comparison, and hence it need not be considered in the final rate equation. Carl Wagner, whom Fromhold quotes, showed that for thicker oxide films for which the parabolic equation holds, ion migration is now the slow process and electron transfer and migration in turn can be neglected.

The differentiation between activation energy and free energy is readily resolved. The free energy of oxidation is given by the Gibbs term ΔG for the over-all reaction

$$M + 1/2\, O_2 \rightarrow MO$$

where ΔG is a negative quantity under the usually considered experimental conditions. It involves both ion and electron migration. The activation energy for the above reaction, on the other hand, is given by the term ΔE in the Arrhenius equation where rate = const. $\exp(-\Delta E/RT)$. The value of ΔE can be obtained by plotting the logarithm of the reaction rate constant with the reciprocal absolute temperature T. According to my model of thin film oxidation the expression $d\ ln k_0/d\ 1/T$ becomes equal to $-e(\phi_0 - \chi - v)/k$ where k_0 is the reaction rate constant for first-stage logarithmic kinetics, k is Boltzmann's constant, ϕ_0 is the work function of the metal, χ is the amount by which the oxide alters the work function at the metal-oxide interface, and v is the electron affinity of oxygen adsorbed on the oxide surface. Comparison with the Arrhenius equation makes it quite clear that the energy corresponding to electron transfer from metal to oxide surface as mentioned in my paper is the activation energy and is not the Gibbs free energy term ΔG. The derivation of the expression above was in fact the first which extended to thin film oxidation the empirical relation proposed much earlier by Rideal and Wansbrough-Jones (5) based on observed activation energies for the oxidation of W, Pt, and C.

The discussion of nonconservation of charge is hardly a relevant matter because it is always implied, such as in the similar development of double layer theory in electrolytes, that a simultaneous positive surface charge is formed in the metal as excess negative charge accumulates in the environment. Excess charge, in other words, can and does exist in the oxide as shown by both Volta potential and other type measurements, but the over-all charge including that of the metal must, of course, remain neutral.

The limiting state of affairs at zero oxide thickness is given by negatively charged adsorbed oxygen on the metal surface rather than by a clean metal surface. In other words my described approach to thin film oxidation kinetics includes the limiting case for which volatile oxides are formed (Pt, W, C). Since the negative surface charge now remains constant in time, the linear oxidation equation is obeyed instead of the direct logarithmic, and the expression for the activation energy of oxidation no longer includes the term χ, but is otherwise the same as is given above. This particular assumption in my derivation answers in large part the long discussion by Fromhold on various possible boundary conditions at the oxide-metal interface, as well as detailed matters relating to conservation of charge.

The image charge in the metal is included in my solution of the Poisson equation. The total negative surface charge, on the other hand, made up of oxygen ions adsorbed on the oxide surface is included in my electron affinity term v equal to 3.6 ev. I have assumed that all adsorption sites on the oxide surface are occupied throughout the oxidation process.

As mentioned earlier, the final proof of any oxidation model is its accord with experiment. It may be worthwhile, therefore, to summarize the contributions which are made by the oxidation model which I have proposed.

1. It leads to the derivation of the direct logarithmic equation which represents most thin-film oxidation data for metals in general. It explains why this equation applies only to thin film oxides characterized by a space charge and not to thicker films for which ion migration is controlling. It furthermore explains that thin-film oxidation rates depend on the Curie tempera-

ture, lattice type, and grain orientation because of corresponding changes in work function of the metal.

2. It accounts for observed two-stage logarithmic oxidation behavior of both polycrystalline and single crystal metals and furthermore predicts the thickness at which second-stage logarithmic kinetics begins.

3. It accounts for an observed much lower thin film oxidation rate for zinc compared to Cu and Ni, despite Zn being a chemically more active metal. The difference is ascribed to a calculated higher negative space charge density in ZnO compared to that in Cu_2O or NiO.

4. It provides a theoretical derivation of the Rideal-Jones relation for the activation energy of oxidation dependent on work function of the metal and electron affinity of adsorbed oxygen.

5. It suggests why many metals in the thin film region oxidize in accord with the cubic equation as well as the two-stage logarithmic equation. Only a slight difference in distribution of excess charge in the diffuse space charge layer determines which type equation is followed.

6. It provides for calculating the density of defect sites in metal oxides which for the limited data so far available are in reasonable accord with similar densities calculated independently by others.

Asymmetric Conduction in Thin Film Tantalum/Tantalum Oxide/Metal Structures: Interstitial and Substitutional Impurity Effects and Direct Detection of Flaw Breakdown

Norman N. Axelrod* and Newton Schwartz*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Asymmetric conduction in a thin film tantalum/tantalum oxide/metal structure depends strongly on the method of preparation of the individual elements as well as the conditions under which the structure is measured. Some of the factors which need to be considered are: (*i*) gas and alloy metal content of the sputtered tantalum film; (*ii*) structural perfection of the tantalum film; (*iii*) nature of the metal counter electrode; and (*iv*) ambient factors such as the presence of moisture during measurement. The principal results from these investigations can be explained on the basis of flaws in the anodic oxide. Evidence exists, however, that some degree of asymmetric conduction exists in nominally flaw-free films.

Many mechanisms have been proposed to explain the rectifying characteristics of anodic oxide films (1). This asymmetric conduction is known to be quite variable and has not been satisfactorily explained in terms of simple solid state band theory.

Two general classes of response can be considered: (2):

(*a*) The homogeneous or uniform response of the entire thin film oxide which depends on the band structure and contact barrier energetics (3-8);

(*b*) The heterogeneous or local response at flaws, (*i.e.*, small areas which differ in electrical properties from the remaining oxide) which may be due to a local variation in the stoichiometry, to a fissure, or to other types of mechanical defects in the oxide (9-11).

Previous studies have indicated that it is possible for both responses to exist. Vermilyea has demonstrated that a transition from type (*a*) to type (*b*) occurs with an increase in anodic oxide film thickness (9). The heterogeneous mechanism, therefore, may be the significant one in the range of film thicknesses used normally for device applications such as capacitors and crossovers. Since flaws may arise in different ways, it is of considerable interest to define the parameters which determine their formation, and to extend the study of nominally flaw-free[1] films to thicknesses greater than those used in Vermilyea's study. A study of these parameters might also result in a definition of the range of metallurgical states of the parent tantalum necessary to obtain reproducible measurements for an investigation of the electronic conduction mechanisms.

The sputtered tantalum-anodic oxide-metal (1b) structure has been shown to have variable asymmetric conduction; the fundamental parameters associated with the asymmetry might be understood if the variability could be controlled. This paper presents some of the factors which determine the asymmetry in this structure; it will be shown that nominally flaw-free films which have nearly symmetric conduction characteristics can be formed in the 2000Å thick range.

Since both homogeneous and heterogeneous responses can exist, each investigator ought to determine the predominant response in the particular samples under investigation. A simple test is reviewed in this study which may allow such a classification.

Sample Preparation

Tantalum films were deposited by sputtering at the rate of about 100 Å/min at argon pressures in the range of 10-20 millitorr of argon. Reactive sputtering techniques (12-15) using small additions of oxygen, nitrogen, methane, or hydrogen in the argon yielded tantalum films with the appropriate amount of the gas going into either interstitial positions or compound formation. Tantalum films alloyed with a variety of different metals were formed by sputtering with wires of the alloying element suspended across the face of a high-purity tantalum cathode (Fig. 1) (16). In all the cases under discussion the structure of the film was the beta-tantalum phase (17) unless specified otherwise. For the studies reported here on the area variation, moisture dependence, and electrolyte contact dependence, the tantalum films were anodized to 100v at 105°C in an ethylene glycol-oxalic acid electrolyte, while for all of the other studies, the anodization was performed at room temperature in a 1% aqueous citric acid solution with a formation voltage of 130v. In both of these anodizations the oxide film thickness was 2300Å. In all of these oxide preparations, the anodization was interrupted at midpoint to allow the back-etching with 0.01% $AlCl_3$ in methanol, although it has been demonstrated that this step does not affect the degree of asymmetric conduction. Metal film counter electrodes, usually gold, were evaporated through masks to form 10-15 capacitors of one size, or else a distribution of sizes (Fig. 2a). Large and small area electrolyte contacts could be isolated on the same anodic film with the use of electroplaters masking tape. The current-voltage characteristics and the non-

[1] "Nominally flaw-free" films are those whose breakdown voltages are independent of counter electrode area and are an appreciable fraction of the formation voltage.

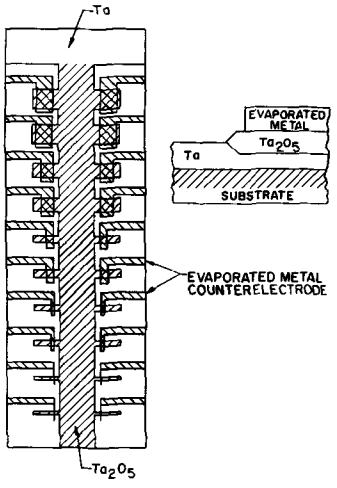

Fig. 2. Structures for the evaluation of printed tantalum oxide capacitors: (a) (left) tantalum anode area variation; (b) (right) schematic capacitor structure.

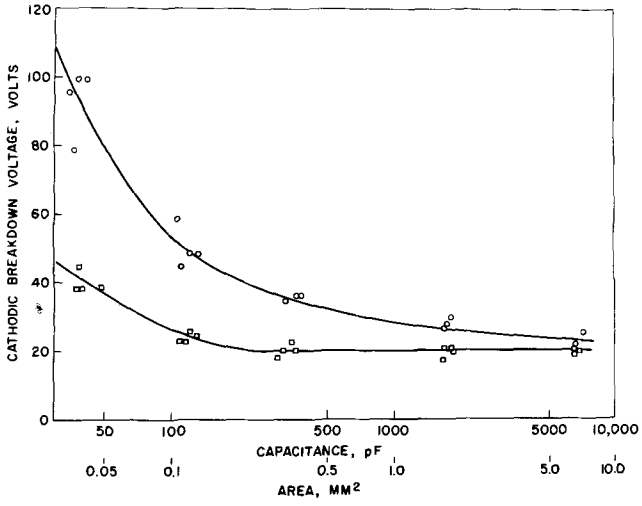

Fig. 3. Cathodic breakdown voltage (Ta^+) as a function of capacitance of printed tantalum oxide capacitors. All oxide formations at 100v at 110°C.

catastrophic breakdown voltages were determined as reported previously (2).

Counter Electrode Area Studies

Vermilyea demonstrated the existence of flaws in anodic oxide films grown on bulk anodes by the use of fine wire contacts and electrodeposition (9, 18). With wire probes, it is possible for the pressure and area of the contact wire on the oxide to vary; in some cases, the wire can puncture the oxide, particularly if the wire had previously conducted current at the site of a local catastrophic breakdown. With evaporated contacts, the pressure problem is avoided, the capacitance of the structure can be measured to assure an appropriate contact and provide information on the area of contact, and there is more flexibility in the kind of experiments that can be done as compared with the use of electrolyte contacts.

A possible ambiguity in the area variation technique illustrated in Fig. 2 is that the perimeter to area ratio increases with decreasing area. If one assumes that flaws are concentrated at the perimeter, and that increasing the perimeter to area ratio increases the probability of making contact to a flaw, the results to be described are incompatible with this assumption.

The results of measurements on the breakdown voltage as a function of the capacitance (*i.e.*, of the calculated area using 26.5 as the dielectric constant and 16.5 Å/v for the anodization constant) for a constant oxide film thickness are shown in Fig. 3 for two different slides prepared under ostensibly identical conditions (2). The reduction in the area of the capacitor sample results in a marked increase in cathodic breakdown voltage. This result is compatible with a model of an oxide film with flaws whose density is on the order of one per 0.05 mm^2 (*i.e.*, with an average separation distance of 0.22 mm). This calculated density assumes one type of flaw which breaks down at a given voltage, but a more realistic treatment would have to include a distribution of flaws breaking down at various voltages.[2]

The difference between the two curves in Fig. 3 may be attributed to two different flaw densities caused by minor changes in the process parameters. In about one third of the samples, the flaw density was so high that no change in cathodic breakdown voltage could be observed in the samples by varying the counter electrode areas.

Large increases in the anodic breakdown voltage when the counter electrode area was decreased from 200×10^{-3} cm^2 to 1×10^{-3} cm^2 have also been reported (20), thus suggesting that flaws can play a role in anodic conduction as well.

[2] See later discussion of direct observation of breakdown at flaws.

The area variation technique utilizing evaporated counter electrodes is a powerful method for detecting flaws if the area of the contact is made small enough. Similar results can be observed with 8*N* sulfuric acid as a contacting electrolyte. For the identical area, where the loosely adherent gold counter electrode was removed with transparent sticky tape, the cathodic and anodic breakdown voltages of the small area samples were significantly larger than those for the large area samples.

Large Area Aqueous Electrolyte Contacts

Studies on anodic oxides have been reported in which aqueous electrolyte contacts were used. To correlate these studies with the present work using metal counter electrodes, the nominal breakdown voltages for both counter electrode types were compared on the same oxide sample. First, the breakdown voltage was determined with a gold counter electrode (see Fig. 4, upper); then the gold counter electrode was removed with aqua regia, the sample reformed at the original anodizing voltage for a short period of time, and then the identical area was contacted with 8*N* sulfuric acid resulting in the lower trace of Fig. 4. This latter sample shows almost complete rectification with a nominal cathodic breakdown voltage of less than 1v, and with anodic breakdown voltages improved over the metal counter electrode sample. Gold counter electrodes were then evaporated over the same area, and results identical to the upper trace in Fig. 4 were ob-

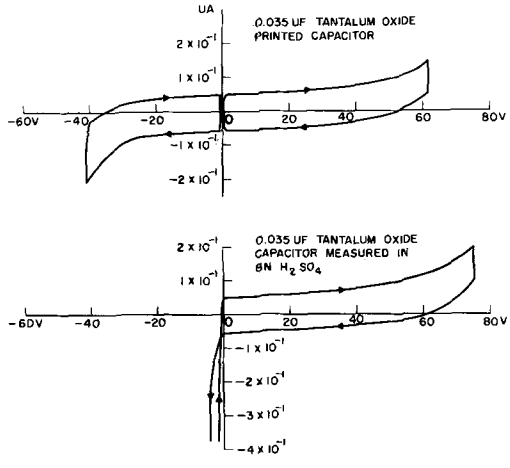

Fig. 4. Comparison of I-V characteristics with gold and aqueous counter electrodes (large area example); positive voltage is for anodic direction (Ta^+).

tained, indicating no irreversible changes occurred in the oxide as a result of these different steps

As indicated in the previous section, however, small area samples showed a similar decrease in cathodic breakdown voltage with an electrolytic contact, but the values of the breakdown voltage were in the 20-30v range. This result indicates that the electrolytic contact results are also area dependent, but with a different sensitivity factor than for the metal counter electrodes. One of the conclusions from this study is that breakdown voltages for gold counter electrodes and for concentrated electrolyte contacts show a similar dependence on the contact area, though the latter contact results in much smaller cathodic breakdown voltages for a given area.

Any model which can be set up to explain these electrolyte results must also take into account concentrations of water less than that associated with an aqueous solution. To investigate this, vacuum baking was employed to remove trace amounts of water from the gold counter electrode samples. Figure 5 shows the breakdown voltage results for both a gold electrode thin film capacitor and a standard tantalum solid electrolytic capacitor. Removal of trace amounts of moisture by heating at 120°C in 10^{-5} Torr vacuum for 3 hr and then cooling in vacuum to room temperature cause a decrease in the anodic breakdown voltage with virtually no change in the cathodic breakdown voltage. These effects are time dependent since applying a voltage of 50v to desiccated samples does not lead to catastrophic breakdown, but a polarization-like phenomenon is observed in which the leakage current decreases with time at constant voltage. An important observation is that the desiccated sample shows almost symmetric breakdown behavior, but with anodic and cathodic breakdown voltages of about one-quarter that anticipated from the 130v anodization voltage. Exposure to room ambient moisture at about 50% relative humidity results in a reversible return of the anodic breakdown voltage to the initial voltage trace. Moreover, the rate of return is proportional to the gold electrode thickness. Small area capacitors comparable to those shown in Fig. 3 with cathodic breakdown voltages in the 100 volts range, do not show this reversible moisture effect, and in fact are quite stable at different moisture levels (see Fig. 6).

The effects of varying degrees of exposure to moisture on the breakdown voltages are pictorially summarized in Fig. 7. The anodic breakdown voltage increases markedly with an increase in the relative humidity, but then has a further smaller increase when an electrolyte contact is used instead of the metal counter electrodes. For the cathodic breakdown voltage, there is essentially no change when the relative humidity is increased, but a decrease results when an electrolyte contact is used.

For meaningful models, there should be a well-defined experimental situation to be described. It has been shown above how the contact conditions can affect the results, and we shall discuss below how variations in the fabrication can affect the electrical characteristics. Thus, instead of proposing or reaffirming specific models based on electronic mechanisms or electrochemical processes, a more modest model based on flaws will be used to correlate the above information. It will point up a level of explanation which is currently suitable for a large number of anodic tantalum oxide films, and emphasizes the difficulty in using more sophisticated models when applied to flaws.

It is assumed that flaws are responsible for the cathodic and anodic breakdown voltages. From the data on moisture dependence, three models may be applicable: (*a*) one type of flaw behaves differently with moisture under biases of different signs; (*b*) there are two separate types of flaws; or (*c*) there is essentially one type of flaw with two different parts. For simplicity, we assume that there are two different types of flaws, one of which responds to low moisture content in a certain way in the anodic direction but is not influenced in the cathodic direction, while the other type of flaw is not influenced in the anodic direction and has a response to high levels of moisture (*i.e.*, electrolyte contacts), albeit a different response, in the cathodic direction.

The two major changes with moisture are (*a*) a large change in the cathodic breakdown voltage when going from a sample in high relative humidity to a sample with an electrolyte contact and (*b*) a large change in the anodic direction between a sample being in a dry ambient to being in an ambient with a high relative humidity. The process responsible for (*a*) might be a H^+ or H atom transport, hydrogen embrittlement, or tunneling across a thin section of oxide which becomes important only at high concentrations

of water. Proposed explanations for the latter change, (*b*), have been oxygen bubble formation under anodic bias or the unlikely collapse of the metal film into the flaw to give closer contact with a thinner portion of the oxide. It is difficult to ascribe a conduction reaction under anodic bias in the absence of water with a metal counter electrode.

Since the current flow is so time dependent at low moisture content, it is possible that an electronic mechanism is operative which depends markedly on the absence or presence of water, perhaps affecting some trap levels in the conducting oxide (2).

The influence of water can also be used to explain the marked effects of different metal counter electrodes on the anodic breakdown voltage, with almost no effect produced on the cathodic breakdown voltage (21). In this case, the free energy of formation of the oxide appears to correlate with the ability of the metal counter electrodes to control the moisture level in the anodic film. Electrodes with large negative free energy of formation, such as the Al-Al_2O_3 couple, result in current-voltage characteristics similar to the desiccated sample in the upper trace of Fig. 4, and show little humidity dependence. The large negative free energy of formation for the Al-Al_2O_3 couple may be correlated with its greater adherence which, therefore, provides a high impedance barrier to moisture transpiration.

Electron microscope examination of stripped tantalum oxide films from thin film anodes have revealed a variety of flaws including cracks and recrystallized areas, but these do not appear with the surface density expected from the area variation data.

The rest of this work is concerned with an understanding of the parameters which will eliminate flaw formation as well as direct experimental verification that destructive cathodic breakdown occurs at discrete flaw sites using *in situ* interferometric microscopy. This course has led to more fruitful results than a continued effort to define the flaw-moisture interaction mechanism.

Effect of Composition of Sputtered Tantalum on Breakdown Voltages

The variations in properties of different samples (*e.g.*, see Fig. 3), has impeded the understanding of the mechanisms involved in the conduction process. As discussed above, the moisture and area conditions under which the measurements are made can change the results. Metallurgical parameters in the preparation of sputtered tantalum samples which have been demonstrated to affect the experimental results markedly are the following: (*i*) gaseous impurities (interstitial) (12-15), (*ii*) metallic impurities (substitutional) (16), and (*iii*) sputtering parameters; these determine bcc or β-tantalum formation (22). In what immediately follows only the effects of the interstitial and substitutional impurities are discussed in detail.

One of the principal differences between sputtering vacuum stations is the ambient gas level prior to and during deposition (23). Increasing the content of nitrogen, oxygen, carbon, or hydrogen in the tantalum film in a controlled manner by reactive sputtering has been shown to alter the conduction characteristics severely. This effect can be seen in Fig. 8 for different samples with gold counter electrodes. The maximum relative cathodic breakdown voltage as a function of the reactive gas pressure in Torr has been plotted. The largest changes in the cathodic breakdown voltage for tantalum films reactively sputtered occur at pressures of 5×10^{-5} Torr of oxygen during the sputtering (*i.e.*, 0.25% in Ar or about 12 (atom per cent) in the film). This gives almost symmetric conduction characteristics. However, oxygen pressures less than 10^{-5} Torr have a measurable and reproducibly large effect on the cathodic breakdown voltage. Similar results for other anodic films grown on tantalum sputtered in methane (for the carbon), oxygen, and hydrogen are illustrated in Fig. 8; pressures of these gases of less than 10^{-5} Torr also had large effects on the cathodic breakdown voltages.

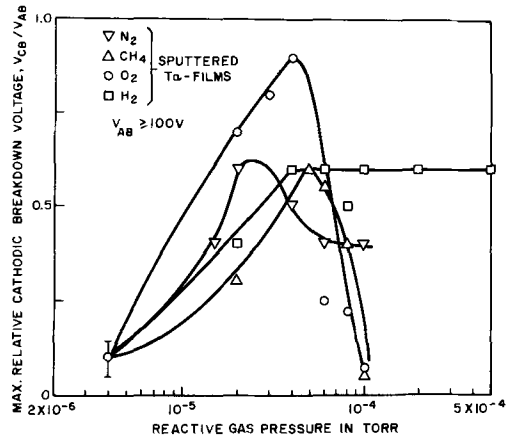

Fig. 8. Maximum relative cathodic breakdown voltage (cathodic breakdown voltage divided by anodic breakdown voltage) vs. reactive gas pressure in Torr for nitrogen, methane, oxygen, and hydrogen (from D. Gerstenberg).

However, the gaseous content of the sputtered tantalum film is but one parameter which determines the properties of the resulting anodic film. An equally important parameter is the metallic impurity content in the tantalum cathode used for the sputtering of the tantalum films (16).

Sputtered alloys of tantalum with molybdenum will be used to illustrate the general effects of alloying on the conduction properties of the thin film tantalum oxide structures, although other metals also have marked effects (16). The preparation of these alloys is illustrated in Fig. 1. The alloying was accomplished by wrapping wires around the cathode as indicated in the figure and then simultaneously sputtering from the wires and the cathode. This yielded uniform films as determined by x-ray fluorescence measurement of the solute element. A tantalum cathode was used whose impurity content was less than 50 ppm per each metallic element in the cathode, with most elements at or below the 10 ppm level. The molybdenum-tantalum alloy films were sputtered in argon under the same conditions which reproducibly gave the lowest cathodic breakdown voltages for tantalum-only controls.

In Fig. 9 the measured anodic and cathodic breakdown voltages are plotted as a function of the atomic per cent of molybdenum as measured in the sputtered films. First, the anodic breakdown voltage is essentially constant up to concentrations on the order of 1-5% of molybdenum in the sputtered film. Second, the cathodic breakdown voltage rises in a semilogarithmic fashion with molybdenum content in the sputtered film. The addition of several hundred parts per million of molybdenum to tantalum cathodes will double the cathodic

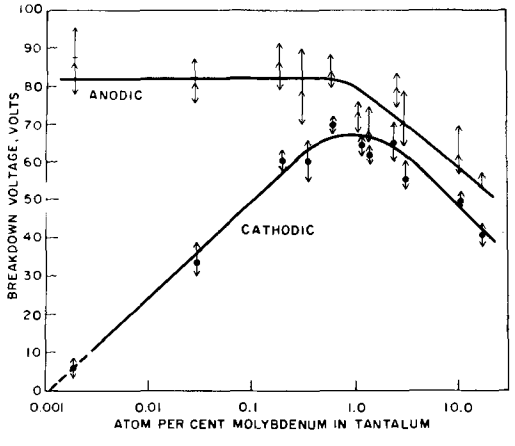

Fig. 9. Cathodic and anodic breakdown voltages vs. the atomic per cent molybdenum in sputtered tantalum films prior to anodization for printed capacitors with gold counter electrodes.

breakdown voltages. Results consistent with this have been obtained using films sputtered from a molybdenum-tantalum alloy cathode. The effect of alloying has been investigated for a wide range of other materials including vanadium, iron, tungsten, cobalt, nickel, copper, gold, and aluminum and, in all cases, over some range of concentration, there has been some increase in the cathodic breakdown voltages.

Thus, changes in the metallic impurities in the cathode and in the ambient residual gas pressures during sputtering can result in changes in the cathodic breakdown of the resulting anodic films; these are, in large measure, responsible for many of the discrepancies seen between thin film samples by different investigators and even between different samples under investigation by the same worker.

The possibility of varying the cathodic breakdown voltage at low concentrations permits further investigation of the flaw problem in a controllable situation. If alloying resulted only in decreasing the density of flaws, then the size of the counter electrode area which has a good chance to be free of flaws should increase with solute concentration. Studies in which counter electrode areas were varied have been made with different concentrations of molybdenum. Measurements consistent with the flaw interpretation, made on separate sets of thin film structures which had been fabricated at different times from different sets of sputtering runs, are shown in Fig. 10.

It is important to note that for small counter electrode areas the breakdown voltages approach constant values; these limiting values are a function of the alloy concentration. Thus, in nominally "flaw-free" films, a homogeneous asymmetric conduction mechanism exists, which can be modified by the addition of alloy agents as molybdenum. This effect may well be associated with band structure modification in the tantalum oxide. The degree of asymmetry in the conduction for these nominally flaw-free films is unusually low; these capacitors appear to have almost symmetric noncatastrophic breakdown voltages.

It should also be noted that the higher concentration alloy films are essentially moisture insensitive; this agrees with the area studies above in which operationally defined flaw-free films are moisture insensitive. There is another interpretation consistent with the area studies on alloy films: instead of, or in addition to, a change in the flaw density there is an alteration of the distribution function over different flaws of the breakdown voltage *vs.* current.

An ion beam probe mass spectrometer has been used to analyze a composite film of (Mo-Ta)-(Mo, Ta)$_2$O$_5$ to verify the presence of Mo in the oxide film. This spectrometer allows analysis of the oxide film in at least 500Å intervals in a 2000Å oxide film. There were positive indications of molybdenum in the anodic oxide films at concentrations compatible with these expected from the grown concentration in the original thin film alloy anode which could also be analyzed.

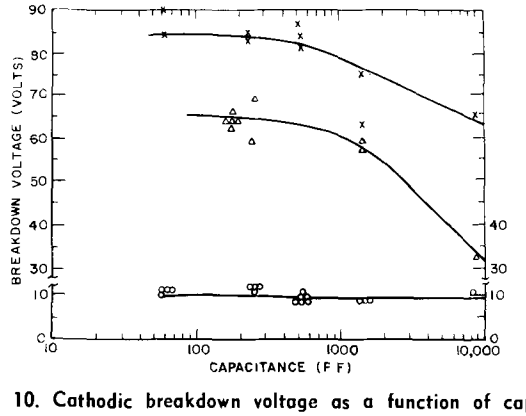

Fig. 10. Cathodic breakdown voltage as a function of capacitance for printed tantalum oxide capacitors formed on sputtered tantalum-molybdenum alloys of different concentrations.

There are some preliminary observations which strongly suggest that the appearance of flaws in the tantalum oxide films are related to minor changes in the surface topography of the sputtered metal film. Additions to the sputtered metal film result in a more uniform metal surface, thereby changing the oxide growth conditions. Tantalum films with a minimum number of microscopic protuberances, or less pronounced protuberances, will result in tantalum oxide films with nearly symmetric I-V characteristics. These conclusions are supported by the *in-situ* microscope observations described in the next section.

Direct Observation of Flaws and Flaw Behavior

Direct observations with a differential interference microscope of flaws, flaws decorated by metallic counter electrodes, growth of the flaws, and irreversible changes at these local inhomogeneities under cathodic voltage provide more direct evidence of the existence and role of the flaws (11).

Tantalum oxide flaws, with and without their surfaces decorated by a thin aluminum counter electrode, are shown in Fig. 11. Decoration by a thick gold counter electrode and the effect of a cathodic voltage are shown in Fig. 12. Here, the irreversible damage at flaws on the application of a cathodic voltage can be seen by comparison of the same field of view before

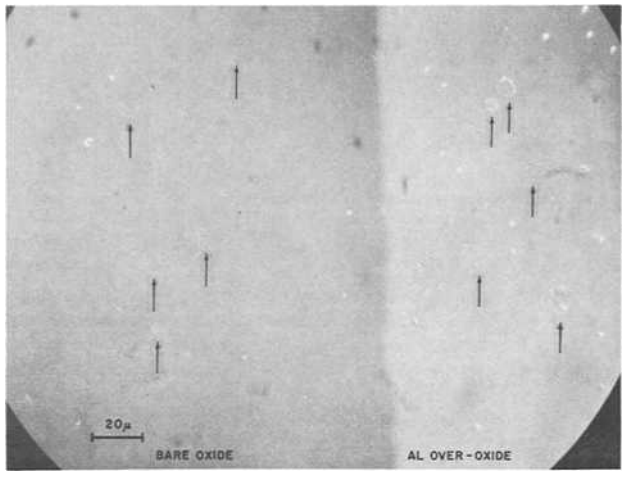

Fig. 11. Nomarski interference microscope (*i.e.*, differential interference microscopy) photograph of tantalum oxide (dark left side of figure) and 400Å aluminum film covering the oxide (light right side of figure). Arrows point to flaws in the oxide and decorated flaws.

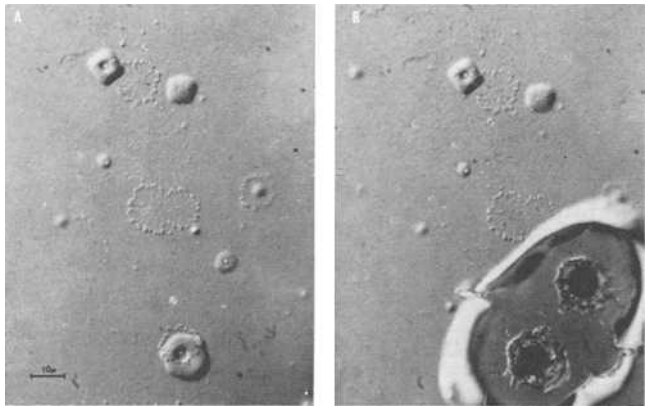

Fig. 12. A (left) Nomarski interference microscope photograph of 2500Å gold counter electrode on tantalum oxide before application of voltage. B (right) Nomarski interference microscope photograph of same field of view as in Fig. 12A after application of cathodic voltage (Ta^-) of 55v.

and after application of voltage; in (A), the flaws are seen before application of voltage, while in (B), the same field of view is shown after application of 55v applied in the cathodic (Ta^-) direction. Similar flaws have been observed, with diameters less than $\frac{1}{2}\mu$ using transmission electron microscopy of carbon replicas. The following observations have also been made using this technique (11):

1. Capacitors have been stressed in the anodic direction to 85v with no optical evidence of irreversible changes; application of 85v in the cathodic direction resulted in irreversible physical changes at the same flaws. This indicates that the flaws are asymmetric in their behavior and supports the hypothesis that the flaws are responsible for the asymmetric conduction.

2. The density of flaws observed under the microscope (*i.e.*, on the order of two per 100μ diameter, or an average area per flaw on the order of 10^{-2} mm^2) as seen in Fig. 11 and 12 is consistent with the order of magnitude of the flaw density obtained from studies of the area dependence of the cathodic breakdown voltage (see Fig. 3). This further supports the hypothesis that the flaws are responsible for the asymmetric conduction.

3. Different flaws in the same field of view have been shown to develop irreversible changes at different rates when the cathodic voltages are applied in steps; these changes stop at different voltages for different flaws in the same field of view. This suggests that the usual method of identifying different conduction mechanisms by the measurement of current-voltage characteristics may only result in the measurement of the distribution function over different flaws of the current-voltage characteristics of the different flaws under one counter electrode.

4. Differential interference microscopic observations of *in situ* growth of flaws indicates that they grow at local imperfections or inclusions in the sputtered tantalum film. Since these films were prepared under clean room conditions, these local imperfections or growths should be less dependent on dirty conditions than such oxide films prepared from sputtered tantalum films deposited under less stringent conditions or from bulk tantalum. Conditions for flaw growth and the flaw density should be different for oxides grown on bulk and thin film tantalum.

5. The current density used for anodization (11, 24), as well as the electrolyte (9), will have an effect on the growth of the flaws.

Summary and Conclusions

The conditions under which the sputtered tantalum films are deposited and the anodic films are grown will strongly affect the conducting properties of the oxide films; the conditions under which the formed films are measured will also determine the results obtained.

Evidence from breakdown measurements as a function of counter electrode area, moisture sensitivity of breakdown voltages, and optical observations indicates that flaws can play a significant role in determining the asymmetric conduction characteristics. It is thought that the presence of metallic and nonmetallic additives in the sputtered film results in a more uniform metal surface which changes the flaw growth during anodization so that the oxide films formed have a less pronounced flaw response.

Previous measurements of the I-V characteristics of tantalum oxide films must be interpreted in the light of results indicating that the flaws may be responsible for the asymmetric conduction and have a distribution of responses on the same film. In order to be meaningful, investigations on conduction mechanisms in tantalum oxide films should demonstrate that the conduction is not flaw dominated; the procedure used here with counter electrodes of different area is a simple method which can be used to establish whether the nominally flaw-free condition has been achieved. This test is only adequate when a counter electrode area of linear dimension of the mean separation between defects is used; in this work, this area is 0.05 mm^2 or less.

Manuscript received Nov. 15, 1968. This paper was presented at the Dallas Meeting, May 7-12, 1967, as Paper 25.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Some Evidence for Duplex Film Structuring Within the Anodic Alumina Barrier Layer

G. A. Dorsey, Jr.

Kaiser Aluminum & Chemical Corporation, Department of Metallurgical Research, Spokane, Washington

ABSTRACT

Direct observations of anodic barrier layer oxide, by transmission electron microscopy, provide further evidence for the duplex film structuring suggested earlier, based on infrared data. Anodic films were prepared with a boric acid electrolyte maintained at 60°C and two film layers were observed: the uppermost layer being extremely thin. Only the layer lying next to the metal (primary phase barrier layer) showed a thickness relationship with respect to forming voltage: 14.8 Å/v. The thickness of the uppermost layer (secondary phase barrier layer) was on the order of 200Å and was essentially independent of forming voltage. With the boric acid electrolyte employed at 90°C, a pronounced increase was found in the thickness of the uppermost layer. The thickness of the layer next to the metal surface remained consistent with the ~14 Å/v relationship. Infrared, coating weight, effluent gas detection, and impedance data were also obtained for these coatings and correlated with the data obtained by transmission electron microscopy.

Aluminum, oxidized anodically, may yield coatings that consist of one or more layers. An electrolyte with little tendency to dissolve aluminum oxide, or otherwise interact with the alumina structure, will generally produce only a single nonporous film. Boric acid or near-neutrality ammonium tartrate are examples of this type of electrolyte. Other aqueous electrolytes such as sulfuric, chromic, or phosphoric acids (or organic acids that have the ability to dissolve alumina) will generally yield two anodic oxide layers. The first layer to form is still a nonporous oxide, however further anodic oxidation yields a thicker porous film above this relatively thin layer. Such composite films are referred to as porous layer oxides to distinguish them from coatings that contain only the single nonporous layer. Various models (1-4) for this type of film growth have been proposed and illustrate many of the physical characteristics of these films.

The nonporous oxide is an insulating layer through which current is carried only by ionic diffusion or charge transfer. During the growth of this oxide, the applied voltage must be continually increased in order to maintain a constant rate of formation. If the voltage is increased to some final value (termed the forming voltage) and thereafter maintained constant, the anodization current density will quickly fall to a low value. Indirectly, then, the forming voltage is a measure of the total number of coulombs that were expended toward the formation of this oxide. The thickness of this film is often calculated using an empirical thickness-to-forming voltage relationship of 14 Å/v (5), assuming a negligible or reproducible current flow after forming voltage is attained. Since the voltage drop through this nonporous film constitutes a barrier to further anodic oxidation, this film is commonly referred to as the anodic barrier layer.

Electron microscopy has often been used to study these barrier and porous-layered anodic oxides (1-3, 6-13) via transmission and replication techniques. This has revealed much regarding the pore structure of thick anodic oxides and of the cellular features involved in the growth of both the anodic barrier and porous layers. Barrier layer coatings appear, by electron microscopy, as amorphous pore-free films (12). Only the observation of an ultrastructure at the barrier layer surface (8) suggests the possibility of multilayered effects within this film. Other techniques, however, indicate that there are at least four layered regions of dissimilar electrical resistance (11) within the barrier layer film and, possibly, at least two regions of dissimilar acid solubility (14).

Key words: anodic aluminas, transmission electron microscopy, IR.

Our own work led to a proposal (15-18) based on just such a layering effect since the data suggested a growth mechanism involving a gradual transition from first one barrier layer oxide structure (primary phase) to yield a duplex film structure (primary plus secondary phase of the barrier layer). Deuteration of the anodic barrier layer from aqueous electrolytes implied a hydrogen-bonded trihydrate structure (primary phase barrier layer) whose surface was altered during the course of film formation. This appeared to produce a second barrier layer oxide that was seemingly less dense, with a lower polymer weight, and comprised of μ-hydroxy linkages (secondary phase barrier layer).

While this secondary phase barrier layer is more characteristic of oxides that also contain a porous layer, its structure can also be detected (by IR) in "pure" barrier layer oxide: the latter prepared by conventional methods in boric acid or ammonium tartrate electrolytes. An IR spectrum of the coating surface, via the ATR effect (19), is required to detect this apparently duplex film characteristic since, with these barrier layer films, the secondary phase barrier oxide is present only in the surface region: the bulk of the film being composed of primary phase oxide.

Since these two barrier phases are apparently involved in a growth process through gradual transition, the primary phase may only gradually blend into the secondary phase. There may be no sharp demarkation between them and, unless experimental conditions were sensitive to a subtle differentiation in structuring, such layering effects might not be observable. If such an arrangement actually exists, the duplex barrier layer structure would likely be more apparent, by electron microscopy, with thin films rather than with the thick porous-layered films that are more often studied with this technique.

Oxide solubility is usually low in these barrier layer electrolytes. The oxide is amorphous, by x-ray diffraction, and there is no electrolyte anion incorporation. Accordingly, porous layer oxide is not present in these films: a factor which might otherwise interfere with the detection of the secondary phase barrier layer in cross sections examined by transmission electron microscopy.

Experimental

Anodic aluminas.—Cleaned, etched, and chemically brightened 99.9% Al (alloy 1199) foil coupons were used as the substrate material, and at least four anodized samples were prepared at each of four forming voltages: 20, 50, 100, and 130v. A 2.0M boric acid electrolyte was employed, with stainless steel cathodes, at 60° and 90°C. Anodization was carried out at

25 ma/dm^2 until reaching a preselected forming voltage; afterwards, the current density was allowed to decay to ~3 ma/dm^2 before removing and rinsing the samples. This equilibrium current density (leakage rate) was reached ~ 3 min after attaining forming voltage at 60°C, but *ca.* 15 min were required with the 90°C electrolyte. Two samples were prepared under the latter conditions: a 100v and a 130v coating.

Transmission electron microscopy (TEM).—Thin cross sections of the anodized foils were prepared, using a diamond microknife, with a Reichert OM/U2 ultramicrotome. These were mounted on carbon grids in a Philips EM 100C electron microscope and transmission photomicrographs were obtained at a magnification of 84,000.

The edge of the microknife cut parallel with respect to the anodic oxide, occasionally producing curls in the film. This artifact appears in the photomicrographs as striations that run nearly perpendicular with respect to the metal surface. Also, a layer of carbon, inadvertently deposited on the sample during examination with the electron microscope, sometimes appears as a featureless gray layer at the outer surface of the anodic coating. This film can readily be distinguished from the coating itself, however, by the sharp contrast boundary and by the absence of microknife marks in the carbon layer (further evidence that this is an artifact layer deposited sometime after the anodic film was cross sectioned).

Infrared analysis.—The samples were examined over the 4000-600 cm^{-1} range of the Beckman IR-7, as before (15) using a reflectance attachment set at 45° angle of incidence. These same coating sections, examined by IR, were later cross sectioned for examination with the electron microscope. Thus, we kept a one-to-one correspondence with the data obtained by both techniques.

Far infrared data were not obtained with these samples since earlier work (15) showed that barrier layer oxides absorb, over the range of from 4000 to 35 cm^{-1}, only in the narrow region of 900-to-1000 cm^{-1}.

Effluent gas detection (EGD).—The EGD data were taken in the usual manner, described earlier (20). Since relatively large sample areas were required however, a separate group of samples were prepared at the two lower forming voltages: 20 and 50v. Only the coatings prepared in the 60°C electrolyte were sampled with EGD; the abnormally thick oxide samples (to be discussed later) were not analyzed with the EGD technique.

Impedance measurements.—Impedance measurements were made immediately after anodizing and air drying the same films that were later examined by IR and TEM techniques. The data reported are average values taken from multiple readings with each anodized coupon. A Twin City Testing Corporation Z-Scope (1000 CPS impedance bridge) was employed for these readings, using a 3.5 w/o NaCl media.

Coating weight.—These data were taken in the standard manner (21) using the chromic-phosphoric acid stripping technique. These were the same samples from which sections had been previously removed for impedance, EGD, IR, and TEM measurements. A separate coating weight determination was made with each of the two abnormally thick oxides (prepared in 90°C electrolyte) whereas the remainder, grouped according to forming voltage, were combined for coating weight analysis.

Results and Discussion

Assuming that the rate of oxygen liberation was low or reasonably constant at both electrolyte temperatures, the coatings prepared at 90°C might be expected to be abnormally thick with respect to the forming voltage that was employed. Thicker than would be anticipated from the 14 Å/v relationship, since more coulombs/surface area were expended in their formation.

Based on interpretations of earlier data (15-18), there should be the normal amount (at 14 Å/v) of primary phase oxide in these films. This would be the oxide layer lying next to the metal surface. However the higher electrolyte temperature might be expected to accelerate the postulated transformation rate of primary-to-secondary phase oxide and more than a nominal amount of secondary phase oxide might therefore be found in the barrier layer oxides formed at 90°C (*vs.* 60°C). Note that the secondary phase oxide (if such exists) is still referred to as a form of the barrier layer, even though it is expected that this oxide may be more permeable to the electrolyte (18) and might therefore present only a minor voltage barrier to further oxide growth. Structurally, based on IR data, the secondary phase oxide differs only slightly from the primary phase oxide and appears to form as a gradual transition product of the primary phase. There is no evidence of Al-O-Al linkage in either oxide phase, which is normally associated with a porous layer oxide, nor is there any detectable porosity in these boric-acid-anodized films (this may be seen in the data that follow and in the earlier literature dealing with electron microscopic surface examinations of these same type of films). We will therefore continue to refer to secondary phase oxide as a form of the barrier layer even though the expected characteristics of this oxide do not necessarily constitute a voltage barrier to further anodic oxidation.

Figure 1 shows the coating weight values (micrograms per square centimeter) plotted *vs.* forming voltage for these barrier layer oxides. The two abnormally thick films (abnormal, judging from the anodizing response) show as clearly displaced points above the normal values: at 100 and 130v, respectively. With the exception of these two points, the coating weight data fit a linear relationship with respect to forming voltage. Essentially the same relation may be seen in Fig. 2, which is a plot of total barrier layer IR absorbance *vs.* forming voltage: primary-plus-secondary phase absorbance, since IR cannot accurately distinguish between various admixture compositions.

Again there are two points that are out of line with the remainder. These two points were from the same films that yielded abnormally high coating weight values. Unlike the coating weight determinations which, for weighing accuracy, required a combining of all samples from the same forming voltage, the IR data show individual points for the four separate films that were prepared at each forming voltage. However the

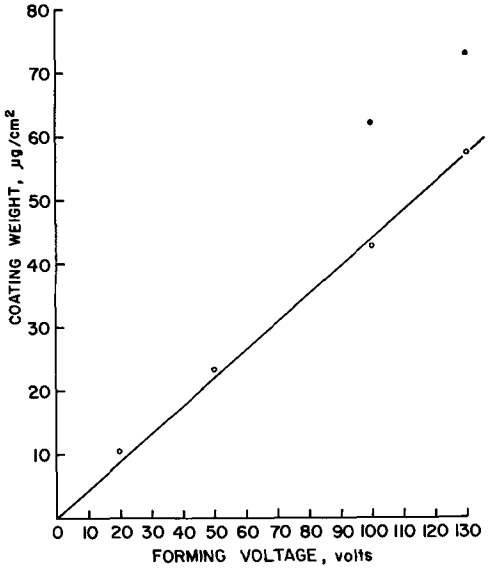

Fig. 1. Coating weight vs. forming voltage. (Solid circles are for abnormally thick films.)

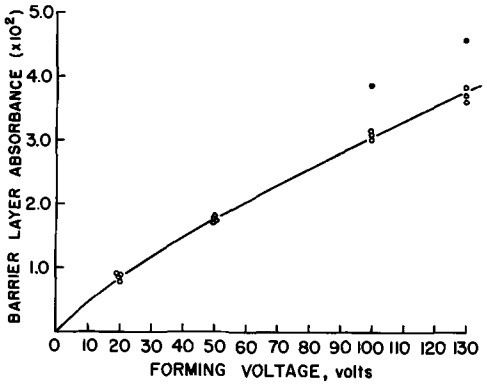

Fig. 2. Infrared absorbance (amount) of barrier layer coatings vs. forming voltage. (Solid circles are for abnormally thick films.)

IR data do not fit a linear relationship with respect to forming voltage; instead, the data seem to give better fit to a curve, as shown in Fig. 2.

Since barrier layer oxides are known to follow a linear thickness-*vs.*-forming voltage relationship (~ 14 Å/v) these IR data present an anomaly. If there are two oxide phases in the barrier layer, but if only one has an appreciable thickness dependence on forming voltage, then this might explain the apparent anomaly in the IR data. However, in order to resolve this question, it would be necessary to determine the various proportions of primary and secondary phases in each of these films.

If such data are to be available at all, then they must come from an examination of the transmission electron microscope data. Earlier reasonings would predict a dark glass-like layer lying next to the metal surface: a low-ordered trihydrate gel, as was suggested (17) in describing the primary phase barrier layer. The thickness of this layer should fit with a nominal 14 Å/v relationship to the forming voltage. Above this layer, there may be a more open structure, less dense and therefore appearing somewhat lighter (more transmittant to the electron beam) in contrast to the lower-lying oxide. This oxide would, as it has been described, be the postulated secondary phase of the barrier layer.

Further, the electron photomicrographs should show an abnormally thick oxide with the two film samples that were prepared at 90°C and gave high values in the coating weight and IR data. The thickness of the primary phase, in these abnormal oxides, should be about the same as that found in all other coatings prepared at the same forming voltage. Only the thickness of the secondary phase (if it can be located in these films) should be different: thicker, perhaps nearly as thick as the primary phase itself.

Figure 3 shows two photomicrographs of coatings prepared with a 20v forming voltage. A carbon deposit is evident on both, but there seemingly are two layers present although the uppermost layer shows only as a thin light band. Figure 4 shows a photomicrograph of a coating formed at 50v. Again there is a lighter uppermost layer, but somewhat thicker than before and better defined. A carbon film still shows but is easily recognized by its light gray shading and by the absence of microknife mark striations that appear in the lower two layers.

Figure 5 shows cross sections of a pair of 100v coatings. Figure 5b is of a coating that appeared to be abnormally thick, seemingly because of an excess of secondary phase barrier layer oxide. The uppermost layer gives the appearance of being composed of a closely packed columnar oxide. It is quite possible, however, that this is an artifact caused by a curling action induced by the cross-cut of the microknife, with this less dense, softer, oxide.

An additional pair of photomicrographs, Fig. 6, exhibit essentially the same features as were seen in Fig. 5. Figure 6b is a cross section of a coating prepared with a 130v forming voltage, but one which yielded abnormally high coating weight and IR absorbance values (total barrier absorbance: primary-plus-secondary layers). The cross section shown in Fig. 6a is also of a 130v coating, but one with a lower coating weight and lower IR barrier layer absorbance.

Quantitative data from these (and their companion) photomicrographs may be seen in Fig. 7, which gives

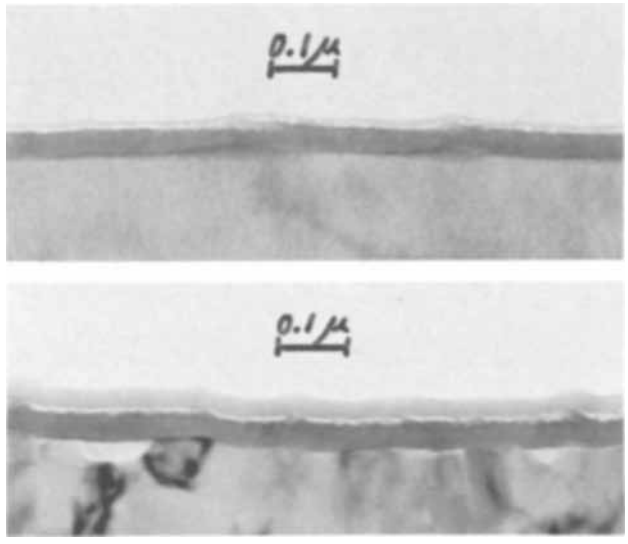

Fig. 3. (a, top, and b, bottom). Cross sections of 20v barrier layer coatings at 84,000 magnification.

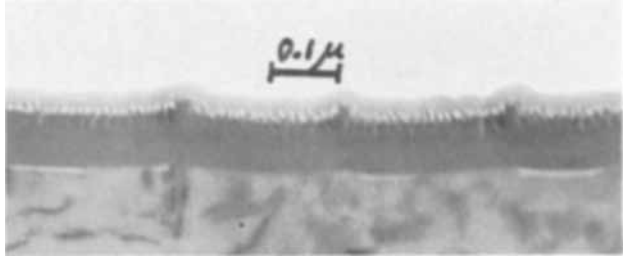

Fig. 4. Cross section of 50v barrier layer coating at 84,000 magnification.

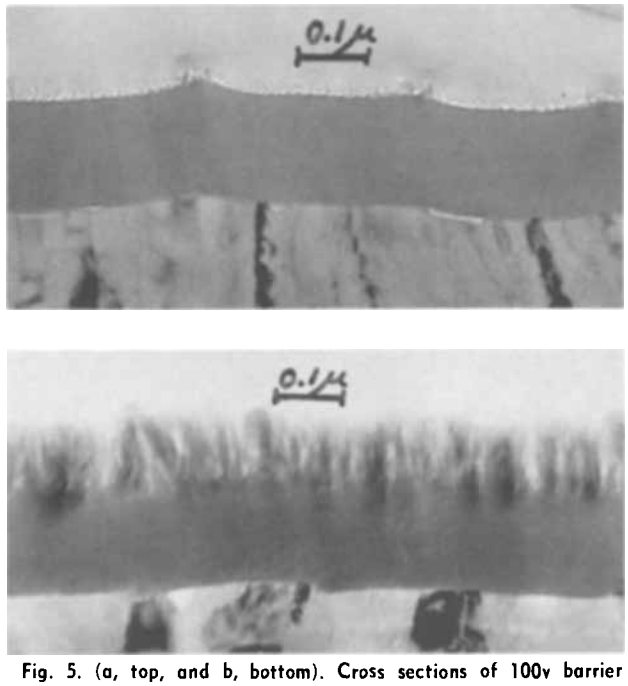

Fig. 5. (a, top, and b, bottom). Cross sections of 100v barrier layer coatings at 84,000 magnification.

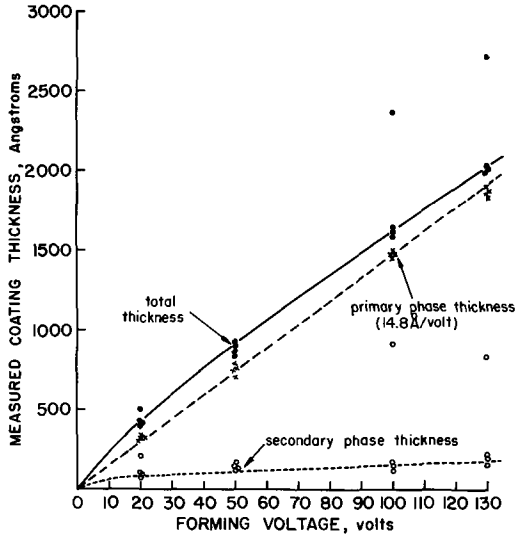

Fig. 7. Measured coating thicknesses (Å) vs. forming voltage

the measured coating thickness data for each group of four coatings that were prepared at the four forming voltages. Three plots are shown, *vs.* forming voltage: total coating thickness, primary phase layer thickness, and secondary phase (uppermost layer) thickness. Even with the abnormally thick coatings (primary-plus-abnormally thick secondary phase barrier layer films) the plot of primary phase barrier layer thickness is linear with respect to forming voltage: 14.8 Å/v. The plot of total coating thickness, *vs.* forming voltage, is displaced upward from this and appears to fit a curve (as do the IR data, Fig. 2) rather than a linear relationship. This is due to the presence of the secondary phase barrier layer, whose thickness seemingly is altered by changes in the anodizing conditions.

There does appear to be a slight thickness increase of this layer as the forming voltage increases: ~ 0.8 Å/v. However the thickness of the secondary phase oxide may be governed more by the temperature and (though minor) by the dissolving action of the electrolyte: both influencing the rate of primary-to-secondary phase transformation. The apparent secondary

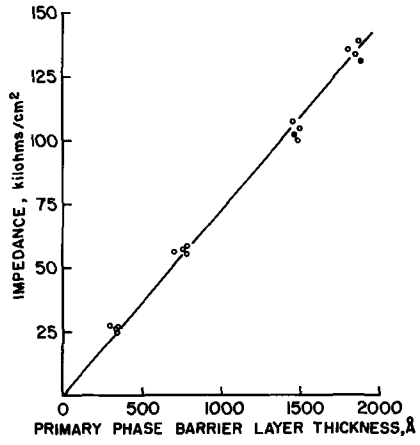

Fig. 8. Impedance values *vs.* primary phase barrier layer thicknesses. (Solid circles are for films with abnormal total thicknesses.)

phase thickness-to-voltage dependence may only be an indirect indication that, at higher forming voltage, the coatings were exposed to the electrolyte for longer time periods.

Figure 8 shows the impedance values that were obtained with these coatings: normal and abnormally thick coatings. As discussed by Hoar and Wood (22), these measured impedance values (at 1000 cps) are due, mainly, only to the capacitance of the barrier layer: not to resistive effects. However there was no measurable difference in impedance between coatings prepared at the same forming voltage regardless of the total coating thickness. This indicates that the impedance of the secondary phase (whatever its actual value) is negligible compared to that of the primary phase barrier layer. It is apparently permeable to the electrolyte and should therefore also have a negligible thickness dependence on forming voltage.

Figure 9 shows EGD data for some of these coatings: those that were normal in thickness, not abnormally thick. The plot is linear with respect to forming voltage and fits with data that were presented and discussed earlier (20). It is interesting to note that, below 300°C, these coatings lost only 1.1 w/o (weight per cent) water *vs.* the 23% water loss experienced by mineralogical trihydrates, when the latter are heated under the same conditions (23). As reported earlier (20) there are indications that the barrier layer oxides lose most of their water of hydration above 400°C, which would indicate a surprisingly tightly bound hydrate network for the primary phase oxide.

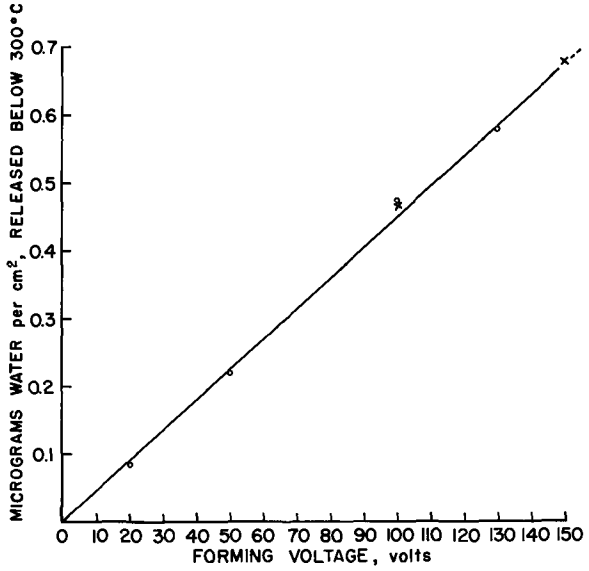

Fig. 9. Effluent gas data (μg H_2O/cm^2) for coatings *vs.* forming voltage. (x points are data points taken from earlier paper (20).)

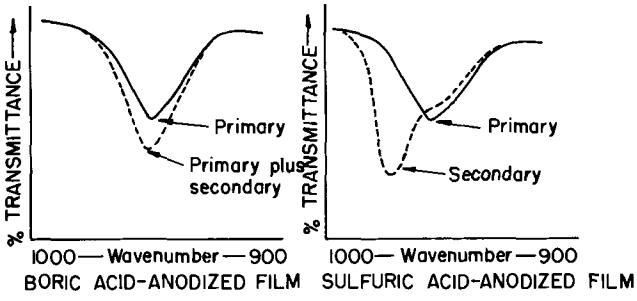
While there is seemingly reasonable correlation between these various data and discussions, there is one final point that now needs to be developed. With IR data, there is little to distinguish between various admixtures of primary and secondary phase barrier layer oxides. Admixture films prepared in boric acid are especially difficult in this respect since the postulated secondary phase still apparently has a high polymer weight.



Instead of a band shift with increased quantities of secondary phase, only the band absorbance markedly changes when the barrier film is prepared in boric acid. However, whether the absorbance is due to "pure" primary phase oxide or due to an admixture of primary-plus-secondary phases, the total absorbance of this IR band should correlate with the total thickness of oxide present: thickness as determined independently from the electron photomicrographs.

To make this correlation, it is first necessary to determine the densities and absorbancy indices of the primary and secondary phase barrier layers. This can be done by combining the available data for coatings prepared at a single forming voltage (where the primary phase thicknesses are equal) but where there is a wide variation in secondary phase thickness (itself not a direct function of forming voltage). For coatings prepared at a forming voltage of 100v, the calculated density and absorbancy index values are given in Table I.

Using these single values, with the Beer's law relationship, an "expected IR absorbance" can now be calculated with any of the barrier layer coatings for which electron microscope data are available.

The ratio of primary and secondary phases varied widely among the various barrier layer oxides that were prepared. Still the calculated IR absorbance values, from the electron microscope thickness data, should match with those values found experimentally. This is assuming that there is a one-to-one correlation between the IR identification of primary and secondary phase barrier layer oxides and the duplex layered film effect found by transmission electron microscopy.

Figure 10 shows a plot of calculated-*vs.*-experimental absorbance for each of these barrier layer coatings. This includes coatings with either extreme in secondary phase thickness. The plot is linear and the calculated values fit the experimental data to within 5%. This, and with the preceding discussion,

Table I. Calculated density and absorbancy index values

Oxide type	Density, g/cm³	Absorbancy index, cm²/g
Primary phase barrier layer	2.73	7.34×10^2
Secondary phase barrier layer	2.41	4.13×10^2

Table II. Data obtained with oxide aged in electrolyte

Initial voltage "A," v	Final voltage "B," v	Primary phase thickness, Å At "A"	At "B"	Secondary phase thickness, Å At "A"	At "B"
100	85	1460	1300	210	550

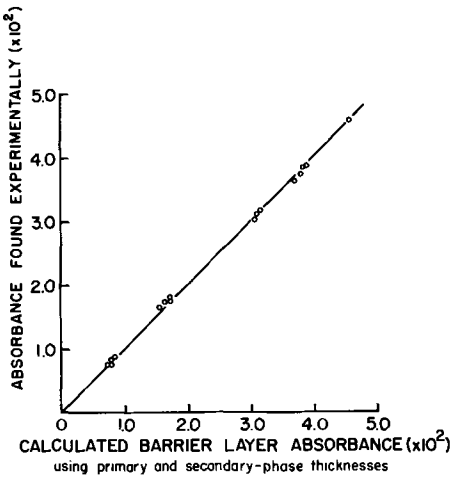


Fig. 10. Calculated IR absorbance data, from coating thickness values, *vs.* experimental absorbance values for each barrier layer coating.

would seemingly indicate that the primary and secondary phases of the barrier layer exist and can be separately identified. The conditions under which these samples were prepared, and the earlier discussion regarding similarities of primary and secondary phase barrier layer IR absorption, argue in favor of regarding the secondary phase as a form of nonporous barrier layer, rather than as a form of porous layer.

One further note regarding the transitions involved with these barrier layer oxides: some cursory data are given in Table II. Primary phase thicknesses were taken by impedance measurements, using the calibration given in Fig. 8, and the secondary phase thickness values were taken from IR data: total absorbance less primary phase absorbance calculated from the impedance estimates of primary phase thickness.

A coupon was taken to the 100v forming voltage, in 2.0M boric acid at 60°C, and then allowed to reach a nominal leakage rate. Afterwards, a section was removed for analysis and the remainder was re-exposed to the boric acid electrolyte for 3 hr at 60°C and 85v.

This type of behavior is essentially the same as the Recovery Effect described by Murphy (24) and Michelson (25). They too discuss a transition effect and, in this respect, their interpretation parallels the preceding discussion.

Acknowledgment

We are indebted to A. T. Melville, D. J. Blew, and Mrs. R. A. Woods, of this laboratory, for their skill and patience in operating the ultramicrotome and obtaining the electron photomicrographs that form the basis of this paper. The author also wishes to thank the Kaiser Aluminum & Chemical Corporation for its support of this work and for its permission to publish these results.

Luminescence from Erbium-Activated Group II-VI Compounds Containing Alkali Metal Compensators

S. Larach,* R. E. Shrader, and P. N. Yocom*

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Group II-VI compounds, doped with trivalent erbium, were prepared with alkali-metal compensators. Striking differences are found in the emission spectra, with respect to intensity and spectral character, and the suppression in host-lattice-emission in lithium-compensated materials. The temperature dependence of the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ and $^2H_{11/2} \rightarrow {}^4I_{15/2}$ transitions was studied. Emission appearing with $^4I_{15/2} \rightarrow {}^4G_{11/2}$ excitation was found and was assigned tentatively to the $^2H_{9/2} \rightarrow {}^4I_{13/2}$ transition. A model is proposed for the observed transitions.

Luminescence from rare earths in II-VI compounds has been of interest for many years (1). Such materials have a discrete ion as the principal source of luminescence emission, the f-f transitions yielding narrow emission bands or lines. As part of a general program on the luminescence of rare earths in II-VI compounds, we wish to treat, in this paper, the effect of alkali-metal ions on the luminescence properties of trivalent erbium in zinc sulfide type materials.

Some optical properties of zinc sulfide containing erbium have been reported by Trapeznikova and Shchaenko (2) for materials prepared with fluxes or coactivators as consisting apparently of band and line emission. Rothschild (3) reported that erbium intensified the emission from silver in zinc sulfide, and that phosphors activated with copper and erbium show the expected emission due to copper, and in addition, lines due to erbium at 5300 and 5480Å. However, with erbium alone in zinc sulfide, Rothschild obtained no luminescence. In 1958, luminescence from erbium in zinc sulfide was reported by Trapeznikova (4) as lines superimposed on broad bands, while in 1963, it was reported by Goldsmith *et al.* (5) that electroluminescence from erbium in zinc sulfide could be obtained as the characteristic rare-earth lines, with minimum broad-band emission. Levshin *et al.* (6) reported in 1965 on the cathodoluminescence of zinc sulfide containing rare earths (prepared without coactivator), and found that erbium showed intensive lines at 549, 533.5, and 527.6 mμ. Also in 1965, Kingsley *et al.* (7) reported on short-range energy transfer from noble metals to rare earths, including erbium, in II-VI compounds, and recently Kingsley and Aven (8) published on epr and fluorescence from erbium in zinc selenide containing copper. The general effect of alkali-metal charge compensation on rare earths in II-VI compounds has been reviewed by Larach (9) and is applied to erbium in zinc sulfide in the present paper.

* Electrochemical Society Active Member.

Materials

The ZnS used in the preparation of these materials was luminescent grade, RCA 33-Z-19. To this base material the various doping ions were added as aqueous sulfate solutions. Enough deionized water was then added to make a smooth slurry, and the *p*H was raised to the basic region with NH_4OH. The slurry was then evaporated to dryness. In the cases of the nonalkali-containing samples, manipulations were carried out using polyethylene vessels. Concentrations are in mole per cent.

The firing of the samples was performed under a slow flow of H_2S at 1150°C. The firing was done in a fused silica tube in which the sample was held in a purified fused silica ("spectrasil") boat. Before firing the rare earth-containing samples, the tube and boat were fired with three consecutive, hour-long firings of the undoped ZnS for scavenging purposes. These special firing methods were evolved to achieve reproducibility from sample to sample, as well as to minimize "host-lattice" emission, which, however, could not be eliminated except with alkali-metal additives.

Measurements

Emission spectra were obtained using "host lattice" absorption, *i.e.*, 3280Å at room temperature, and f-f absorptions, as indicated. Due to the temperature dependence of the absorption characteristic, the exciting wavelength was changed with temperature. The exciting wavelength was obtained with a Bausch and Lomb 500 mm grating, in conjunction with a 150w d-c xenon arc lamp. Emission spectra were obtained photoelectronically with a Spex Czerny-Turner grating monochromator, capable of resolving 0.3Å in first order.

Results

Excitation spectra.—That the addition of an alkali-metal affects the basic electronic processes in ZnS is

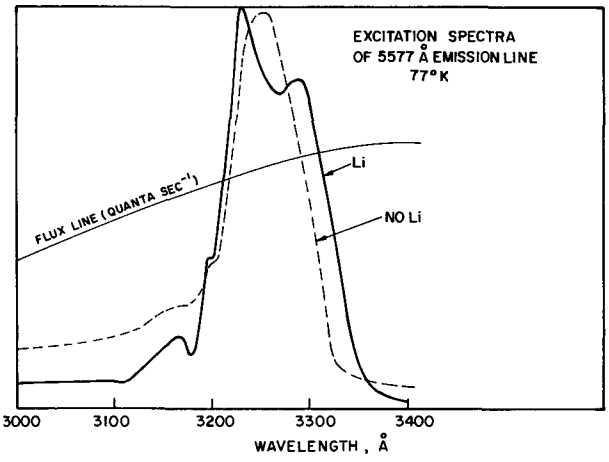

Fig. 1. Excitation spectra of the 5577Å emission from ZnS:Er and ZnS:Er:Li (77°K).

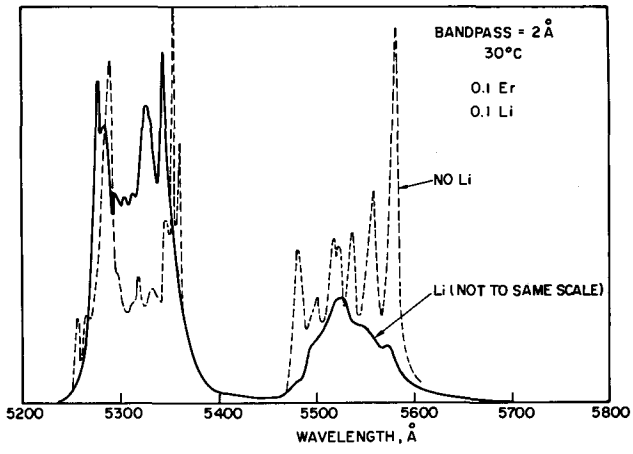

Fig. 3. Emission spectra of manifolds I and II, expanded scale, 30°C, 2Å bandpass. Note that the two spectra are not to the same scale.

shown in Fig. 1. This is a portion of the excitation spectrum of ZnS:Er, with Li and without Li, taken at 77°K. We see that the essentially unstructured excitation spectrum of the non-Li material is changed to a structured spectrum with addition of Li. The structure below 3200Å can be related to host-lattice effects observed in absorption spectra of ZnS materials; however, note the new structure at about 3285Å introduced by Li addition. The flux line (quanta sec^{-1}) is also shown in Fig. 1.

Emission spectra.—The broad-band "lattice-emission," due to vacancies compensated by the rare earth in ZnS (9), is present in ZnS:Er, as shown by curve 1 of Fig. 2. In addition to the broad band peaking at about 4500Å, there are two emission manifolds present, one (I) with a center of gravity at about 5300Å, due to the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ transition, and one (II) manifold centered at about 5500Å, due to the $^4S_{3/2} \rightarrow {}^4I_{15/2}$ transition. Curve 2 is for ZnS:Er:Li, taken with no change in instrumental gain. We see that with Li addition, (*i*) the broad band emission is not detectable, (*ii*) manifold I has increased greatly in intensity, and (*iii*) the smaller increased intensity of manifold II is accompanied by a degradation in the fine structure, and (*iv*) a band at about 4900Å appears, attributable possibly to $^4F_{7/2} \rightarrow {}^4I_{15/2}$ emission. Some of these effects are shown in Fig. 3, where manifolds I and II are shown, with 2Å band-pass. We can clearly see the fine-structure effects of the Li-additive in manifold I, and the degradation of manifold II with Li addition.

The effects of excitation energy are of interest. Thus, as shown in Fig. 4, when 3815Å excitation, which is f-f

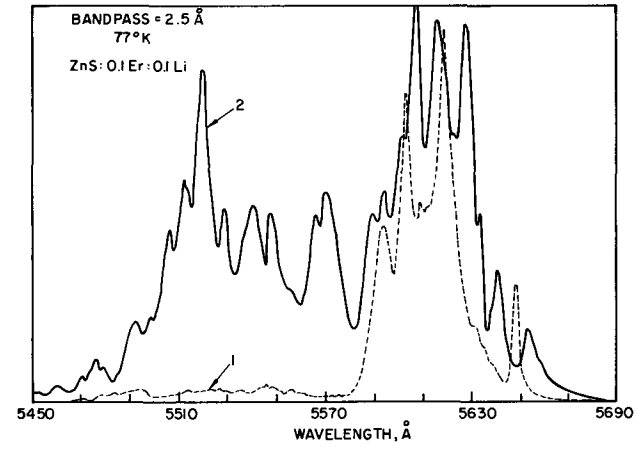

Fig. 4. Emission spectra as a function of exciting wavelength for ZnS:0.1Er:0.1Li; 77°K; curve 1 3815Å excitation, curve 2 3200Å excitation.

in nature, is used, the emission spectrum designated as curve 1 is obtained, at 77°K. When excitation in the host-lattice is used, such as 3200Å, the emission spectrum shown as curve 2 is obtained. It is interesting to compare the results of Fig. 3 and 4. The structured emission from manifold II at room temperature (Fig. 3) terminates close to 5600Å. However, at 77°K, new emission structure appears beyond 5600Å, which is a function of excitation energy (Fig. 4). The materials described in Fig. 5 consist of 0.01 Er and 0.01 Li.

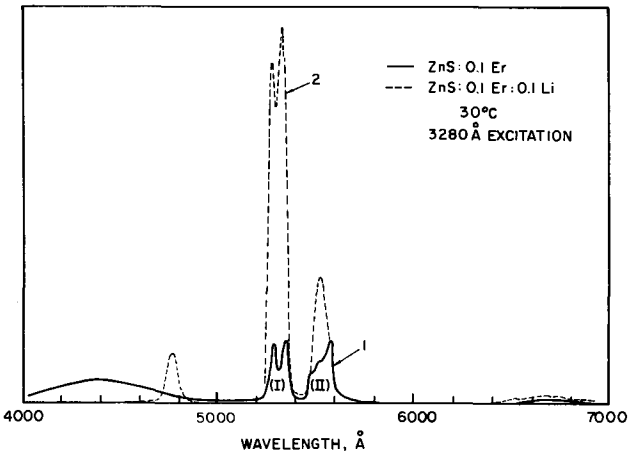

Fig. 2. Spectral distribution curves of photoluminescence from curve 1 ZnS:0.1Er and curve 2 ZnS:0.1Er:0.1Li, under 3280Å excitation (30°C).

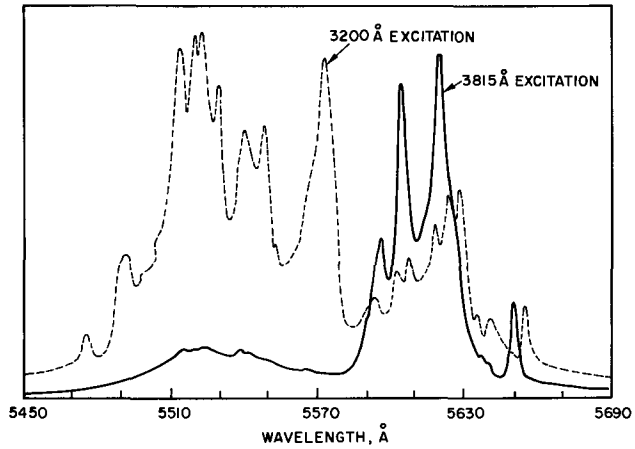

Fig. 5. Emission spectra as a function of exciting wavelength for ZnS:0.01Er:0.01Li; 77°K.

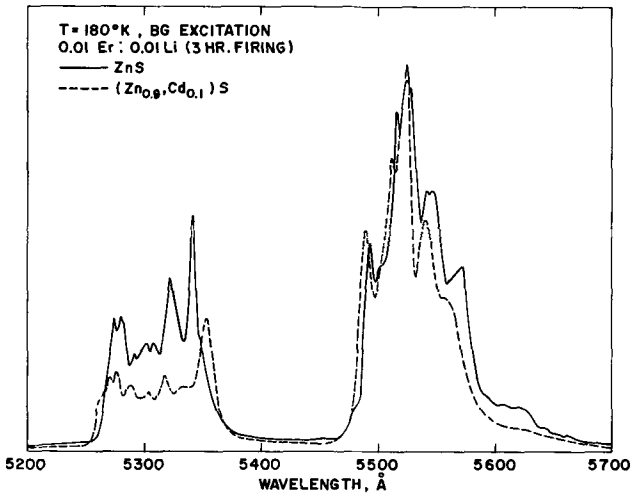

Fig. 6. Emission spectra from ZnS and $(Zn_{0.9}Cd_{0.1})S$, both with Er and Li.

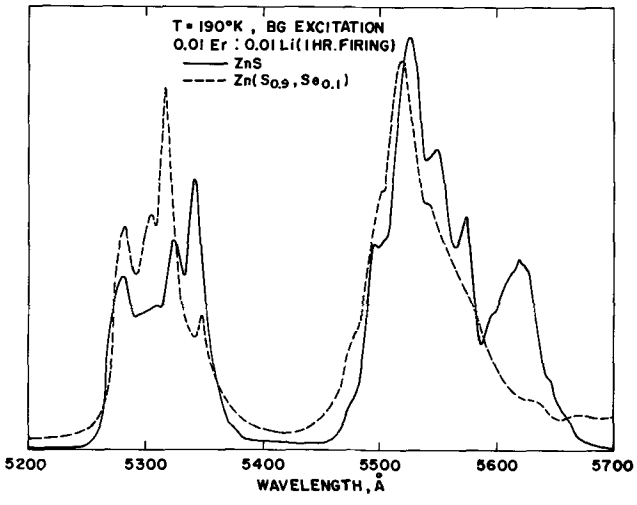

Fig. 7. Emission spectra from ZnS and $Zn(S_{0.9}Se_{0.1})$, both with Er and Li.

Again, we note qualitatively similar effects when 3815Å is used and when 3200Å is used, although quantitative differences are discernible between the two concentrations. The effect of solid solutions of zinc sulfide with cadmium sulfide and with zinc selenide is shown in Fig. 6 and 7. Although the major part of this work was done with lithium as the compensator, similar effects were noted with sodium and with potassium.

Temperature dependence.—The temperature dependence of manifolds I and II is shown in Table I. It is seen that with decreasing temperature, manifold I decreases in intensity. We note that at about 200°K, a new emission (IIA) appears after manifold II, [as we have seen in Fig. 4 at 77°K] which is also shown as a function of temperature. This emission can probably be assigned to $^2H_{9/2} \rightarrow {}^4I_{13/2}$.

Table I. Integrated areas of manifolds I, II, and IIA as a function of temperature

Temp, °K	I	II	IIA	I/[I + II + IIA]	I/[I + II]
333	7.46	1.76		81	81
294	6.40	1.86		77	77
277	4.46	1.76		72	72
256	2.66	1.70		61	61
232	2.55	2.37		53	53
208	2.35	2.80	0.98	39	35

139	0.81	3.23	1.35	15	20

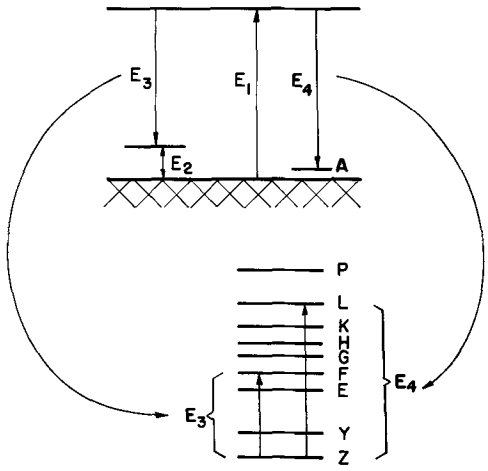

Fig. 8. Proposed model for erbium in zinc sulfide. Arrows upward indicate excitation, arrows downward indicate emission, and the curved arrows indicate energy transfer.

Proposed Model

Bandgap excitation of ZnS:Er results preponderantly in $^2H_{11/2} \rightarrow {}^4I_{15/2}$ and $^4S_{3/2} \rightarrow {}^4I_{15/2}$ emissions. This would indicate that of the roughly 3.7 ev excitation, only about 2.3 ev is available for exciting the erbium ion. This would be the case if the model was that shown in Fig. 8, where $E_2 = 1.4$ ev, and would be the upper limit to the optical acceptor depth, relative to the valence band. Dieleman *et al.* (15) have reported an acceptor depth for alkali metals in cubic zinc sulfide as 1.4 ev. Thus, with bandgap excitation, the energy available for exciting trivalent erbium via an Auger-type transfer would give rise to $^4S_{3/2}$ and $^2H_{11/2} \rightarrow {}^4I_{15/2}$. Level "A" is an acceptor which is available for recombination only at temperatures below 200°K, to excite, via Auger transfer, $^4G_{11/2}$ and/or $^2H_{9/2}$, to yield the manifold IIA emission. However, when 3820°Å photons are used as the exciting source, $^4I_{15/2} \rightarrow {}^4G_{11/2}$ excitation takes place, with $^2H_{9/2} \rightarrow {}^4I_{13/2}$ emission. This emission can also be obtained by exciting into $^2H_{9/2}$ directly from $^4I_{15/2}$ with 4110Å photons.

Site Multiplicity

In the system such as the one under investigation, the problem of site multiplicity and its effects on the luminescence from the rare earth is of great importance. Thus, many of the effects can be interpreted, at least qualitatively, on the basis of erbium in different sites. Another aspect of site multiplicity is indicated in Fig. 4 and 5, where, when Z—K excitation is used, another type of emission spectrum is obtained, as against indirect (bandgap) excitation. ESR-investigations of rare earths in II-VI compounds have been reported recently by Schneider (16) as indicating the existence of a large number of defect centers formed by the rare earth ion associating with, for example, lithium.

Evidence for Eu^{+3} Emission from Two Symmetry Sites in $Y_2O_3:Eu^{+3}$

H. Forest and G. Ban

Zenith Radio Corporation, Chicago, Illinois

ABSTRACT

In $Y_2O_3:Eu^{+3}$ two possible symmetry sites exist for the Eu^{+3} ions, namely S_6 and C_2. The emission spectrum is primarily due to C_2 Eu^{+3} ions but two additional lines are reported corresponding to S_6 Eu^{+3} emissions. The lines were identified by their long lifetime relative to the C_2 emission and represent the Stark splitting of the $^5D_0 \rightarrow {}^7F_1$ transition. This is a pure magnetic dipole transition in S_6 symmetry and consequently has a low oscillator strength. The $^7F_0 \rightarrow {}^5D_1$ absorption transition due to S_6 Eu^{+3} has also been identified. Similar results have been found for the low temperature form of $Gd_2O_3:Eu^{+3}$, which is isostructural with $Y_2O_3:Eu^{+3}$.

Y_2O_3 is a well-known phosphor host material for trivalent activators which are believed to substitutionally occupy Y^{+3} sites (1). The crystal structure of Y_2O_3 is of the rare-earth sequisoxide C-type in which each Y^{+3} ion is surrounded by six oxygens located at the corners of a cube (2). Two of the corners are vacant and can be along a body or face diagonal of the cube which results in two Y^{+3} site symmetries, namely S_6 [1] or C_2, respectively. This is shown in Fig. 1. The unit cell consists of two types of alternating Y^{+3} layers, one composed of only C_2 sites and the other composed of an equal number of S_6 and C_2 sites; the ratio of C_2 to S_6 sites is 3 to 1.

There is some evidence based on paramagnetic studies on $Y_2O_3:Yb^{+3}$ by Mandel and luminescence studies on $Y_2O_3:Bi^{+3}$ by Toma and Palumbo to suggest that in Y_2O_3 activated phosphors, the activator substitutes for both C_2 and S_6 Y^{+3} ions (3). Chang and Gruber in their study of the absorption and luminescence of $Y_2O_3:Eu^{+3}$ have assigned all of their reported emissions to Eu^{+3} ions located at C_2 sites (4). No emissions were found due to S_6 Eu^{+3} ions; however, in the absorption spectrum they report five lines in the region of the $^7F_0 \rightarrow {}^5D_1$ transitions where only three lines are expected based on C_2 symmetry alone. They suggested that the two extra lines are due to Eu^{+3} ions located at S_6 sites, but an assignment was not possible. The present study was initiated in order to establish the two Eu^{+3} symmetry sites in $Y_2O_3:Eu^{+3}$ by searching for the S_6 Eu^{+3} emission.

Symmetry Effects on Eu^{+3} Spectra

The symmetry of the crystal field about the Eu^{+3} ion affects the $4f^6$ absorption and emission spectra in two ways. First, interaction with the crystal field splits the $4f^6$ Eu^{+3} levels, which partly or completely removes the angular momentum degeneracy (Stark effect) and produces a fine structure for each free ion transition. Since the $4f^6$ electrons are substantially shielded from the crystal field by the outer electrons, the Stark splittings are small compared to the spin-orbit coupling. Since the maximum splitting of a level cannot exceed $2J + 1$, the $^5D_0$ level of Eu^{+3} is always a singlet.

The other effect is that the crystal field establishes in part the oscillator strengths of the $4f^6$ transitions. In the case of the free ion all of the $4f^6$ configurations have the same parity so that only magnetic dipole and quadrupole transitions can occur. As is well known, electric dipole transitions are forbidden since this type of transition only connects states of different parity. However, interactions with the crystal field introduce terms into the potential energy part of the Hamiltonian which, depending on the symmetry, can alter the parity of the state. For symmetries which lack a center of inversion these terms are odd and consequently, the parity selection rule breaks down, allowing electric dipole transitions. The selection rules for dipole transitions involving a $J = 0$ emitting or terminal state, which are applicable to the Eu^{+3} $^5D_0$

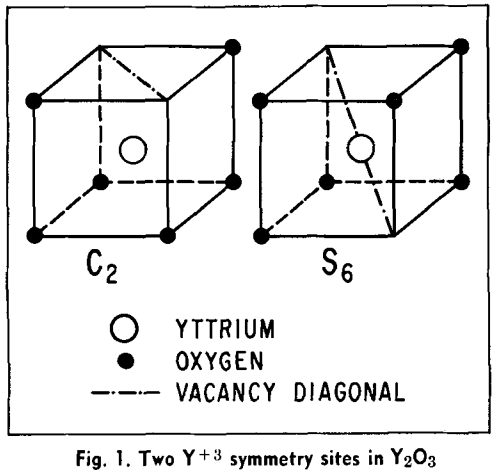

Fig. 1. Two Y^{+3} symmetry sites in Y_2O_3

[1] S_6 is identical to C_{3i}.

state, are: $\Delta J = \pm 1$ for a magnetic dipole transition and $\Delta J = 2, 4, 6$ for an electric dipole transition (5).

In the Eu^{+3} emission spectrum both types of dipole transitions are found: the $^5D_0 \rightarrow {}^7F_1$ is a magnetic dipole transition and the $^5D_0 \rightarrow {}^7F_2$ is an electric dipole transition. Accordingly, when the Eu^{+3} is located at a center of inversion, the $^5D_0 \rightarrow {}^7F_2$ emission should be suppressed and only the $^5D_0 \rightarrow {}^7F_1$ emission should occur. In the above reference, Blasse *et al.* have found this to be true in a series of Eu^{+3} activated phosphors where the inversion symmetry is gradually removed (5). In their phosphors the ratio of the $^5D_0 \rightarrow {}^7F_2$ emission to the $^5D_0 \rightarrow {}^7F_1$ emission was found to increase with asymmetry of the crystal field.

Another factor to consider is the $^5D_0$ lifetime, which will naturally be affected by changes in the probability of the $^5D_0 \rightarrow {}^7F_2$ transition. Since in asymmetric crystal fields electric dipole transitions are more probable than magnetic dipole transitions, an efficient Eu^{+3} emission which consists of the $^5D_0 \rightarrow {}^7F_1$ transition alone will be expected to have a longer radiative lifetime than one dominated by the $^5D_0 \rightarrow {}^7F_2$ transition. Recently, Weber has calculated the $^5D_0 \rightarrow {}^7F_1$ radiative lifetime for C_2 Eu^{+3} ions in Y_2O_3 to be 9.1 msec (6). However, due to the presence of the strong $^5D_0 \rightarrow {}^7F_2$ emission, the observed $^5D_0$ lifetime is actually about 1 msec.

The different nature of the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions is important in separating the S_6 and C_2 emissions in $Y_2O_3:Eu^{+3}$. Since the C_2 site lacks a center of inversion, its Eu^{+3} emission will be composed of both transitions, which is consistent with Chang and Gruber's assignment (4). On the other hand, the S_6 symmetry site possesses a center of inversion and only the $^5D_0 \rightarrow {}^7F_1$ transition is allowed; consequently, the S_6 $^5D_0$ lifetime is expected to be long compared to the C_2 $^5D_0$ lifetime.

Experimental

The phosphors were prepared by firing stoichiometric mixtures of the oxalates for 2 hr at 600°C followed by 2 hr at 1400°C under an O_2 atmosphere. Most of the measurements were made on powders but some were made on a single crystal of $Y_2O_3:Eu^{+3}$ 5% which was obtained from Lockheed Palo Alto Research Laboratory.

Two Jarrell Ash grating monochromators, a ¼-meter Ebert and a 1-meter Czerny-Turner, were used to obtain the spectral measurements. The Czerny-Turner monochromator, which has a dispersion of 8.2 Å/mm, was used for the emission spectra and lifetime measurements, while both monochromators were used to obtain excitation spectra. In the latter experiments, the Czerny-Turner instrument was used to monochromate the light. In all measurements an RCA 1P21 phototube was used as a detector and the exciting source was either a low pressure Hg discharge lamp (CW or pulse) or a 100w Xe lamp.

Results and Discussion

Emission spectra.—The yellow-red portion of the room temperature emission spectrum of $Y_2O_3:Eu^{+3}$ 6% is shown in Fig. 2. The exciting source was a low pressure Hg lamp which corresponds to excitation in the broad Eu^{+3} absorption band in the short u.v. range. Six lines are found in this region and are listed in Table I. The free ion assignments are based on the position of the emissions predicted by the $4f^6$ Eu^{+3} energy level diagram. The $^5D_0 \rightarrow {}^7F_2$ transition is the dominant emission at 6112.9Å. The emission at 5804.5Å is a narrow singlet and its assignment is clear since the $J = 0$ state is not split by the crystal field. However, there is a question about the number of lines occurring in the region of the $^5D_0 \rightarrow {}^7F_1$ transition. Depending on the site symmetry, this transition can be split into a maximum of only three lines, which corresponds to complete removal of the $^7F_1$ degeneracy. Accordingly, there are one or more extra lines in this

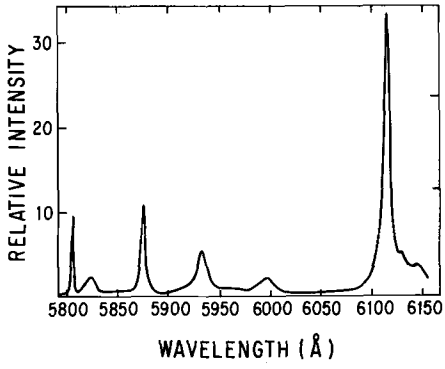

Fig. 2. Yellow-red portion of the emission spectrum of $Y_2O_3:Eu^{+3}$ under 2537Å excitation.

region which can be due to $^5D_1$ emissions or to more than one emitting Eu^{+3} symmetry site. In order to establish the number of additional lines and their origin, the lifetimes of the individual lines were measured using a monochromator to isolate each line.

Table II lists the 1/e lifetimes for the six lines over the concentration range 0.3-10 a/o (atom per cent) Eu^{+3}. The decays were obtained with the pulsed low pressure Hg flash lamp. Some decays were not exponential so that the 1/e lifetimes are to be taken as a convenient reference. It is seen that the five lines marked with asterisks all have roughly the same lifetimes, which indicates that they all originate from the same emitting level. There is little doubt that these are all $^5D_0$ emissions because of unique character of the $^5D_0 \rightarrow {}^7F_0$ singlet. On the other hand, the lifetime of the 5823Å line at low concentrations is too long to belong to this group of lines. Its long lifetime eliminates the possibility of it being a $^5D_1$ emission since the $^5D_1$ level is readily quenched at these concentrations. There are several $^5D_1$ emissions that occur in the 5270Å region and their lifetimes have been measured by us to be about 125-150 μsec. In fact, there is some $^5D_1$ emission overlapping the line at 5873.7Å, which accounts for its slightly shorter lifetime at low Eu^{+3} concentrations. As the Eu^{+3} concentration is increased beyond 1%, the $^5D_1$ emission has been found to decrease relative to the $^5D_0$ emission so that the lifetime of the 5873.7Å line approaches the other four $^5D_0$ values.

The other possibility for the origin of this emission is that the 5823Å line is a $^5D_0 \rightarrow {}^7F_1$ transition which arises from a different Eu^{+3} symmetry site than the other five short-lived $^5D_0$ emissions. We feel that this is the case and the two symmetry sites are S_6 and C_2 mentioned earlier. The emission at 5823Å was not reported by Chang and Gruber, but the five short-lived

ones were and assigned to Eu^{+3} ions situated at C_2 sites. This is reasonable since a strong $^5D_0 \rightarrow {}^7F_2$ transition is possible in C_2 symmetry and the $^5D_0 \rightarrow {}^7F_1$ transition is split into the correct number of Stark components for this symmetry, namely three (4). This suggests that the 5823Å line is an S_6 emission and it will be shown below that this emission possesses all of the characteristics expected for a Eu^{+3} ion situated at an S_6 site.

In the first place, the 5823Å line occurs in the region of the $^5D_0 \rightarrow {}^7F_1$ transition which is the only $^5D_0$ emission allowed in S_6 symmetry. The long lifetime is expected since this transition is a pure magnetic dipole and consequently, has a low oscillator strength. However, the number of Stark components predicted by S_6 is two so that there should be another line in this region which has the same lifetime as the 5823Å line (4). This other Stark component was found but only after the phosphor was cooled to 78°K, where considerable narrowing of the emission spectrum occurs. Figure 3 shows part of the emission spectrum of Y_2O_3:Eu^{+3} 0.6% at room temperature and at 78°K with the two $^5D_0 \rightarrow {}^7F_1$ Stark components indicated by arrows. There is a few angstrom shift in the emission spectrum between room temperature and 78°K. Due to the low Eu^{+3} concentration several weak $^5D_1$ emissions are detected which can easily be indentified by their short lifetime. The lifetime of the two S_6 emissions was found to be identical and equal to 7.7 msec. The lifetime of the C_2 $^5D_0$ emissions at 78°K is about 1.0 msec., which is the same as the room temperature value. The magnitude of the $^5D_0 \rightarrow {}^7F_1$ Stark splitting in each symmetry site is about the same as seen from Table III, which lists the respective lines.

Since the degeneracy of the $^7F_1$ level is not completely removed, one of the S_6 emissions terminates at a doubly degenerate level. This is probably the 5822.3Å line since it is stronger than the 5924.5Å line including an estimated correction for the response of the phototube. We will return to this point.

Gd_2O_3, like all rare-earth oxides, can be made in the cubic C form (8). Therefore, the emission of Gd_2O_3:

Table III. $^5D_0 \rightarrow {}^7F_1$ Emissions, in angstroms, at 78°K

S_6	C_2
5822.3	5875.3
5924.5	5931.5
	5997.9

Eu^{+3} should be similar to Y_2O_3:Eu^{+3} and due to Eu^{+3} ions located at S_6 and C_2 symmetry sites. We have prepared Gd_2O_3:Eu^{+3} and found this to be so.

There is little doubt that the two long-lived emissions found in Y_2O_3:Eu^{+3} and Gd_2O_3:Eu^{+3} are due to S_6 Eu^{+3} ions because of their consistency with crystal field and oscillator strength predictions for the $^5D_0 \rightarrow {}^7F_1$ transition in that symmetry. The splitting of the $^5D_0 \rightarrow {}^7F_1$ transition into two Stark components by S_6 symmetry and its low oscillator strength also supports this assignment.

Excitation spectra.—Some further evidence for the S_6 Eu^{+3} emission in Y_2O_3:Eu^{+3} can be obtained by locating S_6 Eu^{+3} absorptions, which can be used to selectively excite it; two possibilities are the $^7F_0 \rightarrow {}^5D_1$ and $^7F_1 \rightarrow {}^5D_2$ magnetic dipole transitions. Since these two transitions are allowed in C_2 also, their absorption spectra will show lines due to both C_2 and S_6 Eu^{+3} ions. This is in agreement with the five absorption lines reported by Chang and Gruber for the $^7F_0 \rightarrow {}^5D_1$ transition, since this transition is expected to be split into two S_6 and three C_2 Stark components. Assignments of the absorption lines can be established by comparing the S_6 and C_2 Eu^{+3} excitation spectra and determining the preferential emission for each absorption line, since absorptions arising from a particular Eu^{+3} site will be expected to produce the emission of that site. Only the results of the $^7F_0 \rightarrow {}^5D_1$ excitation are reported below. Unfortunately, the absorption spectrum of the $^7F_1 \rightarrow {}^5D_2$ transition, which is composed of many lines, cannot be resolved to the same degree as the $^7F_0 \rightarrow {}^5D_1$ transition. This makes the C_2 and S_6 assignments difficult to establish, but further studies are planned including an analysis of the $^5D_2 \rightarrow {}^7F_1$ emission at low Eu^{+3} concentrations.

Figure 4 shows the absorption spectrum of Y_2O_3:Eu^{+3} 5% in the region of the $^7F_0 \rightarrow {}^5D_1$ absorption transition. This spectrum was taken on a single crystal with a Model 14R Cary absorption spectrophotometer. The five lines agree with those reported by Chang and Gruber. The C_2 and S_6 excitation spectra over the same region are shown in Fig. 5 a and b, respectively. The emission lines at 5823Å and 5873.7Å were used for the excitation spectra since these two lines can be completely isolated by the ¼ meter monochromator. It is seen from Fig. 4 and 5 that every line in the absorption spectrum gives rise to both S_6 and C_2 emission and further there are no lines in the excitation spectra that are not present in the absorption spectrum.

The fact that none of the absorption lines gives one or the other emission exclusively suggests that there may be energy transfer between the S_6 and C_2 Eu^{+3} ions. In some subsequent work, we have found that energy transfer does occur and can proceed in both directions ($C_2 \rightleftarrows S_6$) (9) so that an S_6 or C_2 absorption can produce S_6 and C_2 emission. Due in part to the long lifetime of the S_6 emission, the predominant transfer is $S_6 \rightarrow C_2$. It can be seen in Table II that the S_6 lifetime decreases with increasing Eu^{+3} concentration which is a consequence of the $S_6 \rightarrow C_2$ transfer.

Even though the excitation spectra are complicated by the energy transfer, the assignment of the five ab-

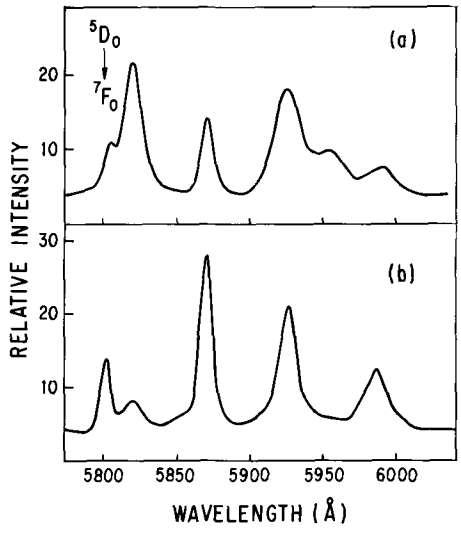

Fig. 6. Part of the emission spectrum of $Y_2O_3:Eu^{+3}$ 5%: (a) Group I excitation, (b) Group II excitation.

sorption lines can still be made. The five lines can be separated into two groups of two and three lines, which are listed in Table IV. The basis for the separation is that the intensity distribution of the lines within each group is constant and only the intensity ratio of Group I to Group II lines varies in each excitation spectrum. In related studies, we have found the latter to depend on Eu^{+3} concentration which is a consequence of the energy transfer dependence. The lines of each group act as a unit and, therefore, are interrelated. It is seen that compared to the lines of Group II, Group I lines are relatively stronger in the S_6 excitation spectrum; this means that this group preferentially excites the S_6 emission. Based on this fact we assign the two lines of Group I to S_6 Eu^{+3} ions and the three lines of Group II to C_2 Eu^{+3} ions. This assignment leads to the correct number of Stark components of the $^7F_0 \rightarrow {}^5D_1$ transition for each symmetry.

If there were no energy transfer, the C_2 and S_6 excitation spectra would only be composed of the Group II and Group I lines, respectively. Since the Group II lines (C_2) are weak in the S_6 excitation spectrum, one can conclude that there is very little $C_2 \rightarrow S_6$ energy transfer.

The above process can be reversed and the emission spectrum can be scanned while exciting at each of the five absorption lines. All five excitations were found to produce one or the other of two emission spectra, where the basic difference was the relative amount of C_2 to S_6 Eu^{+3} emission present. As expected, the two Group I excitations (S_6) yielded the emission spectrum with relatively more S_6 to C_2 Eu^{+3} emission than the three Group II (C_2) excitations. The Group I and Group II emission spectra are shown in Fig. 6a and b, with the respective S_6 and C_2 excitation wavelengths. In Fig. 6a, the S_6 emission at 5823Å is clear but the other one is obscured by the C_2 emission at 5935Å and its presence is detected by a shift toward the shorter wavelengths of the combined emission. By close examination of the two spectra in Fig. 6 the different contributions of the S_6 and C_2 Eu^{+3} emission can be noted and is in accord with the above.

A new feature in Fig. 6a is the presence of a weak emission at about 5959Å. This line is a S_6 Eu^{+3} emission, since it appears with S_6 excitation and also has been found to have a long lifetime. At 78°K this emission resolves into several lines, which indicates that it may be due to vibronic interactions of the S_6 Eu^{+3} $^5D_0 \rightarrow {}^7F_1$ transition.

As is the case with the $^7F_1$ level, the S_6 splitting of the $^5D_1$ level produces a singly and a doubly degenerate Stark level. Based on the relative intensity of the two S_6 absorptions, the more intense low energy absorption at 5262.0Å probably involves the doubly degenerate level. The opposite was found for the $^5D_0 \rightarrow {}^7F_1$ splitting where the high energy emission terminated at the doubly degenerate level. The intensity reversal of the $^5D_0 \rightarrow {}^7F_1$ emission and the $^7F_0 \rightarrow {}^5D_1$ absorption indicates the same type of splitting for the $^7F_1$ and $^5D_1$ levels where the doubly degenerate level is at a lower energy than the singly degenerate level. This is expected since both levels have the same total angular momentum quantum number ($J = 1$) and should, therefore, be split by the crystal field in the same way. A similar situation is found for the $^5D_1$ and $^7F_1$ splitting in $LaCl_3:Eu^{+3}$ (10). The reversal is due to the fact that in absorption the $^7F_0$ level is closer to the doubly degenerate level and in emission the $^5D_0$ level is closer to the singly degenerate level.

Assuming that the degeneracies of the $^7F_1$ and $^5D_1$ levels are properly assigned, the center of gravity of the $^5D_0 \rightarrow {}^7F_1$ and $^7F_0 \rightarrow {}^5D_1$ S_6 transitions can be calculated and compared to the corresponding C_2 transitions. It is found that the center of gravity of both S_6 transitions occurs at higher energies. Although the entire S_6 Eu^{+3} energy level diagram has not been obtained, this implies that the energy separation between the ^5D and ^7F states is greater when the Eu^{+3} is located at the S_6 site. We only mention this as an observation since a discussion of its origin is beyond the scope of this paper.

Growth and Characterization of $Ga_xIn_{1-x}Sb$ Solid Solutions Using Temperature-Gradient Zone Melting

Raymond W. Hamaker and William B. White[1]

Materials Research Laboratory, Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Temperature-gradient zone melting has been utilized to grow a wide range of solid solution compositions of $Ga_xIn_{1-x}Sb$ using indium and lead as zone metals. Single crystal growth was accomplished on {111} InSb seed substrates. Migration velocities as large as 12 x 10^{-7} cm/sec were observed during indium growth experiments, while velocities as large as 7 x 10^{-7} cm/sec were noted during lead growth experiments. All growth runs were performed with the top of the seed substrate at 420°C to provide a reference temperature for the migration experiments. Electron microprobe scans of sections taken along the growth direction have shown gradual increases in the concentration of GaSb in growth layers over the first 2 to 3 mm of solid solution growth. Thereafter, uniform compositional growth is indicated. Photomicrographs of growth surfaces have clearly indicated that growth proceeded by a two-dimensional nucleation mechanism. Etch pit observations taken along the growth direction have indicated noticeable decreases in the dislocation densities of the individual growth layers compared with those in the respective seed substrates.

Since temperature-gradient zone melting (TGZM) was first introduced by Pfann (1, 2) this technique has been utilized to grow both germanium and silicon (3-6) as well as various intermetallic compounds such as GaAs (7), GaP (8-10), SiC (11, 12), InAs (13), and InSb (14). Solid solution growth of $GaAs_yP_{1-y}$ (8-15), $Hg_xZn_{1-x}Te$ (15), and $ZnSe_yTe_{1-y}$ (16) have also been reported recently by various modifications of TGZM. In general, crystals ranging from several millimeters up to several centimeters in length have been grown by this technique.

Growth of solid solutions by any method is difficult and it is important that the resulting crystals be well characterized particularly with respect to compositional zoning. This paper attempts to make a careful examination of the growth of solid solutions by the traveling solvent modification of temperature gradient zone melting using $Ga_xIn_{1-x}Sb$ as a convenient example.

Single crystal layers up to 4 mm in thickness with cross sections of 0.7 x 0.7 cm have been grown using <111> seed orientations of InSb (*i.e.*, both "A" and "B" orientations) at a growth temperature of 420°C. Migration velocity measurements have been made during the growth experiments to determine the effect of changing solid solution composition on crystal growth rate. Chemical etching of growth surfaces has been employed to indicate the type of growth mechanism present. Particular attention was paid to compositional variations and zoning in the resultant growth layers as determined by electron microprobe analysis. Finally, etch pit examinations have been used to determine the relative changes in dislocation density between the individual seed and growth layers.

Experimental

Polycrystalline solid solution charge sections ranging from 3-4 mm in thickness were obtained from ingots (7-10 cm in length) grown at 2-4 mm/hr by a standard vertical Bridgman technique. Indium-rich starting compositions were used to minimize compositional gradients along the growth direction due to segregation during solidification. Single crystal seed sections of InSb were also obtained from Bridgman-grown ingots.

Slow growth rates in the range of 2-4 mm/hr were necessary in the case of solid solution ingots, since faster growth rates usually resulted in a two-phase separation as previously described by Ivanov-Omskii and Kolomiets (17). Such a separation was undesirable for sections that were to be used as charge layers in TGZM experiments, since nonuniform dissolution and unstable zone migration conditions were generally evident from such material. This phase separation was observed through x-ray powder pattern measurements performed on selected thin sections taken normal to the growth direction of an ingot. These measurements indicated either one or two sets of distinct reflection peaks as a function of angular position, which in turn indicated the presence of either one or two solid phases in the crystalline matrix. A Norelco Diffractometer Cu Kα radiation was used.

The uniformity of solid solution sections cut normal to the growth direction of an ingot was determined with an Applied Research Laboratories Electron Microprobe Analyzer. Microprobe beam scans across the individual sections indicated compositional variations in the range of several tenths of a mole per cent (m/o). Scans made along the growth direction indicated compositional variations in the range of 2 m/o over 4 mm of ingot length. The spot size of the scanning electron beam was 10 μm.

Both indium and lead were used as zone solvents in this series of migration experiments. The chemical preparation techniques for both the zone metals and the solids were described previously (14). In order to obtain uniform wetting of the zone metals with the individual solid sections, it was necessary to wet each

[1] Also associated with the Department of Geochemistry and Mineralogy.

layer of solid on a polished silica plate prior to the final assembly of the growth configurations. Subsequent electron microprobe scans have indicated no detectable amounts of silicon in the growth layers of the individual configurations after migration was completed (the limit of detection was about one part in 10^6). Attempts to wet both charge and seed layers together usually resulted in nonuniform wetting. This in turn caused irregular zone migration and unsatisfactory growth conditions.

The rate of zone migration in the individual growth configurations was determined by noting the average velocity of either interface during the first 2 mm of growth with the growth interface initially at 420°C. This was done since no temperature profile could be estimated accurately across either the zone or charge regions during a particular growth experiment because of the unavailability of thermal conductivity data for the two regions. This approximation was reasonable since no significant increases in migration velocity were observed over the limited temperature range for any of the zone configurations. During this series of growth experiments, temperature gradients across the InSb seed substrates ranged from 10° to 12°C/mm, as determined by two-position thermocouple measurements. At the onset of zone migration, the growth interface was not usually visible until ~ 0.2-0.4 mm of growth had occurred. This was due to considerable dissolution of InSb at the top of the seed substrate after the initial mating and wetting of the two specimen layers. Figure 1 shows a pictorial representation of this zone enlargement effect. Indium zones suffered more enlargement than did lead zones. No further changes in zone thickness were noted in any of the migration experiments included in this paper; however, in some experiments where nonuniform wetting had initially taken place, shape irregularities generally increased with zone motion. A telemicroscope assembly having a magnification of x20 and a vernier scale accuracy of 0.005 cm was employed to determine zone movement.

The growth chamber assembly that was used for this series of zone migration experiments has been described in a previous paper (14). Slight evaporation was present during the growth of the solid solutions; however, it was not severe enough to warrant either the use of internal gas pressures within the evacuated chamber or the use of sealed ampoules containing the growth configurations as described by Weinstein and Mlavsky (9).

Results and Discussion

The ten most successful zone migration experiments are listed in Table I. Thick zones were used to minimize interface kinetics effects and this has resulted in an essentially constant zone migration velocity over the entire traverse of the zone. The compositions listed in Table I are those of the polycrystalline feed material. The changing GaSb content of the feed has a pronounced effect on the zone migration velocity and this is shown in Fig. 2. At 10% GaSb concentration, the velocity is nearly halved.

Compositional variations in the growth layers of samples considered in Fig. 2 have been determined by

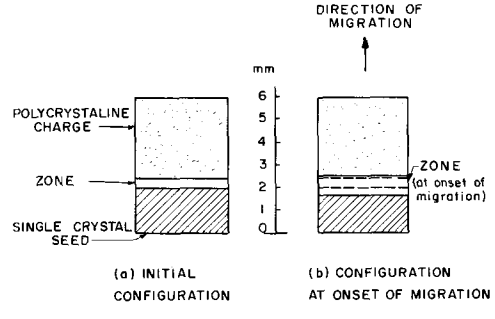

Fig. 1. Pictorial representation of (a) initial zone profile and (b) profile of zone at onset of migration.

Table I. Data for zone migration experiments

Growth run designation	Initial charge composition (X_{GaSb})	Zone thickness (l)	InSb seed orientation
In(1)	0.00	0.90 mm	<111>"A"
In(2)	0.06	0.85	<111>"A"
In(3)	0.27	0.85	<111>"A"
In(4)	0.33	0.90	<111>"B"
In(5)	0.54	0.95	<111>"B"
Pb(1)	0.00	0.90 mm	<111>"A"
Pb(2)	0.13	0.90 mm	<111>"B"
Pb(3)	0.30	0.95 mm	<111>"A"
Pb(4)	0.37	0.85 mm	<111>"B"
Pb(5)	0.47	0.90 mm	<111>"A"

an electron microprobe analysis. Figure 3 indicates the composition of the individual growth layers as a function of distance traversed along the growth direction for indium-rich zones. Figure 4 shows the composition of growth layers as a function of distance traversed along the growth directions for lead-rich zones. All scans were made on sections cut along the growth direction. In all cases, InSb-rich growth layers were evident at the onset of growth. After 2-3 mm of growth, solid solution concentrations became more uniform, indicating that steady-state conditions were approached. Since the indium zones were observed to dissolve more InSb at the onset of a migration run than were the lead zones, it is reasonable to expect that the initial growth layers for indium migration experiments would be more InSb-rich than would be those for lead zone experiments.

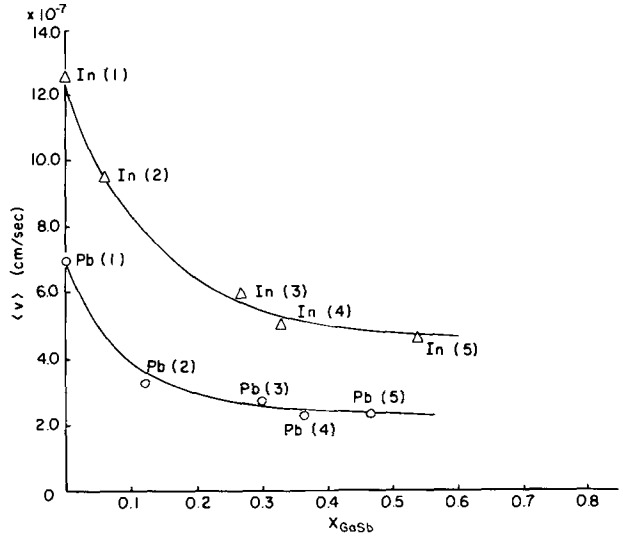

Fig. 2. Migration velocity dependence on solid solution composition in the charge layer for both indium and lead zone configurations.

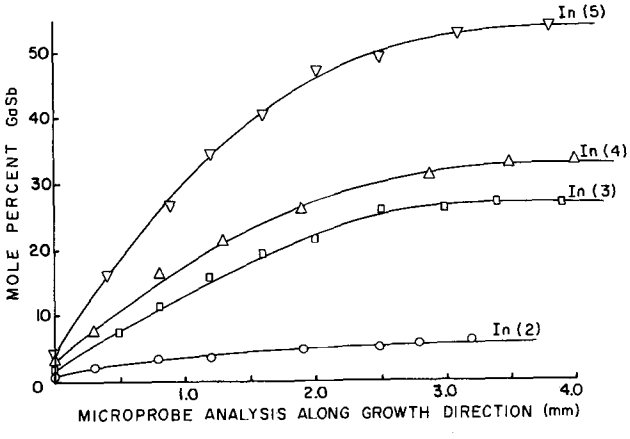

Fig. 3. Solid solution composition along the growth direction for indium zones.

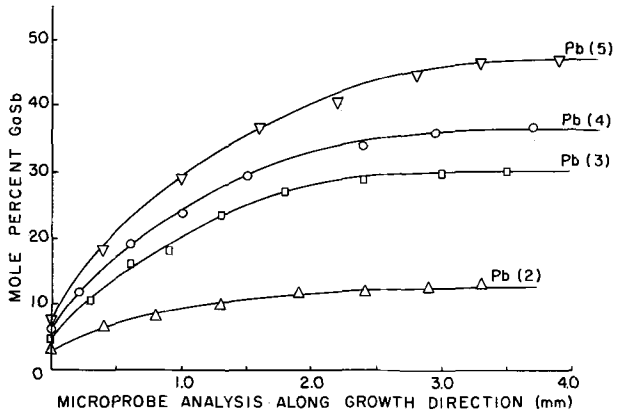

Fig. 4. Solid solution composition along the growth direction for lead zones.

Electron microprobe scans were also made to determine the lead content in the growth layers of solid solution crystals when lead was used as the zone solvent. No detectable amounts of lead were observed in any of the growth regions to a limit of detectability of about one part in 10^5.

Evidence for solid solution crystal growth by the two-dimensional nucleation mechanism has been obtained by etching the regrown region in dilute HCl, after migration of indium zones through the charge sections. Figure 5 shows faceted growth steps observed on an "A" face, while Fig. 6 shows those observed on a "B" face. These step features agree with those for faceted steps observed on pure InSb crystals that were grown under similar growth conditions (14), although the size of the growth steps are somewhat smaller on the solid solution surfaces.

Etch pit observations have been made on polished and chemically etched sections parallel to the growth directions of the individual specimens. Figure 7 shows a photomicrograph of the region bounding the initial growth interface separating the seed and growth regions after migration of an indium zone through a

solid solution charge layer. A noticeable decrease in etch pit density can be observed in the growth region after an initial layer of 20-40 μm of higher etch pit density growth. This initial region of higher etch pit density can be correlated with fine-structure from the electron microprobe scans, which has indicated a rapid change in solid solution composition over the first 25 μm of growth. Such changes in composition have been shown as abrupt in Fig. 3 and Fig. 4, since millimeter scales are used to describe the growth layer composition profiles. Similar etch pit density observations have been noted on growth layers when lead was used as the zone metal as shown in Fig. 8. After the initial region of abrupt compositional change, the etch pit concentrations in the individual growth layers usually decreased by about an order of magnitude. This also agrees with similar observations made on growth layers of pure InSb as shown in Fig. 9. Since a direct correlation of etch pit figures with emergent dislocations is not always present on an etched surface as discussed by Faust (18) and by Sagar and Faust (19) it can only be concluded that the effective dislocation density in a particular growth layer is somewhat less than that in a seed layer for either zone configuration. The most satisfactory etchant used to obtain distinct pit figures on the polished sections was found to be $4H_2O:2HNO_3:1HF$ (by volume). Similar observations of decreased etch pit concentrations in the growth layers of crystals grown by TGZM have been noted by Mlavsky and Weinstein (17), by Weinstein and Mlavsky (9), and by Weinstein *et al.* (20).

The rapid decrease in migration velocity with increasing values of X_{GaSb} for InSb rich solid solutions of (Ga, In)Sb can be reasonably explained by an increased sluggishness of the dissolution interface kinetics for both the indium and lead systems. Evidence of this in both systems has been observed in several migration experiments where the individual grain size in the charge sections was relatively large. In such instances, nonuniform dissolution generally occurred with one grain dissolving more rapidly than an adjacent grain. The growth data from these experiments were sporadic and have not been included in this

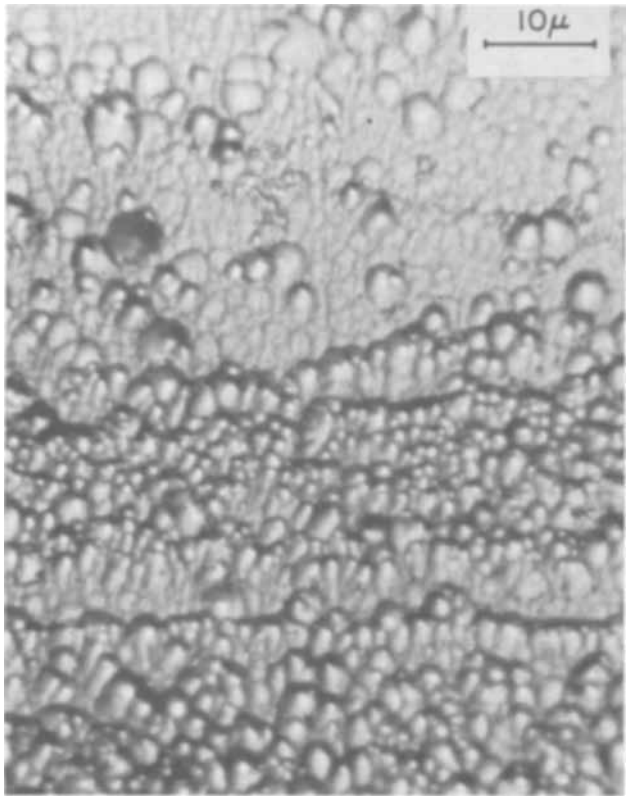

Fig. 8. Etch figures on a surface parallel to the growth direction for a Pb:$Ga_xIn_{1-x}Sb$ growth experiment.

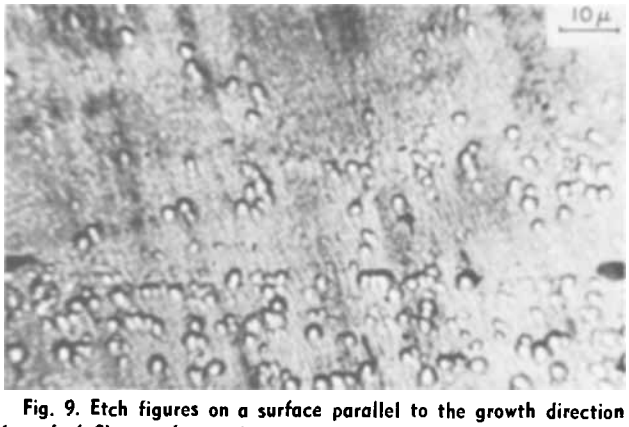

Fig. 9. Etch figures on a surface parallel to the growth direction for a In:InSb growth experiment.

paper. Trumbore *et al.* (21) have observed rapid decreases in the interatomic lattice spacing of InSb rich (Ga, In) Sb solid solutions with small increases in X_{GaSb}. Such decreases in the interatomic spacing could be expected to produce subsequent increases in the interatomic bond energy (*i.e.*, the lattice cohesive energy). An increase in bond energy would, in turn, imply a larger activation energy for the dissolution process as discussed by Jackson and Chalmers (22). Therefore, the rate of zone migration could be expected to decrease in these two systems with increasing X_{GaSb} if dissolution interface kinetics are the rate-controlling factor. Since there was no evidence of migration velocity decreasing during the first few millimeters of growth as successive growth layers were becoming more GaSb-rich, it would appear that atomic interface kinetics at the growth interface of individual growth configuration were rapid enough to allow their over-all effect on zone migration to be negligible.

Another factor that is important in determining the magnitude of the migration velocity in this series of experiments is the liquid diffusion transport term as discussed by Tiller (23) and by Seidensticker (6). Yost (24) has shown that the effective diffusion coefficient for mass transport across an alloy zone is dependent on both the activity of the diffusing substance in the particular solution as well as the viscosity of the liquid. Since no information is available concerning activities or viscosities for either ternary solvent system, no conclusive statement can be made about relative changes in the effective diffusion coefficient of (Ga, In)Sb alloys as a function X_{GaSb}. It is reasonable to conclude, however, that the relative difference in migration velocities between the indium and lead solvent systems could be attributed to differences in viscosity between the two liquids.

A qualitative description of interface conditions during a solid solution: indium:InSb migration experiment can best be explained in terms of the partly hypothetical liquids shown in Fig. 10. After a short transient period in which the solid and liquid compositions at the growth interface equilibrate, the growth interface will be at a temperature of 420°C, while the dissolution interface will be at a temperature of approximately 425°C. At the onset of growth, the liquid compositions at the respective interfaces are indicated by the square and round figures at 420° and 425°C. Equilibrium liquid compositions are considered; however, for sluggish interface kinetics, slight shifts of the square figures on the respective isotherms would be evident to denote nonsaturation conditions at the interfaces. The respective solid compositions are indicated by X_{DI} (dissolution interface) and X_{GI} (growth interface). The respective solid compositions will be denoted as the straight line intercepts on the solid solution binary diagram from the indium end of the Gibbs triangle through the individual points at which the respective liquids lie on the liquidus surface. Actually, these intercepts are tangents to the respective ternary fractionation curves as discussed by Masing (25) and Ricci (26). In the indium-rich region of the ternary diagram, it is reasonable to expect the fractionation curves to be straight lines; Hence a linear extrapolation can be made to indicate

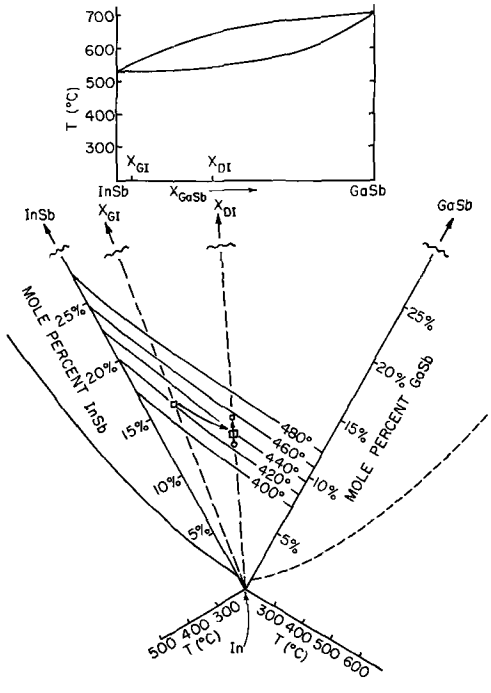

Fig. 10. Portion of a partly hypothetical ternary diagram with bounding binaries for the system In-InSb-GaSb. Since the binary In-GaSb is unknown, the ternary phase boundary connecting the binary eutectics has been omitted. The tie lines connecting the composition of the solid at the growth and dissolution interfaces terminate at different points on the ternary phase boundary and do not necessarily intersect the indium apex.

the general features of solid solution compositions at the respective interfaces during the growth period.

As zone migration progresses, the liquid compositions at the two interfaces change along the paths shown by the arrows. The solid composition at the dissolution interface will remain the same during this period, whereas the solid composition at the growth interface will change gradually until a value of X_{DI} is reached. At this time steady-state conditions have been attained within the zone. The respective interface positions are again indicated by the square and circular figures once both interfaces are in equilibrium (or near equilibrium) with the same composition of solid. Thereafter, both liquid compositions will change along the dotted line from In to X_{DI} with both interfaces being in equilibrium with a solid of composition X_{DI}. A rigorous analysis of this process for similar systems is discussed by Broder and Wolff (8).

Summary

Both indium and lead have provided satisfactory solvent metals for the growth of a wide range of solid solutions of $Ga_xIn_{1-x}Sb$ on InSb substrates. Although it was anticipated that steady-state conditions would occur rapidly within a moving zone, it appears that a region of at least 2-3 mm of growth must occur before steady-state solute conditions exist at the growth interface. This is understandable, since a considerable amount of dissolution initially takes place on an InSb seed prior to zone migration. By utilizing a less soluble seed material it is reasonable to expect that the initial region of nonuniform growth could be decreased considerably.

The growth mechanism operative in this series of TGZM experiments is two-dimensional nucleation. This has been determined by the appearance of faceted growth steps on the {111} surfaces. From the migration velocity dependence on X_{GaSb}, it would appear that dissolution interface kinetics become more sluggish as the GaSb concentration increases. This, in turn, would limit the rate at which solid solution crystals could be grown by this technique.

Noticeable decreases in etch pit density have been observed in the individual growth layers of solid solution crystals compared with those in the respective InSb seed regions, after initial growth regions of 20-40 μm. Since there is usually a high correspondence between the number of observed etch pit figures and emergent dislocations on a crystal surface after polishing and chemical etching, it is reasonable to attribute this observed decrease in etch pit density in the growth region of a solid solution-InSb configuration to a resultant decrease in dislocation density in that region compared with that in the seed region. The initial growth region of higher etch pit density has been attributed to the rapid change in solid solution composition over the first 25 μm of growth as determined by an electron microscope analysis. Such a change in composition could introduce considerable strain, resulting in a high dislocation density at the onset of growth.

Acknowledgments

The authors thank E. W. White, G. R. Zechman, and W. H. Zeigler for obtaining the electron microprobe scan data. The authors also thank J. W. Faust, Jr. for useful discussions concerning the analysis of etch pit observations. R. E. Wilson performed the cutting operations on the crystalline sections used in the TGZM experiments, and W. J. Connor assisted with the initial Bridgman growth work.

Illumination and the Photoengraving of Silicon

R. D. Wales*

Lockheed Palo Alto Research Laboratory, Palo Alto, California

ABSTRACT

Equations have been derived for the rate and depth of engraving of near-intrinsic and low-resistivity n-type semiconductor materials. Semiempirical relationships for n-type silicon have been developed from the derived equations. The low-resistivity material, probably due to the defect structure, etched in triangular pits. The high-resistivity material gave very good engravings with a resolution of better than 12μ. The good quality of the pattern and lens is critical in obtaining fine engravings, and the quality and degree of monochromaticity of the illumination affect the resolution and quality of the engraving.

The effects of illumination on semiconductors have been discussed, studied, and theoretical developments presented under conditions in which the semiconductor material itself is not greatly affected (1-7). Few studies have considered the effects of illumination when the semiconductor material is in contact and reacting with an electrolyte solution (2). It is known that illumination aids, or is necessary, for the etching or polishing of n-type semiconductor materials (7-10). The effect of illumination on the "electrode" potential has been examined (2, 3, 6), and several processing techniques and device applications utilize the effects of illumination to obtain desired results (10). Brattain and Bardeen (11) developed a theory for the surface photovoltage of semiconductors which was applied to semiconductor electrodes (6). The theory has been utilized and modified or expanded to fit particular problems. The effects of illumination have been discussed from a theoretical basis and applied to specific problems or effects (1, 2).

The effects of illumination intensity on the chemical engraving (etching) of n-type semiconductors have not been studied, other than to note the requirement for intense illumination. This paper is concerned with the effects of illumination on the rate of solution of an n-type semiconductor in an electrolyte solution, and with the application of the technique to the engraving of silicon.

Theoretical Considerations

Electrochemical studies of the dissolution of silicon have indicated that the electrochemical reaction is activation controlled, at least over a portion of the ranges studied (10). Thus, when the reaction is not at equilibrium, and the rate in one direction is much less than the rate in the other direction, the rate of the electrochemical reaction in terms of the current density, i, is

$$i = z\mathbf{F}C_0 \exp\left(-\frac{n\mathbf{F}E}{RT}\right) \qquad [1]$$

or, as more commonly represented (as the Tafel equation)

$$E = a + b \log i \qquad [2]$$

The symbols in the above equations have the usual meanings, and C_0 is the concentration of the reacting or rate controlling species.

The electrochemical dissolution of n-type silicon has been studied by Turner (10), Flynn (12), Efimov and Erusalimchik (13), and others. They have found that holes are consumed during the anodic dissolution, and that only holes generated in a region much smaller than the diffusion length for holes can take part in the dissolution reaction. Brattain and Garrett (5, 6), Uhlir (14), Gerisher (2), and others have found that illumination affects the anodic electrode potential, or the anodic current, in proportion to the number of holes produced by the illumination. Thus, the rate-controlling specie in the anodic dissolution of n-type silicon are the holes, p, and Eq. [1] can be written as

$$i = k'p \exp\left(-\frac{n\mathbf{F}E}{RT}\right) \qquad [3]$$

where k' is a proportionality constant.

Many of the chemical processes used for etching or engraving semiconductors are electrochemical processes in which the anodic and cathodic reactions occur simultaneously at the surface of the semiconductor. When an n-type semiconductor is engraved in an electrolyte solution in which the rate of reaction or removal of material is controlled by the concentration of holes in the semiconductor, the rate of reaction is represented by Eq. [3]. Since the rate of engraving, dx/dt (where x is the depth of the engraving), is proportional to the rate of removal of material, Eq. [3] can be written as

$$\frac{dx}{dt} = kp \exp\left(-\frac{n\mathbf{F}E}{RT}\right) \qquad [4]$$

The energy absorbed in the surface of the semiconductor by illumination with nonpenetrating radiation results in the generation of hole-electron pairs. If the illumination is fairly intense, and if the probability for thermal release of trapped holes is small, then the traps will be filled and the hole concentration will be affected by the rate of recombination of holes and trapped electrons, cn_tp, or cp^2, and by the hole current into the bulk of the semiconductor. Since no external electrical field has been used, the hole current into the bulk of the semiconductor is the diffusion current and a field-induced (or drift) current. The drift term is negligible in comparison to the diffusion term if the hole concentration during illumination is much less than the electron concentration (1). Thus, the rate of change of hole concentration is

$$\frac{dp(x)}{dt} = q(x) - cp(x)^2 - Dp\frac{\partial^2 p}{\partial x^2} \qquad [5]$$

where q is the rate of generation of hole-electron pairs due to the illumination and c is the recombination probability or rate constant. Furthermore, if it is assumed that the effects of diffusion can be neglected after the semiconductor has been illuminated for a short time, the rate of change of hole concentration in the semiconductor near the electrolyte surface is

$$\frac{dp}{dt} = q - cp^2 \qquad [6]$$

The concentration of holes, p_i produced by the illumination is, by integration of Eq. [6]

* Electrochemical Society Active Member.

$$p_i = \sqrt{\frac{q}{c}} \tanh \sqrt{cq}\, t \qquad [7]$$

If the recombination rate constant is large, steady state is attained rapidly and Eq. [6] (and [7]) reduce to

$$p_i = \sqrt{\frac{q}{c}} \qquad [8]$$

However, if the recombination rate constant is small, steady state is not attained rapidly and Eq. [7] reduces to

$$p_i = qt \qquad [9]$$

During illumination there is a change of potential due to the holes (electrons) produced (photopotential). This photopotential has been given as (2)

$$Vp_1 = \frac{RT}{n\mathbf{F}} \ln \left(1 + \frac{p_i}{p_o}\right) \qquad [10]$$

for n-type materials and, for p-type materials

$$Vp_2 = -\frac{RT}{n\mathbf{F}} \ln \left(1 + \frac{n_i}{n_o}\right) \qquad [11]$$

Assuming that, in a near intrinsic n-type material, the photopotential, Vp, is

$$Vp = Vp_1 + Vp_2 = \frac{RT}{n\mathbf{F}} \ln \frac{1 + \dfrac{p_i}{p_o}}{1 + \dfrac{n_i}{n_o}} \qquad [12]$$

then, since $p_i = n_i$, $p_i >> p_o$, and $p_o + p_i \rightarrow n_o + n_i$, the photovoltage in a near-intrinsic material is small or nearly constant and can be neglected. Thus, the rate of engraving a strongly n-type material is, by combining Eq. [4], [7], and [10], and setting $E = E_o + Vp$

$$\frac{dx}{dt} = \frac{k\sqrt{\dfrac{q}{c}} \tanh \sqrt{cq}\, t}{1 + \dfrac{\sqrt{\dfrac{q}{c}}}{p_o} \tanh \sqrt{cq}\, t} \exp\left(-\frac{n\mathbf{F}E_o}{RT}\right) \qquad [13]$$

If the rate constant for recombination is large, as is generally the case in highly doped materials, Eq. [13] is

$$\frac{dx}{dt} = \frac{k\sqrt{\dfrac{q}{c}} \exp\left(-\dfrac{n\mathbf{F}E_o}{RT}\right)}{1 + \dfrac{\sqrt{\dfrac{q}{c}}}{p_o}} \qquad [14]$$

The rate of engraving of a near-intrinsic n-type material is, by combining Eq. [4] and [7]

$$\frac{dx}{dt} = k\sqrt{\frac{q}{c}} \tanh \sqrt{cq}\, t \exp\left(-\frac{N\mathbf{F}E}{RT}\right) \qquad [15]$$

If the rate constant for recombination is small, as is generally the case in near-intrinsic materials, Eq. [16] may be written as

$$\frac{dx}{dt} = kqt \exp\left(-\frac{n\mathbf{F}E}{RT}\right) \qquad [16]$$

The depth of the engraving is obtained by integration of Eq. [13-16]. The depth of engraving for strongly n-type material is

$$x = \frac{k\sqrt{\dfrac{q}{c}} \exp\left(-\dfrac{n\mathbf{F}E_o}{RT}\right)}{1 + \dfrac{\sqrt{\dfrac{q}{c}}}{p_o}} (t - t_1) \qquad [17]$$

The depth of the engraving for near-intrinsic n-type material is

$$x = \tfrac{1}{2}\, kqt^2 \exp\left(-\frac{n\mathbf{F}E}{RT}\right) - C \qquad [18]$$

where C is an integration constant.

Many simplifying assumptions have been made which may detract from the theoretical significance of the results. The assumptions that the hole current due to diffusion can be neglected, and that the electron concentration need not be considered (other than in terms of the photopotential) in the near-intrinsic material are probably the most questionable assumptions. However, if these assumptions are not made, the solution becomes quite complex. Since the surface is continually moving, if the diffusion term is not neglected the concentration of holes is not only decreasing due to diffusion, but is also increasing due to the holes in the next increment of depth as a function of the concentration and diffusion from the last increment of depth. Thus the simplest assumption is that these effects tend to be equal, and the effect of diffusion neglected. Furthermore, several probable conditions have not been included, such as the possibility of a space-charge region in the semiconductor at the interface, and the approximately equal hole-electron concentrations in the near-intrinsic material. However, it is believed that the major contributors to the engraving rate have been included, and that the engraving process is described by Eq. [13-18].

The rate of generation of hole-electron pairs is a function of the incident light intensity, I, so that q may be represented as

$$k = \alpha I \qquad [19]$$

where α is a constant including the absorption efficiency. The engraving Eq. [14] and [17] for strongly n-type materials can thus be written as

$$\frac{dx}{dt} = \frac{K\sqrt{I} \exp\left(-\dfrac{n\mathbf{F}E_o}{RT}\right)}{1 + \sqrt{I}/I_o} \qquad [20]$$

and

$$x = \frac{k\sqrt{I} \exp\left(-\dfrac{n\mathbf{F}E_o}{RF}\right)}{1 + \sqrt{I}/I_o} (t - t_1) \qquad [21]$$

and the engraving Eq. [16] and [18] for near-intrinsic materials may be written as

$$\frac{dx}{dt} = K'It \exp\left(-\frac{n\mathbf{F}E}{RT}\right) \qquad [22]$$

and

$$x = \tfrac{1}{2}K'It^2 \exp\left(-\frac{n\mathbf{F}E}{RT}\right) - C \qquad [23]$$

where

$$K = k\sqrt{\frac{\alpha}{c}}$$

$$K' = k\alpha$$

$$I_o = p_o\sqrt{\frac{c}{\alpha}}$$

Experimental Technique

The semiconductor materials used in this study were n-type silicon of 190-225 ohm-cm and 0.5-1.5

ohm-cm resistivity oriented on the (100) and (111) planes, respectively. Before use the silicon was immersed in White etch ($1HF/3HNO_3$) for about 1 min to obtain a polished surface. The photoengraving was performed in Dash etch ($1HF/3HNO_3/10HA_3$).

The source of illumination was a General Electric 1000-w theatrical spotlight, and the patterns used were a solar critical focusing chart (Burke and James, Inc., Chicago, Illinois) and a mask with a 21-mm square opening.

The lens system consisted of an 8-in. diameter glass planoconvex lens with a focal length of 14 in. placed about ½ in. after the pattern and about 28 in. from the light source. Further reduction was obtained with either a Wollensak f 4.5 Enlarging Velostigmat 3½ in. focus or a Wollensak-Dumont CRD 75 mm f 1.9 Oscillo-Anastigmat No. C15413 lens.

The light intensity through the lens system to the silicon substrate was measured with a Spectra-Physics 4018 Power Meter. The engraving depth measurements and the pictures of the engraved surface characteristics were made with a Reichert Research Metallograph MeF No. 300/747.

The electrolyte solution was contained in a 2 in. square polystyrene box. The silicon was suspended in the solution in such a manner that the surface to be engraved was 4 mm from the side of the polystyrene box, perpendicular to and in line with the lens system.

The image of the square mask on the silicon averaged about 3.3 mm on a side and was measured to the nearest 0.1 mm on each sample. The precision of the depth measurements was about 5μ at the greater depths increasing to about 2μ at the smaller depths.

Results and Discussion

Illumination intensity and engraving time.—High-resistivity silicon.—The high-resistivity silicon should be near-intrinsic in its responses so that the experimental data should be described by Eq. [23]. Figure 1 indicates graphically the relationship between the engraving depth and the product of the illumination intensity and the square of the engraving time. This data indicates that the integration constant in Eq. [23] is independent of both illumination intensity and engraving time. Thus, the experimental data is described by the semiempirical equation

$$x = 8.05 \times 10^{-10} [It^2 - 2.00 \times 10^5] \qquad [24]$$

for any illumination intensity and/or any engraving time.

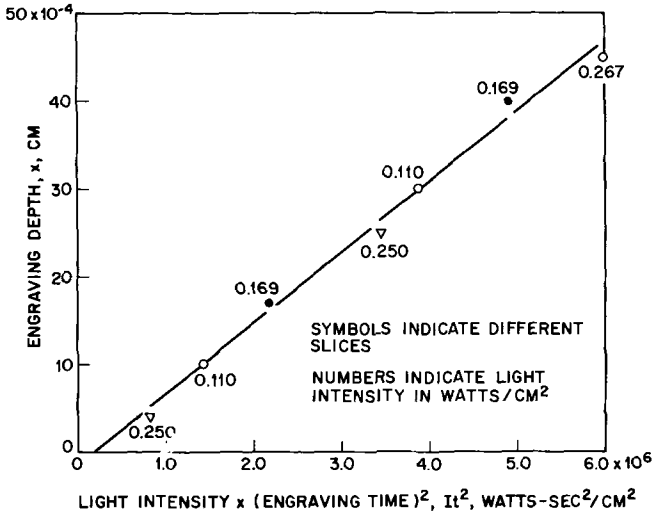

Fig. 1. Illumination intensity, engraving time, and engraving depth relationship for 190 to 225 ohm-cm n-type (100) oriented silicon at room temperature in Dash etch.

This result implies that a certain minimum hole concentration is necessary before engraving commences, the rate of engraving is a function of the concentration of holes (Eq. [16]), and the depth of the engraving is a function of the concentration of holes at the end of the engraving period times the duration of the engraving period. This latter statement implies that the depth of the engraving is independent of the "path" and the same result would be obtained by varying illumination intensity only, varying engraving time only, or varying both illumination intensity and engraving time. Thus Eq. [23] may be written as

$$x = \tfrac{1}{2}K' (It^2 - [It^2]_1) \exp \frac{n\mathbf{F}E}{RT} \qquad [25]$$

Low-resistivity silicon.—The low-resistivity silicon should have a higher concentration of electrons and a low concentration of holes with a high recombination rate constant. Thus, the experimental results obtained with this material should be described by Eq. [20] and [21]. Figure 2 indicates that the engraving depth is a linear function of the engraving time. Rearrangement of Eq. [20] gives

$$\frac{\Delta t}{\Delta x} = \frac{1}{\sqrt{I}K \exp \dfrac{n\mathbf{F}E}{RT}} + \frac{1}{I_0 K \exp \dfrac{n\mathbf{F}E}{RT}} \qquad [26]$$

Figure 3 indicates that the reciprocal of the slopes of the lines in Fig. 2 is a linear function of the reciprocal of the square root of the light intensity. Thus, Eq. [20] is of the correct form for the low resistivity silicon. These results give the semiempirical form of Eq. [21] as

$$x = \frac{5.518 \times 10^{-6} t\sqrt{I}}{1 + 2.649\sqrt{I}} - \frac{5.518 \times 10^{-6} t_1 \sqrt{I}}{1 + 2.649\sqrt{I}} \qquad [27]$$

The value of t_1 can be obtained from the difference between the experimental engraving depth and the depth calculated from the first term on the right side of Eq. [27]. This difference, δ, is described by the relationship

$$\delta = \frac{5.518 \times 10^{-6} t_1 \sqrt{I}}{1 + 2.649\sqrt{I}} \qquad [28]$$

or

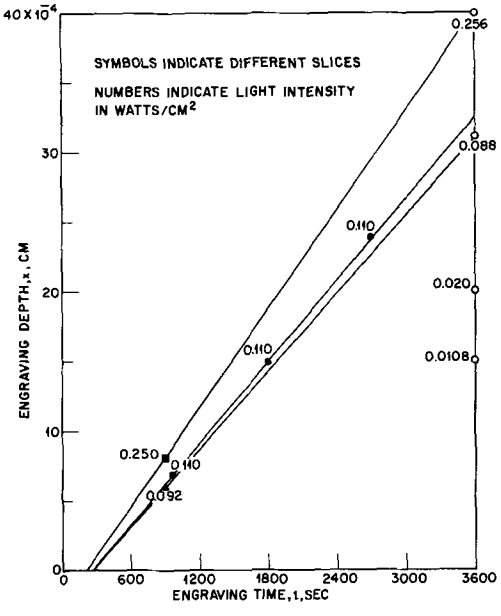

Fig. 2. Engraving time, engraving depth relationship for 0.5 to 1.5 ohm-cm n-type (111) oriented silicon at room temperature in Dash etch.

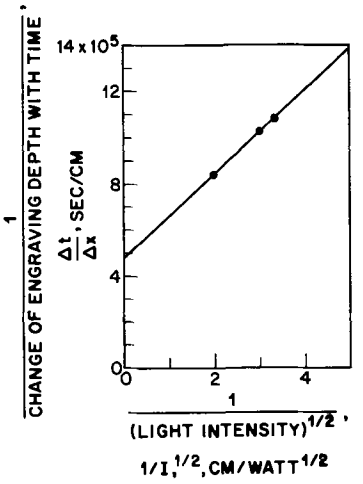

Fig. 3. Rate of engraving (from Fig. 2), illumination intensity relationship.

$$\frac{\delta(1 + 2.649\sqrt{I})}{5.518 \times 10^{-6}} = t_1\sqrt{I} \qquad [29]$$

A plot of the left side of Eq. [29] *vs.* $\sqrt{I}$ is shown in Fig. 4. The slope of the line in this figure gives a value of t_1 or 233 sec. Thus, the semiempirical equation for the low resistivity material is

$$x = \frac{5.518 \times 10^{-6} t\sqrt{I}\left(1 - \dfrac{233}{t}\right)}{1 + 2.649\sqrt{I}} \qquad [30]$$

The values of δ are of such a low magnitude that it is impossible to state conclusively that Eq. [28] is the correct relationship.

Verification of the argument.—Additional experiments utilizing a PEK Industries Model 911 100w mercury arc lamp with a Corning 1-69 infrared filter give results in agreement with the equations presented (Eq. [24] and [30]). The 0.5 to 1.5 ohm-cm material exposed for 1800 sec at 0.982 w/cm^2 was engraved to a depth of 24 x 10^{-4} cm, and when exposed for 8820 sec at 0.016 w/cm^2 was engraved to a depth of 45 x 10^{-4} cm. Calculation of the engraving depth using Eq. [30] gives 23.6 x 10^{-4} cm and 44.9 x 10^{-4} cm, respectively. The 190 to 225 ohm-cm material exposed for 1800 sec at 1.041 w/cm^2 was engraved to a depth of 27 x 10^{-4} cm, and when exposed for the same time at 1.700 w/cm^2 was engraved to a depth of 43 x 10^{-4} cm. Calculation of the engraving depth using Eq. [24] gives 25.6 x 10^{-4} cm and 42.7 x 10^{-4} cm, respectively.

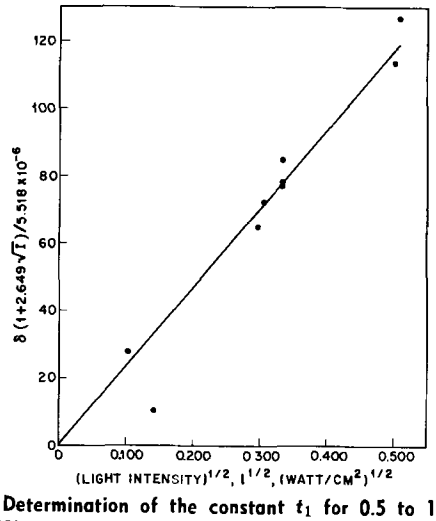

Fig. 4. Determination of the constant t_1 for 0.5 to 1.5 ohm-cm n-type (100) oriented silicon.

Experiments performed with the back of the 195 to 225 ohm-cm material exposed to the solution, with the back masked (with polystyrene film) and with part of the back of the illuminated area exposed to the solution have resulted in (respectively) little or no engraving, engraving as described in this work, and engraving depths equivalent to that in which the total incident illumination is concentrated in only the area for which the back of the sample is insulated from the solution. The 0.5 to 1.5 ohm-cm material was not affected in this manner.

While the effects of masking the back of the 195 to 225 ohm-cm material appear at first glance to be easily explained, such is not the case. Thus, if a space-charge region is developed at the back of the sample, *i.e.*, due to more rapid migration of electrons, it might be postulated that holes would still react at the illuminated surface while electrons react with the solution at the back surface. However, there is (little or) no dissolution of the material. Furthermore, the enhanced dissolution in front of the masked area due to illumination outside this area suggests that migration of holes is not only rapid, but preferentially directed toward the area in front of the mask, where reaction with the solution proceeds. A further complicating factor is that the dissolution reaction (or engraving) proceeds only in the illuminated area when the back is masked. While conclusive results have not been obtained, results suggest that dissolution is enhanced in front of the mask by illumination in unmasked areas in proportion to the illumination on the face opposite the masked surface.

Engraving properties.—The low-resistivity material was not useful for precise engravings. The triangular etch pattern indicated in Fig. 5 has been obtained by other workers (8, 10) and, although they did not indicate orientation, the preliminary treatment used in this work virtually eliminates the possibility that the effect is due to surface faults, although there is a good possibility that it is due to the defect structure (15). Discussions with sales representatives of companies producing material having zero-defect structure have indicated that such pits are not obtained on this material.

The high-resistivity silicon oriented in the (100) plane gives an etched surface as indicated in Fig. 6.

Fig. 5. Pattern obtained on 0.5 to 1.5 ohm-cm, (111) oriented n-type silicon during illumination-induced etching.

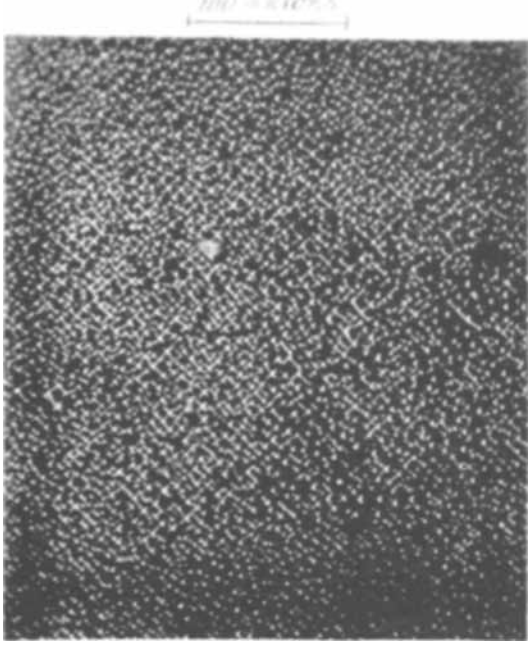

Fig. 6. Pattern obtained on 195 to 225 ohm-cm, (100) oriented, n-type silicon during illumination-induced etching.

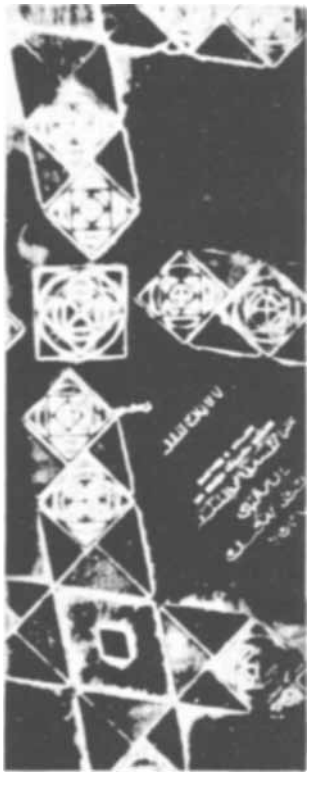

Fig. 7. Engraving obtained on 195 to 225 ohm-cm, (100) oriented, n-type material. The fine lines in the figure are 19-20μ in width on the sample.

This surface is quite good for engravings, the pits being one micron or less in cross-section. Figure 7 is a picture of an engraving in this material using the f 4.5 lens (the better lens). The reduction to the sample is 6.43, the total light intensity was 29 mw and the engraving time was 1 hr. Slightly more than one half the chart is on the sample. The fringe effect is indicated to be about 12μ. That is, there is slight etching indicated up to about 12μ from the light boundary. The only portions of the engraving which are not easily resolved are the portions of the chart consisting of five mil dots spaced five mils apart (black dots on clear area). However, there is a "cross" effect in these areas which is not present in other areas. This effect is probably due to diffraction and can thus be lessened or eliminated by use of a monochromatic light source. The five mil black and clear lines can be easily resolved. There is an over-all etch, but the depth of etch under the center of the black lines is about 4μ compared to about 30μ under the clear lines. On the sample these lines are each about 19-20μ in width. The total depth of the engraving is about 30μ.

The pattern (pictured in Fig. 7) was engraved at a reduction of 10.4 using the mercury arc lamp and infrared filter. The diffraction effect on the 5 mil dots was absent, and the dots were well defined.

Conclusions

The effect of light intensity on the engraving of semiconductors has been indicated. If the recombination rate constant is large, steady-state conditions are attained fairly rapidly and the engraving depth is a linear function of engraving time. If the recombination rate constant is small, the rate of engraving is a function of the instantaneous concentration of holes or the product of illumination intensity and engraving time, and the depth of the engraving is a function of the product of the illumination intensity and the square of the engraving time.

The engraved surface of the (111) material is not satisfactory for fine engravings. The surface consists of steps in a triangular pattern which are probably due to the defect structure of the crystal.

The engraved surface of the (100) material is satisfactory for fine engravings. The surface nonuniformities are 1μ or less. The illumination and lens system used in this study give engravings with a resolution of better than 12μ.

The type of illumination and the lens system become quite critical when fine engravings are desired. Some of the factors, including the more obvious ones, which probably affect the resolution of the engraving and the degree to which it reproduces the original are: (*i*) the pattern: the engraving can be no better than the pattern. (*ii*) The lens system: good lenses must be used to obtain sharp images with good resolution. The depth of field (or focus) of the lenses should be compatible with the depth of the engraving. (*iii*) The light and type of light: the use of monochromatic light of a particular wavelength greatly decreases the possibility of scatter and diffraction through the pattern and lens system, and through the cell wall and engraving solution. (*iv*) The cell window: the window material must not only be inert toward the engraving solution, but must also have good optical properties. (*v*) The diffusion length and other properties of the injected hole-electron pairs, and/or the resistivity of the material: this study indicates that high-resistivity (100) oriented material gives satisfactory results and zero defect structure material may also give satisfactory results. (*vi*) Material crystal form: polycrystalline or monocrystalline material, and the crystal orientation may affect the engraving rate and the type of surface obtained and the defect structure is probably quite important. (*vii*) Technique: the manipulative technique becomes quite critical in obtaining a high degree of resolution. A very stable system and critical means of focus and alignment is necessary.

The back surface of near-intrinsic material should probably be masked if the treatment presented is to be applicable. The study of the effects of masking is beyond the scope of this work, and no attempt has been made to suggest a cause of these effects.

NOMENCLATURE

a, b	Constants in the Tafel equation
c	Rate constant for recombination
C_o	Concentration of reacting species
C, t_1	Integration constants
Dp	Diffusion coefficient for holes
E	Total potential between bulk of semiconductor and bulk of electrolyte solution
E_o	Total potential E less the photopotential, Vp
$\mathbf{F}$	Faraday
i	Current density
I	Incident illumination intensity
I_o	Equal to $p_o\sqrt{\alpha/c}$
$[It^2]_1$	Equal to C
J	Hole current due to diffusion
k, k'	Constants
K	Equal to $k\sqrt{\alpha/c}$
K'	Equal to $k\alpha$
n	Number of equivalents
n_o	Number of free electrons in the bulk of the semiconductor
n_i	Number of electrons produced during illumination
n_t	Number of bound electrons
p	Number of free holes
p_o	Number of free holes in the bulk of the semiconductor
p_i	Number of holes produced during illumination
q	Rate of generation of hole-electron pairs by incident illumination
R	Gas constant
t	Time
T	Absolute temperature
Vp, Vp_1, Vp_2	Induced photopotential
x	Distance
α	Constant relating illumination intensity and rate of hole-electron pair generation
δ	Representation of second term in Eq. [21]

Electrical Properties of Zinc and Cadmium Ion Implanted Layers in Gallium Arsenide

R. G. Hunsperger and O. J. Marsh

Hughes Research Laboratories, Malibu, California

ABSTRACT

Ion implantation has been used to dope high resistivity, single crystal gallium arsenide with cadmium and zinc. Implants were made with 20 kv ions into heated substrates held at 400°C. Electrical characteristics of the implanted layers have been studied as a function of isothermal and isochronal annealing cycles. The surface resistivity, average mobility, and carrier concentration in the layer have been determined by Hall measurements; it has been observed that these electrical properties are dependent on post-implantation annealing and generally tend to improve significantly with annealing at relatively low temperatures for short times. For example, annealing of cadmium implanted samples at temperatures up to 800°C for less than 1 hr was sufficient to increase mobility from a value of 4 cm^2/v sec to approximately 180 cm^2/v sec, and to reduce sheet resistivity from approximately 8 x 10^4 ohm/□ to about 6 x 10^3 ohm/□. Additional annealing for 20 min at 900°C further reduced sheet resistivity to 300 ohm/cm and increased surface carrier concentration to a maximum of 2 x $10^{15}/□^2$. The increased carrier concentration eventually resulted in decreased mobility because of impurity scattering.

Ion implantation has been used to dope gallium arsenide with various elements, producing both n- and p-type layers; proton bombardment has been used to produce electrically isolating semi-insulating layers (1). Initial results have indicated that implantation is a promising method for producing doped regions in gallium arsenide at relatively low temperatures compared with those required for diffusion processes. In addition, ion implanted layers in semiconductors have been found to be more planar than diffused layers (2). Numerous ions have already been implanted in gallium arsenide to produce doped layers, and it is likely that many other ion species also can be used successfully, including some that do not lend themselves well to diffusion techniques. Zinc and tellurium implantations have been reported by Mayer *et al.* (3), and work on zinc implants has also been done by Roughan and Manchester (4). Cadmium implants into

GaAs have been made by Itoh (5), neodymium implants by Gibbons *et al.* (6), and sulfur by Kellet *et al.* (7). This paper describes the electrical characteristics of zinc and cadmium implanted layers in GaAs as a function of implantation parameters and subsequent annealing procedures.

Experimental

Implantations were made into undoped n-type gallium arsenide substrates with room temperature resistivities of 1 to 10 ohm-cm. Substrate wafers 15 mils thick were lapped and subsequently chemically polished to remove surface damage prior to ion implantation. These surfaces were oriented in the <111> direction (± 3°).

All implantations were performed with 20 kv ions. A heated stage was used to maintain the substrate at an elevated temperature (400°C for most samples) during implantation. An arc discharge ion source was used for these implants (8). The pulsed nature of this source makes it very difficult to measure ion current density. The implanted ion densities ranged from 10^{15} to $10^{16}/cm^2$ as determined by Rutherford scattering measurements (9). After implantation the samples were annealed at various temperatures up to 900°C. The annealing was performed in a nitrogen atmosphere, and for temperatures of 600°C or greater the samples were encapsulated in a film of SiO_2 to prevent decomposition of the GaAs and/or outdiffusion of the dopant atoms. The SiO_2 was deposited by decomposition of tetraethyl orthosilicate at 480°C. Below 600°C, extended annealing (24 hr) of the implanted samples showed no observable decomposition of the GaAs even without the protective SiO_2 film.

The electrical characteristics of the implanted layers (sheet resistivity ρ_S, effective surface carrier concentration N_S, and effective mobility μ) were determined using van der Pauw (10) Hall measurement technique. A "cloverleaf" shaped mesa was etched onto the samples to lessen the effect of contact size on the measurements. The junction between the p-type implanted layer and the n-type substrate provided the necessary electrical isolation of the implanted layer during measurement. All Hall measurements were made at room temperature, after the samples were quenched in air from their anneal temperature.

Results and Discussion

Figure 1 shows the change in sheet resistivity as a function of annealing for a sample implanted with approximately $10^{16}/cm^2$ 20 kv zinc ions, with the substrate held at 400°C. The implanted layer was initially p-type (after implantation-before annealing) with a sheet resistivity of approximately 4.5 x 10^4 ohm/□. Annealing at temperatures up to 600° caused the resistivity to decrease. (As one moves to the right on the diagram, each point represents an additional 10 min anneal at the indicated temperature.) Note that

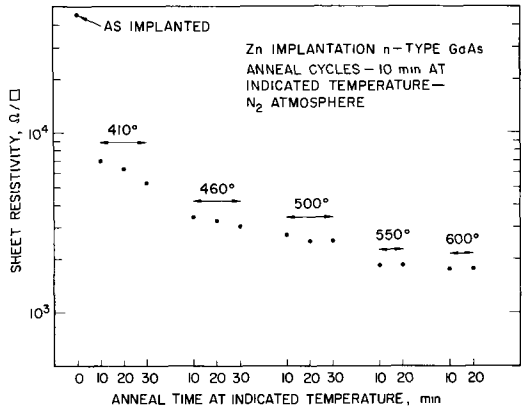

Fig. 1. Variation of sheet resistivity as a result of annealing zinc implanted GaAs.

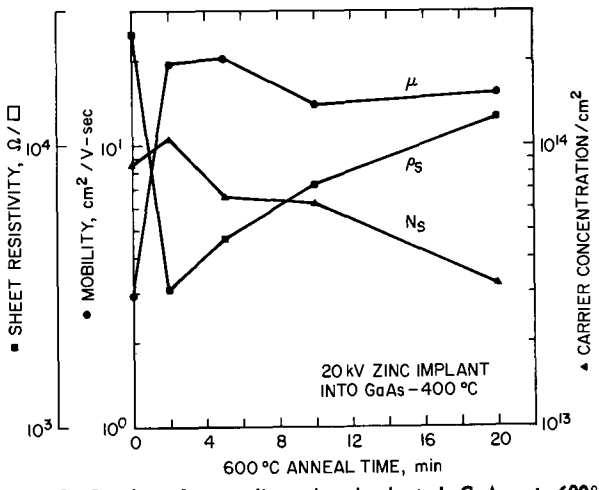

Fig. 2. Results of annealing zinc implanted GaAs at 600°C without surface protection.

most of the decrease in resistivity occurred early in the cycle at temperatures below 450°C. As will be shown later the decrease in resistivity results mainly from improved mobility as crystal damage caused by implantation is annealed away.

It has been found that care must be taken to protect the surface of the sample during anneal at 600°C and above, in order to prevent outdiffusion of the dopant atoms. Outdiffusion of zinc atoms from implanted GaAs has been observed when the surface was not protected during annealing. An example of this effect is shown in Fig. 2, where data are given for a sample annealed at 600°C with no protective covering on the surface. In the first 2 min of the anneal, mobility increased greatly and surface resistivity decreased. After further annealing the sheet resistivity began to increase, while surface carrier concentrations decreased and mobility remained relatively constant. No dissociation of the GaAs was observed when the surface of the sample was viewed under 200X magnification, thus it is felt that the increased sheet resistivity cannot be attributed to dissociation. Instead, it appears to result from outdiffusion of the implanted zinc. The results of an experiment to verify this conclusion are shown in Fig. 3. A sample similar to that of Fig. 2 was annealed at 600°C, but it was covered during the first 10 min by a polished, nonimplanted wafer of GaAs of the same type as the substrate. This cover wafer retarded outdiffusion by reducing the concentration gradient at the surface and thus very little degradation of electrical characteristics was observed. When the cover was removed after 10 min, ρ_S began to increase and N_S began to decrease at rates similar to those observed for the other uncovered sample in Fig. 2. Subsequent

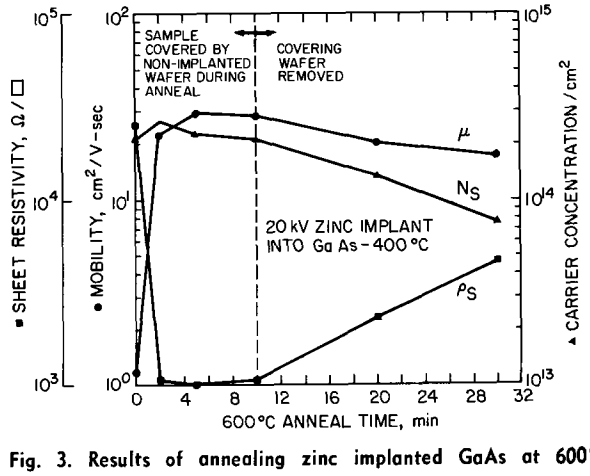

Fig. 3. Results of annealing zinc implanted GaAs at 600°C with surface protection.

to the anneal cycle of Fig. 3 the sample was annealed at 700°C for a total of 30 min without surface protection. This annealing resulted in an increase in ρ_S to 1.04 x 10^4 ohm/□, an increase in μ to 206 cm^2/v-sec, and a decrease in N_S to 2.92 x $10^{12}/cm^2$. Additional evidence of outdiffusion was given by the fact that the cover wafer (although unimplanted n-type material) was found after the anneal to have a p-type layer at the surface which had contacted the implanted layer. A similar effect has been observed for tin implants in GaAs but not for cadmium implants, presumably because tin and zinc diffuse much more rapidly in GaAs than does cadmium. The data of Fig. 2 and 3 emphasize the importance of providing some type of protective covering for ion implanted GaAs during annealing. Such protection can be provided by using a cover wafer or by encapsulating the sample in SiO_2. Both techniques are also effective in preventing the dissociation of GaAs, at least at temperatures up to 900°C.

The use of SiO_2 protective covering allowed the anneal behavior of implanted layers to be studied at elevated temperatures. Figure 4 shows the effect on a typical 20 kv zinc implanted sample of annealing in a series of 10 min anneals from 500° to 900°C. The sample was implanted at 400°C. The sheet resistivity decreased monotonically as a result of increasing mobility, and above 700°C also as a result of increasing carrier concentration. In the temperature range below 700°C the surface carrier concentration first increased and then decreased somewhat with further annealing. The increase is thought to be caused by implanted ions moving to electrically active substitutional positions in the lattice; the decrease is not well understood at present and may be attributed to a number of possible causes. The decrease may result from compensation by defect centers which are released when damage clusters dissociate on annealing. An effect of this type in n-type GaAs has been reported by Fuller, Wolfstern, and Allison (11). The apparent decrease in effective surface carrier concentration may also result merely because the mobility in implanted layers is nonuniform with depth, and the calculation of surface concentration from van der Pauw Hall data is more dependent on the contribution from higher mobility regions. Therefore, even if we assume hypothetically that the concentration profile of electrically active atoms does not change significantly between 500° and 700°C but that the mobility in the more lightly doped regions increases appreciably, the effective mobility in the layer would increase and cause an apparent decrease in the surface concentration N_S. [This effect has been described by Mayer *et al.* (12).]

The relatively large increase in carrier concentration above 700°C results in part from the increased solubility of zinc [7 x $10^{19}/cm^3$ at 700°C to 3 x $10^{20}/cm^3$ at 900°C (13)], in addition to the fact that the doped layer thickens with annealing because of the very rapid diffusion of zinc in GaAs. For an anneal cycle such as that of Fig. 4, calculations based on the work of Shih *et al.* (14) predict a total diffusion depth of as much as 90μ, depending on the initial concentration *vs.* depth profile of the implanted ions. Assuming that there are enough implanted atoms present that the concentration of electrically active (substitutional) zinc per cubic centimeter is constant or increasing with increased solubility, the thickening of the layer because of diffusion would result in a higher measured value for surface concentration per square centimeter.

For a series of isothermal anneals of zinc implanted GaAs, as shown for a typical 20 kv, 400°C implant in Fig. 5, the variation of ρ_S, μ, and N_S with anneal temperature agreed with that observed in the series of 10 min anneals of Fig. 4. In addition, it can be seen from the data of Fig. 5 that much of the change in electrical properties (at temperature up to 700°C) occurred during the first few minutes of each cycle at a new, higher temperature. Mobility increased to a value of about 150 cm^2/v-sec following anneal at 900°C. This behavior is in contrast to that of cadmium implanted samples as shown in Fig. 6 and 7, in that the mobility in the cadmium case peaked after annealing at 800°C and then decreased with further annealing. This difference between the mobility behavior for zinc implants and that for cadmium is believed to result because cadmium diffuses three orders of magnitude more slowly than zinc in GaAs (14, 15). Angle lap and stain techniques on the cadmium implanted samples indicated a junction depth of 0.3μ after the 600°C annealing and showed negligible diffusion after the 900°C anneal (to within the accuracy of measurement of 0.05μ). The junction depth of 0.3μ is considerably greater than the 250Å depth expected from the theoretical Lindhard-Scharff projected range of the ions in amorphous material. It is possible that the larger junction depth is due to channeling and/or enhanced diffusion of the ions during implantation. As more cadmium atoms enter substitutional sites (and become electrically active) as a result of increasing solubility at higher temperature, the doped layer does not thicken as in the case of zinc. Hence the concentration of electrically active cadmium atoms per cubic centimeter increases, and ionized impurity scattering tends to decrease the mobility. A comparison of the observed decrease in mobility with the Brooks-Herring (16, 17) relation for ionized impurity scattering, as-

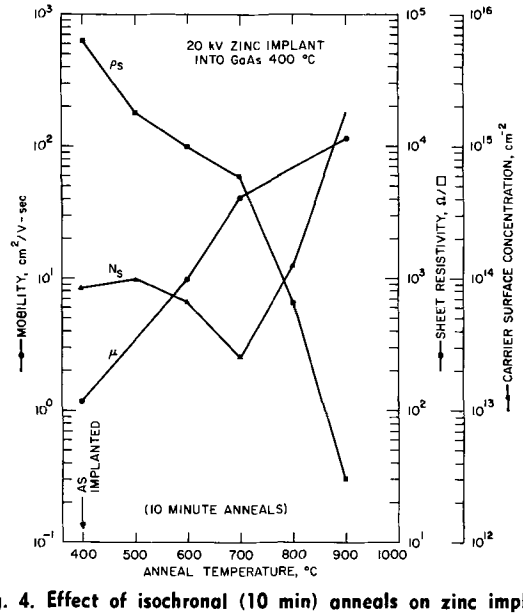

Fig. 4. Effect of isochronal (10 min) anneals on zinc implanted GaAs.

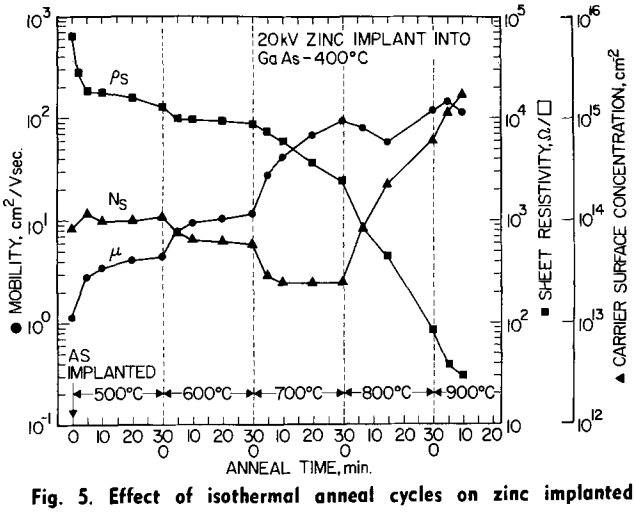

Fig. 5. Effect of isothermal anneal cycles on zinc implanted GaAs.

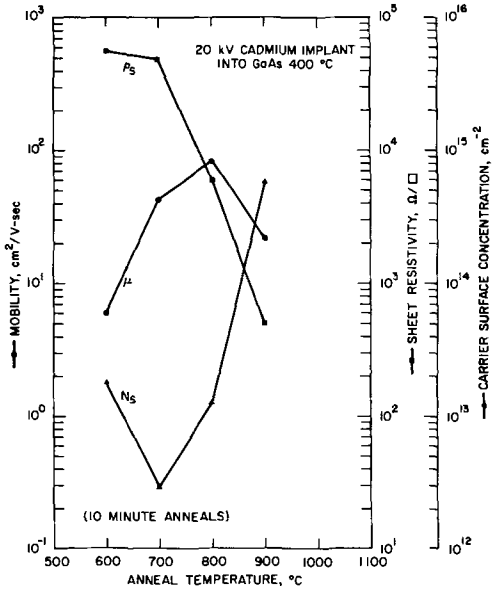

Fig. 6. Effect of isochronal (10 min) anneals on cadmium implanted GaAs.

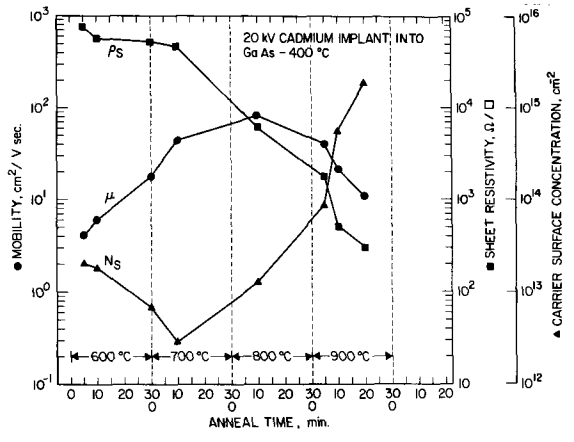

Fig. 7. Effect of isothermal anneal cycles on cadmium implanted GaAs.

suming a lattice mobility of 450 cm²/v-sec (18), shows that the observed mobility decreased somewhat more slowly than would be expected with increasing ion impurity concentration (see Fig. 8). This may result from the competing process of damage annealing, which reduces defect scattering. It can also be seen in Fig. 8 that the mobility remains below the value expected for only ionized impurity scattering until annealing at 900°C for 20 min has been performed. This indicates the presence of lattice damage and resultant defect scattering. Such persistent damage is typical only for the extremely heavy implants (10^{15} to 10^{16} ions/cm²) used in these experiments. The damage produced by smaller doses anneals at temperatures below 600°C (9).

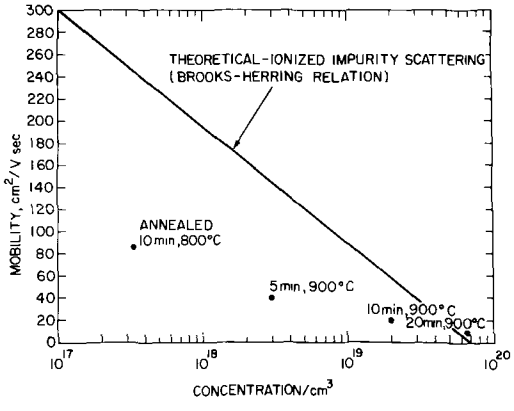

Fig. 8. Variation of mobility with ionized impurity concentration [theoretical curve (16) assumes a hole lattice mobility of 450 cm²/v-sec (18)]. Concentrations were calculated using an implanted layer thickness of 0.3μ obtained from angle section and stain junction depth measurements.

With the exception of mobility, the electrical properties of cadmium implanted samples changed with annealing in a fashion similar to those of zinc implants. The surface carrier concentration increased above 700°C as it did for zinc. For cadmium this increase presumably results almost entirely from the increase in solubility, since negligible diffusion was observed. Another difference between cadmium and zinc implants was that cadmium samples generally had to be annealed to higher temperatures to achieve equivalent values for sheet resistivity and mobility. No measurable p-type layers were obtained in cadmium implanted samples until after anneal at 600°C.

Summary

Ions of both zinc and cadmium can be implanted into GaAs to form p-type layers. The electrical properties of the layers are dependent on post-implantation annealing and generally tend to improve significantly with annealing at relatively low temperatures for short times. The fact that electrical properties continue to change even after considerable annealing is consistent with the results of Rutherford scattering measurements (9), which indicate that for heavily zinc implanted GaAs (dose $\geq 10^{16}$/cm²) considerable damage remains even after annealing at 600°C. For implanted doses $< 10^{16}$/cm² most damage anneals away below 600°C. It also must be remembered that in the case of zinc implants considerable diffusion occurs above 700°C and that this diffusion can affect the electrical properties of the layers. Decomposition of the GaAs and outdiffusion of the implanted atoms during annealing can be limited to an insignificant level by providing a suitable protective covering for the surface of the sample.

The Preparation and Properties of Vapor-Deposited Epitaxial $InAs_{1-x}P_x$ Using Arsine and Phosphine

J. J. Tietjen, H. P. Maruska, and R. B. Clough

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Single crystalline $InAs_{1-x}P_x$ layers have been prepared by a vapor-phase growth technique previously used to prepare very high-quality $GaAs_{1-x}P_x$. These $InAs_{1-x}P_x$ alloys exhibit electron mobilities equivalent to the highest yet reported for this system. Extensive electron mobility data is reported for the alloys at 77°K. At this temperature, a mobility value of 120,000 cm^2/v-sec was measured for InAs, which is slightly higher than previously reported. Vegard's law is obeyed over the entire composition range. Both n- and p-type doping has been achieved during vapor growth to provide a broad range of electrical resistivities and p-n junctions.

$InAs_{1-x}P_x$ alloys have a broad range of band gaps and electron mobilities. Consequently, they have potential advantage for a number of device applications. These include infrared emitting (1) and detecting devices, utilizing their low energy band gaps, and devices operating at high frequencies, which can take advantage of their high mobilities. Although results (2-5) have been reported pertaining to improving the preparation and properties of melt-grown crystals, very little work has involved the vapor-phase growth of these alloys.

Recently, a vapor phase growth method (6) has been described for the growth of $GaAs_{1-x}P_x$ alloys, and the high purity, homogeneity, and crystalline perfection of the crystals prepared by this technique has been demonstrated. With this growth method, Ga is transported as its subchloride via a reaction with HCl gas, and AsH_3 and PH_3 serve as the sources of the group V elements. As a logical extension of this growth technique, a simple substitution of In for the Ga has permitted the preparation of $InAs_{1-x}P_x$ single crystals having very good electrical properties and crystallinity. In addition, both n- and p-type doping has been achieved, and multilayer structures have been prepared.

Experimental

Apparatus and materials.—The apparatus, shown schematically in Fig. 1, is essentially identical to that described previously (6) with the exception that the source Ga is replaced by In. It consists principally of a straight tube through which the pertinent vapors pass. A large bore stopcock separates the growth region from a forechamber which may be purged independently to facilitate insertion and withdrawal of the specimens without contaminating the system. HCl gas, AsH_3, PH_3, and H_2Se (which serves as the n-type dopant source) are all monitored into the apparatus by precision valves and flowmeters. P-type doping is achieved by vaporizing metallic Zn in a heated sidearm and transporting the vapors into the deposition zone with H_2 carrier gas.

With the exception of the use of In,[1] and <100>-oriented InAs single crystalline substrates,[2] the materials employed in this study are as described previously (6). The InAs substrates were mechanically polished to a flat, mirror-smooth finish, and then chemically polished in a solution of 2% by volume of bromine in methanol. Typical substrate dimensions were about 2 cm^2 in area and 0.5 mm thick.

Procedure.—The growth procedure also closely follows that described previously (6). Freshly etched substrates are inserted in the growth chamber and heated in hydrogen at a rate of about 20°C/min. When the substrate temperature reaches 600°C, the AsH_3 flow is started in order to provide an arsenic atmosphere to stabilize the substrate surface. When the final operating temperatures are reached, the HCl flow over the In is started and the epitaxial deposition of InAs occurs. The flow of PH_3 is then initiated and slowly increased to produce a final gas phase mixture of AsH_3 and PH_3 appropriate to the desired alloy composition. The dependence of the alloy composition on the concentration of PH_3 in the AsH_3-PH_3 mixture is presented in Fig. 2. By slowly increasing the PH_3 flow, a region is introduced which is graded in composition from InAs at the substrate to the selected alloy composition. This graded region, which has been as thick as 50μ for phosphorus-rich alloys, is included to minimize strain arising from

differences between the lattice constants of the substrate and the final alloy layer.

The sum of the flow rates of pure AsH_3 and PH_3 are in the range of 20-60 cm³/min. The HCl flow rate is about 5 cm³/min, and between 1 and 2 l/min of hydrogen is used as a carrier. With these flow rates, with a substrate temperature in the range of 675°-725°C, a center zone temperature of 950°-975°C, and an indium zone temperature of between 850° and 950°C, growth rates in the range of ¼ to ½ μ/min are obtained under steady-state conditions. Typical thicknesses for the constant composition region of these deposits have been between 50 and 150μ.

Results and Discussion

Crystallinity and growth morphology.—X-ray analysis by the Debye-Scherrer technique indicates that these layers are single phase, cubic, solid solutions, and show no detectable range of composition. In addition, Laue back-reflection analysis reveals that the layers are epitaxial. The lattice constant is presented as a function of alloy composition in Fig. 3, which demonstrates that Vegard's law of solid solutions is obeyed in this system. This result is in general agreement with those of Folberth (2), and Koster and Ulrich (7). The compositions were determined by chemical analysis (8) with an accuracy of ± 0.5%.

Although no detailed evaluation of the crystalline perfection of these layers was carried out, examination by optical microscopy revealed that macroscopic surface imperfections, such as hillocks, were prevalent only in phosphorus-rich alloys. For alloys containing less than 50% InP, surfaces are obtained which show virtually no gross structure, and to the unaided eye appear to be mirror-smooth.

Electrical properties.—The epitaxial layers were examined by Hall coefficient and resistivity measurements using a technique (6) which permits these measurements to be made on layers as thin as 50μ. Typical electron carrier concentrations for undoped alloys are in the range of 5 x 10^{15} to 1 x 10^{16}/cm³. The electron mobilities are presented as a function of alloy composition in Fig. 4 and 5 for room temperature and 77°K, respectively. The data of other workers (3, 5, 9-11), and the results of a theoretical analysis of Ehrenreich (12) based on polar scattering alone, are included for comparison. In general, the mobility values at room temperature are good. In addition, these data corroborate Ehrenreich's contention that alloy scattering is not dominant in this alloy system, at room temperature. The relatively low mobility values obtained for alloy compositions approaching InP are attributed to strain arising from lattice and thermal-expansion differences between the InAs substrate and the alloy layer. It is anticipated that further compositional grading can alleviate this problem.

The data presented in Fig. 5 are the most extensive data reported for 77°K for this alloy system and compare favorably with the best previously reported mobility values. The mobility value of 120,000 cm²/v-sec for InAs is to be compared to the best previously reported value of 112,000 cm²/v-sec (9). However, the value of 18,000 cm²/v-sec for InP is somewhat lower than the best reported value of 23,400 cm²/v-sec (10).

Doping.—Doping of InAs has been investigated using H_2Se gas as a source of Se for n-type doping, and zinc for p-type doping. Electron concentrations as high as 3 x 10^{19}/cm³ were achieved and in general these crystals exhibit mobilities comparable to the best reported in the literature for untreated samples (11, 13). For example, at carrier concentrations of 1 x 10^{18} and 3 x 10^{19}

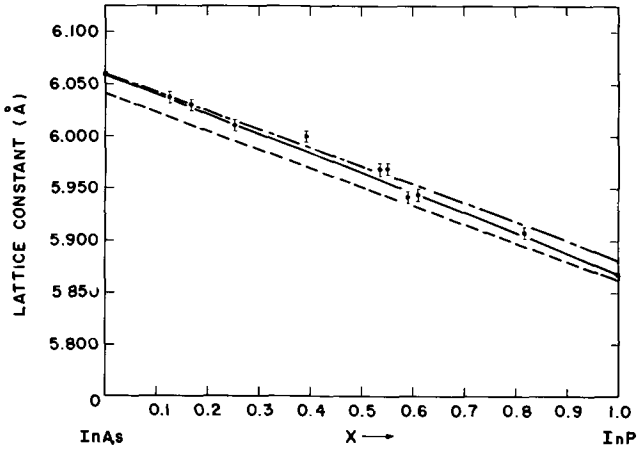

Fig. 3. Dependence of lattice constant on alloy composition in the system $InAs_{1-x}P_x$. The dependence observed by Folberth (2) and Koster and Ulrich (7) is also included: - - - Folberth; — · — Koster and Ulrich; ——— this paper.

cm^{-3} the mobility values at room temperatures are 10,000 and 1,500 cm^2/v-sec, respectively. Thus, doping to these high donor concentrations does not degrade the material. With respect to hole concentrations, values in the range of 5 x 10^{17} to 1 x $10^{19}/cm^3$ can be readily obtained, with mobilities of between 150 and 90 cm^2/v-sec for this doping range. These compare with earlier reported values as high as 120 cm^2/v-sec for hole concentrations of about 2 x $10^{19}/cm^3$ (11).

Both n- and p-type doping were also demonstrated for some $InAs_{1-x}P_x$ alloys, and for InP, as characterized by point-contact breakdown and thermal probe measurements. In addition, multilayer structures involving both n- and p-type regions were prepared for selected alloy compositions.

Conclusions

The ability to prepare good-quality $InAs_{1-x}P_x$ alloys by a vapor-growth method previously used for the preparation of $GaAs_{1-x}P_x$ alloys has been demonstrated. Electron mobilities have been obtained for these $InAs_{1-x}P_x$ alloys which are comparable to the best previously reported values for melt-grown material. Both n- and p-type doping can be achieved over a broad resistivity range, and these doped layers can be incorporated in multilayer structures. Vegard's law of solid solutions was found to be obeyed in this alloy system.

Acknowledgments

The authors wish to express their appreciation to D. Richman for valuable suggestions and discussions, and to R. Paff for performing the x-ray analysis. The research reported in this paper was sponsored by the National Aeronautics and Space Administration, Electronics Research Center, under Contract No. NAS 12-538.

Oxygen Doping of Solution-Grown GaP

L. M. Foster and J. Scardefield

IBM Research Division, Yorktown Heights, New York

ABSTRACT

The solubility of oxygen in Zn-doped, solution-grown GaP was determined from the degree of compensation of the Zn by the oxygen electrons. An oxygen content of 7 x 10^{16} cm^{-3} was obtained for crystals grown at 1144°C from Ga-GaP melts that were doped with 0.016 m/o (mole per cent) Ga_2O_3. The solubility of Ga_2O_3 in Ga as a function of temperature was also determined, and a distribution coefficient for oxygen between the solid and liquid of 0.0055 was derived. The implications of these findings for the generation of red luminescence in GaP are discussed.

Visible luminescence of high efficiency can be achieved in GaP that is doped with Zn and oxygen (1-3). Emission is attributed in part to recombination of an electron bound to a neutral Zn-O complex with a hole on a distant Zn acceptor (4), and in part to an exciton bound to a Zn-O nearest neighbor pair (4, 5). At room temperature this emission is centered at about 7000Å. In addition, there is an infrared band that can be resolved at low temperatures into a spectrum characteristic of ordinary pair emission between Zn and O on distant, randomly spaced sites (6). In the last case the oxygen behaves as an isolated, very deep donor at about 0.9 ev below the conduction edge. For the nearest neighbor case, the donor energy is reduced by coulomb interaction to about 0.4 ev.

Zinc is a fairly shallow acceptor in GaP and has been reported at 0.03 ev (7) and, more recently, at about 0.06 ev (8, 9) above the valence band.

Studies of this luminescence in GaP have almost all employed GaP crystals that were obtained by precipitation from dilute Ga-GaP solutions. To a large extent this has been a matter of convenience. How-

ever, it should be noted that attempts to obtain efficient red-emitting GaP from vapor or bulk growth processes have thus far been unsuccessful.

Little was known about the oxygen content of GaP because of the analytical problems attending its detection and measurement. The present investigation is concerned with the determination of oxygen from its electrical behavior in solution-grown GaP crystals that are co-doped with Zn. For this determination it is assumed that oxygen acts as a singly ionized donor and in p-type material compensates one Zn acceptor for each oxygen atom present. The oxygen content of a crystal can be deduced, therefore, from the reduction in hole concentration that is effected by oxygen doping.

The solubility of oxygen in liquid Ga was also determined, and its distribution coefficient between the Ga melt and the solid GaP was obtained.

Experimental

Crystal growth.—GaP stock material was synthesized from Ga and PH_3 in a quartz, open-tube flow system. Unreacted Ga was removed by digestion in hot, aqueous HCl, then the coarsely granular product was freed of surface silica contamination from the glassware by two successive treatments in cold HF solution (25 parts H_2O : 1 part HF).

The degassed charge, consisting of 50g of Ga and 7g of GaP [8 a/o (atomic per cent) P] was encapsulated in quartz. Dopants, as metallic Zn and Ga_2O_3, were added from a side arm in the system prior to sealing it off. A crystal growth experiment consisted of lowering the capsule through a temperature gradient from 1185°C, through the liquidus (1144°C), to 850°C over a period of 16 hr. The precipitated GaP platelets were separated from excess Ga with HCl. Generally, there was no difficulty in selecting one or more single crystal areas from which a ¼ in.-long Hall bar could be cut. The selected platelet was hand-lapped to a uniform thickness and polished on both sides to render it perfectly transparent. This was essential so that the crystal could be examined microscopically for the presence of free Ga. Gallium inclusions had to be avoided since the distribution coefficient for Zn between solid GaP and the melt is very small and the slightest amount of entrapped liquid could contain enough Zn to invalidate its subsequent quantitative determination.

Zinc determination.—It will be seen that the interpretation of the data depends on very accurate knowledge of the acceptor concentration, since the desired information (the degree of compensation that is brought about by oxygen additions) will, in general, be the difference between two considerably larger numbers. Radioactive Zn was employed as the acceptor dopant to provide the necessary precision.

The Zn determinations were made on the actual Hall bars before contacts were applied for transport measurements. The sample activities were compared with those of standards consisting of evaporated aliquots of solutions of the same Zn source. Zinc sources with several different specific activities were used in the investigation to provide suitable sensitivity over the entire composition range. Based on counting statistics alone, the determination was good to ± 2%, except in two cases where it was ±15%. These latter points fell on the smooth curve through the other data, however, so no further mention will be made of them. Radiochemical purity of the isotope was established by gamma ray spectroscopy and half-life determination.

Three confirming experiments were performed where natural Zn was employed as the acceptor dopant, and its concentration was subsequently determined by radioactivation analysis. Since this is a destructive analysis, the Hall measurements were made first, then the contacts were removed by etching prior to neutron activation. In order to achieve high sensitivity in this analysis it was necessary to effect a quite complete chemical separation of the Zn activity from the tremendously greater P^{32} activity. This is accomplished by first taking the sample into solution with hot aqua regia, then separating the Zn, with carrier added, as $ZnHg(SCN)_4$. It was counted in this form and compared with Zn standards that had been irradiated at the same time. The Zn concentrations determined in this manner agreed with those deduced from radioactive Zn doping to within 2%.

Electrical measurements.—Eight-arm Hall specimens were cut ultrasonically from the single crystal platelets. The identical samples were employed for both the electrical measurements and determination of the Zn concentrations. After determination of the Zn content, which is a nondestructive measurement, ohmic contacts were made with Au-Zn alloy dots, and Hall effect measurements were made by conventional d-c techniques. The electrical measurements were checked over a ten-fold range of current values, and at magnetic field strengths from 500 to 10,000 gauss. Hole concentrations were calculated from $p = 1/R_H e$. Only room temperature data were employed.

Results and Discussion

The nominally undoped crystals were n-type, with a room temperature carrier concentration of 2-4 x 10^{16} cm^{-3} and mobility of about 150 $cm^2/v\text{-}sec$, going to 600 at 77°K. A single lot of synthesized GaP was used for all of the low-doped experiments to avoid scatter of the data in this sensitive region due to different amounts of residual background impurities.

The room temperature hole concentration that results from Zn doping of this material in the 10^{16} to 10^{19} cm^{-3} range is shown as the upper curve of Fig. 1. The fact that the hole-to-Zn ratio is anomalous in GaP, being too high for an acceptor energy level of 0.06 ev and actually greater than unity at the extremities of the curve, has been discussed elsewhere (10) and will not be elaborated on here. It will suffice to say that this situation should exist in the Zn-O samples as well and should not affect the interpretation of the hole compensation that is brought about by co-doping with oxygen.

A second series of Zn-doped crystals was made following exactly the same procedure as before, except that Ga_2O_3 was also added to the system. The oxygen addition was constant throughout the series at 0.016 m/o Ga_2O_3, which is approximately the concentration that experience here and elsewhere had shown to

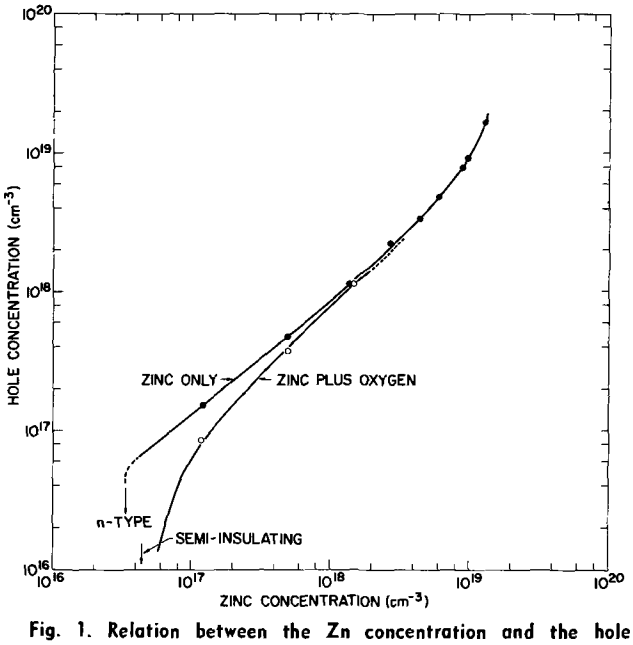

Fig. 1. Relation between the Zn concentration and the hole concentration at 300°K in GaP, with and without oxygen additions.

result in high photoluminescent and electroluminescent efficiencies in the red Zn-O band (2, 11).

The reduced carrier concentration that is brought about by the addition of oxygen is shown as the lower curve in Fig. 1. The reduction, the algebraic difference between the two curves, is essentially constant at 7 x 10^{16} holes cm^{-3} regardless of the Zn concentration up to about 10^{18} cm^{-3}, where this small reduction in carriers becomes lost in the data. At the dilute end, when the hole concentration falls below 7 x 10^{16} cm^{-3}, the compensation of the Zn is complete and the crystal conductivity changes over to very high resistivity n-type, characteristic of a donor deep in the energy gap.

The constant compensation by the added oxygen is not expected behavior; rather, its solubility might be expected to depend on the Zn concentration. Therefore, before the concentration of compensating centers can be identified directly with the oxygen content of the crystal, the situation that obtains when an electrically active solute is added to a crystal of the opposite conductivity type must be examined (13).

When a donor atom dissolves in intrinsic material, the heat of solution includes the energy gain of the electron as it drops to its new equilibrium state at the Fermi level, E^i_f. When the material is doped p-type, the Fermi level lowers to E^p_f and the donor solubility is increased by the Boltzmann factor, exp $(E^i_f - E^p_f)/kT$. However, this is also the factor by which the hole concentration increases when the Fermi level moves from E^i_f to E^p_f. It follows that the donor solubility ratio between p-type and intrinsic material equals the hole ratio, thus

$$\frac{S^p}{S^i} = \frac{\exp(E^i_f/kT)}{\exp(E^p_f/kT)} = \frac{p}{n_i}$$

where E is measured from the valence band, or

$$S^p = S^i \frac{p}{n_i} \qquad [1]$$

where p and n_i are the total and intrinsic holes, respectively. Whether our observation of a constant oxygen content regardless of the Zn concentration is to be expected depends on whether, at the growth temperature, the intrinsic holes predominate over the holes that are contributed by the Zn. We will now consider that aspect.

Determination of n_i.—The intrinsic carrier density at a given temperature can be determined in a number of ways. We will estimate it from the solubility of Zn in GaP as a function of its concentration in the liquid. (These data had been taken while establishing the hole *vs.* Zn relationship for ref. (10); upper curve of Fig. 1 of this paper). It is shown for our crystal growth temperature of 1144°C in Fig. 2. All of the solid does not precipitate at the one liquidus temperature, of course, and the liquidus itself will vary slightly as a function of the Zn concentration in the liquid. This is reflected in the scatter of the data in Fig. 2 as compared to Fig. 1. The Zn concentration in the solid was determined on the small Hall specimen only, but for Fig. 2 this is taken to represent the entire 7g of solid. The error introduced by this approximation is not considered serious for the purpose for which the information is to be used.

Solubility in the solid is determined by the equilibrium (12)

$$Zn(1) + V_{Ga} = Zn^-_{Ga} + p;\ K_1 = \frac{[Zn^-_{Ga}][p]}{[Zn(1)][V_{Ga}]}$$

or

$$Zn^-_{Ga} = \frac{K_1[Zn(1)][V_{Ga}]}{p} \qquad [2]$$

When $p \approx n_i >> Zn^-_{Ga}$

$$Zn^-_{Ga} = \left[\frac{K_1[V_{Ga}]}{n_i}\right][Zn(1)] = K_2[Zn(1)] \qquad [3]$$

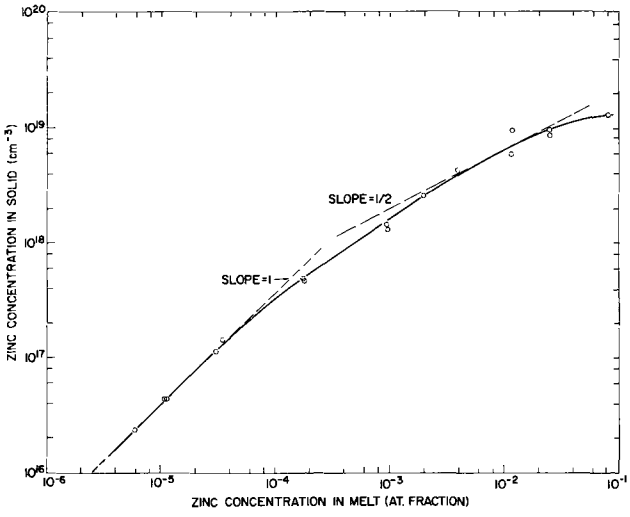

Fig. 2. Zn concentration in solid GaP as a function of its concentration in Ga-GaP melts at 1144°C.

and the Zn dissolved in the solid is directly proportional to its activity in the liquid. This dependence is almost exactly obeyed at low concentrations in Fig. 2.

If the holes are contributed primarily by the zinc, then

$$p \approx Zn^-_{Ga} >> n_i$$

and [2] becomes

$$p = Zn^-_{Ga} = [K_1[V_{Ga}]]^{1/2}[Zn(1)]^{1/2} = K_3[Zn(1)]^{1/2} \qquad [4]$$

and the Zn solubility is proportional to the square root of its concentration in the liquid. A distinct slope of ½ is not seen in Fig. 2 since at the lower side a substantial fraction of holes are still intrinsic, and at the upper side non-ideal behavior of the Zn is becoming evident as the solutions become concentrated. It suffices for our purpose to draw in a ½ slope tangent as seen in Fig. 2.

It remains now to determine the intrinsic hole concentration that, together with the increasing contribution of Zn holes, gives the best fit of the experimental curve between slope 1 and slope ½.

Returning to [2], this cannot be solved explicitly without approximations. However, by invoking the two additional equilibria

$$pn = n^2_i \qquad [5]$$

and the neutrality condition

$$Zn^-_{Ga} + n^- = p \qquad [6]$$

eliminating n and p through simultaneous substitution, and letting $K_4 = K_1[V_{Ga}]$, we obtain

$$Zn^-_{Ga} = \frac{K_4[Zn(1)]}{[n_i^2 + K_4[Zn(1)]]^{1/2}} \qquad [7]$$

By arbitrarily selecting values for n_i to adjust the curve shape, and normalizing to some value of Zn^-_{Ga} (2 x 10^{17} cm^{-3} was chosen) to eliminate the constant, various fits to the experimental curve of Zn^-_{Ga} *vs.* Zn(1) were obtained.

Figure 3 shows the fit for three values of n_i. The solid line is an exact tracing of the experimental curve of Fig. 2. From Fig. 3, n_i is clearly greater than 5 x 10^{17} cm^{-3}. As noted by Trumbore (14), the experimental curve should begin to rise above the theoretical curve when the Zn holes begin to predominate over the intrinsic holes since, rigorously, activities rather than concentrations are required in (4) and the activity coefficient of Zn in Ga is greater than unity in these dilute solutions. We choose 9 x 10^{17} cm^{-3} as the best value for n_i.

Returning now to Fig. 1, it is seen that the constant solubility of oxygen in GaP, irrespective of the

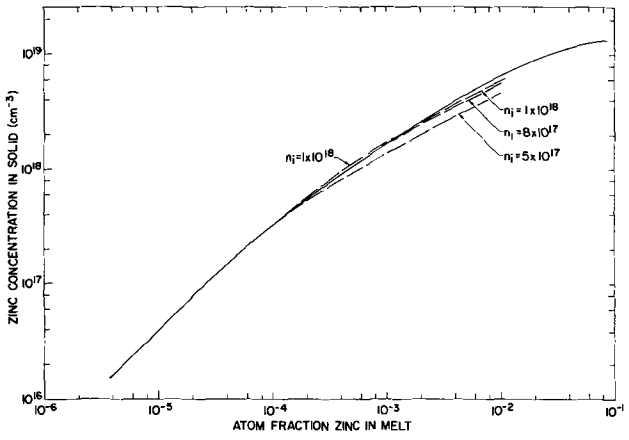

Fig. 3. Comparison of the observed relation between the Zn concentration in the solid vs. liquid at 1144°C with that calculated from various values for the concentration of intrinsic holes.

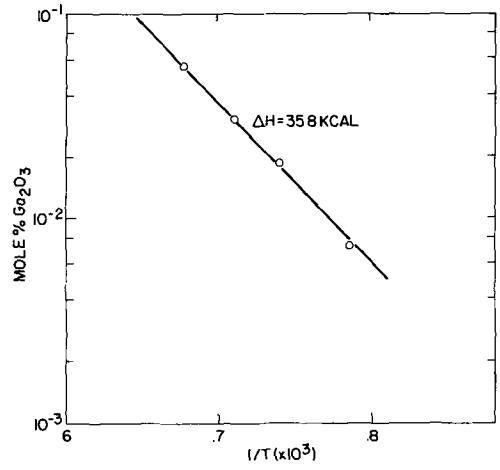

Fig. 4. Solubility of Ga_2O_3 in Ga as a function of temperature

Zn concentration up to almost 10^{18}, is consistent with the large intrinsic hole concentration, according to relation [1]. At Zn concentrations greater than 10^{18} the oxygen solubility would be expected to increase proportional to the increase in Zn. This increase is indicated in Fig. 1 as a dotted line extension of the experimental curve that parallels the "Zn only" curve. The continuation of the curve in this manner is clearly permitted by the data.

Solubility of oxygen in gallium.—In the next section we will determine the distribution coefficient of oxygen between the melt and the solid GaP for the particular conditions employed in this study. Before that can be done, however, the solubility of Ga_2O_3 in Ga must be measured in order to establish the maximum oxygen addition for which such a coefficient would apply.

The solubility was determined by a weight loss method. A solid piece of β-Ga_2O_3 was obtained by flame fusion of Ga_2O_3 powder .The weight of this piece was measured before and after holding it in Ga in a sealed quartz capsule at several temperatures for sufficient times to achieve equilibrium. This ranged from 72 hr at 900°C to 24 hr at 1200°C. Care was taken to ensure that the temperature was uniform over the capsule and did not cycle; otherwise, there could be a continual transport of Ga_2O_3 from the solid piece to the cooler part of the capsule. Before obtaining the weight loss, any Ga that adhered to the piece was removed by boiling in 50% HCl for 3 hr. (In a separate experiment it was established that this treatment did not remove any Ga_2O_3.)

In order to determine the true solubility of oxide in the liquid, it was necessary to correct for that lost in filling the free space of the system. The volatile species is the suboxide, Ga_2O, which is formed in the reaction

$$Ga_2O_3 + 4Ga = 3Ga_2O \qquad [8]$$

for which

$$K = \frac{[p_{Ga_2O}]^3}{[a_{Ga}]^4[a_{Ga_2O_3}]} \approx (p_{Ga_2O})^3 \qquad [9]$$

K had been obtained as a function of T by Cochran and Foster (15). The Ga_2O pressure calculated from [9], together with the known free space in the capsule and the ideal gas relation, $pv = nRT$, permits the calculation of the correction that is to be subtracted from the measured weight loss. The correction ranges from 5.5% at 1200°C to 1% a 1000°C. The final solubility curve is shown in Fig. 4. The consistency of the data is attested to by the straight line plot of log $x_{Ga_2O_3}$ *vs.* $1/T$. From the slope of the line, which is $\Delta H/R$, we obtain an enthalpy of solution of $\Delta H = 35.8$ kcal/mole.

Distribution of oxygen between the melt and solid GaP.—From Fig. 4, the solubility of Ga_2O_3 in Ga at the GaP crystal growth temperature (1144°C) is about 0.034 m/o or approximately twofold greater than the oxygen addition that was employed for the growth of the Zn-O doped crystals. (It is assumed for this purpose that because of their low concentrations the P and Zn do not affect the oxide solubility in the melt.) Therefore, a distribution coefficient, k can be derived for our case which should be applicable to neighboring compositions as well. Again, it is necessary to examine the loss of oxygen to the vapor. In this case, however, since the free space in the system is small (*ca.* 7 ml) and the temperature is moderate, a calculation similar to that in the previous section shows a loss of less than 1%, which can be neglected. From Fig. 1 was obtained an oxygen content of 7 x 10^{16} cm^{-3} for the Zn-O doped GaP crystals. This is an atom fraction of 2.65 x 10^{-6} (considering P and Ga as separate entities). This resulted from an oxygen addition of 0.016 m/o, or 4.8 x 10^{-4} atom fraction, to give a distribution coefficient of 0.0055.

From analysis of the Zn-O exciton and pair band spectra, Henry *et al.* (4) estimated that there were 5 x 10^{16} cm^{-3} Zn-O complexes in GaP crystals that had been grown at 1050°C from a melt that was doped with 0.01 m/o Ga_2O_3. From our distribution coefficient of 0.0055 we too calculate an oxygen content of 5 x 10^{16} cm^{-3} for this case. It is recognized that this perfect agreement must be somewhat fortuitous, considering the approximations that go into the two independent determinations.

Conclusions

The oxygen content of p-type GaP that is grown from Ga-8 a/o P solutions that are doped with 0.016 m/o Ga_2O_3 is 7 x 10^{16} cm^{-3}. This is independent of the acceptor concentration of the crystal up to approximately 10^{18} cm^{-3}. This behavior is consistent with an intrinsic hole concentration at the growth temperature of about 9 x 10^{17} cm^{-3}, which fixes the Fermi level and removes the dependence of the donor solubility on the acceptor content of the sample. Under the experimental conditions of this investigation, the distribution coefficient of oxygen between the solid and liquid is 0.0055. Utilization of this coefficient is limited to Ga_2O_3 additions below 0.034 m/o, which is the solubility of Ga_2O_3 in Ga at the growth temperature of 1144°C.

Some consequences of these findings are noteworthy. Gershenzon *et al.* (11) found that the maximum photoluminescent efficiency in the red Zn-O band was achieved with oxygen additions to the melt of 0.01 m/o Ga_2O_3. From Fig. 4 it is seen that this is essentially the solubility limit of Ga_2O_3 in Ga at their growth temperature of 1050°C. We suggest that the efficiency was limited by the solubility of oxygen in the melt, which in turn limited the solubility in the solid.

There are other observations that confirm this view. Ladany (16) made very large oxygen additions (0.4

m/o Ga_2O_3) to Zn-doped Ga-GaP melts when forming p-n junctions by liquid phase epitaxy onto n-type substrates for the production of EL diodes. Although this is thirty- to forty-fold greater than the oxide addition typically employed in this process (2), the quantum efficiency of the diodes was essentially unchanged. In our laboratory we have observed little difference in the efficiency of red luminescence in GaP whether there was a continuous flow of oxygen through the crystal growth system, whether a small addition of Ga_2O_3 (0.01 m/o) was made, or, as was the case in one instance, a minute accidental admission of air occurred through a crack in the quartz envelope. These observations too can be explained by the very low solubility of Ga_2O_3, which limits the oxygen concentration in the melt to a low value irrespective of the amount of solid oxide phase present.

It appears that because of this low solubility of oxygen in the liquid and its low distribution coefficient between the liquid and solid, the oxygen concentration of 7×10^{16} cm^{-3} that was determined in this work cannot be greatly exceeded. Crystal growth at higher temperatures would increase the oxygen solubility in the liquid according to Fig. 4 and, if the distribution coefficient is insensitive to temperature, this increase would be reflected in a greater oxygen content of the solid. However, practical considerations limit the growth temperature in quartz systems to 1150°-1200°C. From Fig. 1, it is seen that some increase in oxygen solubility should result from increase in Zn doping above the intrinsic range of about 10^{18} cm^{-3}. Whether the increase in Zn-O pairs that could be achieved in this way would result in greater external luminescence efficiencies is doubtful. Concentration quenching can be expected, and the increased free carrier absorption in this doping range begins to darken the crystal.

The very low concentration of the Zn-O luminescent centers in optimally doped GaP suggests that the desired luminescent process might be very vulnerable to degradation by various competing processes. The concentration of impurities such as Si, Ca, Al, Be, and Mg, that form stable oxides, certainly should be maintained well below the oxygen concentration so as not to compete with the Zn. Many other trace impurities that do not form stable oxides could still compete for the electron that is bound to the Zn-O complex and introduce alternative decay paths. The fact that it is difficult to achieve high red luminescence efficiencies reproducibly in GaP probably reflects the difficulty in avoiding very low concentrations of competing centers.

Acknowledgment

The authors wish to thank Mr. J. E. Lewis for performing the radiochemical determinations, Dr. J. F. Woods and co-workers for the electrical measurements, and Mr. R. J. Gambino for supplying the flame-fused Ga_2O_3 for solubility measurements.

Manuscript submitted Nov. 20, 1968; revised manuscript received Dec. 26, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Enhanced Gold Solubility Effect in Heavily n-Type Silicon

S. F. Cagnina

Fairchild Semiconductor Research & Development Laboratory, Palo Alto, California

ABSTRACT

Using radiotracer methods, a study has been made of the increased gold solubility in uniformly heavily n-doped silicon. Data for both phosphorus and arsenic showing gold solubility as a function of doping is presented. The gold solubility at 1000°C begins to increase substantially for concentrations of donor impurity in the range 10^{19} cm^{-3}, although a difference in this increase between arsenic doping and phosphorus doping was noted. The data was related quantitatively to an ion pairing model which appeared to best explain the results.

As gold is useful in silicon for controlling minority carrier lifetime, its properties in silicon have been studied extensively (1, 2). An important effect, little studied to date, is the apparent enhanced solubility of gold in n^+ (phosphorus) layers. Wilcox *et al.* (3) found that the presence of a diffused phosphorus layer resulted in higher gold concentration (in excess of the normal solid solubility) in such a layer. Such an effect was not observed for heavily boron-doped layers. In addition, the diffusivity of the gold was found to be retarded significantly by the presence of phosphorus (3). Joshi and Dash (4) studied the distribution of gold in phosphorus diffused silicon and interpreted their results in terms of the Reiss theory (equivalent Shockley-Moll theory) of solubility enhancement. Some authors have attributed this effect to the formation of gold phosphide precipitates as delineated by transmission electron microscopy and x-ray topog-

raphy (5, 6). While precipitation may occur, the present paper is concerned solely with a solubility effect.

The present paper deals with the enhanced solubility of gold in a quantitative manner, contrasting the gold solubility in silicon wafers heavily doped with phosphorus, arsenic, and boron. To avoid precipitation effects and to ensure that a true gold solubility was being measured, only wafers homogeneously doped were used in the experiments. Thus, large dislocation densities generated during the n^+ diffusion (particularly of phosphorus) and any subsequent precipitation of gold were avoided. Special experiments were performed to ascertain that precipitation was not influencing the results.

Theory

Shockley-Moll theory.—For some time now, interactions between impurities in solids have been described in terms of chemical reactions (7). Reiss *et al.* (8) showed how the law of mass action could be applied to explain enhanced solubility of lithium (a donor) in boron-doped silicon. Using thermodynamic arguments, expressions of a general nature were derived relating the donor concentration (*e.g.*, lithium) to the boron concentration. Subsequently, the same theory was reformulated by Shockley and Moll (9) arguing from a somewhat different point of view. In addition to solubility enhancement of lithium, similar effects have been noted for gallium in germanium (10) and for copper in silicon, germanium, and gallium arsenide (11).

To understand how the presence of one charged impurity can affect the solubility of another charged impurity, we shall consider the basic argument present in ref. (9). If an amphoteric impurity (such as gold) is diffused to saturation in silicon containing a p-n junction, then we state that the concentration of neutral impurity should be uniform throughout the silicon since the only "force" acting on the neutral atoms is diffusion. In other words, the concentration of neutral impurity should be independent of the local electropotential or Fermi level. But the impurity atoms in other charge states will be dependent on the Fermi level; in fact, the ratio of the concentration of impurity in any two charge states will be given by the ratio of the Boltzmann factors. Thus the solubility, or total number of atoms in all charge states, will be altered by the presence of other charged impurities if the concentration of these impurities is sufficiently large to affect the Fermi level.

At room temperature, substitutional gold in silicon possesses a donor level $E_D = 0.35$ ev above the valence band edge and an acceptor level $E_A = 0.54$ ev below the conduction band edge (12). The ratio of gold atoms in each charge state is (negative, neutral, and positive, respectively)[1]

$$N_{Au^-} : N_{Auo} : N_{Au^+} = \exp[(E_F - E_A)/kT] : 1 : \exp[(E_D - E_F)/kT] \quad [1]$$

in which E_F is the Fermi level, k is the Boltzmann constant, and T the temperature. In the following analysis we shall assume that the gold solubility is always much less than N_D, the shallow level donor density, and that the shallow level donors are all ionized since at the temperatures considered the Fermi level is not far from midgap.

Using the equation

$$n = N_D + p \quad [2]$$

and the equilibrium relations[2]

$$np = n_i^2 \quad [3]$$

$$n = n_i \exp[E_F - E_i)/kT]$$

it can be shown after a little algebra that

$$N_{Au^-} = [N_{Au^-}]_i \left\{ \frac{N_D + \sqrt{N_D^2 + 4n_i^2}}{2\,n_i} \right\}$$

$$N_{Auo} = [N_{Auo}]_i$$

$$N_{Au^+} = [N_{Au^+}]_i \left\{ \frac{2\,n_i}{N_D + \sqrt{N_D^2 + 4n_i^2}} \right\} \quad [4]$$

in which the bracket $[]_i$ denotes the value of the enclosed quantity in intrinsic silicon. The total gold concentration (*i.e.*, the solubility) is the sum of the above three terms.

$$N_{Au} = N_{Au^-} + N_{Auo} + N_{Au^+} \quad [5]$$

It is clear that solubility enhancement in n-type silicon occurs through the action of the gold acceptor level. Apparently, in the same n-type silicon, a concomitant lowering of the gold concentration in the donor state also occurs. This is a negligible effect since the concentration of gold in the positively charged state is very small to begin with, as solubility enhancement through the action of the gold donor level is heavily doped p-type silicon has not been observed (3). For the gold solubility to be unaffected by a decreasing Fermi level in heavily p-type silicon, then the ratio of positively charged gold to neutral gold should be considerably less than 1, *i.e.*, $\exp[(E_D - E_F)/kT] \ll 1$. Thus, we assume the donor level E_D to be at least 2 kT units below the Fermi level (about 0.2 ev at 1100°C). Neglecting the small contribution of positively charged gold, the gold solubility as a function of doping is then

$$N_{Au} = N_{Au}(N_D = 0) + \left\{ \frac{N_D - 2n_i + \sqrt{N_D^2 + 4n_i^2}}{2n_i} \right\} [N_{Au^-}]_i \quad [6]$$

A prominent feature of the above equation is that the gold solubility begins to increase when $N_D \sim n_i$ [an extrapolated value of n_i is of the order 10^{19} cm^{-3} at 1000°C (14)] the point at which the silicon is no longer intrinsic. Unfortunately, neither the gold energy levels nor n_i are precisely known at temperatures in the range 1000°-1100°C, so that an exact comparison between theory and experiment is not possible. However, in the limit for large values of N_D, the solubility goes as

$$\frac{N_D}{n_i} [N_{Au^-}]_i$$

Therefore, from an experimental plot of N_{Au} *vs.* N_D, we should observe a slope of one on a log-log plot for sufficiently large values of N_D.

Ion pairing.—As the existence of a phosphorus-gold compound (Au_2P_3) is known, one must also consider the possibility of ion pairing between gold and phosphorus and its effect on gold solubility. The most straightforward approach is that of Reiss *et al.* (8) and the techniques used by these authors will be applied to a hypothetical (but not unique) pairing reaction, *i.e.*

$$\{Au\}_{sub,o} + e^- + p^+ \rightleftarrows \{AuP\} \quad [7]$$

in which $Au_{sub,o}$ is a neutral substitutional gold atom, e^- is an electron, P^+ an ionized phosphorus atom, and {AuP} is a neutral gold-phosphorus ion pair. From the law of mass action it follows that

$$\frac{C_p}{(N_{Auo})\,n N_D} = K \quad [8]$$

where C_p is the neutral pair concentration and K is the reaction constant. From Eq. [2], [3], [8] it follows than [see ref. (8)][3]

$$C_p = K(N_{Auo}) \left\{ \frac{N_D^2 + N_D\sqrt{N_D^2 + 4n_i^2}}{2} \right\} \quad [9]$$

[1] Technically, spin degeneracy factors should be included for each level (13). However, omission will not alter the form of the derived expression.

[2] In these expressions, n denotes the electron concentration, p the hole concentration, n_i the intrinsic carrier concentration, and E_i is the intrinsic Fermi level.

[3] Note that in the limit of N_D large compared with n_i, the pair concentration goes as the square of the doping ($C_p \propto N_D^2$). Also this expression assumes $N_{Au} \ll N_D$.

It is important to realize that the occurrence of ion pairing presupposes solubility enhancement through variation of the Fermi level since both are mass action effects. In addition, those phosphorus atoms that pair will no longer contribute an electron to the conduction band and this will therefore affect the Fermi level, particularly the value of N_D to be used in Eq. [6]. Experimentally, it will be shown that solubility enhancement approaches 10^{17} cm^{-3} for dopings in the 10^{19} cm^{-3} -10^{20} cm^{-3} at 1000°C. Since the gold concentration is always much less than the doping concentration, the number of doping atoms removed if pairing does occur will also be much less than the doping concentration and can therefore be neglected. In summation, the total gold solubility in the presence of ion pairing will be the sum of Eq. [6] and Eq. [9].

Experiment

A brief description of the experimental technique employed is as follows: A known amount of nonradioactive gold was tagged with several millicuries of Au^{198} (half life = 2.7 days) in a solution whose volume was 25 ml.[4] From this, 5λ (1λ = 0.001 ml) was pipetted into a test tube which therefore contained a known amount of gold (by volume ratio) as well as a known activity (measured). This therefore served as a calibration standard for the run relating number of gold atoms to counts per minute. Gold was chemplated onto a lapped surface of the silicon wafers to be diffused (usually five, thickness 200μ or less) by injecting the gold chloride solution into a bath of 10:1 hydrofluoric acid (HF) solution in which the wafers lie (3). Plating was allowed to take place for approximately 5 min. The amount of gold plated was approximately two orders of magnitude larger than that needed to satisfy the solid solubility requirements. The wafers were then rinsed with deionized water, blown dry, and diffused.

The solid solubility was measured at a particular temperature by diffusing the wafers to saturation and measuring the bulk gold concentration. To determine the time required for saturation, a series of equally heavily doped n-type wafers were plated with gold as described and each wafer was diffused for varying lengths of time. Heavily doped n-type wafers were used to determine the time to reach saturation since the diffusion rate for gold is progressively lower the higher the doping. This behavior is due to the increased gold substitutional solubility. That the diffusivity should be concentration dependent was first shown in a paper by Frank and Turnbull which discussed the rapid diffusivity of copper in dislocated germanium crystals (15). Like copper in germanium, gold in intrinsic silicon is believed to have a high interstitial diffusivity with low interstitial solubility, and low substitutional diffusivity with high substitutional solubility (16). An expression was derived in ref. (15) which shows that the effective diffusivity should be approximately inversely proportional to the substitutional solubility. The retarded diffusivity of gold in heavily doped n-type silicon was observed during the course of study. For example, a lightly doped wafer was observed to completely saturate with gold in less than a day at 1000°C whereas a heavily doped sample required seven days. As mentioned, a set of heavily doped wafers were plated with gold and diffused varying lengths of time. That time at which the gold concentration no longer changed with added diffusion was taken as the saturation time. Once the saturation time at a particular temperature was determined, wafers of various doping levels were diffused with tracer gold for that length of time and evaluated as previously described.

In order to avoid surface accumulation of gold (17), each wafer was etched to about 60μ after diffusion and treated with hot "Auro Strip," a commercially available cyanide compound which readily dissolves gold. This latter operation is critical, since it was found

[4] Au^{198} obtained from Nuclear Science & Engineering Corporation.

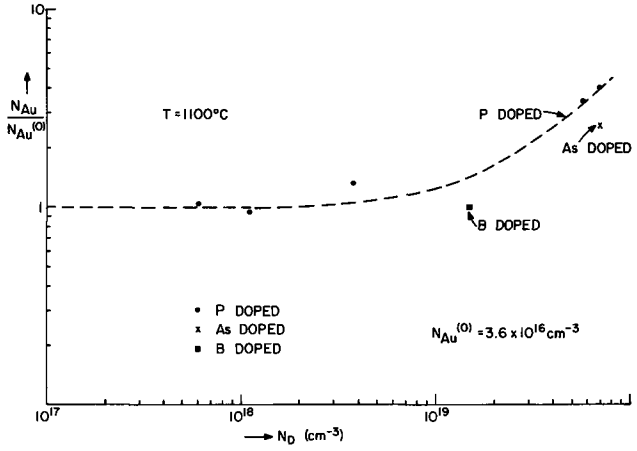

Fig. 1. Gold solubility (normalized with respect to intrinsic solubility) as a function of donor density at 1100°C. The dotted line is intended to represent the locus of experimental points. (Intrinsic solubility at 1100°C, $N_{Au}(o) = 3.6 \times 10^{16} cm^{-3}$.)

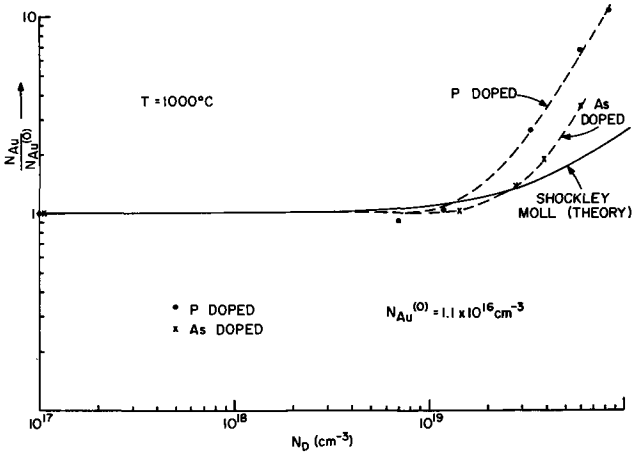

Fig. 2. Gold solubility (normalized with respect to intrinsic solubility) as a function of donor density at 1000°C. The dotted lines are intended to represent the locus of experimental points for the arsenic and phosphorus doped cases. (Intrinsic solubility at 1000°C, $N_{Au}(o) = 1.1 \times 10^{16} cm^{-3}$.)

that a large percentage of the gold contained in the etched silicon plates back onto the wafer. After being rinsed with deionized water and blown dry, the sample was weighed in an anlytical balance to an accuracy of better than 1%. The sample was then dissolved in about 4 ml of HF-HNO_3 mixture and counted repeatedly for times sufficiently long so that the standard deviation was less than 1%. The gamma radiation produced by the Au^{198} was measured using a thallium-activated sodium iodide photodetector assembly in conjunction with an amplifier, single channel analyzer, and scaler. By comparing the count rate of the dissolved wafer with that of the prepared calibration standard, the number of gold atoms in the sample is determined. The weight measurement determines the volume. Thus, the gold concentration is known.

Results and Discussion

The experimental procedure was performed for phosphorus and arsenic (and in one case boron) doped wafers at temperatures of 1000° and 1100°C.[5] Shown in Fig. 1 and 2 are measured gold concentrations at each of these temperatures, normalized with respect to the intrinsic solubility measured as a function of donor density. The donor concentrations were inferred from resistivity measurements using Irving's data (18). Values of intrinsic solubility (*i.e.*, N_D small) found were $(N_{Au})_o = 1.1 \times 10^{16}$ cm^{-3} at 1000°C and

[5] Uniformly antimony doped wafers of sufficiently low resistivity could not be obtained.

$(N_{Au})_o = 3.6 \times 10^{16}$ cm^{-3} at 1100°C, both of which are in excellent agreement with previously reported results (12, 19). Autoradiographs of the gold-doped wafers made by placing an etched sample atop dental x-ray film revealed homogeneity, as best as could be determined, of the gold in the silicon for both the lightly doped and heavily doped samples. Reproducibility of measured gold concentrations from run to run bore out the estimate of about 5% absolute accuracy and better than 2% relative accuracy.

Figure 1, which gives the data for 1100°C diffusions, clearly shows an increased gold concentration (about a factor of 4) for phosphorus doped silicon in the 6 x 10^{19} cm^{-3} concentration range. Unexpectedly, a heavily arsenic doped wafer showed a smaller value of enhanced solubility. A boron doped sample (1.5 x 10^{19} cm^{-3}) gives no indication of the enhanced solubility effect, in agreement with previously reported results (3).

More revealing is the data shown in Fig. 2 which gives the same data for 1000°C. Note that as the temperature is decreased, the silicon becomes more extrinsic for any given value of heavy doping and therefore a larger effect can be expected. Again, heavily arsenic doped wafers showed a consistently smaller value of enhanced solubility than do phosphorus doped samples. Equally interesting is the fact that the slopes of the curve of gold concentration *vs.* donor density is close to a slope of two for both impurities whereas the enhanced substitutional solubility effect predicts a maximum slope of one (see Eq. [6]). At first it was thought that a mobility difference might exist between heavily phosphorus and heavily arsenic doped silicon which might explain the apparent solubility difference.[6] Hall effect measurements made in this laboratory on silicon samples heavily doped with phosphorus and arsenic showed no significant difference in mobility. Mobility difference between phosphorus and arsenic doped silicon has been alleged to exist (20); however, it is too small to explain the difference seen in Fig. 2.

As precipitates of both As and P have been observed in as-grown heavily doped material (21), it is possible that the difference observed could be due to differences in the amount of dopant precipitated. That is, the precipitated As or P could go back into solution at the solubility temperature (and thus be electrically active) whereas the precipitates would be inactive during the resistivity measurement (room temperature).

Since it was recognized that the data used to evaluate the donor concentration from the resistivity (Irvin's data) (18) is a composite made up from various sources, it was decided to re-evaluate Fig. 2 using these original sources. In every case it was found that the shape of the characteristics was approximately the same, the major changes being shifts along the N_D axis.

For comparison purposes, a theoretical curve giving the enhanced substitutional solubility effect (Eq. [6]) is shown in Fig. 2. For this evaluation a value of $n_i = 1.4 \times 10^{19}$ cm^{-3} was used [extrapolated value from data of Morin and Maita (14)]. The parameter $[N_{Au^-}]_i$, the gold concentration in the negatively charged state in intrinsic silicon, was assumed equal to 0.27 $N_{Au}(o)$, where $N_{Au}(o)$ is the gold solubility in intrinsic silicon. Clearly, this curve is inadequate to explain the data. To see if a pairing model might explain these results, the value of gold solubility in excess of the value predicted by Eq. [6] was plotted for phosphorus as a function of doping. In Fig. 3 are shown the resultant points in addition to which is plotted Eq. [9] which gives the predicted pair density. [It was assumed that $KN_{Auo} = (1.2 \times 10^{-39}) N_{Au}(o)$.] As can be seen, good agreement exists between the theoretical curve and the experimental points. In fact, since pairing appears to be the dominant mechanism, no essential assumptions need to be made at which point Shockley-Moll solubility enhancement commences in order to obtain an approximate fit in Fig. 3.

[6] The resistivity is inversely proportional to the mobility.

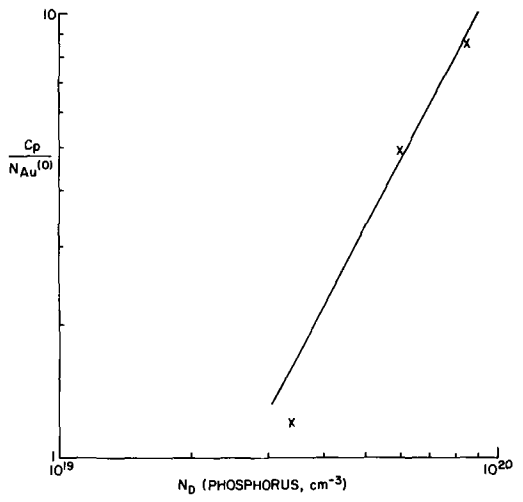

Fig. 3. Pair concentration (normalized with respect to intrinsic solubility) as a function of phosphorus doping. The straight line fit was plotted from Eq. [10] assuming that $KN_{Auo} = (1.2 \times 10^{-39}) N_{Au}(o)$.

As gold and phosphorus are known to form a compound (22) which has also been seen as precipitates in silicon, a pairing model to explain our results is not unreasonable. The author has not been able to find direct evidence of the existence of an arsenic-gold compound but, since arsenic and phosphorus are in the same group in the Periodic Table, their chemical behavior should be similar. Although the data shown for arsenic in Fig. 2 does not cover as wide a range as does that for phosphorus, it too appears to have a slope approximately equal to two. A plot similar to Fig. 3 could also be made for the arsenic case, although it would be less convincing since there are less data.

Joshi and Dash (4), in part, showed a gold profile in a diffused phosphorus region and attempted to correlate the gold concentration at each point with the phosphorus concentration. They pointed to the satisfactory agreement between the gold concentration measured and that predicted by a theoretical Shockley-Moll curve though they still alluded to the formation of gold-phosphorus pairs. Our work corroborates their assertion of gold-phosphorus pairing.

The binding energy for a gold-phosphide pair can be calculated from statistical arguments by considering the product of number of gold atoms in substitutional sites adjacent phosphorus atoms and probability of a "jump" by this gold atom to a pair site. An analysis of this type yields the pair density C_p as

$$C_p = \frac{(N_D)(N_{Au^-})}{N_{Si}} \exp\left[\frac{E_B}{kT}\right] \qquad [10]$$

in which N_{Si} is the density of silicon atoms and E_B is the binding energy. Using the data of Fig. 2 in this expression, we can estimate a binding energy of approximately 1 ev. This number is of the same order as the binding energy of radiation induced pairs in silicon (23).

Effect of dislocations on solubility measurements.— Several special experiments were performed to ascertain any gross precipitation of gold in the bulk silicon after diffusion to saturation. As mentioned previously, autoradiographs of lightly and heavily doped samples indicated uniformity as best as could be determined; however, the resolution of the film used was poor, of the order 10-20 μm. It was thought that if bulk precipitates of gold were influencing the data, then increasing the density of dislocations might increase the measured bulk gold concentration. Accordingly, wafers lightly doped with phosphorus were severely

dislocated by standing the wafers on end and inserting into a 1280°C furnace. The wafers were then fast pulled from the furnace. This procedure was then repeated a number of times (usually 4-6) until the wafers became warped and dislocated as high as 10^7 cm^{-2}. These samples were then annealed in the same furnace, lying flat on a quartz boat. The large dislocation densities produced were thus rendered stable. The same slices were plated with gold and diffused to saturation at 1100°C and pulled quickly from the furnace. Evaluation of the gold concentration proceeded in the fashion given previously. It was found that there was no difference in gold concentration between heavily dislocated and moderately dislocated controls (10^3-10^4 cm^{-3}).

This same experiment was repeated for heavily phosphorus doped wafers ($N_D \sim 5 \times 10^{19}$ cm^{-3}). It was thought that possible formation of auric phosphide precipitates might be influenced by the dislocation count. After diffusion to saturation, wafers were both slow and fast pulled from the furnace. Again, no difference whatever in bulk gold concentration was noted between the dislocated samples and controls.

These experiments do not imply that precipitation does not occur. They do mean that the total amount of gold deep in the bulk, whether precipitated in solid solution or paired with a phosphorus atom at a substitutional site, does not change with dislocation density. Any gold which does precipitate on cooling comes from pair sites or solid solutions; thus the average concentration of gold in the bulk does not change after precipitation.

Segregation of gold in diffused n^+ *regions.*—A dramatic demonstration of the high solubility of gold in diffused n^+ regions was performed as follows: Silicon wafers, which contained diffused silicon diodes on one side, were doped with radiotracer gold from the backside at 900°C using a 2 hr diffusion treatment. Afterward, the slices were back etched (about 15 μm removed) and were then placed in a $POCl_3$ predeposition furnace at a temperature of 1070°C for 15 min. It was found that the phosphorus glass on the backside contained a negligible amount of gold in agreement with an earlier study (24). In all cases unusually large concentrations of gold were found in the 10 μm of backside silicon which contained the n^+ region, whereas the gold concentration in the bulk decreased by two orders of magnitude. The gold-doped wafers without the phosphorus treatment showed a gold concentration (averaged over the central 100 μm of wafer) of approximately 3.8×10^{14} cm^{-3}. Those which received the "gettering" treatment yielded an average gold concentration of approximately 3.5×10^{12} cm^{-3}.

Reverse current *vs.* reverse voltage measurements were made on the diodes fabricated in the gettering samples as well as the gold doped and ungettered ones. For both groups the reverse current varied linearly with reverse voltage on a log-log scale with slope 1/2, corresponding to a p^+n step junction. The current level for the gettered case was approximately two orders of magnitude lower than the ungettered case in agreement with the radiotracer analysis. (The space-charged generation current is directly proportional to the gold concentration.)

Conclusion

The solubility of gold in heavily doped n-type silicon has been measured in such a way as to place a high degree of reliance on the experimental results. Special experiments performed indicated that precipitation of gold was not affecting the data in a deleterious way. A pairing model appears to offer the best explanation for the behavior of gold solubility with doping. Solubility enhancement through action of the Fermi level was found inadequate to explain the data. Probably both of these mechanisms are occurring at the same time, although pairing appears to be the dominant one.

In addition, the enhanced solubility of gold in n^+ regions was effectively demonstrated by using a diffused n^+ region to remove dissolved gold from the silicon bulk.

Acknowledgment

The author wishes to thank K. M. Cooper for his assistance in the experimental portion of this program. In addition, I am grateful to E. H. Snow and W. Oldham for many helpful discussions. Thanks are also due J. Lawrence for his aid with the experiment involving the large dislocation densities and E. Meieran for helping with the radiography.

Oriented Impurity Precipitates in Single Crystals of Sodium Chloride-Barium Chloride

K. N. Swamy Rao and A. S. Parasnis

Department of Physics, Indian Institute of Technology, Kanpur, India

ABSTRACT

Single crystals of sodium chloride pulled from melt containing 1% by weight of barium chloride have been observed to contain a second phase precipitating throughout the interior in the form of thin rods (10-25μ long) and well defined polygonal platelets (10-15μ in size). Two types of rods have been observed, one type oriented along <100> and the other along <110> directions. The platelets are variously in the form of hexagons, octagons, decagons, and rhombi. The hexagonal and octagonal platelets seem to lie on {111} planes. Precipitates disappear on quenching the crystals and reappear on aging the crystals under suitable conditions.

Extraneous phases are known to precipitate in solids when the impurity additive in solid solution begins to exceed the solubility limit as a result of slow cooling. Although a good deal of work has been done on metallic systems of technological importance not much extensive work has been done on nonmetallic solid systems. Alkali halides being transparent to optical wavelengths belong to a convenient class of solids for studying by optical microscopy the processes of precipitation and internal decoration of dislocations. Amelinckx (1) has shown that dislocations in mixed crystals of alkali halides are decorated by particles of a second phase. Suzuki (2) and Toman (3) have studied NaCl-$CdCl_2$ and NaCl-$CaCl_2$ systems by x-ray diffraction techniques and have proposed a model of metastable centers in the form of plate zones due to precipitation. Similarly Lilley and Newkirk (4a, b) have investigated the structural aspects of precipitation in the LiF-MgF_2 system. On the other hand, Dreeben (5) has reported optical microscopic observations on oriented precipitate particles in the CdS-Au system. Precipitates have been observed in KCl crystals by Ewles and Dawson (6), in NaCl crystals by Girard-Nottin and Taurel (7), and in some alkali halide crystals by Bansigir and Schneider (8). In the NaCl-$BaCl_2$ system Harvey (9) has observed decorated dislocations. However, no direct microscopic observation on oriented impurity precipitates in sodium chloride crystals, such as that reported here, seems to have been made.

Experimental Method

The single crystals of sodium chloride used in this investigation were grown in air in the laboratory from melt containing 1% by weight of barium chloride, following a modified Kyropoulos technique (10), the growth rate being 3 mm/hr. The materials used were of B.D.H. Analar grade. As soon as the entire melt had solidified the boule was detached from the chuck holding the seed and was carefully dropped back into the silica crucible in the same furnace. The boule was then cooled at the rate of 1°C/min down to room temperature. Large cubical blocks cleaved from the boule looked turbid. Thin sections of about 0.2 mm thickness were cleaved from the blocks and mounted in Canada balsam for microscopic observations.

Microscopic Observations

On examination under an optical microscope the specimens were found to contain, throughout the interior, precipitates of a second phase. Several different forms were observed (see Fig. 1 to 5).[1] Careful observations made on the geometry of the various precipitate forms enable one to determine the orientations of the precipitates embedded in the NaCl matrix. Most of the precipitates are in the form of either thin rods or hexagonally shaped platelets, but many other forms also are observed (Fig. 1).

Orientation of precipitates in the form of thin rods.— Two types of rods are seen. Those of one type make angles of 45° with the edges of cleavage sections. Figures 2 and 3 show them at lower and higher magnifications, respectively. It is seen that they are oriented along <110> directions. By using the fine focus of the microscope it is possible to see the rods oriented along the other four <110> directions which are inclined to the plane of observation. The second type of rods are parallel to the edges of cleavage sections; this shows that they are oriented along <100> directions. The rods oriented along the third <100> direction normal to the plane of observation would be seen end-on and would appear as "specks." It is, however, possible to follow a "speck" in depth, by using the fine focus, and distinguish it from specks as such. All of the three orientations of <100>-rods are also seen at x in Fig. 2. Clearly they are far less numerous than those of the first type. The length of a <110>-rod is typically in the range of 15-25μ. The lengths of <100>-rods show a wider variation, 5-20μ, but on the whole they are shorter.

Viewed under crossed polarizers, the <110>-rods get extinguished for any orientation of the specimen with the transmission axes of the polarizers, while, for an arbitrary orientation of the specimen, the <100>-rods do not (see Fig. 4a and 4b). This means that either the two types are made of two different materials (one

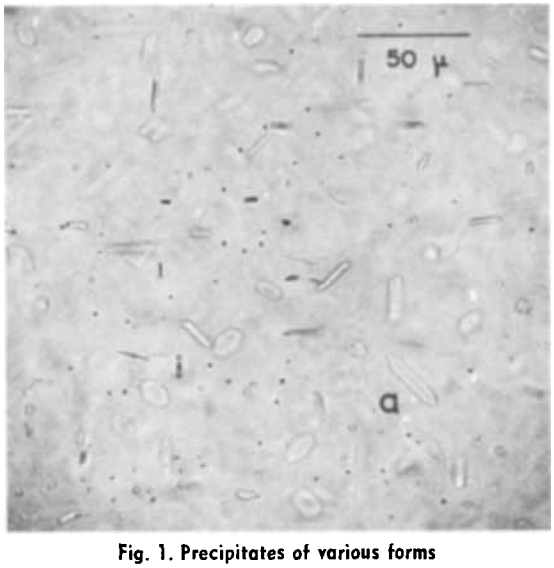

Fig. 1. Precipitates of various forms

[1] The edges of the photomicrographs are parallel to the [100] and [010] directions of the crystals.

being noncubic) or they are made of the same material but their optical orientations are different.

Lilley and Newkirk have published (4b) a photomicrograph of precipitate rods which, according to them, do not seem to correspond to any rational low index direction. Both types of rods described in the present work are, however, definitely oriented along simple crystallographic directions in the matrix. Dreyfus (11) also has observed crystallographically oriented rod-like precipitates in the KCl-$SmCl_2$ system.

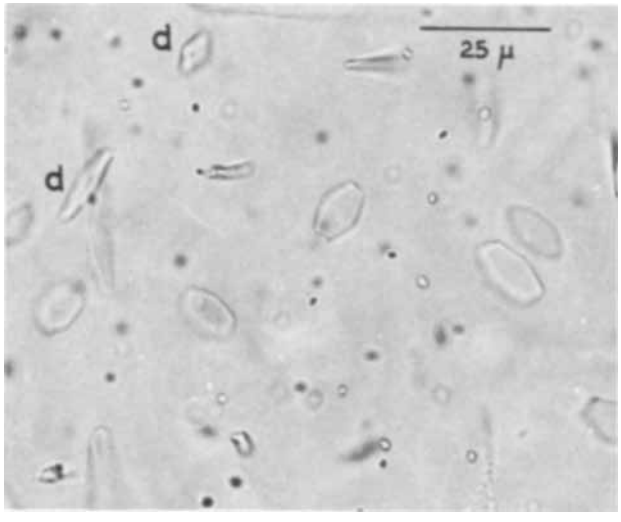

Fig. 6. Several hexagonal platelets and rhombus-shaped platelets

Orientation of precipitates in the form of hexagonal platelets.—Figures 5 to 8 show hexagonal platelets,

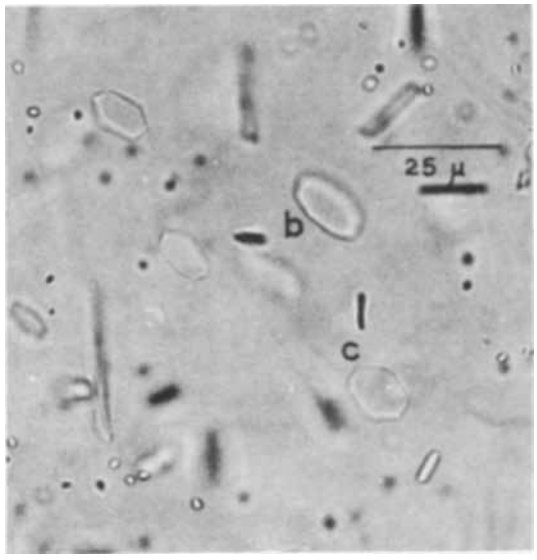

Fig. 7. Platelets in the forms of hexagon, octagon, and decagon seen in relative orientations.

Fig. 8. < 110 >-rods, hexagons, and a decagon

10-15μ in size, as seen on a {001} plane. They are all inclined to the plane of observation, *viz.*, a {001} plane, and although they appear to be irregular they could be regular hexagons in their respective planes. The hexagonal symmetry suggests the possibility that these are {111} planes. Further microscopic observations and x-ray analysis have confirmed that the hexagons in fact lie on {111} planes.

Precipitates of other forms.—(*a*) Figure 5 which is part of Fig. 1 observed at a higher magnification, shows, at "a," an elongated precipitate which appears to be a platelet lying in the plane of observation and oriented along a <110> direction.

(*b*) Figures 5 and 7, at "b," show octagonal platelets. These also are inclined to {001} planes and four different orientations are observed. Thus they, like the hexagonal platelets, seem to lie on {111} planes.

(*c*) Figures 7 and 8 show, at "c," platelets which clearly have ten sides. These decagons too are inclined to {001} planes and preliminary observations indicate that they lie on {111} or near- {111} planes.

(*d*) In Fig. 6 are seen, at "d," platelets which appear to be in the shape of rhombi. They could, however, be rectangular or square platelets and are only seen as rhombi because of their inclination to the plane of observation.

All of these forms are, as can be seen in the photomicrographs, much less numerous than the rods of either kind and the hexagons. In addition to the forms described so far some others also are seen but they are not very prominent.

Nature of Precipitates

The precipitates seen in the present, *viz.*, NaCl-$BaCl_2$, system are all transparent, unlike, for example, those seen by Dreeben (5) in CdS-Au. They are thus some barium compound, not barium metal. It could be barium chloride, hydroxide, or a chloride-hydroxyl complex. Further investigations are in progress to determine the detailed morphology and nature of the precipitates.

All of the precipitates can be dissolved back into the solid by heating the crystal to elevated temperatures below the melting point, and the impurity retained in solution by rapid quenching in air. Such quenched crystals do not show any precipitates when examined under the microscope. Aging the same crystals in air at about 350°C for about 48 hr results in the reappearance of oriented precipitates.

Technical Notes

Silicon Dioxide Thermally Grown in a Silicon Nitride Ambient†

Ronald A. Cohen*

MIT Lincoln Laboratory, Lexington, Massachusetts

and R. Wheeler

Sprague Electric Company, Worcester, Massachusetts

Many techniques have been used to reduce the number of surface states and increase the stability of MIS devices. Recently, much of the emphasis has been on the reduction of alkali metal contamination of the silicon dioxide dielectric. Ultraclean processing techniques and material for formation of ultraclean silicon dioxide, replacement of silicon dioxide as the dielectric with silicon nitride as a more effective alkali barrier, and combinations of silicon dioxide with silicon nitride, controlled phosphorus gettering, and most recently, the use of alkali barrier liners (silicon carbide) to replace conventional quartz tube and alumina liner systems have all been tried with varying degrees of success. This note illustrates the use of silicon nitride as an alkali barrier liner analogous to silicon carbide.

Experimental Procedure

MOS structures were fabricated on <100> p-type 10 ohm-cm silicon material by a routine "clean" MOS process (1) with the oxidation being carried out at 1200°C. The normal quartz oxidation tube and high-purity alumina liner were replaced by a single silicon nitride tube.[1] Electron beam probe analysis of the tube material before and after use showed no observable sodium to the limits of the testing technique. The tube was cleaned by etching in a 10/1 solution of distilled deionized water and concentrated HF for 15 min, rinsed for 1 hr in 18 megohm-cm water, dried in a Class 100 ambient overnight, and finally baked in its entire length at 1000°C with oxygen flowing. Capacitance-voltage measurements (2) were used to evaluate the quality of the oxide. In the course of this work it became necessary to shut down and move the apparatus. Later, the furnace was reactivated and resulting experimental wafers were of low quality. The silicon nitride was then recleaned by the above procedure and the resulting wafers were again of high quality.

Results and Discussion

The capacitance-voltage measurements were carried out at room temperature and after a temperature-bias treatment of 300°C under a 1×10^6 v/cm negative field. Shifts in flat band voltage of 0.1-0.7v were obtained corresponding to 1.0 to 8.0×10^{10} q/cm^2. A comparison of this result to those obtained by Schmidt (3) are shown below:

Liner material	$\Delta q/cm^2$
High-purity alumina (3)	3.0×10^{12}
Silicon carbide (3)	4.5×10^{10}
Silicon nitride	$1.0\text{-}8.0 \times 10^{10}$

† This work was sponsored in part by the U.S. Air Force.

* Electrochemical Society Active Member.

[1] Silicon nitride tube was obtained from Haynes Division of Union Carbide, Kalamazoo, Michigan.

It is shown that the high-purity alumina can contaminate the silicon dioxide dielectric and the ordinary quartz tube which cannot be cleaned of alkali metal and must then be scrapped. The silicon nitride tube, if accidentally contaminated, can be cleaned and returned to satisfactory use. There is no data, to our knowledge, that this is possible with the silicon carbide tube.

The advantage of the silicon nitride tube is based on the fact that silicon nitride does oxidize (4) to a small extent. Although the silicon nitride tube itself does not contain or allow alkali metal contamination to pass through it, the interior work area can be contaminated by accident or by poor material control or processing techniques. In addition, silicon nitride also possesses small diffusion coefficients for alkali metals, negligible alkali metal concentration, good thermal conductivity and thermal shock resistance, slow rate of oxidation, availability, and low price.

Conclusions

Alkali barrier liners appear to be greatly superior to conventional quartz tubes and alumina liner systems.

Silicon nitride liners can be recleaned and returned to use if contaminated. Much data are available in the literature on properties of silicon nitride in relation to silicon/silicon dioxide systems. Further experimentation is necessary to determine the relative advantages of silicon nitride and silicon carbide in this application.

Variation of Contact Resistance of Metal-GaAs Contacts with Impurity Concentration and Its Device Implication

Kenneth L. Klohn and Lothar Wandinger

Electronic Components Laboratory, U. S. Army Electronics Command, Fort Monmouth, New Jersey

For efficient and reliable operation of microwave semiconductor devices which require high-current densities, it is essential to use the lowest resistance ohmic contacts possible. The generation of excessive ohmic heating (I^2R_s) limits the output which can be achieved by such devices as laser diodes, Gunn oscillators, tunnel diodes, avalanche transit time devices, and high cut-off-frequency varactors. In addition, heat must be dissipated rapidly to prevent any buildup in the bulk material and in the vicinity of the junction. This requires a good thermal path with low resistance from the device to suitable heat sinks. Device cutoff frequency, f_c, is another parameter which is limited by series resistance of which contact resistivity, R_c, is a part. A low f_c, in turn, affects the upper operating frequency and power efficiency. Any degradation in power efficiency generates additional heat which if not removed could result in early device failure and poor reliability.

The formation of an intimate metal-semiconductor contact which exhibits low resistance is dependent on: (*i*) surface preparation, (*ii*) metal deposition conditions, (*iii*) post-deposition alloying, (*iv*) barrier height, (*v*) impurity density of the adjacent semiconductor layer, and (*vi*) uniform wetting between metal and semiconductor. A number of investigators (1-11) have developed various techniques to achieve satisfactory ohmic contacts to GaAs. This note presents techniques and metal-GaAs combinations which produced good ohmic, low resistance contacts at moderate alloying temperatures, and shows how these R_c values vary with substrate impurity density. The metals chosen for this investigation have, for the most part, been used previously on an empirical basis and their quality evaluated by the performance of the completed device. Also, it will be indicated how the results of this investigation reduce the series resistance of laser diodes and consequently improve their potential output power capabilities.

Experimental Procedure

The material used for these experiments was Czochralski and boat-grown GaAs having 10^3-10^5 etch pits/cm^2 and oriented in both the <100> and <111> directions. Wafers were lapped down to 4-6 mils using a 3 μm aluminum oxide grit. Impurity concentrations, determined by the van der Pauw technique (12), varied from 2.8 x 10^{17} to 10^{20} cm^{-3} for Zn-doped material and 1 x 10^{17} to 3 x 10^{18} cm^{-3} for Te-doped material. The wafers were cleaned ultrasonically in trichlorethylene followed by a methyl alcohol rinse. The cleaned wafers were then etched in a warm mixture of $1H_2O:1H_2O_2:3H_2SO_4$ to remove approximately ½-mil and stored under methyl alcohol prior to placing them in the vacuum system or plating solution.

The metals used in this study were Ag, Au-4% Zn, In, and Ni. Ag and Au-4% Zn were applied by evaporation using the metals in wire form with a purity of 99.999%. The metal wire was cleaned in KOH and stored under methyl alcohol prior to evaporation. In each case approximately 6000Å of metal was evaporated on both sides of the substrate at 1-5 x 10^{-6} Torr. Subsequent microalloying was carried out in vacuum by heating the substrate to 300°C for 10 min. The Ag samples received an additional 6000Å of Au on each side which was then heated to 150°C for 5 min. The 2.8 x 10^{17} cm^{-3} samples with Au-4% Zn required an additional sintering operation at 400°C for a few seconds on a strip heater in a forming gas atmosphere.

The nickel contacts were plated with an electroless nickel solution (2), rinsed in H_2O followed by methyl alcohol, and placed in the vacuum system for the alloying step. These samples were also heated to 300°C for 10 min.

The indium contacts on n-type GaAs were applied by electroplating, followed by a rinse in H_2O and methyl alcohol. They were then microalloyed on a strip heater in forming gas at 350°C for 2 min. Following the metalization and microalloying, all samples were diced with a wire saw to 8-10 mil squares.

Resistance measurements were made by using a precision Wheatstone bridge. The resistance due to leads, package, and bulk GaAs was subtracted from the total resistance measured to obtain the contact resistance values. Five to ten dice were measured for each point and averaged. The deviation from the average value was typically —30-+40%. Each point for a given impurity concentration involves a separate metalization and alloying procedure.

Results and Discussion

The value of specific contact resistance *vs.* substrate impurity concentration for Au-4% Zn, Ni, and Ag on p-type GaAs and for In on n-type GaAs is shown in Fig. 1. In order to achieve the values of R_c indicated in the figures, it was necessary to exercise great care to achieve and maintain substrate surfaces free of contamination and minimize any oxides which may have been present. Failure to attain good surface conditions would result in substantially higher contact resistance. The values of substrate impurity concentrations used in these experiments ranged from 2.8 x 10^{17} to 9 x 10^{19} cm^{-3} for p-type GaAs and 1 x 10^{17} to 3 x 10^{18} cm^{-3} for n-type GaAs. They correspond to those normally found when fabricating GaAs laser di-

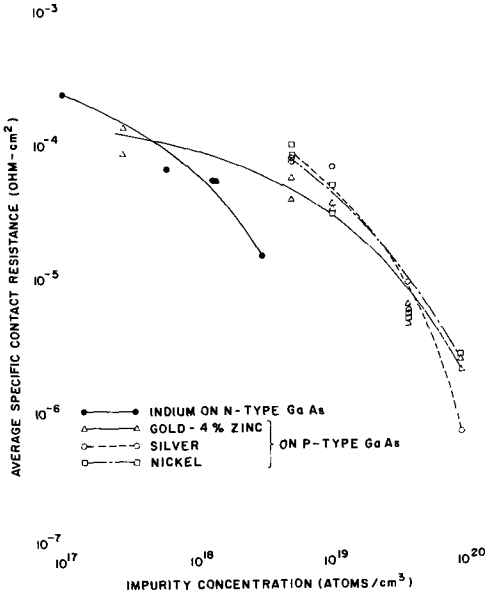

Fig. 1. Average specific contact resistance of gold-4% zinc, silver, and nickel on p-type GaAs and indium on n-type GaAs as a function of GaAs impurity concentration.

odes or emission diodes. Specific contact resistance values measured for p-type GaAs varied from 1.2 x 10^{-4} ohm-cm^2 for Au-4% Zn on 2.8 x 10^{17} cm^{-3} material to 7.3 x 10^{-7} ohm-cm^2 for Ag on 9 x 10^{19} cm^{-3} material and for n-type GaAs with In contacts from 2.5 x 10^{-4} ohm-cm^2 for 1 x 10^{17} cm^{-3} to 1.5 x 10^{-5} ohm-cm^2 for 3 x 10^{18} cm^{-3}.

The curves show only a modest increase of contact resistance with decreasing substrate impurity density of 10^{18} cm^{-3} and lower, but a rapid decrease as substrate doping is increased above 5 x 10^{18} cm^{-3}. In general, the decrease amounted to 1.5 orders of magnitude per order of magnitude increase in doping level. The lowest average R_c value measured was 7.3 x 10^{-7} ohm-cm^2 Ag on 10^{20} cm^{-3} zinc-doped material. It is this behavior which is most important for the design of low series resistance semiconductor devices where heating due to ohmic losses plays an important role, such as in laser diodes.

The desirability of incorporating an n^+ layer adjacent to the metal contact, in order to reduce the series resistance of a device significantly, can be illustrated by calculating the contact resistances and bulk resistance for a typical laser diode such as shown in Fig. 2(a). The n-type material generally used for lasers is 1-3 x 10^{18} cm^{-3}. The p-n junction required for the device is typically generated by the diffusion of Zn at 850°-900°C, yielding a surface concentration of 1-3 x 10^{20} cm^{-3}. Using the dimensions in Fig. 2(a), the experimentally measured contact resistances, and assuming a typical diffusion profile in a 25 μm diffused p-layer with an average density of 4.5 x 10^{19} cm^{-3}, the contact resistance and series resistance for the different layers are calculated and summarized in Table I.

Table I shows that the series resistance R_s for a typical laser structure is of the order of a one tenth of an ohm. In addition, it can be seen that 47% of the total resistance comes from the metal contact to the n-layer. To improve this value a modified structure can be used, as shown in Fig. 2(b). A 3 μm layer can be replaced by an epitaxial n^+-layer doped with Se or Sn with a carrier concentration of 1 x 10^{19} cm^{-3} which represents the highest concentration for any

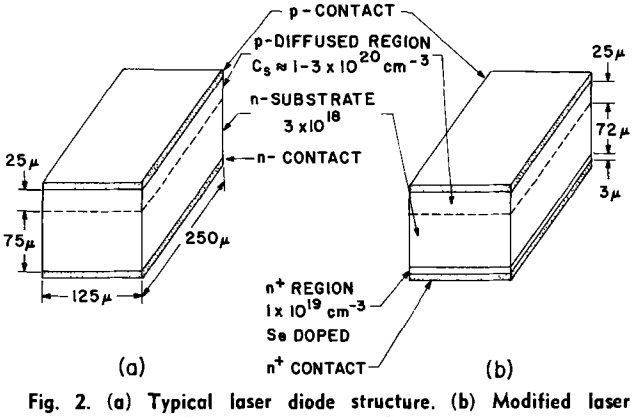

Fig. 2. (a) Typical laser diode structure. (b) Modified laser structure with an n^+ region adjacent to the contact.

Table I. Calculated contact and bulk resistance of typical laser structures based on measured specific contact resistance

Regular structure, Fig. 2(a)			Modified epi-structure, Fig. 2(b)		
Resistance*	(ohms)	Percentage of total resistance	Resistance*	(ohms)	Percentage of total resistance
R_{cp^+}	0.0023	2.3	R_{cp^+}	0.0023	4.1
R_p	0.0223	22.0	R_p	0.0223	39.5
R_n	0.029	28.5	R_n	0.028	49.6
R_{n^+}	—	—	R_{n^+}	0.0006	1.1
R_{cn}	0.048	47.2	R_{cn^+}	0.0032	5.7
R_s	0.1016	100.0	R_s	0.0564	100.0

* R_{cn}, R_{cp^+}, R_{cn^+} = contact resistance to n, p^+, n^+ layers; R_n, R_p, R_{n^+} = bulk resistance of n, p, n^+ layers; R_s = total series resistance.

known n-type dopant for GaAs (13). The p-layer, which is also a big contributor to the R_s, was not changed to illustrate clearly the effect of the impurity concentration of the n-doped semiconductor layer immediately adjacent to the metal layer on the series resistance of a specific device. It can be seen that the R_s of the modified device structure is 44% lower than the one of the original geometry. Significantly, however, the resistance of the n-contact is only 5.7% of the total, a reduction of eight to one. The bulk resistance of the modified structure accounts for 89% of R_s with the n-region being the major contributor. A specific contact resistance of 10^{-6} ohm-cm^2, extrapolated from the In curve at 10^{19} cm^{-3} (Fig. 1) for the n-side and 7.3 x 10^{-7} ohm-cm^2 from the Ag curve at 9 x 10^{19} for the p-side was used in these calculations.

Optimum Abrasive Sizes for Minimizing the Polishing Times of Semiconductors

Sumner Mayburg*

Semiconductor Processing Company, Hingham, Massachusetts

The polishing of glass is a combination of fracturing of the surface by the abrasive particle, a flow of material during the time the particle of abrasive produces the scratch, and some chemical action produced by the abrasive polishing slurry (1). Glass polishing technology has been developed with a large number of variables not the least of which is the variability of glass itself. It is not at all surprising that glass polishing is an art which has not been converted to a straight-forward scientifically understood technology.

Much of the art of glass polishing has been carried over to the semiconductor industry. However, for many semiconductor materials, fast chemical polishes have been found which are significantly better than abrasive polishes in producing damage free surfaces. In silicon polishing, where such a chemical polish (2) exists, abrasive polishing is essentially unnecessary. However, in those materials where good chemical polishing has not yet developed, abrasive polishing continues to be an important step in making useful practical structures. In this paper we attempt to treat some practical aspects of abrasive polishing to see what optimization is available.

Abrasive polishing of good single crystals should be simpler to understand than the polishing of glass. The plastic flow temperature and the thermal conductivity of most semiconductor and dielectric single crystals are much higher than glass. Therefore the probability of creating plastic flow during the polishing is greatly reduced. We shall assume that the polishing operation is simply a scratching procedure in which the material being polished is fractured by the hard abrasive particles moving across the surface and that the maximum scratch depth is the diameter of the abrasive particle. This scratch depth is further defined to be the surface roughness.

In a review of the grinding, lapping and polishing of quartz with silicon carbide abrasive, Bond (3) notes that the rate of removal of material is proportional to the size of the abrasive particle used. Soper (4) has observed this same proportionality in the case of garnet abrasive on silicon. The calculations that follow are based on the assumption that the rate of removal is proportional to abrasive size, an assumption which should be verified for each abrasive and material to be polished. In recirculating slurry systems where the abrasive particles are gradually being broken down through use and are being returned to the surface being polished, a simple relationship between rate of removal of material and abrasive particle size is not likely to exist.

Theory

In our discussion we assume that the rate of removal of material is αS where S is the size of the abrasive particles used and α is a constant with respect to S but does depend on the nature of the abrasive and the pressure used during polishing. We assume α is kept constant in a polishing process which consists of using several steps with an abrasive which has been graded into different sizes. Each subsequent step uses a finer grade of abrasive than the prior step, and the final step uses the finest grade of the abrasive available.

Consider the first step; we start with a surface of roughness S_0 and use abrasive particles of size S_1 to remove material. We need to remove a layer of material which is at least an amount S_0. If we do this, the roughness of the surface now becomes determined by S_1 and, assuming that removal of material is produced by a scratching or plowing action, the maximum roughness is S_1. Let t_1 be the time required to remove a layer of material S_0 from the surface then

$$S_0 = \alpha S_1 t_1 \qquad [1]$$

On the second step we want to convert a surface from roughness S_1 to a surface of roughness S_2 with the minimum of polishing time. Thus, we remove a layer of material S_1 but not more.

$$S_1 = \alpha S_2 t_2 \qquad [2]$$

Similarly, we have for the n^{th} step

$$S_{n-1} = \alpha S_n t_n \qquad [3]$$

and for the final step f

$$S_{f-1} = \alpha S_f t_f \qquad [4]$$

From a practical point of view, it is important to minimize the time required to polish the surface. In principle we could polish the roughest surface with the finest abrasive available and have only one step in the polishing operation. However, this may require an impractically long time.

We can minimize the total time of polishing T in the following way: From Eq. [3]

$$T = \sum_{n=1}^{n=f} t_n = \frac{1}{\alpha} \sum_{n=1}^{n=f} \frac{S_{n-1}}{S_n} \qquad [5]$$

In principle, we are free to choose the abrasive size on any step independent of the abrasive sizes on the other steps. In particular, we may choose the abrasive size on the n^{th} step S_n so that T is a minimum.

We have after differentiation

$$\frac{\partial T}{\partial S_n} = \frac{1}{\alpha}\left[-\frac{S_{n-1}}{S_n^2} + \frac{1}{S_{n+1}} \right] = 0$$

since S_n enters in both t_n and t_{n+1}, but nowhere else in Eq. [5]. The condition for minimum T is thus

$$S_n^2 = (S_{n-1})(S_{n+1}) \qquad [6]$$

Also

$$\frac{S_{n-1}}{S_n} = \frac{S_n}{S_{n+1}} \qquad [7]$$

or

$$t_n = t_{n+1} \equiv t \qquad [8]$$

The polishing time on each step should be the same time t for minimum total polishing time T. From Eq. [5] we have

$$T = ft \qquad [9]$$

From Eq. [3], [4], and [8] we may write the products of each step time as

$$\prod_{n=1}^{f} t_n = t_f \cdot t_{f-1} \ldots t_n \ldots t_1 \equiv t^f = \alpha^{-f} S_0/S_f \qquad [10]$$

By combining Eq. [9] and [10] we find for the total time T

$$T = \alpha^{-1} f (S_0/S_f)^{1/f} \qquad [11]$$

* Electrochemical Society Active Member.

as the total time required for the f step polishing operation.

We may minimize the total polishing time T with respect to the number of steps f. From Eq. [11] we find

$$f = \ln (S_0/S_f) \quad [12]$$

With this number of steps

$$T = fe/\alpha \quad [13]$$

with $e = 2.72$.

Discussion

It is especially interesting to note from Eq. [12] that the optimum number of steps is independent of α and depends only on the starting surface roughness S_0 and the finest abrasive available S_f to be used on the final step.

We can estimate f for the case of diamond polishing of a surface produced by a diamond "internal diameter" cutting blade. These blades usually have diamond pieces of size 40μ. The finest diamond abrasive has particle size typically 0.10μ, so that S_f is 0.10μ. We have from Eq. [8]

$$f = \ln 400 = 6 \text{ steps}$$

for minimum polishing time.

If only three polishing stations were available, we would obtain most efficiency by use of Eq. [6] to determine the abrasive sizes to be used on the first and second abrasive polishing station. We have

$$S_1^2 = S_0 S_2$$

$$S_2^2 = S_1 S_f$$

or

$$S_1^2 = S_0 \sqrt{S_1 S_f}$$

Then

$$S_1^3 = S_0^2 S_f$$

or

$$S_1 = (S_0^2 S_f)^{1/3}$$

Similarly, we find

$$S_2 = (S_0 S_f^2)^{1/3}$$

With $S_0 = 40\mu$ and $S_f = 0.1\mu$ as above we have

$$S_1 = 5.5\mu$$

and

$$S_2 = 0.74\mu$$

As another example, consider the abrasive polishing of Si with garnet. We have established (4) a value of α for the garnet abrasive of (1/6) min^{-1}. Suppose we wish to get a final finish of 0.1μ and suppose $S_0 = 40\mu$ is the surface roughness produced by a diamond ID blade slicing. Then the minimum time T given by Eq. [13] is

$$T = 6(2.72)/(1/6) \text{ min}^{-1}$$
$$= 97 \text{ min}$$

where six polishing steps are required. However, if only two polishing steps are available, we find from Eq. [11] that the required time is

$$T = (6 \text{ min}) \ (2) \ (400)^{1/2} = 240 \text{ min}$$

or roughly 2½ times the minimum time.

For a three-step process

$$T = (6 \text{ min}) \ (3) \ (400)^{1/3} = 124 \text{ min}$$

which is only 29% greater than the minimum time. From a practical point of view, a three-step process may be almost as fast as a six-step process when one considers the clean up time required in going from one step of the process to the next step.

Brief Communications

Preparation of Vitreous Materials in the Form of Well-Defined Hollow Cylinders

N. S. Platakis, H. C. Gatos,* and A. F. Witt*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

A method has been developed for the preparation of vitreous materials which essentially overcomes some of the main problems associated with the characterization and study of such materials. These problems are chemical homogeneity (1,2), porosity (or inclusions), and lack of well-defined geometrical shapes.

The system $x\text{As}_2\text{Se}_3 \cdot y\text{Sb}_2\text{Se}_3$ was employed in the present work since in this type of chalcogenide glasses the problem of chemical homogeneity is quite acute. Furthermore due to their very pronounced brittleness, the mechanical preparation of samples with well-defined geometrical shapes is tedious at best.

The salient steps of the new method are as follows: the constituents of the vitreous system are placed, in the desired proportions, in a quartz ampoule (typical dimensions were 1 cm ID and 10 cm long) which is evacuated (to a pressure of approximately 10^{-6} mm Hg) and sealed off. Then the ampoule is fitted to a horizontal shaft of a motor. The shaft-ampoule arrangement can be placed in and out of a horizontal furnace (by moving the motor or by moving the

* Electrochemical Society Active Member.

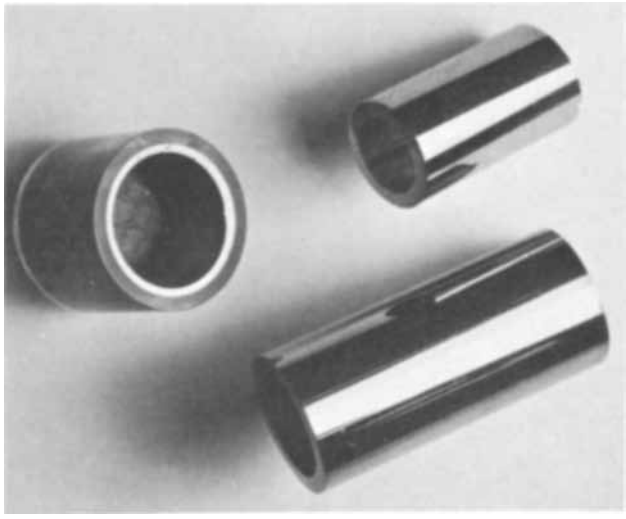

Fig. 1. Hollow cylinder samples of vitreous chalcogenides. The sample on the left is still contained in the quartz tube (after cutting the ampoule). The other two samples have been removed from the quartz tube. Magnification 1X.

furnace) while the ampoule is being rotated in the vicinity of 25 rpm. After the material is molten the ampoule is withdrawn from the furnace and while still under rotation is quenched either in air or other media. (The material can of course be slowly cooled in the furnace if desired.) Subsequently the ampoule containing the vitreous material is cut into the desired lengths (a string saw or ordinary cutting wheels were employed with consistent success). Since the coefficient of thermal expansion of quartz is smaller than that of the chalcogenide glasses, the hollow cylinders of the vitreous material are readily separated from the ampoule by simply immersing the cut pieces into acetone. This obvious requirement that the coefficient of thermal expansion of quartz be smaller than that of the material being prepared (to avoid cracking the cylinder) is essentially met by all materials under consideration (3). Some typical samples of vitreous chalcogenides are shown in Fig. 1.

The hollow cylinders obtained with the present method exhibited no variation in thickness. The thickness could be varied from run to run by controlling the amount of the starting material and the size of the ampoule. It should be pointed out that hollow cylinders are advantageous shapes for quenching since cooling takes place through both their outer and inner surfaces. (In the presence of helium rather than in vacuum quenching can be even more effective.) In fact it was possible to extend the glass formation region of the present system since single phase hollow cylinder samples were obtained with compositions which constantly gave two phase samples by other means of preparation.

No porosity, inclusions, or other macroscopic defects could be detected in the hollow cylinders. This result is not surprising if one considers that solidification proceeds progressively in a layer-type fashion from the outer to the inner part of the cylinders. Because of the rotation, during cooling the melt is in contact with only part of the forming cylinder at any given time. In all instances the hollow cylinder samples exhibited far greater mechanical strength than samples prepared by other methods. Furthermore electron probe analysis along the cylinders and across their thickness revealed no detectable variation in chemical composition.

The hollow cylinder samples lend themselves to electrical measurements (resistivity) which often present serious difficulties. Resistivity measurements were made by immersing the hollow cylinders into silver paste and attaching electrodes in the inner and outer surface (4). The silver paste shorting the inner and outer electrodes was removed by grinding the two ends of the cylinders. For thin-walled cylinders (where the outer area is essentially the same as the inner) the total resistivity R is

$$R = \rho \frac{l}{A}$$

where ρ is the resistivity, l is the length (thickness of cylinder), and A the area of the cylinder. It is apparent that in the present samples the ratio l/A can be made orders of magnitude smaller than in conventional samples and thus facilitate the determination of very large resistance values.

Although the method was primarily applied to the preparation of homogeneous hollow cylinders of vitreous materials it can readily be adopted for a number of polycrystalline materials and even single crystals with the aid of appropriate seeds.

The over-all reproducibility of the method was found to be excellent.

Homogeneous Impurity Incorporation during Crystal Growth from the Melt

August F. Witt and Harry C. Gatos

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

Semiconductor single crystals were grown reproducibly in a Czochralski-type puller with heretofore unattainable dopant homogeneity. No concentration fluctuations of the dopant could be detected by employing the high resolution techniques described elsewhere (1) (linear resolution less than 0.2μ). The effects of thermal asymmetry at the growth interface which are responsible for the commonly observed impurity fluctuations (2) were overcome by dispensing with seed rotation and by virtually eliminating random thermal

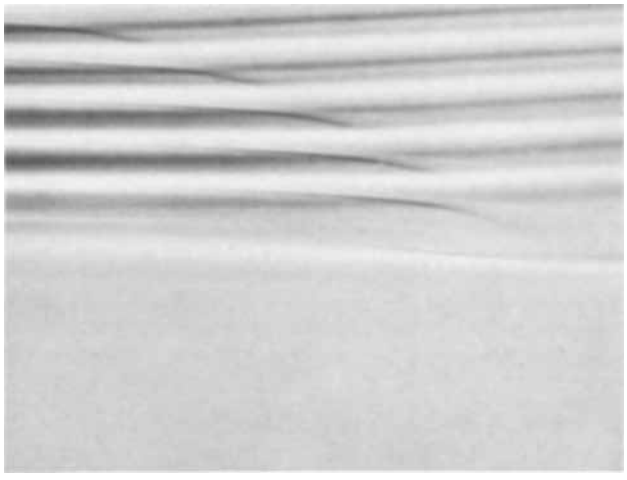

Fig. 1. Impurity distribution in an InSb single crystal as revealed by high resolution etching. The upper part was grown with seed rotation and synchronized crucible rotation in the same direction and exhibits pronounced impurity concentration fluctuations (rotational striations). The "facet" region (upper left part) "off facet" region (upper right part) are clearly delineated. The lower part was grown with crucible rotation alone; it exhibits extremely homogeneous impurity distribution and no rotational striations. Magnification approx. 350X.

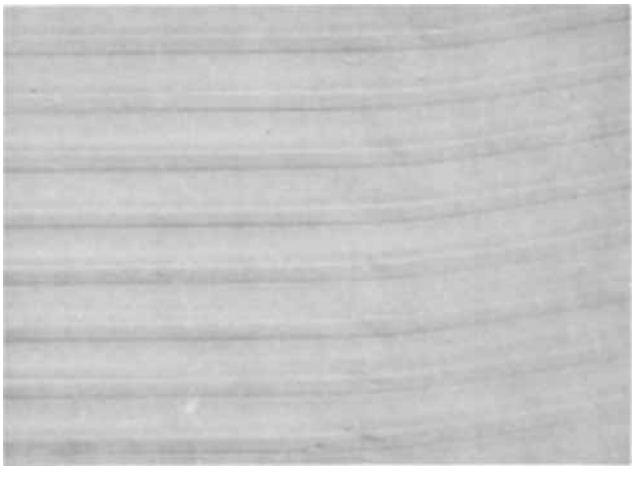

Fig. 2. "Facet" (left-hand side of the figure) to "off facet" (right-hand side) transition regions in InSb pulled under crucible rotation only. The facet region does not exhibit the commonly observed impurity concentration increase; the transition is characterized only by a change of the growth interface from flat to curved. The stripes were introduced by a periodic interruption of crystal pulling so that the growth interface could be clearly delineated. Magnification approx. 360X.

fluctuations in the melt by means of moderate crucible rotation (10-30 rpm).

In previous studies (2,3) it was shown both theoretically and experimentally that thermal asymmetry (whereby the thermal axis does not coincide with the rotational axis) in Czochralski-type pullers leads to fluctuations of the microscopic growth rate which in turn cause the well known impurity striations. Asymmetric heat inputs, which are encountered in nearly all growth systems, establish thermal asymmetry both in the growing crystal and in the melt. Whereas crucible rotation can significantly decrease the effectiveness of thermal asymmetry present in the melt, it does not alter appreciably the thermal configuration in the growing crystal. Thus, when seed rotation is employed, rotational impurity heterogeneities are essentially always present regardless of whether or not crucible rotation is used. Accordingly (and in contrast to the generally held belief), pulling with simultaneous seed rotation and crucible rotation in the opposite

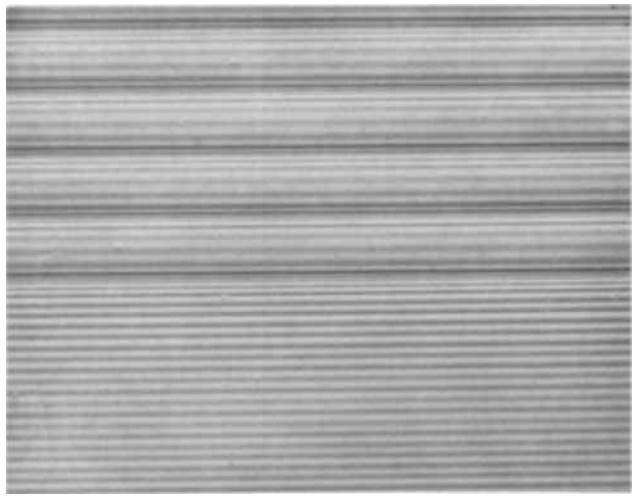

Fig. 3. Growth characteristics of the off facet region of InSb as revealed by vibrational "rate striations." The upper part, grown with seed rotation and synchronized crucible rotation exhibits periodic growth rate changes as seen from the varying spacing of the "rate striations." The lower part, pulled with crucible rotation only, exhibits a constant growth rate (constant spacing of "rate striations") which is a prerequisite for homogeneous impurity incorporation. Magnification approx. 450X.

Fig. 4. Multiple beam interferogram of an etched InSb single crystal. The periodic deflections of the interference fringes in the upper part reflect the impurity concentration fluctuations always present under seed rotation. The homogeneous impurity distribution in the lower part (straight line interference fringes) reflects the growth conditions associated with crucible rotation without seed rotation. Magnification 230X.

direction does not improve the impurity distribution in the resulting crystal. Synchronized crucible and seed rotation in the same direction reduces (but does not eliminate) the commonly observed impurity striations.

By growing without seed rotation, in addition to making any existing thermal asymmetry in the solid ineffective, the growing crystal can readily drift toward the thermal center of the system. This self-positioning process virtually eliminates the effects of thermal asymmetry in the melt and, thus, insures steady-state microscopic growth conditions.

It was further found that in growing with crucible rotation but without seed rotation the facet (on-core) region does not exhibit any noticeable increase in impurity concentration in contradiction to earlier re-

ports (4). The pronounced difference in impurity concentration between the facet and the off-facet regions discussed in these reports was attributed to different growth mechanisms operating in the two regions. In view of the present results a revision of the prevailing views may be necessary.

Experimental results obtained with single crystals of InSb are shown in Fig. 1,2,3, and 4. The crystals were grown in the <111> direction and were studied with techniques discussed elsewhere (1).

Although the bulk of the experiments were performed with InSb, a similar behavior was observed in the case of germanium single crystals. We believe that silicon and other semiconductors should behave likewise. Work is underway to study the electrical characteristics of crystals with the same over-all macroscopic concentration of a given dopant but with different degrees of homogeneity. Preliminary results indicate that the carrier mobilities in InSb are significantly decreased in the presence of impurity fluctuations.

Preparation of Rhenium Hexafluoroacetylacetonate

Harvey J. Anderson and Abner Brenner*

National Bureau of Standards, Washington, D. C.

We were interested in preparing the rhenium derivative of hexafluoroacetylacetone (the latter will be designated by F_6AA) for the purpose of using it to produce a deposit of rhenium by chemical vapor deposition. The F_6AA compounds are known to be stable and yet surprisingly volatile for metallic compounds. Van Hemert and co-workers (1) had prepared thin deposits of copper, nickel, and rhodium by passing the F_6AA chelates of these metals mixed with hydrogen through a hot tube.

The metal chelates are usually easily prepared by simple metathesis of the sodium salt of the ligand with the simple metal salt (chloride, nitrate, or acetate) in aqueous or alcoholic media (1-4). A variation consists in adding the ligand directly to a suspension of the metal chloride in carbon tetrachloride (5). Since none of these methods yielded the rhenium chelate, we investigated several other procedures. The only one that was successful is described below.

We prepared the rhenium compound by the destructive distillation of the anhydrous sodium salt of F_6AA with anhydrous rhenium trichloride. Results with the pentachloride were not as satisfactory. The sodium compound was prepared by adding sodium hydride to an excess of F_6AA dissolved in tetrahydrofuran and by evaporating to dryness. In a typical experiment about 7.2g of the sodium salt were intimately mixed in a mortar with 3.0g of $ReCl_3$. The finely ground powder was transferred to a retort through which dry argon was passed during the distillation. The flow of argon aided the removal of the vapors from the hot zone. The delivery tube of the retort was connected to a vessel which was cooled with solid carbon dioxide. The retort was heated slowly in a small pot furnace. At about 125°C the dark vapor of the rhenium compound began to evolve. Heating was continued until the temperature reached about 400°C at which temperature the dark vapors ceased to form.

The rhenium compound in the receiver was collected by dissolving it in petroleum ether. Partial evaporation of the solution followed by cooling with solid carbon dioxide left a crop of dark purple, almost black crystals. These were purified by sublimation. The yield was 34% based on the rhenium trichloride. The following analysis was obtained:

Calculated for $Re(CF_3 \cdot CO \cdot CH \cdot CO \cdot CF_3)_3$		Found
Rhenium	23.1	22.4
Carbon	22.3	22.0
Hydrogen	0.4	0.7

The compound crystallizes in black needles which are soluble in many organic solvents but insoluble in water. The compound is stable in air. The vapor of the compound has a beautiful purple color resembling that of iodine and the organic solutions of the compound have a similar purple color. A few milligrams of the compound placed in a 100 ml flask, which is then transferred to an oven at 100°C, will maintain a purple vapor for about a day. This indicates that the compound is fairly stable to air oxidation. Passage of the vapor mixed with hydrogen through a tube heated to 400°C yielded a rhenium mirror which, however, was rather dark in color. Details of the experiments on chemical vapor deposition of rhenium will be contained in another publication.

Electrocatalysts for Hydrogen/Carbon Monoxide Fuel Cell Anodes

IV. Platinum-Nickel Combinations

D. W. McKee and M. S. Pak

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The behavior of a series of platinum-base metal binary catalysts as anodes for the oxidation of H_2-CO fuel mixtures has been studied at 85° and 100°C with 85% phosphoric acid electrolyte. Platinum-nickel catalysts show the best tolerance for carbon monoxide and the performance of catalysts with less than 25 w/o (weight per cent) nickel is much superior to that of platinum black. The effect appears to be related to the strength of bonding of chemisorbed carbon monoxide to the alloy surface.

Although platinum black in various forms still remains the most widely used electrocatalyst for fuel cell purposes, for some applications other metals and alloys appears to be superior to platinum alone. For example, in the indirect hydrocarbon system, where the reformer effluent contains small amounts of carbon monoxide, the performance of platinum black anodes is seriously limited by the irreversible chemisorption of carbon monoxide, which causes the anode to polarize rapidly at low current densities. It has recently been found that alloys of platinum-ruthenium (1), platinum-rhodium, and platinum-iridium (2) are much more resistant to poisoning by carbon monoxide than is platinum alone, and improved electrodes for H_2-CO mixed fuels have been developed which utilize these binary catalysts (3).

Synergistic behavior of this type is not confined to alloys of the noble metals, and reports of similar effects are widespread in the catalytic literature. A recent observation by Bond and Webster (4), that addition of small amounts of a transition metal such as nickel, cobalt, or iron increases to a marked extent the hydrogenation activity of platinum catalysts, suggested that such noble metal-base metal combinations might show enhanced activity as electrocatalysts in fuel cell applications. Although corrosive attack of the acid electrolyte on the base metal component was an obvious objection, it was felt that small amounts of base metal incorporated in the platinum lattice might be protected from corrosion in the same way that alloys of copper and gold are known to be resistant to concentrated nitric acid up to 50 a/o (atom per cent) copper (5). The present paper is concerned with the behavior of platinum-base metal catalysts as fuel cell anodes for H_2-CO mixed fuels. Special attention has been devoted to the platinum-nickel combination, which appears to be the most promising of the binary systems investigated.

Experimental

Catalyst preparation and characterization.—A number of platinum-base metal combination catalysts were prepared by a modification of the Adams method previously described (1). This procedure involved fusion of a mixture of chloroplatinic acid and the base metal chloride with an excess of sodium nitrate. After the product was washed to remove soluble salts, the resulting mixed oxides were reduced in suspension with bubbling hydrogen. Before use, the catalysts were dried thoroughly, ground, and sieved through a 400 mesh nylon screen.

The base metal additives was selected so as to fall into one of the following categories:

(i) Platinum-oxide combinations. Metals such as molybdenum, tungsten, chromium, cadmium, and indium would be expected to remain as oxide phases under the conditions of catalyst preparation.

(ii) Alloy combinations. Easily reducible metals such as silver and gold would be expected to form alloy phases with the platinum. Partial alloy formation was also observed in the case of nickel and copper.

(iii) Leachable additives. The reactive metals magnesium, zinc, and tin would be rapidly attacked by the acid electrolyte in the fuel cell, leading to a porous or Raney type platinum structure.

The surface areas of the powdered catalysts were measured in a gas adsorption apparatus by the BET method, using nitrogen as adsorbate at —195°C. The structures of many of the catalysts were examined by means of x-ray diffraction and, for the platinum-nickel series, more detailed studies were made by thermogravimetric analysis. For this purpose, catalyst samples weighing 8-10 mg were contained in a platinum dish suspended from the balance arm of a Cahn Electrobalance coupled with a Fisher Linear Temperature Programmer (Model No. 360). With a stream of 5% hydrogen-nitrogen as reducing gas, initial measurements of weight change at room temperature were followed by measurements of loss in weight of the samples as a function of time, using a constant heating rate of 10°C/min. In this way, information on the reduction characteristics and composition of the catalysts could be obtained.

Evaluation as fuel cell anodes.—As in previous work (3), the catalysts were evaluated in the form of Teflon-bonded anodes in circular cells having 5.06 cm^2 of active electrode area. The catalyst loading was adjusted to about 34 mg/cm^2, and a second electrode containing the same loading of platinum black was used as cathode. The anodes were evaluated with 85% phosphoric acid as electrolyte, with synthetic fuel mixtures containing 2, 5, and 10% carbon monoxide. Oxygen was used as the oxidant, and measurements of anode polarization were made with a Kordesch-Marko bridge, using a separate platinum black electrode as hydrogen reference.

Chemisorption and catalytic activity measurements.—Measurements of the chemisorption of hydrogen and carbon monoxide on the platinum-nickel catalysts and of the gas phase oxidation of carbon monoxide on these materials were carried out in the apparatus described previously (6). This consisted essentially of a calibrated volumetric adsorption apparatus connected *via* a capillary leak to a mass spectrometer (Consolidated Electrodynamics Model 21-610). By this means, the composition of the gas phase in contact with the catalyst could be analyzed at 2-min intervals, and the course of a catalyzed reaction followed as a function of time.

In a typical experiment, a catalyst sample weighing 1.0g was sealed into the apparatus and evacuated to a pressure less than 1×10^{-6} Torr for 16 hr. The catalyst was then reduced at room temperature by treatment with hydrogen/nitrogen mixtures, the hydrogen being admitted slowly into the apparatus by diffusion through a heated palladium thimble. The temperature of the catalyst was then increased slowly to 150°C in contact with hydrogen, and the sample was then evacuated at this temperature for a further period of 16 hr. This procedure was necessary to limit excessive sintering during the reduction process. Adsorption isotherms of hydrogen and carbon monoxide were then determined volumetrically in the usual way. The kinetics of the gas phase oxidation of carbon monoxide were studied by admitting CO-O_2 mixtures to the unreduced catalyst samples and measuring the concentration of carbon dioxide in the gas phase as a function of time. These measurements were generally carried out with the catalyst samples held at 0° and 25°C.

Results and Discussion

Fuel cell performance of platinum/base metal anodes.—A summary of the fuel cell performance of a number of typical platinum/base metal binary catalysts is shown in Table I. The catalysts were tested as anodes for H_2/CO mixtures at 85°C using 85% phosphoric acid as electrolyte. The data are shown as anode *vs.* reference voltages at a number of current densities, the loading of catalyst on the anode being the same in each case. In comparison to platinum black, the lowest polarizations in the presence of carbon monoxide were observed with catalysts containing nickel and copper. Slight to moderate improvement over pure platinum was found with catalysts containing iron, indium, tin, and zinc, although appreciable corrosion of these and other electrodes was observed, as indicated in Table I. The addition of metals such as silver and gold gave rise to a very rapid loss in activity of the catalyst. Alloying with silver and gold is often found to decrease the activity

NPT-2	5.4%Ni	47.6
NPT-1	10.2%Ni	63.1

of the noble metals in gas phase hydrogenation reactions (7). As among all the catalysts tested, only those of platinum-nickel showed good stability, high corrosion resistance and consistently low polarizations in the presence of CO, the properties of this series of catalysts were studied in more detail.

Platinum-nickel catalysts.—Structure. The surface areas of a series of platinum-nickel catalysts, as measured by the BET method, are listed in Table II. A sharp decrease in surface area is indicated on addition of small amounts of nickel to platinum black. The increased tolerance of these catalysts for carbon monoxide does not therefore appear to be a mere surface area effect. On careful reduction of these samples with hydrogen gas at 100°C, the catalysts were found to sinter to a residual surface area of 10-15 m²/g.

Further information on the structure of the Pt-Ni catalysts was obtained by thermogravimetric analysis. Figure 1 shows thermograms obtained with samples of platinum black, Pt-10.2%Ni, and Pt-50%Ni. In all three cases, isothermal treatment with a 5% H_2-N_2 gas mixture resulted in a large weight loss at room temperature. With platinum black, this initial loss could be attributed to reduction of residual platinum oxide to the metal. A further loss in weight on heating to 140°C resulted from desorption of water vapor and no further loss occurred up to temperatures exceeding 300°C. Reduction of Adams platinum black was therefore essentially complete after treatment with diluted hydrogen at room temperature. On the other hand, the thermogram for the Pt-50%Ni sample showed three distinct steps: (*a*) reduction of platinum oxide at room temperature, (*b*) dehydration at 140°C, and (*c*) reduction of nickel oxide at 180°-300°C. The thermogram for the Pt-10.2%Ni sample, however, failed to show a distinct step identifiable as nickel oxide reduction and reduction of this catalyst appeared to be complete at 140°C. This effect was found to be a common feature of catalyst samples containing 10% nickel or less and it seems likely that a true alloy phase is present in these samples. This point is further illustrated in Fig. 2 which shows curves for the total weight loss, the weight loss at room temperature, and the weight loss due to reduction of nickel oxide as functions of the nickel content of the catalysts. Samples containing less than 10% nickel thus showed no evidence of a separate nickel oxide phase.

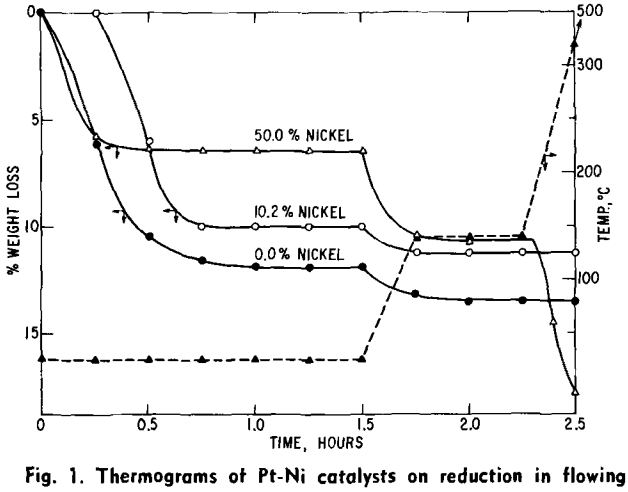

Fig. 1. Thermograms of Pt-Ni catalysts on reduction in flowing 5%H_2/N_2.

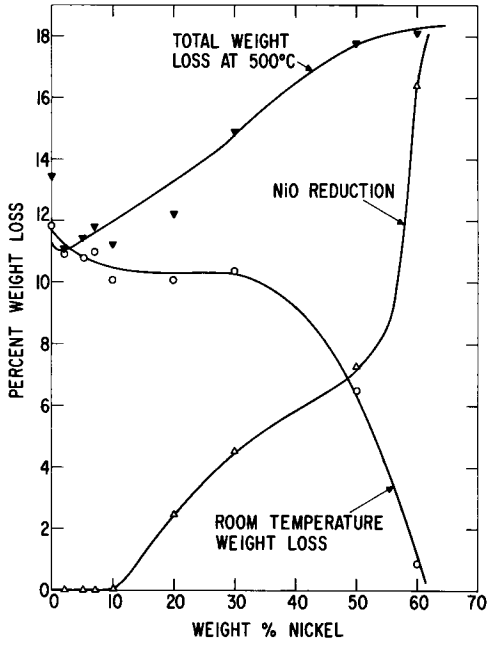

Fig. 2. Weight losses on reduction of Pt-Ni catalysts in 5%H_2/N_2.

Additional evidence for alloy formation was obtained by x-ray diffraction studies. Debye-Scherrer powder patterns obtained with the Pt-Ni catalysts containing 5, 7, and 10% nickel showed clearly the presence of a Pt-Ni alloy phase with lattice spacing $a_0 = 3.86$Å, compared with the spacing of 3.916Å found with platinum black. The existence of this alloy phase may well account for the corrosion resistance and unusual electrochemical activity of this catalyst series.

Fuel cell performance. Typical fuel cell performance data for a Pt-10.2%Ni catalyst are shown in Fig. 3, where anode *vs.* hydrogen reference voltages at 100°C are plotted against current density for H_2-CO fuel mixtures containing 2, 5, 10%CO. Comparable data for a standard platinum black anode under the same conditions are also included in the figure. The improvement resulting from the addition of nickel is very evident. Data obtained at 85°C and 85% H_3PO_4 electrolyte with a 20.3%Ni-Pt anode are shown in Fig. 4 for the three gas mixtures. Also included are comparable data with a 10%CO-H_2 mixture for platinum black and a typical platinum-ruthenium catalyst studied previously (1). It is apparent that the CO tolerance of the Pt-Ni catalyst was definitely superior to the Pt-Ru catalyst.

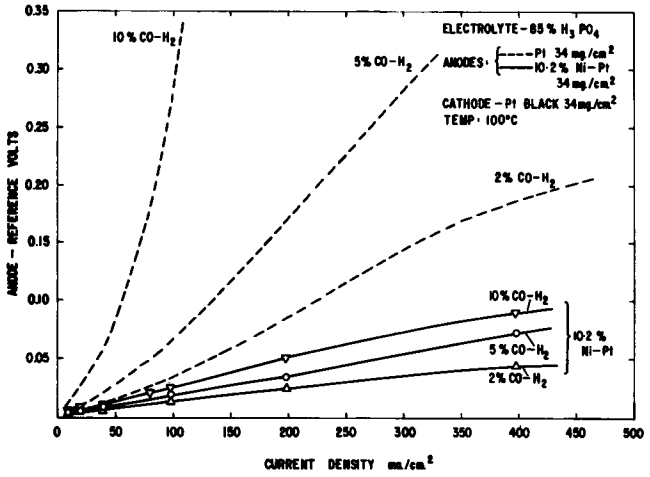

Fig. 3. Performance of 10.2%Ni-Pt and Pt black anodes with H_2-CO mixed fuels, 100°C.

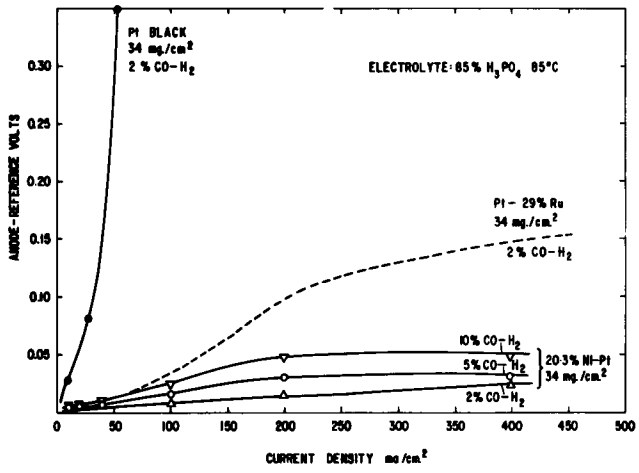

Fig. 4. Performance of 20.3%Ni-Pt anode with H_2-CO mixed fuels, 85°C.

The improved tolerance for carbon monoxide exhibited by these catalysts was also found at lower nickel contents. Figure 5 shows similar data obtained at 85°C with a 5.4%Ni-Pt anode. Even with a 10% CO-H_2 fuel mixture, the polarization of the anode did not exceed 0.1v at 400 ma/cm² C.D. The effect of nickel content on the polarization of the anode is shown in Fig. 6 at a C.D. of 100 ma/cm² for the three gas mixtures. Addition of as little as 2% nickel was apparently sufficient to give rise to a marked improvement in anode performance. Above 30% nickel, corrosion became noticeable and the electrode surface showed a greenish tinge after several hours of operation at 85°C. It is probable that corrosion will become more noticeable at lower nickel contents with increasing temperature. However, below 10% nickel, no trace of corrosion or nickel salts in the effluent electrolyte was observed after tests at 100°C of 3 hr duration. No extended corrosion tests were conducted, and the long-term stability of these catalysts remains uncertain.

In an attempt to provide more detailed information on the nature of the reactions at the anode, analysis of the carbon dioxide content of the effluent gases from a working anode was carried out. Analysis of effluent samples was made with the mass spectrometer after 10-min periods of operation on steady loads at various current densities. Using a Pt-1.4%Ni catalyst as anode and a 5%CO-H_2 fuel mixture, very small amounts of CO_2 were detected in the product gases at current densities below 200 ma/cm². Platinum black electrodes, on the other hand, give rise to large amounts of CO_2 under the same conditions (1). It seems, therefore, that, as with alloys of platinum-ruthenium, platinum-nickel alloy electrodes in the presence of H_2/CO mixed fuels give rise to a higher surface coverage with hydrogen and a higher hydrogen oxidation current than

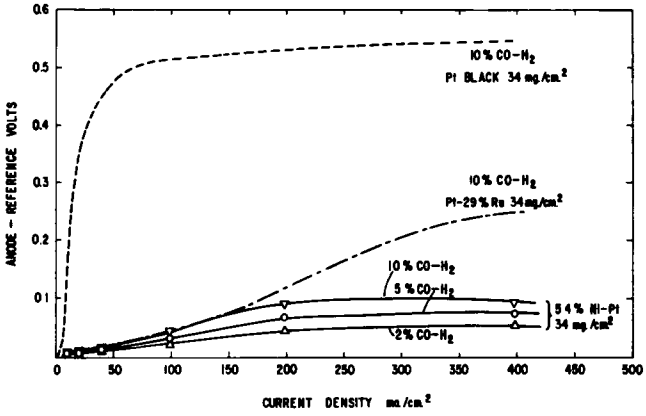

Fig. 5. Performance of 5.4%Ni-Pt anode with H_2-CO mixed fuels, 85°C.

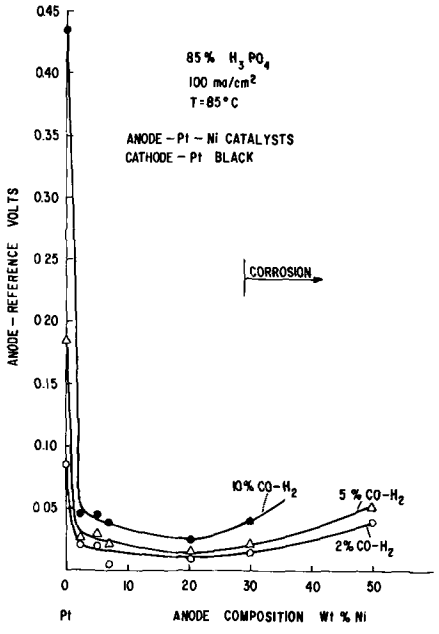

Fig. 6. Effect of nickel content of Pt-Ni anodes with H_2-CO mixed fuels, 85°C.

is the case with pure platinum electrodes, which tend to be rapidly poisoned by the CO in the fuel stream.

Adsorption and catalytic properties.—Previous studies of the co-adsorption and interaction of carbon monoxide and hydrogen from the gas phase on platinum and ruthenium blacks (6) have indicated that CO is much less strongly chemisorbed on ruthenium than on platinum under the same conditions. It seems likely that this fundamental difference in the behavior of the two metals is responsible for the increased CO tolerance exhibited by platinum-ruthenium alloys in fuel cell anodes (1). Similar experiments were therefore carried out with the Pt-Ni catalysts in an attempt to provide a better understanding of the behavior of these materials.

The upper curve in Fig. 7 shows the adsorption isotherm of carbon monoxide at 150°C on a reduced sample of platinum black. The isotherm is of the Langmuir type and adsorption virtually ceases when the metal is covered with a monolayer of adsorbate. At the end of these measurements, the platinum black was evacuated for 16 hr at 150°C and the CO isotherm determined again, as shown in the lower curve of Fig.

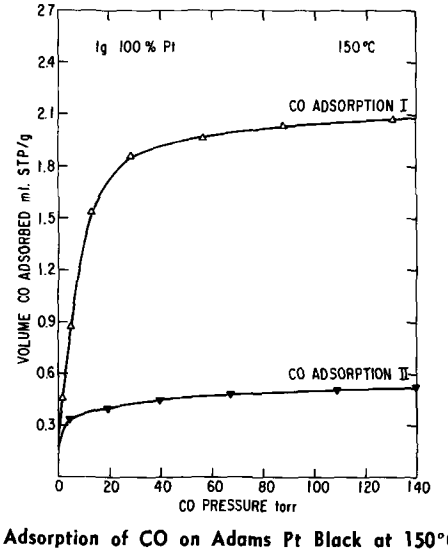

Fig. 7. Adsorption of CO on Adams Pt Black at 150°C: I. adsorption of CO on reduced sample; II. subsequent adsorption of CO after evacuation at 150°C for 16 hr.

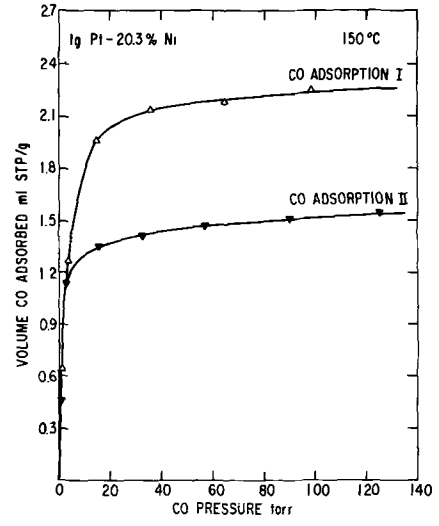

Fig. 8. Adsorption of CO on Pt-20.3%Ni catalyst at 150°C. I. adsorption of CO on reduced sample; II. subsequent adsorption of CO after evacuation at 150°C for 16 hr.

7. If all the chemisorbed CO was desorbed on evacuation, the two isotherms should be coincident. It is apparent, however, that only a small portion (around 25%) of the initially chemisorbed CO could be removed by pumping alone. Similar data for a Pt-20.3% Ni catalyst under the same conditions are shown in Fig. 8. In this case, a much larger fraction (60-70%) of the chemisorbed CO was desorbed by pumping at 150°C for a 16-hr period. The addition of nickel to the platinum thus appears to weaken the bonding of CO to the metal surface.

Fig. 9 illustrates the effect of nickel concentration on the strength of bonding of CO to the catalyst. The solid curve (a) shows the percentage of chemisorbed CO which is desorbable on pumping at 150°C for 16 hr (left-hand ordinate), this quantity reaching a maximum at about 20% nickel. The dashed curve [ordinate (b) on right side] shows the variation in the ratio, volume of CO adsorbed: volume of H_2 adsorbed at 50 Torr and 150°C for the various catalyst samples. A general decrease in this ratio was observed with increasing nickel content of the catalyst. These results suggest that, as in the case of platinum-ruthenium alloys (1), the improved tolerance for CO shown by the alloy catalysts is a result of decreasing CO coverage on the catalyst surface in the presence of hydrogen.

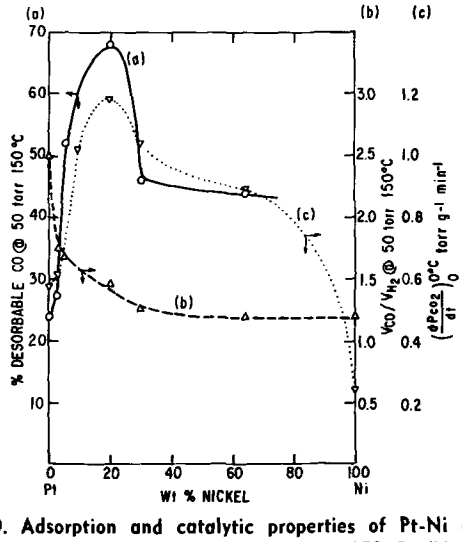

Fig. 9. Adsorption and catalytic properties of Pt-Ni catalysts: (a) per cent desorbable CO at 50 Torr and 150°C; (b) V_{CO}/V_{H_2} at 50 Torr and 150°C; (c) initial rate of formation of CO_2 from 1:1 CO:O_2 mixtures at 0°C, as functions of Ni content.

The Pt-Ni alloy catalysts were also found to be very active for the low-temperature oxidation of carbon monoxide in the gas phase. The formation of CO_2 by the reaction of carbon monoxide and oxygen was found to fit the kinetic expression

$$kT = -P^{o}_{CO} \log (P^{o}_{CO} - P_{CO_2})$$

where P^{o}_{CO} is the initial pressure of carbon monoxide and $P^{o}_{CO_2}$ the pressure of carbon dioxide at time t. A similar expression has been used by Winter (8) to describe the course of the reaction over nickel oxide. The apparent activation energies between 0° and 25°C were in the range 3-5 kcal/mole for all the Pt-Ni catalysts tested. The variation in the initial rate of CO_2 formation at 0°C for an initial ratio of $CO:O_2 = 1.1$ is shown by the dotted curve [ordinate (c) on right side] in Fig. 9. The activity of the Pt-Ni catalysts for this reaction also shows a maximum value at around 20% nickel, in spite of the fact that there is no corresponding maximum in the surface areas of the catalysts.

Although the results of analysis of the fuel cell effluents indicate that electrochemical oxidation of CO plays only a minor role at the Pt-Ni alloy anode, the enhanced activity of these catalysts in the gas phase oxidation of CO may be a reflection of a weaker bonding of carbon monoxide to these alloys than is found with platinum alone.

Conclusions

Of a large number of platinum-base metal combinations tested as anodes in the H_2-CO fuel cell, platinum-nickel catalysts containing 2-20 w/o nickel show an exceptional resistance to poisoning by carbon monoxide. These catalysts are corrosion resistant to phosphoric acid at 100°C and exhibit stable and reproducible performance which equals or exceeds that of the best noble metal alloy catalysts studied previously. The addition of small amounts of nickel to the platinum lattice appears to reduce the heat of adsorption of carbon monoxide on the metal surface resulting in an increase in hydrogen coverage on the electrode during operation of the cell.

The Effect of Electrolyte Flow on the Morphology of Zinc Electrodeposited from Aqueous Alkaline Solution Containing Zincate Ions

R. D. Naybour

Electricity Council Research Centre, Capenhurst, Chester, England

ABSTRACT

The effect of flowing electrolyte on the morphology of zinc electrodeposited from aqueous alkaline solution has been investigated. Aqueous potassium hydroxide solution of 5.8*N* normality containing 19.1 g/dm^3 of dissolved zinc oxide was circulated through a flow tube at flow velocities up to 1.7 m/s, corresponding to Reynold's numbers of up to 13,500. The morphologies of zinc electrodeposits formed on a zinc substrate in the wall of the flow tube were examined over a range of current densities and Reynold's numbers. The results showed that flowing electrolyte under both turbulent flow and laminar flow conditions greatly modified the deposit morphologies. It was possible to construct a morphology, current density, and Reynold's number "phase diagram" to describe the effects of flowing electrolyte on deposit morphology.

The growth of zinc dendrites is a major difficulty in the development of a secondary battery employing zinc as an active material. Consequently, the morphologies of zinc electrodeposited from aqueous alkaline solution containing zincate have been extensively studied in recent years (1-6). It is clear from previous work that dendritic growth occurs during diffusion-limited current conditions, and the rate of growth, rather than the rate of nucleation (2), is the controlling factor. Methods used to control deposit morphologies have included restricting the charging current density to below the limiting current density (1), using current pulses, including both charging and discharging currents (4), and, the use of half-wave, rectified a.c. (5). Each of the above methods have been claimed to prevent the formation of dendrites but, as found in exploratory experiments during the present investigation, they all place limitations on the charging current density without achieving a large increase in the rate at which an acceptable zinc deposit can be formed. Any method of preventing dendritic growth would be successful if the diffusion-depleted

Key words: zinc, morphology, electrodeposition, turbulent, Reynold's number.

layer near the electrode surface was thereby prevented from forming, and it is well known that diffusion-controlled processes in liquids are very dependent on the hydrodynamic conditions. These two conclusions stimulated the present study in which the effect of flowing electrolyte on the morphology of zinc electrodeposits was studied over a range of Reynold's number and current density.

Experimental

The specimen was a single crystal of zinc cut to reveal the basal plane and prepared prior to deposition as previously described (2). The flowing electrolyte apparatus, illustrated diagrammatically in Fig. 1, was designed to obtain Reynold's numbers of up to 10^4 in a tube of length 0.6m and rectangular cross section 0.01 x 0.05m. The specimen was mounted on a holder suitable for examination in the scanning electron microscope. After electropolishing, the specimen was embedded into a hollow plug by means of plasticine. Care was taken to ensure the specimen surface and plasticine were smooth and level with the edges of the plug. The plasticine and specimen surface were covered by a layer of vinyl plastic from an aerosol and, after drying, the plastic was dissolved from the specimen surface. The specimen was then electropolished immediately before placing into the flowing electrolyte apparatus. The removable plug was screwed onto an "O" ring until a previously determined mark indicated the surface of the specimen was level with the inside of the flow tube. After this procedure, the surface of the specimen was about 30μ below the level of the surrounding surface at the start of deposition. During deposition, this difference in surface height decreases until the roughness of the deposit limits the applicability of the Reynold's numbers quoted. The morphologies obtained were not greatly dependent on the charge density and it is concluded that surface modifications to the Reynold's numbers quoted were small. By means of the valves below the flow tube, it was possible to adjust the flow rate in the tube to any value corresponding to Reynold's numbers between 0 and 1.4×10^4. The volume of liquid passing through

the tube in a given time was measured in the calibrated vessel below the flow tube and the Reynold's number, Re was calculated from Re = aV/ρ where a is the distance between the broader walls of the flow tube, V the average velocity in the flow tube, and ρ the kinematic viscosity. The electrolyte used was made from distilled water and Analar grade potassium hydroxide and zinc oxide. The normality of the solution was 5.8N and the solution contained 19.1 g/dm^3 of dissolved zinc oxide. The density and dynamic viscosity of the electrolyte were measured at 20°C and the value of 1.28 x 10^{-6} m^2/s was calculated for the kinematic viscosity. Experiments were performed at ambient temperature which was in the range 20° ± 2°C so that the error in Re due to temperature variations was ±5%. At high Re, above 8 x 10^3, the high rates of flow were measured to ±8% and the error in Re was therefore around ±10%. Experiments using water and ink as a dye confirmed that the flow was laminar below Re of 1.6 x 10^3 and that turbulence was well developed above Re of 2.5 x 10^3.

Electrodeposition was carried out at constant current using a transistorized potential source, constant to 1 part in 2000, and variable resistances. The anodes were pieces of platinum foil and the zinc single-crystal specimen was the cathode. After deposition, the specimen was removed from the flow tube, washed in distilled water and methanol, and placed in the scanning electron microscope.

Results

Stationary electrolyte.—In stationary electrolyte, the deposit morphologies obtained over the range of current densities were similar to those obtained in our previous work (2). At a current density of 10^3 amp/m^2, the deposit was dendritic as shown in Fig. 2. As the current density was decreased, the dendrites became less needle shaped and more platelike; Fig. 3 is an example of the morphology at 500 amp/m^2.

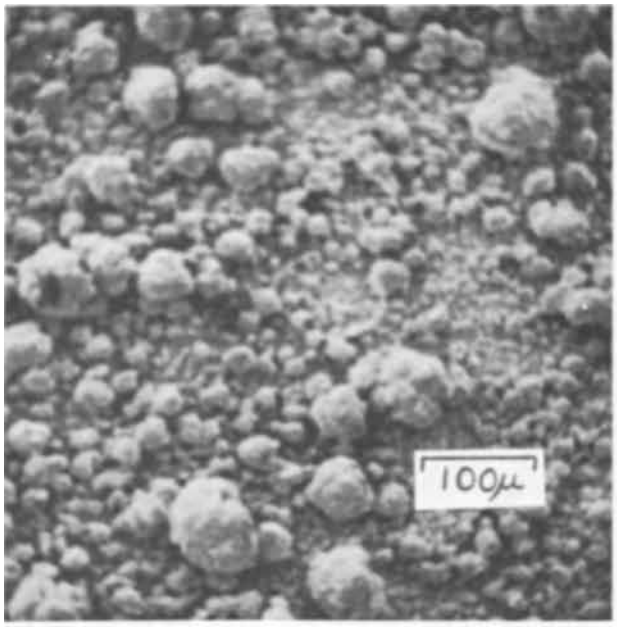

Fig. 9. Scanning electron micrograph of morphology at Re = 7900, 2 min at 3000 amp/m^2 viewed at 10° (X150).

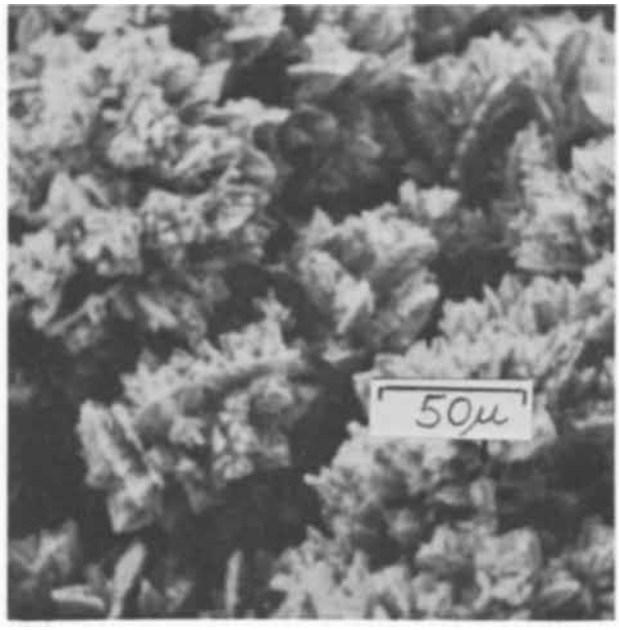

Fig. 11. Scanning electron micrograph of morphology at Re = 13,500, 1 min at 1600 amp/m^2 viewed at 45° (X400).

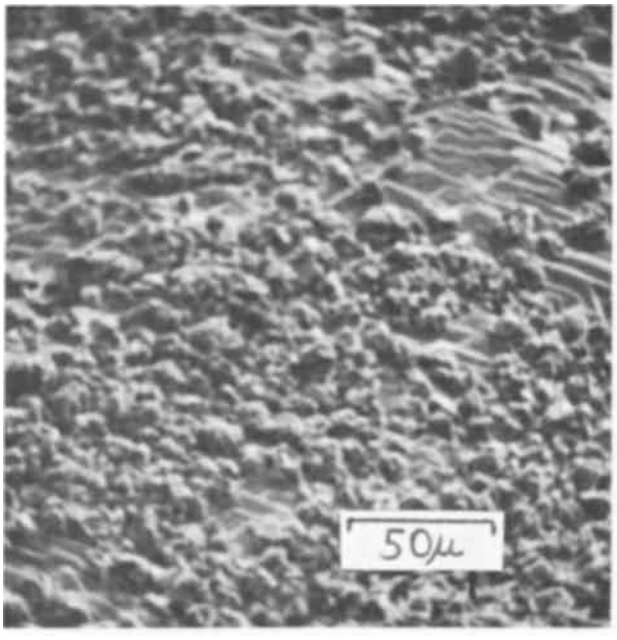

Fig. 10. Scanning electron micrograph of morphology at Re = 7900, 3 min at 2000 amp/m^2 viewed at 45° (X400).

Fig. 12. Scanning electron micrograph of morphology at Re = 13,500, 1 min at 12,000 amp/m^2 viewed at 45° (X400).

Further decrease in current density resulted in a fine granular deposit at 448 amp/m^2 and at 358 amp/m^2 the deposit consisted of a mixture of granular and layerlike deposits as shown in Fig. 4. At 250 amp/m^2, the deposit was essentially granular and layerlike as in Fig. 4 but some bulbous growths were obtained. At 125 amp/m^2, the deposit was in the form of large bulbous growths as shown in Fig. 5.

Flowing electrolyte.—Morphologies produced at current densities up to 16 x 10^3 amp/m^2 and Re up to 14 x 10^3 were examined. Within the above range of current density and Re, three reasonably distinct morphologies were produced. First, at high current densities and low flow rates the deposit was clearly dendritic in form. Increasing the electrolytic movement resulted in a bulbous deposit which was not comparable to any morphology obtained in stationary electrolyte. Finally, at high Re and intermediate current densities the deposit was similar to the flat, granular, deposits obtained at 358 amp/m^2 in stationary electrolyte.

The effect of Re and current density on the type of deposit produced is presented in the form of a "phase" diagram in Fig. 6. The morphologies produced were classified into one of the categories, dendritic, bulbous, or flat. The micrographs in Fig. 7-14 illustrate these three morphologies and the quite sharp transitions among the three types of deposit. Figures 7-10 were obtained at Re = 7.9 x 10^3 and current densities of 8000, 6000, 3000, and 2000 amp/m^2 and show the dendritic deposit at 8000 amp/m^2, the bulbous deposits at 6000 and 3000 amp/m^2, and the flat type at 2000 amp/m^2. The morphologies at Re = 1.35 x 10^4 are shown in Fig. 11-14. The deposit at 16,000 amp/m^2, Fig. 11, was clearly dendritic; that at 12,000 amp/m^2, Fig. 12, was bulbous; and that at 4000 amp/m^2, Fig. 13, was in a transition region between bulbous and flat deposits, while, at 2000 amp/m^2, Fig. 14, the deposit was clearly "flat."

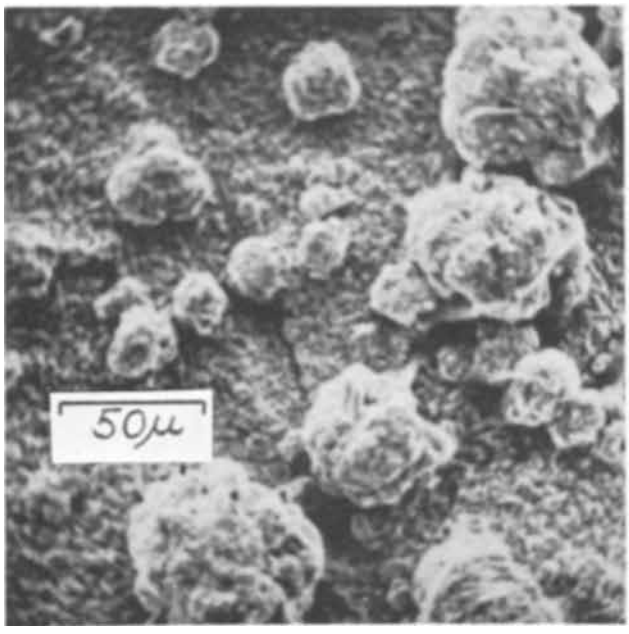

Fig. 13. Scanning electron micrograph of morphology at Re = 13,500, 1 min at 4000 amp/m² viewed at 10° (X400).

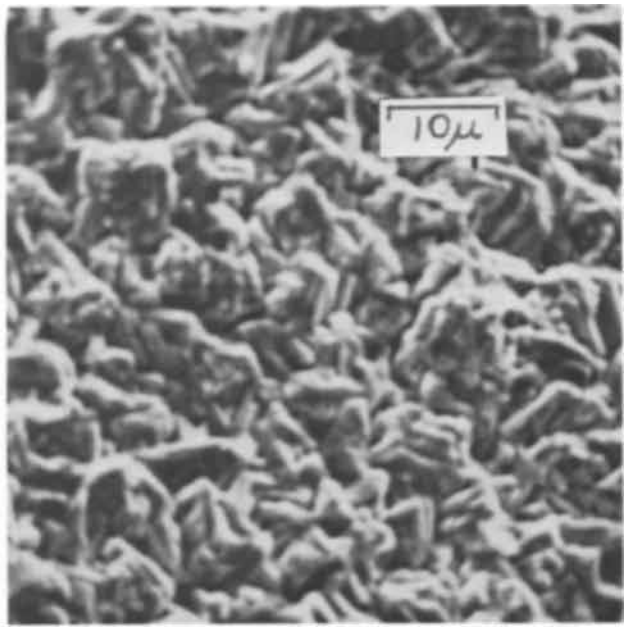

Fig. 14. Scanning electron micrograph of morphology at Re 13,500, 2 min at 2000 amp/m² viewed at 45° (X1500).

The effect of Re on the uniformity of the deposit is shown in Table I in which the maximum protuberance height estimated from the electron micrographs is compared with the theoretical thickness of deposit assuming a current efficiency of 100%.

Discussion

Levich (7) has considered the effect of flowing electrolyte on limiting currents under both turbulent and laminar flow conditions and has calculated that under turbulent conditions the diffusional flow to a plate is approximately proportional to the 0.8-0.9 power of the fluid velocity. For laminar flow, the index is in the region 0.5-0.3. In the present experiments, the "phase" boundary delineating the flat to bulbous transition is a curve in which, approximately, the current density is proportional to $(Re)^{1.0}$. In the case of the bulbous to dendritic transition the current density is proportional to $(Re)^{1.1}$ for $Re > 2000$ and proportional to $(Re)^{0.7}$ for $Re < 2000$. It therefore seems likely, in the light of Levich's theory, that one or other of these curves is in fact the locus of the onset of diffusion-limited current as a function of Re.

The results at 0.5×10^3 amp/m² illustrate the change in morphology produced by flow which is certainly laminar. The dendritic deposit at Re = 0 has been modified to a bulbous deposit at Re = 1100 and it is flat by Re = 1600. This change in morphology produced by flowing conditions which are wholly laminar is not surprising because there is a large amount of microturbulence during the deposition of zinc primarily due to density changes in the electrolyte and to hydrogen evolution. For the same reasons, a sharp transition in morphology when the electrolyte flow changes from laminar to turbulent would not be expected.

Table I

Re	Current, density, amp/m²	Time, min	Theoretical thickness of deposit, μm	Maximum protuberance height estimated from micrographs, μm (±30%)	Ratio (protuberance height / deposit thickness)
0	120	20	6.8	290	43
0	358	8	8.2	33	4.0
0	500	12	17	140	8.2
0	1000	4	12	200	18.0
1570	1000	4	12	120	10.0
3000	1000	4	12	47	4.0
7900	2000	3	17	67	0.6
7900	3000	2	17	50	2.9
7900	6000	1	17	34	2.0
7900	8000	1	23	100	4.4
13500	2000	3	17	7.2	0.4
13500	4000	1	12	32	2.7
13500	12000	1	36	100	2.8
13500	16000	1	46	150	3.3

Previous workers (8-10) have stressed the examination of electrodeposits *in situ* and a number of cells suitable for optical microscopic examination of growing electrodeposits have been used by them. However, even though these cells employed a flowing electrolyte at the surface of the electrode, the flowing conditions were not specified. Indeed the possibility of hydrodynamic conditions affecting the deposit was not considered. The present results show clearly that even flowing conditions which appear to be laminar can affect the deposit morphologies and thus the hydrodynamic condition of the electrolyte is an important factor in the control of the morphology of electrodeposits.

The Electrochemical Behavior of Molybdenum

L. L. Wikstrom*, [1] and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The anodic and cathodic polarization of molybdenum in 1*N* H_2SO_4 was investigated. In deaerated solutions, two stable rest potentials, 0.368 and —0.020v *vs.* NHE, were observed, depending on the activation procedure. In aerated solutions, only the rest potential of 0.368v was observed. From the more noble rest potential, an anodic Tafel slope of 44 ± 4 mv and a corrosion current of 1.5 ± 0.8 μa/cm^2 were obtained. For the h.e.r., a Tafel slope of 70 ± 3 mv and an exchange current of 0.10 ± 0.04 μa/cm^2 were obtained. Two distinct active-passive transitions were observed between the two rest potentials. The short-time galvanostatic transients exhibited two linear regions in the potential-time responses and could be represented by an electrical model of two R-C networks in series. Capacitance values were determined from the slopes of the two linear regions. The first capacitance was attributed to MoO_2 at the Mo-MoO_2 interface and was a constant value of 3.75 μf/cm^2 throughout the potential region investigated. The second capacitance was surmised to be a pseudocapacitance and ranged from 200 to 600 μf/cm^2. However, for sufficiently large polarization from the more noble rest potential, the second capacitance was too large to be measured.

Few investigations have been made of the electrochemical behavior of pure molybdenum. Some early work (1-3) indicated that molybdenum passivated easily and that the end product of its electrochemical oxidation was hexavalent molybdenum. In acidic solutions, experimental rest potentials of 0.390v *vs.* NHE (4), 0.368v *vs.* NHE (5), and 0.000-0.058 *p*H v *vs.* NHE (6) have been reported. Anodic Tafel slopes of 70 mv (7) and 45 mv (4, 5, 8) have been determined for the dissolution reaction and cathodic Tafel slopes of 76-104 mv (6, 9, 10) have been reported for the h.e.r. on molybdenum. More recently, the anodic passivation (11) and the mechanism of the dissolution reaction (8) have been studied.

As indicated above, two different stable rest potentials of molybdenum in acidic solutions have been reported. The anodic region above the more noble rest potential and the cathodic region below the more active rest potential have been investigated previously. It seems appropriate that one laboratory group investigate the electrochemical behavior of molybdenum in the region between these two stable rest potentials and in the potential regions previously investigated.

Experimental

The test cell was a conventional one and made from Pyrex glass with a nominal capacity of 1 liter. The test solution was 1*N* H_2SO_4. Prior to introduction of a molybdenum electrode, the test solution was either aerated or deaerated (Air Reduction Prepurified N_2, 99.997%) for 24 hr.

Planar (0.005 cm thick sheet, 99.9% Mo) and cylindrical (0.625 cm diameter rod, 99.9% Mo) molybdenum electrodes (Fansteel Metallurgical Corporation) were used. Both types of electrodes had an exposed area of 1 cm^2.

Subsequent to fabrication, the general electrode surface preparation procedure was as follows:

1. Mechanical polishing to 4/0 emery paper.
2. Removal of polishing residue with tissue.
2(a). Masking (planar electrode only) with purified paraffin wax.
3. Wash with distilled water.
4. Degrease with absolute ethyl alcohol.
5. Wash with distilled water.
6. Activate in acid for 5 min.
7. Wash with distilled water.
8. Place electrode in cell while still wet.

Once the electrodes had been polished, care was taken to minimize exposure to the atmosphere. The electrodes were activated in different acids: 5, 8, and 12*N* HCl, 5 and 10*N* H_2SO_4, 5 and 10*N* HNO_3, and a 1-1 mixture of concentrated HNO_3-H_2SO_4.

Both galvanostatic and potentiostatic steady-state polarization techniques were used to determine the potential — log *I* curves. Galvanostatic transient techniques were used to determine the differential capacitance.

The potential of the test electrode was measured with respect to a saturated calomel electrode (SCE), which was connected to the test solution near the test electrode through a Haber-Luggin Capillary. The potential difference between the test electrode and SCE reference electrode was measured with a Keithley electrometer. Wenking and Anotrol potentiostats were employed. A Rutherford Model 585 pulse generator with a cathode follower attachment was used for the short-duration galvanostatic pulses used to determine the differential capacitance. A Tektronix dual beam oscilloscope, Model 555, was used to monitor the initial part of the potential-time response of the test electrode.

Results

All molybdenum electrodes in aerated 1*N* H_2SO_4 had a rest potential of 0.368v *vs.* NHE. Molybdenum electrodes in deaerated 1*N* H_2SO_4, except for the polished cylindrical electrodes activated in HCl, also had a rest potential of 0.368v *vs.* NHE. The polished cylindrical molybdenum electrodes activated in HCl had a rest potential of —0.020v *vs.* NHE.

The polarization data are divided into two separate groups. Group I contains all data taken on electrodes with a rest potential of 0.368v *vs.* NHE and includes data taken in both aerated and deaerated 1*N* H_2SO_4. Group II contains all data taken on electrodes with a rest potential of —0.020v *vs.* NHE.

Group I.—Figure 1 shows the steady-state galvanostatic and potentiostatic polarization data obtained for both planar and cylindrical (tangential velocity, v_t = 6.7 cm/sec) molybdenum electrodes in deaerated and aerated 1*N* H_2SO_4. Cathodic polarization was performed prior to anodic polarization. Subsequent to cathodic polarization, the potential was allowed to return to the rest potential, 0.368v before anodic polarization. Identical polarization behavior was observed for both planar and cylindrical electrodes. The anodic Tafel slope, corrosion current, the h.e.r. cathodic Tafel slope, and exchange current density are given in Table I. During

anodic polarization, the color of the electrode changed from silver gray to black at a potential of 0.500 ± 0.010v. In addition, the polarization curve started to deviate from the linear Tafel behavior at this potential. Cathodic polarization appeared to be discontinuous between the rest potential, 0.368v, and the beginning of the h.e.r. Initially, a cathodic overpotential greater than 400 mv was observed by the imposition of the lowest cathodic current density.

Figure 2 shows the anodic-cathodic polarization sequence (lines 1 and 2). It is seen that the initial anodic run affects the cathodic polarization. As shown in Fig. 2, there is a gradual decrease in the potential with increasing cathodic current density rather than the abrupt drop in potential as shown in Fig. 1. This gradual decrease in potential continues up to a current density of approximately 25 ± 10 μa/cm² (0.240v $< \Phi <$ 0.340v). At approximately this point, a limiting current density was observed. Beyond this limiting current density, hydrogen gas was evolved and the cathodic polarization was identical to that shown in Fig. 1. Both the stationary planar and rotating cylindrical electrodes exhibited the same limiting current density. The anodic Tafel slope, corrosion current density, cathodic Tafel slope (h.e.r.), and exchange current density (h.e.r.) determined from Fig. 2 were identical to the data in Fig. 1 and presented in Table I. The electrode also turned to a black color at a potential of 0.500 ± 0.01v.

Lines 3, 1, and 2 show the cathodic-anodic-cathodic polarization sequence. The Tafel slopes, corrosion, and exchange current densities were identical to those values obtained for the other two polarization sequences.

Galvanostatic cathodic polarization of the cylindrical electrodes in aerated and deaerated 1*N* H_2SO_4 after different immersion times at the rest potential, 0.368v, is shown in Fig. 3. In the time interval studied, it is

seen that the cathodic polarization of molybdenum in the deaerated 1*N* H_2SO_4 did not change with immersion time. However, the cathodic polarization behavior in aerated 1*N* H_2SO_4 did change with immersion time. With increasing immersion time, these cathodic polarization curves approached the curve obtained for electrodes which had previously undergone anodic polarization. These two runs were almost identical when the electrode was immersed in the aerated solution for 4 weeks.

Differential capacitance measurements were obtained with galvanostatic pulses. The potential-time responses exhibited two linear regions as shown in Fig. 4. The initial linear region was attributed to the charging of the metal-metal oxide interface. At open circuit and during polarization, this capacitance remained constant at 3.75 μf/cm². The second linear region was attributed to the charging of the metal oxide-solution interface and showed marked changes with potential. The second capacitance as a function of potential for the different polarization sequences is shown in Fig. 1 and 2. This second capacitance remained constant at

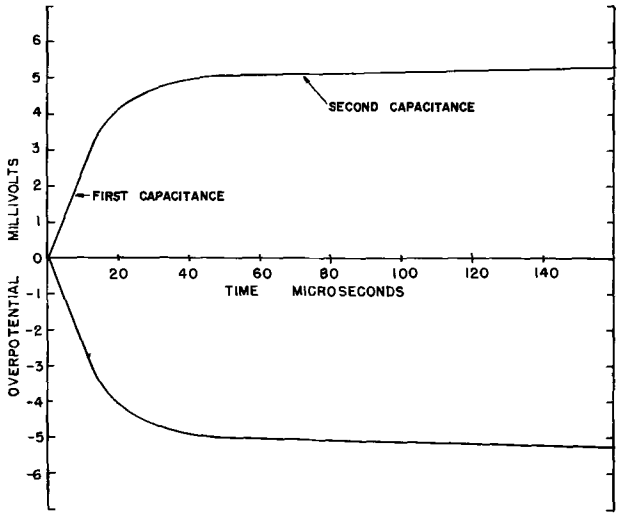

Fig. 4. Potential-time response for galvanostatic pulse. E_0 = 0.368v; 1-hr immersion time. I_p = 1 ma/cm^2.

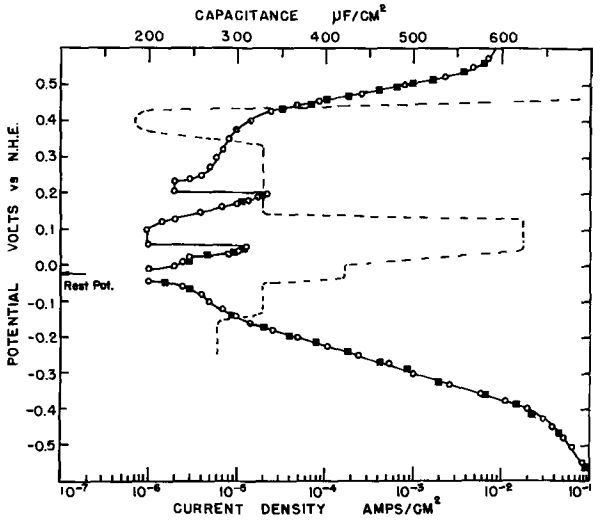

Fig. 5. Polarization of molybdenum in deaerated 1N H_2SO_4. E_0 = —0.020v. ○ Potentiostatic, ■ galvanostatic. Dashed line represents capacitance data.

325 μf/cm^2 at open circuit and during cathodic polarization up to the h.e.r. (except for electrodes which had undergone anodic polarization previously). At the beginning of the h.e.r., the second capacitance decreased sharply to 280 μf/cm^2 and remained constant throughout the h.e.r. Tafel region.

With anodic polarization, the second capacitance increased until it became too large to measure accurately. However, the first capacitance remained constant at 3.75 μf/cm^2. Subsequent to anodic polarization the second capacitance remained at a very high value. Cathodic polarization did not reduce this capacitance value.

In aerated 1N H_2SO_4, the open-circuit second capacitance increased linearly with immersion time until it became too large to measure accurately, while the first capacitance remained constant at 3.75 μf/cm^2. The rate of increase in the open-circuit second capacitance was approximately 14 ± 2.5 μf/cm^2/hr.

Group II. In deaerated 1N H_2SO_4, the rest potential of the polished cylindrical molybdenum electrodes activated in HCl was —0.020v *vs.* NHE. This rest potential stabilized after an immersion time of 2-4 hr. Prior to stabilization, the open-circuit potential fluctuated between 0.080 and —0.160v with potential arrests observed at —0.150, —0.100, and 0.080v. Some electrodes exhibited all three arrests while others exhibited 2, 1, or none. Subsequent to stabilization, the rest potential remained constant for test periods of up to 4 weeks.

The galvanostatic and potentiostatic polarization of molybdenum for the cathodic-anodic polarization sequence and for anodic polarization of a previously unpolarized electrode is shown in Fig. 5. It is seen that cathodic polarization has no apparent effect on the anodic polarization behavior. For current densities greater than 1 μa/cm^2, the cathodic polarization behavior of Group II electrodes was identical to previously unpolarized Group I electrodes.

From Fig. 5, the cathodic Tafel slope and the corresponding exchange current density (h.e.r.) were obtained (Table I). During anodic polarization, two active-passive transitions were observed. The first had a primary passivation potential of 0.035v and a critical current density of 15 μa/cm^2, and the second had a primary passivation potential of 0.190v and a critical current density of 22 μa/cm^2. These values were obtained for experiments on more than six electrodes. Above a potential of 0.390 ± 0.010v, anodic polarization was identical to that observed for Group I electrodes.

In the first active region, the electrode changed from a brilliant silver to a silver-gray color. The silver-gray color was maintained until the potential approached 0.350v. At this potential, the electrode again assumed a brilliant silver color. However, when the anodic Tafel region was reached, the silver-gray color was again observed. The electrode turned black at a potential of 0.500 ± 0.010v.

After anodic polarization to 0.390v, the rest potential changed from —0.020 to 0.368v. The cathodic polarization behavior of this electrode, with the rest potential now at 0.368v, was the same as that of Group I electrodes which had previously undergone anodic polarization.

If potentiostatic anodic polarization of a Group II electrode was discontinued at 0.340v, the rest potential returned to the original value of —0.020v after an arrest at 0.080v. Two types of potential decay behavior were observed. The first was an exponential decay to the potential arrest at 0.080v followed by abrupt decrease in potential to the rest potential of —0.020v. The second was characterized by numerous fluctuations in potential with potential arrests at 0.190v prior to the arrest at +0.080v. Then, as in the first case, the potential abruptly changed from 0.080 to —0.020v.

The anodic polarization of molybdenum subsequent to the above-mentioned decay is shown in Fig. 6. This polarization was not affected by the type of decay observed. In this second anodic polarization run, the first

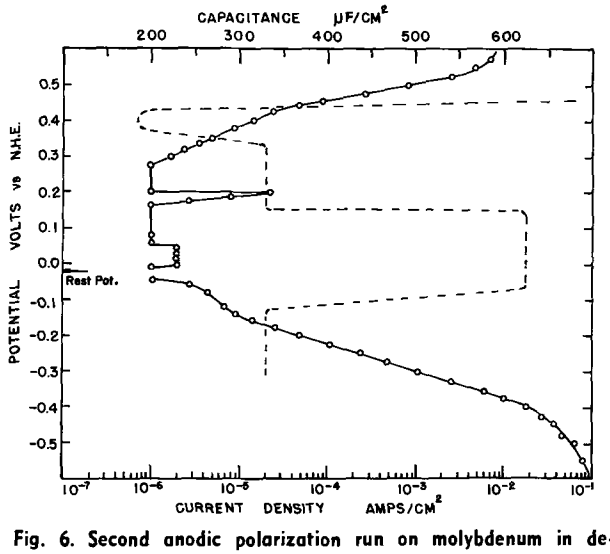

Fig. 6. Second anodic polarization run on molybdenum in deaerated 1N H_2SO_4. E_0 = —0.020v. Dashed line represents capacitance data.

active-passive region almost disappeared. However, the second region exhibited the same primary passivation potential and critical current density as observed for the first anodic polarization run. For the second run, a Tafel region was observed from 0.240 to 0.390v with a slope of 120 mv. Above 0.390v, the anodic polarization behavior was the same for all electrodes. If the second potentiostatic anodic polarization was terminated at 0.340v, the potential did not return to —0.020v but increased to 0.368v and stabilized at this potential.

When short-duration current pulses (10 sec) were utilized for cathodic polarization, the potential-time responses indicated that the passage of 6.4×10^{-4} coulombs/cm^2 was required before a steady-state potential was attained. This result indicates that the surface coverage of hydrogen atoms during the steady-state h.e.r. was about a monolayer.

The anodic transient behavior of molybdenum is shown in Fig. 7. For current pulses (10 sec) less than 150 μa/cm^2, the potential increased monotonically with time. For pulse currents between the range of 150-750 μa/cm^2, it was observed that the potential reached a maximum which was followed by a minimum and then a subsequent monotonic increase with time. Above 750 μa/cm^2, these maxima and minima were not observed and the potential increased monotonically with time. The maximum-minimum phenomena was only observed for electrodes which had not undergone anodic polarization previously. Cathodic polarization prior to the application of anodic pulses had no effect on the potential-time responses. In Fig. 7, the solid lines represent the anodic transients of electrodes which had not been previously anodically polarized. The dashed lines represent anodic transients of electrodes which had previously undergone either pulse anodic polarization (10 sec) above 750 μa/cm^2 or steady-state anodic polarization.

Differential capacitances were obtained at the rest potential, —0.020v *vs.* NHE, and as a function of potential. The potential-time responses were similar to those observed for Group I electrodes. The first capacitance was again constant at 3.75 μf/cm^2 throughout the potential range investigated, while the second capacitance varied with potential as shown in Fig. 5 and 6. It is seen that second capacitance for the first and second anodic polarization runs were identical above

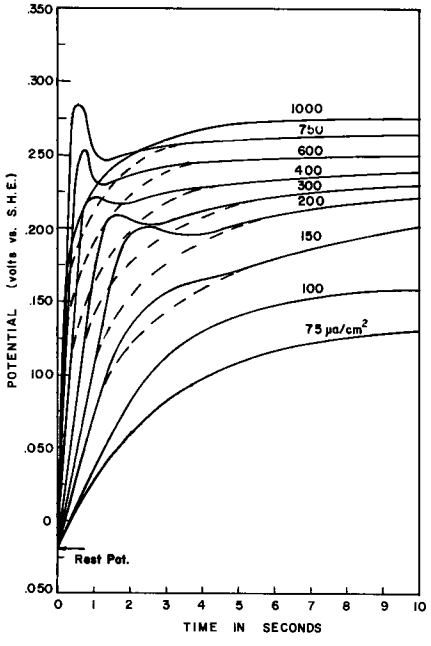

Fig. 7. Anodic transients of molybdenum in deaerated 1*N* H_2SO_4. E_0 = —0.020v. Continuous line—electrodes not previously anodically polarized; dashed line—electrodes previously anodically polarized.

about +0.140v. The open-circuit second capacitance of previously unpolarized electrode was 420 μf/cm^2, while, subsequent to the limited anodic polarization, the open-circuit second capacitance was 625 μf/cm^2. In the h.e.r. Tafel region, the second capacitance of previously unpolarized electrodes was 280 μf/cm^2, while, for electrodes which had undergone limited anodic polarization, it was 330 μf/cm^2. Then, at open circuit, the second capacitance of the former electrodes immediately increased to 330 μf/cm^2 and then slowly increased over a period of 6-8 hr to 420 μf/cm^2. A similar capacitance-time response from 360 $\pm$ 20 to 420 μf/cm^2 was observed after immersion of a fresh electrode and shown in Fig. 8. Electrodes which had undergone limited anodic polarization previously did not exhibit this transient phenomenon. The second capacitance of these electrodes increased from 330 μf/cm^2 to 625 μf/cm^2 at open circuit after cathodic polarization in the h.e.r. Tafel region.

Discussion

The 0.368v rest potential of molybdenum in 1*N* H_2SO_4 (aerated and deaerated) was not changed by repeated anodic and cathodic polarization although the concentration of the oxidation product increased during anodic polarization and in aerated solutions after long immersion times at open circuit. Comparison of the polarization data (Fig. 2, 5, 6) with polarographic data (12) indicates that the product of corrosion and anodic polarization was hexavalent molybdenum. In this potential region, hexavalent molybdenum can be reduced to pentavalent molybdenum (12). These results indicate that rest potential of 0.368v is independent of the concentration of pentavalent and hexavalent molybdenum and oxygen.

The rapid stabilization of the 0.368v rest potential, its independence of Mo (V), Mo (VI), and O_2 concentration, and the differential capacitance data indicate that the molybdenum electrode is covered with an oxide or oxides either before immersion or immediately thereafter. The stoichiometric stable oxides of molybdenum are MoO_2 and MoO_3. The redox reaction involving MoO_2 and MoO_3, $MoO_2 + H_2O = MoO_3 + 2H^+ + 2e^-$, has a redox potential of 0.298v *vs.* NHE. Thus, the 0.368v rest potential is not determined by this redox reaction. However, this reaction may occur as a partial process of a polyelectrode. A process involving this redox reaction must include the reduction of MoO_3 and the formation of MoO_2 since, at open circuit, accumulation of hexavalent molybdenum or increase in differential capacitance was not observed in deareated 1*N* H_2SO_4. A possible mixed process is the following:

$$MoO_2 + H_2O = MoO_3 + 2H^+ + 2e^-$$

$$MoO_3 + 6H^+ + 3e^- = Mo^{+3} + 3H_2O$$

$$Mo^{+3} + 2H_2O = MoO_2 + 4H^+ + e^-$$

In deaerated solutions, molybdenum which has not undergone previous anodic polarization has only a limited amount of hexavalent molybdenum on its surface. Thus, a cathodic current would reduce the hexavalent molybdenum and then shift the potential to the h.e.r.

In aerated solutions, hexavalent molybdenum is continually being formed. However, the rest potential and corrosion current are the same as for deaerated solutions. Since the limiting diffusion current of oxygen reduction to water was not observed, a slower reaction step must determine the rate of production of hexavalent molybdenum. Delahay and Stagg (13), who investigated oxygen reduction on molybdenum, suggested that oxygen reduction involves a peroxyderivative of molybdenum which subsequently reduces to water and a normal oxide state of molybdenum. The formation of the peroxyderivative occurs by the reaction of peroxide with a surface oxide. Thus, the

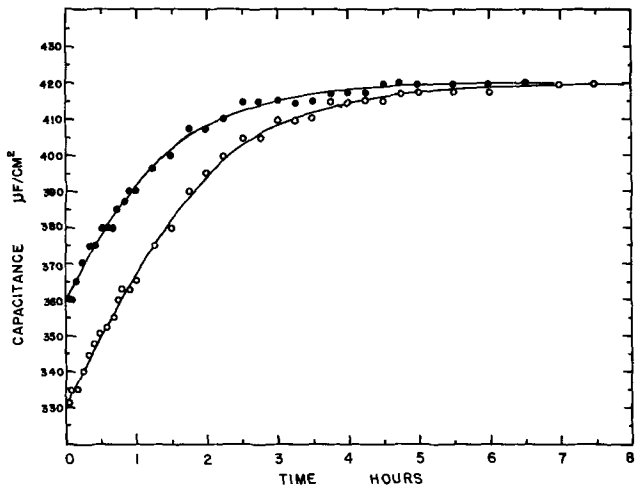

Fig. 8. Open-circuit second capacitance transients. $E_0 = -0.020$v. ● After immersion, ○ after cathodic polarization.

rate of production of the hexavalent molybdenum may be limited by the rate of formation or reduction of this peroxyderivative. The over-all electrode reaction for the formation of hexavalent molybdenum in aerated H_2SO_4 may be as follows:

$$Mo + \frac{3}{2}O_2 + H_2O = HMoO_4^- + H^+$$

As the concentration of hexavalent molybdenum increases, the contribution of the pentavalent/hexavalent redox reaction to the rest potential must be considered. Theoretical cathodic polarization curves for various hexavalent molybdenum concentrations were determined by considering the polarographic studies of Johnson and Robinson (12), the cathodic polarization behavior after anodic polarization, and a limiting current density of 0.5 μa/cm^2 for oxygen reduction. This particular value of the limiting current density for oxygen reduction was arbitrarily chosen to minimize changes in the rest potential and the corrosion current density with changes in the concentration of hexavalent molybdenum. In Fig. 9 are shown the theoretical cathodic polarization curves for hexavalent molybdenum concentrations of 2, 5, and 12.5 μM. It can be seen that the concentration of hexavalent molybdenum has little effect on the rest potential and corrosion current. For example, $E_0 = 0.370$v and $i_{corr} = 1.2$ μa/cm^2 for 12.5 μM, and $E_0 = 0.363$v and $i_{corr} = 0.5$ μa/cm^2 for 0.0 μM Mo(VI). A comparison of the theoretical cathodic polarization curves in Fig. 9 and the experimental curves in Fig. 3 indicate good agreement.

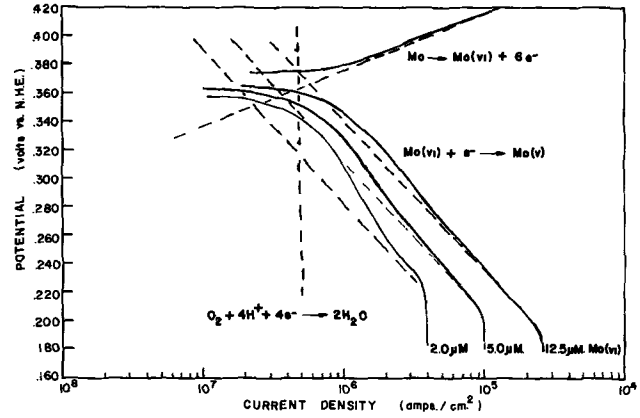

Fig. 9. Partial electrode processes near rest potential of molybdenum in aerated 1N H_2SO_4. $E_0 = 0.368$v. Continuous lines—theoretical polarization curves; dashed lines—single electrode partial process as indicated.

The curves in Fig. 9 represent the following proposed electrode reactions:

$$\text{I.} \quad Mo = Mo(IV) + 4e^- \rightarrow Mo(VI) + 2e$$

$$\text{II.} \quad O_2 + 4H^+ + 4e^- = 2H_2O$$

$$\text{III.} \quad Mo(VI) + e^- = Mo(V)$$

According to Heumann and Hauck (8), the rate-determining step for the anodic dissolution reaction is Mo(IV) → Mo(VI).

The rest potentials of polished cylindrical electrodes activated in HCl were —0.020v which was approximately that of the reversible hydrogen electrode. Prior to stabilization at this steady-state rest potential, potential arrests were observed at 0.080, —0.100, and —0.150v. The arrests occurred at the redox potentials of the reactions (14, 15):

$$Mo + 3\,H_2O = MoO_3 + 6H^+ + 6e^-$$

$$Mo + 2\,H_2O = MoO_2 + 4H^+ + 4e^-$$

and

$$MoO_2 = MoO_2^+ + e^-$$

respectively.

Although the rest potential of —0.020v is the same value as the potential of the reversible hydrogen electrode, there is some doubt as to the actual processes which determine this rest potential. In the potential range in the neighborhood of the rest potential, cathodic polarization indicates a reduction process other than the h.e.r. and anodic polarization indicates oxide growth by the formation of a silver-gray film. Konig and Gohr (11) have concluded that this silver-gray film was MoO_2. Heumann and Hauck (8) have also reported the presence of MoO_2 on the surface of molybdenum in acidic solutions. In addition, the constant value of 3.75 μf/cm^2 for the first capacitance, throughout the entire potential range investigated, suggests the continual presence of MoO_2 on the surface of the molybdenum electrode.

The capacitances determined from the two linear regions in the galvanostatic transients can be interpreted in terms of the electrical model shown in Fig. 10 which describes the charging behavior of molybdenum due to the metal-metal oxide and metal oxide-solution interfaces. The mathematical representation of this model is given as:

$$E = I_p(R_1 + R_2 + R_e - R_1\,e^{-t/R_1C_1} - R_2\,e^{-t/R_2C_2})$$

Where E is the potential, I_p the imposed current, $R_1\,C_1$ refers to the metal-metal oxide interface, $R_2\,C_2$ refers to the metal oxide-solution interface, and R_e is the resistance of the solution. For the potential-time response, the first capacitance is the initial linear region which has the larger slope corresponding to a smaller capacitance value. The second capacitance is determined from the other linear region which has the smaller slope which corresponds to a larger capacitance value. If $R_1\,C_1 << R_2\,C_2$, the capacitance values may be determined independently. Figure 11 shows theoretical $E - t$ curves for $C_1 = 3.75$ μf/cm^2, $R_1 = 5\Omega$, $R_2 \geq R_1$, and various values of C_2 (100, 133, 200, and 400 μf/cm^2). As shown in Fig. 11, the experimental potential-time response for short-time intervals can be very adequately represented by the proposed electrical model. Calculated and experimental potential-time responses for a 1.0 ma/cm^2 current pulse are shown in Fig. 12. The dashed lines represent the upper

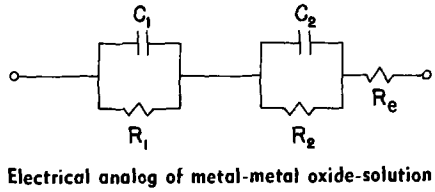

Fig. 10. Electrical analog of metal-metal oxide-solution interfaces

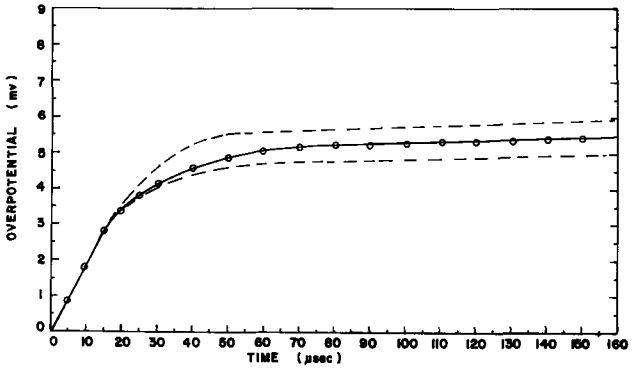

Fig. 12. Calculated and experimental potential-time responses. I_p = 1.0 ma/cm², C_1 = 3.75 μf/cm², R_1 = 5 Ω, C_2 = 420 μf/cm², $R_2 \geq 5$ Ω. Continuous line—calculated data; dashed lines—upper and lower limit of experimental data.

and lower limits of the experimental data (24 runs). The points represent the calculated data.

The first capacitance, 3.75 μf/cm², is ascribed to the MoO_2 at the Mo-MoO_2 interface. Since the first capacitance remained constant throughout the potential range investigated, it seems apparent that MoO_2 was always present on the electrode surface and that the anodic dissolution of molybdenum involves MoO_2. The second capacitance is attributed to the electrical double layer and an adsorption pseudocapacitance which are in parallel and represented by R_2 C_2 in the electrical model. The increase in the open-circuit second capacitance of molybdenum with immersion in aerated solutions and its increase with increase in anodic polarization suggest that the pseudocapacitance may be due to an electroactive intermediate or intermediates produced during the electrochemical oxidation of molybdenum.

Enhancing the Brightness Capability of Color-TV Receivers Through the Use of a Spectrally Selective Tinted Glass

ABSTRACT

An ideal picture tube for color TV would have three efficient phosphors with almost spectrally pure (narrow) bands of emission on a faceplate which transmits only at the same wave lengths and is opaque at other wave lengths. This poses an interesting physics problem, for how do you make a narrow-band filter which works simultaneously in three different spectral regions? Working with practical phosphors and available filters, it is interesting to determine what can presently be achieved. A development program, starting out with the well-known didymium glass, led to the present composition. Measurements have been made to determine the characteristics of a 3% neodymium doped glass having some spectral optical properties approximating the specifications. Such a glass would be used to replace the neutral-density safety glass now used. Data are presented showing its optical properties, and the changes in spectra, brightness, and color coordinates of tricolor picture tubes. It is concluded that there are some demonstrable improvements in color, brightness, and contrast.

Every manufacturer of color TV receivers is desirous of obtaining a brighter picture display capability. All other factors being equal, the receiver having a higher brightness capability will understandably out-perform others in a room having high ambient lighting. The manufacturer wants to attain this higher capability at a minimum increase in cost and, certainly, at no sacrifice in over-all performance. Many laboratories are engaged in research, therefore, to develop brighter phosphors, and every year thousands of new phosphors are prepared and tested.

We have investigated an alternate approach to enhance the brightness obtainable with presently used color picture tubes by 30% or more. The approach endeavors to recover most of the loss in phosphor light occurring with the presently used contrast-improving tinted glass in front of the picture tube.

Instead of a neutral tinting of the glass faceplate, as is now the practice, the glass would be tinted only in the spectral regions where the tricolor phosphor emissions are low. The glass would then be highly transmitting to the phosphor light but still retain its contrast-improving capability. Discussions of this approach are given in Ref. (1-4).

Of the materials presently available, the substances found to be most suitable to produce this type of spectrally selective tinting were compounds containing trivalent neodymium. While neodymium-containing glasses tested were found to have most of the desirable characteristics, they have some which are not desirable, and, because of this, the over-all brightness gain was found not to exceed 12%.

Use of Neutral Tinting to Improve TV Picture Contrast

In black-and-white television, tinting or darkening of the faceplate glass is done to permit viewing of the picture in a room having normal ambient lighting. (With neutral tinting, the transmission of the faceplate glass is deliberately reduced. Some manufacturers make the single-pass transmission about 70%; others prefer a transmission as low as 40%.[1] With neutral tinting, also, the optical absorption is approximately uniform throughout the visible spectral range.) The contrast is improved because the ambient light reflected from the phosphor screen is more greatly attenuated than is the phosphor light; this is because it takes two passes through the tinted glass, whereas the phosphor light passes only once.

[1] The practice now is to make the bulb 70% transmitting and the safety windows either 70 or 55%; the final tubes are 52 or 41% transmitting. Some newer tubes do not use a safety window and have a deeper tinted bulb.

Concept of Spectrally Selective Tinting

If the neutral tinting in the faceplate glass of a color-TV screen were replaced by one having high transmissions in the red, blue, and green spectral regions (where the tricolor phosphors emit) and strong absorptions in the blue-green, yellow, and far red regions (where the phosphor emissions are low), it should be possible to realize a substantial gain in the obtainable brightness without degradation of the contrast. In Fig. 1, the shaded areas represent the regions where strong optical absorptions would be permitted; also shown is the emission spectrum of a typical P22 phosphor (in this case, the red-emitting phosphor is a europium-doped yttrium oxysulfide, while the blue and green are both sulfides) (5). If it were possible to obtain 100% optical absorption in the shaded areas

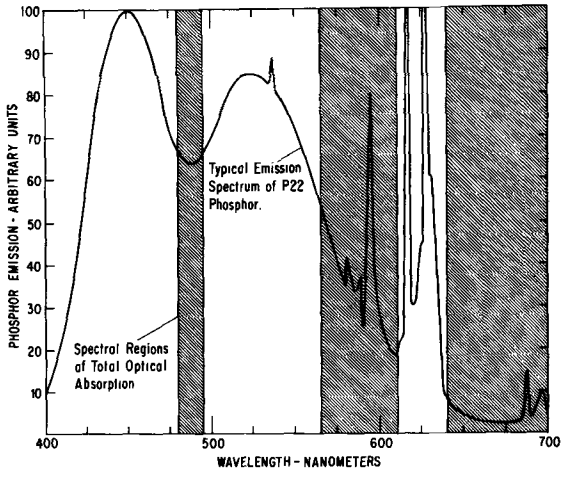

Fig. 1. A selectively tinted glass having total optical absorptions in spectral regions depicted as shaded areas would provide contrast improvement with very little effect on picture brightness. The curved trace describes the emission spectrum of a typical P22 phosphor.

and 100% transmission in the clear areas, the over-all transmission for incandescent light, when viewed by the eye, would be about 53%; for daylight or fluorescent light, it would be about 54%.[2] This is very nearly the same as the double-passage transmission through 70% transmitting neutral tint glass. The amount of reflected light with the spectrally tinted glass would, thus, be the same as with the 70% neutral tint glass. The brightness of the phosphor light, however, for equal beam currents, would be over 30% greater with the spectrally tinted glass.

Of the three desired absorption bands in the spectrally tinted glass, the most effective in improving contrast is that in the yellow region because it is near the peak of the human eye response.

Selection of Material to Produce Spectral Tinting

Unfortunately, a spectrally selective tinting having the desired optical absorbing characteristics is not easily attained. The use of multiple interference-type coatings capable of providing narrow and sharp transmission bands is out of the question; the design of such a filter with three simultaneous spectral regions of transmission (corresponding to the regions of phosphor emissions) is beyond the present state of the art.

Most organic and inorganic tinting materials, incorporable into a glass or plastic, have broad absorption bands with broad edge slope characteristics. Compounds of the lanthanide elements provide spectrally narrow absorption bands at room temperature, but, of these, only Pr and Nd have the desired narrow bands and sharply defined absorption in the yellow spectral region.

The spectral transmissions of water solutions of Pr and Nd nitrates are shown in Fig. 2. The absorptions obtained when the oxides of Pr and Nd are incorporated into glass will be somewhat different in degree and detail but the fundamental absorptive spectral regions will be the same. The shaded areas on the top show the ideal regions depicted in Fig. 1 where absorptions are desired. It may be seen that Pr compounds have an absorption band in the blue region. This would produce an objectionable reduction in the brightness of the blue phosphor. It may also be seen that Nd compounds have undesirable absorption bands in the blue and green regions. However, because of its proportionally greater absorption in the yellow region, it was considered to be the best choice as a tinting material.

Use of Didymium and Neodymium Glasses

At the time of our early measurements and evaluations, a glass with pure Nd_2O_3 was not available as a standard commercial item. However, didymium glass, well known for its yellow-absorbing properties and use in glassblowers' goggles, was available.[3] Didymium is a name given to a group of lanthanide elements, La, Nd, Pr, Sm, and Ce, and is in the extract obtained from monazite sand after most of the Ce is removed. Lanthanum and Nd are the primary constituents, but La compounds do not absorb optically in the visible spectral range.

The spectral transmission of a water solution of didymium chloride solution is shown in Fig. 3. It is identical to the spectral transmission of a Nd chloride solution shown in Fig. 2 except for the greater absorption in the blue spectral region. The latter is attributed to the presence of Pr and Ce.

Figure 4 shows the spectral transmission of a 2-mm thick sample of Corning 5120 glass which contains about 4% of didymium oxide. For comparison, the spectral transmission of 70% transmitting neutral tint glass is also shown. It is shown later that the average double-pass transmission of room light is about the same for the two glasses. Thus, the contrast of a TV picture would be about the same with either tinted glass. The didymium concentration represented in the 2-mm thick glass sample appeared to be optimum for this application. At increasing glass thickness, the attenuations produced by the absorption bands in the blue and green spectral regions increase rapidly. The double-pass attenuation for ambient room light, however, increases only slowly. Thus, a considerable reduction in over-all picture brightness would be experienced without a substantial improvement in contrast.

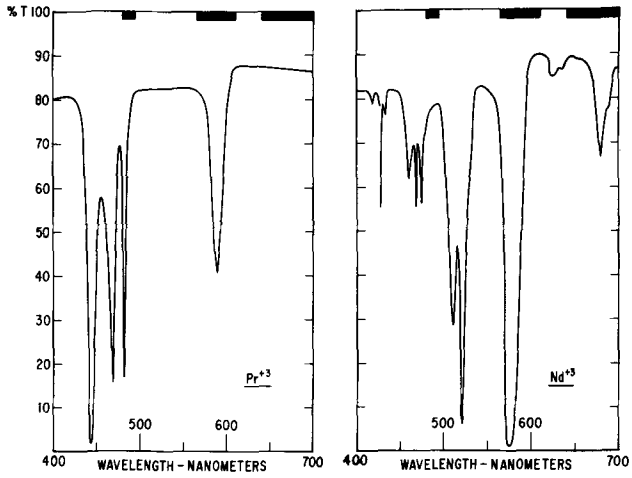

Fig. 2. Relative transmission characteristics of water solutions of $Pr(NO_3)_3$ and $Nd(NO_3)_3$ in the visible spectral range. Shaded areas on top indicate, as in Fig. 1, the spectral regions where total optical absorptions would be desired in a selectively tinted glass.

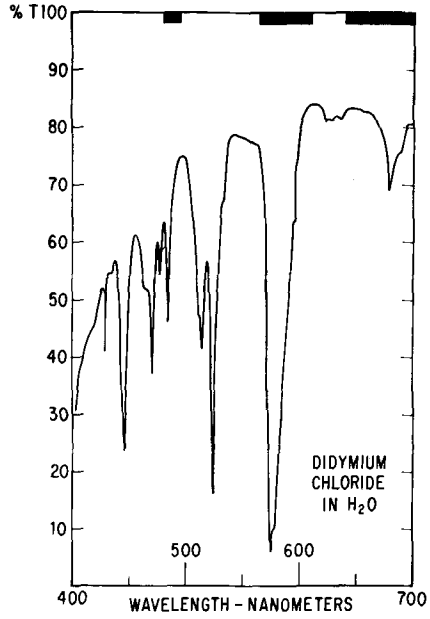

Fig. 3. Relative transmission characteristics of a water solution of didymium chloride in the visible spectral range. Shaded areas on top indicate, as in Fig. 1, the spectral regions where total optical absorptions would be desired in a selectively tinted glass.

[2] These values were computed from the relationship:

$$\overline{T} = \frac{\int_{\lambda = 4000\text{Å}}^{\lambda = 7000\text{Å}} T_\lambda P_\lambda R_\lambda \, d\lambda}{\int_{\lambda = 4000\text{Å}}^{\lambda = 7000\text{Å}} P_\lambda R_\lambda \, d\lambda}$$

where

$\overline{T}$ is the over-all transmission to the room light source (daylight or incandescent)
T_λ is the spectral transmittance of the spectrally tinted glass
P_λ is the spectral distribution of the room light source (daylight or incandescent)
R_λ is the spectral responsivity of the human eye.

[3] Didymium glass is available from Corning Glass Works as their glass number 5120.

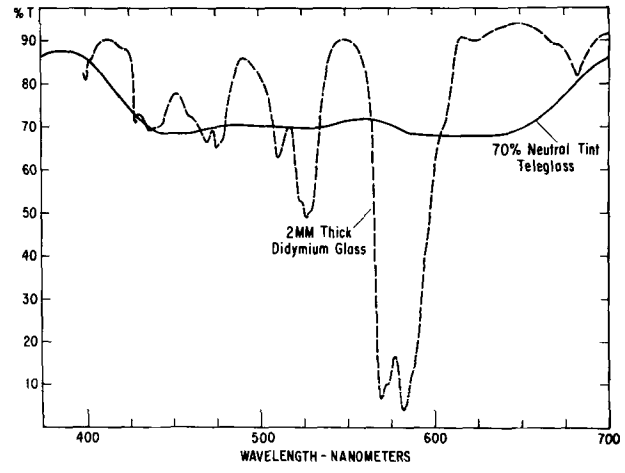

Fig. 4. Spectral transmissions through neutrally tinted and didymium glasses.

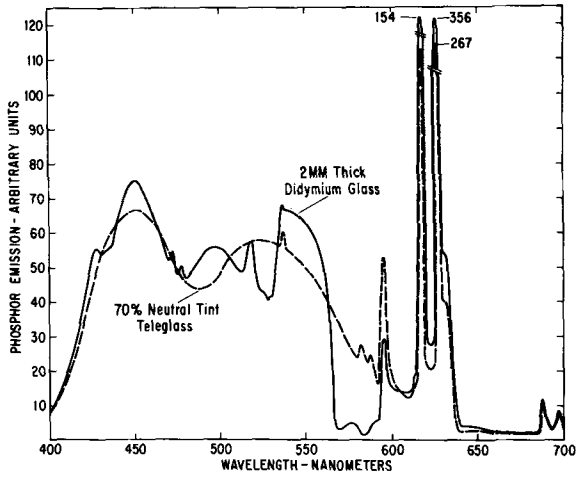

Fig. 5. Computed spectral characteristics of P22 phosphor light through neutrally tinted and didymium glasses. Initial P22 phosphor emission characteristics same as shown in Fig. 1.

The effects of the 70% transmitting neutral tint glass and 2-mm thick didymium glass on the spectral characteristics and intensities of the P22 phosphor emitted light are shown in Fig. 5. The neutral tint glass has no effect on the spectral characteristics of the phosphor light; it acts only to reduce its intensity. The didymium glass, on the other hand, affects both the spectral characteristics and the intensities. Clearly, the red phosphor emission is brighter through the didymium glass than through the neutral tint glass. The yellow component in the red phosphor emission is greatly reduced resulting in a more saturated red color. By the same token, the yellow spectral portion of the green phosphor emission is also reduced, resulting in a more saturated green color as well. Unfortunately, however, some green absorption also occurs which negates any gain in the brightness of the green phosphor emission. In the blue spectral region, some gain in brightness might be realized through the use of the didymium glass.

Glass in which pure Nd_2O_3 was incorporated was available in the latter part of our investigations through the cooperation of the Chicago Dial Corporation.[4] Figure 6 shows the spectral transmission of a glass sample containing 3% Nd_2O_3; the type of glass used as the host is not known. The sample was 3.3 mm thick. It may readily be seen that the absence of Pr and Ce results in greatly reduced absorptions in the blue spectral region. The thickness of 3.3 mm for 3% concentration of Nd_2O_3 appeared optimum in this application, and measurements and observations were made comparing the didymium with the neodymium glass.

Performance with Didymium and Neodymium Glasses

Measurements were made of the transmissions by the 70% neutral tint, didymium, and neodymium glasses of the emitted light from individual phosphors comprising the P22 screen. The results are shown in Table I. Light intensity measurements required for the determination of these values were made with a Weston Photronic Cell having the spectral response of the human eye. The Nd glass is superior to the didymium glass in the extents of the phosphor emissions transmitted. The increase in transmission of the didymium glass over that of the neutral tint glass for the red oxysulfide type phosphor emission is small, but this is due to the loss of the yellow component which is of appreciable magnitude in this type phosphor. The transmissions by didymium and Nd glasses of the red component of the red phosphor emission (either vanadate or oxysulfide types) is thus greater than that indicated in Table I.

Measurements were also made of the transmissions by the 70% neutral tint, didymium, and Nd glasses of white (9300°K) phosphor light and two types of room lighting. The results are shown in Table II. Again, the light intensities required for the computa-

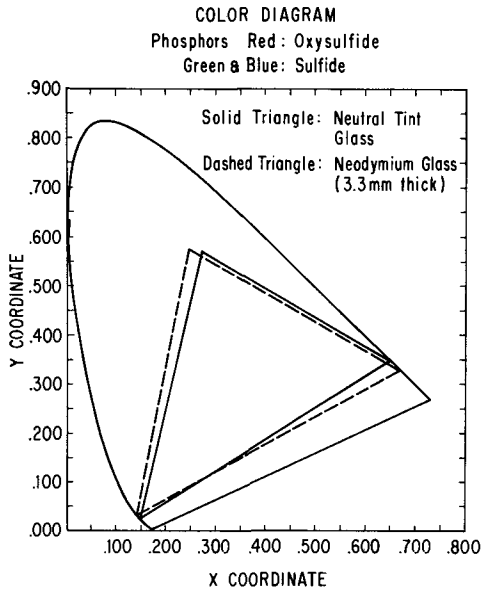

Fig. 7. Trichromatic color coordinates of P22 phosphor light through neutral tint and neodymium glasses.

tion of these values were measured with a Weston Photronic Cell. The double-pass transmissions by all three glasses are about the same for either daylight or incandescent room lighting; for a given TV picture brightness, the reflected light in a room with ambient lighting would, therefore, be the same with either of the three tinted glasses. With identical operating picture tube beam currents, however, the picture on the TV receiver employing the Nd glass was about 12% brighter.

In Fig. 7, we show on a color diagram the change in chromaticity coordinates of the P22 phosphor light resulting from the use of the 3.3-mm thick neodymium glass. The area in the triangle, which shows the gamut of hues obtainable through the mixing of the three primary colors, is larger with neodymium glass. It is possible to generate a greater range of hues, therefore, through the use of neodymium glass. However, the "yellows," which are primarily derived through the excitation of both the red and green phosphors, are somewhat degraded. Visually they appear slightly grayish.

Physical Appearance of Picture Tube Face with Spectrally Selective Tinting

There is a physical appearance attribute evident when using either the didymium or Nd glass. When the TV receiver is off, the face of the picture tube appears to have a bluish cast in a room illuminated by daylight or fluorescent lighting, and a pinkish cast when the room has incandescent lighting. At present, it is considered desirable for the glass to be only neutral-gray. This dichroic effect is a natural consequence of the strong absorption in the yellow spectral region. The effect is not noticeable when the set is on; in this condition, the beneficial effects noted above can probably be maximized by adjusting the color matrixing to match the colorimetric properties of the glass. (This was not done in this investigation.)

Discussion

The use of glasses tinted by Nd compounds in place of neutral tinted glass on the face of a color picture tube has been investigated. Computations indicated that a greater than 30% improvement in brightness capability could be realized, together with the usual reduction in reflected room light, through the use of spectrally selective tinting which would provide total transmission of phosphor light but be opaque in non-emission regions. It was found that Nd compounds come close in providing the desired spectral tinting. Measurements show, however, that the brightness improvement realized with the available Nd glass was only about 12%. The reduced performance is, undoubtedly, due to the undesirable but characteristic Nd^{+3} absorptions in the green and blue spectral regions However, these absorption bands are due to 4f transitions, the probabilities of which are sensitive to the crystal fields surrounding the Nd^{+3} ions.

There is evidence that, when the crystal symmetry is changed, by incorporating the Nd^{+3} ion into different host glasses, the change in the absorption in the green region is not proportional to that in the yellow region. Hirayama and Lewis (6) describe the absorptions of Nd_2O_3 in various host glasses. Comparing their 14.5 Na_2O, 25TiO_2, 60 SiO_2, 0.5 Nd_2O_3 glass with their 33 Li_2O, 66.5 SiO_2, 0.5 Nd_2O_3 glass, it would be seen that, adjusting the thickness to yield the same absorptions in the yellow region, the absorption in the green region will be substantially less in the titanium-containing glass. It is possible, therefore, that through the use of a different host glass brightness improvement closer to 30% might be achieved.

The ideal situation for the ultimate in contrast and brightness would be to have three narrow-band phosphors and one filter with three matching transmission bands. The making of such a filter is an interesting problem in physical optics.

Phosphor Screens for High-Current-Density Cathode-Ray Tubes

Vincent D. Meyer and Frank C. Palilla*

The Bayside Laboratory, Research Center of
General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Phosphors are evaluated for use in high-current-density cathode-ray tubes. Oxide-based phosphors exhibit a linear increase in brightness with current density, whereas conventional II-VI sulfide phosphors show a less-than-linear increase. At high current densities, the sulfides also exhibit spectral shifts and a decrease in decay times. Selected rare-earth-activated oxide phosphors incorporated in a postdeflection focusing tube demonstrated a substantially linear increase in brightness, improved contrast ratio, and good color balance.

The intensity of the luminescence emitted by a phosphor screen excited by cathode rays increases as the number of electrons per unit area incident upon the phosphor is increased. The linearity of the increase in the intensity of the luminescence is, however, generally limited to low current densities with phosphors used in most color-TV display systems (1-5). At high current densities, the increase is less than linear. This nonlinear behavior is called the "saturation" effect. The most common type of color-TV tube in use today is the shadow-mask version in which a perforated electrode is interposed between the electron guns and the phosphor screen in a unipotential drift space. This electrode severely limits the number of electrons reaching the screen since 85% of the electrons emitted by the guns are not transmitted by the mask (6). Other types of color picture tubes are available which considerably increase the current density at the phosphor screen by providing for finer focusing of the electron beam. One such class of tubes, the post-deflection focusing (PDF) type, produces a focusing action at the screen by replacing the unipotential drift space by a retarding field region created by a grill in close proximity to the screen. The "Chromatron" or "Lawrence" tube (7) are examples of this tube type in which either one or three electron guns are used and in which the current densities on the phosphor screens are several orders of magnitude higher than the current densities in the shadow-mask tube. Recently, another type of tube has been announced (8) which utilizes current densities between those encountered in the shadow-mask and the PDF tubes. In this tube, electron guns with improved focus are used, and a grill system having a higher optical transmittance than that of the shadow mask is placed between the phosphor screen and the electron guns. Conceivably, the development of guns having improved focus could also be utilized in shadow-mask tubes to obtain higher current densities.

The brightness advantage which would be expected from the PDF grill has, however, not been realized in practice. The PDF grill has an electron transmission about six times that of the aperture mask and, in addition, provides a focusing action which delivers a higher current density at the screen. However, the phosphor characteristics preclude full utilization of the higher current density because of the nonlinear response of the phosphors at higher current densities and the decrease in contrast ratio[1] caused by secondary electron bombardment of the screen. This is particularly true of the conventional II-VI sulfide phosphors. Also, some phosphors, especially these sulfides, exhibit color variations with changes in current density which can lead to loss of color balance for colors derived from the combination of two or more phosphors.

In conventional screens for color television, at least one of the three phosphors exhibits a nonlinear increase in brightness as the beam current density is increased. A typical phosphor combination which exhibits this nonlinear effect is the "all-sulfide" screen in which ZnS:Ag serves as the blue primary, (Zn,Cd)S:Ag the green primary, and (Cd,Zn)S:Ag the red primary. All three of these phosphors saturate at current densities well within the operating range of the PDF tube. In more recent screens, the red sulfide is replaced by a Eu^{3+}-activated phosphor (9) which has a substantially linear response; the blue and green sulfide phosphors, however, are nonlinear.

This paper describes a cathodoluminescent screen composed of rare-earth-activated phosphors which exhibits a substantially linear increase in brightness, yields improved contrast ratio, and maintains good color balance over the operating range of the PDF tube.

Experimental

The usual method for studying luminescence intensity as a function of current density is to measure the increase in photomultiplier response as the incident current is increased and the spot size is maintained constant. When the screen operates at high voltage, measurement of the current incident upon the screen becomes difficult and often an indirect measurement is made, *i.e.* the cathode current (current leaving the cathode) is taken as a measure of the screen current. This, however, does not account for those electrons which leave the cathode but do not reach the screen. More reliable measurements can be made by maintaining the cathode current constant while the spot size is changed by defocusing the beam. In this way, the number of electrons which reach the screen remains the same. (By screen current, we mean the total primary current incident upon the screen; this must include electrons backscattered from the screen if a direct measurement of the screen current is attempted.)

When the number of electrons incident upon a phosphor is maintained constant but the current density is varied by changing the spot size, the luminescence output remains constant for a strictly linear phosphor, *i.e.* the efficiency does not change. The magnitude of the change in the emission intensity for a nonlinear phosphor therefore gives a measure of the change in efficiency. Although this method does not provide an absolute measurement of the screen current, the usual errors involved in the measurement of relative screen current are avoided.

Such measurements were made using the following procedure. A Sylvania model VMC-8TV monitor was modified to accept 5F cathode-ray tubes equipped with EM-129 electron guns. The high-voltage supply was variable from 0 to 30 kv. Focusing was accomplished by varying the current to a magnetic focusing coil. A pulse generator pulsed the beam on, by driving G_1 positive, for only a fraction of one scan line (typical

* Electrochemical Society Active Member.

[1] The contrast ratio is defined as $(B_o - B_s)/B_s$, where B_s is the brightness of the screen due to stray electrons, and B_o is the brightness of the screen due to the primary beam and the stray electrons. If $B_s << B_o$, the contrast ratio is approximated by B_o/B_s.

pulse duration, 2 μsec). The pulse was synchronized with the signal to the deflection yoke so that the spot always appeared at the same position on the screen. The screen current was not measured directly. Instead, the current leaving the cathode and the current collected by the first grid, G_1, of the electron gun were measured by using two current probes. These probes were connected to a differential plug-in unit in such a way that the display on the oscilloscope shows the current leaving the cathode minus the current collected by G_1. We found this differential method necessary since a current probe measurement of G_1 alone showed that some current was collected by G_1 during the time that G_1 was driven positive with respect to the cathode. The current collected by G_2 was negligible. (The current collected by the anode of the electron gun was not accounted for and therefore the incident screen current may be less than that measured by our method.) The oscilloscope display was then assumed to be a measure of the instantaneous screen current. A typical value was 1.2 ma. The line width or thickness, which varies with spot diameter, was measured using a cathetometer after the response of a 1P21 photomultiplier equipped with a Wratten 106 filter was recorded. The detector combination therefore gives a measure of the luminosity. The total size of the area bombarded by the electron beam was maintained smaller than the photosensitive area of the photomultiplier tube. Therefore, as the spot size is reduced, since the number of electrons incident upon the screen remains constant, the photomultiplier response should remain constant unless the phosphor "saturates." Typical line widths of 0.5-0.02 cm were obtained by varying the voltage drop across the magnetic focusing coil. With this information, the current density can be calculated if several approximations and assumptions are made.

It is well known that the current distribution across a line is not constant, and it is difficult to determine where the intensity falls to zero. Therefore, any definition of spot size and current density is somewhat arbitrary. We have attempted to use a definition which gives a measure of the current density averaged across the line width. We make the following approximations:

1. The spot is assumed to be circular. Although the spot is actually elliptical, with the same scan speed and raster size, the measurements are consistent.
2. The current falls to zero at the point where the eye perceives a sharp cut-off in brightness contrast. This, in actuality, is the point where the brightness drops to approximately 5% of the peak brightness.
3. Although it is known that the intensity is not equally distributed across a line width (probably a bell-shaped, not quite Gaussian, distribution), the distribution is averaged by dividing the current by the area of the spot. This also yields consistent, although not absolute, values.
4. The effects of backscattered electrons, halation, and light scatter in the phosphor are ignored. These effects may vary from one phosphor to another but it is assumed that they are negligible.

Since the scan speed (and therefore dwell time) and the current distribution across the spot are altered as the tube size is changed, there may be a "scaling-up" effect. Indications of this type of effect were obtained by changing the scan speed and also by studying the effect of pulse duration on the degree of "saturation" for a stationary pulsed spot. To increase the scan speed, the beam was pulsed on during the horizontal retrace. To study the effect of increased pulse duration, the deflection circuit was disconnected and a General Radio Model 1217-C pulse generator was added to the grid circuit. The chassis of the pulse generator was "floating"; its potential was determined by the voltage output from a regulated d-c power supply to give cut-off when the pulsing voltage is zero. The pulsing voltage was then increased to produce a stationary pulsed spot on the screen. The pulse repetition frequency was set at 30 Hz, and the pulse width was varied from 2 to 10 μsec.

In addition to measurements of the intensity of the luminescence as a function of the current density, the spectral distribution was recorded at relatively high and low current densities by interposing a quartermeter Jarrell Ash monochromator between the cathode-ray tube and the 1P21 photomultiplier tube.

Results and Discussion

Figures 1,2, and 3 show the relative luminosity *vs.* current density at constant cathode current for several red-, green-, and blue-emitting phosphors. The value 1.0 in the figures corresponds to 1 amp/cm^2 instantaneous current density (or 6 x 10^{-6} amp/cm^2 averaged over time). In all cases, comparison is made with sulfide phosphors of corresponding emission colors. The blue and green sulfides correspond to the blue and green primaries used in the conventional shadow-mask color-TV display tubes, and the red sulfide corresponds

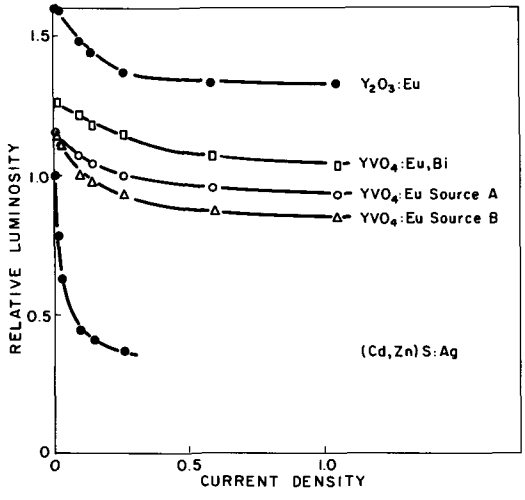

Fig. 1. Relative luminosity *vs.* current density for red-emitting phosphors.

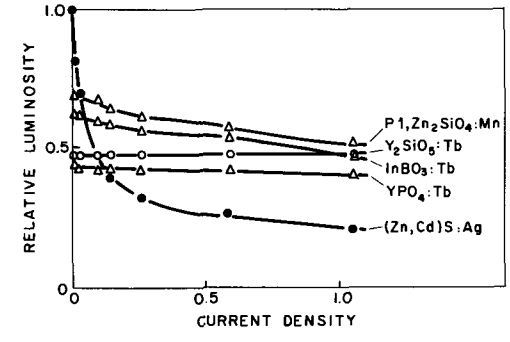

Fig. 2. Relative luminosity *vs.* current density for green-emitting phosphors.

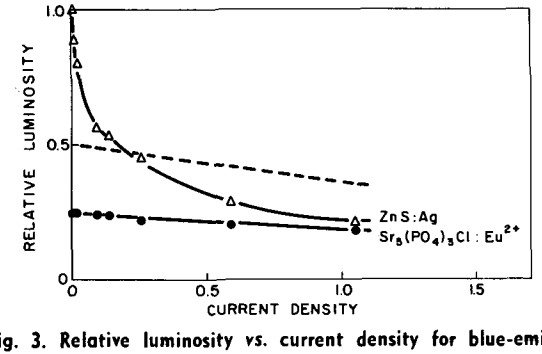

Fig. 3. Relative luminosity *vs.* current density for blue-emitting phosphors. Dashed line represents "effective" efficiency of Eu^{2+} phosphor in producing a white field when mixed with red and green.

to the red primary which had been used prior to its replacement by Eu^{3+}-activated phosphors. It is apparent that the II-VI sulfide phosphors "saturate" (*e.g.*, their efficiencies decrease at high current densities) to a much greater extent than the rare-earth-activated phosphors at the current densities obtainable in a PDF tube. With the red-emitting phosphors of Fig. 1, the Eu^{3+}-activated phosphors are superior to the (Cd,Zn)S:Ag phosphor at both high and low current densities. The Eu^{3+} phosphors show some degree of "saturation," but the effects are not nearly as drastic as with the sulfide phosphor. Therefore, the Eu^{3+}-activated red-emitting phosphors, which are superior to the sulfide red at the low current densities in shadow-mask tubes, show even better relative performance in high-current-density tube designs (Y_2O_2S:Eu behaves similarly to the Eu^{3+}-activated phosphors shown).

Although none of the green-emitting phosphors measured has an efficiency comparable to that of the (Zn,Cd)S:Ag phosphor at low current densities, several phosphors investigated surpass the green sulfide at high current densities (Fig. 2). The Tb^{3+} phosphors (10-12) appear to have an upper limit of 50-60% of the efficiency of (Zn,Cd)S:Ag at low current density, but they maintain their efficiency as the current density is increased and soon exceed the sulfide phosphor at densities above 0.1 amp/cm^2. Other oxygen host systems perform similarly to the Tb^{3+}-activated materials. As an example, Fig. 2 shows the behavior of $Zn_2SiO_4:Mn^{2+}$—a non-rare-earth-oxygen-based phosphor which is closest to the efficiency of sulfide type phosphors. The silicate is, however, characterized by an intrinsically long decay which decreases its utility in color-TV tubes.

In Fig. 3, the response of the phosphor $Sr_5(PO_4)_3Cl:Eu^{2+}$ (13) is shown along with that of the blue-emitting ZnS:Ag phosphor. The measured relative efficiency of the sulfide phosphor is superior to that of the divalent-europium-activated material over the range of current densities studied. However it should be pointed out that the color coordinates of the Eu^{2+} material are $x = 0.152$, $y = 0.032$, and those for the sulfide are $x = 0.145$ and $y = 0.052$. The Eu^{2+} emission is therefore more saturated (more nearly characteristic of a pure spectral color) than the blue emission from ZnS:Ag, and its efficiency requirements for proper color balancing with the other primaries are correspondingly lowered (14). Consequently, $Sr_5(PO_4)_3Cl:Eu$ is more effective, by a factor of 1.9, than ZnS:Ag in producing a white field when it is mixed with red and green. Its "effective" efficiency is indicated by the dashed line which demonstrates that its performance also exceeds that of the sulfide at high current densities.

The magnitude of the deviation from linearity is directly related to the dwell time of the electron beam. This is demonstrated in Fig. 4 and 5 using the test procedures described in the experimental section. Both figures show that the deviation from linearity increases as the dwell time increases either for a stationary or for a scanning spot. The dwell time on the retrace of a scanning spot is about 1/6 that during the normal scan.

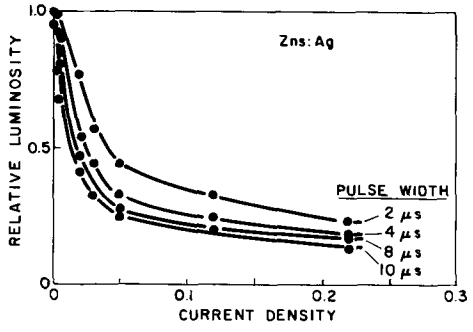

Fig. 4. Relative luminosity *vs.* current density for ZnS:Ag at four different dwell times using a stationary electron beam.

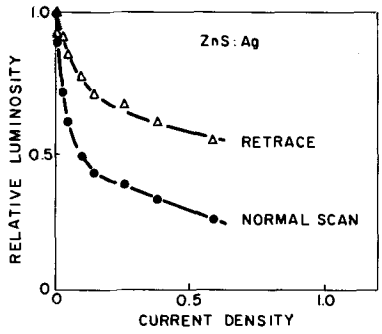

Fig. 5. Relative luminosity *vs.* current density for ZnS:Ag showing the effect of change of dwell time using a scanning spot. The change in dwell time is brought about by pulsing the beam on during normal scan or during retrace.

A limited test of the effect of repetition frequency was made. Using a scanning spot, we were able to pulse the beam on every raster (60 Hz) or alternatively only every eighth raster (7.5 Hz). There was no detectable difference between the saturation effect at 60 and at 7.5 Hz.

For those phosphors which show a drastic deviation from linearity at high current density, we observed a broadening of the emission band and a shift toward shorter wavelength. Figures 6-8 demonstrate the effect. In these figures, the heights of the emission peaks for high and low current densities were set equal by adjusting the gain on the photomultiplier tube. Low current density corresponds to approximately 1 x 10^{-3} amp/cm^2 and high current density to 1.0 amp/cm^2

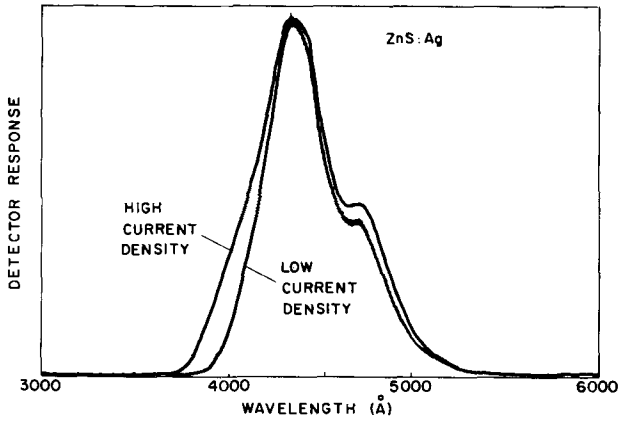

Fig. 6. Spectral shift for ZnS:Ag. The gain was adjusted to equalize the peak heights of the two curves.

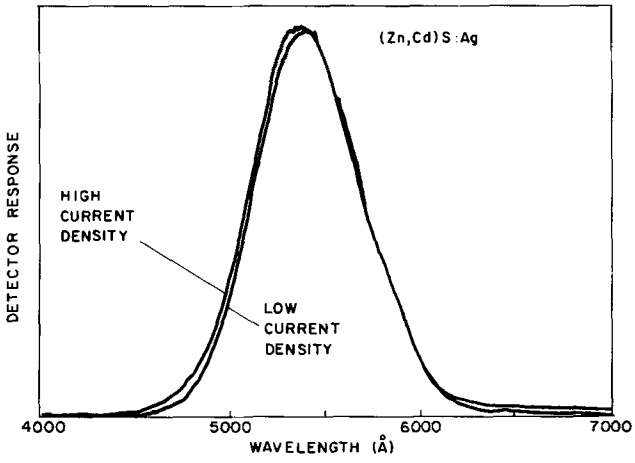

Fig. 7. Spectral shift for (Zn,Cd)S:Ag. The gain was adjusted to equalize the peak heights of the two curves.

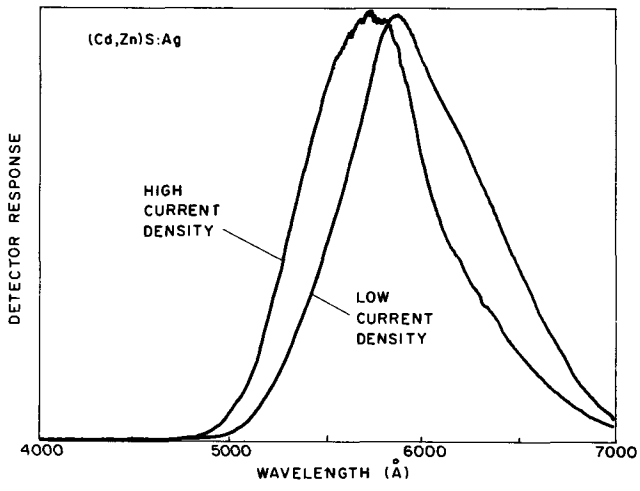

Fig. 8. Spectral shift for (Cd,Zn)S:Ag. The gain was adjusted to equalize the peak heights of the two curves.

according to the definition of spot size discussed previously. No spectral shifts were observed for the other phosphors which showed only small deviations from linearity; that is, the spectral distributions at high and low current density were unchanged.

From our results, we cannot determine if the nonlinearity is due to a true saturation effect (in the sense that the luminescence is limited by the number of luminescent centers available) or due to a temperature increase at high current density.

Inspection of Fig. 2 will show that, while Zn_2SiO_4:Mn is not strictly linear, its nonlinearity is much less pronounced than that of (Zn,Cd)S:Ag. For Zn_2SiO_4:Mn containing 1 m/o (mole per cent) of Mn, we calculate 2 x 10^{20} Mn^{++} ions/cm^3. We can estimate how many Mn^{++} ions are excited by the average incident electron if we use the energy efficiency (8.5%) of Zn_2SiO_4:Mn as measured by Bril and Klasens (15) and assume that the average photon emitted has energy of 2.36 ev (5250Å). If we now estimate the range of primary electrons from that found by Ehrenberg and Frank (16) and by Ehrenberg and King (17) for phosphors with a density nearly the same as Zn_2SiO_4, we can calculate the number of Mn^{++} ions/cm^3 excited by the average electron. For a pulse with a current density of 1 amp/cm^2, we estimate that on the average 4 x 10^{18} Mn^{++} ions/cm^3 are excited per pulse. Therefore a higher current density would be necessary to bring about a very pronounced true saturation effect. By using the same argument for ZnS:0.015 m/o Ag^+ but assuming an energy conversion efficiency of 20%, we estimate that at 1 amp/cm^2 the number of Ag^+ ions/cm^3 excited per pulse is approximately twice the Ag^+ ion concentration. Therefore, at these high current densities, the true saturation effect should be very pronounced for the II-VI sulfide phosphors.

The nonlinearity of the II-VI sulfide phosphors might also result from thermal quenching. Bril and Klasens (15) have shown that thermal quenching for these phosphors begins to set in at about 50°C. We can make a rough estimate of the temperature rise of the phosphor ZnS:Ag by using the thermal properties and the method reported by Archard and Einstein (18). For the case of a stationary pulsed spot, 30 Hz, with a pulse width of 10 μsec and an instantaneous current density of 0.2 amp/cm^2 (Fig. 4), we calculate a temperature of approximately 60°C. We should emphasize that the thermal conductivity of ZnS:Ag and the glass substrate as measured by Archard and Einstein (18) may not be quantitatively appliable to our situation. Therefore, it would not be unreasonable to expect a higher temperature. A higher temperature (about 130°C) would be necessary to attribute all the nonlinearity observed to an increase in temperature alone.

Table I. Decay times for phosphors tested

Phosphor	Time (msec) to decay to 1/10 of initial brightness: Low current density (~5 ma/cm^2)	High current density (~500 ma/cm^2)
(Cd,Zn)S:Ag	0.2*	0.04
$YVO_4:Eu^{3+}$	1.1	0.90
$YVO_4:Eu^{3+}$, Bi	1.1	0.98
$Y_2O_3:Eu^{3+}$	2.5	2.2
(Zn,Cd)S:Ag	0.5*	0.08
YPO_4Tb^{3+}	5.4	5.4
$Y_{1.86}Tb_{0.14}SiO_5$	6.0	6.0
$InBO_3:Tb^{3+}$	19	18
$Zn_2SiO_4:Mn^{2+}$	21	20
ZnS:Ag	0.1*	0.05
$Sr_5(PO_4)_3Cl:Eu^{2+}$	<0.006	<0.006

* These measured values are very sensitive to current density and dwell time.

Table I shows the time in milliseconds for decay to 1/10 of initial brightness for the various phosphors tested. It is obvious that the decay times of the linear phosphors remain constant as the current density is increased, but the decay times of the sulfide phosphors decrease drastically as the current is increased.

Embodiment in PDF tube.—A phosphor screen was fabricated in which phosphors were deposited in vertical stripes across the width of the faceplate. This screen was mated to the grill of the PDF tube after a thin layer of aluminum was evaporated over the phosphor stripes. The phosphors utilized were europium-activated yttrium vanadate, $YVO_4:Eu^{3+}$, terbium-activated yttrium phosphate, $YPO_4:Tb^{3+}$, and divalent-europium-activated strontium halophosphate, $Sr_5(PO_4)_3Cl:Eu^{2+}$. At low current densities, this tube was adjusted to give a white field, and the current was then increased step-wise up to the maximum operating current of the tube. No color shifts were observable, and the brightness increased linearly over the entire operating range.

Figure 9 illustrates the relationship between the luminescence intensity and current density for a hypothetical nonlinear "saturating" cathodoluminescent phosphor and that for a linear phosphor. The contrast ratio for the nonlinear phosphor is B_{on}/B_{sn}, while for the linear phosphor the contrast ratio is B_{o1}/B_{s1}.[2] Since $B_{on} < B_{o1}$ and $B_{sn} > B_{s1}$ it follows that $B_{o1}/B_{s1} > B_{on}/B_{sn}$; that is, the contrast ratio for the linear phosphor is greater than that for the nonlinear phosphor at high current densities. At low current densities, the relative values of the contrast ratio may be reversed because the brightness of the linear phosphor at low current densities is less than that of the nonlinear phosphor. Therefore in cathode-ray tubes such as the shadow-mask tube, which operates at low cur-

[2] The subscript 1 refers to the linear phosphor and n refers to the nonlinear phosphor. The subscripts o and s have the same significance as previously indicated in the definition of contrast ratio.

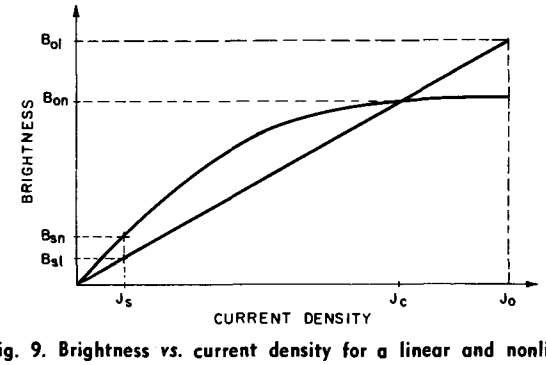

Fig. 9. Brightness vs. current density for a linear and nonlinear phosphor. J_S is the current density of back-scattered electrons, J_0 the current density under operating conditions, and J_c the current density at which crossover occurs.

rent densities, the brighter nonlinear phosphor may perform better than the linear phosphor.

An advantage of the linear phosphor screen over the nonlinear "saturating" phosphor in the PDF type tube is the reduction in the effect produced by electrons scattered back from the screen. Since there is a potential difference between the screen and the grill, electrons which are scattered back from the screen are subjected to a retarding field. Electrons that do not have a large velocity component perpendicular to the plane of the screen follow a parabolic trajectory in the space between the screen and grill and return to the screen with generally less velocity than the primary beam. Since they are distributed over a wider area, the density of these scattered electrons is considerably less than the density of electrons in the primary beam. Therefore, if we again refer to Fig. 9 for the hypothetical linear and nonlinear phosphors, and if we assume that J_s represents the density of back-scattered electrons, it becomes apparent that the brightness due to back-scattered electrons will be greater for the nonlinear than for the linear phosphors. This is true if the nonlinear phosphor is brighter than the linear phosphor at low current densities. For example, this would not be the case where a Eu^{3+}-activated phosphor is compared with (Cd,Zn)S:Ag if the Eu^{3+}-activated phosphor is brighter than the sulfide over the full range of current density.

Conclusion

This paper has described a method by which the "saturation" effect, or the decrease in cathode ray efficiency as a function of current density, can be evaluated. The saturation effect is especially pronounced in conventional II-VI sulfide phosphors. Therefore, although these phosphors have played an important role in the performance of conventional color-TV display systems, their nonlinear performance in high-current-density tubes limits their usefulness. Oxygen-based phosphors, on the other hand, have been found to respond linearly with increase in current density. Specifically, rare-earth-activated phosphors based on Eu^{3+} activation for red, Tb^{3+} activation for green, and Eu^{2+} activation for blue show distinct advantages over the Zn-Cd sulfide phosphors in certain tube designs.

Acknowledgments

The authors would like to express their appreciation to C. Creter for many of the measurements, to H. Dressel and J. Dymon for the fabrication of the PDF tube, and to D. George for helpful discussions.

Hydrogen Sulfide as an Etchant for Silicon

P. Rai-Choudhury* and A. J. Noreika

Research & Development Center, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The etch rates for Si by gaseous H_2S are measured as functions of temperature and found to be limited, at temperatures below about 1000°C, by an increasingly stable reaction product, *viz.* SiS_2. Etched surfaces are evaluated by forming carbon replicas which are subsequently examined by transmission electron microscopy. Some epitaxial layers are grown on the etched Si surfaces and are examined optically and by a spreading resistance method. Neither crystallographic (precipitates) nor electrical (doping) anomalies are introduced by the H_2S treatment. All results are compared to equivalent data obtained from controlled etching experiments in which gaseous HCl and H_2O, respectively, are used as etchants. For comparable temperature and flow conditions, etch rates using H_2S have far exceeded those obtained from both HCl and H_2O; *e.g.*, at 1200°C the ratio of etch rates (H_2S::HCl::H_2O) is roughly 2000::15::1. Considerable difference is also observed in the replicas taken from equivalent Si surfaces. Surfaces etched with H_2S show little detail, indicating considerable smoothness. Etching with HCl and H_2O invariably produces patchy or rutlike features.

The role of substrate perfection on the performance of silicon devices has been the subject of a recent review (1). In general, silicon substrates are observed to suffer from two main classes of imperfection, *viz.* (*a*) defects introduced during processing and (*b*) inherent bulk defects. The former, *e.g.* certain surface oxides and films, mechanical damage, *etc.*, can be removed *in situ* by chemical etching. The latter, *e.g.* dislocations, stacking faults, precipitates, *etc.*, are not readily removable.

* Electrochemical Society Active Member.

To date, the most extensively used gaseous etchants for *in situ* etching of silicon are hydrogen chloride (2) and water vapor (3). Hydrogen chloride reacts with the silicon surface at a moderate rate (*see* Table I), the volatile reaction products being removed by the gas flow. At temperatures > 1100°C, hydrogen chloride has the undesirable property of being an excellent transport agent (4). The etched silicon, consequently, is subject to an influx of contaminants from various components, *e.g.* the susceptor, *etc.*

Water vapor, a much slower etchant (Table I), required temperatures > 1200°C before effective cleaning occurred. Unlike hydrogen chloride, water vapor proves a poor transport agent.

Because of a need for a rapid, effective etchant, the present investigation of the etching properties of hydrogen sulfide on silicon was initiated. Some preliminary work on this etchant was done independently by Chu (5) of these laboratories. (Note: thermodynamic calculations indicated that hydrogen selenide might also prove an efficient etchant.)

Experimental

The vapor etching experiments were performed in a conventional horizontal reaction chamber in which substrates were placed on a SiC-impregnated carbon susceptor and heated *via* rf current, the rf coil being externally mounted. Three etchants were used separately, *viz.* anhydrous hydrogen chloride (ultrahigh purity), doubly distilled water, and 10% hydrogen sulfide in ultrapure hydrogen. Desired concentrations of the etchants were obtained by mixing controlled amounts with palladium-purified hydrogen. Si(111) wafers which were to be etched *in situ* were initially chemically polished then split into three parts, thus enabling the effects of the three etches to be evaluated on a given wafer. Carbon replicas of the split Si wafers were made after etching and these were examined by transmission electron microscopy (TEM). The etch rates were determined from weight loss and wafer thickness measurements. All temperatures reported are uncorrected pyrometer readings.

Epitaxial layers were grown on etched substrates by the hydrogen reduction of $SiCl_4$ and provision for doping with B_2H_6 or PH_3 was made. These layers were subjected to optical examinations and spreading resistance measurements (6).

Results and Discussion

Figure 1 shows the variation of etch rate (change in total thickness per unit time) with temperature for a H_2S partial pressure of 5.5 x 10^{-3} atm and a total hydrogen flow of 100 liters/min (linear velocity $\simeq$ 25 cm/sec). The curve indicates a slowing of etch rate as temperature decreases. Appearances of surfaces etched at 800°, 1000°, and 1100° give a clue to the mechanism by which simple mass transfer which would occur *via* the reaction

$$Si(s) + 2H_2S(g) \rightarrow SiS_2(s \text{ or } l) + 2H_2(g)$$

may be inhibited. Substrates etched at 800°C appeared optically smooth although discolored. When examined by reflection electron diffraction, the surfaces were found to be covered by highly insulating amorphous films, most probably SiS_2. The formation of SiS_2 as the prime reaction product is thermodynamically favored over that of SiS in our temperature range of interest 7). It is also substantiated by data which indicate that SiS (the alternate reaction product) may be obtained in significant amounts only through a gas phase reaction between SiS_2 and Si at temperatures greater than 1400°C (8, 9). In the course of Si etching, the reaction product was observed to condense in the cold part of the reaction tube as small yellowish needles. These were subjected to x-ray diffraction examinations and were found to resemble glasslike structures although the compositions could not be ascertained. Since SiS_2 is known to hydrolize readily

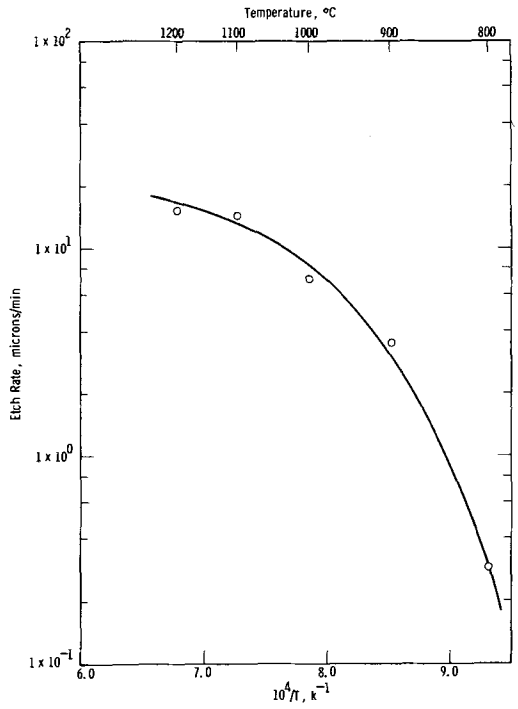

Fig. 1. Effect of temperature on etch rate: $p_{H_2S} = 5.5 \times 10^{-3}$ atm; total flow rate 100 liters/min.

(10), its decomposition to SiO_2 (glassy form) and H_2S is suspected. Substrates subjected to H_2S flow at 1000°C were visibly roughened. The presence of an insulating layer was not detected. At temperatures 1100°C and higher, smooth, highly polished surfaces were prepared, the streaked diffraction patterns being indicative of surface smoothness. The rapidly decreasing slope of the curve for etch rate *vs.* $1/T$, therefore, is most likely due to a surface-limiting activation process. The high- (1100°C) and low-(800°C) temperature results show the respective absence and presence of the amorphous layers. The intermediate temperature ($\sim$ 1000°C) results reflect noncoherent etching due to incomplete removal of the reaction products.

A measure of the relative speed with which H_2S etches at 1200°C is shown in Table I where etch rates of the three etchants are compared. The partial pressures of the HCl and H_2O etchants approximate those used in practice (a higher H_2O pressure, for instance, initiates the formation of SiO_2 and surface pitting). For the pressure and flow parameters chosen, the H_2S etch rate exceeded that of HCl by approximately two orders of magnitude.

The effects of etching at 1200°C on the silicon surfaces are shown by the micrographs of replicated surfaces (Fig. 2). These surfaces were essentially identical, prior to etching, being cut from a single, chemically polished wafer. The results (Fig. 2) indicate a microscopically smoother finish, akin to a rapid nonpreferential chemical etch, for the H_2S etched surface. A total of seven wafers were split and etched, the results being similar.

Although appreciable sulfur doping was not anticipated, the effect of H_2S on doping profiles were investigated. Silicon deposition was initiated on a H_2O etched substrate and a layer of 90μ average thickness

Table I.

Etchant	Etchant partial pressure, atm	Etching temp, °C	Total flow rate, liters/min	Etch rate, μ/min
HCl	1.0×10^{-2}	1200	100	0.183
H_2O	1.3×10^{-4}	1200	100	0.071
H_2S	5.5×10^{-3}	1200	100	15.1

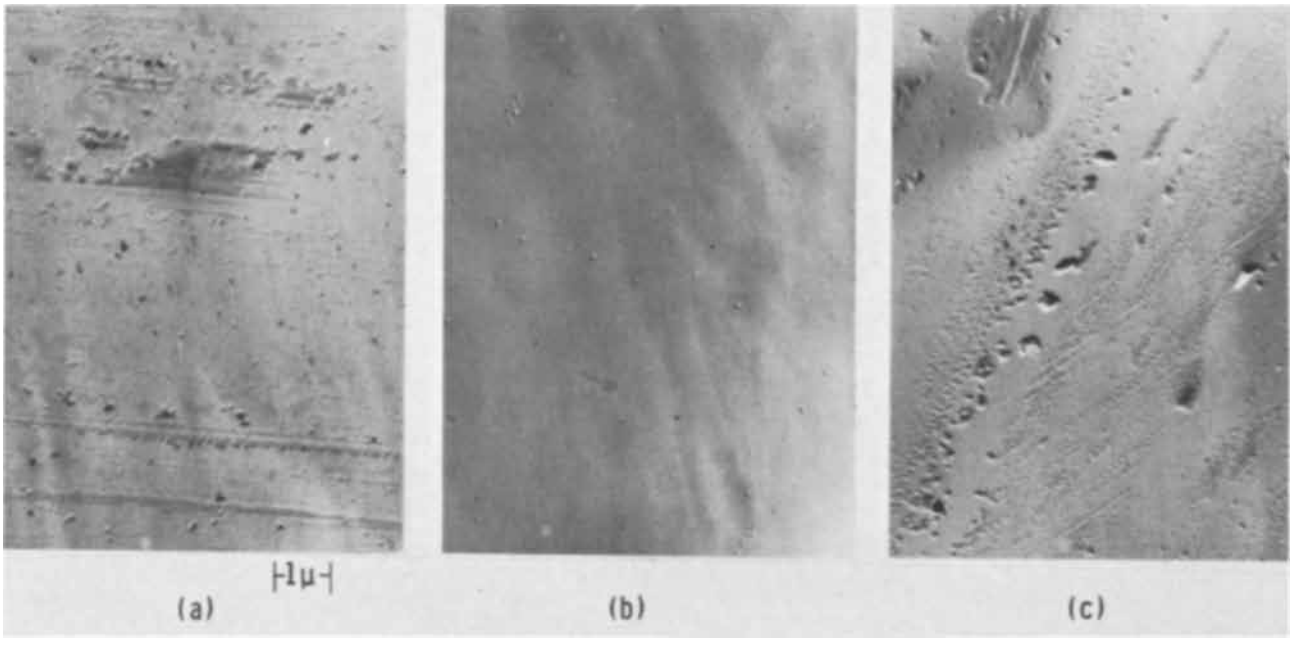

Fig. 2. Transmission electron micrographs of the carbon replicas of silicon surfaces etched at 1200°C using (a) HCl, (b) H_2S, and (c) H_2O.

was formed. Twenty microns of the layer were subsequently removed by etching with H_2S at 1150°C. An additional 75μ of epitaxial silicon were then deposited. These thick epitaxial layers were essentially free from any inclusions and stacking faults, and constitute a severe test of surface cleanliness. Spreading resistance measurements showed no discontinuity in the impurity profile of the combined 145-μ layer, the net donor concentration being 4 x 10^{14} atoms/cm^3 throughout.

Conclusions

Gaseous H_2S is found to be a rapid and nonpreferential etchant for silicon. Sulfur, although a donor impurity in silicon, was not observed to be introduced during the etching cycle.

Acknowledgments

Extra-High-Purity Nickel Powder from Nickel Sulfate Solution by Hydrogen Reduction

N. Zubryckyj,[1] W. Kunda, and D. J. I. Evans

Sherritt Gordon Mines Limited, Research and Development Division, Fort Saskatchewan, Alberta, Canada

ABSTRACT

The method described for the preparation of extra-high-purity nickel powder is based on the reduction of nickel sulfate solution by hydrogen under pressure in an autoclave. To obtain the required purity, the nickel sulfate solution must first be thoroughly purified from the elements that are more electropositive than nickel in the Nernst electromotive series and from the elements, the salts of which are susceptible to hydrolysis above a pH of 4. The methods employed for removing the traces of impurities include cementation of the copper, hydrolysis of the iron salts, and chemical precipitation of the cobalt. Unlike commercial practice of the hydrogen reduction process, the reduction of the purified nickel sulfate solution is carried out without a ferrous salt catalyst. To initiate the reduction reaction, a small amount of ammonium carbonate is introduced into the system. Reduction is carried out at a temperature of 350°F under a hydrogen pressure of 350 psi. The ammonium carbonate presumably promotes the formation of a fine suspension of solid basic nickel carbonate which then plays the role of a catalyst and provides the nuclei on which the nickel precipitates. In this way, contamination by the foreign elements originating from the catalysts normally used is avoided. Final "polishing" of the nickel powder is done using a wet hydrogen treatment at a temperature of 800°F to remove traces of carbon from the nickel powder, and a dry hydrogen heat treatment at 800°F to remove oxygen. The purity and some of the properties of the nickel powder produced are given.

Commercial nickel, whether it is produced by electrolysis, by the decomposition of nickel carbonyl, or by precipitation by hydrogen from aqueous systems, is already a high-purity material. Since more than 75% (1967) of the nickel produced is normally incorporated into alloys with iron or copper, the minor contaminants usually present, such as cobalt, copper, iron, sulfur, and carbon, are low enough in commercial nickel to have no effect on the properties of the final products. The remaining 25% of the nickel produced is used directly as the virtually pure metal or as the feed material for the production of catalysts and chemicals. In some of these applications, specific impurities can be harmful; however, these impurities can usually be avoided by careful selection from the commercial forms available.

The purity of commercial forms of nickel is dependent on the starting material and on the refining process used. Table I shows the chemical analyses of commercial nickel produced by various methods and analyzed by the same laboratory. The elements not listed in Table I, namely Ag, Al, Ba, Be, Bi, Ca, Cd, Cr, Ge, Hg, Mn, Mo, Sb, Si, Sn, Ti, and V, are all reported to be less than 0.001% by emission spectrographic analysis.

From time to time, there is a demand for nickel of very high purity for special applications. Such applications include vacuum tubes for submarine cable repeaters (1), electronic equipment (2), special alloys for nuclear reactors (3, 4) and for the study of the mechanical, electrical, and magnetic properties of nickel and nickel-base alloys. With the sophisticated methods presently available for converting metal powders directly into wrought forms, a very-high-purity nickel powder provides a suitable starting material for many of these applications.

The first attempt to prepare a pure nickel powder was made by de Ruolz in 1841 (5) using an electrolytic precipitation method. Since that time, a considerable amount of work has been carried out to improve the purity of the nickel powder produced by essentially the same electrolytic method, by adding intermediate purification steps.

[1] Present address: S. A. Industrias Votorantim, Brazil.

The hydrometallurgical methods developed by Sherritt Gordon Mines Limited for the commercial production of nickel powders from the aqueous ammonium sulfate system (6) or ammonium carbonate system (7) by reduction, at elevated temperatures, with gaseous hydrogen, do yield a relatively high-purity nickel powder. However, to produce an even higher-purity nickel powder for special applications, it is necessary to modify the procedures developed.

The modified method comprises the dissolution of a commercial grade nickel powder in sulfuric acid, purification of the nickel sulfate solution to remove minor metal contaminants, and precipitation of the nickel with hydrogen in a metallic form using a different catalyst from that used conventionally. The product, in the form of a powder, is then decarburized and deoxidized by treatment with hydrogen at elevated temperature. A block flow diagram for the production of extra-high-purity nickel powder is shown in Fig. 1.

Materials and Equipment

In the investigations undertaken to develop the process, the starting material for the preparation of extra-high-purity nickel powder was commercial "S" grade nickel powder.

The reagents used were: C.P. grades of sulfuric acid, ammonium hydroxide, hydrogen peroxide, 1-nitroso-2-

naphthol, or 1-naphthol and ammonium carbonate. The 1-nitroso-2-naphthol reagent solution was prepared by dissolving 100g of reagent in 250 ml of a 6% sodium hydroxide solution and mixing with 200 ml of a 20% potassium nitrite solution.

The dissolution of the feed nickel powder and the purification of the nickel sulfate solutions were carried out at temperatures below 200°F at solution *p*H values between 0-6.0. For these operations, glass or polypropylene-lined equipment was used. The precipitation of the nickel by hydrogen was carried out at 350°F from ammoniacal solutions, and stainless steel autoclaves were found to be adequate. The decarburization and deoxidation step was carried out at temperatures in the range of 800°-1500°F in a hydrogen atmosphere, and ceramic or nickel trays were used to hold the nickel powder.

It goes without saying that extreme cleanliness with respect to the equipment had to be maintained throughout all of the process stages. Contamination of the final product by airborne dust particles also had to be avoided.

Process Development Investigations

Preparation of nickel sulfate solution.—Nickel sulfate solution was prepared by leaching commercial "S" grade nickel powder in C.P. sulfuric acid in an agitated vessel into which air or oxygen could be sparged. The essential reaction during leaching was:

$$Ni + H_2SO_4 \rightarrow NiSO_4 + H_2 \qquad [1]$$

However, when oxygen was sparged into the system, the reaction taking place was:

$$Ni + H_2SO_4 + \tfrac{1}{2} O_2 \rightarrow NiSO_4 + H_2O \qquad [2]$$

The rate of dissolution was accelerated by the presence of the sparged oxygen. Cobalt and iron, when present in the nickel powder, dissolved at the same rate as the nickel. Copper did not go into solution in the presence of metallic nickel; however, when the nickel powder was completely leached, copper did dissolve although it was readily cemented out by adding a few grams of fresh nickel powder.

By using a 20-50% stoichiometric excess of nickel powder, a final solution was obtained which contained only a few grams of free sulfuric acid. This solution was suitable for further purification. Although the nickel concentration in the final solution could be built up to about 250 g/liter, it was found preferable to limit the nickel concentration to 100 g/liter for practical considerations.

The rate of nickel dissolution and sulfuric acid consumption is shown in Fig. 2(a) and the behavior of the Co, Fe, and Cu impurities during leaching is shown in Fig. 2(b).

Using an excess of nickel powder, the nickel sulfate solution produced contained less than 0.0006 g/liter Cu and this was considered adequately pure with respect to copper.

Purification of nickel sulfate solution.—Using "S" grade nickel powder, the nickel sulfate solution contained only Fe and Co as impurities. These were necessarily removed before the hydrogen reduction of the nickel from solution.

Iron removal. An effective and convenient method for iron removal is to precipitate the iron as ferric hydroxide and to remove the precipitate by filtration. The completeness of the iron precipitation depends on

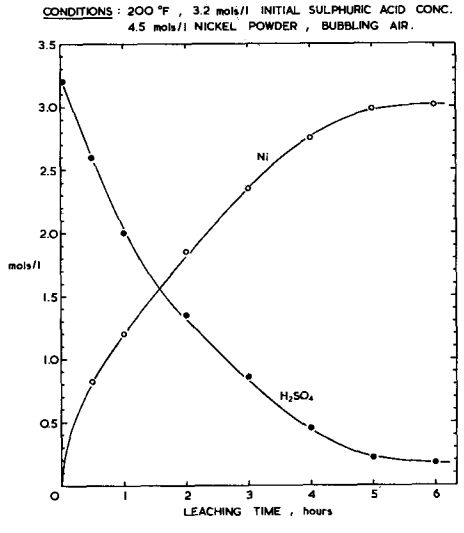

Fig. 2(a). Dissolution rate of nickel powder in sulfuric acid solution.

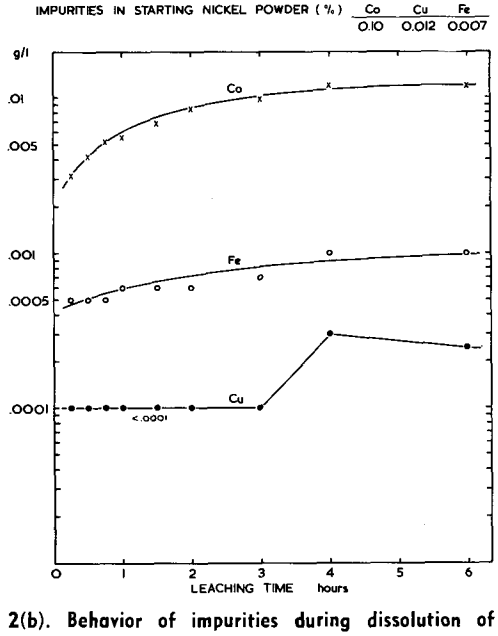

Fig. 2(b). Behavior of impurities during dissolution of nickel powder in sulfuric acid solution.

the iron being present in the ferric form and on the pH of the system. In the above dissolution procedure, the iron in the nickel sulfate solution was present as ferrous sulfate. Two methods were employed to oxidize this iron to the ferric form: (*a*) oxidation with oxygen or air under pressure in an autoclave at elevated temperatures, or (*b*) oxidation with hydrogen peroxide or ammonium persulfate. While the oxidation with air could be carried out at atmospheric pressure, the long retention time made this method impractical.

The important parameters affecting the iron precipitation were the pH of the system and the temperature. The conditions favoring iron precipitation were also conducive to the precipitation of nickel. Oxidation with hydrogen peroxide or ammonium persulfate proved to be more advantageous than oxidation with air under pressure because it could be carried out at lower temperatures. From practical considerations, oxidation using hydrogen peroxide was selected as the preferred procedure.

Under the optimum conditions with hydrogen peroxide and using ammonia for pH control, a nickel sulfate solution was produced containing 0.0002 g/liter Fe as shown in Table II.

The chemical reactions taking place during iron removal were:

$$2FeSO_4 + H_2SO_4 + H_2O_2 \rightarrow Fe_2(SO_4)_3 + 2H_2O \quad [3]$$

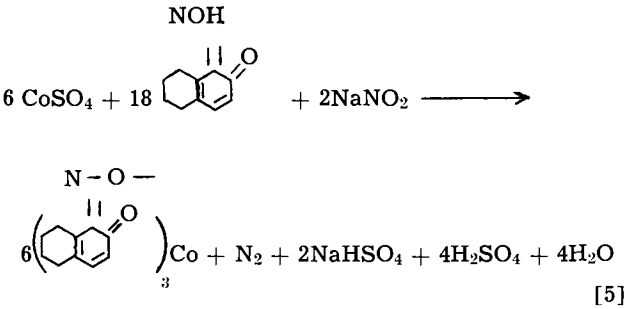
$$Fe_2(SO_4)_3 + 6NH_4OH \rightarrow 2Fe(OH)_3 + 3(NH_4)_2SO_4 \quad [4]$$

Filtration was carried out using a diatomaceous earth filter-aid to insure the removal of the very fine ferric hydroxide particles.

Cobalt removal. Because of the similar chemical behavior of nickel and cobalt in solution, a number of procedures had to be investigated for removing cobalt from the nickel sulfate solution. Two promising methods, one using the preferential electrolytic precipitation of cobalt on a high-speed rotating cathode (8) and the other chemical precipitation by sodium ethyl xanthate (9) in an ammoniacal medium, at a pH of 9.5, using 30 times the theoretically required quantity of reagent, have been reported by other workers. Exploratory tests were carried out in the laboratory on acidic nickel sulfate solution using a wide variety of chemical precipitation agents. The most promising results were obtained by precipitating the cobalt with 1-nitroso-2-naphthol or 1-naphthol and these reagents were chosen for systematic investigations to establish the optimum conditions for the precipitation. The work showed that the quantity of reagent and pH were the most important parameters affecting the completeness of the cobalt removal. The effects of these variables are shown in Table III and Fig. 3.

The results of these investigations, as well as those with 1-naphthol shown in Table IV, demonstrated that iron, as well as cobalt, may be removed to a very low level by these reagents.

The reactions taking place during cobalt precipitation can be expressed by the following equation:



[5]

It is assumed in this reaction that the 1-nitroso-2-naphthol is present in the quinonoid form:

as sugested by Thorne and Roberts (10). The sodium nitrite added with the 1-nitroso-2-naphthol oxidized the cobalt to the cobaltic form. Stoichiometrically, 3 moles of 1-nitroso-2-naphthol are required to precipitate 1 mole of Co. However, for complete precipitation, it was found that a 5-times excess of reagent was required. The completeness of the cobalt precipitation increased with time and a 4-hr reaction time was found to be the optimum. In practice it was found that the filtered nickel solution should be stored for 16 hr and refiltered to remove the very fine particles of cobalt precipitate. The effectiveness of this procedure is shown in Fig. 3.

Nickel reduction.—The reduction of nickel from the aqueous nickel ammine sulfate system by gaseous hydrogen under pressure at elevated temperatures requires a catalyst. In the commercial application of this process, two catalysts are used, ferrous sulfate as a nucleation catalyst and nickel powder as the catalyst in subsequent densifications (11). The procedure used involves a cycle consisting of about 50 densification re-

ductions. The cycle is started with a nucleation reduction using 0.5-1.0 g/liter Fe^{++} in the form of ferrous sulfate as the catalyst. The product of nucleation reduction is a very fine nickel powder with an average particle size of 1-2μ. The subsequent densification reductions are carried out using the nickel powder produced in the previous reduction. The nickel powder becomes coarser as the cycle proceeds and, after about 50 reductions, the cycle is terminated, the nickel product discharged, and a new cycle started.

The following reaction takes place during reduction:

$$Ni(NH_3)_2SO_4 + H_2 \rightarrow Ni + (NH_4)_2SO_4 \qquad [6]$$

In this procedure, about 20% of the iron added as the catalyst in the nucleation reduction, remains with the nickel. During the subsequent densifications, the iron is progressively diluted to less than 0.01% Fe in the final powder and thus does not materially affect the purity of the commercial grades of nickel powder. However, such contamination could not be tolerated if the specifications, arbitrarily set for the extra-high-purity nickel powder, were to be met.

In the search for an alternative catalyst which would not contaminate the final product, it was found that ammonium carbonate was most effective. Ammonium carbonate, added in quantities as low as 5 g/liter, was found to be not only an effective reduction catalyst, as shown in Fig. 4, but its use also resulted in lowering the sulfur content of the final nickel powder from 0.02 to 0.005% S. This finding was a critical advance in the development of the process for the preparation of extra-high-purity nickel powder using hydrometallurgical techniques. Using a similar densification procedure to that in commercial practice, the extra-high-purity nickel powder was prepared from purified nickel sulfate solution in a cycle comprising one nucleation with ammonium carbonate and several densifications. Ammonia was added to the system to give a nickel ammine in solution with an average $NH_{3(free)}$/Ni molar ratio of 2.2/1. In this way, the pH of the system at the end of the reduction was maintained slightly higher than 7.0. With insufficient ammonia, the reduction would finish on the acid side with the

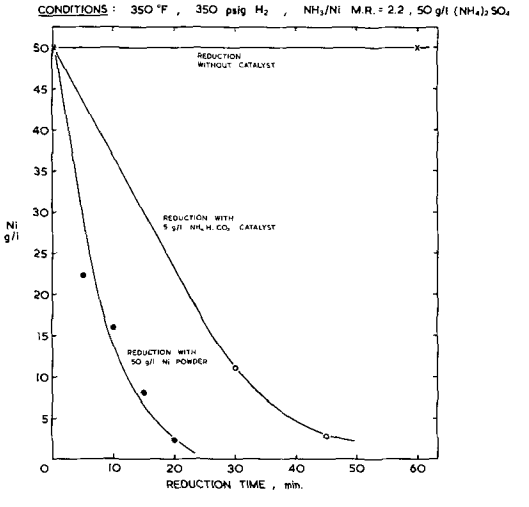

Fig. 4. Rate of nickel precipitation from aqueous ammonium sulfate system with gaseous hydrogen and various catalysts.

possibility of trace contamination of the nickel powder product due to corrosion.

The nickel powder produced by this procedure was superpurity grade with respect to all elements except carbon and oxygen.

Decarburization and deoxidation.—Low carbon and oxygen values in the nickel powder were obtained by subjecting the nickel to treatment with hydrogen at elevated temperatures. Decarburization and deoxidation were carried out at temperatures between 800° and 1500°F. The reactions proceeded at a faster rate at the higher temperatures but the higher temperatures promoted the sintering of powder and the product had to be pulverized. In practice, the temperature was selected on the basis of the particle size of starting material and the required physical properties of the final product. To achieve this final purification without sintering, the nickel powders were treated at 800°F for 2 hr in wet hydrogen followed by an additional 2 hr in dry hydrogen. The wet hydrogen proved most effective for decarburization and the dry hydrogen was necessary for deoxidation. The treated powder was cooled in a dry hydrogen atmosphere and stored in a protective atmosphere of nitrogen if very low oxygen contents were required.

The conditions and procedures worked out in the laboratory were confirmed on a semicommercial scale. The analysis and physical properties of the superpurity nickel powder produced in the semicommercial plant are given in Table V.

Summary

Superpurity nickel powder can be produced by hydrometallurgical methods from the commercial grade nickel. The method developed involves the dissolution of nickel in sulfuric acid under conditions which promote the cementation of copper, purification of nickel sulfate solution from iron and cobalt, and precipitation of a high-purity nickel powder from an aqueous nickel ammine sulfate solution by hydrogen

The Sodium Amalgam-Oxygen Fuel Cell Application to the Chloro-Alkali Industry

J. Adrien LeDuc,* John G. Kourilo*,[1], and Charles Lurie*

The M. W. Kellogg Company, Electrochemical Research Section, Research and Engineering Development Department, Piscataway, New Jersey

ABSTRACT

The ability of the sodium amalgam-oxygen fuel cell to recover power consumed by mercury cells presently employed in the industrial production of chlorine and sodium hydroxide was studied. The effects of temperature, amalgam concentration, current density, as well as the nature of the electrodes, are presented. Results suggest that the power generated by the fuel cell can be supplied directly to the mercury cells on a continuous basis. The sodium amalgam-oxygen cell described operated at voltages up to 1.3v at a current density of 100 amp/ft^2 with special fuel cell cathodes. Utilization of this output would result in a power recovery of up to 35%.

The high conversion efficiencies attainable with fuel cells have stimulated many to consider their application by large energy consumers such as the electrochemical industry.

The production of chlorine and sodium hydroxide by electrolytic methods consumes large quantities of electrical energy. The power demand is becoming increasingly greater with the expansion of the industry. Because power costs represent a large portion of the operating expenses in a chloro-alkali installation, the combination of a sodium amalgam-oxygen fuel cell and a mercury electrolysis cell may become a requirement in the projected expansion of mercury cell plants (1). It is recognized that the extent of industrial application of the fuel cell will be dependent on certain economic factors, principally the power cost in areas where the installations might be considered.

The power recovered by the fuel cell, corrected for products and depreciation, is estimated at 3.5-4.5 mils/kwhr. If variations in local power costs are considered, savings of \$3-\$10/ton of chlorine can be realized.

The sodium amalgam-oxygen fuel cell is an electrochemical device involving the conversion of the free energy of a chemical reaction to useful electrical energy. Its fuel is the sodium of the amalgam, the liquid metal electrode generated continuously in a conventional electrolytic mercury cell. Normally, the amalgam produced by the electrolysis of sodium chloride brine is reacted with steam or water in a physically separated cell, called a denuder or decomposer, to form a sodium hydroxide solution of a concentration of about 50%.

If, however, the sodium amalgam is introduced as the fuel in a fuel cell, up to 35% of the power needed to operate the electrolytic plant may be recovered.

In the early development of mercury cathode cells, it was shown that a decomposer acts as a primary cell in which sodium hydroxide solution is formed as the result of short-circuiting the amalgam to a more noble metal such as iron (2). A simple voltaic cell is thus formed in which the amalgam is the anode and sodium hydroxide is produced. Actually, the mercury acts as a bipolar element: as an anode in the decomposer and as a cathode in the electrolysis cell. The possibility of coupling this primary cell to the electrolysis cell and reducing the voltage requirement on the order of 0.8v presented itself. Such systems are illustrated by Castner and Kellner Short-Circuit and Shunt cells, where large surfaces of iron or graphite are brought into direct contact with the amalgam and alkaline solutions (3). The major difficulty with these systems is that the sodium concentration at the amalgam electrolyte interface drops rapidly to a low value when current is passed and cannot be renewed at a sufficient rate to prevent the emf of the primary cell becoming almost zero.

Dony-Henault effected power recoveries of 13% at a current density of 100 ma/cm^2 and 8% at 200 ma/cm^2 utilizing a similar system (4). In the 1950's, Yeager at

* Electrochemical Society Active Member.
[1] Present address: Aerospace Information Division, Library of Congress, Washington, D. C.

Western Reserve University demonstrated that, when an oxygen half cell is coupled with the sodium amalgam half cell in the presence of low concentrations of alkali, a primary cell is formed capable of generating electrical energy (5).

This primary cell can be run to produce, in addition to the power recovery, 50% sodium hydroxide equivalent to the alkali strength presently made in the decomposer. However, one may elect to operate the fuel cell with 10-20% sodium hydroxide electrolyte (5) to recover higher electrical energy. In most installations, this would be at the expense of evaporation of the caustic liquor to 50% and removal of the heavy metallic impurities. This communication will deal with the 50% electrolyte system.

In a power recovery installation, the liquid sodium amalgam issuing from a mercury cell would constitute the anode, and oxygen or air diffusing through an activated porous electrode would be the cathode. The half-cell reactions of the system are:

Anode $2Na/Hg_x - 2e \rightarrow 2Na^+ + 2Hg_x$ [1]

Cathode $O_2 + 2e + H_2O \rightarrow OH^- + HO_2^-$ [2]

$HO_2^- \rightarrow OH^- + \frac{1}{2}O_2$ [3]

Over-all reaction:

$2Na/Hg_x + \frac{1}{2}O_2 + H_2O \rightarrow 2Na^+ + 2OH^- + 2Hg_x$ [4]

The anticipated performance of the system is calculated from the Nernst equation:

$$E = 1.89\frac{2.30\,RT}{n\mathbf{F}}\log\frac{(A_{Na^+})^2(A_{OH^-})(A_{HO_2^-})}{(A_{O_2})(A_{H_2O})(A_{Na/Hg})^2} \quad [5]$$

Because of the low values of the peroxide ion concentration and the difficulties inherent in its determination, it was of interest to calculate its effect on the oxygen half-cell potential. Figure 1 is a Nernst equation plot and depicts the relationship between cathode potential and peroxide ion concentration (6). The dependence of the amalgam half-cell potential on the sodium activity is shown in like manner in Fig. 2 (5).

Working voltages were calculated by subtracting *IR* drops and electrode polarization from the open-circuit potential estimated from Fig. 1 and 2 and are depicted in Fig. 3. The electrolyte *IR* drop was calculated from a 0.25-in. interelectrode spacing and 50% NaOH electrolyte at 150°F. Electrode *IR* drop assumes a 0.31-in. thick graphite electrode with a resistivity of 0.45 ohm-in. Miscellaneous losses were assigned a value equivalent to 50 mv at a current density of 100 amp/ft^2. The cathodic polarization depicted is the difference between the preceding *IR* losses and the experimental cathodic polarization data reported in Table I.

Experimental

The apparatus used in this investigation (Fig. 4) consists of a horizontal mercury cell (A) of the type currently employed in the industry and an amalgam-oxygen fuel cell (I). The amalgam produced in the mercury cell passes through a flow interrupter (C) to the anode of the fuel cell. The amalgam is depleted in sodium and returned to the mercury cell after flowing through a second interrupter (C). During operation, the mercury was continuously cycled through the system. Conventional steam decomposers (D) provided an alternate route for the amalgam. The fuel cell is composed of a steam-jacketed stainless steel container coated with epoxy resin. This unit contains the elec-

trolyte and electrodes. The anode consists of a low-carbon steel plate whose surface is grooved and welded to a stainless steel frame. The plate and frame form an enclosure into which the amalgam flows. The amalgam overflows through a series of perforations at the top of the plate and flows downward in a continuous film. A porous electrode mounted on a steel frame similar to the anode structure forms the cathode. Oxygen or air is fed to the back of the cathode. The cathodes selected included plain and activated carbon, a commercial metallic electrode containing silver, and a new gas electrode under development at the M. W. Kellogg laboratories. The electrodes had an apparent area of 0.1-0.15 ft^2. The 48-50% NaOH electrolyte was stirred during certain experiments to assure uniform heating.

Working potentials and currents were measured with a vacuum tube voltmeter (V) and an ammeter (A). The presence of two flow interrupters (C) allowed the measurement of these values to be made independent of the performance of the mercury cell. The load imposed on the fuel cell was controlled with variable resistance (E). Half-cell measurements were made with a Luggin probe connected to a reference cell (Hg/HgO/50% NaOH) which was introduced at a point midway between the anode and cathode.

A rapid and accurate potentiometric method for determining the sodium concentration in the amalgam streams was developed. The details of this method are described elsewhere (7).

Discussion of Results

Electrodes.—Initial evaluation of the power recovery system consisted of determining the voltage-current density relationships for the system with various cathodes. Typical curves for carbon electrodes are depicted in Fig. 5. Curves 2 and 3 were obtained with two different activated porous carbon electrodes. Curve 4 represents untreated carbon and demonstrates the significance of the activating catalysts. Curve 1, which is calculated, assumes $(HO_2^-) = 10^{-8}$ moles/liter and is included for comparison. The open-circuit potentials were reproducible to ± 50 mv for different samples of similar electrodes. It is difficult to compare the experimental voltages with the calculated values because the activity of the peroxide ion is unknown. However, Fig. 1 and 2 indicate that for the activated electrodes the peroxide ion activity would be about 10^{-8} moles which does not seem unreasonable. Kordesch (8) has estimated that, with special peroxide-decomposing catalysts, values of 10^{-10} moles are attainable in KOH electrolyte hydrox systems. The role of the catalysts appears to be, at least in part, to decompose the peroxide ion. This effect has been previously studied and reported (9).

A current density of 100 amp/ft^2 was chosen as a reference point and all working voltages are compared at this current load. Voltages of 1.1 and 1.3v at 100 amp/ft^2 were observed with two different activated carbons. The untreated carbon yielded only 0.23v at 50 amp/ft^2. The calculated voltage assuming a peroxide ion concentration of 10^{-8} moles was found to be 1.4.

Two other types of electrodes were evaluated and the results are depicted in Fig. 6. Curves 1, 3, and 4 refer to specially treated silver electrodes obtained commercially and curve 2 refers to a new type of oxygen electrode under development at The M. W. Kellogg Research Laboratories.

In the course of this investigation, it was observed that when the fuel cell is initially subjected to a direct current from an external source complete wetting of the anode surface by the amalgam is obtained. It was also observed that the open-circuit potential and the working voltages increased. To determine the extent to which this effect is reproducible, a typical activated carbon electrode was tested in the fuel cell prior to current treatment. An open-circuit voltage of 1.55v was obtained. The cell was then subjected to the described treatment and an open-circuit voltage of 2.2-2.3v was observed. This potential was not stable and decayed to 1.55v. Measurements were made with an 11 meg vacuum tube voltmeter. The rate of decay is altered if the duration of the treatment with external current is varied. This phenomenon is depicted in Fig. 7.

One may attempt to explain this behavior by the oxidation of the catalytic species in the cathode; however, similar observations were made with leached, unactivated carbon electrodes whose metallic impurities content was not high enough to allow this explanation. It may be possible that the peroxide ion concentration is reduced drastically, in the immediate vicinity of the cathode, when a current is applied, and that this results in a higher initial cell voltage.

Amalgam concentration and depletion.—The sodium concentration in the amalgam has an effect on the voltage of the cell either at open circuit or under load. The results presented in Fig. 8 show the effect of inlet sodium amalgam concentration on open-circuit voltage. Under load, the inlet and outlet amalgam concentra-

tions may be correlated with the cell voltage. Figure 9 demonstrates the relationship of inlet and outlet amalgam concentrations to performance, particularly when under load. Figure 10 shows a typical effect of sodium depletion.

It was observed that the amalgam should contain a minimum of 0.01-0.02% sodium to promote wettability of the steel or nickel anode surface. This concentration minimum is applicable to the amalgam inlet and outlet streams.

Temperature.—The temperature range of 130°-180°F was investigated. The effect of temperature is shown by Fig. 9 and 10. At a current density of 100 amp/ft², an increase of 10 mv/°F was observed. The upper temperature limit is set by the chemical decomposition of the amalgam in the presence of the aqueous electrolyte.

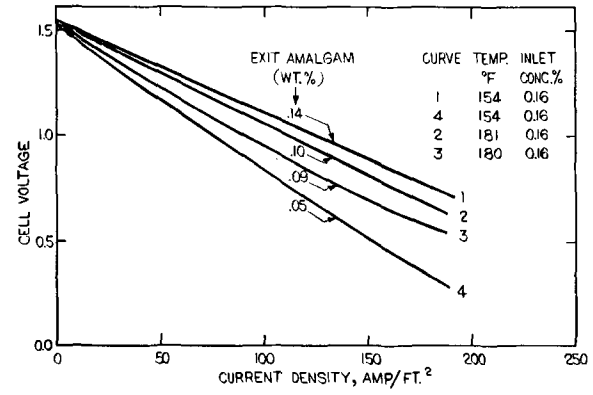

Fig. 10. Effect of amalgam depletion on performance

Table I. Polarization measurements

Cathode = Activated carbon
Electrolyte = 50% NaOH at 150°F
Reference Cell = Hg/HgO/50% NaOH

Current density, amp/ft²	Amalgam half cell, volts	Oxygen half cell, volts	Total cell, volts
2	1.631	−0.063	1.568
5	1.626	−0.087	1.539
21	1.591	−0.168	1.425
41	1.567	−0.213	1.351
117	1.456	−0.366	1.091
142	1.410	−0.453	0.962
200	1.326	−0.578	0.749
263	1.223	−0.729	0.496
309	1.147	−0.839	0.307

The reaction:

$$Na/Hg_x + H_2O \rightarrow NaOH + xHg + \tfrac{1}{2}H_2 \quad [10]$$

is not electrochemical and, therefore, causes low fuel efficiency. Above 180°F, hydrogen evolution becomes evident on the surface of amalgam in contact with the 50% NaOH electrolyte. When the cell was operated at 200°F, an unstable open-circuit potential of about 1.6v was observed.

Half-cell measurement.—It was of interest to determine the extent of anodic and cathodic polarization. A probe from a Hg/HgO/50% NaOH reference cell was inserted midway between the anode and cathode which were 0.25 in. apart. Table I is typical of the data obtained with activated carbon electrodes and demonstrates that oxygen half-cell polarization represents a prime area for system improvement.

Summary and Conclusions

This preliminary study has shown that a sodium amalgam-oxygen fuel cell is capable of generating electric power that can be supplied directly to a mercury cell of the type presently used in the industrial production of chlorine and sodium hydroxide. This cell is capable of delivering a voltage up to 1.3v at a current density of 100 amp/ft² with specially prepared and activated cathodes. The electrical energy recuperated with this type of performance can be equivalent to as much as 23-35% of the power consumed in present-day mercury cells.

Manuscript submitted Dec. 18, 1967; revised manuscript received Dec. 23, 1968.

Any discusson of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Solid Electrolyte Galvanic Cells

R. T. Foley*

Chemistry Department, The American University, Washington, D. C.

There has been a renewed interest in solid electrolyte galvanic cells during recent years because such cells offer solutions to several problems encountered with aqueous systems. One conspicuous shortcoming of aqueous systems is the limited shelf life of the cell which results from corrosion reactions of the electrode materials in highly conducting electrolytes. A second problem is cell leakage and the need to use special sealing techniques. A third limitation is the rather short temperature range over which these cells can efficiently operate. Finally, there is the need, in many applications, to achieve appreciable miniaturization. These are problem areas in which solid electrolyte galvanic cells offer solutions or the promise of improvement over the present situation.

The renewed interest in this field has coincided with the improvement in certain solid electrolytes and the achievement of a better understanding of the mechanism of transport in these solid ionic materials. Further, in the last decade there have been great advances in techniques whereby thin layers may be vacuum deposited. This has made available methods of fabricating cells with electrolytes with very high area to thickness ratios with resulting high internal conductivity.

The purpose of this review is to appraise the state of the art in this field. Major attention is given to the employment of solid electrolyte cells for energy conversion purposes which explains the detailed discussion of cells utilizing electrolytes such as AgI, one of the better ionic conductors. The study is restricted to low-temperature cells which operate at about 300°C, or lower, as distinguished from cells requiring higher temperatures for (oxide ion) conduction. A further restriction excludes those systems that require water for conduction, such as ion exchange membranes or certain inorganic gels. Raleigh (1) has recently reviewed solid state electrochemistry from the viewpoint of utilizing solid electrolyte galvanic cells for the study of solid state reactions, for the determination of free energies of compound formation, related thermodynamic quantities, and the electronic and ionic conductivity of compounds. These subjects are discussed here only where pertinent to the cell in a power producing capacity.

Historical development.—The fact that solid crystalline compounds could function as electrolytes was recognized early in the development of electrochemistry. Haber and Tolloczko as early as 1904 (2) measured the emf's of the cells

$$Pb/PbCl_2/AgCl/Ag \qquad (I)$$

and

$$Cu/CuCl/AgCl/Ag \qquad (II)$$

over the temperature range of 145°-250°C. The open-circuit voltage of cell I was 0.477v at 145° and 0.500v at 250°C. Cell II gave voltages of 0.150v at 150°C and 0.187v at 240°C. These values were essentially in agreement with what was calculated from thermochemical data for the cell reaction. No current was drawn from these cells. In fact, the experimental arrangement, involving a U-tube with substantial distance between the two electrodes, was such that the internal resistance was too high for appreciable current to pass.

Katayama (3) in 1908 constructed and made measurements on three types of cells utilizing solid electrolytes. These included lead amalgam concentration cells of the type:

$$\text{Amalgam I}/PbBr_2/\text{Amalgam II} \qquad (III)$$

chemical cells such as

$$Pb/PbBr_2/Br_2 \qquad (IV)$$

and

$$Ag/AgCl/Cl_2 \qquad (V)$$

and Daniell type cells as

$$Pb/PbBr_2/AgBr/Ag \qquad (VI)$$

and

$$Pb/PbCl_2/AgCl/Ag \qquad (I)$$

The potential of the AgCl chemical cell (V) was measured over the temperature range of 15°-159°C. The emf was described by

$$E = 1.130 + 0.0006\ (20 - t°)$$

The lead chloride-silver chloride cell gave an emf relationship of

$$E = 0.480 + 0.0001\ (60 - t°C)$$

These relations were in agreement with Haber's earlier results and have been confirmed by present day measurements. Lorenz and Katayama (4) showed that the electrical energy developed by these cells could be calculated from the heat of the chemical reaction. The Gibbs-Helmholtz equation, modified for a constant pressure process, was applicable. At approximately the same time, Beutner (5) used measurements on solid electrolyte galvanic cells to study the reactions of various salts in the solid state.

Significant advances in the understanding of the mechanism of conduction as well as the operation of solid electrolyte cells were made by Tubandt and his co-workers. Tubandt and Lorenz (6) published conductivity data for AgCl, AgBr, AgI, TlCl, TlBr, and TlI over the temperature range 100°-700°C. They also observed (7) that Faraday's laws held in the silver halides and they noted the very high mobility of the Ag ion (1.13×10^{-3} cm sec^{-1}) in AgI in the neighborhood of its melting point. Tubandt and Eggert (8) ex-

* Electrochemical Society Active Member.

tended the test of the applicability of Faraday's law to crystals of AgCl, AgBr, $AgNO_3$, $PbCl_2$, $PbBr_2$, and PbI_2. The problem of dendrite formation and consequent short-circuiting of the cell during deposition of the silver was recognized as a problem. These investigators introduced the technique of measuring transference numbers by the isolation and observation of weight changes in the anode and cathode portion of the cell similar to what had been done in aqueous solutions (Hittorf technique). Tubandt (9) recognized the several different types of conductivity that existed in these crystals. For example, conduction in AgI was mainly due to Ag ions, and in $PbCl_2$ the anion migrated as well. In certain crystals, *e.g.* β-Ag_2S between 150°-170°C, the current was carried by electrons as well as ions.

Reinhold in 1928 (10) studied solid electrolyte cells as thermoelements over the temperature range of 150°-500°C. He investigated solid electrolyte thermoelectric elements, as exemplified by

$$Ag/AgI/Ag \quad (VII)$$

$$Ag/AgCl/Ag \quad (VIII)$$

$$Ag/AgBr/Ag \quad (IX)$$

$$Pb/PbCl_2/Pb \quad (X)$$

$$Cl_2/AgCl/Cl_2 \quad (XI)$$

$$Br_2/AgBr/Br_2 \quad (XII)$$

$$Cl_2/PbCl_2/Cl_2 \quad (XIII)$$

in which the thermoelectric power was generated by the anode and cathode held at different temperatures. It is significant that gas electrodes, which exhibit a higher thermogalvanic voltage and represent the more sophisticated case in thermogalvanic technology, as well as metallic electrodes, were considered as thermogalvanic elements. Reinhold (10) also investigated "solid isothermal" galvanic cells such as

$$Ag/AgCl/Cl_2 \quad (V)$$

$$Ag/AgBr/Br_2 \quad (XIV)$$

$$Pb/PbCl_2/Cl_2 \quad (XV)$$

and

$$Pb/PbCl_2/AgCl/Ag \quad (I)$$

recognized as "chemical" cells and Daniell-type cell, respectively. The emf measurements made on the lead chloride-silver chloride cell (I) were compared by Reinhold to those reported by Haber and Katayama as follows:

Temp, °C	Katayama	Haber	Reinhold
67	0.480	—	0.488
151	0.471	0.480	0.472
200	—	0.492	0.463
250	—	0.500	0.451

The good agreement at the lower temperatures is obvious.

For all of these systems, the Nernst heat theorem applies. Reinhold and Blachney (11) extended the theory and experimental work to cells such as

$$Ag/AgCl/PbCl_2/AgCl/Ag \quad (XVI)$$

and

$$Pb/PbCl_2/AgCl/PbCl_2/Ag \quad (XVII)$$

which involved the transfer of ions across electrolyte/electrolyte interfaces. It was shown that the thermogalvanic emf of a multiple system such as those indicated above was additive from the standpoint of the simpler elements, *e.g.*, $Ag/AgCl/Cl_2$ (V).

At the same time (1934), Reinhold (12) and Wagner (13) used solid electrolyte cells to study tarnishing and corrosion reactions using slightly different techniques. To study the reaction

$$2\,Ag + S = Ag_2S$$

a cell such as

$$Ag/AgI/Ag_2S/Pt(S) \quad (XVIII)$$

was required rather than the simpler cell

$$Ag/Ag_2S/Pt(+S) \quad (XIX)$$

because Ag_2S is a mixed (ionic and electronic) conductor.

Thus, by the early 1930's it had been demonstrated that solid electrolytes could be treated entirely the same as aqueous electrolytes from the viewpoint of the theory of chemical and concentration cells, conduction mechanisms, equilibrium reactions, and thermodynamics.

There was little work reported in this field in the late 1930's and in the 1940's, but studies were revived during the early 1950's with Sator's work (14) on vacuum-deposited films and intensive studies of gas depolarized cells to be discussed below. During the 1950's, a large number of studies were reported in the patent literature, in the open literature, and in reports on government-sponsored research. The major problem holding up substantial development of this type of cell was the relatively low conductance of the electrolyte at room temperature in comparison with aqueous electrolytes and at elevated temperatures in comparison with fused salt systems. Techniques to achieve electrolytes with substantially improved conductivity have been realized during the last decade. A further problem has been one of constructing the solid electrolyte cell so that low internal resistances could be achieved. The employment of vacuum-deposited films has made for improvement in this respect.

Solid Electrolytes

A logical basis for discussing solid electrolytes can be based on the nature of the basic transport process, as suggested by van der Grinten (15). This would distinguish cases utilizing (*a*) Ag^+ transport, (*b*) Cl^- transport, (*c*) Na^+ transport, (*d*) H^+ transport, and (*e*) cases wherein the transport is unknown, *e.g.* the tin sulfate case discussed below.

Solid Electrolytes with Ag^+ Transport.—Most of the work reported on solid electrolyte galvanic cells has been based on the transport of Ag cations through silver halides. This is best understood by considering the unusual structure of AgI and the related compound $Ag_2\,Hg\,I_4$.

The use of the silver halides for current-producing cells was based initially on the conductivity data of Tubandt and Lorenz (6, 7). In the study of the temperature dependence of the specific conductance of the halides of silver and thallium over the range 100°-700°C, the unusual behavior of AgI was noted. Unlike the other halides of silver and thallium, the conductivity of AgI rose sharply as it went from the liquid to the solid state. On further cooling, the conductivity-temperature curve had a slope more characteristic of aqueous solutions than the other solid crystals. In the region of the melting point, the mobility of Ag^+ in AgI was approximately double the mobility of Ag^+ in aqueous solutions. As a result of these findings and their subsequent verification, many galvanic cells were based on AgI as the electrolyte.

AgI undergoes a transition from its low-temperature, low-conductance, beta form to its high-temperature, high-conductance, alpha form at 145.80°C according to Tubandt (16). Jost *et al.* (17) reported $\beta \rightarrow \alpha$ transition temperatures of 143.8°, 144.4°, and 146.7° depending on the rate of heating. Lieser (18) found the transition temperature with certain samples at 153.3° and at 149.3° with a sample that had been heated at 300°-450° for a period of time implying some sort of aging effect. The generally accepted transition temperature is 145°-146°C. A third modification of AgI, with an undefined crystal form, stable above 2940 kg/cm² pressure has also been reported (93).

The alpha form of AgI is stable in the temperature range 146°-552°C. The structure and deficiency order of α-AgI has been the subject of a number of investigations. Lieser (19) made dilatometric measurements and structure (x-ray) measurements on the AgI system from —187°C to above the transition point. He observed a negative dilation coefficient in β-AgI over the temperature range studied, a fact important in the employment of this electrolyte in thermogalvanic cells. Jost *et al.* (20) report similar results and characterized α-AgI as a body-centered cubic structure of I^- ions with disordered cations. Lieser (21) reports a lattice constant of $a = 5.046 \pm 0.02$Å at 150°C. In going from the β-form to the α-form, the conductivity of the crystal increases by a factor of about 4000 (8); the resistivity of α-AgI is 0.38 ohm-cm at 500°C and 0.47 ohm-cm at 350°C (21).

The current in AgI is carried almost exclusively by Ag ions, the transport number of Ag being very close to unity as demonstrated by Tubandt (16). The self-diffusion rate of I^- in α-AgI was measured by Jost and Nölting (22) and their data were expressed by the equation

$$D = (4.41 \times 10^{-4})\, e^{\frac{-16.2}{RT}} \text{ cm}^2/\text{sec}$$

Electronic conductivity is also low. Jost and Weiss (23) reported an electronic transport number of about 10^{-7} at an I_2 partial pressure of 3 mm Hg at 179°C. Ilschner (24) used a direct polarization method to measure electronic conduction. A value for the electron hole conductivity of about 10^{-5}-10^{-6} ohm^{-1} cm^{-1} may be read from the plotted data. At elevated pressure, the conduction mechanism changes, the formation of free silver at pressures of 2 and 4 kilobars being indicated (25). Many similar studies on structure and conduction mechanism have been carried out on the other silver halides, but only the work on silver iodide is discussed here because of the unique electrochemical properties of this compound.

The increased conductivity achieved by working above the transition point, *i.e.*, with the highly conducting α-AgI, was demonstrated by Weininger (26) with batteries composed of a number of gas-activated cells of the type

$$\text{Ag/AgI/I}_2\text{ (Pt)} \qquad \text{(XX)}$$

Temp of cell operation, °C	Open-circuit voltage, v	Short-circuit current, μa
25	6	1
200	6	1000

A number of attempts have been made to improve the conductivity of the silver halides. AgI is highly conducting in its high-temperature form, *i.e.* the form stable over 146°C. It would be desirable to render this highly conductive structure stable at room temperature. Weiss, Jost, and Oel (27) measured the electrical conductivity and phase changes in the systems β-AgI-CdI_2, β-AgI-PbI_2, β-AgI-Ag_2Se, β-AgI-KI, and α-AgI-PbI_2 (and CdI_2). The temperature at which the β-form is converted to the α-form is lowered by the addition of PbI_2, *e.g.* from 144.6° to 100°-101° by the addition of 5 mole % PbI_2. The conductivity of the mixed crystal is lower than that of pure AgI. At 120°, the relative conductivity of the 5 mole % compound is about 18% that of the pure AgI. The mixed crystal system of β-AgI-KI was studied but only at low concentrations (0.5 mole %) of KI. Only in the last decade has this system been fully explored. The use of an electrolyte modified by the addition of lead iodide or cadmium iodide in a vapor-activated cell was proposed by Weininger (28).

According to Lieb and De Rosa, additions of tellurium to the silver halide greatly reduced its resistance (29). For example, the resistance of AgCl at 100°C was reduced from 7.7×10^6 ohms to 2.3×10^3 ohms by the addition of 5% Te. Additions of 3-10% were claimed to give this beneficial effect with 5% being the optimum value. The internal resistance of a cell of the type

$$\text{Ag/AgBr/CuBr}_2\text{(C)} \qquad \text{(XXI)}$$

was decreased from 114 to 18K by the incorporation of 5% Te in the AgBr electrolyte. A 16-μa current was observed with an external load equal to the cell resistance.

Lehovec (30) claimed a galvanic cell in which the improved electrolyte was a crystalline compound possessing lattice defects. An example of this galvanic cell was

$$\text{Ag/AgCl (10\% PbCl}_2\text{)/Pb} \qquad \text{(XXII)}$$

The electrolytes were such crystals as 10% $CdCl_2$ in AgCl, 15% $CaCl_2$ in Hg_2Cl_2, 10% $SbCl_3$ in $PbCl_2$, and 12% $BiCl_3$ in $ZnCl_2$. In addition to cation doping, Lehovec and Smyth (31, 32) cited improvements to be gained in the conductivity of silver halides by the addition of anions such as $Te^=$, $Se^=$, or $S^=$. This improvement occurred for additions low in concentration but greater than 0.1 m/o (mole per cent). The addition of Ag_2S to AgCl in amounts up to 0.1 m/o caused an increase of resistance from 7-10 to 30-40 megohm-cm. However, further additions caused a linear decrease in resistance. The mixture with 1 m/o sulfide had a resistance of 3 megohm-cm, and that with 6 m/o 0.4-0.5 megohm-cm.

In recent years, effort has been devoted to the improvement of the AgI electrolyte by modifying its crystal structure. The preparation of α-Ag_3SI, its crystal structure, and the temperature dependence of the electrical conductivities of the α and β forms were worked out and reported by Reuter and Hardel (34). Takahashi and Yamamoto (33) reported a conductivity of about 10^{-2} ohm^{-1} cm^{-1} for the compound at room temperature with the conduction mechanism similar to that of AgI, *i.e.*, the transference number for Ag^+ was measured as 0.977. This conductance figure agrees approximately with the (extrapolated) value reported by Reuter and Hardel in their early work (34) and confirmed in their recent more complete investigation of the conduction mechanism (94).

A number of widely differing values have been reported for the electronic conduction of Ag_3SI. Takahashi and Yamamoto have reported 10^{-8} (33), 10^{-6} (95), and 10^{-4} ohm^{-1} cm^{-1} (96). An extrapolated figure from Reuter and Hardel's recent work (94) would fall between 10^{-4}-10^{-5} ohm^{-1} cm^{-1}. It is very likely that all of these are correct for the particular samples tested, with the discrepancy caused by the metal/nonmetal ratio in the sample reflecting, in turn, the method of preparation as observed by Takahashi and Yamamoto (96). Values as high as 10^{-4} ohm^{-1} cm^{-1} would be undesirable from the standpoint of tarnish rate and long-term stability. The galvanic cell

$$\text{Ag/Ag}_3\text{SI/I}_2\text{(C)} \qquad \text{(XXIII)}$$

was investigated. The open-circuit voltage was close to that calculated from free energy data and iodine vapor pressure relationships. At 20.0°C, the experimental cell voltage was 0.675v as compared with a calculated 0.687v. The internal resistance of the above cell constructed with an electrolyte thickness of 0.15 cm was 10 ohms and the cell voltage did not decay at 100 μa/cm² current density. The polarization was essentially due to the silver anode, but it was found that this could be considerably improved by amalgamation; *e.g.*, relatively little polarization was observed at 1000 μa/cm² at 25°C. Cathode polarization was improved by the selection of the proper carbon; in the case reported, an acetylene black gave the best results. In the improved cell with the Ag_3SI electrolyte, only slight polarization (less than 10 mv) was observed at a current density of 1000 μa/cm² at 25°C. The cell could be discharged at a 1-ma/cm² rate for 3-4 hr with a relatively flat voltage curve. The polarization

behavior of the silver electrode, amalgamated and unamalgamated, was explained by the degree of reaction polarization (35). Up until this point in the investigation of solid electrolytes, the internal resistance of the solid electrolyte itself had been so high that only resistance polarization had been measured. The rate-determining step accounting for polarization in the cell containing the silver plate anode was established as the reaction between interstitial silver ions and silver-ion vacancies. In the amalgamated silver electrode case, the interstitial silver ion reacted with mercury and the reaction polarization was not observed.

Owens and Argue (36) questioned the long-term stability of cells using the Ag_3SI electrolyte and I_2 as the cathode material. They showed experimentally that the reaction

$$I_2 + Ag_3SI \rightarrow 3AgI + S$$

proceeded readily at 65° and 70°. Therefore, upon standing, the cell described above should convert to a cell

$$Ag/Ag_3SI/AgI, S/I_2(C) \qquad (XXIV)$$

with a corresponding increase in internal resistance. The argument offered by Owens and Argue appears convincing, but it is difficult to reconcile these with the results reported by Takahashi and Yamamoto. A possible explanation might be that the former studies were carried out at 65° and 70° where the reaction rate should be considerably greater than at room temperature. These effects would be expected to show up after several years of storage, however.

Recently, improvements in the AgI electrolyte have been reported by Bradley and Greene (37, 38) and Owens and Argue (39). These involved double salts such as KAg_4I_5 and $RbAg_4I_5$. The quantitative values for the conductivities differed between the two laboratories with Owens and Argue reporting the higher values, *i.e.* 0.21 ohm^{-1} cm^{-1} for both the K and the Rb salts at 20°C. Their explanation, which appears reasonable, was that the English investigators had a high contact resistance in their conductivity specimen. These crystals transformed from the high-temperature, highly conductive, α form to the β form at −136°C (KAg_4I_5) and −155 ($RbAg_4I_5$). Bradley and Greene (37) measured transport numbers and found that the current was essentially all carried by Ag^+ and that there was no change in composition of the anolyte or catholyte after electrolysis. Geller (40) reported on the crystal structure of the highly conductive solid electrolyte, $RbAg_4I_5$, as did Bradley and Greene (41). The latter described the structure of M Ag_4I_5 (where M = K, Rb, NH_4) as consisting of Ag^+ essentially in a liquid state inside of a crystal lattice of I^- and M^+ ions. This explains the high mobility of the Ag^+ ions. The structure that they proposed accounts on a geometrical basis for the experimental fact that the K^+, Rb^+, and NH_4^+ compounds have been found but the Cs^+ and Na^+ compounds have not. The Cs^+ ion is too large and the Na^+ is too small to produce stable structures, while the other three ions are the proper size, the ideal M^+ to I^- distance being 3.62Å.

The electrochemical behavior of the α form of Ag_2HgI_4 is similar in several respects to that of the high-temperature form of AgI. Ketelaar measured the electrical conductivity of this crystal (42) and discussed the relation between conduction and structure (43). He interpreted the high conductivity of α-Ag_2HgI_4 as a result of an averaged structure in which the number of atoms in the crystal was smaller than the number of lattice points among which they were distributed. On an average, every fourth lattice point was unoccupied. Although silver ions and mercury ions are present in the structure, only about 6% of the charge is transferred by mercury ions. The conductivity data reported by Ketelaar for α-Ag_2HgI_4 appear to be too high on the basis of later investigations. Suchow and Pond (44) measured the temperature of phase change and the electrical conductivity of Ag_2HgI_4, Cu_2HgI_4, and their eutectoid. Their transition temperatures are in agreement with Ketelaar's and approximate those reported by Jaffray (45, 46).

Substance	Suchow & Pond	Ketelaar	Jaffray
Ag_2HgI_4	50.0°	50.7°	57°
Cu_2HgI_4	66.6°		72°
$Ag_{1.14}Cu_{0.86}HgI_4$	34.2°		

However, the electrical conductivity data are at variance and, in view of the fact that the data of Suchow and Pond (44) have been substantially confirmed by the recent work of Weil and Lawson (47), the later work is taken as correct. The ionic conductivity has been expressed by the equation

$$\sigma = \sigma_0 e^{-Q/RT}$$

where σ is the specific conductivity at absolute temperature T, σ_0 is a constant, Q is an activation energy, and R the gas constant.

The comparison of the several investigations is as follows:

	Suchow and Pond (44)	Ketelaar (43)	Weil and Lawson (47)
Q (cal/g-atom)	10,200	8600	12,100
σ_0 (ohm^{-1} cm^{-1})	7.5×10^3	4×10^2	

Weil and Lawson (47) investigated the pressure dependence of the electrical conductivity of Ag_2HgI_4 as well as the transport properties. Measurements made at 80°C indicated a low electronic conductivity about 10^{-4} ohm^{-1} cm^{-1}, and an ionic conductivity of about 3×10^{-2} ohm^{-1} cm^{-1}. They pointed out some of the difficulties in making d-c conductivity measurements. As a d-c voltage was maintained on the α-Ag_2HgI_4 crystal between electrodes, silver was deposited at the cathode and HgI_2 and I_2 at the anode. Both the ionic and electronic conductivity dropped and the cell was converted to a galvanic cell with an emf of 0.6v.

In several instances, cells have been constructed wherein two electrolytes were used in a series arrangement. Lehovec and Broder (48) utilized the desirable high ionic conductivity of AgI and Ag_2S at elevated temperatures (about 200°C). They worked with cells of two types. The first was

$$Ag/AgI/Ag_2S/S \qquad (XVIII)$$

the role of AgI being to reduce electronic conductance within the cell. This cell had an open-circuit voltage of 0.2v at 200°C which approximated the value calculated from the free energy of the reaction between Ag and S. A short-circuit current of 0.18 amp/cm^2 and a shelf life of 100 min at 200°C was observed. These operating characteristics were compared to those of a second cell

$$Ag/AgI/I_2\ (C) \qquad (XX)$$

which operated at room temperature at current densities of several hundred microamperes and an emf of 0.7v.

An investigation by Smyth and coworkers (49) dealt with XX which was similar to that previously disclosed by Broder (50). An extensive study of the tarnishing of Ag in I_2 atmospheres was conducted on the basis that the shelf life of the cell was limited by electronic leakage through the electrolyte. The rate of consumption of the electrode material was determined by the reaction of Ag and I_2, which tarnish reaction was governed by the diffusion of cations and electrons through the reaction product film. The tarnish rate was found to be sufficiently rapid so that the $Ag/AgI/I_2$ cell system did not retain sufficient shelf life to be of practical interest in the application of interest to the investigators. To overcome this deficiency, the system

$$Ag/AgCl/AgI/I_2 \qquad (XXV)$$

was taken up. This system offered improvement but only partial solution to certain electrochemical and mechanical problems. The disadvantages of this system were the low emf of 0.684v (20°C) and the requirement that the AgCl film over Ag must be nonporous to prevent attack on the Ag and preserve a long life on open circuit. It was further noted that the I_2 vapor was corrosive to the organic compounds used in sealing the cells.

The tarnishing reaction of silver by bromine and iodine was studied by Weininger (51) in connection with the vapor-activated cell with the respective silver halide electrolyte. This study was conducted from the viewpoint of preparing the solid electrolyte film and also contributed to an understanding of the storage problem discussed above. The halide electrolyte formed at room temperature was relatively impervious as shown by photomicrographs. The rate-determining step was established as the diffusion of defect electrons which migrate in a direction opposite to that of silver ions. In common with many other investigations, the presence of water vapor was found to be important, the tarnish rate being reduced by a factor of two in the presence of water vapor.

In the investigation of cells utilizing silver iodide as an electrolyte, Buchinski *et al.* (52) found that a more adherent silver iodide film was formed on silver if the silver contained low alloying contents of Cu and Si (0.05-0.15% and 0.01-0.15%, respectively).

Solid Electrolytes with Cl^- Transport.—In the halide salts of certain bivalent metals, such as $PbCl_2$ and $BaCl_2$, current is carried by anions as well as cations. For example, in the temperature range of 200°-450°, the transference number of the anion is about unity (53). Data have been reported for elevated temperatures but very little for ambient temperature. For room temperature, the ionic conductivities of these halides are quite low and it is likely that both the cation and anion carry equivalent currents. Cl^- transport is involved in the operation of the rechargeable cell

$$Pb/PbCl_2/AgCl/Ag \qquad (I)$$

studied extensively by Sator (53) and discussed below.

Solid Electrolytes with Na^+ Transport.—Alkaline aluminates of the "beta-alumina" type are examples of structures in which Na^+ (as well as other cations) are transported. Beta-alumina is an example of a solid, relatively low-temperature, electrolyte and for that reason is briefly mentioned here. Its significant employment has not been in a solid galvanic cell but one in which both the anode and the cathode were liquids.

Ridgway *et al.* (54) concluded from their experimental results that beta-alumina was not an allotropic modification of alumina as commonly thought at that time (1936) but rather was an alkaline aluminate with the approximate formula of $Na_2O \cdot 12\ Al_2O_3$ or $K_2O \cdot 12\ Al_2O_3$ depending on the cation involved. The transport properties of beta-alumina were determined by Yao and Kummer (55) who measured the self-diffusion coefficients of Na^+, Ag^+, K^+, Rb^+, and Li^+ in single crystals. Of the ions studied, Na^+ had the highest rate, about 1×10^{-5} cm²/sec at 300°C and 40×10^{-7} cm²/sec at 25°C. The mechanism appeared to be interstitial rather than a vacancy movement. The secondary battery reported by Weber and Kummer (56) utilized an anode of liquid sodium, the sodium aluminate electrolyte, and a liquid sulfur cathode. The electrolyte that they used was a sintered product with a resistance of 3-5 ohm-cm at 300°C and about 250 ohm-cm at 25°C. For this reason as well as the need to maintain the cell products in the molten state to prevent excessive polarization, it was necessary to operate the cell above 250°C. At these temperatures, the cell operated at about 2.0v and a current density of 170 ma/cm² of electrolyte surface.

Solid Electrolytes with H^+ Transport.—Very little experimental work has been reported on proton conduction in (anhydrous) solids although such a mechanism would be of considerable significance in galvanic cells. Proton mobility in ice has been found to be appreciably higher than that of any other ionic mobility in a liquid or solid including that of H^+ in water. The experimental data on mobility and conductivity in ice along with theoretical explanations have been summarized by Eigen and de Maeyer (57). Extrapolated values for the specific conductance of water and ice at 0°C are 1.2×10^{-8} and 0.3×10^{-8} $ohm^{-1}\ cm^{-1}$, respectively. Whereas the proton concentration in ice is lower than that in water by a factor of about 2, the proton mobility is higher by 1 or 2 orders of magnitude. Proton transport in ice is much greater than that of other reported ionic mobilities but it differs by only a factor of 50 from electronic mobilities in semiconductors. Eigen and de Maeyer (57) thus consider the ice crystal as a "protonic semiconductor."

The hydrogen bonded structures represented by water and ice are unique and extreme care must be taken before extrapolating this thinking to other systems. Similar theoretical reasoning was cited in the development of solid electrolytes with proton conduction (58). The solid electrolyte was a mixture of urea or a urea derivative with an organic acid. Typical mixtures were urea and formic acid, thiourea and citric acid, or thiourea and toluene sulfonic acid. A mixture of 100g of urea and 8g of acetic acid yielded a conductivity of 5×10^{-3} $ohm^{-1}\ cm^{-1}$** at ambient temperatures. The conductivity of this solid compound was 10^4 greater than that of silver halides at the same temperature. This electrolyte supposedly could be employed in a galvanic cell with a hydrogen electrode (anode), which might be a catalytic electrode or a metal hydride. The cathode could be manganese dioxide, silver iodide, or oxygen.

Solid Electrolytes with Other Species.—Solid electrolyte cells capable of producing high potentials but limited to low currents were described by Ruben (59-61). Cells of the composition

$$Ni/tin\ sulfate/lead\ peroxide \qquad (XXVI)$$

supplied 1.65v and "several microamperes." A modification of this cell but not an improvement (60) substituted bismuth sulfate or antimony sulfate for the tin sulfate. These were hydrolyzable salts, and cells composed of these electrolytes were capable of holding potentials for long times. However, of the sulfates mentioned, tin sulfate was preferred because it was not hydroscopic (61). It was further pointed out that permanganates such as barium permanganate offered improved cathode depolarization so that a preferred cell was

$$Ni/tin\ sulfate/barium\ permanganate + carbon \qquad (XXVII)$$

This cell operated at 1.42v. These systems, described as "potential producing cells," were characterized by current output in the "several microampere" range. This appears reasonable in view of the fact that there was no apparent allowance for anode depolarization unless a redox reaction involving the electrolyte was involved. Typical cell thicknesses were 0.031 in. with the tin sulfate electrolyte contributing 0.020 in. and the Ni-plated steel anode 0.005 in.

Anodic and Cathodic Reactions

The greater part of the experimental work on solid electrolyte galvanic cells has involved cell reactions between silver and the halogens or sulfur. The anode

** Units of ohm-cm were given in the patent.

was furnished as silver strip, foil, or as a vacuum-deposited layer. As was mentioned above, Buchinski and co-workers (52) found that Cu and Si in low alloying concentrations improved the adherence of the AgI film subsequently formed. But, apparently very little effort has been expended to improve the anode reaction. As was pointed out by Takahashi and Yamamoto (33), anode polarization became obvious as a problem only when electrolytes of greatly improved electrical conductivity became available. The polarization due to the silver anode was effectively countered by amalgamation so that current densities of 1000 μa/cm^2 could be sustained at 25°C. Mrgudich, in an investigation of the conductivity of AgI, also found that electrode polarization could be greatly reduced by amalgamation of the silver electrode (62).

In the investigation of thin films, the interaction of the vacuum-deposited film with the substrate (the anode) was observed by Kostyshin (63). For example, films of PbI_2 and CuCl deposited on metal substrates such as Ag, Pb, or Cu show a greatly enhanced photographic sensitivity over that observed when similar materials are deposited on dielectric substrate. The reaction of the silver anode with halogen vapor upon storage was discussed above in connection with the use of AgCl layers in series with AgI layers.

When the anodic reaction was the oxidation of Ag, the cathodic reaction was usually based on the reduction of sulfur, a halogen, or a halogen-producing compound. The emf for the cell was then derived from the free energy decrease associated with the reaction between Ag and the cathode material. Some of the early work used a sulfur cathode. Lehovec (64) in his patent made a broad claim of a primary cell comprising . . . a solid crystalline electrolyte . . . between two reactive electrodes. His specific example was the cell

$$Ag/AgI/S \qquad (XXVIII)$$

with the sulfur electrode being a compressed mixture of 15% sulfur and 85% carbon, and the AgI a 0.0025-mm tarnish coating produced by I_2 vapor. Such a cell reputedly had an open-circuit voltage of 0.2v and a short-circuit current of 0.22 amp/cm^2 for a single cell. The cell described above is actually better represented by

$$Ag/AgI/Ag_2S/S \qquad (XVIII)$$

as Ag_2S is the product formed immediately after reaction begins.

Whereas the Lehovec patent made the broad claim for a solid electrolyte cell, Broder (50) claimed an improved cell of the type

$$Ag/AgI/I_2 \qquad (XX)$$

in which the Ag and AgI were similar to the Lehovec cell but the cathode material was a pressed mixture of 80% carbon and 20% iodine. This cell yielded an open-circuit voltage of 0.67v and a short-circuit current of 3 ma at room temperature.

Van der Grinten (65) appeared to have been the first to use a gas-depolarized cell as a power-producing unit. In his solid electrolyte cell, he used as a cathode material a permeable solid structure which produced a low pressure of a gas capable of reacting with the anode. Examples were $CuCl_2$, $CuBr_2$, and $FeCl_3$.

The type of performance reported by van der Grinten (66) for the gas activated cell was as follows:

Cell type	Emf (volts)	Flash current (ma)	Optimum load current (μa)
$Ag/AgBr/CuBr_2(C)$	0.74	0.22	2
$Ag/AgBr/Br_2(C)$	0.85	1.5	26

With these cells, coulombic capacities up to 3.6 amp-sec were obtained. One of the rate-limiting factors in these gas-activated cells was the vapor pressure of the cathode depolarizer. The required and obtained gas pressure over the $CuBr_2(C)$ electrode was estimated as 10^{-4}-10^{-7} mm Hg. An improved electrode with Br_2 sorbed on carbon yielded 0.1-10 mm pressure. The Br_2 system approximates Nernst law behavior, while the Cl_2 system does not.

Van der Grinten mentioned vacuum deposition as one possible method of fabrication of the halide electrolyte (65). Van der Grinten and Mohler (67) in further work miniaturized this type of cell to the following dimensions:

$$Ag(0.019\text{ mm})/AgCl(0.025\text{ mm})/Ca(OCl)_2 + C(1.0\text{ mm})$$

This cell produced an open-circuit voltage of 0.9-1.0v and a short-circuit current of 0.03 ma/in.^{2} at room temperature. The problem of internal short circuiting during storage was recognized. This was solved by using an insulating annular washer holding the cathode material in a fixed location. The anode, usually Ag or Pb, was also faced on the side exposed to the solid electrolyte with an impervious electrically conducting material. The gas-activated cell was investigated by Weininger who demonstrated (28, 68) that the iodine gas to activate a cell of the type

$$Ag/AgI/I_2(Ta) \qquad (XX)$$

could be produced by a number of ways depending on the physical structure of the cell. For example, the thermal decomposition of a polyiodide (*e.g.*, CsI_4) or reaction with an oxidizing agent ($KMnO_4$ + CuI) could be utilized.

Vapor-activated cells using silver halide electrolytes were intensively studied by Smyth and his co-workers (49, 69, 70). This study involved cells of the type

$$Ag/AgCl/KICl_4 \qquad (XXIX)$$

Potassium tetrachloroiodide is representative of polyhalide compounds that are reasonably stable at room temperature but dissociate at elevated temperatures to give iodine trichloride (ICl_3), I_2, and Cl_2. A large number of salts of this type and literature on the subject were cited (69). Their general property was that they dissociated rapidly enough to furnish the active cathode component but slowly enough so that the shelf life of the cell was not unduly shortened by the tarnishing of the anode. The cell cited by Smyth and Shirn consisted of a silver anode shaped as a cup, a silver chloride electrolyte 5-50μ thick developed by tarnishing with chlorine gas at 200°-300°C for 30 min, and a cathode composed of 30-50% $KICl_4$, 5-10% carbon black, and 40-60% grease (*e.g.*, a Kel-F) binder. The emf of this cell was 1.04v as compared with a theoretical value of 1.04v. This emf was constant to $\pm$ 5% in the temperature range of —40° to +75°C. The tarnish experiments, which are also a measure of the electronic conductivity in the electrolyte, indicated a shelf life of about 25 yr. The cells constructed on this project had an internal resistance of about 10^5 ohms/cm^2 at 25°C. When loaded with a resistance of 10^6 ohms, a ten-cell battery delivered 1.0 μa for 100 min with a flat discharge curve at about 1.0v. The AgCl film produced by the dissociation of $KICl_4$ was actually a dilute solution of AgI in AgCl (a chloride: iodide atomic ratio of 19.5-1 found by analysis). Of the four types investigated by Smyth and co-workers (49)

1.	$Pb/PbCl_2/AgCl/Ag$	(I)
2.	$Ag/AgI/I_2$	(XX)
3.	$Ag/AgCl/AgI/I_2$	(XXIV)
4.	$Ag/AgCl/KICl_4$	(XXIX)

only the fourth was considered to possess suitable characteristics for further development.

The exact influence of water vapor in supposedly dry solid state cells is not known but it may be re-

lated to the cathode reaction. Van der Grinten (66) had observed that vapor-activated cells stored in a chamber in which the air was less than 1% relative humidity dropped in voltage from 0.73 to 0.4-0.5v. Upon return to the more humid laboratory atmosphere, the original voltage was regained. Smyth and Lehovec (71) noted that the exclusion of all water vapor was detrimental and proposed adding a hydrated salt such as $MgCl_2 \cdot 6H_2O$ to their cathode that contained $KICl_4$ as the active material. They visualized the water vapor as being adsorbed in the cathode side and blocking the electronic current, which, of course, would tend to discharge the cell totally in time. They also pointed out that, in addition to improving the electrochemical behavior of the cell, the tarnish rate of silver in the iodine cell is lowered by a factor of 100. Weininger (51) also observed a reduction in the tarnishing rate of silver in bromine and iodine vapor in the presence of water vapor. The presence of water vapor in these solid electrolyte cells is obviously complex because the possibility then exists of other mechanisms such as proton transfer.

Cathode depolarizers other than halogens have been used in cells in which the electrolyte was the silver halide. Louzos (72) reported on a cell of the composition

$$Ag/AgI/V_2O_5(C) \qquad (XXX)$$

The cathode depolarizers were oxides of polyvalent metals in their higher valence state. In addition to V_2O_5, compounds such as PbO_2, MnO_2, NiO_2, Ni_2O_3, AgO, and CeO_2 were cited. These cells with Ag anodes and AgI electrolytes yielded cell voltages ranging from 0.5 to 0.7v. Cells of this type were able to sustain currents in the 1-10 μa range at cell voltages of 0.45-0.55v over the temperature range of —75° to 200°F. An improved version of the cell was described by Evans (73). By an elevated temperature tarnishing reaction (25 mm I_2 at 230°C), a 15-μ layer of AgI was produced on the Ag strip. Subsequent annealing lowered the electronic conductivity. The cathode current collector was constructed from stainless steel. Cells of this composition gave stable voltages of 0.455v and flash currents of 50 $\mu a/cm^2$ at room temperature. These cells were about 0.625 mm in thickness. A number of improvements were made from standpoint of improving performance or in facilitating production.

Rechargeability

The major effort in the field of solid electrolytes, aside from the use of solid galvanic cells to demonstrate thermodynamic principles, has been in the development of primary cells. Moreover, until recently, such effort has involved only high-voltage and low-current application.

Sator appears to have been the first to utilize thin solid ionic electrolytes in galvanic cells (14, 53, 74) and one of the few to attempt to study reversible systems. Perrot and Sator (74) described a method for measuring the electrical resistance of ionic conductors at room temperature. They vacuum-deposited $PbCl_2$ between silver layers and measured voltage-current curves. Upon passing current, they observed the formation of AgCl at one electrode and Pb at the other. This suggested the development of a reversible galvanic cell. Subsequently (14), vacuum-deposited cells of the type

$$Ag/Pb/PbCl_2/AgCl/Ag \qquad (I)$$

were prepared. These cells were then charged at a constant current of 0.5 μa. The cell equations were

$$PbCl_2 + 2\,Ag \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} Pb + 2AgCl$$

The emf of the cell after charging was 0.523v, which diminished to 0.460v during the first hour and stabilized at this point.

Several different techniques were used by Sator in the preparation of the cells. One method involved starting with a Ag electrode upon which AgCl was formed by chemical attack in chlorine. Upon this substrate, a layer of $PbCl_2$ was vacuum deposited, then a layer of Pb, and finally a layer of Ag to complete the cell. The thicknesses deposited in these experiments were in the range of 10^{-5}-10^{-4} cm. Cells of the

$$Pb/PbCl_2/AgCl/Ag \qquad (I)$$

type were carried through nine charge-discharge cycles and were found to be reversible.

Cells of type I construction were prepared by vacuum deposition techniques by Moulton, Hacskaylo, and Feldman (75). The chloride cell exhibited an open-circuit voltage of 0.47-0.50v and the bromide cell 0.33-0.35v, both values being close to theoretical for the cell reaction. They were not successful in preparing the iodide cell.

The $PbCl_2$-AgCl cell (I) was also investigated by Smyth and co-workers (49). The chlorides of Ag and Pb which furnished the electrolytes were prepared in three ways: (*a*) by evaporation, (*b*) by tarnishing, and (c) by anodically chlorinating. Of these, evaporation appeared to be the most successful. It should be noted that the metal and metal chloride layers were relatively thick as compared to the Sator experiment. A typical cell was constructed as follows:

$$Ag(0.150\text{ mm})/AgCl(0.058\text{ mm})/PbCl_2(0.050\text{ mm}/Pb(0.001\text{ mm})$$

Further, evaporation was carried out from a graphite crucible and the possibility of contamination existed. In some preparations, open-circuit voltages in the range of 0.46v (approximating theoretical) were obtained, but in most cases the voltage was lower. These investigators concluded that the system had a major defect, *i.e.* the tendency for local silver metal deposition at the silver chloride-lead chloride interface. This deposition of free metallic silver which was actually observed at the interface led to inner electronic conduction and cell shorting. For this reason, further investigation of the system was abandoned by Smyth and co-workers.

The reversibility of the iodine-activated cell of the type

$$Ag/AgI/I_2(Pt) \qquad (XX)$$

was investigated by Weininger (76). It was possible to recover some cell capacity, but the charging efficiencies were low. A cell charged immediately after discharge yielded only 73% of the capacity, whereas cells stored for 90 min at —210°, 0°, and 25°C yielded 73, 63, and 15% of capacity on charging. It was postulated that this loss in capacity was related to the loss of iodine by diffusion although it was difficult to correlate the rate of the loss with known diffusion coefficients for I_2 and Br_2 in the appropriate halides. Generally speaking, attempts to recharge the gas-activated type of solid electrolyte cell have been unsuccessful.

A thin-film, rechargeable solid-electrolyte battery was described by Mrgudich *et al.* (77) with the composition

$$Ag/AgI/Pt \qquad (XXXI)$$

Pd was also used as the positive electrode. In typical cells, flash currents of 100 $\mu a/cm^2$ and open-circuit voltages of 0.370v were reported. These cells were subjected to a large number of charge-discharge cycles and apparently rechargeability was demonstrated. The author's description of the mechanism is open to question; *i.e.*, it does not appear reasonable that the experimental observations can be explained in terms of a silver concentration cell. The assumption was made that higher flash currents could be obtained from cells without evident cathode depolarization than those in which the cathode depolarization was provided by the halogen gas. It appears more logical

to explain the results obtained with this cell in terms of the air-depolarization mechanism proposed by Hacskaylo and Foley (78). Recently, Mrgudich (79) has reported some experiments wherein the Ag/AgI/Ag cell has been used as a pressure-sensing device and a temperature-sensing device, in the latter case utilizing the thermogalvanic effort described below.

The reversibility of solid electrolyte cells using silver halides was studied by Andes and Manikowski (80, 81) by charging and discharging in short pulses. Their cell used Pt wire and Ag wire electrodes in halide electrolytes, one of the better being a solution of 80 mole % silver iodide and 20 mole % silver chloride. The cells were charged with single pulses varying from a millisecond to more than a second. Discharging was done by pulses of the same magnitude but of opposite polarity. For example, in a typical experiment, a charge voltage of 45v for a time of 10 msec resulted in a current efficiency of 85% and an energy efficiency of 0.86%, the latter due to the higher charging voltage. The ability to charge reversibly with short pulses argues against Mrgudich's viewpoint that the mechanism involves diffusion of Ag into Pt as the cell operates.

Fabrication and Applications

One of the objectives of many investigations has been to counteract the high internal resistance of the solid electrolyte by using thin layers, *e.g.*, those furnished by vacuum deposition. The possibility of printing the various cell components was suggested. Originally, the idea of making batteries by printing techniques was advanced by Bjorksten (82). In his patent, he described a process that involved, first, printing with an ink containing Fe powder. then orienting the Fe particles so that they touched, and then allowing the resin to dry and cure. This process was repeated with another ink containing a second powder such as Ni. Whereas this may be characterized as a thin-film, printed battery, the electrolyte cited in the patent was a solution such as zinc chloride in the vehicle mainly comprised of linseed oil. Conduction was by mechanisms similar to those in aqueous solution rather than those operating in solid ionic crystals.

The fabrication of solid electrolyte batteries, presumably to minimize internal shorting by surface leakage and to prevent the attack of the anode by corrosive (halogen) vapors, was described by Smyth and Lehovec (83). A design of a galvanic cell intended to produce a high current was described by the same authors (84). In a cell of the type

$$Ag/AgI/I_2(C) \qquad (XX)$$

formed with layer configuration, a battery with a voltage of 0.68v and a short-circuit current of 2.5 ma/cm^2 of active cell was claimed. A battery with 20 cm^2 of effective contact between the foils yielded 50 ma of short-circuit current and operated at 5 ma without "appreciable decrease in cell voltage." It was claimed by these authors that these cells could be recharged although no charging efficiency curves were given. The design and method of manufacturing a cell described by Smyth and Shirm (69) of the type

$$Ag/AgCl/KICl_4 \qquad (XXIX)$$

wherein the cathode reaction involved a gas activation process was claimed by Hutt *et al.* (85). A series arrangement of cup-shaped cells was described.

Richter *et al.* (86) described a process for automatically making the cell described originally by Louzos (72). This cell was of the type

$$Ag/AgI/V_2O_5(C) \qquad (XXX)$$

The gas-activated cell utilizing solid silver halides as electrolytes described above was further developed by Weininger (26, 76). He described a method of fabricating a cell of the type

$$Ag/AgI/I_2(Pt) \qquad (XX)$$

intended to operate at elevated temperatures. In a further improvement (87) of this type of cell, a AgI electrolyte of 2-5μ thickness was developed by chemically tarnishing Ag in I_2 vapor at 150°C. A bimetallic corrugated sheet was used to provide space for the gas to diffuse to the active electrode areas. When the cell was activated by I_2 vapor at 0.306 mm at 25°C, a voltage of 0.67v and a short-circuit current of 200 μa was produced.

Miniature cells of a similar configuration gave short-circuit currents of 6.7 ma at 170°C at which temperature the open-circuit voltage was 0.67v (28).

Galvanic cells using silver iodide in its highly conductive form were utilized as thermogalvanic cells (88). The so-called "silver" thermocell

$$(T_1)\,Ag/AgI/Ag\,(T_2) \qquad (VII)$$

wherein T_1 and T_2 were two different temperatures above 146°C, was investigated and proven feasible as a device for solar energy conversion (89). This cell suffered because of transfer of Ag to the cathode and nonuniform, dendritic build-up as the cell operates. This led to the iodine thermocell

$$(T_1)\,(C)\,I_2/AgI/I_2\,(C)\,(T_2) \qquad (XXXII)$$

using the same electrolyte but gas electrodes (90). In the particular configuration described, with electrodes of 10 cm^2 and an electrolyte thickness of 0.1 cm, with iodine electrodes at 1 atm, with one electrode at 350°C and a second at 550°C, an open-circuit voltage of 112 mv and a short-circuit current of 27 amp was obtained. The voltage approximated that calculated by considering the corresponding entropy transfer within the cell. Whereas the current appears high, it is very close to what would be expected from the configuration of the cell and the reported resistance for the electrolyte, as given above (21). Weininger reports typical operating characteristics for the iodine thermocell for a temperature difference of 280°, a ΔE of 347 mv, equivalent to 1.24 mv/deg, and an internal cell resistance of 91 ohms at a current greater than 1 ma (88).

The first substantial improvement in electrolyte development was made by Takahashi and Yamamoto (33) in their work with the silver sulfide iodide electrolyte, as described above. A miniaturized version of the cell was prepared with a thin film (20μ) of this electrolyte (91). This cell could be discharged at several hundred microamperes per square centimeter at 25°C without significant polarization.

The second improvement was that involving double salts with the alkali halides and the silver halides. Batteries utilizing this type of electrolyte were prepared on a proprietary basis (92). Individual cells were reported to have 0.64v open-circuit voltage and to exhibit flash currents of 900 ma/cm^2. A typical discharge curve of a 100 ma-hr cell at 5.55 ma showed a flat voltage curve approximately at 0.64v out to about 16 hr or 88% of capacity.

As has been pointed out above, the mobile species in this cell is Ag^+ ions. As the cell operates, it would be expected that Ag^+ ions would move to the cathode and form a layer of AgI which would have a comparatively high resistance. Thus, if this passivation is to be prevented, some mechanism to prevent cathode polarization must be built into the cathode reaction. A recent report indicates that this effect is achieved by employing a cathode mixture of RbI_3, carbon, and $RbAg_4I_5$ (97).

Conclusions

For a number of reasons cited above, solid electrolyte galvanic cells as energy conversion devices have been the object of a considerable amount of investigation by electrochemists since the turn of the century.

Solutions to the major battery problems have evolved with the disclosure of highly conductive ionic electrolytes, gas-activated cathodes, and fabrication techniques for eliminating internal short circuiting. In addition, the development of sophisticated vacuum deposition techniques renders the fabrication of thin-film configurations possible.

The question of rechargeability has not been answered satisfactorily as yet, with the experimental work of several investigators furnishing contradictory evidence. However, cells based on lead chloride-silver chloride electrolytes—the so-called Sator-Haber type—offer promise in the development of a secondary battery system.

Acknowledgments

I am pleased to acknowledge the valuable criticism of Dr. Joseph L. Weininger and Dr. W. J. van der Grinten of the General Electric Company, Dr. Charles Feldman of the Applied Physics Laboratory, and Dr. George E. Blomgren of the Union Carbide Corporation. Dr. Weininger brought to my attention several papers on the structure of silver iodide, and Dr. van der Grinten made available government reports on the vapor-activated systems.

Manuscript submitted March 18, 1968; revised manuscript received June 10, 1968.

Alternating-Current Field-Induced Forces and Their Biological Implications

Herman P. Schwan and Lawrence D. Sher

Biomedical Engineering Department, The Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

Steady-state, field-induced forces on particles of microscopic size become significant at field strength values of the order of 100 v/cm. They include "pearl-chain formation," *i.e.* the alignment of particles in the direction of the imposed field, and the orientation of nonspherical particles. The time constant, which describes the speed of these phenomena, depends on field strength, and particle and other parameters. For pulsed fields, a lower level of applied average power can suffice to evoke the phenomena mentioned. Biological implications include the possibility of nonthermal effects of biological significance.

Alternating-current, field-induced force effects have been observed for several decades. However, their detailed understanding in general and field-induced effects on biological material in particular seem not to have been of much interest to the scientific community.

We shall report here about two such effects, which we shall classify as "pearl-chain formation" and "orientation" effects (Fig. 1). Two other effects in this category, a-c electrophoresis and dielectrophoresis, have already been discussed by us (1, 2). "Pearl-chain formation" is the ordered arrangement of small particles in a suspending medium which is observed if an a-c field is applied. "Orientation effects" describe the alignment of suspended particles and micro-organisms as an a-c field is applied, so that their long axes are parallel or perpendicular to the field direction.

Alternating-current, field-induced forces on particles of microscopic size can become significant at field strength values of the order 100 v/cm. They have been observed for a variety of biological cells and the question arose under what circumstances nonthermal effects of rf radiation can be biologically significant.

Background Remarks

Muth (3), by exposing fat-particle emulsions to high-frequency fields, was probably the first to observe the phenomenon of pearl-chain formation. Krasny-Ergen (4) stated that the phenomenon can be explained by considerations of potential theory. However, for mathematical simplicity, he erroneously assumed perfectly conducting biological particles. Liebesny (5) observed pearl-chain formation of erythrocytes in a high-frequency field. Manegold (6), following Muth (3), again demonstrated and discussed pearl-chain formation using fat particle emulsions.

Renewed interest in field effects on biological particles developed in the late 1950's and early 1960's. Heller *et al.* (7, 8) noted not only pearl-chain formation but also orientation and preferential directions of motility of micro-organisms in high-frequency fields. Saito and Schwan (9) provided a theoretical treatment of the problem of how fast pearl-chain formation takes place. Quantitative experiments on pearl-chain formation, studying the threshold field strength of this phenomenon, were probably first carried out by

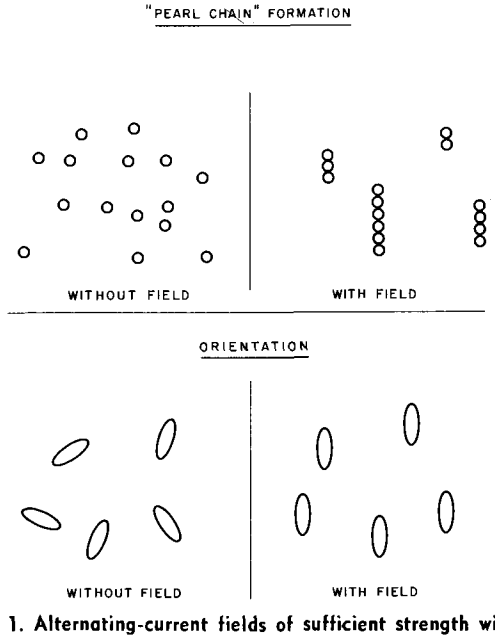

Fig. 1. Alternating-current fields of sufficient strength will cause alignment of particles (pearl-chain formation) and orientation of nonspherical particles parallel or perpendicular to the direction of field.

Sher (10). The results were compared with theoretical equations given by Saito and Schwan (11). A general theory of orientation due to a-c fields was developed by Schwarz, Saito, and Schwan (12). Saito, Schwan, and Schwarz (13) provided a theory of the orientation of biological particles by a-c fields in 1966.

All experimental work so far, with the exception of that done by Sher (10), is not sufficiently quantitative to be suitable for a check against theory. However, Sher's data permit comparison and agree with the theory of pearl-chain formation developed by Saito and Schwan (11). The theory of orientation given by Saito, Schwan, and Schwarz (13) predicts that "turnover" of field-oriented micro-organisms from one direction to another occurs in the high MHz range. This was indeed observed by Heller *et al.*, (7, 8). However, their data are not specific enough to permit a precise quantitative comparison. More experimental work is needed to check fully the orientation theory, even though there appears to be little doubt that the considerations of potential energy by Saito, Schwan, and Schwarz (13) are applicable.

While the response of particles to nonuniform fields is an apparent digression from pearl-chain formation and orientation, both demonstrable in uniform applied fields, it is mentioned here since the individual particles of a pearl-chain do experience nonuniform fields, even when the applied field is uniform. The response of particles to nonuniform fields has been the subject of many investigations. Thus, Debye has proposed a "molecular centrifuge" (14), and separation of biological cells has been achieved by Pohl and Hawk (15) by application of nonhomogeneous fields. The existence of this force and its description for a spherical particle in a d-c field is well-known (16). More recently, Saito and Schwan (11), using the results of Schwarz (17), have shown that pearl-chain formation for complex dielectric media in an a-c field can be described very well by considering each particle of a representative particle pair to be acted upon by the (nonuniform) induced dipole field of its partner. A minimization of their combined potential energy results when the particles are brought to tangency with their line of centers parallel to the field. Pearl-chain formation can thus be considered to be the result of the applied uniform field or, with greater insight, the result of the induced nonuniform fields. The force on single complex dielectric particles in a complex dielectric medium under the influence of an a-c field has been very recently derived and discussed by Sher (2), again basing the derivation on the fundamental work of Schwarz (17).

Pearl-Chain Formation and Orientation

It has been our hypothesis that the above-mentioned effects are manifestations of field-induced forces. We have developed appropriate theoretical concepts by applying potential theory and, in some cases, have conducted experimental work to check the theory. Our group, H. P. Schwan, L. D. Sher, M. Saito, and G. Schwarz, has concentrated on three problem areas which will be described in some detail: Pearl-chain formation and its threshold; time constants of pearl-chain formation; and orientation phenomena and their threshold.

Pearl-chain formation and its threshold.—Pearl-chain formation is the result of attractive forces between induced dipoles on neighboring particles (18). A demonstration of this effect is shown in Fig. 2 (10). Equivalently, it can be considered to occur because, in an electric field, the combined electric potential energy of two particles diminishes with their separation and because any system will move toward that state where its potential energy is minimized. The mathematical treatment of the phenomenon of pearl-chain formation (11) considers the interaction of two spherical particles of complex dielectric constant ϵ_1 and radius R in a medium of complex dielectric constant ϵ_2 under the influence of an alternating field E_0. ($\epsilon = \epsilon' - i\epsilon''$,

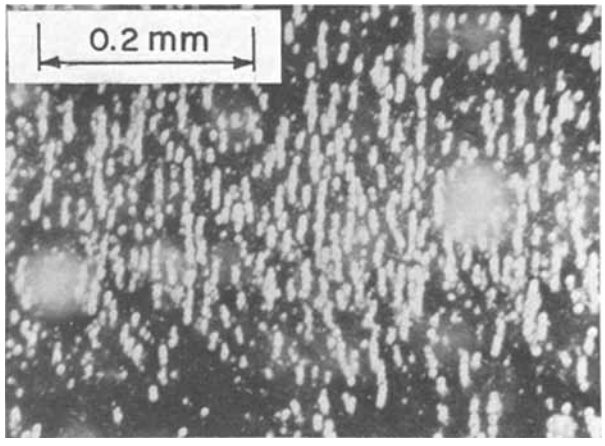

Fig. 2. Demonstration of pearl-chain formation with red blood cells in saline. Field strength is 50 v/cm.

where ϵ' is the real dielectric constant and ϵ'' is electrical, conductivity/angular frequency.) Pearl-chain formation succeeds if the ordering forces, which yield a minimization of potential energy, are greater than the randomizing forces due to Brownian motion. Thus, one anticipates that pearl-chain formation will occur if the change in potential energy due to the particle alignment is greater than kT, *i.e.* if

$$\left[\frac{\epsilon_1 - \epsilon_2}{\epsilon_1 + 2\epsilon_2}\right]^2 \epsilon_2' R^3 E_0^2 > kT \qquad [1]$$

where ϵ'_2 is the real dielectric constant of the suspending phase. In fact, it is found theoretically that the term on the left must be about 9X larger than kT for pearl chains to be observable. Exact numerically evaluated solutions for the minimal, or threshold, field strength needed to cause pearl chains to form have been obtained if the particles are either perfect conductors, perfect dielectrics, or complex dielectrics with any particular set of specified parameters (11). The most general case of complex dielectric constants yields a useful simple closed-form solution (Eq. [2]) if the problem is treated as a dipole-dipole interaction phenomenon, even though the perturbation of a field by a sphere is no longer precisely described by a dipole if there is another sphere in the neighborhood.

For the steady-state case, *i.e.* after the electrical field has been applied for a time which is larger than the time constants characteristic of the process of pearl-chain formation (*see* next section), the following conclusions have been derived:

1. At frequencies for which $\epsilon_1 \approx \epsilon'_1$ and $\epsilon_2 \approx \epsilon'_2$, the threshold value of field strength causing pearl-chain formation is relatively insensitive to changes in the particle concentration but changes rapidly with the real dielectric constant ratio, ϵ'_1/ϵ'_2, of particle and fluid. If the particle's complex dielectric constant becomes identical with that of its environment, the particles cease to be distinguished electrically, and, hence, pearl-chain formation becomes impossible. Thus $E_{th} \to \infty$ as $\epsilon_1 \to \epsilon_2$ (Fig. 3).

2. No frequency dependence for the threshold rf field strength is found in the case where particle and suspending medium have frequency-independent electrical parameters and where either conductive or capacitive currents predominate over the frequency range of interest. This may be recognized from Eq. [2] which gives the threshold field strength E_{th} for pearl-chain formation in complex dielectric media

$$E_{th} = 1.7\, R^{-1.5} \left|\frac{\epsilon_1 + 2\epsilon_2}{\epsilon_1 - \epsilon_2}\right| \sqrt{\frac{kT}{\epsilon_2'}} \qquad [2]$$

Reduction of this general equation to the case where the particle and medium properties are purely conductive or purely dielectric yields equations which

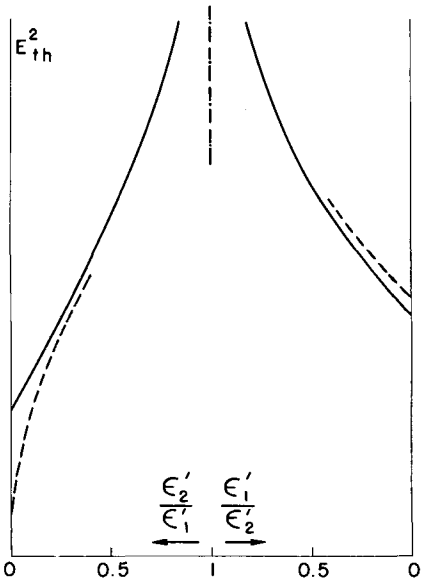

Fig. 3. Threshold field strength E_{th} necessary to cause pearl-chain formation as a function of the ratio of real dielectric constants, if suspended particles (subscript 1) and suspending medium (subscript 2) are pure dielectrics. Notation: – – – – exact value, ——— dipole approximation, – · – – · – asymptote for all curves at the point where $\epsilon'_1 = \epsilon'_2$. The ordinate is linear and is proportional to E^2_{th}. A particle concentration of 1.6% (v/v) was assumed.

predict a frequency-independent threshold value. For example, let us neglect ϵ'_1 and ϵ'_2 which corresponds to the experimental conditions in Fig. 4 ($\epsilon_1' < \epsilon_1''$ due to surface conductance). Then Eq. [2] reduces to Eq. [3]

$$E_{th} = 3.4\, R^{-1.5} \sqrt{\frac{kT}{\epsilon'_2}} \qquad [3]$$

which is independent of frequency, a prediction confirmed experimentally (Fig. 4). The theoretically predicted size dependence of the threshold field strength has also been experimentally confirmed (Fig. 5).

Time constants of pearl-chain formation.—A theory of the transient behavior of pearl-chain formation has been developed. While a complete theory of the speed with which pearl-chains form is difficult, it has been possible to calculate the time constant T if the field strength is at or near zero (in which case T measures the break-up time) or is large in comparison with the threshold value E_{th} (in which case T measures the

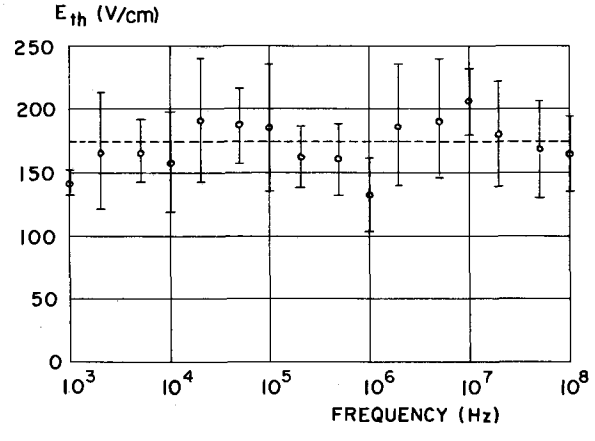

Fig. 4. Experimental threshold field strength values for pearl-chain formation of 1.17μ diameter polystyrene spheres as a function of frequency. Bars indicate ±1 standard deviation. Average of these values is indicated here by a dotted line and in Fig. 5 by the data point and bar numbered "2." Fluctuation of data indicates the experimental difficulty of obtaining precise threshold values, even when the experimental system is very well defined.

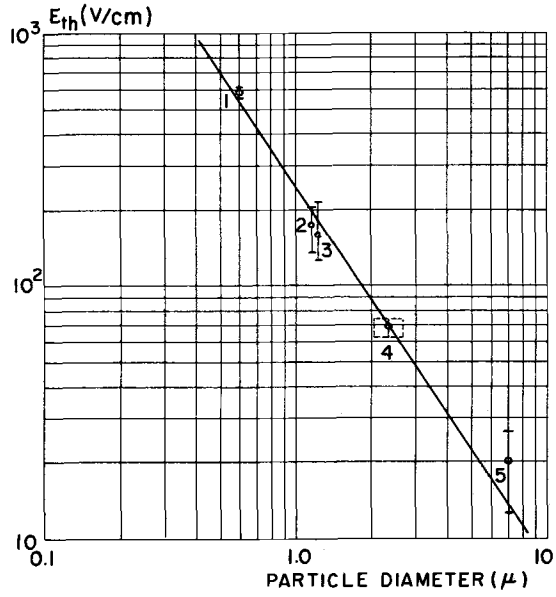

Fig. 5. Threshold field strength for pearl-chain formation vs. particle size. Experimental measurements on five different particle suspensions are shown: 1: 0.6 ± 0.1μ silicone globules; 2: 1.17μ polystyrene spheres; 3: *E. coli* bacteria; 4: 2.3 ± 0.3μ silicone globules; and 5: human erythrocytes. All suspensions are in aqueous media. Vertical bars indicate standard deviations except for 5 in which they indicate the data spread of two (difficult) measurements. Where the E_{th} had a frequency dependence, the values plotted here were the high-frequency limit values. The line is the theoretical prediction using the dipole approximation (Eq. [2]) at its high-frequency limit (where $\epsilon \to \epsilon'$).

formation time). Thus two solutions for small and high values are obtained which, if taken together, indicate the over-all field strength dependence of the time required for pearl chains to form or break up (9). The theory yields the following conclusions:

1. The time constants which characterize how fast pearl-chain formation occurs are proportional to the cube of the radius. For $E \approx 0$, they are of the order of 1 sec for particles of the order of 1μ in radius. For particles of several microns, the time constants become as large as minutes and experimental measurements of the time constants are difficult for such particles.

2. The time constants are not strongly dependent on the field strength when it is small. They are inversely proportional to the square of the field strength when it is large. The transition between the two regions occurs near the threshold field-strength value of pearl-chain formation (Fig. 6). It is apparent from Fig. 6 that appropriately applied pulse trains of high peak field strength can cause pearl-chain formation even though the time average of the field strength applied is less than that needed in the case of continuous fields. To what extent this fact may be utilized to affect biological structures and their function has not yet been studied intensively.

3. However, when the pulse repetition rate is much greater than the reciprocal of the time constant, the pulsed applied field is as effective as is expected from its root mean square value. Personnel hazards due to tissue heating in a radar beam become pronounced at field-strength values smaller than those required for pearl-chain formation for particles smaller than about 20μ in diameter. Thus, with the qualification noted in paragraph 2 above, pearl-chain formation is not likely to be a biological hazard due to microwave irradiation (9).

Orientation phenomena and their threshold.—Positions of stability of nonspherical particles in an rf field were studied theoretically, using a fundamental derivation of Schwarz (17), which gives the potential energy of a complex dielectric body in an a-c field.

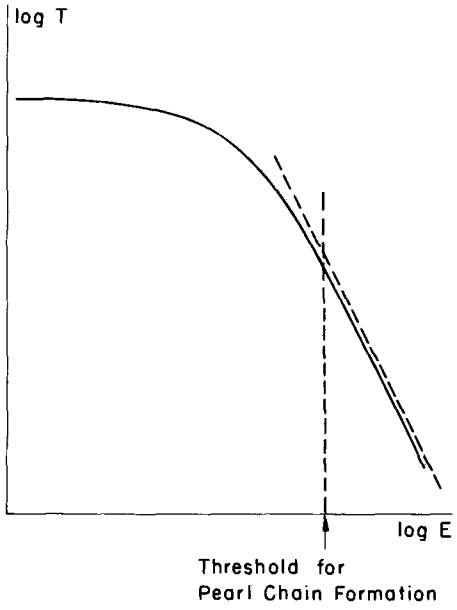

Fig. 6. Field strength dependence of the time constant of pearl-chain formation. The inclined dashed line indicates the $T \propto E^{-2}$ behavior which is approached if E is larger than the threshold field strength for pearl-chain formation.

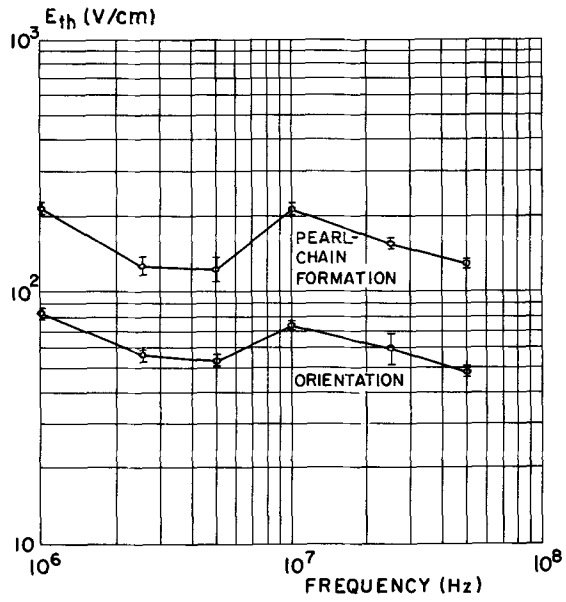

Fig. 8. Comparison of threshold field strengths, E_{th}, for orientation and for pearl-chain formation of *E. coli* in water. Since bacteria possess a highly frequency-dependent complex dielectric constant, the threshold values are frequency dependent. Each point is the average of three measurements whose spread is indicated.

The potential energy of a nonspherical particle of complex dielectric constant in a medium of another complex dielectric constant is found to be a function of frequency, applied field strength, and orientation of the particle. If the particle is free to rotate, then, as the frequency is varied, the particle will rotate from one direction to another in order to maintain a state of minimum potential energy (Fig. 7). A general ellipsoid can assume three possible orientations in the field, while a prolate or oblate spheroid can assume only two, the axis being parallel or perpendicular to the field direction. The transition from one to the other orientation, or "turnover," depends on the frequency and complex dielectric constants of the particle and the suspending medium.

Ellipsoidal particles with and without a shell were treated as special cases. For ellipsoidal particles with parameters of biological interest, the change in orientation with frequency is in the region of 1-100 MHz. In the case where the field intensity is not sufficiently high, the turnover may be blurred by Brownian motion. The threshold field strength necessary to cause a well-defined orientation is usually less than, but of the same order of magnitude as, the threshold for pearl-chain formation (Fig. 8). When both thresholds are exceeded, both phenomena occur simultaneously.

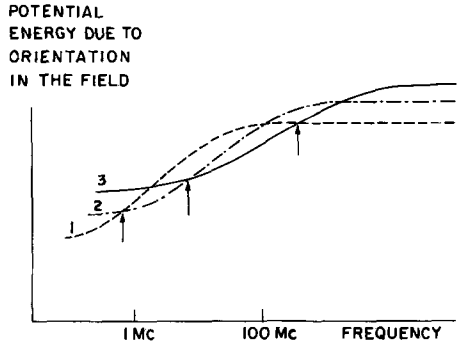

Fig. 7. Each of the curves shown is the potential energy (vs. frequency) of an ellipsoid, one of whose three axes is artificially constrained to be parallel to the field direction. The particle will rotate from one direction to another at the frequencies where curves intersect, as indicated by arrows (see text).

Biological Implications and Conclusions

Biological implications include the possibility of nonthermal effects of biological significance. A phenomenon, which has been reported by several authors, is the direct auditory sensation experienced by persons exposed to pulsed microwave beams. It appears to be related to field-evoked forces (19, 20). The possibility of inducing chromosomal aberrations has been observed (21), but further work appears desirable.

In conclusion, we wish to state that nonpulsed a-c fields are not likely to be biologically significant as a result of nonthermal effects, but that it may be possible to evoke nonthermal biological effects with appropriately designed pulsed fields.

Chemical Behavior of the Components of the $KCN/KAu(CN)_2$ Electroplating System

H. Graham Silver[1]

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania

ABSTRACT

The chemical reactions occurring within aqueous solutions of potassium cyanide, potassium cyanide and metallic gold, potassium gold cyanide, and mixtures of these compounds with potassium hydroxide have been examined. It was determined that aqueous potassium cyanide solutions are unstable to water and air. The major reaction products formed were the formate and carbonate ions which increased in concentration with time. This increase, which was temperature dependent, was accompanied by a corresponding decrease in the cyanide ion concentration. Analyses confirmed that gold would dissolve, to any extent, only in those aqueous potassium cyanide solutions exposed to air. The reactions of potassium cyanide with water and oxygen within solutions of potassium cyanide and metallic gold produced similar products to those found in pure potassium cyanide solutions.

The addition of potassium hydroxide in concentrations greater than ~0.1M to aqueous potassium cyanide solutions depressed the rate of hydrolysis of potassium cyanide. However, concentrations far in excess of 1M potassium hydroxide would be necessary to prevent the formation of formate ion completely. Analyses confirmed that aqueous potassium gold cyanide solutions are very stable to heat, high concentrations of hydroxide ion and atmospheric oxygen, and show no detectable signs of decomposition. The solutions are likewise stable to acid at room temperature down to a *p*H of ~4.5, below which a slow decomposition to insoluble gold cyanide occurs. At *p*H 1, aqueous potassium gold cyanide solutions remain stable indefinitely at a temperature of 1°C. In mixtures of potassium gold cyanide, potassium cyanide, and potassium hydroxide, which are typical electroplating solution components, the stability of potassium gold cyanide was apparently unaffected. The reactions of potassium cyanide with water and oxygen within these mixtures gave no other products but those detected in a pure potassium cyanide solution. Potassium hydroxide merely decreased the rate of hydrolysis of the potassium cyanide.

Activated charcoal treatment of the cyanide solutions did not remove any of the ionic products of decomposition.

For many years, extensive use has been made of the cyanide-type gold electroplating bath within the electronics industry for processing a wide variety of components, devices, and circuitry. Much empirical information has been accumulated and used to control the many variables associated with the composition and performance of such baths.

For example, it is observed that variations in the brightness, porosity, hardness, impurity, and gas content of the gold electrodeposit depend on the plating bath composition, the nature of the bath additives, the current density, stirring rate, the temperature of the bath, and the final treatments of the material to be coated prior to immersion in the plating bath. However, this information has not been adequate to consistently secure gold deposits with reproducible characteristics, which are essential to electron device applications.

Although there is a great deal of the above empirical data available and although, each year, many patents are granted for new or unique plating bath compositions and for improved techniques of gold electrodeposition, surprisingly enough, very little is known about the basic mechanism of gold electrodeposition and, hence, the latter remains more of an art than a science.

It is apparent that, in order to relate the bath composition with the observable characteristics of the deposit and to establish appropriate techniques of control, an understanding of the basic mechanism of gold electrodeposition during electrolysis is desirable.

As a first step in the solution of this problem, there is a need to explore the inherent behavior of the electroplating solution constituents. Some of the first papers on the chemical reactions occurring within aqueous solutions of potassium cyanide are those of Wick (1) and Angles *et al.* (2), who report on the decomposition of cyanides in plating solutions. Their analyses detect substantial quantities of carbonate, formate, and cyanate ions together with minor amounts of urea and ammonia within the plating solutions.

Accordingly, a careful re-examination of the chemical reactions occurring within aqueous solutions of potassium cyanide, potassium gold cyanide, and mixtures of these compounds with potassium hydroxide, has been undertaken.

Experimental

Twelve Pyrex reaction vessels, each containing 200 ± 20g KCN (DuPont, 98.0% minimum purity) dis-

[1] Present address: General Telephone & Electronics Laboratories Incorporated, Bayside, New York 11360.

Key words: electrodeposition; gold electroplating; cyanide decomposition.

solved in deionized water and made up to 2 liters of solution, were placed upon Fisher combination hotplate and variable-speed magnetic stirrers in a conventional hood. The following experimental conditions were imposed on the reaction vessels: (a) six vessels were maintained at 70° ± 3°C, six maintained at 30° ± 2°C; (b) six solutions were exposed to air, six covered with a Pyrex lid to isolate them, but not hermetically, from air (these latter solutions were prepared using deionized water, which had previously been deaerated by bubbling a stream of nitrogen through the water for 18 hr); (c) four vessels were externally sprayed with flat black enamel paint to prevent visible radiation from penetrating through the walls, four vessels were exposed to laboratory visible radiation, while four were exposed to an intense source of visible radiation, produced by a General Electric Type S-4 lamp, placed about 18 in. above the reaction vessels. A diagram of the arrangement is shown in Fig. 1.

All 12 solutions were continuously stirred for 31 days with Teflon-covered stirring rods. A 50 ml sample from each reaction vessel was withdrawn at approximately the same time every day and sealed in a 50 ml glass bottle, which was then cooled to about 5°C. The following day, each solution was quantitatively analyzed for the components listed below

(a) CN^-	(e) $H.COO^-$ formate
(b) $CO_3^=$	(f) $C_2O_4^=$ oxalate
(c) pH	(g) NH_4^+
(d) CNO^-	(h) $CO(NH_2)_2$ urea

The above experiment was repeated exactly as described, except that a piece of gold, 99.99% pure, obtained from Engelhard Industries, of 16 cm^2 total surface area, was now placed on the bottom of each reaction vessel. The 12 solutions were quantitatively analyzed for the above components plus dissolved gold.

Results and Discussion

Experiment I.—The results of the quantitative chemical analyses, the majority of which were done in duplicate, have been plotted and are shown in Fig. 2-5. The accuracy of these results and subsequent results is ±5%. The graphs drawn for this experiment show that:

1. Those solutions (a) not heated and (b) isolated from air (Fig. 2) show little change in CN^- ion concentration over the period of 1 month.
2. Those solutions (a) not heated and (b) exposed to air (Fig. 3) show a drop in CN^- ion concentration (from ~40 to ~30 g/liter), a build-up of $CO_3^=$ ion concentration (from ~2 to ~9 g/liter) and an increase in $H.COO^-$ ion concentration (from 0 to ~2 g/liter) over the period of 1 month.
3. Those solutions (a) heated and (b) isolated from air (Fig. 4) show a drop in CN^- ion concentration (from ~40 to ~0.8 g/liter) and a build-up of $H.COO^-$ ion concentration (from 0 to ~72 g/liter) over the period of 1 month. Note the absence of $CO_3^=$ ion build-up.

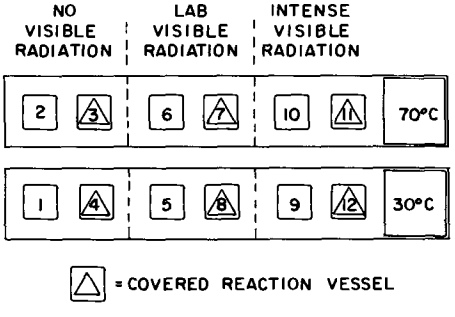

Fig. 1. Solution identification

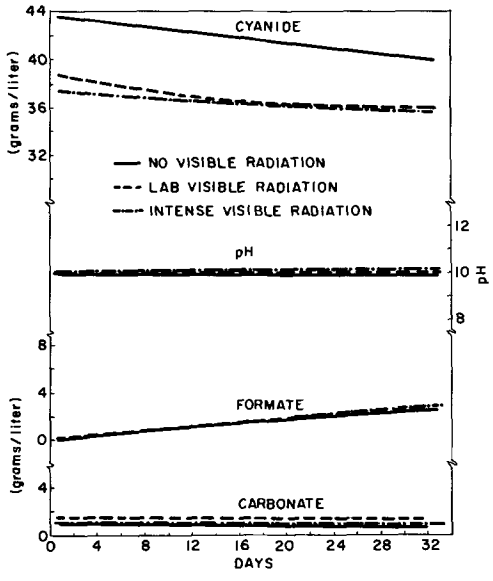

Fig. 2. KCN solution, temperature 30°, no air

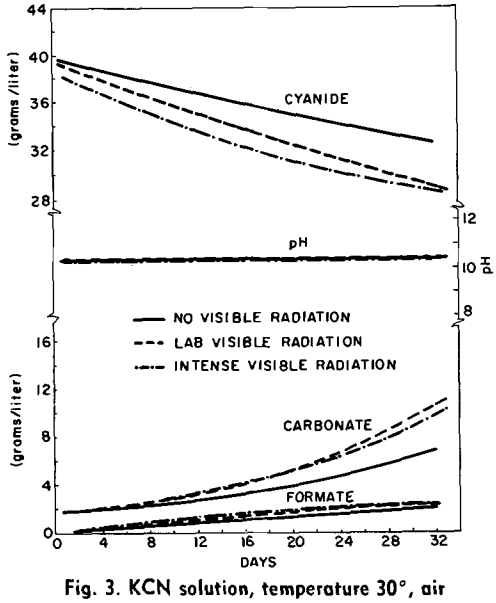

Fig. 3. KCN solution, temperature 30°, air

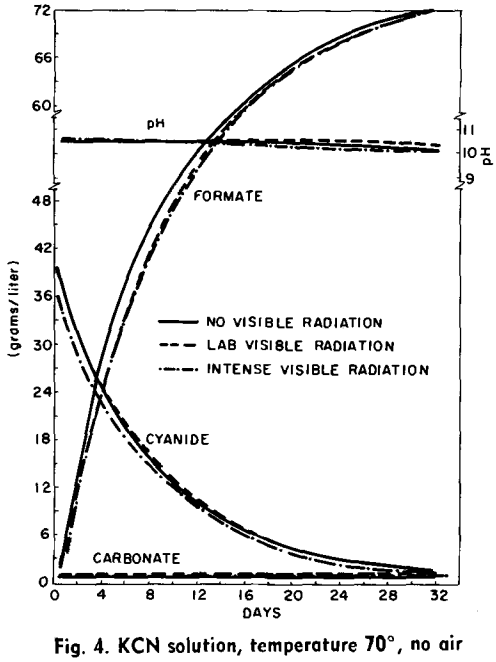

Fig. 4. KCN solution, temperature 70°, no air

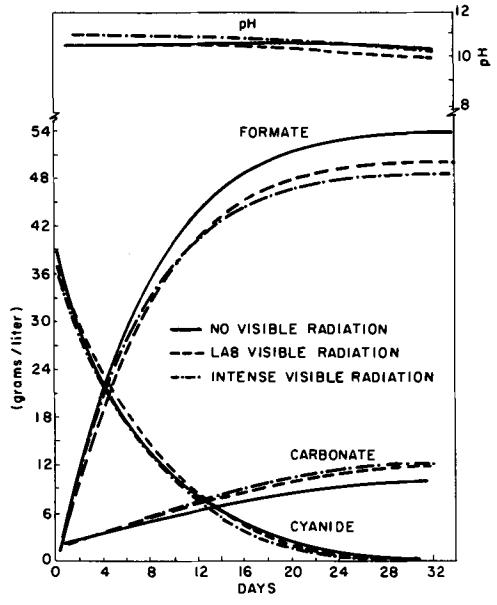

Fig. 5. KCN solution, temperature 70°, air

4. Those solutions (*a*) heated and (*b*) exposed to air (Fig. 5) show a drop in CN^- ion concentration (from ~40 to 0.1 g/liter), a build-up of $CO_3^=$ ion concentration (from ~2 to ~11 g/liter) and an increase of $H.COO^-$ ion concentration (from 0 to ~50 g/liter) over the period of 1 month.

5. The *p*H of all the solutions remains almost constant at 10.3 ± 0.3 over the period of 1 month.

Analytical data which have not been plotted show that:

6. The CNO^- ion concentration in any of the solutions does not exceed ~0.4 g/liter over the period of 1 month.

7. Urea and the $C_2O_4^=$ ion do not form to a concentration greater than 0.5 and 0.2 g/liter, respectively, over the period of 1 month.

8. The NH_4^+ ion is expelled from the solutions as gaseous NH_3. In the heated and covered solutions only (vessels 3, 7, and 11, Fig. 1), its concentration builds up after 7 days to a maximum of ~8 g/liter but then decreases slowly to <0.5 g/liter over the period of 1 month due to gradual escape.

A list of the possible chemical reactions, which may occur between the CN^- ion and atmospheric O_2 and CO_2 in the presence of water and visible radiation, is given below (3, 4)

$$CN^- + 1/2\,O_2 \rightarrow CNO^-$$

$$2CNO^- + 3/2\,O_2 \rightarrow CO_3^= + CO_2 + N_2$$

$$2CN^- + CO_2 + H_2O \rightarrow CO_3^= + 2HCN$$

$$2CN^- + 2H_2O + 2OH^- + O_2 \rightarrow 2CO_3^= + 2NH_3$$

$$HCN + 2H_2O \rightarrow NH_4.OOCH \text{ ammonium formate}$$

$$HCNO + H_2O \rightarrow NH_4.CNO \xrightarrow{H_2O} CO(NH_2)_2 \text{ urea}$$

$$HCN + H_2O \xrightarrow{hv} \begin{matrix} COO.NH_4 \\ | \\ COO.NH_4 \end{matrix} \text{ ammonium oxalate}$$

In the solutions which were heated and isolated from air, the total reaction of the CN^- ion with water to form ammonium formate (Fig. 4), corresponds to an approximate 100% conversion, according to the equations

$$KCN + H_2O \rightarrow KOH + HCN$$

$$HCN + 2H_2O \rightarrow H.COO^- + NH_4^+$$

$$NH_4^+ \rightarrow NH_3\uparrow + H^+$$

The slightly higher, initial *p*H values found for the heated solutions (Fig. 4, 5) probably result from the presence in solution of moderate quantities of NH_3. Since the rate of production of ammonium formate starts to decrease after about the seventh day, but the rate of evolution of NH_3 remains practically constant, the *p*H of the heated solutions also slightly decreases, *e.g.* from 10.3 to 10.1.

In order to determine the free CN^- ion within the solutions, just sufficient $AgNO_3$ solution was added to form the complex ion $Ag(CN)_2^-$. At this point, the *p*H of the solutions was measured, since, then, the CN ion would not contribute to the acid-base equilibrium.

The constant *p*H of ~10.3 observed for all the solutions over the period of 1 month suggests that the bicarbonate-carbonate equilibrium

$$HCO_3^- \rightleftharpoons H^+ + CO_3^=$$

occurring at *p*H 10.25 is responsible for this value. Free hydroxide ion is probably not present since, if it had existed, a higher *p*H would have been expected.

The formation of $CO_3^=$ ion within the solutions exposed to air can occur *via* the reactions

$$CN^- + 1/2\,O_2 \rightarrow CNO^-$$

$$2CNO^- + 3/2\,O_2 \rightarrow CO_3^= + CO_2\uparrow + N_2\uparrow$$

The low concentration of CNO^- ion in all the solutions over the period of 1 month is presumably due to its almost immediate oxidation to $CO_3^=$ ion. Thus, the CN^- ion concentration is reduced.

If the formation were to occur *via* the reaction of CO_2 with the CN^- ion

$$2CN^- + CO_2 + H_2O \rightarrow CO_3^= + 2HCN$$

then regeneration of HCN would result and no drop in the CN^- ion concentration would be observed. This latter prediction is contrary to observation, hence the former reaction path probably predominates.

Similarly, if the formation of $CO_3^=$ ion were to occur *via* the reaction

$$2CN^- + 2H_2O + 2OH^- + O_2 \rightarrow 2CO_3^= + 2NH_3\uparrow$$

then a drop in *p*H of the solutions would be expected owing to the removal of OH^- ions. Since this prediction is again contrary to observation, the first reaction path probably predominates.

Different levels of visible radiation appear to affect only the production of $CO_3^=$ ion from CN^- ion. Those solutions exposed to visible radiation show a concentration of $CO_3^=$ ion 33-50% higher than that in the unirradiated solutions. Thus, it would appear that visible radiation catalyzes the carbonate-producing reaction

$$CN^- + 1/2\,O_2 \xrightarrow{hv} CNO^-$$

$$2CNO^- + 3/2\,O_2 \xrightarrow{hv} CO_3^= + CO_2\uparrow + N_2\uparrow$$

A Kjeldahl test for total nitrogen on one of the solutions indicated that there are no nitrogen-containing compounds present within that solution that are passing undetected. Moreover, a drop in CN^- ion concentration within the solutions may be satisfactorily accounted for by a corresponding increase in the concentration of $CO_3^=$ and $H.COO^-$ ions.

This apparent agreement among the various data gives confidence that all major components of the solutions have been detected.

After the experiment had been run continuously for about 10 days, some crystalline material was observed in those solutions which were heated and exposed to air (reaction vessels 2, 6, and 10, Fig. 1). Approximately a week later, the same crystalline material was observed in those solutions which were heated but isolated from air (reaction vessels 3, 7, and 11). Upon analysis of this material, it was found to consist mainly

of silicon, possibly in the form $K_2SiO_3.(H_2O)_x$, which had been leached out of the Pyrex reaction vessel. Apparently, heating and the presence of air or, more accurately, oxygen, causes an acceleration of the leaching action of the KCN solutions.

A purification procedure widely used throughout the electroplating industry to remove solid material and "organics" from plating baths is to heat and stir the electroplating solutions with a small quantity of activated carbon and subsequently to filter.

In order to assess quantitatively the effect of activated carbon on a KCN solution, two additional samples from reaction vessels 5 and 6 (Fig. 1) were heated and shaken with activated carbon for ½ hr, centrifuged, and finally quantitatively analyzed for the same components as the other 12 regular samples on the final day of the experiment. The results showed that there was essentially no difference in the individual ionic concentrations between the carbon-treated samples 5 and 6 and the untreated samples 5 and 6.

Consequently, activated charcoal is not effective for removing ionic material from cyanide solutions.

A plot of ln[concentration of CN^- ion] *vs.* time for the solutions 3 and 4, 7 and 8, 11 and 12 (Fig. 1), which were isolated from air, gives straight lines, indicative of a first-order or pseudo first-order reaction. The slope of the lines for the solutions maintained at 70°C, 3, 7, and 11, is much greater than for the solutions maintained at 30°C, 4, 8, and 12. In these six solutions, the only reaction occurring was that between the KCN and water

$$(a)\quad KCN + H_2O \rightleftharpoons KOH + HCN$$

$$(b)\quad HCN + 2H_2O = H.COONH_4$$

The absence of air prevented the additional oxidation reaction of CN^- to $CO_3^=$, but, in the remaining six solutions, exposed to air, a deviation from linearity of the ln[CN^-] *vs.* time graphs was observed. Hence, since the hydrolysis reaction (*a*) is very rapid, the rate of formation of ammonium formate (*b*) is directly proportional to the concentrations of HCN and water within the solutions

$$\frac{d[H.COONH_4]}{dt} \propto [HCN]\,[H_2O]^2$$

or

$$\frac{d[H.COONH_4]}{dt} = k[HCN]\,[H_2O]^2$$

where k is the velocity constant for that reaction. Since the water is present in very large excess, its concentration is essentially constant throughout the course of the reaction. The velocity equation, thus takes the form

$$(c)\quad \frac{d[H.COONH_4]}{dt} = k^*[HCN]$$

so that the rate of formation of $H.COONH_4$ is proportional to the concentration of HCN. Thus, this termolecular second-order reaction becomes kinetically of the first order or a pseudo-unimolecular reaction.

Another way of now expressing Eq. (c) would be to state that the rate of disappearance of the CN^- ion is proportional to its concentration at any one instant

$$\frac{-d[CN^-]}{dt} = k[CN^-]$$

This equation upon integration yields

$$-\ln[CN^-] = kt + K$$

where K is the constant of integration.

Thus, the plot of ln[CN^-] *vs.* time for the six previously mentioned solutions yields straight lines of negative slope, as shown in Fig. 6. The gradient of these lines is a measure of the velocity constant k at the temperature chosen for the reaction.

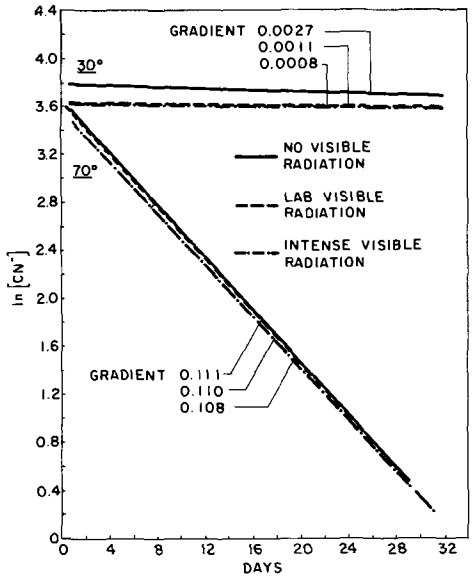

Fig. 6. KCN solution, no air

The half life, $t_{1/2}$, of a first-order reaction may be calculated using the equation $t_{1/2} = 0.693/k$. Hence, for the heated solutions, the half life is calculated to be between 6 and 7 days. This value agrees excellently with the half life observed experimentally for the depletion of the cyanide ion.

Using the integrated form of the Arrhenius equation

$$\ln k = \text{constant} - E/RT$$

where R is the gas constant and T the absolute temperature, the following values for the activation energy E have been obtained

(*a*) $E = 20$ kcal mole^{-1} (k values 0.111 and 0.0027)
(*b*) $E = 24$ kcal mole^{-1} (k values 0.110 and 0.0011)
(c) $E = 26$ kcal mole^{-1} (k values 0.108 and 0.0008)

If any significance can be attributed to the calculated activation energy values and, particularly, the increase in activation energy for the three pairs of solutions exposed to (*a*) no visible radiation, (*b*) laboratory visible radiation, and (c) an intense source of visible radiation, one must conclude that it becomes increasingly difficult for the reaction of HCN with water to occur as the intensity of visible radiation increases.

Experiment II.—Figures 7-10 plotted from the quantitative analytical results obtained for Experiment II

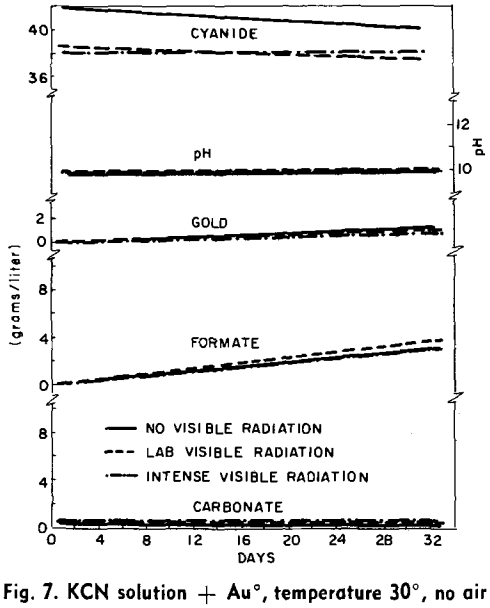

Fig. 7. KCN solution + Au°, temperature 30°, no air

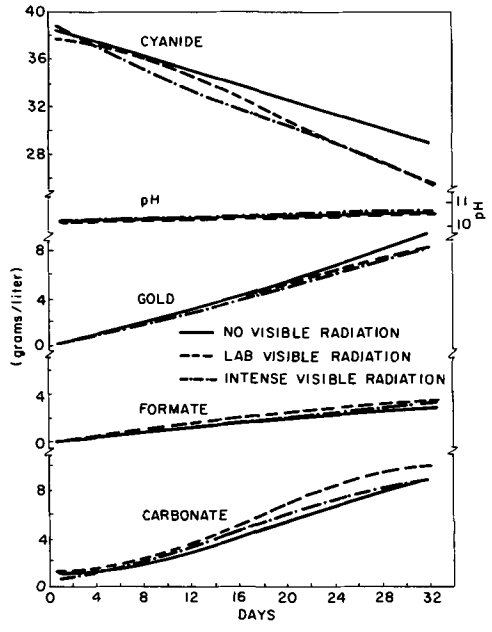

Fig. 8. KCN solution + Au°, temperature 30°, air

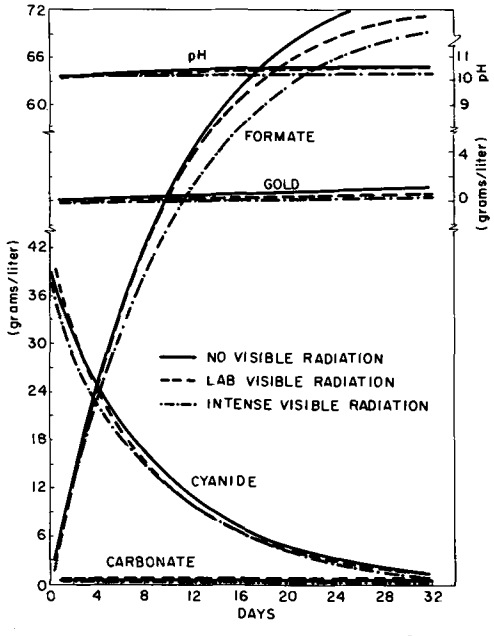

Fig. 9. KCN solution + Au°, temperature 70°, no air

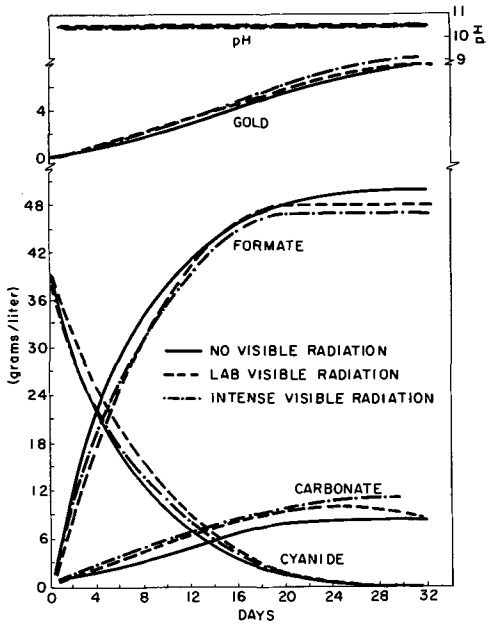

Fig. 10. KCN solution + Au°, temperature 70°, air

reveal a close similarity to those plotted for Experiment I.

1. Those solutions (*a*) not heated and (*b*) isolated from air (Fig. 7) show little change in CN^- ion concentration over the period of 1 month.

2. Those solutions (*a*) not heated and (*b*) exposed to air (Fig. 8) show a drop in CN^- ion concentration (from ~38 to ~27 g/liter), a build-up of Au concentration (from 0 to ~8 g/liter), an increase in $CO_3^=$ ion concentration (from ~1 to 9 g/liter) and a build-up of $H.COO^-$ ion concentration (from 0 to 3 g/liter) over the period of 1 month.

3. Those solutions (*a*) heated and (*b*) isolated from air (Fig. 9) show a drop in CN^- ion concentration (from ~39 to 1.5 g/liter), an increase in Au concentration (from 0 to ~0.8 g/liter), and a build-up of $H.COO^-$ ion concentration (from 0 to ~72 g/liter) over the period of 1 month. Note the absence of $CO_3^=$ ion build-up.

4. Those solutions (*a*) heated and (*b*) exposed to air (Fig. 10) show a drop in CN^- ion concentration (from ~39 g/liter to 0), a build-up of Au concentration (from 0 to ~8 g/liter), an increase in $CO_3^=$ ion concentration (from ~1 to ~10 g/liter), and a build-up of $H.COO^-$ ion concentration (from 0 to ~48 g/liter) over the period of 1 month.

5. The *p*H of all the solutions remains almost constant at 10.3 ± 0.3 over the period of 1 month.

Analytical data which have not been plotted show that:

6. The CNO^- ion concentration in any of the solutions does not exceed ~0.7 g/liter over the period of 1 month.

7. Urea and the $C_2O_4^=$ ion do not form to a concentration greater than 0.5 and 0.2 g/liter, respectively, over the period of 1 month.

8. The NH_4^+ ion is expelled from the solutions as gaseous NH_3. In the heated and covered solutions only (vessels 3, 7, and 11, Fig. 1), its concentration builds up, after 5 days, to a maximum of ~7 g/liter but then decreases slowly to <0.5 g/liter over the period of 1 month, due to gradual escape.

It is immediately apparent from the results that gold dissolves, to any extent, only in those KCN solutions which are exposed to air—oxygen, presumably, being the active ingredient—according to the equation

$$2Au + 4CN^- + 1/2\ O_2 + H_2O \rightarrow 2Au(CN)_2^- + 2OH^-$$

Since the OH^- ion is produced in the above reaction, the *p*H of a solution, in which much gold dissolves, might be expected to rise. This was observed for solutions 1, 5, and 9 (Fig. 1) in which the *p*H rose slightly from ~10.2 at the start of the experiment to ~10.6 at the end of the 1-month period. During this time, ~8 g/liter of gold had dissolved but only ~3 g/liter of $H.COO^-$ ion had been produced.

A similar condition might be expected for solutions 2, 6, and 10 in which ~8 g/liter of gold had also dissolved. But, it was observed that the *p*H of these solutions remained constant at ~10.5 over the 1-month period. A possible reason for this is that the OH^- ion is being neutralized by a small proportion of the 48 g/liter of $H.COO^-$ ion or, rather, the H^+ ion associated with the hydrolysis of formic acid H.COOH, also produced during the reaction. Calculations show that the presence of OH^- ions does not appear to alter the mechanism of formation of $CO_3^=$ ion from CN^- ion, *i.e.*, it proceeds, using oxygen, *via* the CNO^- ion.

An interesting observation made after the third day of the experiment was that the piece of gold, placed on the bottom of reaction vessels 6 and 10, and prob-

ably 2 also (Fig. 1), had become markedly discolored. By the sixth day, on gently shaking vessels 2, 6, and 10 (Fig. 1), thin flakes of gold were seen to become detached from the gold substrate, to float around in the solution for several minutes and then, apparently, to disappear. It was subsequently found that the flakes rejoined the mass of gold, *i.e.*, became reattached to the surface of the gold, which appeared to be "moulting." A bright substrate was visible under the peeling, dark-brown surface film.

Since vessels 2, 6, and 10 were exposed to air, which is required for the dissolution of gold in KCN solution, it was suspected that the dark-brown film observed was a hydrated form of insoluble Au_2O_3 (5) which possibly, is formed as an intermediate in the reaction path to the soluble $Au(CN)_2^-$ ion. After the period of 1 month, an examination of the surface of two different gold pieces by transmission electron microscopy could only detect Au and AuCN diffraction patterns. This failure to detect the diffraction pattern of Au_2O_3 has been commented on previously (5) and a similar problem has been encountered in this work.

Most of the observations and deductions made from the results of Experiment I, in which an aqueous KCN system was alone considered, can be applied to the results of Experiment II. Only those which are different are discussed further.

The production of NH_3 within the solutions does not appear to affect the *p*H of those solutions, as described for Experiment I. Possibly, the formation of the OH^- ion, which is a stronger base than NH_3, overshadows any effect that the NH_4^+ ion may have within the solutions.

Different levels of visible radiation appear not to affect any of the reactions occurring within the KCN/Au solutions, this being contrary, for reasons presently undetermined, to what was observed in Experiment I. The $CO_3^=$ ion concentration in solutions 1, 5, and 9 and 2, 6, and 10 (Fig. 1) are all similar (Fig. 8 and 10). It is also evident that the dissolution of gold in aqueous KCN is not dependent on the catalyzing action of visible radiation (Fig. 8 and 10), but depends solely on the presence of oxygen.

Once again, a drop in CN^- ion concentration within the solutions may be satisfactorily accounted for by a corresponding increase in the concentration of Au, $CO_3^=$ ions, and $H.COO^-$ ions. It would appear that the presence of metallic gold within the KCN solutions adds little more than an extra competitor, along with oxygen and water, for the CN^- ions.

Crystalline material was again observed in reaction vessels 2, 6, and 10 (Fig. 1) after about 10 days and, approximately a week later, the same material became visible in reaction vessels 3, 7, and 11 (Fig. 1). Presumably, it had the same composition and was derived from the same source, the Pyrex reaction vessel, as in Experiment I.

The results of both experiments indicate that visible radiation appears to play a minor role in the majority of reactions occurring within KCN and KCN/Au solutions. From the information gained above, further work was initiated on a less extensive scale to observe the effect of varying quantities of KOH on the reactions of KCN with water; of heat, KOH, and mineral acids on the stability of $KAu(CN)_2$ solutions; and of a low and a high concentration of KOH on the chemical reactions occurring in a solution of KCN and $KAu(CN)_2$.

The experiment performed to observe the effect of varying concentrations of KOH on the hydrolysis of KCN and the reactions of KCN with water and oxygen indicated immediately that the presence of KOH in concentrations greater than ~0.1M depressed the rate of hydrolysis of KCN, and hence the disappearance of the CN^- ion, in proportion to its concentration. A concentration of KOH of 0.1M or less did not appear to affect the hydrolysis of KCN at all, as shown by the following calculations.

A comparison was made between the rate of depletion of CN^- ions in a pure KCN solution, as described in Experiment I, and the rate of depletion in KCN/KOH solutions over the same time interval and under the same conditions. With no air present and over a period of 10 days, a pure KCN solution lost 68% of its CN^- ions. In comparable KCN/KOH solutions, the CN^- ion concentrations dropped (*a*) 68%, (*b*) 64%, and (*c*) 60% for KOH concentrations within the solutions of (*a*) 0.1M, (*b*) 0.5M, and (*c*) 1.0M. With air present and over the same time interval, a pure KCN solution lost 70% of its CN^- ions. In the KCN/KOH solutions, the CN^- ion concentrations dropped (*a*) 70%, (*b*) 64%, and (*c*) 59% for KOH concentrations of (*a*) 0.1M, (*b*) 0.5M, and (*c*) 1.0M.

A drop in CN^- ion concentration within these solutions was satisfactorily accounted for by a corresponding increase in the concentration of $H.COO^-$ and $CO_3^=$ ions, although, at KOH concentrations of 0.5M and 1.0M in those solutions exposed to air, the $CO_3^=$ ion concentrations after 10 days were found to be ~80% and ~120% higher, respectively, than in comparable pure KCN solutions after the same time interval. This increase was attributed to the absorption of CO_2 from the atmosphere. The calculations made above indicated that, as the concentration of KOH increased, so the formation of $CO_3^=$ ion followed the alternative route indicated in the following equation

$$2CN^- + 2H_2O + 2OH^- + O_2 \rightarrow 2CO_3^= + 2NH_3$$

Once again, the CNO^- ion concentration in any of the solutions did not exceed 0.2 g/liter and urea and the $C_2O_4^=$ ion did not form to a concentration greater than 0.5 and 0.2 g/liter, respectively, over the period of 10 days.

The experiment performed to verify the stability of $KAu(CN)_2$ solutions toward heat, alkali, atmospheric oxygen, and mineral acids showed that, for heated aqueous solutions of $KAu(CN)_2$ exposed and isolated from air, a quantitative analysis of the ionic components remained invariant over a period of 10 days.

Treatment of a sample of the above $KAu(CN)_2$ solutions with activated charcoal for ½ hr and subsequent reanalysis for gold showed no change in the gold concentration. This suggests that activated charcoal does not remove gold, as the dicyano complex, from a pure $KAu(CN)_2$ solution which contains no other ingredients.

In solutions of $KAu(CN)_2$ with 1M KOH, a quantitative analysis of the ionic components remained invariant over a period of 10 days, except for the $CO_3^=$ ion, the concentration of which increased from 0 to ~8 g/liter in the solution exposed to air and to 0.8 g/liter in the solution isolated from air. This increase was attributed solely to the absorption of CO_2 from the atmosphere. The above results indicate that $KAu(CN)_2$ solutions are indeed very stable to heat, alkali, and atmospheric oxygen and certainly show no signs of decomposition within the 10 days that the experiment was run.

However, on the addition of dilute HCl, H_2SO_4, or H_3PO_4 to pure unbuffered $KAu(CN)_2$ solutions, yellow AuCN slowly deposited from those solutions which were maintained at room temperature at or below a *p*H of about 4.5, and was first noticed after about 16 hr. The amount of AuCN deposited from the $KAu(CN)_2$ solution, acidified with H_3PO_4, appeared to be less than that observed in the $KAu(CN)_2$ solutions acidified with HCl and H_2SO_4. This could be expected, since H_3PO_4 is a weaker acid than either HCl or H_2SO_4 and therefore may not be able to decompose the $KAu(CN)_2$ as rapidly as the stronger acids. However, by the fifth day of standing, the deposit in the solution containing the H_3PO_4 had increased, while the others remained approximately constant.

A $KAu(CN)_2$ solution acidified with H_3PO_4 to *p*H 1 and left in the refrigerator at 1°C was opalescent after the 16-hr period with only some minor deposition of yellow AuCN. No change in the density of the deposit was observed even after 5 days at this temperature. Thus, the temperature of the solutions plays a large part in determining the rate of breakdown of the $KAu(CN)_2$ to insoluble AuCN. In fact, if any of the above solutions, when freshly prepared, are heated to 65° ± 5°C, AuCN readily precipitates within ½ hr.

The effect of the acids may be similar to the reaction of H_2SO_4 with NaCl, *e.g.*,

$$NaCl + H_2SO_4 \rightarrow NaHSO_4 + HCl$$

so,

$$KAu(CN)_2 + H_2SO_4 \rightarrow KHSO_4 + HAu(CN)_2$$

$$HAu(CN)_2 \rightarrow HCN\uparrow + AuCN\downarrow$$

The acid, $HAu(CN)_2$, is unstable and readily decomposes at elevated temperatures, depositing yellow AuCN and evolving HCN.

The experiment performed to observe the effect of varying concentrations of KOH on the chemical reactions occurring within heated aqueous solutions of KCN and $KAu(CN)_2$ provided results which, as expected, closely paralleled those obtained earlier in this paper. A concentration of, for example, 3 g/liter KOH did not decrease the rate of hydrolysis of KCN, although, at a concentration of 1M KOH, a slight decrease was noted. The gold concentration within the solutions did not change over a period of 10 days, confirming that it was still present as a soluble complex.

A drop in CN^- ion concentration within the solutions was again satisfactorily accounted for by a corresponding increase in the concentration of $HCOO^-$ and $CO_3^=$ ions, although, at the 1M KOH concentration in the solution exposed to air, the $CO_3^=$ ion concentration after 10 days was found to be ~180% higher than in a comparable pure KCN solution after the same time interval. This increase was attributed to the absorption of CO_2 from the atmosphere. From the calculations made above, it appears that, at the 1M KOH concentration, the formation of $CO_3^=$ ion follows the route

$$2CN^- + 2H_2O + 2OH^- + O_2 \rightarrow 2CO_3^= + 2NH_3$$

The CNO^- ion concentration in any of the solutions did not exceed 0.2 g/liter and urea and the $C_2O_4^=$ ion did not form to a concentration greater than 0.5 and 0.2 g/liter, respectively, over the period of 10 days.

Conclusion

In aqueous KCN solutions, isolated from air and maintained at 70°C, the KCN is hydrolyzed to form HCN, which then further reacts with the water to form ammonium formate. This reaction, which is a pseudo first-order reaction with an activation energy of ~24 kcal $mole^{-1}$ and a half life of ~6.5 days, is unaffected by different levels of visible radiation but its rate is much reduced at 30°C.

In aqueous KCN solutions, exposed to air and maintained at either 30° or 70°C, not only is the KCN hydrolyzed, as explained above, to form eventually ammonium formate, but also the CN^- ion reacts directly with atmospheric oxygen to form, *via* the CNO^- ion, $CO_3^=$ ions. This latter reaction appears to be accelerated by visible radiation and by raising the temperature from 30° to 70°C.

The *p*H of aqueous KCN solutions all remain constant at ~10.3, while a Kjeldahl test for total nitrogen and calculations based on the concentrations of reactants and products indicate that all major components of the solutions have been detected and analyzed for.

In aqueous KCN solutions, urea, the CNO^- and $C_2O_4^=$ ions do not form to a concentration greater than 0.5 g/liter and the NH_4^+ ion is expelled eventually from all solutions as gaseous NH_3.

Gold dissolves to any extent only in those KCN solutions which are exposed to air. Its dissolution is not dependent on the catalyzing action of visible radiation but solely on the presence of oxygen.

The reactions of KCN with water and oxygen within the KCN/Au solutions produce similar products to those found in pure KCN solutions.

The addition of KOH to a KCN solution in concentrations greater than ~0.1M depresses the rate of hydrolysis of KCN in proportion to its concentration. The reaction of the HCN produced and of CN^- ions with water and oxygen gives no new products other than those detected in a pure KCN solution. The effect of a 0.1M concentration or less of KOH on the prevention of hydrolysis of KCN solutions would appear to be negligible.

Solutions of $KAu(CN)_2$ are very stable to heat, alkali, and atmospheric oxygen and show no signs of decomposition. However, at room temperature, they slowly decompose over a period of several hours, depositing yellow AuCN at or below *p*H 4.5, while, at 65°C, a thick yellow deposit precipitates well within ½ hr. If the temperature is maintained at about 1°C, solutions of $KAu(CN)_2$ remain stable indefinitely at *p*H 1.

The addition of 3 g/liter KOH to a KCN/$KAu(CN)_2$ solution does not decrease the rate of hydrolysis of the KCN, although, at a concentration of 1M KOH, a slight decrease is noted. The stability of $KAu(CN)_2$ is apparently unaltered in its solutions with KCN and KOH. The reaction of the HCN produced and of CN^- ions with water and oxygen gives no other products but those detected in a pure KCN solution.

Activated charcoal treatment of any of the cyanide solutions does not remove the ionic impurities generated in these solutions by chemical decomposition.

Work is presently in progress to determine the effect of electrolysis on the chemical reactions occurring within aqueous KCN solutions. The results will be reported and discussed in a forthcoming publication.

Acknowledgment

The author wishes to thank Dr. M. J. Elkind for the frequent stimulating discussions, which aided in the interpretation of the results, and the encouragement given to this work. He also acknowledges the technical assistance given by E. W. Hobart, Jr., of Ledoux & Company, in the design of the sample analysis procedure.

Chlorates and Perchlorates Safety

Carl M. Olson*

Industrial Chemicals Division, Hooker Chemical Corporation, Niagara Falls, New York

ABSTRACT

More than 65 years of American production of sodium chlorate and its use have shown that this oxidant can be handled safely, or that misused it can be extremely hazardous. With any oxidizable substance, it can provide oxygen for fire, or even explosion, if ignited by heat, friction, or pressure unless kept wet. This applies to clothing, including gloves and shoes, buildings, equipment, lubrication, and materials. It is relatively innocuous on body contact, but can be fatally poisonous if ingested in quantities of ½ to 1 oz unless proper medical attention is given. Since it is a source of oxygen, fires involving it cannot be smothered but are extinguished by water. CO_2 snow may provide sufficient cooling to extinguish small fires. Fire blankets and dry powder extinguishers are ineffective.

Potassium chlorate manufacture in the U.S.A. started near the end of the 19th century. Sodium chlorate has been produced in Niagara Falls since 1902. By 1967 there were five U.S. producers of it. Domestic production of potassium perchlorate was begun in 1910. With the increasing number of producers and users, it is quite proper to review the hazards of chlorates and perchlorates and the precautions to be taken in order to work safely with them.

Sodium chlorate by itself is relatively stable; potassium chlorate even more so. Provided the properties are known and given due consideration, chlorates can be and are handled safely. It is very important that this be understood by all persons involved.

There are several good references on chlorates safety. Two are the Manufacturing Chemists' Association Safety Data Sheet SD-42, Sodium Chlorate (1952); and the National Safety Council Data Sheet D-371 (1967). American Potash & Chemical Corp. has a 10½-minute movie in color on the subject.

Walter P. Huhn of American Potash & Chemical Corp. presented a paper covering hazards of sodium chlorate and safe procedures to be used at an ASTME meeting in New York, October 26, 1967. It is a concise, well-organized, up-to-date treatise worth careful study. J. S. Sconce of Hooker Chemical Corp. gave a similar paper at that meeting. Material was drawn from both, as well as forty years of experience with chlorates and perchlorates, in preparing this paper.

Sodium chlorate, $NaClO_3$, is a moderately hydroscopic, white crystalline oxidant, which melts at 248°C and starts to decompose at about 300°C liberating oxygen. Decomposition is exothermic and self sustaining above a critical temperature. The large amounts of oxygen released in case of fire can cause burning of combustible material to be explosively rapid.

Many substances catalyze the thermal decomposition and some form explosive mixtures with sodium chlorate. Such mixtures, particularly those involving organic materials, such as alcohols, solvents, sugars, sawdust, paint and painted metals, lint, vegetable dusts, and oils and greases, or with inorganic materials, such as sulfur, sulfides, ammonium compounds, phosphorus, cyanides, acids, metallic oxides, or reducing agents of any sort, may be extremely sensitive to shock, friction, or heat, and burn or explode spontaneously. Paper, wood, cloth and leather impregnated with chlorate by contact with an aqueous solution are dangerously combustible when dry and may be ignited by friction or heat.

Alkaline chlorate solutions do not exhibit strong oxidizing properties. As the *p*H decreases, the oxidizing activity of chlorate solutions increases. Concentrated acid solutions are vigorous oxidizing agents as a result of formation of chloric acid, a powerful, unstable oxidizing acid known only in solution. In the cold, solutions containing up to about 30% $HClO_3$ are stable in the absence of organic matter and reducing agents. More concentrated solutions decompose spontaneously with the formation of oxides of chlorine, chlorine, oxygen, and perchloric acid. With oxidizable matter, the reaction may be violent, especially at elevated temperatures. Also, chlorine dioxide is an explosive gas in certain concentrations.

Handling Precautions

Clean work clothing must be worn each day and laundered afterwards. It must not be taken home. Clothing wet with chlorate solution should be changed before drying. No smoking can be permitted in chlorate work areas or while wearing work clothes. Deluge-type safety showers should be provided. Some prefer jump tanks (a bath tub old or new, or its equivalent) that will more quickly quench burning trouser legs. Salt can be added to this emergency water to prevent freezing in winter. Rubber shoes must be worn and linings rinsed, if contaminated. Only rubber or rubberized gloves are permitted, and without cloth wristlets. Avoid skin oils, greases, or protective creams. Shower before leaving work.

Clothing fires from smoking have occurred. One October 23, 1967 nearly cost a young worker in Michigan his life. He was permitted to work without a rubber apron or rubber shoes, *etc.* Uncomfortable because his clothing became stiff from dried chlorate solution, he went to the locker room to change. He lit a cigarette, his clothing ignited and he suffered burns on 52% of his body. Warnings had not been heeded or enforced.

A worker with dry chlorate dust on one sleeve used an abrasive wheel grinder in a nearby shop. A spark ignited the sleeve. He convalesced 40 days and has a badly scarred arm. Several farm workers have suffered burns from ignition of chlorate-contaminated clothing, one fatally in 1967. These are but a few cases, all unnecessary if the available information had not been ignored.

Sodium chlorate is not irritating or very toxic by contact or by inhalation. Dust masks are worn only if dusting is excessive. Ingestion of 15-30g may be fatal as it changes hemoglobin to methemoglobin, but August 5, 1957 a research physician at the Buffalo University Medical School survived a measured 40g dose taken by mistake instead of sodium chloride. He was saved by an artificial kidney and massive transfusion of 18 pints of blood, and apparently suffered no ill after-effects. [*JAMA* **180**, 1133 (1962).]

Storage

Sodium chlorate should not be stored close to flammable materials, reducing agents or other substances hazardous with it. Buildings in work areas should be

* Vice-Chairman, National Safety Council Chemical Section.

fireproof. Wood becomes dangerously combustible, so should not be used in any chlorate area. (Treatment with sodium silicate water glass beforehand and periodically thereafter may afford some protection). Chlorate-contaminated wood may ignite from pressure or friction. It must not be left where it could be taken or used, but should be disposed of by burning.

Spillage should be picked up for reuse or disposal, which may be sewering with lots of water. If this is not permissible, bury it in an isolated area away from trees as it is a herbicide. Wash drums with water and carefully burn any paper liners.

Discharge dust ventilating systems to a water scrubber designed for easy flushing with water and clean frequently.

Equipment

Dust control or prevention of contamination by chlorate solution is particularly important where motors are used, since mixtures of sodium chlorate with oil or grease are violently explosive. Hooker now uses totally-enclosed fan-cooled ball bearing type electric motors, not oil-lubricated bearings. Once or twice a year, the end bell is taken off and the area around the fan and the air-cooling passages is cleaned. When motors with outside bearings were used in dusty locations, they were completely protected by enclosure in clean air pressurized cabinets. Open motors in other chlorate service had a steel-plate deflection shield at the back to stop any flame from jetting out in case the motor caught fire. An open motor explosion at a rotary drier blew part of roof off and steel window frames out although doors were wide open. Chunks of motor went through remaining roof and brick wall. About the mid-forties, an explosion of a totally-enclosed motor in chlorate service was reported. There were fatalities.

In his paper, Walter P. Huhn of American Potash & Chemical Corp. says, "TEFC motors with sealed bearings (metallic seals) are acceptable, but the bearings should be cleaned and packed before use with one of the recommended lubricants, fluorolube or halocarbon or Kel-F, and should be changed once a year, whether they need it or not, in areas where contamination is possible. Extreme care should be taken in removing the bearings. They should be pressed off with a steel safety shield between them and the mechanic: bearings sometimes explode if tapped with a hammer. After removal, the bearings should be washed free of any sodium chlorate that may have entered them."

The same hazard exists for pumps and bearings. At Hooker, chlorate liquor pumps have braided Teflon packing surface-lubricated with fluorolube (halocarbon or Kel-F could be used) to be graphite-free and processed for oxygen service. As a second precaution, there is in with the packing, a lantern ring for a flow of water of 2-5 gal/hr measured by a purge meter to maintain a pressure of about 5 psi above the chlorate liquor pressure on the seal.

Shaft flingers keep chlorate solutions from creeping into bearings. A fluorinated lubricant should be used for bearings exposed to chlorate dusts or solutions. And be certain that it is not contaminated with other lubricants. Aluminum (and possibly magnesium) seals, sleeves, and cages must not be used as the fluorinated lubricant may break down and explode if finely divided aluminum and other active metals are present. There are some differences of opinion as to whether fluorinated lubricants are always suitable for high speed applications. Where oxidizable lubricants are still used, they are applied frequently to flush out any contaminated lubricant. However, channeling may permit some contaminated lubricant to remain. Samples of such lubricant are analyzed periodically for oxidants. Bearings should not be run hot and should be armored against explosions by at least ¼-in. steel plate with enough space to contain an explosion.

Several incidents have demonstrated the power of minute quantities of chlorate or perchlorate closely confined with oxidizable material. In 1925 while cleaning an inboard bearing of the grinder he had been operating, a man was decapitated by explosion of the bearing. A change was then made to outboard bearings heavily armored. This and other incidents show the importance of proper bearings procedures.

Special procedures are used repairing bearings and pumps as for all work on chlorate equipment. Hot water or wet steam are used to thoroughly clean before starting work in a special area. If heat is to be applied to a plate-patched steel plate, it is first drilled with running water on the drill to provide a vent for any oxygen released from chlorate inside by thermal decomposition.

The National Fire Protection Association reported seven chemical plant fires in 1957 that each resulted in a loss of more than $¼ million. One of these was a bucket elevator explosion in a chlorate plant. A rubber belt carrying 90 aluminum buckets had jammed with the bottom drive pulley still turning. Undoubtedly it was grinding off rubber and heating the belt. There was an explosion. No trace of the 90 lb of rubber belt was found, and only 4 of the 90 aluminum buckets remained. Aluminum had splattered on the walls and "ingots" of it were on the floor under chlorate. Although rubber belt bucket elevators had been in use at Niagara Falls more than 50 years, bronze or malleable steel chain has been used since for all Hooker chlorate elevator installations.

Fire Fighting and First Aid

Since chlorate provides the oxygen, fires with it cannot be smothered, so dry powder is ineffectual. Carbon dioxide may provide sufficient cooling to extinguish a small fire, but water fog or water usually has to be employed on fires involving chlorate, even electrical fires as it has been found that a stream of tap (pure) water is practically a nonconductor an inch away from a 220v electrical power supply. This is not true of a soda-acid extinguisher stream. Fire blankets are of no use.

For burns, use the cold water treatment as speedily as possible and for as long as necessary. Serious burns should be referred to a physician for treatment. Apply no medications beforehand; only the cleanest cold, moist cloth available.

For ingestion, avoid all stimulants including alcohol. Give an emetic and call a physician immediately. Wash out stomach and follow with demulcent drinks. Keep patient warm. Obtain blood electrolytes immediately and apply adequate intravenous therapy. If large amounts of chlorate have been ingested, it may cause renal failure and require an artificial kidney and transfusions. Such occurrence should be extremely rare.

Manuscript submitted July 22, 1968; revised manuscript received September 15, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 273.

DIVISION NEWS

Battery Division

The Battery Division held its annual business meeting at the Montreal Meeting of the Society on October 8, 1968. The luncheon was well attended by Division members and guests.

The Battery Division Research Award was presented to Dr. Donald Tuomi for his work on the nickel electrode. Dr. Joseph C. White presented a Past-Chairman Pin to Dr. J. J. Lander, honoring his service as Division Chairman.

An election of officers was held for the next two-year term.

The results are as follows:
Chairman—Paul C. Milner, Bell Telephone Laboratories, Inc., Murray Hill, N. J. 07974

Vice-Chairman—Alvin J. Salkind, ESB, Inc., Yardley, Pa. 19068

Secretary-Treasurer—Howard R. Karas, Aerospace Division, Clevite Corp., 540 E. 105 St., Cleveland, Ohio 44108

Howard R. Karas
Secretary-Treasurer

Corrosion Division

The Corrosion Division held its annual business and luncheon meeting in Montreal on October 8, 1968. The following officers were elected to serve the 1968-1969 term.

Chairman—Michael J. Pryor, Olin Mathieson Chemical Corp., Metals Research Division, 275 Winchester Ave., New Haven, Conn. 06511

Vice-Chairman—Z. Andrew Foroulis, Esso Research & Engineering Co., P.O. Box 101, Florham Park, N. J. 07932

Secretary-Treasurer—J. Paul Pemsler, Ledgemont Laboratory, Kennecott Copper Corp., 128 Spring St., Lexington, Mass. 02173

Henry Leidheiser, Jr.
Past Chairman

SECTION NEWS

Boston Section

The sixty-sixth meeting of the Boston Section was held on September 17, 1968 at the Ledgemont Laboratory of The Kennecott Copper Corp., Lexington, Mass.

The speaker was Mr. Mark Nigberg, Market Promotion Manager of Digital Equipment Corp., Maynard, Mass. Mr. Nigberg spoke on "The Application of Dedicated Computers to Laboratory Instrumentation" and pointed out that during the past few years small general purpose computers have become increasingly important tools in analytical laboratories as new instruments lead to increased data rates and more stringent limits of accuracy. In the course of his talk Mr. Nigberg surveyed the areas in which small dedicated systems are currently used and explained some potential applications to laboratory systems.

Raymond G. Donald
Secretary

Chicago Section

The Chicago Section met on October 3, 1968 at the Chicago Engineers Club to hear Prof. E. N. Leith, University of Michigan, Ann Arbor, Mich., present a talk on "Modern Holography."

The following is an abstract of his talk.

The basic theory of holography was presented followed by a discussion of recent ramifications and potential applications. The discussion included multicolor holography, holographic interferometry, data storage on thick recording materials, holomicroscopy, holography at nonoptical wave lengths, "white light" holography, coherence requirements, and holography with incoherent sources as well as transmission of holographic data and techniques for bandwidth reduction.

On November 14 the Section heard Dr. R. P. Frankenthal, U. S. Steel Corp., Monroeville, Pa., present a talk on "Origin of Passivity in Iron-Base Alloys."

The following is an abstract of his talk.

The phenomenon of passivity was discussed in detail for the iron-chromium alloy system. It was shown that two distinct, potential-dependent films are formed during the passivation process. The electrochemical properties of these films were examined at various potentials throughout the passive potential region and changes that occur in these properties were discussed in relation to the effectiveness of the films as passivating agents. The applicability of these results to other systems was also considered.

Metropolitan New York Section

The Metropolitan New York Section held its first meeting of the 1968-1969 season at the Stonehall Inn in New York City with members and guests attending the lecture on "New Aspects of Leclanche Cells Research" presented by Prof. Lou Rozeanu of the Technion Israel Institute of Technology. He reported that comparative tests, of amalgamated zinc vs. pure zinc surfaces, showed that the amalgamated zinc had a higher emf, was more reactive chemically, and gave maximum performance at 4.0 to 4.25 mg Hg/sq in. Impurities in the zinc, such as lead, cobalt, copper, iron, nickel, and antimony were harmful since they were insoluble in mercury. Professor Rozeanu reported that he had developed an accelerated corrosion test for amalgamated zinc, based on rotating a sleeve of zinc at 20,000 rpm for approximately 24 hr in dilute hydrochloric acid, to simulate the results obtained over a period of 6 months of storage.

State of the Art of Electrostatic Separation of Minerals

James E. Lawver

Mines Experiment Station, University of Minnesota, Minneapolis, Minnesota

Man's knowledge of electrification of minerals dates back to at least 540 B.C. when Thales of Miletus observed that rubbed amber had the power of attracting small objects. Although the mechanism of Thales' observation of frictional electrification, or triboelectrification as it is now called, is still shrouded with uncertainties, today's engineers are usually able to prevent unwanted static electrification and are often able to use electrical effects as a means of concentrating solids. Materials that have a high surface-area-to-mass ratio readily respond to even weak electrical fields. This is probably the reason that the first electrical concentrator patented in the United States (1880) was a device for purifying ground cereal (1). In 1881 a crude machine (2) was built to concentrate gold ore, and in 1892 Thomas A. Edison also devised an electric machine (3) for the concentration of gold, a sketch of which is shown in Fig. 1. None of these machines was used industrially.

The first commercial process for treating minerals was started in 1908 at Platteville, Wis. (4). This plant, operating under the patents of C. E. Dolbear (5) and the Huff Electrostatic Co. (6), was used to produce lead and zinc concentrates. The process was called the "electrostatic process"—a term often still used for any electrical separation of solids, although such separations rarely are truly static in nature. By about 1914 the electrostatic process had gained considerable favor in the metallurgical industry and was accepted as an industrial process for mineral concentration. It was successfully used on a small scale throughout the world, both as a single process and in conjunction with wet gravity processes. The popularity of concentrating minerals by the electrostatic process, however, was short lived, because about 1912 froth flotation was introduced in the United States as a commercial process. The new flotation process offered numerous advantages over the electrostatic process with respect to both selectivity and cost. As a result, during the following years the flotation process grew with fabulous rapidity, and the electrical method of concentration began to be regarded as little more than a metallurgical curiosity. It was the titanium shortage during World War II that sparked a new interest in the possibility of utilizing electrical separation, and numerous commercial applications using conductivity-type separators were installed to concentrate titanium-bearing, heavy mineral beach sands. Since that time electrical concentration of minerals has steadily increased. Now virtually all physical beneficiation processes producing titanium and tin minerals throughout the world are using conductivity-type electrical concentrators known as "high tension" (7) machines. In 1965 the world's largest electrical concentration plant was installed at Wabush Mines, Que., Canada, to reduce the silica content of a specularite gravity concentrate from 8% to less than 3%. This plant has a "high tension capacity" of over 6 million tons/yr and enjoys a high tension operating cost of about 5¢/ton of dry feed. Figure 2 is a photograph of this modern high tension plant. At present the free world produces about 13 million tons/yr of mineral concentrates (8) by electrical separation. The bulk of this tonnage comes from the beneficiation of iron ore and from the concentration of heavy mineral beach sands.

General Principles

The basic principle of electrical concentration is simply the utilization of body forces acting on charged or polarized solids in an electric field such that a selective sorting of the different species can be ef-

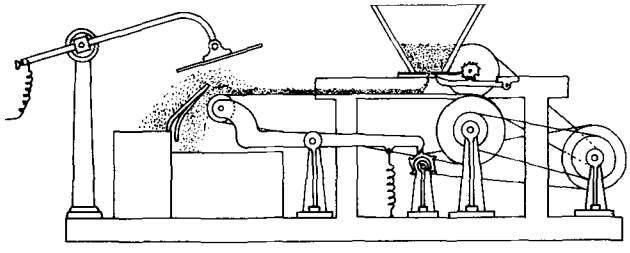

Fig. 1. Thomas A. Edison's electrostatic separator (patented 1892).

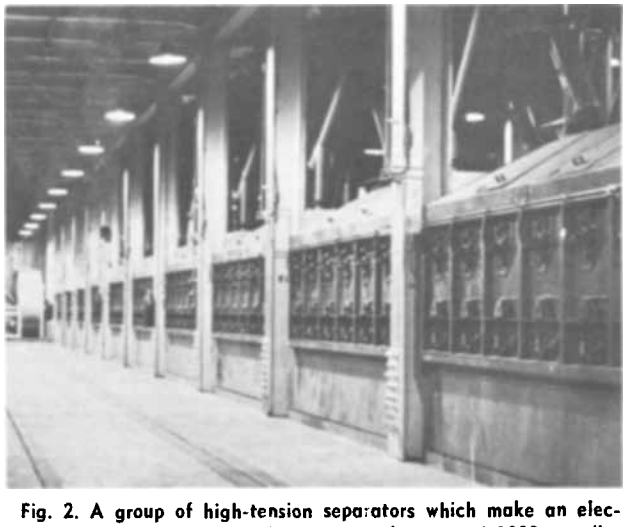

Fig. 2. A group of high-tension separators which make an electrodynamic concentration of iron ore at the rate of 1000 tons/hr.

fected. Both a-c and d-c fields are used at field gradients ranging from about 3 x 10^3 v/m up to the breakdown strength of air (about 3 x 10^6 v/m). Commercial separators use high-voltage power supplies ranging from 5 x 10^3 to 250 x 10^3v. The power requirement is small—rarely exceeding 0.15 kwhr/ton of feed.

The electric body force acting on solid grains in an electric field $\vec{E}$ is:

$$\vec{F}_e = Q\vec{E} + (\vec{p} \cdot \nabla)\,\vec{E}$$

$\vec{F}$ = newtons
$\vec{p}$ = electric moment—coulombs/m^2
Q = total charge on the mineral—coulombs
$\vec{E}$ = electric field—newtons/coulombs

The art and science of electrical concentration depend largely on the ability *selectively* to charge one species differently than the others in the mixture. Once this has been accomplished, they can readily be sorted in an electric field. The important charging mechanisms used commercially for d-c separators are: (*a*) charging by corona discharge; (*b*) charging by conductive induction; and (c) charging by contact electrification. A-C separators usually depend on polarization and shape phenomena to effect a separation.

Charging by corona discharge is effected by passing the solids to be charged through an intense corona glow such as is obtained from needle points or a fine wire charged to a potential exceeding the breakdown strength of air. Special electrodes have been developed for preventing spark-over when treating combustible materials such as coal and grains (9). The corona discharge machine depends almost entirely on the intense electrification caused by a corona wire. Nevertheless, there is a slight tendency to charge conductive particles by the mechanism of conductive induction. The total charge received by conductive induction, however, is very, very slight compared to the corona discharge and is usually unimportant and can be omitted from all calculations.

Charging by conductive induction is accomplished by allowing solids to contact a grounded conductor while the grains are in an electric field whence the conductive particles become charged opposite to the grounded conductor. This type of machine never uses a corona discharge—in fact, the electrodes used are always rather large in diameter and caution is always taken to prevent any sharp edges that might result in corona discharge.

Charging by contact electrification is the same mechanism as is demonstrated by the famous experiment of rubbing hard rubber with catskin. Dissimilar surfaces will always electrify to some extent simply by particle-particle contact. It is sometimes possible to predict the sign of the charge produced from contact electrification on the basis of the band theory of solids. In the usual case, however, contact electrification is controlled by surface films often of unknown composition. For example, quartz and diamonds will strongly electrify by contact electrification at room temperature. According to the band theory, the energy gap for either mineral is such that electrification by contact should be negligible. In this case the transfer of charge is certain to be due to surface films.

Mechanisms (*a*) and (*b*) are invariably used to separate good conductors such as ilmenite, rutile, galena, pyrite, specularite, *etc.*, from poor conductors such as quartz, zircon, monazite, diamonds, *etc.* Mechanism (*c*) is usually used to separate nonconductors such as phosphate rock and quartz from each other.

Commercial Machines

There are virtually hundreds of patents describing various configurations of electrodes and feeding arrangements for making an electrical separation of a mixture of solids. There are, however, only four general types of machines that are used commercially. These are shown in Fig. 3.

The first machine is the corona discharge separator (often called the high tension machine). If a mixture of solids consists essentially of good electrical conductors and good electrical insulators, a high tension machine can separate the conductors from the insulators very efficiently and inexpensively.

Unfortunately, there is very little information in the literature regarding the electrical conductivity of solids. Some insight regarding the conductivity of minerals can be obtained by reference to a Bureau of Mines publication (10) in which 95 minerals have been classified according to the weight per cent that is collected as a conductor (in an electrostatic separator) as a function of the temperature at which the separation was made.

From the standpoint of high tension separation, the criterion used to distinguish conductors from

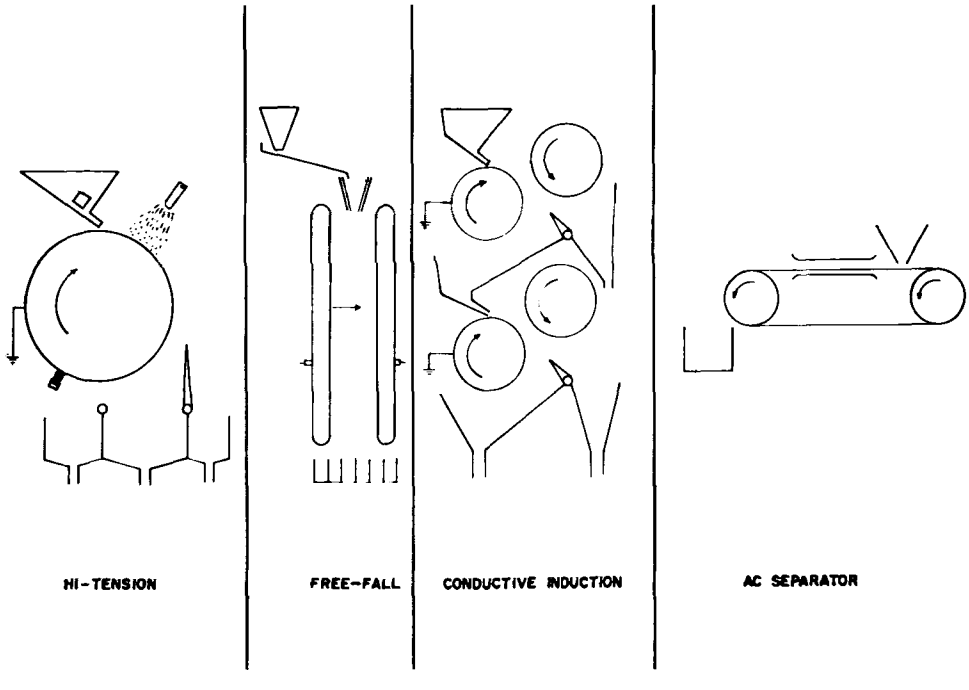

Fig. 3. Common commercial electrical concentrators.

insulators is the relaxation time T_r (11). Relaxation time is defined as the time required for an initial charge density ρ_o to decay to $1/e$ of its original value.

$$\rho = \rho_o e^{\frac{-\sigma}{\epsilon} t}$$

ρ_o = initial charge density
e = charge density at time t
σ = conductivity
ϵ = permittivity

For example, T_r for pyrite is about 10^{-3} sec, while T_r for quartz is about 10^6 sec.

In the high tension machine, conductors and insulators alike are charged as they pass through the corona zone. The limiting charge is a function of the particle radius, the relaxation time, time in the field, and to some extent the permittivity of the particle (12). Particles having a small relaxation time (conductors) share their charge with the grounded rotating cylinder and are thrown free of the cylinder while particles with a large relaxation time (insulators) are held to the cylinder by their image force and must be removed by a scraper. Figure 4 is a photograph of a high tension machine showing the corona discharge.

The capacity of high tension concentrators depends on the particle size distribution and on the electrical properties of the species that are to be separated. The normal range of particle sizes that can be handled is from a coarse value of about 1.5 mm diameter to a fine limit of about 0.03 mm diameter. A good rule of thumb is to estimate capacity at about 175-300 lb/hr/in. of rotor for a particle size distribution that is essentially minus 1 mm plus 0.2 mm. As the mean particle diameter is decreased, the capacity falls rapidly. The capital cost for high tension equipment varies from about $1200 to $1500/ton/hr/pass.

The second most important (conductive-induction) machine (Fig. 3) is a typical twin electrode concentrator. This type of separator can be used to separate conductors from insulators utilizing "charging by conductive induction" or it can be used to separate dielectric particles that have become charged by particle-particle contact or by particle-rotor contact. There are many models available, each with special features of feeding mechanisms, dust control, and

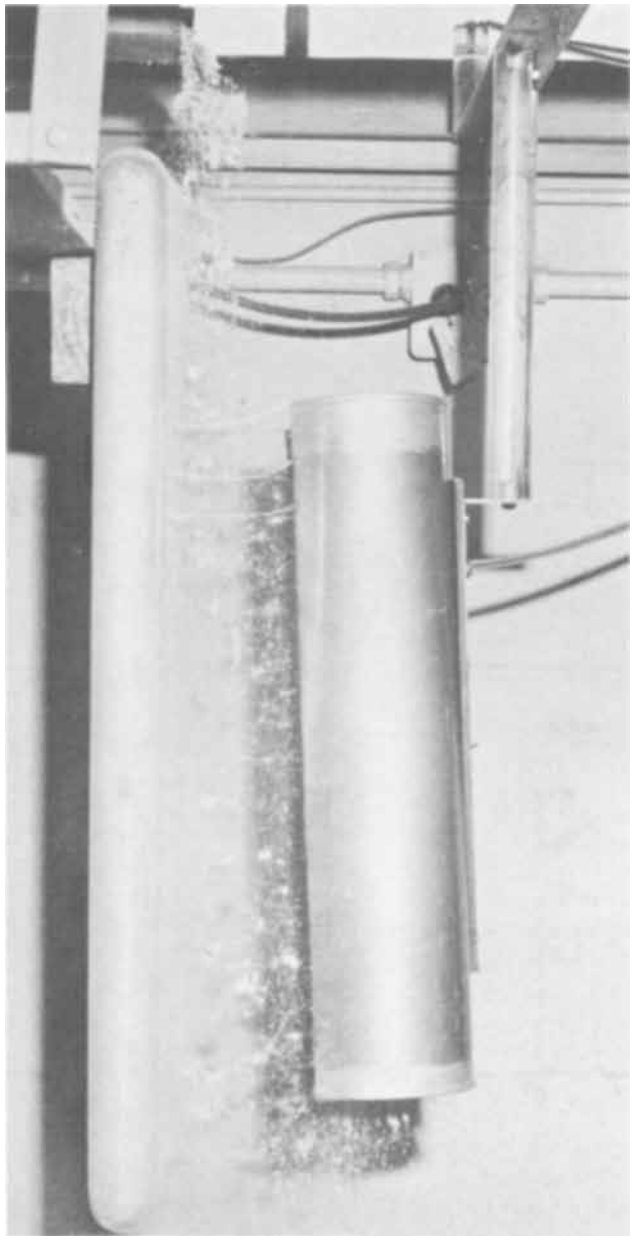

Fig. 6. Carpco Free Fall separator used to concentrate asbestos.

some even having special rotor composition (13) to enhance particle-rotor contact electrification. Figure 5 is a photograph of a Bullock-Simpson electrostatic separator. This is a double-face unit with 5-ft feed rolls for 4 stages of separation. The capacity and capital cost vary widely depending on the material being treated. The approximate capacity ranges from about 85 lb/hr/in. of electrode for fine-grained material to 170 lb/hr/in. of electrode for coarse-grained material. The power cost is negligible.

The free fall machine is used to provide an electric field for separating particles that have become charged by contact electrification. The limiting charge in contact electrification is the electrical breakdown strength of air which limits the charge density on the solids to about 26.6×10^{-6} coulombs/m^2. Several potentially important examples of electrostatic separations based on contact electrification are: separation of Florida phosphate rock from silica sand (14), separation of halite from sylvite (15), and separation of quartz from feldspar (16). The sign and magnitude of the charge obtained from contact electrification depend not only on the electrical properties of the bulk of the material but also on trace quantities of impurities that may be present in the surfaces. It is, thus, impossible to form a meaningful triboelectrification series for minerals since the sample history greatly influences its contact electrification properties. Selective contact electrification is also possible by the addition of a suitable surfactant or cleaning agent (17, 18). The free fall separator has a capacity of about 200 lb/hr/in. of electrode when used to concentrate phosphate rock or feldspar ores. Figure 6 is a photograph of a Carpco Free Fall separator used to concentrate asbestos.

Miscellaneous Separators

There are a variety of a-c machines that have been used for special purposes (19-21) but so far they have not been widely accepted for commercial use. Separations made using a-c fields depend on the fact that conductive and high-permeability particles will oscillate with the field reversals, while nonconductive particles remain stationary (19, 20). Hatfield (22) devised a method for separating minerals on the basis of differences in dielectric constant, but to date the method is restricted to laboratory use since it required the use of dielectric fluids whose cost precluded commercial use.

Applications

At the date of this writing, high tension concentration of iron ore, heavy mineral beach sands, and tin ore accounts for about 95% of the estimated 13 million tons/yr of concentrates produced by electrical methods. The success of the Wabush Plant for concentrating iron ore has aroused considerable interest in the iron and steel industry, and it is likely that corona discharge machines will play an increasingly important part in producing super iron ore concentrates (containing less than 0.5% silica) that can be used for direct reduction processes. Table I lists ten typical applications of the electrical separation processes used throughout the world.

Table I. Ten typical industrial separations

	Mineral combination	Surface treatment	Usual charging mechanism
1.	Specular hematite-quartz	Drying	Corona discharge
2.	Ilmenite and rutile from poorly conducting heavy mineral gravity concentrates (zircon, monazite, *etc.*)	Scrubbing to remove organic slimes Drying (Reducing roast at 650°C)	Corona discharge
3.	Zircon (cleaning)—ilmenite Rutile	Drying	Corona discharge
4.	Cassiterite—scheelite	Drying	Corona discharge or Conductive induction
5.	Feldspar—quartz	Drying HF vapors	Contact electrification
6.	Halite—sylvite	Heating to 340°C or Drying plus 1 lb/ton of fatty acids	Contact electrification
7.	Pyrite—coal	Drying	Corona discharge or Conductive induction
8.	Coal—shale	Humidity control	Corona discharge or Conductive induction
9.	Diamonds—silica	Wet scrubbing in NaCl pulp Drying	Conductive induction
10.	Dry foods and drugs from trash and rodent feces	Drying	Conductive induction

Secondary Silver-Zinc Battery Technology

L. Gaines

Tyco Laboratories, Inc., Waltham, Massachusetts

ABSTRACT

A review of the current status of silver-zinc battery technology is presented as part of an attempt to organize, on a fundamental basis, the varied design improvements developed as a result of empirical studies. Past efforts to improve the secondary silver-zinc system have been devoted to (*a*) stabilization of the zinc electrode structure, (*b*) control of zinc dendrite growth, (*c*) increasing the utilization of the silver electrode, (*d*) separator improvements, and (*e*) development of sealed batteries. Improvements that have been suggested in these areas are often mutually exclusive and interdependent. Clarification of the fundamental processes involved is necessary for the creation of an optimum battery configuration.

The conversion of the primary silver-zinc system, as it was originally devised some 25 years ago, into a high energy density rechargeable energy storage device has been a slow and not entirely successful process. Although a high level of performance (in the vicinity of 100 w-hr/lb) is obtainable in primary applications, currently available secondary silver-zinc cells capable of extended cycle life possess energy densities below those of alternative systems which although possessing a lower energy density, are better able to retain their initial capacity on continued cycling.

Past research, both basic and applied, has elucidated many of the problems inherent in the silver-zinc system, and in addition, has indicated methods for their control.

Many of the difficulties in the design of high energy density silver-zinc batteries relate to the solubility of zinc oxide, the anodic discharge material of the zinc electrode, and of silver oxide, the active material of the positive electrode. The high solubility of ZnO causes a gradual degradation of the zinc electrode structure on repetitive cycling at high depths of discharge. Due to the loss of effective surface area, the zinc may plate back on the electrode in a highly structured dendritic form which tends to grow through the cell separators.

The partial solubility of the silver plate ($\approx 10^{-4}$m) allows diffusion of the Ag(I) ion to the zinc electrode where it is reduced to metallic silver causing self-discharge of the cell. In order to prevent the diffusing silver ions from reaching the zinc electrode, and at the same time to prevent deposited zinc from short circuiting the battery plates, separators are required between alternate electrodes. Historically, these separators have been based on cellulosic materials. These materials are satisfactory for limited cycle life, but improved separators have been developed which are more resistant to oxidation by the Ag(I) ions which eventually reduce the effectiveness of cellophane membranes.

In addition to the development of improved separator systems, past efforts to improve the secondary silver-zinc system have been devoted to (*a*) stabilization of the zinc electrode structure to prevent the loss of surface area due to agglomeration of the zinc particles, (*b*) elucidation and control of the conditions which lead to zinc dendrite growth, (*c*) improving the utilization of the silver electrode to assure maximum performance, and (*d*) development of sealed batteries.

Research into these areas of silver-zinc technology, funded principally by DOD and NASA, has been reported in the contract literature. This review attempts to summarize these experiments, and to integrate the results presented with the basic electrochemical and physical principles of battery operation. Since many of the references cited are subject to distribution limitations, this review has the additional purpose of making their contents more readily available in the open literature.

Zinc Electrode Technology

During the past five to ten years a considerable amount of information has been obtained on the cycling characteristics of the silver-zinc system. These tests have been conducted under varying conditions of temperature, depth of discharge, rates of charge and discharge, electrode structure, separator systems, and caustic concentration. The studies indicate that, for the most part, cycle life and performance of silver-zinc cells are limited by the capabilities of the zinc electrode. The negative electrode limits cycle life because of changes in its physical characteristics (particularly porosity) and/or because of the formation during charge of metallic dendrites which can penetrate the cell separators. These mechanisms result in an inability to accept charge efficiently which, in the case of sealed cells, causes a rapid pressure increase due to hydrogen accumulation.

The extent to which each of the above failure mechanisms occurs in a given system depends in large measure on the individual cycle regime and cell structure. Research programs carried out over the period in question have succeeded in large measure in correlating the above failure modes with the electrode reactions occurring at the surface. In addition, empirical studies have indicated several ways in which electrode performance can be significantly improved and cycle life extended.

Theoretical studies—The most recent and comprehensive survey of the electrochemical reactions of the zinc electrode is provided by Dirkse (1). Although the details of the charge transfer reaction are not established, the anodic or discharge process is generally described in three steps:

(*A*) The zinc is oxidized to solid ZnO or $Zn(OH)_2$.
(*B*) The ZnO or $Zn(OH)_2$ dissolves in the electrolyte to eventually yield $Zn(OH)_4^=$.
(C) The electrolyte becomes saturated with zincate, a ZnO or $Zn(OH)_2$ film forms on the surface, and the electrode passivates.

The rate of formation of the oxidized zinc species in step (*A*) is a simple function of current density. Even though the exact composition of the discharge product is unknown, it is apparent that its solubility in KOH is much higher than any of the stoichiometric zinc oxides currently known, since zinc can be anodically dissolved in KOH which has been presaturated with ZnO. The discharge product of the reaction eventually precipitates out as stable ZnO although the rate of this process appears to be slow (1).

The onset of electrode passivation on discharge is a function of electrode surface, caustic concentration, electrolyte volume, and perhaps time. However, at normal temperatures, anodic passivation is not usually the limiting factor in designing cells with zinc electrodes. Properly fabricated porous zinc electrodes,

formed by reduction of compacted zinc oxide of small particle size, are capable of utilizing in excess of 70% of the zinc present (2). It is also well established that this capability is not long maintained under repetitive discharges and charges.

The cathodic behavior of zinc has also been effectively summarized by Dirkse (1). The generally accepted mechanism involves a two-step process:

$$(i) \quad Zn(OH)_4^{=} \rightarrow Zn(OH)_2 + 2\,OH^-$$

$$(ii) \quad Zn(OH)_2 + 2e^- \rightarrow Zn + 2\,OH^-$$

In practical alkaline batteries with zinc electrodes, the problem has been two-fold: loss of capacity on continued cycling and penetration of the cell separators by deposited zinc.

Capacity loss on cycling is usually attributed to an agglomeration of the zinc with a loss in effective surface area as the zinc is deposited from solution according to the above reactions, and to a displacement of active material towards the bottom of the electrode. These two effects are usually denoted by the terms "shape change" and "shedding."

The conditions which lead to and control the growth of zinc dendrites have recently been elucidated (3, 4). In plating zinc from alkaline zincate solutions, it is observed that the deposit can range from short fine whiskers or sponge at low current densities to the longer more highly structured type of branched, dendritic deposits at higher current densities or greater overpotentials. The type of deposit produced is related to the amount of free zincate available at the electrode surface for reduction. If sufficient zincate is present close to the electrode surface, *i.e.*, under conditions of low current density (1 to 5 ma/cm^2), or sufficient agitation is provided to support higher currents, the zinc is deposited under activation control. The growth of this spongy zinc is thus confined to the zinc electrode. There is no tendency to penetrate the separator since sufficient zinc is available for deposition from the free electrolyte.

If the current density is increased or the amount of free zincate surrounding the zinc electrode is reduced, growth of zinc proceeds under diffusion-limited conditions. Zinc dendrites may now enter and grow through (rather than puncture) the cell separators. Under these conditions cell failure is likely to occur by catastrophic shorting or excessive self-discharge.

Empirical studies—Experimental programs have provided most of the design criteria for secondary electrodes. The zinc electrode, formed from a zinc oxide of appropriate particle size, has been improved on through the use of diverse and often unrelated additives, including organic and inorganic binders, surfactants, and solubility depressants.

The process by which the effective surface area of the zinc electrode decreases has not been subjected to the same type of analytical effort as has the dendrite growth mechanism. Although the initially formed electrode can utilize 80% of its theoretical capacity, a substantial excess of zinc oxide must be provided over and above that required to supply the rated capacity. The penalties in terms of cell weight and volume for this extra zinc are clear.

Goodkind (5) has reported extended cycle life capabilities for zinc electrodes prepared with 5 to 10% by weight of Teflon suspension and cured in the vicinity of 275°C. It seems logical to relate the improvement in cycle life to the creation of an inert interlocking matrix which effectively retards shifting of the active material on continued cycling and, in addition, provides for the maintenance of a highly porous structure. The use of cotton fibers and organic binders such as polyvinyl alcohol is discussed by Lander and Keralla (6). The effect of negative grid geometry has also been investigated (10).

Aside from the development of separator materials having greater resistance to penetration than cellophane, efforts to reduce the growth of dendrites have centered in three areas: cell design, use of surfactants, and the use of solubility depressants.

Most presently available silver-zinc cells operate with an excess of ZnO in the negative electrode and with a KOH electrolyte saturated with ZnO prior to cell activation. These steps are taken to reduce the extent of the concentration gradients caused by consumption of $Zn(OH)_4^{=}$ during charge. Depletion of $Zn(OH)_4^{=}$ and the concurrent change in the morphology of the deposited zinc from mossy to dendritic, occurs as the zinc electrodes densify and less ZnO dissolves. Thus, dendrite growth and shape change are often concurrent processes.

The use of surfactants to control the morphology of zinc deposits was first reported by Kryukova (7), who noticed changes in the shape of zinc dendrites penetrating through cellophane when various surface active agents were used. The general usefulness of organic additions to plating baths has long been established in commercial practice (8).

It is unlikely that the addition of surfactants increases the diffusion of zincate, thereby delaying the transfer into diffusion limited conditions. Dirkse (9) has pointed out that the additives significantly increase the viscosity of the electrolyte, and thus should retard diffusion processes. It is possible, however, that adsorption of a surfactant molecule on the zinc surface could alter the deposition process by poisoning active growth sites on the propagating dendrites.

Stachurski (3) measured the adsorption of various surface active agents by double layer capacity measurements on dropping mercury electrodes. At potentials corresponding to a working zinc electrode, only Igepal CO-730 [a polyphenoxypoly (ethyleneoxy) ethanol] remained adsorbed on the electrode surface. The other surfactants tested, Triton X-100 and the fluorochemical surfactants FC-134, FC-19, and FX-161, were desorbed at the same or lower potentials. The above result was given a practical significance by Lander and Keralla (10) and Dirkse (9) who have reported extended electrode life through the incorporation of alkylated poly (ethyleneoxy) ethanols into the zinc electrode structure in amounts from 1-5%. The materials also seem to improve electrode performance when incorporated in the electrolyte alone (11).

The use of zincate solubility depressants, particularly $Ca(OH)_2$, to reduce or eliminate zincate in the cell electrolyte has recently received some degree of attention. Van der Griten (12) has resolved the conflicting experimental results of Romonov (13) and Zhulidov (14) with the observation that zincate trapping only occurs at concentrations of KOH less than 20%, and that the rate of reaction is inhibited by carbonate contamination of the $Ca(OH)_2$ particles. The use of $Ca(OH)_2$ impregnated zinc electrodes in high-rate silver-zinc batteries is complicated by the need to provide sufficient caustic for rapid cell discharge. The low caustic concentrations involved mandate careful cell design to insure adequate amounts of available hydroxide. In addition, the high freezing point of 20% KOH (— 23°C) introduces environmental limitations, particularly when the caustic concentration in the anolyte falls during cell discharge.

Silver Electrode Studies

Theoretical studies—The anodic oxidation of silver in alkaline solutions is basically a two step process. First, a layer of monovalent Ag_2O is produced on the metal. When this layer reaches a critical thickness, mass transfer of oxygen ions to the Ag-Ag_2O interface becomes slow, and the oxidation of Ag_2O to AgO begins. It has been noted (15) that significant additional Ag_2O is also produced on this second plateau. Further anodization leads to evolution of oxygen.

Similarly, discharge of a silver electrode occurs at two distinct potentials. Consequently, discharge of a silver-zinc battery proceeds at two voltage levels: 1.8v

for the reduction of AgO to Ag_2O and 1.55v for the reduction of Ag_2O to metallic silver.

The mechanism of formation and reduction of Ag_2O and AgO is a matter of some controversy, but published x-ray data (16) indicate the following:

(a) Ag_2O nucleates on Ag and grows with random orientations; there is no evidence of a suboxide, solid solution, or alloy of oxygen and silver during charge or discharge.

(b) AgO forms as a distinct second phase and not by distortion or modification of the Ag_2O lattice; similarly, Ag_2O appears on discharge as a distinct separate phase, and not by shrinking of the AgO lattice.

(c) AgO grows on the surface of the Ag_2O layer during charge, and conversely, Ag_2O is formed on the surface of AgO during discharge.

(d) AgO is not reduced directly to Ag.

The sequence of reactions during both charge and discharge thus involves the coating of either the silver or the AgO by a layer of Ag_2O. The argentous oxide is a semiconductor of relatively low electronic conductivity. For these reasons, the voltage and current efficiencies of the silver oxide electrode are dependent to a large extent on the properties of the Ag_2O.

Argentous oxide is also involved in a major mechanism of cell deterioration in the silver-zinc system. Since Ag_2O is appreciably soluble in KOH the dissolved silver can diffuse to the negative electrode where it reacts directly with the zinc. A direct failure mode is the appearance, upon repeated cycling, of dendritic silver growths which may penetrate the cell separators.

AgO is insoluble in KOH, but it is unstable with respect to the reaction:

$$2\,AgO \rightarrow Ag_2O + \tfrac{1}{2}\,O_2 \quad \Delta G = -9512\ \text{cal}$$

The rate of this reaction is inhibited by the high oxygen over-voltage on silver and by the formation of a film of Ag_2O. The reaction results in a self-discharge rate of the silver electrode equivalent to 16% in 1 year at 30°C (17).

The solubility of Ag_2O in KOH was determined by potentiometric titration (17). The results are summarized in Table I.

Empirical approaches to improving charge acceptance—Two general empirical approaches to improving the charge acceptance of the silver-silver oxide electrode have been first, to vary the porous electrode structure by changing the particle size of the silver or the density of the plate, and second, to alloy the silver with small amounts of a second metal in order to alter the properties of the passivating Ag_2O film.

It has been shown that the utilization of silver at the Ag(I) level is improved by the addition of small amounts (~ 1%) of lead or palladium to the silver powder (10, 18, 19). At a discharge current density of 120 ma/in.^{2}, the utilization of silver at the argentous level was approximately 71% in the fifteenth cycle for hot-pressed plates formed from 0.5μ silver. Plates pressed from unalloyed silver powder exhibited only 20% utilization of the silver after the same number of cycles (19).

Recent work has indicated that for alloys of silver with Pd, Pb, Cu, Au, and S the improvement in charge acceptance comes about from a roughening of the silver surface *via* a preferential etching or dissolution of the alloyed metal (20-22). Once the roughening factor has been taken into account, the remaining improvement due to the increase in the electronic conductivity of the Ag_2O is about 10 to 15%.

Table I. Solubility of Ag_2O in KOH

Normality of KOH	Weight per cent KOH	Normality of silver
1	5	1.7×10^{-4}
1.9	10	2×10^{-4}
4.2	20	4.4×10^{-4}
6	27	4.7×10^{-4}
9.7	40	4.5×10^{-4}
13.5	50	3.4×10^{-4}

Lead seems to be the preferred material for use in the positive electrodes of silver-zinc cells, since the contamination of the zinc electrode with palladium leached from the silver electrode is likely to lower the hydrogen overvoltage on zinc and hence cause increased gassing. The use of Pb additives to the zinc electrode has also been shown to have beneficial effects on the morphology of the zinc deposited during charge (4).

The effect of silver particle size and plate fabrication procedures on the performance characteristics of secondary silver-zinc cells is a question of basic interest. Investigation of various silver powders and several different sintering temperatures indicated that the effect of these variables was small (18). Plates were constructed with silver particle sizes in the range 1 to 12μ and sintering temperatures of 800°, 1000°, and 1200°F. In general, the data indicated that even after 1000 cycles at 25% depth of discharge, all the plate efficiencies were comparable. Photomicrographs taken of the electrodes after formation and after 200, 500, and 1000 cycles indicated that the larger particles broke down on cycling, while the smaller particles tended to grow or agglomerate. The tendency was thus for the particle size to become more uniform on continued cycling.

Variation in the density of the silver plates may also be a significant factor in the performance capabilities of the silver-zinc system. From the standpoint of energy density, the use of a dense silver electrode is preferable, since cell pack thickness is thereby reduced. A brief study of the effect of positive plate density has been carried out (19). Plate densities of 3.0, 3.6, 4.2, and 4.8 g/cm^3 were investigated. The corresponding porosities are 71.4%, 65.8%, 60%, and 54.3% based on a silver density of 10.5 g/cm^3. The results indicated that the lower density positives probably increased cycle life, but the results were not statistically significant because of the large error variance. Also tentatively indicated was a decrease in the rate of silver attack on the cellulose separator as the density increased.

The use of a dense electrode structure, while increasing the electronic conductivity of the plate, has the disadvantage of decreasing the utilization of the active material. This capacity loss arises from the fact that ionic transport to the interior of the plate is impeded by the closely packed structure.

Separator Systems

Proper design and functioning of the separator system in alkaline silver-zinc batteries is crucial to successful cell performance. In addition to electronically insulating alternate plates without impeding transport of K^+ and OH^- ions, the separator system must prevent catastrophic dendritic shorting, reduce or eliminate the transport of silver through the cell pack, and be chemically and physically unaffected by the cell environment.

The relationships between the physical properties of membranes and their resistance to penetration by dendrites have been extensively studied by Stachurski (3). As has already been discussed, zinc penetration of the separator can only begin when the zincate concentration in the catholyte becomes too low to sustain the rate of zinc plating. Once penetration commences, however, the rate of growth and the morphology of the deposit will be determined by the diffusion constant and amount of free zincate present in the interior of the membrane.

In addition to the chemical composition of the separator, the concentration of zincate in the external solution was found to influence the amount of free zincate in the membrane. At low external concentrations of zincate (up to 0.2 mole/liter), the apparent concentration of zincate in the absorbed liquid rises

rapidly and is higher than would be expected if no interaction took place between the membrane and the zincate. At concentrations exceeding 0.2M there is a much smaller increase in concentration, and the concentration of zincate inside the membrane is lower than in the external solution. At concentrations of external zincate greater than 1 mole/liter, the amount of absorbed zincate becomes constant.

Based on these observations, zincate present in the membrane was concluded to exist in two distinct forms (3): chemisorbed zincate adsorbed on the microfibers of the membrane material (experimentally indicated at low external concentration), and free zincate in the electrolyte present within the membrane structure.

Since zinc plating within the membrane can only come from this free zincate, it is the concentration of the free zincate which determines whether penetration of the membrane will or will not occur. In order to increase the overpotential for deposition within the membrane, it is desirable that the free zincate concentration be as low as possible. These points are perhaps best illustrated with reference to a specific example.

Regenerated cellophane, both with and without fibers, has been the usual separator material for an extended period. Consequently, it is the one for which the most data, both empirical and theoretical, is available. In saturated zincate, the concentration of zincate outside the membrane exceeds the concentration of free zincate inside the membrane by only a factor of 1.5. In dilute zincate (0.01M), however, the ratio of the outside to the inside concentration becomes 30 (3). The latter case is representative of the situation where the catholyte has become zincate limited. As long as the concentration of free zincate is much lower inside than outside of the membrane, the overpotential for zinc deposition within the membrane will be relatively high, and zinc penetration will be retarded (23).

In addition to eliminating zinc penetration, the cell membrane also functions as a silver barrier. The slightly soluble Ag^+ ion diffuses to the zinc electrode where it is reduced to metallic silver, which decreases charge efficiency (10). Membranes such as cellophane, which reduce the silver ions to silver metal, are initially effective silver barriers but lose their effectiveness as the metallic silver accumulates within their pores and the membrane structure deteriorates.

Nonoxidizable films which retard the diffusion of the silver ions also retard the passage of potassium and hydroxyl ions and thereby increase cell resistance. If a reasonable cell resistance is to be obtained, it is therefore seen to be necessary to accept a finite rate of silver diffusion. The use of multiple layers of both oxidizable and nonreactive films may provide an acceptable set of properties (24).

Table II summarizes the pertinent properties of several representative membrane materials available for use in silver-zinc cells.

The Borden methylcellulose and Permion films are all relatively resistant to oxidation by silver compared with the "standard" cellulosic material. The Permion films, although exhibiting the greatest oxidation resistance, allow the most rapid silver transport of all the films. The use of the Borden 5-9107-21 film which has a low diffusion rate for silver ion is precluded by its high resistance in KOH. For cells which must be sterilized prior to use, several types of inorganic separators have been developed (26). Use of these rigid, relatively thick (25 mil) separators to retain the zinc electrode material mechanically has been reported to result in extended cycle lives (27).

A rational basis for selection among the films just described can only be made with some knowledge of the effect of silver contamination of the zinc electrode. Lander (10) cycled several cells containing silver additions of 0.01, 0.1 and 1.0% to the negative plates. Cell life was significantly reduced due to decreased charge efficiency at the 1.0% silver level. Since the silver powder was dispersed uniformly throughout the electrode, the results are likely to be optimistic when compared with silver deposited on the surface of a working electrode.

The poor recharge capability of zinc electrodes contaminated by unamalgamated silver can result from two distinct processes. By providing sites with relatively low hydrogen overvoltage, the hydrogen evolution reaction can become more favorable than the reduction of ZnO to Zn. In addition, finely divided silver can catalyze the oxidation of zinc by oxygen present in the cell head space or electrolyte.

At 0.1% silver, the silver concentration in a zinc electrode of typical thickness corresponds to 2 mg/sq in. or 2.9×10^{-3} moles/cm^2 (10). The assumption of a silver diffusion rate of 25×10^{-10} moles/cm^2-sec results in a time period on the order of 10^6 sec or 2 months being required to transport the specified amount of silver to the negative plate. Even though this figure is probably conservative, it is apparent that multiple layers of separator material will be required to assure stable performance of the zinc electrode.

In order to retain maximum energy density, it is important that the thickness of the separator layer be reduced to as small a value as is consistent with the cycle life capabilities of the zinc electrode, and with the type and duration of the mission to be encountered. The trade-off between cycle life and energy density requires that the separator system be specifically designed for the mission contemplated.

As of the present time, no separator has been shown to be more effective than those based on cellophane or methylcellulose in preventing dendrite growth, the assumption being that the elevated temperatures required for cell sterilization will not be experienced. However, McBreen (23) reports that the initially higher zincate exclusion properties of the methylcellulose membrane deteriorate after soaking in KOH at temperatures approaching 60°C. In any event, the rapid oxidation of cellulose by Ag^+ makes the use of cellophane in direct contact with the positive plates unattractive for long-term operation. The use of a methylcellulose-based membrane such as Borden 5-9107-23 is therefore a requirement to retard the rate

Table II. Membrane properties (25)

of silver diffusion and hence slow the oxidation rate of cellophane.

The use of multiple layers of separator material presents some problems in wrapping the electrodes. In the conventional U-wrapping technique (24), two silver electrodes are placed bottom ends opposed across the short dimension of a rectangular separator strip and folded for several wraps (usually 5 or 6). The two electrodes are then folded together to give a U-bend into which the zinc electrode is inserted. When multiple layers of separator are used, the outer layers of separator become stressed at the crease at the bottom of the fold. Small cracks can be produced which may alter the diffusion characteristics of the membrane and allow premature cell failure due to contamination of the zinc electrodes with deposited silver metal, or by dendritic shorting.

Treating the fold area with electrolyte to swell the membrane and make it more resistant to stress cracking has been suggested as a means of eliminating the problem of premature cell failure (24). Alternative methods to eliminate the "U" fold involve changes in the wrapping method.

The use of an "accordian" wrap where a long ribbon of separator is used to wrap the entire cell pack is extensively employed in rectangular nickel-cadmium cells. Its use in silver-zinc cells is precluded by the fact that alternate edges of the silver electrodes are exposed to the free electrolyte, thereby allowing unimpeded diffusion of silver ions to the negative electrodes. The envelope type of wrap, consisting of heat or adhesive sealing of the separator edges around an individual electrode, has also been considered, particularly with regard to the zinc electrode (24).

Sealed Cell Technology

A reliable and predictable method for preventing pressure buildup in sealed silver-zinc cells is a basic requirement. While a pressure relief device is usually included in cell designs to prevent damage to the cell case, frequent venting of excess hydrogen or oxygen on long missions will result in a deterioration of the electrical performance of the cell due to both concentration and volume changes of electrolyte. Four possible methods for recombination of evolved gases have been extensively studied for use in sealed silver zinc cells: internal recombination of gases on the battery plates, use of a third or auxiliary electrode, recombination catalysts placed in the head space of the cell, and finally, the use of externally mounted fuel cells.

Rates of gas evolution and recombination on silver and zinc electrodes.—Zinc is thermodynamically unstable in contact with alkaline solutions, its potential being approximately 0.4v below that required for hydrogen evolution. The rate of gas evolution is strongly influenced by the high hydrogen overvoltage of zinc and by additives which tend to alter the overvoltage, particularly mercury.

Snyder and Lander (28) have studied the rate of hydrogen evolution of zinc electrodes under open circuit conditions. These results indicate that the gassing rate varies inversely with KOH and mercury concentrations and directly with temperature. The presence of ZnO in the electrolyte appeared to have little effect. The use of 2% by weight of HgO dispersed in the ZnO prior to formation was found to yield the lowest gassing rates under most conditions. However, it is not uncommon for increased amounts of HgO (up to 15% by weight) to be employed in applications where it is desirable to maintain the lowest possible gassing rates under a wide range of environmental conditions.

The experimentally observed gassing rate of such an amalgamated electrode (2% HgO) at 100°F in 40% KOH was 1.5×10^{-4} ml/min for each ampere-hour of theoretical capacity. This figure corresponds to a tolerably low self-discharge rate. For a cell containing 20 amp-hours of zinc, this rate of capacity loss corresponds to less than 0.5 ma. For long missions, however, even this low a gassing rate results in an intolerably large pressure buildup in sealed cells, if no provision is made to remove the hydrogen. It is likely that the zinc electrode is always gassing hydrogen at rates similar to the preceding, since the voltage of the electrode always remain close to its open circuit value (assuming the charging potential is closely regulated).

Generation of oxygen at the positive electrode does not present the same degree of difficulty as hydrogen generation at the Zn electrode. The level of free electrolyte in sealed cells is usually maintained at about one-half the plate height to allow any oxygen produced at the silver electrode on stand or overcharge to be reduced by exposure to the high surface area zinc electrodes.

Based on this principle silver-zinc cells are designed to be silver limited so that the silver-electrode reaches full charge and begins to evolve oxygen before rapid hydrogen generation commences at the zinc electrode. In one study a conventional 15 plate, 25 amp-hr cell was shown to be capable of supporting a continuous overcharge current of 0.25 amp without accumulation of excessive oxygen pressure (10). However, buildup of significant oxygen over-pressure has also been reported during initial cycling (29).

The accumulation of hydrogen in sealed cells has presented more of a problem. In addition to the continuous corrosion of zinc as described previously, greater amounts of hydrogen may be evolved as the supply of available ZnO in the negative plate declines during cycling. The zinc and silver electrodes then become mismatched and the zinc electrode must be overcharged to restore full charge to the positive plate.

The extent to which this hydrogen is oxidized to water by AgO is a matter of crucial importance for design of sealed silver-zinc cells. Experimental work has shown that the recombination is fast enough on unwrapped plates to avoid excessive hydrogen accumulation. Completed cells, however, have exhibited the tendency to rupture from excessive hydrogen pressure, particularly at high charge rates.

The existence of the recombination reaction has been shown by both indirect and direct methods. The observation has been made (28) that the pressure buildup in sealed silver-zinc cells on open circuit stand is much slower than would be expected from the amount of hydrogen being generated at the zinc electrode. Rhyne (30) showed that 1g of high surface area AgO moistened with KOH reacts with hydrogen at about 0.008 ml/min at room temperature. Experiments performed on full sized plates (2.5 x 4 in.) have given comparable results (10). Hydrogen recombination rates range from 0.42 ml/min on standard plates to 4.1 ml/min for plates that had been wet-proofed with Teflon to decrease the KOH film thickness and expose more surface area. The total recombination ability of a multiplate, 25 amp-hr battery can be estimated by assuming that ½ the area of each of the 8 positive plates is available for recombination. For the wet proofed electrode the continuous overcharge capability is calculated to be 40 ma (0.039 ma/cm^2) (10).

Sulkes (19) and Lander (10) have both shown that small additions of Pd (about 1%) to the positive plates increase the reaction rate with H_2. However, the rate changes caused by palladium additions were not as great as the changes caused by factors likely to alter the diffusion of H_2 to the electrode surface, *viz.* KOH concentration, choice of separator system, and wetproofing the electrode.

The observed fact that sealed cell failure is due almost universally to hydrogen rather than oxygen accumulation can lead only to the conclusion that the oxidation rate on the positive electrode has a greater kinetic limitation than the oxygen reduction on the zinc electrode. Due to the higher kinetic hindrance for the hydrogen oxidation, it is necessary to provide more surface area for the reaction.

The rate of reaction on the silver positive is thus seen to be more sensitive to factors which may not appreciably affect the reaction rate at the zinc electrode.

In particular, differences in cell pack wrapping or electrode structure which affect either the diffusion of gases through the electrolyte film, or the amount of surface area available for reaction, are more likely to limit the hydrogen rather than the oxygen reaction rate.

Auxiliary electrodes.—The use of AgO electrodes to control hydrogen accumulation has been described previously. Biasing the additional positive plate at a potential lower than that of the working electrodes is not required, since the rate of recombination has been shown to be accelerated by higher potentials (19), and since there is no danger of continuous oxygen evolution from the AgO.

The use of internal fuel cell electrodes to react with evolved hydrogen was investigated by Lander (10). In order for the H_2 electrode to function, it must be connected to the positive plate through a diode to prevent the hydrogen electrode from reaching the oxygen liberation potential.

The electrode investigated consisted of a wetproofed nickel plaque impregnated with a palladium-silver catalyst. Insertion of the electrode into a complete cell required the removal of two plates. Contact of the activated surface with the gas space was maintained by wrapping the electrode in a coarse plastic mesh. The cells were overcharged to an extent limited by a predetermined potential rise. Potential cutoffs in the range 2.00 to 2.19 were investigated. In all cases, cell failure was by dendritic shorting rather than by pressure buildup.

The presence of catalytic materials with low hydrogen overvoltages, *e.g.* palladium, introduces an additional complication. Precautions must be taken to insure that such materials are not transported, either by electrochemical or physical processes, to the surface of the negative electrode, since the result would be to lower the necessarily high hydrogen overvoltage of the zinc. Screening of alternative catalyst materials with relatively high hydrogen overvoltages has indicated that mercury (amalgamated on a silver plaque) has sufficient activity to function as an auxiliary electrode for oxygen reduction (20).

Development of reliable sealed cells with auxiliary electrodes has been hampered by the fact that zinc may plate out on the oxygen electrode. In addition, changes in cell pack dimensions on continued cycling may alter the rates of gas recombinations.

Recombination catalysts.—The use of a recombination catalyst in the head space of the cell has also been investigated (10). Tests indicated that a Pd-Al_2O_3 catalyst was capable of recombining the gases at a significant rate, although some difficulties were experienced. This method can only be successful in recombining stoichiometric amounts of hydrogen and oxygen. A vent of some type is therefore still a requirement.

Externally mounted fuel cells.—The use of an externally mounted device to eliminate the accumulation of gases in sealed cells is attractive since such a device is not exposed to the variable internal cell environment. Programs to evaluate small fuel cells for use in sealed battery operation have been undertaken (29, 31). Fuel cells with from 0.25 to 5.0 sq/cm of electrode area have been investigated.

Successful results have been obtained with commercially available Teflonated platinum black electrodes. Both electrodes are identical and the KOH electrolyte is impregnated in an asbestos matrix.

Since, under most conditions, the internal oxygen recombination reaction has been found to be rapid, the fuel cells are used to oxidize hydrogen. For fuel cells employing two platinum electrodes, an external supply of oxygen is required. Also under investigation is the use of a consumable cadmium or zinc anode for oxygen consumption and a silver or mercuric oxide cathode for hydrogen consumption (31). The results are promising, with efficiencies approaching 90% utilization of the AgO electrodes being obtained at the low current drains required.

Fuel cell operation can be carried out in any of several modes: open end flow without wicking, dead-end flow without wicking, and dead-end flow with wicking of the product water. For long-term operation of the battery and fuel cell system, dead-end flow and return of product water to the cell electrolyte are necessary to assure stable operation.

Since the probable continuous rate of hydrogen evolution is equivalent to less than 1 ma (28), current densities on even the small cells being investigated are quite low. This fact contributes to the maintenance of stable performance. Fuel cells operating in the required mode with an electrode area of 1 cm^2 have exhibited greater than 3000 hr of stable operation at a current density of 5 ma/cm^2.

The implication that the use of external fuel cells is a suitable method for eliminating hydrogen overpressure in sealed silver-zinc cells is clear. If proper formation techniques are followed, and the cells are properly stored while awaiting use, no difficulty should be encountered with oxygen accumulation. The investigation into the gassing rates of silver-zinc cells, which indicated that oxygen pressure became excessive on the first few cycles, employed dry charged batteries which had likely been stored in air prior to their activation (29). Partial surface oxidation of the zinc could have easily occurred, with the result that the oxygen recombination reaction was inhibited for several cycles.

The role of diffusion in sealed cell design.—As has already been pointed out, the reduction rate of oxygen on zinc electrodes is sufficiently rapid to accommodate substantial oxygen evolution from the silver plate. Even though the analogous hydrogen reaction has been shown to occur at the positive electrode, its apparent rate is slower, and in most cases is inadequate to control hydrogen accumulation. Studies on a rotating zinc disk electrode have shown that the rate of oxygen reduction in fabricated cells is limited by the kinetics of the reaction and by the available surface area, rather than by diffusion of the oxygen to the electrode surface (19).

Corresponding studies are not available for the silver electrode. Some conclusions can be drawn from the empirical studies, however, Sulkes (19) has observed that the rate of hydrogen accumulation in sealed cells becomes slower as the temperature is raised. In view of the fact that the rate of gassing at the zinc electrode increases rapidly with temperature (28), it is evident that rate of the hydrogen recombination increases at least as fast as the rate of zinc corrosion. The strong temperature dependence of the recombination rate on silver would thus tend to indicate kinetic rather diffusion control, since diffusion processes would not be expected to exhibit the sensitivity to temperature that has been shown to exist.

Lander (10) investigated the rate of hydrogen recombination on positive plates and found it to be increased by the addition of wet proofing agents such as Teflon and by the use of Pd. Pd has been shown (20-22) to increase the specific surface of the silver electrode and hence provide greater surface area for the recombination reaction. The presence of Teflon would logically have the effect of reducing the thickness of the electrolyte film that the hydrogen must diffuse through in order to react at the electrode surface.

Since the diffusion coefficients of hydrogen and oxygen are of the same order of magnitude, the slow rate of hydrogen recombination on the silver electrode is therefore related to the lower specific surface of the silver-silver oxide plate compared to the zinc plate. The negative electrode has been shown to have a surface area of 200 times its apparent area by double layer capacity measurements (19). In view of this conclusion, the rate of hydrogen recombination may be significantly altered by changes in the porosity and structure of the positive electrode.

Control of hydrogen evolution through the use of externally mounted fuel cells located in the head space of the cell or through internal recombination requires an understanding of the factors which may affect the diffusion of hydrogen from within the zinc electrode. If hydrogen bubbles accumulate in or around the zinc electrode, electrolyte is displaced, the effective current density is increased, and the growth of dendrites is facilitated. In addition, the presence of small discrete pockets of hydrogen may encourage the formation of explosive mixtures due to oxygen diffusing into the bubbles.

The structure of the zinc electrode and the type of electrode-electrolyte interface are the major variables which will determine the amount and size of the generated hydrogen bubbles. Determination of these variables is usually performed on the basis of other performance specifications such as cycle life and zinc utilization. However, many of the design improvements employed for these other reasons have a significant effect on the rate of diffusion of hydrogen from the zinc electrode. In particular, the use of surfactants in the cell electrolyte and of absorbent fibers in the electrode structure may encourage displacement of entrapped hydrogen bubbles by the cell electrolyte.

Summary

A variety of individual improvement factors have been suggested for the zinc electrode. Some of these are mutually exclusive; for example, both hydrophobic and hydrophilic additives are reported to be capable of stabilizing the zinc electrode structure. Some interdependence with factors is to be expected in applying surfactants to control dendrite growth and to prevent zinc agglomeration.

It remains to be determined whether the additives listed above function (*a*) because of their hydrophobic or hydrophilic character, (*b*) because they increase the structural strength of the electrode, (*c*) because they provide for a more uniform structure, or (*d*) through some other mechanism. The appropriate mechanism is, obviously, of concern in choosing the optimum electrode structure.

A number of empirical, factorial studies have related the physical structure of silver oxide electrodes to plate discharge characteristics. These experiments have generally been specific, *i.e.*, related to a single charge-discharge regime; therefore some amplification of work already discussed may be required for use in alternative cycle regimes. Attempts have also been made to improve silver electrode performance by the use of alloyed constituents. It was concluded, for example, that although palladium improved performance, it migrated into the separator. Recent experiments have demonstrated that the effect of many such alloyed constituents is to increase the roughness of the silver electrode and hence to increase the available surface. This same type of basic mechanistic information is required to determine the significance and applicability of individual design features in other areas of battery fabrication.

It is by now apparent that there are several alternative design improvements available in each of the major areas of silver-zinc technology. Selection of any one design procedure must be made so as to insure compatibility with the rest of the cell system and to insure the creation of an optimum cell design.

Acknowledgments

The author wishes to thank his colleagues, Dr. J. Giner and Dr. R. Jasinski for their assistance and guidance in the preparation of this review.

A Review of the Electrochemistry and Technology of Chlorates and Perchlorates

Joseph C. Schumacher*

American Potash & Chemical Corporation, Los Angeles, California

Production of chlorates and perchlorates has increased enormously during the past twenty-five years and appears destined to continue to increase at an accelerated rate in the years ahead.

This growing market, as shown in Table I, has brought increased competition among producers and thus has created new demands for better technology and higher standards of production efficiency. A new drive is being made to increase energy efficiency, also to reduce operating and capital costs. These objectives and related goals can be accomplished only through a better understanding of the electrochemical processes and electrode materials constituting the electrolytic cell system.

At the present time, large-scale commercial sodium chlorate cells operate at 80 to 87% current efficiency with an average requirement of 6000 kw hr (DC) of electrical energy per ton (2000 lbs) of product. Potential improvements include increasing current efficiency to 95% or higher and in reducing the electrical energy requirement to 4000 kw hr per ton or less as shown in Fig. 1. Current efficiency losses in the chlorate cell result from losses of hypochlorite, an intermediate in the formation of chlorate. These losses can occur through formation of oxygen at the anode, reduction at the cathode, catalytic decomposition in the electrolyte, or by volatilization of undissociated hypochlorous acid in the cell gases.

Potential improvements lie also in the area of reduced cooling requirements and anode replacement costs. Recovery and use of hydrogen is now not in common practice, but may be so in the future in order to improve production economics.

Commercial perchlorate cells operate at current efficiencies of 95% or higher, but there is a need for and room for further improvement in energy efficiency and reduction of capital and maintenance costs. Improvements of this type can best be achieved through greater knowledge of the electrode processes and materials.

The following chronology of events traces the evolution and development of the electrochemistry and technology of chlorates and perchlorates and points up areas of current interest.

Evolution of Electrochemistry and Technology of Chlorates

1808 Berzelius reports electrochemical preparation of chlorate (1).

1847 Kolbe confirms electrochemical conversion of chloride to chlorate (1).

* Electrochemical Society Active Member.

Table I. Sodium chlorate production

	United States (Short tons)	Sweden (Metric tons)	Japan (Metric tons)
1940	15,000	2000	
1950	22,085	3000	6370 (1958)
1960	91,585	14,000	11,279
1965	132,689	34,000	22,630 (1963)
1966	—	50,000	
1967	151,000		35,000**
1972	220,000**		

** Estimate.

1866 First commercial electrochemical production of chlorate in France with platinum anodes (1).

1894 Carlson reports the use of graphite anodes in chlorate production in Sweden (1).

1898 Müeller reports diaphragm unnecessary when chromate is added to chlorate cell electrolyte (2). Carlson reports the use of magnetite anodes (3).

1899 Foerster and his students postulate mechanism of electrochemical chlorate formation. Discharge of chloride ions is followed by a series of chemical reactions. Current efficiency losses involve oxygen evolution through discharge of hypochlorite (4).

1900's Graphite becomes the standard anode material for chlorate cells. Monopolar and Bipolar cells are used (5).

1911 Müeller and Koppe report relationship of acidity and current concentration to current efficiency (6).

1915 Magnetite anodes are used in chlorate production in Germany (1, 3).

1920 Knibbs and Palfreeman conclude that the discharge of hydroxyl ions or chlorate ions did not contribute significantly to current efficiency losses (7).

1953 de Valera extends Foerster's theory of formation of chlorate by mathematical treatment and describes important role of anode diffusion layer (8, 9).

1954 Wagner explains the effect film has which forms on cathodes when chromate is added to the electrolyte (10).

1956 Nagai and Takei report cathodic losses are controlled by diffusion of hypochlorite toward the cathode surface (11).

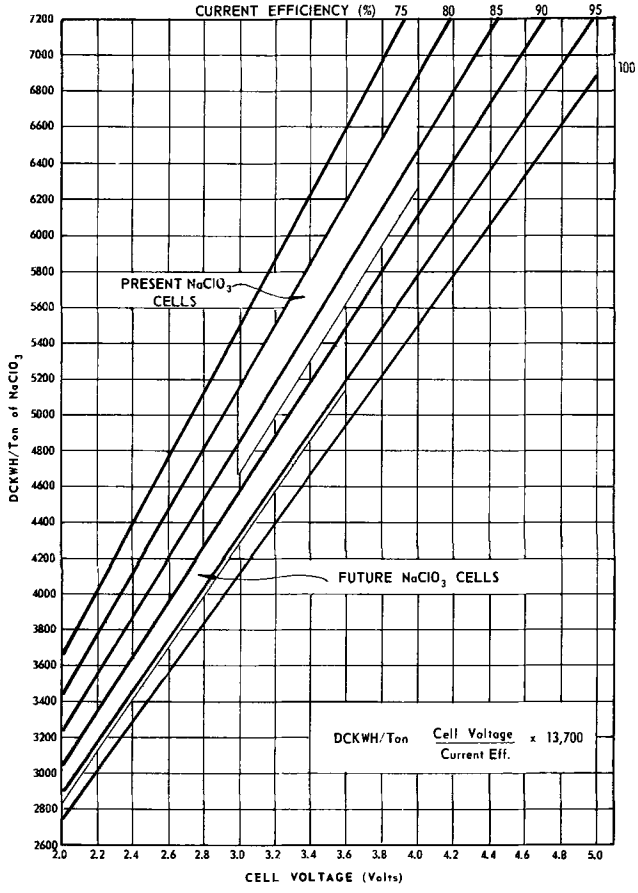

Fig. 1. Current efficiency

1961 Beck's calculations support conclusion that transport of hypochlorite ions from bulk of the solution to the anode is factor which controls rate of reaction (12).

1963 Ibl reports his studies of mass transport during electrolysis in the anodic diffusion layer (13).

Ibl and Landolt postulate chlorine, formed at the anode, is hydrolyzed in diffusion layer. Also diffusion layer is buffered by hypochlorite ion diffusing from bulk of the solution thus maintaining a high *p*H so that chlorine hydrolysis can proceed (14).

1964 de Valera considers hydroxyl ion discharge to be primary step in oxygen evolution anodic reaction (15).

Hammar and Wranglen report their investigations of current efficiency losses in chlorate formation (16).

Evolution of Electrochemistry and Technology of Perchlorates

1816 Von Stadion reports electrochemical preparation of perchlorates (17).

1893 First commercial production of perchlorate in Sweden (18).

1897 Foerster reports studies of electrolytic conversion of chlorate to perchlorate (19).

1903 Oechsli postulates mechanism of perchlorate formation. Discharge of chlorate ions followed by chemical reactions (20).

1916 Bennett and Mack postulate direct oxidation of chlorate by active oxygen at anode (21).

1920 Knibbs and Palfreeman examine losses of current efficiency at the anode. Disagree with Oechsli and Bennett and Mack. Postulate new mechanism involving formation of peroxide followed by rearrangement (22).

1955 Phillip and Morgan postulate direct anodic oxidation of chlorate via high valence platinum oxide (23).

1956 Sugino and Aoyagi report use of lead dioxide anodes. Postulate simultaneous discharge of chlorate and hydroxyl ions followed by combination of radicals (24).

1967 Grotheer postulates direct anodic oxidation of chlorate via oxygen species adsorbed on anode (25).

This historical review shows that reaction mechanisms which occur under operating conditions which exist in industrial electrolytic chlorate and perchlorate cells have not been fully established. Also, the theoretical problems associated with chlorate formation received almost no attention in the published literature during the 33 year period from 1920 until de Valera published his work in 1953. Interest in these problems by other investigators developed rather slowly until approximately 1960. Since then there has been an increasing effort to resolve the mysteries which surround the anode in chlorate cells. Continuing studies along present lines of interest should provide the information required to achieve the previously stated objectives of higher energy efficiencies and lower production costs.

Manuscript submitted September 9, 1968; revised manuscript received October 8, 1968. This paper was presented as an introduction to the Symposium on Chlorates and Perchlorates at the Boston Meeting, May 5-9, 1968.

Francis Laurence LaQue

H. H. Uhlig*

Dr. H. H. Uhlig delivers introductory remarks about the Acheson Medalist.

The Acheson Medal was established in recognition of contributions "to the advancement of any of the objects, purposes, or activities, here or hereafter, fostered or promoted by the Society." Our present Medalist has certainly contributed outstandingly to the professional areas fostered by our Society; he has in addition served the Society itself in several capacities, including the office of President. Whatever the place or occasion, he has added luster to what otherwise would be dull or tarnished and, in more ways than one, he has converted rust into useful metal.

During the time I have had the pleasure of knowing Frank LaQue, the characteristics that identify him above all others, to my mind, are both his clarity of thinking and his ability to persuade others that his thinking is clear. The combination, as you might suspect, is a reasonable formula for success. It has carried him to the top ranks of his profession, to the top echelons of his company, to the top office of three technical societies, and to important advisory and consulting positions in government.

Throughout all of his crowded professional and business responsibilities, Frank has retained an inimitable sense of humor which fits the occasion and which he often uses to drive home his point. For variation or for emphasis he is furthermore not averse to, or perhaps I should say he is not shy about, expressing his thoughts of the moment in verse. He is the Poet Laureate of corrosion engineers and the "Robert Frost" of the Sea Horse Institute. Each year, members of the Sea Horse Institute receive a Christmas card, attractively designed by his daughter Mary, on which is printed one of Frank's delightful contributions to rhyme and jingle. I wish there were time to read several of his poetic creations; I know you would enjoy hearing them. Here are some excerpts:

The time has come the Sea Horse said to talk of
many things . . .
Of ships and rigging and deep ocean pinging
That can sound even better than bar-room singing.

Offshore platforms that are much more stable
than political ones seem ever to be able.

Nodules of manganese, a new kind of ore
never even dreamed of in days of yore.

Houses for people who have the odd notion
they would like to live way down in the ocean.
Vessels designed for deep-sea submergence
with reasonable hope of later emergence.

And another:

Novices may feel they must be quite smart
In knowing so much, right after they start.
But, sooner or later, they may have to confess
What they know for sure becomes less and less.

As time goes on, the wise will discover,
The best thing to do is trade with each other.
Like all good Sea Horses who take their turn
In passing along the new facts they learn.

For relaxation, Frank plays golf and bridge, or he goes fishing or sailing. The latter activities center around his summer home in the Thousand Islands where he was born at Gananoque, Canada. He attended public schools there, demonstrating very early a scholarly ability which insured his eventual admission to Queens University. By remaining at the top of his class, he made himself eligible for local scholarship aid which was essential to the furtherance of his education. He also worked in industry during college years in order to supplement available scholarships. It was during one of his summer jobs at Chatham, Canada, that he met Kate Clark who professed an interest in knowing more about science and mathematics and in particular how to use a slide rule. Frank impressed her with his patient ability as a teacher, a characteristic that has carried through all of his subsequent professional activities. More important, she was impressed with Frank. They were married in Gananoque in 1930 and have two daughters. Kathy is an occupational therapist at the Massachusetts General Hospital in Boston, presently on assignment in California, and Mary, who is now Mrs. Gerard McMartin, is married to a teacher and lives with their four sons near Toronto, Canada.

At college, Frank decided to major in metallurgy, both because of the broad challenge which this field offered, and because of the many job opportunities in Canada in the metals and minerals industry. Upon graduation in 1927, a personal appraisal by his classmates appeared in the college yearbook, "Tricolor," which on reading today, impresses one with its terse accuracy. After describing where Frank came from, the scholarships he won and his interim jobs during college years, the "Tricolor" account closes with: "His specialty is metallurgy and he is particularly interested in steel. Brilliant, witty and good, his success in life is assured." The account, I suppose, might also have mentioned nickel, but iron and nickel, after all, are in the same group of the Periodic Table. Thirty-seven years later, his Alma Mater confirmed the "Tricolor" prediction by conferring on him the honorary degree of Doctor of Laws. The college authorities could by then well afford to describe their distinguished alumnus at greater length and with unrestrained approbation. The citation reads, "Native son of the Thousand Islands, graduate and devoted alumnus of this University, metallurgist extraordinary, more than thirty-five years a vital, creative force within the International Nickel Company, whose sustained work and leadership in the study of corrosion on metals have advanced us towards a secular paradise where rust does not corrupt, and who has given unstintingly of his great knowledge

* Introductory remarks by H. H. Uhlig on the occasion of the presentation of the Acheson Medal Award to F. L. LaQue on October 8, 1968 at the Montreal Meeting.

and experience in helping this University to educate a new generation of engineers for the needs of a changing world." I would personally have retained in this description the earlier term "witty" because somehow it belongs in the record. This characteristic has happily remained with Frank, undiminished since his college days. It would be an omission at this point not to mention Kate LaQue's wit which charmingly supplements that of her husband.

Shortly after graduation and a brief job with the Deloro Smelting and Refining Co., Frank was employed by the International Nickel Co. at their office in New York City. Since the company's products, nickel and nickel alloys, are useful in large part because of their corrosion resistance, the company wanted to employ someone who could help develop corrosion information of value to both its established and its potential customers. Frank had had heretofore no experience, nor special interest in corrosion, but typical of a procedure carried out in many companies even today, he was promptly appointed "corrosion engineer." He explored the subject, finding it to be more than ordinarily fascinating, and learned it thoroughly. On his visits to industries besieged with corrosion problems, he offered them unslanted advice on the proper solution, whether or not this advice entailed the sale of nickel. His perspicacity in diagnosing corrosion problems, plus his surprising candor and honesty, won the complete confidence of managers and engineers wherever he went, and in the long run he probably sold much more of the company's products than a dozen men would have sold using any other approach.

In 1938 he was made Assistant Director of Technical Service and in 1940 he was placed in charge of the Corrosion Engineering Section. This was followed in 1954 by the further promotion to Vice-President and Manager of the Development and Research Division. Since 1962, he has been Vice-President and Special Assistant to the President of the company.

On reviewing Frank's career with the International Nickel Co., we go back to 1935 when he was busily spelling out prescriptions for corrosion maladies. One of the industries he visited was the Bromine Plant of the Ethyl-Dow Chemical Co. at Kure Beach near Wilmington, N. C. He immediately recognized that the company's continuous intake of ocean water made the canal leading to the plant an ideal place in which to immerse corrosion test specimens. He persuaded both his own management and that of Dow to make the necessary arrangements, and at first the Dow Co. personnel took care of the test site. Several other companies in addition to the International Nickel Co. became interested in exposing samples, so that eventually the site was expanded and a permanent staff was employed. Inspection of test specimens took place usually on an annual basis at which time a small group of interested people discussed the meaning of the results, with Frank as discussion leader. More corrosion information passed hands at these meetings than at a multiple of classrooms or technical society meetings; I know because I was one of those who benefited.

The reputation of the Kure Beach test site grew, and with it the number of visitors who were anxious to learn the latest performance of alloys, coatings, galvanic couples, cathodic protection, stress corrosion cracking, and a host of related subjects. In order to distinguish the employees, who acted as guides, from the visitors, Mrs. Paterson, wife of the test station manager, supplied red hats trimmed with green sea horses. Spontaneously, the meeting became known as the Sea Horse Institute and Frank arranged to have made appropriate certificates of membership accompanied by small nickel lapel pins of sea horses. The pins were distributed to visiting corrosion engineers so that as they converged on Wilmington by train or plane, they could identify themselves as members of the friendliest corrosion fraternity in the world.

In 1950, Frank persuaded his company to invest considerable money in a permanent test site up the coast at Harbor Island which was much more secure against the damage inflicted by occasional hurricanes and which provided permanent buildings for test equipment and for a museum where test specimens could be adequately displayed and catalogued. The atmospheric test racks were retained at Kure Beach.

The annual corrosion sessions at the new site were attended by several hundred persons, requiring that the local movie house be taken over for adequate space. At these corrosion clinics, Frank stimulated everybody assembled to exchange data and information which he supplemented by incontrovertible data from the array of test specimens exposed at Harbor Island and Kure Beach. Any misinformation, or superstition, or exaggerated claims for proprietary products were apt to be shattered early in the proceedings. Frank held the reins of discussion with a firm diplomatic hand, not quite avoiding stepping on the toes of those whose products or ideas were suspect, but later healing wounded feelings by apologizing for bringing out the truth which on further thought he wished he had not mentioned. His complete aplomb in handling controversial issues amazed both those who agreed with him as well as those who disagreed.

The Corrosion Laboratory and its adjoining facilities at Harbor Island now constitute the largest sea water test station in the world. Any materials considered for use in sea water, such as for desalination equipment, sea water distillation apparatus, marine structures, condenser tubes, *etc.*, are subjected to a complete going over by systematic tests of all kinds. The atmospheric test results are similarly used to survey materials suitable for use in marine atmospheres. At any one time there are as many as 3000 test specimens immersed in sea water, and 30,000 test specimens exposed to the air. Over 100 companies, research institutions, technical societies, and government agencies from the U.S., and also from abroad, participate in carrying out this tremendous evaluation program.

The Harbor Island Laboratory which reflects so much credit to the International Nickel Co. is one of Frank LaQue's great achievements. Another achievement along the same lines involved the establishment of the International Nickel Co.'s modern research facilities at Sterling Forest, N. Y. As long ago as 1956, he and W. Wesley campaigned to have the company's laboratory moved from the original location in Bayonne to a more suitable suburban area. The new building, formally opened on October 29, 1964, is one of the most modern and most attractive metallurgical research laboratories in the country. It is a tribute to Frank's life-long interest in research and development.

Professional Society, Government and Related Activities

Frank's active interest in many professional societies is matched by his numerous invitations to speak at local, national, and international meetings. I would judge there are very few places remaining in this country, or in Mexico or Canada, wherever technical society meetings are held, where Frank has not appeared as speaker one or more times. This fall, for example, he is invited to be Plenary Lecturer at the Australasian Corrosion Conference in New Zealand. His discerning remarks and forthright appraisals, combined with a keen sense of humor have made him a popular lecturer. I recall a technical society meeting some years ago in Schenectady at which Frank talked. As chairman, I asked the audience if there were any questions. Before the usual quiet preceding the storm of inquiries, Frank whispered into my ear, "Tell them that the peculiarity

of my subject allows me to give some sort of answer to any question that is asked."

He was elected president of the National Association of Corrosion Engineers in 1948-1949 and president of the American Society of Testing and Materials in 1959-1960. He says, with a twinkle in his eye, that his Presidential Address to the corrosion engineers was written by his daughter who was then of school age. Kathy learned at the dinner table that her father was going off again to give another of his corrosion talks. She arose from the table and solemnly announced that she knew exactly what he was going to say: "Are we just going to stand around and let metals corrode?" Frank thought that was the most concise reason for the existence of the National Association of Corrosion Engineers so he used it as the sum total of his remarks.

Frank has been active over the years on many government committees, including those of the Materials Advisory Board, the National Research Council, and the National Bureau of Standards. He was recent chairman of the Department of Commerce Panel on Engineering and Commodity Standards, and he is at present chairman of the Advisory Committee on Ocean Resources of the U.S. Department of Interior. I am told that his activities in government extend as far as Canada where he has been known to argue at length with the authorities on the urgent need to change regulations that make it difficult for U.S. citizens to obtain Ontario fishing licenses.

He is a member of the Board of Directors of the William F. Clapp Laboratories in Duxbury, Mass., now a division of the Battelle Memorial Institute. Frank's close association with the Clapp Laboratories goes back to 1938 when the late Bill Clapp, a colorful, world-renowned expert on marine organisms, found that the corrosion test site at Kure Beach was an excellent place to study the various flora and fauna which attach themselves to, or bury themselves in, various materials exposed to sea water. Frank and Bill's combined studies led to jointly authored papers, and inevitably to such unofficial antics as growing hair-like organisms on billiard balls as proof that natural sea water is a good hair tonic.

In our own Society he has contributed outstandingly to each office he has held. He is a former Chairman of the Membership Committee, Business Manager of the *Journal* at a time when income was of essence, and Chairman of the Sustaining Membership Committee. In connection with the latter appointment, Frank's personal acquaintance with a large cross section of administrative heads and research directors made his letters invaluable for gaining additional corporate friends and supporters of the Society. His campaign brought many gratifying replies and an occasional surprise. One unexpected response came from one of the directors of a large aluminum producer whose primary product, of course, is all made electrochemically. The director regretted he was unable to recommend support of The Electrochemical Society in light of the fact that his company's activities were not primarily concerned with electrochemistry. Frank was tempted to ask permission to frame the letter and display it as an example of how much some top managements know about their own business.

He served on the Executive Committee which organized the "Corrosion Handbook" sponsored by the Corrosion Division. Not only were the chapters he contributed outstanding portions of the final book, but his advice to the Editor was also invaluable in choosing the right author for the right chapter. He served as President of our Society in 1962-1963 and continues to contribute his valued counsel to several committees.

Publications

Despite his occupation with a wide range of activities, Frank somehow found time to write more than 150 papers on corrosion, on metals in general, and on a few miscellaneous subjects related to neither, for example a paper in *Metals Review* for 1961 entitled "The Care and Feeding of Librarians." He co-edited with Harry Copson in 1963 a sizeable monograph "Corrosion Resistance of Metals and Alloys," which is a major reference source for corrosion engineers. His many papers on corrosion of metals in sea water combine to form the chief source of authentic information on this subject. The titles of his remaining papers range from down-to-earth subjects such as "Corrosion in the Home" and "Corrosion of Auto Bodies" to "Corrosion Testing," and "Metals for Space Travel." He wrote a fascinating article in the *1968 Yearbook of the Encyclopedia of Science and Technology* on the design of our present sandwich coins. His expert advice was drawn upon to specify the proper electrical conductivity and density of the nickel alloy-copper laminates making it possible for 15 million coin-operating machines in the U.S. to continue operating normally instead of automatically rejecting the new coins as counterfeit.

Perhaps his paper on "A Critical Look at Salt Spray Tests" is the one which received widest notice, debunking as it does a corrosion test that was used ritualistically for many years by industry and government without a true understanding of what the test implied. LaQue, in typical fashion, has verbally summed up the salt spray test as one which "can be used to provide a recordable reason for accepting or rejecting something, and is valuable for this purpose if the reason does not have to be sound." He wrote furthermore: "One of the characteristics of the salt spray test is its inconsistency. This extends as well to some of the people who make the greatest use of it." But his paper was much more than a witty exposure of careless specification. He presented a variety of data, many of which were obtained at the Harbor Island Laboratory by his own staff, to show that the salt spray test could hardly be called reliable for evaluating the merit of metal performance in other than perhaps a spray of NaCl solution. The results certainly did not accord with the performance of metals exposed to rural or industrial atmospheres, or when immersed in fresh or salt waters, or even necessarily when exposed to atmospheres along the sea coast. The journal *Metaux Corrosion-Industries* translated his paper for the benefit of French-speaking engineers and I daresay that engineers in many other parts of the world quickly learned of it through one source or another. Largely because of LaQue's efforts, this test, once a universal hand-me-down, is now specified with greater caution and with greater respect for its limitations.

Educational Activities

In addition to Frank's many talks to technical societies, his corrosion clinics at Harbor Island meetings of the Sea Horse Institute established his reputation as a patient teacher. Early in his career at the International Nickel Co., he taught sales and technical personnel some of the elements of corrosion so that they could better understand the alloys with which they were dealing. This led eventually to the three-reel educational film "Corrosion in Action" which, with the accompanying book, was completed in 1955 with T. P. May's help and some advice from me. The film has been in great demand ever since it was first issued. With sound track available in any of the major foreign languages, it has been shown to thousands of students and technical society audiences all over the world.

Frank has served as a member of the Visiting Committees of the Departments of Metallurgy at M.I.T. and at the Case Institute of Technology, and of the Division of Electrochemistry at the University of Pennsylvania. In 1964 he published results of a survey he conducted on the education of corrosion engineers in which he proposed various recommendations to meet current needs, emphasizing that basic

research should be supported as a stimulant to participation of teachers and students in the many fundamental and practical corrosion problems begging for some solution. His Presidential Address to our Society at Pittsburgh in 1963 included an evaluation of the present education of students in electrochemistry. He concluded that, despite present trends and obvious changes of emphasis, the education of future members of our Society is in good hands.

Honors

He received the F. N. Speller Award of NACE in 1949, the Howard Coonley Medal of the American Standards Association in 1962, and he delivered the Edgar Marburg Lecture of ASTM in 1951. His Honorary Doctorate, conferred by Queen's University in 1963, has already been mentioned. He well deserves, as I am sure you agree, the added recognition by our Society which is provided by the Acheson Medal Award. His name adds further distinction to an already distinguished list of Acheson Medalists. It has been a pleasure and a privilege for me to outline briefly Frank LaQue's impressive career and accomplishments which make him so deserving of the honor he receives tonight. The tremendous influence he has made on his professional area, on the over-all community within which all of us live, and on The Electrochemical Society, continues to evoke our admiration, our respect, and our continuing good wishes for a long career which I expect will more than adequately project the marked successes already in the record.

At this moment in the evening's proceedings, Frank would have an appropriate poem to recite. Perhaps the best I can do is to quote one of his, which has nothing to do with my previous remarks, but which may nevertheless strike a note of sympathy among many of you who have been attending technical sessions:

> We are gathered from all over the nation
> For studying polarization
> And calomel cells that don't ring any bells
> But provide an excuse for oration.

Electrochemistry and Corrosion

(Research and Tests)

F. L. LaQue[1]

Francis L. LaQue accepts Acheson Medal from ECS President Ivor E. Campbell.

Members of this Society and particularly of its Corrosion Division are not likely to require much persuasion that most corrosion processes are electrochemical in nature. Stemming from this fact, research related to corrosion as a phenomenon has become more and more a series of experiments in electrochemistry dealing with what happens when a metal or an alloy is placed in contact with an electrolyte. The significance of such experiments will vary through wide limits, depending on how corrosion is approached and defined by whoever wishes to make some practical use of the results.

In Dr. Uhlig's "Corrosion Handbook," sponsored by the Corrosion Division of this Society, corrosion is defined as "destruction of a metal by chemical or electrochemical reaction with its environment."

In this definition, the order of the words gives priority to the results of the corrosion reactions rather than to the reactions themselves. Otherwise, the definition would presumably have been written as "chemical or electrochemical reaction causing destruction of a metal by its environment."

This difference in wording of the definition of corrosion has probably in some partly subconscious fashion had a strong influence on how the study of corrosion has been approached. Investigators can be divided into two broad classes. One group must deal with corrosion as an engineering problem. The other is principally concerned with corrosion as an interesting subject for electrochemical experimentation.

What is described as "Corrosion Research" undertaken by these groups may have very little in common. Corrosion engineering research, often more properly described as corrosion tests, may do no more than put selected metals and alloys in a proper order of apparent merit in resisting attack by the environment to which test specimens are exposed. No effort may be made to understand the mechanisms of the corrosion reactions or why one metal performed better than another. Generally, the results are expressed in quantitative terms that are likely to be more useful in giving an impression of the order of magnitude of corrosion rates than as a reliable basis for estimating how long the metals will last in the intended service. The numbers also facilitate placing the metals in an order of rank.

On the other hand, a good deal of what is called basic corrosion research represents no more than exercises in the study of electrochemical phenomena employing combinations of metals and environmental conditions chosen mainly to facilitate experiments for the convenience of the investigator. They also may enable him to make use of equipment and experimental techniques with which he is familiar or which are currently in vogue. This leads to the accumulation and publication of data on combinations of metals and environments rarely if ever encountered in practice and of no real significance with respect to our first definition of corrosion.

No doubt, dilute solutions of sulfuric acid represent a convenient electrolyte for undertaking electrochem-

[1] Acheson Medal Address delivered October 8, 1968 at the Montreal Meeting of The Electrochemical Society.

ical experiments with a potentiostat. No doubt, also, such experiments are easier to undertake as well as to interpret when oxygen is excluded. Probably, also, in many cases the choice of the metal to be studied is not really critical to the experiment so long as it is not subject to erratic behavior in the test environment. All of these considerations probably account for the great amount of data that may be found in the literature dealing with experiments making use of a potentiostat and involving dilute sulfuric acid, frequently free of oxygen.

A casual survey turned up eight papers along this line published between 1957 and 1965. Because of the fact that, in my forty years of concern with corrosion problems, no practical questions have arisen with respect to the behavior of the metals covered in these papers in oxygen-free, one or two normal sulfuric acid, one is tempted to wonder if the investigators could not have satisfied their scientific curiosity as well by choosing combinations of metals and environments that someone might be really interested in.

It will be recalled that our definition attaches prime importance to "destruction" of a metal when this is not desired rather than "destruction" to a degree that may be of little consequence to the investigator. Under these circumstances, the corrosion reactions that are involved in some corrosion research are frequently made to occur so that they can be observed and studied largely for their own sake.

One should not object to research undertaken for its own sake and to satisfy scientific curiosity. However, in the field of corrosion, such exercises should not be described as being specifically aimed at an improved knowledge of corrosion in terms of the definition in common use. The most that can be expected is that the product of such research may in some unplanned way provide a missing piece to complete a particular area of the perplexing jigsaw puzzle of corrosion.

These remarks do not extend, of course, to corrosion research aimed at an improved understanding of the mechanisms of corrosion and particularly of the types, such as localized pitting and crevice corrosion, intergranular attack, and stress corrosion cracking, that are most troublesome. Even here, some problems arise when methods of test designed to facilitate study of the basic phenomena are applied to qualify materials for particular services.

Many electrochemical techniques, and particularly the use of potentiostats, are valuable in throwing light on why, and to what extent, changes in composition of an alloy are effective. They are useful for screening alloys for service in environments reasonably approximated by the electrolytes used in the experiments. These solutions need not try to simulate the environment of use. They should be chosen to permit systematic modification so as to provide a means for characterizing the ability of an alloy to preserve, or regain, passivity under conditions which are progressively and measurably made more aggressive.

Potentiostatic techniques are useful, also, in a somewhat oblique connection with the primary definition of corrosion in the controlled etching of specimens to disclose details of structure which are likely to affect corrosion behavior.

Some of the points just discussed will be illustrated by examples encountered during my struggles with corrosion over the past forty years.

In spite of occasional assertions by others to the contrary and possible misinterpretation of these present remarks, I am in favor of basic research in corrosion. I served for several years as chairman of the Corrosion Research Council and endeavored with only limited success to persuade industry to provide funds for support of such research in universities. This program did yield some valuable results and did attract to the field several very competent scientists who are carrying on their work with other support and, equally importantly, are educating others to continue scientific attention to corrosion.

At the same time, I have been frequently disappointed by programs described as fundamental research in corrosion.

All too often it seems that what is called fundamental research should be described more accurately as "oversimplified" research. The "oversimplification" stems generally from the apparent unwillingness of the investigator to cope with important factors that may be difficult to control and which, if allowed to exert their influence, would have such a tremendous effect on the results that it is more convenient to eliminate their possible effects than to cope with them in the experiments and in the interpretation of the results.

This point is illustrated very well by effects of dissolved oxygen. One of the too-frequent characteristics of what are claimed to be "fundamental" corrosion research experiments is the rigid exclusion of oxygen from the test environment. It is obviously easier to keep oxygen out of a test solution than to study its effects over a broad range of concentration.

When researchers are challenged on this point, they frequently assert that the oxygen-free solution represents only the beginning of a series of experiments in which effects of controlled amounts of oxygen will be observed systematically. Unfortunately, many, if not most, of these projects never get beyond the oxygen-free stage.

Since oxygen-free environments are the exception rather than the rule in situations where destruction is an important practical problem, it is not too surprising to hear complaints from industrial sources of support for corrosion research that they have found it to be difficult to recognize practical benefits from such research.

The situation illustrated by oxygen extends to such other important factors as temperature and velocity of movement. Here, again, the control of these factors is likely to be determined more by the convenience of the experiment and the limitations imposed by the test apparatus than by the need to extend the results to other conditions of temperature and velocity more likely to be encountered in practical corrosion problems.

Reference was made previously to the inclination of some investigators to approach the study of corrosion by the use of apparatus and techniques that are currently in vogue. A prime candidate for this characterization is the potentiostat.

The potentiostat is well adapted to grinding out data rather easily, which can be displayed in a series of impressive-looking curves relating applied voltage to current flow. These provide ample scope for interpretation and comment which often extends to portions of the curves which have questionable relationship to what goes on in normal corrosion reactions not disturbed by the application of current from external sources. Potentiostats are quite capable of applying potentials very much higher than could ever be encountered in a normal corrosion reaction. The data outside such normal ranges of potential frequently occupy large sections of the curves that are plotted and are given probably much more attention than they should receive in drawing conclusions from the experiments

I have seen reports of experiments with a potentiostat designed to compare the resistance of a number of low-alloy steels to corrosion by a sodium chloride solution (assumed to represent sea water). The curves that were plotted covered a range of potential well over a volt even though the maximum difference in potential of anodic and cathodic surfaces of the steels studied would not exceed about 200 mv.

The investigator concluded, properly, that there was no significant difference in the resistance of the several steels to corrosion by sea water. This confirmed data which I had published about twenty years earlier based simply on long-time exposure of similar steels under

conditions of immersion in sea water under natural conditions. The similarity in the conclusions should be considered to be largely a matter of coincidence rather than as evidence of the value and reliability of the potentiostat approach. The reason the steels behaved alike in the test under natural conditions was that the rate of attack of all the steels was determined, not by the corrosion-resisting characteristics of the steels, but by the rate at which oxygen could diffuse through the thick layers of rust and marine growths that accumulated on all the steels to the same extent. Since no such controlling factors were capable of being introduced into a short-duration experiment with a potentiostat, it could not be expected that such a test would reliably measure resistance to corrosion under the natural conditions to which the results were claimed to apply, and where the major controlling factor was not a characteristic of the steel but rather an external factor involving marine organisms.

One may also question the reliability of studying the two halves of a corrosion reaction separately and then endeavoring to combine the results on the assumption that this approach is equivalent to studying the simultaneous reactions concurrently without distortion by impressed currents. Some investigators appear to be convinced that it will suffice to observe the behavior of a metal only as an anode even though there are many corrosion reactions in which what happens at the cathode has the dominant effect. There are many other instances of mixed control.

There is a quite legitimate and proper use of a potentiostat or galvanostat to provide a basis for the application of electrochemical methods of protection—cathodic or anodic. Such experiments are likely to be most reliable if the expected environmental conditions are reproduced in the test, *e.g.* with proper control of aeration, temperature, and velocity, as well as the chemical composition of the test solution.

Too many corrosion engineers practicing the art of cathodic protection continue to be unconcerned, as well as confused, by a lack of understanding of the electrochemical phenomena by which what they accomplish is achieved and monitored.

Fortunately, the margin for error in this field appears to be broad enough to accommodate imperfections. The economic penalty and possible hazards of overprotection are generally tolerable except when alloys susceptible to attack by alkalis or to hydrogen damage are involved. This latter danger is worthy of much more attention by both electrochemists and metallurgists.

On the other hand, the practice of anodic protection appears to have a more substantial scientific basis and to be much better understood by those who use it. This fortunately permits more precise application and control. Failure to provide for proper monitoring and control of anodic protection could have disastrous consequences.

Attempts may also be made to use a potentiostat technique to study the normal corrosion behavior of a metal in a corrosive solution likely to be encountered. Here there is a frequent difficulty associated with the very short interval over which the measurements will be made as compared with very long periods of time during which accumulation of adherent protective films of corrosion products or environmental deposits may have a controlling effect on behavior.

Metals to be studied for normal corrosion behavior can be divided into two general classes:

Class one includes metals that are not expected to survive for the desired life without benefit of some means of protection, *e.g.* by some sort of coating or some treatment of the environment which would have to be duplicated in the potentiostat experiment. The difficulty of dealing with and interpreting results of tests with coated specimens in a potentiostat setup limits its usefulness in this category.

Class two includes materials that are expected to survive without the benefit of supplementary protection. These materials very rarely fail by general wastage in either the active or passive state in the environments in which they are likely to be used. They fail, when they do so, by such forms of attack as pitting, stress corrosion cracking, corrosion fatigue, intergranular attack, impingement attack, hot spot effects, and so on, not readily disclosed by the results of studies with a potentiostat. This device is, of course, applicable to studies of the mechanisms of such forms of damage under conditions designed to create the damage so that it can be studied. It is less reliable for qualifying metals for service in which these forms of damage may be encountered.

Devices and techniques for using response to polarizing currents as a means for observing corrosion behavior have been found to be very useful for monitoring the effects of changes in the environment on its corrosivity toward a metal. For example, such measurements have been found to be more sensitive than other means for detecting excursions in the oxygen content of brines in sea water distillation plants.

Mainly because of the short time interval involved in such measurements, they are of questionable value in predicting long-time behavior or for more than preliminary screening of a number of metals and alloys as a basis for selection of the most appropriate one for a particular application.

One can be equally critical of attempts to attach quantitative significance, in terms of life expectancy, to corrosion tests under natural conditions or as good a simulation of natural conditions as may be achieved. It is not too difficult to secure excellent reproducibility of results of such tests and excellent agreement among the results for several specimens tested at the same time. Reproducibility should not be taken as qualifying the results as being quantitative in terms of predicting life.

A principal reason for this difficulty is that in many, if not most, cases the results are determined to a major extent by the dimensions of the test specimens.

Where pitting is the principal mode of attack, the results will involve both the number of pits and their depth. Since in most cases the occurrence of a pit is a matter of statistical probability and the chance that a pit will be found increases with the area of surface exposed to attack, a large specimen can be expected to disclose greater susceptibility to pitting than will a small one. And, since the pitting mechanism usually involves a sort of galvanic effect between an anode in a pit and a cathode on the surrounding surface, the chance that an anodic pit will be surrounded by a large cathode will be greater on a large specimen than on a small one. Consequently, pits on large specimens are likely to be deeper than on small ones. If the size of specimen happens to yield a population and depth of pitting that may occur under conditions of actual use, this is most likely to represent coincidence more than a truly quantitative test.

A similar area effect pertains to tests for resistance to corrosion in crevices. Here, too, the depth of attack that may be observed in a test will be determined largely by the ratio of the area of the freely exposed surface outside a crevice to the area within a crevice. This is illustrated by Fig. 1. Test setups are not likely to duplicate these area relationships as they exist in large fabricated equipment.

Another example of an area effect is provided by tests for studying the ability of alloys to resist erosion in sea water by spinning submerged metal disks on a shaft at some appropriate number of revolutions per minute.

There will be a velocity gradient from the center to the periphery of a spinning disk and, by ignoring friction film or boundary layer effects, it is possible to calculate the velocity at any radius of revolution. By measuring the decrease in thickness at any radius point, it is possible to relate the rate of attack to the speed of movement as shown by Fig. 2, Unfortunately,

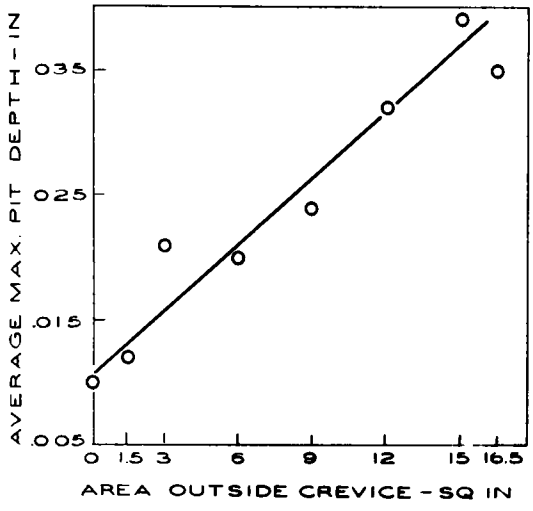

Fig. 1. Average maximum pit depth within the crevice vs. area of specimen outside the crevice.

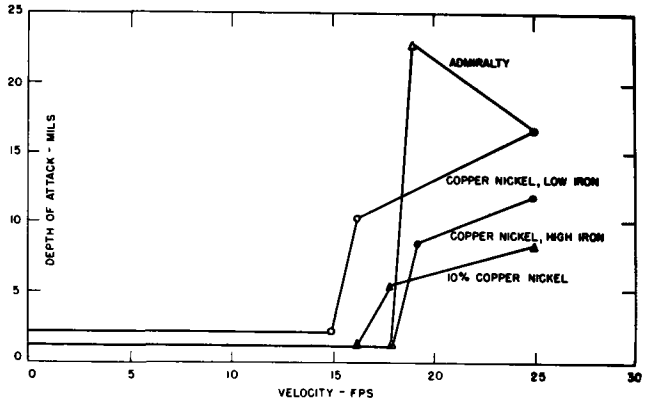

Fig. 2. Effect of velocity on depth of attack in sea water at Kure Beach, N. C., for 60 days.

it has been observed that different rates of attack can be associated with the same velocity depending on the diameter of the disk that is used for the experiment. This is illustrated by a series of tests on copper alloy disks shown in Fig. 3, and the wide spread in rates of attack at the same calculated velocity shown by Table I.

To add further confusion to the interpretation of velocity effect data such as yielded by tests with spinning disks, consider what happens when the materials being tested are iron and its alloys rather than copper and its alloys. Figure 4 shows that, when iron disks are tested, the differential aeration electrochemical phenomena that come into play produce the greatest

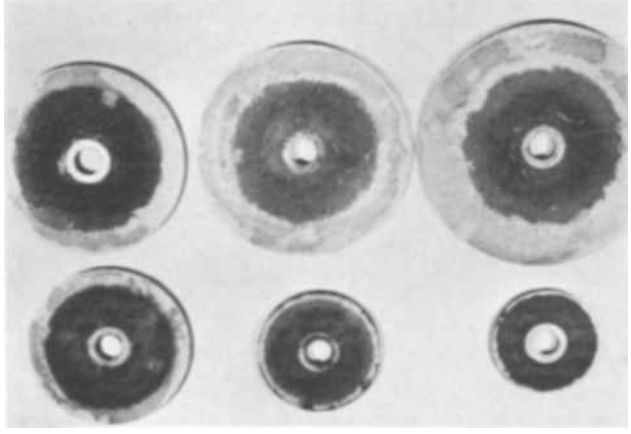

Fig. 3. Distribution of attack on copper alloy disks rotated in sea water at the same speed in revolutions per min.

Table I. Comparison of depths of attack on surfaces of disks of different sizes moving at same speed as periphery of smallest disk

Disk diameter Inches	Cm	Depth of attack at radius of 1.5 in. (3.8 cm) velocity, *15.2 fps 4.5 m/sec In.	Mm
3-1/4	8.3	0.020	0.51

7-3/16	18.3	0.002	0.005

* Calculated from rpm and radius of rotation at point of attack.

attack at the lowest velocity rather than the highest and the size effect becomes as important with iron as it is with copper.

It will be evident also from looking at Fig. 4 that experiments could be conducted that would yield rather amazing and certainly incorrect results. For example, one could decide to study the effects of a range of velocities using small-diameter disks for low velocities and larger disks for higher velocities and measuring the rates of attack at the peripheries of the several disks.

By this means, it would be possible to generate apparently quantitative and reproducible data that would prove that iron is not corroded by sea water at any velocity within the range studied.

Similarly with copper alloy disks, as in Fig 3, it would be just as easy to show that an alloy would be corroded by sea water rather severely at a rate that would be substantially independent of velocity in the range achieved in such a series of tests.

One could also manipulate the choice of size of copper alloy disk to achieve a certain velocity to produce data that would "prove" that one alloy was better than another at the velocity of interest. This would be accomplished by using a larger disk for the alloy one wanted to show to be better and a small disk for the alloy to be downgraded. This would require, or course, that only the velocity achieved, and not the different sizes of disks used to get it, be described in the report of the results.

To make matters worse, the effect of velocity on corrosion is quite different when the method of test achieves a velocity gradient over the surface of the specimen from what it is when the method of test maintains a uniform velocity over the test surface.

A sharp velocity gradient is likely to be more damaging than a high but uniformly distributed velocity. Consequently, any test of velocity effects must be properly related to the expected velocity gradients in the service to which the results of the test are to be applied. It would be reasonable to require the use of both types of test in a search for an alloy that would perform well in the presence of both very high uniform velocities and very high velocity gradients.

Electrochemical measurements including polarization phenomena are not free from the size effects that detract from the quantitative significance of other and more direct means of measuring corrosion behavior. The apparatus generally requires the use of quite

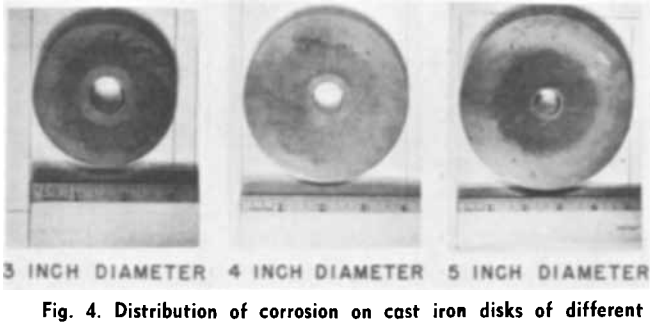

Fig. 4. Distribution of corrosion on cast iron disks of different diameter rotated in sea water at the same speed in revolutions per min: cast iron disks rotating spindle test 30 days at 15°C.

small specimens. Reproducibility is generally favored by making test specimens smaller and smaller. It should be understood, however, that, while reproducibility is a necessary feature of any method of test that gives reliable results, it can also be a characteristic of a procedure that gives consistently wrong answers. One test can be as consistently wrong as another can be consistently right. Either type can be useful once a consistent relationship between the results of the test and performance in the service toward which the test is directed has been established by experience.

Even though the possibility exists that a fundamentally unsound but consistent test can be interpreted properly, one cannot be blamed for preferring the type of test that gives results that point rationally in the right direction.

In summary, I have suggestions for corrosion scientists and for corrosion engineers.

It would be most helpful if electrochemists interested in corrosion phenomena, in their response to scientific curiosity, were more frequently to choose for their experiments combinations of metals and environments that are likely to be encountered in practice, so long as this action does not introduce intolerable or insurmountable experimental difficulties or unduly limit the range of their studies.

Corrosion engineers should develop more scientific curiosity as to the reasons why the metals they test behave the way they do. They should also develop more scientific curiosity about, and a better understanding of, the electrochemical mechanisms of the corrosion reactions responsible for the results they observe. These mechanisms generally determine and frequently restrict the quantitative significance of the data from which they draw their conclusions and on which they make their engineering decisions.

A better understanding of the science of corrosion should lead engineers to abandon improper tests, improve old tests, introduce new tests, make more reliable evaluation and interpretation of results of all kinds of test, good or bad. It would also permit more ready recognition of the faults of a bad or inappropriate test and the merits of a good one.

My friends who know me best will, I am sure, recognize that in making these deliberatively provocative remarks I am, at the same time, hoping that those who feel they have been abused will become determined to demonstrate conclusively that I am mistaken. I shall not be unhappy if they should succeed in such endeavors.

At the same time, there is at least an off chance that one or another of my criticisms has a substantial foundation and that the response to this criticism will show that it has been constructive.

Reports on ECS Summer Assistance Awards and Weston Fellowship Award for 1968

During the summer of 1968, the following graduate students received $800 each, representing three Summer Assistance Awards of The Electrochemical Society.

Karl Doblhofer, Colorado State University, Fort Collins, Colo., was awarded the Edward Weston Fellowship.

Robert A. Bonewitz, Department of Chemistry, University of Florida, Gainesville, Fla., was designated recipient of the Colin Garfield Fink Fellowship.

L. P. Zajicek, University of Hawaii, Honolulu, Hawaii, received the ECS Summer Fellowship Award.

The Summer Assistance Award is made "without regard to sex, citizenship, race, location, or financial need to a fellow or teaching assistant pursuing work between the degree of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." It is intended to cover a period during which the recipient has no financial support for the continuance of his work.

The Edward Weston Summer Fellowship Report

A summary of Mr. Doblhofer's report is given below.

Instrumentation for Interfacial Tension and Differential Capacity Measurements

I am concerned with the measurement of adsorption isotherms of organic materials on mercury electrodes. The amount of adsorbed substance (Γ_O) can be calculated according to the thermodynamic theory of electrocapillarity (1) by means of the equation

$$\left(\frac{\partial \gamma}{\partial \mu_O}\right)_E = -\Gamma_O$$

where γ is the interfacial tension and μ_O is the chemical potential of the sorbate. I am using two experimental methods to investigate the adsorption:

(*A*) Measurement of interfacial tension, using a capillary electrometer.

(*B*) Measurement of differential capacity curves using an a-c bridge.

An improved capillary electrometer was built in our laboratory. It allows the determination of the interfacial tension of the mercury-solution interphase with a standard deviation of approximately 0.02 dynes/cm. Some time last summer was spent evaluating the precision of this instrument. The electrocapillary curves were analyzed by digital computer using the moving fit technique for smoothing and differentiation previously developed in this laboratory (2). As a critical test, double differentiation was performed to obtain the differential capacitance *C*, according to the equation

$$\left(\frac{\partial^2 \gamma}{\partial E^2}\right) = -C$$

The resulting C-E curves for sodium chloride solutions have the characteristic morphology, including the familiar hump (Fig. 1). The general agreement with capacitance values directly determined in our laboratory and also with those reported by Grahame (3) was satisfactory.

A detailed description of the capillary electrometer is being prepared for publication.

The rest of the summer was spent developing the instrumentation for accurate differential capacity measurements. The measurement is carried out with a General Radio type 1615-A transformer ratio-arm capacity bridge. The range of this bridge is not quite wide enough to allow measurement of either capacity or dissipation on the high adsorption-desorption peaks of the differential capacity curves of neutral organic sorbates. However, it was found that satisfactory measurements could be performed by connecting a standard capacitor of 1 μf in series with the electrochemical cell.

Because of the thermodynamic significance of a reference electrode reversible to an ion in the solution [indicator electrode (1)], we wanted to use the very

Cahoon and McKinley Take Office in New York

N. Corey Cahoon

Theodore D. McKinley

As a result of the recent annual elections in which the voting was conducted by mail, N. Corey Cahoon has been elected the new President (1969-1970) of The Electrochemical Society and Theodore D. McKinley has been elected Vice-President (1969-1972).

Mr. Cahoon, Senior Scientist, Electrochemical Development Laboratories of the Consumer Products Division of Union Carbide Corp., Cleveland, Ohio, replaces Ivor E. Campbell, who will continue as Past President on the Board of Directors.

Dr. McKinley, Research Supervisor, Du Pont Experimental Station, Pigments Division, E. I. du Pont de Nemours and Co., Wilmington, Del., begins the first year of his three-year term as Vice-President.

The new officers assume their positions in May 1969.

Offices not affected by the election are those of the two other Vice-Presidents, Charles W. Tobias and Cecil V. King; Secretary, Dennis R. Turner; and Treasurer, R. Homer Cherry, respectively.

DIVISION NEWS

Electronics Division

The bylaws of the Electronics Division of The Electrochemical Society require that the Chairman of the Division appoint, at least six (6) months prior to the convention at which the next election is to be held, a Nominating Committee of at least three (3) division members. This committee is required to nominate a slate of officers and members at large of the Executive Committee. At the last Executive Committee Meeting in Montreal, a Nominating Committee was appointed to nominate a slate of officers for the years 1969-1971. It is with pleasure we announce that the Nominating Committee has selected the following candidates for the next term of office.

Chairman-Electronics Division—Roger Newman, Sperry Rand Research Center, North Rd., Sudbury, Mass. 01776

Chairman-Semiconductor Group—Harry Sello, Fairchild Semiconductor Research & Development, 4001 Miranda Ave., Palo Alto, Cal. 94304

Vice-Chairman—General Electronics Group—Erik M. Pell, Xerox Corp., Research & Engineering Science Division, Xerox Square W114, Rochester, N.Y.

Vice-Chairman-Luminescence—Philip Jaffe, Zenith Radio Corp., Research Dept., 6001 W. Dickens Ave., Chicago, Ill. 60639

Secretary-Treasurer—Bertram Schwartz, Bell Telephone Laboratories, Murray Hill, N. J. 07974

The election of officers will be held at a General Electronics Meeting that will be held during the time of the Society Meeting in New York City.

Additional nominations for officers may be made by petition signed by five (5) members of the Division. Such petitions must be in the hands of the Chairman of the Nominating Committee at least ten (10) days before the election, with the assurance of the nominee's willingness to serve if elected.

The officers and members at large shall be elected by a majority vote of those present at the business meeting of the Division that will be held in New York City. Those elected shall take office immediately after adjournment of the New York National Meeting.

D. K. Hartman
Secretary-Treasurer

Electro-Organic Division

The Electro-Organic Division will hold a luncheon and business meeting at the New York Meeting at 12:15 P.M. on Wednesday, May 7, 1969, at the Commodore Hotel. A vote will be taken on adoption of new bylaws for the Division. The new bylaws include provision for changing the name of the group to the Organic Division. Plans for future symposia will also be discussed. Professor Stanley Wawzonek of the University of Iowa, Divisional Editor of the Electrochemical Science Section of the JOURNAL, will present a brief talk on the publication of scientific papers in the JOURNAL.

The Division's Nominating Committee under the Chairmanship of Manuel Bazer have proposed the following

Ion Retention in Cathodes and Precipitates of Silver Chloride-Magnesium Sea Water-Activated Batteries

Duane W. Faletti

Applied Physics Laboratory, University of Washington, Seattle, Washington

Michael A. Gackstetter

University of Minnesota, Minneapolis, Minnesota.

and John A. Arne

Naval Torpedo Station, Keyport, Washington

ABSTRACT

The magnitude of the retention of ions in the reduced portion of the cathodes and in the precipitate formed in AgCl-Mg sea water-activated cells was studied. Both the ions found in the entering electrolyte and those introduced by the electrochemical reaction were retained in significant amounts. Calculations indicate that underestimations in the voltage losses across the interelectrode space as high as 0.05v occur if this retention is neglected. A method to adequately account for retention is suggested.

As part of a continuing study of the silver chloride-magnesium couple in sea water, an investigation was made of the magnitude of the retention of ions in (*a*) the reduced portions of the cathode, and (*b*) the precipitate. This process, referred to as retention, increases the magnitude of the voltage drop across the interelectrode space by its affect on the composition (hence conductivity) of the electrolyte.

The electrochemical reaction for the silver chloride-magnesium couple

$$2AgCl + Mg \rightarrow 2Ag + MgCl_2 \qquad [1]$$

results in the addition of the soluble salt, $MgCl_2$, to the electrolyte and the formation of a porous layer of silver, known as sponge silver, on the AgCl cathode. The void spaces in the sponge silver fill with electrolyte composed of water and dissolved ions from the free electrolyte entering the cell and the Mg^{++} and Cl^- ions generated from reaction [1].

AZ61 magnesium alloy is the commonly used anode material for such batteries as it forms reasonably non-clogging reaction products [ref. (1) and (2)]. Anode efficiencies are reduced to about 75% by the secondary anode reactions with water during discharge to form H_2 and insoluble reaction products, the latter probably containing the hydroxides (along with hydroxy-chlorides and other double salts) of magnesium, aluminum, zinc, and manganese. The anode constituents tied up in these insoluble products are not considered removed or withheld from the free electrolyte since they play no electrochemical role. However, the tying up of chloride ions, etc., via the formation of double (insoluble) salts and/ or the absorption of ions in the precipitate do constitute another source of ion removal (retention) from the free electrolyte.

Basis for Experimental and Calculation Procedure

In order to simplify the chemical analyses, sea water (Table I) was simulated from only three salts: NaCl, $MgCl_2$, and Na_2SO_4. (The resulting solution corresponds to that used in ref. (3) with the substitution, on an equivalent weight basis, of NaCl for the KCl and KBr, and $MgCl_2$ for the $CaCl_2$, and of Na_2SO_4 for the $NaHCO_3$. The remaining salts used in ref. (3), HBO_3, $SrCl_2$, and NaF, are present in such minute concentrations that they were neglected.) Therefore, the retention of four ionic species, Na^+, Mg^{++}, Cl^-, and $SO_4^=$, constituting over 98% of the ions found in sea water, was studied.

The retention of the above ions, with the exception of Na^+, was determined from a material balance by (*a*) determining the flux of each ionic species into and out of the cells by quantitative determinations of the concentration of the ionic species and the flow rate of the electrolyte; (*b*) calculating the amount of Mg^{++} and Cl^- ions generated by reaction [1] from Faraday's law and a knowledge of the current (held constant) flowing through the cell.

The following items were taken into account: (*a*) the amount of water reacting with the AZ61 anode, (*b*) the effect of the weight of the precipitate on the weight of the effluent, and, (*c*) the amount of water entering the sponge silver, calculated by assuming that the water filled 95% of the voids in the sponge silver (the remaining 5% is an allowance for the effects of volume changes resulting from ion retention).

The results were expressed in the form of gram-equivalents per cubic centimeter of sponge silver determined by dividing the equivalents of each ionic species retained per unit time by the volume of sponge silver formed per unit time (calculated from Faraday's law and the current by assuming that no volume change occurred in the over-all dimensions of the cathode on reduction). From electroneutrality one can write

$$R_{\pm} = R_{Cl^-} + R_{SO_4=} = R_{Mg^{++}} + R_{Na^+} \qquad [2]$$

where $R_{\pm}$ is the total retention coefficient, g-equiv/cm^3, and R_{Cl^-}, $R_{SO_4=}$, and R_{Na^+} are the individual ionic retention coefficients for the chloride, sulfate, magnesium, and sodium ions, respectively, g-equiv/cm^3 of sponge silver.

Since no sufficiently accurate analytical technique was available for the direct determination of the retention of Na^+, the retention of sodium ions was obtained from Eq. [2] by subtracting $R_{Mg^{++}}$ from $R_{\pm}$.

Analyses of the effluents of silver chloride-magnesium batteries showed that, except for magnesium,

Table I. Composition of simulated sea water*

Salt	Chlorinity	
	4.5°/oo	19.0°/oo
NaCl	5.695	24.044
$MgCl_2$	1.404	5.926
$NaSO_4$	0.966	4.079

* Concentrations given in g/kg of solution.

negligible amounts (less than 10 ppm) of the constituents of AZ61 alloy remained in solution; hence, only the four above-mentioned ions need be considered.

Apparatus

The apparatus, essentially that used in a former study [ref. (1)], was designed to maintain relatively constant inlet conditions while discharging the cell at constant current and relatively constant flow rate.

The production of H_2 by the secondary reactions at the anode resulted in a two-phase, slugging flow with a relatively long period between slugs of liquid which degraded the accuracy of the flow measurement. To circumvent this problem, nitrogen was passed into the exit line immediately upstream of the exit valve (used to maintain test pressure) in order to reduce the periods of the alternate slugs of liquid and gas to less than one second.

The desired inlet temperature was obtained for the low and the high temperature discharges by passing the incoming electrolyte through a stainless steel coil, placed in a bath kept within ±4°F of the desired inlet temperature. The coil was removed for runs made at or near 75°F.

The current was determined by placing a 0.01 ohm standard resistor (±0.04% accuracy) in series with the constant current load and measuring the voltage drop with a differential voltmeter accurate to 0.05%.

The average flow rate during the sample period was determined by time-weight measurements. The elapsed time, measured with a stop watch, was accurate to about a second; the weight was measured to an accuracy of 0.01%.

Cell Assembly

The cell assembly is the same as described in ref. (1), except that it was modified for use with only one cell.

Cells of two different lengths were used in the study which were fabricated from 0.0215 in. thick silver chloride and 0.013 in. thick magnesium. The cells had active surface areas 2.125 in. wide by 10.75 in. long for discharges conducted at current densities of 1 asi and 2 asi, and 2.125 in. by 6.25 in. for the discharges at 3.4 asi.

Preparation of Electrolytes

Four electrolytes were studied. Two were made according to Table I, having chlorinities of 4.5‰ (parts per thousand) and 19.0‰. The two remaining electrolytes were prepared from simulated sea water with a chlorinity of 4.5‰ by adding, respectively, 17.5 and 35.0g of magnesium chloride per liter (measured at 77°F). The solutions are designated by the notation "chlorinity-added magnesium chloride" (*e.g.*, 4.5-35.0).

Procedure

To complete decontamination of the entire assembly, the battery was flushed with electrolyte for one to two minutes prior to starting the discharge. During the discharge, the current was held constant (±0.05% tolerance) by continual minor adjustments of the constant current load setting.

The outlet valve and nitrogen flow rate were adjusted to maintain a slugging flow with alternating slugs of vapor and gas (exiting at least once per second).

Two samples per run were taken, the first starting one minute after the initiation of current flow (allowing time to flush out the pre-discharge electrolyte). Sample collection times were, for the 1.0 and 2.0 asi discharges, from the 1.0 to the 4.0 min mark for the first sample and from the 4.5 to the 7.5 min mark for the second sample. Sample collection times for the 3.4 asi discharges were from the 1.0 to the 3.25 min mark for the first sample, from the 3.5 to the 5.75 min mark for the second sample. Sample collection times were so chosen as to eliminate the possibility of false results arising from exhaustion of the cathode. At the end of the discharge, a sample of electrolyte was collected at the entrance to the battery assembly as a check on the composition of the entering electrolyte.

The flow rate was held as steady as possible during the discharge with maximum short term variations of 10%, with more typical short term variations of about 3%. Special care was taken to hold the flow steady during the half-minute before the start of the collection period and the half-minute before the end of the collection period as flow variations would have their greatest effect on the results at this time.

After the weight of the effluent sample was determined, the electrolyte was decanted from the precipitate.

Chemical Determinations

Quantitative determinations for chloride, sulfate, and magnesium were made on each of the electrolyte solutions.

The chlorides were determined gravimetrically by precipitation with silver nitrate. The sulfates were determined gravimetrically by precipitation with barium chloride. Two methods were used to determine magnesium: (*a*) gravimetrically by precipitation with dibasic ammonium phosphate (the magnesium was then calculated from the weight of magnesium pyrophosphate), or (*b*) by titrating with EDTA (ethylenediaminetetraacetic acid), using Erochrome Black T as an indicator. The EDTA was standardized by titrating against pure magnesium.

Presentation of Results

The experimental results are presented in Fig. 1 and 2. The values of uncertainty in the total retention coefficient, $R_{\pm}$, shown on Fig. 1 and 2 are derived from a maximum error analysis based on the effects of uncertainties in flow rate and chemical composition (uncertainties in current measurements were negligible in comparison). Levels of uncertainty of 1.0% in flow rate, 0.2% in chloride concentration, and 1.0% in sulfate concentration were used in the error analysis. These estimates of maximum uncertainty are conservative (on the high side). Since the amount of an ion retained was always considerably smaller than the amounts of that ion entering or leaving the cell, the above uncertainties in flow rate and composition resulted in considerably larger (percentagewise) uncertainties in the retention coefficients.

Discussion of Results

The values of the total retention coefficients, $R_{\pm}$, obtained from the first samples collected during the discharges (Fig. 1) were generally about 25% lower than those obtained from the second samples collected

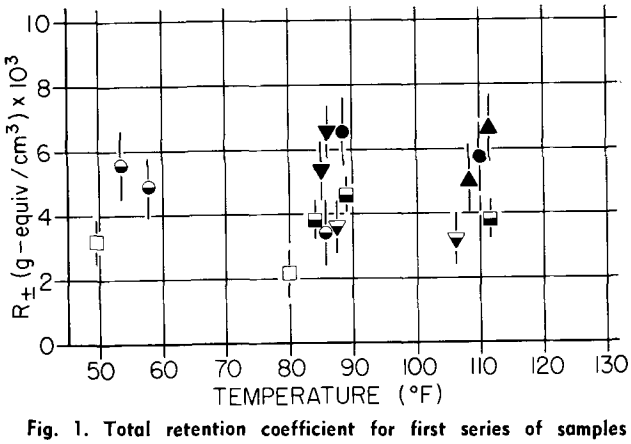

Fig. 1. Total retention coefficient for first series of samples taken during discharge. The symbols designate electrolytes of the following compositions "chlorinity-added magnesium chloride:" □ 4.5-0.0, ○ 19.0-0.0, ▽ 4.5-17.5, and △ 4.5-35.0. Discharges at 1.0, 2.0, and 3.4 asi are designated, respectively, by unshaded, half-shaded, and fully-shaded symbols.

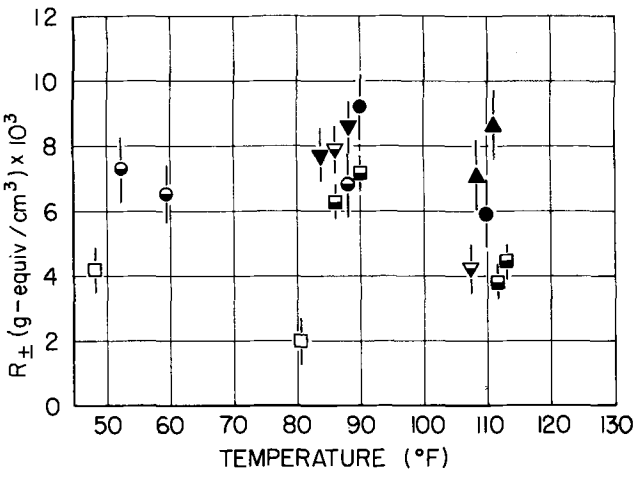

Fig. 2. Total retention coefficient for second series of samples taken during discharge. The symbols designate electrolytes of the following "chlorinity-added magnesium chloride:" □ 4.5-0.0, ○ 19.0-0.0, ▽ 4.5-17.5, and △ 4.5-35.0. Discharges at 1.0, 2.0, and 3.4 asi are designated, respectively, by unshaded, half-shaded, and fully-shaded symbols.

during the discharges (Fig. 2). This result cannot be explained by not allowing adequate time for flushing out the apparatus as this would result in a higher value of $R_{\pm}$, not a lower one. A reduction of the flux of salts leaving the sponge silver as the discharge progresses might explain the increase in $R_{\pm}$ with discharge time; but an increase in the retention due to precipitate effects is unlikely.

The collection time varied from the norm for one discharge at 2 asi in that the first sample was collected between the 3 and 6 min mark, and the second sample was collected between the 6.5 and 8.5 min mark. Though the two values of $R_{\pm}$ obtained with this discharge differ by only 15%, this is not sufficient evidence that the time dependence of $R_{\pm}$ becomes less as the discharge progresses.

For a given collection time, temperature and current density had the greatest effect on the values of $R_{\pm}$; electrolyte composition had no discernible effect. Increased current density caused an increase in $R_{\pm}$, whereas increased temperature caused a decrease in $R_{\pm}$. These results suggest that retention is governed primarily by the diffusion of salt ions from the sponge silver: the effect of higher current density is to increase the rate at which the chloride ions are generated at the sponge silver-silver chloride interface and the effect of temperature is to increase the rate of diffusion.

$R_{SO_4=}$ ranged from 1.6 x 10^{-4} to 1.0 x 10^{-3} g-equiv/cm^3 and ranged from 2 to 20% of the total value of $R_{\pm}$ (note Eq. [2]), except for the case of the two discharges at 1 asi where $R_{SO_4=}$ averaged 35% of $R_{\pm}$. $R_{SO_4=}$ exhibited only a moderate decrease with temperature and had no discernible correlation with current density. However, the ratio of $R_{SO_4=}$ to $R_{\pm}$ was significantly higher at 1 asi than at 2.0 or 3.4 asi, giving weak evidence that $R_{SO_4=}$ was not diffusion controlled to the degree that $R_{\pm}$ (or R_{Cl-}) was.

Of special interest is the fact that the observed values of $R_{SO_4=}$ far exceed those which could be explained by retention in the sponge silver because the only way in which sulfate ion retention in the sponge silver can occur is for the sulfate ion to be carried into the sponge silver by convection via the flow of electrolyte into the void spaces in the sponge silver. Calculations based on convection yield a value of $R_{SO_4=}$ of 1.7 x 10^{-5} g-equiv/cm^3 of sponge silver for the 19.0°/$_{oo}$ chlorinity electrolytes (this value is proportional to chlorinity), which lies far below the values of $R_{SO_4=}$ actually observed (1.6 x 10^{-4} to 1.0 x 10^{-3} g-equiv/cm^3). Molecular diffusion of sulfate ions into the sponge silver is an unlikely explanation for the high observed values of $R_{SO_4=}$ because of the adverse concentration gradient that would be generated. Similarly, electrolytic mobility is ruled out because the electric field inhibits the movement of sulfate ions into the cathode. Therefore, except for precipitation of sulfate ions in the sponge silver, convection is the only method by which the sulfate ion could enter the sponge silver.

The high values of $R_{SO_4=}$ therefore suggest the retention of sulfate ions in the precipitate formed during discharge by the reaction of the AZ61 alloy with water; perhaps by double salt formation or absorption.[1] In order to investigate this hypothesis, samples of electrolyte were collected during discharge of a full-sized battery. The value of $R_{SO_4=}$ calculated from the composition of the clear portion of the electrolyte from the battery was 4.9 x 10^{-4} g-equiv/cm^3 of sponge silver which is well within the range $R_{SO_4=}$ obtained with the single cell discharges. However, when the amount of sulfate ion retained in the precipitate (determined from weight-composition determinations of the precipitate) was taken into account, it was found that essentially all (112 ± 22%) of the sulfate ion retained was retained in the precipitate. The uncertainty value resulted from an error analysis maximizing the effect of experimental errors. The nominal value obtained for the retention of sulfate ions in the sponge silver was of the same order of magnitude (—4.0 x 10^{-5} g-equiv/cm^3 of sponge silver) as that predicted from convection.

The results of a similar full-scale battery test to determine the relative roles played by the precipitate and the sponge silver on the retention of chloride ion showed that 88 ± 1.2% of the chloride ion, produced by reaction [1] was retained in the sponge silver. Two likely mechanisms of chloride retention in the precipitate are: (*a*) the formation of magnesium hydroxychlorides and (*b*) formation of regions of high concentration in the void spaces of the precipitate. The first hypothesis is supported by x-ray diffraction studies which have shown evidence of the presence of magnesium hydroxychlorides in the precipitate; the second hypothesis is supported by an apparent transfer of chloride ions from the precipitate to the electrolyte with time. Whether this transfer is the result of (*a*) molecular diffusion from electrolyte trapped in the pores of the precipitate, (*b*) equilibration between double salts and the surrounding electrolyte, or (*c*) a change in the composition and size of the precipitate particles (*e.g.*, the corrosion of small pieces of magnesium in the precipitate) is not known.

As stated above, the value of R_{Na+} was determined by subtracting R_{Mg++} for $R_{\pm}$. Since the estimated maximum error of the magnesium determination was 1½%, resulting in large uncertainties in R_{Mg++} (see Presentation of Results), and since the values of $R_{\pm}$ exhibit a fair degree of uncertainty (see Fig. 1 and 2), the values of R_{Na+} exhibit a large degree of uncertainty. However, the values of R_{Na+} and R_{Mg++} are of the same order of magnitude and in most cases values overlap when the uncertainties are taken into account. Consequently these results indicate that both the sodium and magnesium ions enter the sponge silver under the influence of the electric field or take part in double salt formation and therefore, one can assume that in a sea water-activated battery, significant amounts of the salts found in the entering sea water and of the $MgCl_2$ formed from the battery reaction are retained.

Effect of Retention on Voltage Losses

In order to estimate the maximum effect of retention on the voltage losses in a sea water-activated battery, two hypothetical and extreme cases were considered: (*a*) only the ions found in the entering elec-

[1] The term "precipitate" will henceforth refer to the precipitate found in the free flowing electrolyte.

Table II. Effect of retention on voltage drop across interelectrode spacing[a]

19.0	85	80	0.09	0.006	0.008

[a] Voltage drop across the electrolyte passage at the point in the cell where temperature of the electrolyte has increased by the indicated amount. Calculated on the basis of cell spacing of 0.022 in., and a current density of 2.00 asi.
[b] For a hypothetical cell with no retention.
[c] The retention of ions is considered to reduce the amount of $MgCl_2$ added by the cell reaction to the electrolyte without affecting the chlorinity of the electrolyte.
[d] The retention of ions is considered to reduce the chlorinity of the electrolyte without affecting the amount of $MgCl_2$ added to the electrolyte by the cell reaction.

trolyte are retained, *i.e.*, the chlorinity of the electrolyte is reduced, and (*b*) only the magnesium chloride generated in the battery is retained. Voltage losses for the two cases are compared to those that would occur in the absence of retention of any form.

A retention coefficient consistent with the data, 6.3 x 10^{-3} g-equiv/cm^3 of sponge silver was assumed. Also, in order to relate retention to the temperature and composition of the electrolyte, which determine its electrical conductivity, the following assumptions were made: (*A*) The cell is adiabatic. (*B*) The thermal energy released by the cell is independent of electrolyte conditions and current density and is 2.4 times as great as the electrical energy produced at 1.065v (the assumed cell emf). This ratio of thermal to electrical energy has been observed in discharges of a typical full-size high-drain battery. Though this ratio cannot be applied to all such batteries it is adequate for the purposes of this calculation. (*C*) The density and heat capacity of the electrolyte are constant at 1.0 g/ml and 1.0 cal/g°C, respectively. (*D*) The effect of ion retention on flow rate is negligible.

The relevant conductivity data were taken from a prior study [ref. (3)]; and the current density and interelectrode spacing were chosen to reflect current design practice; 2.0 asi and 0.022 in., respectively.

The results of the calculations are presented in Table II. The two entering temperatures were 40° and 85°F. The two electrolytes used were of 4.5 and 19.0‰ chlorinity (the former the lowest chlorinity found in the world's oceans, the latter the "normal" chlorinity of the world's oceans). Two temperature rises, 30° and 80°F, were studied.

The results given in Table II show that the increases in voltage losses caused by retention are relatively small at a current density of 2.0 asi for entering electrolytes of 19.0‰ chlorinity, but become significant (0.05v) for electrolytes of low chlorinity. The use of either of the two methods given in Table II to estimate the effects of retention gives results within 0.02v of each other.

Since the two approaches used in Table II are really boundary conditions, and since both sea water salts and the magnesium chloride from reaction [1] are retained in a battery, perhaps the best estimate of the correction needed to account for retention would be obtained by basing the relative amounts of magnesium chloride and sea water salts undergoing retention on the ratio of normality of the salt under consideration (either sea water salts or magnesium chloride) to the sum of the normality of the sea water salts and the normality of the magnesium chloride.

Conclusions

A study of the retention of the four major ions found in silver chloride-magnesium, sea water-activated batteries (Cl^-, $SO_4^{=+}$, Na^+, and Mg^{++}) indicated that the major locus of chloride ion retention was in the pores of the sponge silver formed on the cathode during discharge whereas the major locus of retention of the sulfate ion was in the precipitate formed by secondary reactions at the anode. Both magnesium and sodium were retained in significant amounts indicating that both the salts found in the sea water and the magnesium chloride formed by the battery reaction are retained in significant quantities.

The evidence available suggests that retention in the sponge silver is primarily determined by diffusion as the retention increases with current density and decreases with temperature. Sulfate retention, which occurs primarily in the precipitate, does not appear to be as strongly controlled by diffusion.

A brief study of the effects of retention on battery voltage indicated that increases in voltage losses of 3 to 15% above those predicted without compensating for retention are to be expected. Adequate corrections can be made by use of the retention coefficients presented in Fig. 1 and 2, the method presented herein.

The Performance of Direct Ammonia Fuel Cells

E. L. Simons,* E. J. Cairns*,[1] and D. J. Surd[2]

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Direct ammonia-oxygen or air cells were operated between 25° and 140°C with aqueous potassium hydroxide as electrolyte and with Teflon-bonded electrodes containing either unsupported platinum black or platinum supported on graphite. The effect of platinum on the performance of ammonia, oxygen, and air electrodes was investigated. Power densities of 50 mw/cm^2 at 0.5v (IR-included) were achieved in ammonia-air cells at 120°C with only 2.5 mg Pt/cm^2 on each electrode.

The many advantages of hydrogen as an electrochemical fuel are largely offset, for commercial fuel cell application, by the need to store and distribute it either as a liquid at temperatures below —240°C or as a compressed gas at higher temperatures, *e.g.*, 2000 psi at room temperature. Consequently, much work has been done to develop fuel cell systems in which the hydrogen is generated as needed from fuels that are cheaper and easier to handle than the pure element, such as metal hydrides, ammonia, methanol, and common hydrocarbons. These fuels, except metal hydrides, can also be oxidized directly in fuel cells equipped with the proper combination of electrodes and electrolyte, but power densities at a given voltage are lower than those obtainable by electrochemical oxidation of the hydrogen derived from these fuels.

In a recent review of government-sponsored research on fuel cells, Austin (1) concluded that "ammonia is relatively inert as an electrochemical reactant and requires very active electrodes or high temperatures." Subsequently, Cairns, Simons, and Tevebaugh (2) found that Teflon-bonded platinum black electrodes (3) provided the necessary electrocatalytic activity. The performance levels they observed in a direct ammonia-oxygen fuel cell, operated in the range 100°-200°C with aqueous potassium hydroxide electrolyte, exceeded those reported for any fuels other than hydrogen or hydrazine. More detailed results on ammonia-oxygen and ammonia-air cells are presented in this paper.

The anodic oxidation of ammonia on a platinized platinum surface in contact with aqueous potassium hydroxide has been shown by earlier workers to occur with 100% coulombic efficiency according to the overall stoichiometry (4-7)

$$NH_{3(g)} + 3\,OH^-_{(aq)} \rightarrow \tfrac{1}{2}\,N_{2(g)} + 3\,H_2O_{(liq)} + 3\,e^- \quad [1]$$

The thermodynamic reversible potential ($E°_{298}$) for reaction [1], calculated from free energy data (8), is —0.77v, only 0.06v less negative than the value of —0.83v for a reversible hydrogen electrode in alkaline solution. Experimental open-circuit potentials, however, are 0.2-0.4v less negative than the reversible potential, and calculated exchange current densities range from 10^{-12} amp/cm^2 (9) to 10^{-8} amp/cm^2, compared to about 10^{-3} for hydrogen (5). From attempts that have been made to elucidate the details of reaction [1], it has been suggested that the reaction proceeds by the step-wise oxidation of hydrogen atoms from nitrogen-hydrogen species adsorbed on the catalyst surface (5, 6, 9).

In a complete ammonia-oxygen fuel cell, reaction [1] is accompanied by the cathodic reduction of oxygen, which, in the absence of peroxide formation is represented by (8)

$$3/4\,O_{2(g)} + 3/2\,H_2O_{(liq)} + 3e- \rightarrow 3\,OH^-_{(aq)};\ E°_{298} = 0.40v \quad [2]$$

Performance data for complete gaseous ammonia-oxygen fuel cells are scanty. Wynveen (7) has published a few voltage-current curves for such a cell operating in the range 30°-80°C with the concentrated aqueous potassium hydroxide electrolyte immobilized in a porous matrix. Most other reported work (10, 11) has been performed at temperatures between 140° and 750°C, using fused alkali hydroxide mixtures, usually in a sintered magnesium oxide matrix, as the electrolyte. All cells have used porous flow-by electrodes made of carbon or nickel with platinum as the anode catalyst. Some results have also been reported for cells in which the feed to the anode was a solution of ammonia in aqueous potassium hydroxide (11, 12). The maximum current densities reported for operation below 150°C were about 40 ma/cm^2 at a cell voltage of about 0.4v (11). Current densities of 120-130 ma/cm^2 were achieved only above 200°C (10, 11).

Experimental

Fuel cell assembly.—The fuel cell used in these experiments was like that shown in exploded view in Fig. 1 except that the spacer (electrolyte compartment) was either 1/8 or 1/16 in. thick and the thermocouple well (added to the cell after the first series of runs) did not extend into the electrolyte compartment but ended about 1/32 in. from the circumferential wall. In most experiments the working fuel cell was mounted below an identical reference cell whose gas compartments were kept filled with hydrogen, and the entire system was assembled in a forced convection air thermostat as shown in Fig. 2. Electrolyte flowed under gravity from an upper Teflon reservoir through the working and reference cells into a lower reservoir. Electrolyte was returned by an all-Teflon bellows pump (not shown) from the lower to the upper reservoir, in which the maximum height of electrolyte was set by an overflow pipe through which excess electrolyte was returned to the lower reservoir. The total volume of the electrolyte in the system was 190 cc, of which only 3.6 or 1.8 cc were between the two electrodes of the cell (11.38 cm^2 circular cross section; 0.32 or 0.16 cm thick).

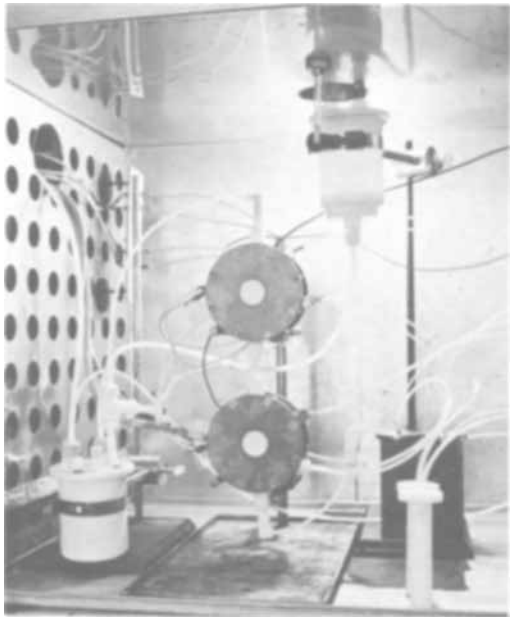

Fig. 2. Fuel cell assembly in air thermostat

In some experiments the total volume of electrolyte was reduced by eliminating the reference cell, electrolyte reservoirs, and bellows pump and installing in their place the electrolyte loop shown in Fig. 3. Thin Teflon tubes (1.7 mm OD) inserted into the upper and lower branches of the electrolyte loop were connected to manually operated syringes and were used to remove gas bubbles that sometimes accumulated in the loop and impeded circulation of electrolyte.

Electrolyte solution and gases.—The electrolyte solution [54 w/o (weight per cent) KOH] was prepared by direct weighing from USP grade KOH pellets and distilled water. Dry gases were fed from tanks into the fuel cell at essentially atmospheric pressure. The air contained 0.035 v/o (volume per cent) carbon dioxide. Ammonia flow rates were 2-3 times stoichiometric and air flow rates 3-4 times stoichiometric.

Electrodes.—Teflon-bonded electrodes (3) were prepared with catalysts that were either unsupported platinum black (Englehard Industries, Inc.) or 10 w/o platinum-on-graphite (American Cyanamid Company designation S-7547-48). The supporting screen was 45-mesh platinum (8-mil wire), and the electrodes were covered on the gas side by a pre-cast film of Teflon containing from 0.04 to 0.22 mg Teflon/cm^2 (~0.2 to ~1.1μ thickness). The amount of catalyst used in preparing the electrodes was chosen to give platinum loadings of 0.9, 1.0, 2.0, 2.4, and 2.5 mg/cm^2 supported on graphite and 51 mg/cm^2 of unsupported platinum black; the total content of Teflon binder was 14-15 w/o. A platinum-free electrode was prepared from Cyanamid 99% graphite. The reference electrodes were made with unsupported platinum black. To obtain reproducible measurements with supported platinum electrodes, the assembled cells were allowed to remain for 24 hr at temperature with electrolyte in the liquid compartment and nitrogen in the gas compartments.

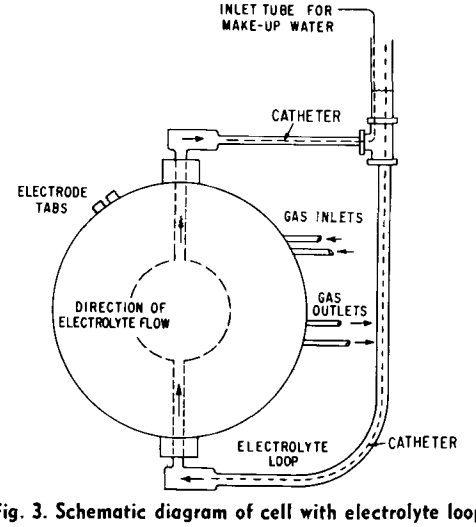

Fig. 3. Schematic diagram of cell with electrolyte loop

Electrical measurements.—Preset currents, measured on a multi-range ammeter, were passed through the cell from a modified 60-cps Kordesch-Marko interrupter bridge (13, 14), and the resulting cell voltage, including resistive losses across the electrodes and electrolyte, was continuously monitored on a Varian strip-chart recorder or measured with a potentiometer. When the cell voltage had reached a constant value for each (average) current, a potentiometer connected to the bridge was used to measure the IR-free voltages between the anode and cathode and between each and the hydrogen reference electrode.

Niedrach and Tochner (14) have shown that a low-frequency interrupter bridge can give erroneous values for IR-free voltages of cells in which the electrodes contain low loadings of supported platinum catalyst because nonresistive voltage changes occur along with the resistive changes during the nonconducting portion of the bridge cycle. Results presented in this paper show similar behavior for low loadings of platinum on carbon in alkaline electrolytes. For cells with low platinum loadings the voltages between anode and cathode and between each and the hydrogen reference electrode were measured while constant currents were being sent through the cells from a d-c power source. In series between the cell and power source was a Clare mercury-wetted relay switch (No. HG2A3033). Additional voltage taps were connected from the cell to the input of a Type H plug-in unit on a Tektronix Type 545 oscilloscope, and the triggering input of the scope was connected in parallel across the coil of the Clare relay. When the coil was energized, by operation of a manual switch, a known current flow through the cell was interrupted in synchronization with a preset oscilloscope sweep rate (usually 10-100 μsec/cm). The voltage step on the oscilloscope screen, resulting from decay of the IR-component of overvoltage, was photographed and measured, the cell resistance calculated from it, and the appropriate correction applied to obtain IR-free values of the cell voltages.

Results and Discussion

Effect of Temperature

The preliminary results already reported (2) for the performance of an ammonia-oxygen cell with platinum black (51 mg/cm^2) electrodes in the range 100°-200°C were confirmed and extended by runs made at ambient temperatures of 140°, 120°, 80°, 60°, and 25°C. The performance data from the runs at 140° and 60°C are presented in Fig. 4 as voltage-current density curves obtained with a Kordesch-Marko bridge. (The data for 120° and 80°C fall between these limits.)

The effect of temperature upon the IR-free performance of the cell in the range 60°-140°C is primarily a reflection of the effect of temperature on the anode performance. The potential-current density curve for the anode at 60°C is roughly parallel to that at 140°C and is displaced upward by about 80 mv. The maximum spread among the four cathode-reference curves is only about 30 mv. No limiting current density was observed up to about 700 ma/cm^2.

The effect of temperature on cell performance is more pronounced when the IR-losses are included in the measurements, because the specific resistivity of the electrolyte increases markedly with a decrease in temperature. The variation of specific conductivity of 54 w/o KOH with temperature is shown in Fig. 5, from which the extrapolated value at 60°C is 0.672 ohm^{-1}

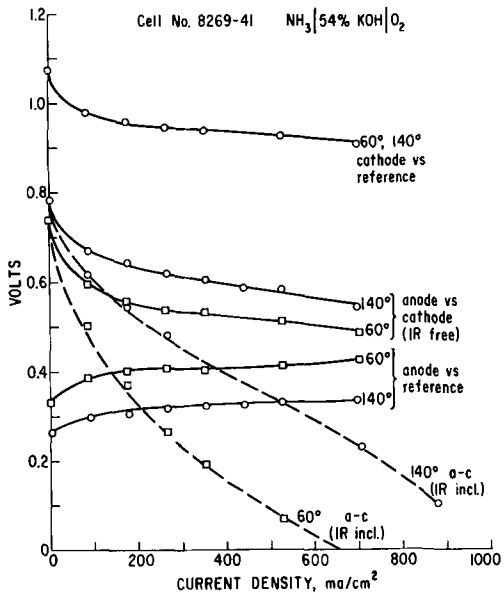

Fig. 4. Effect of temperature on ammonia-oxygen cell No. 8269-41. ——— IR-free data; - - - - - IR included data; Pt black catalyst, 51 mg/cm^2; Teflon coating, 0.22 mg/cm^2.

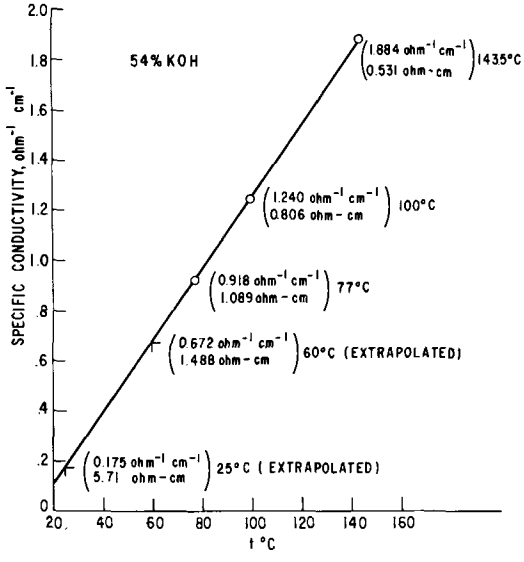

Fig. 5. Effect of temperature on specific conductivity of 54% aqueous KOH.

cm^{-1}, corresponding to a specific resistivity of 1.49 ohm-cm. Thus in the range from 140° to 60°C the specific resistivity increases by a factor of about 2.8. This temperature dependence is in reasonable agreement with that observed by Klochko and Godneva (15) for other aqueous KOH solutions in the range 150°-200°C.

A careful examination of the IR-included anode-cathode voltage curves in Fig. 6 reveals a qualitative as well as quantitative difference between the results at 140°C and those at 120°, 80°, and 60°C. The curve at 140°C shows a change in slope from concave upward at lower current densities to concave downward at higher current densities. The curves at the other temperatures, however, are concave upward over their entire course. In other words, the slope of the voltage-current density curve at each of the lower temperatures decreases continuously with increasing current density in the range covered by these experiments. Furthermore, a comparison of the IR-free and IR-included cell voltages showed that the cell resistance decreased significantly with increasing current density, particularly at 60° and 80°C, indicating that the electrolyte temperature had increased above ambient during operation.

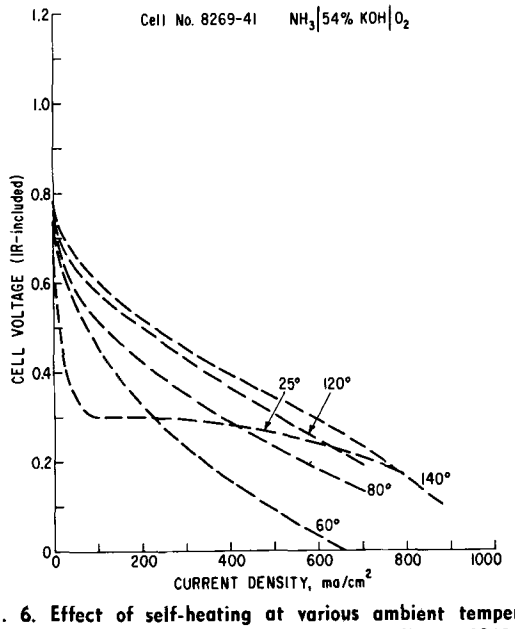

Fig. 6. Effect of self-heating at various ambient temperatures on voltage (IR-included) of ammonia-oxygen cell No. 8269-41. Pt black catalyst, 51 mg/cm^2; Teflon coating, 0.22 mg/cm^2.

The effects of self-heating are dramatically illustrated in Fig. 6 by the performance of a cell whose operation was started at room temperature. The IR-included cell voltage dropped sharply at low current drains, but then remained at about 0.3v over the range 100-300 ma/cm^2. A thermocouple mounted on the outside wall of the anode gas compartment registered ~45°C when the cell was operated at ~800 ma/cm^2, at which point the cell voltage was the same as that observed in the run made at an ambient temperature of 140°C.

The comparison of the performance curves in Fig. 6 can be only qualitative because cell operation was obviously not isothermal at ambient temperatures of 80°C and below. The results, nevertheless, have a two-fold significance: (*i*) They are the first demonstration that a fuel cell operating on a fuel other than hydrogen or hydrazine can be started at room temperature without an external heat source. If room temperature start-up can be achieved in a single cell, such start-up should be even more feasible in a battery designed to reduce initial heat losses; (*ii*) Because of the high electrochemical reactivity of ammonia, which is revealed by these experiments, it should be possible to reduce significantly the amount of platinum catalyst used in the electrodes.

Effect of Platinum Loading

Comparison of 60-cps interrupter bridge and steady d-c drain.—A cell was assembled in which one electrode contained 51 mg platinum/cm^2 as unsupported platinum black and the other contained 6.2 mg platinum/cm^2 supported on Cyanamid graphite. In one run the graphite-based electrode was used as the anode (NH_3); in the other as the cathode (O_2). For both runs, oscilloscope tracings were made of the voltage changes that occurred between anode and cathode during 60-cps operation at several values of the time-average current density. At current densities above 40 ma/cm^2 the tracings from both runs were like that shown in Fig. 7, which is identical in form to those reported by Niedrach and Tochner (14) for a hydrogen-oxygen cell in which the cathode was made with platinum supported on tantalum. The tracings show clearly that at no time in the K-M bridge cycle did the cell voltage reach an IR-free plateau and that significant decay of overvoltage occurred during the zero current portion of the cycle. The magnitude of this decay increased

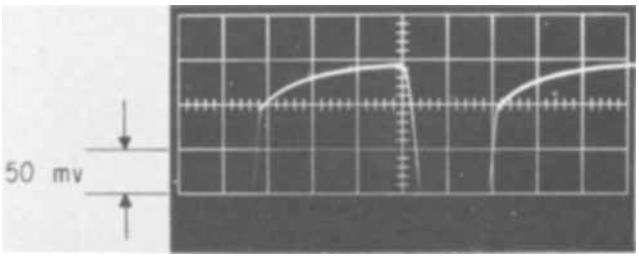

Fig. 7. Cell voltage transient during Kordesch-Marko bridge cycle. If both electrodes had been platinum black, the rapid voltage changes as the current flow was interrupted and then resumed would have been separated by a plateau of constant voltage during the nonconducting portion of the cycle. In this experiment a slow decay of almost 50 mv occurred during the nonconducting portion of the cycle. Run 8446-43-3: $NH_3|54\%\ KOH|O_2$; T = 120°C. Anode, Pt black, 51 mg/cm²; cathode, Pt on C, 6.2 mg/cm²; current density, 88 ma/cm².

with increase in current density to ~150 mv at ~1 amp/cm².

Four pairs of runs were then made with four combinations of high (unsupported) and low (supported) platinum loadings in ammonia-oxygen cells with 54 w/o potassium hydroxide at 120°C. For each combination performance data were obtained both by K-M bridge operation and by steady d-c drain. The voltage-current density relationships are summarized in Table I and Fig. 8, to which the following comments apply:

1. In col. 6. the symbol E_T^{DC} denotes the terminal cell voltage during steady d-c discharge at a constant current (I); the symbol E_T^{KM} denotes the time-average terminal cell voltage during operation of the cell with a K-M bridge at a constant time-average current ($I = I$). The numbers listed in col. 6 are the minimum and maximum values of the difference, $E_T^{KM} - E_T^{DC}$, observed between the members of each pair of runs over the range of current densities from 0 to 350 ma/cm². These values are not significantly different from the differences between duplicate runs made with a given mode. Thus, either mode of operation gives essentially the same values for the IR-included terminal cell voltage of ammonia-oxygen fuel cells with either platinum black or platinum-on-carbon electrodes.

2. By contrast, the four pairs of curves in Fig. 8 show that the relationship between the IR-free voltage *vs.* current density curves obtained by the two modes of operation does depend on the composition of the electrodes. The voltage readings designated as E_{A-C}^{KM} were obtained directly from operation of the K-M bridge. Those designated as E_{A-C}^{DC} were obtained by subtracting from the measured values of E_T^{DC} the appropriate IR-component as calculated from the voltage transients recorded during interruption of the cell at several current levels.

For each pair of runs, the E_{A-C}^{KM} curve lies above the E_{A-C}^{DC} curve; *i.e.*, the K-M bridge gives too high a value for the IR-free anode-cathode voltage. The magnitude of this difference between E_{A-C}^{KM} and E_{A-C}^{DC} is not experimentally significant for cells in which both electrodes are made with unsupported

platinum black. The difference is significant for cells in which one of the platinum black electrodes is replaced by a platinum-on-carbon electrode; it is immaterial whether the substitution is made at the anode or cathode. The difference is even greater for cells in which both electrodes contain 2.5 mg platinum/cm² supported on Cyanamid graphite.

3. This difference between the IR-free voltages obtained by the two modes of operation is also summarized in col. 5 of Table I, which lists the estimated values of the cell resistances. Those for the d-c mode were estimated by the interrupter method already described. Those for the K-M mode were calculated from the relationship

$$R = \frac{E_{A-C}^{KM} - E_T^{KM}}{\bar{I}}$$

and were found to be essentially independent of current.

Effect of platinum loading on individual electrode performance.—In addition to the cells described in the preceding section, three were assembled in which the pairs of electrodes were

Cell No.	Electrode pairs	Total mg Pt/cm²
8446-132	2.5 *vs.* 0.0	2.5
8593-4-2	2.5 *vs.* 0.9	3.4
8593-8-2	2.0 *vs.* 1.0	3.0

Altogether, several runs were made on each of seven different cells in order to test the effect of each level of platinum loading on electrode performance with ammonia, oxygen, and air.

For all runs, the d-c interruption method provided reproducible and internally consistent values for IR-free cell voltages, but not for IR-free values of the individual electrode potentials with respect to the hydrogen reference electrode. Single electrode comparisons have, therefore, been made without correcting for the IR-component of overvoltage. Although these IR-included comparisons cannot provide a basis for quantitative electrochemical calculations, they do

show differences in performance, particularly among ammonia anodes of different platinum contents, that are greater than can be attributed to differences in IR-losses between different electrodes or to the scatter of points in replicate runs.

The effects of platinum loading on the performance of an electrode as an anode or cathode are illustrated by the curves of Fig. 9, in which the voltages relative to a common hydrogen electrode are plotted against current density over the range 0-180 ma/cm^2. Although most electrodes could sustain current densities well beyond this range, the curves were distorted by the effects of internal heating at cell currents above 2 amp.

The ammonia oxidation curves (Fig. 9A) for electrodes made with unsupported platinum black and with 2-2.5 mg platinum/cm^2 on graphite are essentially parallel. At 1 mg/cm^2 the performance of the anode and its reproducibility were poorer, and at zero platinum loading the electrode showed negligible catalytic activity. The cathode curves for the graphite electrodes are virtually parallel, and there is no evidence for a limiting current density with pure oxygen out to 176 ma/cm^2 even for the zero platinum loading; with air the platinum-free electrode could not sustain more than 138 ma/cm^2.

The solubility of ammonia in the alkaline electrolyte is high enough (16) so that in the absence of a barrier to its diffusion some fuel is oxidized at the cathode, with a consequent increase in the overvoltage of that electrode, as illustrated in Fig. 9B. The uppermost curve is for a platinum black cathode run in a hydrogen-oxygen cell; the one immediately below it is for a platinum black cathode run in an ammonia-oxygen cell.

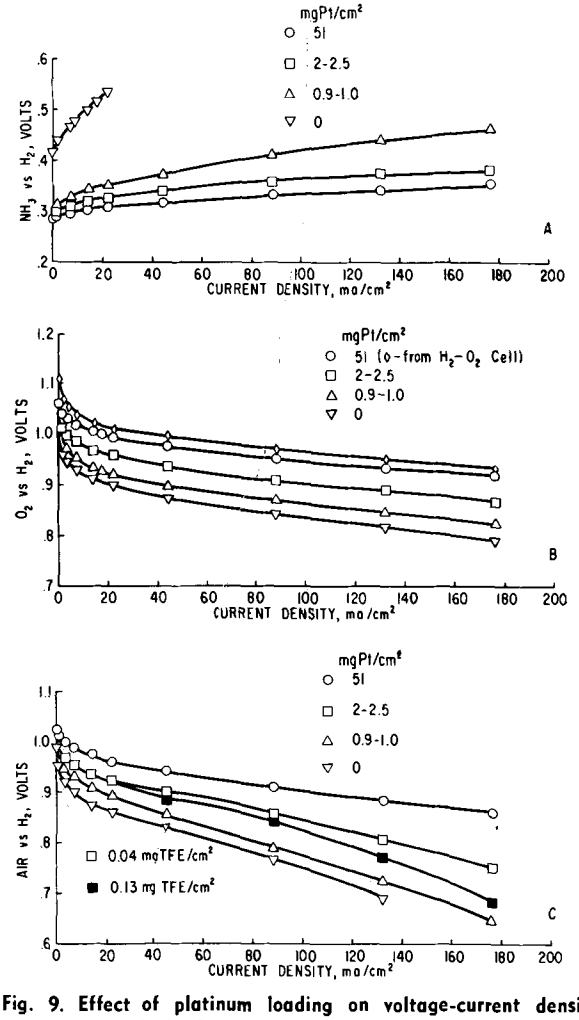

Fig. 9. Effect of platinum loading on voltage-current density curves for individual electrodes (vs. reversible H_2) in cell with 54% KOH (1/15-in. electrolyte space) at 120°C (all voltages include IR component). Except as noted, all measurements were made with ammonia as the anode gas. 9A. Ammonia. 9B. Oxygen. 9C. Air (including two different TFE films).

The performance of an air cathode is affected both by platinum loading and by the thickness of the Teflon film on the gas side. In Fig. 9C the family of air cathode curves includes two at the level of 2-2.5 mg Pt/cm^2. The upper of the two curves is for an electrode with 0.04 mg Teflon/cm^2 ($\sim$0.2μ thickness); the lower, 0.13 mg/cm^2 ($\sim$0.5μ). A similar effect of Teflon thickness was observed with another pair of air electrodes at this platinum level, one with 0.18 and the other with 0.05 mg Teflon/cm^2. No such relation between performance and film thickness was observed when the electrodes were used as oxygen cathodes or ammonia anodes.

Performance of Complete Ammonia-Air Cells

The effects of platinum loading and Teflon film thickness on the IR-included performance of the complete ammonia-air cells used in this investigation are presented in Fig. 10A and B as curves of cell voltage *vs.* current density and power density, respectively.

The upper curve of each figure is for a cell in which both electrodes contained 51 mg of unsupported platinum black per square centimeter. The middle curve is drawn through the points obtained from the cells in which each electrode contained 2.4 mg platinum/cm^2 supported on graphite and in which the film on the gas side of the cathode contained 0.05 mg Teflon/cm^2. One cell was operated in conjunction with a reference cell and electrolyte reservoir (Fig 2); the other was operated with the small electrolyte loop (Fig. 3).

The lower curve is for a cell with virtually the same platinum content (2.5 mg/cm^2) as those for the middle curve, but with a much thicker film on the gas side of the cathode (0.18 mg Teflon/cm^2). This is a reflection of the effect of Teflon film thickness on the performance of the air cathode (see Fig. 9C).

The internal resistances (electrodes plus electrolyte) for the four cells represented by Fig. 10 were 0.023, 0.030, 0.024, and 0.026 ohms, respectively, so even at the highest current density used (176 ma/cm^2 $\equiv$ 2 amp) differences in performance attributable to differences in IR-losses are not more than 14 mv.

Although the total cell performance is diminished by a change from unsupported platinum black to plati-

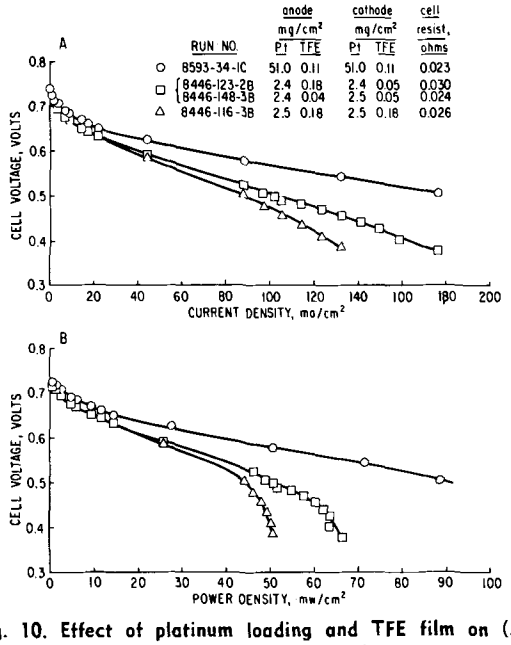

Fig. 10. Effect of platinum loading and TFE film on (A) cell voltage *vs.* current density, and (B) cell voltage *vs.* power density for ammonia-air cell with 54% KOH (1/16-in. electrolyte space) at 120°C. Run No. 8446-148-3B was made with the experimental arrangement shown in Fig. 3.

num-on-graphite, the power density per unit weight of platinum, at 0.5v, is greater with the supported catalyst. For the air cells represented by the middle curves in Fig. 10, the power density of 51 mw/cm^2 at 0.5v was achieved with a catalyst loading in each electrode of 2.5 mg platinum/cm^2, or a total of about 95g of platinum per kilowatt.

Effect of carbon dioxide on air operation.—All of the performance data presented in this paper were obtained during individual runs that lasted no more than a few hours. During the series of experiments reported earlier (2), some cells were operated continuously for periods up to 168 hr with air on the cathode. Cell failures were preceded by sharp decay in performance, and postmortem analyses of the cathodes showed evidence for precipitation of potassium carbonate in the pores of the electrodes. Other experiments showed that aqueous cesium hydroxide is as good an electrolyte as aqueous potassium hydroxide for operation of a cell with oxygen (17) and is better for operation with air because the cesium carbonate that forms does not precipitate in the pores of the cathode but remains in solution, where a steady-state level of carbonate to hydroxide ratio is reached. Although the cell is still operable at this steady state, the performance level is lower than that for a cell with a carbonate-free electrolyte. The most practical solution to the carbonate problem may be to remove the carbon dioxide by scrubbing the incoming air.

During prolonged operation of some cells, droplets of electrolyte appeared on the initially hydrophobic gas-face of the Teflon-bonded electrodes, particularly the cathode. This "weeping" is not caused by cracks in the electrode, but appears to result from a gradual increase in the wettability of the entire electrode by the hot, concentrated alkali solution. If extensive enough, "weeping" can also cause a marked decay in electrode performance.

Conclusions

Most studies that have been made of possible fuel cell power plants for the utilization of ammonia have been based on the thermal dissociation of this gas to provide hydrogen as the electrochemical fuel (18-21). The laboratory experiments described in this paper suggest the feasibility of fuel cell power systems for the direct electrochemical oxidation of ammonia. The direct ammonia-air laboratory cells generated more power per unit weight of noble metal catalyst than laboratory cells using any other fuels except hydrogen and hydrazine. Furthermore, subsequent work on catalyst development (22) has shown that iridium and alloys of iridium and platinum are even more active than platinum alone for the anodic oxidation of ammonia, thus making possible cells with even higher performance than herein reported.

Improved Electrocatalysts for Ammonia Fuel Cell Anodes

D. W. McKee, A. J. Scarpellino, Jr.,[1] I. F. Danzig,[2] and M. S. Pak

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Electrocatalysts containing iridium and platinum-iridium alloys have shown very encouraging levels of performance when used as anodes in ammonia fuel cells. These materials were appreciably more active than platinum alone, and the open-circuit voltage and polarization under load generally improved with increasing iridium content. Data are presented for ammonia/oxygen cells at 100°-120°C using 54% potassium hydroxide as electrolyte and platinum-iridium blacks and Pt/Ir supported on boron carbide and graphite as anodes. The observed electrochemical activity of iridium appears to be related to the unique activity of this metal in the gas phase catalytic decomposition of ammonia. Supported iridium catalysts were also found to be effective in an external cracking unit maintained at 350°-450°C and coupled to a hydrogen fuel cell system. In this case enhanced performance was observed when small amounts of oxygen were introduced with the ammonia into the catalytic reactor.

During the course of investigations into the electrocatalytic activity of noble metals and alloys in fuel cells, it has become evident that the platinoid metals are highly specific in their behavior toward fuels of different types and also that alloys can often show higher intrinsic activities than those of the constituent metals alone. Thus, platinum-ruthenium alloys have been found to be much more active than platinum alone in the electrochemical oxidation of methanol (1), and platinum-ruthenium, platinum-iridium, and platinum-rhodium alloys have demonstrated substantial improvements over platinum as anode electrocatalysts for the oxidation of reformer gas (2). Similar synergistic phenomena have often been observed in gas phase catalytic reactions (3), and it is likely that cooperative electronic effects are responsible in both cases.

This work was extended to include studies of the noble metals and their alloys both as anode electrocatalysts in ammonia/oxygen fuel cells and as catalysts for the gas phase decomposition of ammonia. Although ammonia has frequently been considered as a cheap source of hydrogen in fuel cell applications (4), its oxidation at a platinum anode is generally far less reversible than hydrogen. In spite of the improvements recently reported in the performance of ammonia/oxygen cells with platinum catalysts (5, 6), the major overvoltage loss is still observed at open circuit. It has been found, however, that iridium has a unique ability to dissociate ammonia in the gas phase and that fuel cell anodes containing iridium are capable of oxidizing ammonia electrochemically at distinctly lower overpotentials than those observed with platinum electrodes.

In spite of the many studies of the kinetics and mechanism of ammonia decomposition on the transition and noble metals (7), iridium seems to have been almost completely neglected. In this paper the results of electrochemical and catalytic measurements on this metal are presented.

Experimental

Preparation of electrocatalysts.—Unsupported Pt-Ir alloys and iridium black were prepared by a modification of the Adams procedure (8). Appropriate quantities of chloroplatinic acid and iridium trichloride were intimately mixed with an excess of sodium nitrate and the mixture fused in a silica dish at 500°C for 3 hr. After thorough washing the resulting suspension of mixed oxides was reduced at room temperature by hydrogen bubbling through a fritted disk. The product was then allowed to settle and, after removal of the supernatant liquid, was dried slowly under a heat lamp. Finally the catalyst powder was ground and sieved through a 400 mesh nylon screen.

Platinum and iridium were also deposited together on boron carbide and graphite substrates by thermal decomposition of mixed solutions of platinum "P" salt, $Pt(NH_3)_2(NO_2)_2$, and iridium chloride, $IrCl_3$. Commercial boron carbide ("Norbide" abrasive, Norton Company, Worcester) which had been acid leached to remove iron impurity, and Cyanamid graphite powder were used as support materials. Samples of these substrates, previously ground and sieved to 400 mesh, were intimately mixed with aliquots of the mixed salt solution and the paste evaporated to dryness under a heat lamp. The catalysts were then reduced in flowing hydrogen at 125°C for 3 hr and then cooled in a stream of nitrogen.

Catalysts for the indirect ammonia system were prepared by impregnating ⅛ in. alumina pellets (Harshaw Al 0104T) with appropriate quantities of iridium chloride solution. After evaporation to dryness, the catalyst was reduced at 500°C in flowing hydrogen for 3 hr. Supported iridium catalysts were also prepared using activated carbon (Girdler Company, G-32C, 8-30 mesh granules), silica gel (Davison Company, 40 mesh granules) and 5A type molecular sieve (Linde Company, 1/16 in. pellets) as substrates.

Electrode preparation.—Platinum-iridium powdered catalysts were mixed with Teflon suspension and pressed into thin electrodes of the Niedrach-Alford type (9), the quantity of catalyst being adjusted to give approximately 34 mg of noble metal/cm² of geometrical area. A porous film of Teflon was sprayed on the gas side of the electrode to give about 1.6 mg Teflon/cm².

Supported catalysts were mixed into a stiff paste with Teflon and then painted on the platinum screen current collector according to the method described by Grubb and Michalske (10). The loading of noble metal in this case was generally in the range 2-10 mg/cm² of electrode area.

Fuel cell measurements.—The activity of the electrodes was evaluated in the fuel cell assembly described previously (2), which provided a working electrode area of 5.07 cm². A counterelectrode, containing 34 mg of platinum black/cm² was included with oxygen as the reactant, and a similar but smaller cell containing a single hydrogen electrode served as a reference.

The electrodes were normally tested with 54% potassium hydroxide at 100°-120°C, the cell assembly

[2] Present address: Direct Energy Conversion Business Section, General Electric Company, 930 Western Avenue, West Lynn, Massachusetts.

being mounted in an air thermostat with a thermocouple inserted directly into the electrolyte chamber of the cell. Most measurements of IR-free and IR-included voltages were made with a Kordesch-Marko interrupter bridge (11), although in some cases IR-included voltages were measured directly across the cell during steady d-c discharge through an external load. The measured cell resistance with supported catalysts was found generally to be smaller than that determined by means of the Kordesch-Marko bridge (6). Cell resistances were about 0.3-0.35 ohm for boron carbide anodes and 0.2-0.25 ohm for graphite anodes, using a ½ in. electrolyte gap. Anhydrous ammonia was supplied to the anode chamber at a constant inlet flow rate of 30 ml/min, corresponding to 3-4 times stoichiometric at the highest current densities used.

Measurement of catalytic activity.—For measurements of the activity of iridium black in the gas phase decomposition of ammonia, catalyst samples weighing 1.5g were sealed into the vacuum system described previously (12), where they were evacuated and reduced at 200°C with pure hydrogen admitted into the apparatus by diffusion through a palladium thimble. After this treatment and further evacuation to 1×10^{-6} Torr, the residual surface area of the catalyst, as determined *in situ* by the BET method, was about 5 m^2/g. No further change in surface area was detected during the subsequent measurements.

Measurements of NH_3-D_2 exchange and NH_3 decomposition were then carried out on the reduced catalyst by admitting samples of NH_3, NH_3-D_2, and NH_3-H_2 mixtures and following the rates of the subsequent reactions as functions of time and temperature by means of a mass spectrometer (Consolidated Electrodynamics Model 21-610), connected through a capillary leak to the gas space over the sample. The temperature of the catalyst was kept constant to within ± 0.5°C by means of a furnace and Honeywell controller.

The activities of supported iridium catalysts for ammonia decomposition were measured in a flow system at approximately 1 atm pressure. The reactor was a quartz tube, 30 cm long and 2.5 cm ID, mounted inside a tube furnace. The catalyst pellets were packed in the central section of the reactor and were confined with glass wool plugs. A thermocouple well was inserted radially into the center of the catalyst bed. The inlet flow of ammonia was adjusted by means of micrometer needle valves and calibrated flow meters. The effluent gas was passed into calibrated gas burettes and the undecomposed ammonia absorbed in 1*N* sulfuric acid. By this means the decomposition of the ammonia was studied as a function of flow rate and catalyst temperature.

Indirect ammonia fuel cell system.—Tests were also carried out of the activity of iridium-based catalysts in an indirect ammonia fuel cell system, that is with a separate catalytic cracking unit coupled to a standard hydrogen fuel cell. The catalytic reactor was a 1 in. diameter quartz tube, filled with 100g of a 4% iridium-alumina catalyst (⅛ in. pellets) and mounted inside a tube furnace. Ammonia was passed through this cracking unit at a constant flow rate and the effluent admitted directly to the anode compartment of a standard fuel cell with platinum black electrodes. This cell used 54% KOH as electrolyte and was maintained at 35° or 100°C throughout. The performance of the cell was studied at different temperatures of the catalytic cracking unit.

In later experiments provision was made for introducing small amounts of air or oxygen into the ammonia feed to the reactor. Controlled rates of addition of these gases was achieved by means of sensitive micrometer needle valves and flow meters.

Results

Fuel cell measurements.—Unsupported platinum iridium black anodes.—The performances of anodes having the composition Pt-21.3% Ir and Pt-51% Ir and containing 34 mg noble metal/cm^2 are compared with that of a standard platinum black anode with 51 mg Pt/cm^2 in Fig. 1A. In this figure the anode polarization (*vs.* H_2 reference) is plotted as a function of current density at 120°C. The polarization of these anodes containing iridium was 100-120 mv less than that of the pure platinum electrode and this improvement was maintained up to current densities of at least 300 ma/cm^2. In addition, the open-circuit potential is within 0.15v of the thermodynamic reversible potential ($E^o_{298} = -0.77$v).

In general the anode polarization with ammonia decreased with increasing iridium content of the electrocatalyst. Difficulty was experienced, however, in preparing satisfactory electrodes with pure iridium black, probably as a result of poor wetting of the powder by the Teflon suspension. Performance data (anode *vs.* cathode, anode *vs.* H_2 reference, IR-free) for an iridium black anode at four different temperatures are presented in Fig. 2. Because of the wetting problem, however, these data may not represent optimum performance.

Supported platinum-iridium anodes.—Figure 1B shows anode-H_2 reference data for Pt/Ir-graphite anodes with noble metal loadings in the range 6-7 mg/cm^2. Similar data for a Pt-graphite anode containing about the same loading of noble metal are also included. The improvement resulting from the addition of iridium is again evident, and increasing proportions of iridium result in lower open-circuit potentials and reduced polarization under load, the improvement over platinum in the best case being over 0.1v at 50 ma/cm^2.

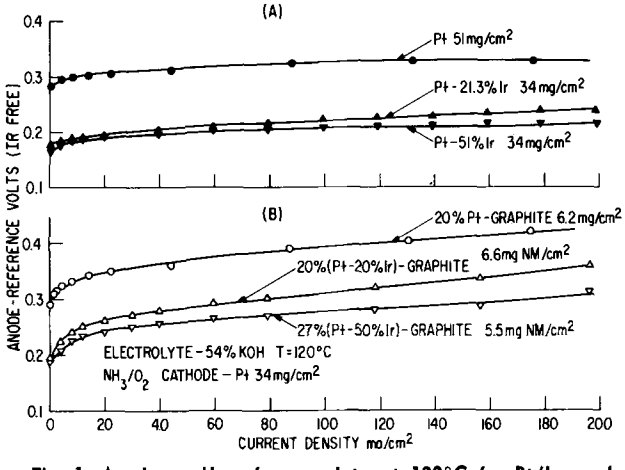

Fig. 1. Anode *vs.* H_2 reference data at 120°C for Pt/Ir anodes for NH_3 oxidation: (A) unsupported blacks; (B) catalysts co-deposited on graphite.

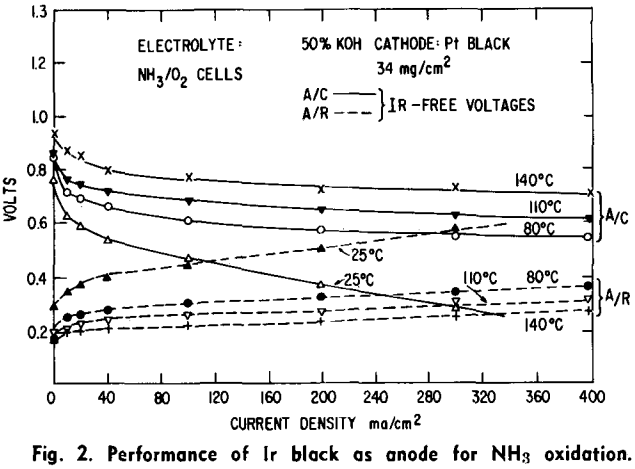

Fig. 2. Performance of Ir black as anode for NH_3 oxidation. Ir-free voltages; H_2 reference.

Satisfactory electrodes were also obtained using boron carbide as the catalyst substrate. Anodes containing iridium again showed less polarization than those with platinum alone. A typical [Pt-20% Ir] $-B_4C$ anode containing 6.8 mg noble metal/cm^2 showed an open-circuit voltage of 0.180v *vs.* SHE and an anode-H_2 reference voltage of 0.255 at a current density of 200 ma/cm^2. Boron carbide-based anodes were, however, generally less reproducible than those prepared from graphite.

Measurements of catalytic activity.—Following the observation of the unexpectedly high activity of iridium in ammonia fuel cell anodes, it appeared logical to inquire whether this metal is superior to platinum in the gas phase decomposition of ammonia. Measurements of the rates of NH_3-D_2 exchange and ammonia dissociation were therefore carried out over iridium black, and subsequently the cracking of ammonia over supported iridium catalysts was studied.

Ammonia-deuterium exchange.—The exchange of ammonia with deuterium took place at a rapid rate over the iridium black at 25°C, the initial rate of formation of the deuteroammonias decreasing with deuterium content. A typical exchange experiment is illustrated in Fig. 3, where the percentage concentration of the isotopic ammonias are plotted against time. In this case a mixture containing equal amounts of NH_3 and D_2 was admitted to the activated catalyst. By analogy with the treatment developed by Kemball (13), the initial rate of substitution of H by D in 100 molecules of NH_3, k_α, was evaluated from the relation

$$-\log_{10}(X_\infty - X) = \frac{k_\alpha\, t}{2.303\, X_\infty} - \log_{10} X_\infty$$

where X is defined by

$$X = \sum_{i=1}^{3} i\, n_i$$

n_i being the percentage of the $NH_{3-i}D_i$ species present at time t, and X_∞ is the equilibrium value of X. Similarly, the rate of removal of NH_3 was calculated in terms of a second rate constant, k_β, defined by the equation

$$-\log_{10}(Y - Y_\infty) = \frac{k_\beta\, t}{2.303(100 - Y_\infty)} - \log_{10}(100 - Y_\infty)$$

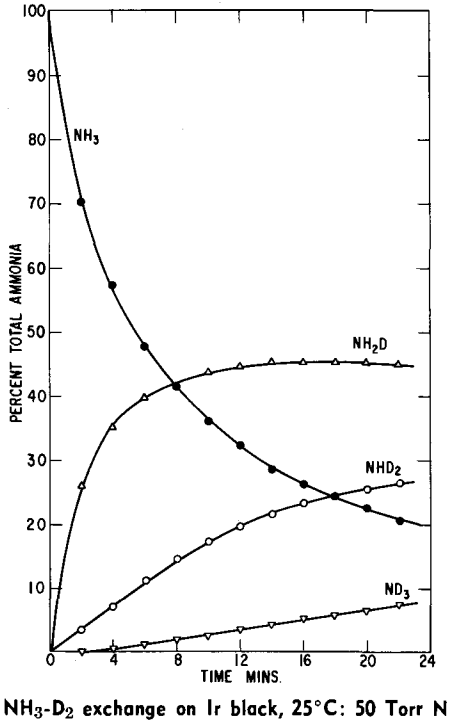

Fig. 3. NH_3-D_2 exchange on Ir black, 25°C: 50 Torr NH_3 + 50 Torr D_2 initially, 1.5g Ir; gas volume = 20.1 ml.

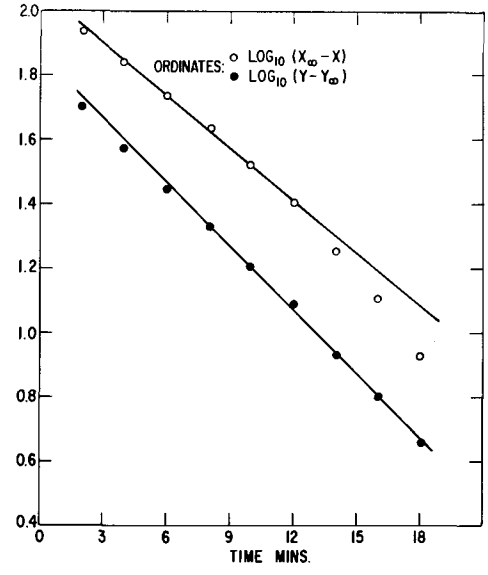

Fig. 4. Plots of $\log_{10}(X_\infty - X)$ and $\log_{10}(Y - Y_\infty)$ *vs.* time for NH_3-D_2 exchange on Ir at 25°C.

Y and Y_∞ being in this case the percentages of NH_3 at time t and at equilibrium. Application of these equations to the exchange data of Fig. 3 is shown in Fig. 4. Good straight lines were obtained over most of the course of the reaction. It is likely that the slight deviation from linearity shown by the lower plot is due to the initial rapid physical adsorption of ammonia on the glass envelope of the apparatus, causing the NH_3 concentration to decrease more rapidly than expected from the exchange reaction. The ratio of the rate constants k_α/k_β is a measure of the average number of hydrogen atoms being replaced by deuterium. The value of this ratio was found to be 1.2 at 25°C, indicating that on the iridium catalyst the hydrogen atoms of the ammonia were being replaced one by one in successive stages.

Ammonia decomposition on iridium black.—Ammonia decomposed rapidly over the iridium black catalyst at temperatures in the range 100°-200°C. Using an initial ammonia pressure of about 50 Torr, the progress of the reaction was followed as a function of time at various temperatures. Figure 5 shows a plot of log (initial rate of formation of N_2) *vs.* 1/T°K. The linear portion of this Arrhenius plot gave an apparent activation energy of 38.5 kcal/mole and a frequency factor, $\log_{10} A = 38.3$, A being in molecules/min.

The initial rate of formation of nitrogen was found to increase with increasing initial ammonia pressure in the range 5-100 Torr, as shown in Table I. A plot of log P_{NH_3} *vs.* log (rate) gave a value for the exponent of ammonia pressure of 0.85 by the method of least squares. The initial rate of nitrogen formation was also found to be strongly retarded by added hydrogen. Figure 6 shows the effect of increasing pressure of hydrogen in premixed NH_3-H_2 mixtures on the initial rate at 160°C. A least squares computation gave a value of -1.4 for the hydrogen exponent. The over-all rate expression was therefore of the form

$$\frac{d[N_2]}{dt} = k\, P_{NH_3}{}^{0.85} \cdot P_{H_2}{}^{-1.4}$$

A few experiments were carried out using platinum black prepared by the same method and having an equivalent surface area to that of the iridium black. It was found that the decomposition of ammonia over platinum was undetectable below 250°C.

Ammonia decomposition on supported iridium catalysts.—In experiments carried out in the flow system, the decomposition of ammonia over supported iridium catalysts was measured as a function of flow rate and temperature.

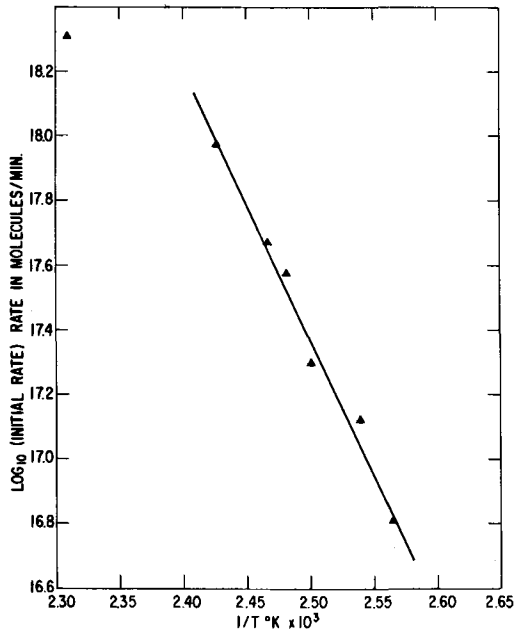

Fig. 5. NH_3 decomposition on Ir black. Plot of $\log_{10}$ (initial rate of N_2 formation) *vs.* 1/T°K.

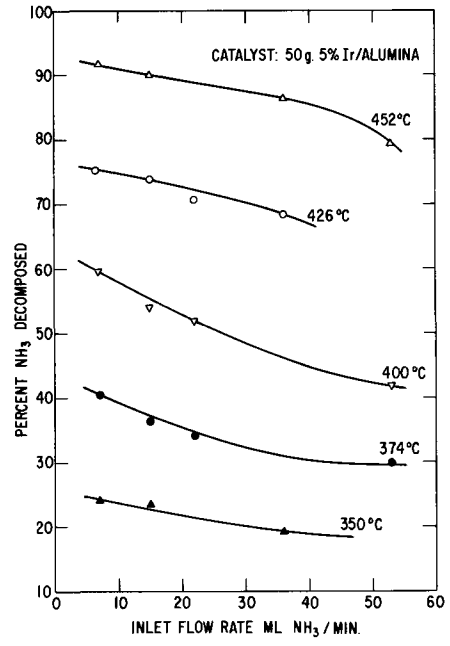

Fig. 7. Decomposition of NH_3 on 5% Ir/alumina (⅛ in. pellets). Conversion *vs.* inlet flow rate.

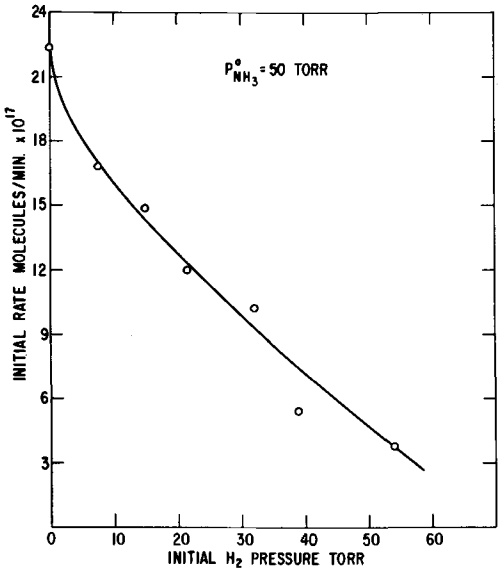

Fig. 6. Effect of added H_2 on initial rate of N_2 formation from NH_3 on Ir black, 160°C.

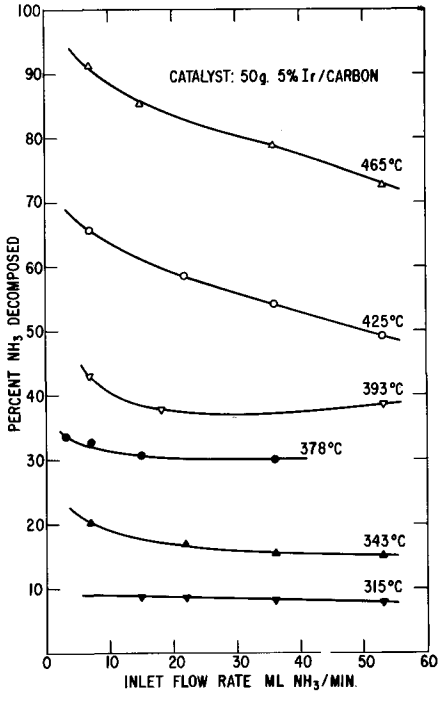

Fig. 8. Decomposition of NH_3 on 5% Ir/carbon (8-30 mesh granules). Conversion *vs.* inlet flow rate.

Figure 7 shows conversion data for a 5% iridium/alumina catalyst in the temperature range 350°-450°C. 50 g of catalyst (⅛ in. pellets) were used in these experiments, and an inlet flow rate of 50 ml NH_3/min corresponded to a space velocity of about 130 hr^{-1}. With this catalyst at low flow rates over 90% of the ammonia was decomposed at a temperature of 450°C. Similar data for a 5% iridium/carbon (8-30 mesh granules) are shown in Fig. 8. For comparison purposes samples of commercial ammonia cracking catalysts were tested under the same conditions. Both nickel/silica-alumina (Harshaw Company, Ni-0901S) and iron/alumina (Harshaw Company, Fe 1401-S) pellets gave much lower levels of activity than the supported iridium catalyst, the per cent NH_3 decomposed at 420°C with a 20 ml/min flow rate being about 15% for both commercial catalysts. The effect of iridium content on the activity of the alumina-based catalysts is shown in Fig. 9. Optimum activity was found with a 2% iridium catalyst, a concentration which may result in a maximum effective metal area. However, even the 0.5% iridium catalyst showed a much higher activity than that previously reported for 0.5% ruthenium/alumina catalyst (14).

The equilibrium percentages of ammonia, extrapolated from the data of Larson and Dodge (15), at 350°, 400°, and 450°C are approximately 1.8, 0.8, and 0.3, respectively, so that equilibrium is not achieved even with the most active catalysts.

Table I. Effect of NH_3 pressure on initial rate of N_2 formation

Temperature = 130°C, 1.5g Ir, gas volume = 69.6 ml

P^{NH_3} init, Torr	Rate N_2 formn, Torr/min	Initial rate, molecules/min	$\log_{10}$ (rate)
22.0	0.115	2.57×10^{17}	17.409
51.2	0.171	3.81×10^{17}	17.581
68.2	0.279	6.22×10^{17}	17.794
82.3	0.297	6.62×10^{17}	17.821
108.0	0.330	7.36×10^{17}	17.867

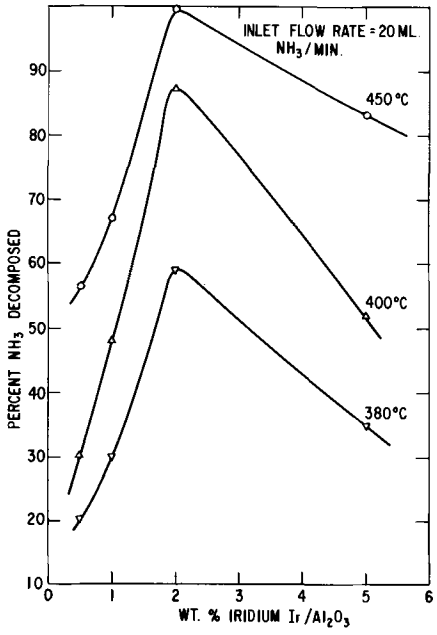

Fig. 9. Decomposition of NH_3 on Ir/alumina (⅛ in. pellets). Effect of Ir loading.

Satisfactory catalysts were also prepared by depositing 5% iridium on silica gel and molecular sieve 5A pellets. These supports generally gave somewhat lower activities than alumina, and large amounts of ammonia were physically adsorbed before steady-state conditions were achieved.

A 5% platinum/alumina, prepared from chloroplatinic acid, was tested after reduction at 500°C under the same conditions as those used for the iridium catalysts. At 480°C less than 15% ammonia was decomposed by the platinum catalyst at the lowest flow rates, whereas below 400°C no decomposition could be detected.

Indirect ammonia fuel cell system.—The results of experiments in which a separate reactor, containing supported iridium catalyst, was coupled to a fuel cell with platinum electrodes, are shown in Fig. 10. Anode-H_2 reference data using pure hydrogen, pure ammonia, and ammonia after passage through the catalytic reactor at various temperatures are indicated. A marked decrease in anode polarization was shown as the cracker temperature increased, the performance being equivalent to that of pure hydrogen at catalyst temperatures of 400°C and above. Figure 11 shows the effect of cracker temperature on the cell voltage under three different conditions, the effect of the cracking

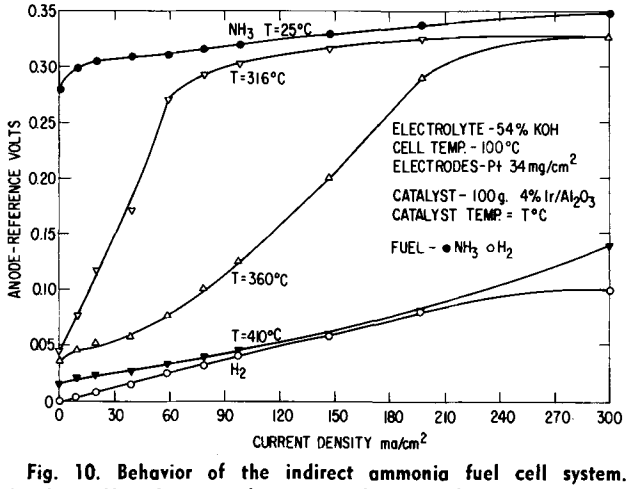

Fig. 10. Behavior of the indirect ammonia fuel cell system. Anode vs. H_2 reference voltages as a function of cracking catalyst temperature.

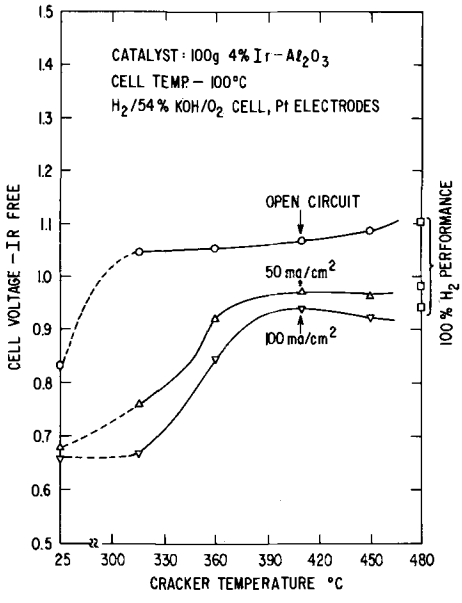

Fig. 11. Indirect NH_3 fuel cell system. Variation of cell voltage (IR-free) with cracker temperature.

catalyst on the open-circuit voltage being especially marked. These results indicate that ammonia acts as an inert diluent in the presence of hydrogen which is more strongly adsorbed on the electrode surface. The fuel cell is thus a reliable indicator of hydrogen concentration in the fuel stream.

The effect of oxygen added to the ammonia inlet of the catalytic cracker on the performance of the fuel cell is shown in Fig. 12. In this case the fuel cell assembly was maintained at 100°C, and the catalytic cracker kept at 367°C initially. The increase in performance shown with added oxygen is a reflection of the heating of the catalyst bed as a result of the exothermic ammonia oxidation reaction: $4NH_3 + 3O_2 = 2N_2 + 6H_2O$. Addition of 19% oxygen to the input ammonia gave fuel cell performance identical with that of pure hydrogen, and the equivalent temperature rise of the catalyst was about 90°C. All the added oxygen was reduced in the reactor unit and none was carried into the anode chamber of the fuel cell.

Figure 13 shows comparable data with the fuel cell maintained at room temperature (about 35°C due to internal heating). In this case, ammonia itself (in the absence of cracking catalyst) showed very poor performance in the cell, although considerable improvement was observed after passage of the fuel through the cracker at 380°C. Additional and marked increase in cell performance was again found when oxygen was introduced into the inlet stream. It appeared to be necessary to preheat the catalyst to around 200°C to

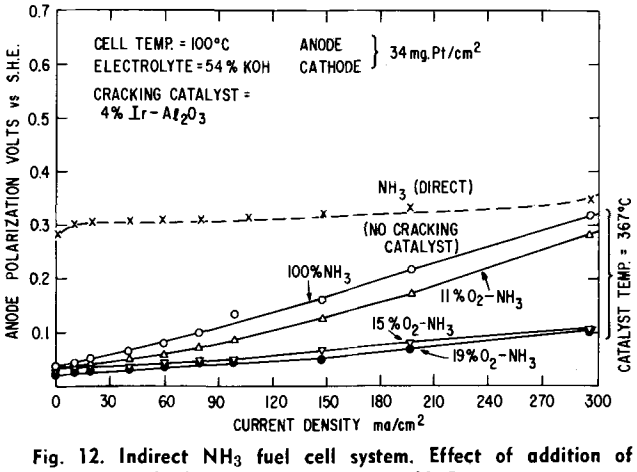

Fig. 12. Indirect NH_3 fuel cell system. Effect of addition of oxygen to NH_3 feed; fuel cell temperature 100°C.

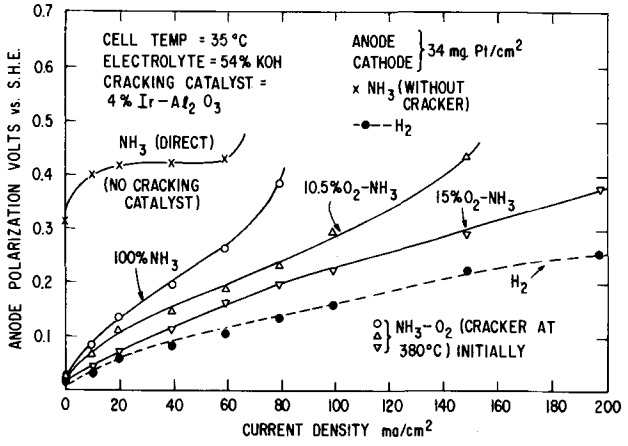

Fig. 13. Indirect NH_3 fuel cell system. Effect of addition of oxygen to NH_3 feed; fuel cell temperature 35°C.

initiate the ammonia oxidation reaction. However, this requirement and the minimum concentration of oxygen needed to produce a given temperature rise, could certainly be improved by optimization of the reactor design and iridium catalyst activity.

Discussion

The high level of activity of iridium and its alloys in the anodic oxidation of ammonia in the fuel cell appears to be directly related to the unusual ability of this metal to dissociate the NH_3 molecule. This analogy between the electrochemical and gas phase decomposition of ammonia has been noted previously by Oswin and Salomon (16). From an analysis of the slopes of the Tafel plots observed with platinized platinum anodes, these authors conclude that the reaction proceeds by a sequence of steps involving the progressive dissociation of ammonia into amine and imine radicals

$$NH_3 + M + OH^- \rightarrow M{-}NH_2 + H_2O + e^- \quad \text{(i)}$$

$$M{-}NH_2 + OH^- \rightarrow M{=}NH + H_2O + e^- \quad \text{(ii)}$$

$$M{-}NH + OH^- \rightarrow M{\equiv}N + H_2O + e^- \quad \text{(iii)}$$

$$M{\equiv}N + M{\equiv}N \rightarrow 2M + N_2 \quad \text{(iv)}$$

It is suggested that at low current densities, reaction (ii) is rate-determining, whereas at high current densities, nitrogen recombination and desorption (iv) may be the slow step. The latter reaction is often regarded as the rate-determining step in the gaseous dissociation of ammonia on active catalysts (17).

Previous studies of the exchange of ammonia with deuterium on evaporated films of platinum, rhodium, and palladium (18) have shown that these metals are very active for this reaction at low temperatures, stepwise exchange being the only mechanism observed. Platinum is the most active metal, the rate of exchange being rapid even at 0°C. By contrast, the decomposition of ammonia on the metals of group VIII requires much higher temperatures, generally in excess of 300°C, and the activity decreases in the order Ru > Rh > Pd (14). Osmium has also been reported to be quite active (19), although the behavior of iridium does not appear to have been investigated previously.

Attempts have frequently been made to correlate the catalytic efficiencies of the group VIII metals for ammonia decomposition with their ability to chemisorb nitrogen and with the number of unfilled d-orbitals in the metal (7). As it is felt that the dissociative chemisorption of nitrogen is the slow step in ammonia synthesis, only those metals which are capable of dissociating N_2 molecules should be active catalysts for the synthesis reaction. Metals which form stable nitrides are not, however, good catalysts, and a weak adsorption of nitrogen atoms is believed to be the most important requisite for high activity in ammonia synthesis and decomposition. Although the ability to chemisorb nitrogen is generally considered to increase on passing from right to left across the group VIII metals, information on the properties of iridium is lacking.

As with the other noble metals, the decomposition of ammonia on iridium appears to be strongly inhibited by hydrogen. Hydrogen is thus more strongly adsorbed than ammonia, a fact that is reflected in the performance of the fuel cell anode, where open-circuit potentials approaching that of hydrogen were observed with NH_3-H_2 fuel mixtures containing only small amounts of hydrogen.

The ratio $(-y/x)$ of the exponents in the rate equation

$$\text{Rate} = k\ P^x_{NH_3} \cdot P^y_{H_2}$$

was observed to be 1.65 approximately. This is in good agreement with the value of 1.7 obtained by Logan and Kemball for evaporated films of platinum and ruthenium (20). Although the Temkin-Pyzhev mechanism, based on nitrogen desorption as the rate-determining step, predicts a value of $(-y/x) = 1.5$, significantly higher values have often been obtained, especially for the metals of the platinum group. It has been suggested (20) that this result is due to the influence of chemisorbed hydrogen atoms which compete with nitrogen atoms for the surface. As the ability to chemisorb nitrogen is expected to decrease in the order Os > Ir > Pt, hydrogen atoms may compete for the surface of iridium more successfully than in the case of osmium. With the latter metal, values of $(-y/x)$ close to 1.5 have been reported (19).

Although the kinetics of ammonia decomposition over iridium agree well with those observed for the other platinum group metals, the high level of activity of iridium is somewhat unexpected. It is interesting to note that iridium and ruthenium, the most active metals for this reaction, have recently been shown to form stable complexes containing molecular N_2 as a ligand (21), in which nitrogen shares two loosely bound electrons with the metal. The corresponding compounds of platinum are very unstable. It is possible, therefore, that the high activity of iridium for the dissociation of ammonia results from an acceleration of step (iv) above, involving the recombination of nitrogen atoms on the metal surface.

Conclusions

In summary it appears that substantial improvements in ammonia fuel cell performance can be achieved by using iridium as the dissociating element. The iridium catalyst can be incorporated directly into the anode structure or used in an external catalytic unit coupled to a hydrogen cell. In the former case, open-circuit voltages of up to 0.934v have been achieved at 100°C with an oxygen cathode, a potential which is at least 0.1v greater than that obtained with the best platinum anodes under the same conditions (5, 6). In the case of an external cracker, the supported iridium catalyst can be maintained at a temperature several hundred degrees lower than that necessary with conventional ammonia dissociators which employ nickel or iron based catalysts.

Acknowledgments

The authors are indebted to E. L. Simons for many useful suggestions and to H. A. Liebhafsky for his continued support of this work and for helpful discussions which led to the experiments on oxygen injection.

Inhibition Mechanism of Medium-Sized Polymethyleneimine

Kunitsugu Aramaki*[1] and Norman Hackerman*

Department of Chemistry, The University of Texas at Austin, Austin, Texas

ABSTRACT

The inhibitive effect of medium-sized polymethyleneimines on the corrosion of iron in HCl solution is particularly good, and this effective inhibition is closely related to the angle of C-N-C bond or to strain in the ring as has been observed previously. The inhibition mechanism of the cyclic imines is developed further in this paper. Comparative studies on inhibition effectiveness of dimethylpolymethyleneammonium chlorides, N-phenylpolymethyleneimines, and the cyclic imines were carried out. Synergistic effects of iodide ion on the inhibition by cyclic imines and cyclic ammonium chlorides were also studied. Corrosion rate measurements on pure iron were made in HCl solution by polarization, hydrogen evolution, and weight loss. From the results, it was concluded that good inhibition of medium-sized polymethyleneimine is caused by donation of the unshared π-electron pair of its nitrogen atom to the metal.

The inhibition effectiveness of medium-sized polymethyleneimines, $(CH_2)_n NH$, with 9 to 12 methylene groups, is markedly high, especially with 10, for iron corrosion in HCl solution (1). It was concluded (1) that this was closely related to the angle of C—N—C bond or to strain in the ring.

In this paper the inhibition mechanism of C_{10} inhibitor is developed further by studying inhibition effects of polymethyleneimine derivatives.

Some factors in the enhanced inhibition of medium-sized cyclic imines[2] are:

1. Because of strong strain in the ring, the angle of C—N—C bond in the C_{10} imine molecule is believed to be near 120°, which means sp^2 hybrid orbital geometry of the nitrogen atom (1). This geometry provides π-electron character on the nitrogen atom. The high inhibition of C_{10} imine may be attributed to adsorption via enhanced metal-nitrogen bonding, including π-electron bonding (1-3).

2. If the cyclic imine is adsorbed on the metal by π-electron bonding, the relative molecular area, the effective area of the metal surface covered by inhibitor molecule (1, 2), is presumed to increase. This may result in a high inhibition effect.

3. Polymerized inhibitors may be produced by decomposition of the cyclic imine caused by ring strain, *e.g.*

$$m\,(CH_2)_{10}NH \rightarrow \left[\,(CH_2)_{10}NH\,\right]_m$$

In fact, formation of resinous matter during distillation of medium-sized cyclic imines suggests the likelihood of this reaction. The polymerized compound may well favor the inhibition effect (4, 5).

In order to confirm these factors, three groups of experiments were carried out. The first was a comparative study of inhibition effectiveness between the series of cyclic imines and cyclic ammonium chlorides. The latter, $(CH_2)_n N^+ (CH_3)_2\ Cl^-$, contained 5 and 8 to 14 methylene groups in the ring.

In the second group of experiments, a synergistic effect of these inhibitors and iodide ion was sought. Hackerman, Snavely, and Payne (6) reported on the synergism between C_8 imine and iodide ion in inhibiting iron in HCl solution. Here, adsorption of medium-sized cyclic imine on the iron surface is studied by comparing the cyclic imine-iodide system with the cyclic ammonium chloride-iodide.

The third was a comparative study of inhibition between cyclic imines and phenyl cyclic imines. In the latter compound, $(CH_2)_n NC_6H_5$ containing 5, 8, 10, 12, and 14 methylene groups in the ring, were tested as corrosion inhibitors. Inhibition effectiveness of N,N-dipentylaniline, $C_6H_5N(C_5H_{11})_2$, a phenyl derivative of dipentylamine (C_{10} secondary amine), was also measured.

Three kinds of measurements were carried out for determining corrosion rates of pure iron wire in 6.1M HCl solution with and without the inhibitors at 30°C.

[2] The terms "cyclic imine," "cyclic ammonium chloride," and "phenyl cyclic imine" used here are, respectively, for polymethyleneimine, for dimethylpolymethyleneammonium chloride, and for N-phenylpolymethyleneimine. Also used are C_n imine, C_n ammonium chloride, and phenyl C_n imine. For example, C_{10} imine for decamethyleneimine, C_{10} ammonium chloride for dimethyldecamethyleneammonium chloride, and phenyl C_{10} imine for N-phenyldecamethyleneimine.

They were made by polarization, hydrogen evolution, and weight loss.

Approximate areas of metal surfaces effectively covered by each inhibitor molecule in the adsorbed position were also determined with properly arranged scale molecular models.

Experimental

Corrosion inhibitors.—Cyclic imines containing 9 to 14 methylene groups were synthesized by known procedures (1). Piperidine and octamethyleneimine were obtained as high-grade commercial reagents. They were all repeatedly purified by fractional distillation or by recrystallization.

N-methylpolymethyleneimines derived from the corresponding cyclic imines with formaldehyde and formic acid (7) were converted to their methiodides. The latter were carefully alkalized with silver oxide and then neutralized with hydrochloric acid. Cyclic ammonium chlorides thus produced were purified by recrystallization. Infrared spectra showed the absence of impurities except for traces of water. They were extremely hygroscopic and melted with decomposition at the following temperatures: C_5,[3] 343°C; C_8, 229°C; C_9, 219°C; C_{10}, 216°C; C_{11}, 243°C; C_{12}, 211°C; C_{13}, 223°C; C_{14}, 217°C.

Phenyl cyclic imines containing 5, 8, 10, 12, and 14 methylene groups in the imine ring were synthesized by reaction of the corresponding cyclic imine with bromobenzene in the presence of sodium amide (8). These imines were purified by fractional distillation and/or by recrystallization. Their purity was verified by infrared spectra and by nuclear magnetic resonance spectra. They have physical constants as follows: C_5, bp 133° C/19 mm Hg; C_8, bp 174° C/16 mm Hg; C_{10}, bp 125° C/1 mm Hg; C_{12}, bp 148° C/1 mm Hg, mp 51°C; C_{14}, 176° C/1 mm Hg, mp 47°C. N,N-dipentylaniline was similarly synthesized from dipentylamine and then purified by fractional distillation at 116°C under 1 mm Hg.

Inhibitor solutions were prepared by dissolving the inhibitors in constant boiling (107°C) HCl solution (6.1M) made from reagent grade material. The solutions containing iodide ion, which was added in 6.1M HCl solution as reagent grade sodium iodide, were stored for short periods under N_2 atmosphere and in a dark cold place. Before use they were refluxed under N_2 for removing traces of iodine produced during the storage.

Corrosion rate measurements.—Corrosion rates of pure iron wire (99.5%, Mallinckrodt Analytical Reagent Grade, 0.36 mm diameter) were determined in 6.1M HCl solution at 30°C by the three kinds of measurements.

Polarization was carried out galvanostatically by supplying current with a coiled Pt wire, a 90v battery, and high variable resistors. Potential of the iron wire was measured with a saturated calomel electrode and an electrometer.

Hydrogen evolution measurements were carried out volumetrically with a graduated gas buret for 120 min. Weight loss measurements were made simultaneously. The details of the experimental equipment and the procedures have previously been given (1).

Relative molecular areas were determined by arranging Stuart-Brieglieb models on a plane in a position corresponding to the appropriate configuration of the molecule adsorbed on the metal surface by formation of a given metal-nitrogen bonding. For example, the nitrogen geometry of cyclic imine molecule adsorbed via the π-electron coordinated bonding was based on the sp^2 hybrid orbitals. The configurations of imine rings were assumed to be analogous to those represented by Dunitz and Prelog (9). All of these molecular areas were compared with that of piperidine. Details of this measurement have also been given (1, 2).

[3] Carbon number in the imine ring.

Results

Corrosion current, i_{corr}, was obtained by the intersection of extrapolated anodic and cathodic Tafel lines. The reproducibility of i_{corr} was good to within less than $\pm$ 4%.

Corrosion currents for cyclic ammonium chlorides are shown as a function of inhibitor concentration in Fig. 1. The results show a regular decrease of i_{corr} with increase of carbon number in the ring.

Hydrogen evolution rates, R_v, were determined by using the average slopes of hydrogen volume versus time curves between 30 and 120 min after the wires were dipped in the solution. Reproducibility was within $\pm$ 4%.

Corrosion rates, R_w, were also measured by weight loss of iron wire in HCl solution. These data were also reproducible to within $\pm$ 4%.

The hydrogen evolution and weight loss rates for cyclic ammonium chlorides are not shown here but are in good agreement with those of Fig. 1. The data for each inhibitor showed the same inhibition efficiencies by all three experimental methods.

Corrosion currents in HCl solution inhibited with iodide ion and either C_{10} imine or C_{10} ammonium chloride were measured as were those inhibited with only iodide ion. Two concentrations of the cyclic inhibitors, 3 x 10^{-3} and 10^{-2} M, were chosen for iodide concentrations at 10^{-4} to 10^{-1} M. Figure 2 gives the log i_{corr} *vs.* iodide ion concentration for the C_{10} imine-iodide system and for the C_{10} ammonium chloride-iodide system, and for the iodide ion alone.

The synergistic effect is evident in these systems since the corrosion currents with the cyclic inhibitors were decreased on increase in iodide concentration.

The synergistic effect was detected with the cyclic imines and with the cyclic ammonium chlorides. The i_{corr} values at 1 x 10^{-2} M of the cyclic compounds and 1 x 10^{-3} M of iodide ion is shown *vs.* ring carbon number in Fig. 3. For comparison, i_{corr} is also given for the system without iodide ion. Both curves for both series are much alike.

Corrosion rate measurements for the phenyl cyclic imine series and for phenyl C_{10} imine were made by polarization, hydrogen evolution and weight loss procedures. Typical curves of log i_{corr} *vs.* concentration of phenyl cyclic imines in imine ring shown in Fig. 4. The trends of the corrosion rates by hydrogen evolution or weight loss were in agreement, all showing rate decrease with increase of carbon number in the imine ring.

In the polarization measurements, anodic oxidation of phenyl cyclic imines was observed at higher concen-

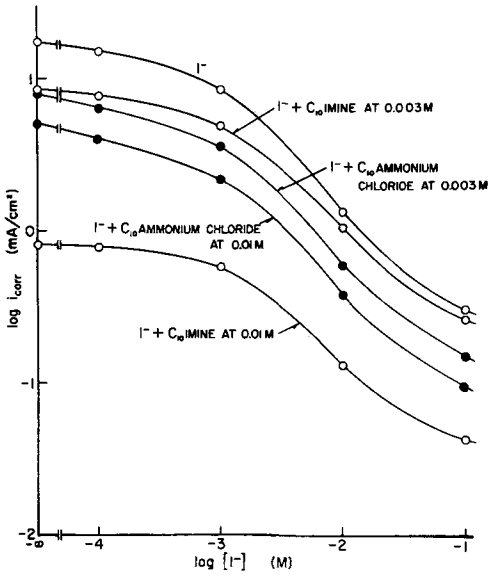

Fig. 2. Synergistic inhibition effect for C_{10} *imine-iodide* ion system and for C_{10} ammonium chloride-iodide ion system.

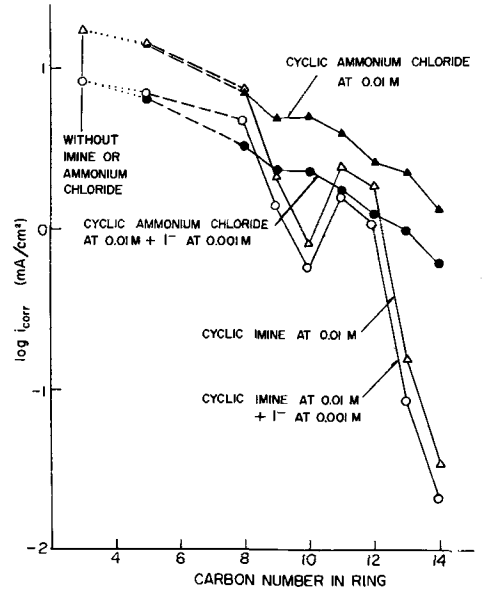

Fig. 3. Synergistic effect of iodide ion on inhibition effectiveness of cyclic imines and cyclic ammonium chlorides.

trations as formation of a red product around the Pt anode. This product is probably a mixture of complex polymers as has been reported for anodic oxidation of dimethylaniline (10). It was found to enhance the inhibition effectiveness of the phenyl cyclic imines. For example, the corrosion current, 0.599 ma/cm^2 for phenyl C_{10} imine at 3 x 10^{-3} M, decreased to 0.300 ma/cm^2 in the first run and to 0.105 ma/cm^2 in the second. Therefore, the i_{corr} values for these inhibitors are reliable at low concentration.

Hydrogen evolution rates with phenyl C_{10} amine are shown in Fig. 5 along with those of phenyl C_{10} imine, C_{10} amine, and C_{10} imine. The data indicate that inhibition effectiveness ability of phenyl C_{10} amine is about the same as with phenyl C_{10} imine. Similar results were also obtained by polarization and weight loss measurements.

Relative molecular areas of cyclic imines adsorbed on the metal by virtue of π-electron bonding are shown in Fig. 6. This also includes those held via σ-electron metal-nitrogen bonding as previously reported (1). Since sp^2 hybrid orbital geometry of the nitrogen atom relaxes the ring strain, there is no irregularity in the relation of molecular area via π-electron bonding to

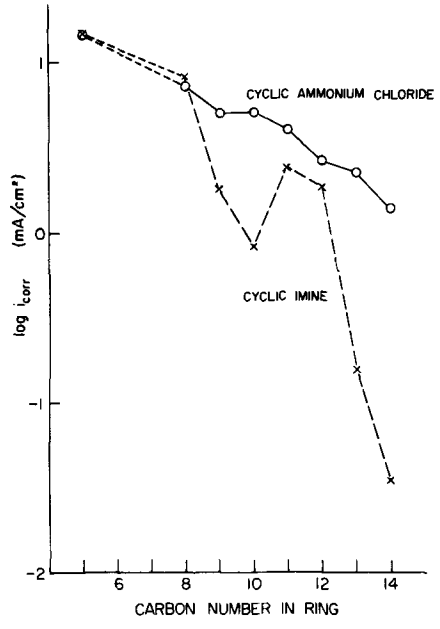

Fig. 8. Relation between corrosion current and carbon number of cyclic ammonium chloride at 10^{-2}M.

carbon number. The two areas differ little from each other at carbon numbers 8 to 10.

Relative molecular areas of the cyclic ammonium ions were also determined. Because there are no unshared electron pairs in these ions, they are adsorbed on the metal surface via coulombic bonding which does not restrict direction. Therefore, simple areal comparison is unavailable even if configuration of hydrocarbon groups are assumed as have been described (9). The maximum and minimum relative molecular areas for cyclic ammonium ions are shown in Fig. 7.

Discussion

To repeat, three effective factors for the enhanced inhibition of medium-sized cyclic imines were considered. To verify the second one, relative molecular areas of cyclic imine molecules adsorbed on the metal by virtue of π-electron bonding were compared with those via σ-electron bonding. The two areas are relatively close to each other at carbon numbers 9 and 10, but not at 11 and 12 (Fig. 6).

C_9 imine, one of the enhanced inhibitors, has almost identical areas by either of the two bonding types. The area of C_{10} imine via π-electron bonding is slightly greater than that by σ-bonding. The i_{corr} value for C_{10} imine remains lower than the value for strain-free cyclic imines,[4] regardless of which area is used. Therefore, increase of the relative molecular area for C_{10} imine is not sufficient to account for the enhancement of inhibition. It is thus concluded that the enhanced inhibition of C_9 and C_{10} imine does not depend on their relative molecular areas while it still might for C_{11} and C_{12} imine.

To decide between the first and third possibilities, corrosion currents for the cyclic ammonium chloride series were compared with those for the cyclic imine series. The rate data for both series, plotted against carbon number in the ring, are shown in Fig. 8. The concentration of each inhibitor was 10^{-2} M.

Comparison of these curves indicates that enhanced inhibition of medium-sized cyclic imine was diminished by converting to cyclic ammonium chloride since there is no peak on the curve for the ammonium chloride series.

Figure 9 shows i_{corr} *vs.* relative molecular areas for cyclic ammonium chlorides. Since the configuration of these inhibitor molecules adsorbed on the metal surface is uncertain, the maximum and minimum areas were used. General consideration of hydrocarbon configuration in adsorbed particles suggest the area is close to the minimum at high inhibition.

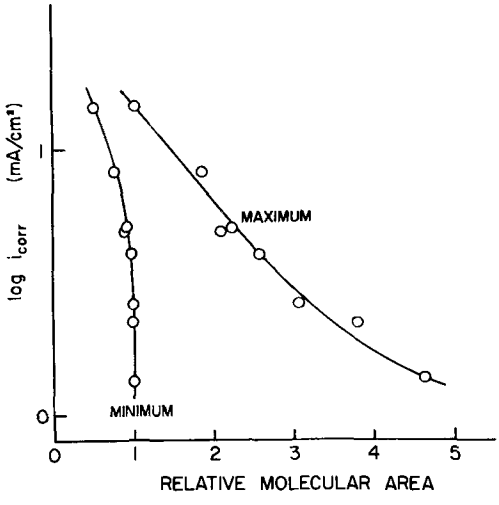

Fig. 9. Log i_{corr} *vs.* relative molecular area of cyclic ammonium chloride at 10^{-2}M.

The curve for cyclic imines is complicated with marked irregularity at the position of the medium-sized compounds (1), whereas Fig. 9 shows a smooth relation with little scattering. The irregularity is the basis in the conclusion relating to strain in the cyclic imine ring.

The difference in this relation between the two inhibitor series thus appears to depend on differences in their molecular structures. Since the unshared electron pair on the nitrogen atom of cyclic imine is blocked by methyl groups, adsorption of cyclic ammonium chloride by means of electron donation to the metal is not likely. However, there is the possibility of polymerization both in cyclic imine and in ammonium chloride because the ring strain persists.

It is concluded, therefore, that the difference in log i_{corr} *vs.* relative molecular area relation is not attributed to polymerization. This leaves donation of the electron pair on the nitrogen atom to the metal as the applicable inhibition mechanism for the medium-sized cyclic imines.

The effect of halide ion on inhibition was studied for developing the inhibiting mechanism of cyclic imines. Synergistic effects between halide ion and amine have been observed and explained by a mechanism which

[4] Refer to Fig. 10 in ref. (1).

includes specific adsorption of the halide ion on the metal (6, 11-13). Iodide is the most adsorbable of the halide ions on iron (14). It enhanced inhibition of both cyclic imine and ammonium chloride in 6.1M HCl solution as shown in Fig. 2.

Murakawa, Nagaura, and Hackerman (13) have expressed synergistic inhibition efficiency, $\eta_{A^+ + X^-}$, of amine and halide ion as

$$\eta_{A^+ + X^-} = \eta_{A^+} + \eta_{X^-} \quad [1]$$

where η_{A^+} and η_{X^-} are inhibition efficiencies due to ammonium ion and halide ion, respectively. The inhibition efficiency, η, is defined here as

$$\eta = \frac{R_o - R}{R_o} \quad [2]$$

where R_o is the uninhibited and R the inhibited corrosion rate.

In this paper, for the cyclic compound and iodide ion not interacting with each other, this relation was expressed with a little modification as

$$\frac{R_{I+I^-}}{R_o} = \frac{R_I}{R_o} \cdot \frac{R_{I^-}}{R_o} \quad [3]$$

where R_I, R_{I^-}, and R_{I+I^-} are, respectively, the corrosion rate of iron in the HCl solution with cyclic compound, with iodide ion, and with both, or

$$\eta_{I+I^-} = \eta_I + \eta_{I^-} - \eta_I \eta_{I^-} \quad [4]$$

where η_I, η_{I^-}, and η_{I+I^-} are, respectively, the inhibition efficiencies of cyclic inhibitor, of iodide ion, and of both.

The efficiency $\eta_{A^+ + X^-}$ can be more than one in Eq. [1] while η_{I+I^-} is limited to less than one.

The R_{I+I^-} value calculated from Eq. [3] was compared to the measured one, R_{I+I^-} by s, defined as

$$s = \frac{R_{I+I^-}}{R_{I+I^-}} \quad [5]$$

This shows the extent of synergism in the cyclic compound and iodide ion system. When there is no interaction between them, s should approach one.

Figure 10 shows the s values calculated from the data in Fig. 2. The s values for C_{10} ammonium chloride plus iodide were almost one and did not change with concentration of either inhibitor. Since these inhibitors are cationic and anionic and are likely to be adsorbed on the metal separately, *i.e.*, the cyclic ammonium ion on the cathode and the iodide ion on the anode, the results are believed to be reasonable. Moreover, there is slight enhancement of the synergism in this system as shown by the values exceeding one at low iodide concentration. This probably arises from stabilization by diminishing coulombic repulsion between charges of the adsorbed ions, as described by Iofa (11), Conway (12), and Murakawa (13).

For the C_{10} imine and iodide ion system, s decreased with increase in concentrations of each. This indicates that adsorption of these inhibitors interferes with each other at high concentrations.

Iodide ion is adsorbed on the anode of the metal surface. Cyclic imine is believed to be adsorbable not only on the cathode areas by coulombic attraction using charge of the protonated molecule, but also on the anode areas by virtue of donation of the electron pair on the nitrogen atom of the unprotonated molecule (15). Therefore, interference adsorption can take place at the anode. Adsorption of C_{10} imine by means of electron donation is probably blocked by the adsorbed iodide ion especially at higher concentrations. Stabilization of the molecules on the metal adsorbed is not likely because the unprotonated imine lacks a charge.

The s values for the cyclic imine series and for the cyclic ammonium chloride series were calculated by using the data in Fig. 3 and are shown in Fig. 11. All the values for cyclic ammonium chlorides are near one. As stated above, there is no interference of their adsorption with iodide ion, but stabilization by diminishing the coulombic repulsion enhances their synergism.

The curve of s *vs.* carbon number for cyclic imines shows a minimum at carbon number 10. This suggests that iodide adsorption on the anode interferes with C_{10} imine adsorption there. Since cyclic imine is adsorbed on the anode by virtue of electron donation, this adsorption is probably blocked by adsorbed iodide. Enhanced inhibition of C_{10} imine is thus again shown to be due to donation of an unshared electron pair to the metal.

The possible effect of chloride ion adsorption on the inhibition of cyclic imine must be considered. In the absence of iodide, chloride ion adsorption on the anode may interfere with cyclic imine adsorption. However, adsorption of chloride ion on iron or steel in acid solutions is less than that of iodide ion (6, 14). Therefore, iodide replaces chloride (16)

$$I^- + Cl^-_{ad} \rightarrow I^-_{ad} + Cl^-$$

Taking into account the high inhibition of cyclic imine in the HCl solution, a similar reaction is possible for cyclic imine, *e.g.*,

$$Cl^-_{ad} + (\overbrace{CH_2)_n NH} \rightarrow [(\overbrace{CH_2)_n NH}]_{ad} + Cl^-$$

But the above results indicate that adsorbed iodide is not replaced by cyclic imine. Therefore, the effect of

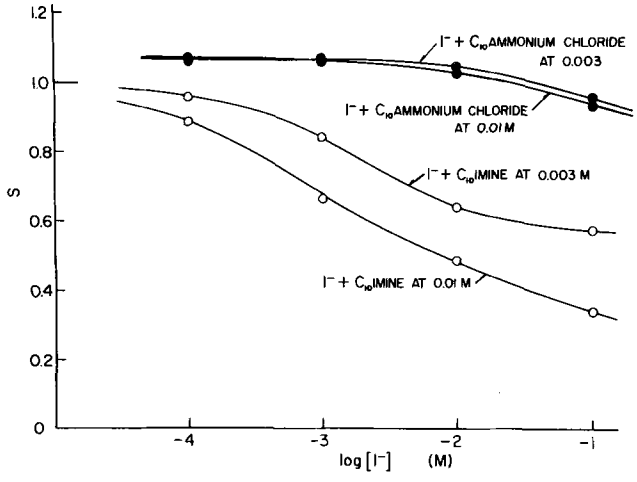

Fig. 10. The s value for iodide ion-C_{10} imine system and for iodide ion-C_{10} ammonium chloride system.

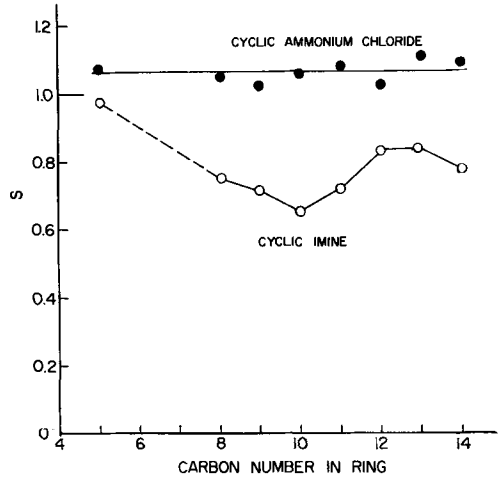

Fig. 11. The s value for cyclic imine-iodide ion system and for cyclic ammonium chloride-iodide ion system.

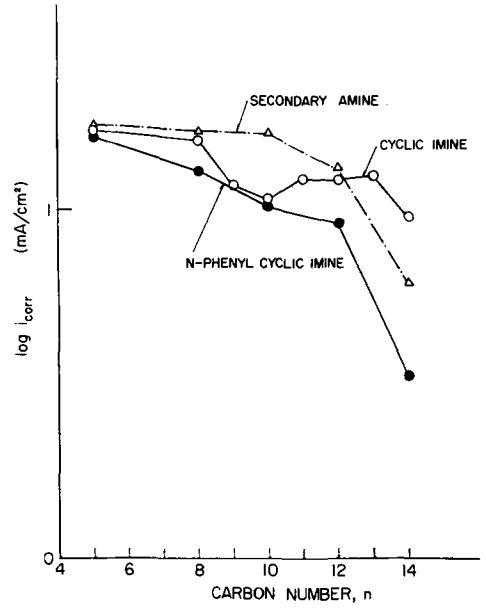

Fig. 12. Inhibition effects of phenyl cyclic imine, $(CH_2)_n N C_6H_5$, cyclic imine, $(CH_2)_n NH$, and secondary amine, $(C_{n/2}H_{n+1})_2 NH$ at 10^{-3}M.

chloride on the synergism discussed here is not believed to be important.

To verify further the effect of π-electrons in C_{10} imine nitrogen on its inhibition, the effectiveness of phenyl cyclic imines was studied. Because the corrosion currents at high concentrations may be in error due to oxidized inhibitor, the data obtained at 10^{-3} M were plotted *vs.* carbon number in the imine ring as shown in Fig. 12, together with those for cyclic imines and for symmetric secondary amines. The curve for phenyl cyclic imine shows no peak at carbon number 10 as is shown for the cyclic imine.

To explain the electron structure of phenyl cyclic imines, phenyl C_5 imine and phenyl C_{10} imine were chosen as typical examples. Because of the ring strain, the geometry on the nitrogen atom of the latter is believed to be sp^2 hybrid orbital, which provides π-electrons on the nitrogen atom, while unshared electrons of the former are σ-type in sp^3 hybrid orbital nitrogen. These unshared electrons are stabilized by participation in resonance with π-electrons of the phenyl group. Electron-delocalized structures of phenyl C_{10} imine are supposed to be stable because of the unshared π-electrons on its nitrogen atom. The π-electrons in phenyl C_{10} imine nitrogen are therefore stabilized more by the resonance than are the unshared σ-electrons in phenyl imine.

Ultraviolet absorption spectra of these compounds agreed with this suggestion. Absorption bands, based on π-π* transition of the phenyl group, shift to longer wavelengths by participation of unshared electrons on a nitrogen atom in resonance of the phenyl group (17). Wavelengths at peak of the E_2 and B band (18) for phenyl cyclic imines measured in cyclohexane are listed in Table I.

The data show a maximum wavelength at carbon number 10. This suggests that the unshared electron pair on phenyl C_{10} imine nitrogen is the most attracted and stabilized by the phenyl group. Therefore, adsorption of phenyl C_{10} imine by virtue of the π-electron metal-nitrogen bonding is weaker than that of phenyl C_5 imine by the σ-electron bonding. This results in no peak on the curve of log i_{corr} *vs.* carbon number as is shown in Fig. 12. This curve and that for secondary amines which are free from the ring strain are similar.

Table I. Ultraviolet absorption spectra of phenyl cyclic imine and phenyl C_{10} amine

	Wavelength, mμ	
	E_2 band	B band
phenyl C_5 imine	253	287
phenyl C_8 imine	263	303
phenyl C_{10} imine	263	304
phenyl C_{12} imine	260	302
phenyl C_{14} imine	258	303
phenyl C_{10} amine	258	303

In order to detect delocalization of unshared electrons in phenyl cyclic imine, other approaches were made by infrared spectra (19) and by nuclear magnetic resonance spectra (20). However, they were not successful except that the electron delocalization in phenyl C_{10} imine was shown to be increased more than in phenyl C_5 imine.

Although the degree of the electron donation to the metal is diminished by the phenyl group, the inhibition effectiveness for phenyl cyclic imine is higher than for cyclic imine. This may be due to increase of the effective molecular area and to bifunctional adsorption via both the nitrogen atom and the phenyl group. Formation of a surface complex (21) would be possible for this inhibitor. Inhibition by cyclic imine is thus concluded to be enhanced by donation of the unshared π-electron pair of the nitrogen atom to the metal.

To confirm this, the inhibition difference between phenyl C_{10} amine and phenyl C_{10} imine was compared with that between C_{10} amine and C_{10} imine. Because of lack of ring strain, there is no unshared π-electrons in the C_{10} amine nitrogen. Therefore, the unshared electrons of phenyl C_{10} amine should be attracted less by the phenyl group than in phenyl C_{10} imine. This agrees with the ultraviolet spectra. Wavelength at the peak of absorption bands for phenyl C_{10} amine is shorter than that for phenyl C_{10} imine as shown in Table I. Thus, adsorption ability of the latter should be decreased more in comparison to that of the former. In fact, as can be seen in Fig. 5, corrosion rates, R_v, for phenyl C_{10} amine and for phenyl C_{10} imine are alike, while R_v for C_{10} amine is much higher than that for C_{10} imine. This result shows that inhibition by phenyl C_{10} imine is decreased by electron delocalization, thereby diminishing the ability of donating unshared π-electrons to the metal.

Conclusion

It is concluded that enhanced inhibition by medium-sized polymethyleneimines on corrosion of iron in HCl solution is caused by donation of the unshared π-electron pair on its nitrogen atom to the metal.

The adsorption of this cyclic imine is improved by formation of coordinated metal-nitrogen bonding via π-electrons. However, there is no evidence for explaining how this bonding enhances the adsorption quality of cyclic imine.

The sp^2 geometry in the nitrogen atom of medium-sized cyclic imine may be changed to the sp^3 geometry to form the metal-nitrogen bonding by chemisorption. However, strong adsorption cannot arise from formation of unstable, deformed sp^3 geometry (1). Formation of stable metal-nitrogen bonding, in which the sp^2 geometry of nitrogen atom remains, may be required for strong adsorption. Little insight into the geometry of adsorbed species by virtue of π-electron bonding is provided by infrared spectra on ethylene adsorbed on metals (22). Direct measurement of adsorption spectra derived from the π-electron metal-nitrogen bonding are needed to confirm this suggestion.

Anodic Polarization of Some Ferritic Stainless Steels in Chloride Media

E. A. Lizlovs* and A. P. Bond*

Research Laboratory, Climax Molybdenum Company of Michigan, Ann Arbor, Michigan

ABSTRACT

Potentiodynamic polarization experiments were performed in 0.1*N* hydrochloric acid with 17% chromium ferritic stainless steels containing up to 3% molybdenum and with 18% Cr-2% Mo ferritic stainless steels containing 0-2% nickel and 0-2% titanium. Potentiodynamic polarization studies with the 17% chromium alloys were also performed in 1*N* hydrochloric acid and in 1*N* sulfuric acid + 0.1*N* sodium chloride media. The critical current densities were significantly decreased with an increased molybdenum content. The pitting potentials were increased with increased molybdenum and titanium contents, whereas nickel additions had no effect. All materials were sensitive to crevice corrosion. Sulfate ions in the $SO_4^=:Cl^-$ molar ratio of 5:1 inhibited pitting corrosion and suppressed crevice corrosion.

The effects of molybdenum on anodic polarization of 17% chromium stainless steels in sulfuric acid have previously been studied in this Laboratory (1). Because of the well-established usage of molybdenum alloying for increasing the resistance of stainless steel to pitting corrosion, interest developed in extending anodic polarization studies to chloride media. It was envisioned that the anodic polarization in acidic chloride media would not only provide information concerning the effect of molybdenum additions on the pitting potential of ferritic stainless steels, but would also provide some information concerning the active-passive transition of stainless steels in the presence of chlorides.

Experimental Procedures

Two sets of laboratory-prepared ferritic alloys and two commercial ferritic stainless steels (Types 430 and 434[1]) were investigated. The high-purity 17% chromium, 17% Cr-1% Mo, and 17% Cr-3% Mo laboratory alloys were prepared by melting and casting in vacuum. The resulting ingots were hot-rolled to 0.64-cm-thick sheet, which was cold-rolled to a 0.32-cm thickness, annealed for 1 hr at 815°C, and water-quenched. The 18% Cr-2% Mo alloys modified by titanium and nickel additions were produced by induction melting in an argon atmosphere, using the split-heat technique. In this technique, the base composition is melted, and part of the melt is poured off to produce an ingot; then to the balance of the melt, the required alloying additions are made and the next ingot is cast. This process is repeated until a series of the desired compositions is cast. The 18% Cr-2% Mo ingots were hot-forged, hot-rolled to 0.76-cm-thick strips, and cold-rolled to 0.38-cm-thick strips. The 18% Cr-2% Mo alloys containing titanium were annealed for 1 hr at 1040°C, the minimum temperature that prevented formation of a second phase in the high titanium alloy, and then water-quenched. The rest of the 18% Cr-2% Mo materials and the hot-rolled, commercial Types 430 and 434 steels were annealed at 815°C for 1 hr and water-quenched. The chemical compositions of all the materials are given in Table I.

The electrodes for the potentiodynamic studies were mounted in acrylic plastic, the exposed surface (0.5 by 0.6 cm) always being a longitudinal section parallel to the rolled surface. A more detailed description of the electrode can be found elsewhere (1). The exposed surface was polished using standard metallographic techniques, ending with a distilled water slurry of 0.3μ alumina. For the pitting potential measurements, the electrode surface was masked with electroplaters

tape (Scotch 470), except for a circular area 0.36 cm in diameter.

The potentiodynamic polarization experiments were performed using standard equipment and techniques. Potentials were measured with respect to a saturated calomel electrode. The auxiliary platinum electrode was isolated from the test solution by a glass frit. All materials were tested in argon-saturated 0.1*N* hydrochloric acid (HCl). The high-purity alloys and commercial steels were tested in argon-saturated 1*N* HCl, 1*N* sulfuric acid (H_2SO_4), and 1*N* H_2SO_4 + 0.1*N* sodium chloride (NaCl). Potential scanning rates for most polarization experiments were 600 mv/hr for the 18% Cr-2% Mo series, and 540 mv/hr for the rest of the materials. For determination of the pitting potentials, the electrode potential was scanned at the rate of 600 or 540 mv/hr up to potentials of about 0.1-0.2v less noble than the expected pitting potential. At this potential the scanning rate was decreased tenfold, *i.e.*, to 60 or 54 mv/hr. Scanning was continued until the pitting potential was reached. The onset of pitting was marked by a sharp and sudden increase in polarization current. The potential scanning was stopped at the pitting potential, and the electrode was allowed to pit for 20 to 30 min. It was then removed from the solution, the tape was stripped, and its surface was examined for pitting and possible crevice corrosion. The potential scanning was usually started at —0.7 to —0.6v, with respect to the saturated calomel electrode (SCE); the scanning was always into the passive potential region. In some experiments, the potential of an actively corroding electrode was changed almost instantaneously to a selected potential in a passive range by switching on a potentiostat, with a potential preset at a desired value.

The experiments with the 18% Cr-2% Mo series of alloys were performed at 24° ± 1°C. All the other materials were tested at 29.6° ± 0.1°C.

Results

Experiments in 0.1N hydrochloric acid.—Typical anodic polarization curves for the Types 430 and 434 stainless steels in 0.1*N* HCl are shown in Fig. 1. The active region for the Type 430 steel exhibited two current maxima, one peak at —0.50v and another at —0.38v. Considerable variations in peak heights were observed for different Type 430 samples, and in some samples the second peak was higher than the first peak. However, the corresponding potentials remained approximately within ± 10 mv of the values given above.[2] The single critical current density peak, shown by the Type 434 steel, was always lower than the corresponding peak for the Type 430 steel.

The passive region for the Types 430 and 434 stainless steels terminated at potentials considerably less noble than the normal transpassive transition range, +0.85 to +0.95v. This passivity breakdown for the unmasked electrodes was characterized by a gradual increase in polarization current. A considerable amount of polarization current could usually be sustained at selected potentials without visible pitting or general corrosion. However, after a long potentiostatic polarization time, microscopic examinations revealed some corrosion at the boundary of the sample and at the acrylic mount. This observation was in accord with the results obtained by Schwenk (2). Thus, in all the potentiodynamic polarization experiments with unmasked electrodes in HCl, the apparent passivity breakdown was not due to pitting corrosion, but was a result of the passivity breakdown inside the extremely fine crevice between the electrode and plastic mount. The presence of crevices with the electrode mounted in metallographic materials was also indicated by Greene *et al.* (3).

The differences in polarization behavior between an unmasked and a masked electrode in the passive state are illustrated in Fig. 1. For the masked electrode the current density beyond the primary passivation potential gradually decreased to the level of 10^{-6} amp/cm^2 or lower, depending on the potential scanning rate, and remained at this level until either pitting or a normal transpassive breakdown occurred. The current density for unmasked electrodes, however, first decreased and then increased gradually, indicative of the onset of crevice corrosion.

Typical anodic polarization curves for the high-purity 17% chromium alloys in 0.1*N* HCl are shown in Fig. 2. As the molybdenum content increased, the critical current density decreased. The primary passivation potential, however, tended to become more noble at higher molybdenum content. A second peak in the active-passive transition region was observed only for the 17% Cr-3% Mo alloy. Critical current density for the 17% chromium alloy varied from 1 to 6 ma/cm^2 for different samples. These variations in critical current density were accompanied by changes in primary passivation potential between —0.49 and

[2] Henceforth, the current density peak at the least noble potential will be referred to as the critical current density, and the corresponding potential as the primary passivation potential.

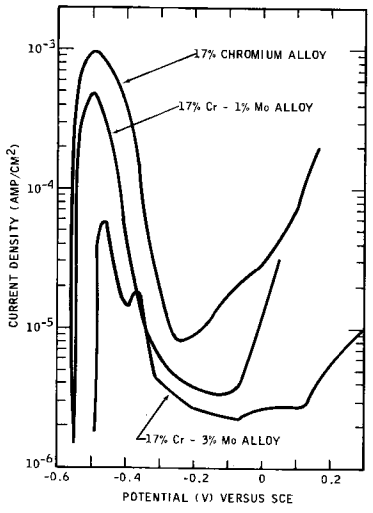

Fig. 2. Anodic potentiodynamic polarization curves for 17% chromium, 17% Cr-1% Mo, and 17% Cr-3% Mo alloys in 0.1*N* hydrochloric acid at 29.6°C (unmasked electrodes).

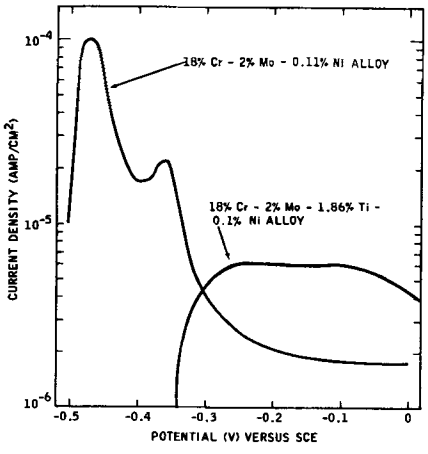

Fig. 3. Anodic potentiodynamic polarization curves for the 18% Cr-2% Mo-0.11% Ni and 18% Cr-2% Mo-1.86% Ti-0.11% Ni alloys (masked electrodes) in 0.1*N* hydrochloric acid at 24°C.

—0.43v; in general, the more noble the primary passivation potential, the higher the critical current density. The passive region for the unmasked electrodes again terminated at potentials less noble than pitting potentials. However, crevice corrosion did not influence the critical current density of the materials, so that unmasked electrodes could be used for the anodic polarization studies in the active region. Furthermore, the minimum current densities, reached in the passive region with unmasked electrodes, appeared to depend on the molybdenum content for both commercial and high-purity alloys. The steels with the highest molybdenum content had the lowest current minima in the passive state (Fig. 1 and 2). Thus, molybdenum appears to improve the resistance of ferritic stainless steels to crevice corrosion in chloride media. However, since the crevice geometry was not intentionally controlled on the electrodes, further experimental work is needed to obtain more quantitative information concerning the effect of alloying additions on crevice corrosion. Representative values of critical parameters for the commercial steels and high-purity alloys are summarized in Table II.

18% Cr-2% Mo-0.47% Ti	>0.8
18% Cr-2% Mo-1.86% Ti	0.63
18% Cr-2% Mo-0.91% Ti-0.57% Ni	>0.8
18% Cr-2% Mo-1.75% Ti-2.08% Ni	0.62

Representative anodic polarization diagrams in 0.1*N* HCl for 18% Cr-2% Mo alloys are shown in Fig. 3. Table III gives the critical parameters for these alloys. Table III also shows that an increase in nickel content, from 0.11% to 0.62%, results in complete suppression of the active region. Although the addition of 0.47% titanium had no effect on critical behavior, an increase in titanium level to 1.86% resulted in a complete disappearance of the active region. In addition to the normal critical current density peaks, considerably lower secondary peaks were observed for most of the 18% Cr-2% Mo alloys in the —0.38 to —0.30v region.

Average pitting potentials for all the materials are summarized in Table IV. A typical polarization run with a masked electrode, exhibiting termination of the passive range due to onset of pitting, is shown in Fig. 4. The onset of pitting corrosion was always marked by a sharp current rise over several orders of magnitude, but crevice corrosion was marked by a gradual current increase. Under the experimental conditions used, the materials that could be scanned beyond the threshold of transpassivity (+0.80v) ought to be considered resistant to pitting corrosion. However, exploratory studies showed that potentiostatic pitting could be achieved with materials that exhibit a full

passive range under potentiodynamic conditions. This occurred under conditions of nearly instantaneous potential switch from an active corrosion potential to a sufficiently noble passive potential. Thus, the 17% Cr-3% Mo alloy was pitted at +0.40v under these conditions.

A repassivation phenomenon was also observed during several potentiodynamic pitting experiments. This phenomenon was usually indicated by current blips at potentials that were lower than those at which continuous pitting occurred (Fig. 4). However, the pitting corrosion was sometimes sustained for 15 to 20 min, and then followed by complete repassivation of the pits. Examination of the electrode revealed visible pits inside the free electrode area, but revealed no evidence of corrosion under the masking tape.

Experiments in 1.0N hydrochloric acid.—Anodic polarization curves for the commercial and high-purity alloys in 1.0*N* HCl are shown in Fig. 5 and 6 (unmasked electrodes). Table II gives the critical current densities and primary passivation potentials. Type 430 stainless steel did not passivate at all in 1.0*N* HCl. Type 434 steel did exhibit a current peak at the expected position for the primary passivation potential,

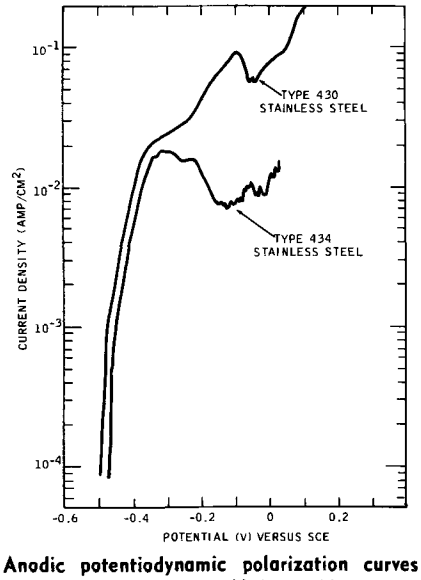

Fig. 5. Anodic potentiodynamic polarization curves for Types 430 and 434 stainless steels in 1*N* hydrochloric acid at 29.6°C (unmasked electrodes).

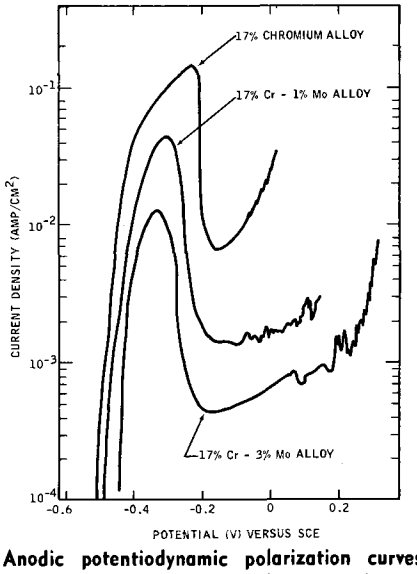

Fig. 6. Anodic potentiodynamic polarization curves for 17% chromium, 17% Cr-1% Mo, and 17% Cr-3% Mo alloys in 1*N* hydrochloric acid at 29.6°C (unmasked electrodes).

—0.310v; however, current densities beyond the critical peak remained quite high. All the high-purity alloys exhibited a critical current density peak, but the current densities at potentials approximately 100 mv more noble than the primary passivation potentials were several orders of magnitude higher than the corresponding current densities in 1*N* H_2SO_4 (1). The potentiostatic passivation experiments, performed in 1*N* HCl with masked electrodes, showed than 17% Cr-1% Mo and 17% Cr-3% Mo alloys could be completely passivated in the —0.20 to —0.10v region. The resulting polarization current densities in the passive state were of the same order of magnitude as those observed in H_2SO_4, 10^{-6} amp/cm² (1). Thus, the apparent high-current densities obtained with unmasked electrodes are an outcome of crevice corrosion, which is much more severe in 1.0*N* than in 0.1*N* HCl.

At any passive potential under potentiostatic conditions, the polarization current densities for the masked 17% chromium alloy and for commercial Types 430 and 434 steel were several orders of magnitude above the 10^{-6} amp/cm² level. Furthermore, the potentiostatic experiments with an unmasked 17% chromium electrode at —0.15v showed that at this potential, the electrode corroded uniformly at a rate corresponding to approximately 10 ma/cm². Thus, for the straight chromium steels and for Type 434 steel, the high current densities in a passive range are primarily the result of the uniform corrosion, but for the 17% Cr-1% Mo and 17% Cr-3% Mo alloys, the relatively high current in the passive range is largely the result of crevice corrosion.

The elimination of the crevice by the use of masking tape was considerably more difficult in 1*N* than in 0.1*N* HCl; in fact, many experiments were invalid because the mask loosened, and crevice corrosion resulted. Therefore, neither the potentiostatic maintenance of the passivity over prolonged periods of time, nor the potential range over which the steels would retain their passivity was investigated.

The critical current density for all materials again decreased with the increase in molybdenum content, and at the same time the primary passivation potentials became more negative. The relationship among molybdenum content, critical current density, and primary passivation potential is shown in Fig. 7.

Potentiodynamic studies in sulfuric acid + sodium chloride solution.—Typical potentiodynamic polarization curves for ferritic stainless steels in the 1*N* H_2SO_4 medium and the 1*N* H_2SO_4 + 0.1*N* NaCl medium are given in Fig. 8, which shows that the critical current density is increased by the addition of the chloride ion

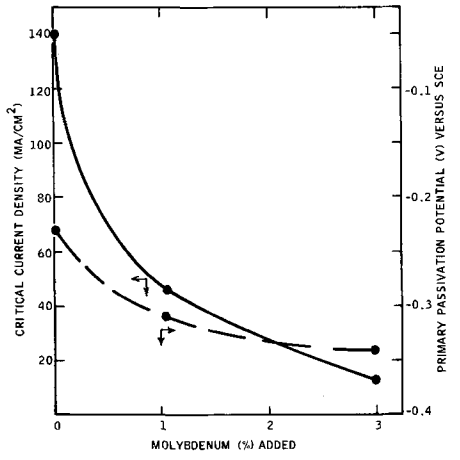

Fig. 7. Effect of molybdenum additions to the 17% chromium alloy on the critical current density and primary passivation potential in 1*N* hydrochloric acid at 29.6°C.

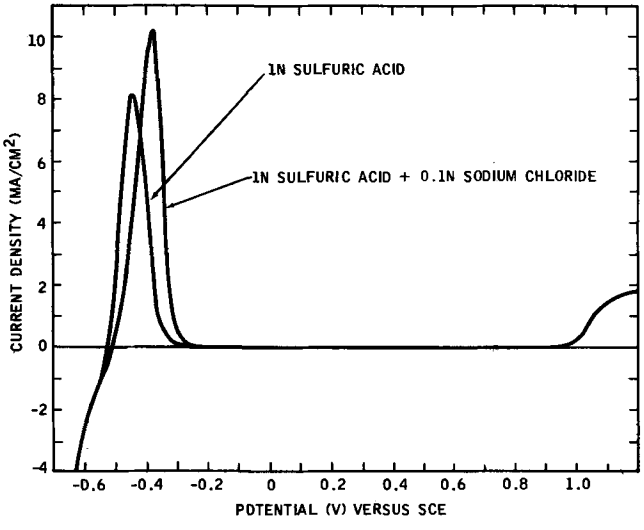

Fig. 8. Potentiodynamic polarization curves for Type 430 stainless steel in 1*N* sulfuric acid and in 1*N* sulfuric acid + 0.1*N* sodium chloride at 29.6°C (unmasked electrodes).

to sulfuric acid; however, this increase is caused by the shift of the primary passivation potential in a noble direction due to the activation effect of the chloride ions. At a given potential up to the primary passivation potential for pure acid, the dissolution rates of Type 430 stainless steel were lower in the chloride-containing acid than in pure acid. This inhibiting effect of chloride ions on anodic dissolution was similar to that reported by Bockris *et al.* (4) for pure iron. Furthermore, in the 1*N* H_2SO_4 + 0.1*N* NaCl solution, the passive range terminated at the same potentials as in the 1*N* H_2SO_4. Similar polarization behavior was observed for Type 434 and all 17% chromium alloys.

Discussion

Pitting potentials in 0.1N hydrochloric acid.—The examination of the average pitting potentials for the 17% chromium alloys (Table IV) discloses that, as the molybdenum content is increased, pitting potentials become more noble (*i.e.*, the resistance toward pitting corrosion increases with the molybdenum content). Since a normal transpassive transition was obtained for the 17% Cr-3% Mo alloy, this material should be immune to pitting corrosion under the experimental conditions. However, Types 430 and 434, which are commercial counterparts of the 17% chromium and 17% Cr-1% Mo alloys, have significantly lower pitting potentials. This difference in pitting potentials is probably the result of the higher carbon levels and impurity contents of commercial steels, as compared with the vacuum-melted laboratory alloys. Furthermore, the average pitting potential for the Type 434 steel is only slightly higher than the pitting potential for the Type 430 steel. The difference in pitting potential was much more in the 17% chromium and 17% Cr-1% Mo alloys. Since the carbon level for the Type 434 sample used in this investigation was considerably higher than that for the Type 430 sample [*i.e.*, 0.069 as compared with 0.046% (Table I)], it may be concluded that the higher carbon level obscured the effect of molybdenum on pitting potential. Higher carbon content in a ferritic matrix will result in more precipitated chromium and molybdenum carbides and in a depletion of the matrix of chromium and molybdenum. Consequently, the ferritic steels with higher carbon contents will probably have a greater sensitivity to pitting corrosion.

The examination of the pitting potentials for the 18% Cr-2% Mo ferritic alloys, with a carbon content of about 0.03%, leads to the conclusion that small nickel additions (up to 1%) do not affect the pitting potentials of these alloys. In contrast to the insensitivity to small additions of nickel, small additions of titanium have a very pronounced effect on pitting potentials. Titanium contents of 0.47 and 0.91% raised the pitting potential above the transpassive transition. A further increase in titanium to about 1.8% reduced pitting potential. Pitting potentials for titanium-modified alloys, however, are still more noble than for titanium-free alloys. This effect of titanium could be indirect. The titanium ties up carbon and nitrogen, preventing the formation of chromium and molybdenum carbides and nitrides and, consequently, prevents the formation of zones depleted in chromium and molybdenum. With larger titanium additions, the considerable amount of second phase that develops might be the preferred site for pitting attack.

The pitting potential for the 18% Cr-2% Mo-0.03% C alloy was about the same as that for the high-purity 17% Cr-1% Mo-0.002% C alloy, and was significantly more noble than that for either Type 430 steel or the high-purity 17% chromium alloy. Thus, in the 17% chromium steels with commercial carbon levels, the increase of molybdenum content to 2% should result in considerably improved resistance to pitting corrosion.

The values of pitting potentials are significantly influenced by experimental techniques (5, 6). In work with molybdenum-containing austenitic stainless steels, a fast potential scanning rate was a more severe experimental condition than a slow scanning rate (7). Consequently, the instantaneous potential rise from the active corrosion potential to a selected passive potential would be one of the most severe experimental conditions for the potentiostatic pitting studies. That the 17% Cr-3% Mo alloy could be pitted by the above method implies that all the materials investigated would pit under conditions of instantaneous potential jump. Thus, the results from the potentiodynamic pitting studies would at best predict only a relative order of resistance to pitting corrosion, but would not necessarily determine the immunity to pitting at a given chloride ion concentration and temperature.

Polarization studies in hydrochloric acid.—The results of the critical current density and primary passivation potential determination in 0.1*N* and 1.0*N* HCl are consistent with previous measurements in H_2SO_4, *i.e.*, molybdenum decreases the critical current density required to produce passivity and, to a lesser extent, shifts the primary passivation potential to more active potentials (1). Thus, molybdenum additions facilitate the attainment of the passive state for ferritic stainless steels in HCl. This effect was especially pronounced in 1*N* HCl for high-purity alloys (Fig. 6). In this series, only alloys containing molybdenum could be completely passivated in 1*N* HCl, *i.e.*, the current densities for masked electrodes decreased to between 10^{-6} and 10^{-7} amp/cm² at some potential beyond the pri-

mary passivation potential. In contrast to such pure alloys as 17% chromium alloy, the commercial Type 430 did not show a critical behavior in 1*N* HCl, and Type 434 showed little tendency to passivate (Fig. 5). This behavior is probably the result of the depletion of the ferritic matrix of chromium and molybdenum by the precipitation of carbides.

Small nickel additions to 18% Cr-2% Mo alloys were somewhat beneficial to the attainment of passivity in 0.1*N* HCl, since these additions depressed the critical current density to the point where no active region was displayed. However, results from work on austenitic stainless steels (7) showed that an 18% Cr-16% Ni alloy free of molybdenum could not be completely passivated in 1*N* HCl, but a similar alloy containing molybdenum could be. Thus, the beneficial effects of small nickel additions to ferritic stainless steel in HCl may be limited to the molybdenum-containing grades.

Polarization studies in HCl solutions revealed that HCl is an effective medium for the potentiodynamic investigation of the effects of alloying elements on the corrosion and passivation properties of stainless steels. The effects of molybdenum additions are very dramatically shown by polarization curves in 1*N* HCl; it is expected than any alloying addition which has a strong effect on the passive film will also have a pronounced effect on the active-passive transition in HCl. Polarization curves in 0.1*N* HCl, especially with the 17% chromium alloy, were characterized by considerable variations in critical current density and primary passivation potential. Such behavior would probably result from the competition of the normal tendency of the alloy to passivate in a weakly acidic medium with the activating effect of the chloride ions. Stainless steels with relatively weak passivation tendencies would therefore be expected to have a more prominently variable passivation behavior than steels with a strong passivation tendency. The active-passive transition region in 0.1*N* HCl was often complicated by the presence of two current density maxima. Since measured current is the difference between the total oxidation and total reduction current, the small secondary current maxima might arise from the changing hydrogen evolution kinetics, which are the result of the passivation of the electrode surface. However, large secondary peaks observed with Type 430 steel could not be explained. Since the potential for either peak is fairly reproducible, the double-peak phenomenon for the Type 430 steel might result from the chromium segregation and different passivation behavior of chromium-rich and chromium-depleted regions. For the Type 434 steel, which has a stronger passivation tendency, the second peak is only slightly indicated (Fig. 1). Some support for the above speculation is given by the work of Voeltzel and Plateau (8) who observed a double-peak phenomenon for sensitized austenitic 18% Cr-8% Ni stainless steel. The double-peak phenomenon was ascribed to chromium depletion along the grain boundaries.

None of the ferritic stainless steels studied was immune to crevice corrosion in HCl, not even those which had a high resistance to pitting.

Polarization studies in sulfuric acid-sodium chloride solution.—Since a complete passive range was obtained for all the materials studied, the results from potentiodynamic polarization studies in 1*N* H_2SO_4 + 0.1*N* NaCl indicate that sulfate ions in the $SO_4^{=}:Cl^-$ molar ratio of 5:1 inhibit pitting corrosion. The inhibiting effect of sulfate ions on chloride pitting of austenitic steels has been described in the literature (5, 9). This investigation showed that pitting corrosion of ferritic stainless steel can also be inhibited by sulfate ions. Furthermore, since crevice corrosion was very prominent in 0.1*N* HCl, it may be concluded that sulfate ions suppress the crevice corrosion to the extent that a normal transpassive transition can be obtained with a potential scanning rate of 0.540 v/hr.

Summary

Molybdenum additions to ferritic stainless steels facilitated the attainment of passivity in 0.1 and 1*N* HCl.

The pitting potential in 0.1*N* HCl became more noble with increased molybdenum content for high-purity 17% chromium alloys and with increased titanium content for 18% Cr-2% Mo-0.03% C alloys. An increase in carbon content generally resulted in less noble pitting potentials, whereas small nickel additions (up to 1%) did not change the pitting potential significantly.

All the ferritic stainless steels studied were very sensitive to crevice corrosion in HCl.

The sulfate ions, in a molar ratio of $SO_4^{=}:Cl^-$ of 5:1 not only inhibited pitting corrosion but also suppressed crevice corrosion for all the steels investigated.

Manuscript submitted Sept. 16, 1968; revised manuscript received Feb. 3, 1969. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 60.

On the Passivity of Iron-Chromium Alloys

II. The Activation Potential

Robert P. Frankenthal*

Edgar C. Bain Laboratory For Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania

ABSTRACT

Precise potential control and measurement have permitted the determination of the primary activation potential, E_a, of an Fe-24% Cr alloy in 2*N* H_2SO_4 to within ± 0.5 mv and the determination of the kinetics of passivating film growth at this potential, as well as at other potentials. Small changes in potential give rise to large differences in film thickness. From the time dependence of the anodic current and the film thickness during passivation, a theory for the primary passivation process is proposed based on different rates of dissolution and different degrees of passivation at various types of surface sites, *e.g.*, kinks, ledges, and terraces; these differences arise from distinct activation energies for anodic dissolution and distinct adsorption energies associated with each type of site. The steady-state film thickness at the activation potential, as measured by cathodic reduction, is 0.36 ± 0.03 mC/cm² and corresponds to between one and three monolayers of film depending on the assumed model of a monolayer and the reduction product. Finally it is shown that secondary film formation can occur at the activation potential after sufficiently long times of passivation.

In an earlier paper (1) it was shown that on an Fe-24% Cr alloy in H_2SO_4 at least two distinct, potential-dependent films are formed during the passivation process. It was concluded that the primary passivation process is phenomenologically reversible; that the primary film is responsible for the initial passivation and is stable only within a few millivolts of the primary activation potential, E_a, defined as the reversible minimum in the cathodic loop (Fig. 2); and that the thickness of the primary passivating film corresponded to no more, and probably less than one $O^=$ ion per surface metal atom. The secondary film, on the other hand, forms at more positive potentials, grows to a thickness greater than 10^{-7} cm and, with increasing time and potential, becomes very stable and resistant to reduction. In this paper we consider in more detail the passivation process and the passivating film at the primary activation potential. We also emphasize the importance of controlling and measuring potentials very precisely (at least to ± 0.5 mv) to obtain reliable and meaningful mechanistic data. It will also be shown that the primary activation potential and the Flade potential (2) are not synonymous as is frequently assumed (3) and that the Flade potential is strictly a kinetic potential and not a thermodynamic one as is frequently assumed (3).

Experimental

The alloy investigated was a high-purity, vacuum-melted, ferritic Fe-24% Cr alloy which has the following analysis: Cr, 23.8%; C, 0.0075%; N, 0.0068%; O, 0.050%; P, <0.005%; S, 0.004%; Si, <0.01%; Al, <0.005%; Cu, <0.01%; Mg, <0.001%; no other elements were detected. The electrodes were machined as previously described (4) and then annealed for a week at 800°C and quenched in water. To remove any scale and to obtain a uniform surface, they were electropolished according to Sewell *et al.* (5).

The glass cell had two concentric compartments connected by four 2-mm diameter fine porosity frits. The outer compartment housed the auxiliary electrode and the inner compartment, the test electrode. A Luggin capillary connected the inner compartment to a hydrogen reference electrode. A solution reservoir was connected to the cell so that fresh de-aerated solution could be introduced into the cell whenever desired. This vessel, as well as both compartments of the cell, was fitted with a bubbler through which helium was continuously passed. The helium was prepurified by passing it over CuO at 440°C, through a liquid nitrogen cold trap, through an activated charcoal cold trap also at liquid nitrogen temperature, and through a bubbler containing doubly distilled water.

The electrolyte was 2*N* H_2SO_4 (*p*H 0.02) prepared from reagent-grade acid and doubly distilled water (resistivity >4 Mohm-cm). In certain experiments the solution was further purified by passing it over activated charcoal as described by James (6) and Barnartt (7). All experiments were conducted at 24°C.

A schematic circuit diagram is shown in Fig. 1. A Wenking potentiostat was used with an external potential programmer. For rapid switching from one potential to another, mercury-wetted contact relays (C. P. Clare & Company HG-1002) with switching times in the microsecond range were used. Potential measurements were made with an Orion pH-meter, the output of which was connected to a Honeywell Electronik 19 recorder, *vs.* a hydrogen electrode in the same solution and are reported relative to the standard hydrogen electrode (SHE). Current was followed by measuring the potential drop across a precision resistor (0.1%) with an oscilloscope or recorder. All potentials were controlled and measured to better than ± 0.5 mv.

Film thicknesses were measured by coulometric reduction with a standard amperostatic circuit consisting

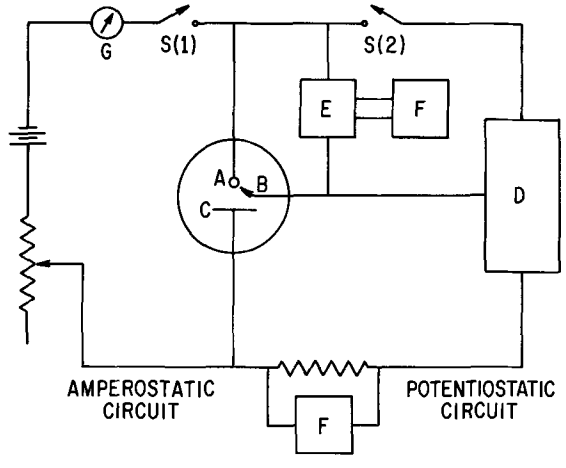

Fig. 1. Schematic circuit diagram: A, test electrode; B, reference electrode; C, auxiliary electrode; D, potentiostat; E, pH-meter; F, recorder; G, ammeter; S, switch.

* Electrochemical Society Active Member.

of a 45v battery and a high resistance to give a constant current density of 1 μa/cm^2 for film reduction. In practice switch S-1 would be closed before S-2 was opened, the potentiostat compensating for the cathodic current introduced by the reduction circuit; this insured that when S-2 was opened, reduction of the film would begin instantaneously with no possibility of side reactions during time at open circuit. The end point for the reduction was taken as the inflection point in the potential-time (E-t) curve. The total current used consisted of the film reduction current plus the hydrogen evolution current at E_a[1] (1). The film reduction potential lies 15 mv negative of E_a and the correction for the hydrogen evolution current should have been slightly greater. As a result the film thicknesses reported may be slightly high.

The real surface area of an electrode was determined by measuring its capacitance at +0.300v and comparing it to the capacitance of an electropolished and cathodically reduced specimen at the same potential, the surface roughness factor of which is assumed to be 1.0. Measurements were made with an a-c bridge (8) at frequencies between 5 and 10 kHz, a region free of frequency dispersion effects. The measured roughness factors were generally between 1.1 and 1.4. All calculations in this paper are based on the real surface area determined in this manner.

The normal operational sequence for any one experiment was as follows. The surface was cathodically reduced at —0.5v and then anodically dissolved at the potential corresponding to the maximum anodic current density, —0.205v; the electrolyte solution was flushed out by fresh solution; the specimen was put on open circuit and allowed to come to its corrosion potential, which normally required about 5 sec; finally the potential was switched to that to be studied. This procedure gave the most consistent and reproducible results. It was found that the cathodic reduction step could be omitted in between experiments in which the specimen was not exposed to the air or to very positive potentials at which thick films grew. Satisfactory cleaning was evidenced by an anodic current density of 28 ma/cm^2 during the dissolution step and by a corrosion potential of —0.261 ± 0.001v. In those experiments in which no secondary film growth was expected, reproducibility of the film reduction potential to within 1 mv was also used as a criterion for an initially clean surface. For a surface that had not been cleaned satisfactorily, the reduction potential was always more negative.

Changing the electrolyte solution between passivation and cathodic reduction was found to have no effect on either the measured film thickness or on the E-t curves for film reduction.

Results

The potentiostatically determined steady-state polarization curve (E-i curve) for this system is shown in Fig. 2. If the potential is not permitted to exceed the primary activation potential, E_a, by more than 5 mv, that section of the E-i plot given by the solid line is measured and exhibits no hysteresis. However, the dashed section always shows a hysteresis (1); the curve in Fig. 2 was measured by changing the potential from negative to positive values. The negative current (cathodic loop, indicated by the discontinuities in the curve) is due to the evolution of hydrogen. The primary activation potential has previously (1) been defined as the potential at which the first increase in the anodic current is observed in going from the passive region into the anodic loop under conditions of reversibility. This corresponds to the minimum in the cathodic loop and lies between —0.108 and —0.109v for this system.

Behavior on open circuit.—If the specimen is potentiostated at a potential slightly negative of E_a, *e.g.*, at —0.111v, until a steady-state current is reached and

[1] 2.3 μA/cm^2.

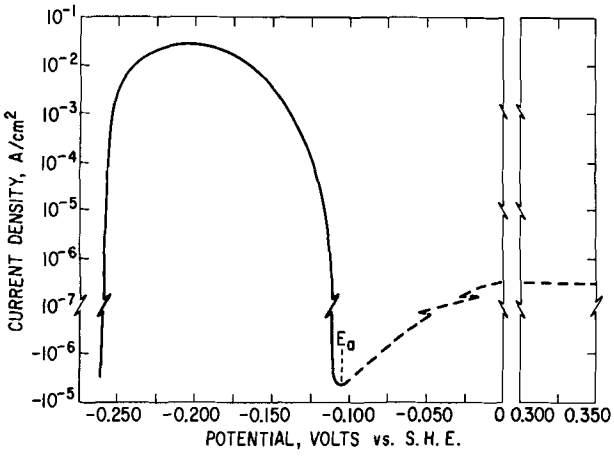

Fig. 2. Potential-current curve for Fe-24% Cr in 2N H_2SO_4. E_a is the primary activation potential. Solid line is region of reversibility; dashed line is region of irreversibility.

then the potentiostat is disconnected so that the specimen is on open circuit, the potential decays to the active state exhibiting a classic Flade potential (2, 9) at the potential at which the specimen had been potentiostated. However, if the specimen is held at a potential positive to E_a until a steady-state current is achieved and then is put on open circuit, the specimen will remain passive and the potential will slowly drift to a value between —0.05 and —0.08v. After passivation at E_a the potential will drift in neither direction on open circuit. At first it appeared that this may provide another definition of the activation potential; however, when these experiments were repeated in the solution purified by passing it over charcoal, the potential corresponding to no drift on open circuit shifted a few millivolts in the negative direction. However, the activation potential as determined by the minimum in the cathodic loop was unaffected by the purification.

Transient phenomena during passivation.—The anodic current-time (i-t) transient (Fig. 3) was obtained by subtracting the steady-state hydrogen-evolution current from the observed i-t curve after switching the potential from the corrosion potential to E_a. Due to iR-drops between the specimen surface and the tip of the Luggin capillary, the potential at the surface differed from E_a by more than 1 mv during the initial half second. At any time during the transient, the thickness Q (in mC/cm^2) of the film formed up to that time could be measured by cathodic reduction. Typical cathodic reduction curves (E-t plots) are shown in Fig. 4 for different times of passivation. The thickness-time (Q-t) transients calculated from the reduction curves are shown for three potentials in Fig. 5. None of the curves shown in Fig. 3-5 was affected by the charcoal

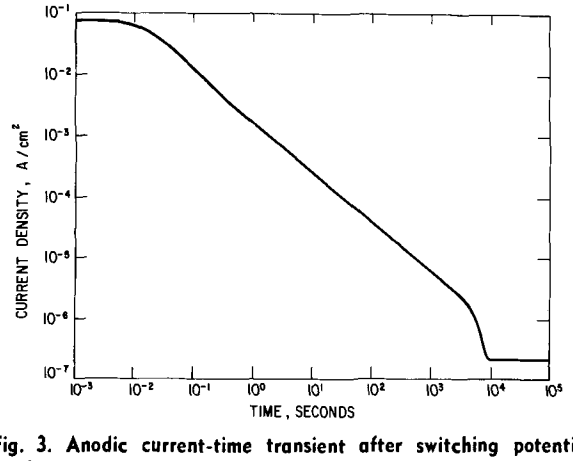

Fig. 3. Anodic current-time transient after switching potential from the corrosion potential to E_a.

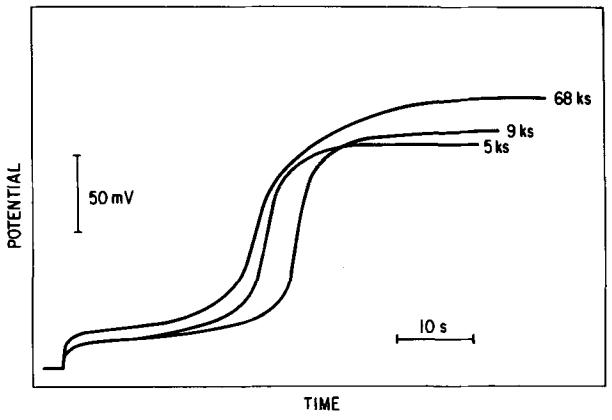

Fig. 4. Cathodic reduction potential-time curves after passivation at E_a for different periods of time. Time of passivation is given next to each curve.

purification procedure so it was generally omitted. A complete material balance between the quantity of metal going into solution and that going into the film was not made because the former quantity is 10^2 to 10^3 times greater than the latter quantity.

To determine whether perhaps more than one reducible film was formed at E_a, the cathodic reduction was allowed to proceed for a time equivalent to the passage of 54 mC/cm^2. No additional break in the E-t curve was observed, indicating that no other reducible species was present on the surface. In an experiment to determine whether all the film formed during the passivation process was being reduced, the potential was switched to E_a immediately after film reduction was completed, as evidenced by the E-t curve, and the i-t transient was recorded. There was essentially no difference between this i-t transient and that obtained after the normal cleaning procedure.

The film reduction potential, the initial potential on the first plateau at which the E-t curve is linear, was measured after passivating the specimen for 9000 sec at E_a as a function of the cathodic current density for reduction and a plot of these data is shown in Fig. 6. The extrapolation to $i = 0.00$ μa/cm^2 intersects the abscissa at —0.107v, or within 1 to 2 mv of E_a.

Discussion

Activation potential.—The previously determined value of the primary activation potential (1) has been confirmed in this study in which more careful potential control and measurements were accomplished. When the surface was carefully prepared, as described, E_a was always within the limits indicated, namely, —0.108 to —0.109v; deviations from this could always be traced to improper surface treatment. The reproducibility of this value over many experiments also indi-

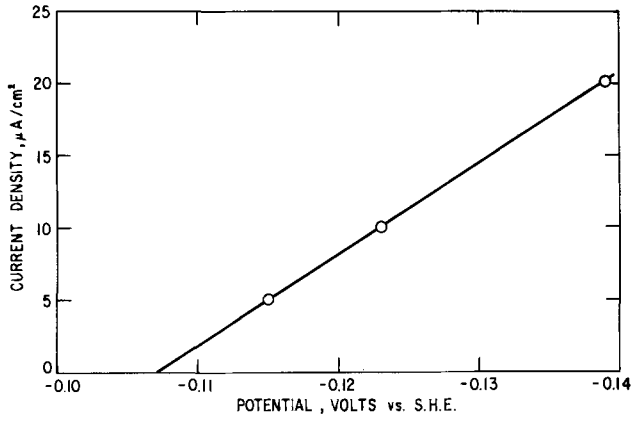

Fig. 6. Plot of film reduction potential against the current density for reduction, illustrating linear polarization kinetics.

cates that the surface composition of the specimen remained constant. To illustrate this point better, it may be pointed out that an Fe-19% Cr alloy has an activation potential of —0.036v in the same solution, a 72 mv difference for a 5% change in Cr content.

The results of the experiments in which the potential decay was followed on open circuit show that in this system the primary activation potential and the Flade potential are not the same. Furthermore, the variation of the Flade potential with purity of the solution indicates that this potential is a kinetic one and not a thermodynamically reversible potential, contrary to what is frequently stated, *e.g.*, ref. (3).

Validity of film thickness measurements.—Before the data can be interpreted, it is necessary to establish that the cathodic reduction procedure measures all the film present. If it is assumed that no film is present at the corrosion potential, then no reducible film other than that measured can be present at potentials between the corrosion potential and E_a because only one break is observed in the E-t curves even when the reduction was permitted to continue for long times. A film with a more negative reduction potential than the hydrogen evolution potential, *i.e.*, the final potential plateau after all film is reduced (Fig. 4), can also be discounted because the hydrogen evolution potential is approximately equal to the corrosion potential at the current densities used for reduction; also if the film were formed at a potential positive of the corrosion potential, but reduced at a more negative potential, we would not observe the reversibility reported, especially in the experiment in which the potential was switched to E_a immediately after film reduction and the i-t transient was observed to be the same as with a clean surface. This same experiment also eliminates the possibility of the formation of a nonreducible film.

A prepassive film, such as might be formed by a dissolution-precipitation mechanism as suggested by Bockris, Reddy, and Rao (10), also does not appear reasonable for this system for several reasons: (*i*) if the prepassive film is converted entirely into the passivating film, then the former must also be of monomolecular dimensions, which is most unlikely for a precipitate; (*ii*) if only part of it is converted, the remainder must either be reducible or nonreducible, possibilities which have been discussed above; (*iii*) after polarizing the specimen at —0.205v, a potential at which the prepassive film would exist, and then putting the specimen on open circuit, the corrosion potential is stabilized within ± 0.1 mv in 5 sec, hardly sufficient time for a film to dissolve and all concentration effects to disappear.

We cannot exclude the possibility that a film forms at potentials negative to the corrosion potential. If so, this film would be present at the corrosion potential prior to the transient experiments. However, it is of no importance because it does not appear to prevent anodic dissolution at potentials in the anodic loop. It

cannot be argued that this film may cover part of the surface and that the passivating film covers the rest because electron microscope examination of the surface shows that it etches uniformly in the region of anodic dissolution (1). Thus we must conclude that it is most unlikely that any film other than that measured is involved in the passivation process at E_a. We also believe that the only cathodic side reaction occurring during film reduction is hydrogen evolution, for which a correction has been made, and hence the remaining current goes solely for film reduction with 100% efficiency because (*i*) the *E-t* reduction curves are very sharp and (*ii*) a linear relationship between the reduction current and potential is observed (Fig. 6) and the extrapolation to zero current comes within 1 mv of E_a. It is highly unlikely that this linear relationship would be followed if side reactions were occurring (11). Self-activation has previously (1) been shown not to be a factor. This was again confirmed in this study when it was found that the film thickness is independent of the current density for cathodic reduction.

Steady-state film thickness.—The limiting film thickness at the primary activation potential is 0.36 ± 0.03 mC/cm² (Fig. 5). The time to achieve this thickness is the same as the time to reach the limiting passive current density (Fig. 3). The apparent decrease in film thickness at longer times at all potentials (Fig. 5) is not real but due to secondary film formation to be discussed below. The deviation of ± 0.03 mC/cm² represents the measured extremes and not the standard deviation, which is much less. We believe this deviation to be due primarily to poor potential control which was generally to within 0.2 to 0.3 mv, although as much as 0.5 mv was tolerated. As may be seen from the curves in Fig. 5, small deviations in potential can give rise to large differences in film thickness. The coulombic equivalent of a monolayer depends on the model chosen for the structure of that monolayer. Assuming the film to be composed primarily of Cr^{+++} and $O^{=}$ ions, reasonable limits for the thickness of a monolayer are 0.4 to 0.7 mC/cm². Inclusion of H_2O, $SO_4^{=}$, or HSO_4^{-} in the film would reduce these values slightly, again depending on configuration. If the passivating film is reduced to the metallic state, *i.e.*, $Cr^{+++} \rightarrow Cr^0$, the measured coulombic film thickness would represent about one monolayer. The reduction to the metallic state seems unlikely because the standard potential for this reaction is —0.74v (12). It is more reasonable to assume that the reduction product is chromous ion soluble in solution.[2] In that case the measured coulombic film thickness corresponding to a monolayer would be 0.13 to 0.23 mC/cm². From this we conclude that the measured limiting film thickness at E_a, 0.36 mC/cm², is equivalent to between 1 and 3 monolayers of film.

Since the reduction potential of the film is constant for thicknesses from 0.02 to 0.36 mC/cm², the structure and composition of the film must be the same throughout this thickness range from fractional to full coverage. Therefore, in the following section on transient behavior we will treat film formation at E_a as an adsorption process, realizing that at complete coverage the film may be thicker than one monolayer.

Transient behavior.—We assume that the limiting thickness of 0.36 mC/cm² represents complete coverage of the surface, *i.e.*, $\theta = 1$, where θ is the fraction of the surface covered. By combining the *i-t* curve from Fig. 3 with the *Q-t* curve from Fig. 5 and converting the coulombic thickness to fractional coverage, a plot of current *vs.* coverage is obtained (Fig. 7). It is seen that a very small coverage affords a high degree of protection. For example, for $\theta = 0.011$ the current is

[2] If the reduction product is chromous chromium, it must be soluble in solution because a corrosion product on the surface is inconsistent with the reproducibility of the *i-t* curve on rapid switching back to E_a after cathodic reduction, as well as for other reasons mentioned in the section on the validity of the film thickness measurements.

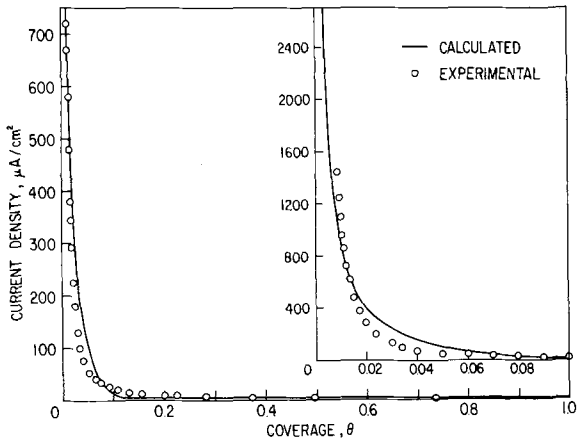

Fig. 7. Effect of surface coverage on the anodic current density at E_a, illustrating large drop in current density with initial coverage. ——— calculated from theory; o - experimental data. Insert is expanded plot of low coverage region.

reduced to 1% of its initial value of 85 ma/cm². This may be explained on an atomistic and kinetic basis.

Anodic dissolution occurs with different rates at different types of surface sites, *e.g.*, kinks, ledges, and terraces (*k*, *l*, and *t*) (13), the rate being governed by the activation energy for the anodic process at that type of site and by the potential, which is independent of the type of site. The current, *i*, may be expressed as the sum of the currents from the different types of sites

$$i = Af(E) \sum_j i_j \, (n_j, \Delta G_j^{\ddagger}) \qquad [1]$$

where $f(E)$ is an exponential function of the potential E, i_j is the current from the *j*th type of site which is a function of the number n_j of that type of site available for anodic dissolution and the activation free energy $\Delta G_j^{\ddagger}$ for anodic dissolution from that type of site, and A is a constant. The passivation process is the deactivation of these sites due to adsorption of, or chemical reaction[3] with, the passivating species; the extent of passivation of any one type of site relative to another type of site depends on the relative adsorption energies of the passivating species at these types of sites. Thus to calculate the variation of i with θ, we must first determine the variation of n_k, n_l, and n_t with θ. We will now treat these ideas quantitatively.

From Parsons (14) we can express the anodic current by

$$i = A \exp\left[-\frac{\Delta G^{\ddagger}}{RT} \right] \exp\left[\frac{(1-\beta) z\mathbf{F}}{\nu RT} E \right] \qquad [2]$$

where $\Delta G^{\ddagger}$ is the activation free energy for the dissolution process, β is the transfer coefficient, ν is the stoichiometric number, and R, T, z, and $\mathbf{F}$ have their usual significance.

Consider a surface atom in a terrace position to be in the standard state. An atom in a ledge position possesses greater free energy and an atom at a kink site still greater free energy, because they form fewer bonds with the substrate. Conversely, the order of the activation energies for dissolution $\Delta G^{\ddagger}$ is

$$\Delta G_k^{\ddagger} < \Delta G_l^{\ddagger} < \Delta G_t^{\ddagger}$$

since the activated state is the same for dissolution from all sites. Combining Eq. [1] and [2] we obtain

$$i = A \exp\left[\frac{(1-\beta) z\mathbf{F}}{\nu \, RT} E \right] \sum_j n_j \exp\left[-\frac{\Delta G_j^{\ddagger}}{RT} \right] \qquad [3]$$

The most prevalent sites on a surface are kink, ledge, and terrace positions. Since $\Delta G^{\ddagger}$ is expected to increase with increasing number of nearest and second-nearest

[3] In this treatment we assume chemisorption, although a completely analogous treatment would follow if we assumed chemical reaction. In that case reaction free energies would be substituted for adsorption free energies.

neighbors and since for each type of site these vary with the orientation of the surface (15), the number of terms in the summation will be larger than three. As an approximation, however, we will consider only one term for each k, l, and t.

Next we evaluate the variation of the n_j's with coverage, θ. Initially at $\theta = 0$, $n_j = n_j^o$ and we assume $n_t^o = 10^{15}/cm^2$, $n_l^o = 10^{14}/cm^2$, and $n_k^o = 10^{11}/cm^2$ (16). As θ increases, the ratio of $n_t : n_l : n_k$ will change due to the different adsorption energies of the passivating species at the different types of sites.[4] Since almost all the passivation occurs during the first few per cent surface coverage (Fig. 7), we can neglect interactions between adsorbed passivating species and assume that the Langmuir adsorption isotherm is obeyed for each type of site. We then define the activity of the passivating species adsorbed on a site of type j as

$$a_j = \frac{\theta_j}{1 - \theta_j} \qquad [4]$$

where θ_j is the fraction of j-sites covered, with the standard state, $a_j = 1$, being $\theta_j = \frac{1}{2}$. Assuming equilibrium between the adsorbed species regardless of the site, so that $\Delta G_k = \Delta G_l = \Delta G_t$ and remembering that

$$\Delta G_j = \Delta G_j^o + RT \ln a_j \qquad [5]$$

where ΔG_j and ΔG_j^o are the free energy of adsorption and standard free energy of adsorption, respectively, of the passivating species on the j-sites, we have

$$\frac{a_k}{a_l} = \exp\left[\frac{\Delta G_l^o - \Delta G_k^o}{RT}\right] \qquad [6a]$$

and

$$\frac{a_k}{a_t} = \exp\left[\frac{\Delta G_t^o - \Delta G_k^o}{RT}\right] \qquad [6b]$$

With

$$\theta = \frac{n_k^o\theta_k + n_l^o\theta_l + n_t^o\theta_t}{n_k^o + n_l^o + n_t^o} \qquad [7]$$

and using Eq. [3], [4], and [6], the i-θ relationship can be calculated if $\Delta G_j^\ddagger$ and ΔG_j^o are known, the constant A in Eq. [3] being evaluated from the measured current at time $t = 0$, when $\theta = 0$. It is not necessary to know the absolute values of the $\Delta G_j^\ddagger$'s but only the differences $(\Delta G_t^\ddagger - \Delta G_k^\ddagger)$ and $(\Delta G_l^\ddagger - \Delta G_k^\ddagger)$ since the value of $\Delta G_k^\ddagger$ can be subtracted from each $\Delta G_j^\ddagger$, taken outside the summation sign in Eq. [3] and included in the constant A. Neglecting changes in entropy which are small (13), the difference between $\Delta G_l^\ddagger$ and $\Delta G_k^\ddagger$ should to a first approximation be equal to the strength of a nearest neighbor bond, or about 12 kcal/mole. The actual difference will probably be lower because H_2O will adsorb more strongly at a kink site than at a ledge site, thereby lowering the free energy of initial state of a kink site more than that of the ledge site. Similarly the difference between $\Delta G_t^\ddagger$ and $\Delta G_l^\ddagger$ should also be less than the energy of a nearest-neighbor bond. For this reason both $(\Delta G_t^\ddagger - \Delta G_l^\ddagger)$ and $(\Delta G_l^\ddagger - \Delta G_k^\ddagger)$ were chosen equal to 9 kcal/mole, and $(\Delta G_t^\ddagger - \Delta G_k^\ddagger)$ then equals 18 kcal/mole. The differences $(\Delta G_l^o - \Delta G_k^o)$ and $(\Delta G_t^o - \Delta G_k^o)$ are more difficult to estimate. Fortunately, however, the results are not very sensitive to variations in these differences, and we arbitrarily chose $(\Delta G_l^o - \Delta G_k^o) = 4$ kcal/mole and $(\Delta G_t^o - \Delta G_k^o) = 8$ kcal/mole. Using the above values the i-θ relationship was calculated as indicated at E_a and compared to the experimentally determined relationship (Fig. 7). The agreement is considered very good.

For $\theta = 0.00$ the anodic current arising from dissolution at kink sites accounts for essentially all the current, *i.e.*, 85,000 $\mu a/cm^2$. The dissolution rate from ledge sites is only 25 $\mu a/cm^2$ and from terrace sites it is only 7.5×10^{-5} $\mu a/cm^2$ or for practical purposes nil. From this it is apparent that the values chosen for the parameters $(\Delta G_t^\ddagger - \Delta G_k^\ddagger)$ and $(\Delta G_t^o - \Delta G_k^o)$ are essentially of no consequence. These calculations were made for the potential E_a. However, even at $E = E_a + 0.2$v, the current from each type of site is increased by a factor of only 55 and the current from terrace sites is still essentially zero.

[4] The concept of preferential adsorption of impurities at active sites is not new (17, 18).

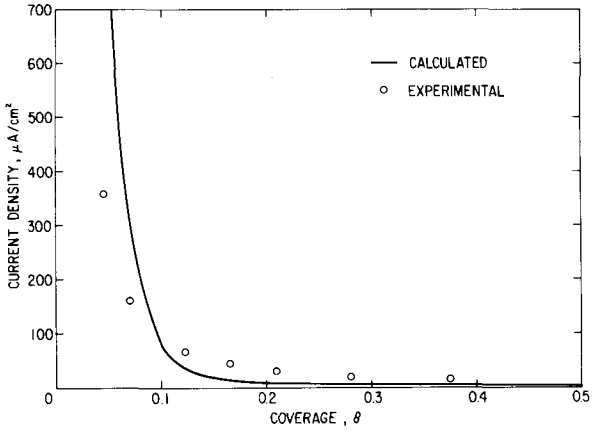

Fig. 8. Effect of surface coverage on the anodic current density at E_a + 100 mv. ——— calculated from theory; o - experimental data.

The effect of potential on the i-θ relationship arises through the factor $\exp\left[\frac{(1-\beta)\, z\mathbf{F}}{\nu RT} E\right]$ in Eq. [3]. Assuming $\beta = 0.5$ and $z/\nu = 1$, and keeping all other parameters constant, we have calculated the i-θ relationship at E_a + 100 mv. This relationship, as well as the experimental data at this potential, is shown in Fig. 8. The agreement between theory and experimental data is satisfactory. At potentials greater than E_a + 20 mv, this theory holds only up to coverages of about $\theta = 0.4$. At higher coverages secondary film formation occurs (19). At potentials above E_a + 200 mv there no longer is any agreement between the theory and the experimental data.

We realize that with the possibility of fixing four parameters $[(\Delta G_l^\ddagger - \Delta G_k^\ddagger), (\Delta G_t^\ddagger - \Delta G_k^\ddagger), (\Delta G_t^o - \Delta G_k^o)$, and $(\Delta G_l^o - \Delta G_k^o)]$, it is not too difficult to get a good fit. However, we have indicated above that the values chosen for two of these parameters are unimportant, and we point out that the same basic shape of the i-θ curve is obtained over a wide range of values of all these parameters. What is important is the basic shape, namely that the maximum decrease in the current occurs with very little coverage. This is a direct consequence of this theory in so far as it requires that almost all the current originates from a small fraction of the surface, the kinks, and that these same kinks are the sites for the initial and strongest adsorption. So while the exact values of the parameters may not be the best ones, the basic theory is in complete agreement with the experimental facts and the values chosen for the parameters have been justified.

Secondary film formation.—It was previously concluded (1) that secondary film formation only occurred at potentials greater than the activation potential. However, the more precise measurements made in the present study indicate that secondary film formation can occur at the primary activation potential and even at slightly lower potentials. This is evidenced by both the E-t curves for cathodic reduction (Fig. 4) and the Q-t curves for film growth (Fig. 5). In Fig. 4 it is observed that the film reduction potential is independent of the time of passivation up to 9000 sec, the time to achieve complete passivation. At longer times, however, the reduction potential increases and the apparent film thickness decreases (Fig. 4 and 5). This is due to the formation of the secondary film which cannot be completely reduced

(1, 19). These changes in reduction potential and film thickness are much more pronounced at higher potentials (19). At E_a the shift in the reduction potential is only about 4 mv at 65,000 sec, and the corresponding reduction in film thickness is about 0.05 mC/cm^2. While these changes are small, they are reproducible and always go together. This, together with the heightening of this effect at higher potentials, leads us to the conclusion that it is a real effect and due to secondary film formation. This will be discussed in more detail in a subsequent paper (19).

Conclusions

The primary activation potential for an Fe-24% Cr alloy in $2N$ H_2SO_4 has been determined to within ± 0.5 mv. It has been shown that the thickness of the passivating film in the potential neighborhood of E_a is very sensitive to small changes in the potential and that, therefore, very precise potential measurements and control are essential if meaningful kinetic measurements are to be made. The time dependence of both the anodic current and the film thickness has been measured, and a theory is proposed to account for the observed behavior. This theory considers different rates of anodic dissolution from kink, ledge, and terrace sites due to differences in the activation free energy associated with different numbers of nearest neighbors; these sites are also passivated to different extents due to different energies of adsorption. The steady-state film thickness of 0.36 mC/cm^2 at the primary activation potential corresponds to between one and three monolayers of film depending on the assumed model and the reduction product. Finally it is shown that secondary film formation occurs at E_a at long times.

Acknowledgments

The author wishes to thank Mrs. A. C. Broz for skillfully performing many of the experiments and Dr. S. Barnartt and Dr. R. A. Oriani for many helpful discussions.

Manuscript submitted Nov. 21, 1968; revised manuscript received ca. Feb. 6, 1969. This paper was presented at the Montreal Meeting, Oct. 6-11, 1968, as Paper 418.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

A Capacitive Divider Technique for Fast Interface Capacitance Measurement

D. E. Aspnes

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A fast method of measuring interface capacitance in electrolyte-semiconductor systems is presented and discussed. The interface capacitance is determined from the voltage response of the interface to a driving voltage applied across the interface and a small series capacitor which form a capacitive voltage divider. In particular, the differential capacitance, related to the derivative of the constant-current charging curve, is obtained directly if a pulse or square-wave driving voltage is used. A further advantage is that capacitance can be determined in shorter time intervals than required by previous methods. Experimental results which demonstrate the method are given for the intrinsic Ge-aqueous electrolyte system, and it is also shown that semiconductor surface fields can be determined in the presence of rapid modulations. Applications to electroreflectance are discussed.

Rapid measurement of the capacitance of semiconductor-electrolyte interfaces has yielded much useful information about processes which occur in both the space charge region of the semiconductor and in the response of slow and fast surface states on the semiconductor (1-6). The recent development of electroreflectance (7-8), in which the optical properties of a semiconducting crystal are modulated by a periodic, rapidly varying electric field in the space charge region (SCR), has placed new demands on capacitance measurement as a means for determining the surface field for the semiconductor in that capacitance measurements must now be performed in the presence of perturbations of the order of volts, repeating at kHz rates, if detailed information about the field variation during a modulation cycle is to be obtained. Various fast capacitance measuring methods have been developed. The first of these (9, 1, 2) utilized square wave current pulses which resulted in a linear charging curve to the extent that the interface could be represented as a constant capacitance. The constant current pulse technique has since been adapted to potentiostatic control (4), and voltage pulses have also been used successfully (5). The use of continuous sinus-

oidal potentials (10) or currents (11) is well-known. These methods are all adequate for capacitance measurement when the interface potential is changing relatively slowly in time (less than 1000 v/sec), but fail under the usual conditions of electroreflectance. In order to meet electroreflectance requirements, a simple method has been developed which permits the direct measurement of differential capacitance at frequencies in the megacycle range, appreciably higher than previously possible. It is easily adapted to either potentiostatic or galvanostatic control of the interface potential. In addition, the short-term time dependence of the interface differential capacitance can be obtained directly, in contrast to other methods which give an averaged value over a measurement cycle. The method and theory are discussed and followed by an application to the particular case of an intrinsic Ge-aqueous electrolyte interface.

Method and Theory

Measurement principle.—Interface capacitance can be obtained by constructing a capacitative voltage divider with the interface capacitance as one branch, as illustrated in Fig. 1. A typical electrolytic cell configuration is shown, with the control circuit at top center. The new features are shown at the left, and consist of a pulse or fast-rise square wave generator $V_i(t)$ driving a small injection capacitor C_i. The principle of the method is straightforward. Let the effective capacitance which describes the interface be denoted as C. Then the injection capacitor C_i and C form a capacitive voltage divider, and if $C_i << C$, a change ΔV_i in $V_i(t)$ injects a charge $\Delta Q \cong C_i \Delta V_i$ into C causing a voltage change $\Delta V_p \cong \Delta Q/C$ to appear at the probe. Therefore

$$C \cong C_i \frac{\Delta V_i}{\Delta V_p} \qquad [1]$$

Although any waveform $V_i(t)$ may be used, a pulse or square-wave time dependent source has particular advantages which will be discussed later. These follow from the fact that the total interface charge remains constant except when $V_i(t)$ is changing levels, at which time charge is injected into the interface [C_i is a high-pass filter element which differentiates $V_i(t)$]. The terminology "charge injection" refers to the capacitive divider technique when such sources are used. Before proceeding with a more detailed analysis, we note that the charge injection technique is closely related to the coulostatic method introduced and developed by Delahay (12), with the difference that the charge is injected into the interface as a result of a rapid potential change across the capacitive divider rather than by discharging a capacitor into the interface. In the limit of long pulse durations, charge injection and the coulostatic method are basically identical. Charge injection is also directly related to constant-current pulse methods (2, 4, 9), since in the linear approximation, the probe response is the derivative of the constant current charging curve, as will be shown.

Detailed treatment.—Having outlined the method, we now analyze it in detail with the objective of relating the probe output $V_p(t)$ to the interface parameters. For the purpose of obtaining interface capacitance, short pulse duration (<10 μsec) or high-frequency square-wave operation (>100 kHz) is preferred, hence we consider only the high-frequency behavior of Fig. 1. The approximate high-frequency equivalent circuit of Fig. 1 is given in Fig. 2. The source $V_i(t)$ is represented with an effective output impedance R_i. The injection capacitor C_i charges the interface effective capacitance C through the electrolyte and sample resistances R_e and R_s. The interface leakage is described by a conductance G, and the control circuit is represented by its high-frequency equivalent impedance Z_c.

The circuit of Fig. 2 can be simplified since the impedance levels of the various elements in general differ appreciably. With proper line termination, R_i will be one-half the generator output resistance, corresponding to the parallel combination of the generator output resistance and the equal line termination resistance (typically, $R_i = 25$ ohms). Either potentiostatic or galvanostatic control may be used, provided Z_c is sufficiently large (or well-determined) at high frequencies. Z_c is always large with galvanostatic control, and can be made large at high frequencies with potentiostatic control by inserting a large resistance R_o in series with the amplifier output (as indicated in Fig. 1) and reducing the response time τ_a of the control amplifier sufficiently, whence from simple circuit theory

$$Z_c \cong \frac{R_o}{1 + i\dfrac{g_o}{\omega_{\min}\tau_a}}, \quad \omega_{\min}\tau_a >> 1 \qquad [2]$$

where $\omega_{\min}$ is the lowest frequency component of $V_i(t)$ and the gain of the control amplifier is

$$g(\omega) = g_o/(1 + i\omega\tau_a)$$

Therefore, Z_c is neglected throughout. The cell resistance R_e and the bulk sample resistance R_s can usually be made of the order of ohms. R_s may include

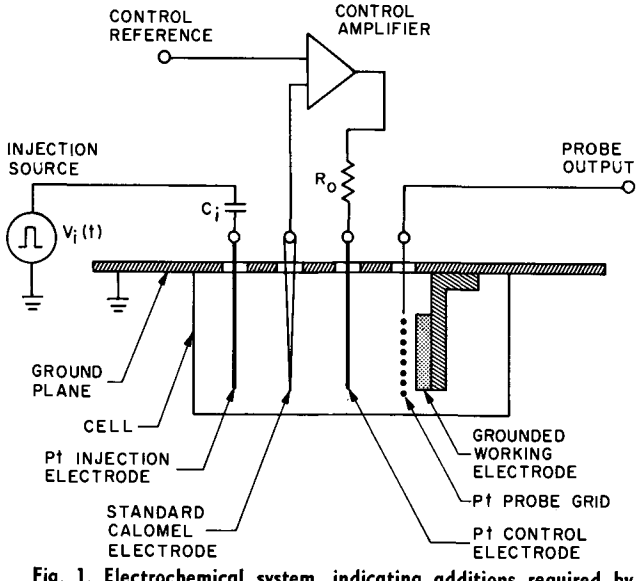

Fig. 1. Electrochemical system, indicating additions required by the capacitive divider technique at left. C_i is the injection capacitor, driven by the source $V_i(t)$. The working electrode is insulated to contact the electrolyte only in the region desired.

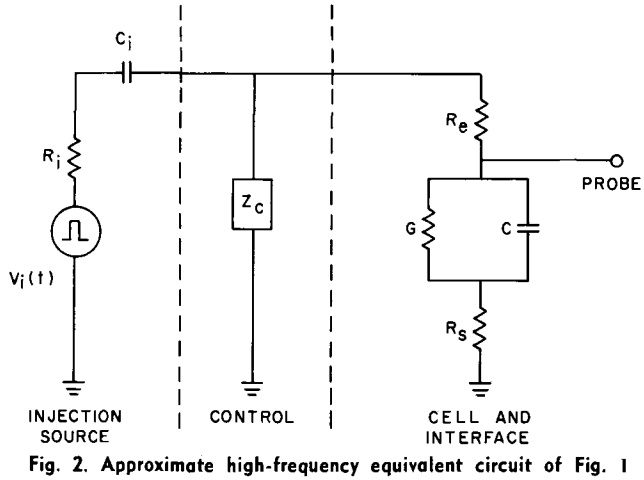

Fig. 2. Approximate high-frequency equivalent circuit of Fig. 1 for calculating the probe response. R_e = electrolyte resistance, R_s = sample resistance, Z_c = control circuit effective impedance; G and C describe the interface and space charge region admittance.

part of the electrolyte resistance, since the probe cannot be located arbitrarily close to the interface.

The interface admittance, represented in Fig. 2 as the parallel combination G and C, is quite difficult to treat in detail, depending on the constituents of the interface as well as on interface biasing conditions, history, and time. Although the following discussion applies in general to any interface, we will discuss explicitly only the semiconductor-electrolyte interface since the objective is to apply the results to these systems. Numerous complicated equivalent circuits have been proposed to describe the admittance of the semiconductor-electrolyte interface (1, 13). However, the problem is simplified considerably for frequencies in the megacycle range, since the most rapid dispersion in C generally occurs at appreciably lower or much higher frequencies, and the leakage conductance G becomes relatively less important. If the charge leakage through G is small, *i.e.*, if $G/C << \omega_{min}$, G is effectively zero and can be neglected. This relation is satisfied in usual capacitance measuring conditions, except when rapid electrochemical reactions occur at the interface. G can be measured independently, since it is approximately the slope of the low-frequency I-V characteristic (1).

The capacitance C is nearly equal to C_{scr}, the capacitance of the semiconductor space charge region (SCR). The Helmholtz capacitance C_h between the semiconductor and electrolyte and the Gouy capacitance C_g of the electrolyte space charge region are in series with C_{scr} so that

$$\frac{1}{C} = \frac{1}{C_{scr}} + \frac{1}{C_h} + \frac{1}{C_g} \qquad [3]$$

but since $C_h \sim 10$ to $20\ \mu f/cm^2$ is typically an order of magnitude larger than C_{scr}, and C_g for aqueous solutions of the order of 0.1M concentration is several times larger than C_h, it follows that $C \cong C_{scr}$. C_{scr} is frequently dependent, and also depends on the SCR potential unless $|\Delta V_{scr}(t)| << kT$, which is easily achieved experimentally. For intrinsic semiconductors, dispersion in C_{scr} occurs when the frequency becomes comparable to the reciprocal of the space charge relaxation time, $\tau_r \sim \epsilon/\sigma$ (14). At lower frequencies C_{scr} is equal to its equilibrium (15, 16) value. If a well-defined minority carrier is present, low-frequency dispersion results from the diffusion of the minority carrier between SCR and bulk, which has a relaxation time $\tau' = L_d^2/D_{min}$, where L_D is the minority carrier diffusion length and D_{min} is the minority carrier diffusion coefficient. If $\tau' >> 1/\omega_{min}$ the capacitance is approximately dispersion-free and may be obtained by dropping the minority carrier contribution to the equilibrium expression, provided an appreciable inversion region is not present (17, 18). Detailed treatments of dispersion in C_{scr} can be found in the literature (17, 18). It is sufficient to point out here that $C \cong C_{scr}$ can be related to SCR parameters such as surface field over a wide range of bulk properties, with the relation determined by the bulk properties. Fast surface states cause complications, but in many cases are not present and in any event can be detected since they produce an additional capacitance which tends to be much larger than the theoretical minimum capacitance of the SCR (17).

Neglecting Z_c and G, the time-dependent probe response $\Delta V_p(t) \cong \Delta V_{scr}(t)$ to a step change in driving potential $V_i(t) = V_o + \Delta V_i u(t)$, where $u(t)$ is the unit step function, is

$$\Delta V_p(t) = \Delta V_i \left\{ \frac{C_i}{C_i + C} + \left[\frac{R_s}{R_s + R_e + R_i} - \frac{C_i}{C_i + C} \right] e^{-t/\tau_c} \right\} \cong \Delta V_i \left\{ \frac{C_i}{C_{scr}} + \frac{R_s}{R_s + R_e + R_i} e^{-t/\tau_c} \right\} \qquad [4]$$

where $\tau_c = [(C_i C)/(C_i + C)](R_s + R_e + R_i)$ describes the decay of the charging transient not included in Eq. [1]. If G is not negligibly small, charge leaks from C_{scr}. This decay can be approximately represented by multiplying the right-hand side of Eq. [4] by $\exp(-Gt/C_{scr})$, where the decay time constant is $\tau_d = C_{scr}/G$.

An actual response $V_p(t)$ is shown in Fig. 3. This signal was obtained from an intrinsic Ge crystal in an aqueous electrolyte, biased near the flat band condition, and represents the response to one cycle of a 1.0 MHz square wave driving voltage $V_i(t)$ of peak-to-peak amplitude 2.6v. Further details of the cell, crystal, and electrolyte are given later. The circuit parameters are $C_i = 100$ pf, $R_i = 25$ ohms, $R_s \cong 5$ ohms, and $R_e \cong 20$ ohms. The small amount of decay following the initial transient in each half of the cycle indicates that G is small and C is independent of time, both to a good approximation. The space charge capacitance C_{scr} can be calculated by measuring ΔV_p as the voltage difference between the baseline defined by the value of $V_p(t)$ at the moment of level change in $V_i(t)$, at $t = 0$ and $t = 500$ nsec in Fig. 3, and the extrapolation of the flat portion of the response past the transient back to the time of level change. We find $\Delta V_p \cong 13$ mv, whence by Eq. [1], $C_{scr} = 0.020\ \mu fd/cm^2$ at this bias condition for the Ge crystal of 1.0 cm^2 apparent surface area [the theoretical minimum value of C_{scr} for intrinsic Ge at 295°K is

$$C_{min} = e\sqrt{\frac{2\epsilon n_i}{kT}} \cong 0.017\ \mu f/cm^2$$

using $n_i = 1.7 \times 10^{13}\ cm^{-3}$ at 295°K (19)]. By Eq. [4], the initial transient should become negligible after a time

$$t_o \cong \tau_c \ln \frac{R_s \cdot C_{scr}}{(R_s + R_e + R_i)C_i} \qquad [5]$$

determined by requiring the time-dependent term to be smaller than the constant term. Using the values relevant to Fig. 3, we have $\tau_c \cong 5$ nsec and $t_o \cong 15$

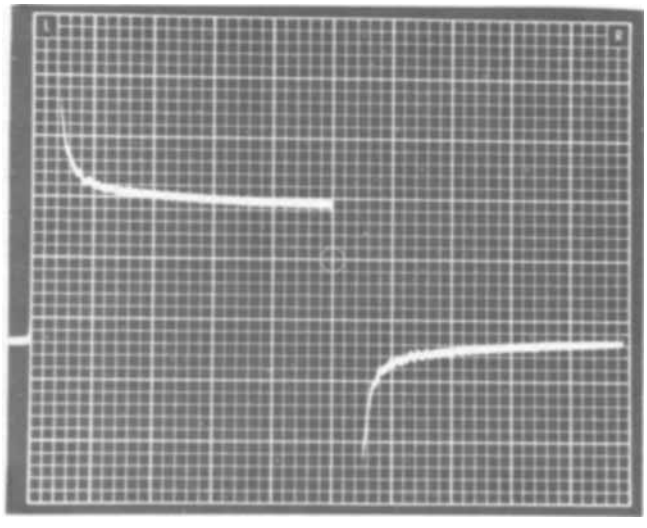

Fig. 3. Probe response to a 2.6 vpp square wave at 1 MHz for intrinsic Ge, biased to approximately the flat-band condition. The horizontal scale represents 100 nsec per large division; the vertical scale 5 mv per large division. The injection capacitor $C_i = 100$ pf.

nsec. C_{scr} can therefore be measured in principle by using a 30 MHz (approximate reciprocal of $2t_o$) repetitive square wave $V_i(t)$, and the magnitude of the response implies measurement capability in the presence of interface voltage changes of the order of 5 mv/50 nsec, or 10^5 v/sec. The actual limit of 100 nsec in Fig. 3 is a result of the measuring instrument recovery time from the initial transient overload, and is appreciably longer than the calculated value (a Tektronix 547 oscilloscope with Type 1A1 preamplifier was used to obtain the experimental results in this paper).

In the linear response limit, where $|\Delta V_{scr}| \cong |\Delta V_p| << kT$, a close connection exists between charge injection and constant current pulse methods of capacitance determination. In this approximation, the space charge response equations can be linearized (17, 18) and the complex admittance $Y(\omega) = G(\omega) + i\omega C(\omega)$ in Fig. 2, including dispersion effects and conductance, can be written as a transfer function $Y(\omega) = 1/Z(\omega)$. After initial transients have dissipated, *i.e.*, by the time that the dependence of the probe output is determined completely by $Y(\omega)$, the time-dependent probe response $\Delta V_p(t)$ can be obtained directly from the input current $I_i(t)$ produced by the source $V_i(t)$ through Fourier analysis

$$\Delta V_p(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} d\omega\ e^{i\omega t} Z(\omega) \left[\int_{-\infty}^{\infty} dt'\, e^{-i\omega t'} I_i(t') \right] \quad [6]$$

It follows immediately from Eq. [6] that if two time-dependent current sources $I_{i1}(t)$ and $I_{i2}(t)$ bear a derivative relationship to each other such that $I_{i2}(t) = d/dt\ I_{i1}(t)$, then their responses also satisfy the same relationship

$$\Delta V_{p2}(t) = \frac{d}{dt}\Delta V_{p1}(t) \quad [7]$$

Now the approximate current waveform for charge injection, $I_2(t) \cong I_{20}\delta(t)$, is just the derivative of that of a constant-current pulse, $I_1(t) \cong I_{10}u(t)$, to within a constant. Therefore, the respective probe responses relate as in Eq. [7], and the response to the charge injection pulse is proportional to the derivative of the constant current charging curve. This result follows even if G is not negligibly small or C is dispersive. If G is negligibly small, the derivative of the constant current charging curve gives the inverse of the instantaneous differential capacitance. The charge injection response gives this inverse directly, differentiation is not required, and in addition the average capacitance obtained by the total change of V_{scr} for a finite constant current pulse (2, 9), or by sinusoidal methods, is avoided.

We conclude this section by noting that even though charge injection and constant-current methods are closely related, it is generally advantageous to use the former. To the extent that conductance and dispersion are negligible, $V_p(t)$ is the image of $V_i(t)$ for charge injection. Shape-distorting effects such as dispersion and finite interface conductivity are much more easily detected in the nominally square wave image $V_p(t)$ than in its integral, the nominally linearly increasing potential of the constant-current response, where distortions only result in deviations from linearity. The change ΔV_p for determining C_{scr} can be established in a shorter time interval than necessary for obtaining the slope of the constant-current charging curve. In single-pulse operation, charge injected on the leading edge is extracted on the falling edge leaving the system unchanged; constant-current methods require two pulses of opposite polarity to accomplish this. It should be pointed out, however, that the derivative relationship between the charge injection and constant current methods fails for $|\Delta V_{scr}| > kT$, in which case the nonlinearities in the system must be explicitly taken into account in calculating the charging curve, and no simple relation between the two methods exists (20). Also, the separation of dispersion in C from discharging through G cannot be done by either pulse method, but requires both amplitude and phase determination which only sinusoidal methods can give. The lack of a suitable phase-sensitive detector for the megacycle region has restricted the use of sinusoidal methods to much lower frequencies.

Experimental Results and Discussion

The method is illustrated by application to a particular case, the measurement of the space charge capacitance of the (111) face of an intrinsic Ge sample, having an apparent surface area of 1.0 cm^2, in a 0.1M aqueous solution of K_2SO_4 (2) buffered with 0.025M KH_2PO_4 and 0.025M Na_2HPO_4 to a pH of 6.86 (21). The sample was prepared by an optical polish ending with ¼μ diamond grit, followed by an anodic etch in solution. The sample and mount were masked with Apiezon black wax. To eliminate impurities which would react with the surface, particularly heavy metals, the electrolyte was previously gettered with Ge crushed in solution. Both potentiostatic and galvanostatic control were used, and the high-frequency output impedance of these control sources was at least $R_o = 20$ kohms. The effective impedance in series with the injection capacitor C_i was $R_i = 25$ ohms, and $C_i = 100$ pf. A Pyrex cell, Pt electrodes, and a standard calomel electrode (SCE) isolated through a capillary tube and stopcock (200 kohms impedance) completed the electrolytic system. The SCE drove an Analog Devices Model 148A operational amplifier having an input impedance of 10^{11} ohms shunted by 3.5 pf. Potentiostatic control was obtained through a second such amplifier, provided with a feedback loop which limited its response time to 2 msec. The probe response shown in Fig. 3 was obtained using this system.

The capacitance of the interface as a function of bias is presented in Fig. 4, in order to test the capacitive divider method against well-known results (2, 22). Figure 4 shows the probe a-c response to an applied square wave of 2.78 vpp at 1.0 MHz, where the interface potential is swept potentiostatically at 100 mv/sec from anodic bias toward cathodic bias, as indicated in the figure caption. The sweep generates two curves which are simply 10^7 repetitions of the square wave response shown in Fig. 3, but each cycle highly compressed and at slightly different bias conditions given by the abscissa voltage. C_{scr} as a function of bias is then obtained by using Eq. [1], where ΔV_p is the separation between the inner edges of the upper and lower curves. This separation is inversely proportional to C_{scr}, and with the 1.0 MHz square wave driving voltage, yields directly the differential capacitance 500 nsec after the charging pulse as discussed earlier. The two curves of Fig. 4 approximately form the outline of the oscilloscope pattern which one would obtain from a constant-current pulse charging technique, as a comparison with Fig. 2 of ref. (2) shows immediately, except that the constant-current technique gives the average capacitance over the pulse duration.

The capacitance determined from Fig. 4 is plotted in Fig. 5, together with the theoretical equilibrium curve (15, 16) which applies to the intrinsic sample. The theoretical minimum capacitance value $C_{min} = 0.0173$ $\mu f/cm^2$ fits the measured minimum exactly, so only an alignment along the abscissa was required. We note, however, that all quantities used in calculating C_{min} are sufficiently uncertain so that no particular meaning should be attached to this minimum fit; a surface roughness factor of 20-30% is typically obtained (2).

The fit is fairly good, but a deviation is observed on the cathodic side where the slope of the plot is about 70 mv, instead of the theoretical 2 $kT \cong 52$ mv. This deviation is consistently observed in other mea-

surements, and is due to the potential drop across the Helmholtz region (2, 22). The deviation also becomes severe for large anodic bais, where Ge passes into solution at the expense of holes from the SCR and the effective leakage conductance G is no longer negligible (23). The fit between theory and experiment in Fig. 5 is comparable to that obtained in other methods (2, 22) and demonstrates the validity of the charge injection method for determining space charge capacitance.

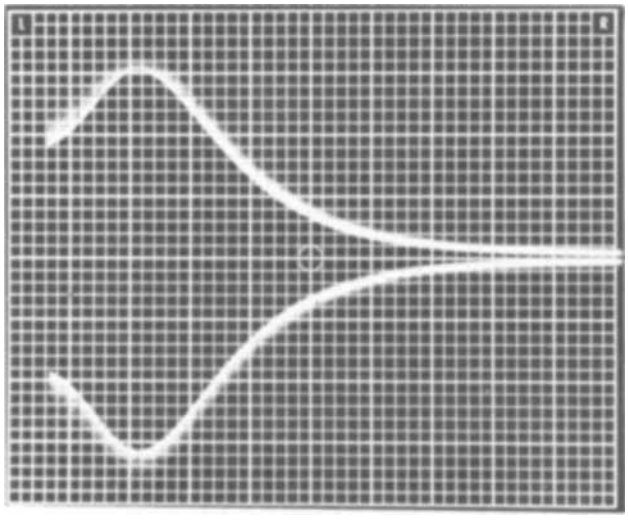

Fig. 4. A-C response of the probe to a 2.78v p-p square voltage wave at 1.0 MHz for the intrinsic Ge sample used in Fig. 3. The interface potential is swept at 100 mv/sec, anodic (left) toward cathodic. The vertical scale is 2.5 mv/large division; the horizontal scale 50 mv/large division. The horizontal scale gives the potential of the Ge electrode with respect to the reference electrode; the left edge corresponds to —100 mv, the right edge, —600 mv. The zero-current (quiescent) potential is —630 mv. The entire curve is taken with the sample biased anodically.

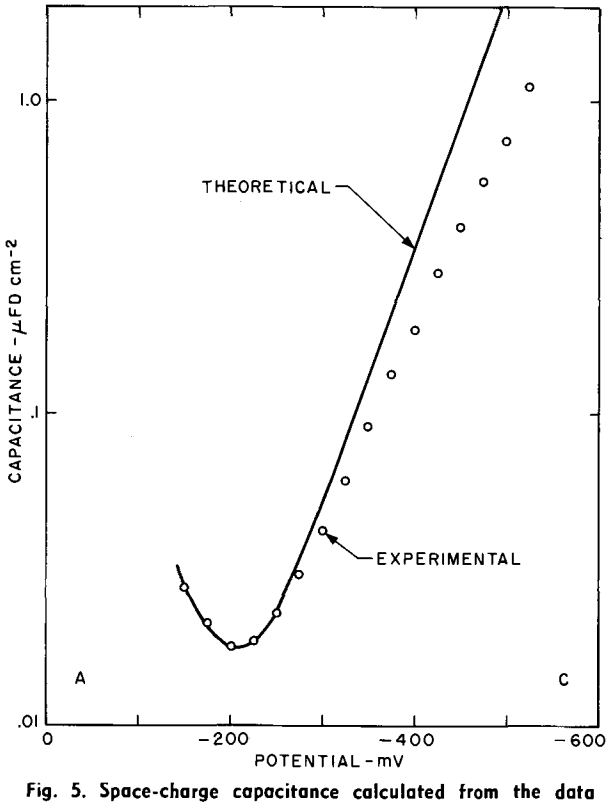

Fig. 5. Space-charge capacitance calculated from the data of Fig. 4, plotted against the theoretical curve for intrinsic Ge. The theoretical curve was normalized for coincidence at the capacitance minimum. The horizontal axis is the potential of the Ge electrode with respect to the reference electrode.

In order to obtain a flat baseline in Fig. 4, the probe output was filtered by a simple L-section high pass RC circuit inserted between the probe and the oscilloscope, with elements $R_f = 100$ kohm and $C_f = 0.01$ μf, having a low-frequency cutoff $\tau_f = R_f C_f = 1$ msec. The low-frequency cutoff was chosen sufficiently long so that the charge

$$\Delta Q_f \cong \frac{\Delta V_i R_s}{R_s + R_c + R_p} \cdot \frac{\tau_c}{R_f} \qquad [8]$$

accumulated on C_f during the initial transient resulted in a voltage change

$$\Delta V_f = \frac{\Delta Q_f}{C_f} \cong \Delta V_i \frac{R_s}{R_s + R_c + R_p} \cdot \frac{\tau_c}{\tau_f} \qquad [9]$$

such that $|\Delta V_f| << |\Delta V_p|$. The sign of ΔV_f is opposite that of ΔV_p and can also occur if a potentiostatic control amplifier is isolated inductively.

We now consider an application to an actual situation arising in electroreflectance, where a relatively large perturbation repeats at high frequency, and it is necessary to determine the surface field as a function of time during a cycle of the perturbation. A 1.0 kHz current square wave was used to drive the intrinsic Ge sample at anodically directed current levels of 90 and 330 μa/cm^2, respectively, for this measurement. Figure 6 shows the resulting probe response, without the high-pass filter used for Fig. 4. The left half of the trace corresponds to $I = 330$ μa/cm^2, and the right half to $I = 90$ μa/cm^2 (flat band). The response of the interface to the 1.0 kHz perturbation alone would be the average of the upper and lower curves. The upper and lower curves correspond to the two curves of Fig. 4, except for being superimposed on the interface response to the 1 kHz current drive. The capacitive divider drive $V_i(t)$ was a 1.0 MHz square wave of amplitude 3.1 vpp. C_{scr} is obtained by measuring the separation of the upper and lower curves of Fig. 6 and using Eq. [1].

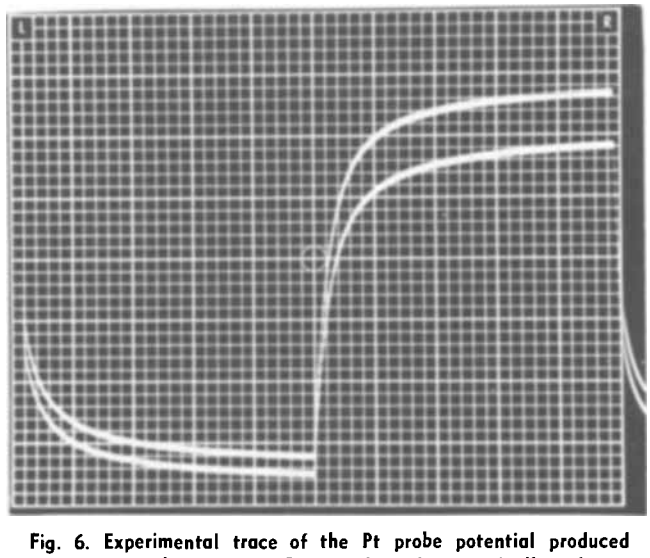

Fig. 6. Experimental trace of the Pt probe potential produced by modulating the intrinsic Ge sample galvanostatically using a 1 kHz current square wave at anodic levels of 90 μa/cm^2 (right half, flat band) and 330 μa/cm^2 (left half). The horizontal time scale of 100 μsec/large division covers one modulation cycle. The vertical scale is the d-c coupled Pt probe voltage at 20 mv/large division, with respect to the grounded Ge electrode. The lower edge is equivalent to +80 mv, the upper edge +240 mv.

Figure 7 shows the calculated surface field E_s as a function of time over one period of the 1 kc current modulation, obtained from point-by-point measurements of expanded portions of the trace of Fig. 6, assuming the intrinsic relation between C_{scr} and E_s applies (15, 16) and that the maximum value of the separation of the upper and lower curves, which occurs over the right half of Fig. 6, corresponds to the flat-band condition where $E_s = 0$ (the sweep was expanded using the Tektronix oscilloscope in the "B intensified by A" time base mode; a type W differential preamplifier was used for this measurement). The last assumption is probably not completely correct, and the true flat band position should be determined experimentally by more sensitive techniques such as photovoltage (15, 24) or electroreflectance (25) response. Notwithstanding this possible uncertainty, Fig. 6 and 7 demonstrate that the surface field as a function of time in the presence of rapid modulations can be obtained relatively easily by charge injection.

The ability to measure the surface field during a rapid modulation cycle has a direct application to electroreflectance, where a comparison of theory and experiment requires the knowledge of the electric field variation over a modulation cycle. Conversely, the capacitance divider or charge injection technique can be used to determine the proper control waveform to obtain the ideal field-on field-off time variation, which would allow a direct comparison of experimental electroreflectance results with theory (26). The simple experimental requirements are compatible with existing electroreflectance technology, which is important for the continuous monitoring of surface field and detection of drifts due to electrochemical reactions during actual measurement. The determination of the true field time dependence in electroreflectance has been almost without exception neglected and as a result serious doubt can be raised about conclusions drawn from the detailed shape of electroreflectance spectra (27). Experiments for more accurately measuring electroreflectance are in progress.

Conclusion

A capacitive divider technique of measuring interface capacitance in electrolytic cells is presented and discussed. A small capacitance in series with the interface acts as a differentiator of pulse or square wave driving voltages and in effect injects charge into the interface during level changes of the driving voltage. The resultant potential response is easily interpreted to give the interface capacitance. The method is analyzed with respect to the semiconductor-electrolyte system and its relation to other capacitance measuring techniques outlined. In particular, it is demonstrated that charge injection produces directly the derivative of the constant-current charging curve in the linear response limit, from which the differential capacitance is obtained. Being faster than other methods, it permits the experimental determination of space charge capacitance in the presence of rapidly changing interface potentials, which is demonstrated by an experimental application to intrinsic Ge. The applications to electroreflectance measurements are discussed.

Gas Content of Gold Foils Deposited from Polymer-Saturated Electroplating Solutions

H. Graham Silver[1]

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania

ABSTRACT

A study of the reactions of the cyanide ion at the anode of a potassium gold cyanide electroplating solution containing free potassium cyanide has revealed that a brown polymeric material is generated there which not only discolors, but also codeposits with the gold electrodeposit. This polymer is responsible for the gaseous impurities evolved from the gold deposit on subsequent heating. However, electroplating solutions, formulated without the addition of free potassium cyanide, produce gold deposits containing only low levels of gaseous impurities.

In a recent publication (1), an evaluation of the chemical behavior of typical cyanide electroplating solution components was described. Quantitative evidence was obtained to show that potassium cyanide solutions, or gold electroplating solutions containing free potassium cyanide, are unstable to water and air, the major reaction products formed being the formate and carbonate ions.

Studies of the effect of electrolysis on aqueous KCN solutions have already been performed (2-4). In the most recent of these (4), the authors reported that the passage of current through the aqueous KCN solution, using Pt electrodes, resulted in the formation at the anode of $(HCN)_x$, which precipitates in high concentration. Polymer formation was inhibited in more strongly alkaline KCN solutions.

This work was repeated and experimentally fully confirmed. In addition, it was found that the production of the brown polymer was independent of the anode material chosen and was most readily observable when oxygen was copiously evolved. Activated carbon treatment readily removed the brown polymer from hot aqueous KCN solutions.

Polymerization of HCN can also occur if the pH of the alkaline KCN solution is less than about 10, particularly in the presence of the NH_4^+ ion (5).

Infrared absorption and dipole moment measurements (6-8), chemical (9) and x-ray diffraction (10, 11) studies of the HCN polymer in the solid state have established that it is a tetramer, existing as diaminomaleonitrile

$$\begin{array}{l} H_2N—C—CN \\ \quad\quad\| \\ H_2N—C—CN \end{array}$$

It is generally accepted that organic compounds, intentionally added to or unintentionally generated by a gold electroplating solution, have an important effect on the physical characteristics of the gold electrodeposit (12, 13), although most of the data available is of a qualitative nature. In order to determine whether the presence of this brown polymer $[HCN]_4$ in gold electroplating solutions is potentially deleterious, an observation was made of the effect of the polymer, artificially generated within the electroplating solution, on the color and gas content of gold foils obtained from that solution.

Experimental

A $KCN/KAu(CN)_2$ electroplating solution of formulation

(68% min. Au)	$KAu(CN)_2$	9 g/l	± 0.1 g/l
	KCN	45 g/l	
	KOH	3 g/l	
	pH	13	

and a conventional dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution of formulation (14)

(68% min. Au)	$KAu(CN)_2$	20 g/l	± 0.1 g/l
dibasic ammonium citrate		50 g/l	
	pH	5.5	

were prepared, without boiling, in deionized water. Using a stainless steel plate cathode[2] of total surface area 8 in.^{2}, placed between flat gold anodes of total surface area 50 in.^{2}, a gold foil was plated from each solution at a current density of 20 ± 5 ma/in.^{2} for 45 min after a "flash" of 1 amp for 1 min to facilitate the initial plate. The temperature of the solutions was maintained at 65° ± 3°C. To both solutions was added a total of 5, 15, 25, 50, 75, and 100 ± 0.1 g/l formate ($H{\cdot}COO^-$) ion in the form of ammonium formate.

[1] Present address: General Telephone & Electronics Laboratories Incorporated, Bayside, New York 11360.

Key words: Electrodeposition, gold electroplating, polymeric impurity, gas content.

[2] All stainless steel plates, used for this purpose in this experiment, were degreased in the vapor of boiling trichloroethylene for 5 min, immersed in acetone for 15 min, acid-cleaned in hot 1:1 HCl for 1 min, and finally rinsed in deionized water.

After each addition of the ammonium formate, a gold foil was plated, as explained above, from each solution, using a fresh stainless steel plate cathode. The thickness of the gold deposits varied slightly, but averaged about 100 mg/in.^{2}.

The seven gold foils thus obtained from each solution were stripped from the substrate, carefully washed and dried, and finally mass spectrometrically analyzed for the evolved gases after vacuum fusion at 1300°C.

The entire process, as explained above, was repeated, but substituting potassium formate and then ammonium sulfate for the ammonium formate. Once again, a total of 5, 15, 25, 50, 75, and 100 ± 0.1 g/l formate ($H{\cdot}COO^-$) ion and sulfate ($SO_4^=$) ion, respectively, were added to both the cyanide and citrate electroplating solutions.

Results and Discussion

The results of the mass spectrometric analyses of the gases evolved from the three series of gold foils on vacuum fusion at 1300°C are shown in Fig. 1, 2 and 3. It is immediately apparent that the gold foils plated from the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution contain low levels of gaseous impurities, which do not increase in concentration as the concentrations of the ammonium formate, potassium formate and ammonium sulfate salts increase. This observation, of course, would be true for any gold electroplating solution, which does not contain free KCN.

However, on the addition of the ammonium salts of $H{\cdot}COOH$ and H_2SO_4 to the KCN/$KAu(CN)_2$ electroplating solution, a rise in the gaseous impurity level within the gold foils is observed to occur. Also, not shown on the figures as a curve, liberal amounts of HCN and cyanogen (C_2N_2) are also detected. On the other hand, the KCN/$KAu(CN)_2$ electroplating solution containing potassium formate does not show this rise in the gaseous impurity level within the gold foils, as the concentration of the salt increases. In fact, the gaseous impurity levels in the latter solution compare very closely with those found in the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solutions.

It is clear that the hydrolysis of ammonium formate and ammonium sulfate reduces the pH of the solutions below pH 10 where it has been shown that $[HCN]_4$ forms (5). Potassium formate, an alkaline salt, reduces the pH only very slightly, so that little, if any, polymer forms.

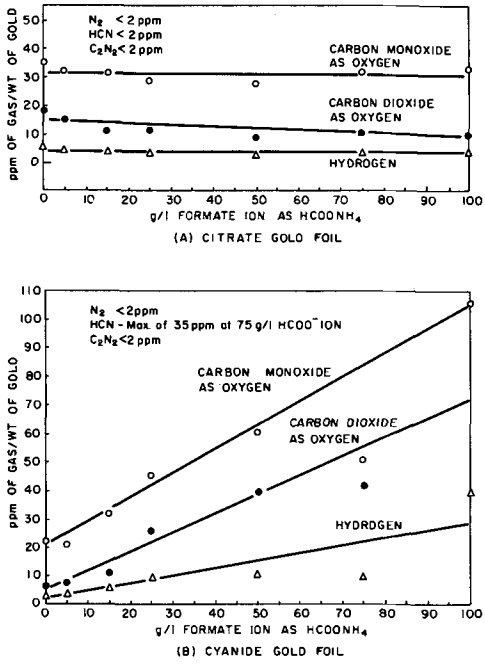

Fig. 1. Gas analysis of gold foils obtained from ammonium formate-rich electroplating solutions.

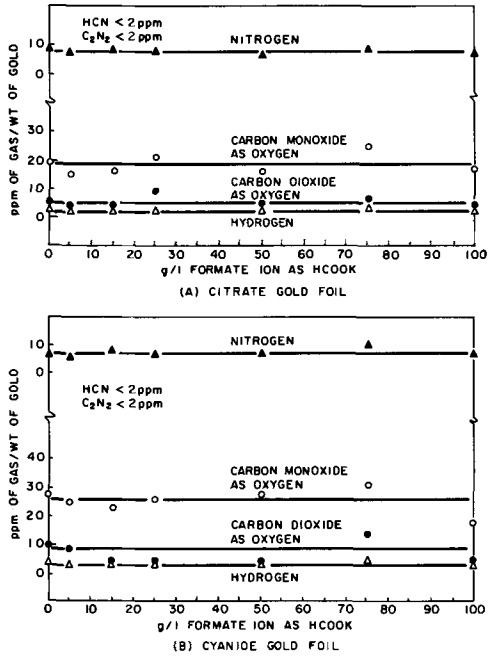

Fig. 2. Gas analysis of gold foils obtained from potassium formate-rich electroplating solutions.

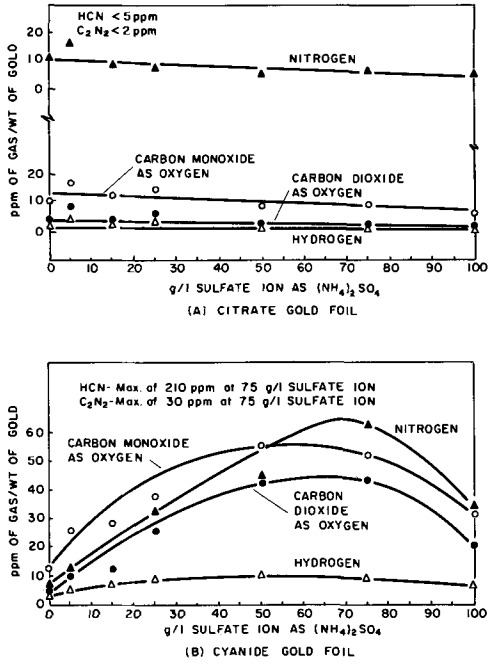

Fig. 3. Gas analysis of gold foils obtained from ammonium sulfate-rich electroplating solutions.

The gold electrodeposits, obtained from those electroplating solutions in which no HCN polymer generation occurs, are all bright yellow and matte. Conversely, those gold deposits obtained from polymer-containing electroplating solutions, progressively become browner and darker as the concentration of polymer absorbed with the gold, increases. The values in ppm of the total gaseous impurity concentration, which correspond to Fig. 3B, are reported in Table I as a function of the concentration of sulfate ion dissolved in the electroplating solution. The gaseous impurities include the following: H_2, CO, CO_2, N_2, CH_4, C_6H_6, HCN, Ar, C_2N_2.

At zero g/l ammonium sulfate in the electroplating solution, the gold deposit is bright yellow and matte in color. This corresponds to the lowest total gaseous impurity concentration (28 ppm), *i.e.*, the sum in ppm of all the gaseous impurities reported in the foil, of

Table I. Total gaseous impurity concentration, ppm

g/l Sulfate ion as $(NH_4)_2SO_4$						
0	5	15	25	50	75	100
28	56	66	171	306	408	149

any of the seven foils. As the concentration of each individual impurity, and hence the sum total of the impurities, increases within the gold foil at any one concentration of the $SO_4^=$ ion, so the color of the foil progressively deepens to a maximum around 75 g/l $SO_4^=$ ion, at which point the total impurity concentration also reaches a maximum of 408 ppm. A similar discoloration of the gold deposits is observed in the $KCN/KAu(CN)_2$ electroplating solution when ammonium formate is added.

For reasons undetermined at present, the polymer was apparently not absorbed to such a high degree on the next gold foil obtained from the $KCN/KAu(CN)_2$ electroplating solution containing 100 g/l $SO_4^=$ ion. This is immediately apparent from the drop in the individual concentrations of H_2, CO, CO_2, and N_2, (Fig. 3B), the resultant drop in the total concentration of the gaseous impurities to 149 ppm and the slight lightening of the gold foil. Thus, the relative discoloration of the gold foils could be used as a qualitative test of the amount of contamination of the foil by the HCN polymer.

It has been postulated that the $H{\cdot}COO^-$ ion, produced as a reaction product of KCN with water (1), is responsible for the large increase of CO, CO_2, and H_2 observed in the gold foils, when the ammonium salts are purposely added to the $KCN/KAu(CN)_2$ electroplating solution (Fig. 1B and 3B). Since the addition of $H{\cdot}COO^-$ ion did not affect the gas content of the gold foils obtained from the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution (Fig. 1A), it was assumed that the HCN polymer was responsible for entrapping or adsorbing the $H{\cdot}COO^-$ ion or maybe the acid $H{\cdot}COOH$, in some manner not determined, as the polymer codeposited with the gold. However, there is the possibility that monomeric HCN absorbed with the HCN polymer within the gold foil, slowly reacts with water to provide an additional, *in situ* source of the $H{\cdot}COO^-$ ion by the reaction discussed elsewhere (1).

It would appear therefore that, within certain limits, the amount of gaseous impurities evolved from an electrodeposited gold foil is proportional to the concentration of the HCN polymer within the foil, which in turn is proportional to the concentration of polymer within the electroplating solution. The concentration of polymer within the electroplating solution increases as the pH is decreased by the hydrolysis of an acidic ammonium compound or by liberation of oxygen at the anode. It has been found experimentally that another source of gaseous impurities, mainly H_2, is derived from the substrate of the device upon which gold has been electrodeposited. The amount of H_2 evolved is usually dependent on the pretreatment of the substrate and can be several times that evolved from the gold deposit alone. Since an examination of the absorptive properties of different substrates was not within the scope of the present work, it will not be discussed further.

A check to reveal whether continual electroplating from a $KCN/KAu(CN)_2$ solution containing some HCN polymer at a current density less than that required to liberate oxygen at the anode, would ultimately result in the elimination of the polymer, due to its codeposition with the gold, was rather disappointing in that no drastic brightening of the gold deposit was observed even after six successive electroplatings from the same solution. It was hoped that eventually a bright yellow matte gold deposit would result. There is the possibility, however, that many more than six electroplatings would be required to clear the solution of the polymer, which was present in abundance.

It has frequently been observed that gold anodes, used continually in $KCN/KAu(CN)_2$ electroplating solutions, become covered with a dark brown coating, somewhat reminiscent of the brown gold deposit obtained from electroplating solutions heavily contaminated with the HCN polymer. In order to clarify the nature of this brown coating, two gold rod anodes, 99.99% pure, were sent for vacuum fusion and electron diffraction studies of the coating on that part of the anode which had been repeatedly immersed over a period of several months in the plating solution.

The vacuum fusion study revealed that the dark brown coating contained at least 100% and up to about 400% more oxygen than any area of the gold anode uncovered by the dark-brown coating. Moreover, the results of the electron diffraction measurements, shown in Table II are consistent, although not identical, with those obtained from the surface of gold heated in an oxygen atmosphere at 500°C (15). This compound was indexed as hexagonal with lattice parameters $a = 5.28$ and $c = 6.75$ and assigned the formula Au_3O_2. This, however, has been disputed (16) and the patterns assigned to spinels formed from impurities in the gold.

Difficulties in the detection of the diffraction pattern of gold oxide have also been experienced by another worker (17).

Since the gold anodes were used in a standard $KCN/KAu(CN)_2$ electroplating solution and never allowed to remain in contact with the solution for any length of time without electrolysis, the source of the oxygen-containing layer is probably electrolytic. It would appear that, as well as gold being dissolved from the anode, oxygen is also being formed, if not evolved.

On aging, in air at room temperature, the brown layer so formed is particularly resistant to a concentrated solution of KCN, a 1:1 HCl solution, and even to prolonged heating in air at about 600°C. This behavior is contrary to what is usually assumed to be a weak gold compound. Only on prolonged usage in a $KCN/KAu(CN)_2$ electroplating solution will the dark brown material disappear, presumably an electrolytic dissolution reaction to form the soluble $Au(CN)_2^-$ ion.

Since the chemical stability of $KAu(CN)_2$ in solution with compounds other than KCN is an extremely important parameter to be considered in these electrochemical studies, it was decided to determine how stable the standard solution of $KAu(CN)_2$ and dibasic ammonium citrate (14) is, before and after boiling. Thus, a solid sample of $KAu(CN)_2$, Engelhard Industries, was analyzed for total cyanide and gold. A solution was made up by mixing 20 ± 0.1 g/l $KAu(CN)_2$ and 50 ± 0.1 g/l dibasic ammonium citrate in deionized water. An aliquot was removed and analyzed for total cyanide and gold. The solution was then boiled for ½ hr, cooled and after volume-loss corrections, an aliquot removed and analyzed again for total cyanide and gold.

The results of the analyses for total cyanide and gold are shown in Table III, together with calculated theoretical values.

Within experimental error, the results obtained for total cyanide and gold in each case lie very close to the calculated theoretical values. The data present evidence of the stability of $KAu(CN)_2$ to decomposition and that, in particular, no new complex of gold is formed with the citrate ion (14, 18, 19, 20). The gold

is present as the gold dicyanide ion, whether the electroplating solution is boiled or unboiled. A similar opinion has recently been expressed from observations made during a study of plating conditions on the porosity in gold electrodeposits (21).

Conclusion

Potassium gold cyanide electroplating solutions containing free KCN are subject to contamination not only by $H{\cdot}COO^-$ and $CO_3^=$ anionic impurities, but also by a brown polymeric material of formula $[HCN]_4$, generated at the soluble gold anode when the *p*H in its vicinity is reduced on the occasional anodic evolution of oxygen. This polymer codeposits with the gold, discoloring the latter, and is the agent responsible for the major proportion of the gaseous impurities found residing within the gold deposit. However, gold deposits obtained from electroplating solutions containing no free KCN, for example the dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution, contain only low levels of gaseous impurities.

Electron diffraction and vacuum fusion studies have shown that the dark brown coating formed occasionally on gold anodes is high in oxygen and may be similar to a compound claimed to be Au_3O_2, but believed by others to be a spinel formed from impurities in the gold. When freshly prepared, this material readily dissolves in an aqueous KCN and a 1:1 HCl solution, but, on aging in air at room temperature, becomes particularly resistant to chemical and thermal attack.

No new complex of gold is formed with the citrate ion within a dibasic ammonium citrate/$KAu(CN)_2$ electroplating solution. The gold is invariably present as the $Au(CN)_2^-$ ion, whether the electroplating solution is boiled or unboiled.

Stabilized Zirconia as an Oxygen Pump

D. Yuan and F. A. Kröger

Department of Materials Science, University of Southern California, University Park, Los Angeles, California

ABSTRACT

Electrolytic cells based on stabilized zirconia as a solid electrolyte may be used to remove oxygen from stationary or streaming gas. The minimum pressures (activities) that can be accurately measured are limited by the onset of electronic conduction in the electrolyte. In buffered gases, the lowest pressure that can be attained either by the capacity of the buffer or by the decomposition kinetics of the buffer molecules. Typical values of the oxygen pressures that can be reached when using commercial high-density sintered stabilized zirconia tubes as an electrolyte, are $\approx 10^{-38}$ atm at 530°C, 3×10^{-30} atm at 700°C, and 3×10^{-27} atm at 800°C.

Stabilized zirconia of the composition $Zr_{0.85}\ Ca_{0.15}\ O_{1.85}$ crystallizes in the CaF_2 type structure with the Ca^{+2} and Zr^{+4} occupying metal sites and oxygen occupying the nonmetal sites. The presence of 15% Ca gives rise to 7.5% vacant oxygen ion sites (1, 2). Electrical conduction in $Zr_{0.85}\ Ca_{0.15}\ O_{1.85}$ at high temperatures in air or oxygen is primarily due to the migration of oxygen ions through the movement of doubly charged oxygen vacancies (1, 3). At lower oxygen pressures electronic conduction sets in (4, 5). The value of the oxygen pressure at which the ionic transference number $t_i = 0.5$ is a function of temperature (6) and varies from sample to sample, possibly as a result of the presence of donor impurities in different concentrations (6, 7).

Stabilized zirconia can be used as a solid electrolyte in a galvanic cell with platinum contacts. Such cells, when operated with different oxygen pressures at the

two sides in the range of pressures where $t_i = 1$, can be used as a fuel cell (8), the voltage being given by

$$E = -\frac{RT}{4F} \ln (p_{O_2})_r/(p_{O_2})_1 \qquad [1]$$

On the other hand, operating with a known oxygen pressure at one side and an unknown one at the other, and again using Eq. [1], the cell can be used to measure the unknown pressure (4). Similar cells can be used to measure gas equilibrium constants or free enthalpies of formation of oxides (9).

In the range where stabilized zirconia is an ionic conductor, the passing of current transfers oxygen from the cathode side to the anode side. This has been used to adjust the stoichiometric composition of uranium oxides (10, 11). It has also been used to pump oxygen gas from the cathode side to the anode side, thus reducing the oxygen pressure at the cathode side in a known way. In experiments carried out by Heyne (12) the oxygen is removed from a closed system. It has been indicated, however, that the same principle can be used to remove oxygen from streaming gas in an open system (13). Strickler *et al.* (14), recognizing the dependence of the ionic current on the presence of oxygen gas at the cathode, used this dependence to determine t_i, but did not remove oxygen by passing current.

It is the object of the work reported in this paper to investigate the effectiveness of stabilized zirconia as an oxygen pump. As we shall see, it is possible to reach oxygen pressures as low as 10^{-38} atm at a flow rate of 4.6 cm³/sec at 530°C.

Experimental

The zirconia tubes used in the experiments were high density sintered calcia-stabilized zirconia, obtained from the Zirconium Company of America. It has the composition $(ZrO_2)_{0.9}(CaO)_{0.1}$ and x-ray analysis shows it to consist of two phases, the major phase being calcia-stabilized cubic zirconia, the minor one being monoclinic zirconia. One of the tubes had an inner diameter of 5 mm, the other of 12 mm, both having a wall thickness of 0.5 mm.

Inner and outer electrodes were made with the aid of Hanovia platinum paste. This is a fluxless mixture of 0.1μ platinum powder and resinous material suspended in an organic solvent; it is marketed in the United States by Engelhard Industries, East Newark, New Jersey. The inner electrode (I) is a continuous porous layer, a few microns thick, extending over $\approx$ 22 cm. It was made by pulling a cotton wool plug, wetted with Pt paste, through the tube, followed by heating to 500°C in air. This procedure leaves only platinum metal particles on the zirconia surface. This inner electrode is grounded. The outer electrode consists of three sections. One (II), the "pump" section, made again with the aid of Pt paste in the manner described above, is 14 cm long. The others (III, IV) are $\approx$ 0.5 cm. long and consist of platinum foil and 0.05 in. platinum wire wound around it, placed, respectively 2 and 6 cm away from the edge of II. Figure 1 shows the electrode arrangement. An additional Pt-Rh wire welded to the Pt contact wire at contact III forms a thermocouple which makes it possible to measure the temperature. The whole assembly is placed in an electric furnace, the temperature of which is kept constant to $\pm$ 2°C. Tank nitrogen is led through the tube at measured flow rates. The outside of the tube is kept in air. Application of a positive voltage at II relative to I leads to the removal of O_2 from the inside of the tube. The effectiveness of this "pumping" is determined by measuring the emf E_m of the cells III-I and IV-I, one being further removed from the pumping cell than the other. This is done with the object of determining whether pumping affects the gas over the entire cross section, or only over a thin layer near the surface. Currents are measured with a Simpson meter, and voltages with a Keithley 610 B high impedance voltmeter.

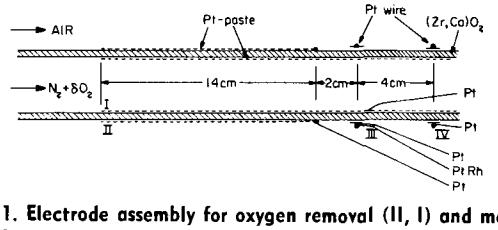

Fig. 1. Electrode assembly for oxygen removal (II, I) and measurement of oxygen pressure (III, I and IV, I).

Results

Initial experiments with no externally applied voltage, using Eq. [1] for E_m, showed that the tank nitrogen contained 2 x 10^{-5} atm O_2. The cell showed the temperature dependence as required by Eq. [1]. No appreciable emf was observed in symmetrical situations, *i.e.*, with nitrogen, air, or oxygen both in and outside the tube.

The results of pumping experiments at 530°C, using the narrow tube with a nitrogen flow rate of 4.6 cm³/sec inside and air outside, are shown in Fig. 2.

The values of the voltage E_m over the measuring cells III-I and IV-I are stationary state values, measured with the Keithley voltmeter without compensation. E_m is seen to increase with increasing current passed through the pumping section II-I. A sharp increase of E_m occurs at pumping currents J_{pump} between 0.7 and 2 ma. In this current range the removal of oxygen from the nitrogen passing through the tube approaches completion. The current at which complete oxygen removal is expected at the given flow rate and the oxygen content of 2 x 10^{-5} atm as determined at $J_{pump} = 0$, should the ionic transference number of the zirconia remain 1, is $J_{pump} = 0.6$ ma. The measuring cells III-I and IV-I, placed at different distances downstream from the pumping section give similar results, but the values of IV-I are systematically $\approx$ 3% lower than those of III-I. The fact that the two voltages are so close indicates that the oxygen is not just removed from a thin layer at the inner surface, maintained by laminar flow, but that there is depletion of oxygen over the entire cross section of the tube. This view finds support in an estimate of the diffusion length l. For oxygen at 530°C, the diffusion coefficient, $D \approx 0.9$ cm² sec^{-1}, and using a transit time $t = 0.1$ sec given by the time it takes the gas to flow from the right-hand edge of II to III at a flow rate of 4.6 cm³/sec in the tube with $d = 0.5$ cm, we find $l \approx (Dt)^{1/2} \approx 0.3$ cm $\approx r$, the radius of the tube. Since diffusion starts well before the edge of II is reached, t may be 2-4 times larger. Accordingly diffusion will

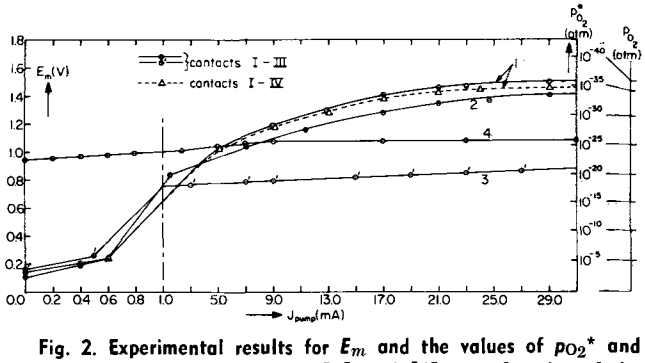

Fig. 2. Experimental results for E_m and the values of p_{O_2}* and p_{O_2} calculated from it with Eq. [1] and [4] as a function of the pumping current, with air as the outside atmosphere and an inner atmosphere consisting of: *1.* $N_2 + 2 \times 10^{-5} O_2$ passed through a liquid nitrogen trap; *2.* $N_2 + 2 \times 10^{-5} O_2$ direct from the tank; *3.* $N_2 + 2 \times 10^{-5} O_2$ passed through water at 25°C; and *4.* wet or dry $N_2 + 4 \times 10^{-5} CO_2$. Inner diameter of tube: 5 mm; flow rate 4.6 cm³/sec. Temperature: 530°C. Note the difference in scale for $J <$ and $>$ 1 ma.

effectively even out the oxygen concentration over the cross section. As we shall see, the small difference between cells III-I and IV-I is probably due to back diffusion from the end of the tube, contact IV being closer to the end than III. Curves 1-4 correspond to different conditions of the experiment. For curve 1 the nitrogen was dried by passing it through a liquid air trap. This leads to the highest voltage (= lowest residual oxygen pressure) attained: E_m = 1.5v, corresponding to $(p_{O_2}^*)_{min} = 10^{-36}$ atm. (Here and below, $p_{O_2}^*$ indicates pressure values calculated from Eq. [1]. As we shall see later, more correct values, given as p_{O_2} without asterisk, are calculated using a more general equation.) Using nitrogen directly from the tank (curve 2) gives E_m = 1.4v, $(p_{O_2}^*)_{min} = 10^{-34}$ atm. Since this suggests a dependence on the water pressure, a third experiment was carried out with nitrogen saturated with water at 25°C (curve 3). Now the minimum pressure obtained is considerably higher, $\approx 10^{-20}$ atm. In the fourth and fifth experiment the oxygen present in the nitrogen was transformed into a mixture of CO_2 and CO by passing the tank nitrogen over graphite at 650°C. For the fourth experiment, tank nitrogen was used as such. For the fifth experiment the gas was predried by means of a liquid air trap. No difference was observed (curve 4). The removal of oxygen in this manner leads to a relatively high E_m without pumping. On the other hand, pumping has little effect on E_m. The no-pumping value of E_m is considerably lower than is expected, should the mixture of CO_2 formed by passing the $N_2 + O_2$ over carbon at 600°C correspond to thermodynamic equilibrium. We shall return to this point later.

Instead of plotting E_m as a function of J_{pump} as shown in Fig. 2, we might plot E_m as a function of the pumping voltage, E_{pump}. There are, however, complications resulting from a time dependence of the current voltage characteristic: J_{pump}-E_{pump} curves obtained by measuring J_{pump} at different times after application of the voltage, are different for $E_{pump} \geqq 4$v. This is demonstrated in Fig. 3, where 1-2-3-4 and 1'-2'-3'-4' represent two different current-voltage sequences. In the first sequence E_{pump} is increased rapidly to 6v and held for 2 hr before decreasing the voltage to 3v. In the second sequence, E_{pump} is kept for 5 min at 9v. In both cases, but especially in the second sequence, lowering the voltage to 3v leaves a small excess current as compared to that in the cell in its initial state.

The change of J_{pump} with time indicates that at these voltages the zirconia of the pumping section is irreversibly changed. This effect is also indicated by the recovery time of the signal of the measuring cell. This recovery time is the time it takes the measuring cell to come back to its original, low, no-pumping value after interruption of the pumping current, indicating that the gas in the tube is again of the original composition. As shown in Fig. 4 for $E_{pump} > 4$v, this time depends on the time during which the pumping has taken place, the recovery time increasing with increasing pumping time. This dependence is stronger for larger E_{pump}. The semipermanent changes in the zirconia of the pumping section are related to its decomposition by electrolysis and/or its becoming polarized when no oxygen is available at the cathode. Thermodynamic data for ZrO_2 and CaO indicate, respectively, decomposition voltages for formation of the pure metals and oxygen at 1 atm of 2.52 and 2.84v at 530°C; in the solid solution employed, the value may be expected to be somewhat higher. The values given correspond to thermodynamic equilibrium. If currents are drawn, the applied voltage will be higher by the ohmic voltage drop. This brings the expected value for the voltage at which electrolysis occurs close to $\approx$ 4v. At voltages smaller than that required for electrolysis, polarization occurs, which gives rise to a change in the stoichiometric composition in the direction of metal excess at the nonreversible electrode. This in turn represents a change in the activity of the components of the compound at this electrode, the metal activity being increased, the oxygen activity being decreased. Note that polarization and electrolysis are closely related: electrolysis occurs when the polarization is so strong that the metal activity reaches the value at which pure metal may be formed. In the strongly polarized state the zirconia assumes a dark color (15, 16) and becomes partly electronically conductive (4-6). The theory of the polarization process and its consequences as far as electronic conduction is concerned is essentially the one given by Wagner for AgBr (17, 18). Phase diagram studies show that tetragonal zirconia saturated with zirconium may contain up to 3 x 10^{-2} excess Zr per molecule ZrO_2 at 1500°C, and probably < 10^{-2} at 530°C. Cubic zirconia, on the other hand, may contain up to 5.5 x 10^{-2} at 1500°C, and a similar value may be expected for calcia-stabilized zirconia. At 530°C this will be reduced to $\approx$ 2 or 3 x 10^{-2}. Although this is still an appreciable concentration, and the building up of this concentration will involve some time, it is doubtful whether it can account for the slow semipermanent changes observed.

A decision as to whether polarization and electrolysis both occur, or whether only polarization occurs, can be reached on the basis of the time dependence of the pumping current. Electrolysis should give a continuously increasing current. Polarization, on the other hand, requires a current approaching asymptotically a certain final value. Our data for voltages > 4v, indicate that electrolysis occurs.

On the basis of these arguments we expect a situation in which we have ionically conductive zirconia in the outer and central sections of the tube, electronically and ionically conducting zirconia, below the inner surface, and zirconium (and calcium) metal at the inner surface. Since application of a strong field tends to give rise to polarization as well as electrolysis, an initial concentration of the field at certain points,

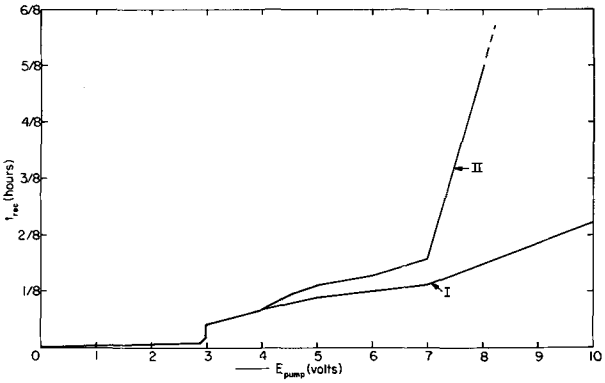

Fig. 4. The time (t_{rec}) needed by the measuring cell (III-I) to revert back to its pre-pumping emf. 1. For interruption of the pumping current immediately after its being established; and 2. for interruption of the pumping current 30 min after its being established.

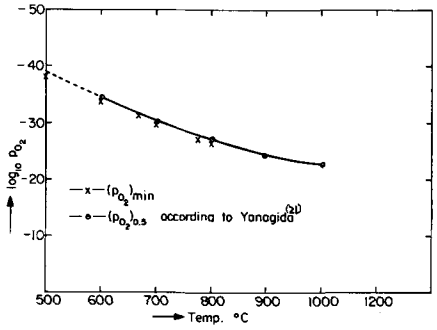

Fig. 5. $(p_{O_2})_{min}$ as $f(T)$ compared to the oxygen pressures $(p_{O_2})_{0.5}$ at which stabilized zirconia is 50% electronic conductor according to Yanagida (21).

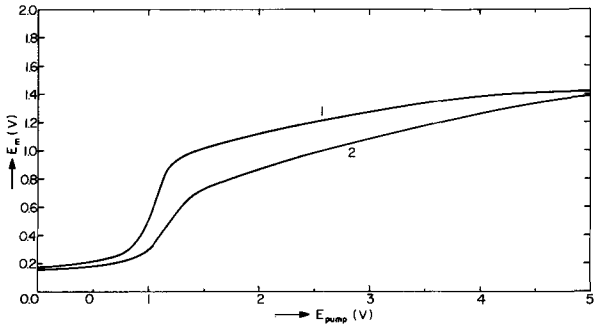

Fig. 6. E_m as $f(E_{pump})$ for a gas flow of 4.6 cm³/sec at 530°C for tubes with different inner diameter d: 1. d = 0.5 cm; 2. d = 1.2 cm.

e.g., at grain boundaries or dislocations, tends to give rise to the local formation of metal and electronically conducting zirconia which in turn tends to strengthen locally the field across the less affected part of the cross section. Thus both effects favor dendrite formation. Such dendrites have been observed with zirconia used in an electrode in magnetohydrodynamic power generators (15, 16).

Electrolysis occurs only at the pumping section which is affected directly by the pumping current. The oxygen-poor, partly decomposed inner surface goes on acting as a pump after interruption of the pumping current until it is reoxidized by the oxygen of the gas. If the oxygen content of the gas is low, as in our experiments, this may take a long time. This explains the long recovery time (measured with the measuring cell) plotted in Fig. 4.

The material of the measuring cell is affected only through the reduced oxygen activity in the gas. If this activity is sufficiently low, it will lead to an oxygen poor, electronically conducting material over part of the cross section. Decomposition with the formation of metallic zirconium will not occur: the lowest oxygen pressure that can be reached corresponds to the coexistence of oxygen-poor zirconia and metallic zirconium, and this does not represent a driving force for the nucleation and formation of metallic zirconium required for electrolysis.

Normally, E_m was measured with the Keithley voltmeter without compensation. Practically the same results are obtained for measurement of E_m with compensation, using the Keithley meter as a zero indicator. This indicates that the small current drawn by the meter does not upset the measurement.

In Fig. 5 the maximum values of E_m reached by pumping are compared with $E_{0.5}$, the emf of the ZrO_2-CaO diffusion cell calculated from Eq. [1] for $(p_{O_2})_{0.5}$; the latter represents the low oxygen pressure at which zirconia has equal ionic and electronic conductivities, Schmalzried's p_θ (20).

It is seen that the values of E_m are close to the values of $E_{0.5}$ found by Yanagida (21) for a tube of the same material as used by us.[1] At 800°C Yanagida's and our values for $E_{0.5}$ correspond to $(p_{O_2})_{0.5} \approx 5 \times 10^{-20}$ atm. Other reported values are considerably lower. Schmalzried's data (20) lead to $(p_{O_2})_{0.5} = 1.6 \times 10^{-32}$ atm. Patterson *et al.* (6) found values of 10^{-34} atm from conductivity measurements, and 10^{-39} atm from polarization experiments. These differences are partly due to differences (and possibly errors) in the measuring techniques, but differences may also result from differences in the composition of the zirconia used. This point deserves further study.

Figure 6 compares E_m as $f(E_{pump})$ for the wide tube (curve 2) and the narrow tube (curve 1) at equal flow rates. As expected, the wide tube is less efficient, although the performance is still satisfactory.

Attempts to measure the pumping efficiency at higher flow rates were complicated by temperature changes, fast flowing gas tending to cool the tube. Although pumping still takes place, uncertainties in the temperature make a quantitative evaluation more difficult. For this reason this line of investigation was not pursued any further.

Instead of removing oxygen from the gas in the tube, we can add oxygen by passing current through the pumping section in the opposite direction. Due to the relatively small pumping currents employed, for flowing gas the effect of oxygen addition is not very spectacular. Figure 7 shows the complete J-E characteristic including both types of operations. As mentioned before, the right-hand part of the characteristic at $E \geq 4$v is time dependent; the curve given corresponds to $t \leq 1$ min. The characteristic differs from that measured on a point electrode [Kleitz (13)] because the various sections of the pumping cell operate in different oxygen pressures. At voltages where the cell acts as a pump, the section near the edge where the flowing gas enters operates in the original oxygen pressure, whereas sections further down operate in an oxygen free environment. Since a change of the oxygen pressure shifts the zero current point of a cell, the total characteristic arises as the sum of contribu-

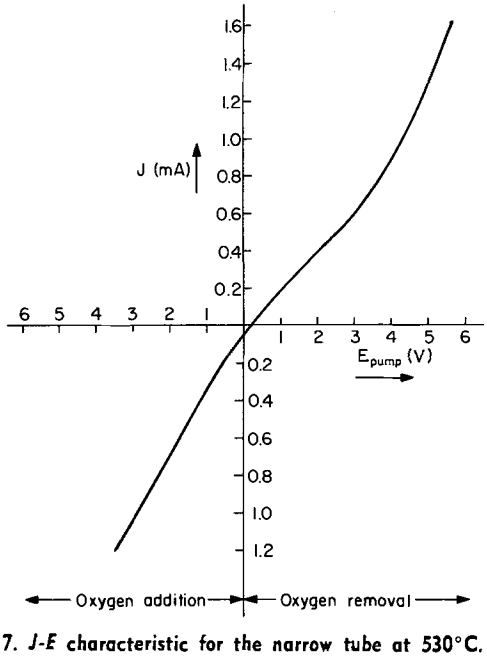

Fig. 7. J-E characteristic for the narrow tube at 530°C. Oxygen addition and removal refer to the inside of the tube.

[1] These values were arrived at by comparing the emf of the cell

$$Al, Al_2O_3 | (Zr, Ca)O_2 | O_2$$

with the theoretical emf calculated from the Gibbs free energy of formation of Al_2O_3 from Al and O_2

$$\frac{E}{E_{th}} = \ln (p_{O_2})_{0.5} \Big/ (p_{O_2})_{Al, Al_2O_3}$$

$(p_{O_2})_{Al, Al_2O_3}$ being the pressure of oxygen over Al in equilibrium with Al_2O_3.

tions from cells, the characteristics of which are shifted relative to each other. As a result the marked S-character of the individual characteristics is largely lost, although some is still observable.

Discussion

It has been shown that under favorable conditions (narrow pumping tube and reasonably low flow rates) stabilized zirconia may be used to reach extremely low oxygen pressures in flowing as well as stationary gases. Two points need closer examination. The first is that, as has been found, the value of $(p_{O_2}{}^*)_{min}$ attained by pumping is dependent on the presence of water vapor and or CO_2, high partial pressures of these gases limiting the lowest oxygen pressures that can be attained. The second point that needs examination is that values of E_m corresponding to values of p_{O_2} as low as reported can be measured at all.

The first effects are due to the capacity of H_2O and CO_2 to produce oxygen by dissociation

$$H_2O \rightarrow H_2 + \tfrac{1}{2}\,O_2 \qquad p_{O_2}{}^{1/2} = K_{H_2O} \cdot p_{H_2O}/p_{H_2}$$

$$CO_2 \rightarrow CO + \tfrac{1}{2}\,O_2 \qquad p_{O_2}{}^{1/2} = K_{CO_2} \cdot p_{CO_2}/p_{CO}$$

with

$$(K_{H_2O})_{530°C} = 6\text{x}10^{-14}\ \text{atm}^{1/2} \quad \text{and}$$

$$(K_{CO_2})_{530°C} = 1.2\text{x}10^{-14}\ \text{atm}^{1/2}$$

After the removal of the free oxygen originally present, dissociation of H_2O and CO_2 establishes a certain residual oxygen pressure. This residual pressure is lowered as more oxygen is removed and as more H_2 or CO is formed. The value actually attained in the relatively short time that the gas passes through the pumping cell depends on the rate of oxygen removal, on the rate of decomposition of the buffer molecules, or on the buffering capacity of the gas for oxygen removal. This buffering capacity must be expected to be greater when more H_2O or CO_2 is present. In the case of water-saturated gas, in which water (and thus oxygen) has been added to the gas, it may well be the increased buffering capacity that is responsible for the decreased pumping efficiency. For the gas mixture made by passing the oxygen-containing nitrogen over graphite at 650°C, no additional oxygen was added. Therefore, in this case the rate of decomposition of the buffer molecule (CO_2) must limit the pumping rate. This view is supported by results obtained by Kleitz (13) with stabilized zirconia in contact with Pt in a mixture of oxygen and CO_2 (Fig. 60, p. 97 of that reference).[2] Oxidation of graphite at $T < 1000$°C leads to partial pressures of CO_2 and CO determined by the kinetics of oxidation rather than by equilibrium (23). The emf of the measuring cell when no pumping is taking place indicates $p_{O_2} = 10^{-22}$ atm, corresponding to $p_{CO_2}/p_{CO} \approx 10^3$. Hence, $p_{CO_2} \approx 2 \times 10^{-5}$ atm (the original oxygen pressure) and $p_{CO} \approx 2 \times 10^{-8}$ atm.

The buffering capacity, but now against oxygen addition, must also be involved to explain why we can measure, without compensation, pressures as low as the ones found in the measurements. The main difficulty lies in the possibility of oxygen leaking back into the tube. There are three ways in which this may occur, *viz.*, (*i*) by counterstream diffusion from the open end of the tube, (*ii*) by diffusion through the tube wall, and (*iii*) as a result of the measuring current. Let us look at these three processes a little more closely.

Counterstream diffusion.—An estimate of the importance of counterstream diffusion may be made by calculating the oxygen pressure, built up a certain distance l up-stream away from the end in the time t required by the flowing gas to cover the distance l, if we start at $t = 0$ with an oxygen pressure step profile with $p_{O_2} = 0$ inside the tube, and $p_{O_2} = 0.2$ atm outside.

$$(p_{O_2})_{l,t} = 0.2\left[\,1 - \text{erf}\left(\frac{l}{2\sqrt{Dt}}\right)\right]$$

For the distances as shown in Fig. 1, with contacts III and IV respectively 6.7 and 2.7 cm from the end, the times involved are ≈0.33 and 0.14 sec. Taking again $(D_{O_2})_{530°C} \approx 0.9$ cm^2 sec^{-1} we find $(p_{O_2})_{III} \approx 2 \times 10^{-17}$ atm and $(p_{O_2})_{IV} \approx 10^{-8}$ atm. These figures have been arrived at with the aid of the tables of error functions given in ref. (24). The relatively large leak at electrode IV due to this mechanism can be largely removed by the use of a somewhat longer tube.

Diffusion through the tube wall.—In the well-sintered tube as used in our experiments, diffusion by neutral species is negligible. The only diffusion of importance involves charged species, moving through the bulk of the crystals. Such diffusion requires the simultaneous diffusion of ionic and electronic defects, *e.g.*, vacancies and electrons and/or holes. If the permeation is diffusion controlled, its rate is given by an expression similar to the one describing the rate of oxidation of a metal according to Wagner's theory of oxidation (12, 25).

$$j = \frac{RT}{8F^2d}\int_{p_{O_2}(\text{inside})}^{p_{O_2}(\text{outside})} \sigma t_i t_{el}\ d\ln\ p_{O_2}\ \text{g-moles/cm}^2\text{, sec} \qquad [2]$$

Here σ is the total conductivity, $t_{el} = 1 - t_i = t_e + t_h$, the total transference number for electrons (t_e) and holes (t_h) and d the thickness of the wall of the tube. Heyne (12) measured the permeation of stabilized zirconia (15% CaO) at 730°C from oxygen to vacuum, conditions under which only t_h is appreciable. Interpretation on the basis of the formula given above gave $t_h = 3 \times 10^{-4}$, smaller by a factor 7 from the value 2×10^{-3}, arrived at by extrapolating to this temperature the conductivity data by Patterson *et al.* (6). A second check can be made by comparing calculated values of $j\,d$ and experimental results by Smith *et al.* (26). At 800°C, from 25 Torr to high vacuum, $(j\,d)_{calc} = 2 \times 10^{-12}$ g-mole/cm, sec whereas $(j\,d)_{obs} = 10^{-14}$ g-mole/cm, sec. Thus in both cases the calculated value is smaller than the observed one. This indicates that the permeation is not entirely diffusion controlled, but is determined to some extent by surface processes. In any case, the formula may be used to find an upper bound to the permeation. Carrying out the integration with

$$\sigma_{el} = \sigma_e + \sigma_h = 4.6 \times 10^7\ p_{O_2}{}^{-1/4}\ \exp\ (-4.3\ \text{ev}/kT) + 8.8 \times 10^4\ p_{O_2}{}^{-1/4}\ \exp\ (-2.12\ \text{ev}/kT) \qquad [3]$$

as found by Patterson *et al.* (6), with outer and inner oxygen pressures of 0.2 and 10^{-38} atm, and $T = 530$°C, we find

$$j = j_e + j_h = 5.2 \times 10^{-17} + 2.6 \times 10^{-17} = 7.8 \times 10^{-17}\ \text{g-mole/cm}^2\text{, sec}$$

Permeation occurs through the wall section between the pumping section and the measuring electrodes with an area of 3.14 cm^2 for contact III and 9.42 cm^2 for contact IV. The times involved are 0.1 sec for III, 0.3 sec for IV. At a gas flow rate of 4.6 cm^3/sec, the permeated gas flows into gas volumes of 0.46, and 1.38 cm^3 respectively for the two cases and gives rise to $(p_{O_2})_{III} \approx 3 \times 10^{-12}$ atm and $(p_{O_2})_{IV} \approx 9 \times 10^{-12}$ atm. Since these are upper bounds, the actual values may be somewhat smaller.

Permeation as a result of the measuring current.—The Keithley 610B electrometer used for the measurements has an entrance impedance of $\geq 10^{14}$ ohms. Therefore a current of 10^{-14} amp flows at $E_m = 1$v. It flows in a direction opposite to that required for pumping, and represents a back flow of oxygen into the system of 2×10^{-20} g-moles/sec. At the rate of flow

[2] Note that Karpachev *et al.* (22), investigating the working of the Pt/zirconia electrode in CO, found rate limitation of the opposite process, the oxidation of CO to CO_2.

Table I. Effect of estimated oxygen leaks

	Electrode III, atm	Electrode IV, atm
Counterstream diffusion	2×10^{-17}	10^{-8}
Permeation	3×10^{-12}	9×10^{-12}
Monitor current	2×10^{-16}	2×10^{-16}

Table II. Combination of partial pressures of H_2O and H_2 in equilibrium with $P_{O_2} = 10^{-38}$ atm at 530°C and the corresponding initial water pressures (units: atmospheres)

p_{H_2O}	$p_{H_2} \approx (p_{H_2O})_{initial}$
10^{-10}	3×10^{-5}
10^{-12}	3×10^{-7}
10^{-13}	3×10^{-8}
10^{-14}	3×10^{-9}
10^{-16}	3×10^{-11}

of 4.6 cm³/sec this corresponds to a partial pressure of 2×10^{-16} atm of oxygen added to the gas in the tube.

Table I summarizes the effect of the various estimated oxygen leaks at electrodes III and IV. The fact that in all cases appreciably lower values are indicated by the voltage of the measuring cells must be due to the removal of the back diffusing oxygen by a buffer. Actually, the emf measured indicates an oxygen activity maintained by the buffer system rather than a real oxygen pressure. We use pressures only as a convenient way to express these activities. For the water system, the buffering action consists of the reaction of oxygen with H_2; for the CO_2/CO system it involves reaction with CO. In the latter case, the calculated p_{CO} is well in excess of the oxygen back flow so that the measurement will not affect the results. In the water system the buffering capacity depends on the presence of H_2. If no H_2 is present in the N_2 initially, all the H_2 active in the measuring section must be formed by decomposition of H_2O in the pumping period. The pressures required, though large relative to the extremely low oxygen pressures involved, are small when considered on an absolute basis; therefore formation of the required amount of H_2 during pumping is not unacceptable. Figure 8 shows the relation between p_{O_2} and possible values of p_{H_2} and p_{H_2O} at 530° in the gas after it has passed the pumping section, calculated under the assumption that equilibrium is attained. Oxygen pressures of $\leq 10^{-38}$ atm are seen to be possible for $p_{H_2} \geq 10^{-11}$ atm and p_{H_2O} between 10^{-8} and 10^{-16} atm. If the hydrogen has been created by the pumping, the initial water pressures must have been equal to $(p_{H_2O})_{initial} = (p_{H_2O})_{residual} + p_{H_2}$.

Table II shows a few combinations of partial pressures p_{H_2O} and p_{H_2} giving $p_{O_2} = 10^{-38}$ atm and the corresponding $(p_{H_2O})_{initial}$. A clue to which of these combinations was actually present when $p_{O_2} = 10^{-38}$ atm was measured at contact III lies in the increase of the measured oxygen pressure to $p_{O_2} \approx 10^{-36}$ atm at contact IV which must result from the countercurrent diffusion leak of $\approx 10^{-8}$ atm. Such an effect is to be expected if the hydrogen pressure, which determines the buffering capacity, is of the same order as the back flow leak, *e.g.*, $p_{H_2} \approx 2 \times 10^{-8}$ atm, $(p_{H_2O})_{residual} \approx 7 \times 10^{-14}$ atm, and thus $(p_{H_2O})_{initial} \approx 2 \times 10^{-8}$ atm. This last value is much higher than the equilibrium pressure of ice at liquid air temperature. However, it is probable that a single stage trap does not remove water vapor down to this theoretical limit, and a residual water pressure of $\geq 10^{-8}$ atm is not unlikely. Under these conditions, all the other leaks are small relative to the buffering capacity and therefore the buffering is practically complete.

Values of E_m actually measured are affected and ultimately limited by the occurrence of electronic conduction in the solid electrolyte at low oxygen pressures. The transition from $t_i = 1$ to $t_i = 0$ is a gradual one. For, whereas the ionic conductivity σ_i is approximately constant, the electronic conductivity $\sigma_e \propto p_{O_2}^{-1/4}$ (4-6). As a consequence $t_i = \dfrac{\sigma_i}{\sigma_i + \sigma_e} = \dfrac{1}{1 + \sigma_e/\sigma_i}$ requires a range of ≈ 10 orders of magnitude in p_{O_2} to change from $t_i = 0.95$ to $t_i = 0.05$. Figure 9 demonstrates this for $(p_{O_2})_{0.5} = 10^{-36}$ atm as observed at 530°C by Yanagida (21) and σ_e as given by Eq. [3]. The variation of t_i in turn affects the value of the measured emf which is given by (20)

$$E_m = -\frac{RT}{4F} \int_{p_{O_2}(\text{outside})}^{p_{O_2}(\text{inside})} t_i \, d\ln p_{O_2} \qquad [4]$$

Equation [4] is equivalent to [1] only if $t_i = 1$. If we apply [4] to our case in which $(p_{O_2})_{outside} = 1/5$ atm, under which condition $t_i = 1$, we find E_m as a function of p_{O_2} by carrying out the integration using t_i as a function of log p_{O_2} as shown in Fig. 9. The result is given in Fig. 10. The shape of the curve is as discussed by Schmalzried (20), the slope at each point

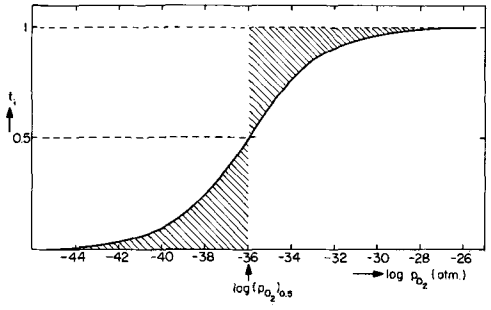

Fig. 9. t_i as a function of log p_{O_2} for σ_i = constant, $\sigma_e \propto p_{O_2}^{-1/4}$ and $(p_{O_2})_{0.5} = 10^{-36}$ atm.

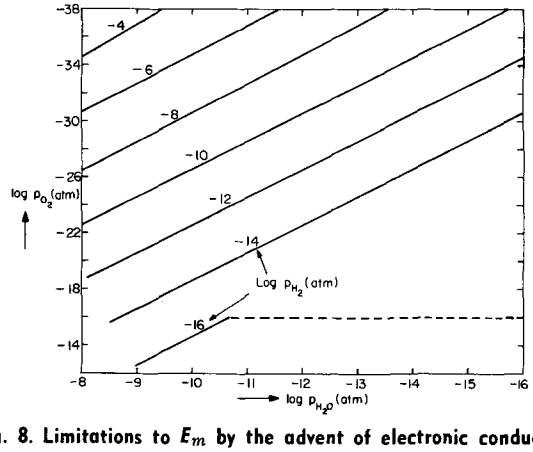

Fig. 8. Limitations to E_m by the advent of electronic conduction in the zirconia and the buffering capacity of various mixtures of H_2O and H_2.

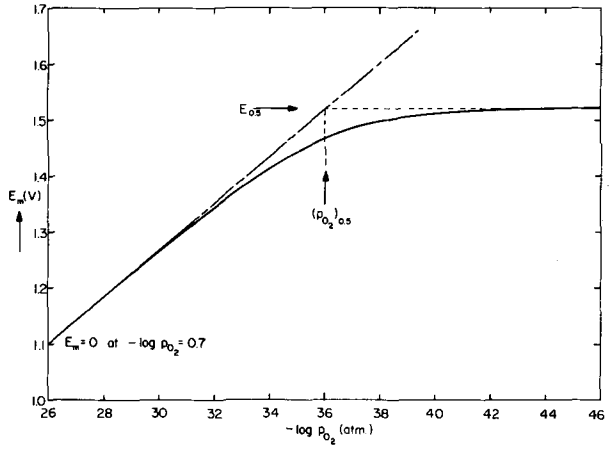

Fig. 10. E_m as a function of log p_{O_2} for the electrolyte characterized by Fig. 9 with $(p_{O_2})_{outside} = 1/5$ atm and $T = 530$°C.

being equal to 2.3 $\frac{RT}{4F}$ t_i. Since the curve t_i *vs.* log p_{O_2} shows inversion symmetry with respect to the point $t_i = 0.5$, the maximum contribution to the integral [4] from the range with $t_i < 0.5$ is just equal to the loss of voltage in the range where $1 > t_i > 0.5$ (the two contributions being proportional to the shaded areas in Fig. 9). Therefore, when the oxygen pressure inside the tube approaches zero, E_m approaches asymptotically the value calculated from [1] at $(p_{O_2})_{0.5}$.

Evidently for $p_{O_2} << 10^{-30}$ atm, the point where t_i starts to drop, values of the oxygen pressure p_{O_2}* deduced from E_m using [1] are considerably too high. The actual oxygen pressures reached in our pumping experiments may be found with the aid of Eq. [4] or Fig. 10. In Fig. 2 these are given as p_{O_2}; the minimum value, $(p_{O_2})_{min} = 10^{-38}$ atm is indeed markedly lower than the corresponding p_{O_2}*. Obviously the nonlinearity of E_m *vs.* log p_{O_2} near $(p_{O_2})_{0.5}$ has to be taken into account when the oxygen pump is used in experiments where the oxygen pressure must be exactly known. It should be pointed out that the results for $(p_{O_2})_{min}$ shown in Fig. 10 and 2 are based on $(p_{O_2})_{0.5}$ as measured by Yanagida (21) on a tube similar to ours, but with $\sigma_e \propto p_{O_2}{}^{-1/4}$ as reported in the literature (6). In case such pumps are to be used in applications where exact knowledge of p_{O_2} is necessary, it is prudent to either restrict the application to the range where [1] holds, or to measure $(p_{O_2})_{0.5}$ and σ_e as f (p_{O_2}) for the tube used and deduce a curve of the type of Fig. 10 for this tube.

Conclusion

Electrolytic cells based on stabilized zirconia as a solid electrolyte may be used to remove oxygen from streaming or stationary gas. Minimum oxygen pressures that can be accurately measured are limited by the onset of electronic conduction in the zirconia at low oxygen pressures. Typical values for the minimum oxygen pressure, reached when using commercial zirconia tubes, were 10^{-38} atm at 530°C and 3×10^{-27} atm at 800°C.

Erratum

An error has been discovered in Table I, p. 611, of the Technical Note "A Study of the Dissipation Factor (Tan δ) of Corrosion Product Films Formed on Aluminum Alloys in Hot Sodium Chloride Solutions" by W. H. Anthony which was published in the June 1968 issue of the Journal, Vol. 115, No. 6, p. 610.

The first row of this table reads:

Alloy	Silicon	Iron	Copper	Manganese	Magnesium	Chromium	Zinc	Titanium
5454H16	0.11	0.22	0.04	0.84	3.90	0.09	0.02	0.009

Subsequent analysis of this alloy has shown that the magnesium content and the zinc content were in error.

The correct analysis is as follows:

5454H16	0.10	0.21	0.04	0.76	2.70	0.10	0.06	0.01

The Formation of Chlorine Pentafluoride in an Electrochemical Cell

I. From Chlorine Trifluoride

Howard H. Rogers,* Sheldon Evans,* and Julian H. Johnson

Rocketdyne, A Division of North American Rockwell Corporation, Canoga Park, California

ABSTRACT

Coulometric experiments undertaken with chlorine trifluoride in anhydrous hydrogen fluoride resulted in the formation of chlorine pentafluoride in a divided or an undivided electrolytic cell. The yields of chlorine pentafluoride, based on current, in the undivided and the divided cell were of the order of 25 and 50% respectively. Fluorine, nickel fluoride, and small quantities of chlorine-oxygen-fluorine compounds were also formed at the anode. At the cathode, hydrogen, hydrogen chloride, and chlorine were formed depending on the degree of mixing of anolyte and catholyte. Nickel electrodes were used almost exclusively; however, chlorine pentafluoride was also formed at a Glassy Carbon anode. The rate of formation of chlorine pentafluoride was found to be a function of the concentration of chlorine trifluoride in the electrolyte. From an analysis of polarization data, it was concluded that the mechanism involved the anodic oxidation of fluoride ion to some form of active fluorine, followed by its reaction with chlorine trifluoride to form chlorine pentafluoride.

Anodic oxidations of oxygen- and/or nitrogen-containing compounds in hydrogen fluoride have shown that nearly complete fluorination generally results. For example, oxygen difluoride was formed from the oxidation of water (1), and nitrogen trifluoride was formed from the oxidation of ammonia (2). In this laboratory, nitroxy fluoride, nitrogen trifluoride, and oxygen difluoride were formed by the oxidation of nitrous oxide at a nickel anode (3). Therefore, it seemed reasonable that chlorine pentafluoride (4), would result from the anodic oxidation of chlorine trifluoride dissolved in anhydrous hydrogen fluoride. Vapor pressure measurements (5) have shown that the vapor pressure of the system, 14 m/o (mole per cent) chlorine trifluoride-86 m/o hydrogen fluoride, at 0°, was 527 mm.

This paper deals with a study of the electrochemical synthesis of chlorine pentafluoride from the hydrogen fluoride-sodium fluoride-chlorine trifluoride system.

Experimental

Electrolytic cell and associated apparatus.—A portion of this study was carried out in an undivided cell which was previously described (6). The divided cell (Fig. 1) was utilized in an effort to gain a better understanding of the anodic and cathodic reactions. The cell was divided in both the liquid and gaseous phases to minimize mixing of both anolyte and catholyte reactants and products. The liquid phase divider was an open end tube of porous Teflon (Pall Corporation, Glen Cove, New York). The bottom end of the tube was closed by a disk of solid Kel-F. The walls of the tube were ¼ in. thick and the mean pore opening was specified by the manufacturer to be 9μ. Since the pore size was relatively large, and since hydrogen fluoride wets Teflon, relatively free flow of electrolyte through the Teflon occurred as a result of slight shifts in electrolyte level or thermal gradients in the cell. The wall temperature in the cathode compartment was about −16°, while the anolyte temperature was 10° during electrolysis. With the exception of the reference electrode and level detection system, the other features of this cell were similar to the undivided cell.

The level detection system consisted of a sight tube and two probes, one of which was also a thermocouple well, while the other probe also supported a mercurous fluoride reference electrode. The probes were connected to an a-c-operated electrical alarm to indicate when the level rose or fell below the indicated maximum or minimum. A mechanical refrigeration system was used to supply chilled (−16°) methanol to the condensers and cell jacket. The anolyte was not cooled directly because of the cell geometry.

The design of the mercury reference electrode (Fig. 2) was based upon the work of Koerber and DeVries (7), except that mercurous fluoride was not added intentionally to the electrode. It was found to maintain its potential within 0.1v even after being made anodic to the normal anode and after passage of several milliamperes of current.

The schematic of the anodic product handling system and electrolytic cells is shown in Fig. 3. A separate cathodic product handling system (not shown) is similar to the anodic system.

Electrical apparatus.—The power supply, constant current regulator, and associated recorders have been described (6). Electrode potentials against the reference electrode were read with either a Keithley Model 621 Electrometer or with a transistorized instrument (8).

Polarization curves were taken automatically with the aid of a potentiostat and ramp generator (9). With this equipment, a linearly increasing and decreasing

anodic or applied voltage (0.17 v/sec usually) could be applied to the electrolytic cell, while the voltage and the logarithm of the current were plotted on an Electro Instruments, Inc., Model 500 X-Y Recorder.

Chemicals.—The Matheson "anhydrous" hydrogen fluoride (99.9% min. purity) was dried overnight in the undivided electrolytic cell (Fig. 3) by periodic reversal of current (6), and then distilled into the divided cell. J. T. Baker Company Reagent Grade sodium fluoride was used after drying at 110° for 16 hr. Matheson chlorine trifluoride (98.0% min. purity) was used directly from the cylinder.

The hydrogen fluoride absorption columns were packed with Harshaw sodium fluoride pellets, No. 0202 T ⅛, mixed with alumina spheres, Norton Alundum Size 8F, E-163, with all particles removed which passed a 12 mesh screen.

Electrolysis procedure.—After electrolytic drying of hydrogen fluoride, about 250 ml were distilled into the divided cell, which contained the dried sodium fluoride, used as a conductivity additive. The dissolution of the sodium fluoride resulted in the formation of a 3 m/o solution. Streams of inert gas (nitrogen or helium) at constant flow rates between 20 and 50 cc/min were fed into the gas space of both the anode and cathode compartments. Up to 6 m/o of liquid chlorine trifluoride was then added to the anolyte (anolyte volume *ca.* 130 ml). When the cell was to run for sustained periods, periodic additions of chlorine trifluoride were necessary to replace that lost by volatilization, anodic oxidation, and diffusion to the catholyte. All electrolyses were carried out at constant current.

After passage through the hydrogen fluoride absorption column, the mixture of anodic products, volatilized chlorine trifluoride, and inert gas (at a known flow rate) passed through the remainder of the anodic system, as indicated in Fig. 3. This product stream was sampled periodically and infrared spectra were taken. The partial pressures of chlorine pentafluoride were then calculated with the aid of the following formulas, where ΔA is the difference in absorbance.

$$P_{mm(ClF_5)} = \Delta A\ (104) \qquad \text{at } 786\ cm^{-1}$$

$$P_{mm(ClF_5)} = \Delta A\ (1.25) \qquad \text{at } 732\ cm^{-1}$$

The data for the above equations were obtained with chlorine pentafluoride which was prepared electrochemically and purified by fractionation through a —112° trap. The only contaminant was a trace of chloryl fluoride. The data (precision ±20%) was in good agreement with that from chlorine pentafluoride prepared by a different route (4). Although more precise analytical procedures were available, they were not required for the purposes of this study. This infrared method was used because it was rapid and convenient, thereby permitting a large number of determinations in a reasonable period of time.

The determination of fluorine in the anode gas stream was carried out by first removing condensable product by passing the stream through —78° and —183° traps. The partial pressure of the fluorine which was mixed with the inert carrier gas, was found by observing the volume change on shaking the mixture with mercury.

Analysis of cathodic products was also carried out by periodic sampling of the gas stream. Mass spectrometry was used for the analysis of hydrogen, chlorine, and hydrogen chloride. Infrared spectrometry was used for fluorine compounds. All yields were based on the amount of current passed.

Anode considerations.—Both smooth and porous nickel anodes of the same outside dimensions, corresponding to an apparent surface area of 66 cm^2, were used for synthesis. Anodic polarization curves indicated that the porous anode had an effective surface area approximately 3½ times greater than the smooth anode. Allowable cell current was limited by heat generation in the anode compartment. Generally, the smooth anode was operated at a constant current of 1 amp, while 2 amp were used with the porous anode. Measured applied voltages ranged from 5 to 7, and anode potentials (against the mercury reference electrode) were about 1½v less.

Results

Results of electrolyses of the hydrogen fluoride-sodium fluoride-chlorine trifluoride system are described below.

Anodic products.—Chlorine pentafluoride yields in the divided cell were larger than 50% for over 2 hr even though no additional chlorine trifluoride was added to the initial 6 m/o. Other gaseous products were fluorine, chloryl fluoride, and occasionally chlorine dioxide and perchloryl fluoride. Large quantities of chlorine trifluoride were entrained with the effluent chlorine pentafluoride. However, yields of chlorine pentafluoride of about 12%, substantially free of chlorine trifluoride, were obtained directly by starting with 0.6 m/o rather than 6 m/o of chlorine trifluoride. Conventional vacuum fractionation was used to remove the by-products.

Cathodic products.—Cathodic products were hydrogen, hydrogen chloride, and chlorine. When 0.6 m/o chlorine trifluoride was used as the starting anolyte, analysis of the products of a typical experiment gave a mole ratio for the above products of 1:0.1:0.02 (82% total cathodic yield). However, when 6 m/o chlorine trifluoride was used, the mole ratio found for a typical experiment was 1:20:6 (85% total cathodic yield). In this latter experiment, chlorine pentafluoride was also found in the cathodic gas stream, in an amount corresponding to an anodic yield of 8%. The chlorine pentafluoride was accompanied by chlorine trifluoride.

Table I. Effect of ClF_3 concentration on yield (current), divided cell

Mole % ClF_3 added to anolyte	% Yield ClF_5 (max.)	% Yield F_2
0.6	12-17	43-52
1.2	17	*
3	36	*
6	51	*

* Not analyzed.

Effect of concentration of chlorine trifluoride.—The yield of chlorine pentafluoride (from the anode compartment) as a function of chlorine trifluoride concentration in the anolyte is shown in Table I. The yield of fluorine obtained when small concentrations of chlorine trifluoride were present in the anolyte is also indicated.

Nickel dissolution.—Nickel was used almost exclusively as an anode material. During electrolysis in the undivided cell, in the hydrogen fluoride-sodium fluoride electrolyte, the current equivalent of the nickel weight loss was 9.5 ma/cm². Such electrolyses were routinely carried out during the electrolytic drying of HF; the equivalent current of the nickel weight loss was highly reproducible. Under the same conditions, but in the presence of 0.6 or 1.2 m/o of chlorine trifluoride, the current equivalents of the anode weight loss were about 4 ma/cm² or 2 ma/cm², respectively.

Studies of other anode materials.—Polarization curves of many materials[1] indicated that only one, Glassy Carbon (Tokai Electrode Manufacturing Company, Tokyo, Japan), had electrical characteristics close enough to nickel to be considered for use as an anode. Electrolysis in the divided cell with a Glassy Carbon anode substituted for nickel resulted in a 35% yield of chlorine pentafluoride after 3 m/o of chlorine trifluoride was added to the anolyte. Although no carbon tetrafluoride was found as an anodic product, complete disintegration of the anode into granular carbon occurred after several hours of operation.

Effect of impurities.—Chlorine pentafluoride was prepared using hydrogen fluoride drawn directly from the cylinder; however, smaller amounts of the oxygen-containing impurities chloryl fluoride, perchloryl fluoride, and chlorine dioxide resulted when the hydrogen fluoride was dried first. In either case, continued electrolysis oxidized the impurities more rapidly than the chlorine trifluoride, so that the quantity of oxygen-containing by-products decreased as a function of time.

Electrochemical data.—Representative anodic polarization curves determined on nickel in the divided cell in the hydrogen fluoride-sodium fluoride and hydrogen fluoride-sodium fluoride-chlorine trifluoride systems are shown in Fig. 4. The low-current portions of the curves are presented to focus attention on the potential region below that corresponding to the oxidation of the solvent. The higher current portions of the curves were not significantly different in the presence or absence of chlorine trifluoride. Polarization curves determined on sheet nickel electrodes in the undivided cell under steady-state conditions were similar to those presented in Fig. 4.

Discussion

Conditions are favorable in the hydrogen fluoride-sodium fluoride system (*e.g.*, indifferent electrolyte, high mobility of fluoride ion) for finding species which would be oxidized below the decomposition potential of hydrogen fluoride. It can be seen (Fig. 4) that, in the hydrogen fluoride-sodium fluoride-chlorine trifluoride system, no substantial oxidation process occurred below the potential corresponding to the oxidation of fluoride ion. During coulometric experiments chlorine

[1] Cu, Au, Zn, Cd, Al, Sn, Pb, Ti, Zr, Nb, Cr, Mo, W, Mn, Fe, Co, Monel, Carbon 371A, Graphite 8826, Pyrographite, Glassy Carbon, Si, and SiC.

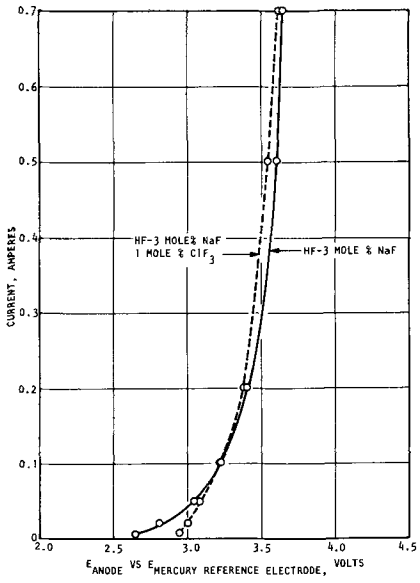

Fig. 4. Polarization curves, HF-NaF and HF-NaF-ClF_3 systems, porous nickel anode (area 66 cm²), divided cell, linear anodic scan rate, 0.17 v/sec, electrolyte temperature, *ca.* 0°C.

pentafluoride was not found at potentials below the decomposition potential of HF. It is concluded that ClF_3 is not electrochemically oxidized below the decomposition potential of HF. The rate of production of ClF_5 increased with increasing anode potentials above the decomposition potential for HF_2^-. Thus, while it may be possible that ClF_3 is directly oxidized at potentials near this decomposition potential, the similarity of the polarization curves (Fig. 4) suggests a common electrochemical reaction, namely the oxidation of fluoride ion.

In one series of experiments, fluorine was bubbled past a nickel anode under conditions which closely approximated those used during electrosynthetic runs, except that no current was passed from an external source. Chlorine pentafluoride was not found among the products. Both short circuit current, and potential measurements, gave no evidence for any electrochemical reaction.

It is postulated that the formation of chlorine pentafluoride results from a reaction at the anode, between chlorine trifluoride and electrochemically generated active fluorine.[2] The basic electrochemical step is shown as Eq. [1].

$$HF_2^- \rightarrow F\cdot + e^- + HF \qquad [1]$$

Subsequent steps are hypothesized which involve reactions of active fluorine with chlorine trifluoride, another active fluorine, or in the case of a nickel anode, with the metal.

$$ClF_3 + F\cdot \rightarrow [ClF_4\cdot] \qquad [2a]$$

$$[ClF_4\cdot] + F\cdot \rightarrow ClF_5 \qquad [2b]$$

$$F\cdot + F\cdot \rightarrow F_2 \qquad [3]$$

$$2F\cdot + Ni \rightarrow NiF_2 \qquad [4]$$

It is obvious from Eq. [2a] and [2b] that an increase in chlorine trifluoride concentration should cause an increase in the rate of formation of chlorine pentafluoride as observed (Table I). At the same time, since the rate of formation of active fluorine should be constant at constant cell current, less active fluorine should have been available for side reactions (Eq. [3] and [4]). Hence the observed large decrease in the extent of nickel dissolution would have been expected.

The participation of complex compounds of nickel has been suggested for the electrochemical fluorination

[2] For convenience, F· is used to represent active fluorine, but does not imply that the form of active fluorine is known.

of organic compounds (10). Since the synthesis of chlorine pentafluoride has been successfully demonstrated at a Glassy Carbon anode, the formation of complex nickel compounds as a necessary condition for the synthesis can be ruled out in this case.

In another investigation in this laboratory, it was found (4) that the following reaction (Eq. [5]) took place when small amounts of water reacted with chlorine pentafluoride dissolved in anhydrous hydrogen fluoride, in an all plastic system. Perchloryl fluoride

$$ClF_5 + 2H_2O \rightarrow ClO_2F + 4HF \quad [5]$$

and chlorine dioxide were also found when the reaction was carried out in metal. The presence of chloryl fluoride, perchloryl fluoride, and chlorine dioxide as products from the metal electrolytic cell could, therefore, easily have been a result of hydrolysis of the primary electrolysis product, chlorine pentafluoride.

Chlorine dioxide, also found as an impurity in the starting material, chlorine trifluoride, would be expected to have been oxidized at the anode during electrolysis, possibly according to the following equation. While Eq. [5] and [6] probably caused reduced

$$ClO_2 + F\cdot \rightarrow ClO_2F \quad [6]$$

yields of chlorine pentafluoride, oxygen-containing impurities were consumed so that the yields of oxygen-containing products decreased during the course of electrolysis.

A negligible degree of mixing occurred in the cell during electrolysis with low concentrations of chlorine trifluoride in the anolyte. Under these conditions, the cathodic product was essentially hydrogen, as expected. At higher concentrations of chlorine trifluoride, significant quantities of chlorine trifluoride were present in the catholyte. The cathodic products were then primarily hydrogen chloride and chlorine.

Acknowledgment

The research described in this paper was supported by the Office of Naval Research under Contract Nonr 1818(00). The suggestion of Dr. Emil A. Lawton that chlorine pentafluoride might be formed by the anodic oxidation of chlorine trifluoride was instrumental in initiating this work.

Manuscript submitted Oct. 2, 1968; revised manuscript received Jan. 20, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Formation of Chlorine Pentafluoride in an Electrochemical Cell

II. From Chlorine

Howard H. Rogers,* Rudolf Keller,* and Julian H. Johnson

Rocketdyne, A Division of North American Rockwell Corporation, Canoga Park, California

ABSTRACT

Galvanostatic experiments were performed at electrolyte temperatures near 0°C with chlorine in anhydrous hydrogen fluoride. Chlorine pentafluoride formed at current yields of up to 18%, and chlorine monofluoride, chlorine trifluoride, fluorine, nickel fluoride, and chloryl fluoride were also found. Both divided and undivided electrolytic cells were used, and the formation of hydrogen and hydrogen chloride at the cathode depended on the degree of mixing of anolyte and catholyte. While the most satisfactory anode was porous nickel, chlorine pentafluoride and chlorine monofluoride were also formed at sheet nickel anodes and at a Glassy Carbon anode. The rate of formation of chlorine monofluoride was found to be a function of the concentration of chlorine at the anode while the rates of formation of chlorine pentafluoride and chlorine trifluoride were not. The addition of chlorine at a nickel anode during electrolysis at constant current above a minimum current density caused a gradual rise in anodic potential. This rise was attributed to the formation of, or a change in, an anodic film. The polarization data were consistent with a mechanism that involved the anodic oxidation of fluoride ion to some form of active fluorine. Chlorine monofluoride, chlorine trifluoride, and chlorine pentafluoride were apparently formed by the stepwise reaction of the active fluorine with chlorine.

The oxidation of chlorine trifluoride during electrolysis in anhydrous hydrogen fluoride has been shown (1) to result in the formation of chlorine pentafluoride. It was of considerable interest to determine whether elementary chlorine also would react at the anode and be oxidized to the plus five state. This paper describes a study of the oxidation of chlorine during electrolysis in anhydrous hydrogen fluoride.

Experimental

Equipment including the electrolytic cells, procedures, experimental conditions, and analytical techniques were almost the same as those previously em-

* Electrochemical Society Active Member.

Key words: chlorine pentafluoride, electrolysis, hydrogen fluoride, electrochemical synthesis, chlorine.

ployed in the synthesis of chlorine pentafluoride from chlorine trifluoride (1). All yields were calculated on the basis of current, which was maintained constant during all electrolyses. Although both divided and undivided cells were used, most of the experimental work was carried out in the divided cell using a porous nickel anode (Kwikset Powdered Metal Products, Anaheim, California). Chlorine (Matheson High Purity Grade, 99.5% min.) was passed through the porous metal into the anolyte.

Cleaning of the anode was accomplished by washing with water and then heating to approximately 600° in a hydrogen atmosphere for several hours. Nickel fluoride hydrates that had not been removed by washing with water were converted to nickel, water, and hydrogen fluoride.

A Glassy Carbon anode (Tokai Electrode Manufacturing Company, Tokyo, Japan) was also used. Since this material is impervious, chlorine was passed through a series of small holes drilled into a Teflon plug placed in the lower end of the tubular carbon anode. This arrangement sufficed to test the effectiveness of the Glassy Carbon in the hydrogen fluoride-sodium fluoride-chlorine system.

Early experiments were carried out in the undivided electrolytic cell using a sheet nickel anode (2). This system was similar to those of Schmeisser (3) and Sartori (4). The chlorine was fed to the anode surface from a short length of pierced Teflon spaghetti tubing, attached along the bottom edge of the anode.

Partial pressures of chlorine monofluoride and chlorine trifluoride were calculated with the aid of the following formulas, where ΔA is the difference in infrared absorbance. The baseline method was used to obtain the data for Eq. [1]. More satisfactory results

$$P_{mm(ClF)} = \Delta A\ (500) + 10 \qquad \text{at } 788\ cm^{-1} \qquad [1]$$

were obtained when the difference in absorbance from the background was used to obtain the data for Eq. [2].

$$P_{mm(ClF_3)} = \Delta A\ (78) + 2 \qquad \text{at } 761\ cm^{-1} \qquad [2]$$

Results

Products.—The gaseous anodic products of the electrolysis of the system consisting of anhydrous hydrogen fluoride, 3 m/o (mole per cent) sodium fluoride and chlorine were found to be chlorine pentafluoride, chlorine monofluoride, chlorine trifluoride, fluorine, and chloryl fluoride. The oxygen-containing compounds resulted from impurities in the chemicals used. Typical yields in the divided cell were chlorine pentafluoride 12%, chlorine monofluoride 49%, and chlorine trifluoride 2%, at a current of 2 amp (30 ma/cm^2) and a flow rate of chlorine through the anode of 50 cc/min.

The primary gaseous cathodic product was hydrogen. However, hydrogen chloride was also found as a cathodic product as a result of mixing of anolyte and catholyte. Mole ratios of hydrogen to hydrogen chloride of 19:1 and 9:1 were found when chlorine flow rates through the anode were 10 and 25 cc/min, respectively.

Effect of chlorine flow rate.—The yield of chlorine pentafluoride was determined in the divided cell as a function of the flow rate of undiluted chlorine through the porous anode. It was found that the yield of chlorine pentafluoride increased as the flow of chlorine was increased from 10 cc/min to 60 cc/min. From 60 cc/min to the largest flow used, 100 cc/min, there was no further change in the yield.

Changing the flow rate of chlorine through the anode could have caused changes in the concentration of chlorine in the anolyte. In addition, the efficiency of the anode as a gas electrode could also have been affected because of changes in diffusion conditions. To isolate the effect of changes in chlorine concentration, the partial pressure of chlorine was varied in a chlorine-nitrogen mixture. The total gas flow was kept constant to minimize variations in the diffusion conditions at the gas electrode. In a separate experiment, nitrogen was found to be unreactive at the anode during electrolysis.

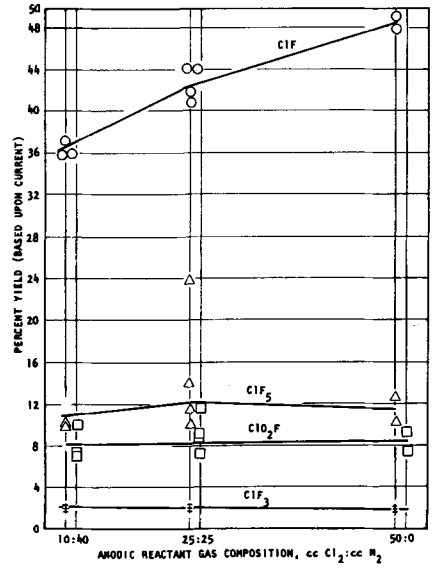

Fig. 1. Effect of partial pressure of Cl_2 on yield, electrolyte temperature, *ca.* 0°C.

The results (Fig. 1) show that the amount of chlorine monofluoride produced increased with increasing partial pressure of chlorine, whereas the chlorine pentafluoride yield remained constant. Furthermore, the amount of chlorine trifluoride determined in the gaseous products did not vary significantly.

After electrolysis had been carried out at a constant flow rate of a 1:4 chlorine-nitrogen mixture for 2½ hr, the chlorine flow was stopped and the nitrogen flow was increased to maintain a constant total gas flow. The yield of chlorine monofluoride decreased drastically from 37 to 15%, whereas the yields of the other products were unaffected (Fig. 2) during the period of measurement. Similar results were obtained when starting with undiluted chlorine.

Effect of impurities.—As with previous work when the starting material was chlorine trifluoride (1), oxygen impurities caused the yield of chlorine pentafluoride to decrease. The oxygen-containing by-product was primarily chloryl fluoride (Fig. 1), although small amounts of perchloryl fluoride and chlorine dioxide were occasionally found. As the amount of chloryl fluoride decreased during electrolysis in the divided cell, the yield of chlorine pentafluoride increased (Fig. 2). In another set of experiments when impurity levels were lower, 18% yields of chlorine pentafluoride were observed.

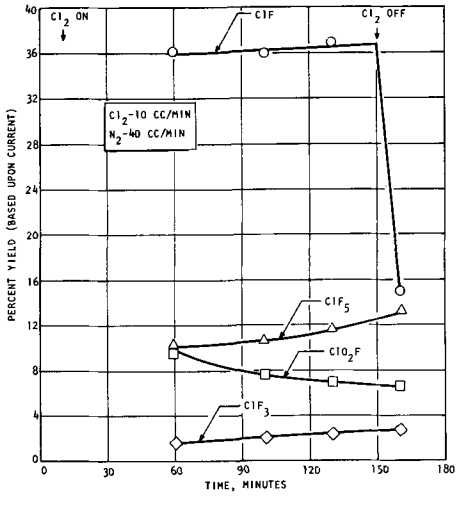

Fig. 2. Effect of Cl_2 on yield (total flow: Cl_2 + N_2 = 50 cc/min), electrolyte temperature, *ca.* 0°C.

Analysis of the anolyte at a time when the yields of chlorine pentafluoride and chloryl fluoride were approximately equal showed 0.015 m/o of chlorine dioxide.

Solubility of chlorine in hydrogen fluoride.—The anolyte was analyzed both before and after the addition of chlorine through the anode at a rate of 10 cc/min for 30 min. The concentration of chlorine at an anolyte temperature of —16° was 0.002 m/o. At —64°, the solubility of chlorine in hydrogen fluoride was found to be at least 2 m/o.

Electrochemical data.—Typical steady-state conditions for the formation of chlorine pentafluoride were: applied cell voltage, 7v at 2 amp (30 ma/cm^2) in the divided cell using a porous nickel anode, or 1 amp (15 ma/cm^2) in the undivided cell using a sheet nickel anode. Variations of the cell voltage as great as ±2v were observed in steady-state operating conditions.

Electrolysis (undivided cell) in the hydrogen fluoride-sodium fluoride-chlorine system with a nickel anode was accompanied by a characteristic, gradual rise in measured anode potential from about 4 to 6v. This rise was obtained only when the current was sufficiently large (Fig. 3), and only after the introduction of chlorine (Fig. 4); inert gas was ineffective. Chlorine pentafluoride was not found as a product unless the anodic potential had risen to the 6v level.

Representative anodic polarization curves determined on nickel in the divided cell in the hydrogen fluoride-sodium fluoride and the hydrogen fluoride-sodium fluoride-chlorine systems are shown in Fig. 5 and 6. As in the previous paper (1), the low-current portions of the curves (Fig. 5) are presented to focus attention on the potential region below that corresponding to oxidation of the solvent. The higher current portions of the curves (Fig. 6) are shown to illustrate the effect of the characteristic rise in potential on the polarization curves.

Polarization curves taken in the undivided cell with sheet nickel electrodes were similar to those taken in the divided cell with a porous nickel anode (Fig. 5 and 6). It was found, however, that a current of at least 2 amp was required to initiate the characteristic rise in potential at the porous anode compared to a current of 0.5-1.0 amp found for the sheet nickel anodes. The electrochemical data obtained from the divided cell with a smooth nickel anode were similar to that obtained in the undivided cell with sheet nickel electrodes.

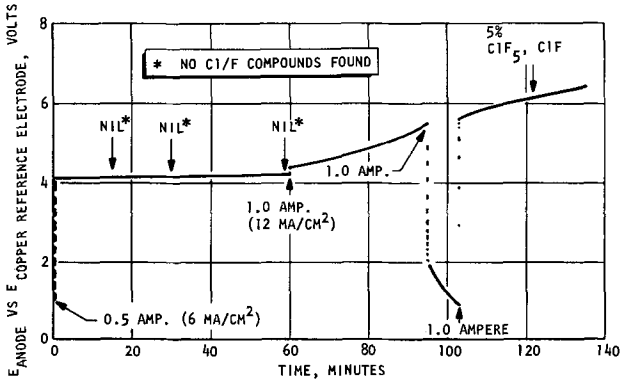

Fig. 3. Behavior of anode potential during a typical run with HF-NaF-Cl$_2$ system, undivided cell, electrolyte temperature, *ca.* 0°C.

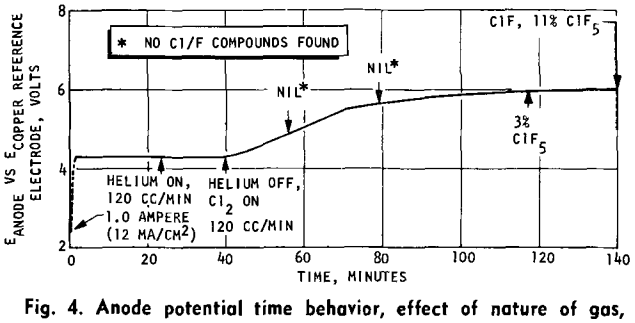

Fig. 4. Anode potential time behavior, effect of nature of gas, electrolyte temperature, *ca.* 0°C.

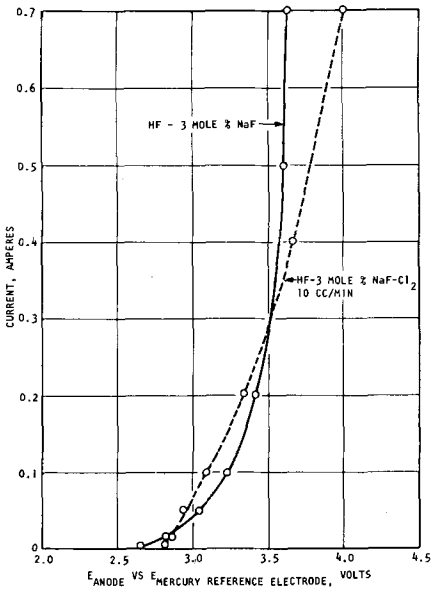

Fig. 5. Polarization curves, HF-NaF and HF-NaF-Cl$_2$ systems, porous nickel anode (area 66 cm^2), divided cell, linear anodic scan rate, 0.17 v/sec, low current region, after several hours electrolysis at 3.2 amp, electrolyte temperature, *ca.* 0°C.

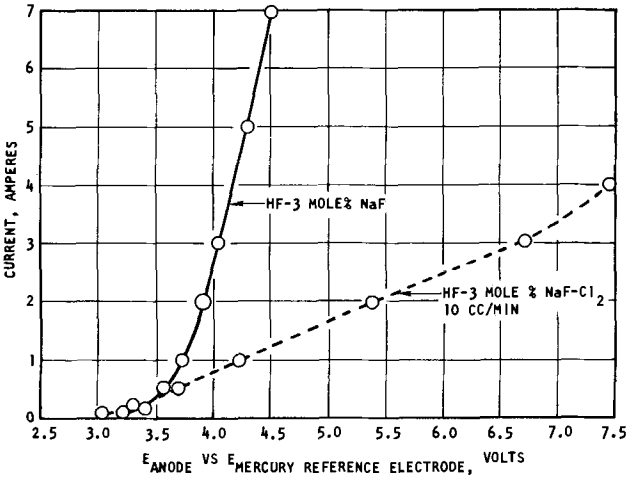

Fig. 6. Polarization curves, HF-NaF and HF-NaF-Cl$_2$ systems, porous nickel anode (area 66 cm^2), divided cell, linear anodic scan rate, 0.17 v/sec, high current region, after several hours electrolysis at 3.2 amp, electrolyte temperature, *ca.* 0°C.

When a Glassy Carbon anode was substituted for a nickel anode in the divided cell, yields of chlorine pentafluoride of 3.5% and of chlorine monofluoride of 4.3% were obtained at a constant current of 2 amp, an applied voltage of 8v, and a chlorine flow rate of 50 cc/min. The gradual rise in potential, which was characteristic of nickel, was not observed with Glassy Carbon. Instead, a rapid 1.5v increase was observed 3 min after the introduction of chlorine. However, potentials at the Glassy Carbon anode were erratic during the first 40 min of electrolysis.

Discussion

The oxidation of chlorine at the anode in a hydrogen fluoride-sodium fluoride electrolyte seems to take place by a mechanism generally similar to that proposed (1) for the anodic oxidation of chlorine trifluoride. Examination of the polarization curves (Fig. 5) for the

hydrogen fluoride-sodium fluoride-chlorine system shows that no substantial oxidation process occurs below the potential corresponding to the oxidation of fluoride ion. As in the oxidation of chlorine trifluoride (1), the similarity of the polarization curves (Fig. 5) again suggests a common electrochemical reaction (Eq. [3]).

$$HF_2^- \rightarrow F\cdot + e^- + HF \quad [3]$$

Subsequent steps probably involve the reaction of active fluorine with chlorine-containing species, as shown below.

$$Cl\text{-}Cl + F\cdot \rightarrow ClF + Cl\cdot \quad [4]$$

$$Cl\cdot + F\cdot \rightarrow ClF \quad [5]$$

$$F\cdot + F\cdot \rightarrow F_2 \quad [6]$$

$$Cl\cdot + F_2 \rightarrow ClF + F\cdot \quad [7]$$

$$\left.\begin{aligned} ClF + F\cdot &\rightarrow [ClF_2\cdot] \\ [ClF_2\cdot] + F\cdot &\rightarrow ClF_3 \end{aligned}\right\} \quad [8]$$

$$\left.\begin{aligned} ClF_3 + F\cdot &\rightarrow [ClF_4\cdot] \\ [ClF_4\cdot] + F\cdot &\rightarrow ClF_5 \end{aligned}\right\} \quad [9]$$

$$Ni + 2F\cdot \rightarrow NiF_2 \quad [10]$$

Chlorine monofluoride and chlorine trifluoride appear as intermediate products in this reaction sequence. Chlorine trifluoride, as the most soluble compound, accumulates in the electrolyte and its concentration directly affects the yield of chlorine pentafluoride (1). Chlorine monofluoride is soluble to a much lesser extent and its concentration in the electrolyte may be the limiting factor in the formation of chlorine pentafluoride from chlorine.

A change in chlorine partial pressure is equivalent to a change in the concentration of chlorine at the anode and thereby affects the yield of chlorine monofluoride (Fig. 1 and 2), according to Eq. [4], [5], and [6]. The yields of the other products are unchanged, apparently because the electrolyte is saturated with chlorine monofluoride so that its concentration is constant.

When oxygen-containing impurities (*e.g.*, water) are present, they compete with the intermediate products and are apparently preferentially fluorinated. The primary by-product is chloryl fluoride, which appears to be formed at the expense of chlorine pentafluoride. The yields of chlorine pentafluoride and chloryl fluoride are approximately inversely proportional.

Anodic polarization curves in the hydrogen fluoride-sodium fluoride-chlorine system with a nickel anode showed higher potentials at high currents than had been found for the hydrogen fluoride-sodium fluoride system alone (Fig. 6). At constant current, a characteristic gradual potential rise with time was observed above a minimum current density (6 ma/cm², Fig. 3) and only on the introduction of chlorine (Fig. 4). It was found that neither chlorine pentafluoride nor chlorine monofluoride was generated until the potential had reached 6v (Fig. 3 and 4). A possible explanation for the increase in potential is an increase in resistance at the nickel anode seen as a change in the slope of the polarization curves (Fig. 6). This increase in resistance may be attributed to the formation of, or a change in, a film at the anode.

It is of significance that the formation of chlorine-fluorine compounds is not dependent on the chemical nature of the anode material (nickel). Both chlorine monofluoride and pentafluoride were formed at a Glassy Carbon anode which had operating potentials close to that of nickel.

Electrochemical Behavior of Sulfide in Fused LiCl-KCl Eutectic

F. G. Bodewig* and James A. Plambeck**

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

ABSTRACT

Liquid sulfur has been reduced coulometrically in fused LiCl-KCl eutectic at 420°C. Nernstian behavior is observed for the cell C, S(l)/$S^=$, LiCl-KCl// Pt^{++}, LiCl-KCl/Pt. The standard potentials of the sulfur/sulfide couple at 450°C with respect to the appropriate standard platinum reference electrode are —1.008, —1.039, and —1.219v on the molar, molal, and mole fraction scales, respectively. Voltammetric studies showed an anodic wave at +0.03v ascribed to $2S + 2Cl^- \rightarrow S_2Cl_2 + 2e^-$ and a cathodic wave at —0.92v ascribed to $S + 2e^- \rightarrow S^=$. The diffusion coefficient of the (poly)sulfide ion was found to be 3.12×10^{-6} cm²/sec at 420°C by chronopotentiometric measurements. The observed blue color of sulfur-sulfide solutions is ascribed to polysulfide ions.

Solutions of heavy metal sulfides in fused chlorides are believed to be ionic (1-3), and a reversible sulfur vapor electrode has been used in a recent study (3) of the cell Ag/AgCl, Ag_2S/C, S_2(g) over the temperature range 490°-860°C. Kiukkola and Wagner (4) have measured the emf of the cell Ag(s)/AgI(s)/Ag_2S(s), S(l), C to obtain the standard molar free energy of formation of Ag_2S. A large body of emf data now exists in the fused LiCl-KCl eutectic at 450°C (4, and references cited therein); it therefore appeared de-

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.

sirable to obtain comparable data for the sulfur-sulfide couple. Sulfide has been studied voltammetrically in fused halides by Delarue (6, 7) and Rempel and Malkova (8), Delarue's work being in the LiCl-KCl eutectic. Potentiometric, voltammetric, and chronopotentiometric techniques were used in the present study.

Experimental

Apparatus.—Potentials were measured with a digital voltmeter (Model 3440A, Hewlett-Packard). Coulometric generations employed a Model IV Coulometric Current Source (E. H. Sargent and Company). An Anotrol Model 4100 Potential Controller modified to operate with a Model 4510 linear scan unit (Magna Electronics) was used for voltammetric investigations. Chronopotentiometric investigations employed a Model 6824A power supply-amplifier (Hewlett-Packard) in a constant current configuration controlled by appropriate mercury-wetted relay switching circuitry; measurements were recorded on a Hewlett-Packard Model 175A oscilloscope equipped with 1750B and 1781B plug-in units and a Model 196B camera using ASA 3000 Polaroid film.

The temperature of the 3 in. diameter vertical tube furnace was controlled by a Model 3120-SCR-477 temperature controller (Marshall Products Company). Temperatures were measured with a chromel-alumel thermocouple calibrated at the melting point of zinc.

The electrolytic cell and glassware preparation have been described previously (9).

Solvent.—The LiCl-KCl eutectic solvent [59.5 m/o (mole per cent) LiCl, mp 352°C] was prepared by the method of Maricle and Hume (10) modified as described below.

A total of 600g of the component salts was mixed and melted without previous drying. Chlorine gas dried over magnesium perchlorate was bubbled through the melt for 2 hr. After purging the melt with nitrogen for 4 hr, magnesium ribbon was introduced to displace any heavy metal ions. Subsequently, chlorine was again introduced to oxidize any magnesium metal that may have dissolved in the melt, followed by nitrogen. The molten eutectic was transferred to large test tubes in charges of 120-140g inside a glovebox purged with nitrogen. The test tubes were sealed and stored for future use.

Chemicals.—Reagent grade LiCl (Fisher Scientific Company) and KCl (Shawinigan Chemicals) were used. The sulfur (sublimed; Fisher Scientific Company) was dried at 100°C prior to use. Graphite electrodes were Special Spectroscopic Electrodes ⅛ in. in diameter (National Carbon Company). Nitrogen was purified over hot copper turnings and dried by passage through a magnesium perchlorate column.

Procedure.—The crucible containing the frozen eutectic and isolation compartments with electrodes was placed inside the outer glass jacket of the electrolytic cell which could be connected to a vacuum pump. Transfers of frozen eutectic to the jacket were made inside the glovebox. The outer jacket could also be closed off with a machined Teflon stopper with holes for up to five isolation compartments, a thermocouple, and a nitrogen inlet tube. The isolation compartments were made of Pyrex sealing tubes with 10-20μ frits (D porosity; Ace Glass Inc.) and protruded through the Teflon stopper. A hole below the Teflon stopper allowed entry of nitrogen into the otherwise closed compartments to equalize pressure. The temperature of the cell was then raised slowly to 420°-430°C under vacuum in order to dry thoroughly the glass equipment and electrodes before fusion of the eutectic. The compartments were allowed to fill with eutectic during a further 8 hr at this temperature. Finally, purified nitrogen was introduced and allowed to pass over the melt during all experiments.

A reference electrode based on the Pt(II)/Pt couple (about 0.04M) was generated coulometrically for each experiment by anodization of a 3 cm^2 Pt foil sealed into Pyrex tubing; a current density of 7 ma/cm^2 was employed. All potentials were measured against this reference electrode and are reported with reference to the Pt(II) (1.0M)/Pt standard molar platinum electrode (SMPE) (11), conforming to the IUPAC "Stockholm" sign convention. The counter and indicator electrodes each consisted of a graphite rod.

The boiling point of sulfur (444°C) being very close to the temperature of 450° at which the emf data were desired, it was necessary to work either with a vapor electrode or a liquid electrode and extrapolate from higher or lower temperatures to 450°. The liquid electrode appeared simpler [ref. (3) then not being available], and the sulfur electrode used consisted of an isolation compartment with a pool of liquid sulfur floating on the melt. Electrical contact with the pool was made by a graphite rod attached to Nichrome leads well above the sulfur pool. Sulfide was initially added to the compartment as Li_2S, but this proved unsatisfactory due to hydrolysis and the difficulty in transferring known amounts to the compartment. The addition of sulfide by cathodic coulometric reduction of the sulfur pool proved more satisfactory and was used for all experiments reported here. Precautions were taken to ensure that an excess of liquid sulfur was always present, and more was added as necessary.

The sulfide electrode emf was measured against the same reference electrode for each run which normally included three different sulfide compartments. During the course of one run the sulfide concentration in each of the compartments was successively increased by coulometric reduction of sulfur. The reduction product was blue in color (see below). The graphite electrode had a geometric area of about 2.5 cm^2 and a current density of 8 ma/cm^2 was employed. The thermoelectric potential between the graphite and platinum electrodes was found to be +1.5 mv with respect to the platinum electrode in the temperature range of 400°-450°C. All emf values were corrected accordingly.

The electrodes used in the chronopotentiometric investigations were gold wires (0.05 cm in diameter) suspended in the melt or rhenium wires sealed in glass. Other metals such as tungsten or platinum were unsatisfactory because they became coated, presumably with insoluble sulfide. The geometric area of the gold electrode was calculated from its diameter and depth of immersion, that of the rhenium electrode from its diameter and the length of metal exposed. The carbon rods used in the emf studies were also used as the voltammetric indicator electrodes.

The amount of solvent in each isolation compartment was determined by a potentiometric chloride analysis. When necessary, sulfide was removed from aqueous solution as H_2S by addition of nitric acid and purging with nitrogen. The concentrations of $S^=$ and Pt^{++} ions were determined from the coulombs passed and the solvent volume as described previously (11).

Least square calculations were carried out on the University of Alberta IBM System/360 computer.

Results

Standard potential of the sulfur-sulfide couple.—Five runs were carried out with new compartments, electrodes, and eutectic charge used in each. A total of 89 concentration-potential data points were taken over the range 400°-440°C, each point the mean of two potentials measured 15 min apart. In general the emf became constant, to within 0.5 mv, 15-30 min after coulometric reduction of sulfur had been terminated and did not change more than 1 mv over a period of several hours. The temperature of the melt was recorded at the time of each potential measurement. The effect of temperature on the emf was determined for various sulfide ion concentrations with both increasing and decreasing temperature. Plots of measured potential against temperature were linear over the range 400-440°C for a fixed sulfide ion concentration. Plots of $\Delta E/\Delta T$ against the logarithm of the molar con-

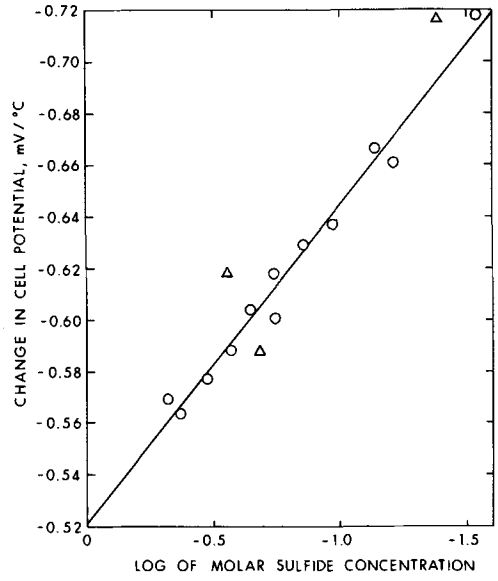

Fig. 1. Temperature dependence of potential as a function of sulfide ion concentration. Line is that given by least-squares analysis. Points indicated by triangles not included in least-squares analysis.

centration of sulfide were linear over the concentration range 0.03-0.5M as shown in Fig. 1. Least square analysis gave, for the temperature dependence of the cell (—)C, S(l)/$S^=$, LiCl-KCl//Pt^{++}, LiCl-KCl/Pt (+), $\Delta E/\Delta T = +0.124 \log [S^=] - 0.520$ mv/°C with a relative standard error of 4.4% in the slope and of 1% in the intercept. This equation was used to extrapolate all measured potentials to 450°. Linear Nernst plots were obtained for these extrapolated potentials over the concentration range 0.03-0.5M sulfide. Less stable potentials were obtained at lower sulfide concentrations. A typical plot of potentials against the logarithm of sulfide concentration (Fig. 2) shows that Henry's law is obeyed over the concentration range studied. A summary of all runs is given in Table I. Least square analysis of all points gave a standard potential (molarity scale) at 450°C of —1.008v with a standard deviation of 0.002v. This corresponds to values of —1.039v and —1.219v with the same standard deviation on the molality and mole fraction scales, respectively (11), all potentials being with respect to the appropriate standard platinum electrode. The slope of the Nernst plot was —0.0772 v/log unit with standard deviation of 0.0015, corresponding to a value of 1.86 ± 0.04 for the number of electrons taking part in the reaction. This is in good agreement with the theoretical value of 2 expected for $S + 2e^- \rightarrow S^=$.

* Two emf readings taken at each point 15 min apart, except for run 1; temperature converted to 450°C; all potentials given with respect to SMPE; each entry is a separate compartment, the first two being run 1 and the remainder, other runs with three compartments per run.

Voltammetric results.—Voltammetric scans of the pure eutectic melt with a graphite electrode gave the curve denoted by circles in Fig. 3. The potential was increased in the reduction direction and the current was measured after it had become constant (generally 5-10 sec). After addition of sulfur to the compartment, the curve denoted by triangles in Fig. 3 was obtained. For the cathodic rise, which we ascribe to the reaction S (l) + $2e^-$ → $S^=$, extrapolation of the lower part of the curve to zero current gave —0.92 ± 0.02v for the "decomposition" potential (mean and standard deviation of 5 experiments), in agreement with the potentiometric measurements cited above. We ascribe the anodic wave to the reaction 2S(l) + Cl^- → S_2Cl_2 + $2e^-$ which Delarue (7) estimated to occur at about —0.05v. The "decomposition" potential determined in this study is +0.03 ± 0.02v (mean and standard deviation of 5 experiments). These measurements were carried out at 420° ± 2°C as were all other voltammetric and chronopotentiometric studies reported here.

Voltammetric curves were also obtained in compartments in which sulfur was present and sulfide had been generated coulometrically at concentrations ranging from 0.1 to 0.5M. Two typical curves are shown in Fig. 4, obtained from two different concentrations in the same compartment. Identical straight lines were always obtained regardless of the direction of voltage change as long as precautions were taken to prevent significant change in the sulfide concentration between measurements. These precautions included stirring and, when necessary, oxidation or reduction such

that the zero-current potential remained within 3 mv of its original value. The slopes of these lines ranged from 10-15 ohms and represent the cell resistance. These curves show the sulfur/sulfide couple to be reversible under these conditions.

Chronopotentiometric results.—One set of measurements was made with an uninsulated gold wire indicator electrode (diameter 0.055 cm, area 0.43 cm^2), others with rhenium wire (diameter 0.062 cm, area 0.34 cm^2) sealed in Pyrex so as to isolate it from the liquid sulfur pool. A total of 67 anodic chronopotentiograms were obtained. Each contained a single transition whose $E_{\tau/4}$ (corrected for *IR* drop) was within 30 mv of the equilibrium emf for that sulfide concentration. The times for this transition, which we ascribe to $S^= \rightarrow S + 2e^-$, were measured and the results are summarized in Table II. All separate values of $i\tau^{1/2}/A$, except those obtained at 93.6 mmol/l sulfide, were subjected to least square analysis; this produced the linear plot of $i\tau^{1/2}/A$ against concentration shown in Fig. 5. This linearity indicates that the transition is diffusion-controlled and that the Sand equation $i\tau^{1/2} = \frac{1}{2}\pi^{1/2}nFACD^{1/2}$ is obeyed by the sulfur/sulfide system with both rhenium and gold electrodes. From the slope of the line in Fig. 5 and the Sand equation, the diffusion coefficient of the diffusing sulfide species was calculated to be 3.12, standard deviation 0.11, x 10^{-6} cm^2/sec at 420° ± 2°C. This value is almost an order of magnitude smaller than the smallest value reported for a divalent metal ion, Pb^{++}, which we calculate as 1.3 ± 0.2 x 10^{-5} cm^2/sec at 420°C from literature data (12), indicating that the diffusing species is a somewhat larger entity, perhaps a polysulfide ion $S_X^=$. There appears to be a trend towards smaller $i\tau^{1/2}/AC$ values with increasing sulfide concentration (Table II), but it is doubtful whether any significance can be attached to this in view of the standard deviations of these values.

Some of the curves indicated a very ill-defined second transition whose $E\tau/4$ was estimated as —0.08 ± 0.05v and which we therefore ascribe to $2S + 2Cl^- \rightarrow S_2Cl_2 + 2e^-$. No measurements of the transition time were possible due to poor definition and the proximity of chlorine evolution.

Some difficulty was encountered with deposition of sulfur on the electrode. It was necessary to strip off the sulfur produced in each chronopotentiogram cathodically and wait 10 min between polarizations for the solution to become uniform. Erratic results (extremely short transition times, probably due to blocking of electroactive surface) were sometimes obtained, apparently due to attachment of sulfur from the pool to the electrode. A small residual transition time was observed (intercept, Fig. 5), but it was much less than that reported by others (13) in fused salt media and can be ascribed to trace impurities and/or double layer charging.

Discussion

It is unfortunately not possible to compare the potential data for the cell Ag/AgCl, Ag_2S/C, S_2 (g) studied by Thompson and Flengas (3) with the results of this work since Ag_2S is completely miscible with AgCl but practically insoluble in the LiCl-KCl eutectic.

The standard potential of the $S^=$/S couple cannot be used to calculate thermodynamic functions of formation of metal sulfides in the LiCl-KCl solvent since metal sulfides (with the exception of lithium sulfide) have neither an anion nor a cation in common with the solvent (14). In the cell M/MCl_n, LiCl-KCl/LiCl-KCl, Li_2S/S (1), C employed in this study, the formation of M^{n+} and $S^=$ takes place in two separate cell compartments.

The present voltammetric studies appeared to be in disagreement with those of Delarue (6), who attributed an anodic wave in sulfide solutions at $E_{1/2}$ = — 0.45v to the reaction $S^= \rightarrow S + 2e^-$. His melt was not purified nor was an inert atmosphere used, and the sulfide was added as $Na_2S \cdot 9H_2O$ and an alkaline earth chloride. The necessity of scrupulously anhydrous and oxide-free melts has been discussed (10, 15), and it originally appeared that impurities in his melt might account for the discrepancy. On duplicating his experiment with a purified melt and a platinum stationary microelectrode, it was found that the voltammetric curves were not reproducible, but that waves of $E_{1/2}$ near —0.45v were sometimes obtained. The poor reproducibility was unaffected by addition of sulfur, $CaCl_2$, and/or water. The equilibrium potential at the microelectrode was always near —0.9v. The platinum surface immediately became dark on immersion in a melt containing sulfide. The discrep-

ancy between our work and that of Delarue appears to be due to formation of a surface layer, probably PtS, on the platinum electrode in his work. We have been unable to obtain reproducible voltammetric results with platinum electrodes in melts containing sulfide.

Delarue (6) has observed the formation of S_2Cl_2 in this solvent when a strong oxidizing agent was added to melts containing sulfur. We therefore ascribe the anodic wave, which we observe voltammetrically and, with less reproducibility, in the chronopotentiometric studies, to the reaction $2S(l) + 2Cl^- \rightarrow S_2Cl_2 + 2e^-$. From the data of Lewis and Randall (16) we calculate ΔG for this reaction as -12.6 kcal/mole at 420°C, while from our voltammetric curves we calculate -12.4 ± 0.9 kcal/mole at the same temperature, in excellent agreement. Our attempts to trap and identify the gaseous S_2Cl_2 product were, however, unsuccessful.

It has long been known that sulfur produces a blue color in certain solvents. This has been observed in fused KSCN (17, 18) and fused LiCl-KCl (19). The nature of the colored sulfur species has not been established, and the following experiment was therefore performed.

Chlorine was generated in a compartment on a graphite electrode to remove any remaining traces of impurities which could reduce sulfur to sulfide ion. The chlorine was then removed by repeated alternation of vacuum and nitrogen purging. Sulfur pieces, obtained by heating sublimed sulfur to 200°C and cooling under vacuum, were added to the melt. No blue color developed even after 1 hr. When sulfide was then generated by cathodic coulometry the blue color developed close to the electrode surface. On stirring the color spread throughout the compartment and was clearly visible at a concentration of about 10^{-5}M calculated as sulfide ion. Further cathodic generation intensified the color. The color disappeared when chlorine was generated or when the potential of the graphite electrode was held at -0.3v with respect to the SMPE, both resulting in oxidation of sulfide to sulfur. The color also disappeared under vacuum after about 2 hr and reappeared on addition of sulfur to the melt. We are unable to explain these results, which indicate that both sulfide and sulfur are necessary to produce the blue color, other than by postulating that the color is due to a polysulfide ion formed by sulfur and sulfide, *i.e.*, $S^= + xS \leftrightarrows S_{x+1}^=$ (blue). The molar extinction coefficient is so high, 16,600 (17), that a small amount of trace impurities present in the fused LiCl-KCl (19) could reduce enough sulfur to sulfide to produce the color. The situation in the fused KSCN system is more complex (17, 18, 20) but both sulfur and sulfide could well be present. Spectrophotometric studies of sulfur species in the LiCl-KCl system are now in progress.

On Dissolved Oxygen in Bulk Platinum

James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

The hydrogen overvoltage was determined on the front side of a bright Pt foil in $2N$ H_2SO_4 solution while the solution on the back side was stirred with H_2, N_2, or O_2. No change in the η was detected when the foil was connected as a diaphragm and when H_2 stirring was replaced with O_2 stirring on the back side. With the foil connected as a bielectrode, the η increased after an induction period depending on the thickness of the foil when H_2 stirring was replaced with O_2 stirring on the back side. These results indicate that under anodic polarization, oxygen can be dissolved in Pt. The dissolved oxygen can penetrate to the front side of the Pt foil where its presence as dermasorbed oxygen modified the catalytic activity of the Pt surface for the H_2 evolution reaction. In the absence of anodization, oxygen sorbed from solution can penetrate the Pt lattice no further than the dermasorbed region.

From a survey of the literature (1), it becomes obvious that the noble metals are not inert to oxygen. When oxygen is adsorbed from solution on a "bare" platinum surface a dissociative adsorption process takes place (2) resulting in the formation of a hydrated, adsorbed layer of oxygen atoms.

It is likely that the adsorbed oxygen can diffuse into the metal. Kalish and Burshtein (3) reported that the work function increased when oxygen was adsorbed on a Pt surface because of the presence of the negative dipoles of the adsorbed oxygen atoms. This effect was also observed by Giner and Lange (4). After about 11 hr, they (3) found that the work function decreased, which was interpreted to mean that some adsorbed oxygen had dissolved in the Pt. From repeated cathodic stripping determinations (3), the equivalent of about 3 or 4 monolayers of sorbed oxygen were detected. Rapid dissolution of oxygen in Pt was reported by Schuldiner and Warner (5), but this oxygen penetrated no further into the Pt surface than the first 2 or 3 atomic layers (5, 6). The term "dermasorption" was suggested (5, 6) to describe this form of occluded oxygen and to distinguish it from oxygen (known as absorbed oxygen) which had penetrated deeper into the metal lattice.

It is possible that anodization causes a penetration of oxygen into the metal lattice deeper than the dermasorbed layer. Supporting evidence for two kinds of sorbed oxygen is obtained from the results of stripping the adsorbed oxygen films with H_2 (7), from the hysteresis effects observed in potentiostatic polarization curves (8) and from triangular sweep traces (9-11).

Treatment with concentrated HNO_3 (12) causes even more oxygen to be dissolved in the Pt lattice to such an extent that it is referred to (13) as a Pt-O alloy. X-ray diffraction data (14) support this conclusion.

As noted in the literature (15-19), a preanodized Pt electrode has different electrochemical properties than one not preanodized, and this effect was explained (20) by the presence of dissolved oxygen in the Pt metal. The dissolved oxygen concept offers a possible explanation [ref. (20) p. 43] for the observation (21-24), that for charging curves obtained on Pt under certain circumstances, the amount of charge, Q_a, required to form a monolayer of adsorbed oxygen anodically is not equal to that, Q_c, required to remove it cathodically; but after a number of cycles of anodic and cathodic polarization, $Q_a = Q_c$.

To determine whether it is possible for oxygen to penetrate the Pt lattice more deeply than the dermasorbed region, an investigation of the diffusion of oxygen through thin platinum foils was undertaken. An account of the results of this work is presented in this report.

Experimental

Platinum lead wires were spot welded to small pieces of Pt foil about 1 cm square. The Pt foil was cleaned by repeatedly heating it to white heat in a burning H_2 jet followed by quenching in concentrated HNO_3. After cleaning, the foil was mounted with polyethylene washers between the compartments of a clean dual Teflon cell (7) in place of the usual glass frit. A Pt gauze counterelectrode, a small Pt gauze reference electrode, gas entrance and exit tubes through the cell tops, and a removable Pt wire preelectrolysis electrode are in each compartment. After the cell was assembled it was soaked in triply distilled water (with numerous changes of water) for at least 72 hr to leach out impurities. The cell was then filled (~20 cc per compartment) with $2N$ H_2SO_4, sealed, and preelectrolyzed for about 16 hr.

Purified hydrogen was bubbled through each compartment until virtually zero v was recorded between all pairs of Pt electrodes. Finally the steady-state, hydrogen-overvoltage curve was determined for stepwise increasing and decreasing current density on the front side of the foil with purified H_2, N_2, or O_2 bubbling in the back-side compartment. Note that H_2 is always bubbled in the front-side compartment. A constant current interrupter (25, 26) was used to correct for the solution iR and to monitor the cleanliness of the system by observing the pseudocapacitance of the H_2 reaction on the Pt foil (27). It was necessary to determine the iR correction for each reading because gas bubbles forming over the Pt surface caused large variations in the value of the solution iR, chiefly in the high current density region. To minimize mass transfer effects, the gases were bubbled through the electrolyte at rates above 300 cc/min.

Two electrical hookups were investigated; the Pt diaphragm (Fig. 1) and the Pt bielectrode (Fig. 2). In the diaphragm case only the front side of the foil was polarized while the back side was unpolarized. Both the front and the back sides of the foil were polarized when the foil was connected as a bielectrode. Since

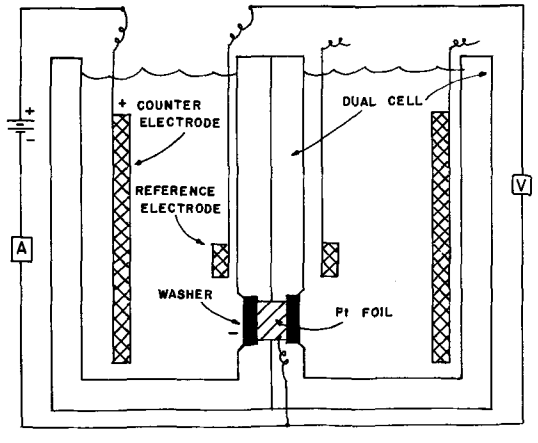

Fig. 1. Dual Teflon cell with Pt foil connected as a diaphragm

* Electrochemical Society Active Member.

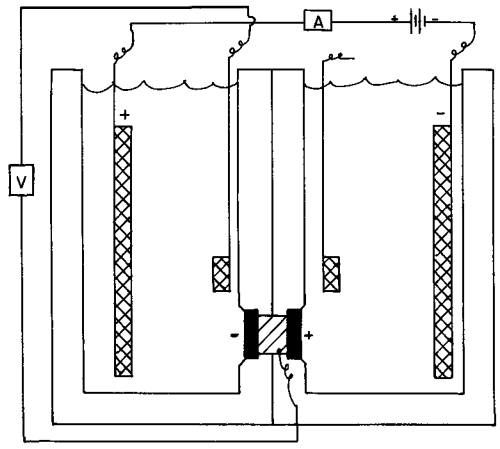

Fig. 2. Dual Teflon cell with Pt foil connected as a bielectrode. Notation same as in Fig. 1.

the iR correction cannot be determined in the bielectrode setup, the overvoltage was determined only over the low current density range where bubble formation on the cathode surface did not interfere with the iR readings and when the iR values obtained with the diaphragm set up could be used.

The hydrogen overvoltage, η, was studied on three thicknesses of Pt (99.9+% pure) foil; 0.00127, 0.00254, 0.00762 cm. Examination for pinholes was made by observing the foil with an intense light behind it. The temperature of this work was 24° ±1°C, and the potential was read on a General Radio Electrometer, Model 1230A.

Results

A plot of the hydrogen overvoltage as a function of the log of the apparent current density is given in Fig. 3 for a 0.00127-cm Pt diaphragm. It is seen that the data do not depend on the nature of the gas bubbled in the back-side compartment since they are the same for H_2, N_2, and O_2. The data points are the average values of at least four complete cycles of increasing and decreasing cathodic polarization on the front side of the diaphragm. Although the spread of data at the higher current densities extended over about 2 mv, the data at the lower current densities could be reproduced within ±0.3 mv. These data are in agreement with hydrogen overvoltage data recorded

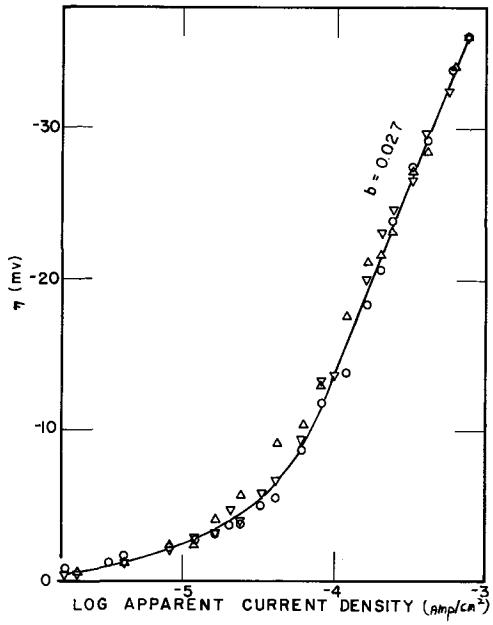

Fig. 3. Hydrogen overvoltage on the front side of a 0.00127-cm thick Pt diaphragm in 2N H_2SO_4 with H_2 (⊙), N_2 (△), and O_2 (▽) bubbling on the back side. Data points are the average of 4 complete cycles of increasing and decreasing polarization.

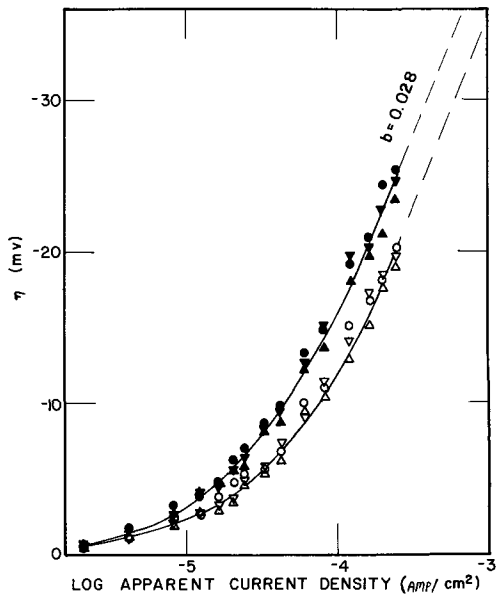

Fig. 4. Hydrogen overvoltage on the front side of Pt bielectrodes with thicknesses of 0.00127 cm (⊙), 0.00254 cm (△), and 0.00762 cm (▽) in 2N H_2SO_4. Open symbols are data with H_2 and filled with O_2 bubbling on the back side. Data points are the average of 4 complete cycles of increasing and decreasing polarization.

in the literature (28) for bright Pt in sulfuric acid electrolytes.

For the Pt bielectrode, Fig. 4, the η is higher with O_2 bubbling in the back-side compartment than with H_2, and although a thickness effect was not observed, a time effect was. After the H_2 in the back-side compartment was replaced with oxygen, the cell had to be polarized at the highest current density studied for a certain time before a change in the η could be observed on the front side of the Pt bielectrode. This induction period was independent of the time during which O_2 was bubbled through the back-side compartment before the polarization procedure was begun. It was difficult to determine exactly the length of the induction period since the change in η was a gradual process. However, at a current density of 0.25 ma/cm², it was estimated that it required a polarization time of about 20-30 min for the 0.00127-cm foil, about 90 min for the 0.00254-cm foil, and about 3-4 hr for the 0.00762-cm foil, before reproducible H_2-η data could be obtained. These data were reproducible within ±1 mv of the average value.

When the O_2 bubbling on the back side of the 0.00127-cm foil was replaced with H_2 again, the η on the front side did not return to the original curve until polarization was continued for several hours.

Discussion

When Pt is placed in contact with O_2-saturated acid solution, a partial monolayer of adsorbed oxygen atoms (Pt-O) is formed on the surface by a dissociative adsorption mechanism (2). Once this partial layer is formed, a local cell can be set up (1, 17) between the O_2/H_2O reaction

$$O_2 + 4H^+ + 4e \rightleftarrows 2H_2O \qquad [1]$$

and the Pt/Pt-O reaction

$$Pt\text{-}O + 2H^+ + 2e \rightleftarrows Pt + H_2O \qquad [2]$$

A steady state is reached after about 24 hr, and the system exhibits a mixed potential of 1.06v.

Schuldiner and co-workers (29) found that above about 1v, oxygen can be dissolved in the surface layers of the Pt metal. Ellipsometric studies (30) have shown that no changes in the platinum-oxygen system are observed until a potential greater than 0.98v is reached. Consequently, a Pt surface in contact with O_2-saturated

acid solution could, in time, dissolve oxygen in the metal derma (first 2 or 3 atom layers) under the driving force of the local cell action.

The data in Fig. 3 are consistent with this viewpoint since no effect was observed on the η on the front side of the Pt diaphragm when H_2 was replaced with O_2 on the back side. Because the back side is not polarized, O_2 is dissolved in the metal no deeper than the dermasorption region and cannot affect any process occurring on the front side of the Pt foil.

As noted by Schuldiner *et al.* (29), the dissolved oxygen penetrated more deeply than the derma when Pt was anodized at 1.7v because the effects of the dermasorbed oxygen could be detected for extended periods of time after the potential had been lowered below 1v. This observation was explained by diffusion of absorbed oxygen from the metal interior into the dermasorbed region.

In the bielectrode case, the front side of the Pt foil is cathodized while the back side is anodized. At a current density of 0.25 ma/cm^2, the potential of bright Pt in O_2-saturated acid solution is in the vicinity of 1.9v (31). It is possible for dissolved oxygen to penetrate into the interior of the Pt metal. As demonstrated in Fig. 4, the oxygen can diffuse all the way through the Pt foil to the dermasorption region of the front side where its presence is detected by catalytic effects on the H_2 evolution kinetics. When H_2 is replaced with O_2 on the back side of the Pt bielectrode, the hydrogen η on the front side increases after a certain induction period depending on the thickness of the foil. Since the value of the Tafel slope did not change, the electrode mechanism is the same whether the back-side compartment is stirred with H_2 or with O_2. The change in i_o, however, indicates that the catalytic nature of the cathode surface does change.

It has been reported (5, 32) that the presence of dermasorbed hydrogen or oxygen in Pt can exert catalytic effects on certain electrode reactions. In the present case, a similar explanation may account for the results shown in Fig. 4.

The rate-determining step for the cathodic evolution of H_2 on bright Pt is assumed to be the combination of adsorbed hydrogen atoms (Tafel mechanism) to form H_2 molecules (33)

$$H + H \rightarrow H_2 \qquad [3]$$

which gives a Tafel slope of $RT/2F$ (28)[1]. If the presence of dermasorbed oxygen in the cathode surface makes a tighter bond between the adsorbed hydrogen and the metal surface, this effect would slow down the hydrogen combination reaction with the resultant inincrease in η and decrease in i_o. The data in Fig. 4 are consistent with such an explanation.

This viewpoint also affords an explanation for the observation that replacement of the O_2 by H_2 on the back side did not lower the η on the front side immediately to the original value but only after an extended period of cathodic polarization (several hours) had been applied. Although dermasorbed oxygen is eventually removed by migrating to the surface to react with hydrogen, it can be replaced by the absorbed oxygen migrating from the interior of the metal. Under these conditions, it would require long periods of time before all of the dissolved oxygen could be removed by reaction with hydrogen. Once all of the dissolved oxygen is removed, the η falls to its original value as observed experimentally.

From the results of this work, it is possible to distinguish between two situations. In the first case, oxygen sorbed from solution penetrates the Pt lattice no deeper than the dermasorption region. In the second case under the influence of anodic polarization, the sorbed oxygen penetrates to much deeper levels of the Pt lattice than the dermasorbed region, and, in fact, oxygen may be made to pass completely through thin Pt foils. The presence of dermasorbed oxygen can modify the catalytic activity of the Pt surface for the hydrogen evolution reaction. Similar observations appear in the literature [*e.g.*, (5), (12), (15-19), (32)].

Other possible explanations for these observations involving the diffusion of hydrogen from the cathode to the anode side are not considered favorably because it was shown (34) that hydrogen would not diffuse through Pt foils which had clean surfaces. The high degree of cleanliness of the Pt surfaces used in this work was confirmed by the large pseudocapacitance observed on the pulses obtained from the current interrupter (28, 35).

[1] A H_2 diffusion-controlled process should show no dependence on the catalytic nature of the electrode surface.

Manuscript submitted Oct. 14, 1968; revised manuscript received Feb. 13, 1969. This paper was presented at the New York Meeting, May 4-9, 1969, as Paper 256.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Technical Notes

Cathodic Crossed Hydrocoupling of Acetone with Pyridine

Tsutomu Nonaka and Kiichiro Sugino*

Department of Applied Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan

In previous works (1), cathodic crossed hydrocoupling of acetone with activated olefinic compound was accomplished by using acrylonitrile and maleic acid as starting materials. In the case of acrylonitrile, more than 70% current efficiency was obtained, but in the case of maleic acid the current efficiency was only about 10%. A proposed mechanism for the crossed hydrocoupling and the reason for the difference in current efficiency in two cases were described there.

Further investigation of the cathodic process of acetone with other activated olefines has led to the discovery of the occurrence of a similar crossed hydrocoupling between acetone and pyridine. The current efficiency was as high as 70%. The reaction could be obtained at a potential of −1.30v *vs.* SCE at mercury. The product was a mixture of [2-(1,2,3,6-tetrahydro)-pyridyl]dimethylcarbinol, [2-(1,2,5,6-tetrahydro)pyridyl]dimethylcarbinol, and a small amount of 2-piperidyldimethylcarbinol.

Proof for the formation of the tetrahydro derivatives was the catalytic reduction of the products to the known 2-piperidyldimethylcarbinol and the oxidation with potassium permanganate to a mixture of β-alanine, glycine, α-hydroxyisobutyric acid, and oxalic acid.

Experimental

Electrolysis was carried out in an H-type cell with a sintered glass diaphragm similar to that described earlier (2) using a mercury cathode (area 12.6 cm^2) and a platinum disk anode. The catholyte consisted of a mixture of 14.2g (0.08 mole) of pyridine sulfate, acetone (40g) and 20% sulfuric acid (by weight) (40g); the anolyte was 20% sulfuric acid. The amperage varied from 0.82 to 1.02 amp and gave a cathodic current density of 6.5-8.1 amp/dm^2 (average 6.7 amp/dm^2). The electrolysis was carried out at about 20°C with a controlled cathode potential of −1.30v *vs.* SCE. The amount of current used was 4.23 amp·hr (0.158**F**).

After the electrolysis the catholyte was neutralized with 30-40% aqueous sodium hydroxide and the resulting solution was extracted with ether. Analysis by v.p.c. of the ether extract showed the formation of isopropyl alcohol (0.062g) and pinacol (0.008g).

The aqueous layer was concentrated under reduced pressure and made alkaline with 30-40% sodium hydroxide. The resulting oily layer was extracted with ether and analyzed v.p.c. using Triton 305X on Flusin T6 column at 160°C. The products were [2-(tetrahydropyridyl)]dimethylcarbinol (4.03g) and 2-piperidyldimethylcarbinol (0.42g). These migration times were 10.5 and 8.8 min, respectively, when the flow rate of carrier gas (hydrogen) is 40 ml/min (column diameter, 5 mm; length, 2m). These amounts represent current efficiencies of 73 and 11%, respectively. No piperidine could be detected, but the formation of propane was observed in the electrolysis.

Separation and identification of products was performed as follows. The ether extract containing the basic substances was dried over anhydrous potassium carbonate and gave a brownish oil after removing the solvent. By repeated distillation of the oil at reduced pressure, a fraction boiling at 102.5-103.5°C/19 mm was obtained as the main product; n_D^{30}, 1.4929.

Anal. Calcd. for $C_8H_{15}NO$: C,68.04; H,10.71; N,9.92
Found: C,69.02; H,10.86; N,9.95.

The picrate (recrystallized from benzene) melted at 129°-132°C.

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: C,45.41; H,4.90; N,15.13
Found: C,45.50; H,5.10; N,15.61.

The nitrate (recrystallized from absolute alcohol) melted at 85.5°-86.5°C.

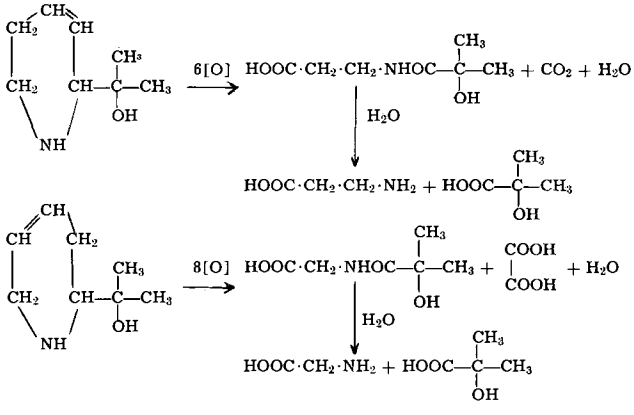
Anal. Calcd. for $C_8H_{16}N_2O_4$: C,47.05; H,7.90; N,13.72
Found: C,46.63; H,8.04; N,14.13.

The N-benzoate (recrystallized from benzene) melted at 101°-103°C.

Anal. Calcd. for $C_{15}H_{19}NO_2$: C,73.44; H,7.81; N,5.71
Found: C,73.25; H,7.81; N,5.60.

This product is a mixture of [2-(1,2,3,6-tetrahydropyridyl)]dimethylcarbinol and [2-(1,2,5,6-tetrahydropyridyl)]dimethylcarbinol since it absorbed one mole of bromine in acidic medium and absorbed one mole of hydrogen using a nickel catalyst and gave 2-piperidyldimethylcarbinol; bp, 107°-107.5°C/26 mm; $n_D^{28.5}$, 1.4777. The picrate melted at 138.5°-139°C. These properties and the infrared spectrum were identical with those of an authentic sample (3).

The location of the double bond in the 2-tetrahydropyridyldimethylcarbinol was indicated by the oxidation products obtained using potassium permanganate. 2-Tetrahydropyridyldimethylcarbinol (0.18 mole) purified by repeated distillation was oxidized with aqueous potassium permanganate (0.97 mole) in basic medium at 25°-32°C. The reaction mixture was concentrated and, then acidified with hydrochloric acid, gave an evolution of carbon dioxide. The resulting solution was again concentrated to a syrupy mass. After esterification with methanol, the syrup was subjected to distillation and gave dimethyl oxalate and a yellow viscous oil. The latter was found to be a mixture of the amides of α-hydroxyisobutyric acid with β-alanine methyl ester and glycine methyl ester, since it gave α-hydroxyisobutyric acid, β-alanine and glycine by hydrolysis with hydrochloric acid; bp 135°-138°C/2 mm, yield, about 20%. The oxidation reaction and the hydrolysis reaction were presumed to proceed as follows:



* Electrochemical Society Active Member.

(2-Piperidyl)dimethylcarbinol itself was also present, although in minor quantity, in the reduction product; it could not be separated from the main product by fractional distillation. The amount was determined however by gas chromatography.[1]

Two-Dimensional Electric Field between Elliptical and Wire Electrodes

G. N. Ellison

The National Cash Register Company, Electronics Division, Hawthorne, California

Continuous wire plating processes frequently require the use of single or multiple electrodes distributed around a substrate for electropolishing and electroplating operations. An asymmetric distribution of these electrodes around the substrate wire may result in an electric field symmetry which is enhanced or diminished by the substrate geometry. The current distribution resulting from this electric field is the "primary current distribution," *i.e.*, the current distribution for vanishing polarization. The following calculation treats the electric field from which the primary current results and is exact only when polarization phenomena are absent.

The theoretical analysis of the electric field is performed for the electrode geometry shown in Fig. 1. A grounded, conducting substrate with an elliptic cross section is used to provide the field asymmetry due to the substrate. A charged double wire electrode is placed above and below the substrate to test the possibility of compensating for the substrate asymmetry. The length and cross-sectional dimensions of the electrodes used in continuous wire plating processes are such that only the two-dimensional field in the x-y plane needs to be considered. Numerical results are given for the points P and Q on the ellipse.

Formulation of the Problem in Elliptical Coordinates

The transformation from the cartesian coordinates x, y to the elliptic coordinates μ, θ is given by (1)

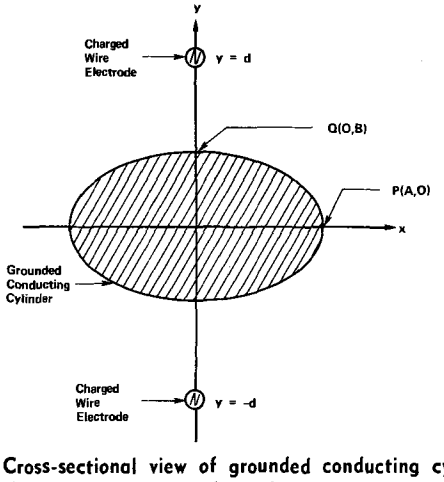

Fig. 1. Cross-sectional view of grounded conducting cylinder in presence of two charged wire electrodes.

$$x = (a/2)\cosh\mu\cos\theta,\ y = (a/2)\sinh\mu\sin\theta \quad [1a]$$

The coordinate μ is an ellipse with semimajor and semiminor axes given by

$$A = (a/2)\cosh\mu,\ B = (a/2)\sinh\mu \quad [1b]$$

respectively. The coordinate θ is measured in a counter clockwise direction from the positive x-axis.

The electric field $E\ (\mu_o, \theta)$ at the surface of the grounded conducting cylinder is given by the gradient of the potential ϕ in the direction normal to the surface μ_o defined by the conducting cylinder

$$E\ (\mu_o,\theta) \propto \frac{2/a}{(\cosh^2\mu_o - \cos^2\theta)^{1/2}}\left(\frac{\partial\phi}{\partial\theta}\right)_{\mu=\mu_o} \quad [2]$$

The potential ϕ is just the solution to Laplace's equation in elliptic coordinates. The potential is calculated in the following sections by superposition of the potential for the two line charges and the potential for the grounded conducting cylinder.

Potential Due to Two Line Charges

The potential of a single charge at μ_1, θ_1 is (2)

$$\phi = -2\mu - 2\ln a + 4\sum_{n=1}^{\infty}\frac{1}{n}e^{-n\mu_1}(\cosh n\mu\cos n\theta\cos n\theta_1 + \sinh n\mu\sin n\theta\sin n\theta_1)$$

A multiplying constant $\lambda/(\pi\epsilon_o)$ containing the line charge density λ and the free space permittivity ϵ_o has been eliminated by setting it equal to one. The potential due to the two line charges at $\mu = \mu_1$ and $\theta = \pi/2$, $-\pi/2$ is found by superposition to be

$$\phi = -4\mu_1 - 4\ln a + 4\sum_{n=1}^{\infty}\frac{(-1)^n}{n}e^{-2n\mu_1}\cosh 2n\mu\cos 2n\theta$$

Total Potential for Two Line Charges and Conducting Cylinder

The θ dependence of the potential due to the conducting cylinder can be written down immediately by noting that the symmetry about $\theta = 0$, $\pi/2$, $-\pi/2$ must be maintained. Clearly the angular dependence is then $\cos 2n\theta$.

The μ dependence is determined by the boundary conditions $\phi = 0$ at $\mu = \mu_o$, ϕ is finite or zero for $\mu_o = 0$, and

$$\frac{2/a}{(\cosh^2\mu_o - \cos^2\theta)^{1/2}}\left(\frac{\partial\phi}{\partial\theta}\right)_{\mu=\mu_o} = 0$$

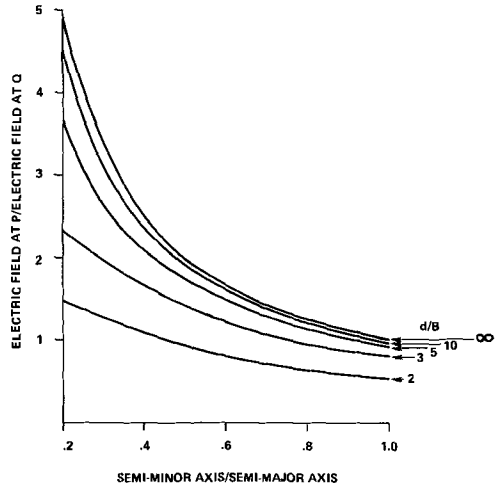

Fig. 2. Ratio of electric fields at points P and Q (see Fig. 1) of elliptic cylinder in presence of double wire electrode.

The multiplicative and additive constants are determined from the requirement that the potential due to both the cylinder and line charges is zero at $\mu = \mu_o$.

The potential ϕ_c due to the elliptical cylinder only is therefore

$$\phi_c = -4(\mu - \mu_o) + 4\mu_1 + 4\ln a - 4\sum_{n=1}^{\infty} \frac{(-1)^n}{n} e^{-2n\mu_1} \cosh 2n(\mu - \mu_o) \times \cosh 2n\mu_o \cos 2n\theta.$$

The total potential of the two line charges and the conducting cylinder is then

$$\phi = -4(\mu - \mu_o) + 4\sum_{n=1}^{\infty} \frac{(-1)^n}{n} e^{-2n\mu_1} \sinh 2n\mu_o \times \sinh 2n(\mu - \mu_o) \cos 2n\theta \qquad [3]$$

Electric Field at Extreme Points of Ellipse

The evaluation of the electric field requires the substitution of Eq. [3] into [2]. The infinite series in the final expression for the electric field at $\mu = \mu_o$ can be summed by writing the hyperbolic and trigonometric functions in their exponential form such that each term of the infinite series may be recognized as a term of a binomial expansion. The electric field at $\mu = \mu_o$ and any angle θ is then

$$E(\mu_o,\theta) = \frac{-2/a}{(\sinh^2\mu_o + \sin^2\theta)^{1/2}} \times \left\{1 - \left[\frac{(1+\tan^2\theta)\tanh(\mu_o - \mu_1)}{1+\tan^2\theta\tanh^2(\mu_o - \mu_1)} + \frac{(1+\tan^2\theta)\tanh(\mu_o + \mu_1)}{1+\tan^2\theta\tanh^2(\mu_o + \mu_1)}\right]\right\}$$

It is sufficient to compare the electric field at the two points P and Q (see Fig. 1) on the surface of the cylinder. The ratio of the electric fields is

$$\frac{E(P)}{E(Q)} = \frac{A}{B}\left[\frac{\tanh(\mu_o - \mu_1) + \tanh(\mu_o + \mu_1) - 2}{\tanh(\mu_o + \mu_1) + \tanh(\mu_o - \mu_1) - 2\tanh(\mu_o - \mu_1)\tanh(\mu_o + \mu_1)}\right] \times \tanh(\mu_o - \mu_1)\tanh(\mu_o + \mu_1)$$

where A/B is the ratio $E(P)/E(Q)$ for $d/B = \infty$. The coordinates μ_o and μ_1 can be determined in terms of A, B, and d using Eq. [1a] and [1b]. Figure 2 is a graph of $E(P)/E(Q)$ *vs.* the ratio B/A for several values of d/B. It is noteworthy that the double wire electrode has only a small effect on the electric field at the substrate for values of d/B greater than 10.

Stress in Thin Films of Silane Vapor-Deposited Silicon Dioxide

Richard Lathlaen and Donald A. Diehl

Philco-Ford Corporation, Microelectronics Division, Research and Development Department, Blue Bell, Pennsylvania

ABSTRACT

The stress in thin films of silane vapor-deposited SiO_2 on Si substrates was measured by an optical technique which is sensitive to changes in focal length. The optical method requires only a single measurement for each value of stress determined and, therefore, is suitable for processing a large number of samples. The equipment used to build the focal length measuring stand was inexpensive. The vapor-deposited films exhibited tensile stress which: (*i*) increased linearly as a function of film thickness, (*ii*) was a linear function of the logarithm of the SiO_2 deposition rate, and (*iii*) increased asymptotically to a constant value as a function of the volume ratio of oxygen to silane, for a constant deposition rate. A typical value for the stress of a 7500Å layer, plated at 4000 Å/min and 400°C, was 2.5 x 10^9 dynes/cm^2.

The low-temperature deposition of SiO_2 by the oxidation of silane is a relatively economical method of coating a microcircuit device with an insulating material which is chemically inert, electrically stable and physically strong. The method was reported by Evitts *et al.* (1), and a detailed description of the process was given by Goldsmith and Kern (2) and by Hammond and Bowers (3).

Vapor-deposited films can be used as the deposited dielectric in multilevel metallized integrated circuits.

Since the elastic condition of silane vapor-deposited SiO_2 was of interest, a sensitive, rapid, and easy to implement method of measuring the stress in thin films on silicon substrates was devised. The stress in thin films of chemically deposited SiO_2 was studied and was observed to be sensitive to the deposition parameters.

The study showed that it was practical to characterize empirically the effect of realistic permutations of the reaction ingredients on the elastic properties of the chemically deposited SiO_2 films.

Stress is a mutual force between contiguous surfaces, which in films is manifested by elastic deformation of the film-substrate pair. The chemical deposition of SiO_2 on a silicon substrate results in an imbalance of forces which deforms the composite Si-SiO_2 system until equilibrium is established. Therefore, the stress of the SiO_2 layer is reflected by the amount of deformation which the substrate must undergo to establish equilibrium. The rigorous mathematical expression for the stress of thin films on thick plates has been derived by Davidenkov (4).

Several authors have described methods by which the deformation of a thin, flexible, rectangular substrate which is clamped rigidly along one edge and free to deflect at the other can be measured (5-7). The edge deflection has been measured using a microscope (5), using a mechanical transducer (6), and as a function of the capacitance between the substrate and a nearby fixed metal plate (7). In general, either the methods were not amenable to the study of a large number of samples within a reasonable period of time or they required the use of expensive equipment. The calculations presented by Glang *et al.*, (8) were used as the framework for an experiment which permitted the stress of vapor-deposited SiO_2 films to be measured without the forenamed limitations.

According to Glang, the stress, σ, in films on thin circular single-crystal substrates can be written as follows

$$\sigma = \frac{1}{3}\frac{E}{1-\nu}\frac{t_s^2}{t_f}\frac{\delta}{r^2} \qquad [1]$$

Key words: thin film stress, vapor deposited SiO_2.

where E and ν are Young's modulus and Poisson's ratio, respectively, for the substrate; t_s is the substrate thickness, and t_f is the deposited film thickness. The quotient of the substrate deflection, δ, divided by the square of the distance r from the center in Eq. [1] may be considered as a functional unit and, consequently, be rewritten in a new form with an arbitrary parameter f. The term $1/4f$ can, therefore, be substituted for δ/r^2, where f is equivalent to the optical focal length of the paraboloid of revolution with a cross-sectional profile defined by the equation

$$4f\delta = r^2$$

Equation [1] may be rewritten in the form

$$\sigma = \frac{1}{12}\frac{E}{1-\nu}\frac{t_s^2}{t_f}\frac{1}{f} \qquad [2]$$

where $(E/1-\nu) = 2.30 \times 10^{12}$ dynes/cm^2 for <111> oriented Si substrates.

The technique which is described in the next section measures f in Eq. [2] instead of the deflection of the substrate at the edge.

Experimental Procedure

The silane vapor deposition system used to prepare the samples for this investigation has been described by Hammond and Bowers (3). The substrates that were used were 2-3 mils thick, <111> oriented Si single-crystals which were supplied by the Monsanto Company. The substrates were close to 3 cm in diameter and were chosen so that any inherent curvature was not measurable using the focal length measuring system described below. The substrates were held flat by a vacuum chuck inside the substrate pedestal of the hotplate to preclude their deformation during deposition.

The stress in the thin films of chemically deposited SiO_2 was determined by measuring the focal length of the substrates on which the films were deposited. A high intensity mercury arc lamp was used to illuminate a pinhole which was then optically positioned at infinity by a collimator. The exit pupil of the collimator could be varied between 1 mm and 1 cm. The collimated illumination was reflected by a front surface mirror on the substrate which was positioned horizontally on a microscope leveling stage. When the source and substrate were properly aligned, the light reflected from the substrate was directed along the optical axis of the system and viewed on a ground glass screen, with the aid of a partially reflecting surface inserted in the path of the illuminating beam of light. The components were rigidly mounted to a calibrated optical bench which enabled measure-

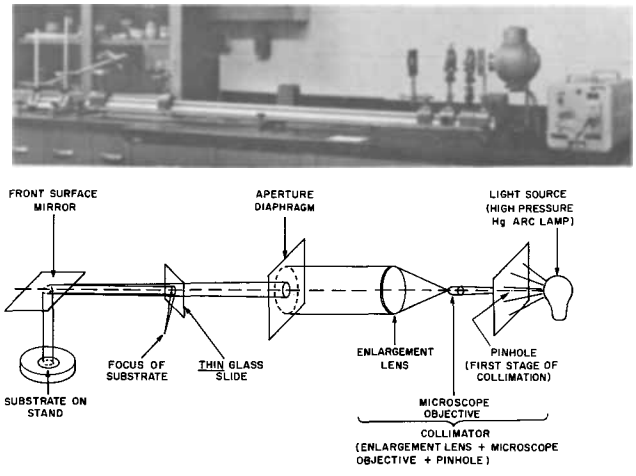

Fig. 1. Top, focal length measuring stand; bottom, path of the light relative to the components of the stand.

ments of the position of the focus of the substrate to be made accurately and reproducibly. Figure 1 shows a photograph and a schematic diagram of the optical stand.

Stress was measured as a function of three parameters of the SiO_2 film: (*i*) film thickness, (*ii*) deposition rate, and (*iii*) volumetric ratio of oxygen to silane. The films were deposited at 400°C and the stress measured at room temperature.

Each sample of vapor plated SiO_2 was prepared by one of two different ways for the measurement of stress as a function of film thickness.

1. An initial thickness of SiO_2 was deposited on a substrate, and subsequent thicknesses were obtained by selectively etching away the initial deposit.
2. A fresh layer of SiO_2 was deposited for each measurement of σ.

In both cases the deposition parameters were constant: 23 cc/min of silane was diluted by 7.6 l/min of N_2, then oxidized by 75 cc/min of O_2.

A fresh layer of SiO_2 7500Å thick was deposited for each measurement of stress as a function of the deposition rate and volume ratio of oxygen to silane.

The film thickness was calculated from the number of interference fringes of yellow light in a wedge formed using a chemical etchant. The deposition rates were calculated from the film thicknesses and deposition times, and the gas volume ratios were monitored by standard gas flow meters.

Results and Discussion

The chemical vapor-deposited SiO_2 films warped the substrates concave upward, thereby forming a real image of the light source; that is, the films were in tension. A typical value for the tensile stress of a 7500Å thick SiO_2 layer deposited at 4000 Å/min was between 2.4×10^9 and 2.7×10^9 dynes/cm^2.

Figures 2, 3, and 4 summarize the quantitative results of the work. Figure 2 is a plot of the stress *vs.* the thickness of the SiO_2 film for a constant deposition rate of 4000 Å/min and a constant volume ratio of oxygen to silane of 3.25 to 1. The range of SiO_2 thicknesses tested was from 3000 to 26,000Å. The graph shows that the stress was consistently higher for the freshly prepared films than for the films prepared by chemical etching. The stress was a linear function of the deposited film thickness for both cases.

Figure 3 is a plot of the stress *vs.* the deposition rate of the SiO_2 film for a constant film thickness of 7500Å and for three different volume ratios of oxygen to silane.

Figure 4 is a plot of the stress *vs.* the volume ratio of oxygen to silane for a constant film thickness of 7500Å and for three different deposition rates.

Figures 3 and 4 were obtained from the same body of data. Figure 3 shows the stress to be a linear function of the logarithm of the deposition rate. Figure 4 shows that the stress increases asymptotically to a constant value, as a function of the volume ratio of oxygen to silane, for a constant deposition rate.

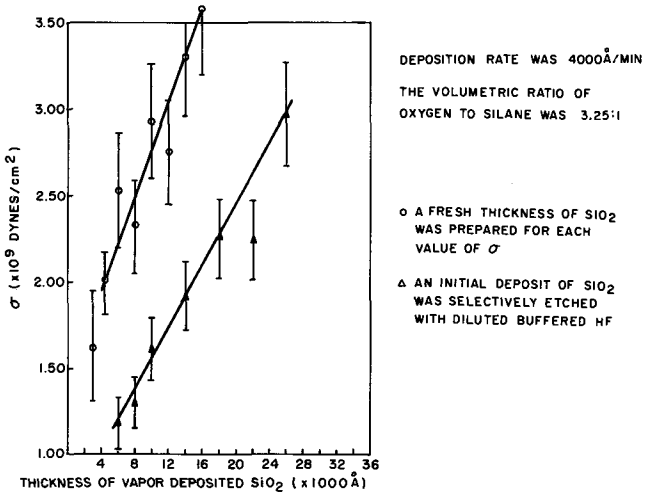

Fig. 2. Stress *vs.* thickness of the SiO_2 film. The deposition rate was 4000 Å/min and the volume ratio of oxygen to silane was 3.25 to 1. ○ A fresh thickness of SiO_2 was prepared for each value of σ. △ An initial deposit of SiO_2 was selectively etched with diluted buffered HF.

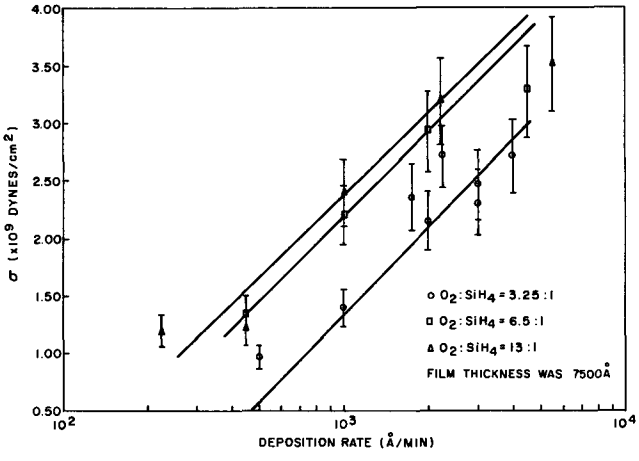

Fig. 3. Stress *vs.* deposition rate for constant oxygen to silane ratios. The film thickness was 7500Å. ○ O_2:SiH_4 was 3.25 to 1. □ O_2,SiH_4 was 6.5 to 1, △ O_2:SiH_4 was 13 to 1.

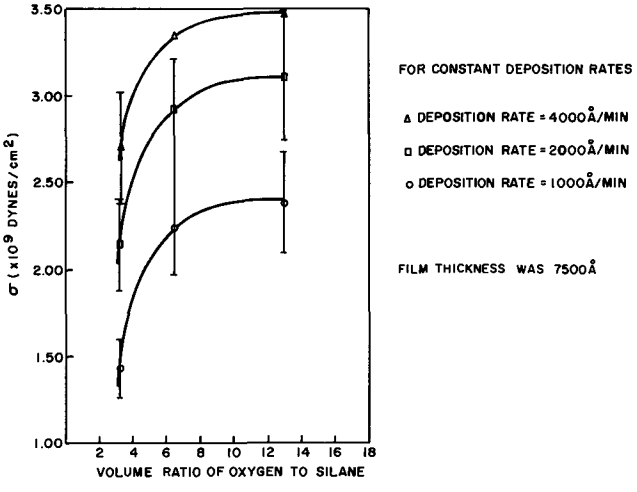

Fig. 4. Stress *vs.* volume ratio of oxygen to silane for constant deposition rates. Film thickness was 7500Å. △, The deposition rate was 4000 Å/min; □, deposition rate was 2000 Å/min; ○, deposition rate was 1000 Å/min.

Experimental errors and limitations.—Stress is a function of three independent variables in Eq. [2]: the substrate thickness, t_s, the film thickness, t_f, and the focal length, f. The error involved in the stress measurement is dependent on the uncertainty associated with each of the independent variables, and was calculated to be typically ±10%, but always less than ±17%.

The following uncertainties were estimated for each of the independent variables in Eq. [2], and for the abscissae shown in Fig. 2, 3 and 4:

1. The substrate thickness was measured gravimetrically, and had an error of less than 1%.
2. The uncertainty in the values of the film thickness was less than ±10%.
3. The error associated with the measurement of the focal length was governed by the factors sketched below and was typically ±10%.
4. The deposition rate errors were governed by the same factors which influenced the film thickness errors, and were, therefore, less than ±10%.
5. The error for the volumetric ratio of oxygen to silane did not exceed ±5%.

The boundary limits for the calculation of the stress are set by factors involving the measurement of the focal length.

The lower detection limit for stress was determined by the unevenness of the substrate. The measurement of the focal length involves the discrimination of the focus from neighboring regions of the reflected light beam. An uneven substrate distorts the geometry of the focus, so that the uniqueness of the focus with respect to neighboring regions of the reflected light beam is compromised. Consequently, the decreased maximum convergence angle of the reflected light at long focal lengths significantly influences the identification of the focus when the substrate is uneven. For example, at about 6 x 10^8 dynes/cm^2, the focal lengths for 2-mil thick substrates were approximately 100 cm, with a corresponding uncertainty of 50%. This was considered to be the lower limit of measurable stress.

The upper measurement limit of stress was fixed by the substrate thickness and the aperture of the collimated light beam. Equation [1] and, therefore, Eq. [2] are valid only when the maximum deflection measured is much less than the substrate thickness. Therefore, since the focal length is directly proportional to the ratio of the square of the beam diameter to the deflection at the perimeter of the illumination, an upper limit of permissible deflection impresses an upper limit to the stress that can be measured with a given substrate thickness and beam diameter. The upper stress limit for 2-mil thick substrates and a 1-cm beam diameter is 3.5 x 10^9 dynes/cm^2.

The upper measurement limit of stress could be raised by decreasing the aperture of the collimator and/or increasing the thickness of the substrate. However, since the aperture should be several times larger than the size of the average abberation in the surface contour of the substrate, the minimum useful aperture is determined by substrate unevenness. On the other hand, the sensitivity of measuring low values of stress decreases sharply by increasing the thickness of the substrate. Therefore, for a given film thickness, the maximum thickness of the substrate which can be used is determined by the minimum value of stress to be measured.

The optimum substrate thickness, t_s, for this experiment was found using Eq. [1] and letting r = beam diameter/2, $\delta = t_s/10$, and assigning realistic values to σ and t_f (see Fig. 2). The 2-mil thick substrates used in this experiment were approximately half the optimum substrate thickness calculated according to the procedure outlined above.

A constant uncertainty of ±10% was observed in locating the position of the focus. The error cannot be accounted for by the same factors which influenced the boundary limits of the stress. However, the eye is relatively insensitive to changes in brightness, which introduces a calculatable error into the judgment of the position of the focus. It is therefore likely that a large portion of the uncertainty can be accounted for by the lack of sensitivity of the eye.

The flatness of the substrate was characterized by two properties: (*i*) the focal length for zero stress, and (*ii*) the unevenness of the surface. The unevenness was given by the maximum possible normal component of the set of vectors connecting any two points of the surface, for zero stress. The focal length of all substrates used in this experiment was much longer than the detectable limit of the 200-cm long optical bench, and the unevenness was less than 1250Å when the stress was zero.

Conclusions

The optical method used to measure stress in this experiment required only a single measurement for each determination, and therefore was effective in processing a large number of samples. The equipment used to build the measurement apparatus was inexpensive.

In general, the stress of deposited films has two components: (*i*) the intrinsic stress, which is independent of the substrate onto which the films are deposited, and (*ii*) the thermal stress, which is due to different thermal expansion coefficients for film and substrate, and which results whenever the measurement temperature differs from the deposition temperature. The thermal stress is compressive because the thermal coefficient of expansion of Si is an order of magnitude higher than for SiO_2. An extrapolation of the data presented by Jaccodine and Schlegel (9) indicates that the thermal stress would not exceed 1.0 x 10^9 dynes/cm^2 for a layer 8000Å thick. Since the deposition temperature was constant in the experiment, the relative shapes of the curves in Fig. 2, 3, and 4 were not influenced by the thermal stress, and the curves can be considered to be characteristic of the intrinsic stress.

No theoretical model was suggested at this time by the observed dependence of the intrinsic stress on the deposition parameters.

Phosphors Based on Rare Earth Phosphates

II. Reflection Spectra of Rare Earth Phosphates

R. C. Ropp*

Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Because PO_4 does not absorb at wavelengths longer than about 2000Å, the rare earth phosphates, $LnPO_4$, where Ln is any rare earth (other than La, Pm, or Lu), represent an ideal system for the study of rare earth absorption. Reflectance spectra of all compounds are presented for wavelengths between 2000 and 8000Å. Only $TbPO_4$ and $EuPO_4$ produce luminescence when excited by the proper wavelength. Major, broad absorption bands are catalogued but not identified, except for that of Eu^{+3} and Tb^{+3}, where $Eu(III)O_n^{-2n} \rightarrow Eu(II)O_n^{-2n+1}$ and $4f^8 \rightarrow 4f^75d$, respectively, are the probable mechanisms.

A number of prior studies of rare earth absorption spectra have been reported (1), including infrared spectra (2), visible spectra (3), and ultraviolet spectra (4). Perhaps the most extensive of these was published by Jørgensen and co-workers (5). Most of their studies concentrated on the pure and mixed oxides which begin to show strong absorption bands around 2600-2800Å. It would have been desirable to extend their absorption studies at least to 2000Å, particularly in view of the assignments made by Jørgensen *et al.* (5) for the 4f → 5d transition bands and those made for charge transfer bands of the several rare earths. Their results were obtained by correlation of the expected positions of the 4f → 5d bands and also by the observed absorption edge of the oxides.

Because PO_4^{-3} does not absorb appreciably for wavelengths longer than 2000Å and because the peak absorption occurs close to 1800Å, as shown recently by Halmann and Platzner (6), one would hypothesize that rare earth phosphates should represent an ideal system for the study of far-ultraviolet spectra of the rare earths. Any absorption, (1 — R) observed for $LnPO_4$ compounds for wavelengths longer than about 2000Å could only be attributed to rare earth absorption.

A prior paper (7) has already shown that it is possible to obtain resolution of the order of 1-2Å in powder reflectance spectroscopy.

The rare earths occur in nature as xenotime, and monazite (orthophosphates) and as bastnasite and euxenite (fluorocarbonates and complex oxides, respectively). The synthesis of rare earth orthophosphates has been described previously. Fusion methods (8), hydrothermal crystallization from aqueous solutions (9), and chemical reactions (10) are some of the methods to be found. However, there are no previous reports on the absorption properties of the rare earth phosphates.

Experimental Methods

Method of preparation.—The rare earth phosphates were prepared by precipitation from an H_3PO_4 solution, as described previously (11). Since the solubility of the rare earth phosphates is an inverse function of precipitation temperature and a direct function of phosphoric acid concentration, it is possible to prepare crystalline materials of controlled particle size (see Fig. 1) by carefully adjusting the conditions of precipitation. Note that the distribution is size-limited, as would be expected for a chemical growth process. Crystalline materials can be obtained as mono- and hemi-hydrates as shown in Fig. 2, for YPO_4 and $LaPO_4$, respectively. Firing at 1200°C in air then gave crystalline materials with unit cells, as determined from x-ray powder diffraction patterns, whose values matched very closely with published data (12).

Chemical purity.—Commercial raw materials were employed, rare earth oxides having a stated purity of 99.9%, or better, while the H_3PO_4 employed was of reagent grade quality. The oxides were analyzed by spectrographic means and found to contain no detectable amounts of transition element impurities, minor amounts of Al and Si, and several parts per million of alkaline earths. Thus, the only major impurities were rare earths. Since the maximum was only about 1:1000 in ratio, the spectral properties measured are regarded as typical and not affected by the impurities

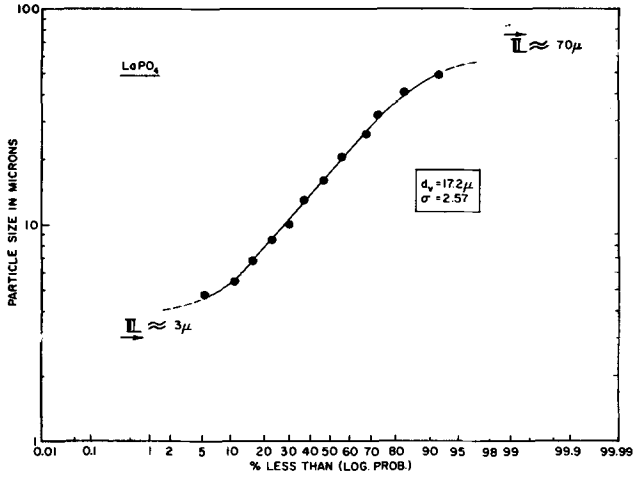

Fig. 1. Particle size distribution produced by precipitation

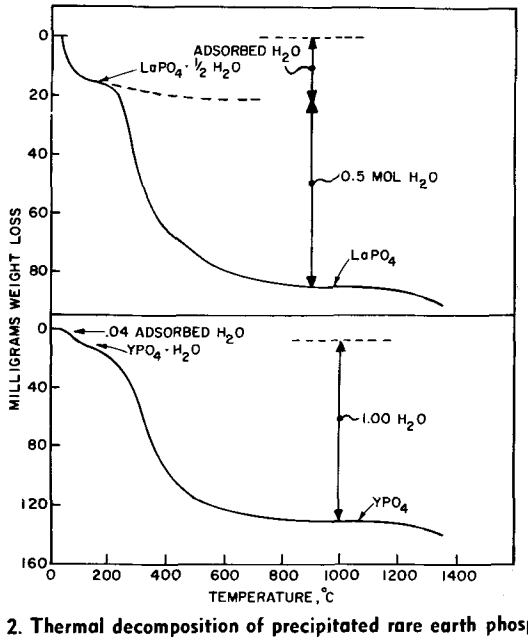

Fig. 2. Thermal decomposition of precipitated rare earth phosphates

* Electrochemical Society Active Member.

present. In addition, the method of preparation effects a further purification (with the exception of other rare earths) since both alkaline-earths and transition elements are complexed, not precipitated, by H_3PO_4 and tend to remain in solution.

Spectral measurements.—Excitation and emission spectra were obtained with the aid of a commercial instrument (13) having two monochromators. The excitation monochromator provided a constant energy excitation beam over the range of 20,000-50,000 cm^{-1} (5000-2000Å). Either monochromator could be programmed separately to provide excitation or fluorescence spectra directly, the former automatically corrected to constant energy, the latter compensated for instrumental energy losses. Resolution in the instrument varied from a few angstroms in the ultraviolet to about 10Å in the red region of the spectrum.

Reflectance measurements were made employing a double-beam Model 15 Cary spectrophotometer equipped with two diffuse reflectance heads, coated with $BaSO_4$. The method was described in detail previously (7).

Resolution.—Resolution of the absorption bands obtained in this work was sufficient to determine that, in most rare earth phosphates, the individual half-widths of the Stark components vary between 55 and 15Å.

However, in order to present a complete reflectance spectrum, as seen below, it was necessary to plot the experimental data on a compressed scale and just to indicate the number of Stark components observed, so as to show the broad bands observed more clearly.

Experimental Results

Structure.—Powder reflectance spectra were obtained for all rare earth phosphates, except for $CePO_4$, which could not be prepared in a pure form by the method. No broad band absorption was observed for YPO_4, and $GdPO_4$ up to 1980Å, the beginning of the phosphate absorption band. Transitions within the $4f^7$ multiplet of Gd^{+3} were observed, however. Various structures are formed by the rare earths, the lighter rare earths being monoclinic (monazite structure) and the heavier rare earth phosphates being tetragonal (zenotime structure). The x-ray diffraction pattern results determined in this study agreed very closely with those already published for the rare earth phosphates (10, 12). Mooney has already shown (10) that certain rare earth phosphates can exist in a low temperature hexagonal modification. Transition from the low to the high temperature form generally occurs below 1000°C (14). The materials studied herein all had the high temperature form, including $TbPO_4$, which is dimorphic.

Reflectance spectra.—$PrPO_4$.—Two broad absorption bands occur in the visible region of the spectrum as shown in Fig. 3, giving rise to the green body color of $PrPO_4$. The figures given in the parentheses in Fig. 3 show the number of individual Stark components observed. In Fig. 3, it is evident that the transition $^3H_4 \rightarrow {}^1D_2$ is greatly broadened in relation to the other transitions which form the band near to 4500Å. This latter band is composed of at least four separate

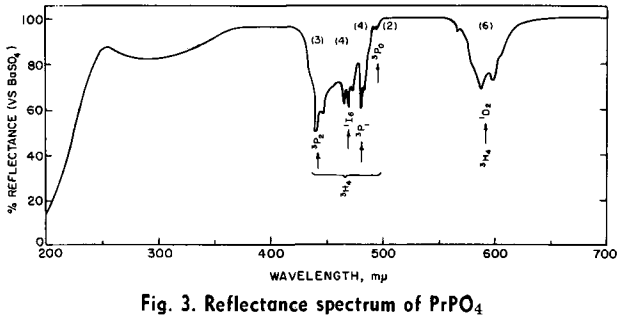

Fig. 3. Reflectance spectrum of $PrPO_4$

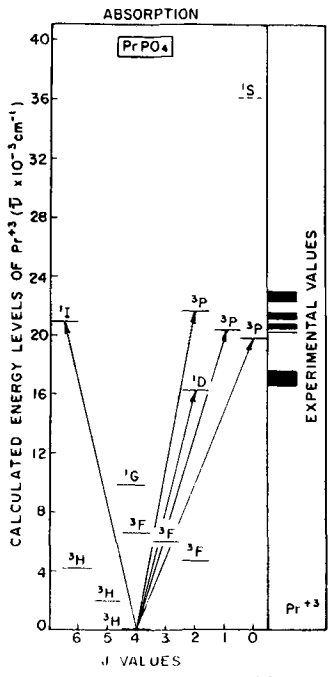

Fig. 4. Transitions found for Pr^{+3} absorption

transitions between $4f^2$ electron states. The average band width was estimated, from the chart, to be about 15Å, nearly three times those of the other phosphates. In Fig. 4 is presented a Grotrian diagram showing the transitions assigned for Pr^{+3}. Note that transitions from the ground state, $^3H_4$, to all known Pr^{+3} states were observed. Undoubtedly transitions to the other ^3H, ^3F, and ^1G states occur in the infrared region of the spectrum, a region not measured in the present work because of lack of instrumental capability. Table I shows the lines observed, transitions between Stark states, the transitions identified, and a comparison of the baricenters of the observed and calculated absorption bands.

There is another broad band which occurs around 3000Å and another whose peak lies below 2000Å. While identification cannot be certain for these bands, they are probably caused by transitions from the ground state to upper state configurations. Jørgensen *et al.* (5) have calculated the positions of these upper state levels to be about 32,000 cm^{-1} for the $4f \rightarrow 5d$ transition and 55,000 cm^{-1} for the charge transfer transition of Pr^{+3}. These values agree very well with those of the present work. However, Sugar (15) has also calculated the configurational levels of Pr^{+3} and surprisingly enough, a transition such as $4f \rightarrow 4f^{n-1}6p$ can occur as low as 3000Å even though the transition is partly forbidden. Apparently, the 4f ground state has a certain percentage of 6s character admixed with the 4f state, thereby raising the transition probability somewhat. At the present time, the broad bands cannot be positively identified.

$NdPO_4$.—$NdPO_4$ absorbs strongly in the green and yellow regions of the spectrum as shown in Fig. 5. Up

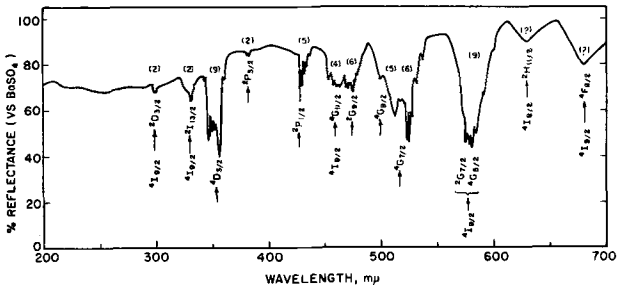

Fig. 5. Reflectance spectrum of $NdPO_4$

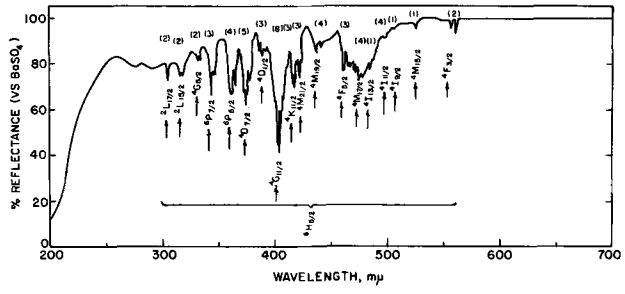

Fig. 6. Reflectance spectrum

to nine components were observed in some of these transitions. However, no broad band was observed in contrast to the results for Pr^{+3}. Neither did a band appear which could be considered the beginning of the phosphate absorption band. Table II gives the spectral data observed for $NdPO_4$.

$SmPO_4$.—$SmPO_4$ absorbs weakly in the blue and blue-green regions of the spectrum as shown in Fig. 6. The strongest absorption band occurs about 4000Å and is caused by transitions to a ^4G level. The numbers given in the parentheses are the number of components observed for each band. Table III gives the spectral data observed. Much of the complexity of Sm^{+3} arises from the fact that the $4f^5$ free-ion configuration of Sm^{+3} is characterized by 198 SLJ states involving sextet, quartet, and doublet states. In the presence of the crystal field (C_1 symmetry) each SLJ state splits into a maximum of J + ½ crystal sublevels (the Kramers degeneracy) to give rise to as many as 2002 crystal states. However, not all of these may participate in the absorption. Polarization data are required to unravel the crystal states which are responsible for the transitions observed.

In addition, there are also two weak, but broad, absorption bands near 2750 and 2900Å whose identity remains uncertain. Since these bands are broad, it is not believed that they can represent 4f →4f transitions. More likely they are upper-state transitions or phosphate absorption bands. The broad band at 2000Å cannot be identified with the present data.

$EuPO_4$.—The reflectance spectrum of $EuPO_4$ is given in Fig. 7. It is characterized by a very strong and broad absorption band occurring around 2300Å with a number of 4f → 4f transitions occurring in the near ultraviolet region of the spectrum. Of all the rare earth phosphates, the strong absorption band of $EuPO_4$, whose width is about 800-1000Å at the 50% point, appears at the lowest energy. The absorption bands representing 4f → 4f transitions were fairly narrow (about 4Å in width) with those from the ground-state to ^5D, ^5L, ^5G, ^5F multiplets being represented. It is interesting to note that, although transitions from the ground state, $^7F_6$, to all of the ^5D states do occur, transitions from an upper-state, $^7F_1$, to all of the same states were

also noted. There is little doubt that these transitions do take place and can be proved by comparing the number of Stark components observed, with those possible, as shown in Table IV. Thermal energy at 293°K is sufficient to populate the $^7F_1$ state. Since these levels produce fluorescence, their apparent intensity appears to be low and loss of resolution must certainly have occurred. However, experimental bands involving the lowest ^7F and ^5D states allow unequivocal assignment of transitions between these states. Table V presents the spectral data observed.

The broad absorption band observed in $EuPO_4$ is certainly much different than any observed, or described below, both in position and in apparent width. This is the charge transfer band for Eu^{+3} as asserted by Jørgensen (16) and Borchardt (17) for which substantiating data have been published by the author (18). The mechanism can be postulated as follows

$$Eu(III)O_n^{-2n} \rightarrow Eu(II_n^{O-2n+1})$$

There are probably a number of 4f states which are masked by the charge transfer band.

$TbPO_4$.—The body color of $TbPO_4$ is an off-white. A continuous decrease in the reflectance was seen as a function of shorter wavelengths as shown in Fig. 8 irrespective of the 4f →4f transitions of Tb^{+3} and may be due to the presence of Tb^{+4}. Table VI presents the assignments for Tb^{+3} transitions.

Table IV. Comparison of predicted and observed transitions

* G. S. O'Felt, *J. Chem. Phys.*, 38, 2171 (1963).

There is also a broad band occurring around 2100Å, which is the $4f^8 \rightarrow 4f^7 5d$ transition as noted by Jørgensen (6).

$DyPO_4$.—The ivory body color of $DyPO_4$ arises because of the lack of strong absorption in the visible region of the spectrum, as shown in Fig. 9. A great number of near ultraviolet bands were noted due to 4f → 4f transitions. Table VII gives the spectral data observed. It is notable that no broad bands were observed in this reflectance spectrum.

$HoPO_4$.—The body color of $HoPO_4$ is beige. A great number of absorption bands occurs in the visible region of the spectrum and throughout the ultraviolet with a large number of Stark components observed as shown in Fig. 10. Table VIII presents the spectra data measured. No broad bands were observed.

$ErPO_4$.—The pink body color of $ErPO_4$ can be attributed to the strong absorption bands occurring in the green region of the visible spectrum as shown in Fig. 11. A Grotrian diagram of the transitions assigned is shown in Fig. 12. Transitions to ^4F and ^4G multiplets were identified as well as those to individual ^2K, ^2H, ^2L, and ^2P states. Note that a broad band, was also observed. Table IX presents the spectral data observed.

$YbPO_4$.—The $4f^{13}$ configuration of Yb^{+3} is the "one-hole" conjugate of $Ce^{+3}(4f^1)$ and, with the exception of a $^2F_{5/2}$ level near 10,000 cm^{-1}, has no energy states much below 50,000 cm^{-1} (2000Å). Figure 13 shows the reflectance spectrum measured for $YbPO_4$. Only one broad band near 2200Å was seen which may be a charge transfer band (19).

Fluorescence.—Only two of these phosphates produced fluorescence when irradiated by ultraviolet. This is shown in Fig. 14 for $EuPO_4$ and $TbPO_4$.

$EuPO_4$.—Essentially the same emission spectrum was obtained as for Eu^{+3} in $LaPO_4$ [see Fig. 3, Part I (11)]. In the excitation spectrum, the band at 38,500 cm^{-1} (2580Å) can be identified as the charge transfer band, particularly since the relative intensity of this band changes with Eu^{+3} concentration in the $LaPO_4$:Eu phosphor, eventually showing that presented in Fig. 14, as the Eu^{+3} becomes 100%.

This excitation spectrum may be compared to the absorption spectrum (Fig. 7). One notes that $EuPO_4$ is not an efficient phosphor probably because of concentration quenching.

$TbPO_4$.—The emission spectrum of $TbPO_4$ is quite similar to that of Tb^{+3} in $LaPO_4$ ($LaPO_4$, $EuPO_4$, and $TbPO_4$ all have the same structure; YPO_4 does not). Thus, one concludes that emission occurs from the $4f^8$ energy levels of Tb^{+3} (21). In the excitation spectrum of $TbPO_4$, several separate bands appear which are not as distinct in the absorption spectrum (Fig. 8). In comparing the figures, it becomes apparent that the excitation band at 39,000 cm^{-1} (2550Å) could be assigned to the transition, $4f^8(^7F_6) \rightarrow 4f^8(^5F_2)$ while the

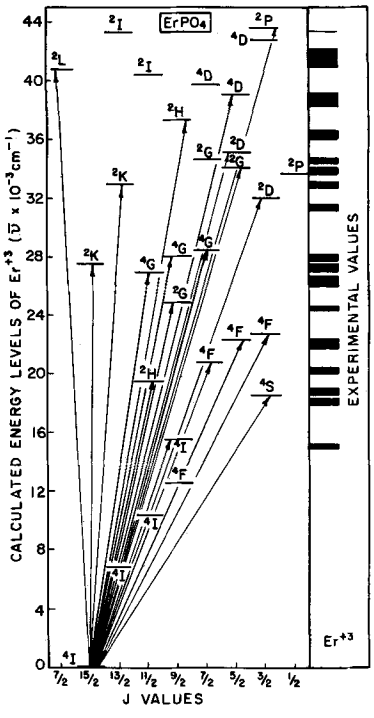

Fig. 12. Transitions found for Er^{+3} ion

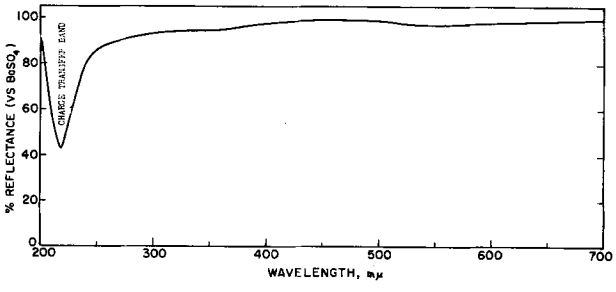

Fig. 13. Reflectance spectrum of $YbPO_4$

bands at 43,000 cm^{-1} cannot be identified with the present data.

Laser application.—It is apparent that several of these materials should be possible candidates for fabrication of lasers. Those materials which absorb in the visible region ($ErPO_4$, $HoPO_4$, and $NdPO_4$) could be used in conjunction with a high intensity xenon arc lamp, with selected activators such as Tm^{+3} and Pr^{+3}. Since the phosphate does not absorb, one should have a rare earth coupled system with host-sensitization as the main excitation process. Such systems should then

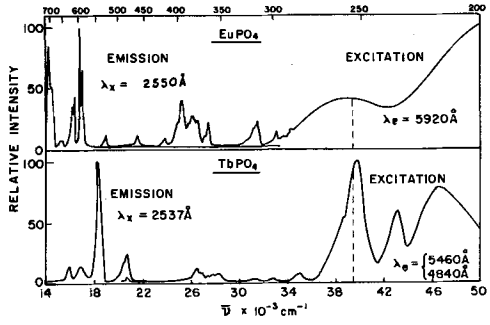

Fig. 14. Spectra of some rare earth phosphates

depend only on the coupling of the two rare earths. For such systems, low threshold values would be expected. In addition, fabrication of single crystals of rare earth phosphates has already been reported (14).

Conclusions

The absorption spectra (1 — R) of the rare earths, as phosphates, have been presented. It is interesting to note that 4f → 4f transitions were identified for all compounds except the $4f^{13}$ configuration ($YbPO_4$). Note that this ion has 4f energy levels between 10,000 and 12,000 cm^{-1} and that sharp line spectra would be expected only below 8000Å, a region not measured because of instrumental incapability.

In regard to luminescence, rare earth ions having ^7F ground states do not interact as strongly with their environment as those with H or I ground-states (21). Thus, only $EuPO_4$ and $TbPO_4$ would be expected to produce luminescence, as noted experimentally. In examining reflectance and excitation data, it becomes clear that excitation is a much more sensitive method of observing energy transitions, although the combination and comparison of both excitation and absorption data leads to conclusions not tenable with just one method of measurement. It has already been noted that only Eu^{+3} and Tb^{+3} produce broad excitation bands (11). It is of interest to summarize the origin of these bands. For Eu^{+3}, the band arises from a charge transfer transition involving nearest oxygen neighbors

$$Eu(III)O_n^{-2n} \rightarrow Eu(II)O_n^{-2n+1}$$

Thus, the efficiency should be dependent on the polarizability of the oxygen atoms. For the rare earth phosphates, where the oxygen atoms are covalently bonded within the phosphate group, phosphor efficiencies should be much lower because of the inherently higher saturation of charge within the PO_4 groups as compared to an individual oxygen atom whose 2p shells remain unfilled in an ionic matrix. This effect on efficiency has already been noted in a prior paper (11).

For Tb^{+3}, the primary band in $TbPO_4$ arises from a perturbed 4f → 4f transition ($^7F_6 \rightarrow {}^5F_2$) whereas in $LaPO_4$:Tb, the primary transition is probably $4f^8 \rightarrow 4f^75d$ in nature, with transitions involving other upper states not identified.

Eu^{2+} Luminescence in the Ternary EuO-Al_2O_3-SiO_2 System

P. M. Jaffe*[1]

Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

A study has been made of the ternary EuO-Al_2O_3-SiO_2 system. Several phosphors activated by divalent Eu were found, some of which are very efficient under u.v. excitation. Several new compounds containing divalent Eu are reported. Some of these are fairly efficient photoluminescent phosphors. The materials studied are Al_2O_3:Eu; SiO_2:Eu, Al_2O_3:Si,Eu; SiO_2:Al,Eu; $(1-x)Al_2O_3 \cdot xSiO_2$:Eu; $EuAl_2Si_2O_8$; $Eu^{3+}AlO_3$:Eu^{2+}; $Eu_2Al_2SiO_7$, and $Eu_6Al_{18}Si_2O_{37}$. All but the last two are luminescent.

An attempt to prepare Eu^{2+} activated sillimanite (Al_2SiO_5) by firing a 1:1 Al_2O_3:SiO_2 mixture containing 1 a/o (atom per cent) Eu in NH_3 resulted in a bright blue-white band emitting phosphor. X-ray analysis showed this phosphor to be mainly a mixture of Al_2O_3 and SiO_2 plus a trace of sillimanite and mullite ($3Al_2O_3 \cdot 2SiO_2$). In an attempt to identify the phosphor matrix, the ternary EuO-Al_2O_3-SiO_2 system was studied. As a result of this study, several other phosphors activated by Eu^{2+} were found. In addition, some new compounds containing Eu^{2+} were synthesized, some of which were luminescent.

Experimental Procedure

All phosphors were prepared from mixtures of Eu_2O_3 (Lindsay, 99.8%) and Mallinckrodt's SL $Al(OH)_3$ and SiO_2. The mixtures were slurried, dried at 110°C, and ball milled. Firings were done in silica crucibles for samples high in SiO_2 and in alumina crucibles for samples high in Al_2O_3. The firing atmosphere used was NH_3; somewhat similar results were obtained in H_2 or H_2-N_2 mixtures. Except where otherwise noted, the firings were done at 1250°-1350°C.

Emission spectra were obtained with a Bausch and Lomb 1/2 meter grating monochromator equipped with a wavelength drive. The spectra were corrected for spectral sensitivity of the photomultiplier and instrument transmission. The exciting sources were a 2537Å Germacidal lamp and a 3650Å 100w Hg lamp. Excitation spectra were taken with the same apparatus using a 150w d-c Xenon lamp. The excitation spectra are given relative to a 0.2% fluorescein solution which has a constant quantum efficiency from 250 to 500 nm (1). Diffuse reflectance spectra were obtained with a Beckman DU spectrophotometer equipped with a diffuse reflectance attachment. The data are reported as absorption spectra, using the relationship % absorption = (100 − % reflectance). Brightness measurements were made with a Spectra brightness spot meter.

Experimental Results

Al_2O_3:Eu^{2+} and SiO_2:Eu^{2+}.—Since the x-ray analysis indicated the main components in the 1:1 Al_2O_3:SiO_2 phosphor to be α-Al_2O_3 and SiO_2, these materials were first examined to see if one or the other was the primary phosphor matrix

Eu^{2+} activated SiO_2.—These samples were activated with 0.01-1.0 a/o Eu. They were given two 2-hr firings at 1250°C. After the first firing, the samples developed a strong electrostatic charge on grinding. This charge disappeared after the second firing. X-ray examination

* Electrochemical Society Active Member.
[1] Present address: Zenith Radio Corporation, Chicago, Illinois.

of these samples showed that increasing Eu caused an increase in crystallinity but no apparent compound formation. The body color varied from white to yellow and the emission shifted from blue to yellow with increasing Eu. The maximum blue emission was obtained with 0.05 a/o Eu. Figure 1 shows the emission spectra of samples containing 0.01, 0.1, and 0.5 a/o Eu excited by 2537Å u.v. The 3650Å u.v. excited spectra are similar but the emission peaks are shifted about 15 nm to longer wavelengths.

The absorption spectrum of the SiO_2:1 a/o Eu sample is shown in Fig. 2A. It consists of a broad band peaking around 275 to 300 nm, the intensity of which increases with increasing Eu. The excitation spectrum is shown in Fig. 3A. There are three peaks, increasing in intensity in the order 270, 300, and 330 nm.

Eu^{2+} *activated* Al_2O_3.—The effect of Eu concentration was examined over the range of 0.01-10 a/o. The body color of samples having 1 a/o Eu or less was white; the luminescence was weak blue. The 10 a/o Eu sample had a pale yellow body color and a green-yellow emission.

X-ray examination of the 0.1, 1, and 10 a/o Eu samples gave the following results:

0.1 a/o Eu	α-Al_2O_3 (S),	θ-Al_2O_3 (W)
1 a/o Eu	α-Al_2O_3 (S),	θ-Al_2O_3 (W), unknown (VW)
10 a/o Eu	α-Al_2O_3 (S),	$EuAlO_3$ (W)

(S = strong; W = weak.)

Most likely, the unknown material in the 1 a/o Eu samples is $EuAlO_3$. This compound will be discussed later.

The emission spectra from the Al_2O_3 phosphors containing 0.1, 1, and 10 a/o Eu are shown in Fig. 4. For 0.1 and 1 a/o Eu, the emissions are similar for 2537Å excitation but show a slight long wave broadening with 10% Eu. Under 3650Å excitation, the emission from the 0.1 a/o Eu phosphor is similar to that of the 2537Å excited phosphors. However, as the Eu concentration increases, there is a shift of the emission to longer wavelengths. This shift is due to emission from $EuAlO_3$:Eu^{2+} which is present as a separate phase.

The absorption spectrum of the Al_2O_3:1 a/o Eu phosphor is shown in Fig. 2A. There are several weak bands and one strong one all due to Eu^{2+}. The main band peaks at 275 nm. The excitation spectra of the blue emission is shown in Fig. 3A. It consists of three bands, two major ones at 310 and 350 nm, respectively, and one minor one at 270 nm.

The brightness of the best Eu activated Al_2O_3 and SiO_2 phosphors was much lower than the original 1:1 Al_2O_3:SiO_2 preparation (see also Table I).

Eu *activated* Al_2O_3 *with silica and silica with alumina.*—Since the Eu activated Al_2O_3 and SiO_2 were of low brightness, the possibility of limited solid solutions of Al_2O_3 in SiO_2 and vice versa was investigated. This was done by preparing the following two series of samples: (*a*) Al_2O_3:$x$$SiO_2$,1 a/o Eu where x = 0, 0.01, 0.05, 0.1, and 0.5 m/o; (*b*) SiO_2:xAl,0.05 a/o Eu where x = 0, 0.01, 0.05, 0.1, 0.5, and 1 a/o.

The Al was added as the hydroxide which was freshly precipitated from the nitrate.

After two 2-hr firings, the Al_2O_3:SiO_2,Eu phosphors had a fairly uniform emission. Increasing SiO_2 additions resulted in a shift of the emission, for 3650Å excitation, from blue to blue-green; for 2537Å excitation, the emission was blue for Eu concentrations below 0.05 a/o and blue-white for concentrations above. The intensity of the blue emission, measured through the blue Spectra spot meter filter, had a minimum at about 0.01% SiO_2.

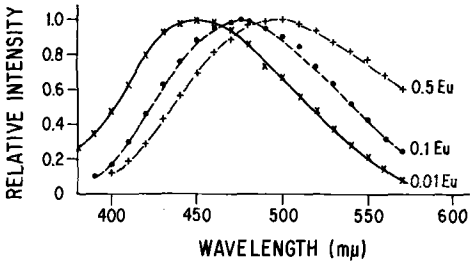

Fig. 1. Emission spectra for SiO_2:xEu^{2+} for 2537Å excitation. The 3650Å excited spectra are similar to the corresponding 2537Å excited spectra but are shifted about 15 nm to longer wavelengths.

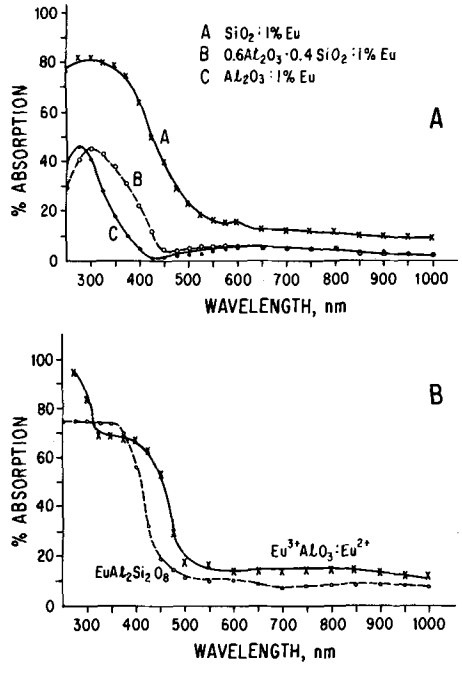

Fig. 2. Absorption spectra for (A) SiO_2, Al_2O_3 and $0.6Al_2O_3 \cdot 0.4SiO_2$; (B) $Eu^{3+}AlO_3$:Eu^{2+} and $EuAl_2Si_2O_8$, all containing 1 a/o Eu^{2+}.

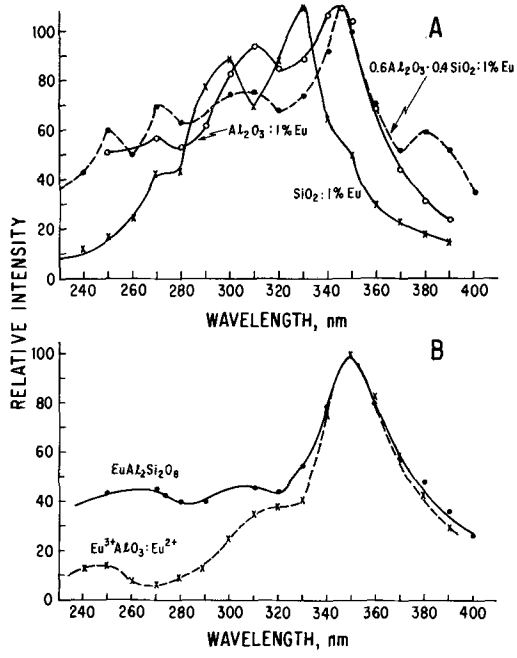

Fig. 3. Excitation spectra for (A) blue emission of SiO_2, Al_2O_3, and $0.6Al_2O_3 \cdot 0.4SiO_2$; (B) green emission of $Eu^{3+}AlO_3$:Eu^{+2} and green-yellow emission of $EuAl_2Si_2O_8$, all containing 1 a/o Eu^{2+}. The ordinate is proportional to the relative number of fluorescent quanta.

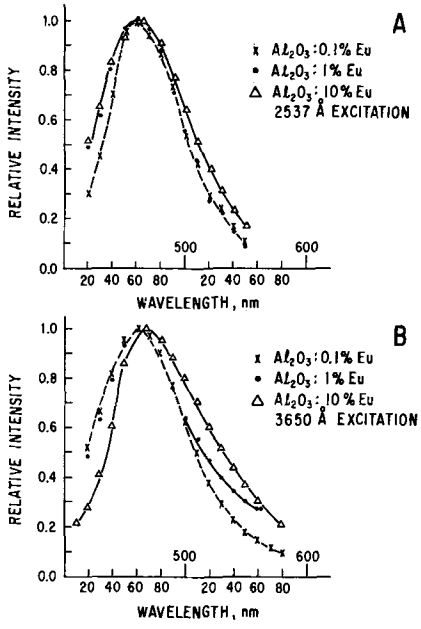

Fig. 4. Emission spectra of Al_2O_3:x a/o Eu^{2+}. (A) For 2537Å excitation; (B) for 3650Å excitation.

The emission of the SiO_2:xAl, Eu samples shifted from blue-green under 3650Å excitation and from blue-white under 2537Å excitation for zero Al to blue with increasing Al additions. The intensity of the blue emission progressively decreased with increasing Al.

In no case was the blue emission from these phosphors as bright as the original Eu^{2+} activated 1:1 Al_2O_3:SiO_2 or the mixed $Al_2O_3 \cdot SiO_2$ phosphors discussed in the next section.

The Al_2O_3-SiO_2 *system* (2).—Since the phosphor obtained by firing a 1:1 Al_2O_3-SiO_2 mixture was found to contain mainly Al_2O_3 and SiO_2 plus some mullite, no further attempts were made to prepare the 1:1 compound.

A sample of almost pure mullite activated by Eu^{2+} was obtained by a series of firings at 1250°C for a total time of 100 hr. The resultant phosphor was much less bright than a sample having the same raw mix composition but having two 2-hr firings. X-ray analysis of the latter phosphor showed it to be primarily a mixture of α-Al_2O_3 and SiO_2 plus a trace of mullite. The emission spectra of these two phosphors, however, were similar.

Since these data indicated that mullite was not needed to give a bright phosphor, no further work was done with it.

The effects of compositional variations, at constant added Eu (= 1 a/o), on the mixed Al_2O_3-SiO_2 system, were examined. Samples having the raw mix composition $(1-x)Al_2O_3 \cdot xSiO_2$ where x varied from 0 to 1 were prepared by firing at 1250°C for 2 hr. X-ray examination of this series showed them all to be essentially the same, namely a mixture of Al_2O_3, SiO_2, and a trace of mullite.

The intensity of the blue emission from this series is shown in Fig. 5. There is a maximum around the composition $0.3Al_2O_3 \cdot 0.7SiO_2$. The brightness of several of these phosphors relative to ZnS·Ag and $CaWO_4$:Pb is shown in Table I. It must be pointed out that even though these phosphors have not been optimized, they have high brightness.

The effect of Eu concentration was examined for both the $0.6Al_2O_3 \cdot 0.4SiO_2$ and $0.3Al_2O_3 \cdot 0.7SiO_2$ raw mixes. The Eu concentration was varied from 1.7 x 10^{-3} to 2.2 a/o. The results for both compositions are similar and are shown in Fig. 6. For both 2537 and 3650Å excitation, the optimum Eu concentration is about 1 a/o.

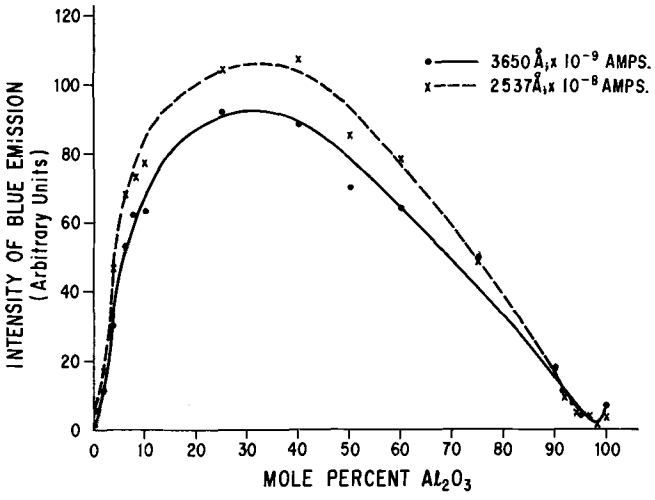

Fig. 5. Intensity of the blue emission from $(1-x)Al_2O_3 \cdot xSiO_2$:1 a/o Eu^{2+}. Data given for excitation by 2537 and 3650Å radiation.

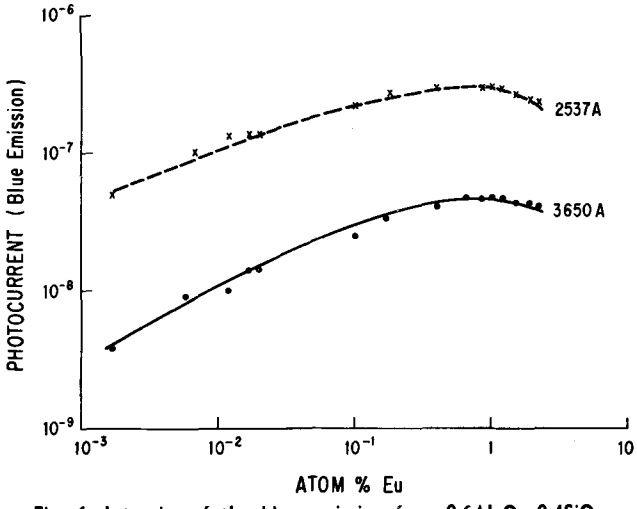

Fig. 6. Intensity of the blue emission from $0.6Al_2O_3 \cdot 0.4SiO_2$ as a function of Eu^{2+} additions. Data given for excitation by 2537 and 3650Å radiation.

The emission spectrum of the $0.6Al_2O_3 \cdot 0.4SiO_2$,1 a/o Eu phosphor is shown in Fig. 7. The spectrum of similar phosphors having the Al_2O_3 to SiO_2 ratio varying between 1:5 to 9:1 is essentially the same. The absorption spectrum of the $0.6Al_2O_3 \cdot 0.4SiO_2$:1Eu is shown in Fig. 2A. There is only one strong absorption band, peaking at about 300 nm. The excitation spectrum of this phosphor is shown in Fig. 3A. It consists of five main peaks which are at 346, 305, 270, 250, and 380 nm (in order of decreasing intensity).

The EuO-Al_2O_3-SiO_2 *system* (3).—During the study of the $(1-x)Al_2O_3 \cdot xSiO_2$ system, x-ray analysis of phosphors having 10 a/o Eu indicated the presence of a new phase, $EuAl_2Si_2O_8$, isomorphous with $SrAl_2Si_2O_8$. Test preparations yielded a bright green-yellow emitting phosphor excited by 2537 and 3650Å. The body color was green-yellow.

Table I. Relative brightness of several blue emitting Eu^{2+} activated Al_2O_3-SiO_2 phosphors

Composition	Eu conc., a/o	Brightness 2537A	Brightness 3650A
SiO_2	0.05	0.85	1.7
Al_2O_3	1	0.85	2.58
$0.6Al_2O_3 \cdot 0.4SiO_2$	1	3.9	20.0
$0.4Al_2O_3 \cdot 0.6SiO_2$	1	4.0	22.0
$0.3Al_2O_3 \cdot 0.7SiO_2$	1	4.3	20.0
$CaWO_4$:Pb	—	4.9	—
ZnS:Ag	—	—	22.5

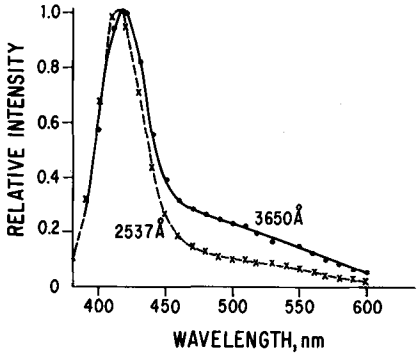

Fig. 7. Emission spectra of $0.6Al_2O_3 \cdot 0.4SiO_2$:1 a/o Eu^{2+} excited by 2537 and by 3650Å ultraviolet.

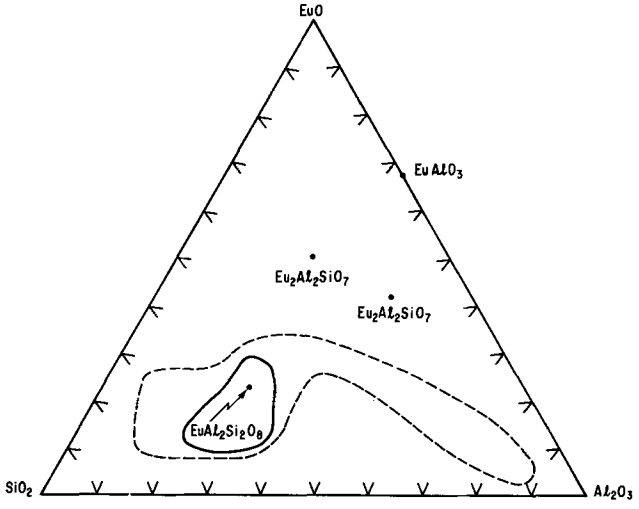

Fig. 8. Approximate phase diagram of the ternary EuO-Al_2O_3-SiO_2 system showing the compounds prepared in this system. The area around $EuAl_2Si_2O_8$ bounded by the solid line is single phased. The area bounded by the dashed line is multiphased but contains some $EuAl_2Si_2O_8$.

The effect of varying the ratio of EuO, Al_2O_3, and SiO_2 on the luminescence was examined over a wide range around the stoichiometric point. Based on visual observation of the emission and body colors and x-ray examination, it appears that $EuAl_2Si_2O_8$ can tolerate a slight excess of Al_2O_3, SiO_2, or EuO. The solid line in Fig. 8 shows the region where x-ray indicates the presence of only one phase, $EuAl_2Si_2O_8$. The region within the dashed line is multiphase but still contains some $EuAl_2Si_2O_8$.

Brightness measurements of samples lying within the area bounded by the solid line of Fig. 8 were made. The results show that the brightness varies with Eu concentration for the basic composition $Eu_xAl_2Si_2O_{(7+x)}$ over the range $x=0.1$ to 2 with a maximum at $x=0.4$. For an Eu concentration of 0.4, there are two regions of maximum brightness, namely $Eu_{0.4}Al_2Si_{(1.5\text{-}1.8)}O_{(6.4\text{-}7)}$ and $Eu_{0.4}Al_{(2.0\text{-}2.2)}Si_2O_{(7.4\text{-}7.7)}$. Phosphors lying within this region are brighter than the stoichiometric compound, Table II. Also shown in Table II are the brightnesses of a (ZnCd)S:Ag phosphor having a similar emission color and a standard Zn_2SiO_4:Mn phosphor.

Table II. Relative brightness of some $Eu_xAl_ySi_2O_{(x\ -\ 1.5y\ +\ 2z)}$ phosphors

Phosphor composition	Brightness 2537Å	Brightness 3650Å
$EuAl_2Si_2O_8$	0.066	25
$Eu_{0.4}Al_{2.1}Si_2O_{7.55}$	0.073	36
$Eu_{0.4}Al_2Si_{1.65}O_{6.7}$	0.078	37
Zn_2SiO_4:Mn	0.92	—
(ZnCd)S:Ag (green-yellow)	—	36

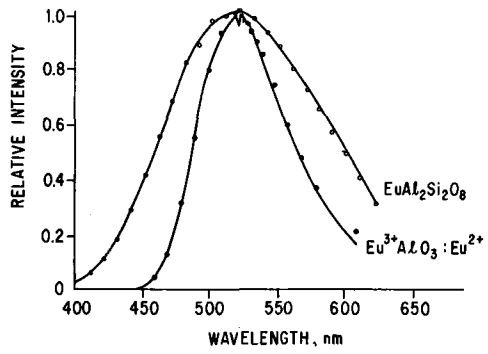

Fig. 9. Emission spectrum of typical $EuAl_2Si_2O_8$ and $Eu^{3+}AlO_3$:-Eu^{2+} phosphors. The lines on the $EuAlO_3$ curve are due to absorption by Eu(III). There are also weak lines, not shown in this figure, at 390 and 470 nm.

The emission spectrum of a typical $EuAl_2Si_2O_8$ phosphor is shown in Fig. 9. It consists of a broad band peaking at 520 nm. Phosphors within the area bounded by the solid line of Fig. 8 have essentially the same emission. The absorption spectrum of these phosphors is shown in Fig. 2B. It consists of a broad band in the u.v. and extending slightly into the visible. The excitation spectrum is shown in Fig. 3B and is the same for the stoichiometric compound and the compositions in the region of maximum brightness. It consists of three peaks. The major one is at 350 nm and the other two are at 265 and 310 nm.

Two other compounds were found in the EuO-Al_2O_3-SiO_2 system, *viz.*, $Eu_2Al_2SiO_7$ and $Eu_6Al_{18}Si_2O_{37}$. They have the same structure as the corresponding Sr analogs. These two compounds have a gray-green body color and are nonluminescent.

The $EuAlO_3$ *system.*—It was mentioned earlier in the section on Al_2O_3:Eu that NH_3-firing a sample with 10 a/o Eu resulted in a phosphor having a green emission. X-ray showed the presence of another compound. Since Eu^{2+} and Sr^{2+} have similar ionic sizes, 1.10 and 1.13Å, respectively, Eu^{2+} may have formed a compound similar to one of the compounds in the SrO-Al_2O_3 system. Those that have been reported are $4SrO \cdot Al_2O_3$, $3SrO \cdot Al_2O_3$, $SrO \cdot Al_2O_3$, $Sr \cdot O \cdot 2Al_2O_3$, and $SrO \cdot 6Al_2O_3$ (4). Firing stoichiometric compositions of Eu_2O_3 and Al_2O_3 corresponding to these Sr analogs at 1000°-1500°C in NH_3 resulted in samples containing mixtures of Al_2O_3, $EuAlO_3$, and $EuO \cdot 6Al_2O_3$. $EuAlO_3$ was the main component in these preparations. Two 2-hr firings of the $Eu_2O_3 \cdot Al_2O_3$ composition at 1300°C resulted in almost pure $EuAlO_3$. However, a slight excess of Al_2O_3 was needed to compensate for Al_2O_3 lost during the firing. A sample of $EuAlO_3$ fired in O_2 was white and nonluminescent. The NH_3 fired samples had a pale yellow body color and a green emission. This phosphor is relatively efficient under 3650Å excitation. Compared to a (Zn,Cd)S:Ag phosphor of about the same color, it is 75% as bright. However, the $EuAlO_3$ phosphors have not been optimized.

The emission spectrum of $EuAlO_3$ is shown in Fig. 9. It consists of a band with a peak at 520 nm plus some superimposed absorption lines. The absorption spectrum is shown in Fig. 2B. It consists of two strong bands and one weak one.[2] The excitation spectrum is shown in Fig. 3B. It consists of three peaks located at 250, 310, and 350 nm with the amplitudes increasing in the order given.

Discussion

The goal of this investigation was to identify the matrix responsible for the bright blue-white fluorescence obtained when mixtures of Al_2O_3 and SiO_2 containing 1% Eu are fired in a reducing atmosphere. Analysis of the x-ray results of various compositions

[2] The absorption lines found in the emission spectrum, Fig. 10, are due to the Eu^{3+}. They do not show up in the absorption spectrum, Fig. 2B, because the former was measured by a continuous scan and the latter was point by point.

of Al_2O_3 and SiO_2, after firing, shows that Al_2O_3, SiO_2, and a trace of mullite ($3Al_2O_3 \cdot 2SiO_2$) are present. Activation of these three compounds by Eu^{2+} results in materials whose emission is much weaker than fired mixtures of Al_2O_3 and SiO_2. Even phosphors containing limited solid solutions of Al_2O_3 in SiO_2 and SiO_2 in Al_2O_3 result in weak emission. An examination of the optical properties of all of these phosphors shows them to be different from the mixed "$Al_2O_3 \cdot SiO_2$:Eu" phosphors. The only conclusion that can be reached is that both Al_2O_3 and SiO_2 are necessary for phosphor formation but the specific host is not known. Subsequent to this work, Wachtel (5) also worked on this system. He believes that the Eu^{2+} is located at the interface between mullite and a second phase which may be Al_2O_3 or SiO_2.

The band emission of these phosphors is due to the presence of Eu^{2+} since Eu^{3+} causes line emission (6). Further evidence for the presence of Eu^{2+} is the need for firing in a reducing atmosphere, the body color in the case of $EuAlO_3$ and $EuAl_2Si_2O_8$ and the lack of luminescence or line emission when fired in O_2.

Normally Eu^{2+} emission is blue. However, in $EuAl_2Si_2O_8$ and in $EuAlO_3$, the Eu^{2+} emission is green-yellow and green, respectively. Note, however, Fig. 9, that both of these phosphors peak at the same wavelength. Their visual color difference is due to the wider emission band of the $SrAl_2Si_2O_8$ phosphor. The difference in emission color, blue *vs.* green, is most likely due to a different lattice environment of the Eu^{2+} ion.

There are other Eu^{2+} activated phosphors that have green emissions, for example, some of the alkaline earth silicates (7), $Na_2B_4O_7$ (8), and Al_2O_3-AlN (9). In fact, it appears that almost any emission color can be obtained with divalent Eu. For example, Jaffe and Banks have obtained yellow, orange, and red band emissions with the alkaline earth sulfides (6).

The interesting thing about the $EuAl_2Si_2O_8$ phosphor is that even with such high Eu concentrations, the phosphor is very efficient, Table II. At these concentrations, one would expect concentration quenching to occur, resulting in relatively low efficiency. The $EuAlO_3$:Eu^{2+} phosphor is interesting in that Eu is present in both the +2 and +3 oxidation states. Examination of Fig. 3B shows that the excitation spectra of Eu^{3+} AlO_3:Eu^{2+} and $EuAl_2Si_2O_8$ are somewhat similar. The main peak at 350 mn is most likely due to a $4f^7$ to $4f^6$ $5d^1$ transition of the Eu^{2+}.

Acknowledgments

The writer would like to thank Mr. G. Scanlon, Mr. F. Escudero[3] and Miss K. Wolejko[3] for their aid in sample preparation and for performing some of the measurements, and Drs. C. K. Lui Wei and G. Arai[3] for the x-ray measurements.

$LiYO_2$:Eu as a Red Phosphor

Philip M. Jaffe* and John D. Konitzer*

Zenith Radio Corporation, Chicago, Illinois

ABSTRACT

$LiYO_2$ can be activated by Eu(III) to give an efficient red emitting phosphor under cathode-ray and under 2537Å excitation. This phosphor has optical properties which indicate its possible use as the red component in color television screens. Unfortunately, during tube fabrication, the phosphor decomposes to Y_2O_3:Eu. The main cause of this deterioration has been found to be hydrocarbons which are present during tube manufacture.

The search for new and efficient red cathodoluminescent phosphors over the past several years has resulted in a number of interesting host materials activated with rare earth elements. Among these hosts are compounds having the general formula $LiMO_2$ where M is a rare earth element. Hoppe (1), Vorres (2), Bertaut and Gondrand (3) have described the preparation of the pure undoped hosts while Blasse (4) and Brixner (5) have described the luminescent properties of some of the Eu activated compounds.

We have investigated $LiYO_2$:Eu for possible use in color television screens. Cathodo and photoluminescent properties of this phosphor as well as some problems involving its use in CR tubes are presented here.

Experimental Procedure

Phosphor preparation.—The preparation of the host has been most completely described by Bertaut and Gondrand. They fired a mixture of the rare earth oxide with an excess of Li_2CO_3 for two days at 900°C in an alumina crucible in air.

We prepared the compound $LiYO_2$, without prior knowledge of the papers listed, by firing a mixture of Li_2CO_3 and $Y_2(C_2O_4)_3$ at 1000°C for 2 hr in an oxygen atmosphere. We found that the materials attacked platinum and that recrystallized alumina crucibles should be used. Following a procedure which was similar to that of Bertaut and Gondrand, we fired samples in an excess of Li_2CO_3 in order to force the reaction to completion. X-ray diffraction patterns for these samples were much stronger and better resolved than for similar samples without excess Li_2CO_3.

Bertaut and Gondrand state that firing above 900°C results in a room temperature metastable tetragonal structure which, after some time, changes to the monoclinic form, while firing at 900°C or below results in the stable monoclinic form. We fired our charges at

* Electrochemical Society Active Member.

temperatures up to 1200°C for 2 hr and obtained only the monoclinic form. This difference might be due to Bertaut and Gondrand's long firing time and/or may also be due to the incorporation of europium in our samples. We have found that the europium doped monoclinic form results in a bright red phosphor while Eu doped samples which were fired at temperatures high enough and for times long enough to form the tetragonal structure were not luminescent.

In our procedure, firing time is critical. If the materials are fired for periods much longer than 2 hr we obtain mixtures of $LiYO_2$:Eu and Y_2O_3:Eu as evidenced by the presence of Y_2O_3:Eu lines in the emission spectra.[1]

Our phosphors were prepared by ball milling a water slurry of the freshly coprecipitated oxalates of yttrium and europium with about a 1.2 fold excess of Li_2CO_3. This was dried and fired for 1 hr at 1000°C in oxygen. After cooling, the sample was ground finely in a mortar and refired an additional hour. The resultant phosphors have a white body color and are efficiently excited by both 2537Å uv rays and cathode rays. The determined density of the phosphor is 4.29 ± 0.032 g/cc. The maximum solubility in water was 0.06% by weight. The pH of this material was determined to be 12.2. After several washings with boiling water to remove the excess Li_2CO_3, the pH was about 9. After about 1 hr, however, the pH rose to 10 indicating either that some hydrolysis of the sample occurred or that all the Li_2CO_3 was not removed.

Preparations using freshly coprecipitated hydroxides of europium and yttrium mixed with Li_2CO_3 result in even better yield of the phosphor than those obtained using the oxalates. The phosphors resulting from the two methods have the same spectral properties, but the hydroxide method results in a purer and a brighter product.

Measurements.—Emission spectra were obtained with a Jarrell-Ash 1/4 meter grating monochromator equipped with a wavelength drive and a photomultiplier whose output was recorded on a B&L VOM 7 recorder. The spectra were corrected for spectral sensitivity of the photomultiplier and instrument transmission. For the photoluminescent emission, the exciting source was a 2537Å Mineralight while excitation spectra were taken under a 150w d-c Xenon lamp. All spectra are given relative to a 0.2% fluorescein solution which has constant quantum efficiency over the range of 250-500 nm (6). Diffuse reflection spectra were obtained by attaching a Beckman diffuse reflectance unit to the output of the Jarrell-Ash monochromator. The reflected light was detected by a Hitachi 913B photomultiplier and its output recorded on the B&L recorder. The reflection spectra were taken relative to $MgCO_3$. Absorption spectra are reported using the relationship: % absorption = (100 — % reflectance).

The cathodoluminescent data were taken using a demountable cathode-ray tube.

Discussion of Experimental Results

Figure 1 shows the brightness of $LiYO_2$ as a function of europium concentration for both 2537Å and cathode-ray excitation relative to a commercial batch of YVO_4:Eu. The optimum europium concentration occurs in the vicinity of 4-5 a/o (atom per cent) for both modes of excitation although the actual intensities are quite different. This curve represents a larger number of points than is indicated and agrees with the data reported by Brixner (5). However, our data, not shown here, indicate that a small dip occurs at about 5½ to 6 a/o europium. Our original hypothesis was that this dip represented differences in preparation and purity of our samples and so the curve is drawn smoothly through this region ignoring this dip.

[1] The emission spectrum of a sample was much more indicative of the presence of Y_2O_3:Eu than x-ray analysis. The latter technique cannot detect less than 3-5 w/o Y_2O_3:Eu. The former method could detect less than 1%.

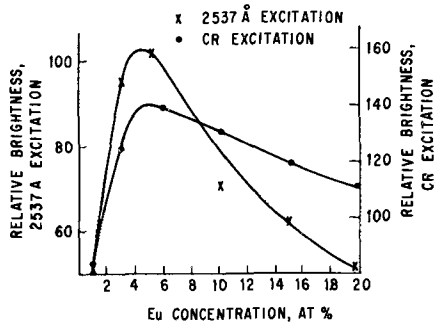

Fig. 1. Emission intensity of $LiYO_2$:Eu relative to YVO_4:Eu under cathode-ray excitation and 2537Å excitation.

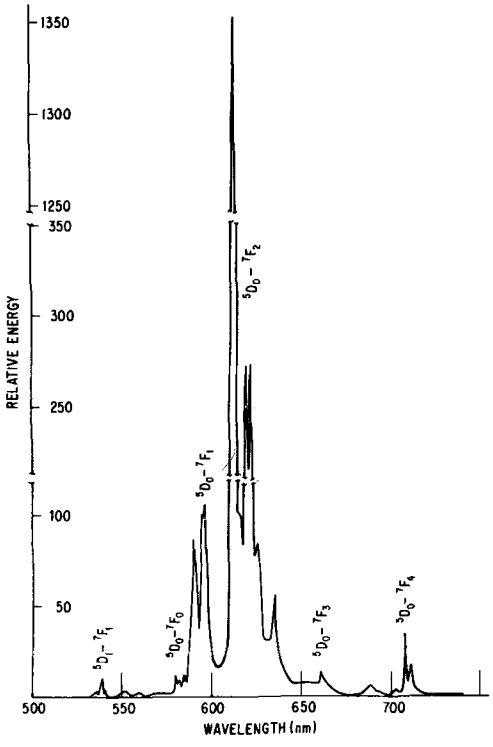

Fig. 2. Expanded scale emission spectrum of $LiYO_2$:Eu under 2537Å excitation. The same spectrum is obtained with cathode-ray excitation.

More recent work indicates that this dip may be real, but if so, we do not know the reason for it.

The emission spectrum of $LiYO_2$:3 a/o Eu is shown in Fig. 2 for uv excitation. The same spectrum is obtained with cathode-ray excitation. It consists primarily of a very strong line at 613 nm and a weaker doublet at 620 and 622 nm.

The transitions shown in Fig. 2 are derived from El'Yashevich (7). According to Blasse, the splitting of these lines should be such that two lines appear for each of the $^5D_0 \rightarrow {}^7F_1$ and the $^5D_0 \rightarrow {}^7F_2$ transitions. It seems that the 613 and 620 nm lines may represent the $^5D_0 \rightarrow {}^7F_2$ transition except that the 620 nm line is further split into two lines. Blasse reports that $LiYO_2$ has a distorted unit cell (4). This may be the cause of the additional splitting. Evidence for the 620 nm lines being due to additional splitting of the $^5D_0 \rightarrow {}^7F_2$ transition and not to an impurity is found by measurement of its persistence. The persistence of the 5920, 6118, 6132, 6200, and 6217 nm lines is the same as that of the 620 lines indicating that all these lines originate from the same $^5D_0$ level, Fig. 3.

Under both uv and cr excitation, $LiYO_2$:Eu shows a slight color shift as a function of the europium concentration as shown in Fig. 4. This is an enlarged view of the lower right side of the chromaticity diagram. Also shown, for comparison, are the color shifts for

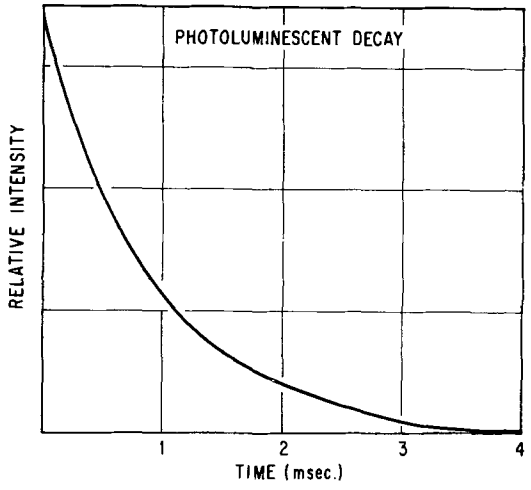

Fig. 3. Relative decay of the 5919, 6118, 6132, 6200, and 6217Å lines from LiYO$_2$:Eu for 2537Å excitation. Identical curves are obtained with europium concentrations of 2 and 10 a/o.

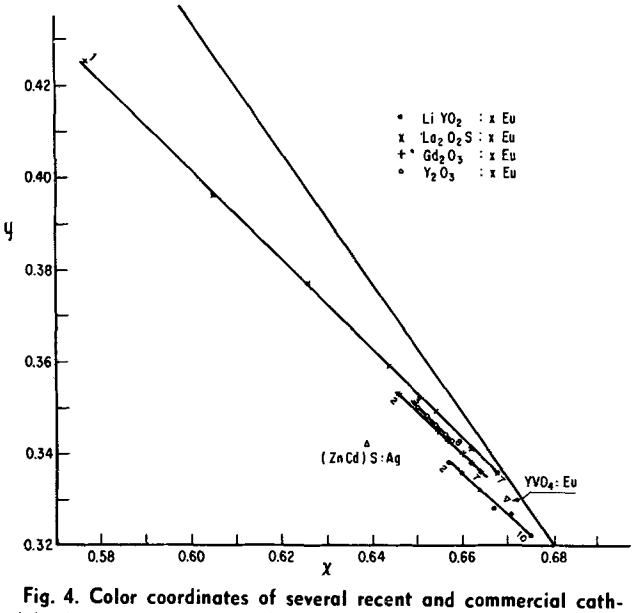

Fig. 4. Color coordinates of several recent and commercial cathodoluminescent phosphors. This figure is a greatly expanded portion of the lower right corner of the C.I.E. chromaticity diagram.

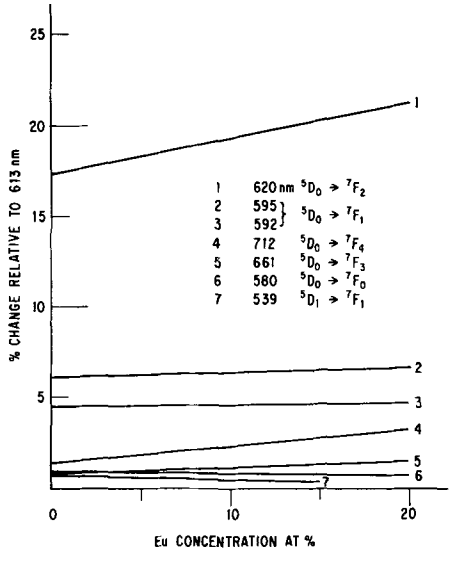

Fig. 5. Ultraviolet excited emission intensities of selected lines from LiYO$_2$ as a function of europium concentration compared to the emission intensity of the 613 nm line. This diagram shows the emission lines which are responsible for the color change as a function of the europium concentration.

La_2O_2S:Eu, Y_2O_3:Eu and Gd_2O_3:Eu and the color coordinates for YVO_4:5 a/o Eu and P22 (ZnCd)S:Ag. Figure 5 shows a least-squares plot of the per cent intensities of selected spectral emission lines from LiYO$_2$: 5 a/o Eu relative to the 613 nm line. From Fig. 5 it can be seen that the color shift is due to a combination of a decrease in the $^5D_1 \rightarrow {}^7F_{1,2}$ and $^5D_0 \rightarrow {}^7F_0$ emissions and an increase in the $^5D_0 \rightarrow {}^7F_{3,4}$ emissions as well as in the doublet at 620 and 622 nm (hereafter called the 620 nm lines).

Figure 6 shows the absorption and excitation spectra of LiYO$_2$ containing 0, 2, and 10 a/o Eu, respectively. The undoped sample exhibits no excitation spectrum. Its absorption spectrum has no structure, but shows a weak band below 240 nm. The absorption and excitation spectra of the Eu containing samples show a strong band lying below 280 nm plus fine structure above 280 nm. The fine structure is due to direct excitation or absorption in the Eu centers (f → f transitions). The band below 280 nm is most likely due to a charge transfer process (8). Blasse (4) reports similar data.

Figure 7 compares the phosphorescent decay of LiYO$_2$:4 a/o with a YVO_4:5 a/o Eu production phosphor under cathode-ray excitation at ambient temperature. Both phosphors show an exponential decay. The LiYO$_2$:Eu has a decay time of 1.08 msec which is twice that observed for YVO_4:Eu, but still well within the limits necessary for use in color television.

Figure 8 shows the brightness of LiYO$_2$:Eu as a function of electron beam current density under an

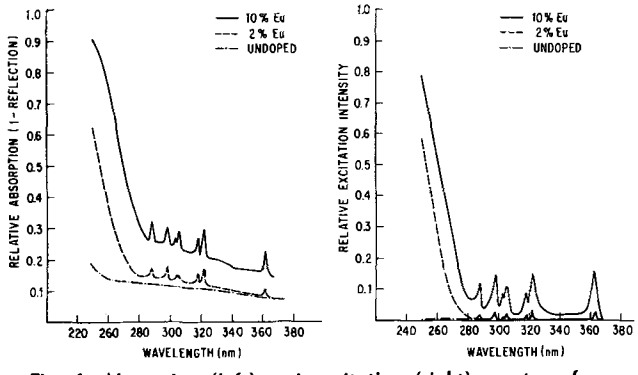

Fig. 6. Absorption (left) and excitation (right) spectra of pure undoped LiYO$_2$ and of europium doped LiYO$_2$.

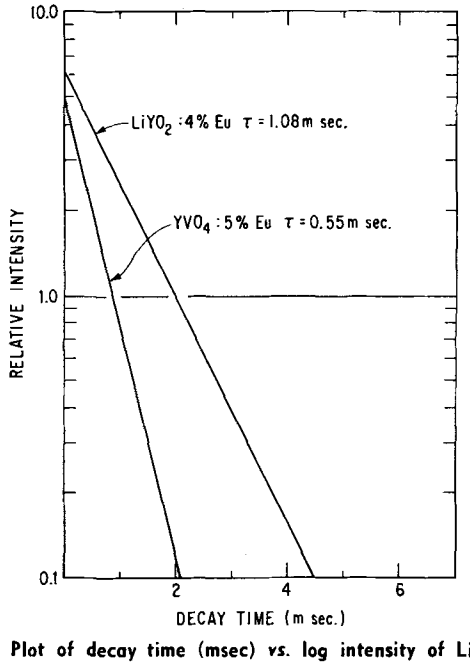

Fig. 7. Plot of decay time (msec) vs. log intensity of LiYO$_2$:Eu compared to YVO_4:Eu. The time constant of the LiYO$_2$:Eu is about twice that of YVO_4:Eu.

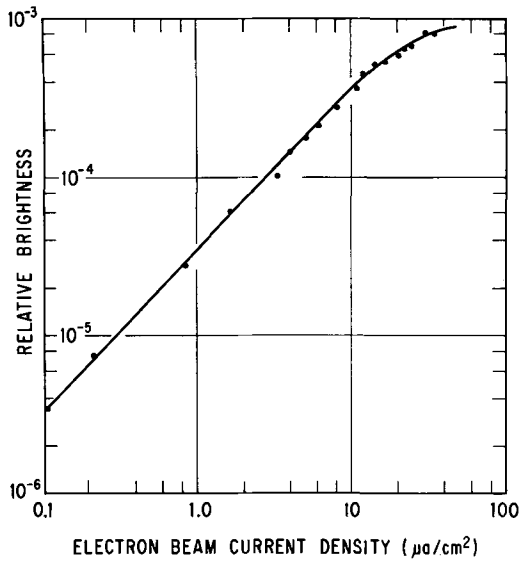

Fig. 8. Relative brightness of $LiYO_2$:Eu phosphor as a function of electron beam current density for a constant accelerating potential of 20 kv. Linear portion indicates usable range of current densities. Saturation of the phosphor is indicated by the deviation from linearity.

accelerating potential of 20 kv. Below 10 μa/cm^2 the curve is linear; above this value the phosphors start to saturate. This saturation occurs above the normal operating current density of 0.8 μa/cm^2. Since we were able to reproduce this curve on the same sample we conclude that the phosphor is stable under cathode-ray bombardment.

In Table I we list some of the luminescent properties of $LiYO_2$:Eu which are important for evaluating the phosphor for possible use in color television tubes. The relative luminosity compares the brightness of $LiYO_2$:Eu and YVO_4:Eu assuming 100% for YVO_4:Eu. The luminosity factors were calculated from the cathode-ray spectra of both phosphors. The fact that the luminosity factors are the same implies that the emission spectra are quite similar. This is also apparent from the color coordinates listed in Table I and the data in Fig. 4. The last column of Table I, relative luminous conversion efficiency, also indicates that the $LiYO_2$:Eu is about 1.5 times brighter than the commercial YVO_4:Eu phosphor.

Experimental Tube Production

All of the data so far presented indicate that $LiYO_2$:Eu should be a successful color television phosphor. However, our attempts to produce a monochrome tube were very disappointing. The resultant tube was low in brightness and showed the emission spectrum of Y_2O_3:Eu indicating that the $LiYO_2$:Eu decomposed during the tube fabrication process.

Table II lists some of the steps in tube fabrication processes which could cause decomposition of the phosphor. Table III shows the actual observations that we made under simulated conditions.

Examination of Table III shows that heating of the phosphor in the presence of hydrocarbons, *i.e.*, pump oil, polyvinyl alcohol, polymethylmethacrylate, but not benzene, resulted in complete degradation to low brightness Y_2O_3:Eu.

Conclusions

The phosphor $LiYO_2$:Eu is a very efficient one which could be used as the red component in cathode-ray tubes, but is not compatible with present tube fabrication processes. Coating the phosphor with silicate could help to stabilize the phosphor in production methods.

Table I. Cathodoluminescent data for $LiYO_2$:Eu and YVO_4:Eu

Phosphor	Relative luminosity	C.I.E. color coordinates x	y	Luminosity factor	Luminous efficiency lumens/rad. watt	Relative luminous conversion efficiency
$LiYO_2$:4 a/o Eu	155	0.664	0.332	0.493	335	1.54
YVO_4:6 a/o Eu	100	0.661	0.336	0.493	335	1.00

Table II. Steps in CR tube manufacture in which $LiYO_2$ could decompose

a. Vacuum heat-treatment;
b. Water washing;
c. Air or vacuum heating in contact with metallic Al;
d. Vacuum heating in the presence of organic materials such as polyvinyl alcohol or polymethylmethacrylate;
e. Air heating in the presence of the above organics.

Note: All heating done at 400°-500°C.

Table III. Effects of various tube fabrication procedures on the $LiYO_2$:Eu phosphor

Treatment	Observation
Heat in vacuum	no change
Heat in O_2, N_2, air, H_2	no change
Wash with water	slight change over long time
heat in vacuum in	
a. presence of carbon	no change
b. vacuum pump oil	degradation
c. contact with aluminum foil	degradation of portion in contact with the aluminum
d. presence of polyvinyl alcohol	degradation
e. presence of polymethylmethacrylate	degradation
f. presence of benzene	no change

Our attempts to do this did not appear to help. Perhaps a dusting process would help, but there still remains the problem of decomposition after deposition of the aluminum film. Because the phosphor is unstable in the presence of the organic materials currently used, a new process of applying it to a screen and a means to prevent its contact with aluminum would have to be developed. In view of these difficulties and the difficulties which new processes would generate, it is concluded that $LiYO_2$:Eu has no immediate application to color television tubes.

Acknowledgments

The authors wish to thank Mrs. H. Stanczyk and Miss K. Wolejko for their assistance in preparing these compounds, Mr. L. Flemming for the cathodoluminescent data, Dr. G. Arai for the x-ray data, and Dr. A. Liberman for the chemical tests performed.

Manuscript submitted Dec. 30, 1968; revised manuscript received *ca.* Feb. 1, 1969. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 43.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Origin of Secondary Phases in Melt-Grown Fluorapatite Crystals

R. H. Hopkins and W. E. Kramer

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Czochralski-grown fluorapatite boules contain inclusions identified as CaF_2 and $Ca_3(PO_4)_2$. The morphology and composition of the inclusions depends on the fluoride content of the melt from which a crystal is pulled. Evidence of precipitation in these crystals suggests that some solid solution occurs in fluorapatite at high temperatures. Both inclusions and precipitates promote cleavage of the pulled crystals.

Neodymium-doped fluorapatite (Nd:FAP) was shown to be a promising laser material by Mazelsky *et al.* (1, 2). Most efficient lasing action obtains in crystals free from color centers, dislocation arrays, and inclusions of additional phases. We have investigated the occurrence of such defects in synthetic fluorapatite and reported the results on point and line defects elsewhere (3, 4); in this paper we describe our observation and interpretation of included phases in melt grown FAP crystals.

"Opalescent" inclusions (presumably a second phase) were seen by Johnson (5) in the first large single crystals of FAP produced directly from the melt. Similar feathery inclusions were observed in Czochralski-grown Nd:FAP by Mazelsky *et al.* (1) who noted that their occurrence was minimized by slow growth rates (3-5 mm/hr). These authors sugested that some relation existed between the inclusions and fluoride-ion vacancies in the apatite structure.

We observe two types of inclusions in synthetic FAP and find that they markedly enhance fracturing of the melt grown crystals.

Crystal Growth and Analysis

The ideal composition of fluorapatite, $Ca_5(PO_4)_3F$, lies on the pseudobinary join CaF_2-$Ca_3(PO_4)_2$ at 25 m/o (mole per cent) CaF_2 (6). The inclusions in our crystals strongly suggest that departures from the ideal apatite composition occur during crystal growth. We investigated this possibility by ranging melt composition from 20 to 30 m/o CaF_2 along the join thus producing fluoride-rich or deficient crystals with respect to the ideal FAP composition.

We employed the same materials and methods of crystal growing reported previously (1, 3); no Nd doping was used here. Pull rates were between 2 and 6 mm/hr; $<0001>$ and $<10\bar{1}0>$ were the growth axes. After slow cooling of the crystals to room temperature, sections were cut longitudinal and transverse to the growth axes and prepared for optical examination either by mechanical polishing ending with 6μ diamond paste or by chemical polishing in 1:5 HCl/H_2SO_4 (4). Immersion of samples for 15 sec in 50% HCl/H_2O produces clear dislocation etch pits (and associated "tails") (4, 7) on most crystal planes in FAP.

Observations

Crystal morphology.—When grown from melts of ideal composition and at slow rates, $<0001>$ crystals of FAP exhibit circular cross sections having smooth surfaces marred only by small $\{10\bar{1}0\}$ facets. Boules grown parallel to $<10\bar{1}0>$ have a characteristic paddle shape displaying large basal and smaller prism facets (3). As the melt composition is shifted from $Ca_5(PO_4)_3F$ the surface of a growing crystal becomes quite wrinkled and feathery inclusions like those seen in previous studies (1, 5) become obvious regardless of the crystal growth direction. Crystals grown from both fluoride-rich and fluoride-poor melts contain these feathery inclusions. However, at a given growth rate, *e.g.*, 4 mm/hr, a 3% deficiency of CaF_2 is necessary to induce the inclusions while less than 1% excess CaF_2 is sufficient to produce a similar result. At any composition deviating from the ideal inclusions form when some critical growth rate is exceeded.

Fracture characteristics.—Natural fluorapatite has imperfect basal and $\{10\bar{1}0\}$ cleavage (8); Prener (9) observed no easy cleavage in solution-grown crystals. Melt-grown FAP crystals sometimes fracture by cleaving during growth or cooling to room temperature. We determined from Laue photographs of cleavage surfaces that $<0001>$ crystals cleave on both basal and $\{1\bar{2}10\}$ planes, while $<10\bar{1}0>$ crystals cleave on both prism planes of the hexagonal lattice. The tendency toward cleavage was enhanced by conditions which also favored inclusion formation, *i.e.*, high growth rates and off-ideal composition melts. Some relation then probably exists between the propensity of FAP to cleave and the inclusion content of the crystals. This possibility is discussed further below.

Inclusion morphology.—Optical examination of sections cut from FAP crystals reveals that two types of inclusion are present depending on the growth conditions.

Typically we observe tubular inclusions (type I) in crystals grown from fluoride rich melts, Fig. 1, while crystals grown from CaF_2 deficient melts contain smaller jagged particles (type II), shown in Fig. 2. Both these photomicrographs were taken of unetched longitudinal sections of $<0001>$ crystals grown at 4 mm/hr. The c axis (growth direction) is vertical in each photograph. The highest concentration of defects in these 2 m/o off composition samples is nearest the center of the pulled crystal. Note also that type I inclusions lie parallel to the c axis (Fig. 1) while the long dimension of type II inclusions is normal to c.

The morphology of type I inclusions in CaF_2-rich $<10\bar{1}0>$ crystals is somewhat different from that observed in $<0001>$ samples grown under the same conditions. The photograph of a longitudinal section from a $<10\bar{1}0>$ shown in Fig. 3 illustrates this difference. The inclusions though still tubular are now "T" shaped. However, the longer bar of the "T" is parallel to the c axis of FAP.

The $<10\bar{1}0>$ crystals grown from 1-3% CaF_2-deficient melts contain a general distribution of particles very similar to that illustrated in Fig. 2. Again, the long axes of the inclusions lie normal to $<0001>$. However, as the deficiency of CaF_2 exceeds about 3%, tubular inclusions parallel to c and having a morphology very similar to the type I inclusions shown in Fig. 3 develop in $<10\bar{1}0>$ crystals. Some small jagged type II particles are also distributed within the crystals. Recall from the section on Crystal morphology that inclusions visible to the naked eye in fluoride-poor

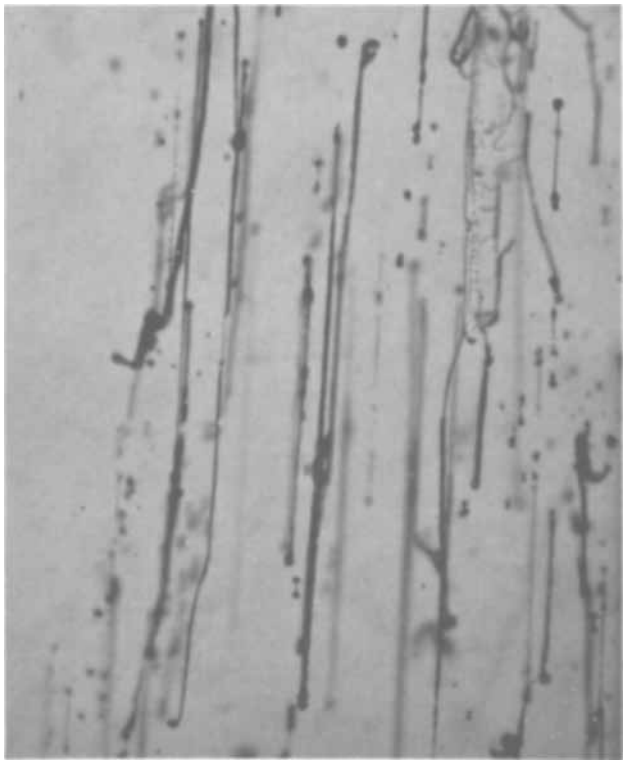

Fig. 1. Type I tubular inclusions in a FAP crystal grown from a fluoride rich melt. <0001> growth direction vertical. Transmitted light. Magnification approx. 50X.

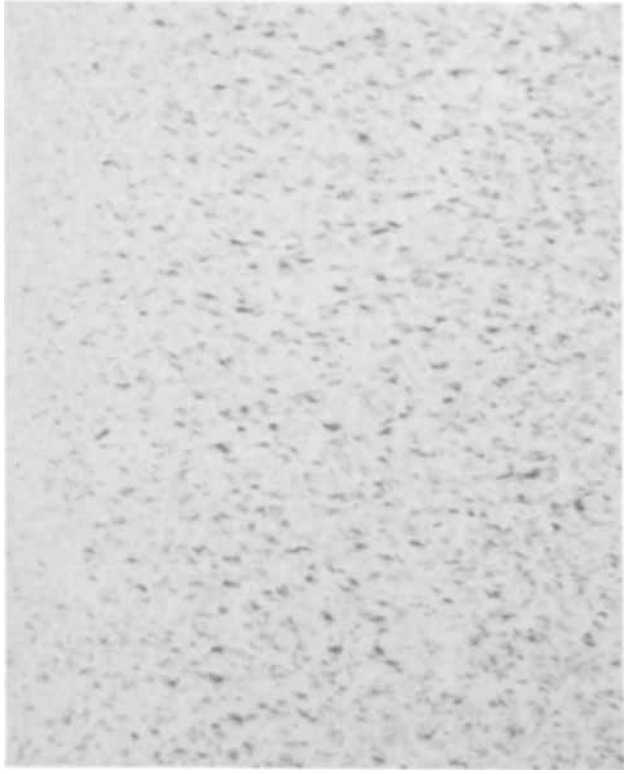

Fig. 2. Jagged type II inclusions in a crystal grown from a fluoride deficient melt. <0001> growth direction vertical. Transmitted light. Magnification approx. 50X.

samples did not develop until a 3% deviation from the ideal FAP composition was exceeded.

Another important observation is that both <0001> and <10$\bar{1}$0> crystals grown from melts of ideal FAP composition contained small amounts of particles with the same morphology as type II inclusions. In this case, however, particles were not randomly distributed

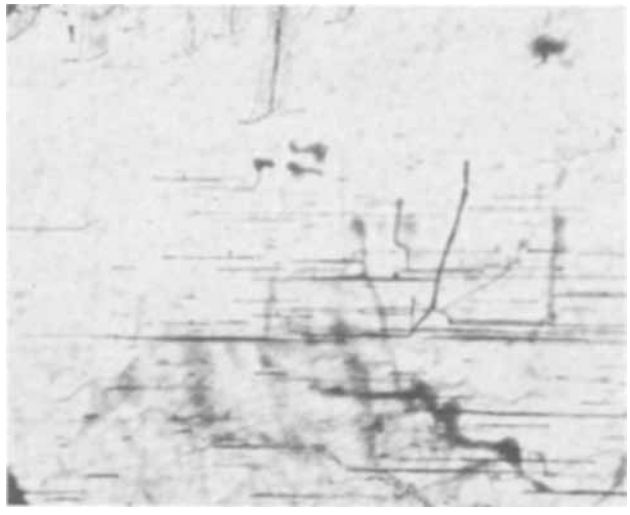

Fig. 3. "T" shaped type I inclusion. Crystal growth direction from top to bottom parallel to <10$\bar{1}$0>. c axis horizontal. Transmitted light. Magnification approx. 36X.

but were localized along dislocation lines. This has been verified by x-ray topographical analysis (4).

Inclusion analysis.—To successfully eliminate the inclusions detected in FAP we must characterize their chemical composition as well as the conditions under which they form. From the phase diagram (6) we expect CaF_2 to be present in fluoride-rich crystals and $Ca_3(PO_4)_2$ to co-exist with FAP in fluoride-poor crystals.

We analyzed type I inclusions by electron microprobe finding that they contained no oxygen or phosphorus within experimental error. The measured fluorine and calcium contents of the inclusions confirmed that they were CaF_2.

The analysis of type II inclusions was slightly complicated by the small size of these particles and their chemical similarity to fluorapatite. The chemical composition of type II inclusions determined by microprobe analysis appears in Table I. The computed amounts of Ca, P, F, and O in fluorapatite and $Ca_3(PO_4)_2$, assuming ideal chemical formulas, are also given for comparison in the table. We conclude from this data that type II inclusions are $Ca_3(PO_4)_2$. The compositions of all other calcium phosphates give poorer agreement than $Ca_3(PO_4)_2$ with the measured composition of the inclusions. We cannot explain the small amount of fluorine found in the inclusions but speculate that either the microprobe beam penetrated the particles thus exciting x-rays from the FAP matrix or that $Ca_3(PO_4)_2$ can hold small amounts of fluorine in solution.

Discussion

We have termed the second phases found in FAP crystals inclusions. However, type II $Ca_3(PO_4)_2$ inclusions are really discrete euhedral particles (seen end on in Fig. 2). This morphology (10, 11) and the tendency of these particles to form along dislocation lines (12) suggests that the origin of type II "inclusions" is through precipitation rather than mechanical

Table I. Experimental and ideal composition of type II inclusions

Element	Inclusion analysis, microprobe	$Ca_3(PO_4)_2$, theoretical	FAP, theoretical
P	19.3* ± 0.2†	20.0	18.4
Ca	38.3 ± 0.1	38.7	39.7
F	0.9 ± 0.1	0.0	3.97
O	44.6 ± 2.8	41.2	37.9

* Compositions are in weight per cent.
† Deviations indicated are variation from sample to sample not instrumental error.

entrainment as the term inclusion implies. The morphology of type I particles is typical of CaF_2 inclusions in solution grown FAP crystals (9) and inclusions in other materials (13).

The evidence of $Ca_3(PO_4)_2$ precipitation in crystals grown from ideal FAP composition melts indicates that CaF_2 vaporizes during crystal pulling thus enriching the melt in $Ca_3(PO_4)_2$. Johnson has also suggested this possibility (5). Our x-ray powder analysis of the white residue condensed on the colder portions of the growth system during a run confirms this hypothesis; the residue was mainly CaF_2. These observations coupled with the findings of Mazelsky *et al.* (3) that the maximum melting point in the vicinity of the composition $Ca_5(PO_4)_3F$ lay at 23% CaF_2, not 25%, lead us to believe that the phase diagram (6) is in error and that FAP can contain an as yet undetermined amount of second component in solution.

Assuming this reasoning correct we can now understand several aspects of second phase formation in pulled FAP crystals. CaF_2 exhibits little solubility in FAP and when it is present to excess in the melt forms a diffusion controlled boundary layer at the growing crystal interface. At high growth rates or high CaF_2 concentrations the planar crystal-liquid interface becomes unstable (14) and CaF_2 is entrapped as inclusions in the growing crystal. Since $Ca_3(PO_4)_2$ is partially soluble in FAP, slight excesses (<3%) of this component result only in precipitation of a second phase, type II inclusions, while larger composition deviations from ideal again lead to interface instability and true second phase entrainment as observed.

We pointed out above that crystal fracture and inclusion formation were both promoted by high growth rate and off-composition melts. It is well known that large stresses can be generated by differential rates of thermal contraction between a particle and its surrounding matrix. In ductile materials these stresses are relieved by dislocation generation and movement (15); this mode of stress relief is difficult in a brittle material. Preliminary studies[1] indicate FAP is highly plastic above about 1375°C but brittle below this temperature. At temperatures above this ductile-to-brittle transition the stress generated between particle and matrix produces dislocation generation. The high etch pit concentration surrounding the CaF_2 inclusion in Fig. 4 demonstrates this fact. However, if all stress cannot be relieved in this manner before a crystal cools below 1375°C then cracks are nucleated at the particle-matrix interface. This is strikingly illustrated in Fig. 5. Here cleavage cracks initiate at many precipitates and propagate into the brittle apatite along {0001} planes.

Conclusions

Our results indicate that the published pseudobinary join between CaF_2 and $Ca_3(PO_4)_2$ is in error; fluorapatite may exist over a solid solution range on the CaF_2 deficient side of the ideal composition. Included phases in pulled fluorapatite crystals form under conditions of constitutional supercooling in the melt and should be suppressed by slow growth rates, high thermal gradients, and stable melt composition. Precipitates of $Ca_3(PO_4)_2$ develop in FAP when CaF_2 volatilizes during crystal growth. The fracture of FAP crystals is caused primarily by cleavage cracks which nucleate at the inclusion (precipitate)-apatite interface then propagate rapidly through the brittle apatite matrix. Cleavage is greatly reduced by removing harmful second phases from pulled crystals.

Acknowledgments

Mr. P. J. Walitsky, Westinghouse Electric Corporation, Bloomfield, New Jersey, carried out the microprobe analysis. We also gratefully acknowledge the capable technical assistance of Mr. A. M. Stewart and the many helpful comments of Dr. G. W. Roland during preparation of the manuscript. This work was supported by the AF Avionics Laboratory under contract F33615-C-68-1550.

Manuscript submitted Dec. 16, 1968; revised manuscript received Jan. 20, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

[1] Prismatic single crystal bars of FAP 1 × 3 × 15 mm were loaded in three point bending at various temperatures. Above about 1375°C these bars could be bent plastically into a "V" shape; below this temperature bars fractured in a brittle manner immediately on loading.

Phase Studies Using the Traveling Solvent Method of Crystal Growth: The Bismuth-Tellurium System

John Strassburger

Research Division, Carrier Corporation, Syracuse, New York

ABSTRACT

The traveling solvent method (TSM) of crystal growth was evaluated as a means of determining the solidus in a phase diagram, by investigating a portion of the bismuth-tellurium phase system. Sections of ingots grown by TSM were chemically analyzed and these results, combined with the crystallization temperatures of the same sections, were used to define equilibrium solidus lines. A comparison of these results with those obtained from long-term annealing experiments performed by another investigator essentially showed agreement between the two techniques. Much less time and effort is required to obtain the same information if TSM is used. An ingot was grown across a peritectic reaction temperature in the Bi-Te system to demonstrate the ability to prepare a peritectic compound and a congruently melting compound in the same ingot.

Inconsistencies in much of the available phase diagram data probably stems first from the inability to obtain equilibrium conditions, and second from the method of analysis. The importance of obtaining semiconductor materials at their "equilibrium" composition is becoming recognized more every day in the study of phase diagrams and, in general, annealing techniques are being used for studying "equilibrium" phase relationships. These methods are laborious and necessitate the preparation and analysis of a large number of samples. Glatz (1) showed the importance of long-term annealing of fine powders for obtaining "true" equilibrium in the bismuth-tellurium system and pointed out that the phase data presented by Hansen (2) for this system is in error apparently because thermodynamic equilibrium was not attained. Because of the availability of Glatz's data, a direct comparison can be made which shows that crystal growth by the traveling solvent method (TSM) is as good a method, if not better, for elucidating specific portions of an equilibrium phase diagram. Complete solidus lines can be elucidated in much less time and equilibrium seems to be more closely approached.

Although crystal growth by the traveling solvent method was first referred to by Pfann (3) as temperature gradient zone melting (TGZM), we prefer the former name suggested by Mlavsky (4).

Although the theory for preparing compounds by a traveling zone (5, 6) or "controlled solidification" (7) technique is similar in many respects to TSM, the conditions for recrystallization by TSM seem to be more favorable than zone leveling methods for obtaining "equilibrium" compositions. In TSM, all systems are static and the driving force (concentration gradient across the molten zone) for travel of the molten zone is strictly governed by the equilibrium phase diagram, whereas in zone leveling methods the rate of travel of a heater or ingot can regulate purity and repeated passes are usually required because of this limitation. Utilizing TSM one can elucidate a complete solidus line of varying composition by a single pass through one ingot. To obtain similar information by zone leveling techniques seems to require extreme care in manipulation of experimental conditions such as mixing (7) or cooling rate, etc.

Goodman (5) and Pfann (6) forsaw various uses for zone refining such as purification of the elements and the preparation of compounds, both congruently melting as well as those from peritectic reactions. Many investigators have utilized zone refining to study phase relationships. McHugh and Tiller (8) studied the pseudobinary system Bi_2Te_3-Bi_2Se_3 and Umeda *et al.* (9) studied the Sn-Te system.

With a stationary temperature gradient, Pfann (3) used TSM to fabricate semiconductive devices, grow single crystals and measure diffusivities in liquids. More extensive diffusivity studies have since been made by Wernick (10). Because of the interest in semiconductor research, extensive investigations (11-13) have been conducted to determine the solid solubility of various metals in silicon and germanium. Trumbore (14) summarized much of the available solubility data and observed that "over the years there has been a pronounced tendency for the accepted equilibrium solid solubilities to decrease." An interesting case in point has since been brought out by McCaldin and Wittry (15) when they showed that the "Ga concentration in a TSM specimen was reduced some 27 percent from that in the 'regrowth' specimen."

Mason and Cook (16) prepared the peritectic compound $CdIn_2Te_4$ by employing a traveling heater and Armstrong *et al.* (17) studied the compound $AgSbTe_2$ by a similar method. Since then, others (18-22) have used this or a static temperature gradient to prepare congruently melting compounds.

Experimental

Apparatus.—The furnaces used for growing crystals by the traveling solvent method were fabricated from Vycor glass and produced a linear temperature gra-

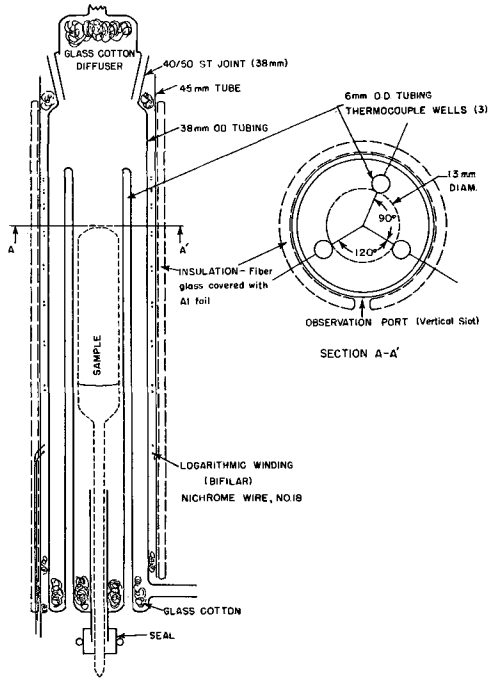

Fig. 1. Furnace for crystal growth by TSM

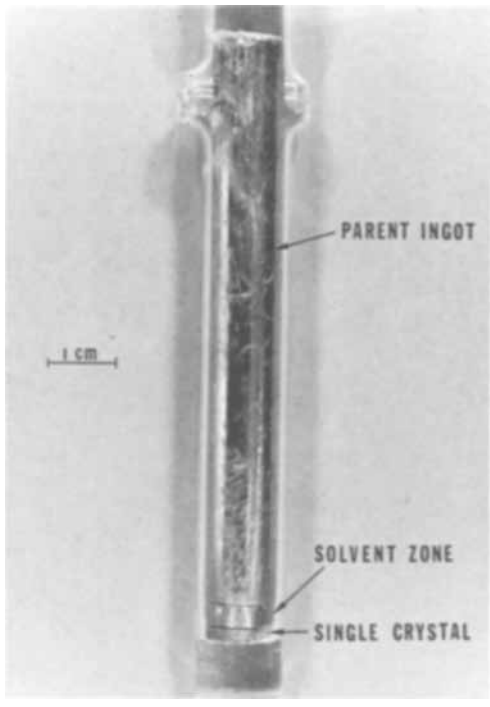

Fig. 2. Crystal growth ampoule before recrystallization

dient of approximately 10°C/cm. As seen in Fig. 1, nichrome wire No. 18 was bifilar wound about the inside furnace tube with logarithmic spacing to produce the desired temperature gradient at the center of the furnace. This furnace was placed inside a glass tube and packed at the ends with glass cotton to form a dead air space. The entire furnace was then insulated with Fiberglass covered inside and outside with aluminum foil except for a long, narrow vertical opening used as an observation port, which was helpful for monitoring the process of the liquid zone. The furnace was designed to be sealed so that crystal growth could be carried out in an inert atmosphere if desired. Three thermocouple wells, which extended essentially the length of the furnace, were placed as close to the sample as possible.

Vertical temperature profiles of the furnace were taken with the specimens in place and also by substituting a fourth thermocouple in place of the sample held in place by a heavy walled glass tube. When three thermocouples were placed as in Fig. 1, Section A-A' and a fourth in the center, the radial temperature distribution across any given horizontal was within 2°C. With an ingot in place, the three outside thermocouples again read within 2°C although it is recognized that the radial temperature distribution could change due to the added heat capacity of the sample.

Originally attempts were made to grow the crystal in a dynamic argon atmosphere but this resulted in volatilization of the solvent zone, and the ingots were consequently sealed in evacuated ampoules, as shown in Fig. 2. A single crystal wafer was placed at the bottom of the ampoule to be used as a deposition site on top of which the solvent zone was placed. The parent material to be recrystallized was placed on top of the solvent zone and supported near the top (hot end) by a glass rod as shown. This was necessary to keep it from falling when the solvent zone melted, thus forcing the solvent up the sides of the ampoule. The ampoule was sealed with a minimum void volume and supported with a glass rod attached to one end.

Materials.—The bismuth metal shot and the tellurium used for preparing the samples were not purified further after being obtained from the manufacturers. The bismuth metal (99.9999+%) was obtained from Cominco Products, Inc., and the tellurium (99.999+%) from the Kawecki Chemical Company.

Crystal growth procedure.—It becomes helpful, when choosing starting compositions for both parent ingot and solvent zone, to have some knowledge of the phase diagram in which one is working. For this reason, the data presented by Glatz (1) for this system was utilized. The solvent chosen for growing Bi_2T_3 (γ-phase, mp = 585°C) was material of tellurium-eutectic composition ($Bi_{10}Te_{90}$) which has a melting point of 414°C. The temperature varied along the polycrystalline ingot between 425° and 530°C; so that when the ingot was recrystallized (solvent zone passed completely through the ingot) its composition followed the tellurium-rich solidus line of Bi_2Te_3 from 425° to 530°C, as is represented in the bismuth-tellurium phase diagram (Fig. 3). The initial thickness of the solvent zone was about 4 mm.

Solvent zones were passed upward through three Bi_2Te_3 ingots with an elapsed time for each of about one month. The zones passed through the entire length of the ingots in about a week or less and the remain-

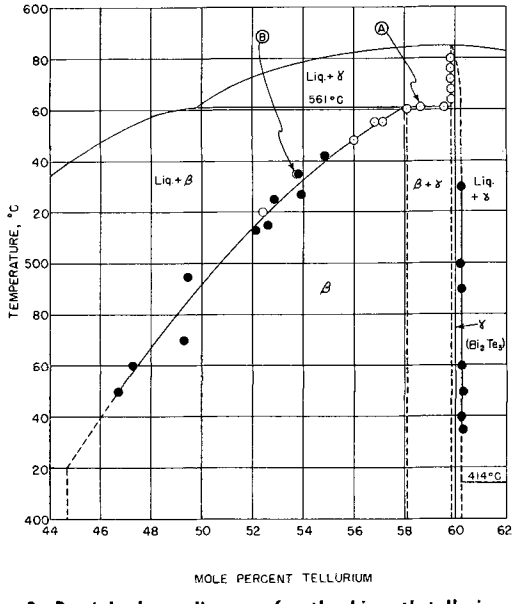

Fig. 3. Partial phase diagram for the bismuth-tellurium system. Open and closed circles are equivalent.

ing time was given to allow possible liquid entrapments to diffuse to the top. The lengths of the resulting ingots varied between 2½ and 3 in., since the liquid zone usually disconnected before reaching the top of the original ingot (3½-4 in.). The diameter of all of the ingots grown was 11 mm.

In an effort to produce a single crystal ingot, a single crystal seed was used as a deposition-site. This seed crystal was cut from an ingot pulled from a Czochralski-type furnace. This configuration was later varied by using an ampoule with a constriction near the bottom. The bulb formed by the constriction was filled with solvent zone and then run through the procedure described above. Although large crystallites were obtained in some ingots, no ingot was grown as a single crystal.

The existence of a peritectic compound (β-phase) on the Bi-rich side of Bi_2Te_3 was reported by Glatz (1) as well as by Abrikasov and Bankina (23). Glatz used long-term annealing of fine powders and established the peritectic invariant point at 562°C and 55 m/o (mole per cent) tellurium. This information was used as a guide in choosing the starting composition for the preparation of the β-phase by TSM. The procedure was the same as that for the preparation of the congruently melting γ-phase except different starting compositions were required. The parent material was a rapidly quenched ingot of composition $Bi_{47}Te_{53}$ and the zone had the composition $Bi_{80}Te_{20}$. Due to the large single-phase region of the β-phase, pure bismuth metal was also used as a zone to furnish enough Bi to reach the saturation point. A starting zone of about 5 mm thickness was used. No seed was used since no parent β-phase material was available as was the case with the γ-phase preparation. The crystallization temperatures of the ingots prepared varied between a minimum of 425° and a maximum of 550°C, except in the unique case described in the next paragraph.

In one case an effort was made to prepare both the β-phase peritectic and the congruently melting γ-phase in one ingot. This ingot could be used to determine the solubility of Bi in Bi_2Te_3 above 562°C as well as an added proof for the existence of the β-phase. A sharp change in the composition of Bi noted as one analyzes along this ingot will be strong evidence for the existence of a peritectic reaction. Quenched Bi_2Te_3 was used as a starting ingot and pure Bi metal was used for the solvent zone. Again no deposition-site was used. The temperature varied from 505°C (cold end) to 580°C (hot end) thereby crossing the peritectic temperature (562°C). Almost a week was necessary for the zone to travel to the top of the 3-in. ingot, and two extra weeks were allowed for annealing.

Analysis of ingots.—After cooling to room temperature, each ingot was cut into representative horizontal slices for chemical, microscopic, and differential thermal analysis (DTA). DTA was used to determine the melting point (first formation of liquid) of a given segment which had also been analyzed chemically.

The DTA thermograms were obtained by plotting the difference in temperature between an aluminum oxide reference standard and the sample on a Honeywell X-Y recorder (Model 153X33). The reference and the sample (ground into powder) were sealed in Vycor ampoules containing thermocouple wells and placed symmetrically in a high thermal capacity Kanthal furnace. The heating rate of the furnace was 5°C/min controlled with a Honeywell cam-type program controller (Model 152). Using sodium chloride as a calibration standard, melting points could be determined well within an accuracy of ±2°C. The melting point defined the ordinate and chemical analysis the abscissa for locating one point on a given solidus. A 4 mm segment was necessary to obtain enough material for duplicate chemical analyses and one 0.75g DTA sample. DTA was also used to determine the presence of any eutectic solvent which may have been trapped in grain boundaries. This was also checked by mounting slices for microscopic inspection. Representative sections, usually near both ends and the middle, were polished so that eutectic phases could be observed under polarized light. Eutectic material must be absent in order to validate the chemical analyses used for determining the equilibrium solidus lines.

The chemical analyses performed by our analytical section were essentially the method of Reed (24) with minor modifications. The analyses were always performed by the same chemist and the accuracy checked by periodically inserting knowns along with the TSM samples. The known standards were prepared by sealing carefully weighed metals of at least 5 9'S purity in an evacuated ampoule. The samples were then melted, rocked, and quenched to insure uniformity. The entire ingot was ground, mixed, and sectioned. The results of a representative analysis is shown in Table I.

The results of other analyses were always approximately the same. One sees that the accuracy for the Te analysis is well within the one to two parts per thousand claimed by Reed and is at least ±0.05 w/o (weight per cent) Te, but the Bi analyses are high. Since the Te analyses were consistently reliable, the %Bi was always taken by difference.

Results

Congruently melting Bi_2Te_3 *(γ-phase).*—Three ingots of γ-phase Bi_2Te_3 were recrystallized by TSM, all of which were tellurium-rich as determined by chemical analyses. All three ingots prepared contained crystallites varying from about 1 to 3 mm in cross-section.

The first ingot grown was removed from the furnace immediately after the solvent zone traveled the length of the parent ingot. Twelve days were required for growth. Differential thermal analyses of sections of this ingot showed the presence of anywhere from 0.1 (near the bottom) to 1.0% (near the top) uncombined tellurium eutectic (solvent), thereby invalidating the chemical analyses for determining the solubility of Te in Bi_2Te_3. Because of these entrapments, it became necessary to anneal the samples past the time for complete zone passage. Microscopic inspection showed that more than 90% of the eutectic material present was located in the outer skin of the ingot and the remainder in grain boundaries.

This distribution was also found in the next two ingots (annealed three weeks) but the total quantity of solvent was at least an order of magnitude less. Separate DTA's were made on sections along the ingots of both the interior and exterior portions. In the thermograms of the sections where the outer skin was concentrated, a very small eutectic peak was seen; and on sections where only the inside of the ingot was used no peak was visible.

The outer skin is a distribution of eutectic material in the outside layer of the ingot and might be as thick as 0.1 mm in some locations. A radial temperature distribution in the furnace is one explanation for the formation of this "skin" since it is quite likely that a slightly cooler temperature exists in the center of the ingot than on the outside on a given horizontal plane. The amount of Te-eutectic located in the grain boundaries (disregarding outer skin) was negligible. The results of all the slices from both ingots were

essentially the same. Chemical analyses of the inside sections of these two ingots indicate a solubility of 0.22 m/o tellurium in Bi_2Te_3 above 420°C, and also indicate that the composition of the equilibrium solidus varies very little (if at all) between 430° and 530°C. The Te concentration variation *vs.* temperature approached the reliability of the chemical analyses (±0.05), therefore, the tellurium concentration was considered invariant over the temperature range studied. The Te-rich solidus is depicted in the partial phase diagram (Fig. 3) as a vertical straight line at the composition 60.22 ± 0.05% Te. The line is solid only where data points were taken. Each segment taken from the two ingots was analyzed in duplicate and considered to be independent. The DTA thermograms for all of these segments were identical, all showing initial melting at about 565°C. The traces showed gradual breaks at the melting point indicative of a solidus transformation. Since the first sign of melting appeared at 565°C, we can draw the Te-rich solidus vertical up to this temperature.

Since the most likely source of error in the chemical analysis is that due to Te-rich eutectic material in the samples, the phase boundary could only be closer to the stoichiometric composition than the value 60.22 ±0.05% Te. Close inspection of the DTA's showed that the Te-eutectic peak was always larger on the cooling cycle (after sample has been completely melted) than on the heating cycle and if no peak was seen on the heating curve, one was usually seen on the cooling curve. The equilibrium solubility of Te in Bi_2Te_3 is apparently disrupted when the sample melts and not restored when refrozen.

Peritectic β-phase.—Four ingots of β-phase bismuth telluride were grown with no variations necessary from the original procedure. The crystalline size obtained from these ingots was markedly larger than those obtained when growing the congruently melting γ-phase. Crystallites up to five or six millimeters in two dimensions were observed and up to one or two centimeters in length. The entrapment of an eutectic phase (including outside skin) was essentially nonexistent as evidenced by microscopic inspection and also DTA. No bismuth-eutectic peak was noted on the heating curve on any of the thermograms obtained. Back reflection x-ray Laue photographs were taken of single crystal sections of one of the β-phase ingots grown and showed very good crystalline perfection. This was also evidenced by the good cleavage obtained with these crystals.

The data obtained from the first three ingots defining the equilibrium solidus are tabulated in Table II and plotted as closed circles in Fig. 3 and those obtained from the last ingot (discussed in the next section) as open circles.

Again, each data point is an average of two chemical analyses plotted *vs.* temperature of first melting as seen on a DTA thermogram. The thermograms of all alloys between 50 and 58% Te showed double peaks indicating that the 561°C peritectic tieline is essentially correct as drawn, meeting the liquidus boundary at about 50 m/o Te. This is in agreement with data found by Glatz (1). The solidus curve calculated by the least squares method was found to follow the equation

$$T(°C) = -0.0031792x^3 + 0.11351x^2 + 24.202x - 604.59$$

where x = m/o Te. The standard deviation for this curve is 5.6°C.

Table II. Melting points of β-phase as obtained from DTA, with corresponding chemical analysis

Melting point, °C	Te, m/o
450	46.71
460	47.27
470	49.29
493	49.48
512	52.21
515	52.62
525	52.97
527	53.96
533	53.83
541	54.86

Along this curve the points obtained from four ingots agree well with each other except for a pair of points at approximately 50 m/o Te. The observed temperature difference of about 25° is much greater than the estimated reliability in the melting point determination. Therefore, there exists the possibility that this pair of points indicates a discontinuity in the solidus line. On close inspection of the DTA's an apparent small peak was seen at about 500°-510°C partially masked by the larger liquidus peak. Another interesting fact was noted. On thermograms of all compositions below 50 m/o Te a bismuth-eutectic peak (268°C) was observed on the cooling curve only, after the sample had been melted. This is evidence that equilibrium solubility is not easily attained in this region. Using annealing techniques to study the same region of the phase diagram, Glatz (1) found difficulty obtaining equilibrium below 52 m/o Te. Whether an actual compound or reaction occurs at this composition necessitates further investigation.

Peritectic jump (β- and γ-phase in same ingot).—The results obtained from the one ingot grown across the peritectic reaction temperature are shown as open circles in Fig. 3. All thirteen data points were obtained from consecutive 4 mm segments starting immediately below the solvent zone which was clearly outlined on the frozen ingot. The chemical analyses showed no temperature dependence of solubility of Bi in Bi_2Te_3 (γ-phase) between 561° and 580°C, but a constant solubility of 0.17 ± 0.05 m/o bismuth. All of the first five samples (crystallized above 561°C) showed sharp melting points at 585° ± 2°C, which is indicative of a vertical solidus line. Since the melting points for these first five samples were essentially the same, and their crystallization temperatures were known to lie from 560° to 580°C, they defined the Bi-rich γ-phase solidus and were plotted as such in Fig. 3. A representative DTA of these five segments is shown in Fig. 4 accompanied by the average chemical composition of each of the five ingots.

The next two segments had a sharp thermal arrest at 561°C followed by the large peak due to γ-phase melting (Fig. 5). This clearly defined the peritectic reaction temperature in agreement with the value (562°C) reported by Glatz (1). The fact that the peritectic reaction was seen in two segments (although very small in one) is explained by assuming that a nonhorizontal or nonplanar isotherm existed in the ingot at the peritectic temperature because of temperature variations within the furnace. When horizontal slices were made, the alloy corresponding to the 561°C crystallization composition was found in two segments.

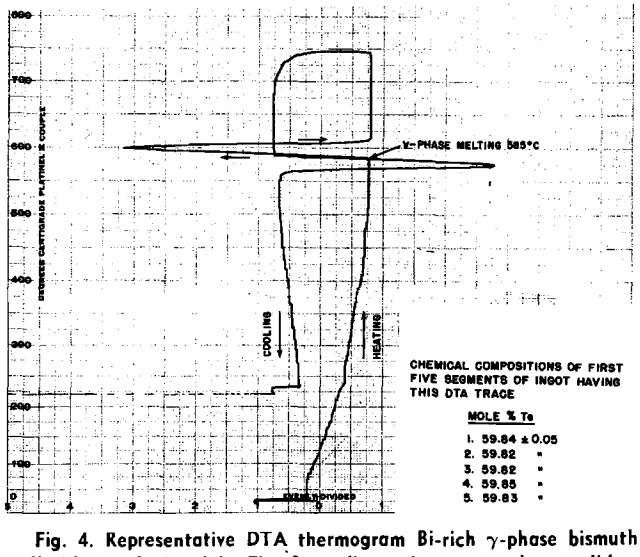

Fig. 4. Representative DTA thermogram Bi-rich γ-phase bismuth telluride as depicted in Fig. 3 as five points on γ-phase solidus.

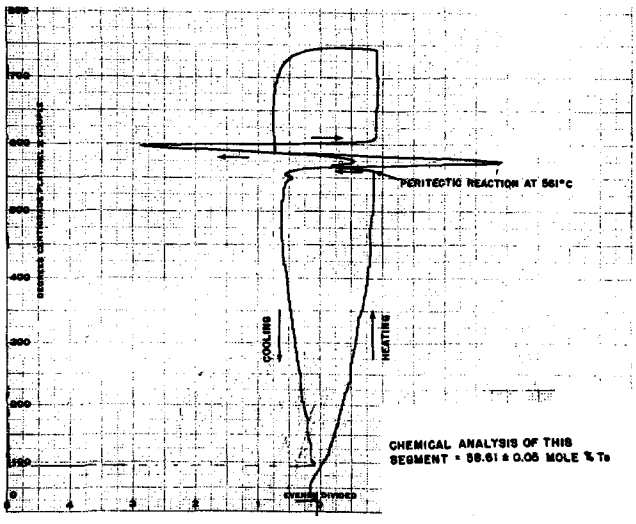

Fig. 5. DTA thermogram showing peritectic reaction at composition A in Fig. 3.

The remaining points tail off to define the β-phase solidus and the lower points are shown overlapping results from the other ingots. The overlapping data are in very good agreement with each other, and two of the points are essentially superimposed. A representative DTA depicting β-phase melting is shown in Fig. 6 from which point B was obtained in Fig. 3.

The calculated β-phase solidus is seen to intercept the peritectic reaction temperature (561°C) at 58.1 m/o Te, thereby defining the peritectic invariant point. Although not as certain, extrapolation at the lower end of the solidus to the 420°C peritectic tieline shows the β-phase region extending to 44.7 m/o Te.

Discussion and Conclusions

The remainder of the partial phase diagram (Fig. 3) is drawn in broken lines. Exactly where the Bi- and Te-rich solidus lines combine on the liquidus might still remain debatable, although the evidence favors a bismuth-rich maximum melting point and was drawn as such. This would agree with Glatz (1), Offergeld and Van Cakenberghe (19), and with Satterthwaite and Ure (20). The evidence favoring a bismuth-rich maximum melting composition is: (I) The data points show a bismuth-rich solidus up to 580°C, whereas data points on the tellurium-rich solidus were taken only to 530°C. (II) The bismuth-rich DTA thermograms show very sharp breaks (Fig. 4) at the melting point, while the tellurium-rich samples show a more gradual break at 565°C which is indicative of incongruent melting of the type shown in Fig. 6 at 535°C. One must therefore conclude that the Te-rich phase boundary slopes toward the Bi-rich side of Bi_2Te_3 above 565°C and the maximum melting composition occurs at 59.83 ± 0.05 m/o tellurium.

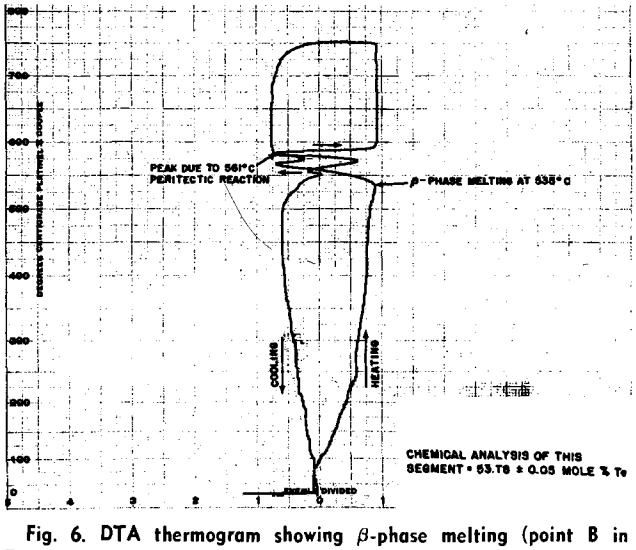

Fig. 6. DTA thermogram showing β-phase melting (point B in Fig. 3) and peritectic transformation.

It must be kept in mind that all data points in Fig. 3 are average values obtained from 4 mm slices. Since the temperature varies continuously across an ingot during crystal growth, a sample with a finite crystallization temperature cannot be chosen and chemically analyzed. Across 4 mm the crystallization temperature may vary as much as 4°C and the concentration as much as 0.4 m/o tellurium, where the slope of the curve is small.

It becomes expedient at this point to compare our results with those obtained by Glatz (1) who used a completely different approach (long-term annealing of fine powders) to define the equilibrium phase relationships for the Bi-Te system. Table III compares significant points and, in general, good agreement is seen except for the peritectic point where Glatz (1) used visual examination of photomicrographs to determine this value.

One concludes that, although either technique is satisfactory for determining equilibrium phase relationships, the advantages for TSM are: (*i*) the results can be obtained in a shorter time; (*ii*) the resulting material is in a condition for practical applications, and (*iii*) the complete solidus curve can be defined from one or two ingots, whereas much more time and effort is necessary when using annealing techniques to obtain the same information. Annealing techniques, however, must be used to study solid-solid equilibria while TSM becomes practical only where the solid phase of interest is in equilibrium with a liquid.

Although fairly large (5 x 5 x 20 mm) single crystals were obtained by TSM crystal growth, an ingot containing only one crystal was not. It is believed that this could be realized by decreasing the temperature gradient across the ingot thereby slowing the crystal growth process and eliminating spurious nucleation. The fact that some Te-eutectic was found in the grain boundaries after two to three weeks of annealing is evidence for an oxide or other high energy barrier at the grain boundaries which prohibited diffusion. Another less likely possibility might be vertical channeling of eutectic phase.

Summary

TSM has been found to be a valuable technique for the preparation of equilibrium binary compounds, both peritectic and congruently melting. The extension into ternary and more complicated systems should be relatively simple. It has been relatively easy to prepare the β-phase peritectic bismuth-telluride from a quenched ingot of Bi_2Te_3. The problem of preparing large single crystals of bismuth telluride by TSM apparently necessitates better control of crystal growth parameters.

From a single ingot of bismuth telluride grown across a peritectic reaction temperature, the following information was obtained: (*i*) the Bi-rich γ-phase solidus was well-defined above the peritectic temperature; (*ii*) the peritectic temperature was easily derived from sharp breaks on DTA thermograms: (*iii*)

Table III. Comparison of results obtained by long-term anneal experiments [Glatz (1)] with those obtained from TSM crystal growth (Strassburger)

	Long-term anneal	TSM
Te-rich γ-phase Solidus limit (% Te)	60.35 ± 0.15	60.22 ± 0.05
Bi-rich γ-phase Solidus limit (% Te)	59.70 ± 0.10	59.83 ± 0.05
Peritectic point (% Te)	55.0	58.1
Lower limit of β-phase (% Te)	~45.0	44.7
Maximum melting of γ-phase (% Te)	59.8	59.83

the peritectic (β-phase) solidus was defined within the temperature range covered, and (*iv*) the peritectic invariant point was found by slight extrapolation of the least squares β-phase solidus curve to the peritectic temperature.

Control of Boron Diffusion from a Pyrolitic Borosilicate Glass Source

K. M. Whittle and G. L. Vick

Instrument/Controls Division, Conrac Corporation, Duarte, California

ABSTRACT

A diffusion system is described for the diffusion of boron into silicon which is independent of deposition parameters over wide ranges of values. The diffusion depends only on diffusion time and temperature. A pyrolytically deposited boron-doped oxide is used as the impurity source. Wet oxygen is used to control the diffusion of boron from the oxide into the silicon.

Diffusion systems which use pyrolytically deposited doped oxides as diffusion sources have been discussed by several authors (1, 2). Diffusion from such a source may be performed in either an oxidizing or nonoxidizing atmosphere. For diffusion in a nonoxidizing atmosphere the resulting diffusion profile will depend on the composition of the doped oxide, the segregation coefficient, the diffusion coefficients of the dopant in the oxide and the semiconductor, and the thickness of the oxide. For diffusion in an oxidizing atmosphere, the diffusion profile will depend on all of the above parameters in addition to others relating to the kinetics of oxide growth compared to the diffusion rate of the dopant through the oxide. The diffusion may be carried out in two steps: (*i*) diffusion in a nonoxidizing atmosphere to provide a thin highly doped layer of semiconductor followed by (*ii*) a redistribution cycle in which an oxidizing atmosphere inhibits further doping from the oxide while diffusion continues until the desired junction depth and surface concentration are achieved. The diffusion profiles obtained, in general, depend on a high degree of control over the parameters relating to the deposition of the doped oxide.

This paper describes a system which minimizes or eliminates the dependence on deposition parameters. It does this by satisfying two conditions: (*i*) an oxide of sufficient impurity concentration and thickness that throughout the doping cycle, the diffusion of impurities from the oxide into the semiconductor depends only on the solid solubility and diffusion coefficient of the impurity in the semiconductor, and (*ii*) an oxidizing atmosphere sufficiently effective that oxidation will occur at the semiconductor-oxide interface faster than the impurities can diffuse through it, thus completely preventing further doping during the redistribution cycle. (The doped oxide could be removed by chemical etching eliminating this requirement on the oxidizing atmosphere. It is often undesirable, however, to introduce this step into the diffusion cycles.) The work of Pliskin and Gnall (3) shows that thermal oxidation does proceed at the oxide-silicon interface, but it is not obvious from this work that doping will be prevented at diffusion temperatures (*e.g.*, 1150°C) or in the presence of thick (*e.g.*, 4000Å) doped oxides.

Key words: diffusion, boron, silicon, pyrolysis.

Deposition and Diffusion Systems

The experiment described deals with diffusion of boron into silicon from a borosilicate glass film deposited on the silicon by pyrolysis of tri-n-propyl borate and tetraethyl orthosilicate.

The borosilicate glass film is deposited on the wafers in the system shown in Fig. 1. The wafers are deposited five at a time lying flat on a boat. The quantity of borate and silicate introduced into the deposition

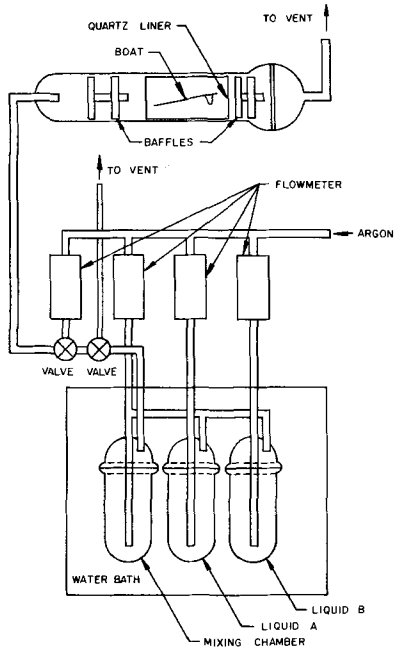

Fig. 1. Deposition system. Liquid A, tetraethyl orthosilicate; liquid B, tri-n-propyl borate.

furnace is determined by the temperature of the water bath and by the flow rate of carrier gas bubbled through the borate and the silicate. It is assumed that the geometry of the bubblers is such as to ensure that the carrier gas is saturated with the dopants. The temperature of the borate and silicate is maintained at 32° ±0.5°C. The furnace temperature is 688°C. Deposition time is 10 to 25 min and gas flow is 600 cc/min through the borate, 47.2 cc/min through the silicate with a diluting flow of 15 SCFH of argon. In this experiment, the deposition parameters were varied one at a time about these values to determine the dependence of the final V/I on the deposition parameters.

The diffusion furnace is operated at 1151° ±2°C and is provided with sources for dry nitrogen and for wet or dry oxygen. The wet oxygen is obtained by bubbling through water at 85°C. Flow rates are 1420 cc/min for the nitrogen and for the oxygen. The diffusion consists of a doping period during which nitrogen flows through the furnace followed by a drive-in period during which the nitrogen is turned off and wet or dry oxygen is introduced into the furnace. The total diffusion time (doping plus drive-in) is held constant at 180 min.

Figure 2 shows the calibration curves of sheet resistivity *vs.* doping time. The curve labeled nitrogen only is plotted for wafers which were removed from the diffusion furnace after the doping time indicated. The wafers for the other two curves were left in the furnace for the drive-in cycle for a total diffusion time of 180 min. It may be seen from these curves that for a dry oxygen drive-in cycle the sheet resistivity continues to decrease during the drive-in, indicating that the dry oxygen is not "turning off" the boron source. This is also indicated by the fact that the sheet resistivity for zero doping time is only 9 ohms/square. The wet oxygen on the other hand turns off the boron source so completely that for zero doping time, the surface of the silicon is not converted from n to p type. (The wafers were originally 3 to 6.5 ohm-cm, phosphorous-doped silicon.) The increase in sheet resistivity during the wet oxygen drive-in results from some of the boron-doped layer being converted to SiO_2 and also some segregation of boron back into the newly grown oxide. It should be pointed out that the doped oxide film used with the dry oxygen is only half as thick as that used with the wet oxygen.

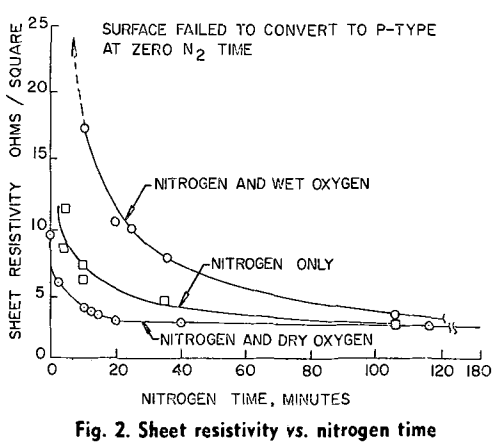

Fig. 2. Sheet resistivity *vs.* nitrogen time

Deposition Parameters

The deposition parameters were varied one at a time about the values given above. The dependence of the resulting sheet resistivity on these parameters for diffusions using wet oxygen to stop the doping process is compared with diffusions using dry oxygen. In Fig. 3 through 7 diffusions of 105 min in N_2, 75 min wet O_2 are compared to the diffusion in dry oxygen which gives roughly the same total number of diffused impurities, namely 30 min N_2, 150 min dry O_2.

Figure 3 shows the dependence of sheet resistivity on deposition time. The curve for diffusion in wet oxygen indicates an approach to an infinite source as the slope approaches zero for a deposition time of 25 min. The curve for diffusion in dry oxygen continues to drop rapidly because of the failure of the dry oxygen to stop the doping reaction. The dependence of final V/I on deposition time is 0.47%/min of deposition time for wet O_2 diffusion and 3.3%/min for dry O_2.

Figure 4 shows the dependence of sheet resistivity on deposition temperature. The two curves compare a 10-min deposition with dry oxygen diffusion to a 25-

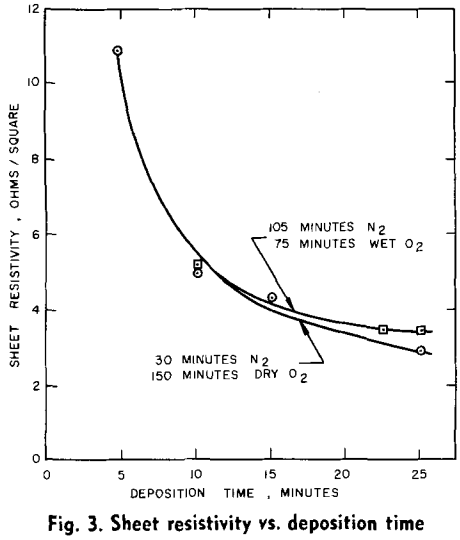

Fig. 3. Sheet resistivity vs. deposition time

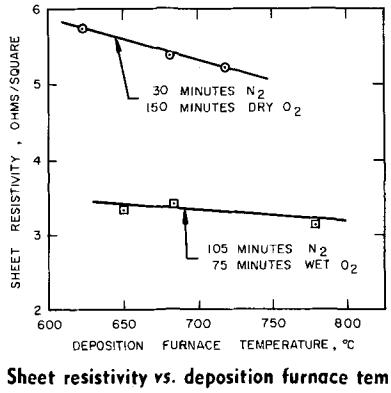

Fig. 4. Sheet resistivity *vs.* deposition furnace temperature

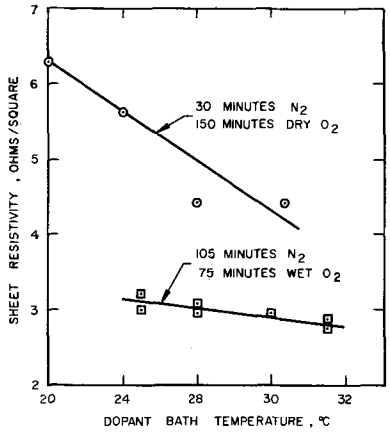

Fig. 5. Sheet resistivity vs. dopant bath temperature

min deposition with wet oxygen diffusion. The latter is found to be insensitive to deposition temperature.

A comparison of the dependence of sheet resistivity on dopant source temperature for dry as opposed to wet diffusion is made in Fig. 5. The 10-min deposition followed by the dry oxygen diffusion cycle is found to show a strong dependence on dopant source temperature, while the 25-min deposition with wet oxygen diffusion is nearly independent of this parameter.

Figure 6 shows the effect of changes in carrier flow through the borate source.

Figure 7 shows the effect of variations in silicate carrier flow rate.

Results

151	1	4/11	3.24	0

control described above. The repeatability from run to run is ±6.5%. However, this spread is nearly within the tolerance (6%) to be expected from diffusion temperature variations of ±2°. The repeatability of sheet resistivity over a single wafer is ±1.5%. The resistivities were measured with a four-point probe. The run numbers listed are not consecutive; those omitted were experimental runs not done in accordance with this process or were subjected to inadvertent departures from the process, the most common being water contamination in the dopant bubblers. The deposition tube was cleaned between runs 112 and 114 by etching away the accumulation of deposited glass with a 1:1 solution of hydrofluoric and nitric acids. The consistency of results before and after this cleaning indicates that the process is not dependent on reaching a steady state or equilibrium condition where the walls of the deposition tube are saturated with dopant.

It has been found that the surface concentration after the nitrogen cycle is independent of nitrogen time over periods ranging from 20 to 105 min lending strong support to the assumption that the concentration is limited by solid solubility. The final diffusion profile indicates that significant quantities of boron have segregated out into the oxide during the wet oxygen drive-in cycle, resulting in a maximum concentration at 1.5μ depth.

Staining of the diffused areas resulting from formation of suboxides of boron and silicon (4) or a boron-rich phase (5) which commonly occurs in highly doped boron diffusions did occur on wafers subjected to the

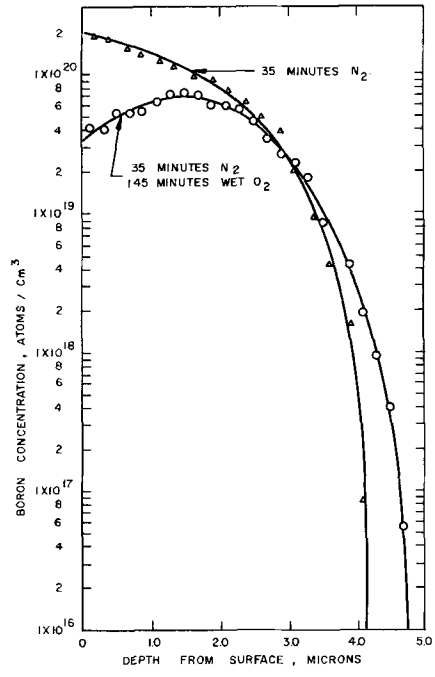

Fig. 8. Boron concentration vs. depth from surface

dry oxygen diffusion, but was eliminated by diffusion in wet oxygen.

Conclusion

It has been shown that a deposition-diffusion system for boron in silicon can be made to be highly independent of the deposition parameters. This is accomplished by using highly doped pyrolytic oxide as an impurity source together with an atmosphere of wet oxygen to control the diffusion of boron from the oxide into the silicon.

Zinc Diffusion into Gallium Phosphide under High and Low Phosphorus Overpressure

S. F. Nygren[1] and G. L. Pearson

Stanford Electronics Laboratories, Stanford University, Stanford, California

ABSTRACT

The acceptor zinc has been diffused into n-type single crystal gallium phosphide at temperatures between 700° and 1000°C from diffusion sources which lie in two different regions of the Ga-P-Zn phase diagram. One source (pure zinc) provides low phosphorus overpressure and leads to p-n junctions which are distinctly nonplanar. The other (zinc plus excess phosphorus) provides high phosphorus overpressure and leads to smaller diffusion coefficients and considerably more planar p-n junctions. These effects are consistent with the interstitial-substitutional model for diffusion of zinc in GaP. With either source, diffusion induced dislocations are formed throughout the diffused layer after an incubation time. The p-n junction depth corresponding to the first appearance of the induced dislocations is found to be greater when the high phosphorus pressure source is used.

Zinc diffusion into gallium phosphide has generally been described as anomalous. Concentration profiles cannot be fitted by complementary error functions, and the diffusion coefficient is found to be dependent on zinc concentration as well as temperature (1). Moreover, p-n junctions formed by diffusion from a pure zinc source are usually quite nonplanar.

Recent results from experiments with GaAs (2-4) suggest that the nature of zinc diffused junctions in GaP may be changed and perhaps even improved by using a diffusion source other than pure zinc. Hence, it is the purpose of this study to examine the depth and planarity of zinc diffused junctions in GaP, using temperature, phosphorus overpressure, and time as independent variables. It is found that substantial changes can be made in the diffusion results by changing the diffusion source. Diffusion sources which provide high phosphorus overpressures lead to diffusion coefficients which are smaller than those associated with low phosphorus pressures, and they also lead to considerably more planar p-n junctions. However, with any diffusion source, diffusion induced dislocations appear throughout most of the diffused layer after the p-n junction has reached a critical depth. The onset of these dislocations increases the diffusion coefficient considerably and provides sites on which the zinc can precipitate. Nevertheless, when the induced dislocations are taken into account, the relation among phosphorus overpressure, junction depth, and junction planarity is described quite adequately by the interstitial-substitutional model that was first proposed for Zn diffusion in GaP by Chang and Pearson (1).

The Ga-P-Zn System

In order to understand the relationship among the thermodynamic variables that control diffusion properties, the Ga-P-Zn system must be examined. Figure 1 presents the relationship among the condensed phases at 900°C, as determined by Panish (5). The diagram has this general shape for all temperatures between 700° and 1040°C, the only differences being slight movements of the liquidus lines as temperature changes. Within the temperature range of 700°-1040°C, two regions of the phase diagram are of special interest for diffusion studies. They are labeled regions 1 and 2. In either region, the system contains 4 phases: solid GaP doped with Zn, solid Zn_3P_2 doped with Ga, a liquid ("a" in region 1, "b" in region 2), and a vapor which is discussed below. Both regions are monovariant; that is, within either one the diffusion conditions are fixed as soon as a single variable such as temperature is fixed. This means that reproducible diffusions can be carried out even though rather loose control of the diffusion source is allowed.

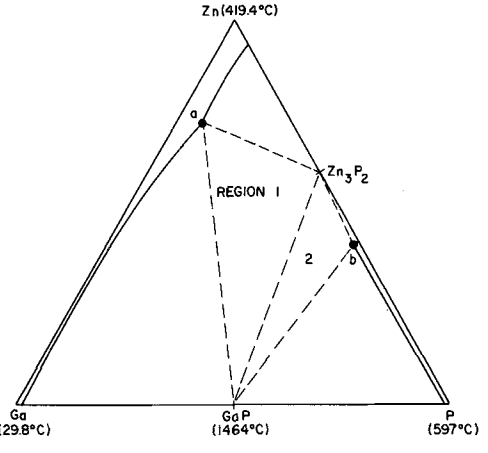

Fig. 1. Ga-P-Zn phase diagram at 900°C (after Panish)

[1] Present address: Bell Telephone Laboratories, Reading, Pennsylvania.

Before diffusion sources for regions 1 and 2 can be prepared, it is necessary to know the vapor pressures that exist in equilibrium with liquids "a" and "b" at the temperatures of interest. Since these pressures are not available in the literature, they must be calculated. From thermodynamic considerations,

$$P_{Zn} = X_{Zn}\ \gamma_{Zn}\ P^{o}_{Zn} \quad [1]$$

$$P_{P_4} = (X_P\ \gamma_P)^4\ P^{o}_{P_4} \quad [2]$$

where P_i, X_i, and γ_i are the vapor pressure, mole fraction, and activity coefficient of substance i for a given liquid, and P^{o}_i is the vapor pressure of substance i over pure liquid i. The values of P^{o}_i are given by the JANAF Tables (6) in the case of phosphorus, and by averaging the data of Barrow *et al.* (7) and Nesmeyanov (8) in the case of zinc. The X_i may be read or extrapolated from Panish's phase diagram (5), and the γ_i are calculated by the regular solution method of Furukawa and Thurmond (9).

Results of the calculations are shown in Fig. 2. It is seen that P_{Zn} is somewhat lower over liquid b than over liquid a, and that P_{P_4} is considerably higher over liquid b than liquid a. Similar calculations show that P_{Ga} is negligible and that other phosphorus species can be neglected over liquid b. The accuracy of these calculations is somewhat difficult to determine, but it can be shown that they give values which are within 25% of those reported by Thurmond (10) for P_{P_2} and P_{P_4} over the GaP binary liquidus.

Experimental Procedure

The GaP single crystals used in this study were grown by an open tube chloride transport process similar to that described by Oldham (11). Epitaxial GaP layers were grown on (111)Ga faces of GaAs seeds. The 50-100 μm of GaP closest to the seed contained about 1 x 10^8 dislocations/cm^2. The remaining portions of the layers were fairly uniform, having about 10^6 dislocations/cm^2 and a density of stacking faults and microtwins of 300-500 cm^{-1}. The layers were n-type with carrier concentrations of 1-5 x 10^{15} cm^{-3}. Samples were prepared for diffusions by lapping away the heavily dislocated portions of the GaP crystals and then mechanically polishing both faces in Linde A 0.3 μm alumina. Each sample was loaded into a clean, evacuated (1 x 10^{-5} Torr) quartz ampoule along with a diffusion source which was located in a quartz container designed to minimize contact between the sample and the ternary source liquid. The net internal volume of the ampoule was 0.170 $\pm$ 0.025 cm^3.

Two different diffusion sources were used. For diffusions in region 1 the source was 1.0 mg of a pulverized mixture of 75% undoped vapor epitaxial GaP and 25% 5 nine's pure Zn. The mixture was annealed at 1000°C for 24 hr before it was pulverized (12). One milligram of this mixture is sufficient to provide a diffusion source in region 1 yet small enough to minimize the amount of liquid in the system.

For diffusion in region 2, the source was 2.7 mg high purity phosphorus, 3.4 mg zinc, 0.87 mg of 7 nine's pure gallium, and 5 mg crushed GaP. These amounts were calculated to provide a diffusion source in region 2 for all temperatures between 750° and 1000°C even if the pressure calculations were in error by 40%. As a check, a diffusion was carried out at 900°C with less than 2.7 mg phosphorus. The resulting sample had almost no surface damage, suggesting that no liquid had been present in the system. The junction depth after 1 hr was 16 μm. When a diffusion was carried out at 900°C using the full 2.7 mg phosphorus, some damage had been done to the sample surface, indicating that liquid had been present in the system, and the junction depth after 1 hr was 10.6 μm. Comparison of these two results suggests that the full 2.7 mg of phosphorus provides a system which is in region 2.

In this study p-n junctions were revealed by cross sectioning diffused samples on (111)Ga planes that are inclined to the surfaces of the samples, and then etching the cross sections in the dislocation etchant 8g $K_3Fe(CN)_6$:12g KOH: 100g H_2O (13). This etchant reveals both the p-n junction and crystal defects so that irregularities in the p-n junction may be correlated with the defects. As shown in Fig. 3, three depths are typically measured: the minimum p-n junction depth, x_j; the minimum p^+-p junction depth, x_j'; and the average depth of a diffusion spike, x_s. The spike depth is measured at a fault that extends from the surface of the sample beyond the p-n junction. Such diffusion spikes have a rather consistent depth, and comparison of x_j and x_s is a good measure of junction planarity. Each of the measured depths is corrected for the thickness of the surface layer that had been removed by the etchant, typically 1-2 μm per side.

Experimental Results

Diffusion with low phosphorus overpressure.—Diffusion of zinc into GaP with liquid a in the diffusion system (region 1 of the phase diagram) typically results in moderate damage to sample surfaces and in p-n junctions that are very irregular. Figure 4 shows a highly magnified picture of a p-n junction and associated crystal defects as revealed by etching a 5° beveled surface on a sample that had been diffused in the presence of liquid a at 1000°C for 15 min. The p-n junction is seen to be quite irregular, and there are two regions where particularly enhanced diffusion is seen. One region is associated with a stacking fault or microtwin (center of the figure) and the other is associated with a cluster of dislocations (right).

The correlation between junction depth and dislocation density is further illustrated by observing how junction depth changes with diffusion time. All samples for this experiment were cut from the same GaP crystal (n = 1.3 x 10^{15} cm^{-3}) so that the initial dislocation and fault densities would be roughly the same in each sample. The results of four diffusions at 800°C and four diffusions at 900°C are shown in Fig. 5. For either temperature, the junction depth is proportional to the square root of time for shallow diffusions. For

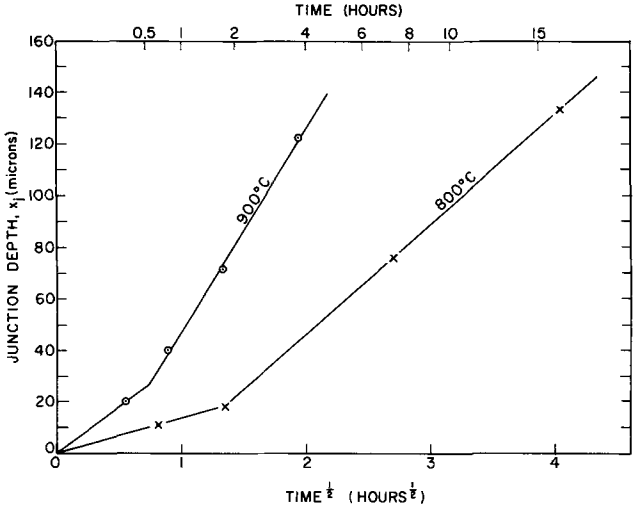

Fig. 5. p-n junction depth vs. the square root of diffusion time for samples that were diffused at 800° and 900°C with liquid a.

diffusions deeper than 20-25 μm, however, the diffusion depth is considerably deeper than would be predicted by proportionality to the square root of time. Previous workers (14) concluded that junction depth is proportional to the square root of time for all depths at 1000°C.

The knee in the curve is a demarcation between two very different diffusion conditions. First, as mentioned above, the diffusion coefficient is smaller below the knee than above. Second, samples with shallow junctions have no diffusion induced defects, while samples that are diffused beyond the knee have diffused layers containing about 1 x 10^8 induced dislocations/cm^2 which are distributed almost uniformly throughout the layer. Only the region within a few microns of the p-n junction escapes the induced dislocations. This is illustrated in Fig. 6, where etch patterns are shown on samples that were diffused below and beyond the knee. Third, samples with shallow junctions remain transparent, while the diffused layers of samples diffused beyond the knee become opaque. Since undiffused samples containing 10^8 dislocations/cm^2 are transparent, the opaqueness is attributed to zinc precipitation. Lastly, Ting (15) has shown that a knee in the x_j *vs.* $\sqrt{t}$ curve also exists for zinc diffusion in GaAs. In that case shallow diffusions have zinc concentration profiles which decrease smoothly with increasing distance; diffusions beyond the knee have concentration profiles which stay relatively constant near the surface and then decrease sharply. It is reasonable to assume that the same effect occurs in GaP. It should be noted that the depth corresponding to

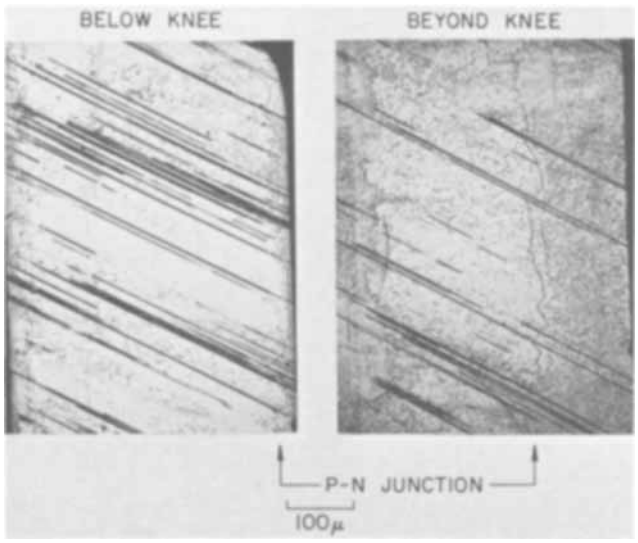

Fig. 6. Etched cross sections of samples that were diffused to different depths at 900°C with liquid a. The sample diffused below the knee in the x_j vs. $\sqrt{t}$ curve (t = 0.31 hr) has no induced defects; the sample diffused beyond the knee (t = 3.75 hr) has a heavily dislocated diffused layer.

the knee in the GaP curve varies slightly from crystal to crystal.

The relationship between diffusion temperature and p-n junction depth has also been measured. Again, all samples were cut from the same crystal. Table I summarizes the results, and both $x_j/\sqrt{t}$ and $x_s/\sqrt{t}$ are plotted against reciprocal temperature in Fig. 7. For the 998°C sample, the diffusion time was so short that warm-up time was appreciable; in this case an effective time was found by fitting $x_j(998°C)/\sqrt{t}$ to the straight line defined by the other points. In view of the fact that x_j is not proportional to $\sqrt{t}$, Fig. 7 should not be used to predict the junction depth that would be reached for specific diffusion temperatures and times. However, the relationship between $x_j/\sqrt{t}$ and $x_s/\sqrt{t}$ does provide a good measure of the irregularity of the junction. At 1000°C, the spikes penetrate 1.5 times as far into the crystal as the shallowest part of the junction. Due to the smaller activation energy associated with the spikes, they become more pronounced at lower temperatures; and at 700°C, they penetrate 5.5 times as deep as the shallowest part of the junction.

Diffusion with high phosphorus overpressure.—Diffusion of zinc into GaP in the presence of liquid b (region 2 of the phase diagram) differs in detail, but not in principle, from diffusions done with liquid a. Liquid b diffusions generally give better results, the sample surfaces being somewhat less damaged, and the p-n junctions being considerably more planar. A comparison of junction irregularity in samples that were diffused to similar depths at 900°C is shown in Fig. 8. (The surface damage on these samples and on the samples shown in Fig. 10 occurred when the samples were cross sectioned and was not present during diffusion.)

As with liquid a diffusions, the relation between junction depth and induced dislocations was studied

by observing how the p-n junction depth changes with time. All samples were cut from the same GaP crystal (n = 2.1 x 10^{15} cm^{-3}), and the diffusions were performed at 900°C. Results are summarized in Fig. 9, where the 900°C curve from liquid a has been included for comparison. For liquid b, both x_j and x_j' are proportional to the square root of diffusion time for medium depths. However, for times greater than about 60 hr, both are deeper than would be expected from proportionality to the square root of time, and for short times the junctions seem too shallow. The shallowest point in Fig. 9 was checked by diffusion into two different crystals; the same junction depth was found in each.

The knee in the curve provides the same demarcation with liquid b as with liquid a. Here again faster diffusion, zinc precipitation, and diffusion induced dislocations occur beyond the knee. It is seen, however, that the knee in the curve does not occur until a considerably greater depth than it does with liquid a. This is consistent with the Zn diffusions performed in GaAs by Black and Jungbluth (16). They found that the use of a high arsenic pressure diffusion source increased the diffusion depth necessary for diffusion induced defects to occur. It is also seen that the diffusion induced defects produced by liquid b do not appear to be as uniformly distributed as those produced by liquid a.

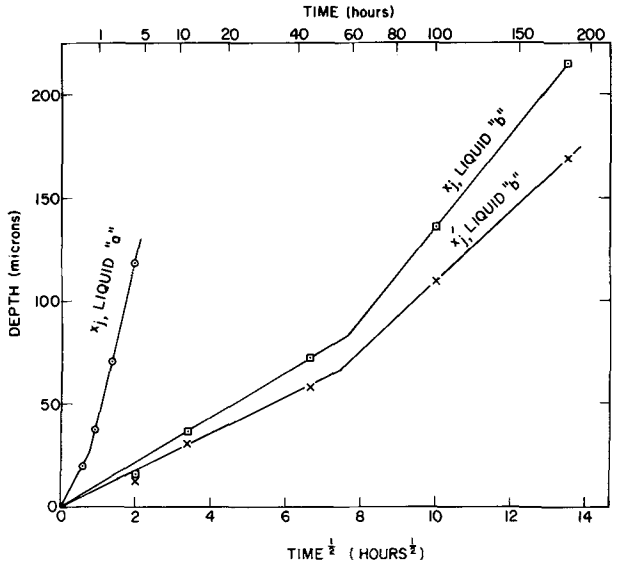

Fig. 9. p-n junction depth x_j, and p^+-p junction depth, x_j', vs. the square root of diffusion time for samples that were diffused at 900°C with liquid b. Data from liquid a are included for comparison.

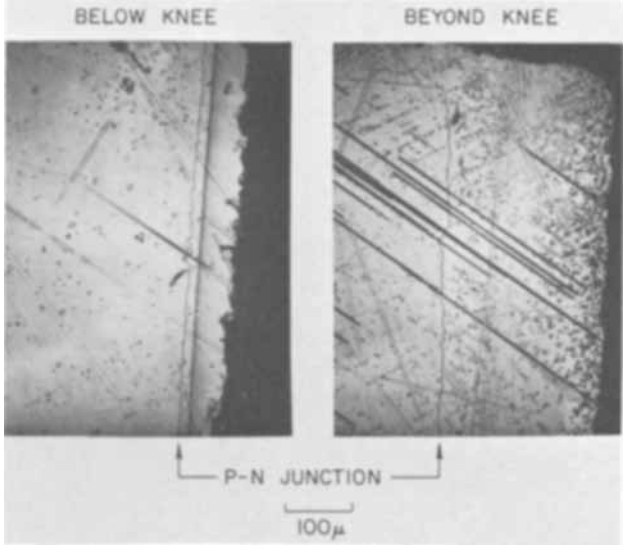

Fig. 10. Etched cross sections of samples that were diffused at 900°C with liquid b. The sample diffused below the knee in the x_j vs. $\sqrt{t}$ curve (t = 45.7 hr) has no induced defects; the sample diffused beyond the knee (t = 182 hr) has a heavily dislocated diffused layer.

A comparison of samples diffused above and below the liquid b knee at 900°C is given in Fig. 10.

For liquid b diffusions, the relationship between junction depth and temperature was measured in an undoped crystal with n = 3.1 x 10^{15} cm^{-3}. Table II summarizes the results, and $x_j/\sqrt{t}$ and $x_s/\sqrt{t}$ are plotted in Fig. 7. Again, since x_j is not proportional to $\sqrt{t}$, the interpretation of these curves must be restricted. Still, it is clear that liquid b diffusions have a smaller diffusion coefficient than liquid a diffusions, and that liquid b diffusions are considerably more planar. The

Table II. Minimum p-n junction depth, minimum p^+-p junction depth, and spike depth for samples diffused with liquid b at temperatures between 750° and 1000°C

T, °C	Sample	t, hr	$t^{1/2}$, hr$^{1/2}$	x_j', μm	x_j, μm	x_s, μm

spikes go only about 1.3 times as far into the sample as the shallowest part of the junction, and since the activation energy for the spikes is almost the same as the activation energy for diffusion in the bulk, junction irregularity is hardly any worse at low temperatures than at high.

Discussion

Because the diffusion coefficient of zinc in GaP is concentration dependent, the diffusion equation cannot be solved analytically. Nevertheless, it has been shown (14) that the p-n junction depth obtained under such conditions is

$$x_j = \sqrt{D_o t}\, f\left(\frac{C_d}{C_o}\right) \qquad [3]$$

where D_o and C_o are the diffusion coefficient and concentration of zinc at the surface of the sample, t is the diffusion time, C_d is the background donor concentration, and f is an unknown function. In the case of zinc in GaP, the zinc concentration changes very rapidly near the p-n junction so that x_j is only weakly dependent on f. In fact, f may be taken as a constant, f_o, for most purposes.

Diffusion of zinc into GaP is viewed as a parallel mode process, with the zinc existing as both interstitial and substitutional species (1). Casey *et al.* (17) have given the effective diffusion coefficient for this process as

$$\overline{D} = \left(2 + \frac{C_s}{\gamma_p}\frac{d\gamma_p}{dC_s}\right)(K_1^{-1} D_i C_s^2\ \gamma_p^2\ P_{P_4}^{-1/4} + D_s) \qquad [4]$$

where D_i is the interstitial diffusion coefficient, C_s and D_s are the concentration and diffusion coefficient of substitutional zinc, γ_p is the hole activity coefficient, P_{P_4} is the overpressure of P_4, and K_1 is an equilibrium coefficient which is dependent only on temperature. In deriving this equation it was assumed that the interstitial zinc atoms are fully ionized single donors, and that the concentration of interstitial zinc is orders of magnitude smaller than that of substitutional zinc. Expressions for the substitutional diffusion coefficient and the surface concentration of zinc may be obtained from the chemical equilibrium relating gallium vacancies to phosphorus pressure, and from the equilibrium relating zinc in the vapor to zinc in the crystal:

$$1/4\, P_4(g) \rightleftarrows V_{Ga}^{+u} + P_s + ue^- \qquad [5]$$

$$Zn(g) + V_{Ga}^{+u} \rightleftarrows Zn_s^{o} + ue^+ \rightleftarrows Zn_s^{-} + (u+1)e^+ \qquad [6]$$

Here Zn_s^o and Zn_s^- are un-ionized and ionized zinc atoms in substitutional sites in the gallium sublattice, and P_s is a phosphorus atom in a substitutional site in the phosphorus sublattice. V_{Ga}^{+u} is a vacancy in the gallium sublattice which is given an arbitrary charge of $+u$. Applying the law of mass action to the above equations gives

$$C_{V_{Ga}} = K_2\ C_s^u\ \gamma_p^u\ P_{P_4}^{1/4} \qquad [7]$$

and

$$C_s = (K_3\ P_{Zn}\ P_{P_4}^{1/4}/\gamma_p)^{1/2} \qquad [8]$$

where $C_{V_{Ga}}$ is the concentration of gallium vacancies, P_{Zn} is the overpressure of zinc, and K_2 and K_3 are equilibrium coefficients. The substitutional zinc is assumed to be fully ionized so that $C_s = p$. By making the common assumption that the substitutional diffusion coefficient is proportional to the concentration of gallium vacancies, Eq. [3], [4], and [7] may be combined to give an expression for p-n junction depth as predicted by the interstitial-substitutional model

$$x_j = f_o\sqrt{t}\left\{\left(2 + \frac{C_o}{\gamma_p}\frac{d\gamma_p}{dC_s}\bigg|_{C_o}\right)(K_1^{-1}D_i\ C_o^2\gamma_p^2\ P_{P_4}^{-1/4} + K_4 C_o^u \gamma_p^u P_{P_4}^{+1/4})\right\}^{1/2} \qquad [9]$$

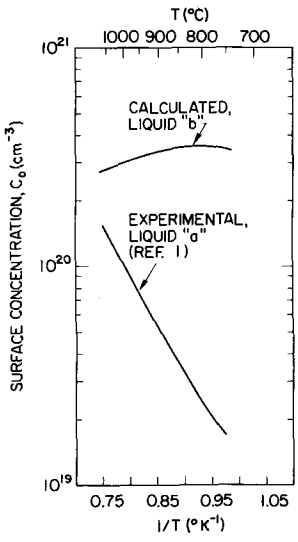

Fig. 11. Surface concentration of zinc in samples that were diffused between 750° and 1000°C with liquids a and b. Values for liquid b were calculated from the experimental values for liquid a.

where γ_p is given by Panish and Casey (18) and the factors inside the square root are evaluated at the surface of the sample in accordance with Eq. [3]. Values of C_o are shown in Fig. 11; the values for liquid a are given by Chang and Pearson (1), and the values for liquid b have been calculated using Eq. [8].

Equation [9] states that, for a fixed time, the junction depth will be determined by the two factors within the second square root. The first factor contains the effects of the built-in electric field and the concentration dependence of the hole activity coefficient. In the second factor, the first term is due to interstitial zinc, and the second term is due to substitutional zinc. In the range where the interstitial zinc is dominant, the junction depth will be proportional to $\gamma_p\ C_o\ P_{P_4}^{-1/8}$; in the range where substitutional zinc is dominant, the junction depth will be proportional to $\gamma_p^{u/2}\ C_o^{u/2}\ P_{P_4}^{1/8}$. In either case, the dominant factor is $P_{P_4}^{\pm 1/8}$ (unless $u < -4$, which seems highly unlikely). Since the experimental evidence shows that the junction depth is decreased by an increase in phosphorus pressure, it is concluded that the interstitial diffusion mode is dominant for all liquid a diffusions in the temperature range studied, and that it is also dominant for at least most of the range between liquid a and liquid b.

Previous workers (1) have shown that Zn diffusions into GaP at 800°, 850°, and 900°C give concentration profiles which decrease smoothly with increasing distance, while diffusions at 950°, 1000°, and 1100°C give profiles which stay relatively constant near the surface and then decrease sharply. This was taken as evidence that the interstitial diffusion mode was dominant only at temperatures above 950°C. However, the low-temperature diffusions of ref. (1) are all shallow, about 45 μm at 900°C, less than 25 μm at 800° and 850°C, while the high-temperature diffusions are all deeper than 75 μm. In light of the present work and that of Ting (15), it seems likely that the low-temperature diffusions involved no diffusion-induced dislocations, while the high-temperature diffusions had created induced dislocations. Thus, the difference seen in the two sets of profiles in ref. (1) is probably due to the differing numbers of dislocations present, and not to the relative importance of the interstitial mode.

It is clear from Fig. 4 that the diffusion of zinc is enhanced in regions near dislocations in GaP. This fact is the basis of a model which is proposed here to

explain why the p-n junction depth is not proportional to the square root of time as predicted by Eq. [3]. Initially, due to some unknown nonequilibrium process, the diffusion proceeds more slowly than expected, as seen in Fig. 9. Before long, however, the junction depth begins following the square root of time law according to the interstitial-substitutional model. As diffusion proceeds, stress is built up within the crystal because of the size difference between Zn and Ga atoms. [The tetrahedral covalent radius of Zn is 1.31Å; of Ga, 1.26Å (19).] During the early stages of diffusion this stress is simply tolerated within the crystal. Finally, at some critical junction depth, the internal stress within the sample exceeds the yield stress of the crystal, and dislocations are formed. These dislocations appear throughout the diffused layer so that almost the entire layer has a uniformly high concentration of diffusion induced dislocations. Moreover, as the diffusion front continues to move into the crystal, new dislocations are formed so that the dislocated layer continues to be almost the same thickness as the diffused layer. The interstitial diffusion coefficient, D_i, is higher in the dislocated region of the diffused layer than it is in the undisturbed bulk, and most of the diffusion now takes place in the dislocated layer. This increases the rate of diffusion, but otherwise the diffusion is the same as before. The junction depth now follows

$$x_j = f_o\sqrt{D_o t_o + D_1(t - t_o)} \qquad [10]$$

where D_1 is the new effective diffusion coefficient, and t_o is the time at which the induced dislocations were formed. For $t >> t_o$

$$dx_j/d\sqrt{t} = f_o\sqrt{D_1} \qquad [11]$$

For times not much greater than t_o, $dx_j/d\sqrt{t}$ is different from that given by Eq. [11]. In the cases presented in Fig. 5 and 9, however, the changes in the diffusion coefficient are relatively small, making the deviations from Eq. [11] too small to be seen experimentally.

According to this model, Eq. [9] should apply to the two time periods in which the x_j *vs.* $\sqrt{t}$ plot is a straight line, and it turns out that the model is in good quantitative agreement with experiment. For example, at 900°C, taking the interstitial mode to be dominant for all phosphorus pressures, the equation predicts that the ratio between liquid b junction depths and liquid a junction depths will be

$$\{x_j/\sqrt{t}\ \text{(liq. b)}\}/\{x_j/\sqrt{t}\ \text{(liq. a)}\} = 0.37$$

Using Fig. 9, the experimentally determined value of this ratio in the shallow, straight line portions of the curves is 0.30. For deep diffusions, beyond the knee in the curves, the experimentally determined slopes of the curves are applicable to Eq. [9] and at 900°C the result is

$$\{\Delta x_j/\Delta\sqrt{t}\ \text{(liq. b)}\}/\{\Delta x_j/\Delta\sqrt{t}\ \text{(liq. a)}\} = 0.31$$

In view of the approximations involved in calculating the pressure over the Ga-P-Zn system, this correspondence between calculated and experimental values is very good. The change in junction depth between liquid a diffusions and liquid b diffusions is correctly predicted within 10%. The fit would not have been as good if the interstitial zinc had been taken as doubly charged, a suggestion that has appeared in the literature (1). This is taken as additional evidence that the appropriate charge state of an interstitial zinc atom is +1.

Several features of this model must be discussed in more detail. It might be argued that the zinc precipitation occurs while the sample is at the diffusion temperature and that the precipitates cause the stress that results in dislocations. However, Panish and Casey (18) have effectively argued against this. They point out that if precipitation occurs during diffusion, then the zinc solubility would be expected to change with time. Moreover, the surface concentration of zinc in a diffused sample would be expected to be different from the zinc concentration found in a solution grown sample. Neither of these effects occur, so it is more reasonable to assume that the presence of unprecipitated zinc can cause dislocations. Calculations similar to those of Black and Lublin (20) suggest that zinc diffusion into GaP may indeed generate sufficient internal stress to cause plastic flow which results in misfit locations (21). The precipitation is then taken to occur on cooling, using the existing dislocations as nucleation sites.

The mechanism that defines the p-n junction depth at which induced dislocations are first nucleated is not clearly understood. The change in critical depth with diffusion source indicates either that diffusions done with liquid b initially place less stress on the crystal or that crystal yield strength near the surface is increased by the use of high phosphorus pressure. The first possibility seems unlikely. For equal p-n junction depths a liquid b diffusion would be expected to have a steeper concentration gradient than a liquid a diffusion since liquid b gives a higher surface concentration. This suggests that a liquid b diffusion would create more, not less, strain in the lattice. Taking the other possibility, Maruyama (22) has suggested that high phosphorus pressure will cause interstitial phosphorus atoms to precipitate onto dislocations, rendering them immobile, and increasing the yield stress of that part of the surface layer with which the phosphorus comes into equilibrium. Since the zinc surface concentration associated with liquid b is substantially larger than that associated with liquid a, the change in yield stress would have to be quite large. Unfortunately, there is no data to suggest how large a change in yield stress might be obtained by this effect.

It was noted above that liquid b diffusions are considerably more planar than liquid a diffusions. This is consistent with the interstitial-substitutional diffusion model. For diffusions with liquid a the interstitial mode is dominant, and the diffusion coefficient is strongly concentration dependent. In this case, any crystal defect that causes a local change in the zinc concentration also causes a local change in the diffusion coefficient, resulting in an irregular diffusion front. When the phosphorus pressure is increased and the diffusion is performed in the presence of liquid b, two effects occur. First, the gallium vacancy concentration in the crystal is increased so that clusters of vacancies near crystal defects are no longer so different from the rest of the lattice. Second, the substitutional diffusion mode increases in importance, decreasing the dependence of the diffusion coefficient on zinc concentration (providing the charge on a gallium vacancy is 0 or ± 1). Both effects would reduce the influence that crystal defects have on diffusion. However, the interstitial diffusion mode appears to have remained dominant for all phosphorus pressures used in these experiments. Thus, the second effect has negligible importance in this particular set of experiments.

Conclusion

The results of zinc diffusions into GaP were found to be strongly dependent on the diffusion sources that were used. When the diffusion source was a sufficient amount of pure zinc, the resulting diffusion system was monovariant, containing a liquid which was mostly gallium and zinc and a vapor which had low phosphorus pressure. Diffusions from this source resulted in highly irregular p-n junctions since the diffusion coefficient was highly sensitive to crystal defects. A second monovariant system could be obtained by using a diffusion source that contained proper proportions of zinc and excess phosphorus; the resulting system contained a liquid that was mostly phosphorus and zinc and a vapor with high phosphorus pressure. Diffusions from this source had smaller diffusion coefficients than the previous source and resulted in p-n junctions that were consistently more planar since the diffusion coeffi-

cient was much less sensitive to crystal defects. Both of these effects can be explained quite adequately by the interstitial-substitutional model for zinc diffusion in GaP.

The results of zinc diffusion were also strongly dependent on diffusion time. Regardless of the diffusion source, short times resulted in diffused layers which had no induced crystal defects. However, if diffusion was continued beyond an incubation time which was dependent on the diffusion source, the stress generated within the diffused layer by the incorporation of zinc into the crystal lattice exceeded the yield stress, and almost the entire diffused layer became filled with a high concentration of dislocations. When this happened, the diffusion coefficient within the diffused layer was suddenly increased, causing a corresponding increase in $dx_j/d\sqrt{t}$. Again, the high phosphorus pressure source resulted in more desirable diffusion properties, allowing a greater junction depth to be reached before the induced dislocations appeared.

Epitaxial Films of Germanium Deposited on Sapphire via Chemical Vapor Transport

R. F. Tramposch*

Airco Speer, Research Laboratory, Niagara Falls, New York

ABSTRACT

Single crystal films of germanium have been deposited on sapphire (α-alumina) by chemical vapor transport using a disproportionation reaction involving water vapor and a technique in which the source and substrate are closely spaced. The heteroepitaxial process was found to be sensitive not only to substrate orientation and temperature, but also to impurities in the source material. Monocrystalline films were only obtained on substrates oriented in the (0001) or basal plane when heated to 800° ± 10°C, and only when using source wafers heavily doped ($\sim 10^{19}$ at./cc) with arsenic. Under identical growth conditions, polycrystalline films invariably resulted if the source materials used were either undoped, or doped with gallium, indium, or antimony in a wide range of concentrations. In addition to a high density of dislocations and low angle grain boundaries, the films also contained stacking faults of the single-line type, believed to occur primarily as a consequence of lattice mismatch. The electrical characteristics, as well as crystalline perfection, approach that of bulk material as film thickness increases; however, p-n junctions fabricated in these films were inferior to those formed in bulk material.

Heteroepitaxial films of germanium on single-crystal aluminum oxide appear to offer a real potential in microcircuit applications requiring high-speed, minority-carrier active film devices (1). Growth and perfection have been studied as part of an effort to obtain the crystalline quality essential in the fabrication of useful bipolar devices.

* Electrochemical Society Active Member.

Single-crystal films of germanium were deposited on sapphire wafers at 800°C by chemical vapor deposition, using a disproportionation reaction and water vapor as the reactant. The process

$$Ge + H_2O \rightleftharpoons GeO + H_2$$

was first investigated by Lever and Jona (2) and applied to germanium epitaxy using a closed-tube

system and slightly higher temperatures. Employing an open-tube flow system and an arrangement in which the source and substrate are closely spaced, similar to the technique used by Nicoll (3) to deposit epitaxial GaAs films, we obtained films of uniform thickness on sapphire at growth rates several orders of magnitude higher. It is believed that the increased growth rate and uniform film deposition are important factors in obtaining good heteroepitaxial films.

Experimental Technique

The vapor growth apparatus consisted essentially of a gas purification train, a means of introducing the water vapor into the carrier gas, and a deposition chamber (20 mm diameter). In the latter, as detailed in the lower portion of Fig. 1, a source wafer and substrate are sandwiched between two graphite blocks inductively heated by rf. Quartz spacers were used to maintain a parallel separation between the source and substrate. For most film depositions the surfaces were separated by about 0.5 mm. The substrate was heated in the temperature range of 750°-850°C. By differential rf coupling and the relative size difference between the heater elements, the source could be heated 25°-50°C higher. In this temperature gradient the disproportionation reaction as indicated is assumed to occur. At the surface of the source, the reaction proceeds to the right, forming a volatile oxide for temperatures above 700°C. Germanium is transported to the cooler substrate via the oxide as the reaction proceeds in the opposite direction.

The source temperature was maintained by a controller and sensing element inserted in a hole in the side of the heater. Prepurified, dry hydrogen was employed as the carrier gas at flow rates of 10-60 cc/min. After the temperature of the source was stabilized, the hydrogen was diverted to pass over a small volume of distilled water. Provisions were made for heating or cooling the water to control vapor pressure; however, best results were obtained with the water bubbler at room temperature.

Source materials used were wafers sliced from single crystal ingots of Ge grown in the (111) or (110) direction, and doped with As, P, Ga, In, or Sb to concentrations of 10^{16} to 3 x 10^{20} at./cc, or the solubility limit. The wafers, nominally 0.025 in. thick, were lapped and etched in CP-4 prior to use and could be used for a number of film depositions.

The sapphire substrates were obtained commercially in the form of 20 mils thick, mechanically polished disks, ⅜ in. or ½ in. in diameter, sliced from Verneuil or Czochralski-grown boules, and oriented in the (0001), near the (11$\bar{2}$3), or (11$\bar{2}$0), *i.e.*, pole directions of 0°, 60°, or 90° with respect to the c-axis. The pulled material, having a lower dislocation density and no visible subgrains, was used to examine the effect of substrate perfection on film quality. For the most part, the substrates were used as received without further surface treatment, except for the usual predeposition cleanup. In a few instances, films were deposited on chemically polished sapphire by wet chemical (4) or gas phase etching techniques (5) to investigate the effect of surface preparation. An evaluation of film quality was made by comparing the electrical characteristics of thick films with that of bulk single-crystal material. Conductivity and Hall effect measurements were performed on the films at room temperature using the van der Pauw technique (6).

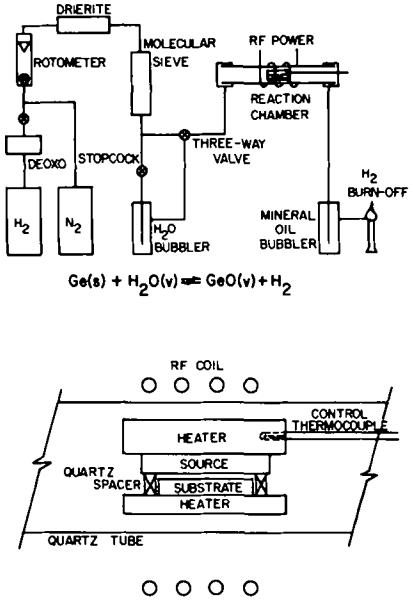

Fig. 1. Schematic of vapor growth apparatus

Results and Discussion

Film growth.—We have found that at least three conditions must be satisfied to obtain perfect heteroepitaxy: (*i*) the substrate must be oriented in the (0001) or basal plane; (*ii*) it must be heated to a temperature of 800° ± 10°C; and (*iii*) the source material must be heavily doped with As (~ 10^{19} at./cc).

Highly oriented films resulted when Ge wafers used as source materials were heavily doped with phosphorus; or the substrate surface was oriented in the (11$\bar{2}$3) plane, *i.e.*, 60° with respect to the c-axis, if the other two conditions were satisfied.

Polycrystalline films having no preferred orientation were obtained consistently for all growth conditions in which the Ge wafers used were doped with Ga, In, Sb, or lower concentrations of As; or the substrates used were oriented in the (11$\bar{2}$0) plane, *i.e.*, 90° with respect to the c-axis.

Substrate orientation had little effect on film growth rate. Films grown under ideal conditions as stated were deposited at a rate of 0.3 to 0.5 μm/min. Deposits grown at lower rates by reducing water vapor pressure and/or source temperature, or at higher rates by increasing these parameters, were invariably polycrystalline or composed of large individual crystallites.

Typical examples of perfect heteroepitaxial, highly oriented, and polycrystalline films of Ge on sapphire, all deposited under identical conditions of substrate temperature and source doping, are shown in Fig. 2, illustrating the effect of substrate orientation on film crystallinity. The film thickness of these and other films described in this work is of the order of 30-50 μm. In the film deposited on the 0°-oriented substrate, the growth features characteristic of epitaxy and the x-ray diffraction pattern in the Laue back reflection photograph are evidence of its single-crystal orientation. The structure and the x-ray diffraction pattern of the surface of a film deposited on a 60°-oriented substrate indicate a high degree of preferred orientation. Films grown on 90°-oriented sapphire exhibit growth facets which are randomly oriented, as is further evidenced by the ring diffraction pattern in the Laue photograph.

Film perfection.—Characteristic growth defects that have been observed in films deposited on 0°-oriented substrates under optimum growth conditions are shown in Fig. 3. The surface was etched lightly in a warm ferricyanide solution to reveal the crystalline imperfections. In addition to stacking faults which appear principally as single and intersecting etched lines along the (110) direction, there is also present a large density of etch pits typical of dislocations and low-angle grain boundaries. The stacking faults have the appearance of the single line type reported by Mendelson (7) as observed in epitaxial silicon films deposited on mechanically polished substrates. We have observed similar effects in epitaxial Ge films.

Substrate perfection and surface treatment.—The effect of using mechanically polished sapphire was ex-

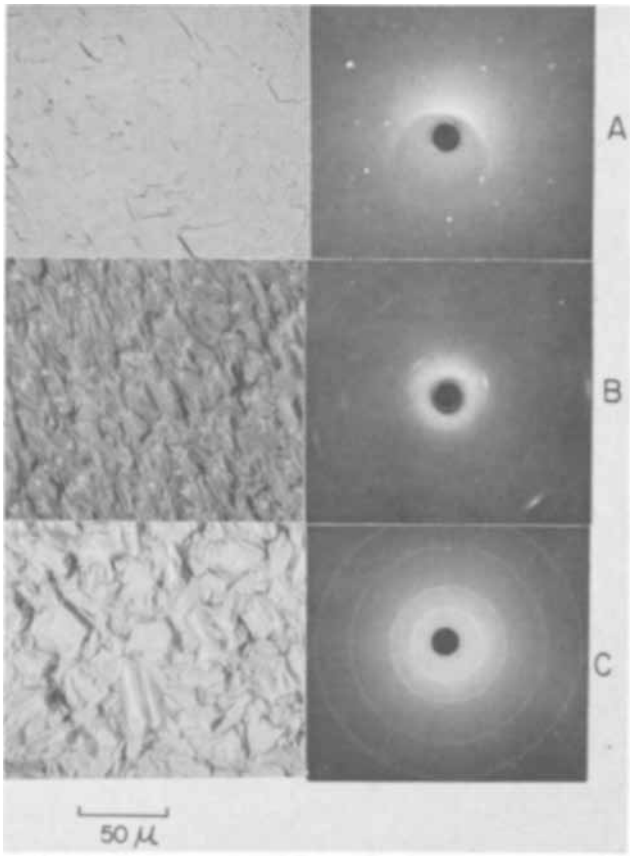

Fig. 2. Films of germanium on sapphire oriented in the (a) 0001, (b) near the $11\bar{2}3$, or (c) $11\bar{2}0$ directions. Magnification approx. 225X.

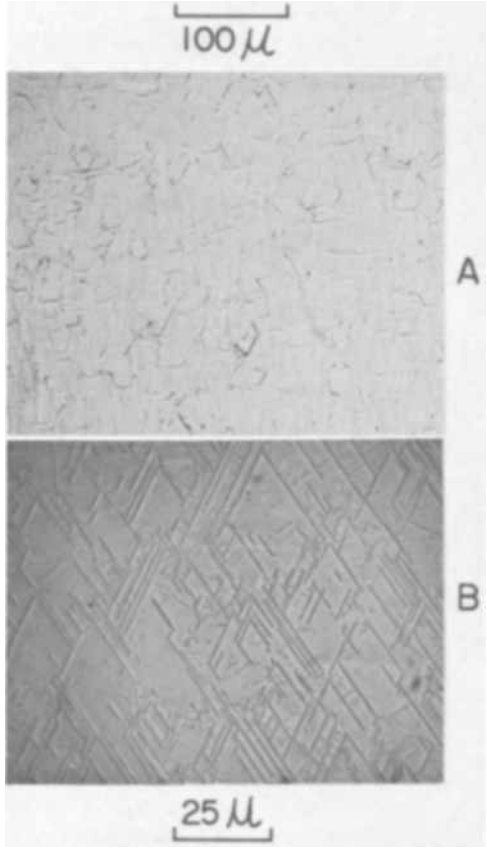

Fig. 3. Defect structure in a Ge film on a (0001) oriented sapphire substrate: (a) as-deposited (175X), and (b) etched surface. Magnification approx. 400X.

amined in a number of ways. Films of Ge were deposited on Ge substrates mechanically polished with different abrasives and the defects produced in these epitaxial films were compared with those found in heteroepitaxial films on sapphire. Figure 4 shows that the defects are indeed similar and appear to result from using mechanically polished substrates. However, in several films deposited on sapphire polished by wet chemical and gas phase etching techniques, the crystalline perfection was found to be as poor as that of films deposited on unetched substrates. In addition, films deposited on etched sapphire under identical growth conditions were generally found to be poorly oriented, multicrystalline, exhibiting only a few single-crystal regions. It was also found impossible to grow well-oriented films on used substrates, *i.e.*, substrates from which previously deposited films were removed by etching. In some cases mechanically polishing these used substrates with 0.25 μm diamond lapping compound seemed to assist in promoting epitaxy; however, the results were not entirely satisfactory.

With regard to the crystalline perfection of the sapphire, it has been noted that films deposited on better quality substrates, *i.e.*, Czochralski-grown material, were more uniformly oriented due to the absence of subgrains, or regions of slight misorientation found in the poorer quality, Verneuil-grown material. The surface of a typical film grown on this latter material is shown in Fig. 5. As a result of perfect epitaxy, subgrains present in the substrate are propagated in the Ge deposit. The darker regions of the etched surface are those having a higher density of stacking faults. The difference in density in adjacent areas is evidence that the stacking faults are produced by lattice mismatch, since these areas differ only in orientation and not in surface treatment.

Although the dislocation density in the better quality substrates was a factor of 10^3-10^4 lower than the standard, Verneuil-grown material, we could find no evidence of film perfection being related to the dislocation density of the substrate.

These results apparently confirm that crystalline defects observed in films of germanium on sapphire are not related primarily to substrate perfection and surface treatment, but rather are a consequence of lattice mismatch inherent of heteroepitaxy, or film deposition on a foreign substrate.

Electrical Characteristics

A comparison of the electrical characteristics of thick films with that of bulk single crystal material is given in Fig. 6, a plot of Hall mobility as a function of excess charge carrier density. The smooth curves represent bulk values and were obtained from both published and unpublished Hall effect data. A pronounced substrate orientation dependence is evident. Films deposited on 0°-oriented substrates have the highest mobilities and, in fact, closely approach bulk values. These data relate electrical characteristics to film crystallinity, *i.e.*, films deposited on 0°-oriented substrates are more highly ordered than those deposited on 60°-oriented substrates, have less structural defects and consequently a higher charge carrier mobility. All films represented here were heavily doped with arsenic, except those indicated otherwise. Films doped with Sb, or low concentrations of arsenic, exhibit low mobilities, are polycrystalline and p-type. Gallium-doped films, on the other hand, exhibit very high hole mobility, approaching that of single crystal material, even though these films are all polycrystalline. This apparent anomaly has been reported by other investigators in vacuum deposited Ge films on alumina (8), glass (9), and GaAs (10).

The effect of arsenic concentration in the source wafer on the film crystallinity and Hall mobility is shown in Table I. The table lists typical results of a large number of film depositions on 0°-oriented sapphire under identical and optimum growth conditions in which the sources used were doped to various

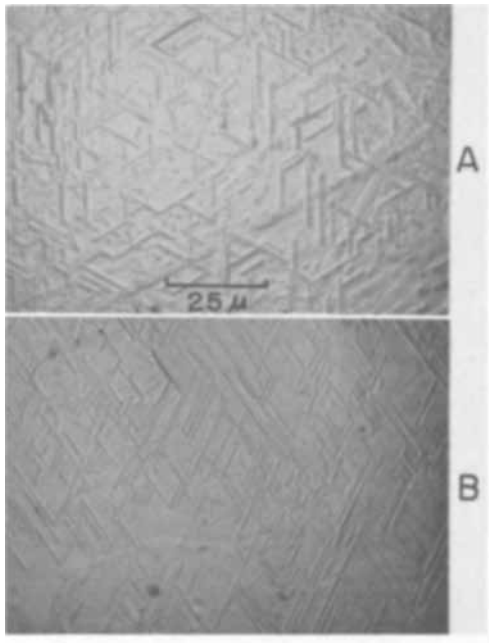

Fig. 4. Stacking fault generation in films of Ge deposited on: (a) polished Ge substrate, and (b) polished sapphire substrate.

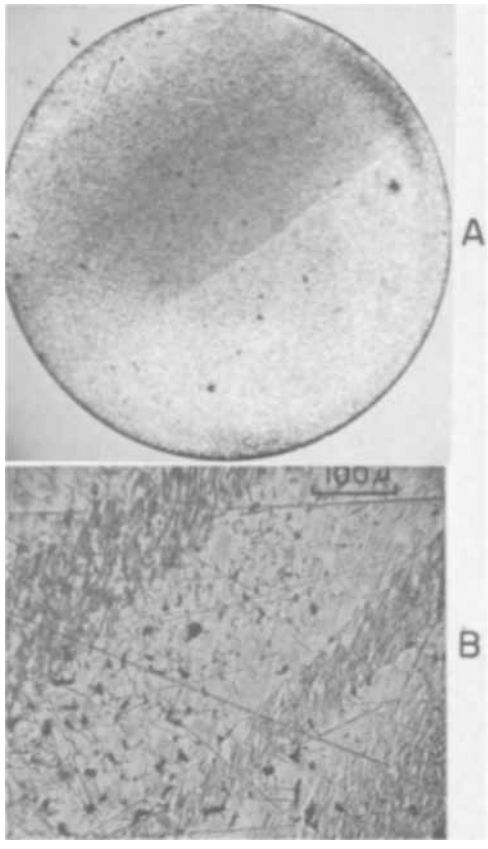

Fig. 5. Effect of substrate perfection on film crystallinity: (a) as-grown surface of a Ge film deposited on a sapphire containing subgrains, (b) same surface, mechanically polished and etched.

levels of arsenic concentration. The mobility in the films is compared to values in bulk material of equivalent excess charge carrier density. There is apparently an optimum arsenic concentration for which good quality films can be obtained, *i.e.*, about 10^{19} at./cc. It is interesting to speculate on the role of arsenic in promoting oriented growth. It may be that As bonds to Al on the reduced surface of the aluminum oxide, forming an interfacial or intermediate layer of

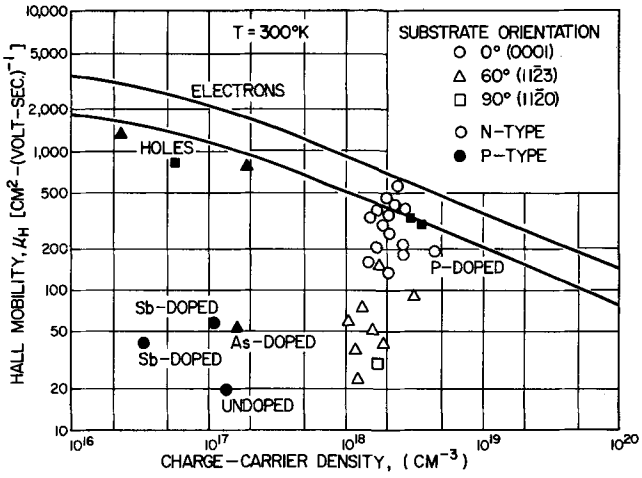

Fig. 6. Hall mobility as a function of excess charge-carrier density in Ge films on sapphire.

AlAs from which a single-crystal film of Ge could propagate, since it has the same crystal structure and a lattice parameter that matches to within a half a per cent (Ge = 5.65Å; AlAs = 5.62Å). Other III-V compounds which could also form an intermediate layer if source materials were doped with P or Sb, *i.e.*, AlP and AlSb, apparently do not promote oriented growth to any great extent because their a spacings differ from that of Ge by 4 and 9%, respectively.

Effect of film thickness.—We have found that film crystallinity and perfection improve with thickness. As film thickness increases, the number of stacking faults appearing in the etched surface are reduced. A correlation was made of the electrical characteristics and crystallinity as a function of film thickness from room temperature measurements of the Hall effect and from x-ray diffraction studies.

The electrical measurements were performed on films that were etched to reduce their thickness in increments, the average charge carrier density and mobility determined for each thickness. A plot of the data for a film exhibiting high electron mobility is shown in Fig. 7. For comparison, the Hall mobility of electrons in bulk material having equivalent charge carrier density is also plotted. Both the number of charge carriers, N, and their mobility, μ_F, increase with increasing film thickness, the latter approaching bulk values. The difference in film and bulk mobility appears to be due to the presence of structural defects, probably dislocations associated with stacking faults, since they are found in increasing numbers as film thickness decreases. The variation in the average excess charge carrier density, *i.e.*, the difference in the density of donor and acceptor levels, $(N_D - N_A)$, indicates that the density of acceptors is decreasing with increasing film thickness, assuming of course, films are uniformly doped with donor atoms. Since dislocations behave as acceptors in Ge, one might conclude that the variation in the electrical characteristics with thickness

Table I. Effect of arsenic concentration in source wafer on the characteristics of Ge films deposited on 0°-oriented sapphire

Concentration cm^{-3}	Film crystallinity	Hall mobility cm^2/v-sec	% Bulk mobility
3×10^{19}	Polycrystalline (highly preferred orientation)	192	37
9×10^{18}	Single-crystal	560	83
9×10^{18}	Single-crystal	385	50
9×10^{18}	Single-crystal	335	44
5×10^{18}	Polycrystalline (preferred orientation)	110	14
5×10^{18}	Polycrystalline (preferred orientation)	82	10
5×10^{16}	Polycrystalline (random orientation)	110	3

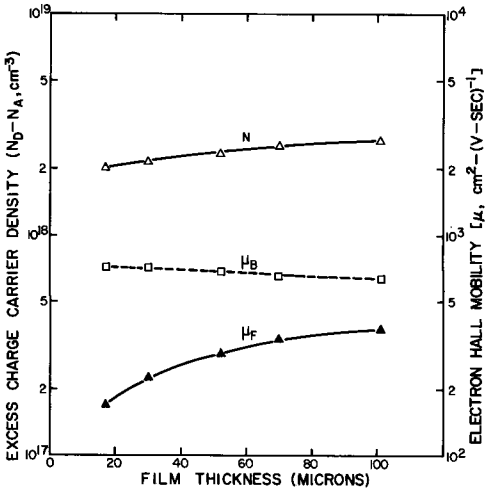

Fig. 7. Electron Hall mobility and charge-carrier density as a function of film thickness of Ge on 0°-oriented sapphire.

is due to dislocations associated with stacking faults which introduce acceptor levels in sufficient concentration to compensate films doped to donor levels in excess of 10^{18} at./cc.

One might speculate that films are being contaminated by the substrate. The presence of aluminum in silicon films deposited on sapphire has been reported by Dumin and Robinson (11). However, they observed that the aluminum diffusion only becomes appreciable at temperatures above 1250°C. For the deposition temperature used and the growth conditions under which Ge films are deposited on sapphire, contamination of films by aluminum from the substrate should be negligible. Similar conclusions have been reported for Ge deposits on spinel (12).

A correlation between film thickness and crystallinity was determined by comparing the x-ray diffraction pattern of a single film grown to various thicknesses. The film was grown to the desired thickness, a Laue back-reflection photograph was made, and then the film thickness was increased by continuing its growth. Results of interrupting its growth at various thicknesses are shown in Fig. 8. At a thickness of 8μ, the film appears to be twinned and highly strained. The diffraction pattern consists of reflections from both the substrate and the film. At a thickness of 35μ, the film is predominantly (111)-oriented, with only a few misoriented regions. The diffraction pattern now shows only three-fold symmetry. At a final thickness of 52μ, the film is well oriented having no misoriented regions.

Device aspects.—Mesa diodes fabricated in these thick Ge films, both by diffusion and by epitaxial techniques, exhibited current-voltage characteristics that were generally inferior to those of p-n junctions formed in simultaneously processed bulk material. This is evidenced by a high reverse leakage current, and lack of a well-defined breakdown voltage, *i.e.*, very soft junction characteristics, due presumably to the high defect density in the heteroepitaxial layer.

Recent results suggest that it may be possible to form reasonably good p-n junctions in epitaxial layers of Ge deposited on the heteroepitaxial films. Using a low-temperature chemical vapor deposition process, the epitaxial films were found to be free of stacking faults, although the substrate film contained high densities of these defects. Details of these results will be reported in a subsequent paper.

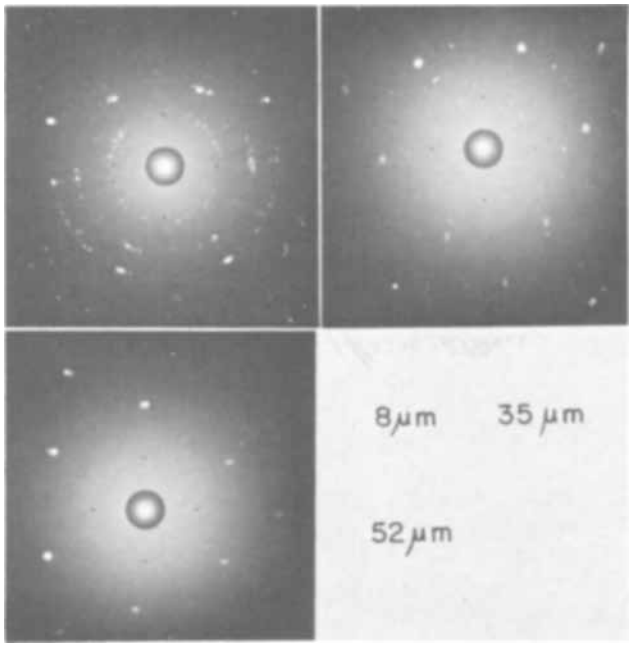

Fig. 8. Laue back-reflection photographs of a Ge film on a (0001)-oriented sapphire showing film crystallinity as a function of thickness.

Summary

In depositing single-crystal films of germanium on sapphire using a wet hydrogen process and close-spacing technique, we have found that, in addition to substrate temperature and orientation, heteroepitaxy is dependent on the presence of high concentrations of arsenic in the source wafer. The films contained many crystalline defects that were characteristic of heteroepitaxy or lattice mismatch, rather than due to surface treatment of the substrate. Although the crystalline perfection and electrical properties were found to improve markedly with thickness, diodes fabricated in thick films were inferior to those formed in bulk material.

Oxidation Studies on Zirconium Alloys in High-Pressure Liquid Water at 360°C

E. A. Gulbransen* and K. F. Andrew*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Corrosion studies were made on 22 zirconium alloys in liquid water at 360°C and 2708 psi for time periods up to 112 days. These alloys include dilute alloys of Zr with V, Cr, Ni, Fe, Sn, and Cu, intermetallic alloys of Zr with V, Cr, Ni, Fe, Sn, and Cu, intermediate alloys of Zr with V, Cr, Ni, Fe, Cu, and Zircaloy-2 and -4. Weight gain and hydrogen contents were determined.

The corrosion of zirconium alloys in liquid water at high pressure and at a temperature of 360°C is a subject of both scientific and technical interest since the corrosion behavior is determined by both oxidation processes and by the hydrogen pick-up and its effect on the metal structure.

This paper presents the results of autoclave corrosion tests on 20 alloys in liquid water at 360°C and 2708 psi for time periods up to 112 days. Alloys were chosen on the basis of the hydrogen reaction of the alloying element's intermetallic phases (1-3). Many of the alloying elements were chosen from the first long period of the periodic table where a wide variation in the hydrogen reaction occurs. These include V, Cr, Fe, and Ni. Cu, Nb, and Sn alloys were also included. Copper forms an intermetallic which breaks down on reaction with hydrogen; Nb does not form intermetallic phases with zirconium. Two separate Zr and Nb rich phases exist in Zr-Nb alloys. Tin is of particular interest since it forms the major alloying element in the Zircaloy alloys.

Types of Hydrogen Reaction of Zirconium Alloys

Four types of hydrogen reaction have been found for the intermetallics (1-3). 1. Hydrogen reacts to breakdown the intermetallic to form δ-$ZrH_{1.4}$ and another metallic or intermetallic phase depleted in Zr after first saturating the alloy. ZrCu and Zr_2Cu are examples. 2. New and unique hydride phases form when the intermetallic is reacted with hydrogen after first saturating the alloy. ZrNi and Zr_2Ni are examples. 3. Solid solution of hydrogen occurs in the intermetallic over an extended composition range. $ZrCr_2$, ZrV_2, and Zr_4Sn are examples. 4. No appreciable reaction with hydrogen is found. $ZrFe_2$ and $ZrCo_2$ are examples.

Zirconium reacts with hydrogen to form δ-$ZrH_{1.4}$ and ϵ-$ZrH_{1.98}$ after saturating the metal. For multiphase alloys, such as the Zr-Nb alloys where no intermetallics form, the hydrogen reactivity depends on the hydrogen stability of each phase. β-Nb absorbs hydrogen only at relatively high hydrogen pressures and after zirconium has taken up large quantities of hydrogen as δ-$ZrH_{1.4}$.

Literature

A complete survey of the literature will not be given. Many papers exist on the effects of alloying, specimen preparation, and heat-treatment on the reaction of zirconium alloys in high-temperature water and steam. Excellent reviews have been given by Wanklyn (4, 5), Coriou (6), and Hillner (7). Douglas (8) has reviewed the physical metallurgy of zirconium alloys.

Preparation of Alloys

High-purity metals were levitated, melted, and cast into a copper mold under purified argon atmosphere to assure homogenous specimens and minimum of contamination. Table I shows the procedures used in the preparation of the alloys while Table II shows the composition of the metals used in preparing the alloys. Many of the alloys were extremely brittle and difficult to cut in 20 mil thick slices. We found it impossible to cast the intermetallic $ZrCr_2$ without cracking of the ingot.

Table III shows a list of the alloys prepared. They can be classified in four major groups: 1, the dilute alloys having compositions at or near the eutectoid composition and containing two phases; 2, the 10 w/o (weight per cent) alloys containing two phases; 3, the intermetallics containing one phase; and 4, the niobium alloys containing two phases, *i.e.*, α-Zr and β-Nb.

Table III shows the annealing treatments used in preparing the alloys. Annealing was done at 10^{-6} to 10^{-7} Torr in Ta and Zr containers. The temperatures were chosen from considerations based on the phase diagrams of the respective systems.

The composition of each ingot was determined by the initial weights of the respective metals. In each case the weight after melting and casting was determined to check for volatilization of the more volatile metals. The final weights of the 10g cast ingots checked within a few milligrams of the weight of the components taken initially. Chemical analysis was made of the alloys and standards set up for x-ray fluorescence analysis. In this way the composition of each sample could be determined before testing. X-ray diffraction patterns were taken of each alloy to check the melting and heat treatment procedures. Light micrographs were taken of each alloy to evaluate the phases present and to compare where possible with photomicrographs in the literature.

Table I. Procedures for preparation of alloys

Crystal bar zirconium	Alloying metal
Sliced under benzene	Sheared or cut into small pieces (air)
Sheared into small pieces (air)	
Cleaned with petroleum ether and alcohol	Cleaned with petroleum ether and alcohol

Compacted under pressure into button for melting

Levitation melted in purified argon atmosphere

Cast into copper mold

Vacuum annealed in Ta or Zr container at 10^{-6}-10^{-7} Torr

Cut into specimens, soft samples with SiC wheel, hard specimens by electric discharge machine

Polish through ¼μ diamond paste

Cleaned using acetone, petroleum ether, and alcohol

Weighed and specimen area measured

Composition checked by x-ray fluorescence analysis

X-ray diffraction and micrographs taken

Reacted

High-Pressure Autoclave Test Apparatus

A high-pressure autoclave at the Westinghouse Atomic Power Laboratory was used for reacting the zirconium and zirconium alloys in high-purity liquid water at 2708 psi and 360°C. This apparatus had been used previously, and its operation had been checked and qualified.

The autoclave is 12.5 cm inside diameter, 50 cm long, constructed of stainless steel. The volume is 6.6l. The test specimens were supported from a special frame constructed from Ni-Cr alloy sheet using small sections of platinum wire. The frame was placed on a stainless steel tree and then lowered into the autoclave. Before using the autoclave, the tree and supporting specimens were preoxidized. Before each run the autoclave was cleaned with alcohol.

The water was demineralized water having a pH of 6.5-7.5 and a resistance of 1-2.5 x 10^6 ohms cm. The samples and support tree were placed in the autoclave and 3.2l of water were added. The cover was then bolted on to the vessel. The air space was evacuated for 10 min before heating. After heating to 120°-150°C, 100 cc of water was withdrawn as steam to eliminate air from the space over the H_2O. A period of 6 hr was used to heat between 25° and 360°C. Although the initial volume of water was 3.2l this volume expanded to 4.8l at 360°C and 2708 psi.

The test cycle was 28 days after which the heaters were turned off and the system allowed to cool for 8 to 9 hr before opening. Samples were carefully removed and dried. All operations were carried out using platinum tipped tweezers and clean cotton gloves.

Hot Extraction Method for Hydrogen Analyses

The method (9) was designed to use samples of 0.01-0.2g and to determine hydrogen contents of zirconium and zirconium alloys with a sensitivity of 10^{-7} g of H_2 or 1 ppm on an 0.1g sample. The hydrogen was extracted by heating the sample to 1200°C and condensing the gas into a liquid helium cooled trap. The hydrogen was then vaporized and the pressure measured by a sensitive capacitance manometer.

Results

Preliminary oxidation study.—Twenty-two standard size specimens of about 1 cm^2 area and two large control specimens of about 10 cm^2 area of Zircaloy-4 were reacted for 28 days at 2708 psi and 360°C in high-purity water. Table IV shows the alloys, the oxygen weight change calculated from the total weight

change and the hydrogen uptake, the increase in hydrogen content of the alloy, and the per cent of theoretical hydrogen taken up by the alloy. The theoretical hydrogen value was calculated from the oxygen weight gain using the weight ratio of H_2/O of 1/8.

Table IV shows that all the tested intermetallic alloys, *i.e.*, Zr_2Ni, ZrNi, Zr_2Cu, ZrCu, $ZrFe_2$, ZrV_2, and Zr_4Sn were reacted to 75% or more. All of the vanadium alloys were disintegrated in the 28-day cycle. The dilute alloys Zr-1.3 Ni, Zr-1.0 Cr, Zr-2.2 Fe, the two Zircaloy alloys, and Zr showed low oxygen weight gains. The hydrogen taken up by the alloys varies greatly from 0 μg for the Zr-1.0 Cr alloy to greater than 250 μg for the Zr-10 Ni and the Zr-10 Cr alloys. This was the approximate upper detection limit for the hydrogen analysis apparatus used in these early tests. The sample sizes used in the later tests were reduced so the complete hydrogen content could be measured.

Multiple cycle oxidation study.—Four 28-day oxidation tests were conducted. The total accumulated oxidation time for some samples was 112 days. On the basis of the preliminary oxidation study all of the intermetallic alloys and the three vanadium alloys were eliminated from the longer period oxidation studies.

Seven samples of each of eight alloys listed in Table V were placed in the high-pressure 360°C autoclave. After 28 days of reaction all samples were weighed. One sample of each of the alloys was removed from the series for hydrogen analysis. The remaining samples were brushed to remove loose corrosion products and reweighed. The weight after brushing was taken as the initial weight for the second 28-day oxidation run. This procedure was repeated for the 3rd and 4th oxidation cycles except duplicate samples were removed for hydrogen analysis on the 3rd cycle.

Tables V and VI show a summary of the experimental data and calculations made on the various alloys for the 28, 56, 84, and 112 day oxidation tests. Table V shows the results on the dilute alloys, and Table VI shows the results on the 6.4 to 50 w/o alloys. Zircaloy-2, Zircaloy-4, and crystal bar zirconium were included with the dilute alloys.

Tables V and VI show the alloys tested, the oxygen weight gain calculated from the total weight change and the hydrogen uptake, the oxygen weight gain/cm², the increase in hydrogen content resulting from the reaction, and the per cent of theoretical hydrogen produced in the reaction which was taken up by the alloy.

Both Zircaloy-2 and Zircaloy-4 showed low oxygen weight gains and hydrogen pickup with Zircaloy-4 showing the lower values. Of the other tested alloys, only Zr-1.0 Cr showed low oxygen weight gain and low hydrogen absorption.

The oxidation tests on the Zr-2.5 Sn alloy in contrast to the other dilute alloys showed a wide variation in reactivity. Two of the seven samples showed a low reactivity during the first 28-day cycle while the other five samples showed a large amount of reactivity. One of the five samples showing a large amount of reactivity is shown in Table V. The 56-day tests show that all of the Zr-2.5 Sn specimens have large weight gains even though several of the specimens in the first 28-day cycle showed very low total weight gains. One unusual feature of this alloy is the low hydrogen uptake values for the large amount of reactivity.

Zr-5.0 V showed complete reaction for the 28-day test cycle while the Zr-1.6 Cu alloy showed a large amount of reaction and a large hydrogen uptake. In fact, the hydrogen uptake was greater than that expected from the oxygen weight gain. This fact suggests that the Zr-1.6 Cu specimens were gettering hydrogen from the hydrogen produced by the other samples reacting with water.

Zr-1.3 Ni and Zr-2.2 Fe react at a fairly low rate with water. The Zr-2.2 Fe samples have the lower hydrogen uptake values. The Zr-1.3 Ni alloys take up 98-132% of theoretical hydrogen while the Zr-2.2 Fe take up 36-61.4% of theoretical hydrogen. Zr-1.0 Cr alloy has the lowest oxygen weight gain of all of the alloys tested and near zero hydrogen pickup.

High-purity zirconium showed erratic-corrosion behavior in liquid water. Thus, the preliminary screening 28-day test showed a low corrosion rate while seven samples of the same sheet showed complete reaction after 28 days in the first cycle of the multiple cycle tests. All of the specimens had been mechanically polished through 1/4μ diamond paste and cleaned. A second set of seven samples was mechanically polished and reacted in the second cycle of the multiple cycle test. All were completely reacted. Two additional sets of seven samples each were cut from two high-purity crystal bars of zirconium and etched in a solution containing 50 cc of 30% H_2O_2, 30 cc of HNO_3, and 2 cc of HF. Both sets of samples showed a high level of corrosion. A hydrogen analysis was made on the heavily reacted zirconium samples. The unreacted

metal showed a hydrogen content of 46% of theoretical.

Table VI shows the results and calculations for the 6.4-50 w/o zirconium alloys. The Zr-10 Ni, Zr-10 Cu, and Zr-10 Cr showed large oxygen weight gains for the 28, 56, 84, and 112 day oxidation periods. The Zr-10 Ni alloy showed hydrogen uptakes of 154 to 263% of theoretical. The Zr-10 Cu also showed hydrogen uptakes greater than theoretical. Although the Zr-10 Cr alloy showed the highest oxygen weight gains, the hydrogen uptakes were 26-50.6%.

The Zr-6.4 Nb shows oxygen weight gains of 2266-4637 μg. However, the hydrogen uptake values were 3.4-4.7% of theoretical. The Zr-50 Nb alloy showed oxygen weight gains of 1463-3285 μg and hydrogen weight gains of 8.5-14% of theoretical. Considering the extent of reaction the two Zr-Nb alloys show very low hydrogen uptake values.

None of the more concentrated zirconium alloys showed good corrosion behavior in liquid water under the given reaction conditions. The Zr-10 V and Zr-10 Cr alloys showed the highest corrosion rates.

Discussion

Corrosion results.—Our results show that crystal bar zirconium exhibits variable but usually extensive reactivity in liquid water at 360°C and 2708 psi under static conditions. The preliminary 28-day test showed zirconium to have a low corrosion rate while later tests showed poor corrosion resistance. Earlier studies (10, 11) at 375°C using a water vapor plus helium gas mixture in a flow reactor showed zirconium to have a consistently low rate of corrosion. In these experiments the hydrogen formed in the corrosion reaction was removed by gas flow from the reaction interface. In the autoclave tests the hydrogen produced and not absorbed remains in the autoclave atmosphere to be absorbed by other alloys.

Many elements have harmful effects on the corrosion of zirconium as shown by the extended studies (12) which led to the development of Zircaloy-2 and -4. Nitrogen in concentrations above 130 ppm causes rapid corrosion in liquid water at 360°C. Tin was found to reduce the harmful effects of nitrogen (12) although too much tin is harmful. An autoclave test on a Zr-2.5 Sn alloy shown in Table V shows that the Zr-2.5 Sn composition is not a good corrosion resistant alloy. This is in agreement with the conclusions reported by Hillner (7).

Table V shows the excellent corrosion resistance and zero hydrogen pickup of the Zr-1.0 Cr alloy. The Zr-1.3 Ni alloy showed low oxygen weight gains and a hydrogen pickup greater than theory. We conclude that this alloy was gettering hydrogen from the autoclave atmosphere. The Zr-1.6 Cu alloy reacted at a rapid rate with water and had hydrogen pickups greater than theoretical. The Zr-1.0 Cr alloy was less reactive than the two Zircaloy alloys, both in oxygen weight gain and in hydrogen pickup.

The concentrated zirconium alloys Zr-5 V, Zr-10 V, and Zr-10 Ni alloys disintegrated after 28 to 56 days in the autoclave tests. Both the Zr-10 Cr alloy and the Zr-10 Cu alloy reacted rapidly in the autoclave over the 112-day test with the Zr-10 Cu alloy absorbing more hydrogen than theoretical. The most interesting concentrated alloys are the Zr-6.4 Nb and the Zr-50 Nb alloys where β-Nb is present as a second phase in the α-Zr matrix. Both alloys reacted with liquid water at moderate rates of corrosion. Only small amounts of hydrogen were absorbed. Hydrogen absorption experiments on a Zr-25 Nb alloy (3) showed that β-Nb does not absorb appreciable hydrogen until high hydrogen pressures were reached.

The single phased zirconium alloys ZrV_2, $ZrFe_2$, Zr_2Ni, ZrNi, Zr_4Sn, Zr_2Cu, and ZrCu all showed high corrosion rates in liquid water compared to the dilute zirconium alloys containing the intermetallics as second phases. Zr_2Cu and ZrCu were studied earlier by us using a water vapor reactor at 375°C (10). Both alloys reacted rapidly when compared to the dilute alloys.

Differences do exist between the reactivities of the several intermetallics in liquid water corrosion. These differences were not shown in the 28-day liquid water experiments since the alloys were completely reacted. Comparison of the rates of corrosion of the dilute alloys, the 10 w/o alloys, and the intermetallics show that the rates of corrosion were a function of the amount of intermetallic in the alloy.

The following points will be considered in discussion of the mechanisms of corrosion of zirconium alloys in liquid water at 360°C and 2708 psi: 1, the crystal structure and thermodynamic stability of the intermetallic phase; 2, the type and extent of the hydrogen reaction and the stability of hydrogen in the several phases; 3, the distribution of hydrogen between the several metal phases and the hydride phase; 4, the size and distribution of the particles of the several phases in the zirconium matrix; and 5, the nature of the oxide film over the several phases and the transport of oxygen, hydrogen and metal ions through the oxide film.

Crystal structure and thermodynamic stability of the intermetallic compounds.—Table VII shows a summary of the structure types, lattice parameters, ratios of ionic radii of zirconium to the alloying element, electronic structures of the outer shell electrons, elec-

‡ C_{14} and C_{15} are Laves phases.

tron to atom ratios, latent heats of sublimation of the alloying elements, ratios of the latent heats of sublimation to that for zirconium, and estimates of the heats of formation of the intermetallic compounds. The heats of formation were calculated for us by Kubaschewski (18) and checked by us (3) using an independent analysis of the data. The values given are our calculated values.

The basic hypothesis of the method (19) is that the stability of a metallic multicomponent phase is due to a decrease in heat content from an increase in coordination on formation from the component metals. The coordination numbers are not those used by crystallographers since mutual attraction occurs also between atoms some distance beyond the first shell of nearest neighbors. The heats of formation are estimated from the change in coordination of the alloy when compared to the metals and from the heats of sublimation of the component metals alone. The electronic contribution is neglected.

Table VII shows that $ZrCo_2$, $ZrFe_2$, $ZrCr_2$, and ZrV_2 intermetallics have varying number of electrons in the 3d shell, crystallize in the C_{14} and C_{15} structure of varying lattice parameter, have varying electron to atom ratios and widely varying heats of formation. Zr_2Ni and Zr_2Cu do not crystallize in the C_{14} and C_{15} structures. Zr_4Sn could not be calculated since the structure has not been determined.

All of the intermetallics which crystallize in the C_{14} and C_{15} structures do not react appreciably with hydrogen or they react to take up hydrogen in solid solution. The intermetallics which crystallize in less stable structures react with hydrogen to form hydrides after saturating the metal. Zr_2Cu and Zr_2Ni are examples of these structures. We conclude that the type of hydrogen reaction and the stability of hydrogen in solid solution is a function of the crystal structure, lattice parameter, and the heat of formation of the intermetallic compound.

Correlation of corrosion reaction with thermochemistry of the hydrogen reactions of zirconium and its intermetallics.—Table VIII shows a summary of the important thermochemical data on zirconium and its intermetallics (1-3). The partial molal free energies of formation of hydrogen in the solid solution phase ($\bar{G}_H^\circ - 1/2\ G_{H_2}$), Sievert's law constant, k_H, the terminal solubility, n_H/n_{Zr}, and the hydrogen pressure, p_{H_2}, are tabulated. Positive values of ($\bar{G}_H^\circ - 1/2\ G_{H_2}$) and small values of k_H indicate weak bonding for hydrogen in the metal or alloy. This occurs for hydrogen in the intermetallics $ZrCr_2$ and $ZrFe_2$. Negative values of ($\bar{G}_H^\circ - 1/2\ G_{H_2}$) and large values of k_H indicate strong bonding for hydrogen. Column 6 of Table VIII shows the equilibrium hydrogen concentration in the several intermetallics at 360°C and at the hydrogen concentration where zirconium precipitates $\delta - ZrH_{1.4}$. Column 9 shows values of the partial molal free energy of formation, ($\bar{G}_H^\circ - 1/2\ G_{H_2}$), for the first hydride phase at 360°C when hydrides are formed.

The values of k_H in Table VIII show that Zr_2Cu takes up about 1/2 as much hydrogen in solid solution as does α-Zr at the same hydrogen pressure. In contrast Zr_2Ni takes up 2½ times as much. The calculated value for the hydrogen concentration of α-Zr at the terminal solubility at 360°C is 143 ppm. $ZrCr_2$ and $ZrFe_2$ for the same conditions take up less than 0.5 ppm of hydrogen. Zr_4Sn for these conditions would take up about 8 times as much hydrogen as α-Zr.

Zirconium forms the most stable hydride of the three hydride formers Zr, Zr_2Cu, and Zr_2Ni. With Zr_2Cu or Zr_2Ni as second phases in α-Zr hydrogen reacts with the alloy to first saturate the α-Zr and the intermetallics. Above a hydrogen concentration of $X_H = 0.013$ for α-Zr at 360°C δ-$ZrH_{1.4}$ forms with an equilibrium hydrogen pressure of 2.3×10^{-5} Torr. Zr_2Cu will not form δ-$ZrH_{1.4}$ until a hydrogen pressure of 6.3×10^{-4} Torr is reached while Zr_2Ni requires a hydrogen pressure of 1.59×10^{-4} Torr. Local kinetic conditions involving the permeability of the oxide film over the several phases could lead to hydriding of the intermetallic phases rather than α-Zr.

The corrosion data of Tables V and VI suggests that the intermetallic compounds are a critical factor in the corrosion process. This could occur if the oxide film over the α-Zr matrix were resistant to the penetration of hydrogen. The fact that the Zr-1.0 Cr alloy does not absorb hydrogen suggests that both α-Zr and the intermetallic are resistant to hydrogen. Since larger quantities of second phase makes a poor alloy, *e.g.*, Zr-10 Cr, we propose that stresses exist in the alloy at the phase boundaries between intermetallic and α-Zr where more rapid reaction can occur.

We would predict that Zr-1.0 Fe and Zr-1.0 Co also may have good corrosion properties. The Zr-2.2 Fe alloy tested here is too concentrated to compare its corrosion behavior with that for the Zr-1.0 Cr alloy.

On the basis of Table VIII we would predict that copper and nickel are not good alloying elements since hydrogen is not only taken up in solid solution but both alloys contain hydride forming intermetallics.

Table VIII shows us that tin and vanadium form intermetallics which are strong hydrogen absorbers in solid solution. Lattice parameter changes occur on adsorption of the large amounts of hydrogen with the development of additional stresses between the zirconium and the intermetallic lattices. However, permanent changes in the intermetallic lattice through the formation of hydrides does not occur as was the case for the copper and nickel intermetallics. We would predict that both Sn and V should have fair corrosion resistance at the 1 w/o level. The good corrosion resistant properties of Zircaloy-2 and -4 support this interpretation.

Experimental corrosion data are not extensive enough to make exact correlations between the thermochemical data on the hydrogen reaction and the corrosion reactivity. The critical importance of the amount of second phase on the corrosion properties was not recognized in choosing our alloy compositions. In addition close control must be given to the size and distribution of the second phase particles in the various alloys. There is the difficult problem of characterizing the large number of alloys which need to be studied.

Table VIII. Hydriding calculations zirconium and zirconium alloys at 360°C solid solution region

We can conclude that the thermochemical behavior of hydrogen in α-Zr and in the intermetallic phase is of major importance in the alloys corrosion reactivity. Other factors such as the transport of oxygen, hydrogen, and metal ions through the oxide films over the α-Zr and the intermetallics and the stresses developed between the intermetallics and α-Zr and between the oxide and metal phases also are of major importance.

The Structure of Thin Oxide Films Formed on Nickel Crystals

J. V. Cathcart,* G. F. Petersen, and C. J. Sparks, Jr.

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

A study was made of the structural details of thin oxide films formed on the (100), (111), (110), and (311) of nickel. Oxidation temperatures ranged from 400° to 600°C, and the oxide films produced were between 25 and 500Å thick. An x-ray technique was utilized to measure the average strain in the films, the mosaic spread, the thickness, and the epitaxial relationships between oxide and metal. The oxide films on all crystal planes studied were observed to contain large numbers of short circuit diffusion paths. A change in the extent of these diffusion paths in the oxide on a given crystal plane produced a corresponding change in the oxidation rate. Furthermore, there was a variation in the extent and efficiency of the short circuit diffusion paths as a function of crystallographic orientation of the substrate, and this variation correlated directly with the marked oxidation rate anisotropy exhibited by nickel.

Our previous studies (1-6) of the thin-film stage of the oxidation of copper led us to the conclusion that thin Cu_2O films, with thicknesses ranging up to a few hundred angstroms, are subject to large epitaxial forces which give rise to the development in the films of extensive arrays of paths of easy diffusion. We found several correlations between the extent and efficiency of these paths of easy diffusion and the oxidation rates exhibited by the copper specimens. In fact, there was a correspondence between the oxidation rate anisotropy of copper and the anisotropy of the extent of paths of easy diffusion in the oxide films. Other investigators, *e.g.*, Lawless and Gwathmey (7), Smeltzer and coworkers (8), Ali and Wood (9), and Gibbs (10), have also called attention to the potential significance of such structural defects in oxide films.

This paper describes a study of the thin-film stage of oxidation of bulk nickel. Some significant differences were found between the oxidation of nickel and copper especially with regard to the magnitude and nature of the strains which develop in the oxide films. However, there were broad areas of similarity between the two systems. For example, high concentrations of paths of easy diffusion also exist in the NiO films, and we observed that for those crystal planes where the extent of paths of easy diffusion in the oxide was large, the rate of oxidation was high, and vice versa.

Experimental Procedures

Specimen preparation.—All our work was done on single crystals of nickel. Single crystal disks with (100), (111), (110), or (311) surfaces were cut from cylindrical rods with a spark cutter. After mechanical polishing, the specimens were either chemically or electrolytically polished. Just prior to oxidation the specimens were annealed in hydrogen at the oxidation temperature for 10-15 min. The oxidation chamber was then pumped down to a pressure of about 10μ with a mechanical pump, and oxygen was admitted to the system at a pressure slightly less than 1 atm. Oxidation temperatures investigated ranged from 400° to 600°C with most of our work being done at 500°C. The time of oxidation was varied from a few minutes to several hours in order to produce film thickness of 25 to 500Å.

A comment is in order concerning this experimental procedure. Our main concern in this investigation was to establish procedures which yielded reproducible results, and the oxidation methods outlined do that fairly

well. Obviously, however, we have been studying crystals with "dirty" surfaces. Hydrogen was a major impurity in our system, and we know from our own experience as well as that of Gwathmey's group (11) several years ago that the presence of hydrogen can influence the oxidation characteristics of nickel. Surface impurities from the polishing solutions may also have had an effect on our results. Throughout the work we have felt that the important thing was to try to explain the marked oxidation rate anisotropy exhibited by nickel under a given, if arbitrary, set of conditions.

Measuring techniques.—In attempting to characterize these oxide films, we used many of the same methods we employed in our study of copper. X-ray diffraction techniques (12, 13) represented our major research tool in determining the structure of the films. We also used electron microscopy and electron diffraction in investigating other properties of the films.

The x-ray method is a very sensitive one; *e.g.*, we could study a 20Å film with little difficulty. Its success depended on the oxide film being sufficiently well oriented so that, when the specimen was set at the appropriate Bragg angle, virtually all the oxide was in position to diffract.

The x-ray results yielded a variety of information about the films. The 2θ scans allowed us to measure the average d-spacing (and, hence, the average strain) in a direction normal to the surface of the film. The relative line broadening of a pair of first and second order Bragg peaks yielded an estimate of the film thickness and the magnitude of any microstrains in the film. Rocking curves gave a measure of the mosaic spread of the films, and the determination of the area under these curves produced an independent estimate of the average film thickness. Of course, x-ray measurements also permit one to investigate the details of the epitaxial relationships between the oxide and the metal.

Results

Oxidation rate anisotropy.—We used single crystal spheres of nickel to obtain a qualitative measure of the oxidation rate anisotropy. The major crystallographic planes in the order of decreasing oxidation rates were (110), (100), (111), and (311). For a specimen oxidized 30 min at 500°C, the oxide film thickness varied from about 50 to 500Å between the (311) and (110). The film thickness on the (100) was about half that of the (110). For reasons discussed below, the oxidation characteristics of the (111) were quite sensitive to the effects of surface contaminants. Under "standard" conditions the oxidation rate of the (111) was roughly twice that of the (311), but in some experiments the rate increased to a value only slightly less than that for the (100). Thus we characterize the (110) as a high rate plane, the (100) and (111) as intermediate rate planes, while the (311) is a slow-rate orientation.

X-ray Results

Average strain in films.—Figure 1 shows the difference between the average d-spacing observed for the NiO films and that of bulk NiO plotted as a function of thickness for the four major planes of nickel investigated. Previously published data (6) for the oxide on the (110) and (111) of copper is also included for comparison. In every case the thin NiO films exhibited a d-spacing equal to that of the bulk oxide with the exception of very thin films on the (311). There the d-spacing values were slightly smaller than bulk. These results were surprising since the lattice parameter of NiO is about 18% larger than that of Ni (see Table I for the epitaxial relationships). One would expect that the forces arising from this misfit would tend to compress the films in the plane of the metal surface and produce a corresponding expansion normal to the surface (*i.e.*, in the direction in which the d-spacings were measured). As may be seen, the Cu_2O films were, in general, expanded in just this fashion relative to their bulk properties.

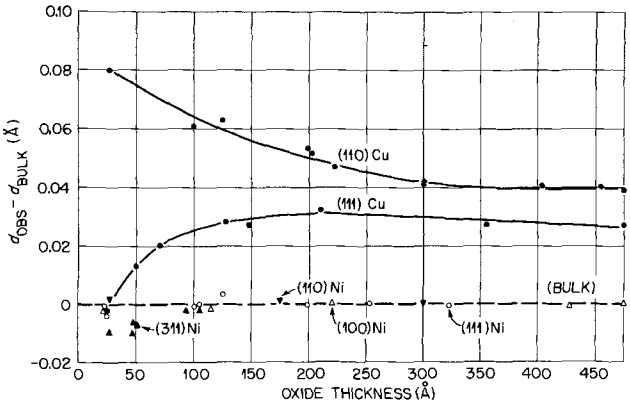

Fig. 1. Deviation of the observed, average d-spacing from bulk values plotted as a function of thickness for oxide on several crystallographic planes of Cu and Ni. In all cases the d-spacing was measured normal to the surface of the oxide film.

Line shape analysis.—Despite the fact that the average lattice parameter of the NiO films was essentially equal to that of bulk material, an analysis of the line shapes of the Bragg maxima for the films indicated that substantial strains existed in the films. X-ray line broadening can result from two general effects: small particle size and the presence of strain gradients (17). Small particle size (in our case, film thickness) causes the widths of first and second order peaks, expressed in terms of sin θ, to broaden equally. Strain effects, on the other hand, produce a greater broadening of the second order than the first order peak. We did, in fact, observe an excessive broadening of second order peaks, a result which we interpret as indicating that strain effects of some sort are important in the NiO films.

These data were analyzed in terms of the model developed by Borie (2, 12) for Cu_2O films in which it is assumed that the strain varies approximately linearly across the oxide film. On the basis of this model, a 2% variation of d_{111} from one interface to the other was indicated for a NiO film formed on the (111) of Ni. The results are shown in Fig. 2 along with comparable data for the oxide on the (110) of copper. Note that the strain gradient in the two films is of the same order of magnitude; however, the fact that the average d-spacing for the NiO films was that of the bulk oxide forced us to conclude that part of the film was in compression and part in tension.

We rationalized the strain gradient in the oxide on the (110) of copper in terms of the development of an array of growth dislocations which permitted a

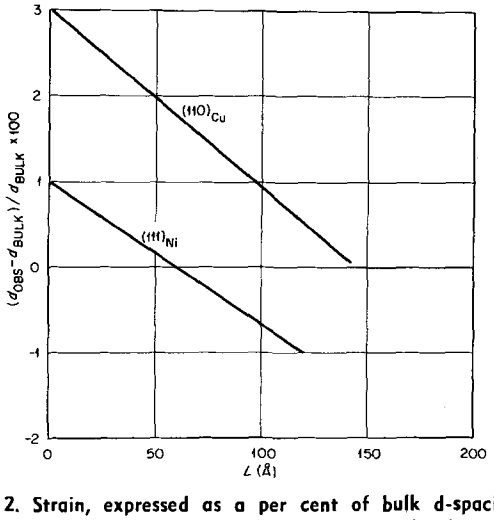

Fig. 2. Strain, expressed as a per cent of bulk d-spacing, vs. position within the oxide for films formed on the (111) of Ni and the (110) of Cu. The d-spacings were measured normal to the film surface, and "L" is the position parameter within the oxide film.

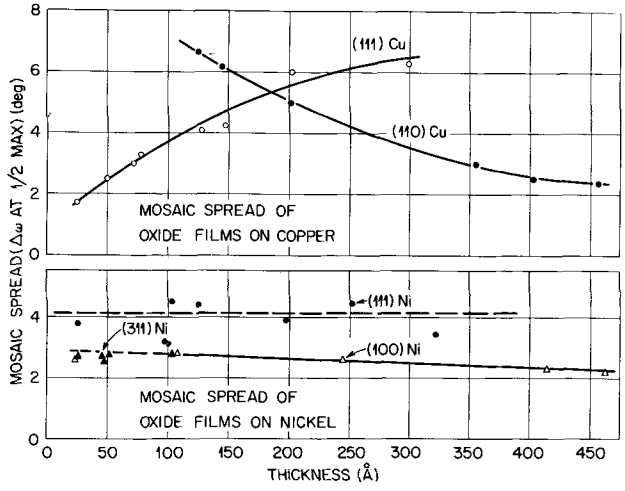

Fig. 3. Mosaic spread vs. film thickness for oxide films formed on several crystallographic planes of Cu and Ni.

relaxation of the epitaxial strains as the film grew (2). In this model, however, the lattice parameter of the Cu_2O, measured normal to the film surface, was never less than that of bulk Cu_2O (see Fig. 2). A situation comparable to that observed for NiO occurred in the Cu_2O films only when they were stripped from the copper surface. The strain gradient in the stripped film was essentially the same as before stripping, but the average strain dropped to zero, reflecting the removal of the epitaxial constraint imposed by the copper surface. Thus, if the dislocation model developed for Cu_2O films is to be applicable to the NiO films, one must assume that a mechanism exists by which the epitaxially induced strain in the oxide at the oxide-metal interface can relax either during film growth or during cooling after oxidation. Conceivably this relaxation could be triggered by the small change in lattice parameter which accompanies the phase transformation NiO undergoes at about 250°C (18, 19). For the present, however, it is not clear what the precise explanation is for the substantial strain effects which exist in the NiO films.

Mosaic spread.—Figure 3 shows the mosaic spread of a series of NiO and Cu_2O films plotted as a function of film thickness. We defined mosaic spread in terms of the width at half-maximum intensity of the rocking curves for the films. Except for the (110) films, which were essentially polycrystalline, the NiO films were better oriented than corresponding Cu_2O films. Note that, in contrast to the Cu_2O, the mosaic spread of the NiO films was approximately constant with thickness.

Epitaxy.—The last of the x-ray results has to do with the epitaxial relationships between the oxide and metal. Except for the formation of polycrystalline oxide on the (110), we found that NiO-Ni exhibited the same epitaxial relationships as Cu_2O-Cu. These data are summarized in Table I, and, with the exception of the results for the (110), are in agreement with the data of Lawless *et al.* (11).

Table I. NiO-Ni epitaxial relationships

Planes $(hkl)_{Ni}$ // $(hkl)_{NiO}$		Directions $[hkl]_{Ni}$ // $[hkl]_{NiO}$	
(100)	(111)	[011]	[0$\bar{1}$1]
		[011]	[01$\bar{1}$]
		[0$\bar{1}$1]	[0$\bar{1}$1]
		[0$\bar{1}$1]	[01$\bar{1}$]
(111)	(111)	[01$\bar{1}$]	[0$\bar{1}$1]
		[0$\bar{1}$1]	[01$\bar{1}$]
(311)	(110)	[011]	[$\bar{1}$10]
(110)	Polycrystalline oxide		

Note that these epitaxial relationships serve as a basis for dividing the NiO films into three general categories. At one extreme is the oxide on the (311). These films are pseudosingle crystals, and while they have a mosaic structure, the mosaic boundaries are all low-angle boundaries (see Fig. 3). On the other hand, the oxide on the (110) is essentially polycrystalline and contains, therefore, a high concentration of high angle boundaries.

The oxide films on the (111) and (100) fall into a third category. These films consist of arrays of small crystallites which may be present in two or more orientations, orientations which bear a twin relationship to one another. The first oxide orientation indicated for the (111) (see Table I) is one in which the oxide and metal lattices are essentially parallel to one another (parallel orientation); the second orientation may be derived by a 180° rotation of the oxide lattice about its surface normal to produce the so-called antiparallel orientation.

Two sets of these twin-related orientations[1] exist in the oxide on the (100). The first pair of orientations shown in Table I form one set, the latter pair the other.

Discussion

Films on the (100) and (111)

Incoherent twin boundaries.—An assessment of the nature of the boundaries between oxide crystallites in the films on the (100) and (111) is essential to an estimate of their importance as paths of easy diffusion. It is not known (*i*) whether actual twinning occurs within a given oxide crystallite as the film grows or (*ii*) whether each oxide crystallite extends untwinned completely through the thickness of the film, maintaining either the parallel or antiparallel orientation throughout its growth. As discussed at greater length in ref. (5), there is some evidence in the case of Cu_2O films that the latter condition prevails; however, as our diffraction data show, if true twinning does occur within the oxide crystallites, the twinning plane is always the (111), *i.e.*, the plane parallel to the film surface. Thus any coherent twin boundaries that develop in the oxide are parallel to the film surface. On the other hand, the boundaries which have a component perpendicular to the film surface and which separate oxide nuclei of different orientations must be incoherent twin boundaries.

Therefore, in either of the two cases just described, regions of incoherent twin boundaries will exist within the films. Such boundaries constitute paths of easy diffusion which are almost as efficient as high angle boundaries (20, 21). Thus if incoherent twin boundaries are present in the oxide film in sufficiently large numbers, they could play a very important role in mass transport processes across the oxide.

The factors which determine the total area of incoherent twin boundaries in the oxide are (*i*) the size of the oxide crystallites, (*ii*) the distribution relative to one another, of oxide crystallites having differing orientations, and (*iii*) the relative amounts of oxide in each possible orientation.

Crystallite size and distribution.—Dark field electron microscopy of stripped NiO films showed the films to have a mosaic structure, the diameter of the mosaic blocks (or oxide crystallites) varying from about 200 to 500Å. This value did not appear to vary with substrate orientation or with film thickness in the range of thicknesses considered in this study. Furthermore, as nearly as we could tell on the basis of electron diffraction experiments, the distribution across the specimen surface of oxide crystallites having a given orientation was essentially random. We concluded, therefore, that films containing sizable quantities of the various possible oxide orientations should be rich in incoherent twin boundaries; *i.e.*, rich in efficient paths of easy diffusion.

[1] For the sake of brevity we shall hereafter refer to the multiple, twin-related orientations described above simply as "twins' or "twin orientations."

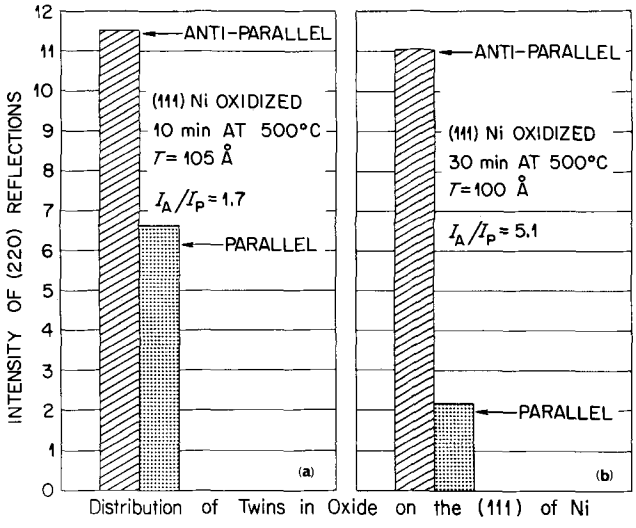

Fig. 4. Bar graphs showing the relative quantities of oxide present in the parallel and antiparallel orientations in oxide films grown on the (111) of Ni. Figure 4a shows results typical of those obtained for chemically polished specimens, while the data in Fig. 4b are characteristic of electropolished specimens.

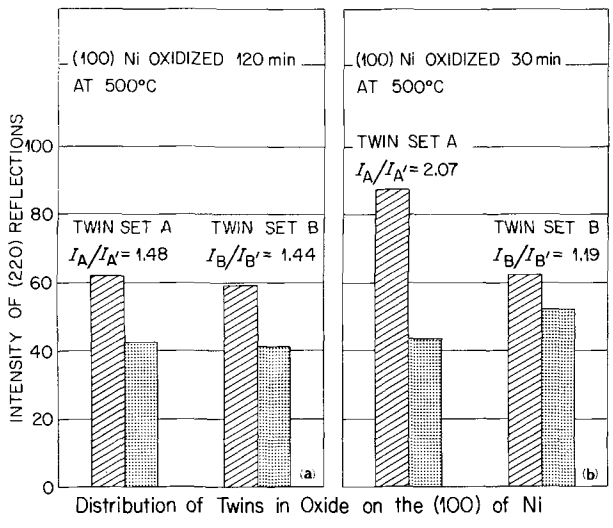

Fig. 5. Bar graphs showing the relative quantities of oxide in the four possible orientations present on the (100) of Ni. The results in Fig. 5a are typical; the results in Fig. 5b are atypical and probably reflect a subtle variation in the degree of the initial surface contamination of the specimen.

Relative quantities of different oxide orientations.— Since, as outlined above, the "twinning plane" in the oxide was parallel to the metal surface, we could not detect the presence of twins in the oxide by x-ray techniques as long as the specimen was kept in the normal diffraction geometry. However, by tilting the specimen so as to bring the (220) planes into diffracting position, we could measure the relative amounts of the twins present in a given oxide film. The mosaic spread for these (220) peaks was the same for all peaks, thus making the peak height proportional to the amount of oxide in a given twin orientation. The results for the (111) are summarized in Fig. 4. The intensity of the (220) reflection is shown for each twin orientation in bar graph form. In all cases investigated we found the antiparallel orientation to predominate in the (111) oxide, but the relative amount of each twin was dependent on the surface treatment given the specimen. The results shown in Fig. 4a are typical of chemically polished specimens, and the ratio of I_a/I_p was 1.7, where I_a and I_p are the (220) peak intensities for the antiparallel and parallel twin orientations, respectively. An electropolished crystal was used to obtain the data shown in Fig. 4b, and I_a/I_p was about 5.

Note the difference in the oxidation rates for the two specimens. The crystal for which I_a/I_p was larger (Fig. 4b) required an oxidation period three times longer than the other in order to attain the same oxide thickness. Obviously, the specimen with the more nearly equal quantities of the parallel and antiparallel orientations of oxide and, thus, with the oxide film containing the greatest extent of incoherent twin boundaries, exhibited the higher rate of oxidation.

The twin distribution in two different (100) films is shown in Fig. 5. The (220) intensity is plotted for each of the four orientations (*i.e.*, for each of the two sets of twins) occurring in the film. Generally the twin ratio was the same for both sets of twins, the results in Fig. 5a with ratios of about 60/40 being typical. Occasionally, however, we found a variation in the twin ratio between the two sets of twins as shown in Fig. 5b where the ratio for the A set was about 2/1 while that for the B set was almost 1/1. This rather atypical result probably reflects a slight difference in the degree of the initial surface contamination of the specimen.

These results for the (100) and (111) may be summarized as follows:

1. The size of the crystallites of which the oxide films are composed ranges from 200 to 500Å and is constant.

2. Crystallites having any one of the orientations observed are distributed essentially randomly through the film.

3. The relative quantities of the oxide crystallites having different orientations vary according to the precise conditions of oxidation. The maximum extent of paths of easy diffusion in the oxide, *i.e.*, of incoherent twin boundaries, is realized when the quantities of oxide of various possible orientations are equal. As this condition was approached in the oxide on the (111), the rate of oxidation was observed to increase.

Analysis of the Oxidation Rate Anisotropy of Nickel

These general observations make clear the important structural aspects of NiO films. In many ways the properties of NiO films are similar to those of comparable Cu_2O films, and it is possible on the basis of these results to propose an explanation for the oxidation rate anisotropy of nickel which is consistent with that already suggested for copper (1, 6). The pattern which emerges is as follows:

1. The oxide films, while generally well oriented, consist of large numbers of small mosaic blocks, 200 to 500Å in diameter in the case of NiO. Assuming a grain boundary width of approximately 10Å, this means that 5 to 10% of the transverse area of the films is associated with mosaic boundaries.

2. Depending, of course, on the exact nature of these boundaries, one expects that the diffusion coefficient, D_{gb}, in such regions will be different from the volume diffusion coefficient, D_v. For the case of the diffusion of Ni along high angle boundaries in NiO, Smeltzer and Perrow (8) have estimated that D_{gb} exceeds D_v by a factor of 10^2-10^4. Such a large value for D_{gb}/D_v is consistent with measured values of this ratio for materials such as silver (14), NaCl (15), and Al_2O_3 (16). Therefore, we feel justified in assuming that at 500°C, D_{gb} for NiO is at least a few orders of magnitude greater than D_v. If that be the case, given the large fraction of oxide area associated with the grain boundaries in the NiO films, one can easily imagine situations where short circuit diffusion in the NiO might swamp out volume diffusion.

3. The numbers cited above apply for high angle boundaries, and obviously not all the mosaic boundaries in the NiO films are high angle boundaries. Our x-ray data indicate that the character of these boundaries varies with crystal plane. Very low angle boundaries exist in the oxide on the (311), and for these films we would expect $D_{gb} \approx D_v$. The resulting oxidation rate of the (311) should be relatively small, as indeed, we observe.

The oxide on the (110) is at the other extreme, the mosaic boundaries being for the most part high angle boundaries. For these films $D_{gb} >> D_v$, and we expect and observe a relatively large rate of oxidation.

The oxide on the (111) and (100) is characterized by the presence of incoherent twin boundaries which in metals, at least, have interfacial energies 50-80% as high as high angle boundaries (21). For these films, therefore, we would predict that $D_{gb} > D_v$, and that, as a consequence, the oxidation rates for these two faces would be significantly greater than that for the (311) but less than that for the (110).

The differences in rate between the (111) and (100) can be rationalized in terms of the fact that the ratio of the amounts of each twin orientation in the (100) oxide tends to approach unity more closely than is the case for the (111) oxide. For that reason one would expect the extent of incoherent twin boundaries to be greater in the (100) oxide. There is also the added factor on the (100) that there are two sets of twin-related orientations rotated at 90° to each other, thus producing two kinds of "incoherent twin" boundaries in the (100) oxide.

We have already reported a similar correlation between the oxidation rate and the extent of short circuit diffusion paths in the oxide on the major planes of copper (1, 6). Only the (110), which is a "slow-rate" plane on copper, deviates from the order of oxidation rates reported for nickel. The reason for this difference lies in the fact that the oxide formed on the (110) of copper, in contrast to that of nickel, is well oriented with but a single orientation. Paths of easy diffusion through it are confined largely to low angle boundaries; hence one expects its oxidation rate to be small.

We conclude, therefore, that for nickel as for copper, paths of easy diffusion in the oxide play an important role in determining the rate of oxidation. Furthermore, a strong correlation exists between the oxidation rate anisotropy exhibited by nickel and copper and the anisotropy of the extent of paths of easy diffusion in the oxide films.

Technical Notes

Effect of Kilovolt Electrons on the Etch Rate of Al_2O_3 and Ta_2O_5

B. H. Hill

Advanced Electronic Devices Branch, Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio

It has been established recently that the chemical etch rate of thermally grown SiO_2 is enhanced (~3 times) when the sample is bombarded with energetic electrons. This process is called the bombarded enhanced etch rate (BEER) effect and is a function of electron dose. In fact, this new and highly promising technique has been used to fabricate planar silicon transistors without the use of conventional photoresist by opening holes in the SiO_2 diffusion mask for subsequent diffusion and contacting. Process resolution is very high, and windows as small as 0.6 x 5μ have been obtained (1).

In order to determine whether the BEER effect would open discretionary windows in other dielectric materials, electron irradiation studies were conducted on films of Al_2O_3 and Ta_2O_5. The Westinghouse Model 504 Scanning Electron Microscope (SEM) was selected as the source of kilovolt electrons (15 kv). Precise electron-bombarded patterns could be generated since the SEM allowed direct observation of the oxide surface during the irradiation. The characteristic area of the patterns was on the order of 1 mil^2 since exposure time for larger areas would take too long, *e.g.*, $\sim 10^8$ sec for a 1 cm^2 total exposure area using typical SEM operating conditions of a 0.1μ-diam beam at 10^{-8} amp beam current. First, the primary beam current was measured (2); then, this value and the predetermined area to be irradiated were used to calculate the exposure time required to produce the desired electron bombardment dose

$$Q = tI_p/A$$

where Q is electron dose in coulombs/cm^2, t is exposure time in sec, I_p is primary beam current, and A is area in cm^2.

The 0.6-cm^2 specimen was mounted on a TO-5 header at the same height as and adjacent to the Faraday cup using silver print as an adhesive (3). In order to prevent charging of the oxide deposited on the glass microscope slides, the same silver print was used to form a conductive path from the oxide to the specimen holder. All irradiations were conducted in an oil-pumped system at 5 x 10^{-6} Torr with the sample surrounded by a cold finger at liquid nitrogen temperature. This cold finger protected the specimen surface from pump-oil vapor which otherwise would be polymerized by the electron beam.

Films of evaporated Al_2O_3 and anodic Al_2O_3 and Ta_2O_5 were used because of their ease of fabrication and interest to this Laboratory. Table I summarizes the types of films studied, the substrates, and the methods used to produce the films (4). The BEER effect experiment in SiO_2 was repeated in order to develop a standardized experimental technique and to determine the effectiveness of the cold finger. If oil were being polymerized under the beam, then a retardation effect would be obtained on the SiO_2; however, this was not the case.

The unbombarded etch rates and oxide thickness were obtained by masking a portion of the specimen surface with paraffin, etching the specimen for a specified time, and then measuring the step with a Zeiss interference microscope. Films of Al_2O_3 formed by both evaporation and anodization were etched in phosphoric acid (85%) at 70°C. The evaporated films etched at the rate of 500 Å/min and the anodic ones at approximately 1200 Å/min. The etchant for Ta_2O_5 was a solution of 200 cc of hydrofluoric acid (48%), 80g ammonium fluoride, and 20 cc deionized water (5). The etch rate at room temperature was 300 Å/min.

Table I. Sample preparation

Film	Substrate	Method of formation	Etch result
SiO_2	Si wafer	Thermal oxidation	Enhancement
Al_2O_3	Si wafer	Evaporative deposition of sapphire	Retardation
Al_2O_3	Microscope slide	Evaporative deposition of sapphire	Retardation
Anodic Al_2O_3	Microscope slide	Evaporative deposition of Al and anodization	Retardation
Anodic Ta_2O_5	Microscope slide	Triode sputtering of Ta and anodization	Retardation

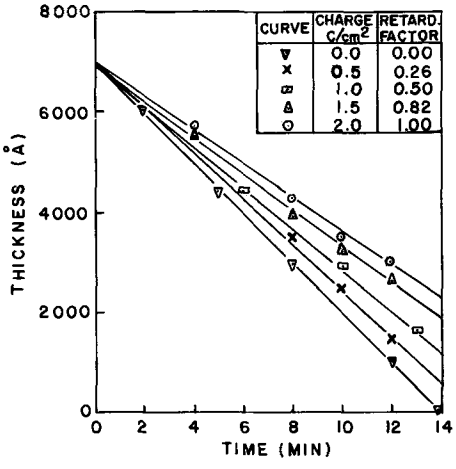

Fig. 1. Etch curves for evaporated Al_2O_3

In a series of irradiations made on samples of evaporated Al_2O_3, the accumulated electron doses ranged from 0.5 to 10 coulombs/cm^2. After a series of etch cycles, a very distinct line of hillocks remained where the surface had been irradiated. Each hillock corresponded to an area which had been irradiated. Exposure to the electron beam had retarded the etch rate, which is an opposite effect to that observed in SiO_2. Figure 1 shows the etching behavior of a 7000Å-thick evaporated Al_2O_3 layer after bombardment by 15 kv electrons, with electron dose as a parameter. The inset summarizes the results with the retardation factor normalized at the value where saturation occurs (2 coulombs/cm^2), *i.e.*, continued bombardment above 2 coulombs/cm^2 produces no further decrease in the etch rate. Any effect of dose below 0.5 coulombs/cm^2 could not be measured with the Zeiss interference microscope and was, therefore, considered negligible.

Films of Al and Ta were electrolytically anodized to form Al_2O_3 and Ta_2O_5, but samples with oxide thickness greater than ~2500Å could not be fabricated due to equipment limitations. The thinness of the samples and the fact that the measurements were hampered further by somewhat uneven etching of the surface resulted in qualitative data only. However, observation of the interference color changes of the bombarded and unbombarded regions after each etch cycle showed that the colors of the bombarded region followed one or two etch cycles behind the unbombarded region. From this observation, and the fact that the oxide on the unbombarded portion of the substrate etched away first leaving a hillock where the oxide had been irradiated, it could be concluded that the etch rate of both anodic films had been definitely retarded after bombardment.

Determination of Mobility and Its Profile in n/n$^+$ Silicon Epitaxial Layers

Dinesh C. Gupta*[1]

Sylvania Electric Products, Inc., Woburn, Massachusetts

Current needs of achieving good quality epitaxial silicon for applications in integrated circuits and microwave devices make it desirable to know the mobility in epitaxial layers. Hall measurements can be made on layers deposited on substrates of opposite conductivity type such as p on n or n on p (1) or on layers deposited on insulating substrates such as silicon films grown epitaxially on sapphire (2). However, most applications require high resistivity layers on low resistivity substrates of the same conductivity type in which case Hall measurements cannot be made.

There is an increasing interest in depositing thin silicon layers at low temperatures (3, 4) because of the need of achieving controlled doping impurity gradients. At very low temperatures, however, the crystallinity of the layers deteriorates, enhancing the surface (5) and defect scattering (6) and, thus, reducing the carrier mobility. Recently, the MOS capacitance method has been used to measure epitaxial layer resistivity (7) and the effective mobility (8). The mobility of the carriers calculated by this method is usually less than the bulk mobility because it depends on the physical structure of the silicon-insulator interface, which introduces another scattering process.

The spreading resistance probe method (9) has been used to measure the electrical resistivity and the resistivity profile in n/n$^+$ and p/p$^+$ epitaxial layers and the diode voltage-capacitance method (10) has been used to determine the impurity density profile in these layers. These two methods are independent of each other and can be used to determine the carrier mobility in the layer.

Method and Results

In a semiconductor, the conductivity is approximately given by

$$\sigma = q\mu \mid N_D - N_A \mid \qquad [1]$$

if the impurities are fully ionized.

For an uncompensated n-type semiconductor

$$\mu_n \approx \sigma/qN_D \qquad [2]$$

Equation [2] enables one to calculate the majority carrier mobility if independent measurements of the electrical conductivity, σ, and the majority carrier impurity density, N_D, are available. Kennedy *et al.* (11) have pointed out recently that the diode voltage-capacitance method establishes the distribution of majority carriers rather than the impurity atoms. Thus, this technique together with the spreading resistance probe method can be used to determine a value for the majority carrier mobility in an epitaxial layer.

Table I gives the comparison of mobility data calculated by the above measurements and from Hall measurements on n-type bulk silicon. Hall measurements were made by the Van der Pauw method (12). The same specimens were measured by the spreading resistance probe. Diffused junctions were then formed and the impurity densities were calculated from diode voltage-capacitance measurements. The calculated mobility is dependent on the impurity density because of impurity scattering (13) and correlates well with the values calculated from the Brooks-Herring equation at 300°K (14).

Figure 1 shows the mobilities determined in n-type epitaxial layers of about 5 μm in thickness deposited on n$^+$ As-doped (111)-oriented substrates of resistivity about 0.002 ohm-cm by different processes such as hydrogen reduction of $SiCl_4$, SiH_4 pyrolysis and two temperature deposition cycle using SiH_4 in hydrogen. The results are plotted on the curve calculated from the Brooks-Herring equation. Each data point in Fig. 1 is the average of measurements on five layers deposited by the process shown. The spread in the values of mobility was found to be 8-12% and the spread in the values of impurity density was 3-5%.

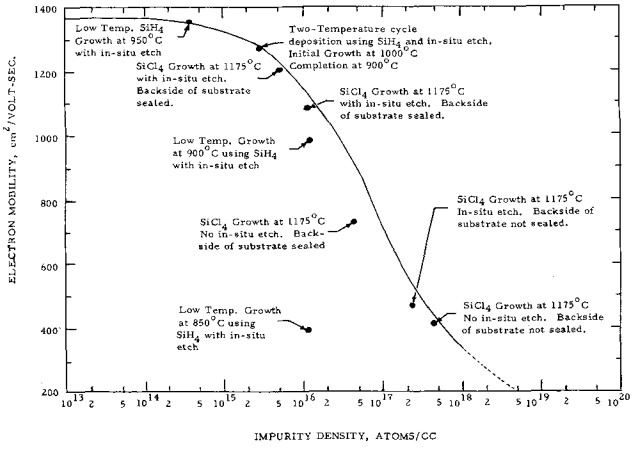

Fig. 1. Electron mobilities in various n/n$^+$ silicon epitaxial layers. Solid line is calculated from Brooks-Herring equation at 300°K for constant activation energy of 0.039 ev and uncompensated n-type silicon.

Figure 2 gives the mobility profile of two epitaxial layers, one deposited by the hydrogen reduction of silicon tetrachloride and the other deposited by the pyrolysis of silane on (111)-oriented substrates of resistivity about 0.002 ohm-cm. Each specimen was scribed into two pieces; one was successively etched in a modified CP_4 etch (60 ml 48% HF, 400 ml acetic acid and 100 ml HNO_3)[2] and measured by the spreading resistance probe; diffused diodes were made on the other half and the diode voltage-capacitance measurements were taken. From the resistivity and impurity density profiles, the carrier mobility was calculated.

Discussion

Results plotted in Fig. 1 show that the same carrier mobilities can be obtained as those reported in bulk semiconductors. However, these values depend on the deposition process used. This may be because the

[2] For small layer thicknesses, a modified pyrocatechol etch (170 ml or 98% ethylenediamine, 30g pyrocatechol and 80 ml water) can be used (15). The temperature of the bath should be kept constant at 100°C during etching.

Table I. Comparison of mobility by Hall and spreading resistance measurements on n-type bulk silicon

Impurity density, atoms/cc	Hall mobility, cm²/v-sec	Mobility calculated from spreading resistance probe measurements, cm²/v-sec
1.55×10^{15}	926	890
5.04×10^{15}	920	1020
5.80×10^{15}	920	905
3.25×10^{16}	540	577
3.50×10^{16}	860	870
5.30×10^{18}	390	372

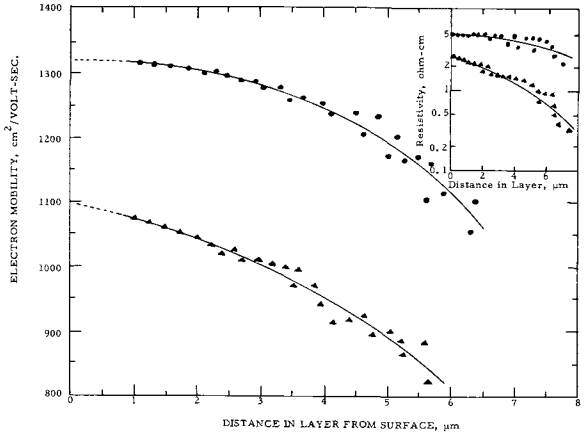

Fig. 2. Mobility profiles in n/n$^+$ silicon; •—SiH_4 deposition at 950°C with *in-situ* etch, ▲—$SiCl_4$ deposition at 1175°C with *in situ* etch. Thickness of these epitaxial layers is about 8 μm. The graph in the upper right corner is a direct resistivity profile from spreading resistance probe measurements.

layers deposited by some processes have greater amounts of surface or defect scattering or both. Layers processed with *in situ* HCl vapor etch yield a higher mobility than those processed without *in situ* etch which may suggest that stacking faults or stair-rod dislocations also give rise to scattering. The mobility in layers deposited at low temperatures with a two-temperature cycle seem to be approaching those obtained in bulk semiconductors. Layers whose surfaces are visibly free of misoriented growth and in which dislocation density readings are fairly low (<1000/cm^2) also have mobility approaching the maximum attained at a given impurity density. A detailed analysis on the dependence of the mobility on defects is not possible at this time.

The data in Fig. 2 show some scattering, probably because of the accuracy limitation in spreading resistance probe measurements. Because the layers were successively etched, the etched surfaces might have caused the variation in the total contact resistance measurements.

Conclusion

Measurements of mobility in n-type silicon epitaxial layers deposited on n$^+$ substrates show that it is possible to obtain values in layers comparable to those in bulk semiconductors. However, the values depend on the deposition process used. A two-temperature cycle yields higher mobilities. *In situ* etch also helps in obtaining higher mobility in layers. The accuracy of the technique is dependent on the accuracy of the spreading resistance probe and diode voltage-capacitance measurements. The technique could also be used on p/p$^+$ silicon epitaxial layers as well as on gallium arsenide epitaxial layers.

Acknowledgments

The author wishes to express his thanks to J. Chan and P. Keating for taking Hall measurements and C-V data, to P. Parekh for diodes fabrication, to V. Lyn for taking dislocation readings, and to P. Wang for helpful suggestions.

Brief Communications

Comments on the Paper "Optical Properties by Far Infrared Ellipsometry"

B. Rao and R. A. Griffin

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

An infrared ellipsometric method to measure the thickness of thin epitaxial layers of silicon and germanium has been described recently by Jones and Hilton (1, 2). Optical constants derived using their method were compared with those calculated from the Lyden expression (3) for free carrier and lattice absorption in semiconductors. The differences were ascribed as due to surface (ellipsometric technique) rather than bulk (electrical method) optical properties. An alternative explanation which considers the fundamental aspects of the ellipsometric method in the far infrared is proposed.

Ellipsometry (4) relates changes in the phase Δ and amplitude ψ components of monochromatic polarized radiation after reflection at a surface, as a function of wavelength λ of the radiation, optical constants of surface and environment, and the angle of incidence θ. The optical constants so determined depend very much

Table I. Penetration depth for various materials for radiation in different regions of the spectrum

Material	Electrical conductivity, sec^{-1}	Penetration depth in A units for radiation at 1μ	10μ	100μ
Copper	5.14×10^{17}	20	62	193
Pure silicon	9.0×10^{16}	46	145	460
n-type silicon (0.016 ohm cm)	5.62×10^{13}	1800	5800	18,000
Germanium	1.96×10^{10}	100,000	311,000	1,000,000

on the surface preparation (5). This phenomenon has been elucidated by Mott and Jones (6), in attempting to explain the widely different optical constants obtained by different workers for ostensibly the same specimen, as due to the limited penetration of the radiation into the material medium. The extent to which the optical constants are a characteristic of the bulk specimen depends, therefore, primarily on the penetration depth of the radiation into the material medium.

The penetration depth d is defined according to the equation

$$d = \frac{1}{4\pi}\sqrt{\frac{c\lambda_0}{\mu\sigma}}$$

where c is the velocity of light, λ_0 the wavelength in vacuum, μ the magnetic permeability, and σ the electrical conductivity (7). Some typical values of d for $\mu = 1$ are shown in Table I. Considering 0.016 ohm cm n-type silicon, the optical constants measured in the far infrared by the ellipsometric method will be essentially independent of the surface properties, as the penetration depth is of the order of 10,000Å in this region. The differences in optical constants observed by electrical methods (1) (A, B, and C) in comparison with the ellipsometric method (2) (D and E), as shown in Table II, must therefore be due to other factors.

The independence of optical constants with the angle of incidence is assumed in the ellipsometric method. The generality of this statement has been doubted by several workers (4, 7). In Table II, the refractive index and adsorption coefficient of n-type silicon determined by ellipsometric method (1, 2) at two different angles of incidence are compared with those derived from the electrical methods. A wide range of values of the absorption coefficient is found in both electrical and ellipsometric observations of the same silicon surface. The different values of optical constants observed at two angles of incidence may be due to systematic errors in the technique of ellipsometric measurement used in the far infrared.

Table II. Optical constants of n-type silicon obtained by different methods

Method		Angle of incidence	Refractive index, n	Absorption coefficient, k
Electrical (1)	A		2.18	2.44
	B		2.48	2.18
	C		2.21	1.49
Ellipsometry (2)	D	50°	2.59	1.38
	E	70°	2.34	2.64

The Lyden expression (3) is based on a theoretical model of single carrier conduction with attendant assumptions regarding the total dispersion attributable to a lattice contribution and the infrared reflectivity minimum. In mobility measurements, n and k are observed at a frequency different from that employed in the ellipsometric method. Thus, coincidence in optical constants for both methods should not be expected. Other workers and ourselves find that the intensity ratio method (8-10) (which involves the measurement of relative intensities for different azimuthal positions of the analyzer, the polarizer being held at a fixed azimuth) without a quarter wave plate is superior to the technique of visible ellipsometry at these wavelengths.

Identification of the (0001) and the (000$\bar{1}$) Surfaces of Silicon Carbide

J. M. Harris,* H. C. Gatos,* and A. F. Witt*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

An alkaline solution of $K_3Fe(CN)_6$ has been employed at its boiling temperature (somewhat above 100°C) for differentiating reliably and reproducibly between the (0001) or silicon and the (000$\bar{1}$) or carbon surfaces of α-silicon carbide. Bubbling oxygen or air through the solution during etching enhances the differentiating action of the etchant and decreases the etching time from approximately 20 min down to a few minutes.

In a typical etching test the silicon carbide platelet, polished with 3μ diamond powder, is placed in approximately 50 cc of the etchant which consists of equal volumes of aqueous solutions of $K_3Fe(CN)_6$ and NaOH, both saturated at 22°C. The etchant is then brought to a boil in an open beaker of 200 cc capacity. Isolated etch figures begin to appear on the silicon surface in about 20 min (Fig. 1). They increase in number and intensity with time.

Approximately 15 min of etching without gas bubbling and 10 min with gas (O_2 or air) bubbling could

* Electrochemical Society Active Member.

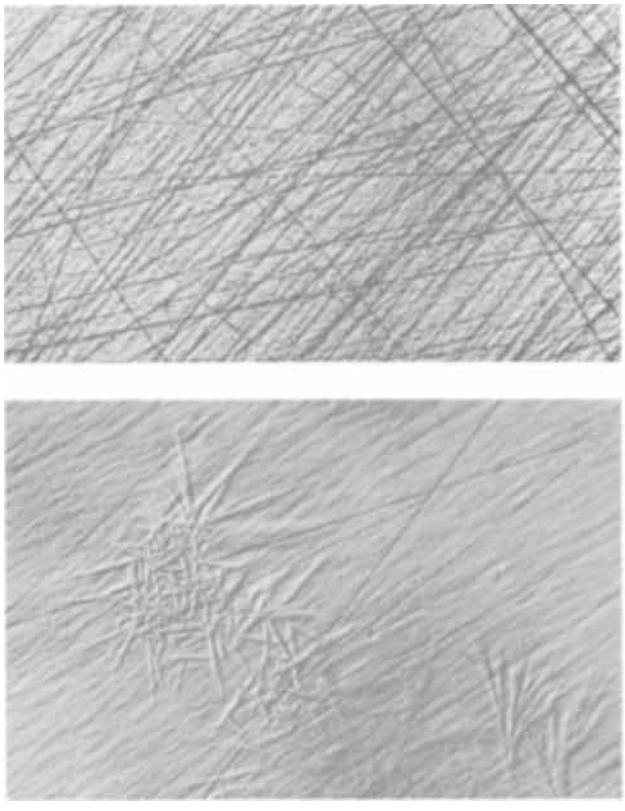

Fig. 1. Carbon surface, $(000\bar{1})$, (upper) and silicon surface, (0001), (lower) after etching for 22 min in the alkaline $K_3Fe(CN)_6$ solution. Both sides were polished with 3μ diamond past prior to etching; the scratch lines on the carbon surface are accentuated during etching but no etch figures develop. Magnification 90X.

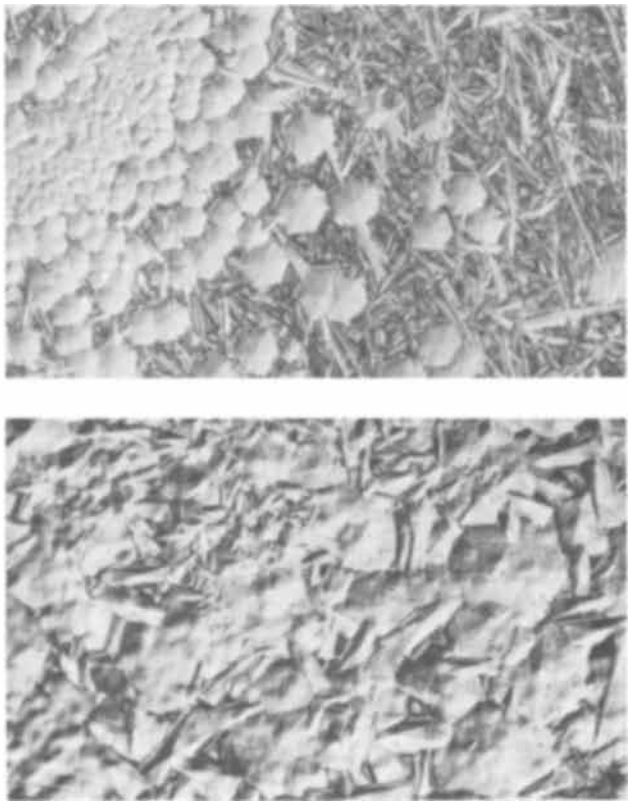

Fig. 2. Silicon surface of SiC exhibiting fully developed etch patterns (upper part). The lower part depicts a typically over-etched condition. Magnification 90X.

be sufficient for the identification of the two surfaces. The silicon surface develops a brownish tint (before any etch figures develop) whereas the carbon surface is not detectably attacked. [Twinned regions of (0001) orientation on the carbon $(000\bar{1})$ surface have typical (0001) appearance.] After about 25 min of boiling (in the open beaker) the solution becomes quite viscous and the silicon surface shows general attack. Representative cases of etched silicon carbide surfaces are shown in Fig. 1 and 2. It is seen that the final etch pattern is dependent on the etching time and concentration of the solution. The particular method of preparation of the surfaces prior to etching (polishing with a diamond abrasive, etching in molten KOH, or high-temperature etching in hydrogen) has no detectable effect on the etching process.

Since in the above described etching process (without gas treatment) the concentration of the etching solution constantly increases with time (boiling in an open beaker) a number of experiments were carried out to examine the effect of concentration. The concentration of the solution was maintained constant by employing a reflux system. Under these conditions it was found that in the solution saturated at room temperature (boiling point 104°C) no etching action is detectable within 35 min. In solutions saturated at 48°C (boiling point 113°C) and at 70°C (boiling point 115°C) etching action became detectable in about 25 and 5 min, respectively. No change in the general features of the etch patterns was observed in the various concentrations. Among a large number of oxidizing agents tested, $K_3Fe(CN)_6$ gave by far the best results in differentiating between the two types of surfaces. The only others which in boiling alkaline solutions exhibited some preferential attack of the silicon surfaces were $KMnO_4$ and $K_3Co(CN)_6$. While evidence of attack could be observed, no clear etch figures developed under these conditions.

It is apparent from the present results that the silicon and carbon surfaces of α-SiC retain to a large extent the characteristics of the surfaces of the corresponding elements silicon and carbon. Indeed, elemental silicon samples exhibited similar etching patterns in the above solutions whereas graphite was not attacked. The detailed mechanism of this process should be of special relevance to the over-all behavior of the surfaces of compounds with a crystallographic polarity.

Solutions of $K_3Fe(CN)_6$ have been used for some time as a cleaning solution for silicon carbide (1) but not for identifying the (0001) and the $(000\bar{1})$ surfaces. The methods usually employed for such identification involve etching at temperatures in excess of 300°C or electrolytic action (2). The present etching process has the distinct advantage of employing aqueous solutions (rather than molten salts) and relatively low temperatures (approximately 110°C) at which ordinary Pyrex glass containers are suitable.

A New Etchant for Thin Films of Tantalum and Tantalum Compounds

J. Grossman* and D. S. Herman

Westinghouse Electric Corporation, Aerospace Division, Solid State Technology Laboratory, Baltimore, Maryland

The etchants for thin films of tantalum and tantalum compounds, *i.e.*, tantalum nitride and tantalum pentoxide, usually contain hydrofluoric acid as one of the constituents. If the thin film of tantalum (or a tantalum compound) is deposited on a substrate which contains silica, *i.e.*, glass, glazed ceramic, or SiO_2 coated silicon, the etchant will also attack the substrate once it has penetrated through the film. This difficulty either requires great care in etching the film or the use of other methods such as depositing an underlayer of Ta_2O_5 or aluminum (1-3). The Ta_2O_5 does not etch as rapidly as TaN or Ta in HF and therefore acts as a protection for the substrate surface. Aluminum acts as a rejection mask, *i.e.*, it can be etched with an aluminum etch which will remove the tantalum overlayer from portions of the substrate where it is unwanted. These methods require additional processing steps with inherent reliability problems.

The use of TaN and Ta_2O_5 in hybrid and monolithic applications as resistor and capacitor elements where the substrate contains silica has presented us with the usual etching difficulty. This problem was extensively examined, and a new etchant found which attacks thin films of tantalum (or one of the tantalum compounds) at a rate equal to, if not faster, than the etches containing HF. It also attacks silica but at a much slower rate than the etches containing HF.

Because the new etchant is highly reactive, it also attacks negative photoresists. Therefore, gold is used as a mask to etch the tantalum (or tantalum compound) thin films. The desired pattern is delineated, using standard photoengraving techniques, in a gold film deposited over the tantalum (or tantalum compound) thin film. After the photoresist is removed the etchant is used to remove the tantalum (or tantalum compound) thin film from portions of the surface where it is not wanted. The gold can then be removed from the entire surface using any of the gold etches. However, the gold can also be selectively removed from the surface using photoengraving techniques. The gold left on the surface makes an ideal contact to resistors or an excellent capacitor electrode. Thus, the deposited gold can perform two functions.

The etchant is made up of a very highly concentrated solution of 30% sodium (or potassium) hydroxide and 30-35% hydrogen peroxide. The proportion is about 9 or 10 to 1 of NaOH to H_2O_2. A small Pyrex beaker (~50 ml) is filled half full of the NaOH solution. The solution is heated to 90°C and the H_2O_2 is added. The substrate is then etched in the mixture. Fresh reactants are used for each substrate; otherwise an insoluble residue remains on the substrate. Sodium or potassium peroxide can also be used for etching, but they leave an insoluble residue on the substrate similar to the one previously mentioned.

This mixture etches tantalum and tantalum nitride at the rate of 1000-2000Å/min and tantalum pentoxide at the same rate. No etching of the silica substrate has been noted after the etching of the tantalum (or tantalum compound) thin film has been completed.

The figures are for tantalum sputtered onto a thermally oxidized silicon wafer followed by a gold deposition. The tantalum is 1500Å thick. Figure 1 is a photograph of the tantalum film exposed through openings in the gold film. The width of the smallest set of gold lines is 1 mil. Figure 2 shows the tantalum etched away down to the oxide and the gold removed in this region. No attack of the oxide surface was noticed. Undercutting occurs, but the amount is very small.

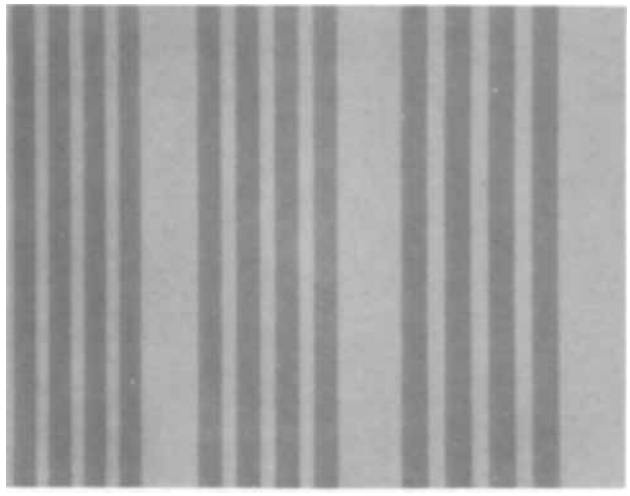

Fig. 1. Gold (3000Å) and tantalum (1500Å) deposited onto a thermally oxidized silicon wafer. The gold has been etched to expose the tantalum, dark on the photograph.

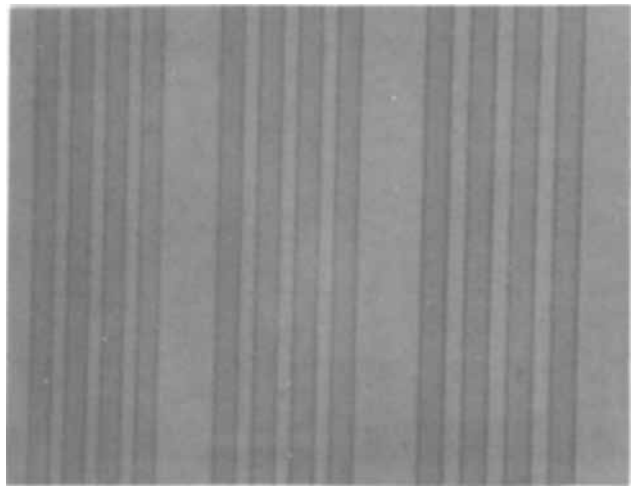

Fig. 2. Same wafer with the tantalum etched and the gold removed.

Manuscript received Jan. 16, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Calculation of Current Density Distribution and Terminal Voltage for Bipolar Electrolyzers; Application to Chlorate Cells

I. Rousar

Department of Inorganic Technology, Technical University, Prague, Czechoslovakia

ABSTRACT

Criterion equations are derived to enable the calculation of voltage and local current densities in one cell of a bipolar chlorate electrolyzer. For the cell system, expressions for current losses due to parasitic currents are derived for two models (with common bubble separator channel or with bubble separator channels for each cell). The calculation includes also the determination of the circulation rate of electrolyte in the cell system. Finally, the influence of specific parameters on the terminal voltage, parasitic currents, and circulation rate of electrolyte is discussed.

The importance of bipolar electrolyzers in chlorate production is indicated by new patent applications (1, 2) and especially by three installations put in operation recently (3-5). In the present paper, we carry out the chemical engineering calculations for this type of electrolyzer, *i.e.* for a bipolar, diaphragmless flow electrolyzer with the formation of a gas phase in the interelectrode space and with recirculating electrolyte. The present work is a continuation of a series of studies devoted to electrolyzers for chlorate production (6-8).

The Model System

The bipolar electrolyzer consists of a series of identical cells (Fig. 1 and 2). Each cell is in the form of a vertical channel of a rectangular cross section. Two channel walls that are opposite to each other are formed by the electrodes; the other two are made of an insulating material. The electrolyte is led into the cell at the bottom; a mixture of bubbles and electrolyte leaves the cell at the top and enters the bubble-separation channel or channels located along the side of the cells.

All bipolar plane electrodes of the height L and width w are made of a single material of thickness $S_A + S_K$ (from symmetry it follows that $S_A = S_K$). The mutual distance of the electrodes is d. Insulating walls of height L_1 and thickness $S_A + S_K$ lengthen the interelectrode channel to the total height L_T ($= L + 2L_1$). The system of n-interelectrode channels in one row is located in the electrolyzer tank in the distance L_2 from the bottom and from the cover of the tank.

Between two rows of interelectrode channels, there is a common bubble separator channel of width w_1 (model Q). The bubble separator space can be divided using n insulating walls of thickness d_2 into n small bubble separator channels (model W).[1] The connecting inlet electrolyte channels (of length L_{SB} and cross section F_{SB}) are placed on the side of the tank. Outlet connecting channels of length L_{ST} and cross section F_{ST} lie on the cover of the electrolyzer.

Similar arrangements for one-row systems can be seen in Fig. 3 and 4.

The cell is situated in a rectangular system of coordinates x, y, and z with the origin located at the bottom of the cell. Q(O, O, O); Fig. 1 and 2.

Supposing that all cells in the system are identical, we derive first the equations for the j-th cell. Unknown quantities included in these equations are the current load I_j(amp) in the j-th cell and the inlet volume flow rate of the electrolyte V_E (cm³/sec). Both quantities depend on the arrangement of the whole system and will be determined later. The calculation of the temperature of the electrolyte is given in the Appendix.

[1] Equations that refer only to the model Q or only to W are denoted with numbers combined with Q or W, respectively. Other equations are denoted with numbers.

Mathematical Description of the j-th Cell

We suppose that the cell is isothermal with the temperature t_{EB} and that processes on both electrodes are controlled by the rate of the electrode reaction. If the electrodes are large, the distance between them is small, and b_A and b_K in the Tafel equations are large, we can assume that the lines of force in the electrolyte and in the electrodes are perpendicular to the electrode surface. Then the current density in a given height y is the same at both electrodes. The voltage distribution in the j-th cell is given by

$$U = \epsilon_A - \epsilon_K + U_A + U_K + U_M \qquad [1]$$

where U means terminal voltage, U_M ohmic voltage drop in the electrolyte in the x-direction, U_A and U_K ohmic voltage drops in the bipolar electrode (anode

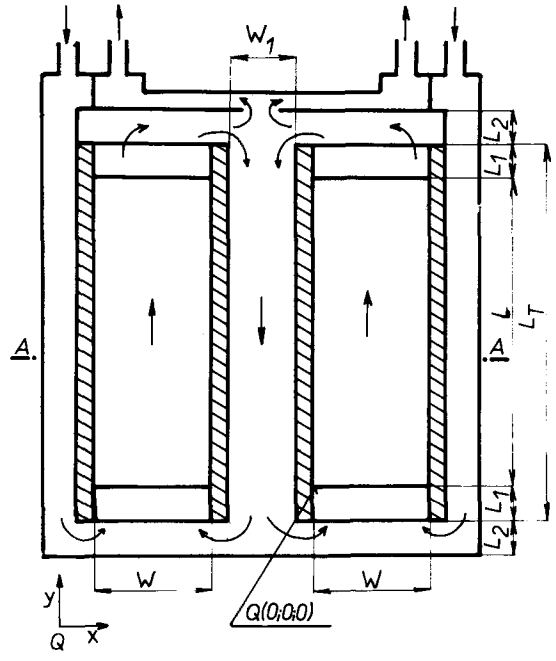

Fig. 1. Model electrolyzer (side view), two-row system: w—width of the bipolar electrode, L—height of the bipolar electrode, L_1—height of the insulating walls, L_2—height of the channel connecting interelectrode channel with bubble separator channel, W_1—width of the bubble separator channel, Q(O, O, O)—origin of the coordinates x, y, z. Arrows indicate the direction of the electrolyte flow.

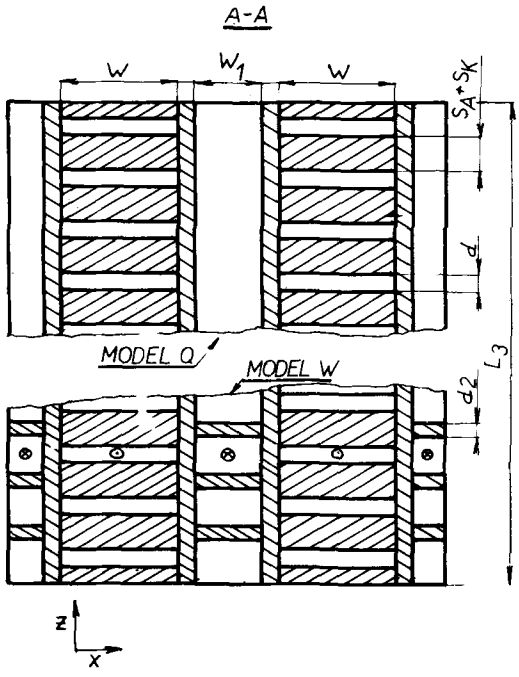

Fig. 2. Model electrolyzer (top view), two-row system: d—distance between electrodes, S_A, S_K—thicknesses of the anode and cathode plates, w—width of the bipolar electrode, w_1—width of the bubble separator channel.

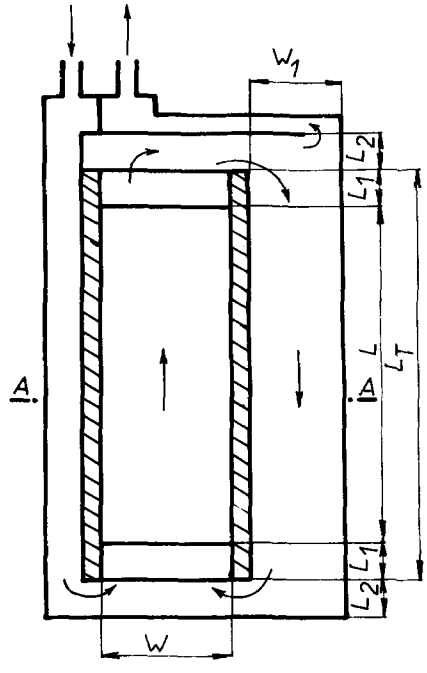

Fig. 3. Model electrolyzer (side view), one-row system. The description is given in Fig. 1.

and cathode, respectively), ϵ_A and ϵ_K local electrode potentials at the anode and cathode, respectively. All parameters except U depend on the distance from the origin of coordinates Q(O, O, O), hence they are functions of y.

The dependence of the local electrode potentials ϵ_A and ϵ_K on the local current density i is given by equations:

$$\epsilon_A = a_A + b_A \ln i, \qquad -\epsilon_K = a_K + b_K \ln |i| \qquad [2a,b]$$

In order to solve Eq. [1] analytically, Eq. [2a,b] must be linearized. For small deviations of i from mean current density in the j-th cell ($\bar{i}\,\eta_{Sj}$),

$$\epsilon_A = a_A' + b_A' i, \qquad -\epsilon_K = a_K' + b_K' i \qquad [3a,b]$$

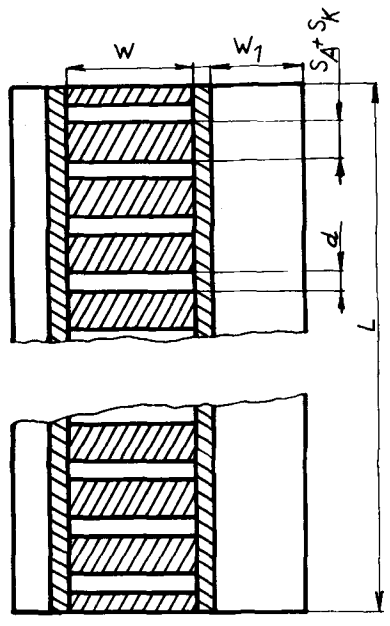

Fig. 4. Model electrolyzer (top view), one-row system. The description is given in Fig. 2.

where

$$a' = a_A - b_A + b_A \ln (\bar{i}\,\eta_{Sj}),$$

$$a_K' = a_K - b_K + b_K \ln (\bar{i}\,\eta_{Sj})$$

$$b_A' = b_A/\bar{i}\,\eta_{Sj}, \qquad b_K' = b_K/\bar{i}\,\eta_{Sj}$$

mean current density $\bar{i}$ is given by $\bar{i} = I_o/wL$, where $I_o = I_T/n_R$ is the input current load for one row, and the current efficiency (dependent on the flow of parasitic current) is defined as

$$\eta_{Sj} = I_j/I_o \qquad [4]$$

The ohmic voltage drops in the anode and cathode are given by Ohm's law,

$$U_A = i\,S_A\,\rho_A, \qquad U_K = i\,S_K\,\rho_K \qquad [5a,b]$$

The voltage drop in the electrolyte is given by the equation

$$U_M = i\,d\,\rho_M$$

in which ρ_M is the specific resistance of the electrolyte containing bubbles. This quantity can be simply calculated from the modified Maxwell (6) equation

$$\rho_M = \rho_E(1 + 1.5F_G/F_E) \qquad [7]$$

where F_G and F_E are hypothetical cross sections of the interelectrode channel corresponding respectively to gas and electrolyte, and

$$F_E = wd(1-\alpha), \qquad F_G = wd\alpha \qquad [8a,b]$$

where α means the fraction of bubble volume (void fraction).

For laminar two-phase flow in vertical channels (9, 10), the relation between the linear velocities of gas (v_G), electrolyte (v_E), and velocity of small bubbles (in the presence of surface active compounds) due to buoyancy (v_R) is

$$v_G = v_E + v_R(1-\alpha)^{3.5} \qquad [9]$$

Equation [9] can be simplified for small void fractions ($\alpha \to 0$) (6-8) to $v_G = v_E + v_R$, or for large bubble volume fractions ($\alpha \to 1$) (11) to $v_G = v_E$.

Using volume rates of gas flow or electrolyte flow and Eq. [8a,b], we obtain

$$v_G = (V_G + V_{GBS})/wd\alpha, \quad v_E = V_E/(1-\alpha)wd \qquad [10a,b]$$

The volume rate of recirculating gas (V_{GBS}) must be determined experimentally. The volume rate of gas

flow V_G in a given height y in the cell can be calculated from Faraday's law and from the equation of state of an ideal gas as

$$V_G = V_{GT} P_r \int_0^{y_r} i_r \, dy_r \quad [11]$$

where

$$V_{GT} = (RT/(P_o - P_S))\,(I_o \eta_{Sj}/\mathbf{F})\,(\eta_A/n_A + \eta_K/n_K) \quad [12]$$

$$P_r = (P_o - P_S)/(P - P_S) \quad [13]$$

$$i_r = i/\bar{i}\,\eta_{Sj} \quad [14]$$

$$y_r = y/L \quad [15]$$

In Eq. [12], the current efficiencies η_A and η_K refer to the evolution of a gaseous phase in the anodic and cathodic processes, respectively. P_o denotes the pressure on the top of the electrolyzer, P the pressure in a given height, and P_S water vapor pressure in the given system.

Substituting linear velocities from [10a,b] into [9] and rearranging, we obtain for α at a height y

$$\alpha = (V_G + V_{GBS})/(V_G + V_{GBS} + V_E + w d v_R (1-\alpha)^{4.5}) \quad [16]$$

and for the ratio F_G/F_E

$$F_G/F_E = \alpha/(1-\alpha) = K_3 P_r F_3 \int_0^{y_r} i_r \, dy_r + K_3' F_3 \quad [17]$$

where (setting α_T for α at $y = L$)

$$K_3 = V_{GT}/(V_E + w d v_R (1-\alpha_T)^{4.5}) \quad [18a]$$

$$K_3' = V_{GBS}/(V_E + w d v_R (1-\alpha_T)^{4.5}) \quad [18b]$$

$$F_3 = (V_E + w d v_R (1-\alpha_T)^{4.5})/(V_E + w d v_R (1-\alpha)^{4.5})$$

The functions P_r and F_3 are generally dependent on y but we can assume that $P_r \approx F_3 \approx 1$.

Assuming that the mean bubble diameter D_G is known and that $s_E >> s_G$, the v_R value can be calculated as

$$v_R = g D_G^2/18\nu \text{ for } Re_G \leq 1.9$$

or

$$v_R = (4/3)^{5/7} (g D_G/18.5)^{5/7} (D_G/\nu)^{3/7}$$

for

$$Re_G = D_G v_R/\nu \; \epsilon < 1.9; 505>$$

Substituting the expressions [3a,b], [5a,b], [6], [7], and [17] into [1], we obtain the equation describing the potential distribution in the electrode-electrolyte system in the following integral form:

$$U = a_A' + a_K' + i(b_A' + b_K' + \rho_A S_A + \rho_K S_K + d\rho_E(1 + 1.5K_3')) + id\rho_E 1.5K_3 \int_0^{y_r} i_r dy_r \quad [19]$$

Since the U value is unknown, we need a boundary condition, which may be written as

$$\int_0^1 i_r \, dy_r = 1 \quad [20]$$

Using following definitions for criteria $K_1 - K_4$

$$K_1 = (U - a_A' + a_K')/\bar{i} d \rho_E \eta_{Sj} \quad [21]$$

$$K_2 = (b_A' + b_K')/d\rho_E \quad [22a]$$

$$K_4 = (\rho_A S_A + \rho_K S_K)/d\rho_E \quad [22b]$$

we obtain from Eq. [19]

$$K_1 = i_r(1 + K_2 + 1.5K_3' + K_4) + 1.5K_3 i_r \int_0^{y_r} i_r dy_r \quad [23]$$

Solving Eq. [23] together with [20] leads to the expressions for K_1 and i_r

$$K_1 = 1 + K_2 + 1.5K_3' + K_4 + 0.75K_3 \quad [24]$$

$$i_r = (K_5 + 0.5)/(K_5^2 + 2K_5 y_r + y_r)^{1/2} \quad [25]$$

Table I. Influence of K_3 on K_1 for Model Q

$K_2 = 0.8266$-0.8360; $K_4 = 0.000447$; $\bar{i} = 0.09$ amp/cm²

K_3	K_1	w_1 (cm*)	V_E (cm³/sec)	U_S (v)
0.1003	1.9118	20	1107	3.092
0.1079	1.9158	10	1028	3.093
0.1377	1.9360	5	796	3.097
0.2438	2.0122	2	439	3.111
0.3620	2.0986	1	293	3.125

* The change of K_3 is due to the change of w_1.

where

$$K_5 = (1 + K_2 + 1.5K_3' + K_4)/1.5K_3 \quad [26]$$

Calculated K_1 values for several K_3 values are summarized in Table I. K_3 depends on V_E; the influence of K_3 on the distribution of the relative current density i_r is shown in Fig. 7. An increase of K_3 results in an increase of the difference between local (i) and average current densities ($\bar{i}\,\eta_{Sj}$).

The terminal voltage U of the j-th cell is then found by substituting [24] into [21] and rearranging as

$$U = A + B\,\eta_{Sj} \quad [27]$$

where $A = a_A' + a_K'$, $B = (1 + K_2 + 1.5K_3' + K_4 + 0.75K_3)\bar{i} d\,\rho_E$. The values of A and B are slightly influenced by changes of η_{Sj}. Nevertheless, we suppose

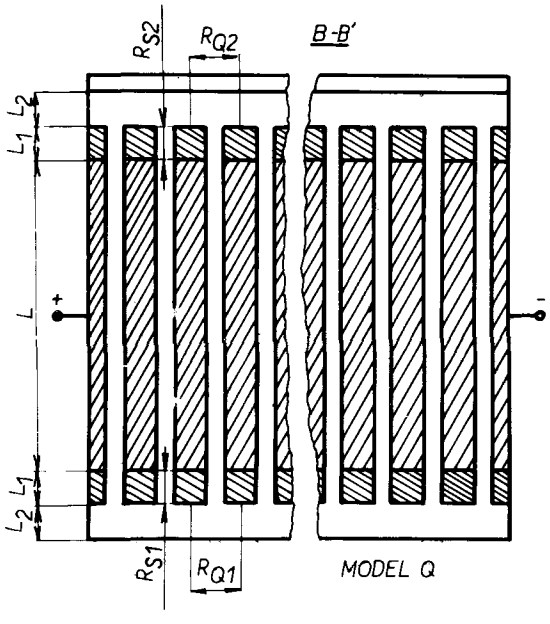

Fig. 5. Model electrolyzer, side view: R_{S1}, R_{S2}—resistances of the electrolyte in the interelectrode channel with insulating walls of the height L_1. R_{Q1}, R_{Q2}—resistances of the electrolyte including bubbles in the connecting channels between two cells of the height L_2.

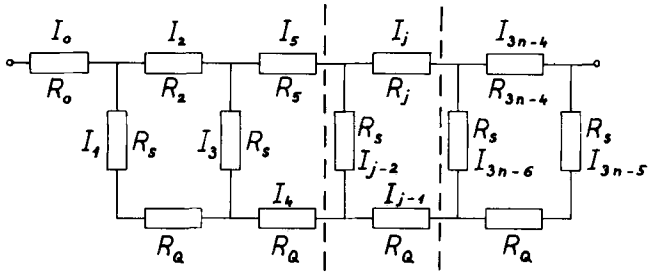

Fig. 6. The electrical basic circuit equivalent to Fig. 5: R_o, R_2, R_5, R_j, R_{3n-4}—bipolar cell resistances, R_S—resistance in the interelectrode channel with insulating walls, R_Q—resistance in the connecting channels between two cells.

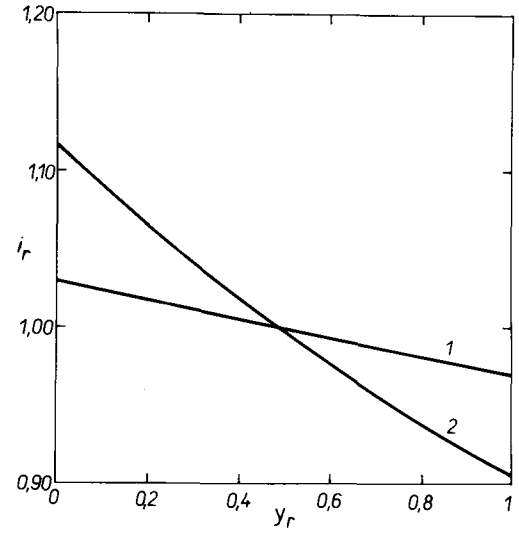

Fig. 7. Dependence of local relative current density i_r on the dimensionless distance y_r from the bottom of the cell for Model Q. K_2 = 0.8266-0.8360; K_4 = 0.000447; Curve 1—K_3 = 0.1003, Curve 2—K_3 = 0.3620.

that for $\eta_{Sj} \to 1$ it is possible to calculate A and B for the mean value of η_{Sj}, which is defined by

$$\eta_S = (1/n) \sum_{j=1}^{j=n} \eta_{Sj} \qquad [28]$$

Calculation of the Parasitic Current

The parasitic current flows through the electrolyte between inlet and outlet channels, which form electrical shunts to the cells.

According to Wilson (12), we can describe such a system by a network of three types of resistances R_j, R_S, and R_Q. R_j denotes the resistance of the j-th cell (more properly, it is the resistance of the j-th bipolar electrode with one half of the electrolyte resistance in the interelectrode channel at each side). The cell resistance R_j is equal to the cell voltage U, Eq. [27], divided by the current I_j. From this point of view, the first and last electrode form a cell loaded by the total current (I_o). R_S is the resistance of the electrolyte in the inlet (R_{S1}) and outlet (R_{S2}) parts of the cell channel(s). R_Q denotes the resistance of the electrolyte in the channel connecting two neighboring cells (on the bottom R_{Q1}, on the top R_{Q2}). We suppose that all resistances of the type R_S are equal and that the same applies for R_Q. This simplification leads to the expressions

$$R_S = ((1/R_{S1}) + (1/R_{S2}))^{-1},$$

$$R_Q = ((1/R_{Q1}) + (1/R_{Q2}))^{-1}.$$

Equations for R_{S1}, R_{S2}, R_{Q1}, and R_{Q2} depend on the model used. Equations leading to the lowest η_S value are as follows.

Model Q:

$$R_{S1} = \rho_E(1 + 1.5K_3 + 1.5K_3')\,(L_1/wd) \qquad [Q\text{-}29a]$$

$$R_{S2} = \rho_E(1 + 1.5K_3')\,(L_1/wd) \qquad [Q\text{-}29b]$$

$$R_{Q1} = \rho_E(1 + 1.5K_3 + 1.5K_3')\,(S_A + S_K + d)/(L_2(w + w_1) + (L + 2L_1)w_1/2n_R) \qquad [Q\text{-}30a]$$

$$R_{Q2} = \rho_E(1 + 1.5K_3')\,(S_A + S_K + d)/(L_2(w + w_1) + (L + 2L_1)w_1/2n_R) \qquad [Q\text{-}30b]$$

Model W:

$$R_{S1} = \rho_E(1 + 1.5K_3 + 1.5K_3')\,((L_1/wd) + 0.5(w + w_1)/L_2d) + \rho_E(1 + 1.5(V_{GT}/V_p))\,(L_{ST}/F_{ST}) \qquad [W\text{-}29a]$$

$$R_{S2} = \rho_E(1 + 1.5K_3')\,((L_1/wd) + 0.5(w + w_1)/L_2d) + \rho_E(L_{SB}/F_{SB}) \qquad [W\text{-}29b]$$

$$R_{Q1} = \rho_E(1 + 1.5(V_{GT}/V_p))\,(S_A + S_K + D)/F_{QT} \qquad [W\text{-}30a]$$

$$R_{Q2} = \rho_E(S_A + S_K + d)/F_{QB} \qquad [W\text{-}30b]$$

Using Kirchhoff's law for the electrical basic circuit (Fig. 6) equivalent to the described system of cells (Fig. 5), we obtain $3n - 4$ linear equations (for n-cells), which can be simplified by introducing the dimensionless parameters $I_{Rj} = I_j/I_o$, $\alpha_R = A/I_oR_S$, $\beta_R = B/I_oR_S$, and $\gamma_R = R_Q/R_S$.

Table II contains coefficients for the dimensionless current and for the right-hand side of the mentioned $3n - 4$ linear equations. It is obvious from Table II that the transition from n-cell system to $n + 1$ cell system is connected with expansion of the matrix by three rows (j, $j + 1$, $j + 2$).

The Thomas method (13) for calculating this tridiagonal matrix leads to the desired values for η_{Sj} and consequently to η_S.

$$\eta_S = (1/n)\left(1 + \sum_{j=1}^{n-1} I_{R(3j-1)}\right)$$

The total voltage U_T for the n-cell system is then given by

$$U_T = n(A + B\,\eta_S) \qquad [30]$$

and the total consumption of energy W for the desired reaction

$$W = n\,\eta_I I_o(A\,\eta_S + B\,\eta_p) \qquad [31]$$

where

$$\eta_p = (1/n)\left(1 + \sum_{j=1}^{n-1} I_{R(3j-1)}{}^2\right)$$

The mean cell voltage U_S is defined by $U_S = U_T/n$. Energy efficiency $\eta_w = W/U_TI_o$ is given by

$$\eta_w = \eta_I(A\,\eta_S + B\,\eta_p)/(A + B\,\eta_S) \qquad [32]$$

and the specific consumption of energy E_{sc} in kilowatt-hours per ton of product can be calculated as

$$E_{sc} + (A + B\,\eta_S)/3.6p\,\eta_I\,\eta_S \qquad [33]$$

where p is gram-equivalents of the product (p = 17.741 g-equiv. for $NaClO_3$).

Calculation of the Volume Flow Rate of the Electrolyte

The value of the volume flow rate of the electrolyte V_E is involved in calculating K_3 and η_I. The latter quantity depends considerably on the volume flow rate (1, 14) and its dependence on V_E (or on the Reynolds criterion) must be found experimentally.

The calculation of V_E is based on the pressure balance for the j-th cell with bubble separation channel or channels situated along the side of the cell row(s). The driving force of the flow is buoyancy acting on the bubbles in the interelectrode space; pressure losses are due to friction in the interelectrode space (Δp_M), in the inlet and outlet channel of the cell (Δp_C), and in the bubble separator channel (Δp_{BS}). Neglecting the acceleration of the electrolyte with rising bubbles and assuming a linear dependence of α on y, we have

$$gL_T s_E(1-\alpha_{BS}) - gL_T s_E(1-0.5(\alpha_T+\alpha_0) = \Delta p_M + \Delta p_{BS} + \Delta p_C \quad [34]$$

The left-hand side of Eq. [34] represents the difference between the pressure at the bottom in the bubble separator channel and in the interelectrode channel; on the other side are friction losses in the recirculation circuit.

The relation between V_E and α_T is given by Eq. [16]. In the bubble separator channel, the buoyancy acts on the bubbles in the direction opposite to the electrolyte flow; hence

$$v_{GBS} = v_{EBS} - v_R(1-\alpha_{BS})^{3.5} \quad [35]$$

where α_{BS} is known from experiments. Substituting the two following equations for v_{GBS} and v_{EBS}

$$v_{GBS} = V_{GBS}/F_{BS}\,\alpha_{BS} \quad [36a]$$

$$v_{EBS} = V_{EBS}/F_{BS}(1-\alpha_{BS}) \quad [36b]$$

where

$$F_{BS} = w_1 L_3/n\,n_R \quad [Q\text{-}37]$$

$$F_{BS} = w_1(S_A+S_K+d-d_2)/n_R \quad [W\text{-}37]$$

into [35] we obtain for V_{GBS}:

$$V_{GBS} = \alpha_{BS}V_{EBS}/(1-\alpha_{BS}) - \alpha_{BS}F_{BS}v_R(1-\alpha_{BS})^{3.5} \quad [38]$$

Using V_{GBS}, we can evaluate the inlet gas volume fraction at the bottom of the interelectrode channel α_0:

$$\alpha_0 = V_{GBS}/(V_{GBS}+V_E+wdv_R(1-\alpha_0)^{4.5}) \quad [39]$$

Equations [16], [39], and

$$V_E = V_{EBS} + V_p \quad [40]$$

express the dependence of α_0 and α_T on V_E or V_{EBS}.

Pressure loss due to friction in the interelectrode channel is given by

$$\Delta p_M = \lambda_M(L_T/D_M)(s_E/2)(V_E/wd)^2/(1-0.5(\alpha_T+\alpha_0)) \quad [41]$$

where λ_M and D_M depend on the shape of the channel cross section; for $w >> d$, we use the relations

$$\lambda_M = 96/Re_M \text{ for } Re_M < 2300$$

or

$$\lambda_M = 0.316/Re_M^{0.25} \text{ for } Re_M > 2300$$

According to Zuber (10), in the calculation of the Reynolds number the dynamic viscosity μ for the two-phase flow has to be replaced by $\mu(1-0.5(\alpha_T+\alpha_0))^{2.5}$, so that

$$Re_M = (V_E D_M/wd\nu)(1-0.5(\alpha_T+\alpha_0))^{2.5}$$

for

$$s_G << s_E$$

where

$$D_M = 2wd/(w+d)$$

Pressure loss in the bubble separator channel is given by

$$\Delta p_{BS} = \lambda_{BS}(L_T/D_{BS})(s_E/2)(V_{EBS}/F_{BS})^2/(1-\alpha_{BS}) \quad [42]$$

λ_M, λ_{BS}, and D_{BS} for

$$L_3 = n(S_A+S_K+d) >> w_1 \text{ (model Q)}$$

or for

$$w_1 >> S_A+S_K+d-d_2 \text{ (model W)}$$

are defined as

$$\lambda_{BS} = 96/Re_{BS} \text{ for } Re_{BS} < 2300$$

and

$$\lambda_M = 0.316/Re_{BS}^{0.25} \text{ for } Re_{BS} > 2300$$

with

$$Re_{BS} = (V_{EBS}\,D_{BS}/F_{BS}\,\nu)(1-\alpha_0)^{2.5}$$

and

$$D_{BS} = 2w_1(S_A+S_K+d-d_2)/(w_1+S_A+S_K+d-d_2) \quad [W\text{-}43]$$

$$D_{BS} = 2w_1L_3/(w_1+L_3) \quad [Q\text{-}43]$$

Pressure losses due to the change of the electrolyte velocity and of its direction in the connecting parts between interelectrode channel and bubble separator channel can be derived from the velocities in the cross section L_3L_2 (model Q) or L_2d (model W). Friction coefficients at the top and at the bottom are denoted as ξ_1 and ξ_2, respectively. Thus, we get

$$\Delta p_C = \xi_1(s_E/2)(V_E/F_C)^2/(1-\alpha_T) + \xi_2(s_E/2)(V_{EBS}/F_C)^2/(1-\alpha_{BS}) \quad [44]$$

where

$$F_C = L_2L_3/n \quad [Q\text{-}45]$$

$$F_C = L_2d \quad [W\text{-}45]$$

Setting [41], [42], [44] together with [16], [39], and [40] into [34], we obtain an implicit formula for evaluating V_{EBS} or V_E.

Discussion of the Influence of Several Parameters on V_E, η_S, U_S, and E_{sc}

The influence of the change of F_{BS} (or w_1) on V_E is given in Table I for model Q. V_E decreases with decreasing w_1 (F_{BS}); this is due to the increase of pressure loss in the bubble separator channel.

The values of V_E, K_3, and U_S depending on the thickness of the insulating wall in the bubble separator channel (d_2) are summarized in Table III for model W. V_E decreases with decreasing F_{BS} (increasing d_2).

The influence of the height of the insulating channel walls L_1 on η_S and η_w for various numbers of cells n for model Q can be seen from Table IV whence the great influence of the increasing number of cells on η_S and E_{sc} is comparable with the influence of L_1. The dependence of η_{Sj} on the cell number j is visualized in Fig. 9. As shown in Fig. 8, η_{Sj} becomes larger with increasing L_1.

Table III. Influence of d_2 on V_E and U_S for Model W

$\bar{i}$ = 0.09 amp/cm²

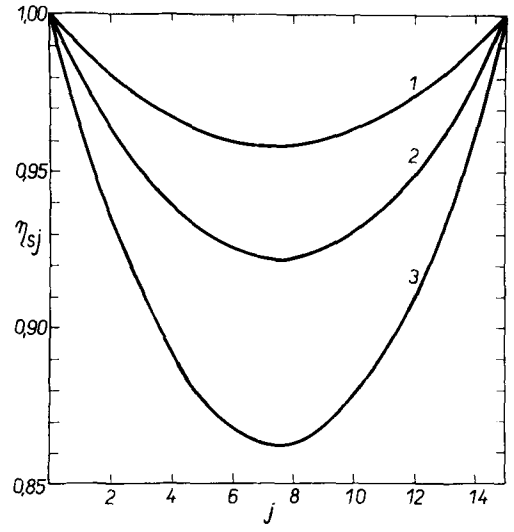

Fig. 8. Dependence of η_{Sj} on the cell number j for Model Q. Curve 1—L_1 = 40 cm; Curve 2—L_1 = 20 cm; Curve 3—L_1 = 10 cm.

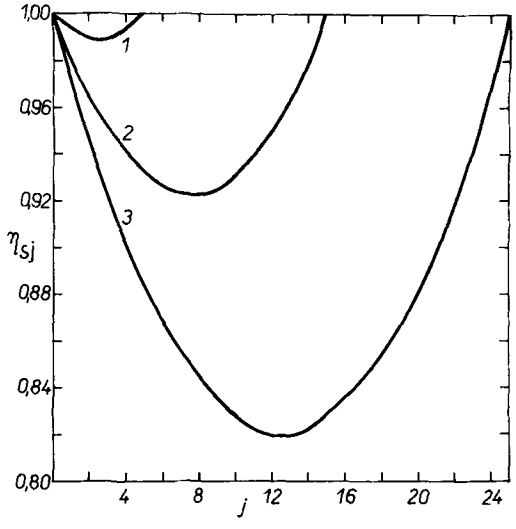

Fig. 9. Dependence of η_{Sj} on the cell number j for Model Q. Curve 1—n = 5; Curve 2—n = 15; Curve 3—n = 25.

The models Q and W can be compared in terms of η_S and E_{sc} values (η_I = 1) using the data in Table V. These parameters are nearly the same for both models with a small number of cells in one row.

With increasing n (25-45), the decrease of η_S for model Q is much greater than for model W. Therefore, the latter shows only a small increase of E_{sc} with rising n.

From the practical point of view, it is necessary to know the time dependence of U_S and E_{sc}, which is due to corrosion of graphite anodes. Supposing that the corrosion rate is constant, we can introduce the parameter

Table V. Influence of the number of cells (n) on η_S and E_{sc}
η_I = 1

η_I = 1	Model Q		Model W	
n	η_S	E_{sc} (kwhr/ton)	η_S	E_{sc} (kwhr/ton)
5	0.9942	4721	0.9999	4726
15	0.9512	4913	0.9995	4728
25	0.8844	5247	0.9986	4731
35	0.8144	5655	0.9975	4736
45	0.7529	6076	0.9960	4742

$C(\leq 1)$ which gives us the ratio of the final thickness of graphite anode to the initial one. The distance between the electrodes changes from d to $d_1 = d + (S_A + S_K)(1 - C)$ and the thickness of the graphite plate changes from $(S_A + S_K)$ to $(S_A + S_K)C$.

The dependence of η_S, U_S, and E_{sc} on C (hence on time) for both models is given in Table VI. For η_I = 0.9, the mean E_{sc} value for model Q is ~5809 kwhr/ton of $NaClO_3$, whereas for model W only ~5619 kwhr/ton of $NaClO_3$, in accord with the published (5) value 5400 kwhr/ton.

APPENDIX

Calculation of Electrolyte Temperature in the Electrolyzer

The previous considerations were made with the assumption that the temperature of the recirculating electrolyte t_{EB} in the electrolyzer was known. Nevertheless, this quantity can be evaluated from the inlet electrolyte temperature t_p using the following procedure.

The enthalpic balance will be made for the interelectrode channel. The heat evolved in this channel as a result of the electrochemical reaction is $T(\Delta S_{rev} + \Delta S_{irrev})$:

$$Q_1 = \left(U - \sum_K (\Delta H_K \eta_{IK}/\eta_{KK})/0.239\mathbf{F} \right) \cdot 0.239\, \bar{i}\, \eta_S w L \qquad \text{[A-1]}$$

where $\Delta H_K \cdot \eta_{IK}$ and η_{KK} refer to partial electrochemical reactions with the enthalpy change ΔH_K (cal/mole) and with current efficiency η_{IK}. The number of equivalents per mole for the k-th electrochemical reaction is η_{KK}.

A part of the heat is absorbed during saturation of the gas phase with water vapor:

$$Q_2 = (\bar{i}\, \eta_S w L/\mathbf{F})\ (P_S/(P_o - P_S))\ ((\eta_A/\eta_A) + (\eta_K/\eta_K))r \qquad \text{[A-2]}$$

where r is the heat of water evaporation (cal/mole) in the given system.

A part of the heat is evolved in the electrolyte by the passage of parasitic current:

$$Q_3 \approx \alpha_H\, 0.239\, U(1 - \eta_S)\, \bar{i}\, w L \qquad \text{[A-3]}$$

and another portion is led off through the side walls of the electrolyzer:

$$Q_4 \approx (t_p - t_F)(S_A + S_K + d)(L_T + 2L_2) \qquad \text{[A-4]}$$

Table VI. Influence of corrosion of the anode plate on η_S, U_S, and E_{sc}

Table VII. Influence of recirculation rate on t_{EB} and t_V at $V_p = 200$ cm³/sec, $t_p = 40°C$ for Model Q

w_1 (cm)	V_B (cm³/sec)	t_{EB} (°C)	t_V (°C)
20	1107	41.42	41.73
10	1028	41.39	41.73
5	796	41.29	41.73
2	439	40.94	41.74
1	293	40.55	41.75

The temperature of the outlet electrolyte rises to t_V:

$$Q_5 = -V_p S_E C_{PE}(t_V - t_p) \qquad [A\text{-}5]$$

The heat balance in the steady state takes the form

$$\Sigma Q_i = 0 \qquad [A\text{-}6]$$

On substituting [A-5] into [A-6] and rearranging, we get

$$t_V = t_p + (Q_1 + Q_2 + Q_3 + Q_4)/(V_p S_E C_{pE}) \qquad [A\text{-}7]$$

In calculating the electrolyte temperature at the inlet into the interelectrode channel, we assume that the temperature of the electrolyte passing through the separating channel is t_V. The enthalpic balance at the channel inlet with the assumption that the electrolyte density is independent of temperature is:

$$V_p t_p + V_{EBS} t_V = (V_1 + V_p) \cdot t_{EB} \qquad [A\text{-}8]$$

The electrolyte temperature at the inlet of the interelectrode channel is found by combination of Eq. [A-7] with [A-8]. Since $V_{EBS} >> V_p$ in practical cases, it follows that $t_{EB} \approx t_V$ and the system can be considered as isothermal.

Diminution of the cross section of the inner separating channel causes an increase of t_V and of the difference between t_{EB} and t_V (Table VII).

On introducing the temperature coefficients of certain quantities used in the calculation (*e.g.*, a_A, b_A, a_K, b_K, ρ_E), we can obtain the values at the temperature t_{EB} instead of t_p and use them in further calculations. The temperature coefficients δ_i are defined by equations of the type

$$f_i = f_{i,p}[1 + \delta_i(t_{EP} - t_p)] \qquad [A\text{-}9]$$

Experimental work is under way to test these calculations.

Studies on Chlorate Cell Process

IV. Effect of Neutral Salts on Conversion of Available Chlorine to Chlorate

M. M. Jaksić,* B. Z. Nikolić, I. M. Csonka,[1] and A. B. Djordjević

Electrochemistry Department, Institute of Chemistry, Technology and Metallurgy, Beograd, Yugoslavia

ABSTRACT

It has been shown that neutral salts, such as NaCl and $NaClO_3$ and their mixtures, cause an apparent increase in the thermodynamic dissociation constants of weak acids and bases. The pH value of aqueous salt solutions at fixed hydrogen ion concentration decreases linearly with increasing content of neutral salt and represents a linear function of the salt's heat of hydration (12). The hydrogen ion activity coefficient and, hence, the thermodynamic dissociation constants of weak acids and bases apparently follow a corresponding dependence. In solution for the electrolytic chlorate formation, the dissociation constant of hypochlorous acid is thus apparently enlarged by one order of magnitude. As a consequence, in solutions for the electrolytic chlorate production the optimal pH region for the conversion of available chlorine is shifted toward lower values (pH 5.7-6.1), as shown both in theory and practice. The same phenomenon is shown to be of some importance for what happens in the anode diffusion layer, where chlorine hydrolysis may hence be affected.

The conversion of hypochlorous acid and hypochlorite ion, in other words the total available chlorine, into chlorate was investigated by Foerster (1, 2), who pointed out that it follows the equation:

$$2\ HOCl + OCl^- + 2\ H_2O \xrightarrow{k_1} ClO_3^- + 2\ H_3O^+ + 2\ Cl^- \ldots \quad [1]$$

The conversion kinetics is defined by the following kinetic equation (1, 2, 3):

$$v_1 = -\frac{d\{[HOCl] + [OCl^-]\}}{dt} \cdot V = 3V \cdot \frac{d[ClO_3^-]}{dt} = 3f^2 \cdot k_1 \cdot [HOCl]^2\,[OCl^-] \cdot V \ldots \quad [2]$$

where f is the activity coefficient of hypochlorous acid; k_1, the rate constant for reaction [1]; and V, total volume of the electrolyte.

More recent investigations by Skrabal (4), Imagawa (5), D'Ans and Freund (7), and Jaksić *et al.* (8) in concentrated chloride and chlorate solutions, characteristic for the electrolytic production of the latter, confirmed the mechanism suggested by Foerster.

Lister (9) showed that the formation of chlorite is the slow step in the available chlorine conversion to chlorate, while further oxidation proceeds extremely fast, so that it is practically impossible to identify the presence of chlorite in the solution [*cf.* (7)].

On this account it is not unjustified, at least theoretically, especially for the slightly alkaline region, in which the conversion of available chlorine still proceeds at a sufficiently measurable rate, to assume the possibility of the presence of the following mechanism

$$HOCl + 2\ OCl^- + H_2O \xrightarrow{k_2} ClO_3^- + H_3O^+ + 2\ Cl^- \ldots \quad [3]$$

Namely, for the subsequent fast step of oxidation of chlorite ions to chlorate, it is quite the same, from the theoretical point of view at least, whether it is done by hypochlorous acid or hypochlorite ions. Therefore, two theoretically possible mechanisms have to be considered (Eq. [1] and [3]).

Flis (10, 11) pointed out that the oxidizing ability and character of the oxidizing action of available chlorine to a very large extent depends on the hydrogen ion activity, whereby, with the decrease of pH value of the solution, the oxidation potential becomes proportionately more positive. This can be ascribed to the fact that such changes favor the predominant presence of hypochlorous acid. Therefore, for a long time it has been a common belief that, owing to a considerably higher positive potential, hypochlorous acid oxidizes hypochlorite ion in the process of disproportionation of available chlorine to chlorate. From this point of view, there is no doubt that the mechanism suggested by Foerster (1, 2) is the more plausible one, particularly if one has in mind that, in the highly alkaline region and especially at lower temperatures, the conversion of available chlorine fully ceases.

In a closed-loop system for electrolytic chlorate production, in which the electrolyte is circulated between the cells and a holding volume at any point of the cycle at steady-state conditions, the amount of available chlorine (C_s)

$$C_s = [HOCl] + [OCl^-] \ldots \quad [4]$$

remains practically constant during the operation.

On the other hand, the thermodynamic dissociation constant (K_a) of hypochlorous acid

$$K_a = \frac{a_{H_3O^+} \cdot f_{OCl^-} \cdot [OCl^-]}{f \cdot [HOCl] \cdot a_{H_2O}} \ldots \quad [5]$$

can be expressed in a form more suitable for our consideration, *i.e.*

$$K^* = \frac{a_{H_3O^+} \cdot [OCl^-]}{[HOCl]} = K_a \cdot \frac{f \cdot a_{H_2O}}{f_{OCl^-}} \ldots \quad [6]$$

By substituting the values from Eq. [4] and [6] in Eq. [2], and also in the corresponding kinetic equation relating to Eq. [3], one obtains the rates for two possible mechanisms of available chlorine conversion as a function of hydrogen ion activity

$$v_1 = -\frac{dC_s}{dt} \cdot V = 3 \cdot f^2 \cdot k_1 \cdot V \cdot \frac{K^* \cdot (a_{H_3O^+})^2 \cdot C_s^3}{[K^* + (a_{H_3O^+})]^3} \ldots \quad [7]$$

or

$$v_2 = -\frac{dC_s}{dt} \cdot V = 3 \cdot \beta \cdot k_2 \cdot V \cdot \frac{(K^*)^2 \cdot (a_{H_3O^+}) \cdot C_s^3}{[K^* + (a_{H_3O^+})]^3} \ldots \quad [8]$$

where β represents a kinetic activity factor.

Finally, by differentiating the rates with respect to hydrogen ion activity, pH values are obtained which

* Electrochemical Society Active Member.

[1] Present address: "Jugovinil," Kastel Sućurac, Split, Yugoslavia.

provide maximal conversion for the two theoretically considered mechanisms [for the condition $(dv/d(a_{H_3O^+}) = 0)$]

$$pH_M = pK^* - \log 2 \ldots \quad [9]$$

or

$$pH_M = pK^* + \log 2 \ldots \quad [10]$$

Thus, by applying the thermodynamic value of dissociation constant ($\sim 5.10^{-8}$), one would expect the maximal conversion rate of available chlorine at pH 7.0 for the Foerster mechanism, and 7.6 for the other theoretically possible kinetic path (Eq. [3]).

In dilute solutions, Flis and Byniaeva (11) obtained the maximal conversion rate in the middle of the range defined by the optimal pH values (Eq. [9] and [10]) for the two possible mechanisms and thermodynamic value of dissociation constant, which would in a way be a confirmation of the assumption that the reaction simultaneously proceeds by both theoretically possible kinetic paths.

Critchfield and Johnson (12) showed that, at a fixed constant hydrogen ion concentration, the pH value of an aqueous salt solution is a linear function of ionic strength, *i.e.* of the concentration of neutral salts and of their heats of hydration; that is

$$pH = -\log [H_3O^+] - J)\,(0.18 + 6 \cdot 10^{-3} \cdot \Delta H_s) \ldots \quad [11]$$

where $J = n/2 \times M$, and M the molarity, n the number of ions composing the salt, and ΔH_s the heat of hydration. Thus, in a mixture of NaCl and $NaClO_3$ in concentrations characteristic for chlorate production, the pH value of the electrolyte should be decreased by more than one pH unit (*cf.* [13]), compared to that at zero ionic strength, or, in other words, *hydrogen ion activity coefficient should be larger by one order of magnitude.* Considering that activity coefficients of other components constituting the HOCl dissociation equilibrium (HOCl, OCl^-, and H_2O) are close to each other and close to unity (3, 5, 6, 14),[2] one could conclude that the apparent dissociation constant, K*, should be larger by one order of magnitude, at least, than the one found in dilute solutions. As a direct consequence, the maximal conversion rates of available chlorine into chlorate for the two possible mechanisms should be in the pH range between 6.0 and 6.5, rather than between 7.0 and 7.5, as suggested by some authors (3, 15, 16).

Imagawa (6) also recently found the same phenomenon of the pH decrease in the acid region of sodium chloride solutions containing available chlorine. Such a pH value decrease was explained by the effect of an analogous change of elemental chlorine activity coefficient with increasing neutral salt concentration (6). However, in the alkaline region and in the absence of chlorine, the same pH decrease has also been observed (12, 13). It is, hence, quite evident that such behavior is caused by the presence of neutral salt and depends mainly on its concentration.

Experimental

In a closed-loop system, recently described (8) and consisting of a cell with platinum gauze electrodes and a holding volume, both acting as back mix flow reactors, the effect of pH value of the electrolyte on the degree of conversion of available chlorine inside the latter was investigated. The cell was kept at 25°C so that, apart from the anodic oxidation, the available chlorine consumption was predominantly taking place in the holding volume by chemical conversion to chlorate. Namely, the cell was acting as a steady-state available chlorine generator, and subsequent conversion to chlorate inside a gas-tight holding volume was followed as a function of pH (*cf.* [8]).

The electrolyte was 300 g/liter NaCl and 2.0, 4.0, and 8.0 g/liter of sodium dichromate. Electrolysis was carried out to 30 g/liter of sodium chlorate, whereupon the electrolyte was renewed.

pH values in the holding volume were varied between 4.20 and 10.0, and currents of 2.0-8.0 amp, or current densities of 2.94-11.76 amp/dm^{-2}, were used.

Two quantities were measured simultaneously: the pH values and the total available chlorine of the inflowing and outflowing electrolyte of the holding volume.

The holding volume used was 2.2 liters, and the flow rate, provided by a suitable diaphragm pump, could be varied from 1 to 4 liters/hr, while the temperature was varied between 40° and 60°C.

Results and Discussion

Available chlorine conversion to chlorate inside the holding volume as back mix flow reactor, according to Foerster (1, 2) and Eq. [2] and [7], is given as follows

$$-\left(\frac{dC_{sh}}{dt}\right) \cdot V_h = 3 f^2 \cdot k_1 \cdot V_h \cdot [HOCl]_h^2 \cdot [OCl^-]_h = 3 \cdot f^2 \cdot k_1 \cdot V_h \frac{K_h^* (a_{H_3O^+})_h^2 \cdot C_{sh}^3}{[K_h^* + (a_{H_3O^+})_h]^3} \ldots \quad [12]$$

where all values have a previous meaning, but the subscript h refers here and throughout to the quantities relating to the holding volume.

At the same time, available chlorine conversion inside the holding volume (V_h) is given by the following relationship

$$-\left(\frac{dC_{sh}}{dt}\right) \cdot V_h = q\,(C_{sc} - C_{sh}) \ldots \quad [13]$$

where q is electrolyte flow rate (liters/sec), and C_{sc} and C_{sh} are the total available chlorine concentrations (moles/liter) of inflow and outflow of the holding volume, respectively.

In a previous paper (8), it was shown that current efficiency, t_1, in the case of negligible conversion of available chlorine inside the cell, may be expressed by the equation

$$t_1 = \frac{2}{3} + \frac{2}{3} \cdot \mathbf{F} \cdot \left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) \ldots \quad [14]$$

where **F** is the Faraday constant, and I the load in amperes. Hence, the second term in Eq. [14] defines the yield of the conversion inside the holding volume to the over-all current efficiency of the system.

The effect of hydrogen ion activity on the degree of available chlorine conversion under the actual conditions of industrial chlorate production is represented by the functional relationship of the pH value of the electrolyte inside the holding volume and the second term in Eq. [14], as illustrated in Fig. 1 for temperatures in the range between 40° and 60°C.

It can be clearly seen that the maximum appears in the pH region which has previously been theoretically predicted and expected. Namely, from Eq. [12], [13], and [14], one finds that maximal yields to the over-all current efficiency due to an available chlorine conversion inside a holding volume result at the same optimal pH value [for the condition $dt/d(a_{H_3O^+}) = 0$], which provides maximal reaction rates (Eq. [9]).

[2] According to Imagawa (6), activity coefficient of hypochlorite ion (f_{OCl^-}) in 5.43M NaCl solution is 1.064. Weiss (14) gives activity coefficients of hypochlorous acid for 4.986M NaCl : 1.304, and for 5.468M NaCl : 1.404. Finally, activity of water was recently calculated by Gazith (23): for 5.0M NaCl, $a_{H_2O} = 0.8068$; for 5.4M, $a_{H_2O} = 0.7883$; and for 6.0M NaCl, $a_{H_2O} = 0.7598$; cf. [3]. Therefore,

$$\frac{f \cdot a_{H_2O}}{f_{OCl^-}} \to 1$$

and, from Eq. [6], it follows

$$K^* = \frac{a_{H_3O^+} \cdot [OCl^-]}{[HOCl]} = K_a \cdot \frac{f \cdot a_{H_2O}}{f_{OCl^-}} \to K_a$$

or, apparent dissociation constant of hypochlorous acid, K*, is a linear function of activity coefficient of hydrogen ion, which increases with increasing concentration of neutral salt, NaCl and $NaClO_3$.

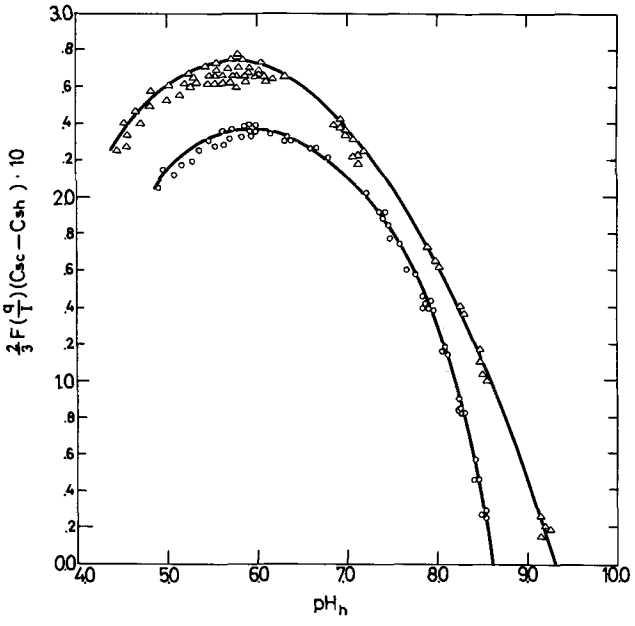

Fig. 1. Contributions of available chlorine conversion to chlorate inside a holding volume to the over-all current efficiency as a function of pH of the holding volume, pH_h: ○ and △ represent curves for temperatures in a holding volume of 40° and 60°C, respectively.

In addition, it has been shown experimentally that in the presence of 5*N* NaCl all the usual buffer solutions show a decrease in pH values for more than one pH unit as compared to the values characteristic for pure aqueous solutions. On this ground, one would also expect an apparent change in the dissociation constants of various acids as a function of ionic strength of neutral salts. Namely, if one has in mind that the maximal buffer capacity is obtained at pH = pK, and that this pH region is changed, it would be reasonable to expect that the dissociation constant itself follows the same dependence.

By titrating solutions of hydrochloric acid and sodium hydroxide of known concentrations, each containing 5*N* NaCl in order to keep the ionic strength unchanged during the titration at 25°C, the ratio $a_{H_3O^+}/[H_3O^+] = f_{H_3O^+}$ was determined for each point of titration and, by the least-squares method, the conversion factor was obtained, $f_{H_3O^+} = 10.0$.

Filippov (17) experimentally showed that losses of graphite anodes in the chlorate production are lowest at pH 6.0, which might be interpreted by the effect of maximal available chlorine conversion in this region, since it has previously been shown that these losses are proportional to the amount of available chlorine present inside the cell (18).

Filippov (19) also pointed out without entering into theoretical considerations, that, in a closed-loop flow system for chlorate production, the maximal efficiency is achieved when the pH value of the cell is 6.0-6.1. Since the whole system was operated at one and the same temperature, the total volume of the electrolyte could be considered integrally, and the results obtained be brought into agreement with the theory presented here and serve as its additional confirmation.

Wranglen (15) recently suggested that current efficiency of the chlorate cell is independent of the pH value of the electrolyte. However, in his experiments the current efficiency was evaluated from the gas analysis and in more alkaline solutions the evolved carbon dioxide was absorbed by the electrolyte. This we consider as a possible source of error that may have led to dubious conclusions (15).

The authors (24) pointed out earlier that the pH value inside the cell directly contributes to the current efficiency by affecting the equilibrium inside the anodic diffusion layer, thus determining the conditions for the hydrolysis of chlorine inside it. On the other hand, it has been shown here that the pH value constitutes a measure of the available chlorine conversion through the system. Therefore, the control of this value at main points of a closed-loop system for the electrolytic chlorate production is of particular importance. From this consideration and taking into account the figures obtained elsewhere (24), it can be concluded that the optimum conditions for chlorate production are provided in the pH value range of 5.7-6.1 and 6.5-6.8 at the point of outflowing the holding volume and the cell, respectively.

It could easily be shown using the usual engineering considerations (20) that a steady-state plug flow reactor under identical working conditions provides higher degrees of conversion than the back mix flow reactor of identical dimensions, so that the former constitutes a more favorable holding volume for industrial chlorate production. Nevertheless, depending on the working cell conditions, the herein previously defined optimal pH value should be maintained at the exit of the reactor, by successively adding hydrochloric acid or caustic soda through it.

The above-described effect of neutral salts also provides for the maximal buffer capacity of the system (HOCl) and (NaOCl) to be just in the pH region which provides maximal conversion of available chlorine. Wagner (21) earlier showed that only minimal and limited chromate reduction at the cathode makes it possible to suppress completely the cathode reduction of hypochlorite ions. Thus, it was here pointed out that it is possible to reduce the presence of dichromate in the electrolyte under the concentration of 1 gpl in order to achieve all the necessary effects (buffering effect and OCl^- cathodic reduction to be suppressed enough). This facilitates pure crystalline chlorate to be obtained in the absence of chromate.

The formerly derived general equation for current efficiency in electrolytic chlorate production (8) has been confirmed under the practical conditions of operation and found to hold only if the values of the apparent thermodynamic dissociation constant are applied, which is another confirmation of the theory (8).

Further Consequences

By analogy, one might expect an apparent change in the equilibrium constant for the hydrolysis of chlorine

$$Cl_2 + 2H_2O \rightleftharpoons HOCl + H_3O^+ + Cl^- \qquad [13]$$

in agreement with the increase in the hydrogen ion activity coefficient, caused by the presence of neutral salts under the conditions of electrolytic chlorate production. Namely, by applying the thermodynamic values which hold for dilute aqueous solutions, Ibl (22) came to the conclusion that, for current densities of practical importance, the hydrolysis of chlorine is not accomplished inside the diffusion layer, but extends into the bulk of solution.

However, by using the apparent values of the equilibrium constants for the hydrolysis of chlorine, corresponding to the actual conditions of the chlorate production and, in agreement with our consideration, by one order of magnitude higher than the known thermodynamic values, it may be shown that the hydrolysis of chlorine in the diffusion layer may be complete. This has actually been confirmed by the experimental and operating practice of chlorate production.

At the same time, one comes to the conclusion that neutral salts, by causing dehydration of the ionic shell of hydrogen ions in aqueous solutions, bring about, on the one hand, a considerable increase in the hydrogen ion activity coefficient and acidity at all, and, on the other, an adequate apparent increase of the value of the thermodynamic dissociation constant of weak acids and bases, as compared to the values pertaining to dilute solutions. The magnitude of this effect is a function of the concentration and heat of solution of the salt (12). Salts with the highest positive heat of

hydration produce the greatest change in pH, hydrogen ion activity coefficient, and apparently in thermodynamic dissociation constant. In this way, the values for thermodynamic dissociation constants, which are constant for any given ratio of components constituting the dissociation equilibrium itself, are no longer invariable with an increased variable composition of neutral salts, as foreign ionic species having a predominant and specific effect on hydrogen ion activity coefficient.

Our measurements and results (Fig. 1) could also be considered as further confirmation of Foerster's (1, 2) mechanism (Eq. [1] and [9]) between two possible ones, including, in equations for one order of magnitude, apparently increased values of the hypochlorous acid dissociation constants.

Acknowledgments

This work has been carried out at the Electrochemistry Department of the Institute of Chemistry, Technology and Metallurgy of Belgrade, and was supported by the Faculty of Chemical Technology of Split.

The authors gratefully acknowledge and are greatly indebted to Professor Dr. A. R. Despić of Belgrade for his personal interest in this work, useful advice, and contributions to the direct preparation of the present paper.

Statistical Studies of Rechargeable Battery Systems

J. P. Elder*, [1] and E. M. Jost**

Research and Development Department, Metallurgical Materials Division, Texas Instruments Incorporated, Attleboro, Massachusetts

ABSTRACT

The application of the 2^n factorial experiment to the study of the factors influencing the behavior of hermetically sealed, rechargeable Ni-Cd cells is discussed. The characteristic cell parameters may be expressed as logarithmic functions of the pertinent charge-discharge conditions. Data fitting is accomplished by means of a linear regression analysis. Both primary and factor interaction effects contribute to the behavior of the cells. The magnitudes of the effects are dependent on the cell operating conditions. The effects resulting from a cobalt addition to the positive electrode are primarily related to the kinetics of the charge and discharge reactions.

Numerous investigations, aimed at elucidating the effect of process and other experimental variables on the parameters characterizing the operation of a rechargeable battery system, have been performed. In many cases, a meaningful interpretation of the data is difficult, since one cannot separate the effects of the various factors controlling the over-all operational behavior. The term "factor" will be employed to describe any independent variable of the system under the control of the investigator, with the exception of those pertaining to the operating conditions, *i.e.* the charge-discharge routine.

Generally, factors may be of a qualitative or quantitative nature. For example, in a sealed Ni-Cd cell, the nature of the separator material is a qualitative factor, while the electrode thicknesses and the total volume of electrolyte are quantitative factors. In many cases, the composite effect of two or more factors is synergistic; the factors are said to interact. Considerable advantage is gained if the experimental design is such that the effect of changing any one factor can be stud-

ied independently of the others. Furthermore, it is of considerable importance to be able to assess the significance of both primary factor effects and factor interaction effects separately. Of the various planned statistical procedures available, the factorial experiment affords a promising method of achieving these objects. It must be noted that the magnitudes of the various factor effects will vary according to the charge-discharge conditions to which the cell is subjected. Thus, a factor, such as an electrode additive, may affect the charge acceptance capabilities of the electrode but show little or no effect on the charge delivery characteristics. By performing a series of cell behavior studies over a range of operating conditions, it should be possible to predict the conditions under which a factor or combination of factors will exert a dominant effect. The results of such studies should prove useful to the battery manufacturer in designing and fabricating cells to be operated under a specific charge-discharge routine.

Factorial Experiments

The reader is referred to Cochran and Cox (1), Davies (2), and Ostle (3) for detailed discussions of this statistical procedure. In this experiment, the effects of a number of factors, set at two or more levels, are examined. For example, in one experiment one may wish to examine two types of separator material, four positive electrode thicknesses, and three electrolyte concentrations. Such an experiment is referred to as a $2^1.3^1.4^1$ factorial. Twenty-four cells are required, each containing a different combination of the three factors at the different levels. Generally, the number of factor combinations required for a complete study is given by $\pi_i L_i^{n_i}$, where L_i is the number of levels of each of the n_i factors. The term "factorial" refers to the manner in which the various factor combinations are formed and not to any basic type of design (3). As can be seen, when one is considering setting up a laboratory-scale experiment with a number of factors at more than two levels, the number of combinations can very easily become prohibitive. It is possible to gain insight into the effect of the various factors by employing only a fraction of the maximum number of combinations. The reader is referred to Davies (2) for a discussion of fractional factorial experiments. The most simple factorial experiment is one in which n factors are examined at two levels only, *i.e.*, the 2^n factorial. The particular factor arrangement for this type of experiment will be elaborated on at a later stage. The procedure is as follows. Having chosen the type of factorial, the various factor-level combinations are incorporated into the requisite number of systems under study. A parameter, characteristic of the system, is measured for each member of the factorial set. An effect is then calculated for each member. Each effect is a measure of the deviation of the parameter value from the set average taking into account the specific factor-level combination contributing to the deviation. In the case of the 2^n factorial, one calculates the effect due to changing a factor from one level (low) to the second level (high) averaged over the two levels of the remaining factors. With a knowledge of the experimental error associated with each measurement for each member of the set, the significance of each calculated factor or factor combination effect is then estimated by means of the statistical F-test.

Factorial experiments have been widely and successfully employed in many fields. However, to the knowledge of the authors, applications of this procedure in electrochemical research, and in particular battery research, have been sparse. Resnic (4) employed a $2^4.4^1$ half factorial in a study of the effect of charge rate and charge level on the faradaic capacity of sealed Ni-Cd cells of various types at various ambient temperatures. Cupp (5) examined the effects of various factors, including positive electrode additives and electrolyte additives, in a $3^4.2^4$ factorial experiment pertaining to the performance of both sealed and vented Ni-Cd cells. The experimental design, referred to as the basic plan for factors was not described in any detail and, furthermore, a literature reference was not given. Panzer and Schaer (6) employed a fractional 2^5 factorial experiment in an optimization study relating to the performance of molten alkali thiocyanate cells. Very recently, Blickwedel (7) has reported on the results of a 2^4 and a 2^3 full factorial experiment performed on Ni-Fe and Ni-Zn cells, respectively. The factors included electrode geometry, electrolyte concentration, electrolyte additive, and separator material. The faradaic capacity was expressed as a linear function of the primary factors and first-order factor combinations. Data fitting was accomplished by means of a multilinear regression analysis. Each partial regression coefficient was used as an indicator of the effect of its associated factor or factor combinations on the capacity independent of the other factors. The computed t-values were used to rank the order of importance of the various factor combinations in affecting the capacity.

Although the limitations of the factorial experiment should not be minimized, the disadvantages are outweighed by the advantages, which may be summarized as follows:

1. Maximum efficiency in the statistical evaluation of a minimal quantity of data.
2. Information on factor interaction effects is obtained, necessary to preclude misleading conclusions.
3. Latent replications inherent in the factorial arrangement result in a comprehensive study over a range of experimental conditions.

There are three main requisites for a successful battery 2^n factorial experiment:

1. The parameter response should be a linear function of the factor level between the chosen limits.
2. The parameter response should be reproducible under identical experimental conditions.
3. The sample cells should have the capability of withstanding a variety of charge-discharge conditions.

It is difficult to realize the first condition. In the case of quantitative factors, one can assume that it is approximated by selecting close limits for the two levels. One of the most significant problems plaguing the battery industry has been the lack of reproducibility of electrodes and cells fabricated under identical conditions. In this laboratory, a great deal of effort has been devoted to determining the causes of these variances, and eliminating them. As indicated by Jost and Popat (8), with the present state of our art, these variances have been reduced to a point where a factorial experiment becomes meaningful. Such experiments have been carried out in this laboratory only after achieving this close uniformity and reproducibility. As indicated in the experimental section, the third condition has been met.

A number of factorial experiments, pertaining to the effect of various factors on the performance of sealed, sintered plate, Ni-Cd cells, have been carried out in this laboratory. This paper deals with the findings of one such study.

Ni-Cd Cell 2^4 Factorial Experiment

The effect of the presence of cobalt on the behavior of the positive electrode in the sealed Ni-Cd cell has been studied relatively extensively in comparison with other metallic ion species. While Yamashita (9) and Doran (10) indicate that this additive improves charge retention, Januszkiewicz (12) indicates little or no effect. Doran (11) reports that the effect of a cobalt addition is to raise the positive electrode potential during discharge and, with up to 20% addition, the efficiency is enhanced (12). During impregnation with hot, concentrated nickel nitrate solution, the sintered nickel plaque corrodes. The extent of corrosion is markedly affected by replacing from 0 to 15% of the nickel content of the impregnation liquor with cobalt (13). Furthermore, the extent of corrosion is dependent on the physical nature of the carbonyl nickel employed to

Table I. Physical characteristics of carbonyl nickel and sintered plaque

INCO designation	Avg particle diameter (μ)	Avg density (g/cc)	Plaque porosity (%)	Weight per cent plaque corroded 0% Co	5% Co
#287	2.9-3.6	0.88	90	18.7	26.5
#255	2.6-4.3	0.59	93.3	25.5	27.0

Table II. Ni-Cd cell, 2^4 factorial experiment

Designation	Factors Description	Levels Low (0)	High (1)
		INCO	INCO
A	Carbonyl nickel plaque material	#255	#287
B	Ratio $Cd/Cd(OH)_2$ at 100% charge level	1.73	6.9
C	Percentage pore filling with 30% KOH	64	82
D	Percentage cobalt in positive plate	0	4.4

fabricate the sintered plaque. As a result of these observations, it is pertinent to reconsider the role of cobalt. Two positive electrode factors were chosen for study: 1—cobalt additive, 2—sintered plaque physical characteristics. The relevant physical parameters of the two types of carbonyl nickel powder used are shown in Table I. As can be seen, sintered plaque fabricated with INCO #255 powder corrodes more than that made from the more coarse-grained #287 powder. However, 5% cobalt in the impregnation liquor only increases the extent of corrosion of the #255 plaque by 6%, whereas a 40% increase is effected in the case of the #287 plaque.

The electrolyte distribution is an important factor in governing the cell behavior. It will be influenced both by the structure of the positive plate and the total amount of electrolyte. Turner (14) has shown that the rate of oxygen recombination in sealed Ni-Cd cells is directly proportional to the state-of-charge of the negative electrode. However, the rate will also be governed by the oxygen diffusion rate through the separator, which will be highly dependent on the amount of electrolyte available for distribution within the separator. These two facts formed the basis for the choice of the remaining factors: 3—volume of 30% potassium hydroxide added to the cell, and 4—ratio of cadmium to cadmium hydroxide in the negative electrode at full charge. The two levels chosen for the four factors are summarized in Table II. A four-digit code, which must not be confused with a number written in binary notation, is employed to describe the cells comprising the factorial set. The digits 0 and 1 are assigned to the low and high levels, respectively, of each factor. The 16 factor combinations are shown in their specific order in the second column of Table III.

Experimental

Cell theoretical capacities.—Weight gain data cannot be used to calculate the theoretical capacity of an electrode, prepared by impregnation of a sintered nickel plaque with nickel or cadmium nitrate solution, since it does not correctly account for the Ni^{2+} produced as a result of plaque corrosion. Analytical procedures have been developed in this laboratory, whereby the total amount of Ni^{2+} may be determined in the presence of Co^{2+} and/or metallic nickel. Similar analytical techniques have been developed for the selective determination of metallic cadmium and Cd^{2+} in the presence of metallic nickel and Ni^{2+}. The theoretical capacity of the positive electrode is calculated on the basis of the total amount of $Ni(OH)_2$. Since there is no evidence that cobaltic ion, which is more stable than nickelic, takes part in the discharge reaction, the amount of $Co(OH)_2$ in the "cobalt additive" plates is not included in the capacity calculation. The theoretical capacities of both electrodes are given by $N\ A\ L\ X$, where N is the number of plates, each of geometric area, A in.^{2}; L is the plate loading, *i.e.* grams of $Ni(OH)_2$ or $Cd(OH)_2$ per in.^{2}; and X is the appropriate conversion factor, 0.292 AH/g $Ni(OH)_2$ and 0.367 AH/g $Cd(OH)_2$. The electrodes, following production, are charged at the 3-hr rate and discharged at the 2-hr rate in the flooded condition. The delivered capacities agree very closely with those calculated from the analytical data.

Experimental cells.—Prismatic cells, of nominal capacity, 1 *AH*, were used for this study. Replicate cells were not assembled. Nylon separators (Pellon) were used throughout. The electrolyte was carbonate-free 30% (6.9M) potassium hydroxide. All cells were filled under vacuum with the requisite volume of electrolyte. The 16 cells were positive limited, and remained so during the entire course of the experiment. No electrical shorts, electrolyte leakages, or excessive cell pressures developed during the various charge-discharge routines.

Data acquisition and test routines.—The factorial sets were located on individual series-connected test stations. All tests were performed under constant current conditions, using a 36v-5 amp regulated power supply (Hewlett-Packard, Harrison model 6266A). Each station was equipped with an adjustable level, voltage and pressure switch, whereby any cell could be electrically bypassed independently of its neighbors. Cell voltage data were automatically recorded, using the DYMEC data acquisition system (Hewlett-Packard, model 2010F), coupled to an IBM card punch. Internal resistances were measured by means of the superimposed a-c technique. Elapsed time meters (Cramer,

* Significant factor effects.

type 636Y, Giannini Controls Corporation) were employed to measure discharge times to the 1v cut-off, from which faradaic capacities were calculated. Bourdon gauges (Ashcroft #1850, Manning, Maxwell and Moore, Inc.) were attached directly to each cell. Following the automatic recording of voltage data, internal pressure, and discharge time data, test routine information and cell factor-level codes were manually punched. For each charge-discharge routine, two cards per cell were required to record all pertinent information. The IBM s/360, model 30 computer was employed to analyze all data. The analysis of variance and multilinear regression analysis programs were written in Fortran IV.

Thirty-two separate test routines, covering the ranges: 70-150% charge input level, C/50-C/1 charge rate, and C/10-2C discharge rate, were performed at random. During each test, cell voltages were measured at end of charge, E.C.V., on open circuit, O.C.V. following a 2-hr stand period, and at 25, 50, and 75% depth of discharge, based on the theoretical capacity. The cell internal resistances and pressures were measured at end of charge (E.C.R. and E.C.P.). During the stand period, pressure decay data were recorded. There was no capacity degradation after the completion of the entire test routine.

Results

For each test routine, factor effects were calculated for each type of data, with the exception of cell voltages, at 25 and 75% depth of discharge. The Yates sum and difference iterative technique (15) was employed for this purpose. The reader is referred to Davies (2) for an account of this procedure. There are two means whereby an estimate of the experimental error may be made. One or more replicates of each cell of the factorial set may be assembled and tested. The second method, which does not involve the use of replicates, is based on the assumption that true high-order interaction effects are insignificant; *i.e.*, the effects calculated for those cells with three or four high-level factor combinations are due to experimental error. The error variance is then given by the mean square effects for these combinations in the factorial set. It is the opinion of the authors that the uniformity of the cells produced in this laboratory justifies the use of this second method in this factorial experiment. As an example, the efficiency, end-of-charge, and open-circuit voltage data, measured under the conditions 150% charge input level, C/10 charge rate, and C/2 discharge rate, are shown in Table III. Since the analysis calculates only the effect of one or more high-level factors on the parameter value, no effect is calculated for cell #1. The error variance is the mean-square effect for cells #8, 12, 14, 15, and 16. These estimates of error are comparable with those measured from an independent source in this laboratory (8). The variance ratio is given by:

$$V = \frac{2^{n-2}\,(\text{Effect})^2}{\text{Error variance}} \qquad [1]$$

If $V > 1$, then the level of significance of the effect is calculated from the relationship:

$$P = \int_v^\infty F(x, \phi, \theta)\, dx \qquad [2]$$

where $F(x, \phi, \theta)$ is the F-distribution function for ϕ and θ degrees of freedom (3). It has been decided that no significance should be attached to an effect if $P \leq 0.95$. Thus, under the charge-discharge conditions shown in Table III, only three primary effects can be considered significant.

As the experiment proceeded, certain patterns emerged as regards the primary and interaction effects of the four factors on the several parameters. Over the entire range of test conditions, the presence of the INCO 287 more coarse-grained and highly corroded carbonyl nickel substrate resulted in an increase in E.C.V., E.C.R., and E.C.P. The cell voltage at 50% depth of discharge is lowered by this factor, and the efficiency decreased. The high ratio of $Cd/Cd(OH)_2$ emerged as a significant factor only when the cells were overcharged at a relatively high rate. Under these conditions, the E.C.V. is raised. At high charge rates, the presence of this factor tends to effect a reduction in E.C.P. The effect of the high-percentage pore fill was consistent throughout the series of tests. On overcharge, the E.C.V. is raised. The O.C.V., the cell voltage at middle of discharge, the E.C.P., and the efficiency are raised, and the E.C.R. reduced. The effects of the cobalt additive were the most interesting feature of this study. The direction of the effect of this factor on the several parameters is highly dependent on the charging conditions, and to a lesser extent on the discharging conditions. This additive primarily affects the E.C.V., E.C.P., O.C.V., and the efficiency.

During the course of the tests, it was observed that for a constant charge input the faradaic capacity increased linearly with the logarithm of the charging current, when discharged at a constant rate. Similarly, under constant charge and discharge current conditions, the delivered capacity increased linearly with the logarithm of the charge input. A similar dependency between delivered capacity and discharge current, following constant charging conditions, was indicated, although not so well defined. Based on these observations, an attempt was made to fit the predischarge parametric data to an equation of the form:

$$\text{Parameter} = K_0 + K_1 \log_{10}(C.L.) + K_2 \log_{10}(C.R.) \qquad [3]$$

and all other data to an equation of the form:

$$\text{Parameter} = K_0 + K_1 \log_{10}(C.L.) + K_2 \log_{10}(C.R.) + K_3 \log_{10}(D.R.) \qquad [4]$$

where the charge level, charge rate, and discharge rate are given by

$$C.L. = C.T./C.R. \quad [5], \qquad C.R. = T.C./C.C. \quad [6],$$

$$D.R. = T.C./D.C. \quad [7]$$

$T.C.$ is the theoretical cell capacity, calculated on the basis of a chemical analysis of the active material in the positive plates, as previously indicated, $C.C.$, $D.C.$, and $C.T.$ are the charging current, discharging current, and charging time, respectively. The data fitting was accomplished with the aid of a multilinear regression analysis program. In Tables IV and V are shown the regression coefficients and associated statistical data for the E.C.V. and efficiency for each cell in the factorial set. The efficiency is the ratio of the faradaic capacity to the theoretical capacity. Each independent variable is separately correlated with the dependent variable; r_i^2 is the square of the correlation coefficient, corrected for degrees of freedom, of the ith independent variable, $i = 1$, 2, and 3; S_i is the standard error associated with the coefficient, K_i; t_i is the absolute value of the ratio, K_i/S_i; $S.E.E.$ is the standard error of the estimate; $M.C.C.$ is the multiple correlation coefficient; F is the statistical F-value. As can be seen, both the E.C.V. and the efficiency data correlate well with the logarithms of the charge level and the charge rate. The values of r_3^2 indicate a low dependency of the efficiency on the discharge rate. The values of t_i for each cell give a relative measure of the importance of each independent variable in governing the magnitude of the dependent variable. Thus, the E.C.V. is more dependent on the charge rate than on the charge level. For most cells, the charge rate and the charge level are of equal importance in determining efficiency. It is to be noted that certain factors markedly affect the relative r_i^2 and t_i values. Thus, for example, with reference to the E.C.V. data, Table IV, compare t_1 and t_2 for cells 9 and 10 in relation to the values for the remaining cells.

The introduction of cobalt into the positive plate causes the E.C.V. to be much more dependent on the charge rate than in the cells not containing cobalt in the nickel hydroxide electrode. Although not so marked, a similar effect is observed with regard to the efficiency data, Table V. The high values of *M.C.C.* indicate that only a small percentage of the experimental data over the entire range of charge-discharge conditions was removed by the regression. The high *F* values indicate that the data fit the proposed equations very well. For the E.C.V. equation, with 2 and 29 deg of freedom, an *F* value exceeding 8.85 is significant at the 0.999 level. For the efficiency equation, with 3 and 28 deg of freedom, an *F* value exceeding 7.19 is significant at the 0.999 level. From the values of the standard error of the estimate, it is seen that, over the operating range covered, the experimental and calculated value of E.C.V. agree to within 1-2%. Similarly, efficiencies are predictable to within 5%. Similar analyses have been performed for the other parametric data recorded. In all cases, the experimental data have been shown to fit the proposed equations.

The factor effects causing the variations in the values of the various regression coefficients may be calculated and tested for significance in the same manner as previously described. For the constant term, K_0, there is no independent estimate of the error. Again, it is assumed that high-order interactions are insignificant and, therefore, the calculated effects for the cells with the second- and third-order interaction factor combinations may be employed to estimate the error variance. In the case of the remaining coefficients, K_i, the regression analyses result in independent estimates of error, S_i. For each cell in the factorial set, the error variance is given by S_i^2. The effects are calculated by the Yates technique, and the significance level, *P*, is given by Eq. [2] with $\phi = 1$ and $\theta = 5$ for the analyses of variance pertaining to K_0. For the analyses of variance pertaining to the K_i coefficients, θ is given by

θ = Number of observations
— Number of independent variables — 1

In Table VI are summarized the findings of the analyses of variance for the following cell parametric data, E.C.V., O.C.V., E.C.R., E.C.P., the cell voltage at mid-discharge and the efficiency. Only *P* values ≥ 0.95 are shown. The signs in parentheses show the direction of the effect on changing the factor from the low to the high level. It has been shown in this laboratory that, if a 50% charged positive plate is employed in a Ni-Cd cell as a reference electrode, then the electrode potentials with respect to this reference, at various stages of the charge-discharge routine, may be correlated with the cell operating conditions by equations of the types [3] and [4].

Discussion

The method of summarizing experimental Ni-Cd battery data, obtained under a variety of operating conditions, by means of the logarithmic parametric equation has proved very successful. First, it allows one to present a large amount of data in a highly compact form. Second, the independent correlation coefficient data, resulting from the regression analyses, indicate the relative importance of the three operational conditions, charge input level, charge rate, and discharge rate, in governing the over-all performance.

For the particular cells employed in this study, the cell efficiency is determined primarily by factors which affect, and conditions associated with, the charge acceptance capabilities of the positive electrode. The end-of-charge voltage and pressure, and to a certain extent the open-circuit voltage and the end-of-charge resistance, serve as useful indicators of this capability, which is governed by the electrode structure and the availability of the electrolyte. The effects produced by the incorporation of certain factors, specifically *A* and *C*, into the cell design, were, to a certain extent, predictable. However, as indicated in the introductory

paragraphs, their inclusion was considered necessary in order to be able to interpret the cobalt effect.

Factor A.—Cells containing positive electrodes, produced by impregnating the more dense, less porous, sintered #287 carbonyl nickel plaque, are significantly less efficient over the entire range of operating conditions. The correlation coefficient data show that this factor causes the efficiency and the cell voltage data to become less dependent on the charge level, and more rate dependent. However, the opposite effect results for the end-of-charge pressure. The E.C.V. and E.C.R. are increased by this high-level factor, while the cell voltage at mid-discharge is decreased. In the overcharge region, the E.C.P. is raised by this factor.

Factor B.—The negative electrode, high state-of-charge factor shows little effect on the parametric data. In the overcharge region, it does manifest itself in contributing to an increase in both the end-of-charge voltage and pressure. The pressure decay data, although not presented, have been shown to follow the logarithmic relationship (14), $p_t/p_o = \exp(-t/\tau)$. The presence of the excess amount of metallic cadmium at full charge has no significant effect on the oxygen recombination relaxation time constants. Although there is no substantiating evidence, it appears that the higher pressures developed, in the presence of this high-level factor, are due to enhanced hydrogen evolution.

Factor C.—As is fully expected, the effect of the higher percentage pore fill is beneficial to the over-all cell performance. The correlation coefficient data indicate that this high-level factor causes the efficiency, the end-of-charge voltage, and pressure to be more dependent on the charge input level than on the charge rate. However, the end-of-charge cell resistance becomes markedly more dependent on the charge rate than on the charge level. The open-circuit voltage, cell voltage at mid-discharge, and the efficiency are raised, and the end-of-charge resistance is markedly decreased. The oxygen diffusion rate through the cell is impaired by the relative increase in the amount of electrolyte. This is mirrored in the significant increase in the end-of-charge pressure, and a significant decrease in the relaxation time constant for oxygen recombination.

Factor D.—As is indicated in Table I, the inclusion of cobaltous ion in the impregnation liquor causes the two types of nickel plaque to be corroded to the same extent. Thus, the effect of the cobalt additive is to oppose the primary effect of factor *A*. This is further emphasized by the efficiency data for cells #9 and #10 (*see* Table V). Irrespective of the original nature of the substrate, the efficiency regression coefficient data for the electrodes containing the cobalt additive are very similar. The primary effect of the cobalt additive is to enhance the kinetics of the charge acceptance and charge delivery reactions. Thus, the correlation coefficients associated with the charge level regression coefficients of the efficiency and cell voltages are markedly decreased, while the correlation coefficients associated with rate dependency are greatly increased. The fact that there is a cobalt effect *per se*, independent of the positive electrode structure modification effect, is shown by the significant primary factor *D* effects shown in Table VI. Following charge at a high rate, the end-of-charge and open-circuit voltages and the efficiency are raised. Thus, under certain operating conditions, a cobalt additive can enhance the efficiency. However, under other conditions, cobalt can exert a detrimental effect. By considering the relative values of the four terms in the efficiency equation, in the absence and presence of a cobalt additive, one can predict the over-all effect of this additive under different test routines. The predicted effects agree very well with those actually observed, which may be summarized as follows:

1. At or below the 100% charge level, the effect of cobalt is to increase efficiency, especially after charging at high rates.
2. At medium to low discharge rates, C/5-C/50, cobalt contributes to an increase in efficiency.
3. When the positive electrode is overcharged, the presence of a cobalt additive is detrimental to the efficiency.

Conclusion

Provided that high uniformity in cell fabrication and operation can be maintained, the 2^n factorial experi-

ment is a very useful tool whereby the effects of factors on the behavior of a battery system may be examined. The significance of factor interaction effects in determining the performance characteristics of Ni-Cd cells should not be overlooked. The combination of the two statistical techniques has proved highly useful as a cell performance optimization procedure. Thus, it allows one to establish the most favorable choice of factors which should be incorporated into a cell designed for operation according to a prescribed charge-discharge routine.

Manuscript submitted May 10, 1968; revised manuscript received Jan. 16, 1969. This paper was presented in part at the Philadelphia Meeting, Oct. 9-14, 1966 as Paper 19.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.
