A High Energy Density Lithium/Dichloroisocyanuric Acid Battery System

D. L. Williams,* J. J. Byrne, and J. S. Driscoll

Monsanto Company, New Enterprise Division, Boston Laboratory, Everett, Massachusetts

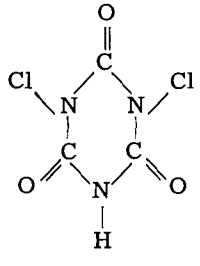
ABSTRACT

The N-chloro compound, dichloroisocyanuric acid (DCA), has been discharged *vs.* lithium in organic nonaqueous electrolytes. The Li/2M $LiClO_4$ (methyl formate)/DCA system has an open-circuit voltage of 4.0v. The solubility of DCA in 2M $LiClO_4$ (methyl formate) is 13 w/o (weight per cent) or 0.65M. Chronopotentiometry at platinum electrodes indicates an irreversible electrode reaction ($\alpha n_a = 0.074$). However there are no separate voltage plateaus at platinum or carbon. Coulometric and battery discharge data are complex, probably because of precipitates formed during the reduction of DCA in the presence of lithium salts in methyl formate. At constant 3.2v discharges, average current densities are 5.8 and 3.4 ma/cm^2 at 4 and 8 hr, respectively. Excluding grid and container weights 200 whr/lb is achieved in 8 hr. High energy densities (180 whr/lb) are obtained under constant load at 3-10 hr discharge rates. When the cell is activated immediately prior to discharge, self-discharge and anode passivation are relatively minor problems.

Nonaqueous, organic electrolyte batteries can potentially achieve energy densities of 200 whr/lb. Most research in this area has been done using lithium anodes and inorganic cathodes composed of metal salts, such as halides and oxides of silver, nickel, and copper. Problems with these systems are associated with low cathode discharge rates, short activated shelf life, or both.

The system described here uses an organic cathode material, dichloroisocyanuric acid (DCA), which is highly soluble in the electrolyte. The system has been designed primarily for Dry Tape battery (1, 2) use. In this device, a thin-layer battery system is activated as it enters between the current collector heads. Since the collectors are unipotential surfaces, discharge of a tape section is at constant voltage. In this paper, the discharge of the Li/DCA couple is described under both constant voltage and constant load conditions. The constant voltage condition simulates Dry Tape discharge, while constant load is applicable to conventional reserve-activated batteries.

The structure of DCA is shown below.



Dichloroisocyanuric acid (DCA)

DCA is a positive N-chloro compound. The two chlorine atoms are formally in the +1 oxidation state. Based on a four-electron transfer, the coulombic capacity of this compound is 32.5 amp-min/g, which is similar to that of cupric fluoride (33.0 amp-min/g). The open-circuit voltage of DCA *vs.* lithium is 4.0v, which is approximately 0.4v higher than that of a lithium/cupric fluoride cell.

Experimental

Materials.—Cells were discharged in an argon atmosphere. Materials were transferred in a glove box when possible. Materials were obtained and purified as follows:

Methyl formate—Matheson Coleman & Bell Spectroquality—Purified by contact with Linde 4A molecular sieve, followed by distillation;

Lithium perchlorate—G. Frederick Smith Company—Dried under vacuum (<1 Torr) for 72 hr at 130°C;

Lithium ribbon—Foote Mineral Company—Thickness 0.38 mm, used as received:

Dichloroisocyanuric acid (DCA)—Monsanto Company, ACL-70®—Ground with mortar and pestle, and dried under vacuum (<0.5 Torr) over P_2O_5, for 24 hr;

Carbon black—Shawinigan Chemicals Ltd., Shawinigan acetylene black, 50% compressed—Dried under vacuum (<1 Torr) at 130°C for 24 hr;

Carbon fibers—H. I. Thompson Company—Cut in Waring blender and dried under vacuum (<1 Torr) at 130°C for 24 hr;

Polypropylene nonwoven separator—Pellon Corporation—Thickness 0.076 mm, used as received.

Cathode preparation.—The cathode plate was prepared by blending dry powders of dichloroisocyanuric acid (83%), carbon black (16%), and carbon fibers (1%), and pressing them at 300 psi (0.21 kgf/mm^2). The loading was approximately 100 mg/cm^2 of total material, which corresponded to 2.5 amp-min/cm^2 of active material. This gave a cathode plate, or tape, which was 1 mm thick.

Cell discharge.—Cathode contact was made by pressure against a platinum collector. Contact to a lithium tab was made with an alligator clip. Cell weights and energy densities were calculated on the weights of the anode, cathode, electrolyte, and separator.

Discharge at constant voltage employed a Harrison Laboratory 6200B power supply to maintain the desired cell voltage across a 1-ohm resistor, which was then connected across the test cell. The circuit is shown schematically in Fig. 1. All other circuitry was standard. Average voltage and ampere-minute values were obtained by planimeter integration of recorder outputs.

Results and Discussion

Development of the system.—In the initial stage of this program, lithium was discharged in half-cell experiments using a Luggin capillary and a high resistance normal calomel electrode (NCE). About 30 electrolyte-solvent systems were screened for use with a lithium anode (3). Observations of gassing and electrolyte-anode changes, as well as steady-state voltages at several currents, and oscilloscope traces of polarization were determined. Methyl formate was found to

Key words: battery, lithium, dichloroisocyanuric acid, chloramines, chlorine compounds, methyl formate.

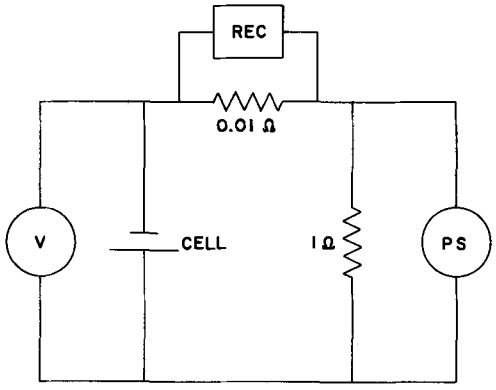

Fig. 1. Schematic of constant voltage discharge circuit

be the best solvent for the support of high current densities, and $LiClO_4$ was the best of the solutes tested. At 100 ma/cm², anodic polarization of lithium anodes in 1M solutions of $LiClO_4$ in methyl formate (MF) was 0.8v. The analysis of polarization relaxation showed that 0.2v could be attributed to resistance polarization.

During the second stage of this investigation, several cathode materials were mixed with carbon and discharged *vs.* lithium in 1M $LiClO_4$ (MF). On the basis of these results, DCA was chosen for further study. A study of the effect of $LiClO_4$ molarity on the discharge characteristics of this cathode showed a decided advantage for a 2M concentration. At higher molarities the viscosity and density of the electrolyte increase, and the conductivity decreases as shown in Fig. 2.

The solubility of DCA in 2M $LiClO_4$ (MF) is 0.65M, or 13 w/o. This value was determined by iodine-thiosulfate titrations of saturated solutions. The solubility varies only slightly with $LiClO_4$ concentration. The dissolved DCA however, changes the 2M $LiClO_4$ (MF) solution conductivity from 2.4×10^{-2} to 1.7×10^{-2} ohm^{-1} cm^{-1}, and changes the kinematic viscosity from 1.0 centistokes to 1.5 centistokes.

DCA voltammetry.—Chronopotentiometric data are shown in Table I for DCA and for trichloroisocyanuric acid (TCA) in 2M $LiClO_4$(MF). Values for $i\tau^{1/2}/C$ are constant for each compound and are 2/3 as large for the dichloro- as for the trichlorocompound. Since battery efficiencies of over 50% are realized for DCA, based on a 4-electron transfer, the 4-electron transfer is assumed for the chronopotentiogram of DCA. Similarly for TCA we assume a 6-electron transfer. Using the Sand equation, the calculated diffusion coefficient is 1.4×10^{-6} cm²/sec for each compound. Analysis of the DCA chronopotentiometric potential-time curve (platinum electrode) showed the reduction to be irreversible. Figure 3 shows a plot of E *vs.* log $(\tau^{1/2} - t^{1/2})/\tau^{1/2}$ from which a value of $\alpha n_a = 0.074$ can be calculated (4). There is no evidence of separate voltage plateaus either in these experiments or with a carbon-epoxy electrode (5).

assuming $n_{DCA} = 4$, $n_{TCA} = 6$

Coulometric experiments, using a smooth platinum electrode, yielded a precipitate on the electrode surface. Infrared spectra indicated the product to be similar to cyanuric acid. LiCl also precipitates on the electrode since the solubility of LiCl in the electrolyte is only 0.12M. Figure 4 shows a coulometric voltage-time plot obtained at constant current, 0.010 ma/cm². There is an initial increase in voltage followed by voltage oscillations and continued reduction at a lower potential. The voltage oscillations are believed to be caused by coverage of the surface by a precipitate and subsequent breakdown of this layer. Finally, a more stable, porous, precipitate layer is developed, and the voltage adjusts to compensate for the reduced diffusion rate and decreased active area at the electrode. The initial voltage increase may be explained by the decreased overpotential required to grow formed crystals relative to that required for the nucleation of crystals.

Cell discharge characteristics.—The lithium-DCA cell component weights are shown in Table II. The cathode plate is prepared with 83% dichloroisocyanuric acid and 17% carbon. A void structure of 60-70% is obtained by using the high structure Shawinigan acetylene black and carbon fibers.

The constant voltage discharge characteristics of this cell are also shown in Table II. A static discharge time of 4 hr simulates a residence time of 4 hr on the

collector plate in a dynamic Dry Tape test. At 3.2v, this simulated tape throughput gives an average current density of 5.8 ma/cm², 57% cathode efficiency, and 173 whr/lb. This energy density is based on the weight of the anode, cathode, separator and electrolyte. With increased discharge time the average current decreases, and the efficiency and energy density increase. With a simulated 18-hr residence time, 216 whr/lb is obtained.

The current and energy density profiles for the constant voltage discharge of the system are shown in Fig. 5. At constant voltage, the greatest drain occurs when the cathode is fresh, and the electrochemical reaction competes effectively with self-discharge reactions. The current minimum and plateau, observed in Fig. 5, are not indicative of electrode reaction complications, since the chronopotentiometric data were regular. The cause may be due to precipitation effects, since minima and plateaus have been observed in coulometric experiments at smooth electrodes where precipitates were formed.

Cathode efficiencies averaged 60-70% in these tests. Most of the remaining capacity is left undischarged on the tape, as determined by iodine-thiosulfate titrations. After an 18-hr discharge test, 67% had reacted electrochemically, 25% remained unreacted and 8% had decomposed.

The system described above was also discharged under constant load conditions. Data are shown in Fig. 6 for a 3-hr rate (20-ohm) discharge. A voltage minimum and plateau are discernible, and the voltage drops sharply beyond 2.5v. The initial closed circuit voltage is 3.6v at this drain rate, which is 0.4v below the open-circuit value. The average voltage is 3.1v to a 2.0v cut-off.

A series of discharges was run through various resistances. The energy density data are shown in Fig. 7. The energy density of the system rose sharply with

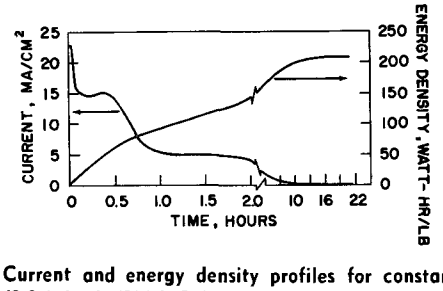

Fig. 5. Current and energy density profiles for constant voltage discharge (3.2v) for Li/2M $LiClO_4$ (MF)/DCA.

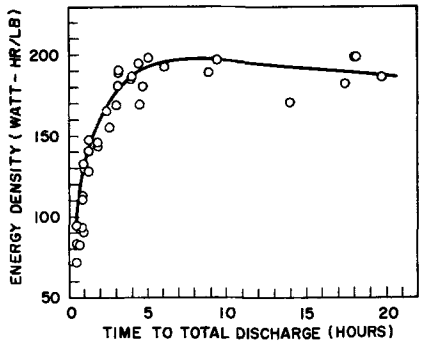

Fig. 7. Energy density of Li/DCA cells as a function of drain rate at constant load (2.0v cut-off).

time to the 3-hr rate and then levelled off. At low discharge rates, methyl formate evaporation was a problem because of the test cell design, and discharges of longer than 20 hr were not attempted. Flash currents of 200 ma/cm² were obtainable at short circuit. As in the constant voltage tests, the efficiencies were about 60%, and most of the remaining capacity was left in the cathode, undischarged.

Conclusion

The lithium-DCA couple is a high energy density battery system that can be discharged effectively at the 3-10 hr rates to give energy densities of 180 whr/lb. Work is in progress to increase the coulombic efficiency and current density of this cell.

Chromium Coatings Prepared by Chemical Vapor Deposition

Gene F. Wakefield

Chemical Materials Research and Development Laboratory, Texas Instruments Incorporated, Dallas, Texas

ABSTRACT

The formation by chemical vapor deposition (CVD) of chromium metal as coatings on various substrates was studied using the reaction

$$CrCl_2 + H_2 \rightarrow Cr + 2HCl$$

Process parameters of temperature, gas flow rate, and chromium chloride concentration influenced the deposition rate. The chromium metal deposited had properties similar to high-purity "iodide" chromium. Surface appearance and grain structure differed from materials such as titanium, deposited in earlier studies. This is suggested to result from difference in the controlling mechanism of the reduction reaction and evidence for this mechanism was observed.

The commercial use of Chemical Vapor Deposition (CVD) processes for preparation and forming of metallurgical materials is increasing. Several practical aspects are encouraging this investigation into the nature and application of CVD process methods. One aspect is the capability of producing a wide variety of shaped materials, such as boron or silicon carbide (1) filaments, since the deposit usually conforms to the contour of the substrate. Another is production of materials of controlled purity, such as semiconductor grade silicon (2) or tungsten metal (3). Another is the ability to form materials having unusual or unique properties such as anisotropic pyrolytic graphite (4).

The CVD preparation of bulk chromium metal has commonly been carried out by the transfer reaction utilizing chromous-chromic iodide equilibrium or simply thermal decomposition on a heated filament (5). A mass of coarse, loosely bound crystals usually results. This material is commercially available with a stated purity of 99.99%.

Preparation of unalloyed chromium coatings has been carried out (6) by the thermal dissociation of organochromium compounds such as dicumene chromium, $Cr[C_6H_5CH(CH_3)_2]$. Because of their low boiling points, use of such compounds is a convenient procedure for obtaining chromium in a vapor state, and the compounds can be decomposed at moderate temperatures. Care must be exercised over the reaction conditions to avoid the introduction of carbon from the organic radical decomposition.

The procedure designated as "chromizing" (7) is used for preparation of chromium-containing coatings. Chromizing differs from the present subject in that it is limited to diffused coatings, which consist of an alloy containing a major concentration of the substrate material. The coating mechanism often involves displacement in addition to reduction reactions. Because of its vapor pressure, chromium can be evaporated and condensed on a substrate material. This procedure can produce high-purity metal, but is usually restricted to thin coatings.

The applications of chromium as a bulk material or as a coating on another material are usually for corrosion resistance, appearance, or high-temperature strength. The vapor process is a preferred preparation method to obtain a high-purity metal and thus a relatively ductile material. This study was conducted to investigate the deposition process for the formation of high-purity chromium metal, primarily as coatings on various metal substrates, although the method is also applicable to bulk metal preparation.

Equipment

Equipment for CVD processes consists basically of a controlled supply of reaction gases delivered into a heated reaction area where the gases impinge on the deposition site. The reaction which occurs produces the desired material as a solid product, and the remainder of the products are given off as gases.

The equipment used in this study contained all equipment for measurement and control of the parameters in the process in a single control unit. Temperature controllers for the system were Honeywell Versatronik temperature controllers (accuracy ±5°C) on the chromium reservoir and argon purifying furnaces and a Honeywell Pyro-Volt proportional controller (accuracy ±2°C) for reactor temperature. Gas flows were measured with Brooks Sho-Rate flow meters having a stated accuracy of 5%, and the meters were calibrated with a Precision Scientific Company wet test meter having a stated accuracy of 0.5%. The results of the calibrations showed a deviation of less than 3% from the smoothed curve values.

A schematic diagram of the reactor used is shown in Fig. 1. Two gas streams of controlled flow rate and composition entered the top of the reactor. The hydrogen chloride-argon stream flowed through the heated bed of chromium metal where reaction (A) produced $CrCl_2$. The hydrogen stream flowed around the chloride generation chamber and mixed with the exiting $CrCl_2$-argon stream in the nozzle above the specimen. The diameter of the reactant nozzle (0.62 in.) and the nozzle to substrate distance (1.5 in.) were adjusted to give a uniform deposition over a 1 in. diameter circle. Thus, uniform mixing of reactants over at least this area was indicated. The specimen rested on a support above the center of the heater. Temperature of the heater was controlled by a thermocouple-actuated controller on a saturable core reactor. Calibration of the control was done with an optical pyrom-

eter using a sample containing a black body hole. The gate valve and lock chamber permitted the insertion and removal of specimens without the introduction of impurity gases into the system. Exclusion of impurities was a major aid in obtaining consistent experimental results and permitting more rapid operation.

Gases in the reactant stream were hydrogen, purified by passage through a palladium diffusion purifier; argon, purified by passage over a bed of heated titanium chips; and chromium chloride generated by the reaction of high-purity hydrogen chloride gas and chromium metal. The substrate material used for most of the chromium depositions was a niobium alloy, B-66[1] (89% Nb, 5% Mo, 5% V, 1% Zr), although deposition on other materials has produced essentially the same results.

The reaction

$$2HCl(g) + Cr(s) \xrightarrow{\text{argon}} CrCl_2(g) + H_2(g) \quad (A)$$

occurred in the chloride generating chamber at a temperature of 900°C. The reversal of this

$$H_2(g) + CrCl_2(g) \rightarrow Cr(s) + 2HCl(g) \quad (B)$$

occurred at the substrate surface in the presence of excess hydrogen and at higher temperatures.

Experimental Plan

A statistical plan of the experimental variables of reactor temperature, chromium chloride concentration, and flow rate[2] of gases was carried out to determine the influence of these upon the rate of metal deposition. The basic design (8) of the series was a two-level, three-variable cube with fourfold replication at the center of the cube. Such a plan was selected because it can be analyzed by Analysis of Variance, and Multiple Regression and Correlation Analysis to identify the first order and the interaction effects of the variables. The mathematical description from this standard analysis is strictly empirical since it is based on assumed linearity of the model.

Listing of the experiments and the resulting deposition rates is given in Table I. The concentrations are given in terms of molar per cent. The flows were measured at 25°C although the values given are calculated for the gases heated to 900°C assuming ideal gas laws, as this is more representative of the actual deposition conditions.

[1] Westinghouse Astronuclear Laboratory, Pittsburgh, Pennsylvania.

[2] Note that the flow rate change was accomplished by variation of the hydrogen flow.

Results and Discussion

The resulting deposition rate data are plotted *vs.* the three independent variables in Fig. 2a, 2b, and 2c. The curves exhibit self-consistency and indicate that each of the three variables contributes positively to the deposition rate. The mathematical analysis of the results, based on a linear model for the system, is given in Table II and is in agreement with this conclusion. This analysis yields the deposition rate equation

$$\text{Rate } X_4 = 1.74 \times 10^{-3} X_1 + 2.94 X_2 + 0.128 X_3 - 3.127 \quad [1]$$

Statistical analysis of the deposition rate data indicates that the variables are significant at the 95% confidence level. On the basis of the T values of Table II, the major influence exerted on the deposition rate results was the flow rate of gases, with a lesser influence exerted by the chromium chloride concentration, while the reaction temperature has the least effect. Process studies indicate that for these experimental conditions the deposition is controlled by several, rather than a single, identifiable factor.

Variable	Regression coefficient	Observed T value	T for 95% level
X_1	1.741×10^{-3}	1.99	2.36
X_2	2.941	3.36	2.36
X_3	1.277×10^{-1}	5.84	2.36

Intercept: −3.127
Standard error of estimate: 0.185
Multiple correlation coefficient: 0.9359

A second mathematical analysis of the data was made, based on a classical kinetic model. This analysis used only concentration of reactants without regard to flow rate. The dependence of deposition rate on the concentrations of the reactants was derived as an equation of the form

$$R = k[H_2]^{0.85}\,[CrCl_2]^{0.92} \qquad [2]^3$$

The values of k and the calculated rates using this equation are given in columns 4 and 5 of Table I, and illustrated in Fig. 3. The average deviation from the mean of the values is less than 8% of the value, which is near the limits within which the experimental variables could be fixed.

The exponents on the concentrations of the rate Eq. [II] indicate approximate first order in both reactants. First order dependence on the chromium chloride concentration is reasonable in relation to the availability of chromium chloride for reaction. For these experiments, the gas phase concentration of hydrogen varied from 60 to 500 times that of the $CrCl_2$. At such excess concentrations, an apparent first order dependence with hydrogen was not expected and could more likely also have been affected by variation in flow rate since the experimental parameters were varied in a fashion which did not entirely separate the flow rate and hydrogen concentration effects.

A Factorial Analysis of Variance indicated no interaction between the variables significant at the 95% confidence level. An Arrhenius plot of the deposition rate is shown in Figure 4. The data divide into four separate lines, and the lines of the higher flow rate (A and B) have a slope of 10 kcal/mole. The separation of the curves substantiates the independence of the variables. The slope of the lower flow rate lines (C and D) is 14 kcal/mole. The average slope of these curves is 12 kcal. The thermodynamic value of ΔH for this reduction can be calculated from the data (9) for ΔH: $\Delta H = -14{,}710 - 2.38T + 1.91 \times 10^{-3}\,T^2$. For the midrange of temperatures studied, $\Delta H_{calc} = 13$ kcal/mole. This value is in reasonable agreement with the values observed in this study.

From the temperature dependence of k, a value can be calculated for the effective energy of activation for the over-all reduction reaction. The values of k are shown on the Arrhenius plot of Fig. 4 and indicate an activation energy of 12 kcal/mole from the slope. This value is in reasonable agreement with the values of ΔH from the rate data and the thermodynamic calculation.

An apparent efficiency of the reaction can be obtained from the ratio of the amount of chromium retained on the sample to that passed over the sample. This ratio varied from 0.05 to 0.07 for the lower hydrogen concentration, and 0.07 to 0.10 at the higher hydrogen concentration. This efficiency is lower than would occur at equilibrium conditions, as shown in Table III, because the sample interrupted only a portion of the gas stream.

A photomicrograph of a cross section of a chromium deposit is shown in Fig. 5a displaying the absence of

[3] Average deviation on coefficients: $[H_2] = 0.85 \pm 0.03$, $[CrCl_2] = 0.92 \pm 0.07$

a reaction between the coating and the niobium substrate. The columnar grain structure of the deposit is commonly observed with CVD materials. The uneven top surface shows many crystal facets and shapes. A photograph of this surface is shown in Fig. 6, together with a deposit of titanium prepared in a similar fashion; a considerable difference in appearance is noted. Other coating characteristics noted during some of the experimentation are shown in Fig. 5b, where the appearance of voids in the coating is related to the rate of formation of the deposit.

The morphology of the surfaces of materials obtained by vapor deposition can be sometimes correlated (10) on the basis of the supersaturation ratio (S) defined as the ratio of the observed metal vapor pressure (Pa) to the equilibrium vapor pressure (Po), *i.e.*,

$$S = \frac{Pa}{Po}$$

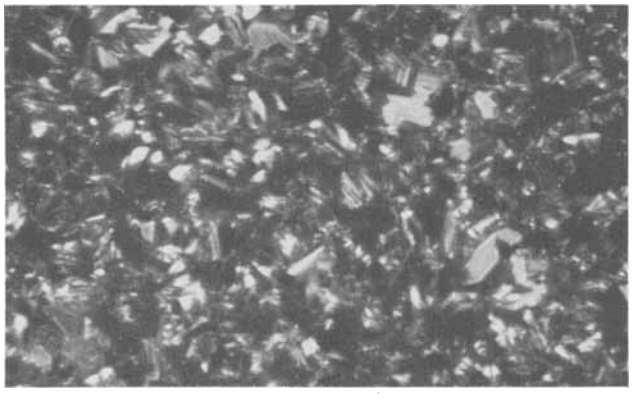

Fig. 6a. Surface of as-deposited chromium (250X)

In general, high values of S result in discontinuous deposits such as powders, dendrites, etc., while low values of S result in a more regular deposit. For the specific data discussed here, the value of S (see Table IV) changes from 110 to less than one; for the latter case, the equilibrium vaporization flux is greater than the net deposition rate. This calculated vaporization flux would be 0.15 mg/cm^2/min at 1200°C and 2.65 mg/cm^2/min at 1350°C.

The difference in surface appearance of the chromium and titanium deposits was interpreted as resulting from different deposition mechanisms. The titanium deposited in an "epigranular" fashion and thus had a smooth surface. The supersaturation ratio for this deposit was approximately 10^3.

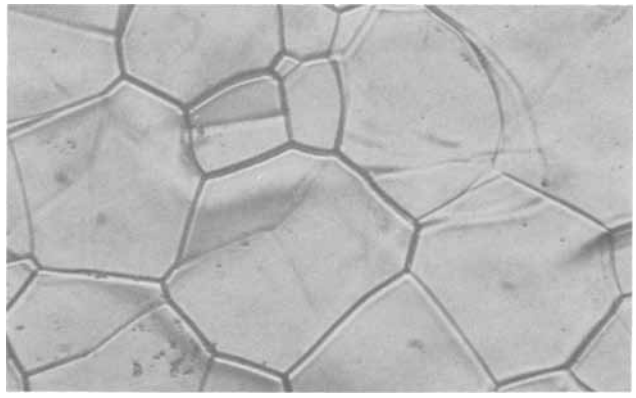

Fig. 6b. Surface of as-deposited titanium (150X)

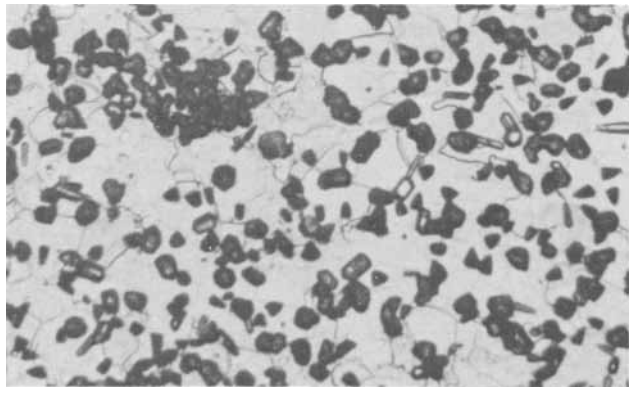

Fig. 7. Initial growth of chromium on niobium (400X)

Chromium apparently has a tendency to form agglomerates when deposited at these supersaturation values either due to preferential adsorption of the reactants or to surface diffusion of the adsorbed species after deposition. This is demonstrated by the photograph in Fig. 7 of the surface of a sample where the deposition was terminated and examined at an early stage during the deposition. The chromium deposit had formed as isolated nodules. At a slightly later stage in the deposition, coalescing of the nodules to form larger islands, and then finally a continuous coating, was observed. The voids observed in a cross section of a coating which had been deposited rapidly could easily result from mismatch as the islands coalesced.

The metals obtained were relatively soft, Rockwell B75, and ductile, as would be expected to result from a vapor deposition process, and could undergo a 4T bent test without fracture.

Conclusions

The formation of high-purity coatings of chromium metal by the CVD process using hydrogen reduction of chromous chloride was investigated. The reaction mechanism was controlled by several variables rather than a single variable. For the range of variables investigated, the rate of metal deposition onto a substrate can be described by the equation

$$\text{Rate mg/cm}^2\text{/min} = k[H_2]^{0.85}[CrCl_2]^{0.92}$$

Table IV. Chromium deposition supersaturation ratio data

T °K	P_o − log atm	P_s − log atm	log S
1300	8.336	6.29	2.05
1400	7.222	6.10	1.12
1500	6.260	5.92	0.36
1600	5.421	5.62	0 20
1700	4.686	5.30	−0.62

where $k = 4.67 \times 10^5$ at 1200°C and 6.78×10^5 at 1350°C. The activation energy calculated from the temperature dependence of k is 12 kcal/mole. An approximate first order dependence on the concentrations of both reactants is indicated even though the gas phase concentration of hydrogen varied from 60 to 500 times the stoichiometric requirements.

An Experimental Investigation of a High-Voltage Electron-Bombardment Ion Thruster

David C. Byers

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio

ABSTRACT

The performance of a mercury electron-bombardment thruster at large values of net accelerating potential is described. A 20-cm diameter thruster was tested at values of ion beam current and net accelerating potential up to 0.165 amp and 70 kv, respectively. A maximum beam power of about 10 kw was obtained. The maximum supportable electric field strength between accelerator grids was approximately constant at 2×10^6 v/m for spacings between 0.5 and 3.0 cm. The ion chamber performance was qualitatively similar to that at low accelerating voltage. The energy dissipated per beam ion in the ion-chamber discharge was related to the percentage of Child's law ion current extracted over a wide range of accelerator spacings and potentials. The maximum percentages of Child's law current transmitted were about 60 and 80% for thrusters with 20 and 7.5-cm diameter accelerator grids, respectively, and were essentially independent of grid spacing and thickness. Ion focusing characteristics, at ion beam current densities of about 10 amp/m^2, indicated that the ratio of center-to-center grid spacing to grid thickness should be between about 2.5 and 4 to avoid direct ion impingement.

The power efficiency was measured and found to be consistent with data taken with low voltage thrusters operated at similar conditions. A power efficiency of 0.8 was obtained at a net accelerating potential of 18 kv and rose to 0.88 at a net accelerating potential of 36 kv. Over-all thruster efficiencies of about 0.80 and 0.82 were obtained at net accelerating potentials of 28 and 36 kv, respectively.

The operation of an electron-bombardment ion thruster at high values of net acceleration potential is described. The electron-bombardment thruster is an ion source conceived by H. R. Kaufman (1) of the NASA Lewis Research Center. This source consists basically of a discharge chamber, where ions are produced by electron bombardment, and a grid system which electrostatically accelerates ions produced in the discharge chamber.

The present interest in the electron-bombardment ion source is its attractiveness as a space thrust system (2). The present paper emphasizes parameters germane to this application. This ion source is, however, capable of operation over a wide range of electrical and physical parameters and with a variety of atomic species. Electron bombardment thrusters have operated at net ion accelerating potentials from 400v (3) to the 70 kv operation reported herein. Source diameters have ranged from 5 cm (4) to 1.5m (5). The propellants most utilized to date with this source have been mercury and cesium. Large atomic masses are of interest for thruster application due to the increase of thrust per beam ion with ion mass. This source has, however, been operated with a variety of gases (6) and molecular types (7). In addition, the electron-bombardment thruster has demonstrated extremely long term, stable operation (8).

The operation of electron-bombardment thrusters at high values of net acceleration potential has promise of increasing the over-all thruster efficiency (1). Higher specific impulses (and therefore higher accelerating voltage) also become more necessary as

mission difficulty increases and propulsion system specific mass decreases (9). This investigation was carried out to determine the operating characteristics of mercury electron-bombardment thrusters at net ion accelerating potentials between 10,000 and 70,000v. Previous thruster data had been limited to a maximum potential of approximately 10,000v (10).

The discharge chamber efficiency and the current carrying characteristics of the high voltage grid system were investigated and compared with data obtained at low values of net accelerating potential (11). Ion impingement currents were measured and compared with an existing analysis (12) extrapolated to high voltage. Over-all thruster efficiencies are discussed both as a function of propellant utilization efficiency and net accelerating potential and in addition are compared with low voltage data.

Apparatus and Procedure

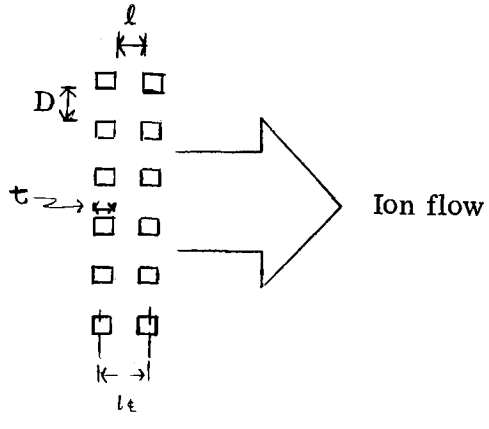
Thruster

The electron-bombardment ion thruster utilized in this program is shown in Fig. 1. The principle of operation of the thruster has been described in many references [*e.g.*, ref. (10)]. In brief, a mercury vaporizer was heated with steam slightly above atmospheric pressure to provide close thermal control of the vaporizer. Interchangeable vaporizer orifices were utilized to change propellant flow rates. The propellant flowed into the ionization chamber through an annular slot distributor. A small screen was placed between the vaporizer and the distributor to prevent plasma leakage to the vaporizer (13).

Electrons are emitted from the cathode and reach an energy nearly equal to the potential difference between the anode and the cathode. These electrons, which are constrained by an axial magnetic field, ionize some of the mercury. The mercury ions diffuse to the accelerator grid region and are accelerated into the exhaust beam.

For all tests, a 20-cm diameter anode was used. The cathode was tantalum ribbon 0.05 mm thick, 40 mm long, and about 5 mm wide.

Accelerator grid system.—A typical accelerator configuration is shown in sketch a.



Sketch a

The value of the ratio of center-to-center grid spacing to hole diameter, l_t/D, was varied between 0.5 to 3.0 by insertion of shims between the downstream insulators and the screen grid extensions (Fig. 1). The screen and accelerator grids were of equal thickness unless otherwise stated. All the data presented in the figures of this report were taken with accelerator grids with hole diameters of 2.2 cm because, as will be later explained, the use of larger holes, 5 cm, led to undesirable thruster performance.

Insulators.—The high voltage thruster was initially designed with spherical insulators scaled from insulators used successfully up to about 10 kv. The 5-cm diameter aluminum oxide spheres were capable of supporting 22 kv before severe flashover occurred. Insulators utilizing shielded negative terminals were also fabricated and tested. These tests are presented in the section Results and Discussion. The final design, shown in Fig. 2, was capable of withstanding potentials up to 250 kv in vacuum.

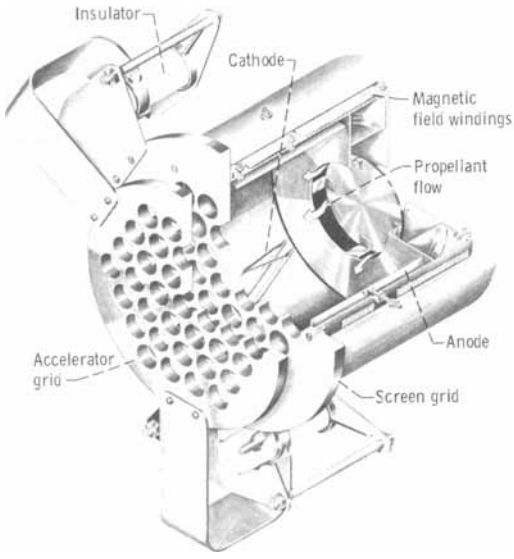


Fig. 1. 20 cm Kaufmann thruster

Facility

The facility was one of the 5-ft diameter, 16-ft long vacuum tanks at the NASA Lewis Research Center. The tank has three 32-in. oil diffusion pumps feeding into a common ejector pump followed by a mechanical pump. Cryogenic pumping (liq. N_2) was used in conjunction with the diffusion pumps so that thruster operation was possible in the 10^{-6} Torr pressure range. A more complete description of this facility is included in ref. (14).

Measurements

All electrical measurements in this program were made with standard meters with an accuracy of about 3% at full scale deflection. The propellant utilization efficiency could not be fixed to much better than 5%. This accuracy was estimated from measured variation in neutral propellant flow rate from several tests where the same orifice size was utilized.

Results and Discussion

The results of the high voltage breakdown characteristics over insulators and between accelerator grids are described first. The ion chamber performance is considered next. The effects of accelerator parameters on the maximum attainable ion current are then presented. Finally, a discussion of over-all thruster efficiencies at high voltage is presented.

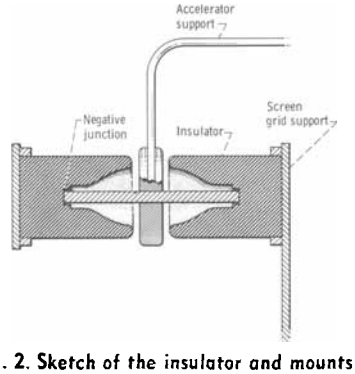

Fig. 2. Sketch of the insulator and mounts

High Voltage Breakdown Studies

The maximum value of the ion current or thrust per unit area of a Child's law current limited system is directly proportional to the square of the electric field supported by the accelerator grid system (15). The value of the maximum supportable field strength in vacuum has, in general, been found to decrease with increasing spacing (16). The voltage breakdown characteristics of accelerator grids at spacings of interest in this program (roughly 0.5-5 cm) were therefore studied.

In addition, initial tests indicated that spherical insulators were unacceptable for use at the intended voltage levels. A test program was carried out to find a suitable insulator design.

All the breakdown tests described below were carried out at pressures less than 1 x 10^{-5} Torr. Breakdowns should then be independent of pressure (17).

Insulator studies.—Spherical insulators (such as utilized in low voltage thrusters), 5 cm in diameter, were found to break down at 22 kv. A program was carried out to improve the insulator design to meet the voltage requirements of the study. The guideline for this program was the data of ref. (18) and (19) which indicated that the primary cause of insulator flashover was electron emission initiating at the negative metal-dielectric junction.

The final insulator design (Fig. 2) was found to eliminate insulator flashover breakdown up to voltages of 250 kv, at which point the insulator failed due to puncture through the dielectric. This design increased the flashover voltage for two reasons. First, the electric fields which can liberate electrons are reduced near the negative junction, as suggested by Ref. (18). Second, the discharge at the negative junction was constrained to the hollowed out section of the insulator.

Plate breakdown studies.—Breakdown tests between simulated accelerator grids were carried out in a bell jar facility. The effects of spacing and surface conditioning on the maximum supportable electric field strength were investigated at voltages up to 285,000v. The grids were attached to independent holders which were connected to high voltage feedthroughs at opposite ends of the bell jar. This mounting technique eliminated the need of spacing insulators and allowed comparison of grid-to-grid breakdown separate from insulator flashover.

Stainless steel plates 0.31 cm thick and 25 cm in diameter were fabricated. Plain plates and plate sets with up to 37 holes (all holes 2.54-cm diameter) were utilized. The edges of one side of each of the plates were left unfinished while the edges of the opposite side were machined to approximately 0.06 cm radius.

The results of these tests are presented in Fig. 3, where the maximum supportable field strength is plotted against the face-to-face spacing between the plates. Above the maximum field strength the breakdowns would become nearly continuous. In addition, this field strength was the highest that could be supported without breakdowns for times greater than about 5 min after prolonged conditioning, *i.e.*, repeated breakdowns. A breakdown was defined as a discharge between the plates greater than 1 ma (which tripped the power supplies).

Figure 3 shows that the maximum supportable electric field does decrease with increasing spacing as expected. The fields are, however, considerably greater than the maximum supportable fields for low voltage thruster operation, which are generally from 2 to 3 x 10^6 v/m (12). Figure 3 also shows that the maximum field is somewhat dependent on the number of holes. In general, the voltage breakdown level decreased with the number of holes drilled in the plates. Although not shown, the critical electric field was larger when rounded edges rather than

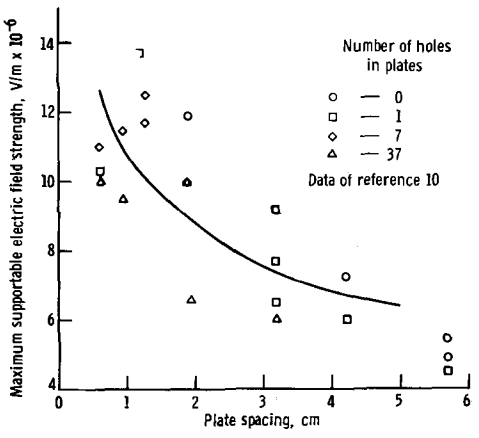

Fig. 3. Effect of spacing on the maximum supportable electric field strength between stainless steel plates. Plate diameter, 25 cm; hole size, 2.2 cm.

square edges faced each other. This difference in critical electric field was, however, always less than 20%. It is seen that the data agree relatively well with the data of ref. (20), which were taken with unpolished stainless steel plates.

It was found that the characteristics of the breakdowns which occurred at spacings less than 1 cm spacing differed substantially from those of breakdowns at spacings greater than 1 cm. At the smaller spacings the breakdowns were localized, data were quite repeatable, and the current between the plates approached zero at the maximum voltage difference, after conditioning for a few minutes. At larger spacings, however, breakdowns were not localized; the leakage current did not decrease significantly with time near the maximum field strength. In addition, the data at large spacings were never repeatable to much closer than about 20%.

Thruster breakdown tests.—Data were taken throughout the thruster program of the maximum supportable field during thruster operation (utilizing the improved insulator design previously described). The results are shown in Fig. 4. Comparing these data with Fig. 3 it is seen that the levels of field strength are approximately a factor of 3 or 4 lower than those obtained in the bell jar tests. The data do not, however, show significant degradation from field strengths obtained previously with thrusters operating at lower voltages. The reason for the low maximum supportable field strength between grids of operating thrusters, as compared with breakdown between plates of the same physical geometry in vacuum, is not certain. During operation, however, the grids of a thruster suffer ion impingement, and become heated to about 700°K (12). These factors would probably tend to reduce the maximum supportable field strength.

Ion Chamber Performance

For flight applications, the energy required to form a beam ion is of importance. This energy, eV/ion,

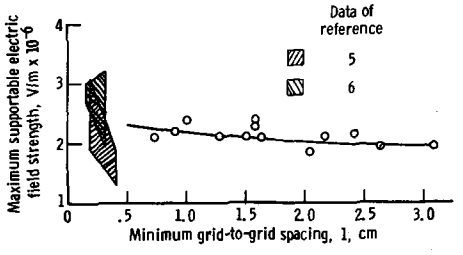

Fig. 4. Maximum supportable electric field strength between the accelerator grids of the operating electron bombardment thruster as a function of the grid spacing; *t*, 1.18 cm; *D*, 2.2 cm; 37-hole grid.

is defined as

$$\text{eV/ion} = \frac{\Delta V_I (J_I - J_B)}{J_B} \qquad [1]$$

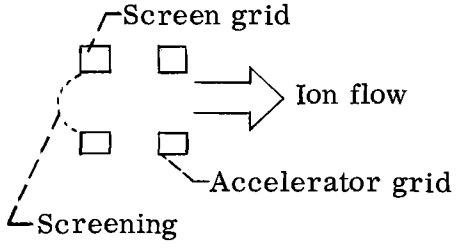
All symbols are defined in the symbol list.

The ion chamber was tested over a large range of thruster operating conditions. In general, the qualitative trends were the same as those obtained with low voltage thrusters utilizing tantalum cathodes. Figure 5 shows the eV/ion as a function of the propellant utilization efficiency, net accelerating potential, ion-chamber discharge potential, and magnetic field strength. As is generally true (10) the eV/ion increased with propellant utilization efficiency, decreased with net accelerating potential, and exhibited a minimum at some value of both ion chamber potential difference and magnetic field strength. These data are not optimum for a 20-cm thruster. Use of a discharge chamber configuration employing a hollow cathode (21) or different propellant introduction modes (22) would probably lower the chamber losses.

Discharge stability.—During the investigation it was found that some limits had to be placed on various thruster parameters in order to maintain stable thruster operation. The instability of the discharge would manifest itself both by breakdowns from the thruster anode potential to ground and by quenching of the ion-chamber discharge. Such instabilities are similar to those experienced during operation with short anodes (7, 10). The factors most strongly affecting the discharge stability were the propellant utilization efficiency and the accelerator grid hole size. The grid spacing and thickness did not significantly affect stability over the range of values tested.

The discharge chamber was unstable with the 2.2 and 5.0-cm diameter grid holes at propellant utilization efficiencies greater than about 0.90 and 0.30, respectively. Data presented herein at propellant utilization efficiencies greater than these values (with the specified hole sizes) were taken during repeated breakdowns and/or discharge quenching.

Operation with the large hole grids was characterized by very severe breakdowns which would often destroy the cathode. When wire mesh was placed over the screen grid holes (sketch b), breakdowns



Sketch b

from the anode to ground were eliminated. Use of such screens proved unsatisfactory, however, because the mesh would quickly burn through. In addition, the eV/ion was 2 to 3 times that obtained without mesh screening.

The above statements indicate that the accelerator field can interact with the ion chamber plasma. The grid hole size strongly affected the maximum propellant utilization efficiency that could be attained. The data suggest that discharge quenching, at high utilization efficiencies, may be inherent with the grid geometries required at high voltage.

Accelerator spacing and net accelerating voltage.—Throughout the test it was found that the eV/ion was strongly dependent on the accelerator geometrical and electrical parameters within the region of stable discharge operation. Accelerator grids with hole diameters of 2.2 cm and 7 or 37 holes were utilized for the tests discussed below. The ratios of center-

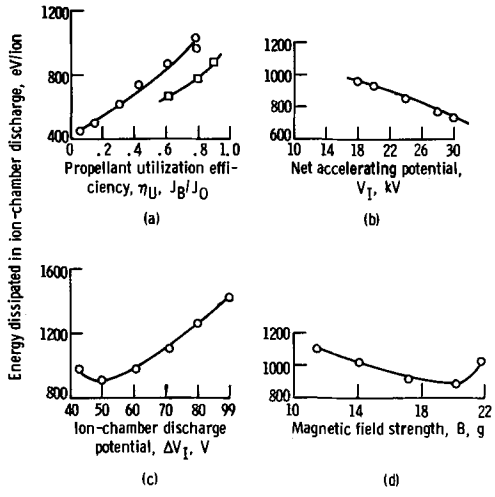


Fig. 5. Ion chamber performance as a function of several thruster parameters. ΔV, 50v; V_I, 20 kv; J_O, 0.165 amp; η_U, 0.79; B, 17.4g; R, 0.8; l_ℓ/D, 1.29; D, 2.2 cm; t, 18 cm; 37-hole grid, unless otherwise noted.

to-center spacing and grid thickness to the hole diameter were varied between 0.8 to 2.5 and 0.34 to 0.86, respectively.

Figure 6 shows the energy loss per beam ion as a function of the center-to-center grid spacing. The center-to-center spacing was chosen because it allows reasonable agreement with Child's law currents (11) and with predicted values of charge-exchange ion impingement currents (12). It is seen from Fig. 6 that the eV/ion tends to increase with both grid spacing and thickness at fixed values of accelerating voltage and propellant utilization efficiency (the hole size was constant for the data of Fig. 6).

To present data concisely over a wide variety of operating conditions, the eV/ion was plotted as a function of the ratio of beam current to the Child's law current predicted by use of the center-to-center grid spacing (11). This ratio is hereafter referred to as percentage of Child's law, and for reference is given by Eq. [2]

$$\left(\frac{J_B}{J_{CH}}\right) = 2.59 \times 10^{10} \frac{J_B l_\ell^{\,2}}{A_A \Delta V_T^{3/2}} \qquad [2]$$

Figure 7 shows this variation and is typical of all data taken in that the energy lost per beam ion always rose monotonically with the percentage of Child's law.

Comparison of Fig. 5(a) and 7 show that the eV/ion is less sensitive to the propellant utilization

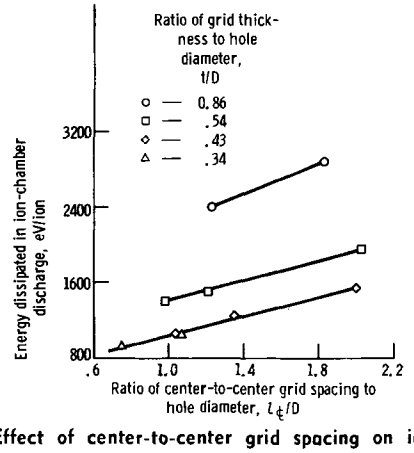

Fig. 6. Effect of center-to-center grid spacing on ion chamber performance. ΔV_I, 50v; V_I, 16 kv; J_O, 0.165 amp; η_U, 0.12; B, 17.4g; R, 0.8; D, 2.2 cm; 7-hole grid.

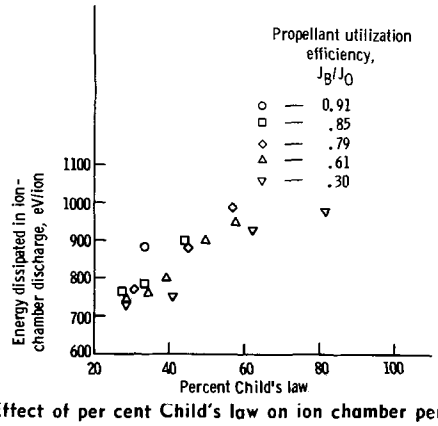

Fig. 7. Effect of per cent Child's law on ion chamber performance. ΔV_I, 50v; J_O, 0.165 amp; *B*, 17.4g; *R*, 0.8; l_t/D, 1.29 cm; *D*, 2.2 cm; *t/D*, 0.54; 37-hole grid.

efficiency when the percentage of Child's law current, rather than the net accelerating potential, is held constant. This fact is more clearly demonstrated by Fig. 8 which presents, at one grid spacing, the variation of eV/ion with propellant utilization efficiency at three values of percentage of Child's law ion current.

For the data of Fig. 8, at a fixed percentage of Child's law, an increase of propellant utilization efficiency from 0.3 to 0.9 corresponded to increases of ion beam current and net accelerating potential by factors of about 3 and 2, respectively. At a fixed propellant utilization efficiency, the net accelerating potential decreased (Eq. [1]) by a factor of about 1.4 as the percentage of Child's law current increased from 30 to 50%.

Figure 9 shows that to a good approximation the eV/ion was not a strong function of grid spacing if the accelerating voltage was adjusted to provide a constant percentage of Child's law ion current. The data of Fig. 6 (fixed net accelerating potential, 7 hole grid) indicate that the eV/ion nearly doubled as the spacing ratio increased from 0.8 to 2.0. The increase

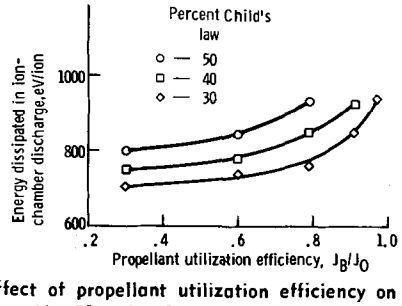

Fig. 8. Effect of propellant utilization efficiency on ion-chamber performance. ΔV_I, 50v; J_O, 0.165 amp; *B*, 17.4g; l_t/D, 1.29; *D*, 2.2 cm; *t/D*, 0.535; 37-hole grid.

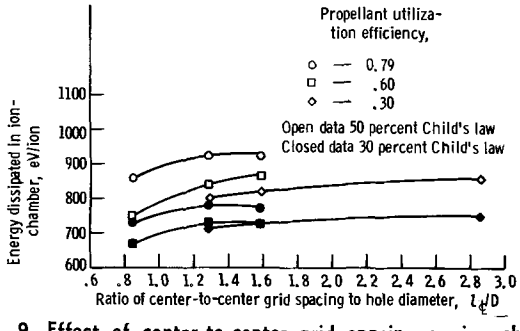

Fig. 9. Effect of center-to-center grid spacing on ion chamber performance at several values of per cent Child's law and propellant utilization efficiency. ΔV_I, 50v; J_O, 0.165; *B*, 17.4g; *R*, 0.8; *D*, 2.2 cm; *t/D*, 0.54; 37-hole grid.

in eV/ion for the same spacing ratio variation at fixed percentage of Child's law current (Fig. 9) was about 15%.

The basic energy requirement of producing a beam ion is, of course, most strongly a function of propellant type and the geometrical and electrical parameters of the ionization chamber (23). Within this framework, however, the accelerator parameters can play an important role in determining the eV/ion.

The ion extraction efficiency could be a function of either the ion sheath withdrawal area or long range extraction phenomena such as axial electric field gradients in the discharge chamber. Figures 7 and 8 of ref. (24) indicate that small changes in the percentage of Child's law can result in large variation in ion sheath withdrawal area. Reference (24) indicates, for example, that the sheath area increased by about 50% when the ion current was varied to decrease the per cent Child's law from approximately 27 to 17%. On the other hand, increased extraction efficiency is almost certain to change the plasma parameters, at least near the accelerator grids. Variation of the electron temperature, for example, could affect the ion drift velocity toward the accelerator grids (23).

A consequence of the above discussion is that the eV/ion does not decrease indefinitely with increasing net accelerating potential. For a fixed grid spacing the energy expended per beam ion will decrease with increasing acceleration voltage up to the voltage limit determined by grid-to-grid breakdown. In order to increase further the acceleration potential it is necessary to increase the grid spacing. An increase in spacing has the effect (Eq. [2]) of increasing the percentage of Child's law current represented by a given ion beam current density and net accelerating potential, and as previously seen, the eV/ion will increase. This implies a serious limitation in the attainable discharge power losses or beam current densities with simple two grid accelerators at large spacings.

Beam Current Density Measurements

The maximum beam current density of an ion source is of interest, particularly for thruster applications due to the direct influence of maximum beam current density on the maximum attainable thrust per unit area. Calculation of the grid aperture effect (11) indicated that no decrease in the maximum transmitted percentage of Child's law ion current would occur due to operation at high voltage (large spacings).

Grid spacing.—Figure 10 shows the variation of the maximum percentage of Child's law current as a function of the ratio of accelerator grid spacing to hole diameter. Data for both the 37 and 7 hole grids (sketch c) are included in Fig. 10. The maximum beam current was determined by the "knee" method of ref. (11) and can contain considerable error due to the difficulty of locating the knee exactly. Briefly, the "knee" method is the determination of the total voltage between the grids at which the impingement current begins to rise rapidly when the thruster is

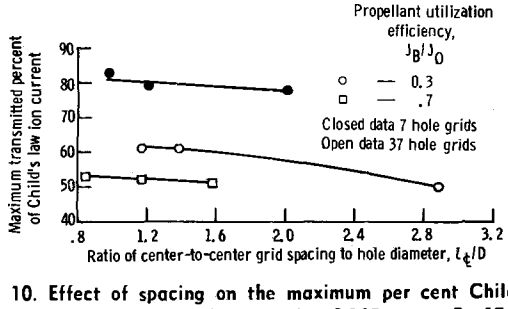

Fig. 10. Effect of spacing on the maximum per cent Child's law ion current transmitted. ΔV_I, 50v; J_O, 0.165 amp; *B*, 17.4g; *R*, 0.8; *D*, 2.2 cm; *t/D*, 0.54.

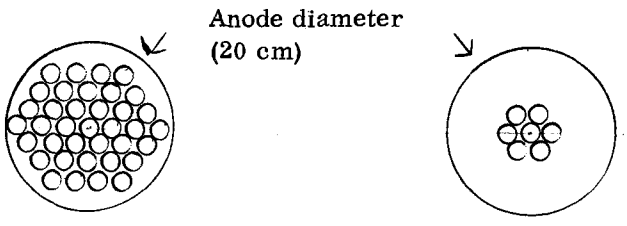
operated at a constant beam current. For a fixed spacing the Child's law ion current can be calculated for the "knee" voltage and the data of Fig. 10 is the ratio of the actual ion current at the "knee" to the calculated Child's law value.



It is seen from Fig. 10 that the value of the maximum percentage of Child's law current does not vary significantly with grid spacing for a fixed number of holes. The general levels of maximum percentage of Child's law ion currents were higher for the 7 hole than the 37 hole system. The defining diameters, within which all holes were contained, were about 7.5 and 20 cm, respectively, for the 7 and 37 hole configurations. It was found the closing the central 7 holes on the 37 hole system increased the maximum transmitted percentage of Child's law ion current for the remaining 30 holes but the maximum current from the thruster was reduced.

It is likely that there was a larger variation in the discharge ion density across the 37 hole system than the 7 hole system. The radial ion number density gradient is probably most strongly affected by the basic geometry of the discharge chamber which had a constant anode diameter for both grid configurations. The presence of a large ion density gradient thus might lead to defocusing of the central holes before the outer holes become defocused as the total thruster current approaches the Child's law current limit.

Focusing characteristics.—Tests were performed with 7-hole accelerator grids in order to evaluate the focusing characteristics over a large range of spacings and grid thicknesses. Figure 11 shows the ratio of ion impingement to ion beam current as a function of grid spacing at three values of percentage of Child's law ion current. The data were taken at fixed values of ion beam current, ratio of net to total accelerating potential, and propellant utilization efficiency.

It is seen from Fig. 11 that the variation of the impingement current with spacing is a function of both the percentage of Child's law ion current and the ratio of grid thickness to hole diameter. In general, at 30% of Child's law the impingement current decreased slightly with increasing grid thickness and was rather insensitive to the grid spacing. At 80% of Child's law ion current the impingement current is, however, a rather sensitive function of the grid geometry. The ion beam appeared to defocus at both large and small spacing for the thinner grids (data were not taken with the thickest grids at a large enough spacing for defocusing to occur). As the grid thickness increased, both the maximum and minimum spacing at which defocusing initiated increased.

The data of Fig. 11 indicate that if thruster operation at a large value of percentage of Child's law is desired, care is necessary in selection of the grid geometry in order to operate at low values of impingement current. If the thruster is to be operated at a low percentage of Child's law, the impingement will be substantially constant over a wide range of grid geometries. The lack of dependence of the impingement current upon the grid configuration at low values of per cent Child's law is probably due to the fact that in this region the ion beam becomes strongly focused into the center of the accelerator holes [see Fig. 9 and 10 of ref. (24)]. As the value of the percentage of Child's law increased, the ion beam spreads, due to sheath readjustment, and the ion focusing becomes more strongly dependent on the specific grid geometry.

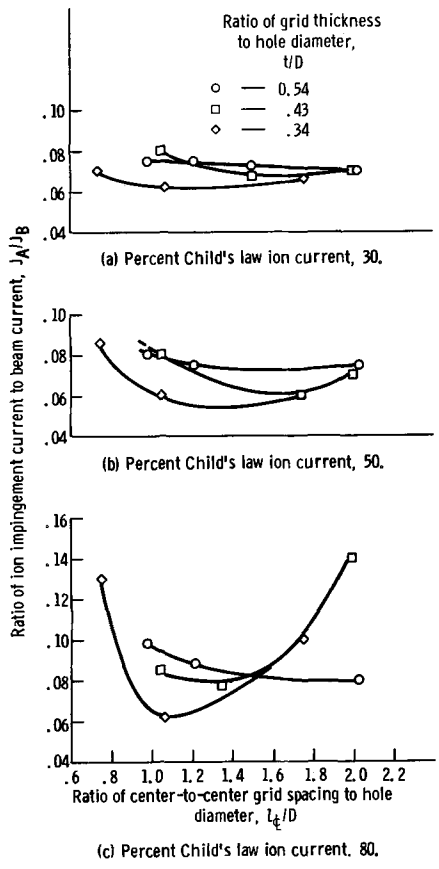


Fig. 11. Effect of grid spacing on the ratio of ion impingement current to beam current, 7-hole system; J_O, 0.165 amp; η_U, 0.12; R, 0.8.

Charge-exchange ion impingement.—In the region of good ion focusing, the value of impingement current due to charge-exchange has been calculated in ref (12). The value of the charge-exchange currents in the present investigation will differ from those of ref. (12) due to the large differences in net accelerating potential and spacings utilized. For fixed values of neutral mass flow rate, propellant utilization efficiency and open area, the values of the charge-exchange current will be considerably larger than at low voltage operation. The cross section for charge exchange does decrease somewhat with increasing voltage. Large uncertainties exist in the literature, however, regarding the exact variation, *e.g.*, ref. (25-27). For purposes of later calculation the charge-exchange cross section will be assumed to be constant at 5×10^{-15} cm^2 for the net accelerating potentials (15,000-70,000v) used in this investigation.

Figure 12 shows the variation of the ratio of impingement to beam current as a function of grid spacing. These data were taken with the 37-hole grid system with a grid thickness to hole diameter ratio of 0.54. This grid thickness ratio was selected as it allowed operation over a wide range of percentage of Child's law ion currents and accelerator grid spacings (Fig. 11). Also shown are the calculated values of the impingement to beam current ratio obtained by use of equation (B16) of ref. (12). This equation is given below with the charge-exchange cross section assumed to be 5×10^{-15} cm^2 rather than 6×10^{-15} cm^2 as in ref. (11).

$$\frac{J_A}{J_B} = 2.63\,(1-\eta_U)J_O\left[1.5\frac{l_t}{A_A}+\sqrt{\frac{\beta V_I^{3/2}A_I f(R)}{A_O^2\eta_U J_O}}\right] \quad [3]$$

It is seen from Fig. 12 that, in general, the values of ion impingement were within about a factor of 2 of those predicted from the calculated charge-exchange impingement current of ref. (12). This agreement, ap-

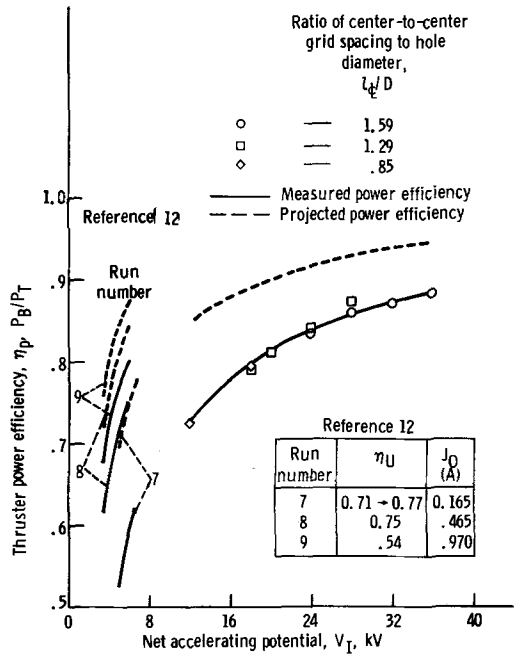

Fig. 13. Effect of net accelerating potential on thruster power efficiency ΔV_I, 50v; J_O, 0.165 amp; *B*, 17.4g; *D*, 2.2 cm; 37-hole grid; *t/D*, 0.54; *R*, 0.8; η_U, 0.8 except where otherwise noted.

proximately the same as that obtained at low voltage (12), held as long as care was taken to operate in the aforementioned region of good focusing. It is thus likely that the impingement in the good focusing region was due primarily to charge-exchange ions. The data of Fig. 11 (7-hole grid) also agreed with Eq. [3]. The higher values of impingement arose primarily because the low utilization efficiencies and reduced open area at which the 7-hole grids were operated.

Power Efficiency

One of the primary advantages of high-voltage operation is the increase to be expected in the power efficiency, or ratio of beam power to total expended power. As was previously shown (Fig. 9), the value of the energy loss per beam ion does not vary substantially over a large range of spacings so that the power efficiency can be expected to reflect directly the increasing ion beam energy.

Figure 13 shows the power efficiency as a function of the net accelerating potential for three values of accelerator spacing. Power losses in the cathode, magnet, accelerator, and ion chamber were included in these data. The power efficiency is a steadily increasing function of net accelerating potential for a fixed value of propellant utilization efficiency. Unfortunately power supply limitations did not allow data to be taken in excess of approximately 70 ma of ion beam current with net accelerating voltages in excess of 50 kv. It was found that the combination of large neutral propellant flow rates and ion beam power would result in vacuum system pressure increases which would lead to anode to ground breakdown. The upper limits were neutral flow rates of about 0.2 equivalent ampere and beam power levels of approximately 7000w at net accelerating potentials in excess of 20 kv.

The data of Fig. 13 indicate that the value of the power efficiency was greater than 0.80 at net accelerating potentials larger than 20 kv. Reduction of the eV/ion would not appreciably affect these data. Because of the small ion beam currents (imposed by Child's law considerations) these losses were always less than 150w. The use of permanent magnets and hollow cathodes (21) would reduce the power losses by about 300w or more. The cathode power of the tantalum cathodes was typically about 12% of the total thruster power; that of a hollow cathode is about 2%. The increase in power efficiency that would result from a 300w saving is shown by the projected power efficiency on Fig. 13.

Also shown on Fig. 13 are data taken at low voltage with a 20-cm-diameter thruster (12). Magnet and cathode losses of 150 and 200w, respectively, were used to determine these power efficiencies. The data selected from ref. (12) were those closest to 0.80 propellant utilization efficiency and which were available over some range of net accelerating potential. The power efficiency, at a fixed net accelerating potential, is not strongly affected by variation of the propellant utilization efficiency between about 0.60 and 0.80. A comparison between the low and high voltage power efficiencies can, therefore, be made.

The extrapolated power efficiencies at high voltage best match the data of ref. (12) when the value of the neutral flow rates were approximately equal. In general, the value of the power efficiency increased with the neutral flow rate at a fixed propellant utilization and net accelerating potential. This occurred because of fixed losses that did not vary significantly with ion beam current. The high and low voltage data, with the assumed savings of 300w, show that thruster power efficiencies in excess of 0.85 and 0.90 should be obtained at net accelerating potentials greater than about 10 and 20 kv, respectively.

Over-all Thruster Efficiency

The over-all thruster efficiency as a function of the net accelerating potential is shown in Fig. 14(a). For reference the same data is plotted as a function of specific impulse in Fig. 14(b). The projected power efficiencies from Fig. 14 were utilized in calculation of over-all efficiency. It is seen that the over-all efficiency should be greater than 0.80 for net accelerating potentials greater than 16 kv at propellant utilization efficiencies of 0.90 or larger. To achieve this over-all efficiency at lower propellant utilizations would require higher net accelerating potentials.

Data are not presented at values of propellant utilization efficiency greater than 0.91 since this was the largest value at which the thruster operated

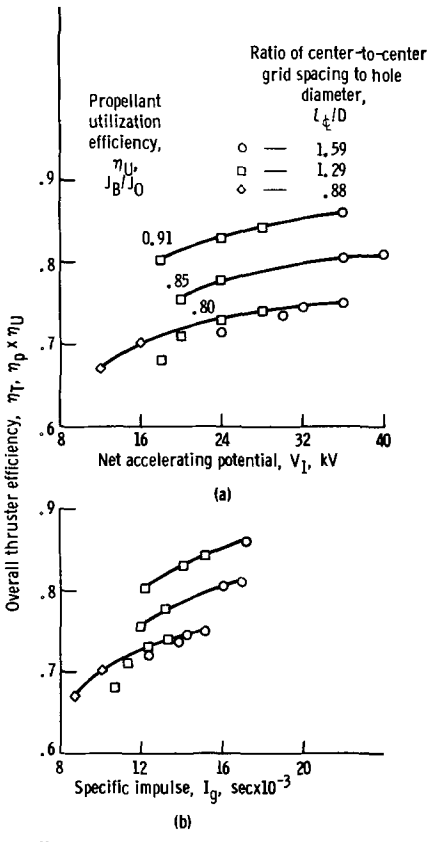

Fig. 14. Over-all thruster efficiency as a function of net accelerating potential and specific impulse. ΔV_I, 50v; J_O, 0.165 amp; B, 17.4g; D, 2.2 cm; t/D, 0.54; R, 0.8.

stably. From previous consideration it would appear that the maximum stable propellant utilization efficiency could probably be increased by decreasing the grid hole size. Because of the spacings required for high voltage (Fig. 4), however, and the fact that there exists a maximum ratio of center-to-center spacing to hole diameter [ref. (11) and Fig. 11] for good ion focusing the hole diameters could not be significantly reduced.

Concluding Remarks

It was found that the maximum supportable electric field strength between accelerator grids of operating thrusters was about 2×10^6 v/m over a large range of spacings. This field strength refers to grid-to-grid breakdowns after 2 to 20 hr conditioning.

The qualitative variations in eV/ion were found to be quite similar to that at low voltage. In addition, the eV/ion was nearly independent of the net accelerating potential and center-to-center grid spacing if the propellant utilization efficiency and per cent of Child's law current were held constant.

It was found that the ratio of center-to-center grid spacing to grid thickness should be between 2.5 and 4 to provide good ion focusing. The value of the grid thickness alone did not strongly affect the ion focusing, however, unless the beam current was in excess of approximately 50% of Child's law value.

The maximum values of ion beam current density were about 80 and 55% of the Child's law value for 7 and 37 hole grid systems, respectively. The maximum current densities were nearly independent of spacing. The accelerator impingement current, at beam current densities less than the maximum, were essentially those predicted from charge exchange interactions.

The thruster power efficiency can be expected to be in excess of 0.85 at all net accelerating potentials greater than 20,000v. The over-all thruster efficiency (the product of the power and utilization efficiencies) was limited to 0.86 in the present study because of discharge chamber stability problems and was substantially less for most conditions investigated. High current densities at high voltage probably require more complex accelerator grid systems to avoid stability problems and excessive ion chamber losses.

Electrolytic Degradation and Electrode Structure

William A. Nystrom*

Stackpole Carbon Company, St. Marys, Pennsylvania

ABSTRACT

The anode degradation of electrographitic materials was investigated in concentrated oxyacid electrolytes and in saturated brine solutions. Both light microscopy and electron microscopy were used to follow the progressive attack of the graphite surface. The rate of wear in the concentrated oxyacid electrolytes could be correlated with the relative tendency to form graphite intercalation compounds, and a number of interesting possibilities are suggested for the use of such a process. In brine solutions, it was observed that the binder materials were attacked more rapidly than were the graphitized coke particles, and the pattern of attack within the coke particles was observed to follow the original coke structure.

Graphitic materials are found in many commercial applications. Certainly one of the most important of these is the use of graphite electrodes in electrolysis cells. When used as a cathode, and barring the formation of compounds, graphite can be expected to last indefinitely. However, in chlorate and in chlor-alkali cells, graphite is used either solely or else periodically as an anode material where it is subjected to strongly oxidizing conditions. Since it is only due to the high irreversibility of the oxygen evolution process in brine solutions that chlorine can be generated, it is inevitable that some water is discharged to yield molecular oxygen and carbon dioxide at the anode. It is the formation of this latter product along with the chemical oxidation of graphite by chlorate which results in graphite electrode wear.

In this study, the anodic degradation of carbonaceous electrode materials was investigated in both brine solutions and in concentrated oxyacids. Although the behavior of electrode materials in concentrated oxyacids has been previously reported by Thiele (1), it was felt that another look at this phenomenon might yield useful information as to possible relationships between anode wear and both macro and microstructures. Also, the effect on anode wear of various mixtures of the oxyacids has not been previously reported. The experiments in brine solutions were carried out to either verify or disprove certain widely held generalizations as to the effect of microstructure on anode wear. These were (*i*) anodes consisting of a large proportion of coarse filler particles wear more slowly than do anodes which have a fine filler particle size and (*ii*) regions consisting of binder material wear faster than do the adjacent filler particles.

Experimental Procedure

Degradation in concentrated oxyacid electrolytes.—A schematic illustration of the electrolysis cell for the anodic degradation studies in concentrated oxyacids is shown in Fig. 1. This cell consisted of a 1500-cc Pyrex vat into which was fitted a cylindrical, type 302 stainless steel cathode. For the most part, cylindrical anodes measuring approximately 2 in. high by 0.5 in. in diameter were used in this study. They were positioned as indicated in the center of the cell. The effect of various oxyacids and mixtures of oxyacids on electrode wear was studied by using a special high-purity grade of extruded electrographitic rod having an ash content of less than 0.001%. As will become apparent, the results obtained for this material are to be regarded only as generalizations; changes in the specific nature of the electrode material will give rise to different rates of attack although the general features common to a given type of material are expected to remain the same.

The concentrated oxyacids investigated in this study included sulfuric acid, nitric acid, phosphoric acid, and mixtures of phosphoric and nitric acids. All of these acids were of reagent-grade quality. Test anodes were corroded at constant total current, and the electrolysis time was monitored by a stop watch. At the end of selected intervals of electrolysis time, the current was switched off, and the diameters of the test anodes were measured by a micrometer. In selected cases, photographs of the degraded samples were also taken for a record of the nature of the anodic attack. The test anodes were then placed back into the electrolysis cell and electrolyzed for the next interval of time, etc., until the point of complete destruction of the anode was achieved. The specific values of the selected interval times varied with the nature of the electrolyte and were chosen so as to obtain a reasonable number of data points for plotting the electrode diameter as a function of time.

Degradation in brine solutions.—The experimental setup for the electrolysis runs in the saturated sodium

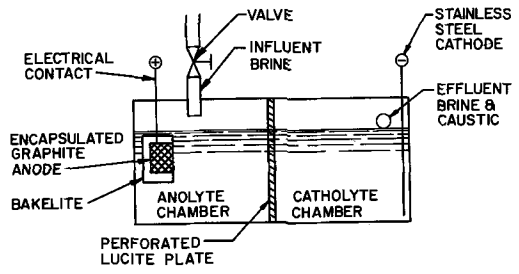

Fig. 2. Electrolysis cell for anodic corrosion in saturated brine solution.

chloride electrolyte is shown in Fig. 2. The cell consisted of a 1-l Lucite box which was subdivided by means of a perforated Lucite plate into two equal 500-cc compartments. The anode compartment, or anolyte chamber, was continuously fed fresh, saturated brine solution at the rate of 7 cc/min, thus creating a positive pressure head to prevent intermixing of the caustic produced in the catholyte chamber with the anolyte chamber brine. A vent was placed in the side of the catholyte chamber to allow the continuous removal of caustic and brine during the electrolysis run.

The graphite samples used for these experiments consisted of 0.5-in. diameter extruded rods of electrographitic materials which were encapsulated in Buehler No. 1385AB transoptic mounting powder. The surface exposed to the electrolysis consisted of the 0.5-in. diameter cross section of the extruded rod which was polished using conventional metallographic procedures to a Linde B finish (0.05μ) before commencing electrolysis. Electrical connection to the encapsulated samples was made by drilling and tapping a metal screw into intimate contact with the graphite, as is shown in Fig. 2. Stop-off lacquer was used to insulate the surface of the screw from the electrolyte.

The results found for two basic types of electrographitic electrode materials are reported herein. They consisted, respectively, of a pitch-coke, pitch-binder material and a petroleum-coke, pitch-binder material. The latter material also contained a conventional linseed oil impregnation treatment whereas the former material was tested in the untreated condition. Both of these materials are composed of relatively coarse particles of filler particles although of necessity some fines are also present. Their microstructures are representative of typical anode materials.

Reagent-grade sodium chloride and high-purity demineralized water were used to prepare the saturated brine solutions. The acidity of the influent brine was adjusted to pH 4 using reagent-grade hydrochloric acid or caustic soda as necessary. A type 302 stainless steel cathode was used in all of these experiments.

Prior to electrolysis but subsequent to polishing, a fiducial mark was scribed onto the surface of the graphite samples in order to facilitate the location of selected areas which were photographed in the as-polished condition. Each sample was then electrolyzed at 158 ma/cm^2 in the brine solution for the sequence of times of 1, 2, 4, 8, 16, and 32 hr, at the end of each specific time of which it was removed from the solution, carefully dried, and the previously selected areas were located and photographed. The samples were then placed back in the cell and electrolysis continued for the next interval of time until the desired 32 hr of electrolysis on a given sample had been realized (this gave a nominal sample wear of about 1 mil). In this manner, a sequence of photographs were prepared which illustrated the nature of the electrode wear in relation to its microstructure as a function of time. As before, deposition time was monitored by means of a stop watch. The photographs of the surface microstructure of the degraded anodes were taken at a magnification of 250X (reduced to 235X for publication) as this was adequate to discern the pattern of sample attack. All work of this nature was performed on a Bausch and Lomb metallograph.

After the photomicrographs of the 32 hr of anode electrolysis had been taken, the samples were submitted to electron microscopy in order to determine the fine-scale features of the anode wear. Two-stage replicas of the samples were prepared by replicating the degraded surfaces with Bioden RFA acetyle cellulose. Preshadowed carbon replicas of the plastic originals were then prepared using chromium as the preshadow. The resulting composites were immersed in acetone and the plastic dissolved away to give the two-stage carbon replicas. The examination of these replicas was performed on a JEM 30 electron microscope manufactured by the Japan Electron Optics Laboratory Company, Ltd.

As it was desirable to know the true magnification of the electron micrographs as well as to distinguish between hills and holes on the replicated surfaces, 0.365μ diameter latex balls were placed on the plastic first-stage replicas prior to chromium preshadowing. In the final image of the surface, those formations which show shadowing on sides opposite to the shadowed sides of the latex balls correspond to raised projections on the graphite surface. Those which show shadowing on the same side as the latex balls correspond to depressions or cracks in the corroded sample surface.

Results and Discussion

Degradation on oxyacid electrolytes.—The composition and operating conditions of the oxyacid electrolytes used in this study are given in Table I along with the value of the time interval selected for the measurements of electrode diameter as a function of electrolysis time. Table II lists the experimental data obtained from these runs, part of which was used to prepare Fig. 3, which presents the data in a graphical fashion for the phosphoric and nitric acid combinations. Also shown in Fig. 3 are the results for elec-

trolysis in nitric acid and in phosphoric acid alone. It is quite obvious from these data that the higher the ratio of nitric acid to phosphoric acid in the electrolyte, the faster is the degradation rate of our purified graphite electrodes. Also, the higher the nitric acid content of the electrolyte, the rougher the degraded electrode surface becomes. Figure 4 shows this aspect of the electrode degradation quite nicely as those samples which were degraded in electrolytes having appreciable percentages of phosphoric acid present smooth surfaces whereas the sample corroded in concentrated nitric acid is covered with a voluminous degradation product. In the latter case, if the degradation product is washed off the electrode, a core of relatively undisturbed material is found; but the point is that this operation is not required for corrosion in phosphoric acid containing electrolytes. Also, the smoothest corroded surface is found in the case of degradation in pure phosphoric acid; with the addition of higher percentages of nitric acid, there is a progressive deterioration in electrode smoothness along with the increasingly faster degradation rates. Electrolytes containing up to about one part of nitric acid to two parts of phosphoric acid give a relatively smooth degraded surface. At intermediate nitric acid contents (one part nitric acid to one part phosphoric acid), a roughening of the corroded surface is noticeable, and at high concentrations of nitric acid of from two parts of nitric acid to one part of phosphoric acid on to pure nitric acid, very rough surfaces are formed along with the voluminous corrosion products previously mentioned. The quality of surface finish obtained as a function of phosphoric acid content is also shown schematically on Fig. 3.

The theoretical explanation for the observed differences in the anodic degradation behavior of pure nitric acid and of pure phosphoric acid on graphite has been given previously by Thiele. He states, "Graphite does not swell in alkalies and in acids of the phosphoric acid group, in that these bodies do not penetrate into its structure and oxidation only occurs at the surface with the formation of humic acid

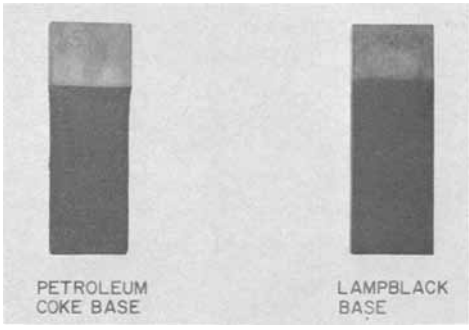

Fig. 5. Anodic corrosion of gas-baked carbons in 35% nitric acid solution. Anode C.D., 144 asf; electrolyte temperature, 25°C; time, 1 hr.

and carbon dioxide. Acids of the sulfuric acid group (including nitric acid) on the other hand, penetrate into the interior of the graphite crystal. The graphite swells, and the carbon atoms become accessible to oxidation." The explanation of the differences in degradation behavior therefore lies with the formation of graphite intercalation compounds in the case of strongly oxidizing acids such as perchloric, sulfuric, and nitric acids; weakly oxidizing acids such as phosphoric acid give only an exterior surface attack of the graphite. In this connection, it is interesting to note Fig. 5 which compares the degradation of two gas-baked carbons in nitric acid under the conditions given in Table III. One immediately notes the much more pronounced attack of the petroleum-coke base sample as compared to the lampblack-base sample. Hence, those materials which possess structures which are capable of being graphitized show a much more pronounced rate of degradation in nitric acid than do the black-base materials which can be only partially graphitized. Obviously, it is the tendency to form intercalation compounds in the case of the coke-base structure which is creating the difference here even though the usual voluminous degradation products are not present. This result suggests the use of anodic degradation in nitric acid or nitric acid-phosphoric acid combinations as a method of evaluating the potential degree of graphitizability of carbonaceous material. For example, those gas-baked materials which show the greatest degree of degradation after electrolysis for a selected period of time may be the ones which will yield the most graphitic structures upon graphitization.

In addition, the results obtained for the degradation of graphitic materials in phosphoric acid and nitric acid mixtures also suggests two more uses for this technique. The first of these is as a destructive test for electrode quality with respect to macrostructural defects such as internal cracking and lamination. Figure 6 illustrates this possibility by showing the results obtained for three different electrolysis-electrode material combinations. Sample No. 1 was a fine-grained, extruded electrographitic material which was corroded in phosphoric acid to about 75% destruction. One notes the presence of wormlike holes on the corroded surface which indicate the presence of internal cracks and gaps in this material. Sample No. 2 is the same material except corroded in concentrated nitric acid for a short period. In this instance, the presence of lamellar layers is easily noticed in the voluminous corrosion products. Indeed, on sectioning and polishing a sample of the as-received material, it was found to consist of a distinctly cored structure which was created by the extrusion process. Sample No. 3 consisted of a relatively coarse-grained,

extruded electrographitic material which did not contain either a cored structure or internal microcracks. On removal of the voluminous surface sludge formed in this case, one sees only a severely corroded surface indicating to some extent the size of the filler particles.

Another possibility for this technique lies in the potential use of these electrolytes as electrochemical machining and polishing media for carbon and graphite materials. The data of Table II and Fig. 3 indicate that one can vary the rate of wear and quality of surface finish produced by the oxyacids by suitable manipulations in electrolyte composition. In fact, these data are susceptible to the following theoretical analyses:

If we assume that the rate of wear (or decrease in volume) is a linear function of the total coulombs of electricity passed through the system, we have

$$-\Delta V = KI\,\Delta t \qquad [1]$$

where K is a constant dependent on both the electrolyte and the electrode material, I is the current, V is the electrode volume, and t is the electrolysis time. For a cylindrical anode, Eq. [1] becomes

$$-\Delta\left(\frac{\pi D^2}{4}h\right) = KI\Delta t \qquad [2]$$

where D is the electrode diameter and h is the depth of immersion of the electrode in the electrolyte. Since the depth of immersion can be treated as a constant during a given electrolysis run, integration of Eq. [2] and solving for the electrode diameter as a function of time gives

$$D_t = \left(D_o^2 - \frac{4KIt}{\pi h}\right)^{1/2} \qquad [3]$$

where D_t is the electrode diameter at time, t and D_o is the initial electrode diameter at time zero. Equation [3] indicates that we should have a parabolic decrease of the electrode diameter as a function of time until at time $t_{D_t=0}$ the electrode should be completely consumed, where $t_{D_t=0}$ is defined by

$$t_{D_t=0} = \frac{\pi h D_o}{4KI} \qquad [4]$$

Figure 3 shows that the electrode wear does indeed follow a parabolic curve for cylindrical anodes in these solutions, and Table IV lists the values of the experimental constant K and the time of corrosion for zero electrode thickness calculated from Eq. [4] and compared to the actual value obtained by the extrapolation of the data of Fig. 3 to zero electrode thickness. Also given in Table IV are the calculated K values for two electrolysis runs conducted in the same electrolyte and on the same type of electrode material but for the two different values of the total current of 5 and 10 amp. The reasonably good agreement of the K values for these two runs show that our initial assumption that the rate of electrode wear is a linear function of the total coulombs passed through the system is valid. If there were not so, K would be a function of the current density, which it is not. Hence, by first determining the value of the experimental constant K for a given combination of electrolyte and electrode material by a simple degradation test using a cylindrical anode, one can then choose those operating conditions such as current and time to produce the desired electrochemical machining for any given nominal surface area on this material. In fact, one might choose to use a combination of two separate electrolysis treatments in order to first achieve rapid electrochemical machining of the graphite part (*e.g.*, by using one part nitric acid to one part phosphoric acid) followed by a period of electrolysis in phosphoric acid alone to produce polishing of the electrochemically machined surface. The one requirement remaining to be met (as with all electrochemical machining techniques) is that one be able to achieve a uniform current distribution over those areas where machining is desired. In many cases, this can be attained by the use of thieving, stop-off procedures, and conforming counter electrodes.

Table IV. Experimental and calculated degradation parameters

Electrolyte	Current, A	Avg K, in.^{3}/amp hr	$t_{D_t=0}$/min	
			Calc	Exp
H_3PO_4	10	0.0094	314	296
2 Pt H_3PO_4 1 Pt HNO_3	10	0.021	141	149
2 Pt H_3PO_4 1 Pt HNO_3	5	0.023	257	265
1 Pt H_3PO_4 1 Pt HNO_3	10	0.047	63	64
HNO_3	10	0.130	23	23

Although the specific use of sulfuric acid has not been previously mentioned save for references to its effects by Theile, it should be obvious from the data of Table II that sulfuric acid could be substituted for nitric acid to produce the same effects described above. In fact, sulfuric acid containing electrolytes may well give a better surface finish than that found for the comparable nitric acid-phosphoric acid mixtures owing to its more syrupy nature [see, for example, the general theory of electropolishing as given by Tegert (2)]. Also, no use was made of perchloric acid additions to replace the nitric acid owing to the explosive hazards which present themselves when one uses this acid in the presence of organic materials.

Degradation in brine solutions.—The composition and operating conditions of the brine electrolyte are given in Table V. Photomicrographs of the anodic wear produced under these conditions of a typical oil impregnated, pitch bonded, petroleum-coke base electrographitic material are shown in Fig. 7 to 13. Figure 7 is a photograph of the sample in the as-polished condition prior to electrolysis. A number of relatively large coke particles as well as a considerable number of dark black pores of varying sizes are present in this area of the sample. Also, a number of light gray, structureless areas are present in this photomicrograph which indicates pores which have been successfully impregnated with the conventional linseed oil treatment. With increasing electrolysis time of this material in the pH 4 brine solution, a progressive deterioration of the sample occurs with the most rapid attack being noted at the boundaries of the graphitized coke particles. In fact, after 32 hr of electrolysis, the original coke particles are seen to be standing in relief over the sample surface as is shown by Fig. 13. These results obviously suggest that

it is indeed the binder material which constitutes the weak link in conventional electrode materials. Furthermore, comparison of area A of Fig. 7 with the same area of Fig. 4 reveals that a rather large filler particle has become detached from the electrode between 2 and 4 hr of electrolysis. This obviously points out that, if the filler particles are poorly bonded together, rapid detachment of them from the electrode surface will occur with attendant rapid electrode wear. Also, area B of Fig. 7 is seen to consist of a relatively large number of fine particles of filler particles bonded together. Since finer particles have a larger surface area per unit weight than do coarse particles, they require more binder material on a weight per cent basis to glue them together in the electrode. Hence, this area contains a high proportion of graphitized pitch binder to petroleum-coke filler particles on a unit of surface area basis, and it should therefore have a higher wear rate than the surrounding electrode areas in light of the foregoing observations. That this is indeed the case is borne out by Fig. 13, which shows area B after 32 hr of electrolysis. Obviously, more electrode wear has occurred in this fine-grained area than has occurred over the relatively coarse-grained areas as is shown by the presence in area B of many deeply corroded fissures. This fact probably explains why, as a rule, relatively fine-grained electrodes give poorer performance as evidenced by higher wear rates than do those electrodes prepared from coarser filler particles distribution. It is also interesting to note that the graphitized coke particles are attacked in such a way as to reveal the original lamellar coke structure. This is either due to the presence of microcracks within the coke particle, or more likely, the resistance to electrochemical oxidation of the coke varies in a lamellar fashion with its structure.

For the longer times of electrolysis such as 16 and 32 hr, Fig. 12 and 13 indicate that some pore enlargement has already occurred (compare, for example, area C on these photomicrographs with area C on Fig. 7). This enlargement appears to be due to the wear of binder materials which allows the surrounding filler particles to drop out of the electrode. This results in a progressive enlargening of the pores and permits internal electrolysis and chemical wear of the anode to occur. Of course, the function of conventional oil impregnations of diaphragm cell anodes is to minimize just such internal attack, but the efficacy of the treatment will obviously depend on how many and how well filled are the pores.

As it was observed above that areas of the electrode which represented binder material or probable high binder material concentrations were wearing at a faster rate than the surrounding filler material, it was decided to anodically degrade a pitch-bonded, pitch-coke base electrographitic material having the same approximate particle size distribution as the petroleum-coke based samples. The photomicrographs of this study are shown as Fig. 14 through 20, where Fig. 14 shows the as-polished surface of this material. Although this material is obviously wearing away

progressively with time, as all carbon and graphite materials will do under these conditions, its degraded surface presents a rather nondescript appearance consisting of a wavy pattern of corroded channels uniformly distributed over the sample surface. Save for a few local areas such as area D where there was obviously a poor bond developed between adjacent agglomerates of particles, the sharp delineation of

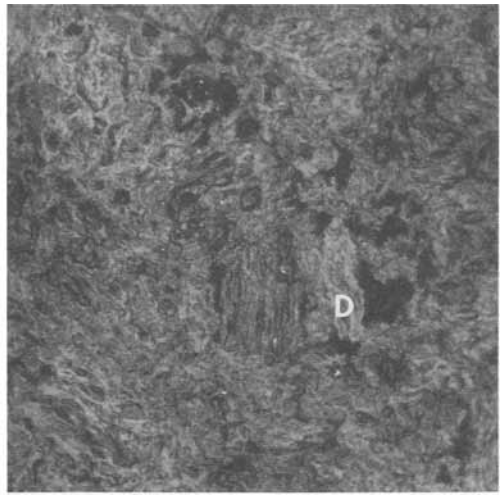

Fig. 20. Thirty-two hours of electrolysis on the pitch-bonded, pitch-coke electrographite. Magnification 235X.

the filler particles as observed for the petroleum-coke whose sample is absent here. Rather, a relatively uniform over-all pattern of wear is observed. This observation agrees well with the previously mentioned fact that the pitch-binder areas wear faster than the petroleum-coke areas inasmuch as in this material all areas should represent graphitized pitch-coke and should therefore be wearing uniformly. Such is indeed the case. Unfortunately, the over-all wear rate of this material is substantially greater than that observed for the pitch-bonded petroleum-coke base material previously examined. This was to be expected, however, as all components of this electrode are now wearing at the much higher rate of graphitized pitch coke rather than at the lower wear rate of graphitized petroleum-coke.

The nature of the really fine-scale attack of the graphitized coke particles is shown in Fig. 21, which is an electron micrograph of the anode surface of the petroleum-coke base sample after 32 hr of electrolysis. It is seen that the fine-scale pattern of wear consists of the formation of small "islands" of material surrounded by corroded channels. Such a pattern of attack is reminiscent of intergranular attack in fine-grained metals. As the size of the observed "islands" of graphitic material is of the same order of magnitude as the expected graphitic crystallite size (*e.g.*, 0.1μ), it may well be that something of a similar nature is occurring here, with the less organized material between the graphite crystallites being more susceptible

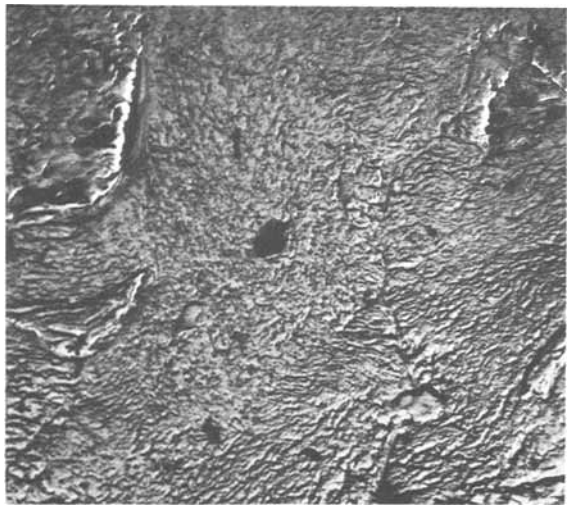

Fig. 21. Electron micrograph of the pitch-bonded, petroleum-coke base sample after 32 hr of electrolysis showing the intersection of a number of particles and the nature of the fine-scale wear of the electrode. Magnification ca. 4200X.

to electrolytic oxidation. This suggests a possible fruitful area for further research efforts in the future.

In view of the fact that air oxidation studies have shown that the pitch-binder areas of pitch-bonded samples are oxidized away more readily than the filler particles, the use of static air oxidation tests to evaluate potential electrode material ingredients as to their resistance to oxidation might be a possibility. Unfortunately, in this respect however, the supply of available electrode materials is limited from both a cost and a material standpoint and is of questionable reproducibility from shipment to shipment. Therefore, further improvement in anode quality will probably depend to a large extent on how well the existing technology can continue to use the known processes of fabrication and the available materials to make a more sound and defect-free anode with respect to such macrofactors as internal cracking, separations and laminations, and the uniformity of and the quality of various impregnation treatments.

Summary and Conclusions

The anodic degradation of graphitic materials was investigated in both concentrated oxyacid electrolytes and in brine solutions. From the oxyacid studies it was seen that:

(*A*) The relative resistance to anodic degradation in a given oxyacid is governed by the presence or absence of a graphite or graphitizable structure in conjunction with the relative tendency of the oxyacid to form a graphite intercalation compound. A possible use of this technique would therefore be to correlate the degree of graphitizability of a material with its rate of degradation in an intercalation compound forming concentrated oxyacid solution. Materials having a high degree of graphitization may degrade more rapidly than those whose degree of graphitizability is lower.

(*B*) The possibility of using mixtures of oxyacids to machine and polish carbon and graphite materials electrochemically is a good one. In particular it was seen that if an empirical constant, which relates electrode wear to current density and which contains both electrolyte and electrode material factors, is first evaluated by a simply cylindrical anode degradation test, it ought to be possible to choose those solutions which will give the desired machining rate and surface finish on a working part of any desired shape. This is, of course, subject to the provision that conforming cathodes or the judicious use of stop-off lacquer is used to bring about a uniform, nominal current density over the corroding surface.

From the studies in brine solutions it was seen that:

(*A*) The areas between the graphitized coke particles, which presumably represent graphitized pitch-binder materials, wear slightly faster than the surrounding material. As a result, any poorly bonded particles are quickly detached from the electrode and represent economic loss to the users of graphite electrodes.

(*B*) The graphitized coke particles are attacked in such a way as to reveal the original lamellar coke structure. This may be caused by either microcracking or by lamellar variations in the resistance to electrochemical oxidation of the coke particle.

(*C*) For the longer times of electrolysis, some pore enlargement was noted in unimpregnated materials or around those pores which were not adequately impregnated to start with. This enlargement appears to be due to wear of the binder materials which allows particles to drop out of the electrode. With time, this results in a progressive enlargening of the pores and permits internal electrolysis of the anode to occur.

(*D*) A fine-scale attack within the graphitized coke particles was also observed by electron microscopy. It consisted of the formation of small islands of material surrounded by corroded channels. Such a pattern of attack is reminiscent of intergranular attack in fine-grained metals. Indeed, the size of the observed islands of resistant material is of the same order of magnitude as the expected graphite crystallite size which suggests that something of a similar nature is occurring here.

pH Changes at Anion Selective Membranes under Realistic Flow Conditions

ABSTRACT

The flow conditions and solution concentrations used in the investigation were similar to those present in practical electrodialysis cells. The concentration of hydroxyl ions which appeared on the receiving side of the polarizing anion selective membrane was measured as a function of current density. The important finding was the large effect traces of dissolved organic matter in the feed water had on the onset and concentration of alkali produced in the receiving stream. For unpoisoned membranes an i_o/c value of 4000 amp cm equiv^{-1} was obtained. This is an order of magnitude greater than reported in previous studies.

Multicompartment electrodialysis depends on the principle that the transference number of the counterion in an ion-selective membrane is greater than the transference number of the same ion in the surrounding solution (1). Thus for the layer of solution adjacent to the membrane on the donating side (2) there is for each ion an inequality in electrical migration and counterions are removed through the membrane at a greater rate than they are replaced from the bulk solution. Continuity of counterion migration is maintained by convective and diffusive transport from the bulk solution. As the membrane surface is approached the contribution due to convective transport decreases.

It is customary to simplify the real situation (3, 4) by postulating a layer of thickness δ (cm) adjacent to the membrane in which convective transport normal to the membrane is zero. By assuming a smooth flat membrane surface and a homogeneous current distribution it is then possible to describe the steady state for a single electrolyte by the following equation.

$$\frac{i(\bar{t}-t)}{\mathbf{F}} = \frac{D(c-c')}{\delta} \qquad [1]$$

where i is the current density (amp cm^{-2}), $\bar{t}$ and t are the counterion transference numbers in the membrane and solution, respectively, **F** is the faraday, D the diffusion coefficient of the electrolyte in the external solution (cm^2 sec^{-1}), and c and c′ are the concentrations of electrolyte in solution in the bulk and at the membrane interface, respectively, (g equiv cm^{-3}). c′ is less than c. (The situation on the receiving side is described by transposing c and c′, and c′ is greater than c).

The maximum inequality in electrical migration that can be balanced by diffusive transport is obtained when the solution concentration at the membrane interface is zero ($c' = 0$). From Eq. [1] the critical current density i_c at this condition is

$$i_c = \frac{DC\mathbf{F}}{(\bar{t}-t)\delta} \qquad [2]$$

At current densities higher than i_c additional current carriers are necessary. These are hydroxyl ions through anion-selective membranes and hydrogen ions through cation-selective membranes (5, 6). While this appears true for anion-selective membranes (7, 8) the amount of hydrogen ion transport through cation-selective membranes above the critical current density is much less than expected, and additional transport mechanisms have had to be invoked (7-11). This behavior with cation-selective membranes is not fully understood, but need not concern us further as the situation at the anion-selective membrane has proved to be of much greater importance in practical electrodialysis. A refinement is that the transport of hydroxyl ions through anion-selective membranes should commence not when the conditions are such that the interfacial concentration has fallen to zero but at a current density slightly lower than the critical value of Eq. [2] when the interfacial concentration is sufficiently small for the natural hydroxyl ion concentration of the donating solution to be competitive as an alternative migratory species (5, 6, 12).

In the vicinity of and above the critical current density the effects described give rise in practical electrodialysis units to (*i*) increased ohmic resistance due to layers of reduced concentration on the donating sides of membranes, (*ii*) increased counter concentration potentials across the membranes, (*iii*) reduced coulombic separation efficiencies, and (*iv*) transport of hydroxyl ions through the anion-selective membranes to make the receiving stream alkaline (12). Of these effects (*iv*) has the most serious repercussions (12, 13) as it results in the precipitation of hydroxides and carbonates of the alkaline earth metals which are present in most natural waters.

It is mandatory that electrodialysis units be operated below the critical current density. This is an important limitation since economically, current densities higher than the accepted critical values are desirable (13-16). Although suitable programming of electrodialysis operation (17) can reduce the economic effect of this limitation, the onset of hydroxyl ion transport through anion-selective membranes at the critical current density is probably the most serious restriction to electrodialysis at the present time (18).

All the effects (*i*)-(*iv*) above have been used to study polarization phenomena. Cooke (7, 8) and Cooke and van der Walt (19) have demonstrated the advantages of the concentration potential method whereby actual interfacial concentrations are deduced. The method is most useful at current densities less than the critical value. Unfortunately the theoretical basis is less convincing in the vicinity of the critical current density when the potential due to different interfacial electrolyte concentrations may be complicated by pH values which also differ on the two sides of the membrane. Voltage-current or voltage-time plots to indicate an increased ohmic resistance and an in-

Key words: Anion-selective membranes, concentration polarization, desalination, electrodialysis, limiting current density, multicompartment cells, organic poisoning.

creased counter concentration potential under critical conditions (9, 20-24) have the merit of simplicity. A small yet damaging transport of hydroxyl ions at current densities less than the main critical value could, however, be undetected by the voltage method. Cooke and van der Walt have mentioned this possibility (19), and in practical units such conditions could also arise from nonuniform flow distribution, inhomogeneous membranes (25), and nonuniform current distribution. Cooke (26) has improved the sensitivity of the method, without entirely removing the objections, by the use of overpotential which is obtained by subtracting an extrapolated estimate of the voltage of a hypothetical unpolarized condition from the voltage of the real polarized condition. The expected decrease in coulombic efficiency has been observed above the critical current density (5, 6, 27, 28) but is not sufficiently sensitive to be useful. The measurement of *p*H changes, (5, 6, 11, 21) particularly of alkalinity on the receiving side of the membrane utilizes the most serious effect of polarization and is, therefore, the most direct method. Cooke has criticized the *p*H method (7), but his arguments apply only to cation-selective membranes with their low hydrogen ion transport above the critical current density. The measurement of alkalinity on the receiving side of the membrane has been preferred in this work.

While systems stirred mechanically (11, 19) and by natural convection (5, 7, 8, 11, 21, 23, 26) have provided valuable insight into the polarization phenomena, the uncertainties in extrapolating to practical systems are too great for these results to be of real value to the designer. Flowing systems must be used (6, 9, 19, 20, 22, 24, 28) under hydrodynamic conditions which approximate as closely as possible to those present in practical units (24). Data from flowing systems of small exposed membrane area, *e.g.*, 0.64 cm^2 (19), where the entry and exit conditions to the compartment may have a disproportionate influence on the hydrodynamic conditions within the compartment, must be regarded with caution. Block (25) has demonstrated the heterogeneity of many commercial membranes, and Solt (29) and Cooke (26) have reported particular examples. It is, therefore, important that the scale of scrutiny should be appropriate. From the design viewpoint this is a further argument against the use of very small areas of membrane. For flowing systems it is also desirable to provide information on flow distribution so that one can ascertain that the noted effects are not seriously complicated by stagnant regions within the compartment. The value of F-diagrams (30, 31) in this respect does not appear to have been appreciated.

The present work formed part of a design study, and everything possible was done to ensure that conditions were similar to those that would be present in the actual stack. Compartment dimensions, compartment filling, linear flow rate, and exit and entry arrangements were identical. It was not practical in the laboratory to carry out very prolonged runs, and we compromised by following the *p*H of the receiving solution for 3 hr. Our important findings are consequent on the continuation of runs for this period. No information is given on the duration of runs in previous studies (6, 19, 20, 22, 24). Theoretically (Eq. [2]) and experimentally (11, 17) the critical current density is directly related to the donating-side concentration. Thus the polarization limitation is first apparent at the most dilute donating concentration in the unit, *i.e.*, the effluent concentration of the dialysate stream. This study was therefore carried out with a donating concentration equivalent to the planned concentration of the dialysate effluent.

Experimental

The membrane and flow arrangement is shown in Fig. 1. The anion-selective membrane whose polarization was under examination was at position 3. The

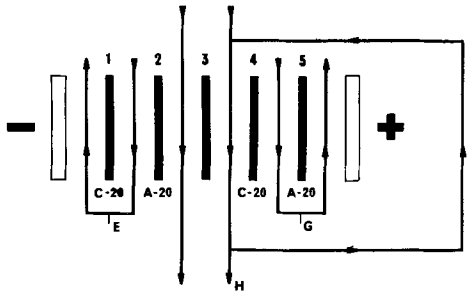

Fig. 1. Membrane and flow arrangement

donating and receiving solutions for this membrane flowed through compartments 2-3 and 3-4, respectively.

Membranes.—Two membranes were used in position 3, Permaplex A-20 (The Permutit Company Ltd.) and T.N.O. C-60 (Nederlandse Centrale Organisatie voor toegepast—Natuurwetenschappelijk Onderzoek). Permaplex A-20 and C-20 membranes were used in positions 1, 2, 4, and 5.

Permaplex A-20 is of the heterogeneous type and consists of a finely divided conventional anion exchange resin imbedded in an inert polyethylene binder with an inert reinforcing fabric of fine open mesh pressed against each face (32). The basic membrane has been described (5), and the influence of the reinforcing fabric is similar to that already noted for the cation-selective type (33).

The homogeneous membrane T.N.O. (34, 35) A-60 is based on a polyethylene film in which styrene and a few per cent of divinyl benzene have been polymerized. Quarternary ammonium groups are introduced on the aromatic nuclei by established procedures. In regard to the homogeneity, the comments of Block (25) and Cooke (26) are noteworthy.

Cell design.—Each compartment was bounded by two membranes (or a membrane and an electrode) and a Klingerit gasket 0.127 cm thick. The plan of the gasket for compartment 2-3 is shown in Fig. 2. The central square area is 27 x 27 cm. Rectangular holes A registered with similar holes in other components of the stack to form the supply conduits to the compartment. Similarly holes B formed part of the withdrawal conduits.

Flow between conduits and the compartment was via inserts C (36). The inserts were 0.127 cm thick, to correspond with gasket thickness, and were made from rigid epoxy resin. A series of small circular tunnels, 0.051 cm diameter, on the thickness center-line and spaced with centers 0.127 cm apart formed the connecting passages. Experience has shown that these inserts prevent intercompartmental solution leakage which is a serious problem in other stack designs (37).

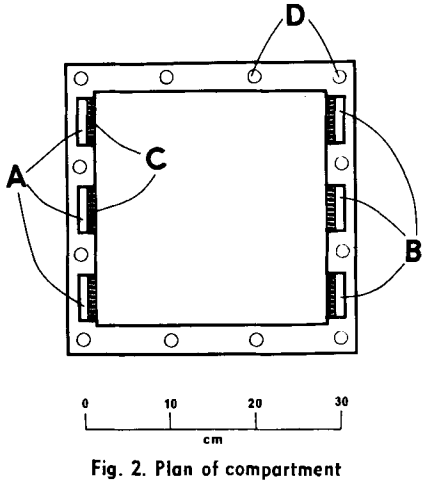

Fig. 2. Plan of compartment

The solution thus entered substantially all along one edge of the compartment and left by exits substantially all along the opposite edge (38). Such an arrangement encouraged uniform liquid distribution. Good distribution was further aided by a close fitting filling of a corrugated perforated sheet of polyvinyl chloride (39, 40) which was orientated so that flow resistance was greater in the forward than in the sideways direction (40), *i.e.*, with the corrugations normal to the direction of flow. This orientation promotes turbulent flow (24), thus reducing δ and increasing the critical current density (Eq. [2]). The polyvinyl chloride sheet was 0.025 cm thick and perforated with holes of diameter 0.23 cm to give an open area of 44.5%. The amplitude and wave length of the corrugations was 0.064 cm and 0.43 cm, respectively. A slightly higher pressure was maintained in the compartments on either side of compartment 2-3 so that the membranes conformed to the corrugated filling thereby ensuring a uniform 0.127 cm thickness throughout compartment 2-3.

The gasket for compartment 3-4 was similar except that solution now flowed between the other two edges, *i.e.*, at 90° to the flow in compartment 2-3. The filling was also turned through 90° to maintain the corrugations normal to the direction of flow. The remaining compartments were similar. Each end assembly consisted of an impregnated carbon electrode in a rigid polyvinyl chloride mounting, and a steel backing plate. The whole was held together by suitably insulated nuts and 1.27 cm diameter threaded rods, which passed through holes D.

To establish hydrodynamic suitability of the compartment design, additional experiments were made to obtain an F-diagram (30) and a log (pressure loss)-log (flow rate) plot (24).

Operating conditions.—The feed to compartment 2-3 was 0.01N NaCl. This compartment was bounded by two anion-selective membranes to avoid bulk concentration changes which complicate the interpretation of polarization data (6). The feed to compartments 1-2, 3-4, and 4-5 was 0.2*N* NaCl.

The flow rate in compartment 2-3 was 1500 cm^3 min^{-1} (7.3 cm sec^{-1}). The flow rate in compartment 3-4 was 1000 cm^3 min^{-1} and the feed-and-bleed rate 100 cm^3 min^{-1}.

The transport of hydroxyl ions to compartment 3-4 was measured by monitoring *p*H at position H. The *p*H was also monitored at positions E and G to ensure that the effects noted at H were not complicated by the *p*H changes which occurred in the electrode compartments. A series of current densities was used and at each the run duration was 3 hr. In this time 270 liters of solution passed through compartment 2-3. Unless stated otherwise hydroxyl ion transference numbers were calculated from measurements made at the finish of the 3-hr runs.

Room temperature was used for all runs. There are claims that critical current density is not very dependent on temperature (11, 41).

Power supply was single phase, 50 cycles sec^{-1} with full wave rectification unless otherwise noted.

Some experiments were also carried out in a smaller cell (exposed area 10 x 10 cm). General design principles, gasket thickness, and linear flow rates were identical with those used in the larger cell. There was no significant difference between the results obtained with the two cells.

Concentration of organic matter.—During the program it became necessary to assess the amount of organic matter in the solutions fed to the electrodialysis cell. The standard procedure of measuring the oxygen absorbed by the solutions from acid permanganate under precisely specified conditions was adopted. We used 4 hr at 27°C (42) which is one of several conditions that are standard practice. The results depend on the oxidation conditions chosen and the various procedures are, therefore, not directly comparable. The concentration of organic matter is obtained in terms of oxygen absorbed (O.A.) from permanganate and is expressed throughout this work as ppm O.A. Unpublished work at the Permutit Laboratories has shown that an approximate weight concentration for the organic matter present in these studies may be calculated by mutliplying ppm O.A. by three.

The chemical method is time consuming, and it was frequently more convenient to use an optical method (43) in which the optical density of a solution is compared with that of triply distilled water at a wavelength of 3000Å. Silica cells 10 cm in length were necessary for the required sensitivity. For the organic matter present in these studies, optical absorbency is related to chemically determined concentrations by the following equation

$$\frac{30 \times \text{optical density}}{\text{optical path length (cm)}} = \text{ppm O.A.}$$

Results and Discussion

Hydrodynamic considerations.—Consider liquid A flowing through a vessel and suppose at some instant a property of the liquid, *e.g.*, color, concentration, etc., is changed so that from this instant a second liquid, B, enters the vessel. A plot from this instant of the fraction of the new liquid B in the effluent against the ratio, effluent volume/vessel volume, is an F-diagram (30). Holdback, which may be determined from the F-diagram, is the fraction of liquid A that is in the vessel after a volume of liquid B equal to the volume of the vessel has entered the vessel (30). If perfect piston flow exists in the vessel, holdback is zero. If flow is confined to a narrow channel with a large proportion of the liquid in the vessel stagnant, then holdback approaches unity. Holdback for our compartment design was 0.05. With Newtonian fluids perfect piston flow is not possible due to the viscous drag of the walls of the vessel and in our case also of the compartment filling. A value of 0.05 for the holdback indicates very good flow distribution and a close approach to perfect piston flow.

The change in the log (pressure loss) *vs.* log (flow rate) plot from unit slope to a higher value occurred at a linear flow rate of 2.2 cm sec^{-1}. (Linear flow rates are not corrected for compartment filling.) This is in general agreement with Wilson's reported slope change at 4.4 cm sec^{-1} with a similar filling and identical filling orientation (24). His compartment was thinner so the higher figure is to be expected. In compartment 3-4 the flow rate was 7.3 cm sec^{-1}, which is above the point of slope change, and we conclude that the flow in our work was of turbulent type. Seko (44) has deduced from the value of the slope that flow is of turbulent type in Asahi's design of compartment in the same region of linear flow rates. [Although Seko (44) cites 1.51 for the slope, the plot given has a value of only 1.26.]

Polarization experiments.—Permaplex A-20 was studied first. Initial results were puzzling in that the amount of alkali found in the receiving stream under apparently identical conditions was quite irreproducible. Further, although a steady state should be attained fairly quickly the *p*H of the receiving stream in polarizing runs, *i.e.*, those in which there was hydroxyl ion transference, drifted upward and had not reached a steady value after 3 hr or even, when runs were extended, after 6 hr.

Our first constructive results were obtained from a cyclic series of runs in which current density was increased and then decreased in successive steps. Hydroxyl ion transport, shown in Fig. 3, exhibited hysteresis. The hydroxyl ion transference number when current density was decreasing was much higher than had previously been obtained when current density was increased.

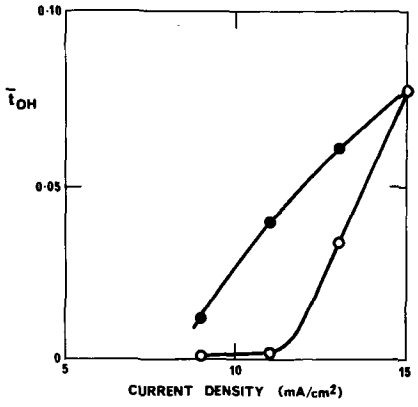

Fig. 3. Hydroxyl ion transference number vs. current density, Permaplex A-20. ○ after increase in current density, ● after decrease in current density.

These results might be explained by an accumulation of hydroxyl ions within the membrane. Thus during the run at 15 ma cm^{-2} hydroxyl ions accumulated, and the subsequent gradual release of these from the membrane when current density was decreased caused the hydroxyl ion transference number to be higher than the values obtained on the increasing part of the cycle. To check this suggestion the effect of prior conversion of the membrane to the hydroxyl form by immersion in alkali was investigated. Figure 4 shows that hydroxyl ions initially present were cleared from the membrane in 90 min at 4 ma cm^{-2} and in 60 min at 7 ma cm^{-2}. Thus at the higher current densities used in the cyclic series, 9-15 ma cm^{-2}, one would expect any hydroxyl ion content present at the start of a run to be cleared from the system after about 40 min. Certainly no effect on measurements taken after 3 hr would be expected. Further evidence against this suggestion was obtained by suddenly dropping the current density to 5 ma cm^2 during a run on the decreasing part of the cycle whereupon the hydroxyl ion transference number fell to zero.

For the work described so far demineralized water was used to prepare the sodium chloride solutions. The anion-exchange resin in the unit was weakly basic and of a type which removed very little of the organic matter in the supply water (Metropolitan Water Board, London). During the investigation the organic content of the M.W.B. supply water varied between 0.7 and 1.5 ppm O.A., and most of this passed into the electrodialysis cell. The affinity of the organic matter in supply waters for strongly basic anion-exchange resins and the accompanying fouling problems are well known (45, 46). The functional groups in Permaplex A-20 and in most anion-selective membranes are strongly basic. Accumulation of organic matter by the membrane would thus be expected and might result in a gradually increasing polarization tendency. Hysteresis could be explained in these terms.

For the next stage of the work the sodium chloride solutions were prepared with M.W.B. water that had been demineralized by mixed bed ion exchange with a strongly basic anion-exchange resin. The solutions were further treated by passage through trap columns (4 in. diameter x 18 in.) of De-Acidite FF (The Permutit Company Ltd.) in the chloride form immediately before entering the electrodialysis cell. By this means the organic matter in the solutions fed to the cell was reduced more than tenfold to 0.06 ppm O.A. With these conditions the upward drift of pH with time was rectified except in the sensitive region between pH 6 and 8 (Fig. 5). pH was constant for at least the final hour. Figure 6 shows that hysteresis had also disappeared. This demonstrates that our earlier difficulties were the result of organic matter in the influent solution accumulating on the anion-selective membrane. The only previous workers to report a reversibility or hysteresis examination are Cowan and Brown (20) and they noted irreversibility. Since they used a flowing system and treated municipal water to prepare their solutions it is possible that organic matter may have been the responsible factor in this case also.

Figure 6 clearly shows there is no sharp onset of hydroxyl ion transport with either of the membranes examined but a gradually accelerating increase in transference number. Similarly Cooke and van der Walt (19) found no sharp change in interfacial concentration at a particular current density in flowing systems although this was observed under naturally convective conditions (7, 8). The compartment filling presumably causes local variations in linear flow rate, film thickness δ and current density which could blur the effects of criticality. However Cooke and van der Walt (19) have indicated there was no sharp change in interfacial concentration even in the absence of compartment filling. Poor flow distribution on a macroscopic scale could account for the interfacial concentration results (19), but is unlikely in the present

work in view of the holdback of only 0.05. Cooke (26) favors an explanation in terms of a variation in δ on the membrane surface. A much smaller variation in δ would be expected in a naturally convective system (26), and hence the criticality observed in this case (7, 8) is explained. Absence of sharp changes could also be explained by nonuniform current distribution due to membrane heterogeneity on a macroscopic (25, 26, 29) or microscopic scale. The latter could result from partial poisoning of the membrane. The absence of sharp changes in flowing systems emphasizes the dangers of using methods dependent on such effects. The rapidity of change is unimportant in the pH method, and in principle the amount of acid required to maintain any desired pH in the receiving stream is directly calculable from data such as is shown in Fig. 6.

Mention has been made in the literature of effects due to periodic changes in current (47, 48). It seemed desirable to ascertain whether the periodicity of current that results from full wave rectification of single phase a.c. was affecting our data. A few experiments were therefore carried out with full wave rectification of three phase a.c., where the amplitude of the ripple is much less, and with a battery source. Figure 6 indicates that there was no significant difference in the hydroxyl ion transference number with the three types of power supply.

Although the T.N.O. A-60 membrane used for the data in Fig. 6 was new, the Permaplex A-20 membrane had previously been in contact for three runs with solutions which had not been subjected to precautions to reduce organic matter. Further runs were therefore made with a series of new Permaplex A-20 membranes using solutions in which the organic matter had been reduced to 0.06 ppm O.A. The surprising result was that under these conditions the critical region was much higher at 35-40 ma/cm². Furthermore the phenomenon of an upward pH drift reappeared and steady values were not obtained within the period of the runs. The difference between the two conditions is illustrated in Fig. 7. For the first 150 min of operation, at least, hydroxyl ion transport through a new membrane at 45 ma/cm² was less than that through the used membrane at 12 ma/cm². A steady pH was reached with the used membrane after 80 min, but such was not achieved after 150 min with the new membrane.

The following points have now emerged. The critical current density region of new unpoisoned Permaplex A-20 membrane under our specified flow conditions is much higher than might be suspected from the literature. The critical region is, however, very sensitive to the condition of the membrane in that even an influent with as little organic matter as 0.06 ppm O.A. caused steady deterioration during the short time of a run. Further a few hours running with an influent containing 0.7-1.5 ppm O.A. which is by no means an excessive level, *i.e.*, the condition of the used membrane, reduces the critical current density approximately fourfold. The apparently steady, reproducible and reversible conditions obtaining for the data on Permaplex A-20 in Fig. 6 must have occurred because the amount of organic matter accumulated by the membrane during the runs was small relative to the amount already on the membrane at the start of this series.

Further work served to confirm the above interpretation. Runs were carried out in which current density was varied so as to maintain a constant concentration of alkali in the receiving stream. A new membrane was used for each run. Figure 8 shows that a much faster reduction of current density was necessary when the organic matter in the influent solution was 0.7-1.5 ppm O.A. than when it was 0.06 ppm O.A. However, even with an influent containing only 0.06 ppm O.A. of organic matter a fairly rapid reduction in current density was necessary. Obviously it was de-

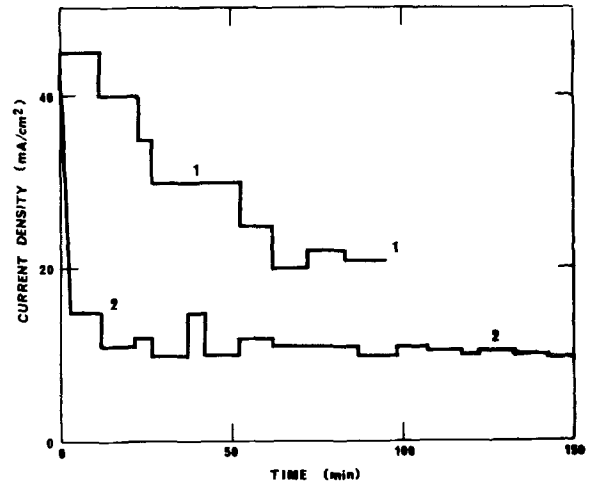

Fig. 8. Current density vs. time, receiving stream alkalinity 0.0027*N*, new Permaplex A-20. 1, organic matter 0.06 ppm O.A.; 2, organic matter 0.7-1.5 ppm O.A.

sirable to show that no reduction in current density was required when organic matter was completely absent from the influent solutions. In spite of considerable effort we were unable to produce solutions of this purity on the scale required. By the use of activated carbon (Chlorosorb, British Carbo Norit Union) columns (4 in. diameter x 18 in.) after the DeAcidite FF trap columns the influent organic matter was halved to 0.03 ppm O.A. (49), but pH drift indicating membrane poisoning still occurred with this solution.

In another series the effect of deliberately poisoning a Permaplex A-20 membrane for various times was studied. Poisoning was carried out at 5 ma cm^{-2} by passage of a 0.01*N* solution containing 0.85 ppm O.A. Reasonably reproducible results were obtained only if the poisoning was followed by a 6-hr conditioning run carried out at 5 ma cm^{-2} with the 0.06 ppm O.A. influent solutions, before proceeding to the standard pH runs. Even then the results after the longest poisoning of 16 hr were very scattered. For this work the normal compartment filling was omitted, and the membrane was supported by rigid plastic strips (2 mm wide) spaced parallel to the direction of flow and with centers 1.0 cm apart. The results shown in Fig. 9 clearly demonstrate the extreme sensitivity of Permaplex A-20 to poisoning by organic matter. After six or more hours poisoning it appears from Fig. 9 that there is substantial hydroxyl ion transport at any current density. This behavior is similar to that shown by bipolar membranes (50) and could result from acidic groups of the organic matter that are free, *i.e.*, in excess of those participating in bonds with the membrane, causing the surface to become cation selective. Cooke (26) has made similar comments.

The T.N.O. A-60 membrane was unaffected by 20-hr poisoning runs. While this cannot be extrapolated to long-term performance it does represent a remarkable difference from the sensitivity of Permaplex A-20. Other differences which may be related to the same prime cause are the ready attainment of steady-state conditions with new T.N.O. A-60 membranes and a lower critical current density region. The structure of the two membranes is of course quite different. Cooke and van der Walt (15) have provided evidence that with Permaplex A-20 the diffusion layer is not entirely irradicable by stirring as it is with a homogeneous A.M.F. membrane. This may be due to the Permaplex A-20 being of the heterogeneous type (19) or to its fabric reinforcement (32). A few runs with a new homogeneous A.M.F. membrane showed that this also was different to the T.N.O. A-60 membrane. The A.M.F. membrane showed a critical current density region as high as 45-50 ma cm^{-2} and the same upward drift of pH with influent solution containing 0.06 ppm O.A., indicating sensitivity to organic poisoning. We, therefore, think that the lower critical current density region and the short term insensitivity to poisoning of T.N.O. A-60 are not due to its homogeneous structure,

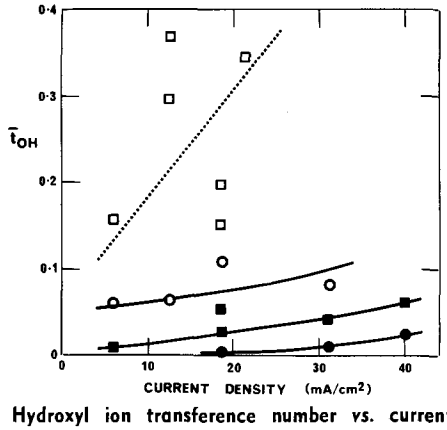

Fig. 9. Hydroxyl ion transference number *vs.* current density, Permaplex A-20. ● after poisoning for 0 hr; ■ after poisoning for 2 hr; ○ after poisoning for 6 hr; □ after poisoning for 16 hr.

but rather that it was partially poisoned at the outset of the work. Obviously this is only supposition, and the nature of the poison is unknown although it may be remarked that the membrane was stored with a T.N.O. C-60 membrane from which a little polystyrene sulfonate may have been leached. Cooke (26) has shown that polystyrene sulfonate poisons anion-selective membranes. Although the present paper has dealt only with poisons introduced with the water it is clear there must be absolutely no tendency for the cation-selective membrane to shed soluble polymeric anions which would poison anion-selective membranes. Wegelin (51) noted that homogeneous membranes were less resistant than heterogeneous membranes to the effects of poisoning by a polluted water from the Rhine.

General comment on organic poisoning.—Information on the deleterious effects on strongly basic anion-exchange resins of organic matter, tenaciously absorbed from water, accumulated during the 1950's (45, 46, 52-54). Similar problems would be expected with anion-selective membranes which in the main have similar structure and functional groups. One might anticipate even greater difficulties as there is no frequent regeneration procedure and the additional force of electrical potential is present to drive the organic matter into the membrane. It is thus surprising that prior to about 1962 there is hardly a mention of undesirable effects due to organic matter. Analyses of waters to be treated do not contain figures for organic matter. Resistance to organic fouling is not a specified membrane requirement. Even in major works there is no discussion related to organic matter in water sources. Since 1962 there has been a gradual awakening (12, 13, 18, 37, 44, 55, 56) although comments are mostly limited to unsupported statements. Even in 1963 Wilson (24), studying polarization to explain the failure of the Free State Geduld plant to meet design predictions, did not appear to give any consideration to organic poisoning of the membranes. Few authors (26, 29, 51) have provided positive information on organic poisoning.

Although the precise nature of organic matter in water varies with location and season, much is known in general terms (57). It is sufficient for the present purpose to note only that these materials, collectively termed humic and fulvic acids, have acidic groups of pK value about 4 (46, 58) and a range of molecular weights which includes a fraction capable of penetrating, albeit slowly, the interior of ion-exchange materials (26, 45, 46). There is no sparsity of acid groups in the molecules. Unpublished work at the Permutit laboratories indicates equivalent weights of around 100. Van der Waals' forces between the organic acids and the organic framework of the ion-exchanger (46) probably contributes to the tenacious binding, and in this respect the performance of the new inorganic membranes (59, 60) would be interesting.

Organic acids adsorbed on an ion-selective membrane can effect the critical current density region in three ways. First, as already mentioned, they can provide a surface of acid groups which is cation selective and results in a membrane of bipolar character (50). Second, the adsorption of a species of zero or low mobility on the most accessible membrane sites must result in the counterions having to reach less accessible sites before being subjected to the selective influence of the membrane. This is equivalent to an increase in δ in Eq. [2]. Finally the heterogeneous distribution of low mobility species in the membrane will divert current to paths where such species are relatively few, thus causing nonuniform current distribution on a microscopic scale.

The results obtained with new Permaplex A-20 membranes and indicated with homogeneous A.M.F. membranes show that, with properly designed compartments and suitable hydrodynamic conditions, i_c/c

values of about 4000 amp cm equiv^{-1} may be achieved. This value corresponds to a value of δ of 0.0008 cm which seems reasonable. Previous workers have reported much lower critical i_c/c values. For example at our linear flow rate, Cowan's formula for filled compartments (41) yields a figure of 340 amp cm equiv^{-1}, and Mandersloot and Hicks (61) obtained about 400 amp cm equiv^{-1}. One is tempted to suspect the influence of organic poisoning. Seko (44) on the other hand found no critical polarization up to 1000 amp cm equiv^{-1} which was the highest value he studied. A critical value of 4000 amp cm equiv^{-1} leaves ample scope for the choice of an economically optimum current density. We conclude, therefore, that the main limitation to electrodialysis is not polarization *per se* but poisoning of the anion-selective membrane which reduces the critical current density region to an economically unattractive level.

Conclusion

The measurement of pH changes at the anion-selective membrane is advocated for determination of critical current density regions.

Organic acids in the feed water, even in very small concentrations, drastically reduce critical current density.

For unpoisoned membranes the critical i_c/c values are much higher than has previously been appreciated and leave scope for an economic choice of current density.

The main limitation on electrodialysis is not polarization *per se* but poisoning of the anion-selective membranes.

The Standard Potential of Glucose Oxidase

F. R. Duke,[1]* R. N. Kust,[2] and L. A. King[3]

Departments of Chemistry, Texas A&M University, College Station, Texas, and Purdue University, Lafayette, Indiana

ABSTRACT

Glucose oxidase was titrated with Cr(II) and with Ti(III) over a pH range from 5.0 to 6.0, and a temperature range of 25° to 40°C. The two inorganic reagents were used, rather than just one, to ensure that there was no specific interaction between the enzyme and the reagent. Simultaneously, it was shown that the stoichiometry of the enzyme-inorganic reductant reaction was identical to that of the enzyme-glucose reaction and that the reduction products were identical in each case. Thus, it is shown that the potentials found are truly those which apply in the enzymatic oxidation of glucose. Glucose could not be used as reductant in the potentiometric studies because neither the enzyme nor the glucose reacts at the electrode. The values of E_o' (median reduction potential at pH 7) are —0.061v at 40°C, —0.028v at 30°C, and —0.008v at 25°C.

Glucose oxidase (EC 1. 1.3.4) from Aspergillus niger catalyzes the reaction: β-D-glucose + $O_2 \xrightarrow{E}$ gluconolactone + H_2O_2. The enzyme contains, as prosthetic groups, two molecules of flavin adenine dinucleotide (FAD) per mole of protein (1). Past potentiometric studies of the enzyme result in rather gross disagreement (2, 3), which needs to be resolved. Furthermore, it is of fundamental importance to determine the degree of cooperation between the flavin molecules. For example, if the two FAD moieties are closely associated in the reduction, a four-electron step might be expected for complete reduction; on the other hand, if the flavins occupy remote and nearly identical positions in the enzyme molecule, a single two-electron step might be expected. If they occupy remote but differing functions in the protein, two two-electron steps might occur. Finally, semiquinoid intermediates could show up in coupled or uncoupled one-electron reductions.

A group of flavins including FAD have been subjected to careful potentiometric study (4); in addition, the flavin-containing "old yellow" enzyme was the subject of a study by Vestling (5). Lowe and Clark found that at high acidities there was appreciable formation of semiquinoid material when FAD was reduced. Studies by Beinert and Sands (6) and by Mason *et al.* (7) indicate no semiquinoid intermediates are formed in the mechanics of glucose oxidase action. Gibson *et al.* (8) reached the same conclusion in an extensive mechanistic study.

The glucose-gluconolactone system and the enzyme system do not react at electrodes. To surmount this difficulty, Vestling used a potential mediator which equilibrated with old yellow enzyme and also with the electrode. In the present study, the inorganic reductants, Cr(II) and Ti(III), were the reductants chosen because they indicate readily and reversibly at platinum electrodes, and, although they were indicating at considerable potential difference from their standard potentials, the high impedance detector used still allowed for reversible measurements. It remained to show that the reaction with the inorganic reductants produced the identical reduction product of the enzyme with the same stoichiometry as did glucose.

Experimental

The glucose oxidase was obtained from Nutritional Biochemicals Corporation, pure grade. The buffers used were cp sodium acetate-acetic acid mxitures and cp cacodylic acid and its sodium salt.

The titanium (III) and chromium (II) solutions were prepared by reduction of Ti(IV) and Cr(III) using a Jones reductor in a chloride solution; electrolytic reduction of Ti(IV) was also employed to avoid the presence of Zn^{++} in the solutions. No difference was found between the solutions containing Zn^{++} and those not containing it. The glucose was reagent grade.

Potentiometry.—A cell consisting of a 25 ml glass vessel with a sealed-in platinum electrode, a microcalomel electrode, and a small opening covered with a serum cap, was placed in a small black box. Deaerated enzyme solution, 1 mg/ml, was added by means of a Roger Gilmont Teflon syringe. The electrode vessel was continuously purged with argon which had been passed over tantalum chips heated to 800°C to remove oxygen. The reducing agent in solution was added through the serum cap using a Vernier type Roger Gilmont Teflon syringe calibrated to the nearest microliter.

The potential between the electrodes was measured on an L & N K3 potentiometer; a Kiethley 603 electrometer was used in place of a galvanometer as a null instrument. After each addition, the potential change with time was registered on a Rustrak recorder attached to the electrometer. When a reading had come to a steady state (about 5-10 min), the potentiometer was adjusted to null the electrometer, and the potential was read from the potentiometer.

Stoichiometry.—The desired amount of enzyme was weighed and transferred to a centrifuge tube equipped with a rubber serum cap. The tube was thoroughly flushed with argon, then filled to the desired amount with buffer solution. After the enzyme dissolved, the solution was centrifuged, and a known volume (about 11 ml) of the clear liquid was transferred to an argon-flushed Beckman 40 mm pathlength spectrophotometer cell. The cell had a glass top sealed on with Apiezon W wax. The top had two holes in it which were closed with serum caps. All transfers of solutions were done with hypodermic syringes and considerable care was exercised to exclude oxygen. The solutions contained typically 2 mg enzyme per ml.

The absorption of light at 450 mμ was followed by a Beckman Model DB spectrophotometer for some of the experiments. In these cases, oxidized enzyme was used on both sample and reference sides of the instrument. Glucose was added, using a Roger Gilmont 0.2 ml micrometer syringe, to the reference side, resulting in an apparent decrease in transmittance as seen by the instrument. A Beckman Model DU spectrophotometer was used for the remaining experiments, with ordinary demineralized water as a reference. These experiments were conducted conventionally with the glucose added to the sample cell. A small Teflon covered stirring bar was inside the cell to mix the reagents after each addition.

Kinetic experiments.—All solutions were prepared in vigorously deoxygenated water or 0.05M acetate buffer solutions, pH 5.5. The enzyme concentration was about 2 mg/ml, and in distilled water solution, the resulting pH was about 4.5. All solutions were kept in volumetric flasks stoppered with rubber serum caps. At no time in their use were the solutions exposed to air. Methylene blue concentration was 10^{-3} M.

The enzyme was reduced stoichiometrically with each reductant. In turn, the methylene blue was added with the micrometer syringe and the rate of appearance of the 450 mμ band was measured with the Beckman DB.

Results and Discussion

Stoichiometry.—The molar absorbency index for glucose oxidase has been determined to be 28.2 x 10^3 cm^{-1} (7). Using this value, the stoichiometry of the glucose-enzyme reaction ranged between 1.9 and 2.1 β-glucose molecules oxidized per mole of enzyme. A plot of moles of β-glucose *vs.* moles of enzyme reacted yielded a straight line, showing that the stoichiometry is constant throughout the titration. The stoichiometry of the reaction with Cr(II) and Ti(III) was found, by potentiometry, to correspond to the addition of two hydrogen atoms to each flavin. As it turns out, the potential of the flavin in the enzyme is sufficiently far removed from that of FAD that the break in the potential measured only the enzyme, even though there might be some free FAD present.

To show that the reduction products of the enzyme were indifferent to the nature of the reducing agent, the rate of reoxidation of the stoichiometrically reduced enzyme was studied using methylene blue as oxidant, and using the inorganic reagents and glucose as reductants. The kinetic results were not analyzed in detail, but plots of rate of appearance of the 450 mμ peak of the enzyme *vs.* time under carefully controlled conditions with respect to concentrations and starting time yielded plots which were coincident irrespective of the nature of the reducing agent. Thus, it was concluded that the inorganic reagents yielded a reduced enzyme identical to that formed using glucose.

Potentiometry.—Reproducible potentials were not obtained even in diffuse fluorescent light. After some time of futile experimentation, it was found that placing the cell in a black light-proof box yielded reproducible results. The photoexcitation of flavins has been noted previously, and the added energy is reflected in the potential observed (9).

Only one break in the titration curves was found. A typical titration curve is shown in Fig. 1. This break corresponded to a two-electron reduction of the enzyme. The precision was such that there could have been a small percentage of semiquinoid material present. In general, however, the flavins in the enzyme acted like independent identical molecules. This does not mean that a cooperative or coupled effect may not be involved as the enzyme reacts with glucose. It does suggest, however, that the two FAD molecules occupy remote and identical, as far as the potentiometric titration is concerned, sites in the protein.

The E_o (median potential at pH 7) for the enzyme is calculated from the data using the Nernst expression

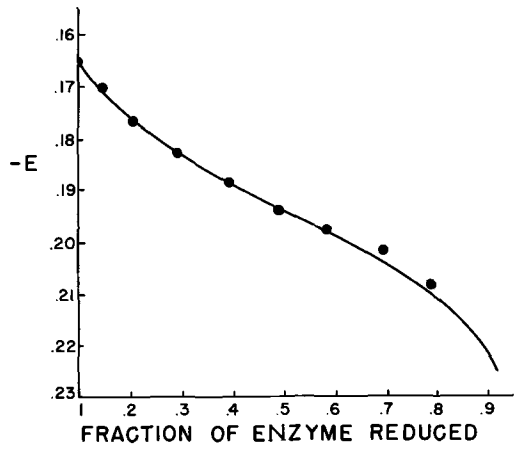

Fig. 1. Titration curve of glucose oxidase using $CrCl_2$ as titrant at 25°C. This curve is typical of all titrations resulting in the values in Table I.

and shown in Table I. The enzyme is a considerably more energetic oxidant than is FAD (E_o' = — 0.219v).

The results of Yamano *et al.* (2) who found E_o' = + 0.08v, may be in error because they simultaneously measured the potential and the absorbance at 450 mμ. It is known that light may affect the potential observed (9). The high reduction potential found is probably a reflection of photoexcitation.

On the other hand, Walter (3) kept light from the sample being titrated; he used leucosafranin which had been reduced by dithionite as titrant and methylene blue was the potential mediator. It is possible that one of the dyes or some of the reduction products of dithionite preferentially combine with the oxidized form of the enzyme as found by Swoboda and Massey (10), to lower the potential to the value of —0.144 v for E_o'. An alternate explanation is that titanium and chromium complexes of the reduced enzyme are formed which raise the standard reduction potential in the work here presented. However, it would be highly coincidental for these two metal ions to combine with the reduced form of the enzyme to the same extent. At any rate, our values fall close to half way between those previously reported.

Thallium-Thallous Halide Reference Electrodes in Propylene Carbonate

Friedrich G. K. Baucke and Charles W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The performance of thallium amalgam-thallous halide electrodes with thallium concentrations from 1 to 20 a/o (atomic per cent) has been investigated in propylene carbonate (PC). Measurements of bias potentials, polarization measurements, and comparison of emf's of amalgam concentration cells without transference with data on cells in aqueous solutions show reversibility and good stability of the electrodes. The solubilities of thallous chloride, bromide, and iodide were found in the order of 1 to 5 x 10^{-6} moles/1000 ml. The pure thallium-thallous chloride electrode was also found to be suitable for reference purposes in propylene carbonate.

In recent years propylene carbonate, PC (mp: —48°C, bp: 242°C, dielectric constant: 64.5 at 25°C) has attracted much interest as an ionizing solvent for application in high energy density batteries. For measurements of thermodynamic properties of electrolytes and for studies of electrode processes in this solvent a reversible reference electrode of the second kind is required, which, for practical reasons, should involve a halide as sparingly soluble salt since this allows the experimental establishment of concentration cells without transference. Halides of sufficiently low solubilities in PC include mercurous, silver, and thallous halides.

At first sight the calomel and the mercury-mercurous bromide electrodes promise to be suitable systems. Mercurous chloride and bromide, however, disproportionate instantaneously when they are added to solutions of the corresponding alkali halides in propylene carbonate. Disproportionation also takes place in absence of indifferent halides; only the reaction rate is very low. Slow disproportionation of mercurous chloride has been reported to occur in contact with solutions of the corresponding halides in acetonitrile (1) and in dimethyl sulfoxide (2). Rapid spontaneous reaction, however, has not been reported thus far.

The low intrinsic solubility of silver chloride in propylene carbonate (2 x 10^{-5} mol/1000 ml) (3) suggests the application of the silver-silver chloride electrode in this solvent. However, excess chloride ions increase the solubility to such an extent that it becomes approximately equal to the excess chloride concentration (3-5). We have, therefore, not investigated further the application of this electrode in propylene carbonate.

The thallium amalgam-thallous chloride electrode is a reliable reference electrode in aqueous solutions, especially for measurements above 80°C, and is commercially available with 40 w/o (weight per cent) thallium as "Thalamid-Elektrode" (6). Recently it has been shown by Smyrl and Tobias (2) and by Cogley and Butler (7) that it is also reversible and well suited as a reference electrode in dimethylsulfoxide solutions. Furthermore, the solubilities of thallous chloride, bromide, and iodide determined by means of emission spectroscopy are in the order of 5 x 10^{-6} (TlCl), 1 x 10^{-6} (TlBr), and 2 x 10^{-6} (TlI) moles/1000 ml solvent and hence an order of magnitude below that of silver chloride. These values yield solubility products in the order of 10^{-12} to 10^{-11} (moles/1000 ml) (8), if complete dissociation and no complex formation of the salts at these low concentrations is assumed. Quantitative tests on the effect of excess halides on the solubility of thallous halides have not been performed in the frame of this study. Unlike in the case of silver chloride, however, no effect could be discerned by visual observation.

Therefore it seemed promising to examine the behavior of thallium amalgam electrodes in connection with thallous halides in propylene carbonate. Lithium chloride (10^{-3}M), lithium bromide (0.1M), and potassium iodide (0.1M) were chosen as indifferent electrolytes because of their relatively high solubility in PC; the thallium concentration of the amalgams ranged from 1 to 20 a/o (atomic per cent). The experiments also included measurements on oxide free thallium metal electrodes covered with an electrolytically formed layer of thallous chloride.

Experimental

Propylene carbonate (Jefferson Chemical Company, Houston, Texas) was distilled at 0.5 mm Hg by means of a commercially available column[1] packed with stainless steel helices.[2] The reflux ratio was 50 to 60, the head temperature 65°C. The first 10% and the last 20% of the solvent were discarded.

Because of the high tendency of the solvent to dissolve stopcock greases the receiver system of the column was designed with glass drip tips and needle valve stopcocks[3] equipped with Teflon "O"-rings.

Gas chromatographic analysis[4] of the product showed the presence of two impurities at very low concentration, one of which could be identified as water. The

concentration of water as determined by the Fischer method was below 5 ppm.

Thallous chloride (reagent grade, Fisher Scientific Company, New York) and thallous bromide and iodide (prepared by precipitation from aqueous solutions of thallous nitrate with the corresponding alkali halides) were dried *in vacuo* with phosphorus pentoxide. In contact with PC they are slightly sensitive to light; the effect increases with increasing molecular weight of the halides. Solutions and galvanic cells were, therefore, kept in dark as far as possible.

Thallium wire used for preparation of amalgams and thallium electrodes was 99.999% pure (United Mineral and Chemical Corporation, New York). The surface was freed from oxide by washing with oxygen-free water under argon atmosphere. The silvery white metal dissolved readily in mercury. The thallium concentrations of the amalgams were determined by the acidimetric titration method given by Richards and Daniels (9).

Electrolyte solutions, amalgams, and cells were prepared in dry argon atmosphere inside a glove box, which could be evacuated to below 1μ Hg. The argon passed a U-tube with dried magnesium perchlorate for removal of water and a U-tube with BTS catalyst[5] for removal of oxygen. The water content was 1 ppm by volume.[6]

The Pyrex cells used for equilibrium emf and polarization measurements consisted of six compartments, five of which were equidistant from a center compartment (Fig. 1). This arrangement permitted the combination of any two of six reference electrodes for test purposes.

Electrode cups containing about 5 ml of the amalgam exposed 0.5 and 1 cm^2 of the metal surface to the electrolyte. The amalgams were covered with a thin adherent layer of thallous halide. Since it was found that propylene carbonate tends to creep between glass and amalgams, a tightly fitting Teflon "O"-ring was attached to the glass stem of the platinum contact below the mercury surface preventing contact between electrolyte and platinum.

The cells were tightly sealed, and 1 atm of argon was maintained over the solution throughout the measurements. The temperature was kept at 30° ± 0.02°C.[7]

Thallium-thallous chloride electrodes were prepared from thallium wire. Thallous chloride well adhering to the metal surface was formed by anodization inside the sealed cells with current densities of 0.2 ma/cm^2 for a period of 30 min, yielding an amount of 0.85 mg TlCl/cm^2 and an average layer thickness of 1.2 x 10^{-3} mm. Dissolution of this layer was prevented by presaturating the electrolyte solutions with thallous chloride.

Electrode potentials and overvoltages were measured with a potentiometric electrometer.[8] Constant current was supplied by a constant current power supply[9] and measured with a multirange electrometer.[10] Each of the six electrodes of each cell studied was subjected to positive and negative galvanostatic polarization (from 10^{-8} to 10^{-6} amp/cm^2), as counter and reference electrodes served any two of the other amalgam- or thallium-thallous chloride electrodes.

Results

Bias potentials.—Thallium amalgam (1-20 a/o)-thallous halide and thallium-thallous chloride electrodes were set up in propylene carbonate solutions of the corresponding alkali halides. Measurements of bias potentials and electromotive forces were conducted at 30°C for at least six months.

Bias potentials of "good" amalgam electrodes never exceeded 0.05 mv, and it could be foretold from the appearance of the surface when, in few cases, they had higher values (up to 3 mv). Good electrodes had a certain appearance: Their surface was completely covered with a thin layer of very fine crystals of thallous halide. The velvet layer was produced by shaking the amalgam before it was immersed into the solution; the salt spread readily over its surface and was not removed on wetting with propylene carbonate solution. Salt in excess over the adherent quantity was usually ejected out of the electrode cups by this procedure; its presence was found to be unnecessary for a good performance of the electrodes. Only a few amalgam electrodes could either not completely be covered with thallous halide or lost the coherence of the adherent film on wetting with propylene carbonate. They showed patches of shiny amalgam, and their bias potentials were up to 3 mv and not quite constant.

Solid thallium wires employed as metal phases for thallium-thallous chloride electrodes were immersed in the PC solutions saturated with thallous chloride. Acting as electrodes of the first kind they exhibited bias potentials of less than 0.2 mv and constant emf's with amalgam-thallous chloride electrodes showing identical states of metal and surfaces. Directly after anodization and formation of the thallous chloride layer the potentials were usually off by several hundred millivolts; they changed, however, rapidly returning to their preceding value: Bias potentials were below 1 mv after 2 hr and below 0.2 mv after 6 hr. The erroneous potentials directly after anodization seem to be caused by nonuniform concentrations of electrolytes in the freshly formed layer of thallous chloride.

Polarization measurements.—In order to characterize their actual performance and reversibility, the electrodes were subjected to positive and negative polarization with current densities from 10^{-8} to 10^{-6} amp/cm^2.

The overvoltages of amalgam-thallous halide electrodes were in every case proportional to the current flowing; no hysteresis could be observed (Fig. 2). Overvoltages of electrodes with 9 a/o thallium were corrected for the iR-drop obtained from resistance measurements at 10,000 Hz between corresponding electrodes and the electrode in the center compartment. The corrected overvoltages allow the calculation of i_o^*, the effective exchange current density

$$i_o^* = \frac{RT}{n\mathbf{F}} \left(\frac{\partial i}{\partial \eta} \right)_{\eta \to 0}$$

Its magnitude is determined by the slowest reaction at

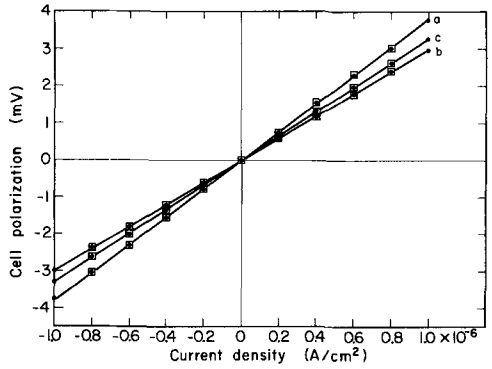

Fig. 2. Typical behavior of thallium amalgam electrodes under current. Cell polarization refers to potential measured between two identical electrodes. the electrode surface. For the electrode

$$9\ \text{a/o Tl(Hg)/TlCl(sat'd), LiCl}(10^{-3})\text{M}$$

i_o* is in the order of 2 to 5 x 10^{-5} amp/cm².

Concentration cells.—Richards and Daniels investigated thermodynamic properties of thallium and its amalgam from 0.33 w/o to saturation (over 40 w/o) in concentration cells without transference and used aqueous 2% thallous sulfate as electrolyte (9). As long as only the reversible electrode reaction determines the potential of the electrodes, the electromotive forces of these cells should be independent of the electrolyte, its concentration, the solvent, and whether the electrodes are of the first or second kind. The emf's should only depend on the ratio of the thallium activities of the amalgam.

Accordingly, electromotive forces between thallium amalgam electrodes of the second kind with different thallium concentrations (1-20 a/o) and with thallous chloride, bromide, and iodide as sparingly soluble salts and also thallium-thallous chloride electrodes were measured in concentration cells without transference in solutions of corresponding alkali halides at 30°C. The values were compared with those for aqueous solutions at the same temperature given by Richards and Daniels. For more correct interpolation the literature data were treated by a method used by Lewis and Randall (10). As illustrated in Table I, agreement of these interpolated values with our measurements was in every case better than 0.1 mv.

Discussion

The results reported indicate that thallium amalgam electrodes in connection with thallous chloride, bromide, and iodide as sparingly soluble salts as well as thallium-thallous chloride electrodes with electrolytically formed thallous chloride layer are suitable as constant, reproducible, and reversible reference electrodes of the second kind in propylene carbonate solutions. The three amalgam electrodes provide a wide and useful range of applicability, especially for thermodynamic measurements in cells without transference, since they allow the selection of the most soluble and most suited halide of a given cation to be studied. The concentration of thallium in the amalgam may be chosen within broad limits (9), however, concentrations below 1% by weight are not recommended. It is to be emphasized that oxygen has strictly to be excluded from the system, since solid thallium and its amalgam undergo oxidation very rapidly.

When the amalgam electrode is used as a reference electrode in connection with a solution containing other than halide ions, and therefore a liquid junction is involved, the choice of the thallium halide is optional. Since alkali bromides are more soluble than chlorides, and because the thallous bromide is less sensitive to light than is the iodide, the use of the bromide electrode may be preferable, with LiBr as the supporting halide.

Solid thallium-thallous chloride electrodes are somewhat less reproducible than the amalgam electrode and require a longer time after their preparation for equilibration. However, these electrodes may have advantages for "practical" reference purposes. For example, it may be convenient to be able to insert a thin wire into a galvanic cell under study, a requirement that is rather difficult to meet by amalgam electrodes.

The Electrochemical Oxidation of Adsorbed Hydrogen and Carbon Monoxide on Noble Metals and Their Alloys

R. J. Roethlein*[1] and H. J. R. Maget*

R & D Laboratory, Direct Energy Conversion, General Electric Company, West Lynn, Massachusetts

ABSTRACT

The mechanism of electrochemical oxidation of H_2-CO mixtures was investigated on noble metals (Pt, Rh, Ru) and their alloys (Pt-Rh, Pt-Ru), by a voltage pulse technique. The relative coverage of adsorbed hydrogen in the presence of CO was found to be approximately 5% for all of the Pt-Rh alloys investigated and the total surface coverage dependent on the alloy surface area. For Pt-Ru alloys the degree of hydrogen coverage in the presence of CO was found to be a function of the Ru content of the alloy.

Considerable interest has been raised in the past few years concerning the electrochemical oxidation of reformate gas mixtures containing varying amounts of H_2, CO, CH_4, and CO_2. Conventional electrocatalysts, such as platinum black, commonly employed as anodes for the oxidation of hydrogen have displayed severe polarization losses under current drain when H_2 is substituted with reformate gases at temperatures ranging from ambient to 90°C. Investigations of the various components in reformate gases have shown that CO_2 and CH_4 do not affect directly electrode polarization during the oxidation of hydrogen, but act merely as diluents in the fuel mixture. CO has been shown to be strongly adsorbed on many electrode materials and does not oxidize until an appreciably high overvoltage (~0.4v) is reached. Studies (1-7) conducted on both smooth and platinized platinum have shown that CO replaces most of the adsorbed hydrogen and is preferentially adsorbed on the electrode surface; these authors have also shown that CO adsorption occurs in at least two isomeric forms. Earlier investigations of CO adsorption on supported platinum substrates (8) employing infrared techniques have labelled these isomers as linear (one site adsorption) and bridge (two site adsorption).

Several binary noble metal alloys permit the oxidation of hydrogen containing CO as part of the fuel gas mixture (9,10); these catalysts have shown an exceptional tolerance for carbon monoxide in reformate fuels and are far more resistant to poisoning than platinum. These authors conclude that the improved performance of these catalysts appears to result from the greater availability of sites for hydrogen adsorption rather than through promotion of the oxidation of carbon monoxide. It was the purpose of this work to determine the quantity of hydrogen and carbon monoxide adsorbed on some of these catalyst materials and thereby gain some understanding of the over-all oxidation process. Rapid voltage scanning techniques were employed so that investigation of the adsorption effects of hydrogen and carbon monoxide on smooth alloy and metal surfaces could be determined. These techniques also kept the rate of CO adsorption from solution at a minimum.

Experimental

Study electrodes were composed of 30 mil diameter polished metal wires obtained from Engelhard Industries and sealed in soft glass tubes having coefficients of expansion similar to those of the wires. The metals consisted of pure platinum, rhodium, ruthenium, and binary platinum alloys of the latter noble metals; see Table I for exact composition. The geometric area for each sample depended on the length of wire extending from the glass capillary tip, but ranged between 0.15 and 0.35 cm^2. The experiments were carried out in a standard three-compartment Pyrex glass test cell, each section separated from the other by fritted glass disks. All potentials refer to a hydrogen saturated platinum-black electrode in 3*N* H_2SO_4 which was prepared from doubly distilled water and reagent grade chemicals. All tests were carried out at either 25° or 80°C + 1° in a P.M. Tamson constant temperature oil bath, and the gases used in these experiments were research grade quality.

A triangular wave voltage ramp was obtained by means of a Servomex waveform generator used in conjunction with a Wenking 61R fast-rise potentiostat in applying potential ramps on the test electrode. Current variations were measured across a 10 ohm standard resistor and recorded on a 551 Dual Beam Tektronix Oscilloscope using a type-D plug-in. Simultaneously, the voltage change across the test electrode could be monitored on the other oscilloscope beam via a type-L plug-unit. Traces were then photographed with a C-12 Polaroid Oscilloscope camera.

The instrumentation and procedure followed for electrode precleaning prior to the adsorption of the oxidizable species was similar to that employed by Gilman (1-3). The electrolyte was thoroughly saturated with CO and the test electrode brought to an oxygen evolution potential of 1.8v for 30 sec to remove oxidizable impurities from the electrode. The electrode potential was then lowered to 1.3v and molecular oxygen was swept from solution after which the electrolyte was allowed to become quiescent for an additional 60 sec at this potential. The electrode potential was then lowered to the desired adsorption potential for various durations or adsorption times. A linear anodic potential ramp was then imposed on the electrode during which adsorbed CO was oxidized and the electrode surface was covered with adsorbed oxygen.

Q_H = total charge for H_{ads} oxidation.
Q_H^{CO} = total charge for H_{ads} oxidation in CO-saturated solution.
Q_{CO} = total charge for CO oxidation.
All Q-values expressed in millicoulombs/cm² geometric area.

The same procedure was followed after thoroughly purging the solution with N_2 and the traces obtained from both runs were superimposed on the same photographic plate so that the charge due to surface oxidation could be eliminated and to permit a more accurate determination of the charge due to CO oxidation. Measurements of the quantity of hydrogen adsorbed on the same electrode surface were also made. All potentials were previously adjusted via a Fluke potentiometer and potential sweep speeds the order of 100 v/sec were used in order to minimize the measurement of currents due to diffusional processes.

Results

The smooth wire electrodes were examined by a voltage pulse technique in order to determine the charge due to the oxidation of hydrogen and carbon monoxide adsorbed on the electrode surface. Following the electrode precleaning procedure described in the experimental section, the electrode potential was held at an adsorption potential until hydrogen or carbon monoxide adsorption on the electrode surface was complete. In the case of H_{ads} full surface coverage was realized in less than 50 msec.

Figure 1 shows typical traces obtained on a Pt-Ru electrode in a nitrogen and carbon monoxide saturated system. The shaded areas being the regions of interest: Q_{CO} = CO oxidation, Q_H = hydrogen oxidation, and Q_H^{CO} = hydrogen oxidation in the presence of CO. Q represents the charge due to the oxidation of the adsorbate in millicoulombs per square centimeter of geometric area. The charge due to hydrogen oxidation in the presence of CO, Q_H^{CO}, decreased rapidly with increasing adsorption times and reached a steady value after approximately 10 sec; however, adsorption times

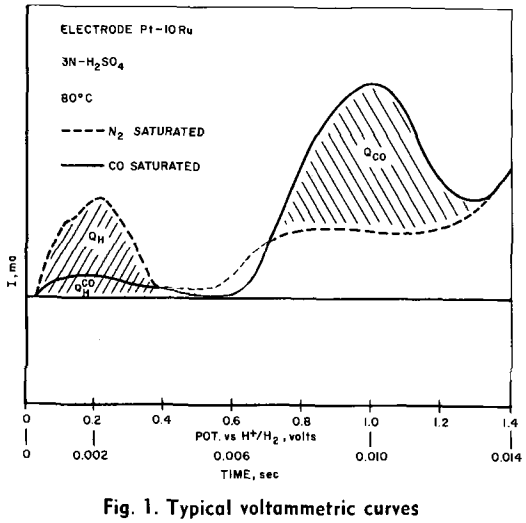

Fig. 1. Typical voltammetric curves

the order of 60 sec were employed since it has been reported (1) that the final CO molecules may adsorb slowly. The quantity of adsorbed hydrogen oxidized was attributed to the charge measured between the start of the sweep up to 0.4v where hydrogen coverage is zero and double layer charging begins (11).

Hydrogen saturation coverages were measured from a starting potential of +0.030v in order to minimize effects due to hydrogen evolution. A correction for the capacity contribution to the charge in the presence and absence of CO was applied to the values obtained by integration of the area under the curves between +0.030 and 0.400v. Since the double layer capacity is almost constant in this potential range (12) a value of 40 μfd/real cm² (13), in the absence of an organic adsorbate, and 8 μfd/real cm² (14) in the presence of CO was employed in making the corrections. The surface roughness of each electrode was also taken into consideration in applying the corrections. The double-layer contribution to the charge due to CO oxidation is negligible since they tend to cancel one another (3, 15) in the presence and absence of CO.

Measurements of hydrogen coverage were made using the current and time coordinates that provided the largest amount of display. These values were also checked by the method of hydrogen codeposition (1), where the electrode after a precleaning cycle was held at an adsorption potential of +0.400v and a cathodic sweep applied to hydrogen evolution potentials. Analysis of the charge due to hydrogen deposition in the presence and absence of CO was in good agreement with the values obtained by the application of anodic sweeps.

With sweep speeds ranging from 50 to 200 v/sec, the amount of charge due to the oxidation of adsorbed hydrogen and carbon monoxide maintained a constant value after repeated measurements employing the fore-mentioned potential sequence on Pt and all of the Pt-Rh alloys tested below 50 w/o rhodium. Both rhodium and the Pt-95 Rh alloy did show a small increase in charge within the first few potential cycles, possibly indicating an increase in surface area. However, after several cycles reproducible values were obtained. On pure ruthenium it was found that for anodic potentials greater than 1.4v an oxide formed on the electrode surface which could only be removed by mechanical polishing. Consequently, electrode precleaning on the material was carried out at an applied potential of 1.0v, and all measurements of hydrogen adsorption were made by anodic potential ramps that did not exceed 1.0v. Charge measurement on the Pt-Ru alloys tested, employing the original potential sequence, did not show any significant variation during repeated measurements or oxide build-up on the surface.

Electrode surface reproducibility was measured as a function of sweep rate and adsorption time for the

amount of charge required to oxidize hydrogen from an electrode surface held at an adsorption potential of 0.030v. For a wide range of sweep speeds (5-2000 v/sec) the charge corresponding to the oxidation of hydrogen has an average deviation of less than 2%. Measurements of charge variation as a function of adsorption time has shown that under the worst condition (violent gas bubbling through the electrolyte) the number of sites lost to impurity adsorption has been low. With gas bubbling, adsorption times of the order of 60 sec produce a 5% loss in charge; after 180 sec 18% of the sites were covered with impurities.

The degree of hydrogen coverage on platinum and rhodium was measured as a function of potential at 25°C; for platinum, hydrogen adsorption is present up to 0.300v, in contrast to rhodium which is relatively free of adsorbed hydrogen at potentials greater than 0.200v. No significant change in the range of hydrogen coverage was noted on these metals when the electrolyte temperature was raised to 80°C. Measurements of hydrogen coverage on pure ruthenium as a function of potential were difficult, except at low adsorption potentials $\leq$ 0.05v, due to the rather ill defined double layer region obtained during an anodic or cathodic voltage sweep. High electrode capacity has been attributed to the adsorption of oxygen at potentials in the region of the double layer (16).

The charge due to the oxidation of CO as a function of adsorption potential was also investigated on several materials. Figure 2 shows that for platinum at 80°C the total charge is constant up to an adsorption potential of 0.700v. At some potential between 0.700 and 0.800v CO is no longer adsorbed on the electrode surface. This is in contrast to values obtained at 25°C on platinum where the charge due to CO adsorption was constant up to 0.900v. This may suggest that adsorbed oxygen forms on platinum at slightly lower potentials as the temperature is increased. To insure removal of any oxide formed at higher potentials during the pretreatment procedure an additional step was added to the potential sequence. Prior to the adsorption step the electrode was cathodized for 1 sec at 0.100v and then brought to the appropriate adsorption potential for 60 sec duration.

A similar investigation was carried out on two platinum alloys; 50% Rh-Pt and 15% Ru-Pt. For these materials the charge due to CO oxidation was a steady value up to adsorption potentials of 0.600v. At 0.700v the charge due to CO oxidation was too small on both materials, see also Fig. 2. The behavior of rhodium toward CO oxidation was similar to that of the alloys, Fig. 3; the charge remained constant up to an adsorption potential of 0.600v on a prereduced surface. Higher oxides, however, were not fully removed until significantly lower adsorption potentials were achieved. At 0.400v some residual oxide still remained on the surface preventing a saturation coverage with carbon monoxide.

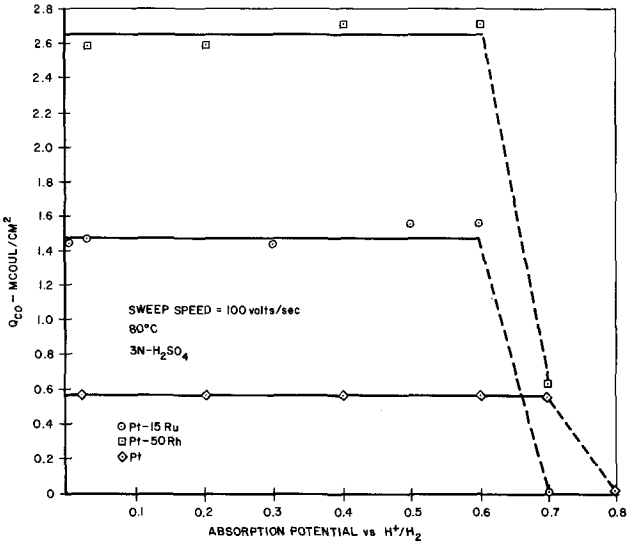

Fig. 2. Charge due to CO oxidation as a function of potential

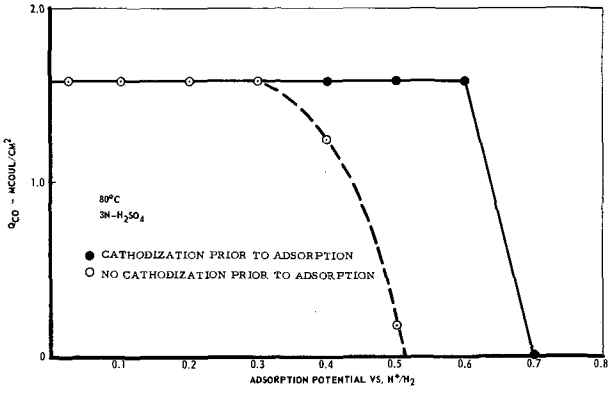

Fig. 3. Charge due to CO oxidation on rhodium as a function of potential.

The charge due to the oxidation of hydrogen and carbon monoxide measured for saturation coverages at 80°C on pure metals and several Pt-Rh and Pt-Ru binary alloys is summarized in Table I. The analysis of the data obtained on the various metals and alloys is based on two assumptions: that the values obtained for Q_H represent adsorbed hydrogen coverages approaching saturation and that the adsorption of CO molecules takes place mainly on those sites previously covered with adsorbed hydrogen. The results indicate that for Pt-Rh alloys the quantity of hydrogen adsorbed on a smooth electrode surface in a CO-saturated condition is directly related to the amount of hydrogen it can adsorb in the absence of carbon monoxide. Although values for the charge due to adsorbed hydrogen vary with each electrode because of its roughness factor the ratio of hydrogen coverage in the presence of CO to that obtained in its absence remains fairly consistent for this whole series of alloys; values of Q_H^{CO}/Q_H vary slightly from 3.5 to 6.0%.

Ruthenium and the binary alloys of this series do not however follow the previously described relationship. For these materials the quantity Q_H^{CO}/Q_H, seems to reach a plateau and does not vary significantly. Pure ruthenium, however, exhibits a higher percentage of hydrogen coverage which may possibly be a maximum for this series.

If the assumption is maintained that CO molecules adsorb on the same sites previously occupied by adsorbed hydrogen, then charge comparison for these two species indicates that approximately a two to one ratio exists for platinum, rhodium, and most of the alloys. Providing a two-electron transfer is necessary for the complete oxidation of carbon monoxide, then these values may be a good indication that the main form of CO bonding to these materials at 80°C is of the linear type.

Discussion

From the studies conducted on pure metals and alloy wire electrodes some observations can be made regarding the role these catalysts play in oxidizing impure hydrogen. For alloys of the Pt-Rh series, adsorption data indicate that the amount of charge due to hydrogen coverage in a CO saturated solution, Q_H^{CO}, is a function of electrode surface area. For pure platinum, rhodium, and their alloys, the relative hydrogen coverage in the presence of CO compared to hydrogen coverage without CO present on the same surface is approximately 5% and independent of alloy composition. This would indicate that the same proportion of sites are available for hydrogen adsorption in the presence of CO on Pt and on the Pt-Rh alloys.

Since the oxidation of CO occurs on all of these alloys at potentials far removed from the region of

hydrogen oxidation, catalytic activity for the electrochemical oxidation of H_2 would then be confined to those residual sites not covered with adsorbed CO. It would seem then that catalytic activity of these alloys is not due to a larger portion of sites available for hydrogen adsorption but to some other factor which will enhance activity for specific alloy compositions, such as a higher total surface area.

The adsorption data obtained on the Pt-Ru alloys indicate that for these materials the degree of hydrogen coverage in the presence of CO is dependent on the Ru content of the alloy. The relative degree of hydrogen surface coverage (Q_H^{CO}/Q_H) in a CO saturated solution increased rapidly up to approximately 10 w/o ruthenium; at this point approximately 20% of the electrode surface is covered with residual hydrogen. The value remained fairly constant on the remaining higher weight per cent ruthenium alloys tested. Thus specific alloy composition of the Pt-Ru series shows a greater tendency to adsorb hydrogen in the presence of reformate fuels. The results obtained on pure ruthenium agree with this observation since values for the relative hydrogen coverage are higher for the pure material than for any of the alloys.

Electrochemical Methods for the Measurement of High-Temperature Diffusion in Metals

D. O. Raleigh and H. R. Crowe

Science Center, North American Rockwell Corporation, Thousand Oaks, California

ABSTRACT

Previous determinations of the diffusion coefficient of silver in single-crystal Ag-Au alloys at 394° by the measurement of diffusion-limited currents in solid electrolyte cells Ag|AgBr|Au have been extended to cover the complete alloy composition range and to determine the effects of electrode surface preparation, direction of diffusion, compositional cycling, and use of a bulk Ag-Au alloy as the starting electrode. In addition, the experimental and theoretical principles are discussed more thoroughly. In selected systems, the method permits the accurate measurement of D values as low as 10^{-16} cm^2/sec, at a time scale of about 1 hr per data point, over the range of miscibility of diffusant and solute metals, with a single cell. In the present study, D values from duplicate runs in the range 10^{-14} cm^2/sec agreed to ~3%. The method permitted, for the first time, direct comparison of D values corresponding to inward and outward diffusion in a substitutional solid system. Out-diffusion D values were systematically higher, a result attributed to vacancy injection. Extension of the present and related methods to fused salt electrolytes and other solid electrode materials is discussed.

In a previous publication (1), preliminary results were reported on a high-temperature electrochemical method for the rapid and sensitive measurement of low-level diffusion in selected metal systems. In applying the method to the diffusion of silver in silver-gold alloys at 400°C, it was found possible to measure D values of order 10^{-14} cm^2/sec at five points in the alloy composition range 10-60 a/o Ag in a one-day experiment with one metal sample. By contrast, conventional metallurgical techniques involving radiotracers and sectioning generally cannot be extended below $D \sim 10^{-11}$ cm^2/sec and require several weeks of annealing as well as precise sectioning techniques. In the application reported, the method involved the measurement of diffusion-limited currents in the solid electrolyte cell Ag|AgBr|Au. In the present work, we report more extensive studies on the Ag-Au system, examining the theoretical and experimental principles more thoroughly and discuss the applicability of this and related methods to other metallic and electronically conducting systems.

Key words: silver diffusion in gold, electrochemical diffusion method, solid electrolytic cell.

The cell Ag|AgBr|Au is one of a class of solid electrolyte cells, (Me or X)|MeX|M', termed polarization cells, which contain one electrode that is electrochemically reversible to the electrolyte and one which is chemically inert toward it. If an external voltage is applied to such cells, there is a wide range of the voltage over which there can be no steady-state ionic current. For instance, if the Ag side of the cell Ag|AgBr|Au is made negative, a steady-state electrolytic current could only occur through electrodissociation of the AgBr or oxidation of the Au. If the cell

voltage is kept below the values required for these reactions, no steady-state faradaic process is available to permit current flow. Under these conditions, the Au electrode is current-blocking and, in essence, functions like a capacitor. Wagner (2) has pointed out that in such cells the applied voltage V uniquely fixes the chemical activities of the electrolyte components at the inert electrode surface. In the present cell, for instance, the activity of metallic silver at the gold surface is given by $a_{Ag} = \exp(-V\mathbf{F}/RT)$. The activity in this case is manifested as a partial monolayer of electrodeposited silver (3, 4) which, on application of the voltage, is achieved on the time scale of the electrode double-layer charging. If the charging process is carried out at a cell temperature where the diffusivity of silver in gold is negligible, the ionic cell current drops to zero on its completion.

Suppose, however, that the temperature has a value at which the silver diffusivity is appreciable. In this event, silver at the surface will migrate into the gold, but the cell will act to maintain the surface concentration by electrodepositing more silver. The result will be an ionic cell current that is precisely equivalent to the flux of diffusing silver into the electrode at the fixed surface concentration. In consequence of the value of the Faraday constant, one can measure directly and continuously a material transport of $\sim 10^{-11}$ moles/sec as a 1 μa current.

Because of the action of the cell to maintain a fixed surface concentration of the diffusant, it becomes possible by the use of voltage-step techniques to determine D values over a wide composition range. If, in the above case, the applied voltage is maintained at the value V, the diffusion current will persist until the rate of the diffusion process becomes negligible. At this point, the Au electrode has the characteristics of an Au-Ag alloy of silver activity a_{Ag}. If the applied voltage is now changed to a value V', corresponding to a new surface activity a_{Ag}', the situation corresponds to a well-known solution of the diffusion equation. If C_0 and C_1 are the silver concentrations corresponding to a_{Ag} and A_{Ag}', the diffusion flux will be given by

$$J = -D\frac{dC}{dx}\bigg|_{x=0} = -D(C_1 - C_0) \times \left[\frac{d}{dx}\operatorname{erfc}\frac{x}{2\sqrt{Dt}}\right]_{x=0} = (C_1 - C_0)\left(\frac{D}{\pi t}\right)^{1/2} \quad [1]$$

and the corresponding diffusion current by the well-known Cottrell equation

$$i = \mathbf{F}A(C_1 - C_0)(D/\pi t)^{1/2} \quad [2]$$

where A is the electrode area. Thus, if concentrations C_1 and C_0 corresponding to activities a_{Ag}' and a_{Ag} are known (as is the case for the Ag-Au system), a plot of i *vs.* $t^{-1/2}$ should yield a straight line whose slope may be used to derive D. Repeated cell voltage changes would then permit measurement of D in sequential steps across the alloy composition range. Moreover, because of the capability to apply voltage steps that either increase or decrease the surface diffusant concentration, it becomes possible to study not only the conventional "in-diffusion," but extractive or "out-diffusion" as well.

Several factors deserve consideration. First, one should distinguish between the gold electrode potential, relative to the silver potential, and the actual voltage applied to the cell. Where the former directly fixes a_{Ag}, the latter may also contain contributions from polarization at the Ag electrode and iR drop in the electrolyte. If these were appreciable, the result would be an uncertainty and a time variation in the value of a_{Ag}. In fact, one or both of these are invariably important in the early stages of applying a voltage step, and determine the "sharpness" of the step with respect to time scale for the surface activity change. When a voltage step is applied to a cell of this type, the step voltage initially appears across the electrolyte as iR drop and, on the time scale of the RC time constant of the cell, is transferred to the current-blocking electrode. Accordingly, the Cottrell equation becomes applicable at times large compared with the electrode charging time. In our own cells, the charging time is in the millisecond range, permitting diffusion current analysis for times at least as short as 1 sec. Residual portions of the double layer charging persist out to $\sim$ 5 sec but, since the charging is essentially complete at much shorter times, this will only have the effect of adding a transient increment to the diffusion current.

If the electrolyte resistance is large, the iR drop associated with residual double layer charging and even early portions of the diffusion current may be appreciable. This was not the case in our cells, where currents for $t > 1$ sec were in the microampere range and the electrolyte resistance was several ohms, but may well be the case in other systems. In such instances, potentiostatic arrangements with resistance compensation may be employed (5). Likewise, counter electrode polarization may be removed as a factor by the use of a potentiostat with a reference electrode, though, as previously reported (1), this was found unnecessary in our system.

A further consideration is the general presence of a low-level electronic current in such cells. While conduction in our own electrolyte was predominantly ionic, there is in many such cell systems a small steady-state electronic current at any finite applied voltage. This current exists as a consequence of a stoichiometry gradient in the electrolyte and is constant at any particular voltage (2, 6). In a cell Me|MeX|M' with n-type electronic conduction, the current is given by

$$i_e = (\sigma_e{}^o RTA/L\mathbf{F})[1 - \exp(-V\mathbf{F}/RT)] \quad [3]$$

where $\sigma_e{}^o$ is the specific electronic conductivity of MeX at equilibrium with metallic Me, and L and A are the thickness and area of a cylindrical electrolyte pellet. For cells with p-type or mixed electronic conduction, analogous expressions apply. The important point, however, is that, since the electronic current is constant at a given potential, it appears merely as a nonzero intercept in a plot of i *vs.* $t^{-1/2}$. Thus, it is not necessary to know the magnitude or type of conduction in advance. This current, however, together with the electrode charging, defines a lower limit for the size of diffusion currents that may be measured. As mentioned previously (1), it is required that the diffusion current be large enough to be seen against the steady-state electronic current once the double-layer charging process is complete. This depends on the values of D, ΔC, $\sigma_e{}^o$, and the electrode charging kinetics, but can be examined empirically in a given cell system by seeing whether the current in response to a particular voltage step contains a well-defined region of $t^{-1/2}$ variation.

Finally, in examining successive D values across a composition range by applying sequential voltage steps, it is necessary to know how long to wait between successive steps. Ideally, to conform exactly to the boundary conditions for the Cottrell equation, one should wait until the diffusant becomes uniformly distributed throughout the electrode at the concentration corresponding to the previous step. In practice, however, this is often not possible. In our own system, we study D values $\sim 10^{-14}$ cm^2/sec. For a 0.1 cm thick electrode, this would require a characteristic wait time of $x^2/D = (0.1)^2/(10^{-14}) = 10^{12}$ sec! However, several regressions from such a prohibitive wait time are possible. For instance, if one waits merely until the diffusion current becomes negligibly small on the current-measuring apparatus, the electrode will behave to all intents and purposes as though the diffusant were uni-

formly distributed. Even this approximation, however, leads to inconveniently long waits between steps, because of slowness of $t^{-1/2}$ current decay. If currents were recorded up to a minimal time t_1 and we required the current to drop to 1% of its value at t_1 before applying the next step, this would require a wait time $\tau = 10^4\ t_1$. Experimentally, it has been found that much shorter waits may be tolerated, but it is of interest to inquire theoretically why this should be so.

The relevant diffusion problem is one in which we start with a substrate with uniform initial diffusant distribution C_0 and change the surface concentration successively to fixed values C_1, C_2, etc. at equal time intervals τ, the electrode geometry being appropriate to semi-infinite linear diffusion. In our actual system, the uniform initial concentration is achieved either exactly by use of an alloy electrode whose bulk composition is the same as the surface composition fixed by the starting voltage V_0, or is achieved to satisfactory approximation by a sufficiently long initial wait at V_0. An exact analytic solution to the multistep diffusion problem is possible, but only for the case where D is composition-independent. While D indeed varies with composition in our system, it is instructive to present the composition-independent solution and inquire as to what may be a reasonable approximate form for a nonconstant D.

The solution for a constant D may be derived analytically by a treatment described by Carslaw and Jaeger (7), but a simpler approach that supplies the same answer and gives more insight into the physical situation is to make use of the superposition principle (8). In this, one may arbitrarily subdivide a diffusion process into a number of conveniently treated constituent contributions, solve the diffusion problem separately for each, and then sum the solutions. Consider in the present case that we label as Ag_{01} each silver atom deposited on the electrode surface during voltage step $V_0 \rightarrow V_1$ and similarly label each silver atom that is deposited to replace an Ag_{01} atom when it diffuses into the electrode. Likewise we label as Ag_{12} each Ag atom that is deposited during step $V_1 \rightarrow V_2$ or that replaces an Ag_{12} atom on the surface, and so on for further steps. Then the effect of voltage V_1 is to maintain a fixed surface concentration of Ag_{01} atoms, the effect of V_2 is to maintain simultaneously fixed concentrations of Ag_{01} and Ag_{12}, and so on. The net result is that for each newly introduced species of Ag atom, the boundary condition for the Cottrell equation is obeyed for all time, irrespective of previous and subsequent steps. Accordingly, the total current after n steps is given by a sum of Cottrell terms for each constituent Ag species

$$\begin{aligned} i = {} & \mathbf{F}A(C_n - C_{(n-1)})\,(D/\pi)^{1/2}t^{-1/2} \\ & + \mathbf{F}A(C_{(n-1)} - C_{(n-2)})\,(D/\pi)^{1/2}(t+\tau)^{-1/2} + \cdots \\ & \mathbf{F}A(C_2 - C_1)\,(D/\pi)^{1/2}[t + (n-2)\tau]^{-1/2} \\ & + \mathbf{F}A(C_1 - C_0)\,(D/\pi)^{1/2}[t + (n-1)\tau]^{-1/2} \quad [4] \end{aligned}$$

where t is the time after application of the nth step. Note that for $t << \tau$, only the first term on the right shows time variation. (For $t \leq 0.1\tau$ and equal-sized concentration jumps, the error in neglecting t in the other terms is $\leq 1\%$.) Thus, for the nth step, the slope of a plot of i *vs.* $t^{-1/2}$ for data in this time range is unaffected by prior steps, as we have found experimentally. Since the terms for prior steps are effectively constant, the effect on the i *vs.* $t^{-1/2}$ plot is merely to shift its intercept.

This analysis for the case of a constant D suggests that, for a nonconstant D that varies smoothly and gradually with composition, a reasonable approximate expression for the diffusion current should be similar in form to Eq. [4]. We assert, in fact, that we may conceptually separate the contributions from the various steps so that for times $t << \tau$ following the latest step, only the current associated with this step will be varying as rapidly as $t^{-1/2}$, the others varying with time in some manner similar to $(t + n\tau)^{-1/2}$. Thus, a Cottrell expression involving the D for the latest step should still give the slope of the i *vs.* $t^{-1/2}$ plot.

It is useful to consider what we mean by the D for a given step when D is, in fact, composition-dependent. The D values we measure determine the chemical, as opposed to the tracer, diffusion coefficient. That is, we are measuring the D associated with the diffusion of Ag into a substrate at diffusant concentration $C_{(n-1)}$ from a surface concentration C_n. This is inevitable in any study of chemical diffusion. We follow the practice in the literature (9) of assigning the effective D value we obtain to the median composition $\frac{1}{2}(C_{(n-1)} + C_n)$, designating it by $D_{(n-1)n}$.

Given the experimental fact that the D value is not appreciably influenced by the application of prior steps, we need not actually acquire an approximate form of Eq. [4] to evaluate D when it varies with composition. It is instructive, however, to do so, both to see what increments to the current intercepts we might expect, and to explore the general physical picture. Consider that a second step has just been applied and $i(t)$ for $t << \tau$ is being studied. Since the diffusion associated with the prior step has been taking place for the relatively long time $t + \tau$, the characteristic penetration depth associated with it will be large compared with that for the second step. Accordingly, the bulk of the substrate region involved in this diffusion will be in the same composition range as when the step was first applied, there being only a small compositional perturbation near the surface from the subsequent step. Likewise, in a multistep diffusion process, each past previous step would be associated with a greater penetration depth. While the differences between these depths would not be as great as between any of them and the step just applied, it is also true that the contributions of past steps to the total current should be much diminished as new steps are applied. Thus, it may be a reasonable approximation to assume that each contributing diffusion proceeds with the D value originally associated with it, so that Eq. [4] is modified to

$$\begin{aligned} i = {} & \mathbf{F}A(C_n - C_{(n-1)})\,(D_{(n-1)n}/\pi)^{1/2}t^{-1/2} \\ & + \mathbf{F}A(C_{(n-1)} - C_{(n-2)})\,(D_{(n-2)(n-1)}/\pi)^{1/2}(t+\tau)^{-1/2} \cdots \\ & + \mathbf{F}A(C_2 - C_1)\,(D_{12}/\pi)^{1/2}[t + (n-2)\tau]^{-1/2} \\ & + \mathbf{F}A(C_1 - C_0)\,(D_{01}/\pi)^{1/2}[t + (n-1)\tau]^{-1/2} \quad [5] \end{aligned}$$

The usefulness of this expression is that, since the coefficient of each term $(t + j\tau)^{-1/2}$ is the slope of the i *vs.* $t^{-1/2}$ curve obtained from that step, we may evaluate the equation from existing data to see what the intercept shifts should be.

Experimental

As described previously (1), a working cell consisted of a single-crystal AgBr pellet springloaded between a square of Ag foil and the appropriate gold electrode. For the latter, gold single crystals and 50:50 a/o Ag-Au alloy single crystals were employed in different runs. The electrodes were shaped from larger crystals and provided with a smooth, planar surface by spark cutting, followed by mechanical polishing and electropolishing. Because of the short diffusion length involved ($\sqrt{Dt} \approx 10^{-6}$ cm), it was critically important to have the smoothest possible electrode surface with minimal surface damage. In the early runs with pure Au electrodes, the electropolishing was carried out in fused 1:1 NaCl-KCl at 750° at a constant current of $\sim$ 150 ma/cm^2. In the later runs, including all the alloy runs, an aqueous electropolish was employed, using an H_2SO_4-containing saturated thiourea solution (10). In all cases, a specular surface was obtained. Electron micrographs showed no significant roughness down to 500Å. Laue diffraction patterns showed slight to moderate surface damage, unavoidable in a soft metal such

as gold. In general, the aqueous polish gave more consistent results and less surface damage.

In the runs with a pure Au electrode, the assembled cell was outgassed and heated under vacuum to just below the AgBr melting point with an applied voltage corresponding to a 10 a/o alloy composition at 400°. Interface contact was achieved by flash-melting the electrolyte in the neighborhood of the electrodes or, in one run, by prolonged annealing under pressure just below the melting point. No difference in results was noted. In the gold alloy runs, essentially the same procedure was followed, except that at each temperature, a potential corresponding to the 50:50 composition at that temperature was maintained. Following the interface contacting, the cell was cooled to the operating temperature, placed under an argon flow, and allowed to equilibrate for about an hour. All runs were made at approximately 394°. Minor temperature variations from run to run and within a run were accounted for in the D value calculations by employing a diffusion enthalpy factor from the data of Slifkin *et al.* (11) as will be discussed later.

As reported previously (1), the cell voltage and voltage steps were applied via a straightforward battery-voltage divider setup in which a mercury relay provided noise-free stepping between two preadjusted d-c bias levels. The cell current was recorded by the previously described low-impedance amplifier-recorder arrangement.

Following cell equilibration at the operating temperature (394°), voltage steps were applied at 75-min intervals and the cell current recorded in each case. The voltages employed were generally chosen to correspond to 10 a/o composition intervals in the completely miscible Au-Ag solid solution system. In runs with eight cells in all, the alloy composition range 10-90 a/o Ag was covered for both pure Au and 50:50 Ag:Au alloy as the initial electrode material, and for the two electrode surface preparation techniques described. Cell currents in the range 0-10 μa were read with a sensitivity of 0.01 μa. Cell voltages corresponding to the various compositions ranged 10-231 mv and were set to the nearest millivolt with a resolution of 0.1 mv. At the end of a run, the cells were removed from the furnace assembly and the gold electrode area determined by photographing and weighing the photograph cutout. In all cases, the electrolyte was found to be bonded tenaciously to both electrodes. Electrodes to be used in subsequent runs were repolished mechanically and electrolytically.

For the cell voltages corresponding to the various compositions, the most careful relevant studies were those of Wachter (12) and of Kubaschewski and Huchler (13). Wachter measured the emfs of solid-electrolyte concentration cells Ag|AgCl|Ag-Au for seven different alloy compositions over the approximate range 200°-400° and derived emf-composition plots at 200° and 400°. Kubaschewski and Huchler used similar cells, but with silver-ion-containing Thuringia glass as a solid electrolyte. Eleven alloy compositions were studied in the range 300°-600°. Because of the small temperature coefficient of emf ($\lesssim$0.1% per °C), data at 400° could be employed for our cell systems. Smooth emf-composition curves at 400° were drawn separately from the Wachter and Kubaschewski-Huchler data and a best median curve drawn between them. The average discrepancy of the median curve from either of the parent curves was 3½%.

Results

In all cases, plots of i *vs.* $t^{-1/2}$ were linear over a wide time range. This was the case for both forward (in-diffusion) and reverse (out-diffusion) steps. Figure 1 shows a typical plot for a forward step, showing the time range 6-4500 sec, the latter time being wait time τ (75 min). At times below 10 sec, currents showed a general upturn from linearity attributable

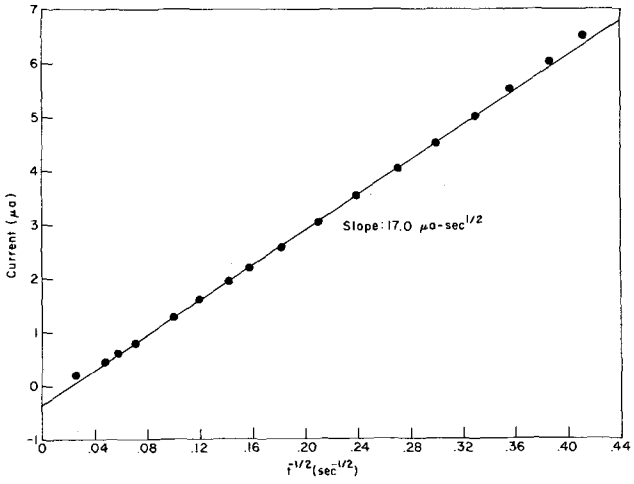

Fig. 1. Current-time data, run 2, 20 → 30 a/o Ag compositional step.

to residual double layer charging. At times in excess of several hundred seconds, there were often small drifts from linear variation, 0.1-0.3 μa at most. Since these were larger than expected from the nonlinearity in $t^{-1/2}$ in Eq. [5] and did not show a consistent direction, they probably represent small furnace temperature drifts. In general, the time range 10-100 sec was used for the slope determinations.

The current intercept in Fig. 1, of opposite sign from the forward diffusion current, represents the sum of the electronic cell current and the time-independent terms in Eq. [5], as previously discussed. All current intercepts were compared with predictions based on Eq. [3] and [5], using the prestep cell current in the equilibrated cell and the current intercept from the first step to predict electronic currents at other cell voltages, and using the slopes of the i *vs.* $t^{-1/2}$ curves to evaluate the terms in Eq. [5]. The match with predictions ranged fair to excellent, the discrepancy averaging 15%. In each case, the qualitative variation predicted for the series of steps in question was observed. The scatter is believed to reflect the sensitivity of the steady-state electronic cell current to temperature fluctuations and low-level impurities.

Several duplicate runs were used to measure the reproducibility of the D values determined. In three early runs, pure Au electrodes, polished by the fused salt technique, were used for 10 a/o forward steps in the composition span 10-60 a/o Ag. In the first two runs, the same Au electrode was simply repolished and used in a new cell. In the third run, a new Au electrode crystal was employed. D values for each composition deviated from their mean by an average of 3%. In addition, duplicate runs were carried out with two 50:50 Ag-Au alloy electrodes, using the aqueous electropolish technique, for 10 a/o forward and reverse steps in the composition span 50-90 a/o Ag. Forward-step D values agreed to an average of 3% and reverse-step values to 10%. As will be discussed later, the latter result is a consequence of the inherently more irreproducible nature of the extractive diffusion process.

The main source of the 3% factor for forward steps is believed to be temperature uncertainty in the runs. Because of the predominant interest in the electrochemical aspects of these runs, insufficient attention was admittedly paid to temperature control. In consequence, the cell temperature was only defined to about ½°. Since Slifkin's data indicates a temperature dependence of D in the Ag-Au system of 5% per °C at our temperature, an approximate 2½% figure can be applied to errors in temperature definition.

In run 8, a pure Au starting electrode was employed, using the aqueous electropolish technique. A series of eight 10 a/o forward steps covered the composition

range 10-90 a/o Ag. This was followed by four 10 a/o reverse steps, the entire run requiring two days. Because of the wide composition range covered, and the more reliable, damage-free surface produced by the aqueous electropolish, the results of this run will be used as a standard of comparison with other runs and with data in the literature.

The most recent and careful study of diffusion in the Ag-Au system has been carried out by Slifkin *et al.* (11) with radiotracer techniques, using nine alloy compositions and temperatures 635°-1010°C. Measurements at lower temperatures were not possible because of the prohibitively low D values. The results, however, were presented in the form of empirical expressions for the various compositions, which could be used to predict values at lower temperatures. Radiotracer diffusion coefficients D^* at 394° were calculated from these expressions and interpolated values taken at our compositions. These were converted to chemical diffusion coefficients by the use of the Darken equation

$$D = D^* [1 + (d \ln \gamma_{Ag})/(d \ln N_{Ag})] \quad [6]$$

a procedure which has previously been found reliable in the Ag-Au system (14). Here, γ_{Ag} and N_{Ag} are the activity coefficient and mole fraction of Ag in the alloy. Since $d \ln \gamma_{Ag} = d \ln a_{Ag}$ and the emf in the Wachter and Kubaschewski-Huchler concentration cells is given by $-F\mathcal{E} = RT \ln a_{Ag}$, the Darken equation reduces to

$$D = D^* \left[1 - \frac{FN_{Ag}}{RT} \frac{d\mathcal{E}}{dN_{Ag}} \right] \quad [7]$$

where $d\mathcal{E}/dN_{Ag}$ can be evaluated directly from the emf-composition curve. Values for the bracketed term ranging from 2.56 to 3.18 were obtained.

Figure 2 shows the run 8 diffusion coefficient data for forward steps and compares it with values calculated from Slifkin's data. All our D value-composition curves showed the same smooth compositional variation with a minimum close to 50%. The slightly different compositional behavior reported previously (1) was found to be the result of less carefully chosen voltage values from the Wachter and Kubaschewski emf-composition data. In Fig. 2, D values in the range 10-50 a/o Ag agree with those calculated from Slifkin's data to an average of 25%, which is reasonable, considering the extrapolation represented and the use of the Darken equation. The calculated values, however, do not show a minimum and hence deviate progressively at more silver-rich compositions. Slifkin's data, however, included a D value-composition plot for Ag at 875° that showed the same type of minimum as ours in the neighborhood of 50 a/o Ag. The appearance of this minimum at 875° and not at 394° is related to the empirical expressions employed. In these expressions, of the usual form $D^* = D^*_0 \exp(-Q/RT)$, a minimum occurs at 875° because of increases in both D^*_0 and Q with increasing silver content. At 394°, the exponential term dominates and no minimum is predicted. Since only small changes in D^*_0 and Q are required to create the minimum at 394°, it is felt that its absence is an artifact of extrapolating the empirical expressions to this temperature. The narrow range of Q values reported (40.2 to 44.5 kcal/mole) and the reasonable agreement with a fair portion of our data allow the use of an average Q value in this range to correct our D values for run-to-run temperature variations of several degrees, as was done.

Figure 3 shows the effect of surface preparation technique on the D value results. The curve for runs 2, 3, and 4 represents an average of the closely agreeing D values from these runs. In these runs, a fused salt electropolish was used, while the aqueous polish was used in run 8. The former curve is seen to be higher by a factor 1.4 to 1.6. As we have noted, aqueous polishing gave more consistently specular surfaces and less surface damage. One effect of aqueous polishing may have been a lower microscopic surface roughness. In this respect, surface roughness is a factor in diffusion measurements if the scale of the roughness is large compared with the characteristic diffusant penetration distance. In this event, in our own experiments, the effect would be to increase the electrode area A in the Cottrell equation. The somewhat greater surface damage from the fused salt polish, however, may also play a role. The reasonable partial agreement between the run 8 values and the extrapolations from Slifkin's data would indicate that the roughness factor in run 8 was not severe. It should be pointed out that these effects of surface preparation are not unique to the electrochemical method, but would be common to any method that measured D values from characteristic diffusant penetration distances this small (30-100Å). In the measurement of larger D values, such effects become correspondingly smaller.

In several runs, the effect of previous compositional cycling was studied. In run 3, for instance, 10 → 60 a/o Ag steps of 10 a/o size were applied to a pure Au electrode, followed by a step 60 → 50 and a repeat 50 → 60 a/o step. A 7% higher D value was obtained for the repeat step. Following this, the cell was stepped to 90 a/o in three further steps, reverse-stepped to 10 a/o in one large step, and the first 10 → 20 a/o step repeated. A 10% larger D value was obtained. In

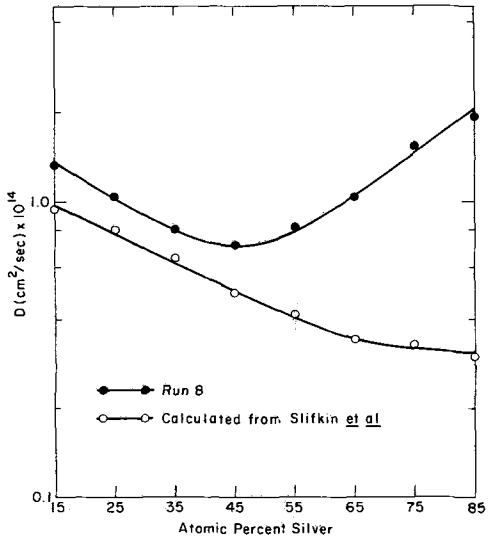

Fig. 2. Calculated and measured (run 8) chemical diffusion coefficient of Ag into Ag-Au alloys at 394°.

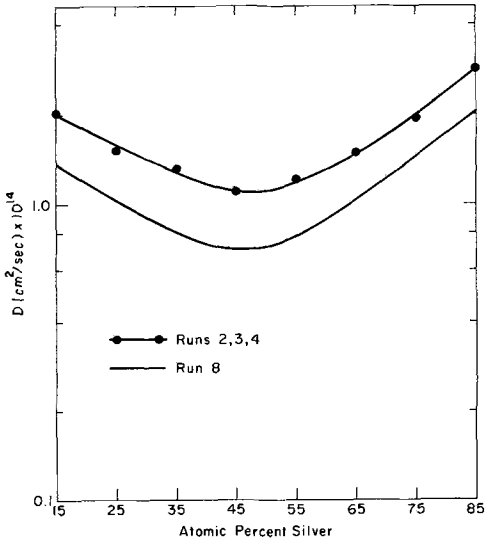

Fig. 3. Comparative in-diffusion D values from runs 2, 3, 4 (fused salt electropolish) and run 8 (aqueous electropolish).

run 4, the same initial sequence 10 → 60 → 50 → 60 a/o was followed, yielding an 8% higher D value for the repeat 50 → 60 step. The cell was then stepped back to 10 a/o in 10 a/o steps and the entire 10 → 60 step sequence repeated. The respective D value increases in these five steps were 15%, 17%, 52%, 70%, and 97%. It was concluded that extensive cycling over the composition range results in significantly increased D values, the increase increasing with the extent of cycling. As will be discussed, the development of surface roughness is felt to be responsible.

The above effect made it a possibility that the D value for any given step in a step sequence may be influenced by the application of prior steps, even for a simple, unidirectional sequence. To check this possibility, it was desirable to do experiments on a bulk Ag-Au alloy of known composition, with steps starting at this composition. For this purpose, 50:50 alloy electrodes were employed in runs 6, 7, and 9. In run 6, the composition was stepped 50 → 10 →50 in eight consecutive 10 a/o steps while, in duplicate runs 7 and 9, the same was done for the range 50 → 90 → 50. A composite D value-composition curve for the forward steps in these three runs is shown in Fig. 4, together with the run 8 (pure Au) curve for comparison. All the electrodes were prepared by the aqueous polishing technique. The good match of the 50-90 points in runs 7 and 9 with the run 8 values shows that no significant "memory" effects are involved in a simple forward step sequence across the composition range. In run 6, however, where the 10 → 50 forward steps were preceded by a reverse step sequence, the D values are about 14% higher. This would indicate that a reverse step sequence introduces such a "memory" into a subsequent forward step sequence.

The electrochemical method permitted, for the first time, a direct comparison between D values corresponding to in-diffusion and out-diffusion in a solid-state system. Wagner and co-workers (15, 16) have examined the process of out- or extractive diffusion from solid-solution alloys in connection with liquid-metal leaching and selective anodic dissolution, but quantitative measurements were not made. In general, no distinction has been made between in-diffusion and out-diffusion in terms of D values. Indeed, the macroscopic equations developed from Fick's laws are symmetric in this regard, permitting no such distinction. Nonetheless, since the electrochemical method permitted such measurements, it was of interest to make them.

In all the measurements, the reverse-step D values showed the same general compositional variation as the forward-step values, but were invariably higher. This was true even when comparing the first reverse step on a 50:50 alloy (50 → 40) with the corresponding forward step (40 → 50) on a pure Au electrode, where cycling effects could not be involved. Likewise, an isolated reverse step in a sequence of forward steps (*e.g.*, 10 → 20 → 30 → 40 → 50 → 60 → 50 → 60) gave a higher D than the corresponding forward step on each side of it. Moreover, as previously noted, more scatter in duplicate runs was observed for reverse steps. Figure 5 shows the combined forward and reverse D values for 50:50 alloy runs 6, 7, and 9.

Forward-reverse D value ratios were available from some 30 steps in various runs. When plotted as a function of composition on a common graph, however, they showed too much scatter to ascertain even a well-defined compositional trend. Scatter between duplicate runs was as great as between runs under different conditions. Accordingly, a smoothing procedure was adopted. In each run, such as in Fig. 5, where a range of forward and reverse D values was obtained, a best smooth curve was drawn through each set of points and the factor relating the two curves determined at each composition. The smoothed data from the various runs clustered together in the range 10-50 a/o Ag, but showed considerable scatter at more silver-rich compositions. In the 10-50 range, the average values of the D_{rvs}/D_{fwd} ratio at 15, 25, 35, and 45 a/o Ag were 1.34, 1.32_5, 1.31_5, and 1.33_5, suggesting a composition-independent ratio of 1.33 ± 1% in this range. At more Ag-rich compositions, there were indications of a general increase, but the scatter of the data was too great to ascertain this.

Finally, in several runs, the effect of step size was examined. In four instances, 10 a/o compositional steps were split into two constituent 5 a/o steps. No significant difference in D values was obtained. In addition, however, in several runs with pure Au electrodes, terminating at high Ag concentrations, a final reverse step was applied to restore the initial pre-step 10 a/o Ag composition. In these cases, considerably enhanced D values were obtained. For the 60 → 10 step in run 2, we obtained $D = 3.4 \times 10^{-14}$ cm²/sec, compared with an average of 1.30×10^{-14} cm²/sec for forward steps in the 10-60 range and an expected average reverse-step D of 1.73×10^{-14} cm²/sec from the use of the 1.33 factor for D_{rvs}/D_{fwd}. For a 90 → 10 step in run 3, a D value of $10.9_5 \times 10^{-14}$ cm²/sec was obtained, clearly in excess of the average D value expected from smaller steps in the run. In such cases, it is apparent that the sudden gross compositional change at the electrode surface results in a drastic alteration in the nature of the surface, making comparison with smaller-sized steps questionable. Finally, it should be

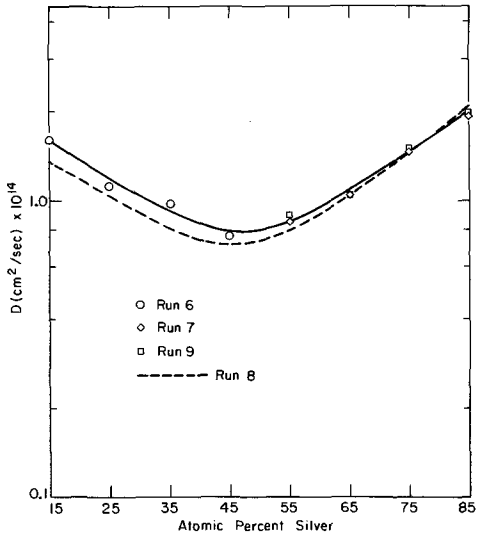

Fig. 4. Comparative in-diffusion D values from runs 6, 7, 9 (Ag-Au alloy electrode) and run 8 (Au electrode).

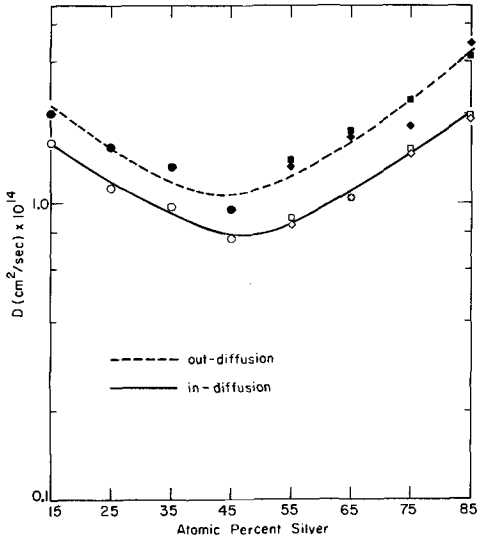

Fig. 5. Comparative in-diffusion and out-diffusion D values for runs 6, 7, and 9. Point designations as in Fig. 4.

pointed out that in all reverse steps, where one is dealing with an anodic removal of Ag into the electrolyte, co-anodization of Au may be ruled out on both thermodynamic and experimental grounds, independent voltammetric experiments in our laboratory having shown that a potential of ~0.6v is required for Au oxidation.

Discussion

In discussing the results, one needs some sort of microphysical picture to describe diffusion processes occurring on and in the neighborhood of the electrode surface. Specifically, explanations must be offered for the observed enhancement of out-diffusion and for the apparent generation of surface roughness in this process. In what follows, we offer what we feel to be a plausible model on the basis of present understanding in this area.

Metallic silver and gold have the same crystal structure (fcc), almost equal lattice parameters, and form a continuous series of substitutional solid solution alloys. Accordingly, diffusion occurs by a vacancy mechanism. In the process of in-diffusion, the Au concentration will be increasing from the surface of the electrode to the interior. Hence, in accordance with Fick's first law, there must be, through any fixed plane parallel to and several atom layers below the surface, an Au flux toward the surface as well as the Ag flux away from it. Therefore, to maintain the fixed Ag:Au ratio in a thus-defined "surface region," more Ag must be plated onto the surface than is diffusing through this plane. Thus, the electrode is growing towards the electrolyte from such a fixed plane. We consider the surface growth in terms of the usual kink-step-terrace picture (16, 17). Previous work in our laboratory (3, 4) has shown that, when a voltage step appropriate for in-diffusion occurs, there is a rapid and uniform enhancement of the Ag concentration in the first atom layer. This, plus considerations of entropy, kink-step populations, and simple kinetics insures that Ag atoms will be deposited mainly on terrace sites, where they may possibly be considered "ad-atoms" (17). To maintain compositional homogeneity, Ag atom diffusion toward step and kink sites must be accompanied by Au atom diffusion, ultimately from the electrode interior. It is suggested that free exchange occurs between Ag atoms on terrace sites and underlying Au atoms, and that the resulting mixture of Ag and Au atoms on terrace sites, in the ratio fixed by the electrode potential, migrates to step and kink growth sites. Thus, plated Ag atoms may be incorporated into the electrode either by migration to such sites or by exchange with Au at terrace sites. In either event, subsequent in-diffusion occurs by the arrival of vacancies from within the electrode. A relatively orderly surface growth pattern is expected, not unlike that for low-current electroplating. An equilibrium concentration of vacancies is assumed to exist throughout the electrode and to be built in on the growing surface at step and kink sites.

In the process of out-diffusion, the same arguments as above require that a reverse voltage step result in a very large concentration of vacancies at terrace sites, produced by electrolytic stripping. In a 50 → 40 a/o Ag step, for instance, one-third of the surface Ag atoms present would be stripped off in several milliseconds. By contrast, one may estimate from Shewmon (18) that the equilibrium vacancy mole fraction in Au at ~400° should be about 3×10^{-8}. Since the diffusion rate by a vacancy mechanism is proportional to the local vacancy concentration, it is apparent that if all or even an appreciable fraction of the electrolytically created vacancies migrated into the electrode interior, there should be an enormous enhancement from the in-diffusion rate in the 30-100Å effective diffusion distances we are studying. The relatively modest enhancement we observe suggests that most of them coalesce on the surface, but that, from strictly random atom movements, enough are "injected" into the interior to cause the observed effect. What we expect, then, is a local supersaturation of the vacancy concentration. Since the exact degree of supersaturation might well be a matter of the precise electrode surface or interface condition, the observed scatter for reverse-step D values is reasonable.

Vacancies thus produced that are not injected into the interior could migrate to step and kink sites, but it seems more likely, from their large concentration, that most of them would coalesce to form local patches. Since the "floors" of such patches are also subject to Ag stripping and vacancy coalescence during the continued out-diffusion process, one has a mechanism for the generation of surface roughness. Harrison and Wagner (15) have asserted, from a macroscopic argument, that a plane alloy surface is unstable during the selective leaching of a component by liquid metal extraction or electrolysis, and that a rugged interface develops. The surface roughness thus introduced would account for the enhanced forward-step D values obtained after a series of reverse steps, both in the runs where cycling effects were encountered, and in the 50:50 alloy runs for the 10 → 50 steps.

In the case of large (60 → 10 and 90 → 10) reverse steps, we are of course dealing with electrolytic dissolution of the major portion of the electrode surface. In such a situation, one actually expects the effective collapse of the entire electrode surface. The observed enhancement of the diffusion rate would then not be surprising in view of the greater likelihood of excess vacancy incorporation.

Applications

In this section, we would like to discuss some of the general applications and limitations of electrochemical methods in studying diffusion in metals and other solid electronically conducting systems at elevated temperatures. Some of the limitations were mentioned in the previous communication. For instance, it is necessary in cells Me|MeX|M′ to employ an electrolyte MeX that does not react chemically with substrate electrode M′. In metal-electrode systems, this requires a metal M′ that is reasonably more noble than Me, and remains a basic limitation. M′, however, might well be a chemically saturated electronically conducting material, such as a compound semiconductor. In this case, one requires the absence of chemical addition and replacement reactions with the electrolyte. It may be possible, in fact, to study thin-layer diffusive doping in systems such as, for instance, Ag or Cu in CdS. A precaution in such systems would be to insure that the diffusion current does not result in excessive iR drop in the semiconductor, or to compensate for such effects, either instrumentally or in the data analysis. A distinct possibility that follows from the ability to conduct out-diffusion as well as in-diffusion would be the creation of junctions, such as by following a long in-diffusion period with a short-lived out-diffusion. Selective doping of particular surface areas might be accomplished by suitable shaping of the solid electrolyte, either in pellet or evaporated-film configuration, or by conventional masking.

While the above-described methods were developed for solid electrolytes, one may in principle conduct similar studies with fused salt electrolytes. In our own laboratory, we have observed suitable polarization characteristics in the cell Ag|AgBr(l)|Pt. While steady-state cell currents were higher than for AgBr(s) cells, they showed the expected voltage dependence for electronic currents and can be handled by the use of current-compensating potentiostatic power supplies. A variation would be the use of the diffusant compound in question, MeX, as a dilute solute in an inert fused-salt solvent such as an alkali halide mix. There remains, however, a range of un-

explored solid electrolytes (halides of Cu, Pb, Cd, Tl, alkali and alkaline earth metals) as well.

We have noted that a diffusion current, to be observable in cells of this type, must be large enough to be seen against the steady-state cell current for a reasonable time after the electrode interface is charged. While current compensation can be used to remove a portion of the steady-state cell current, residual currents and noise define a lower limit. The Cottrell equation (Eq. [2]) shows the factors involved in the size of the diffusion current. Electronic and noise effects increase linearly with cell area A, so A is not a parameter of interest. The quantity $\Delta CD^{1/2}$ is the controlling one. Since the maximum value of ΔC in the system is the diffusant solubility C_s, there is an inverse relation between the lowest detectable value of D and C_s. In our own system (complete solubility), D values $\sim 10^{-14}$ cm^2/sec were measured readily; less accurate values several orders of magnitude lower could have been measured with one or several large steps. Using this as a criterion for the lower-limit size of $C_sD^{1/2}$, a dopant-level C_s of 2 x 10^{18} carriers/cm^2 with a D value of 10^{-9} cm^2/sec could be studied, provided similar influences of the interface charging time and steady-state cell current prevailed.

An important consideration in our own work was the activity-composition relation in the Ag-Au system, in that the surface diffusant concentration could not be fixed electrochemically without these data. In alloy systems with wide solid solution ranges, such data would be required, either from pre-existing work or from a separate series of concentration-cell experiments with a number of alloys of suitable composition. In systems with C_s small enough to obey Henry's law, a knowledge of this solubility would suffice. These considerations, however, apply to systems with relatively small D values.

In systems where the D value is large enough for $\sqrt{Dt}$ to be comparable with the thickness of a thin-film electrode in a reasonable time t, a number of methods are available for determining D and C_s in the same experiment. In the coulometric titration method of Wagner (19), for instance, the cell voltage can be stepped from one value to another, the cell permitted to equilibrate completely, and the total charge transfer used to determine the material dissolved corresponding to the known change in activity level in an electrode of known volume. In another method, Rickert (20) has shown in the case of oxygen diffusion in silver, that D and C_s may be separated by studying semi-infinite linear diffusion and inward diffusion from the surface of a cylinder in separate cells, since the differing forms of the diffusion equations for the two cases allow such separation when $\sqrt{Dt}$ is comparable with the radius of the cylinder. Rapp (21) has measured both D and C_s, in studying oxygen diffusion in copper, by analysis of the current-time function where an electrode is being saturated with oxygen by joined cells on either side.

In systems with relatively high D values, some intriguing experiments should be possible by using separate cells on a common electrode to "transmit" and "receive" the diffusant. A possible arrangement of this type would be Me|MeX|M'|MeX|Me. If both cells are initially set to define a low, common value of a_{Me} in a slab or foil electrode of metal M', and the voltage on one is stepped to an appreciable a_{Me}, metal Me will be transmitted into M' from this cell and, when it arrives at the other side, will be anodically stripped by the second cell, giving rise to an observable stripping current. Eventually, the same current is seen in both cells, corresponding to the steady-state flux of diffusant down a known, linear activity gradient. The steady-state flux and the time required to reach it provide determinations of D and C_s. The method is analogous to the well-known "lag time" method for studying gas permeation in solid membranes (22). A plot of the integrated diffusion current in the second cell as a function of time would give a linear "steady-state" portion which may be back-extrapolated to the time axis to give lag time $\tau = x^2/6D$, where x is the electrode thickness. A sequence of alternating a_{Me} increases on the two sides would in principle permit determination of D and C_s values over the full range of diffusant activities. In a variation of this approach, it might be possible to study surface diffusion on a metallic specimen by means of Me|MeX> "probe" cells (Me wires coated with MeX), serving as diffusant sources and sinks at various points on the surface.

Finally, mention should be made of possible galvanostatic methods for studying diffusion electrochemically. In an alloy cell Me|MeX|M'-Me, for instance, we may apply a constant current sweep that anodically strips Me from the alloy and monitor the potential-time variation. In this, the sweep ultimately depletes the alloy surface of diffusant, resulting in a potential surge; the "transition time" for this is given by the Sand equation (23). An alternative galvanostatic method was employed by Rapp in the above-mentioned copper-oxygen study (21), where D was measured from the slope of a current-time function plot. Such methods do not offer any advantages over potentiostatic ones in separating D and C_s, are subject to interference from double layer charging and electronic cell currents, and give a mean value of D when compositional variation is involved, but may supply useful and rapidly obtained complementary data in suitable circumstances.

Acknowledgments

The authors are extremely grateful to Professor Lawrence M. Slifkin for the gift of a 50:50 Ag:Au alloy single crystal and to Mr. James Savage of our laboratory for growing several gold single crystals. Helpful discussions and suggestions from Professor Carl Wagner and Dr. A. Sosin are gratefully acknowledged. The authors are grateful to Professor Carl Wagner for pointing out that the diffusion treatment in the present case should include a correction to account for the movement of the electrode boundary during diffusion. Because of its complexity, this correction will be discussed in a future communication.

Manuscript submitted June 17, 1968; revised manuscript received *ca.* Aug. 21, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1969 JOURNAL.

Void Fraction and Current Density Distributions in a Water Electrolysis Cell

J. E. Funk
University of Kentucky, Lexington, Kentucky

and J. F. Thorpe
University of Cincinnati, Cincinnati, Ohio

ABSTRACT

An analytical basis defining the steady-state conditions occurring in an electrolysis cell is stated. Several assumptions are made which permit a theoretical determination of the void fraction and current density distributions. The effect of void fraction and inlet velocity on cell performance is shown. Experimental data for the void fraction and slip ratio occurring in an electrolysis cell are presented. It is found that the slip ratio is near unity. This result is of importance in defining the cell void fraction distributions and is prerequisite to an analysis of pressure drop in electrolysis cells.

There has been a renewed interest recently in the water electrolysis process. This is due to the potential of this process for life support systems in both space and deep-sea applications (1, 2). The water electrolysis process is also being considered on a large scale in connection with industrial complexes which can desalt water, produce power and other products such as hydrogen, oxygen, ammonia, ammonium nitrate, and nitric acid (3, 4). The energy source for such a complex could be a very large nuclear reactor which would be coupled to a large electrolyzer system (5).

In the design of water electrolyzers there is a need for basic engineering information concerning electrode materials, electrolytes, electrolyzer control, and the two-phase hydrodynamics and heat transfer. The current density distribution and the pressure drop, in particular, are two areas of research in which there is little published data. Concurrent with these problems is that of predicting the void fraction (or slip ratio) in an electrolysis cell. The present paper presents the results of the first of two research programs (6) designed to fill this need. The first program is an experimental and analytical investigation of void fraction (or slip ratio) in an electrolysis cell. This program is prerequisite to the second research program which involves an experimental investigation of pressure drop in an electrolysis cell. Both programs require an analytical model for experimental data reduction. The first part of this paper presents the analytical basis while the later section presents the void fraction and slip ratio data. The pressure drop data and correlations will be presented in a separate paper since this work is still in progress.

The electrolysis process is complicated because of the simultaneous occurrence of coupled, nonlinear transport of mass, momentum, and energy in the presence of electrochemical reactions in the electrolyte and on the electrodes. The precise definition of these processes requires the statement and simultaneous solution of a set of coupled, nonlinear, partial differential equations. In view of the magnitude of the task of solving this set of equations, one dimensional (or hydraulic) equations will be used to define the flow in an electrolysis cell configuration such as is sketched in Fig. 1. The approach is essentially that which has been outlined by Brodkey (7) and used extensively in the field of two-phase flow (7-9). In this problem, however, there is the additional complication of interchannel cross flow through the porous membrane.

The first significant work on such a problem was by Tobias (10) who discussed previous work and then presented an analytical solution for the void fraction subject to the assumptions: (*a*) zero cell inlet velocity, (*b*) no membrane in the cell, (c) gas velocity independent of void fraction, and (*d*) constant electrode polarization.

Aside from Tobias' work there seem to be no significant publications directly applied to the water electrolyzer cell. There are, however, several papers on electrochemical machining (ECM) in which an allied problem is discussed (11-14). The purpose of this paper is to present a more general analytical basis for the flow in an electrolyzer cell and to provide some preliminary experimental data which may be useful in electrolyzer engineering.

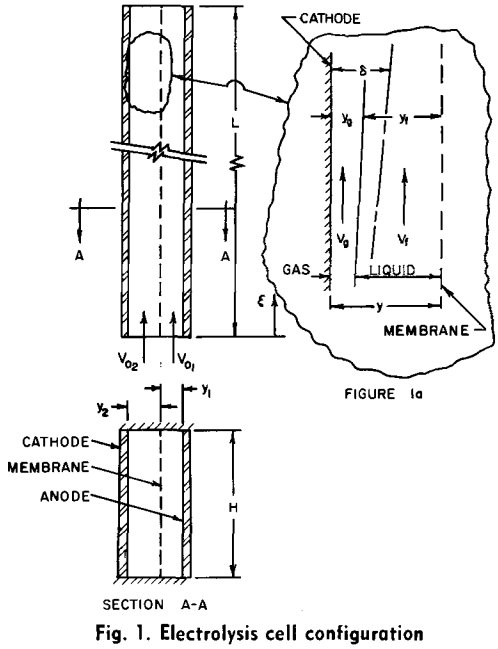

Fig. 1. Electrolysis cell configuration

Analytical Basis

Consider the electrolysis cell configuration sketched in Fig. 1. The electrolyte flow is from the bottom toward the top in a cell of width H and length L. The cell consists of two parallel channels separated by a membrane. Flow in the hydrogen side consists of a mixture of hydrogen gas and electrolyte in a thin rectangular channel (H by y_2) formed between the membrane and cathode. Flow in the oxygen side consists of a mixture of oxygen gas and electrolyte in a rectangular channel (H by y_1) formed between the membrane and anode. The membrane is assumed to be porous to OH^- ions and possibly to liquid electrolyte. Subscript 1 denotes the flow properties on the oxygen side while subscript 2 denotes properties on the hydrogen side. Various species within a given channel are identified by the subscripts g for gas, f for electrolyte, and i for hydroxyl ion. Since only an alkaline electrolyte is considered, the hydrogen ion is neglected.

The transverse current density (current flux) ϕ in the cell is a function of axial position ξ. If the cell is vertical then ξ is identical with the coordinate z. The current flux generates hydrogen gas on the cathode at the local mass flux rate $\dot{m}_{2g}$. The hydrogen gas flows upward with average velocity V_{2g} in some equivalent area proportional to the dimension y_{2g}. The gas bubbles, or voids, are contained within an electrolyte layer near the cathode surface which is called the hydrogen bubble layer of thickness δ_2.

The liquid electrolyte flow on the hydrogen side occurs with average velocity V_{2f} in an equivalent area proportional to y_{2f} where

$$y_2 = y_{2g} + y_{2f} \qquad [1]$$

A similar flow configuration exists on the oxygen side where oxygen gas is liberated on the anode at the local mass flux rate $\dot{m}_{1g}$ and then flows upward with average velocity V_{1g} in an equivalent area proportional to y_{1g}. The oxygen bubble layer thickness is δ_1 and the electrolyte flow on the oxygen side has velocity V_{1f} in an area proportional to y_{1f} where

$$y_1 = y_{1g} + y_{1f} \qquad [2]$$

A hydroxyl ion flux occurs through the membrane which has the net effect of transporting H_2O from the cathode side to the anode side of the cell. In addition to the ion flux, the membrane may be porous to the liquid electrolyte. These fluxes through the membrane are denoted by $\dot{m}_i$ and $\dot{m}_f$, respectively.

The definitions and derivations which follow will apply to either hydrogen or oxygen sides of the cell so that, in the interest of simplifying the notation, the numerical subscript will be omitted.

The gas quality x, sometimes called the flowing quality, is defined by the equations

$$x = \frac{w_g}{w}\,;\ (1-x) = \frac{w_f}{w} \qquad [3]$$

where

$$w_g = \rho_g A_g V_g = \text{mass flow rate of gas} \qquad [4]$$

$$w_f = \rho_f A_f V_f = \text{mass flow rate of liquid} \qquad [5]$$

$$w = w_g + w_f = \text{total mass flow rate} \qquad [6]$$

and ρ_f = liquid density, ρ_g = gas density, $A_f = Hy_f$ = area occupied by liquid, $A_g = Hy_g$ = area occupied by gas, V_f = average liquid velocity, and V_g = average gas velocity.

The gas volume fraction α, sometimes called the void fraction, and the liquid holdup $(1-\alpha)$ are defined by

$$\alpha = \frac{A_g}{A}\,;\ (1-\alpha) = \frac{A_f}{A} \qquad [7]$$

where

$$A = A_g + A_f = Hy \qquad [8]$$

If Eq. [3] to [7] are combined, the following equation is obtained

$$\left(\frac{1-\alpha}{\alpha}\right) = \sigma\left(\frac{1-x}{x}\right)\left(\frac{\rho_g}{\rho_f}\right) \qquad [9]$$

where σ is the slip ratio (also called the phase velocity ratio) defined by

$$\sigma = \frac{V_g}{V_f} \qquad [10]$$

In general, the slip ratio σ depends on pressure p, void fraction α, mass flow rate w, channel area A, density ratio ρ_g/ρ_f, and channel orientation (15-17). That is, in general

$$\sigma = \sigma(p,\alpha,w,A,\rho_g/\rho_f) \qquad [11]$$

One of the major efforts of two-phase flow research is to determine the function σ.

Most of the engineering quantities of interest in an electrolysis cell, such as ohmic resistance of electrolyte or pressure drop, are functions of the void fraction α; the void fraction depends, in turn, on the slip ratio σ which is generally unknown. There are several models which express the void fraction-slip ratio relationship (15-17). The simplest model is called the fog-flow or homogeneous model in which σ is taken to be unity.

Continuity equations.—Assuming the flow in the cell to be steady, application of the law of conservation of mass to the gas and liquid electrolyte phases of Fig. 1a yields the following equations

$$\frac{d}{d\xi}(\rho_g y_g V_g) = \dot{m}_g \qquad [12]$$

$$\frac{d}{d\xi}(\rho_f y_f V_f) = -\dot{m}_g + (\pm)\dot{m}_i + (\pm)\dot{m}_f \qquad [13]$$

where the mass flux rate $\dot{m}_g$ is given by

$$\dot{m}_g = \lambda_g \phi \qquad [14]$$

and

$$\lambda_g = \frac{M_g}{\epsilon_g} \qquad [15]$$

The atomic weight of the gas is M_g while its valence on electrolytic decomposition is ϵ_g. The proportionality constant λ_g is the electrochemical equivalent.

The mass flux $\dot{m}_f$ is nonzero only if the membrane is porous to liquid electrolyte; if the membrane does have this porosity, then both the magnitude and sign of the term $\dot{m}_f$ depend on the pressure distributions along the two sides of the membrane.

The hydroxyl ion flux $\dot{m}_i$ can be related to the flux $\dot{m}_g$ from the equation of the electrochemical reaction occurring in the channel. On the cathode side, for example, the equation is

$$\textit{cathode:} \qquad 2H_2O + 2e^- \rightarrow 2\,OH^- + H_2 \qquad [16]$$

For every gram of hydrogen generated on the cathode side, there are 17g of hydroxyl ions passing through the membrane; this ion flow is provided by the liquid electrolyte phase. Thus on the cathode side, the minus (—) sign is selected for $\dot{m}_i$ and

$$\textit{cathode:} \qquad \dot{m}_i = -17\dot{m}_g \qquad [17]$$

On the anode side, the electrochemical reaction is

$$\textit{anode:} \qquad 2\,OH^- \rightarrow \frac{1}{2}O_2 + H_2O + 2e^- \qquad [18]$$

Thus for every gram of oxygen generated, there are 2.125g of hydroxyl ions flowing through the membrane into the oxygen channel. In this instance, the plus (+) sign is selected for $\dot{m}_i$ and

$$\textit{anode:} \qquad \dot{m}_i = 2.125\dot{m}_g \qquad [19]$$

Using the definitions made previously, the continuity equations can be rewritten in the forms

$$\frac{d}{d\xi}(\rho_g \alpha \sigma y V_f) = \lambda_g \phi \quad [20]$$

$$\frac{d}{d\xi}[\rho_f(1-\alpha)yV_f] = (\gamma - 1)\lambda_g\phi + (\pm)m_f \quad [21]$$

where

$$\left\{ \gamma = \begin{matrix} -17 \text{ cathode side} \\ +2.125 \text{ anode side} \end{matrix} \right\} \quad [22]$$

Equation of motion.—Application of the law of motion to the two-phase mixture flowing in the channel between membrane and electrode gives the equation

$$\alpha\rho_g \frac{d}{d\xi}\left(\frac{\sigma^2 V_f^2}{2}\right) + (1-\alpha)\rho_f \frac{d}{d\xi}\left(\frac{V_f^2}{2}\right) + \frac{dp}{d\xi} + \frac{2\tau}{y} + [\alpha\rho_g + (1-\alpha)\rho_f]g\frac{dz}{d\xi} + \frac{\sigma\lambda_g\phi V_f}{y} = 0 \quad [23]$$

In deriving this equation, the following assumptions have been made

(*a*) The production of gas has been assumed to occur at the electrode surface from liquid electrolyte which is at rest on the electrode surface. This gas must be accelerated to the gas velocity V_g by the gas phase pressure gradient. This effect is represented by the momentum flux term which is the last term of Eq. [23].

(*b*) The transverse pressure gradient has been assumed negligible so that the same axial pressure gradient occurs in each phase.

Energy equation.—The energy transport of the gas phase will be assumed negligible due to the low thermal conductivity and heat capacity of the gas compared to the electrolyte. Application, then, of the first law of thermodynamics to the liquid electrolyte gives the equation

$$\rho_f V_f \frac{dT}{d\xi} = \frac{R\phi^2}{C_f(1-\alpha)y} + \frac{\mu\Phi}{C_f} \quad [24]$$

where R is the electrical resistance of the electrolyte-bubble mixture, C_f is the liquid specific heat, and μ is the viscosity. The first term on the right side is the electrical dissipation while the second term is the viscous dissipation.

Electrical equations.—Consistent with the one-dimensional transport equations of continuity, momentum, and energy, stated above, is a one-dimensional transport equation of charge within the electrode gap. However, such an equation will involve ion mobilities, electrochemical reactions, and other complicated processes and will not be presented here. Rather, the electrical phenomena will be represented by a simple form of Ohm's law.

Let the sum of the electrode polarization and decomposition potentials be denoted by ΔE while the applied voltage is E. Then the voltage E' available for overcoming Ohmic resistance of the two-phase electrolyte is given by

$$E' = E - \Delta E \quad [25]$$

and

$$E' = \phi R_c \quad [26]$$

where R_c is the Ohmic resistance of the cell. This resistance consists of a membrane resistance R_m in series with resistances R_1 and R_2 of the electrolyte-bubble mixtures in the oxygen and hydrogen channels of the cell. That is

$$R_c = R_1 + R_m + R_2 \quad [27]$$

The resistances R_1 and R_2 are functions of the properties of pure liquid electrolyte, the void fraction α, and the temperature T.

The cross section of a channel occupied by gas at position ξ is proportional to y_g. This void is distributed within some bubble layer of thickness δ. The void fraction α' based on bubble layer thickness (that is, the void fraction within the bubble layer) is defined by

$$\alpha' = \frac{y_g}{\delta} \quad [28]$$

The resistance within the bubble layer is some function of α' rather than α.

The total transverse resistance, per unit cross sectional area perpendicular to y, is

$$R = r_{tp}\delta + r_f(y - \delta) \quad [29]$$

where r_{tp} is the two-phase resistivity in the bubble layer and r_f is the liquid electrolyte resistivity. The quantity r_f is, in general, temperature dependent. That is

$$r_f = r_f(T) \quad [30]$$

The two-phase resistivity, in the bubble layer, is a function of α' assumed to be of the form

$$r_{tp} = r_f f(\alpha') \quad [31]$$

The function f is determined from some void fraction-resistivity model which assumes a homogeneous distribution of bubbles within an electrolyte matrix. The simplest such relation would be

$$f(\alpha') = \frac{1}{1-\alpha'} \quad [32]$$

Tobias (10) proposed that

$$f(\alpha') = \frac{1}{(1-\alpha')^{1.5}} \quad [33]$$

while Mashovet's (18) equation is

$$f(\alpha') = \frac{1}{1 - 1.78\alpha' + \alpha'^2} \quad [34]$$

Mashovet's equation is empirical and valid for spherical inclusions forming void fractions up to 74%.

It can be noted that

$$\alpha' = \frac{y}{\delta}\alpha \quad [35]$$

so that Eq. [29] can be written as

$$R = r_f\left[(y - \delta) + \delta f\left(\frac{y}{\delta}\alpha\right)\right] \quad [36]$$

The electrode polarization overvoltages are assumed to obey Tafel (19) equations of the form

$$\Delta E_p = a + b \ln \phi \quad [37]$$

where a, b are constants depending on electrode material, electrolyte, temperature, and pressure. Denoting the decomposition potential by ΔE_d, then

$$\Delta E = \Delta E_{p1} + \Delta E_{p2} + \Delta E_d \quad [38]$$

Equations [25], [26], [27], [36], [37], [38] can be combined to give an implicit relation between the applied voltage E, current density ϕ, void fractions α_1, α_2, bubble layers δ_1, δ_2, and temperatures T_1, T_2. That is

$$\phi = \phi(E, \phi, \alpha_1, \alpha_2, \delta_1, \delta_2, T_1, T_2) \quad [39]$$

Recapitulation.—The equations above represent a one-dimensional approximation of the processes occurring within the electrolysis cell. As they stand, they involve more unknowns than there are equations so that additional relations are required. Additional equations will be the equations of state of oxygen and hydrogen gases, empirical relations for the shear stresses, and either empirical or theoretical expressions for the slip ratios. Although this is a complicated system it does represent a sound description of the electrolysis cell hydrodynamics and could be programmed for computer solution if desired.

One of the objectives of the present paper is to present a parametric study of void fraction and current density distributions as functions of certain input variables. Consistent with this limited objective are certain simplifying assumptions which can be listed as follows:

(*A*) Both gas and liquid flows are assumed to be incompressible and isothermal. This assumption permits a great analytical simplification of the problem in that it decouples the continuity and resistivity equations from the momentum and energy equations.

(*B*) The bubble layers are assumed to extend completely across the channels. This assumption is justified from experimental visual observations which show the bubble layer to fill the channel except in a short entrance region.

(C) The membrane is assumed to be permeable only to the hydroxyl ion flux and not to liquid electrolyte.

With the above assumptions, the system of equations reduces to a set in which there are only three more unknowns than equations; these unknowns are the applied voltage E and the slip ratios σ_1, σ_2. If E, σ_1, σ_2 are regarded as parameters, then the system of equations can be solved simultaneously for the α and ϕ distributions; this suggests a parametric study of the effect of slip ratios σ_1, σ_2 and cell voltage E on void fraction and current density distributions. Since integration of the equations will bring the cell inlet velocity into the problem as a boundary condition, the inlet velocity will also be a parameter.

Void fraction and current density distributions.— Equations [20], [21], can now be written in the forms

$$\frac{d}{d\xi}(\alpha\sigma y V_f) = \frac{\lambda_g}{\rho_g}\phi \qquad [40]$$

$$\frac{d}{d\xi}[(1-\alpha)yV_f] = (\gamma-1)\frac{\lambda_g}{\rho_f}\phi \qquad [41]$$

Assuming the electrolysis cell is vertical ($\xi = z$) and integrating these equations from inlet ($z = 0$) to some point z, it can be shown that

$$\frac{\alpha}{1-\alpha} = \frac{\frac{\rho_f}{\sigma\rho_g}I}{(\gamma-1)I + \Gamma_0} \qquad [42]$$

where

$$\Gamma_0 = \left(\frac{y}{L}\right)\left(\frac{\rho_0 V_0}{\phi_0 \lambda_g}\right) \qquad [43]$$

$$I = \int_0^{z^0} \phi^0 dz^0 \qquad [44]$$

$$\phi^0 = \frac{\phi}{\phi_0} \qquad [45]$$

$$z^0 = \frac{z}{L} \qquad [46]$$

Equation [42] can be applied to either the oxygen or hydrogen sides by affixing subscripts 1 or 2, respectively, to the quantities α, σ, γ, Γ_0, ρ_g. The subscript 0 denotes inlet conditions where $\alpha = 0$. The superscript 0 denotes dimensionless quantities.

The electrical requirement can now be expressed by the equation

$$E - [(a_1 + a_2) + (b_1 + b_2)\ln\phi + \Delta E_d] = \phi\{R_m + r_f[y_1 f(\alpha_1) + y_2 f(\alpha_2)]\} \qquad [47]$$

Equation [47] along with two equations of the type [42] are a set of three equations in three unknowns α_1, α_2, ϕ and four parameters E, σ_1, σ_2, V_0. These equations have been programmed for numerical solution on a digital computer and solved for a specific cell design as defined in Table I. The computations were carried out using Mashovet's equation [34] for f along with the assumption that the slip ratios σ_1, σ_2 on the two sides of the cell are the same.

Table I. Cell design and conditions

Geometry	Properties	Parameters
y_1 = 1/16 in. y_2 = 1/8 in. H = 2 in. L = 48 in.	p = 300 psi T = 160°F 6M KOH ΔE_d = 1.2v r_f = 0.31 ohm-in. R_m = 0.58 ohm-in.^{2}	σ = 1.1, 10 V_0 = 0.05, 0.25 ft/sec E = 3, 5.3, 8.9v

Polarization overvoltages

ϕ, amp/ft^2	ΔE_{p1}, v	ΔE_{p2}, v
0	0	0
400	0.38	0.17
800	0.43	0.21
1200	0.46	0.24
1600	0.48	0.25

The results are displayed in Fig. 2, 3, and 4. Figure 2 shows dimensionless current density distributions as functions of cell voltage and slip ratio. The effect of slip ratio is more pronounced at higher cell voltages and the reason lies in the effect of slip ratio on void fraction. As the slip ratio increases the void fraction decreases causing a decrease in the ohmic resistance

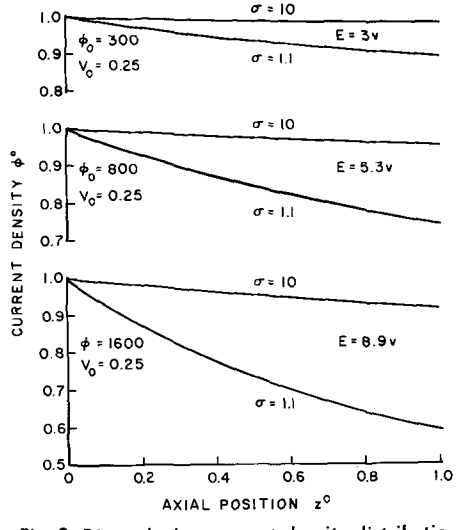

Fig. 2. Dimensionless current density distribution

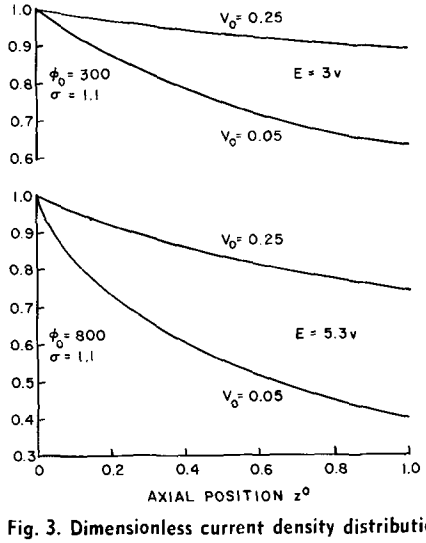

Fig. 3. Dimensionless current density distribution

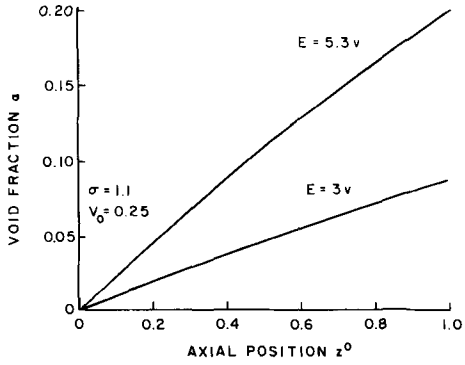

Fig. 4. Axial void fraction distribution

of the electrolyte. At high cell voltages the void fraction will be high and more sensitive to the slip ratio.

Figure 3 shows the effect of the inlet velocity and cell voltage on current density distributions for a slip ratio of 1.1. It is seen that cell inlet velocity is very important and becomes most important for higher cell voltages. This effect is due to the fact that at higher electrolyte velocities the cell void fraction is lower.

Figure 4 shows the void fraction distributions along the cell for two different cell voltages and a slip ratio of 1.1. The void fraction distributions were found to be practically identical in the two sides of the cell so that only single curves are shown in Fig. 4. This result occurs because the inlet velocities were assumed equal in both hydrogen and oxygen channels and is discussed in more detail below.

Approximate relations.—In a forced convection electrolysis cell, the liquid throughput mass flow rate will ordinarily be much larger than the mass rate of conversion of liquid to gas. In other words the term Γ_0 of Eq. [42] is much larger than the term $(\gamma - 1)I$. Under such circumstances, Eq. [42] simplifies to

$$\alpha = \frac{1}{1 + \frac{\rho_g}{\rho_f}\sigma\frac{\Gamma_0}{I}} \qquad [48]$$

Suppose, in designing a cell, the channel dimensions, y_1, y_2 of the oxygen and hydrogen sides are to be chosen so that the void fractions α_1, α_2 are the same in the two flow channels. Equation [48] then will show that

$$\frac{y_1}{y_2} = \left(\frac{\lambda_{g1}}{\lambda_{g2}}\right)\left(\frac{\rho_{g2}}{\rho_{g1}}\right) \qquad [49]$$

where it has been assumed that the cell inlet velocities and slip ratios are identical. Now

$$\frac{\lambda_{g1}}{\lambda_{g2}} = 8\,; \quad \frac{\rho_{g2}}{\rho_{g1}} \cong \frac{1}{16}$$

Therefore

$$\frac{y_1}{y_2} = \frac{1}{2}$$

This result is expected because there are 2 moles of hydrogen gas formed for each mole of oxygen gas; this result serves as a check on the analytical formulation. It should be emphasized, however, that simply setting $y_1 = 1/2\ y_2$ will not assure equal void fractions in the two channels because the inlet velocities V_{20}, V_{10} will not necessarily be equal. The values V_{20}, V_{10} depend strongly on the pressure distributions in the two parallel channels.

By combining the expression [48] with an approximation for the pressure drop across the cell it could be shown that the pumping power of an electrolyzer is related to void fraction through an equation independent of electrical resistance. Use of these relations would make possible an optimization study of total cell power requirements with respect to the cell parameters.

The results shown in Fig. 2, 3, and 4 indicate the importance of the slip ratio to the axial current density distribution. This parameter also plays an important role in the axial pressure distribution. For these reasons the experimental apparatus described below was constructed. One of the main objectives of this apparatus was the experimental determination of the slip ratio for both hydrogen and oxygen gases.

Experimental

Apparatus.—The flow loop used to perform the electrolysis experiments is shown schematically in Fig. 5. The loop comprises a pump, filter, rotameters and valving, the electrolyzer cell, and separators for the hydrogen and oxygen gases. The cell has an entrance length of 20 in. to allow the flow to become established before entering the electrolyzer section. As shown in Fig. 6, the cell is made up of two rectangular channels separated by a semipermeable membrane. The membrane is polystyrene coated Nylon held between two thin slotted pieces of Plexiglas. Polystyrene coated Nylon is used as the membrane because it combines low channel cross flow with acceptable electrical resistance.

The electrodes are segmented axially, and the current flow to each of the six sections is controlled. Pressure taps are placed axially along the cell at the inlet to each of the electrode sections and at the channel outlet on both anode and cathode sides. The axial pressure distribution is measured and recorded for each experiment. The void fraction is measured by means of a gamma ray attenuation system utilizing a Cesium 137 source of 0.62 Mev gamma rays. This system is shown schematically in Fig. 7.

A typical experiment is run by first setting the electrolyte flow on both the hydrogen and oxygen sides of the cell. The same voltage is then applied to

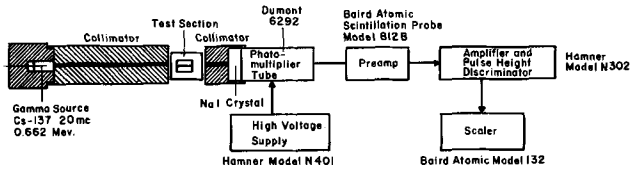

Fig. 7. Void fraction detection system

each of the six electrode sections. The total current flow is recorded and is used to calculate the total mass flow of gas at the channel outlet. The total vapor flowrate is calculated by assuming that the hydrogen and oxygen gases are saturated with water vapor. The outlet void fraction is determined from the gamma ray attenuation. The total 3-min count was measured three times and averaged. The void fraction is calculated directly from the increased (over-all liquid) count when the gases are present.

Results.—The experimental results are shown in Fig. 8 through 12. Figures 8 and 9 show the data plotted so that Eq. [9] can be used directly to determine the slip ratio, σ. The limits of experimental error are also shown and indicate that the experimental accuracy becomes very poor at low void fractions. These results indicate that the slip ratio is very near unity in both channels and possibly slightly higher (about 1.1) in the hydrogen channel. This result is consistent with calculations made assuming that there is no interaction among the flowing bubbles and that the bubbles are small. Visual observation shows that the flow is bubbly; there are a large number of finely dispersed bubbles. Photographs taken in a static cell using the same electrodes and electrolyte show that the bubble diameter is between 0.002 and 0.007 in. The bubbles are large enough so that the surface tension effect on pressure is negligible and small enough so that their terminal rise velocity is very small.

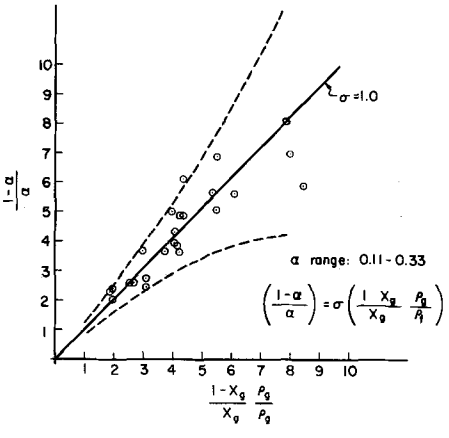

Fig. 9. Experimental void fraction, oxygen channel, design 8. The description is the same as Fig. 8.

Figures 10 and 11 show outlet void fraction as a function of quality. This is a common way of presenting two phase flow experimental data and the $\sigma = 1$ curve is calculated directly from Eq. [9]. Bankoff's model is discussed in ref. (16) in which it is shown that

$$\sigma = \frac{1-\alpha}{K-\alpha} \qquad [50]$$

where K is a parameter which is determined from the transverse distribution of velocity and voids in the channel. A value of $K = 0.89$ provides agreement between Bankoff's theory (16) and the Martinelli-Nelson correlation (20) and is shown in Fig. 10 and 11 for this reason.

Figure 12 shows outlet void fraction *vs.* the channel outlet gas volume fraction for both hydrogen and oxygen. The definition of β is

$$\beta = \frac{\sigma\alpha}{\sigma\alpha + (1-\alpha)} \qquad [51]$$

which, when combined with [50] yields

$$\alpha = K\beta \qquad [52]$$

For a slip ratio of unity the simple result that $\alpha = \beta$ is obtained. Both $\sigma = 1$ and $K = 0.89$ are shown on Fig. 12.

Discussions and Conclusions

The major conclusions drawn from the earlier part of the investigation have been stated earlier in conjunction with Fig. 2, 3, and 4. It was shown, quantitatively, that the slip ratio and inlet velocity are important electrolysis cell design variables.

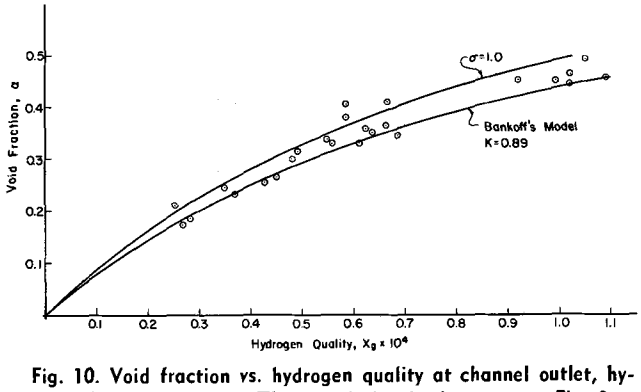

Fig. 10. Void fraction vs. hydrogen quality at channel outlet, hydrogen channel, design 8. The description is the same as Fig. 8.

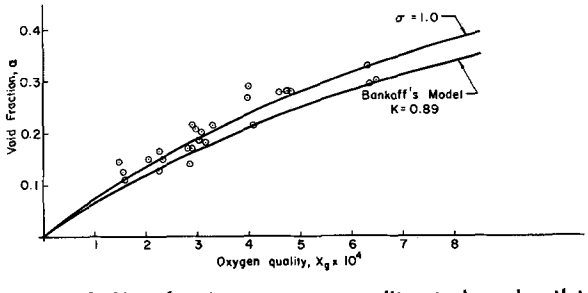

Fig. 11. Void fraction vs. oxygen quality at channel outlet, oxygen channel, design 8. The description is the same as Fig. 8.

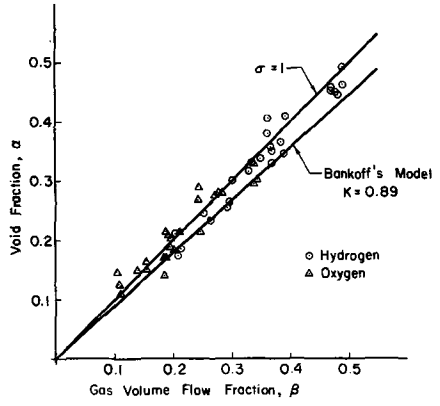

Fig. 12. Void fraction vs. gas volume flow fraction, design 8. The description is the same as Fig. 8.

The experimental results indicate that the slip ratio is, for practical purposes, equal to unity. This experimental result has been obtained from void fraction measurements and means that the void fraction can be determined directly from Eq. [42] by setting $\sigma = 1$. In an experimental apparatus, the current density distribution is measured so the void fraction is then given explicitly by Eq. [42] with $\sigma = 1$.

The current density distribution is not known, *a priori*, in designing a cell, and in this situation the void fraction and current density distribution must be determined simultaneously by using Eq. [42] (with $\sigma = 1$) along with the other equations described earlier.

Since the pressure drop calculations required in reducing experimental pressure drop data are directly dependent on the slip ratio, use of the above data can be made in formulating pressure drop correlations. Such experimental data is presently being obtained and pressure drop correlations are being developed. When this work is completed it will be presented in a separate paper.

A critical test of any analytical model for predicting the performance of an electrolysis cell is a comparison of measured current density and void fraction distributions with those predicted analytically. Such a direct comparison was not possible from the work described in this paper due to the uncertain electrical properties of the membrane which was designed primarily to permit accurate and reliable void fraction measurement and pressure drop data. Future work is planned to overcome this limitation of the existing apparatus.

Field Dependence of the Tafel Slopes for Formation of Anodic Oxide Films

S. G. Christov and S. Ikonopisov

Department of Physical Chemistry, Higher Chemico-Technological Institute, Sofia (Darvenitza), Bulgaria

ABSTRACT

An explanation of the field dependence of Tafel slopes for formation of anodic oxide films is proposed on the basis of an earlier general consideration of charge transfer over potential barriers. An expression for the activation energy as a function of the field strength is derived which contains a quadratic term arising from the shifting of both the barrier top and the equilibrium position of the ion under the influence of the electric field. The treatment includes the usual parabolic approximation of a continuous potential-energy function in the regions of its maximum and minimum. A comparison with the experimental data for anodic oxidation of Ta, Nb, and Al shows this approximation to be quite satisfactory. The theoretical expression permits the determination of the actual barrier parameters at a given field strength $\mathcal{E}_0$ near the experimental field range, as well as an extrapolation to zero field strength. This theory is applicable equally well to any possible mechanism of the current flow in the anodic formation of oxide layers.

The growth of homogeneous oxide layers during anodization of film-forming metals such as Al, Ta, Nb, Zr, etc., in a suitable electrolyte is interpreted by passage of ions across the oxide, surmounting some potential energy barrier in their way. Measurable rates of growth require considerable electric fields (more than 10^6 v/cm)[1] so that the ionic transitions can be considered to occur only in the direction of the field.

On the basis of elementary kinetic considerations, one obtains the well-known equation for ionic current density

$$j_i = A \exp [-W(\mathcal{E})/kT] \qquad [1]$$

with the activation energy being a linear function on the field strength $\mathcal{E}$

$$W(\mathcal{E}) = W_0 - aq\mathcal{E} \qquad [1a]$$

where W_0 is the activation energy in the absence of an external field ($\mathcal{E} = 0$), a the activation distance, and q the charge on the moving ion. The pre-exponential factor A has a different meaning depending on the assumptions for the kind and location of the potential barrier. In this respect, the various theories could be classified on the basis of the following three assumptions:

(*a*). *Internal control.*—According to Verwey's model (1), the limiting factor is the rate at which ions move from one interstitial position to another. It was proposed later (2-4) that the high field produces Frenkel defects (pairs of interstitial cations and cation vacancies) by drawing out metal ions in interstitial positions. Recently, a new theory for the internal control was developed by Dignam (5) on the basis of a dielectric mosaic model of the anodic oxide film.

(*b*). *Interface control.*—Mott and Cabrera (6, 7) considered as rate determining the first barrier which metal ions have to surmount to enter the oxide. This was shown to be the case with anodization of sputtered tantalum films (8). Jukova and Odynec (9) assumed that the electrochemical reactions at the oxide/electrolyte interface play a certain role in the growth of nonporous anodic films as well.

(*c*). *Internal-interface control.*—That is an extension of the mentioned models for including effects of space charge due to ions in transit, so that barriers at the metal/oxide interface and within the oxide both play a part in controlling the ionic current flow (10-13).

Equation [1] with expression [1*a*] for $W(\mathcal{E})$ has been experimentally confirmed many times. However, some measurements have shown that, for anodization of tantalum, the reciprocal Tafel slope

$$\partial \ln j_i/\partial\mathcal{E} = -\partial W/\partial\mathcal{E}$$

is field dependent, which is inconsistent with expression [1*a*]. It was proved by Young (14, 15) that this dependence could best be described if the activation energy is represented by an expression of the form

$$W(\mathcal{E}) = B - \alpha\mathcal{E} + \beta\mathcal{E}^2 \qquad [2]$$

where B, α, and β are positive constants. Later this expression was found to be in excellent accord with the data for the growth of anodic oxide films on aluminum (16) and niobium (17, 18) as well.

Various theoretical interpretations of Eq. [2] have been proposed by Young (19), Dignam (5, 20) and Ibl (21). All of them, however, are based on special assumptions concerning the shape of the barrier or the oxide film properties. There exists, however, another possibility to explain the appearance of the quadratic term in Eq. [2], which ensues from more general properties of the potential barriers. This approach has already been applied by Christov in the cases of electrode kinetics (22 a,b,c), electron emission (23), and chemical kinetics (24). A deduction is given below, leading directly to expression [2] which is the usual form of determining the ionic conduction of oxide layers by means of Eq. [1].

Derivation of the Expression for Activation Energy

Figure 1 shows the potential energy $V(x)$ of an ion as a function of distance x in the direction of the electric field.[2] The curve $V_0(x)$ represents the potential barrier which the ion has to overcome in passing from one equilibrium position ($x = 0$) to another ($x = L$) in the absence of an external field, and curve $V(x)$, the barrier in the presence of a linear electric field with strength $\mathcal{E}$. Hence

$$V(x) = V_0(x) - q\mathcal{E}x \qquad [3]$$

where q is the charge of the ion. By the action of the field, the barrier is lowered by the magnitude ΔW, expressed approximately by

[1] The total current is $j = j_i + j_e$, with j_i the ionic and j_e the electronic current; j_e is negligibly small at high fields, but at $\mathcal{E} < 10^6$ v/cm exceeds j_i many times and makes it indeterminable.

[2] We consider the more general case of a barrier which is asymmetrical in the absence of an external field, which will be the case with control by the entrance barrier. The same results are obtained in the case of a symmetric barrier, too.

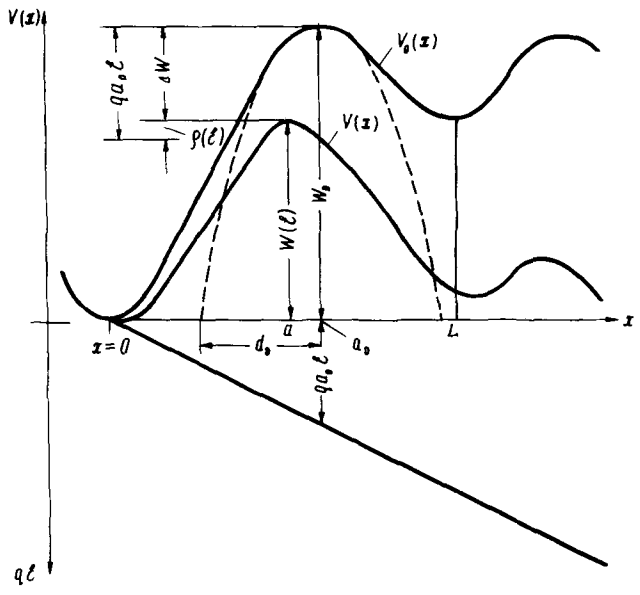

Fig. 1. Potential energy of the mobile ion vs. distance. The shifting of the barrier top is illustrated: $V_0(x)$, in the absence of external field; $V(x)$, when an external electric field is applied.

$$\Delta W = W_0 - W(\mathcal{E}) \approx a_0 q\mathcal{E} \qquad [4]$$

Here, a_0 determines the position of the barrier top when $\mathcal{E} = 0$, *i.e.*, the maximum of the function $V_0(x)$. From that follows the conventional expression [1*a*] for the ion transfer activation energy $W(\mathcal{E})$. Such a deduction ignores the shifting of the potential energy maximum from $x = a_0$ to $x = a$. Accounting for this, the lowering of the barrier is accurately given by (see Fig. 1) (22c)

$$\Delta W = W_0 - W(\mathcal{E}) = a_0 q\mathcal{E} - \rho(\mathcal{E}) \qquad [5]$$

where the quantity $\rho(\mathcal{E})$ increases with $\mathcal{E}$ and could be neglected only if the field strength is sufficiently low.

On principle, an exact expression for the activation energy $W(\mathcal{E})$, including the term $\rho(\mathcal{E})$, could be derived by the analytical method for determining of the maximum of potential energy $V(x)$, if the form of the function $V_0(x)$ in Eq. [3] is known. Explicit expressions for $W(\mathcal{E})$ are easily obtained for simple models of potential barriers,[3] but they have only limited applicability for some special cases.

A rather general solution of the problem may be obtained without any hypotheses about the entire barrier shape, by means of a simple method, proposed earlier by Christov (22c). This method is based on the usual parabolic approximation of the function $V_0(x)$ in the region of its maximum (transition state), which may be written in the form (22 b, c)

$$V_0(x) = W_0\left[1 - \frac{(x-a_0)^2}{d_0^2}\right] \qquad [6]$$

where d_0 is the half-width of a parabolic barrier of height W_0 (Fig. 1). If the region of validity of this approximation is sufficiently wide, the height of the barrier $V(x)$ at not very high fields may be easily found by calculating the maximum of the function

$$V(x) = W_0\left[1 - \frac{(x-a_0)^2}{d_0^2}\right] - q\mathcal{E}x \qquad [7]$$

[3] Such are, for instance, the parabolic barrier (22b) and the Schottky image force barrier (23), on which the potential of the electric field is superimposed. With more complicated functions (such as the Eckart potential in combination with an electric potential (22a), the condition of the maximum $dV/dx = 0$ leads to transcendental equations; that is why only approximate solutions are possible in this case (22a).

which is obtained from Eq. [3] and [6]. Thus, from the condition $dV/dx = 0$, we obtain the position of the maximum

$$a = a_0 - \frac{d_0^2}{2W_0} q\mathcal{E} \qquad [8]$$

and the barrier height

$$W(\mathcal{E}) = W_0 - a_0 q\mathcal{E} + \frac{\gamma_0^2 a_0^2}{4W_0} q^2\mathcal{E}^2 \qquad [9]$$

where $\gamma_0 = d_0/a_0$.

A comparison of Eq. [5] with Eq. [9] gives the correctional term for $W(\mathcal{E})$

$$\rho(\mathcal{E}) = \frac{\gamma_0^2 a_0^2 q^2}{4W_0}\mathcal{E}^2 = \frac{q^2}{2L_a}\mathcal{E}^2 \qquad [10]$$

where

$$L_a = -\left(\frac{d^2V}{dx^2}\right)_{x=a} = \frac{2W_0}{d_0^2} = \frac{2W_0}{\gamma_0^2 a_0^2} \qquad [11]$$

is the curvature of the barrier [7] at the top ($x = a$), which is a constant, *i.e.*, is independent on the top displacement ($L_a = L_{a_0}$).

Expression [9] coincides with the empirical relation [2] provided that

$$B = W_0, \quad \alpha = a_0 q, \quad \text{and} \quad \beta = \frac{\gamma_0^2 a_0^2 q^2}{4W_0} \qquad [12]$$

The dependence [9] would clearly be exact enough on condition that the curvature at the top of the real barrier $V(x)$ remains constant when the field changes, so that it could be represented by expression [11] for the curvature of the parabolic barrier [7]. Then, according to Eq. [11] and [12]

$$\beta = \frac{q^2}{2L_a} = \frac{q^2}{2L_{a_0}}$$

will really be a constant. The smaller the curvature L_{a_0}, *i.e.*, the flatter the barrier in absence of an external field, the wider the field region, within which the foregoing condition will be valid. According to Eq. [11], L_a decreases with the increase of the quantity $\gamma_0 = d_0/a_0$ which is a criterion for the deviation of the barrier from a parabolic shape (for the latter $\gamma_0 = 1$). The possible cases are $\gamma_0 < 1$ ($d_0 < a_0$) and $\gamma_0 > 1$ ($d_0 > a_0$); *i.e.*, the real barrier may be wider or narrower than the corresponding parabolic barrier, having the same curvature at the top.

At sufficiently high fields, one should expect the parabolic approximation [7], appropriate to low fields, to be invalid, since a considerable change of the field will surely cause a noticeable change in the curvature of the barrier top ($L_a \neq L_{a_0}$). It is possible, however, to approximate the upper part of the barrier with a parabolic function of type [7] in each not very wide region of fields between $\mathcal{E}_0$ and $\mathcal{E}_0 + \Delta\mathcal{E}$, if the quantities W_0, a_0, and d_0 (or $\gamma_0 = d_0/a_0$) are referred to a certain value of the field $\mathcal{E} = \mathcal{E}_0$ (instead of $\mathcal{E} = 0$) and if $\mathcal{E}$ is replaced by $\mathcal{E} - \mathcal{E}_0$. In this way, we obtain again expression [2]

$$W(\mathcal{E}) = B - \alpha\mathcal{E} + \beta\mathcal{E}^2 \qquad [13]$$

where

$$\begin{cases} B = W_0^* + a_0^* q\,\mathcal{E}_0 + \dfrac{\gamma_0^{*2} a_0^{*2} q^2}{4W_0^*}\mathcal{E}_0^2 \\ \alpha = a_0^* q + \dfrac{\gamma_0^{*2} a_0^{*2} q^2}{2W_0^*}\mathcal{E}_0 \\ \beta = \dfrac{\gamma_0^{*2} a_0^{*2} q^2}{4W_0^*} \end{cases} \qquad [13a]$$

The system of three equations [13*a*] permits computation of the three unknown parameters W_0^*, a_0^*, and γ_0^* of the barrier at a certain value of the field strength $\mathcal{E}_0$ on the basis of the experimental data for the constants B, α, β in the given field region (from $\mathcal{E} = \mathcal{E}_0$ to $\mathcal{E} = \mathcal{E}_0 + \Delta\mathcal{E}$).

If the more simple expression [9], *i.e.*, relation [12] is used instead of equation [13] with coefficients [13*a*], one might calculate from the experimental data for B, α, and β the quantities W_o, a_o, and γ_o which will then represent the apparent barrier parameters in the absence of a field ($\mathcal{E} = 0$). It is quite improbable, indeed, for the dependence [2], which is established in a fairly narrow field range at very high fields (between 10^6 and 10^7 v/cm), to hold true with the same values of the coefficients B, α, and β right up to $\mathcal{E} = 0$. Therefore, the quantities W_o, a_o, and γ_o, computed by means of Eq. [12], should represent a very far-reaching extrapolation, having no direct physical significance as far as these quantities cannot be identified with the true barrier parameters in absence of an electric field.

In the above consideration, only the shifting of the barrier top is taken into account. A more general treatment should include also the displacement of the initial equilibrium position of the ion under the influence of the external field from $x = 0$ to $x = x_o$, which cannot be neglected if the potential well is wide. Such a situation is represented in Fig. 2. Then the lowering of the barrier is given by

$$\Delta W = W_o - W(\mathcal{E}) = a_o q\mathcal{E} - [\rho(\mathcal{E}) - \rho'(\mathcal{E})] \quad [14]$$

The quantity $\rho'(\mathcal{E})$ could be found using again (22c) the familiar parabolic approximation of the potential energy about the equilibrium position, *i.e.*

$$V_o(x) = \frac{f_o x^2}{2} \quad [15]$$

in the absence of external field ($\mathcal{E} = 0$) and

$$V(x) = V_o(x) - q\mathcal{E}x = \frac{f_o x^2}{2} - q\mathcal{E}x \quad [16]$$

if not a very high electric field is applied. The quasi-elastic force constant f_o is related to the frequency of the harmonic ion vibration

$$\nu_o = \frac{1}{2\pi}\sqrt{\frac{f_o}{m}} \quad [17]$$

where m is the mass of the ion. From Eq. [16], we find for the equilibrium position

$$x_o = \frac{q\mathcal{E}}{f_o} \quad [18]$$

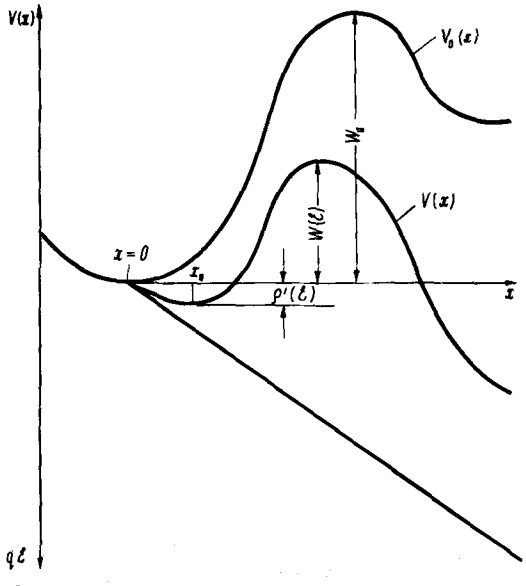

Fig. 2. Potential energy vs. distance for illustrating the shifting of the equilibrium position of the ion in addition to the barrier top displacement: $V_o(x)$ in the absence, and $V(x)$ in the presence, of external electric field.

and for the potential energy minimum

$$V(x_o) = \rho'(\mathcal{E}) = -\frac{q^2\mathcal{E}^2}{2f_o} \quad [19]$$

Equations [10], [14], and [19] lead to the expression

$$W(\mathcal{E}) = V(a) - V(x_o) = W_o - a_o q\mathcal{E} + \left(\frac{\gamma_o^2 a_o^2 q^2}{4W_o} + \frac{q^2}{2f_o}\right)\mathcal{E}^2 \quad [20]$$

which is identical with the empirical relation [2] if we set

$$B = W_o, \quad \alpha = a_o q,$$

$$\beta = q^2\left(\frac{\gamma_o^2 a_o^2}{4W_o} + \frac{1}{2f_o}\right) = \frac{q^2}{2}\left(\frac{1}{L_a} - \frac{1}{L_o}\right) \quad [21]$$

Here the curvature L_a at the barrier top is given by Eq. [11] and the curvature L_o at the equilibrium position is determined from Eq. [16] and [17] by

$$L_o = -\left(\frac{d^2V}{dx^2}\right)_{x=x_o} = -f_o = -m(2\pi\nu_o)^2$$

When $|L_o| >> |L_a|$ Eq. [21] turns into relations [12]. If the barrier parameters W_o, a_o, γ_o, and f_o are related to a given value of the field strength $\mathcal{E} \neq 0$, we obtain in a similar manner again Eq. [2] with

$$\begin{cases} B = W_o^* + a_o^* q\mathcal{E}_o + \left(\dfrac{\gamma_o^{*2} a_o^{*2} q^2}{4W_o^*} + \dfrac{q^2}{2f_o^*}\right)\mathcal{E}_o^2 \\ \alpha = a_o^* q + \left(\dfrac{\gamma_o^{*2} a_o^{*2} q^2}{2W_o^*} + \dfrac{q^2}{f_o^*}\right)\mathcal{E}_o \\ \beta = \dfrac{\gamma_o^{*2} a_o^{*2} q^2}{4W_o^*} + \dfrac{q^2}{2f_o^*} \end{cases} \quad [22]$$

These expressions include relations [13*a*] as limiting cases for large values of the force constant f_o^* (*i.e.*, for $|L_o^*| >> |L_a^*|$), for which the terms containing f_o^* become negligible.

Comparison with Experimental Data[4]

Effect of barrier top shifting.—We will first assume that the potential well in the initial position of the ion is not very wide (Fig. 1). Then using Eq. [13*a*] and available experimental data for B, α, and β, one can compute the quantities W_o^*, a_o^*, and γ_o^* at a given value of the field strength $\mathcal{E}_o$. As such, we take $\mathcal{E}_o = 10^6$ v/cm, which is closed by the usual experimental field range. The extrapolated barrier parameters at $\mathcal{E} = 0$ may also be calculated by means of Eq. [12*a*].

Tantalum.—The relation [2] was established by Young (14, 15) who investigated the anodizing of Ta at temperatures between 0° and 95°C and fields between 4.5 x 10^6 and 7.5 x 10^6 v/cm. Taking for the ion charge a value $q = 5e$, the experimental data yield $B = 2.185$ ev; $\alpha = 3.497 \times 10^{-7}e$ cm; $\beta = 1.675 \times 10^{-14}e$ cm²/v. The barrier parameters calculated by Eq. [13*a*] with $\mathcal{E}_o = 10^6$ v/cm are as follows

$$W_o^* = 1.852 \text{ ev}; \quad a_o^* = 6.325 \times 10^{-8} \text{ cm}; \quad \gamma_o^* = 1.114$$

The apparent values at $\mathcal{E} = 0$, computed by Eq. [12] are

$$W_o = 2.185 \text{ ev}; \quad a_o = 6.995 \times 10^{-8} \text{ cm}; \quad \gamma_o = 1.094$$

Niobium.—The kinetics of anodization of Nb in 0.2*N* H_2SO_4 was investigated by Young and Zobel (17) in the field range from $\mathcal{E} = 3 \times 10^6$ to $\mathcal{E} = 4.5 \times 10^6$ v/cm and at temperatures 25° and 75°C. The values B =

[4] This comparison does not concern the case of two-barrier control.

Table I. Kinetic parameters for anodizing of niobium in different electrolytes

		H_2SO_4	HCl	HNO_3	H_3PO_4
Experimental data	I_o, A cm^{-2}	5.72×10^{-7}	3.57×10^{-7}	8.0×10^{-10}	7.5×10^{-13}
	α', 10^{-6} cmV^{-1}	1.63	1.23	4.78	7.40
	β', 10^{-14} cm^{2}V^{-2}	9.74	5.20	37.7	54.0
Values of the constants in Eq. [2] with $A = 10^{7.44}$ A/cm^2	α, $10^{-7}e$ cm	0.4118	0.311	1.201	1.870
	β, $10^{-14}e$ cm^{2}V^{-1}	0.246	0.1314	0.9525	1.364
	B, ev	0.796	0.808	0.962	1.146
Apparent barrier parameters by Eq. [12] ($\mathcal{E} = 0$)	a_o, 10^{-8} cm	0.824	0.621	2.415	3.740
	W_o, ev	0.796	0.808	0.962	1.146

Barrier parameters by Eq. [13a] $\mathcal{E}_o = 10^6$ v/cm^{-1}	a_o^*, 10^{-8} cm	0.725	0.569	2.034	3.194
	W_o^*, ev	0.757	0.778	0.932	0.973
	γ_o^*	2.380	2.248	1.853	1.442

2.167 ev; $\alpha = 1.074 \times 10^{-7}e$ cm; $\beta = 8.36 \times 10^{-15}e$ cm^2/v were found. For $\mathcal{E}_o = 10^6$ v/cm, these data lead to

$$W_o^* = 2.068 \text{ ev}; \quad a_o^* = 1.814 \times 10^{-8} \text{ cm}; \quad \gamma_o^* = 2.90$$

and at $\mathcal{E} = 0$

$$W_o = 2.167 \text{ ev}; \quad a_o = 2.148 \times 10^{-8} \text{ cm}; \quad \gamma_o = 2.506$$

The growth of anodic oxide films on this metal was found by Shatalov and Bondareva (18) to be very sensitive to the nature of the anodizing electrolyte. As such normal aqueous solutions of H_2SO_4, HCl, HNO_3, or H_3PO_4 have been used. A law of the form

$$j_i = I_o \exp(\alpha'\mathcal{E} - \beta'\mathcal{E}^2) \qquad [23]$$

proved to fit the data very well. Depending on the electrolyte, however, quite different values for the constants I_o, α', and β' were obtained (*see* Table I). Unfortunately, these measurements have been made at 20°C only. The needed constants $B = (\ln A - \ln I_o)kT$; $\alpha = \alpha'kT$; $\beta = \beta'kT$ could be obtained from Eq. [23], if a value for A is assumed. For the purpose, a value $\lg A = 7.44$ was adopted, which is the mean value from available data ($A = 10^{7.24}$ and $10^{7.64}$ A cm^{-2}) for this constant (13, 17). (If any of these values for A were assumed instead of the mean value, the value for B would differ no more than ±2%.) The estimated values for the quantities in question are given in Table I. One can clearly see the strong dependence of the barrier parameters on the nature of the anodizing electrolyte.

Aluminum.—Unfortunately, the numerous investigations of the dependence $j_i(\mathcal{E},T)$ were carried out in conditions which do not provide the opportunity to determine the field dependence of the Tafel slope. The only data (16) available for this purpose were obtained at a single temperature ($T = 298.2$°K); therefore, only the term $A \exp(-B/kT) = 10^{-29}$ amp/cm^2 is known. If a value $A = 10^8$ amp/cm^2 is taken by analogy with the values of this constant for Ta and Nb [as the quoted authors have also done (16, 20)], we can find the values

$$A = 2.19 \text{ ev}; \quad \alpha = 2.38 \times 10^{-7}e \text{ cm}; \quad \beta = 7.4 \times 10^{-15}e \text{ cm}^2/\text{v}$$

Hence, the barrier parameters at $\mathcal{E}_o = 10^6$ v/cm will be

$$W_o^* = 1.96 \text{ ev}; \quad a_o^* = 7.44 \times 10^{-8} \text{ cm}; \quad \gamma_o^* = 1.16$$

and at $\mathcal{E} = 0$

$$W_o = 2.19 \text{ ev}; \quad a_o = 6.793 \times 10^{-8} \text{ cm}; \quad \gamma_o = 1.249$$

Effect of displacement of ion equilibrium position.—Assuming that the potential well of the ion is wide (Fig. 2), so that the curvatures L_o and L_a at the equilibrium position ($x = x_o$) and at the barrier top ($x = a_o$) are of the same order ($L_o \sim L_a$), we have to use Eq. [21] or [22]. However, the experimental data for the constants B, α, and β in the empirical relation [2] are not sufficient for computing all the barrier parameters W_o, a_o, γ_o, and f_o. Taking into account; Eq. [17], we can calculate the force constant f_o if the frequency of ion vibration ν_o is known [it may not be the same at very low and very high fields ($\mathcal{E} > 10^6$ v/cm)].

According to the models of Verwey (internal control) and Mott-Cabrera (interface control), ν_o is the vibrational frequency of the ions in the oxide or in the metal, respectively. This is known (25) to vary from 5×10^{12} s^{-1} to 10^{13} s^{-1} [Young (26) also assumed for ZrO_2, a value of $\nu_o = 10^{13}$ s^{-1} as reasonable]. With these limiting values for ν_o, the values for f_o and for the term $q^2/2L_o$ in the expression [21] are given in Table II. The quotient $(q^2/2L_o)/\beta$, which indicates the effect of displacement of potential well minimum, is also given. The term $q^2/2L_o$ appears to have small effect on the constant β from expression [21]. Hence, the real value of γ_o would not be much different than that, calculated by means of Eq. [12] in which the term $q^2/2L_o$ is disregarded.

Table II. Estimation of the effect of displacement of potential well minimum

	f_0 10^5 dynes/cm	$q^2/2L_0$ 10^{-17}e cm²/v	$100\,(q^2/2L_0)/\beta$ %
Ta	11.8-2.95	1.7-6.78	0.1-0.4
Nb	6.07-1.52	3.3-13.2	0.4-1.6
Al	1.76-0.44	4.1-16.4	0.55-2.2

The values are calculated for: $\nu_0 = 10^{13}$ and $\nu_0 = 5 \times 10^{12}$ s^{-1}.

In the mosaic model of Dignam (5), the importance of this term cannot be estimated. However, it is clear that depending on the accepted model the term $q^2/2L_0$, related to the potential well, may be less or more or as important as the term $q^2/2L_a$ related to the barrier peak.

Discussion

The first attempt to explain the empirical equation [2] was made by Young (19) on the basis of a postulated variation of the activation energy with the condenser pressure. Dignam (20) pointed out that the effect of condenser pressure is probably too small to account for the observed phenomena. In any case, there are no experimental data for the magnitude of this effect with the oxides in question.

Dignam (20) derived an expression of the form [2] in principle in the same way as earlier done by Christov (22) *i.e.*, by determining the maximum and the minimum of the potential energy. Dignam described the potential curve in absence of external field with special functions, namely a clipped parabolic, a cosine, and a Morse function, and found that the third function gave best agreement with the experimental data. The Morse function, however, has no maximum, so that the linear potential of the electric field has to be superimposed to give a maximum of the resulting potential energy. This picture obviously does not agree with the periodic variation of the ion potential in the oxide and therefore is not acceptable from physical standpoint, as already was remarked by Young and Zobel (17). That is why the agreement found by Dignam between the theoretical expression derived by using the Morse potential and the experimental data cannot be regarded as a real justification for the assumption of this potential.[5]

Recently, Ibl (21) showed that relation [2] could be derived on the basis of the transition-state theory if the polarization of the dielectric is taken into account. This possibility presupposed an internal control for the growth of the oxide layer and is consistent with Dignam's mosaic model only (21).

In contrast to the above explanations, it is shown in the present paper that the field dependence of Tafel slopes in anodic oxidation has to be expected without any special assumptions if only we determine more accurately the change of the barrier height, caused by the electric field. The appearance of the quadratic term in expression [2] for the activation energy is a result of shifting the position of the barrier top, as well as the equilibrium position with the field. This can be taken into account quantitatively, using the method proposed by Christov (22b, c), which includes the usual parabolic approximation of a continuous potential energy function in the regions of its maximum and minimum. In supposing that only the displacement of the barrier peak is important, we can compute the barrier parameters from the experimental data in a unique way. Thus, one concludes that for Ta and Al the parabolic approximation is valid in a wide barrier region because the quantity γ_0 (or γ_0^*), which accounts for the deviation from the parabolic shape, proved to be very close to unity. The larger value for γ_0 at some conditions of anodizing of niobium is an indication for a rather flat barrier, which also seems not to be improbable. Assuming that the shifting of the potential energy minimum is sufficiently significant, we obtain more or less smaller values for γ_0; however, this seems not to be really the case from the viewpoint of both the theories of the internal and the interface control.

Equations [13*a*] and [22] permit the determination of the actual barrier parameters at a given field strength $\mathcal{E}_0$ near the experimental field range instead of the very doubtful extrapolation up to $\mathcal{E} = 0$ by means of Eq. [12].

The theoretical interpretation of the field dependence of Tafel slopes, proposed earlier (22a, b, c), is based on general properties of the potential barriers, including changing of their shape under the influence of a variable factor. Therefore, the results obtained in this work present an immediate application of this theory to the case of anodic formation of oxide films, which is valid independently of any special assumption on the nature and the location of the potential barrier, *i.e.*, about the concrete mechanism of ion current flow.

The theoretical expression [9] for the activation energy agrees well with the experiment as far as it predicts the order of the observed deviations from Eq. [1] with [1*a*] (Tafel-Frenkel relation) in anodic oxidation of film-forming metals. The quadratic term in Eq. [9] becomes, indeed, appreciable in the investigated high-field range (10^6-10^7 v/cm) if the values of barrier parameters corresponding to the experimental data at a given field strength are introduced. This conclusion is valid in a larger extent if the more general expression [20] is considered.

An inspection of Table I clearly shows that the barrier parameters for anodic oxidation of Nb vary strongly with the change of the electrolyte. It is not the aim of the present paper to discuss this dependence which is an indication for a change of the oxide structure. On the basis of the theory presented here, it is possible, however, to determine the variations of both the dimensions and the shape of the barrier with the change of the physical properties of the homogeneous oxide films, depending on the conditions of anodization.

It must be stressed that, from the standpoint of the theory developed previously (22), relation [2] is only an approximate expression, which is valid for a not very large variation of the field. In wider field ranges, one should expect the appearance of higher order terms (22c) as seems to be the case of the electrolytic deposition of silver (27). However, such deviations from relationship [2] are not observed in the restricted ranges of the field in which the anodic formation of oxide films has been investigated at present.

Manuscript submitted June 24, 1968; revised manuscript received Sept. 30, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

[5] It is very doubtful that the potential energy of the ion near its equilibrium position may be expressed by Morse function, which is appropriated to diatomic molecules. Using the (non-periodic) clipped parabolic curve, Dignam (20) assumes a fixed barrier peak, so that the quadratic term in expression [2], arising entirely from the shifting of the potential minimum, proved to be very small.

Eu^{2+} Activated Aluminosilicate Phosphors

A. Wachtel*

Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Within the system $xSiO_2$ $(1 - x)Al_2O_3:Eu^{2+}$, there exist two maxima of luminescence intensity: "phosphor I" a $x = 0.9$-0.95 consisting of mullite + amorphous SiO_2 and "phosphor II" at $x = 0.15$-0.175 consisting of mullite + θAl_2O_3. Excitation, emission, and ESR spectra of both phosphors are the same. It is concluded that in each case, Eu^{2+} is located at the interface between mullite and the second phase.

Recent investigations by a number of authors (1-11) have shown that Eu^{2+} is an efficient activator in a variety of phosphor matrices. In the present study, an attempt is made to characterize the luminescent phases which occur in the system $xSiO_2$ - $(1\text{-}x)Al_2O_3:Eu^{2+}$ reported by Jaffe (12).

Experimental

Solid-state reaction between SiO_2 and Al_2O_3, even from hydrated raw materials, is known to be very slow (13) and normally confined to the immediate vicinity of contact between the two reactants. The usual method to overcome this difficulty is by use of gel coprecipitates for which various techniques are reported by authors investigating aluminosilicates (14-19). A simple technique suitable for the present study consisted of adding excess alcoholic NH_4OH to a solution of $Al(NO_3)_3$ + $Eu(NO_3)_3$ + $Si(OC_2H_5)_4$ in about 70% alcohol. Hydrolysis of the $Si(OC_2H_5)_4$ then proceeds in the interstices of the mixed $Al,Eu(OH)_3$ gel and produces a quasihomogeneous raw material which requires very little thermal diffusion for subsequent compound formation. The gels were then water-washed, dried at up to 950°C, and fired in air followed by grinding and refiring in a reducing atmosphere. The air firing was at 1250°C, except where it was intentionally varied, while the temperature of the second firing was maintained at 1100°C.

Fluorescence intensity was measured under 254 nm excitation, using a Spectra Brightness Spot Meter at the "blue" ($\bar{z}$) setting whose sensitivity nearly coincides with the spectral energy distribution of the phosphors.

Emission and IR absorption spectra were obtained on commercial instruments. Excitation and absolute reflectance spectra were measured on an instrument designed by Thornton (20), the latter by the method of Middleton and Sanders (21).

Results

Figure 1 shows the fluorescence intensity as a function of composition. The fact that at this temperature pure mullite was obtained at $0.6Al_2O_3 \cdot 0.4SiO_2$, as well as the presence of only those unreacted components which are in excess over this ratio, may be taken as evidence that equilibrated reaction products were obtained. It should be noted that well-defined single phases (θAl_2O_3, $3Al_2O_3 \cdot 2SiO_2$, amorphous SiO_2) are non- or poorly luminescent, while there are two strongly luminescent compositions, arbitrarily designated as phosphors I and II, each consisting of two phases, one of which is mullite. In these phosphors, the strongest x-ray diffraction line of mullite (210) is seen to be about one-tenth of the height in the pure compound; moreover in the weaker phosphor (II), there is a sixfold decrease in line height which occurs as one goes from $x = 0.2$ to $x = 0.175$. Since over this interval the mullite concentration differs by only 12.5%, the increase in luminescence is primarily associated with decreased particle size, *i.e.*, increased surface area of the mullite.

Figure 2 shows emission spectra of phosphor I as a function of Eu concentration, and Fig. 3 shows the absorption (1- absolute reflectance) and the excitability of the sample with 3 x 10^{-3}Eu/0.925 $SiO_2 \cdot 0.075Al_2O_3$.[1] The fluorescence of this phosphor is very

[1] All concentrations are expressed in gram atoms. Reproducibility of excitation spectra of phosphors prepared with minor variations was good as pertains to general features, but they frequently differed in relative peak heights. An additional peak at 205 nm was also noted on occasion.

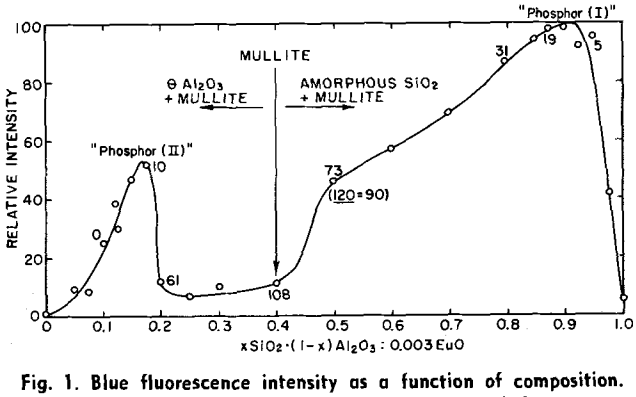

Fig. 1. Blue fluorescence intensity as a function of composition. Numbers in figure denote the relative height of the 210 x-ray reflection of mullite.

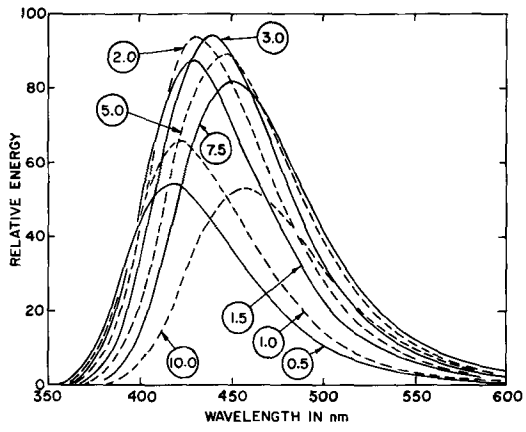

Fig. 2. Special energy distribution of $0.925SiO_2$ $0.075Al_2O_3$: $10^{-3}xEu^{2+}$. Values of x are shown in figure.

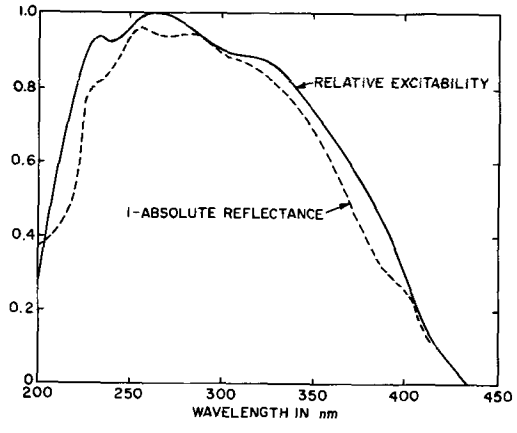

Fig. 3. Excitability and absorption plotted as 1-absolute reflectance of $0.925SiO_2 \cdot 0.075Al_2O_3 : 3x10^{-3}Eu^{2+}$.

intense, and under 254 nm excitation values of quantum efficiency approaching unity have been measured. The pronounced shift of emission to longer wavelength which occurs with increasing Eu can be explained by the region of overlap with the excitation spectrum where self-absorption and re-emission at longer wavelength occurs. Accordingly, this has also been observed to occur (to a lesser extent) with increasing particle size, *i.e.*, decreased scattering of the powder layer. The optimum Eu concentration of phosphor II lies in the neighborhood of $1.5 \times 10^{-3}Eu/0.175SiO_2 \cdot 0.825Al_2O_3$. Its spectral distributions are essentially the same as those of phosphor I with equal Eu concentration. As already seen in Fig. 1, the fluorescence of phosphor II is considerably weaker; moreover in contrast to phosphor I, it is unstable in that the activator begins to oxidize at only slightly elevated temperatures, *e.g.*, 100°C. The weak luminescence of $3Al_2O_3 \cdot 2SiO_2 + Eu^{2+}$ is broader (half-width = 118 nm) and peaks at 460 nm. Its excitability is essentially the same as that of the two phosphors, although only two peaks located at 268 and 304 nm were detected.

Trivalent Eu, unless stabilized in a suitable matrix, is readily reducible under present experimental conditions, and Eu^{2+} may therefore be assumed to exist, at least as a separate compound with θAl_2O_3, $3Al_2O_3 \cdot 2SiO_2$, or amorphous SiO_2. Among IR absorption bands characteristic for these substances, a fairly strong band was also noted at 1390 cm^{-1} which, however, is present only in the two phosphor compositions and in $3Al_2O_3 \cdot 2SiO_2 + Eu^{2+}$, but absent in $\theta Al_2O_3 + Eu^{2+}$, amorphous $SiO_2 + Eu^{2+}$, and a sample of phosphor I, prepared without Eu.

Figure 4 shows ESR spectra of phosphors I and II at 4.2K and 9447 megacycles, plotted as the derivative of absorption. The sample weights were arbitrary, but

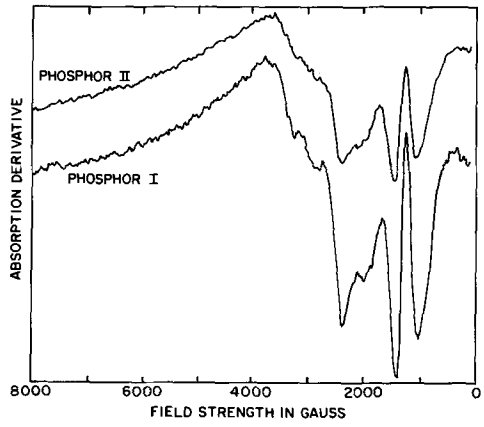

Fig. 4. Electron spin resonance at 4.2K of Eu^{2+} in phosphors I and II, plotted as the derivative of 9447 mc absorption as a function of magnetic field strength.

by correcting to the same amount of Eu in the cavity, the spin density of phosphor II is found lower by a ratio of 1.44. [2] Otherwise, the spectra are identical and therefore indicate that the environment of Eu^{2+} is the same in both phosphors.

The present materials appear to be characterized by dispersions of $3Al_2O_3 \cdot 2SiO_2 + Eu^{2+}$ in another matrix. In the case of phosphor I, this consists of amorphous SiO_2 whose relatively structureless appearance makes it possible to show the presence of the mullite directly. This is seen in Fig. 5a where one notes particles of 100Å most easily discernible near the periphery. When the prefiring of the phosphor was carried out at 1500°C, the SiO_2 was converted to α-cristobalite which is readily noted in Fig. 5b; moreover, the small particles are now absent which means that the mullite has also undergone extensive particle growth. For both reasons, it is evident that the area of contact between the two phases must have diminished. Prefiring at 1600°C causes fusion to an opalescent glass which, after grinding and refiring at 1100°C, was found to contain considerably less α-cristobalite. Figure 5c shows that the over-all structure of this phosphor consists of an amorphous matrix containing evenly dispersed particles, again of about 100Å in size. Moreover, x-ray powder diffraction analysis of this specimen indicates the presence of the same amount of mullite as a separate phase, *i.e.*, it has not dissolved irreversibly in the silica. The small particles, therefore, consist at least in part of mullite which is in contact with amorphous silica.

Figure 6 shows the dependence of fluorescence intensity of prefiring temperature. X-ray powder diffraction analyses taken on one of the series (gel precipitates, NH_3-refired) show the relative height of the 101 reflection of α-cristobalite, and the samples prepared at 1250°, 1500°, and 1600°C are the ones shown in the previous three figures. At least qualitatively, there is a correlation between fluorescence and the crystallinity of the SiO_2 in contact with $3Al_2O_3 \cdot 2SiO_2$, and therefore by inference, the area of the interface. By way of illustration, Fig. 6 also shows that refiring in H_2 is preferable to NH_3, and that a raw material of the same over-all composition but consisting of a mechanical mixture (prepared by wet slurry) of $Al(OH)_3$, $SiO_2 \cdot xH_2O$, and $Eu(NO_3)_3 \cdot 6H_2O$ is not sufficiently reactive to provide the needed dispersion until it is fused.

Discussion

The present system is probably unique in the sense of requiring not one but two host matrices to evoke luminescence. This admittedly unorthodox conclusion follows from direct experimental evidence (Fig. 1)

[2] The phosphors contained 2×10^{-3} Eu/mole. Assuming complete incorporation in phosphor I, this ratio indicates 1.39×10^{-3} Eu/mole in phosphor II which is in good agreement with the optimum activator concentration in this composition.

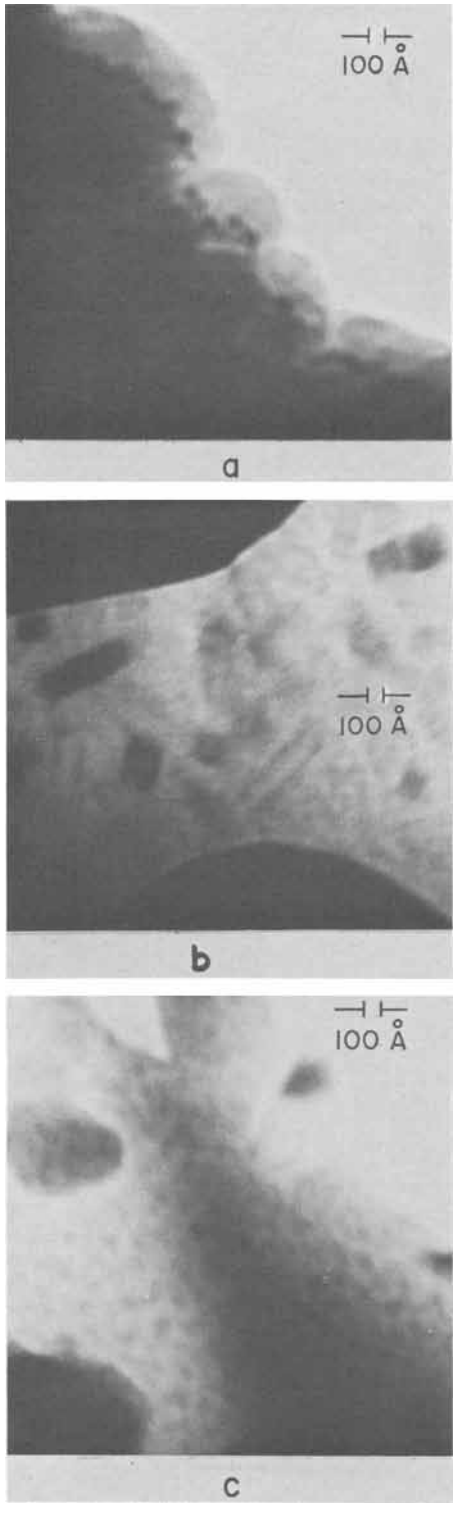

Fig. 5. Transmission electronphotomicrographs of thin edges of $0.925SiO_2 \cdot 0.075Al_2O_3$:3 x $10^{-3}Eu^{2+}$, prefired at: a, 1250°C; b, 1500°C; c, 1600°C.

and is supported by other data which may be summarized as follows.

1. The ionic size of Eu^{2+} (1.09Å) is too large to allow incorporation into Al_2O_3(Al^{3+} = 0.51Å) or $3Al_2O_3 \cdot 2SiO_2$(Si^{4+} = 0.41Å). The disordered lattice of amorphous SiO_2 is known to accommodate large ions; however, no luminescence was noted in this compound until Al is introduced. Then, luminescence rises very steeply and, therefore, one might wish to ascribe this effect to charge compensation such as $2Al^{3+} + Eu^{2+} = 2Si^{4+}$. Maximum luminescence obtains, however, at a Al/Eu ratio near 50/1 where a separate phase (mullite) is already detectable. Moreover, the need for charge compensation is questionable especially in the disordered SiO_2 network, where vacancy formation has little meaning and a configuration such as $2Eu^{2+} = 1Si^{4+}$ seems equally plausible.

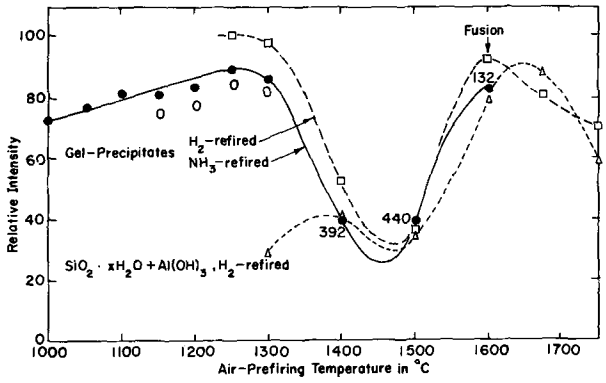

Fig. 6. Blue fluorescence intensity of $0.925SiO_2 \cdot 0.075Al_2O_3$:3 x $10^{-3}Eu^{2+}$ as a function of prefiring temperature. Different techniques of preparation are shown in figure.

2. Luminescence does not require the presence of free SiO_2, since the same excitation and emission spectra are obtained in both phosphors. Although Eu^{2+} is unstable in phosphor II (apparently no effective means of charge compensation is operative) the identical spectra suggest the presence of the same activator center in both phosphors. This further supported by the same ESR absorption of Eu^{2+}. The IR absorption band observed only in compositions containing both $3Al_2O_3 \cdot 2SiO_2$ and Eu^{2+} further supports this conclusion. The fact that this absorption occurs also in the absence of excess SiO_2 or Al_2O_3 indicates that the environment of Eu^{2+} is uniquely determined by its association with $3Al_2O_3 \cdot 2SiO_2$, while only the radiative emission probability of this center is influenced by the presence of the second phase.

3. The dependence of luminescence on the particle size of the mullite phase in phosphor (II) (steep slope between $x = 0.175$ and 0.2 in Fig. 1) and on the crystallinity of SiO_2 (Fig. 5 and 6) suggests that it depends on the area of the interface and consequently, that it originates therein. Owing to the presence of SiO_4 and AlO_4 tetrahedra, as well as AlO_6 octahedra in the structure of aluminosilicates, the interface with neighboring similar units in SiO_2 or Al_2O_3 is likely to involve sharing of oxygen bonds and is therefore not merely mechanical.

The model proposed for the present system may be thought of as Eu^{2+} ions dispersed in the interface between mullite and the second phase and whereby the concentration of activator centers obviously increases with decreasing particle size of the mullite. Alternately, the "association" of Eu^{2+} with mullite may consist of one of the luminescent compounds, *e.g.*, $EuAl_2Si_2O_8$ reported by Jaffe (12, 22). The latter would then be similar to the system $Zn_3(VO_4)_2$ - ZnO recently described by Bernikov and Zelikin (23), *i.e.*, the dispersion of a phosphor in an excess of one of its constituent oxides. It is attractive from the standpoint that at least in the absence of excess SiO_2 or Al_2O_3, Eu^{2+} must form a separate phase, and that the luminescence presently observed in $3Al_2O_3 \cdot 2SiO_2 + Eu^{2+}$ is at least at slightly longer wavelength[3] and can be weak because of its low (activator) concentration. This model would, however, require that only one such compound, *e.g.*, $EuAl_2Si_2O_8$, can exist regardless of over-all stoichiometry which is contrary to Jaffe's results, and that in the present environment, its spectral energy distribution is altered. Finally, the luminescence intensity of a discrete Eu^{2+} compound should not be so strongly influenced by dispersion in the mullite-silica or mullite-alumina interface. Instead, it

[3] The emission of $EuAl_2Si_2O_8$ peaks at 510 nm (22).

should depend on its concentration which would be maximized at Al/Si ratios other than those presently found to yield maximum luminescence (Fig. 1). In view of these considerations, the former model involving discrete Eu^{2+} activator sites appears to be more plausible.

Acknowledgment

The author is indebted to Miss I. Walinski for phosphor preparation and measurements, and also wishes to thank G. Wagner, R. Fitzmaurice, C. K. Lui Wei, and W. A. Thornton for valuable help and discussions.

Manuscript submitted Aug. 8, 1968; revised manuscript received *ca.* Sept. 18, 1968. This paper was presented as a Late News Paper at the Boston Meeting, May 5-9, 1968.

Any discussion of the paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Effects of Impurities on the Luminescence Processes in YVO_4: Eu

Tsuyoshi Kano and Yoshiro Otomo

Central Research Laboratory of Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Effects of impurities on the photoluminescence, cathodoluminescence, and thermoluminescence of YVO_4:Eu are investigated. Such impurities as Zr, Th, Mo, or W that would give charge defects in the crystal lattice lead to strong quenching of cathodoluminescence, weak or no quenching of photoluminescence at room temperature, and remarkable change of the glow curve. Energy transfer from lattice to Eu by way of excited Eu-O state that is sensitive to trapping by charge defects in the lattice is proposed from the specific quenching of photoluminescence below glow-peak temperature in the Mo- or W-doped phosphor.

Efficient host sensitization in YVO_4:Eu was first indicated by Van Uitert *et al.* who observed the remarkable deviations from a linear dependence of the emission intensity on the Eu^{3+} content in the regions of low concentration by 254 nm or 366 nm uv excitations (1). Since YVO_4:Eu was developed for use in color picture tubes by Levine and Palilla (2), excitation and energy transfer processes in various orthovanadate phosphors have been reported and discussed by many authors (3-13), but more experimental bases are required to make clear the mechanism of these processes. In this paper, the effects of charge defects introduced by impurities on the luminescence intensity and the thermoluminescence properties with 254 nm uv, 365 nm uv, or 10 kv cr (cathode-ray) excitation were investigated to explain the excitation and energy transfer processes in YVO_4:Eu.

Experimental

The powder samples were prepared by firing the precipitates obtained from a mixture of component solutions at 1250°C for 2 hr with sodium pyrovanadate flux. The Eu content was 5 m/o (mole per cent). Various impurities in the form of oxides or oxyacids were intimately mixed with the precipitates before firing. The contents of impurities in this paper refer to the amounts of impurities added before firing. The firing of vanadate precipitates serves as a suitable method of preparing samples for the purpose of this paper, because it can constantly provide bright phosphors for laboratory scale experiments. Nb and Ta in the final products were analyzed by x-ray fluorescence method with IKF-3 x-ray spectrometer made by Rigaku Denki Company, Ltd. A high-pressure mercury lamp (100w) was used for long wave uv (mainly 365 nm) exciting light source and a low-pressure mercury lamp (10w) with a quartz tube was used for short wave uv (mainly 254 nm) exciting light source. For the cathodoluminescence measurement, the phosphors were settled on a metal panel in thin layers (0.06 g/cm^2) and irradiated with 10 kv electrons at 1 μa/cm^2. Luminescence spectra were obtained using Hitachi recording spectrophotometer EPS-2R which gives spectral energy distribution curves automatically corrected for the characteristics of the system. Excitation spectra were obtained with Hitachi spectrofluorometer MPF-2, using 40w hydrogen lamp as a light source and sodium salicylate as a reference phosphor showing constant quantum yields in the wavelength region studied. The thermoluminescence measurements were carried out by a conventional technique, using an EMI 6256S photomultiplier as a detector.

Results

The effects of such added impurities as Ce, Pr, Nd, U, Th, Mo, W, Nb, or Ta on the luminescence intensities of YVO_4:Eu with 365 nm uv, 254 nm uv, or cr excitation are shown in Fig. 1. As shown, these impurity effects can be classified into three types: (*A*) the strong quenching which is independent of the way of excitation, (*B*) the strong quenching of cathodoluminescence, weak quenching of photoluminescence by short-wave uv excitation and no remarkable effect observed on photoluminescence by long wave uv excitation, and (*C*) minor effects observed. Type A, B, and C are typically observed by the doping of rare earth impurities, group IV or VI elements and group V elements, respectively. By Ce- or U-doping, the quenching effects on the cathodoluminescence and the photoluminescence by 365 nm uv excitation were found to be of the same degree, but minor quenching effects were observed on the photoluminescence by 254 nm uv excitation. This difference is explained in the following way. Ce- or U-doping causes coloration of samples which gives rise to absorption of luminescence. When the phosphors are excited deeply from the surface by 365 nm uv or cr, the absorption of luminescence by those impurities is expected to be stronger than that when the phosphors are excited at the surface by 254 nm uv which is shorter than the absorption edge (about 320 nm). The dopings of other impurities shown in Fig. 1, on the other hand, do not result in the remarkable coloration of samples. Thus, the effects of Ce- or U-doping can be interpreted to belong to type A essentially. Type A quenching is ascribed to the interaction between electronic energy levels of impurity ions and excited electronic energy levels of Eu that are commonly involved in the luminescence process with uv excitation and in the process with cr excitation. This type of interaction is expected to be observed between many rare earth ions which transfer energy with each other by resonance. To estimate the quenching effect by this mechanism, an important parameter is a critical transfer distance Ro, which is defined as the distance of a donor-acceptor pair at which the probability of energy transfer from the donor to acceptor becomes equal to the probability of the internal transition of the donor (14). For the quenching of Eu^{3+} luminescence by Nd^{3+}, Ro was estimated to be 12.8Å from the analysis of the decrease of emission intensity of Eu^{3+} by Nd^{3+} (14). By using this value, it is estimated that Eu^{3+} luminescence decreases by half by 0.9 a/o Nd^{3+} in YVO_4:Eu. This is in qualitative agreement with the result shown in Fig. 1. Type B quenching, on the other hand, is ascribed to the action of charge defects in the highly excited lattice, since it is characteristic of those ions that give surplus charges replacing constituent ions. Other luminescence properties of Mo or W-doped phosphors which are characterized by type B quenching will be described in the following and the detailed discussion of type B quenching will be given in the next chapter.

Minor effects of type C may be due to the lack of energy levels interacting strongly with Eu^{3+} and also due to the lack of charge defects formed by incorporation of the impurities. The anxiety that the minor effects of type C might be due to small amounts of these impurities actually incorporated in the final products could be eliminated by analyzing the content of Nb or Ta in the final products by x-ray fluorescence spectroscopy which confirmed the nearly quantitative incorporation of these elements.

The thermoluminescence of YVO_4:Eu has already been reported (12, 15). The remarkable changes of the glow curve as a result of Mo- or W-doping were found after uv irradiation at 77°K as are shown in Fig. 2. The doping of Mo or W gives rise to a new glow peak at the expense of the native glow peak by 254 nm uv excitation. By 365 nm uv excitation, however, no thermal glow was observed in the Mo-doped phosphor and only a little glow was observed in the W-doped phosphor. These thermoluminescence properties of Mo- or W-doped phosphors provide contrasts to those of undoped phosphor which exhibits nearly identical glow curve by 365 nm uv excitation with that by 254 nm uv excitation. By cr excitation of the Mo-doped YVO_4:Eu, a similar glow curve with that by 254 nm uv excitation was obtained. By keeping the irradiated Mo-doped YVO_4:Eu at 77°K for 30 min in the dark, 20% decrease of the resultant light sum was observed. As for the case of the doping of group IV elements, strong or complete quenching of the native glow-peak was observed by Th- or Zr-doping. No remarkable new peak, however, appears in this case. The difference between the effects of group IV elements and group VI elements may be related to the difference of substituted sites, V site by Mo or W and Y site by Zr or Th being expected to be substituted, respectively.

The glow curves of YVO_4 not activated with Eu are shown in Fig. 3. Several glow peaks were found in the sample which had been fired without flux. A simpler glow curve was obtained with the sample fired

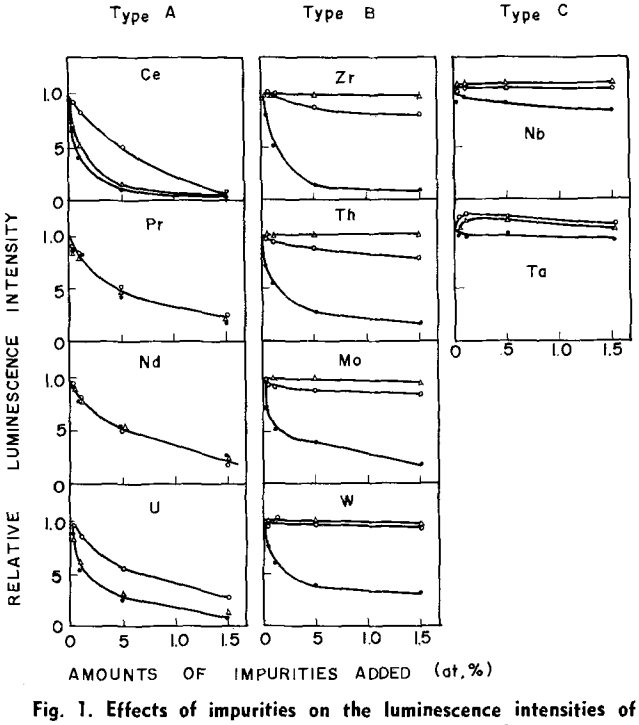

Fig. 1. Effects of impurities on the luminescence intensities of YVO_4:Eu excited with 365 nm uv (△), 254 nm uv (○), or cathode rays (●) at room temperature.

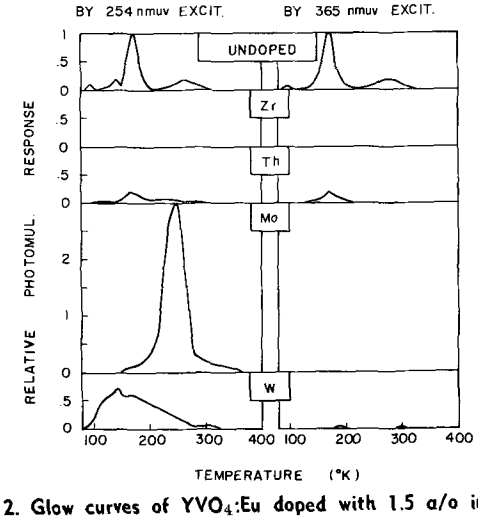

Fig. 2. Glow curves of YVO_4:Eu doped with 1.5 a/o impurities. Heating rate, 25°K/min.

with flux, where only two peaks were distinguished. The glow peaks that disappeared as a result of using flux may be due to some crystal defects that are removed by using flux. The major glow peak at 160°K lies very near to the reported value, 164°K (12) and corresponds to the major glow peak of undoped YVO_4:Eu. By Mo-doping, a new glow peak around 240°K appears in the glow curve of YVO_4 or YVO_4:Eu. From these glow curve measurements, it is obvious that the trapping levels of YVO_4:Eu lie not in the excited state of Eu but in the host lattice and charge defects introduced by impurity dopings strongly affect the native trapping level or provide new levels.

In Fig. 4, the spectra of photoluminescence and thermoluminescence are compared by observing the dependences of the transmitted light intensity on the cut-off wavelength of filters. The thermoluminescence spectrum of Mo-doped YVO_4:Eu appears to be similar with that of photoluminescence of YVO_4:Eu.

Cathodoluminescence spectrum of YVO_4:Eu and that of Mo-doped YVO_4:Eu are compared in Fig. 5, where no difference of spectral energy distribution was observed. Excitation spectrum of YVO_4:Eu and that of Mo-doped YVO_4:Eu are shown in Fig. 6. Mo-doping decreases the luminescence intensity only under short wavelength region, as is consistent with the results shown in Fig. 1.

Temperature dependences of the luminescence intensity of Mo-doped YVO_4:Eu by cr, 254 nm uv, or 365 nm uv excitation are compared with those of undoped YVO_4:Eu in Fig. 7. By 254 nm uv excitation, stepwise temperature-dependent quenching of luminescence is induced by Mo-doping at low temperatures. Increasing

quenching effects with the decrease of temperature are also observed with cr excitation, while marked effects of Mo-doping are not found from 77° to 450°K with 365 nm uv excitation. The luminescence spectra do not depend much on temperature except that a feeble host luminescence, which is cut by a filter, appears at low temperatures. In Mo- or W-doped YVO_4:Eu with 254 nm uv excitation, correlations between the temperature dependences of photoluminescence intensities and the glow curves are shown in Fig. 8. As shown in the figure, quenching by Mo- or W-doping occurs below the temperature around which thermoluminescence appears. The decrease in luminescence intensity at low temperature is not due to simple energy storing, be-

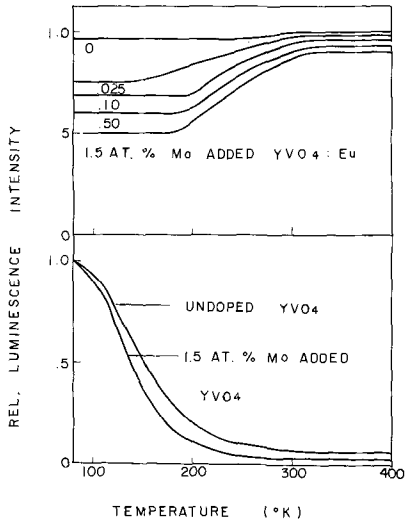

Fig. 9. Effects of Mo doping on the temperature dependence of luminescence intensities with 254 nm uv excitation. In the case of the host luminescence of YVO_4, normalized intensities are shown.

cause the resultant thermoluminescence intensity is orders of magnitude weaker than the luminescence intensity under excitation. In the case of Mo-doped YVO_4:Eu, steady intensity of photoluminescence was instantly obtained from the beginning of excitation at 77°K where the number of filled traps giving rise to thermoluminescence was increasing. This result indicates that the quenching induced by Mo-doping below glow-peak temperature is not due to the filled traps which will give rise to thermoluminescence at elevated temperatures. Figure 9 shows the temperature dependences of luminescence intensities of YVO_4:Eu doped with various amounts of Mo and the effect of Mo-doping on the temperature dependence of the host luminescence of YVO_4. In the case of host luminescence, specific quenching due to Mo-doping at low temperatures does not occur in contrast with the case of the luminescence of Eu in YVO_4:Eu. An explanation for the specific quenching effect of Mo-doping at low temperatures is given below.

Discussion

It has been indicated by Van Uitert *et al.* that the excitation of YVO_4:Eu by 254 nm uv or 366 nm uv proceeds through the host process because the relative brightness per Eu content increases with the decrease of Eu concentration (1). The identical excitation spectra of related vanadate phosphors around 320 nm reported by Palilla *et al.* show that the exciting energy is absorbed by VO_4^{3-} ions and is transferred to activators (4), but the broad absorption or excitation band in the shorter wave uv region has been the subject of discussions (7, 9). Recently Mooney and Toma indicated a continuous overlap of π-bonding orbitals of vanadate ions and f orbitals of the rare earth ion to explain the efficient photoluminescence of YVO_4:Eu (13).

The specific quenching of Eu luminescence below the glow peak temperature in Mo-doped YVO_4:Eu provides another experimental basis for the discussion on the nature of interaction between the host lattice and Eu. Various possible quenching mechanisms are discussed in the following. There are several possible stages from absorption of exciting light to emission of luminescence on which Mo-centers can play a part. The quenching due to ineffective additional absorption by impurity ions has been indicated in the luminescence quenching of $CaWO_4$ or $MgWO_4$ by Fe, Cr, Cu, or Mn by Kröger (16). Following this mechanism, quenching effects are stronger with long wave uv excitation than with short wave uv excitation in the neighborhood of absorption edge. The quenching due to Mo-doping, however, is rarely observed by 365 nm uv excitation and appreciable by 254 nm uv excitation in contradiction of the prediction of the above mechanism. Absorption of the red luminescence by doped Mo-center may be negligible, because it does not affect the white body color of the phosphor. It is evident from the minor effect of Mo-doping with 365 nm uv excitation that the emitting state of Eu, $^5D_0$, does not suffer quenching interaction from the doped Mo center. Therefore, the doped Mo center is supposed to act in the intermediate luminescence process. By the way, P substituted for V in YVO_4:Eu reduces luminescence of Eu but enhances host luminescence in YVO_4 (10). These effects result from the cutting of the energy transferring chain by PO_4^{3-} group substituted for VO_4^{3-} group. If this mechanism is dominant in Mo-doped YVO_4:Eu, native feeble host luminescence observed at 77°K should be enhanced at the expense of the luminescence from Eu. Such enhancement of host luminescence by Mo-doping could not be observed. In the case of Y_2W_{1-x} Mo_x O_6: Eu, it has been reported that doped Mo plays a role of sink in the course of exciton migration with subsequent energy dissipation (17). It seems hard to explain by this mechanism the temperature-dependent quenching due to Mo doping in YVO_4:Eu, because the host luminescence in YVO_4 does not suffer this specific quenching. It is to be noted in this discussion that the exciton migration in the lattice of YVO_4:Eu is supposed to be comparatively rapid even at 77°K, because only a feeble host luminescence could be observed in YVO_4:Eu at 77°K. This feeble host luminescence in the case of YVO_4:Eu provides an interesting contrast to the remarkable host luminescence in Ca WO_4:Sm at low temperatures (18). The phonon-assisted energy transfer from lattice to an activator suggested in the case of YVO_4:Sm by Ropp (9) may have few connections with the quenching by doped impurities, because the phonons in the host lattice may not be so sensitive to doped impurities. It is most likely that highly excited states of Eu-O state which is closely coupled with the lattice suffer quenching interaction from doped Mo center at low temperatures. The broad excitation spectra of various Eu-activated mixed oxides in the region from 220 to 310 nm have been assigned as charge transfer bands by Blasse (19). It is quite possible that the charge transfer state play a part in the energy transfer process from lattice to an activator. This possibility has already been referred to in the case of $CaWO_4$:Sm (18). As a higher energy state to which Eu^{3+} is excited by receiving energy from the vanadate lattice with short wave uv excitation, the charge transfer state is preferred to excited states of Eu^{3+} perturbed by crystal field, because the sensitivity to charge defects in the lattice is expected to be higher in the former than the latter. The continuous overlap of π-bonding orbitals of the VO_4^{3-} group and f orbitals of Eu^{3+} proposed by Mooney and Toma to explain the efficient energy transfer (13) might contribute to the trapping by doped Mo center below glow peak temperature. The quenching is explained by assuming that the charge transfer state of Eu is sensitive to the charge trapping action of doped Mo center at low temperatures and as a result, its energy is transferred to the doped Mo center and dissipated nonradiatively there or stored. The trap depth of the doped Mo center was roughly estimated from the initial rise of thermoluminescence to be distributed from 0.48 to 0.65 ev. The condition indicated by Bräunlich (20) should be checked before the establishment of the value.

Finally, it is to be indicated that the comparison between glow curve and temperature dependence of luminescence of insulating phosphors, preferably doped with impurities giving surplus charges, will provide useful information concerning intermediate processes from excitation to luminescence.

Spectroscopic Identification of Europium-Oxygen Complexes in Calcium Fluoride

R. L. Amster and C. S. Wiggins

The Bayside Laboratory, Research Center,
General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

The emission and excitation spectra for $CaF_2:Eu^{3+}$ have been analyzed. The spectra have been attributed to four main Eu^{3+} species. Three of these species are composed of $Eu^{3+} - O^{2-}$ complexes which arise as a result of the charge compensation of Eu^{3+} substituting in a Ca^{2+} site. The complexes have been associated with both $(Eu - O)^+$ and $(Eu_2 - O_2)^{2+}$ groups with the relative concentration of the complexes depending on the total Eu^{3+} concentration. Broad and intense uv excitation spectra have been identified as $Eu^{3+} - O^{2-}$ charge transfer bands. The high intensity of $^5D_0 - {}^7F_0$ transitions attests to the linear asymmetry of the complexes at the Eu^{3+} site.

Replacement of Ca^{2+} in CaF_2 by trivalent europium requires compensation of the excess positive charge (1, 2). This may be effected by the inclusion of an interstitial fluoride ion or by the isomorphous substitution of an O^{2-} ion for a F^- ion adjacent to the cation site. The latter mode of compensation predominates when $CaF_2:Eu^{3+}$ is prepared in an oxidizing atmosphere (1).

The presence of an oxide ion in the immediate vicinity of Eu^{3+} gives rise to charge transfer bands in the absorption and fluorescence excitation spectra of several Eu^{3+} activated materials (3). For example, Blasse and Bril (4) have observed broad uv bands in the fluorescence excitation spectra of $NaGdO_2:Eu^{3+}$ which they attribute to charge transfer from O^{2-} to Eu^{3+}. Their observations are in agreement with Jørgensen's (5) interpretation of the uv absorption spectra of Eu^{3+} in solution. Similarly, Kingsley and Prener (6) have reported observing an intense charge transfer band when CdS is introduced into $CdF_2:Eu^{3+}$; the absorption peaking at 283 nm is associated with the $Eu^{3+} - S^{2-}$ complex. It was the intention of this investigation to examine the charge transfer bands in the spectra of $CaF_2:Eu^{3+}$ (prepared in air) in an attempt to identify the $Eu^{3+} - O^{2-}$ complexes formed through the mechanism of charge compensation. The identification was assisted by studying the effects of linear asymmetry at the europium site as a result of compensation by O^{2-} ions. Blasse and co-workers (7) have studied several Eu^{3+}-activated phosphors in which there exists linear asymmetry at the Eu^{3+} site. They observed that the generally forbidden $^5D_0$-$^7F_0$ transition in Eu^{3+} gives rise to unusually high fluorescence intensity in the compounds examined. The intense $^5D_0$-$^7F_0$ fluorescence is explained by inclusion of a linear term in the crystal field expansion (8).

Since the $^5D_0$-$^7F_0$ transition cannot be split by a crystal field, the appearance of more than one $^5D_0$-$^7F_0$ emission line for $CaF_2:Eu^{3+}$ can be interpreted as proof of the existence of more than one symmetry site for Eu^{3+} ions charge compensated by oxide ions. Eu^{3+} ions in CaF_2 can be expected to yield emission and fluorescence excitation spectra which depend on local europium site symmetry. In the present study, several Eu^{3+} species with different site symmetries are identified by isolating groups of emission and excitation lines which undergo equivalent intensity changes with variations in europium concentrations.

Experimental Procedure

Preparation of $CaF_2:Eu^{3+}$.—Calcium fluoride activated with Eu^{3+} was prepared by a high-temperature, 1050°C, reaction between CaF_2 (Fisher Reagent grade) and anhydrous EuF_3 (Trona Division, American Potash Company). The reaction was carried out in open alu-

mina crucibles in a muffle furnace which had openings to permit free flow of air through the furnace.

Emission spectroscopy.—Emission spectra were recorded in terms of energy *vs.* wavelength with a radiometer which includes a 3/4M Spex grating monochromator and an ITT 4013 photomultiplier [S-20 response, sapphire window]. Correction for instrumental sensitivity was obtained by comparison with a standard lamp and applied automatically.

Excitation spectroscopy.—A double monochromator, consisting of two ¼-meter Jarrell-Ash monochromators linked and driven together was used to select the excitation wavelength from the output of a 900-watt xenon-arc source. Correction for the lamp output spectrum as well as the transmission of the double monochromator was applied automatically.

Experimental Results

When CaF_2:Eu^{3+} is excited by 3130Å radiation, fluorescence emission is observed between 5000 and 7100Å. The four most intense emission lines are located at 6308, 6162, 5809, and 5731Å (Fig. 1). As the Eu^{3+} concentration is increased from 0.002 to 0.02 gram atom mole CaF_2, these lines remain nearly constant in intensity giving no indication of Eu^{3+} concentration quenching. However, emission lines at 5763, 6100, and 6262Å show some increase in intensity with rising Eu^{3+} concentration (Fig. 2). The first set of Eu^{3+} emission lines is attributed to a specie I while the second set is associated with specie IV to be discussed below. Excitation spectra for emission lines attributed to specie I are identical and contain lines at 5731, 5281, 4622, and 4594Å (Fig. 3). In addition, two broad uv excitation bands are observed at 3000 and 3150Å and are accompanied by a series of lines in the 3500-4200Å region (Fig. 4). The broad uv bands are attributed to charge transfer absorptions in Eu^{3+} — O^{2-} groups; lines in the 3500-4200Å region are associated with f-f transitions of europium in these groups. The intense sharp line at 5731Å which is observed in emission and excitation is identified with the $^5D_0$-$^7F_0$ transition in Eu^{3+} which occupies a linearly asymmetric site in specie I.

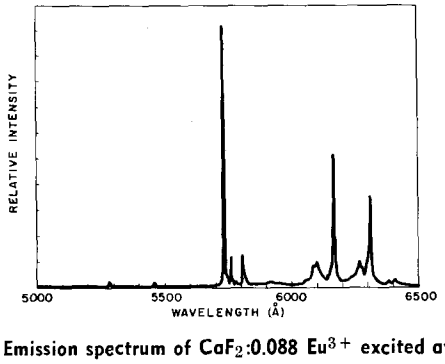

Fig. 2. Emission spectrum of CaF_2:0.088 Eu^{3+} excited at 3130Å

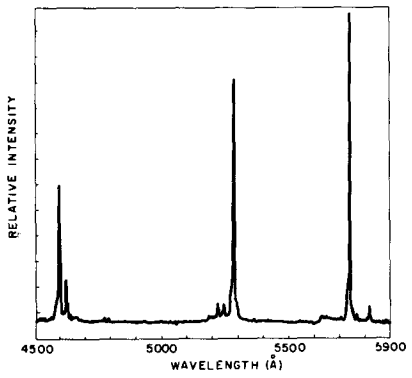

Fig. 3. Visible excitation spectrum of CaF_2:0.02 Eu^{3+} for specie I emission at 6308Å.

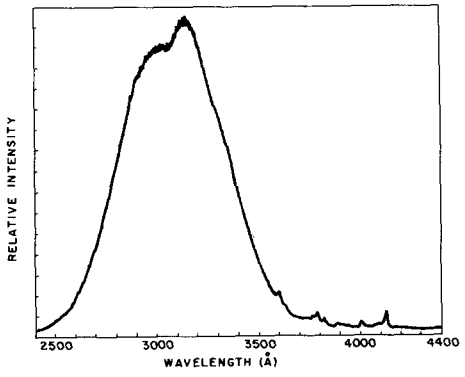

Fig. 4. Ultraviolet excitation spectrum of CaF_2:0.01 Eu^{3+} for specie I emission at 5732Å.

Spectral lines and bands associated with specie I are listed in Table I. The wavelengths listed are nearly identical with those observed by Feofilov and Stepanov (1, 9) for "Type-I" CaF_2:Eu^{3+}; it is clear that specie I reported herein and type I discussed by Feofilov are the same entity and can be identified as a Eu^{3+} — O^{2-} complex with nonlinear symmetry. The spectral transitions were assigned by comparing the spacings of emission and excitation lines in different spectral regions. The lack of equal spacing between spectral lines within any set of $^5D_0$-^7F_J emissions indicated that the lines were not of vibronic nature. These lines were, therefore, identified with pure electronic transitions with the aid of results obtained for $LaCl_3$:Eu^{3+} by DeShazer and Dieke (10). The sharp fluorescence line at 6308Å may be assigned to a $^5D_0$-$^7F_2$ transition. This would indicate an unusually large separation of the $^7F_2$ terminal level involved in this transition from those $^7F_2$ terminal levels associated with the $^5D_0$-$^7F_2$ emission lines at 6054 and 6162Å. The line at 6308Å, therefore, may instead be associated with a $^5D_0$-$^7F_3$ transition. Present evidence, however, does not allow for a definite assignment to the 6308Å emission line. It is clearly not attributable to a transition from a $^5D_1$ state since it is strongly excited by selective absorption into the $^5D_0$ level.

The relative intensities of the specie I charge-transfer bands vary with concentration. The lower wavelength band becomes relatively less intense at higher Eu^{3+} concentration and is just observable when [Eu^{3+}] = 0.088 g-atom/mole CaF_2. Exciting a given CaF_2:Eu^{3+}

sample at the maximum of each of the broad uv bands leads to no differences in emission spectra. Apparently, specie I is composed of two separate $Eu^{3+} - O^{2-}$ entities with identical emission spectra but with charge transfer transitions of different energies. In a later section of this paper, spectra of specie I will be compared with those of other species to be discussed. Identification of the various types of Eu^{3+} groups present will then be made and the intensity dependence of the charge transfer bands upon Eu^{3+} concentration will be discussed.

Excitation of CaF_2:0.002 Eu^{3+} by 2537Å radiation leads to emission between 4500 and 7000Å (Fig. 5a). As the Eu^{3+} concentration is increased from 0.002 g-atom Eu^{3+}/mole CaF_2 to 0.02 g-atom Eu^{3+}/mole CaF_2, a large group of emission lines decreases in intensity and disappears upon further increase in europium concentration to 0.088 g-atom/mole CaF_2 (Fig. 5b and 5c). This group of lines is associated with specie II. (Specie II emission in the 4500-6000Å region is more readily observed in a high-gain recording of the emission spectrum of CaF_2:0.002 Eu^{3+}; Fig. 6.) The most intense emission line for this specie is observed at 6162Å. This line, which is accompanied by a less intense line at 6172Å, coincides with the most intense line of specie I. The excitation spectrum for the 6162Å emission contains, in addition to the excitation spectrum for specie I, lines at 5379 and 4669Å and a band peaking at 2600Å (Fig. 7 and 8). The specie I excitation spectrum can be distinguished from that of specie II because the latter does not appear in excitation spectra of specie I for emission lines other than 6162Å. The group of lines associated with specie II is listed in Table II. The emission spectrum of this specie II agrees closely with that of "type II" reported by Feofilov and Stepanov (1, 9) for CaF_2:Eu^{3+} prepared in the absence of oxygen and the presence of graphite. Specie II is, therefore, associated with Eu^{3+} ions which are not charge compensated by oxide ions. Since Eu^{3+} ions of specie II do not form $Eu^{3+} - O^{2-}$ charge transfer complexes, the broad uv excitation band at 2600Å may then be ascribed to "host" absorption. Since CaF_2 is transparent to 2600Å radiation, the presence of occluded hydroxyl and oxygen anions in air fired CaF_2 probably accounts for the broad uv absorption band (11). For trivalent europium a maximum of three $^5D_0$-$^7F_1$ transitions is allowed.

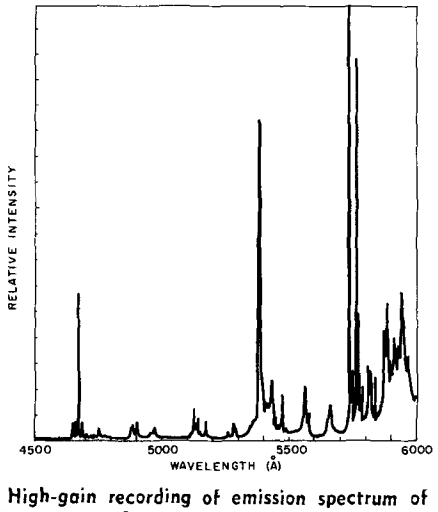

Fig. 6. High-gain recording of emission spectrum of CaF_2:0.002 Eu^{3+} excited at 2537Å; emission covers 4500-6000Å range.

Observation of more than three such lines in the emission spectrum of specie II indicates that this specie is a collection of Eu^{3+} ions occupying dissimilar symmetry sites. These Eu^{3+} ions are most probably charge compensated by nearby interstitial fluoride ions or experience nonlocalized compensation giving rise to cubically symmetric Eu^{3+} sites.

As has been observed from spectra shown in Fig. 5a, excitation of CaF_2:0.002 Eu^{3+} by 2537Å radiation yields line emission at 6262, 6082, and 5763Å in addition to emission associated with species I and II. (Specie I can be excited by 2537Å since the low-wavelength tails of specie I charge transfer bands extend below 2500Å.) As the Eu^{3+} concentration is increased to 0.02 g-atom Eu^{3+}/mole CaF_2, lines at 6262, 6100, 6082, and 5763Å

become prominent, while those lines attributable to specie II diminish in intensity (compare Fig. 5a and 5b). A further increase in Eu^{3+} concentration to 0.088 g-atom Eu^{3+}/mole CaF_2 leads to an increase in the intensity of lines at 6100 and 6262Å relative to that at 6082Å; this concentration increase also leads to increased emission at 5781, 5915, and 5951Å and to a group of lines near 6530Å (Fig. 5c). Increasing the Eu^{3+} concentration leads to the appearance of emission from two additional species: a specie III emitting primarily at 6262, 6082, and 5763Å and a specie IV emitting at 6262, 6100, and 5763Å. (Lines and bands associated with species III and IV are listed in Tables III and IV.) The latter specie is observed primarily at high Eu^{3+} concentrations. Excitation of CaF_2:0.02 Eu^{3+} by 5763Å radiation leads to the emission of two lines of nearly equal intensity at 6082 and 6262Å (Fig. 9a),

while excitation of the CaF_2:0.088 Eu^{3+} by 5763Å gives rise to emission lines at 6100 and 6262Å (Fig. 9b). This supports the conclusion that specie III and IV have the 5763Å and 6262Å emissions in common but differ in the wavelength position of the emission near 6100Å. The relative intensities of spectral lines corresponding to emission from the $^5D_2$, $^5D_1$, and $^5D_0$ levels of a given Eu^{3+} specie are not a function of Eu^{3+} concentration. There is no evidence for concentration quenching of $^5D_2$ or $^5D_1$ accompanied by an enhancement of emission from the $^5D_0$ level. Appearance of specie III and specie IV emission and simultaneous disappearance of emission from specie II on increasing the concentration of Eu^{3+} is readily ascribed to a change in absolute concentrations of the individual species. The changes in emission intensities may not be attributed to a concentration dependent variation of fluorescent lifetimes of the ^5D_J levels.

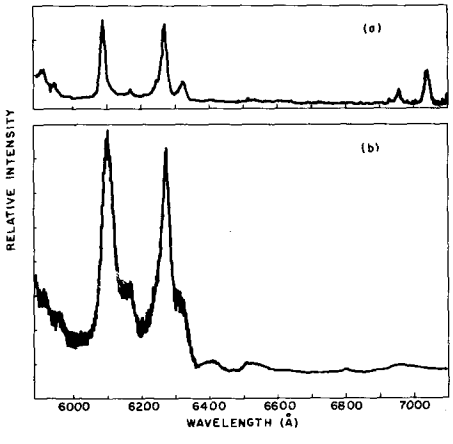

Fig. 9. Emission spectrum of (a) CaF_2:0.02 Eu^{3+} and (b) CaF_2: 0.088 Eu^{3+} excited at 5763Å.

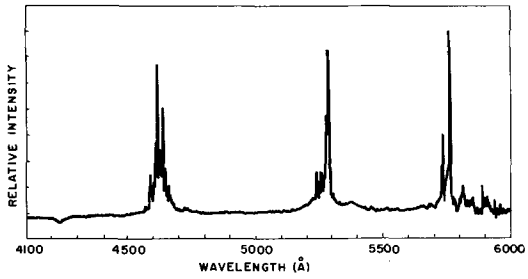

Fig. 10. Visible excitation spectrum of CaF_2:0.02 Eu^{3+} for emission at 6262Å.

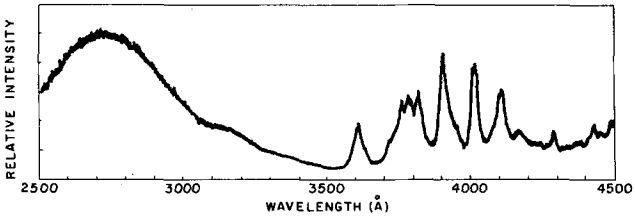

Fig. 11. Ultraviolet excitation spectrum of CaF_2:0.02 Eu^{3+} for emission at 6262Å.

Excitation spectra for the primary specie III and IV emissions (6262, 6100, 6082, and 5763Å) are identical; as an example, the excitation spectra for 6262Å emission in CaF_2: 0.02 Eu^{3+} are shown in Fig. 10 and 11. The resemblance between excitation and emission spectra for species III and IV indicates that the site symmetry for Eu^{3+} ions involved in these $Eu^{3+} - O^{2-}$ complexes are similar. A comparison of the four europium species mentioned now follows.

Discussion

Kreitman and Barnett (12) have calculated the concentration dependent probabilities for finding a given impurity ion in various clusters in a face-centered cubic lattice. In CaF_2, for example, for concentrations of impurity up to 0.05 g-atom/mole CaF_2, the impurity ions are predominantly isolated from each other (singles) or form nearest and next-nearest neighbor pairs. Above a concentration of 0.05 g-atom/mole CaF_2, the probability for finding singles and pairs becomes less than that for finding triads and higher order clusters.

In the present investigation the impurity concentration of Eu^{3+} in CaF_2 ranged from 0.002 to 0.02 g-atom/mole CaF_2 and from 0.042 to 0.088 g-atom/mole CaF_2. For low europium concentrations (0.002-0.02 g-atom range) most Eu^{3+} ions are single or paired. For single (isolated) Eu^{3+} ions, the charge compensation by oxide ion can be achieved by an O^{2-} ion replacing F^- in a site adjacent to Eu^{3+}. The Eu^{3+} ion would, thus, possess C_{3v} site symmetry (Fig. 12a). A nearest neighbor pair of Eu^{3+} ions can be compensated by a pair of oxide ions (occupying F^- ion sites), forming a bridge between the europium ions (Fig. 12b). The Eu^{3+} ions in such a bridged pair possess C_{2v} site symmetry. For next-nearest neighbor pairs, one may assume that the individual Eu^{3+} ions are too far separated to interact appreciably. Therefore, when O^{2-} compensated, such a Eu^{3+} ion pair may be considered to form two slightly interacting $(Eu - O)^+$ complexes. Thus, the Eu^{3+} ion in each complex may be treated as possessing somewhat perturbed C_{3v} symmetry with emission excitation spectra similar to nonperturbed $(Eu - O)^+$ complexes.

X-ray crystallographic evidence exists for the formation of both $(LnO)^+$ and $(Ln_2O_2)^{2+}$ complexes in rare earth oxides and oxy-salts (13). In addition, Forrester and McLaughlin (14) have interpreted ESR measurements of Tm_2O_3-activated CaF_2 in terms of Tm^{3+}-Tm^{3+} nearest neighbor cation pairs bridged by two charge compensating oxide ions. Such evidence

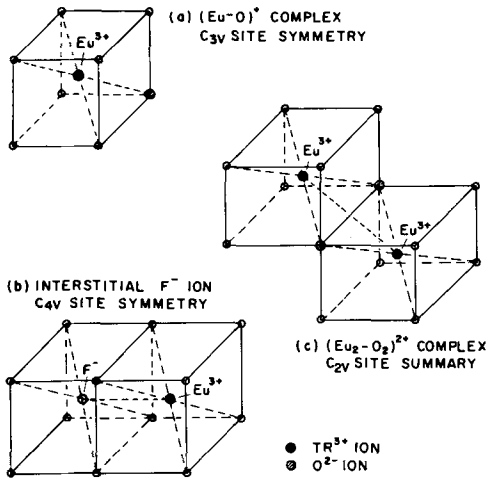

Fig. 12. Modes of charge compensation for Eu^{3+} in CaF_2

supports the contention that Eu^{3+} when O^{2-} compensated exists as $(Eu - O)^+$ and $(Eu_2 - O_2)^{2+}$ entities.

In the higher Eu^{3+} concentration range, more europium ions are clustered in triads and high-order groups than exist as singles or pairs. However, assuming again that next-nearest neighbor interaction of Eu^{3+} ions can be ignored, most triads can be looked upon as associations of singles or pairs and singles. The emission and excitation spectra of Eu^{3+} ions in these triads will probably be similar to the spectra of singles and pairs with any differences ascribed to weak interactions with nearby $Eu^{3+} - O^{2-}$ complexes.

Barnes and Hincott (15) have shown that the wavelength of the charge transfer band of $Eu^{3+} - O^{2-}$ complexes increases with an increase in the number of ligands coordinated to the Eu^{3+} ion. Thus, the charge transfer band associated with  complexes is expected to lie at longer wavelengths than that associated with an isolated Eu^{3+} ion coordinated to a single oxide ion.

For specie I Eu^{3+} in CaF_2 (Table I), the charge transfer bands associated with this specie are at the longest wavelength observed for such bands, suggesting that the entity discussed is a  complex. The appearance of two charge transfer bands for specie I excitation has earlier been attributed to the presence of two separate entities. One of these may be identified as an isolated $(Eu_2 - O_2)^{2+}$ complex. The second may be a $(Eu_2 - O_2)^{2+}$ complex which forms part of a triad or high cluster and is far enough removed from other Eu^{3+} ions in the cluster to exhibit a $(Eu_2 - O_2)^{2+}$-type spectrum. Since europium-oxygen charge transfer bands shift to longer wavelength with increased coordination of O^{2-} to Eu^{3+}, the longer wavelength transfer band in specie I can be ascribed to the $(Eu_2 - O_2)^{2+}$ group weakly coordinated to a nearby $Eu^{3+} - O^{2-}$ grouping. It may be recalled that the probability for isolated $(Eu_2 - O_2)^{2+}$ pair formation decreases with increased Eu^{3+} concentration while the probability for triad formation increases. Therefore, the increase in the relative intensity of the long wavelength charge transfer band with Eu^{3+} concentration can be attributed to the increased presence of pairs that are parts of higher-order clusters.

For both specie III and IV, the charge transfer excitation band is observed at 2750Å which is appreciably lower in wavelength than the charge transfer band of specie I. This indicates that the Eu^{3+} ions in the species III and IV are coordinated to fewer O^{2-} ligands than are Eu^{3+} ions of specie I. Specie III,

which is prevalent at lower concentrations, is, therefore, associated with an isolated $(Eu - O)^+$ complex. Specie IV, which is observed at higher Eu^{3+} concentrations is associated with a $(Eu - O)^+$ complex which is next-nearest neighbor to another $(Eu - O)^+$ or $(Eu_2 - O_2)^{2+}$ group, *i.e.*, it is part of a next-nearest neighbor pair or part of a triad.

Finally, as previously noted, failure to observe a $Eu^{3+} - O^{2-}$ charge transfer band for specie II indicates that the Eu^{3+} ions involved are far removed from oxide ions. The number of $^5D_0$-$^7F_1$ emissions observed for specie II is greater than the maximum allowed assuming complete removal of $^7F_1$ degeneracy. Thus, specie II is the collection of all Eu^{3+} ions in both noncompensated and F^- ion compensated sites. Europium compensated by an oxide ion not localized at the Eu^{3+} site would also be included in specie II. Specie II Eu^{3+} ions compensated by an interstitial F^- ion would possess C_{4v} symmetry which, according to group theoretical calculations, would allow for a $^5D_0$-$^7F_0$ transition. Judd (8), however, in his discussion of hypersensitive rare earth ion transitions states that the linear asymmetry at a rare earth ion required for observation of such transitions must involve symmetry distortion caused by nearest neighbor ions. Since F^- ions compensating Eu^{3+} in CaF_2 are not nearest neighbor to Eu^{3+}, one may conclude that they are ineffective in distorting the local Eu^{3+} symmetry sufficiently to allow observation of a $^5D_0$-$^7F_0$ transition.

Strain Compensation in Silicon by Diffused Impurities

T. H. Yeh* and M. L. Joshi

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

A method to avoid dislocation generation in boron or phosphorus-diffused layers is presented. This method, called strain compensation, considerably reduces dislocation generation in the diffused layers. This strain compensation is brought about because impurities such as tin and boron, or tin and phosphorus, have been diffused simultaneously into the silicon, with tin counteracting the stresses produced by the solute lattice contraction of the boron or the phosphorus. Transmission electron micrographs are provided as evidence of this phenomenon.

Diffusion of high concentration of impurity in silicon is known to introduce stresses in the lattice and cause the generation of dislocations in the diffused region. Such dislocations, particularly those due to phosphorus and boron, have been the subject of detailed study in the past (1-11). The amount of maximum stress being induced in the silicon lattice by the homogeneously distributed impurity is understood to be dependent on both the size of the impurity atom relative to the size of the lattice site it occupies in the silicon matrix and on the maximum solubility of the impurity in the silicon at the diffusion temperature. On the basis of Pauling's tetrahedral covalent radii, both phosphorus and boron radii are smaller than that of silicon (12). Also, the maximum solid-solubility of these two elements in silicon (13) is relatively high. Therefore, the amount of maximum stress introduced by them can easily exceed the elastic limit of silicon (14). Heavy homogeneous doping of phosphorus and boron in Si is, however, not expected to introduce dislocations. An impurity gradient with the concentration in the surface exceeding a critical limit is necessary for the generation of misfit dislocations. There are two well-known basic theories on diffusion induced misfit dislocations, one by Prussin (3) and the other one by Queisser (4). Modifications of these theories also exist (5-11) but have no substantial advantage over them. Prussin's theory shows that the total number of dislocations generated via diffusion is directly proportional to the surface concentration, C_o. This concentration has to be in excess of the critical concentration, C_g, for which the surface stress exceeds the elastic limit of silicon. Queisser, on the other hand, considers the total integrated doping Q as a criterion for dislocation generation. In order to avoid dislocation generation in these diffused layers, one generally has to diffuse these impurities (B and P) into the silicon in such a way that the total number of solute atoms per unit surface area of the diffused layer, Q, is below a certain critical value (4). This can be achieved by either diffusing these impurities at concentrations well below their solid solubility limits, *i.e.*, in the case of where the surface concentration of the boron- or phosphorus-diffused layer is below 3×10^{19} cm^{-3} or 5×10^{20} cm^{-3}, respectively, with a relatively large diffusion length (4, 8); or alternatively, by diffusing these impurities to the limit of solid solubility, but with a small diffusion length (15). This is so be-

* Electrochemical Society Active Member.

cause Q[1] is proportional to the product of Co and $(Dt)^{1/2}$, where Co is the surface concentration of the diffused impurity in silicon and $(Dt)^{1/2}$ is the diffusion length.

In this article, a method to avoid dislocation generation in boron or phosphorus-diffused layers is presented. This method—strain compensation—considerably reduces dislocation generation in either boron- or phosphorus-diffused layers, even though these surface concentrations exceed the limits mentioned above.

Experimental procedure.—Silicon wafers of <111> orientation were cut from Czochralski-grown boron or phosphorus-doped single crystals. The net impurity concentration of these crystals was on the order of 10^{16} cm^{-3}. Wafers were lapped and chemically polished to remove surface damage. (The dislocation etch-pit count on one of the wafers was taken and was found to be less than 500/cm^2.) The silicon wafers were annealed at 1000°C for about an hour in an open tube through which dry nitrogen flowed. This treatment was used only as a precaution to eliminate any remnant strains in the surfaces of the wafer. One of the wafers was again tested for etch-pit count and was found to show no increment in dislocation content, thereby indicating that the chemical polishing did actually remove almost all of the surface strains. Diffusions were carried out in the evacuated capsules (16) (<10^{-6} mm Hg) at 1200°C for 60, 120, and 180 min. For the single diffusion of phosphorus, boron, or tin, certain amounts of crushed powders obtained from the doped silicon crystal of that particular impurity with known concentrations were included in the capsule as the source of diffusion. For the simultaneous diffusion of tin and boron, or tin and phosphorus, equal amounts of crushed powders obtained from these two doped silicon crystals (such as tin-doped and boron-doped, or tin-doped and phosphorus-doped) of known concentrations were included in the capsule as the sources of diffusions. For the phosphorus-, boron-, or tin-doped silicon source, concentrations of 1.7 x 10^{21} cm^{-3}, 1.7 x 10^{20} cm^{-3}, and 8 x 10^{19} cm^{-3}, respectively, were employed.

Chemical staining was used on a bevelled sample to determine its diffusion depth, and a four-point probe was used to measure its sheet resistivity. The surface concentration of the boron or phosphorus-diffused sample was then determined according to Irvin (17). Radiotracer technique was used to determine the tin's profile in a tin-and-boron- or in a tin-and-phosphorus-diffused wafer.[2]

Transmission electron microscopy examination was used to study the dislocations induced in the phosphorus- or boron-diffused layers; it was also used to study or confirm the absence of dislocations in the phosphorus-tin-, or boron-tin-diffused layers. X-ray diffraction technique was used to study the changes of lattice parameter of silicon due to boron, phosphorus, or tin impurities. Details of these two techniques have been described elsewhere (8, 18).

Results and Discussion

Table I summarizes the diffusion data. In the case of single diffusion, the wafers in the capsule achieve the same concentration as the source powders at the surface after equilibrium conditions are established at the diffusion temperature. However, in the case of simultaneous diffusion, it was found that the surface concentration of those phosphorus- or boron-diffused wafers are almost one-half the values of those singularly diffused P or B wafers. They are 8.0 x 10^{20} cm^{-3} and 6.5 ~ 7.5 x 10^{19} cm^{-3}, respectively, instead of 1.7 x 10^{21} cm^{-3} and 1.7 x 10^{20} cm^{-3}. This result can be explained by the flux continuity in the mass transport phenomenon. When the tin-doped and the boron-doped silicon source powders are simultaneously included in the capsule, the tin-doped source actually acts as a sink for the boron-doped source, and *vice versa*. (These sample wafers, although they act as a sink for both of the sources, actually constitute a negligible fraction of surface area when compared to the surface area of the silicon powders.)

If one assumes that (*i*) that the vacuum space offered very little resistance to mass transport, (*ii*) the rate of evaporation of impurity is much higher than the rate of diffusion of that impurity in the solid, and (*iii*) the diffusivity of that impurity in the source and in the sink are the same and are constant, then the impurity profiles in the source and in the sink can

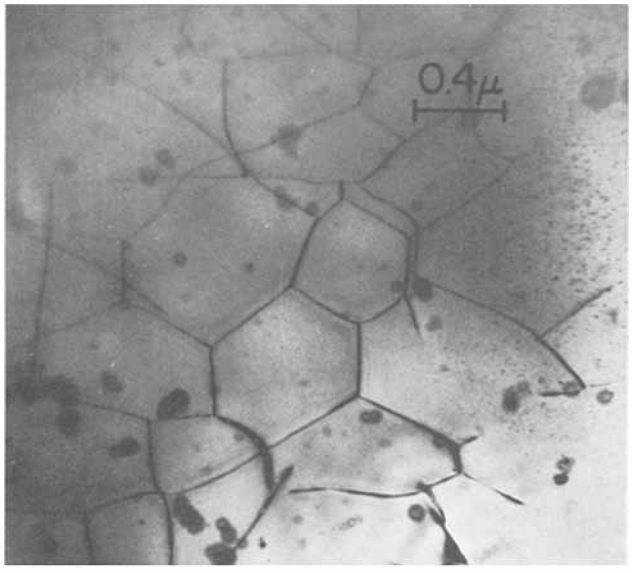

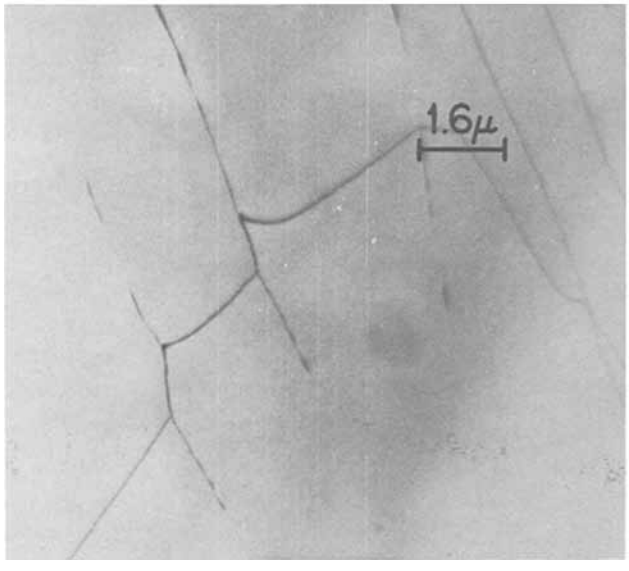

Fig. 4. Dislocations generated by (a) (top) P and (b) (bottom) B alone in the diffused layers having surface concentrations of 8.0 x 10^{20} and 6.5 ~ 7.5 x 10^{19} cm^{-3}, respectively.

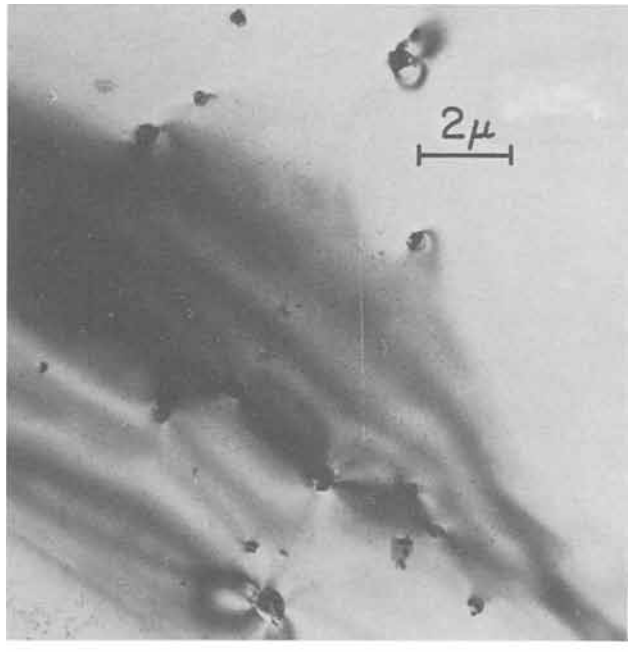
tration of the wafer is given by

$$C_0 = C_{II}(0,t) = C_{I_i}\frac{A_I}{A_I + A_{II}} \qquad [8]$$

Since both powdered sources are of the same particle size and have equal amounts in the capsule, they therefore have the same surface area. Consequently, the surface concentration of the wafer, according to Eq. [8], should be one-half of the value of the initial concentration of the source.

Because tin is a neutral impurity in silicon, a radiotracer technique was used to determine its profile. Figures 1a and 1b are the tin's profile in a tin-boron- or in a tin-phosphorus-diffused wafer. The surface concentration of tin in both of these samples (~5 x 10^{19} cm^{-3}) is only about one-half of the value of tin diffused alone into silicon (8 x 10^{19} cm^{-3}), as it should be according to Eq. [8]. This, in turn, further substantiates the surface concentration values of boron or phosphorus, determined by sheet resistivity and junction depth measurements, in the presence of tin, as given in Table I.

Examination by x-ray diffraction of bulk-doped silicon with impurities having larger (Sn) or smaller (P and B) atom sizes than that of the silicon showed distinct measurement differences in the lattice parameters (Fig. 2). The important result of this x-ray examination is that the impurity having the larger atomic size also had the larger lattice parameter, *i.e.*, lattice expansion of silicon, whereas those impurities having the smaller atomic size also had the smaller lattice parameter, *i.e.*, lattice contraction of silicon. Also, their respective lattice differences increase with increasing impurity concentrations. However, bulk-doped crystals with the highest possible concentration of either P, B, or Sn did not produce dislocations. This is understandable since only impurity gradients cause dislocations. Dislocations are produced only in the diffused wafers when either one of these impurities exceeds a certain concentration level at the surface. For P, B, and Sn, this critical level is 5 x 10^{20} cm^{-3}, 3 x 10^{19} cm^{-3}, (ref. 7, 8) and 10^{19} cm^{-3}, respectively. The cross point in Fig. 2 indicates such a lattice parameter measurement in the surface layer of the phos-



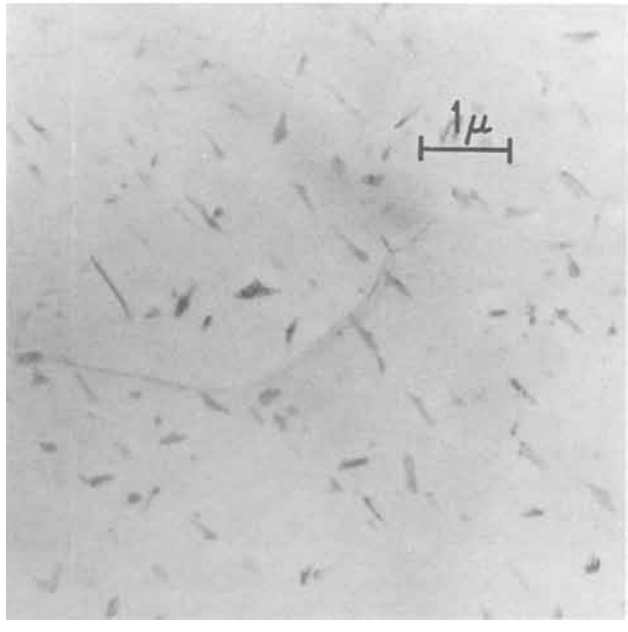


Fig. 5. No dislocations in (a) (top) P+Sn simultaneously diffused layer having surface concentrations of 8.0 x 10^{20} cm^{-3} for phosphorus and of 5.0 x 10^{19} cm^{-3} for tin; (b) (bottom) B+Sn simultaneously diffused layer having surface concentrations of 7.5 x 10^{19} cm^{-3} for boron and of 5.0 x 10^{19} cm^{-3} for tin.

phorus-diffused wafer. It shows a return of the lattice parameter in the diffused surface to a value corresponding to the lattice parameter of silicon with lower concentrations of phosphorus as dopant (18), strong evidence that the strained lattice tends to relax when the dislocations are produced.

Figure 3 shows an electron micrograph of the dislocations produced by the P, B, and Sn alone in the diffused layers having surface concentrations of 1.7 x 10^{21} cm^{-3}, 1.7 x 10^{20} cm^{-3}, and 8 x 10^{19} cm^{-3}, respectively; the dislocation densities for those samples are in the order of 10^9, 10^8, 10^7 cm^{-2}, respectively. If the surface concentrations of phosphorus or boron diffused wafers have reduced to 8.0 x 10^{20} cm^{-3} and 6.5 ~ 7.5 x 10^{19} cm^{-3} (from 1.7 x 10^{21} cm^{-3} and 1.7 x 10^{20} cm^{-3}), respectively, the dislocation densities for those samples are also reduced to about 10^8 and 5 x 10^6 cm^{-2} (from 10^9 and 10^8 cm^{-2}), respectively, as evidenced in Fig. 4a and 4b, by the electron micrographs.

However, when those simultaneously diffused P-Sn or B-Sn wafers were examined by transmission electron microscopy (even though they have the same surface concentrations as those singly diffused wafers, namely, 8 x 10^{20} cm^{-3} and 6.5 ~ 7.5 x 10^{19} cm^{-3}) they clearly show the lack of dislocations. Figures 5a and 5b are the electron micrographs of those simultaneously diffused wafers. From this result one can conclude that the stresses ordinarily caused by the phosphorus or boron atoms in silicon have been compensated by the stress caused by the tin atoms to the extent that no relief of the stresses in the lattice is necessary.

Furthermore, preliminary results indicate that Ge can also be used for strain compensation in silicon with boron or phosphorus, *i.e.*, simultaneously diffused P-Ge or B-Ge in silicon produces no dislocations in the diffused layers.

Conclusion

A method to avoid dislocation generation in boron- or phosphorus-diffused layers is presented. This method, strain compensation, considerably reduces dislocation generation in either boron- or phosphorus-diffused layers, even though their surface concentrations are exceeded by the critical values (4, 8). The strain compensation is brought about through simultaneous introduction into silicon of impurities such as tin and boron, or tin and phosphorus. Since the TCR (tetrahedral covalent radius) of tin is larger than that of Si, whereas the TCR of boron and phosphorus is smaller than that of Si, it is felt that the silicon lattice, which would be expanded by tin atoms, counteracts the contraction ordinarily due to phosphorus or boron is either eliminated or considerably reduced below the elastic limit.

Acknowledgments

The authors wish to thank Dr. S. M. Hu for his critical comment on the manuscript, and Dr. R. H. Kastl for obtaining the profiles of Sn^{113} through the radiotracer technique.

The Preparation and Properties of Amorphous Silicon

R. C. Chittick, J. H. Alexander, and H. F. Sterling

Standard Telecommunication Laboratories Limited, Harlow, Essex, England

ABSTRACT

A radio-frequency glow discharge is used to deposit films of amorphous silicon from silane gas on to substrates at 25°-650°C. These films have resistivities at 21°C of up to 10^{14} ohm-cm and have large temperature coefficients of resistivity. A photoconductive effect is observed which reaches a maximum for films deposited at 300°C, and a sample is compared with a CdS cell. The effects of heat-treatment, ageing, and doping on the properties of amorphous silicon are reported. The variation of properties with deposition temperature is related to the structural changes with temperature that have been observed for this material.

Various processes are available for the deposition of silicon. The element may be transported by vacuum evaporation, for example, or be deposited from the vapor phase by the chemical reduction of a suitable compound. When the substrate is heated, crystalline deposits are obtained, and under certain conditions single crystal or epitaxial growth takes place. Silicon in the crystalline form is well characterized, and its electrical behavior is understood.

The vapor depositions of silicon onto unheated substrates are microcrystalline or "amorphous" in form and exhibit electrical properties which significantly depart from those of the crystalline state. Since the microcrystallinity or degree of amorphousness is un-

defined and very process dependent, the same consistency of standard electrical properties in comparison with single crystal silicon is not obtained.

Silane gas is a useful and important source material for the preparation of high-purity elemental silicon in crystalline form. By pyrolysis at 1000°C it liberates silicon and can be used for the bulk preparation of semiconductor grade material. In order to suppress gas phase decomposition of silane, the pyrolysis is usually carried out at reduced pressure.

If silane gas at low pressure is subjected to a high-frequency electrodeless glow discharge, the deposition of amorphous or vitreous silicon takes place (1). Although higher electron temperatures exist in the gas it is molecularly near room temperature, so that deposition on to virtually cold substrates results in very short range ordering in the structure which is not necessarily of tetrahedral form. In appearance the material resembles the crystalline form but breaks with a conchoidal fracture. Electrically it has a room temperature resistivity of up to 10^{14} ohm-cm with a large temperature coefficient. Specimens deposited under certain conditions exhibit marked photoconductive effects.

The object of this paper is to report details of the apparatus and method used and to give results of some electrical measurements which have been made.

Experimental Technique

The apparatus used is comparatively simple (Fig. 1). A silica tube 3 cm diameter and 40 cm long acts as the reaction chamber and is fed with pure silane gas through a flow meter and needle valve. (The silane used in these experiments was obtained from Matheson and was nominally 50 ohm-cm p-type as crystalline silicon.)

The gas pressure is reduced by means of a vacuum pump, fitted with a throttle valve, so that the dynamic pressure can be set in the range 0.1-1 Torr and measured on a McLeod gauge. A radio-frequency coil surrounds this reaction tube and stimulation is provided by a 500w oscillator operating at 1 MHz. Deposition of amorphous silicon takes place on the walls of the reaction tube and in the glow discharge area generally. Substrates placed in this area are coated at a rate of a few microns per hour. Provision is also made for substrates to be heated during deposition or subsequently, so that structural changes, associated with ordering and the onset of crystallization and their electrical effects, can be studied. Since the heating of a susceptor and the provision of a glow initiating field are derived from the same oscillatory source, modifications have been made to the tuned circuit so that these effects can be varied independently.

During the first stages of deposition the film is yellow changing to red by transmitted light and shows interference colors by reflection. As growth proceeds toward 1μ thickness, the film becomes opaque and black when deposited on polished surfaces and looks matt gray on rough surfaces. Experimental work has shown that deposition rates may be speeded up considerably, but the effect of these increased rates on the properties of the material has not yet been assessed.

Special care was taken with apparatus design and with the experimental techniques to ensure that oxygen and other atmospheric gases were excluded from the reaction chamber during deposition. A leak rate of less than 1 Torr per liter volume over 24 hr is always maintained.

Samples for measurement have been prepared mainly on glass substrates (Corning glass 7059 7/16x 1/2 in.) with two evaporated aluminum electrodes in either coplanar or parallel planar form. Temperature measurement was carried out optically using an infrared pyrometer (Thermodot TD6B). Electrical measurements were made with a Keithley electrometer (610B) and film thicknesses with a Talystep.

Electrical Resistivity

Measurements carried out on coplanar samples gave the following results. A number of samples were grown at 21°C with thicknesses from 0.2 to 4 μm and an electrode spacing of 1 mm. The resistivity was inversely proportional to the thickness, that is, normal conduction in a uniform material (Fig. 2). Assuming $I = A \exp(-\phi/kT)$, with A a constant independent of temperature, a discrete activation energy (ϕ) of 0.8-0.83 ev was obtained for these samples. It was found also that the resistance was directly proportional to the electrode separation. A typical resistivity value for amorphous silicon deposited at room temperature by this technique is 1.5 x 10^{10} ohm-cm at a field of 100 v/cm.

On parallel-planar samples (Al-Si-Al sandwich), measurements indicate a higher value for the electrical resistivity of the material. For example, at a field of 100 v/cm a value of 2.5 x 10^{14} ohm-cm was obtained. Similar high resistivity values have been obtained for evaporated silicon films (2).

Variation of Resistivity with Deposition Temperature

The effect of deposition temperature on the resistivity of amorphous silicon is plotted in Fig. 3, curve a. Measurements were carried out at 21°C, and from the curve it will be seen that the resistivity decreases with increasing deposition temperature, the effect being most marked between 250° and 500°C. At temperatures above 500°C, the resistivity stabilizes near 4 x 10^4 ohm-cm. No depositions were carried out above 650°C on glass.

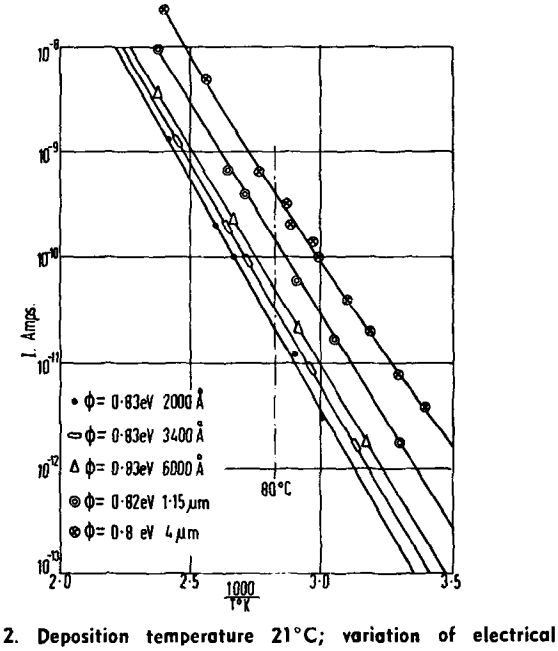

Fig. 2. Deposition temperature 21°C; variation of electrical conduction with temperature for various thicknesses.

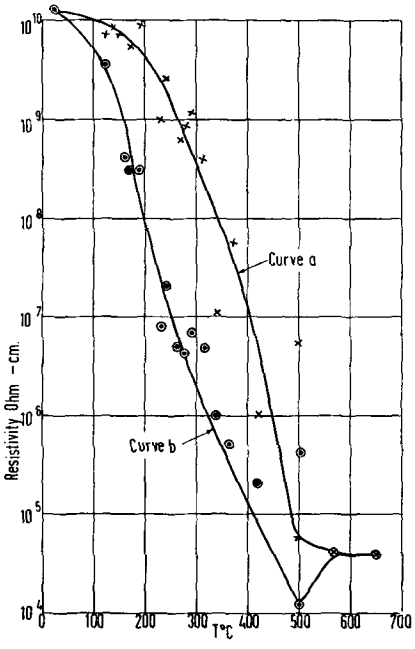

Fig. 3. Resistivity measured as a function of deposition temperature at 21°C. Curve a, dark; curve b, light (20 ft candles).

Variation of Activation Energy with Deposition Temperature

It is interesting to note that well-defined activation energies have been observed over fairly large temperature ranges. A sample deposited at 21°C has an activation energy of 0.8-0.85 ev over the range 0°-150°C. For 160°C deposited samples the activation energy is 0.65-0.7 ev for the temperature range 21°-80°C and for 80° to 150°C is 0.8-0.85 ev. The changeover appears to increase with increasing deposition temperature until ϕ = 0.65-0.7 ev over the whole range 21°-150°C for deposition temperatures of 270°-300°C. Further increases in deposition temperature give lower activation energies. At the low resistivity plateau (4 x 10^4 ohm-cm, Fig. 4) the activation energy = 0.21 ev. It can be seen from the curves that the resistivity changes from 1.5 x 10^{10} ohm-cm at 21°C to 1 x 10^6 at 140°C for material deposited at room temperature.

Optical Properties

A photoconductive effect has been observed in samples of amorphous silicon and shows a dependence on deposition temperature (Fig. 3, curve b). The effect is absent in room temperature depositions, but reaches a maximum for near 300°C depositions and decreases with further temperature increase. A decrease in resistivity of about 3 orders of magnitude is obtained from dark to normal laboratory illumination (100 ft candles). Under these conditions the frequency response of cells made from this material appears to be superior to those made from cadmium sulfide. A commercial cadmium sulfide cell was compared with a glow-discharge deposited silicon cell. Both were exposed to chopped light from a tungsten lamp and their responses, adjusted to have the same value at 5 Hz, were displayed on an oscilloscope. At a frequency of 2000 Hz the silicon cell output dropped by 50% compared with a fall in output of 93% for the particular CdS cell used. This comparison is shown in Fig. 5. The dependency of the photocurrent on light intensity is sublinear $I = (Int)^n$ where, in this case $0.5 \leq n \leq 0.85$. In these measurements a tungsten filament light source was used in conjunction with neutral density filters.

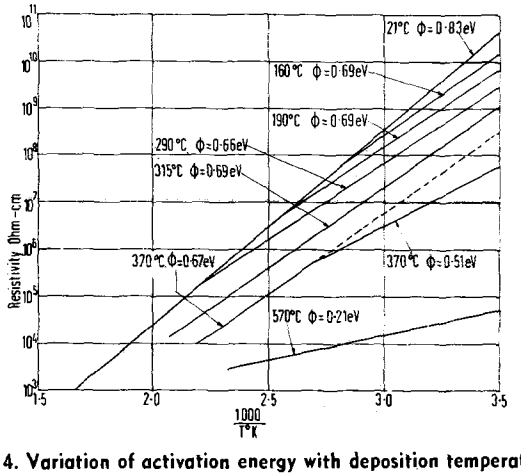

Fig. 4. Variation of activation energy with deposition temperature

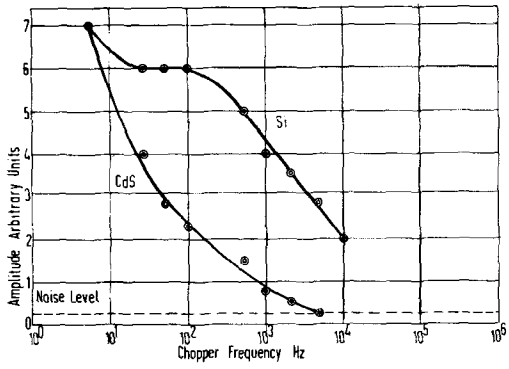

Fig. 5. Relative time responses of photoconductivity in amorphous silicon and cadmium sulfide.

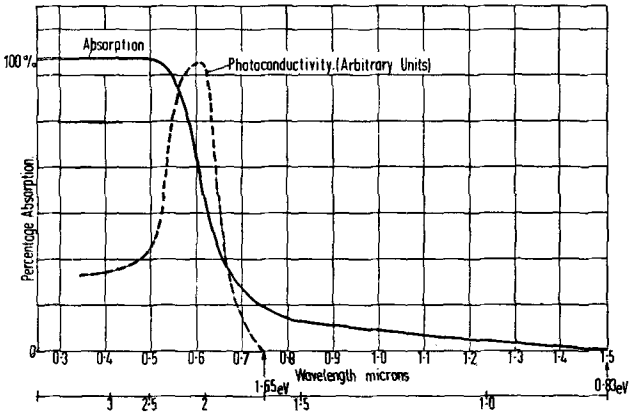

Fig. 6. Optical absorption and photoconductivity for amorphous silicon deposited at 300°. Film thickness, 5000A; interference fringes on the absorption spectrum which occur from 0.7μ to higher wavelengths have been neglected.

A smeared absorption edge between 1.5 μm and 0.5 μm (Fig. 6) is obtained for amorphous silicon films. This is consistent with the concept of localized states at the band edges. The onset of the photoconductivity, however, is at 0.75 μm and reaches a maximum at about 0.6 μm. Carriers are, therefore, not being produced by photon energies below 1.65 ev. Possibly transitions in the energy range 0.8-1.65 ev occur only to the localized states at the band edges.

If this is the case, a voltage dependence of the threshold energy would be expected at high fields since there is a possibility of Poole-Frenkel emission or tunneling from the localized states.

This has yet to be investigated as only low field measurements have been made. Further experimental work is being carried out on absorption and spectral response of this material.

Heat-treatment

Heat-treating films to temperatures above those of deposition changes their electrical properties. For example, when heated, room temperature films become

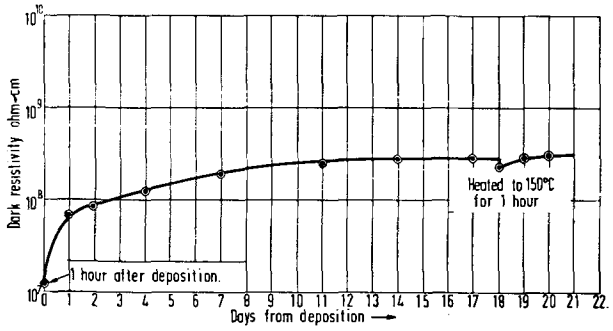

Fig. 7. Ageing in air of amorphous silicon grown at 300°C

photoconducting and, at the same time there is a drop in dark resistivity. A sample grown at room temperature and heated to 400°C for 2 hr has properties which approach those of a sample grown at this temperature.

Samples grown at temperatures between 21° and 150°C show no change in activation energy with heat treatment at 150°C under an applied field of 100 v/cm.

Ageing

Films of amorphous silicon grown under certain conditions exhibit ageing effects in resistivity as has been reported by other workers for germanium (3). The effect of ageing in air on glow discharge deposited material appears to be dependent on deposition temperature. Films grown from 21° to 200°C show no significant ageing effect either short term (1 hr) or long term (6 months). At deposition temperatures of 500°C and above, ageing effects are not noticeable. However in the intermediate range of temperatures 200°-500°C an ageing effect is apparent and has a broad maximum around 300°C.

Figure 7 shows the ageing curve for a sample grown at 300°C. The first point corresponds to the dark resistivity measured 1 hr after deposition. As can be seen, the ageing rate is greatest just after deposition and falls off in time until the resistivity approaches stability between 2 and 3 weeks after deposition. A slight decrease in resistivity occurs when the material is heat treated for 1 hr at 150°C. These effects of ageing and their interrelation with heat-treatment need further study.

Parallel Planar Structures

The current-voltage characteristics for these structures reveal an ohmic region at low field intensities of less than 10^4 v/cm. Under fields greater than this until breakdown occurs at 10^5 v/cm there is a relationship $I = A \exp \alpha V^{1/2}$ (see Fig. 8) where α is inversely proportional to the absolute temperature and the square root of film thickness. Hence we have the expression of the form $I \propto \exp. (\epsilon\beta E^{1/2}/kT)$ with β the Schottky or Poole-Frenkel coefficient, which suggests Schottky or Poole-Frenkel emission. However there is no quantitative agreement between theory and practical results.

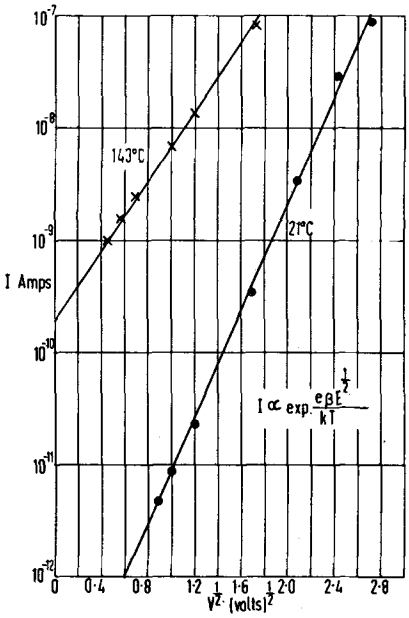

Fig. 8. Current/voltage characteristics for Al-Si-Al sandwich structure at 21° and 143°C.

Effects of Doping

The electrical effects of the addition of significant impurities in crystalline silicon are well known and understood. Experiments were carried out to assess the effect of adding phosphorus to amorphous silicon during the deposition. Phosphine was chosen for this purpose, diluted with hydrogen, and added to the silane prior to its decomposition. Quantities of 40-200 ppm of phosphine in silane did not give the dramatic changes in resistivity which would normally be associated with these doping levels in single crystal silicon. The resistivity was reduced by a factor of 20 to 100 on samples deposited at room temperature depending on the doping level. However these samples were unstable, but stabilized after heat treatment at 150°C in air. Results were as follows:

ppm phosphine in silane	Activation energy, ev	Resistivity 21°C ohm-cm
40	0.83	10^{10}
100	0.77	4×10^9
200	0.75	2×10^9

Films deposited above 200°C still show relatively high resistivities at the doping levels previously mentioned. However, instability made accurate measurements difficult, so only approximate figures are possible. An undoped sample deposited at 280°C has a typical resistivity near 6×10^8 ohm-cm. A sample deposited from silane doped with 200 ppm of phosphine at this temperature gives a resistivity value of the order of 10^6 ohm-cm.

The photoconductive effect is reduced as doping increases. Experiments were also carried out at extremely high doping levels, *i.e.*, 0.4 and 4.0% of phosphine in silane. Room temperature deposition at these levels showed resistivities of 1×10^6 to 1×10^4 ohm-cm.

Although some discrete activation energies were found they tended to vary with time. Room temperature samples were more stable than others grown at higher temperatures. Figure 9 refers to these measurements.

In order to assess the amount of phosphorus incorporated in amorphous silicon for a given gas percentage the material was investigated by electron-probe analysis. A gas mixture containing 50% phosphine in silane showed an actual phosphorus in silicon content of near 30%. A second mixture containing 5% phosphine in silane gave a figure of approximately 1% phosphorus in silicon.

Discussion

Many of the properties of amorphous silicon are dependent on the temperature of deposition, for example, there is a gradual drop of resistivity with temperature and an increase in photoconductivity up to a maximum. This suggests that structural differences exist when material is deposited at different temperatures, and it seems apparent that some transition of structure occurs as evidenced by the photoeffects. In other words, these changes are not seen as a straight transition from amorphous to diamond structure with temperature, but indicate that some intermediate structure is involved.

It has been shown by Coleman and Thomas (4) for amorphous silicon and by Grigorovici and Manaila (5) for amorphous germanium, that the structure contains fivefold planar rings of atoms as well as the more normal sixfold puckered rings of the crystalline material.

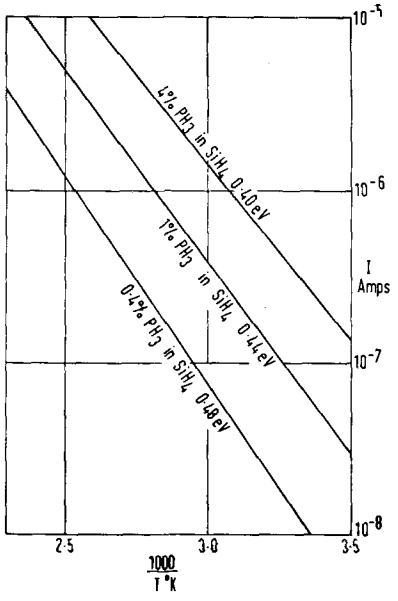

Fig. 9. Inverse temperature-current characteristics for phosphorous doped amorphous silicon; deposition temperature 21°C.

This fivefold structure is stable up to temperatures in excess of 500°C. Films grown at up to 500°C have been shown to be amorphous when deposited on cleaved single crystal magnesium oxide, however, the specimens used for electrical evaluation were deposited on glass which contain a mixture of potential impurities, some of which are known to have an effect on the crystallization rate of these amorphous films.

Acknowledgment

The authors wish to thank their colleagues at STL for helpful discussions and with the measurements. Thanks are also due to Mrs. S. Y. Hughes for work concerned with sample preparation and to the management of STL for permission to publish this work.

Growth Rate and Surface Morphology Studies in the $GeCl_4$-H_2 System

V. J. Silvestri*

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York

ABSTRACT

Growth rate studies of the $GeCl_4$-H_2 reaction are reported for an epitaxial system. The experimentally observed deposition rates are described in terms of a "quasi-equilibrium" model in which only a limited portion of the gas achieves equilibrium composition. Smooth surfaces are obtained under conditions where epitaxial growth appears to be mass transport controlled. For any given Ge concentration, the observed dependence of growth rate on temperature and substrate orientation indicates that a surface limitation controls growth at lower growth temperatures. When this condition prevails, structured deposits result. Structureless surfaces are favored by operating at high temperatures and low Ge concentrations.

Since the initial work by Theurer *et al.* (1), the reduction of $GeCl_4$ with hydrogen for epitaxial deposition of germanium has been used extensively (1-11). Cave and Czorny (2) and Goorissen and Bruijning (10) have described the epitaxial process as it applies to the preparation of semiconductor devices. Hornberger (3) studied the low-temperature growth aspects of the reduction system. Miller and Grieco (11) studied the etch reactions involving Ge-HCl and Ge-$GeCl_4$. These authors (4-9) investigated growth conditions and surface morphology for different crystallographic orientations, and Grossman (12) has described a kinetic theory for the origin of auto-doping for the epitaxial process.

With increasing complexity of device structures, requirements on epitaxial smoothness and doping control have become more critical, and further understanding of the factors affecting surface character and doping appeared warranted. The present study was undertaken partially to meet these needs.

Experimental results obtained for the analogous $SiCl_4$-H_2 reaction indicate that the silicon deposition systems in use are mass transport limited (13). Reisman and Berkenblit (14) have defined two distinct types of mass transport limitations which are considered below. In the first, the over-all reaction or deposition rate depends simply on the rate of introduction of gaseous reactants into the reaction chamber. In such a case, complete mixing occurs, chemical equilibrium is essentially achieved, and we have an "input-limited" system. The second type of mass transport limitation, called "lateral gas flow limited," results when the chemical deposition reaction is so rapid compared to the rate of transport of reactants through the gas phase by all processes (*i.e.*, diffusion, convection, turbulent flow, *etc.*) that large gradients of reactants and products exist throughout the chamber. In this latter case,

* Electrochemical Society Active Member.

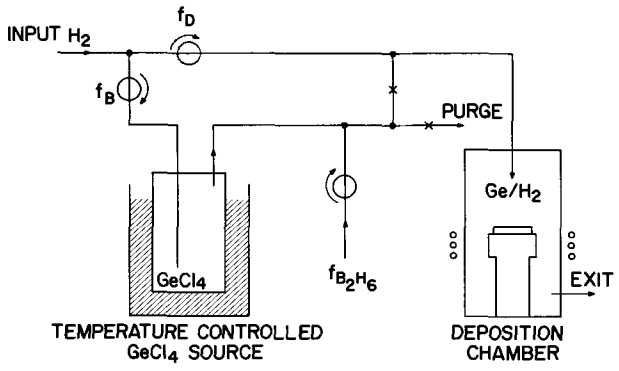

Fig. 1. Pertinent features of the $GeCl_4$-H_2 system

typical of many epitaxial growth systems, portions of the input gas flow by the heated substrates unreacted, and the portion which is unreacted is very dependent on system geometry and flow conditions. The "quasi-equilibrium" model as proposed by Sedgwick (15) for the $SiCl_4$ reduction treats in a simple way systems which are subject to this second mass transport or a "lateral gas flow limited" case. Using Lever's (16) thermodynamic data, Sedgwick was able to explain the main features of reported Si growth data by assuming that a varying but limited portion of the input gas reacted, depending on the exact conditions employed.

An initial goal of this work was the investigation of growth phenomena, in order to determine experimentally growth limitations in the analogous Ge system. Subsequent studies were aimed at relating these growth studies to the surface morphology of the films.

Experimental

The essential features of the experimental system employed in the investigation are shown schematically in Fig. 1. The temperature of the high-purity $GeCl_4$ source could be varied from —40° to 25°C. In addition, the system contained a hydrogen dilution line which bypassed the $GeCl_4$ bubbler. It was therefore possible to vary the Ge/H_2 ratio[1] flowing into the reaction chamber by either changing the vapor pressure at the $GeCl_4$ source, while keeping the total flow constant, or by adding pure hydrogen through the dilution line (f_D) at a fixed $GeCl_4$ source temperature. This latter method maintains a constant germanium flux through the deposition chamber at varying gas velocity. Linear gas stream velocity changes could also be made at a constant Ge concentration by adjusting both the $GeCl_4$ vapor pressure and the hydrogen flow.[2] By using these experimental approaches, one can examine the effects of flux, concentration, and linear gas stream velocity on the course of the $GeCl_4$-H_2 reaction.

Chemical analysis of the germanium content of effluent gas provided assurance that for the flow rates (f_B) employed through the $GeCl_4$ source, saturation of the vapor was achieved for all experimental conditions to be described.

All substrates had been polished to mirror smoothness with sodium hypochlorite as described by Reisman and Rohr (18). Standard cleaning procedure prior to deposition consisted of a 2-min etch in a 3:1 solution of H_2O; NaOCl (5%). After rinsing in distilled water, the substrates were dried in a high-pressure nitrogen stream. They were then heated in the reactor at $T >$ 700°C for 15 min in order to complete the cleaning operations.

Depositions took place on Ge substrates placed perpendicular to the gas stream. A 1-in.-diameter germanium pedestal acted as the susceptor in the rf heated system, and comprised 25% of the internal cross-sectional area of the reaction tube. Deposition of germanium occurred only on the heated substrate and pedestal sides, since the reactor walls were water cooled to prevent any reduction of the halide. Substrate temperature was measured using an optical pyrometer, and was controlled by means of a thermocouple embedded in a well in close proximity to the Ge wafer. The depositions were carried out for the most part on <110> oriented substrates. In order to determine if growth rate was orientation dependent, <111>, <211>, <100> oriented surfaces were employed for a few specific experiments. Thickness measurements were obtained on the epitaxial layers using infrared interference (17) or angle lapping techniques. For doping experiments, diborane mixed in high-purity hydrogen was used. Carrier concentrations were determined from Hall effect, differential junction capacitance, and 4-point probe techniques.

Total deposition experiments were conducted in order to compare theoretical[3] with experimental deposition rates. In such cases, the material weighed included the Ge deposited on the substrate and the heated area of the germanium pedestal.

Results

Growth rate data.—Growth rate was found to be independent of deposition time for all experimental conditions employed. Growth rate was evaluated as a function of substrate temperature, Ge/H_2 ratio variation, and linear gas stream velocity. In Fig. 2, the Ge/H_2 ratio or Ge input flux variations were achieved by changing the vapor pressure at the $GeCl_4$ source while keeping the total flow or linear gas stream velocity constant. The data shown in Fig. 2 indicate a strong growth rate dependence with temperature in the lower temperature range (region *A*) at each Ge/H_2 input ratio. At higher temperatures (region *B*), there is little or no growth rate dependence with temperature.

In Fig. 3, growth rate is shown as a function of Ge/H_2 ratio at two substrate temperatures, 700° and 780°C. It is to be noted that the growth rate at 700°C shows a maximum as the Ge/H_2 ratio is increased, while flow rate is held constant (at the same value as that used to take the data shown in Fig. 2).

An alternative way of changing the Ge/H_2 ratio which at the same time maintains a constant Ge flux

[3] Appendix.

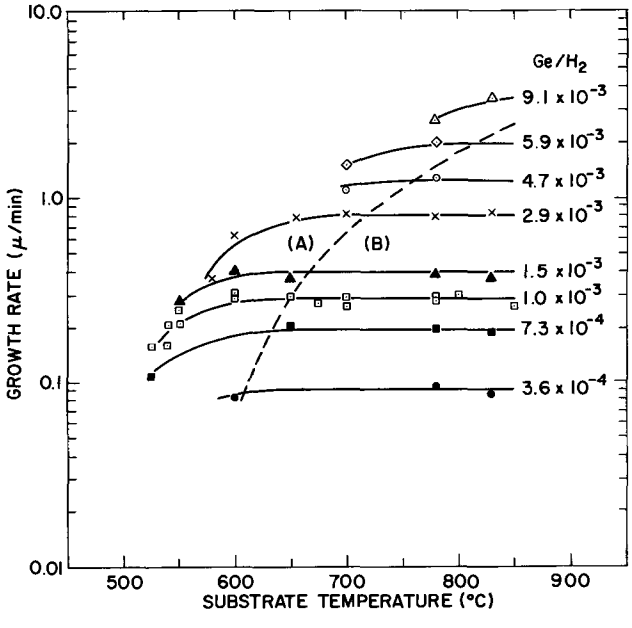

Fig. 2. Growth rate as a function of varying substrate temperature for different Ge/H_2 inputs at a constant linear gas stream velocity of 175 cm/min. The dashed curve is taken from Fig. 9.

[1] The Ge/H_2 ratio is defined as the ratio of moles of $GeCl_4$/min, divided by the moles of H_2/min flowing into the reaction chamber.

[2] The linear gas stream velocity is referred to the total flow in cc/min at room temperature divided by the entire cross-sectional area of the reaction tube. It should be noted that this is a reference point only and, since the pedestal perturbs flow, the average linear gas stream velocity is higher along the sides of the pedestal than on the top.

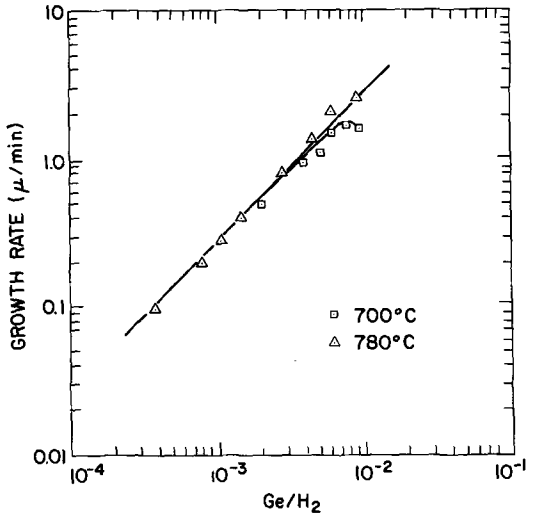

Fig. 3. Growth rate as a function of $GeCl_4$ input for a constant linear gas stream velocity of 175 cm/min.

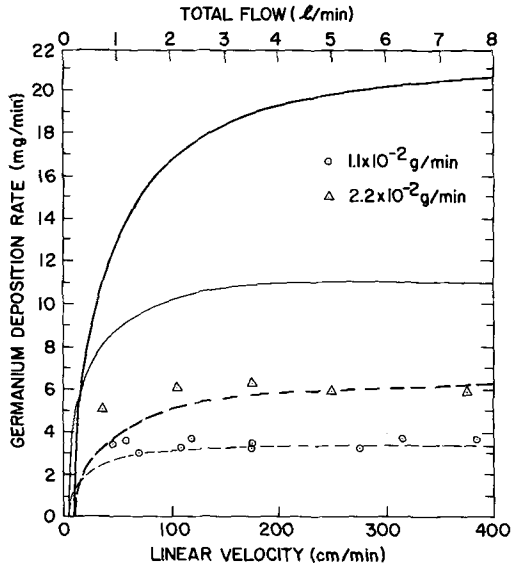

Fig. 4. Germanium deposition rate as a function of linear gas stream velocity at constant germanium tetrachloride flux values. Temperature, 780°C. ——— theoretical; – – – theoretical ÷ 3.3.

involves dilution of the $GeCl_4$ source effluent at a constant source temperature and bubbler flow. This method leads to the data points shown in Fig. 4 where each point is representative of a different linear gas stream velocity and Ge vapor phase concentration. Data are shown for two different germanium input rates. The germanium deposition rates shown as experimental points in Fig. 4 were calculated from growth rates measured on the substrate and the assumption of a uniform growth over the entire heated region of the susceptor.[4] The solid and dashed curves in Fig. 4-7 represent theoretical rates computed in two ways to be discussed in the following section. Experimental data shown in Fig. 5 and 6 are based on the weighed amount of Ge deposited on the substrate plus susceptor. Figure 5 data were obtained under conditions similar to Fig. 2 and 3 in which Ge concentration was varied at a constant linear gas stream velocity. Figure 6 gives total Ge deposition rate in mg/cm²/min under conditions of constant Ge/H_2 ratio and varying linear gas stream velocity. The constant Ge concentration was achieved by readjusting the vapor pressure at the $GeCl_4$ source

[4] In Fig. 6, both the growth rate on the substrate and the total amount of Ge deposited were assessed. Using the growth rate data on the substrate and assuming an equal and uniform thickness over the heated susceptor, the total amount of Ge deposited could be calculated on the basis of area ratio and agreed in every case to within better than 20% with the value as measured by net weight gain.

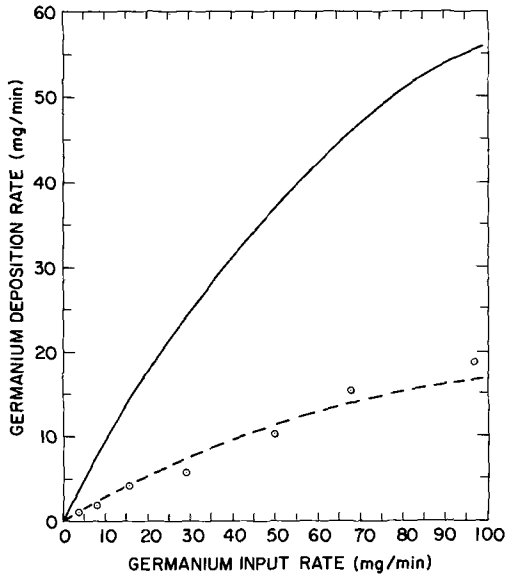

Fig. 5. Germanium deposition rate for varying germanium input rates at a linear gas stream velocity of 175 cm/min. Temperature, 780°C. ——— theoretical; – – – theoretical ÷ 3.3.

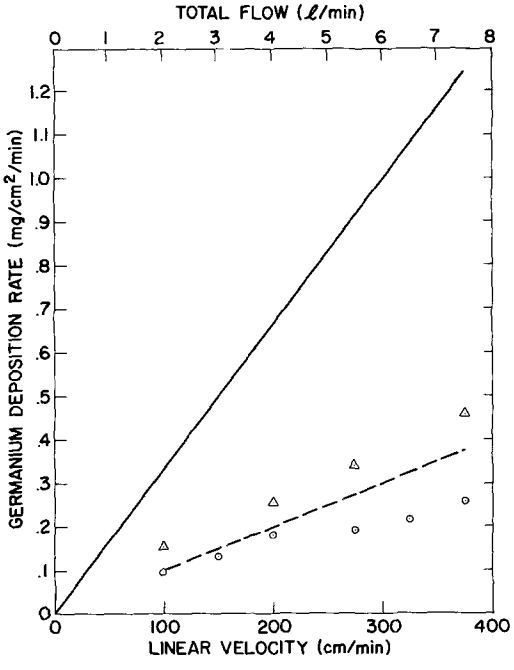

Fig. 6. Germanium deposition rate as a function of varying linear gas stream velocity at a constant Ge concentration. $Ge/H_2 = 1.1 \times 10^{-3}$. ——— theoretical; – – – theoretical ÷ 3.3; △, deposition rate on the substrate with an SiO_2 masked susceptor; ⊙, deposition rate on the substrate and the Ge susceptor.

for each linear gas stream velocity change. The data shown as circles and triangles differ in the following way. The circles represent deposition rates which are based on the total Ge deposited on both the substrate and the susceptor having a total heated area of approximately 18.5 cm². For the data points given as triangles, the Ge susceptor was masked with an SiO_2 film (upon which Ge will not nucleate). The deposition rates shown for this latter case are therefore calculated from the total amount of Ge deposited solely on substrates having areas of approximately 4.4 cm². The data in Fig. 4, 5, and 6 have been acquired since they are pertinent to the discussion of the effects of mass transport limitations on surface morphology to follow.

In order to compare the experimental deposition rates with the theoretical rates as a function of temperature, we have plotted in Fig. 7 deposition rate for

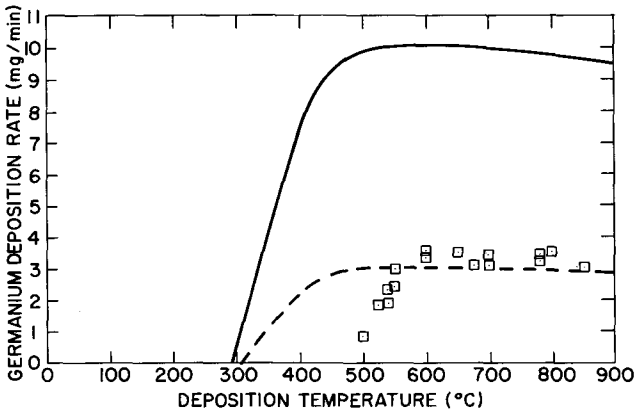

Fig. 7. Comparison of theoretical deposition rates with deposition temperature variation. $Ge/H_2 = 1.0 \times 10^{-3}$. ——— theoretical curve; – – – theoretical curve ÷ 3.3; ⊡, experimental data.

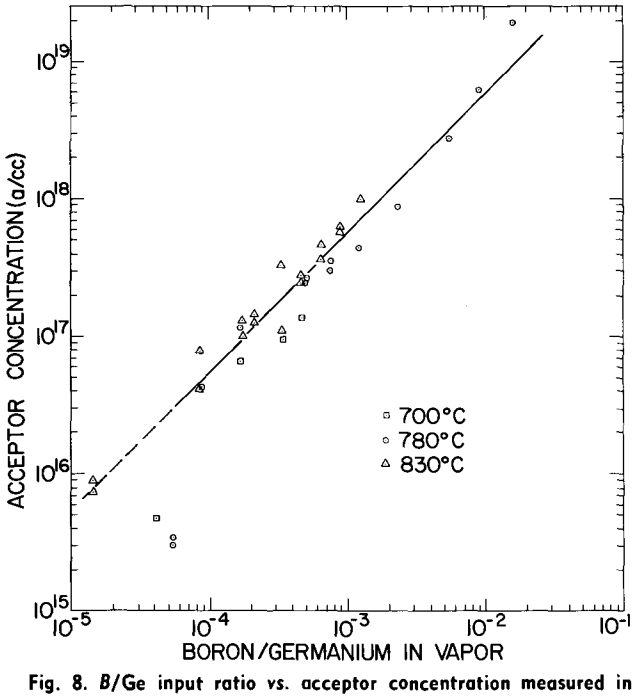

Fig. 8. B/Ge input ratio vs. acceptor concentration measured in the deposited layers for three substrate temperatures for a constant total flow of 3.5 liters/min.

a specific Ge/H_2 input value. The germanium deposition rates shown were evaluated from the growth rate data given in Fig. 2 by assuming a uniform growth rate over the entire pedestal. In Fig. 8, the input B/Ge ratios are plotted *vs.* the acceptor concentration measured electrically in the epitaxial layer.

Surface morphology.—Upon microscopic examination of surfaces grown under the conditions described for Fig. 2, it became obvious that the surface morphology of the epitaxial deposits was related to the temperature-concentration conditions used for growth of the films. To analyze this observation more thoroughly, the substrate temperature was varied at a constant Ge/H_2 ratio and *vice versa*. It was found that: (*a*) increases in substrate temperature over certain intervals for a given Ge/H_2 ratio will yield progressively smoother surfaces; (*b*) increasing the Ge/H_2 ratio for a constant substrate temperature will produce more structured surfaces; (c) changes in surface morphology were observed irrespective of substrate orientation. Epitaxial layers investigated included <211>, <111>, <110>, and <100> oriented surfaces. Figure 9 summarizes the above-described observations. The microscopic evaluations of surface morphology placed the samples in one of two categories having either smooth or structured

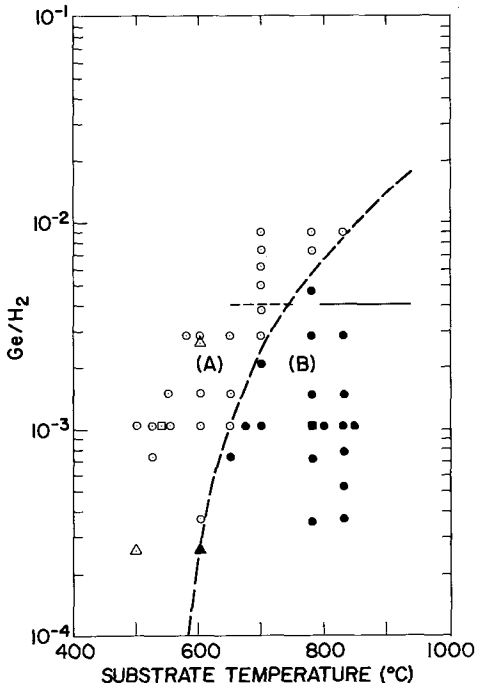

Fig. 9. Morphology diagram for the $GeCl_4$-H_2 system. The solid points indicate smooth surfaces; open points, structured surfaces. The dashed curve demarks conditions for obtaining smooth and structured surfaces. Triangles are data from Ref. (3). The horizontal dashed and solid lines at 4×10^{-3} show, respectively, the temperature intervals at which authors in Ref. (7) and (8) observed structured and smooth surfaces. The squares indicate conditions at which <111>, <110>, <211>, and <100> orientations were employed.

films. Deposits were considered "structured" which exhibited growth figures characteristic of the particular substrate orientation employed. Smooth surfaces exhibited essentially a mirror finish and were free of growth figures. The morphology diagram, Fig. 9, describes the surface morphology of the epitaxial layers obtained for various substrate temperature-Ge/H_2 input conditions employed. The solid points (region *B*) define the temperature-Ge/H_2 combinations where smooth surfaces were obtained. Open symbols designate conditions (region *A*) where structured surfaces result. The square symbols in Fig. 9 represent data for the four different substrate orientations mentioned above. For the conditions represented by the solid square in region *B*, no growth rate variation with substrate orientation was observed. In region *A* for the experimental condition represented by the open square, the following growth rate variations with substrate orientation were observed: <211>, 0.11 μ/min; <111>, 0.15 μ/min; <110>, 0.17 μ/min; <100>, 0.20 μ/min. The data shown as triangles are data derived from previously published reports in which similar morphological observations were made (3). The solid horizontal line at a Ge/H_2 value of 4.0×10^{-3} gives the temperature interval for which Sheftal *et al.* (7, 8) obtained smooth surfaces. The horizontal dashed line indicates the temperature span for which the same authors report structured surfaces.

Discussion

In Fig. 2, region *B*, both the observed independence of growth rate with temperature at a particular Ge/H_2 ratio and increase in growth rate with germanium input in Fig. 3 indicate that region *B* of Fig. 2 represents mass transport limited growth. In addition, it has been observed that for the experimental conditions in region *B*, Fig. 2, growth morphologies on the various orientations are similar (Fig. 9) and that there is no growth rate dependence found with these variations of surface orientation. In contrast, in region *A* of Fig. 2, growth

rate varies with both temperature and surface orientation.

The comparison of the theoretical deposition rates based on the total amount of Ge deposited with linear gas stream velocity, concentration, and temperature in Fig. 4-7 further supports these conclusions.

The theoretical deposition rates shown in Fig. 4-7 as solid curves are based on thermodynamic calculations. The computer calculations for the Ge-H-Cl system included the gas species $GeCl_4$, $GeCl_2$, $GeHCl_3$, HCl, and H_2, and were made in the manner reported by Lever (16) for the analogous Si-H-Cl system. For the case of a mass transport limited system which is "input limited," one would expect the theoretical deposition rate based on a thermodynamic calculation of chemical equilibrium to be identical to the observed deposition rate. In Fig. 4-7, we note that, although the shapes of the theoretical curves resemble the experimental data, the experimental rates are much lower than theory predicts. In Fig. 5 where data are given for a single linear gas stream velocity, it was found that the experimental data could best be approximated by dividing the theoretical rates by a constant factor, 3.3. This proportionality between the theoretical and experimental rates is explainable if we consider the second possible kind of mass transport limitation discussed earlier, namely, where "lateral gas flow" is rate limiting and the deposition rate is very dependent on system geometry.

In the Si-H-Cl system, Sedgwick proposed in accordance with this second mass transport case that the deposition rate D in g/min in many epitaxial systems may be represented to first order by

$$D = J \cdot \alpha\beta \qquad [1]$$

where J is the flux of Ge in g/min into the reaction tube and α the theoretical efficiency factor based on equilibrium calculations. The actual fraction of incoming gas which equilibrates with the heated Ge surface and consequently attains this theoretical efficiency is designated as β. The remaining fraction of gas $(1 - \beta)$, in this model, streams by unreacted. The magnitude of this remaining fraction is highly geometry dependent, and could comprise either a large or small portion of the total gas input.

Applying Eq. [1] with $\beta = 0.3$ to the theoretically calculated curves (solid lines), we obtain the dashed lines in Fig. 4-7. We note that, while the data of these figures are in much closer agreement to the theoretical predictions, some discrepancy exists. The assumption of a constant β factor for the system is not expected to be valid in a system with varying linear gas stream velocity, particularly under conditions of very low velocities where equilibration is more complete and at very high linear gas stream velocities when residency times of molecules in the vicinity of the susceptor become short. In Fig. 4, the higher deposition rates at the lower velocities, where there is a longer gas residence time and in general better gas mixing, actually indicate an increase in the value of β. Consistent with this, the experimental data in Fig. 6 at the higher linear gas stream velocity show an apparent decrease in β. The experimental data shown in Fig. 6 are of two types. The points represented by circles were obtained from the total Ge deposited on both the substrate and the pedestal, whereas the points shown as triangles are from the Ge deposited solely on the substrate. The intent of obtaining the experimental data involving the SiO_2 coated pedestal (triangles) was (*a*) to evaluate the effect of gas velocity on deposition rate for a Ge surface perpendicular to the gas stream (Ge wafer only) separately from the case in which heated Ge surfaces are both perpendicular and parallel (wafer plus pedestal sides) to the gas stream (circles), and (*b*) to observe the effect on β of reducing the total heated Ge surface area. The ratio, substrate plus pedestal to substrate area for the two sets of data in Fig. 6, is 4.2 and a β of 0.1 was found for the reduced area experiments (triangles) at a velocity of 100 cm/min. Assuming uniform growth, the expected β at this same velocity, for the larger area data (circles), would be 0.42; experimentally it is found to be 0.3.

This difference in β for the two sets of data in Fig. 6 is expected if we attribute the variation to gas depletion effects. These are effects which one would normally consider to be operative in a mass transport limited system. The earlier cited results, namely for the data in Fig. 6 (circles), indicated that growth rate could be considered essentially uniform to within 20% and would imply that reasonably good mixing of the gas occurs at heated surfaces. In view of these results, one would therefore expect the growth rate to increase with a reduced available surface area due to a reduced gas depletion effect.

The general features of both sets of data in Fig. 6, which include the dependence of growth rate on surface area, clearly indicate mass transport limited behavior.

The foregoing experimental growth data support, therefore, the conclusion of a specific type of mass transport limited system, *i.e.*, "lateral gas flow limited" in the higher temperature intervals, where only approximately 1/3 of the gas flowing through the reaction tube is capable of diffusing to and reacting with the heated Ge surface.[5]

The hypothesis that mass transport control of growth is more readily achieved at higher temperatures is further supported by the results of doping experiments. It was found that the boron concentration in the epitaxial Ge layers deposited at 700°, 780°, and 830°C increased linearly with gas phase B_2H_6 content and independently of temperature. The input B/Ge ratios shown could be obtained experimentally by either varying the diborane or the germanium input to the system. The linear nature of the results are in agreement with the work reported by Goorissen (10), and are expected for a mass transport controlled system. The data show a distribution ratio C_s/C_v of 0.0125 between the solid and vapor, where C_s = B/Ge ratio in the solid and C_v = B/Ge ratio in the vapor.

In Fig. 7, the theoretical curves fail to explain the temperature dependency of deposition rate in the low-temperature region. In Fig. 2 (region *A*), we note that temperature-dependent regions on the plot cover a wide range of substrate temperatures and input concentrations. Experimental evidence suggests that in these temperature-dependent intervals the growth rate is no longer dominated by mass transport, but instead is inhibited by a surface limitation. This is consistent with the model proposed by Reisman and Berkenblit (14). In the present study, structured surfaces were consistently observed for surface limited experimental conditions and the growth rate has been found to vary with substrate orientation. These observations are in agreement with orientation studies which have been reported by Givargizov *et al.* (8, 7) for similar growth conditions. The surface morphology changes described previously would further suggest that a different growth limiting mechanism is involved.

It will be noted that the conditions for smooth surfaces in Fig. 9 (region *B*) are for high substrate temperatures and low Ge/H_2 ratios. The intimate relationship of the morphology data illustrated in Fig. 9 to the growth rate data in Fig. 2 has been demonstrated by superimposing the "dashed curve" of Fig. 9, which demarks conditions for obtaining smooth and structured surfaces, on the growth rate data in Fig. 2. It can be seen that the dashed curves in Fig. 2 and 9 divide the data into a region *B* where mass transport limited growth conditions prevail and smooth surfaces

[5] Independent experimental observations which also support these conclusions have been made by Papazian (25). Using a reaction chamber of smaller diameter, such that a greater portion of the inside cross-sectional area was blocked by the heated pedestal surface, Papazian observed a β of 0.56 for comparable growth conditions.

are obtained, and a surface rate limited region *A* where structured surfaces are obtained.

In summary, the above studies have shown: (*a*) that deposition rates observed for the system studied can be explained using a "quasi-equilibrium" model; (*b*) the temperature and substrate orientation independence of growth rate, for a specific Ge/H_2 input value at higher temperatures, indicate a mass transport controlled system. Smooth surfaces are obtained under such conditions; and (c), at lower temperatures, dependence of growth rate on both temperature and substrate orientation indicates that surface limitations predominate. This latter case is coincident with structured surfaces.

APPENDIX

The theoretical calculations made use of the following equations along with the appropriate vant Hoff expressions relating the equilibrium constant, *K*, with temperature.

$$Ge(s) + 4HCl(g) = GeCl_4(g) + 2H_2(g) \quad [A\text{-}1]$$

$$[1a] \quad \log K_1 = \frac{6730}{T} - 8.02$$

$$Ge(s) + 2HCl(g) = GeCl_2(s) + H_2(g) \quad [A\text{-}2]$$

$$[2a] \quad \log K_2 = \frac{-465}{T} + 1.12$$

$$Ge(s) + 3HCl(g) = GeHCl_3(g) + H_2(g) \quad [A\text{-}3]$$

$$[3a] \quad \log K_3 = \frac{7580}{T} - 7.45$$

Equation [1*a*] is based on room-temperature enthalpy and entropy data for Ge(s), H_2(g), HCl(g) (19) and $GeCl_4$ (20) corrected for temperature using the tables of Kelley (21). The linear relationship for $\log K_1$ is the best fit of data corrected for a number of temperatures in the temperature interval 400°-1100°K. Sedgwick's (22) equilibrium data, Eq. [4*a*], for the reaction

$$GeCl_4(g) + Ge(s) = 2GeCl_2(g) \quad [A\text{-}4]$$

$$[4a] \quad \log K_4 = \frac{-7660}{T} + 10.25$$

were used along with Eq. [1*a*] to obtain Eq. [2*a*]. The reported K_4 data for reaction [A-4], was extrapolated to include the entire range of the calculations.

Thermodynamic data for $GeHCl_3$ are not known, and the room-temperature enthalpy and entropy were estimated by linear interpolation for the series GeH_4, GeH_3Cl, GeH_2Cl_2, $GeHCl_3$, and $GeCl_4$. This procedure is based on the assumption that bond energies are additive in generating the above series. Approximations of this type have been demonstrated in the analogous carbon series and were used in estimating heats for the Si series (16). Using this method, $\Delta H°_{298}$ was estimated at 90 ± 10 kcal from the room-temperature enthalpy of $GeCl_4$ and an estimated enthalpy of from 0 to −12 kcal for GeH_4. The approximation of the GeH_4 enthalpy was obtained using the approach of Roth and Schwartz (23) in which estimations of enthalpies are made by plotting heats of formation against an atomic number. An interpolated room-temperature entropy of 75.6 eu was used since the linear assumption was found to hold well for the above series for calculated values for GeH_4, $GeHCl_3$, and $GeCl_4$ as reported by Kelley (24). Equation [3*a*] was written assuming that $\Delta H°_{298}$ and $\Delta S°_{298}$ for reaction [A-3] is constant for the temperatures of the calculations.

Because of the large uncertainty in the thermodynamic constants for $GeHCl_3$, the enthalpy of formation was varied between −100 and −85 kcal. The enthalpy value changes for $GeHCl_3$ had no effect on the values of predicted deposition rates at higher temperatures; however, below 500°C, the use of a heat of formation value of −100 kcal caused significant reduction in predicted deposition rate. Equation [3*a*] was written using a −100 kcal value for $GeHCl_3$(g). The theoretical calculations were made adopting the approach described by Lever (16).

The thermodynamic efficiency, α, was defined as reported earlier by Sedgwick (15) for the analogous Si-H-Cl system

$$\alpha = \frac{\eta_{input} - \eta_{equi}}{\eta_{input}}$$

where, in general, η is the ratio of the total density of Ge atoms in the gas phase divided by the total density of Cl atoms in the gas phase summed over all species. η_{input} refers to the input gas consisting of $GeCl_4$ and H_2 and is, therefore, 0.25. η_{equi} refers to the gas phase Ge/Cl ratio at equilibrium. This efficiency value was employed in Eq. [1] to obtain the theoretical curves shown.

The thermodynamic calculations show that, above 600°C for Ge/H_2 ratios $< 3 \times 10^{-3}$, the efficiency is above 0.8 and that the reaction of $GeCl_4$ with hydrogen yields predominantly Ge and HCl as reaction products.

Acknowledgments

The author wishes to acknowledge gratefully, in particular, T. O. Sedgwick and R. F. Lever for their sustained interest, stimulating discussions, and critical evaluations throughout the course of this work. In addition, the author wishes to thank R. Gereth, A. Reisman, R. A. Laff, and Mrs. S. A. Papazian for their helpful suggestions. Thanks also to A. G. Blachman and M. E. Cowher for electrical data, and W. P. Hornberger who designed the original experimental system.

Manuscript submitted July 29, 1968; revised manuscript received Sept. 5, 1968. This manuscript was presented in part at the Dallas Meeting, May 7-12, 1967, as paper 104, and at the Chicago Meeting, Oct. 15-19, 1967, as paper 163.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Application of Multilayer Potential Distribution to Spreading Resistance Correction Factors

P. A. Schumann, Jr.,* and E. E. Gardner*

IBM Corporation, Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

The potential distribution of a flat circular area contact on a multilayered structure of infinite radial extent is presented. The solution is applied to the three-point spreading resistance probe and appropriate correction factors are obtained. This solution is compared with existing solutions, and it is shown that there is disagreement with the published values for the insulating back surface case but agreement with the conducting back surface. The results were checked with an electrolytic tank and good agreement was obtained.

All of the four-point potentiometric and spreading resistance probes require a knowledge of the potential distribution due to a point or finite area contact. Many authors (1-10) formulated solutions to the point contact problem with infinite and finite geometries, but with only one layer of material on a perfectly insulating or conducting substrate. Other authors (11-13) have discussed the finite area contact in similar geometries. Very early work (14-17) has been published for point contacts on multilayered structures but very few calculations were carried out. A numerical analysis (18) was made of a finite area contact on a multilayered structure. This paper outlines a technique of solving for the potential distribution due to a finite area contact on a multilayered geometry which is infinite in extent in the radial coordinate direction. This solution is then applied to the spreading resistance probe (19-23) to derive correction factors. Part of the model was used previously to derive correction factors for the delta probe (24).

The geometry considered is shown in Fig. 1. A flat circular probe makes a contact of radius, a, with the top surface of the semiconductor. Cylindrical coordinates are used as shown. The sample is infinite in extent in the r direction. There are three regions of different resistivity. Region 1 has a resistivity ρ_1 and a thickness h_1. Region 2 has a resistivity ρ_2 and a thickness d. Region 3 has a resistivity ρ_3 and is infinitely thick.

Several assumptions made which limit the accuracy and usefulness of the technique are:

1. The area contact is uniform. When a point is brought in contact with a sample, both the point and sample deform. Since neither are perfectly smooth or clean, the area of contact between the two is not uniform. The contact is usually made up of a collection of small contact areas. It is assumed here that the collection of small contact areas can be treated together as a single contact of effective radius, a.

2. The metal-semiconductor contact is ohmic. A small area metal-semiconductor contact is not ohmic in general. But experience has shown that in most cases, if low current levels are used, the resistance of the contact is not a function of current direction or magnitude.

3. There are no resistive layers between the contact and semiconductor. In silicon, particularly, it is obvious that there is always present an oxide of silicon on the surface. This is tied in with the first assumptions and it is further assumed that the pressure of the point is sufficient to break through the oxide.

4. Low current levels are used. It is necessary to use low current levels because of heating effects, high field effects, and junction effects.

5. All layers are of the same conductivity type. This is merely a restriction on the applicability of the solutions. For cases where a junction is present, it can be assumed that the junction insulates and an infinite resistivity can be used.

6. The resistivity is homogeneous throughout each layer. In actual practice, the resistivity change at an interface is never abrupt. This is a mathematical approximation to reality.

7. Laplace's equation is valid. It is not strictly true that Laplace's equation can be used to solve this type of problem. Charge accumulation or depletion occurs at the boundary between semiconductor regions of different resistivity depending on the bias conditions. We assume that this is a second order effect in many types of problems employing low current levels. Exact solutions taking into account charge accumulation or depletion at the inter-

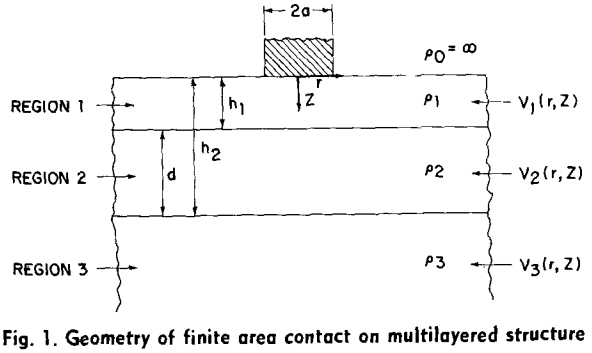

Fig. 1. Geometry of finite area contact on multilayered structure

* Electrochemical Society Active Member.

face between layers would require solution of Poisson's equation. Poisson's equation is nonlinear for this type of problem and solutions have been obtained for only a few one dimensional cases (25-27). Solutions for two dimensions are unknown to the authors.

8. The current distribution at the contact-semiconductor interface can be determined by the electrostatic analog of a flat disk in a semi-infinite medium. In order to carry over Laplace's equation from electrostatics to a current flow problem, a current analog model must be developed. By assuming a surface current distribution both under the contact and elsewhere on the surface it is possible to eliminate mixed boundary conditions in the solution of Laplace's equation.

Only the last two assumptions bear at all on the mathematics of the problem. We are in a sense completely wrong in using Laplace's equation, but the complete problem is not easily solved. Also, we believe that the effects due to the charge accumulation will be small, and, furthermore, comparisons between the spreading resistance probe using these solutions and other techniques are favorable.

It is important to produce the current analog of the electrostatic problem and provide a boundary condition under the contact. In certain cases (12) it is possible to avoid this second problem by solving two simultaneous integral equations. It did not look feasible to attempt this in the case considered. In all cases where checks have been possible, these solutions converge to the solutions presented by other authors for special cases.

The first six assumptions limit the applicability of the mathematics to reality. They are necessary conditions for the solutions as presented and seem reasonable in light of experience. The first four are of very minor importance to the four-point probe techniques, but become important to the spreading resistance measurements.

The mathematical solutions are valid for the problem as described under these assumptions, but no general statement can be made about how well the mathematical model matches the physical situation. Rather, each individual limit taken on the solution must be considered and evaluated.

To proceed with the solution of the problem, the sample is divided into three regions as shown in Fig. 1. Cylindrical coordinates are used, and it is noted that there will be symmetry in the θ direction. Potential V_1 (r,z) is the solution for region 1, V_2 (r,z) for region 2, and V_3 (r,z) for region 3. The solutions take the form

$$V_n(r,z) = \frac{I\rho_1}{2\pi a}\left\{\int_0^\infty \frac{e^{-\lambda z}\sin(\lambda a)J_0(\lambda r)\,d\lambda}{\lambda} + \int_0^\infty \frac{\theta_n(\lambda)e^{-\lambda z}\sin(\lambda a)J_0(\lambda r)\,d\lambda}{\lambda} + \int_0^\infty \frac{\psi_n(\lambda)e^{\lambda z}\sin(\lambda a)J_0(\lambda r)\,d\lambda}{\lambda}\right\} \quad n = 1,2,3 \quad [1]$$

The boundary conditions for this type of problem are relatively standard with the exception of the current distribution under the contact. These boundary conditions are:

Surface

$$\frac{\partial V_1(r,z)}{\partial z} = 0 \quad \text{when } r > a \text{ and } z = 0 \quad [2]$$

$$\frac{\partial V_1(r,z)}{\partial z} = \frac{-I\rho_1}{2\pi a(a^2-r^2)^{1/2}} \quad \text{for } r \leq a \text{ and } z = 0 \quad [3]$$

These first two conditions relate to the field at the surface. Equation [2] states that there is no current flow out of the surface away from the contact. Equation [3] is developed from considerations of the current flow under a flat circular contact on an infinite geometry.

Region 1

$$\lim_{r\to\infty} V_1(r,z) = 0 \quad [4]$$

First Interface

$$\frac{1}{\rho_1}\frac{\partial V_1(r,z)}{\partial z} = \frac{1}{\rho_2}\frac{\partial V_2(r,z)}{\partial z} \quad \text{for } z = h_1 \quad [5]$$

$$V_1(r,z) = V_2(r,z) \quad [6]$$

The equations at the interfaces state that the current density must be the same across the boundary and that the potential is continuous.

Region 2

$$\lim_{r\to\infty} V_2(r,z) = 0 \quad [7]$$

Second interface

$$\frac{1}{\rho_2}\frac{\partial V_2(r,z)}{\partial z} = \frac{1}{\rho_3}\frac{\partial V_3(r,z)}{\partial z} \quad [8]$$

for $z = h_2$

$$V_2(r,z) = V_3(r,z) \quad [9]$$

Region 3

$$\lim_{r\to\infty} V_3(r,z) = 0 \quad [10]$$

$$\lim_{z\to\infty} V_3(r,z) = 0 \quad [11]$$

These conditions are then imposed on the solutions given in Eq. [1] to specify $\theta_n(\lambda)$ and $\psi_n(\lambda)$. This results in a series of linear equations which can be solved with determinants. In general, if N is the number of layers of finite thickness, a $2N$ by $2N$ determinant must be solved. The solution to the equations for two layers are

$$\theta_1(\lambda) = \frac{k_1e^{-2\lambda h_1} + k_2e^{-2\lambda h_2}}{1 - k_1e^{-2\lambda h_1} - k_2e^{-2\lambda h_2} + k_1k_2e^{-2\lambda d}} = \psi_1(\lambda) \quad [12]$$

$$\theta_2(\lambda) = \frac{k_1 + k_1e^{-2\lambda h_1} + k_2e^{-2\lambda h_2} - k_1k_2e^{-2\lambda d}}{1 - k_1e^{-2\lambda h_1} - k_2e^{-2\lambda h_2} + k_1k_2e^{-2\lambda d}} \quad [13]$$

$$\psi_2(\lambda) = \frac{(1 + k_1)k_2e^{-2\lambda h_2}}{1 - k_1e^{-2\lambda h_1} - k_2e^{-2\lambda h_2} + k_1k_2e^{-2\lambda d}} \quad [14]$$

$$\theta_3(\lambda) = \frac{k_1 + k_2 + k_1k_2 + k_1e^{-2\lambda h_1} + k_2e^{-2\lambda h_2} - k_1k_2e^{-2\lambda d}}{1 - k_1e^{-2\lambda h_1} - k_2e^{-2\lambda h_2} + k_1k_2e^{-2\lambda d}} \quad [15]$$

and

$$\psi_3(\lambda) = 0 \quad [16]$$

where

$$k_1 = \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \quad [17]$$

and

$$k_2 = \frac{\rho_3 - \rho_2}{\rho_3 + \rho_2} \quad [18]$$

For most probe problems, only the potential at the surface is important, and since $\theta_1(\lambda) = \psi_1(\lambda)$

$$V_1(r,0) = \frac{I\rho_1}{2\pi a}\int_0^\infty \frac{[1 + 2\theta_1(\lambda)]\sin(\lambda a)J_0(\lambda r)}{\lambda}\,d\lambda \quad [19]$$

This specifies the potential at any point on the surface. But, for a spreading resistance measurement, the potential drop due to current flow through the contact area is needed. Since the contact probe will average out any gradients in potential that exist

$$V_S = \frac{\int_0^a\int_0^{2\pi} V_1(r,0)\ \mathrm{r}\,\mathrm{d}r\,\mathrm{d}\theta}{\int_0^a\int_0^{2\pi} \mathrm{r}\,\mathrm{d}r\,\mathrm{d}\theta} \quad [20]$$

which is the spreading resistance voltage or self potential of the contact. Substituting Eq. [19] for $V_1(r,z)$ and noting there is no dependence on θ

$$V_S = \frac{I\rho_1}{\pi a^2}\int_0^\infty \frac{[1 + 2\theta_1(\lambda)]\sin(\lambda a)J_1(\lambda a)}{\lambda^2}\,d\lambda \quad [21]$$

It is almost always more convenient to work with a dimensionless system. This can be obtained in this case by letting $t = \lambda a$. In dimensionless form, the solutions for the surface take the form

$$V_1(R,0) = \frac{I\rho_1}{2\pi a}$$

$$\int_0^\infty \left[\frac{1 + k_1e^{-2H_1t} + k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}{1 - k_1e^{-2H_1t} - k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}\right] \frac{\sin t\, J_0(Rt)}{t}\,dt \quad [22]$$

and

$$V_S = \frac{I\rho_1}{\pi a}$$

$$\int_0^\infty \left[\frac{1 + k_1e^{-2H_1t} + k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}{1 - k_1e^{-2H_1t} - k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}\right] \frac{\sin t\, J_1(t)}{t^2}\,dt \quad [23]$$

where

$$D = \frac{d}{a} = \frac{h_2 - h_1}{a} = H_2 - H_1,\ R = \frac{r}{a},\ \text{and}\ Z = \frac{z}{a} \quad [24]$$

These functions can be integrated as a convergent series for $\theta_1(t/a)$ can be found. The series can be integrated term by term and values for V_1 $(R,0)$ and V_S can be found from the new series. However, in practice it was found to be much quicker to integrate the functions numerically using Simpson's rule rather than sum the series.

The three-point spreading resistance probe as commonly used in our laboratory (22) is shown in Fig. 2. Current is passed between the inner probe and one of the outer probes. The voltage is measured between the inner probe and the other outer probe. By superposition, the measured voltage will be given by

$$\Delta V_2 = V_S - 2V_1(s,0) + V_1(2s,0) \quad [25]$$

Superposition is valid in this situation since the probe spacing is large compared to the radius of contact.

Using the values given in Eq. [22] and [23]

$$\Delta V_2 = \frac{I\rho_1}{4a}$$

$$\left\{\frac{4}{\pi}\int_0^\infty \left[\frac{1 + k_1e^{-2H_1t} + k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}{1 - k_1e^{-2H_1t} - k_2e^{-2H_2t} + k_1k_2e^{-2Dt}}\right] \sin t\left[\frac{J_1(t)}{t^2} - \frac{J_0(St/2)}{t} + \frac{J_0(St)}{2t}\right] dt\right\} \quad [26]$$

where

$$S = 2s/a$$

Or,

$$\Delta V_2 = \frac{I\rho_1}{4a} I_2 \quad [27]$$

Since $I\rho_1/4a$ is the normal spreading resistance obtained from a flat circular contact on an infinitely thick sample, I_2 is the appropriate correction factor. Numerically calculated values of I_2 are shown in Fig. 3 and 4 for two different probe spacings.

In these figures, note that the correction factor approaches one for large values of H_1. The case where $k_1 = 1$ is the insulating back surface condition and

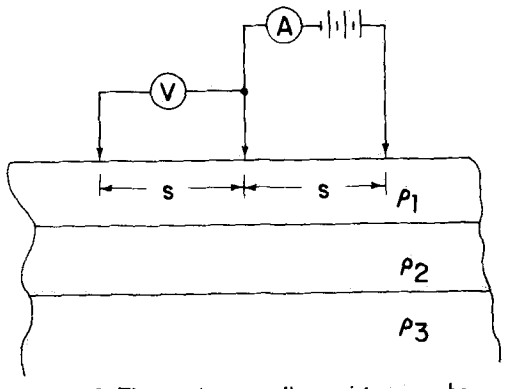

Fig. 2. Three-point spreading resistance probe

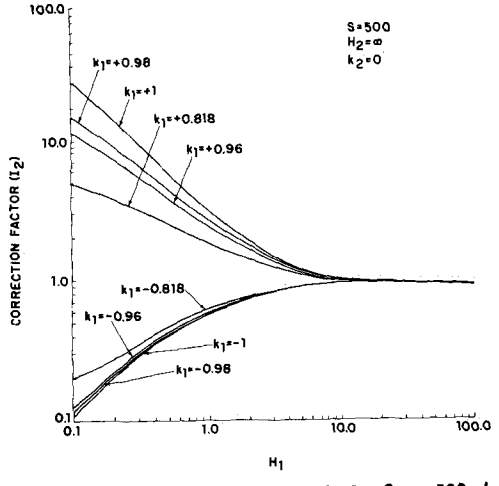

Fig. 3. Values of the correction factor I_2 for $S = 500$, $k_2 = 0$, and $H_2 = \infty$ plotted for various values of k_1 between ± 1 as a function of H_1.

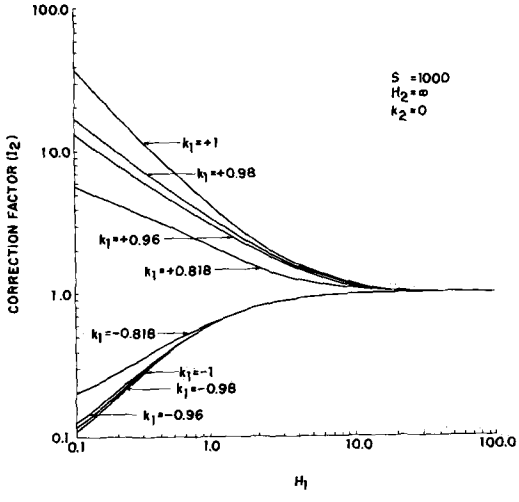

Fig. 4. Values of the correction factor I_2 for $S = 1000$, $k_2 = 0$, and $H_2 = \infty$ plotted for various values of k_1 between ± 1 as a function of H_2.

was solved by Dickey (13) using an image system. These values differ from Dickey's by about 25% at $H_1 = 0.1$ and 10% at $H_1 = 1.0$. Agreement is good at large H_1. This is due to the inaccuracy of his image system which renders it only applicable for large H_1. For the case where $k_1 = -1$, conducting back surface, good agreement is obtained between these solutions and results published by Foxhall and Lewis (12). As would be expected, this solution also goes to the cylinder resistance for small H_1.

The function I_2 was also calculated for $k_2 = \pm 1$, and the dependence on D studied. There is very little dependence on this parameter in most cases. The same

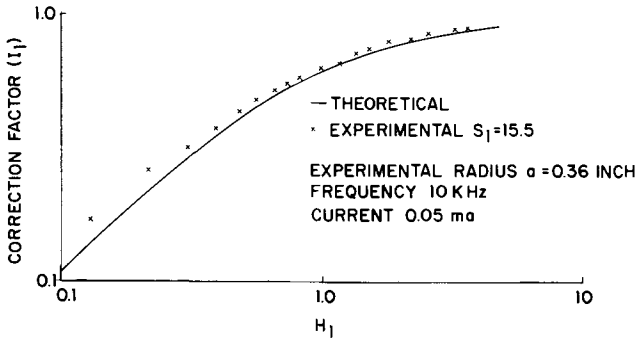

Fig. 5. Comparison of experimentally obtained correction factor from an electrolytic tank with theoretical values for $a = 0.36$ in., $S = 15.5$, $I = 0.05$ ma, and $f = 10$ kHz.

is true of the probe spacing as noted by comparing Fig. 3 and 4.

A useful method of checking these results is the electrolytic tank. A tank was constructed which could hold a 0.01M KCl aqueous solution with a nominal resistivity of 700 ohm-cm. For the conducting back surface case, $k_1 = -1$, the results are shown in Fig. 5. An a-c power supply was used and operated at a frequency of 10 kHz at a current of 0.05 ma. Good agreement is obtained between the experimentally and theoretically determined correction factors. The experimental value was obtained by measuring the resistivity of the solution with a four-point probe. Then knowing the resistivity and depth of the solution, an experimental correction factor can be obtained. The slight divergence at small H_1 is probably due either to measurement errors in the depth of the solution or to the fact that the conducting back surface was neither perfectly conducting nor infinitely thick.

Solutions to this type of problem have been obtained for more complicated geometries and an extrapolation to N layers has been obtained where N is the number of layers of different resistivity and finite thickness. With a many layered solution, approximations can be made to graded profiles through the use of step functions. Such a case is shown in Fig. 6. Here various approximations up to $N = 4$ are made to an exponential resistivity profile that decreases from a value of 0.5 ohm-cm at the surface to 0.0050 ohm-cm at the interface in a distance of $H_1 = 2.0$. The resultant correction factor was calculated for each case and is shown in Fig. 7 as a function of the number of layers

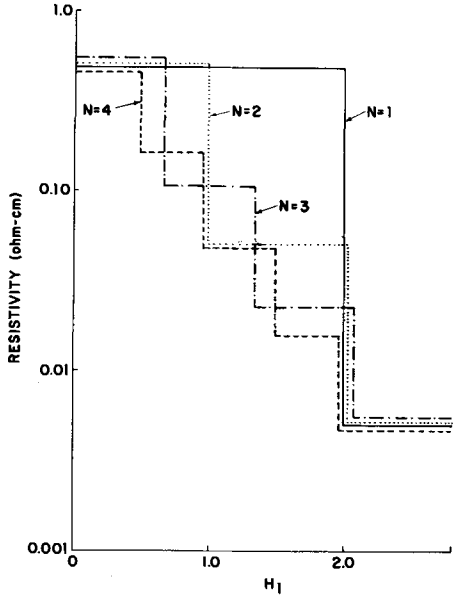

Fig. 6. Step function approximation to an exponential profile. The value of resistivity at the surface is 0.5 ohm-cm and at the interface is 0.005 ohm-cm.

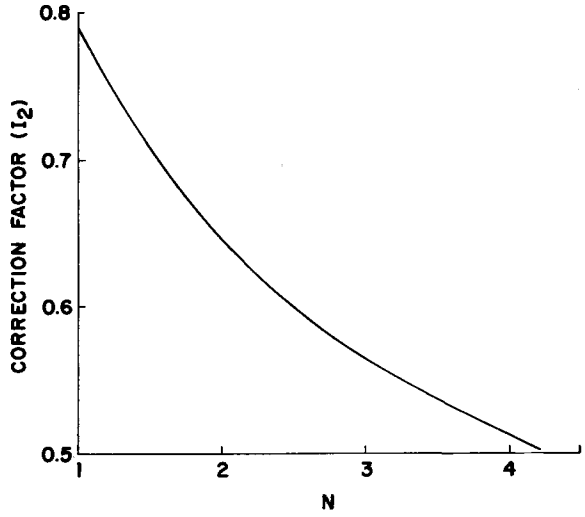

Fig. 7. Correction factor for approximated decreasing experimental resistivity profile plotted as a function of the number of layers used for approximation.

or steps. It is apparent that there is a strong dependence on the profile and that care must be taken in interpreting resistivity profiles obtained with a spreading resistance probe. This is certainly an area for further investigation.

An outline of the solution to the potential distribution due to a finite area contact on a multilayered structure has been given. It was applied only to a particular version of the three-point spreading resistance probe. The same solutions are applicable to all the four-point potentiometric probes, inline, square, over-under, and delta, and to all the spreading resistance probes, two-point, another three-point, and one-point. In all cases where other valid solutions have been found, this solution will converge to the published values if appropriate limits are taken. In addition, it provides a much wider range of application and can be extended to finite horizontal geometries through images and to N layers.

The application of the mathematics to the physical situation leaves some question. Perhaps the largest unanswered question is whether Laplace's equation is a valid representation of the physics when semiconductors are used. Also, there is much yet to be done with graded profiles rather than the step changes required by this analysis. However, in the use of the mathematics to problems such as the spreading resistance, good experimental agreement has been found between this and other techniques (21, 22). It would seem then that the mathematics is a fairly good approximation to reality in most cases. Great care must be used though in indiscriminate use of the integrals as each limit and assumption must be analyzed for that specific problem.

Polymorphism in Silver Telluride at High Pressures and Temperatures

Mario D. Banus* and Mary C. Finn

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The phase diagram of Ag_2Te at pressures to 40 kbar and temperatures to 300°C has been determined by resistivity, DTA, and x-ray diffraction measurements. Two high-pressure phases were found. Ag_2Te II, which has a resistivity ~4 times that of the atmospheric pressure monoclinic phase Ag_2Te I, is stable between 22 and 25 kbar. Ag_2Te III appears above 25 kbar. Its resistivity is about half that for Ag_2Te I. X-ray diffraction patterns for both high-pressure phases can be indexed on tetragonal cells with different lattice parameters.

The structures of Ag_2Se and Ag_2Te are orthorhombic and monoclinic, respectively, at room temperature. The electrical properties of both chalcogenides could best be studied by measurements on single crystals. However, it is not possible to grow single crystals of the room-temperature phases from the melt because each has a transformation to a face-centered-cubic phase at 133° and 148°C, respectively. When melt-grown single crystals are cooled through this transformation, they become highly polycrystalline. Since the molar volume increases on entering the high-temperature phase, the application of pressure raises the transition temperature from the low-temperature phase. If the phase boundary intersected the liquidus at a higher pressure, single crystals of the desired phase might be grown from the melt under pressure. [The polymorphism of stoichiometric Ag_2Te at atmospheric pressure is complicated by a second transformation to a body-centered-cubic phase occurring at 802°C, near its melting point (1, 2).]

A pressure-temperature phase study of Ag_2Se (3) was carried out by measuring the change of resistivity with temperature and pressure to 48 kbar. This showed that the rate of increase of the transition temperature between the orthorhombic and face-centered-cubic phase decreased with increasing pressure, so that this phase boundary was not expected to meet the liquidus. Resistivity measurements and x-ray diffraction studies, which were made to over 50 kbar at room temperature, showed no change from the low-temperature orthorhombic phase.

Preliminary experiments by the same methods on Ag_2Te showed a somewhat steeper initial slope for the boundary between the monoclinic and face-centered-cubic phases, and also gave evidence for additional phases at high pressure. This paper reports a more detailed investigation of the pressure-temperature phase diagram of Ag_2Te by electrical resistivity, differential thermal analysis, and x-ray diffraction measurements.

Experimental

All experiments were performed on samples cut from an n-type ingot, grown from the melt by the horizontal Bridgman technique. The composition of the ingot is very close to stoichiometric, since the carrier concentration is only 1 x $10^{17}/cm^3$. [It is necessary to specify the composition because the transition temperature between the Ag_2Te phases at atmospheric pressure depends strongly on sample stoichiometry. Thus, it was reported (1, 2) that the temperature of the monoclinic to face-centered cubic transition decreases from 145° ± 3°C on the Ag-rich side to 105°C on the Te-rich side of the stoichiometric compound.] Electrical resistivity (four-lead) and differential thermal analysis measurements under hydrostatic pressures to 18 kbar and temperatures to about 400°C were made in a 1-in.-diameter by 4-in.-high piston-cylinder device using isopentane or a mixture of isoamyl alcohol and n-pentane as the pressure-transmitting fluid. A carefully insulated resistance-wound furnace surrounded the sample inside the pressure chamber. The maximum temperature was limited by the thermal decomposition of the liquids. Resistivity measurements under hydrostatic conditions to 28 kbar and temperatures to about 100°C were made in a liquid cell (4) containing the same liquids. This cell was heated by circulating hot oil through the jacket around the cylinder restraining rings. Temperatures in both devices

* Electrochemical Society Active Member.
[1] Operated with support from the U.S. Air Force.

were measured with Cr-Al thermocouples in thermal contact with but electrically isolated from the specimens. No corrections were made for the effect of pressure on the emf of the thermocouples.

The structures of the phases have been studied by obtaining x-ray diffraction powder patterns for samples squeezed between diamond Bridgman anvils of the type first described by Piermarini and Wier (5). Since the anvil configuration results in substantial pressure gradients across the sample, more than one phase may be present. Even with a finely collimated x-ray beam, portions of more than one phase may be intercepted by the beam, especially if one of the phases has a very narrow pressure range. Where the unknown structures have symmetries other than cubic or close-packed hexagonal, however, patterns which are unambiguously single phase are essential for correct indexing. The problem was solved by using the Bassett modification of the diamond anvil squeezer (6) which permits visual observation of the phases with a metallographic microscope. Since the Ag_2Te is not transparent, reflected light, either normal or polarized, was used. Figure 1 is a photomicrograph taken through the anvil diamond showing the three phases of Ag_2Te. The desired phase could be positioned in the area of the x-ray beam by changing the loading on the piston diamond while observing the growth, disappearance, or movement of the phases. It was necessary to wait for about 24 hr after a pressure change to allow phase change or motion to go to completion. Sample flow or kinetics of the phase transformations may have caused the slow change in phase locations. Photomicrographs made before and after the 200-300 hr exposures for the x-ray diffraction patterns showed that no further changes took place during the exposures.

Results and Discussion

Phase diagram.—In our first experiments, the resistivity was measured as a function of temperature at various fixed pressures between atmospheric and 16 kbar. The phase change to face-centered-cubic Ag_2Te with increasing temperature was readily observed by the sharp increase in resistivity, fourfold at 1 atm, accompanying this transformation (Fig. 2). The transition temperature was found to increase smoothly from 148° ± 1°C at atmospheric pressure to 193° ± 3°C at 6 kbar. This increase was expected because the molar volume is greater for the face-centered-cubic phase than for the monoclinic phase. At about 8 kbar, however, there was an abrupt increase in the slope of the transition temperature *vs.* pressure curve (*see* Fig. 4, below). In order to check this unexpected result, the transition temperatures were then determined by means of differential thermal analysis measurements. The results of these measurements are in good agreement with the resistivity data. The shape of the temperature-pressure curve suggested the presence of a triple point at about 8 kbar, resulting from the intersection with the boundary of a high-pressure phase.

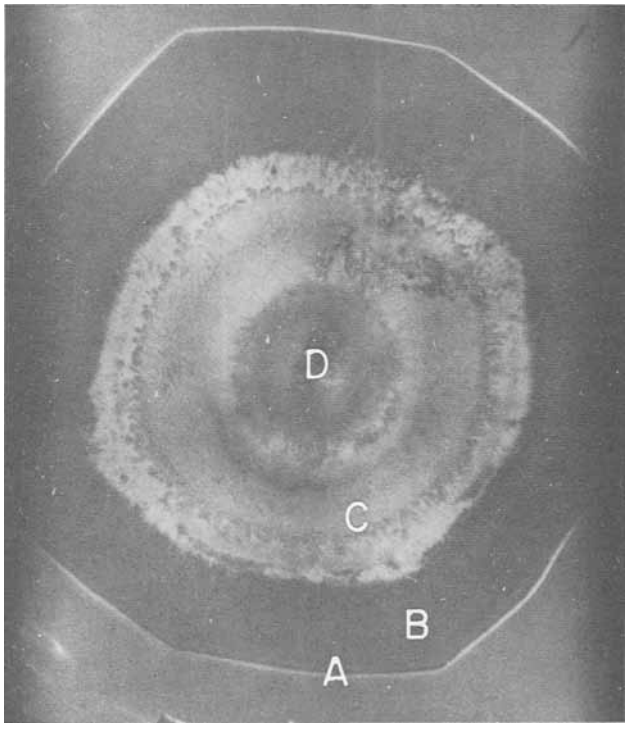

Fig. 1. Photomicrograph of Ag_2Te pressed between diamond Bridgman anvil faces and viewed by reflected light: *A*—outline of 0.5-mm-diameter piston-diamond face; *B*—Ag_2Te I; *C*—Ag_2Te II; *D*—Ag_2Te III.

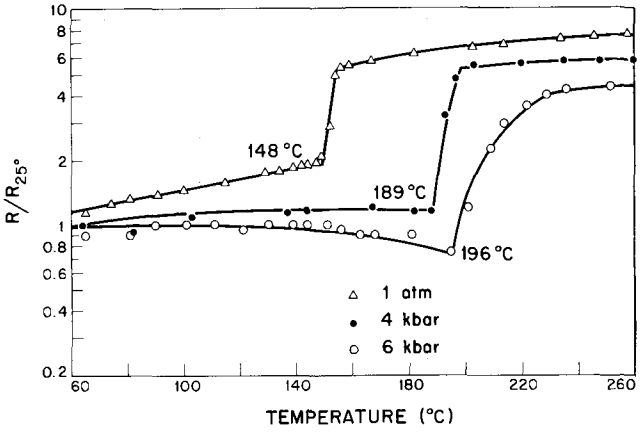

Fig. 2. Relative resistivity of Ag_2Te vs. temperature at constant pressure. Temperatures for monoclinic to fcc transition indicated.

Resistivity *vs.* pressure measurements were then made at room temperature to confirm the existence of a high-pressure phase. These measurements show an abrupt increase in resistivity by a factor of 4 at 22.0 ± 0.5 kbar, followed by an abrupt decrease by a factor of 7 at 25.0 ± 0.5 kbar. The resistivity-pressure curves (Fig. 3) are very similar in shape to the curves for cesium (7) used to establish the phase boundaries of cesium III, which has a pressure stability range of only 1.5 kbar at room temperature. These curves therefore indicate that transformations occur first to a phase (Ag_2Te II) of higher resistivity than the monoclinic phase (Ag_2Te I) and then to a phase (Ag_2Te III) with the lowest resistivity.[2] With increasing temperature, the magnitude and sharpness of the resistivity changes decrease so that accurate phase boundary data cannot be obtained by resistivity *vs.* pressure measurements above ~75°C. However, at 8 and 10 kbar, resistivity *vs.* temperature curves showed changes in slope which are characteristic of phase changes, although it is more difficult to determine the precise temperature of the transition.

The pressure-temperature diagram based on these data is shown in Fig. 4. The slope of the boundary between Ag_2Te II and Ag_2Te III suggests that it is this boundary which gives the triple point at 8 kbar and 200°C. Thermodynamic considerations require a second triple point including Ag_2Te I. However, the data are not sufficient to show whether this point is between Ag_2Te I, II, and III at about 10 kbar and 175°C or between Ag_2Te I, II and the face-centered cubic phase very close to the triple point shown. In the latter case, the I-II and II-III boundaries do not intersect. The phase diagram shows that it is not possible to grow

[2] We have adopted Roman numerals to designate these phases because this is the customary usage in the literature on high-pressure research. It should be noted that Frueh has used Roman numerals to identify the three phases of Ag_2Te which are stable at atmospheric pressure, but this procedure has not been followed by other investigators of Ag_2Te, and it is contrary to the usual practice of designating atmospheric pressure phases by lower-case Greek letters.

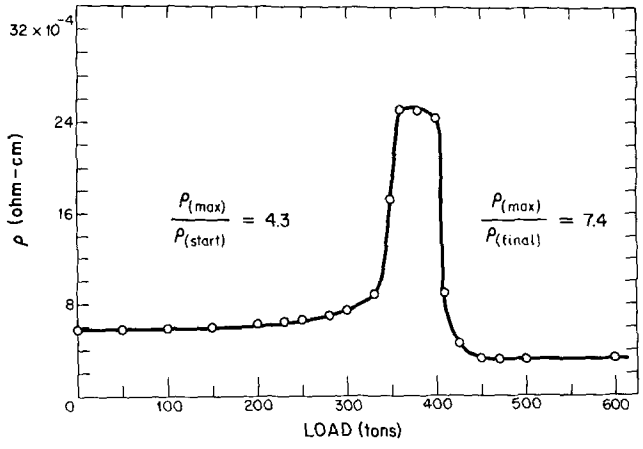

Fig. 3. Resistivity (four-lead) vs. increasing load for Ag_2Te in hydrostatic system at 25°C; 330 tons corresponds to 22 kbar and 410 tons corresponds to 25 kbar.

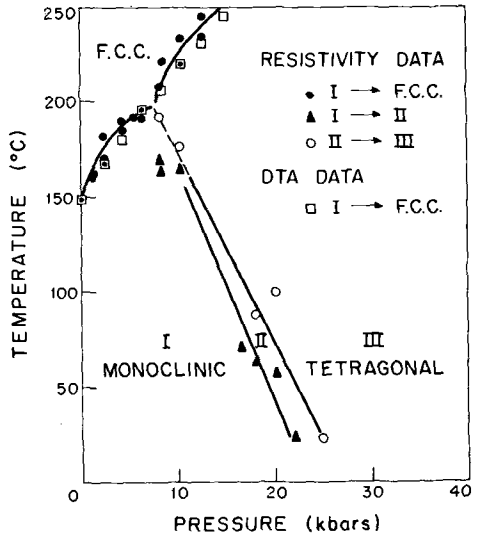

Fig. 4. Pressure-temperature phase diagram of Ag_2Te from resistivity and DTA data.

crystals of the room temperature Ag_2Te I phase from the melt at high pressure.

Resistivity measurements (four-lead) were also made at room temperature to ~90 kbar in a quasihydrostatic system using AgCl as the pressure medium. The abrupt resistivity changes at 22.5 and 25 kbar were duplicated. Above 26 kbar, the resistivity increases slowly by about 15% to a maximum between 44 and 48 kbar, then gradually decreases by ~20% to 90 kbar. These small gradual changes probably do not result from further structural changes but rather from the effect of pressure on the conduction mechanism, complicated by decreases in sample dimensions due to compression.

Structure of high-pressure phases.—The diffraction patterns of both high-pressure phases have been indexed on tetragonal cells. A summary of the d-spacings and indexing is given in Table I. Table II lists the lattice parameters and densities of Ag_2Te I, II, and III. The diffraction pattern at atmospheric pressure agrees with the pattern for monoclinic structure reported by Frueh (8). There is an increase in density of 12% between Ag_2Te I at 1 atm and Ag_2Te II at 24 kbar, part of which is due to the compressibility of the monoclinic structure. The 5% density increase between Ag_2Te II at 24 kbar and Ag_2Te III at ~40 kbar is probably due mostly to the change in molar volume at the transition rather than to compressibility.

Table II. Phases of Ag_2Te

I Monoclinic (1 atm)	II Tetragonal (24 kbar)	III Tetragonal (40 kbar)
a = 8.13Å	a = 8.92Å	a = 8.68Å
b = 4.48		
c = 8.09	c = 6.09	c = 6.09
β = 112°55′	c/a = 0.68	c/a = 0.70
M = 4	M = 8	M = 8
ρ = 8.40 g/cc	ρ = 9.41 g/cc	ρ = 9.91 g/cc

The space groups for the high-pressure phases have not been determined. Although the two phases have the same c-parameter and similar a-parameters, they probably have different space groups, since the intensity distribution is quite different for the two diffraction patterns. For example, compare the 310, 311, 400, and the 410, 302 doublet reflections. The electrical and optical properties emphasize the sharp difference between these two phases. The structure of Ag_2Te III appears to be isotypic with that of high pressure Ag_2S (9), the space group of which has not been determined either. The ratio of the unit cell volumes between Ag_2Te III and the high pressure Ag_2S (1.31) is similar to the ratio of the atomic volumes for tellurium and sulfur (1.32). Thus, in its high-pressure behavior, Ag_2Te appears to be similar to Ag_2S rather than to Ag_2Se, which has no high-pressure phases to more than 45 kbar (3).

Acknowledgments

The authors are pleased to acknowledge the assistance of Messrs. T. E. Stack and R. Westberg in carrying out the high-pressure measurements, and thank Mrs. M. J. Button for reading the x-ray diffraction patterns. We thank, also, Dr. A. J. Strauss for providing us with the ingot of Ag_2Te.

Electron Beam Exposure of Silicones

Yasuo Yatsui, Toshitake Nakata, and Kazuo Umehara

Research and Development Center, Sanyo Electric Company, Ltd., Hirakata, Osaka, Japan

ABSTRACT

An investigation has been carried out on silicone etch-resists which can be exposed by electron beam irradiation. Thin silicone films with a thickness of about 5000 and 10,000Å were irradiated by scanning electron beam accelerated at 10 and 25 kv, over defined area. The thicknesses of silicone films after development were measured for each different irradiation charge density; thus the exposure characteristics of a few kinds of silicones were obtained. With the most sensitive silicone, methylvinylpolysiloxane, it was possible to form developed pattern with irradiation charge density 8.8 x 10^{-7} coulombs/cm^2 at 10 kv. The chemical resistances of the electron beam irradiated silicone films to the chemical reagents which were thought to be the constituents of common etchants were also investigated. It has been shown that flood-beam irradiation onto the developed silicone films was effective to increase chemical resistance and adhesive force to the substrate. Such silicone resists are practically useful to almost all etchants other than sulfuric acid.

It has been well known that electron beam irradiation causes cross-linking of polymers (1). In several alterations of the chemical and physical natures of the cross-linked polymers, the change of polymer solubility to organic solvents can be utilized for the formation of submicron sized etch-resist patterns by sectional electron beam irradiation over the polymer films.

Etch-resists that have been used for the above mentioned purposes were in almost all cases photosensitive resins which can be cross-linked essentially by uv light irradiation; these resins are also successsfully cross-linked by electron beam irradiation (2). If other materials having high sensitivities not to uv light but to the electron beam, and having good resistance to acids and alkalis were obtained, these materials would be better for electron beam sensitive etch-resists.

As the silicones are among the more chemically stable classes of compounds, cross-linking of a few kinds of silicones by electron beam irradiation was tried for the formation of the etch-resists. Although some experiments have been done to form silicone films by electron beam irradiation, their processes were fairly slow since silicones were supplied onto the surface of substrate from vapor phase along with electron bombardment (3-11). In other experiments the precoated organosilicon compound, triphenylsilanol, was polymerized by electron beam, but its sensitivity was also low (12-13). Recently it was proposed to use electron beam irradiated silicones as diffusion barriers (14).

To put silicones to practical use as etch-resist, the following conditions should be met: (*i*) the possibility of making thin and uniform silicone films with a thickness less than 1μ; (*ii*) high cross-linking sensitivity by electron beam irradiation; (*iii*) good chemical resistances of the cross-linked silicones. As a result of investigations concerning the radiation chemistry of polymers, it has been shown that the polymerization degree and the organic groups contained in polymers play important roles in cross-linking by irradiation (15), and so several silicones having different polymerization degree and organic groups were employed.

Experimental Procedure

The electron beam apparatus used in the experiments was Japan Electron Optics Laboratory's JSM type scanning electron microscope. Although this apparatus can form a fine electron beam with diameter less than 0.1μ, the electron beam was focused to 1-2μ diameter, so as to obtain uniform exposure over the area of raster scan which was nearly square.

Exposing charge density is given by

$$Q\,(\text{coulombs/cm}^2) = i \times t/s$$

where i is the electron beam current in amperes, t is the scanning time in seconds, and s is the scanning area in square centimeters. To vary the exposing charge density, ranging from 10^{-8} to 10^{-4} coulombs/cm^2, the scanning time and scanning area were varied with the beam current held constant.

Exposure conditions by the electron beam were as follows: beam current, 10^{-10} amp; accelerating voltage, 10 and 25 kv; scanning area, 4 x 10^{-4} — 10^{-2} cm^2; scanning time, 1.1-1279 sec; scanning lines, 125, 250, and 500 lines/frame.

The silicones used in the experiments and their properties are listed in Table I.

Silicones were dissolved into isoamylacetate which was found to be the most suitable solvent for the silicones; solutions were spun onto mirror-polished silicon slices, after which the solvent was volatilized thoroughly at room temperature. If the dilution rate was appropriate, uniform films with arbitrary thicknesses from 500 to 20000Å were easily obtained by this method. In the following experiments 5000 or 10000Å films were employed. After the drying was completed samples were inserted into the scanning electron microscope and subjected to the electron beam irradiation. Irradiated samples were then soaked in isoamylacetate for 2 min for the purpose of development. The residual film thickness after development will depend on the quantity of the irradiation charge. Development longer than 2 min made no observable change in residual film thicknesses determined by the exposure conditions. For the expression of the exposure characteristics of silicones for electron beam irradiation, the relations between the irradiation charge density and film thickness remaining after development were adopted. Resist removal during development was uniform over the entire exposed surface, whether the irradiation charge densities are high or low. Because the thicknesses of the exposed film areas were too small to measure by an interferometer, interference color was

Key words: electron beam exposure, etch-resist, silicone.

Table I. Silicones used in the experiments

Silicones	Organic groups	Remarks
SH 200 (10^5 c.s.)[1]	Methyl	Oil, polymerization degree 1400[3]
SH 200 (2.5×10^6 c.s.)[1]	Methyl	Oil, polymerization degree 2600[3]
TSE 200[2]	Methyl	Gum, polymerization degree 15000-20000
SH 410[1]	Methyl, vinyl	Gum, vinyl; more than 1 m/o ?[4]
SH 430[1]	Methyl, vinyl	Gum, vinyl; less than 1 m/o ?[4]
SH 440[1]	Methyl, phenyl	Gum, phenyl; about 10 m/o ?[4]

adopted as the measure of thickness. Precise relations between interference colors and silicone film thicknesses on silicon substrates were obtained previously with relatively large area silicone films whose thickness could be measured by an interferometer. The same conditions were applied in all interference color observations.

Resistances of electron beam irradiated silicones to the common chemical agents were also examined. In these experiments, silicone films about 5000Å thick were employed. Since it had been shown in the preliminary experiment that flood-beam irradiation with high charge density after development increased chemical resistance and the adhesive force of silicones, charge densities irradiated prior to the chemical test were 10^{-5} and 10^{-4} coulombs/cm^2. Flood-beam irradiation corresponds to the postbake process of photosensitive resins. The irradiated silicone films were then immersed in chemical reagents for 15 min at room temperature, and diminution of film thickness was measured by interference color observation. Some errors in measurement would occur, for refraction constant may be altered by absorption of chemical reagent, and interference color may change independently with thickness. However these errors would be negligible.

Experimental Results

Exposure characteristics of silicones listed in Table I with thicknesses about 5000 and 10000Å for the electron beam accelerated at 10 and 25 kv are shown in Fig. 1-a, b as the relations between the charge density and the percentages of residual film thicknesses after the development relative to the thickness before development. The charge density which results in 90% residual film thickness is designated as efficient charge density, and for convenience these quantities may be used as the comparison of the sensitivities of silicones. Efficient charge densities of the silicones with thickness about 5000Å for the electron beam accelerated at 10 kv are listed in Table II.

Although the electron beam current was 10^{-10} amp in those cases, irradiation by an electron beam carrying 10^{-12} amp was also tried, but the exposure characteristics were identical with that obtained by the electron beam carrying 10^{-10} amp within the limits of experimental error. So we may conclude that there exists no reciprocity failure in the range of these electron beam currents.

The chemical resistances of silicones irradiated by the electron beam accelerated at 10 kv are listed in

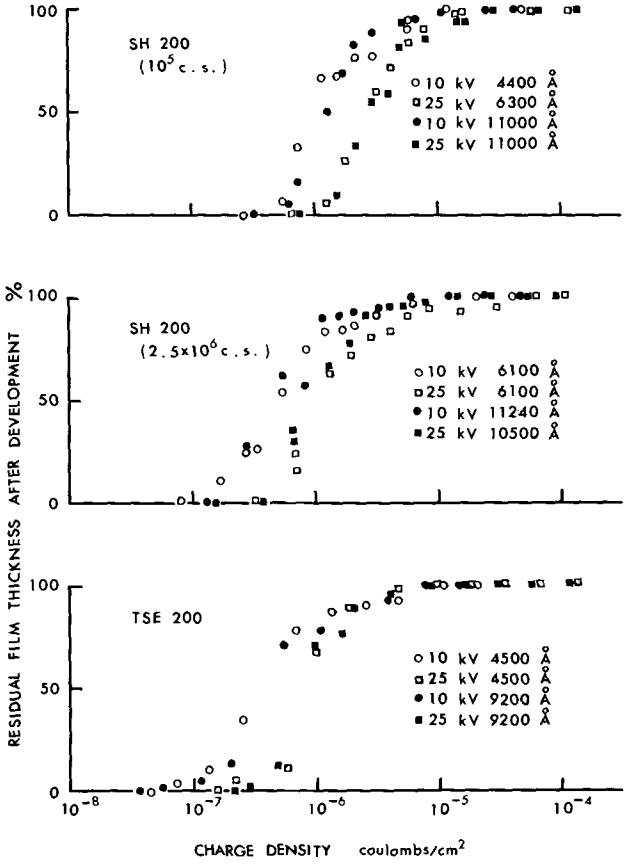

Fig. 1a. Exposure characteristics of silicones, SH 200 (10^5 c.s.), SH 200 (2.5×10^6 c.s.), and TSE 200.

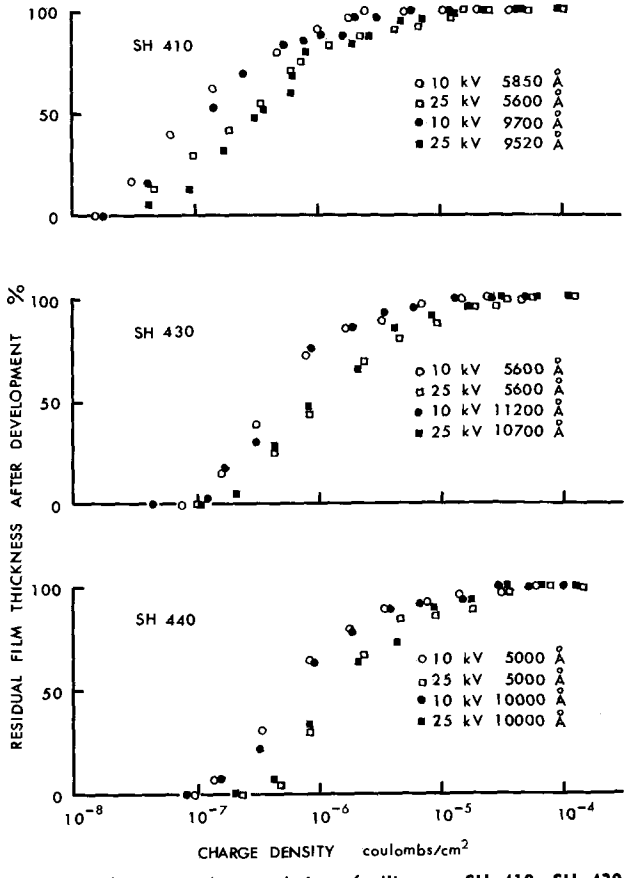

Fig. 1b. Exposure characteristics of silicones, SH 410, SH 430, and SH 440.

Table II. Efficient charge density for silicones

Silicones	Efficient charge density, coulombs/cm²
SH 200 (10^5 c.s.)	3.9×10^{-6}
SH 200 (2.5×10^6 c.s.)	2.9×10^{-6}
TSE 200	2.2×10^{-6}
SH 410	8.8×10^{-7}
SH 430	2.8×10^{-6}
SH 440	5.0×10^{-6}

Table III. In this table residual film thicknesses after immersion in chemical reagents for 15 min at room temperature are expressed in percentages relative to the film thickness before immersion (5000Å). The left-hand figures in each column are the results for films irradiated with 10^{-5} coulombs/cm² charge densities, and the right-hand figures for those with 10^{-4} coulombs/cm² charge densities. For the comparison, methylvinylpolysiloxane and dimethylpolysiloxane were also immersed in boiling trichloroethylene, but no dissolution or peeling were seen in these cases.

Although the silicone films were dissolved slowly in hydrofluoric acid (49%), they were dissolved very little in buffered etchant, and SiO_2 of which thickness was 3000Å was successfully etched without damage of resist films (Fig. 2).

To know the resolution of silicone resist, line exposure of SH 200 (10^5 c.s.) of which thickness was about 3000Å was carried out using 0.1μ electron beam, and developed pattern about 0.4μ was obtained as shown in Fig. 3. It was difficult to obtain a finer exposure line because of the spreading of exposure area by scattering of electrons in the resist and substrate.

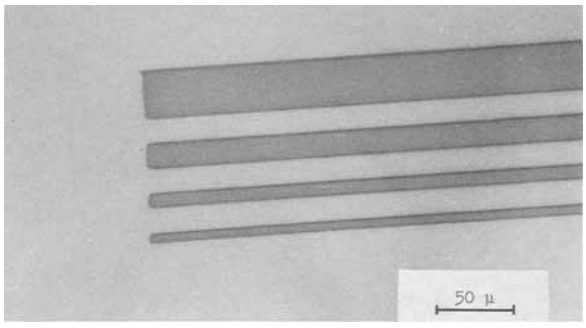

Fig. 2. Etching test of 3000Å SiO_2 by buffered etchant, using SH 200 (10^5 c.s.) resist, after stripping off the resist.

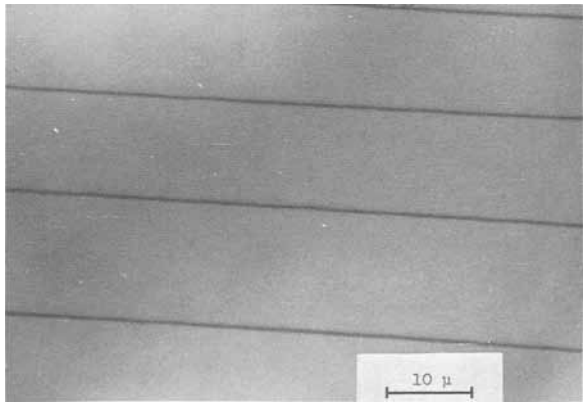

Fig. 3. Fine line pattern of SH 200 (10^5 c.s.), exposed by 0.1μ beam at 25 kv, after development. Line width is about 0.4μ.

Discussion and Conclusions

It can be seen that the silicones show decreasing sensitivity in the order of those having vinyl groups, methyl groups, and phenyl groups. Especially, methylvinylpolysiloxane thought to contain more than 1 m/o (mole per cent) vinyl groups shows a few times higher sensitivity than the conventional photoresists for electron beam exposure (16). The high sensitivity of methylvinylpolysiloxane to the electron beam is reasonable and to some extent anticipated. The relatively low sensitivity of methylphenylpolysiloxane may be explained by the radiation protective effect of phenyl groups for the cross-linking, which is well known in the study of radiation chemistry (17). According to this phenomenon, the energy transferred from the bombarding electron to the molecule, will be further transferred to the phenyl groups, and the bombarding energy is diminished without causing any chemical reaction. When more sensitive silicone is required, one containing phenyl groups must be avoided.

Comparison between silicones that have the same methyl groups but different polymerization degrees shows that one having higher polymerization degrees has higher sensitivity. However in the matter of contrast, silicones having higher polymerization degrees show poorer contrast than those having lower polymerization degrees.

Silicones were more sensitive to the electron beams accelerated at 10 kv than to those accelerated at 25 kv because the energy transfer to the resist per unit length increases as the energy of the incident electrons decreases. However no dependences on the film thickness were seen within the limits of experimental error.

The chemical resistance of silicones exposed to the electron beam is poor to sulfuric acid, and in this case films were dissolved completely in 1 min, so the silicone resist cannot be used in etchant containing sulfuric acid. Also some damage to the resist was seen with hydrofluoric acid and in a sodium hydroxide solution. However higher irradiation charge density provided by flood-beam irradiation improved the resistance to those reagents. For instance, in the case immersing TSE 200 in hydrofluoric acid for 15 min, films subjected to 10^{-4} coulombs/cm² irradiation showed only 33% decrease in thickness, while those subjected to 10^{-5} coulombs/

[1] Shrinking and partial peeling of the films were seen.
[2] Dissolved in 1 min.
[3] Films were lost by peeling.

cm^2 showed 67% decrease. Such silicone films come to have perfect resistance to the buffered hydrofluoric acid that is ordinarily used to etch SiO_2. Resistances to the other acids were excellent, and these facts demonstrate that the silicone films subjected to flood-beam after development are useful as an etch-resist for the etchants composed of the acids or alkalis listed in Table III except for sulfuric acid. The difficulty involved in stripping of the resists after etching may be anticipated as the result of excellent resistances to the organic solvents. To remove exposed resist films, swabbing with cotton after boiling in trichloroethylene for 20 min is required. Soaking in sulfuric acid at room temperature is also effective, if it is permissible.

It is expected that the oxygen atoms contained in silicones make strong metal-oxygen bonds at the interface of resist and substrate. In fact, adhesion of irradiated silicone films to a silicon substrate was excellent.

In conclusion, silicones can be good material for electron sensitive resist in place of the conventional photosensitive resists because of the high sensitivity to the electron beam, strong resistance to most chemical etchants, and good adhesion to the substrate.

Acknowledgment

The authors wish to express their thanks to H. Fukuda for his assistance in operating the scanning electron microscope, and to Dr. T. Hayashida for his encouragement during this work.

Carbon in Epitaxial Silicon

P. Rai-Choudhury,* A. J. Noreika, and M. L. Theodore

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

Epitaxial Si layers have been doped with carbon from a silicon tetrachloride-methane system, and the carbon content has been chemically analyzed. The levels of carbon content range from 9.7×10^{17} atoms C/cm^3 (undoped) through 2.6×10^{19} atoms C/cm^3 (moderate doping), to a saturation content which induces complete conversion to SiC. Influence of the carbon content on the crystalline perfection of the Si layers is found to be negligible up to concentrations of 10^{18} atoms C/cm^3; at concentrations near 10^{19} atoms C/cm^3 many polycrystalline inclusions are formed. Spreading resistance measurements which reveal doping profiles show significant increases in resistance only in layers which can show some change of phase. Direct evidence is presented demonstrating that the retention of carbon in the deposited layers is both by diffusion induced substitution and by chemical reaction. The retention of excess carbon interstitially is inferred.

Epitaxial Si layers, grown in the presence of carbon contaminants, are often observed to contain crystallographic defects. Some of these defects, *e.g.*, tripyramids, are presumed to arise from the formation of SiC platelets at the substrate surface (1,2). No data are available, however, which directly relate the carbon impurity concentrations to the type or number of defects which are formed.

Studies of carbon in bulk Si are more quantitative. Bulk Si, regardless of the method of preparation, has been reported to retain at least 3×10^{18} atoms C/cm^3 (3). This impurity level represents the substitutional saturation limit of carbon in Si at the melting point (3,4); hence, retention of this concentration at lower temperatures denotes a supersaturation of carbon in Si.

The present study seeks the following: (*i*) to confirm the quantitative measurements for concentrations of carbon in bulk Si; (*ii*) to extend these measurements to carbon in epitaxial Si deposits; (*iii*) to alter controllably carbon concentrations in epitaxial Si; and (*iv*) to correlate the relative numbers of observable defects with known carbon impurity concentrations.

* Electrochemical Society Active Member.

Experimental

Epitaxial layers of Si were grown in a conventional horizontal reaction chamber by the hydrogen reduction of $SiCl_4$ as well as by the pyrolysis of silane. Chemically polished Si(111) wafers were used as substrates. Heating of the substrates was done via the rf heating of a SiC coated graphite susceptor on which the substrates lay. Predeposit etching of the substrates with water vapor (5) was done *in situ*. Group V doping of the layers where desired was accomplished by injecting phosphine into the main gas stream. The source carbon supplied to the growing Si layers arrived via

the gas flow as a methane (CH_4)-hydrogen mixture. The partial pressure of silicon tetrachloride was held constant at 8 x 10^{-3} atm; all relative $(C/Si)_g$ ratios were produced by altering only the methane partial pressure.

The carbon contents of both the epitaxial deposits and the substrates (bulk) were analyzed chemically. The method of analysis (see Appendix) imposed a lower limit on the weight of the Si sample, *viz.*, 0.3g at which 20 ppma could be detected unambiguously. Two epitaxial layers from a single experiment with substrates removed provided the necessary 0.3g of Si.

The sirtl etch technique (6) and optical microscopy were used to note surface defects. Precipitates and/or inclusions were detected by transmission electron microscopy (TEM) of thin regions near the surface and identified where possible by transmission electron diffraction. The layers were subjected to both TEM and Lang topographical x-ray analyses to obtain a measure of crystalline perfection. Spreading resistance measurements gave resistance profiles (7) of the layers together with any resistance inhomogeneities which may have been carbon induced.

Results

The experimental data are presented relative to increasing levels of carbon (gas phase) doping. Carbon concentrations of the various silicon samples are presented in Table I and compared there to bulk data. The thicknesses of all deposits were nominally 200μ (grown at $\simeq$ 1 μ/min), the initial 70μ of which were deposited with no carbon doping. To provide a standard resistivity, all deposits were phosphorus doped to a level which would provide n-type, 30 ohm-cm Si.

$(C/Si)_g$ = 0.—With no intentional carbon doping, the carbon content of the epitaxial Si layers formed by the hydrogen reduction of $SiCl_4$ was 2.3 x 10^{18} atoms C/cm^3. This concentration was approximately half that observed in bulk specimens, the latter value comparing favorably with data published by Schink (3). Layers prepared by the pyrolysis of silane showed a still smaller carbon concentration, as noted in Table I.

The crystalline perfection of these layers was typically good. TEM studies and x-ray topographic examinations showed no precipitatelike inclusions or stacking faults. The observed dislocation densities were of the order of 10^2/cm^3.

$(C/Si)_g$ = 1/80; $(C/Si)_g$ = 1/34.—Specimens grown in both the $(C/Si)_g$ = 1/80 and $(C/Si)_g$ = 1/34 concentrations were physically very similar. Dislocation densities and resistivities of both differed negligibly from those of the deposits described in section 3.1. Unlike the latter (undoped) deposits, however, small, roughly circular inclusions occasionally appeared. The small size ($\sim$0.1 mm) and the sparse numbers ($< 1/cm^2$) made identification impossible. No attempt was made to characterize further these particular inclusions. The carbon content of deposits with $(C/Si)_g$ = 1/34 was 3 x 10^{18} atoms C/cm^3 concentration measurements were not made on the $(C/Si)_g$ = 1/80 specimens.

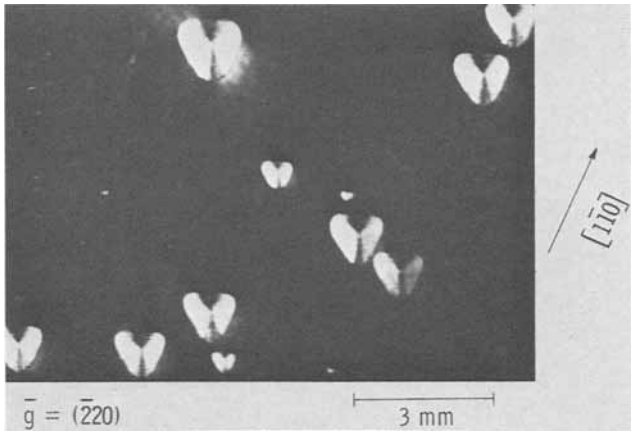

Fig. 1. X-ray topograph of an epitaxial Si layer doped with moderately high level of carbon. Triangular features correspond to polycrystalline inclusions.

$(C/Si)_g$ = 3/10.—At $(C/Si)_g$ = 3/10 the carbon concentration was found to be 2.6 x 10^{19} atoms C/cm^3. Visual observation of the deposited surfaces showed the epitaxial layer to be interspersed with large equilateral triangular shapes. Analyses of electron diffraction patterns of thinned surface regions of these areas identified them as mixed polycrystalline regions of Si and graphite. It is possible, however, that regions more removed from the surface may have had sufficient time to form SiC during the extended growth period. Normal edge dimensions of the triangular shapes ranged from 0.3 to 1.5 mm, the larger ones being more numerous. Figure 1, a Lang x-ray topograph, shows the general two-dimensional shape of these regions and indicates an intense strain at their junction with the epitaxial deposit. The figure also shows, in marked contrast, the relative absence of additional strain-induced effects in the epitaxial component of the deposit, the dislocation density nominally being the same as in undoped layers. To determine the three-dimensional shape, the deposits were sectioned. When viewed in cross section, the polycrystalline regions again appeared triangular, the vertex angles being extremely obtuse, *viz.*, $\sim$ 170° - 175° and the maximum thickness being $\sim$ 140μ.

To gain some measure of the carbon content of the polycrystalline regions, the deposits were annealed in hydrogen for 6 hr at 1050°C. In the thinned regions of the triangular areas, after the anneal there was complete conversion of the Si to SiC (both α and β-forms, $\beta > \alpha$), *i.e.*, the carbon to Si ratio was at least unity. In the epitaxial region of the deposit, the anneal had precipitated the small agglomerates shown in the micrograph, Fig. 2. This region had been, prior to anneal, devoid of any contrast producing objects. The agglomerates failed to give an electron diffraction pattern, but the originally high concentration of carbon suggests they are carbon precipitation out of solid solu-

Table I. Carbon content of silicon

Sample No.	Method of silicon preparation	Approximate dislocation density, No./cm^2	Carbon concentration in silicon, atoms C/cm^3	Macroscopic effects of carbon on surface
1	Bulk, float zone	10^5	5.1 x 10^{18}	None
2	Bulk, Czochralski	0	5.9 x 10^{18}	None
3	Epitaxial silicon from $SiCl_4$, undoped	10^2	2.3 x 10^{18}	None
4	Epitaxial silicon carbon doped $(C/Si)_g$ = 1/34	10^2	3.0 x 10^{18}	Polycrystalline areas
5	Epitaxial silicon from $SiCl_4$, carbon doped, $(C/Si)_g$ = 3/10	10^2	2.6 x 10^{19}	Triangular polycrystalline areas
6	Epitaxial silicon from SiH_4, undoped	—	9.3 x 10^{17}	None

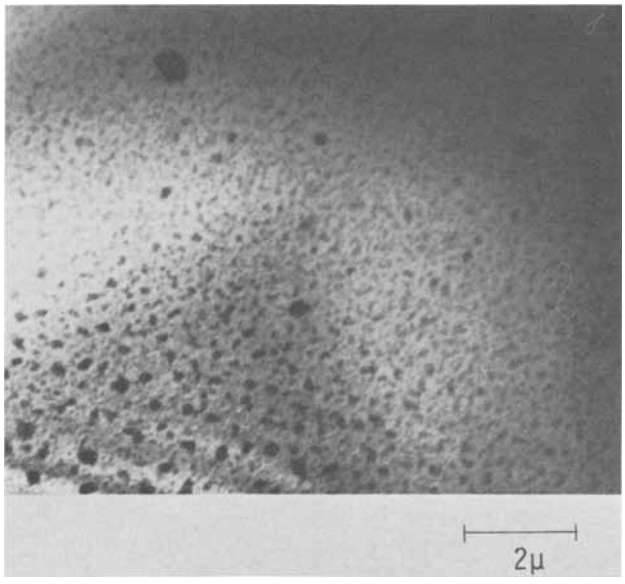

Fig. 2. Transmission electron micrograph of an annealed, carbon-doped, epitaxial deposit. Annealing temperature, 1050°C; depositing temperature, 1225°C.

tion. Resistivity measurements corresponded closely to those of undoped (carbon) deposits.

$(C/Si)_g = 1/2$.—Layers produced at this level of carbon doping mainly consisted of polycrystalline regions of Si and graphite; the epitaxial component of the deposit represented about 30% of the surface area. The polycrystalline regions possessed no simple geometric shapes. Average resistivities continued to be of the order of 30 ohm-cm.

$(C/Si)_g = 1$.—At $(C/Si)_g = 1$, the deposit was completely polycrystalline. Electron diffraction showed the presence of both Si and SiC. Spreading resistance measurements showed a marked increase in resistance at the onset of carbon injection. The resistivity up to the time of carbon doping was 30 ohm-cm; the equivalent spreading resistance is 3.5×10^4 ohms; after doping the spreading resistance rose to 10^6 ohms.

$(C/Si)_g = 5/1$.—The deposited layers at this doping level were completely composed of polycrystalline SiC, the average crystal size being 2000Å. Both α and β forms were detected, the latter form predominating. Spreading resistance measurements gave values greater than 10^7 ohms.

Discussion

The experimental results described above noted that carbon, chemically introduced during the epitaxial growth of Si, either (*i*) reacted to form SiC, or (*ii*) initiated the formation of mixed polycrystalline areas of Si and graphite, or (*iii*) might be incorporated in yet another way, *e.g.*, interstitially. Growths of both the SiC layers and of the unreacted polycrystalline areas were likely to have had similar beginnings, *viz.*, at pyrocarbon nuclei. The reduction of methane to carbon for methane concentrations equivalent to $(C/Si)_g > 1/8$ at 1200°C was based on thermodynamic calculations, *i.e.*, the input partial pressures of methane are equal to or greater than the equilibrium value. At 1200°C, SiC formation from $SiCl_4$, CH_4, and H_2 involves the reaction (8)

$$Si(s) + C(s) \rightarrow SiC(s)$$

and was observed in the present study for $(C/Si)_g > 1/2$. Its inhibition in the range, $1/8 < (C/Si)_g < 1/2$, however, was unexpected. Initial speculation linked the effect to the reaction kinetics and suggested a minimum carbon concentration below which SiC was not formed.

The generation of both reacted and unreacted polycrystalline regions from carbon nuclei was partly confirmed through measurements of the thicknesses of these deposits. Depths of the large triangular regions produced where $(C/Si)_g = 3/10$ corresponded to growth initiated during the deposition of the first few doped monolayers. Similar findings were noted for all ratios of greater magnitude; the few inclusions observed in layers where $(C/Si)_g$ had been 1/80 or 1/34 showed no such correspondence. The predicted pyrocarbon formation for $(C/Si)_g \geq 1/8$ thus coincided with the onset of polycrystalline layer formation. The presence of the small triangular regions (Fig. 1) demonstrated that some nucleation may occur at later stages of growth. Polycrystalline growth in lightly doped layers was regarded as a rare event.

An intriguing feature of the polycrystalline regions produced where $(C/Si)_g = 3/10$ was the pyramidal shape which they adopted. The three faces of the pyramid, inclined to the surface of the deposit, showed no simple crystallographic relationship with the surface plane. The bounding edges of the face parallel to the substrate surface, however, aligned themselves along the three <110> directions common to the adjacent epitaxial (111) surface. A possible explanation considered is the packing of newly arrived Si and C atoms. Close packing of atoms on the original Si(111) surface occurs along equivalent <110> directions. Surface steps of atomic dimensions generally lie along these directions. Si atoms engaged in forming an epitaxial layer favor such steps as nucleation sites, hence align themselves along them (and the <110>'s). If a foreign element, *e.g.*, carbon, was interposed during the Si buildup and was able to assimilate the others of its species, a region, out of register with the epitaxial Si, would be formed. The subsequent build-up of such a region is that of an expanding island bounded by Si atoms, the latter favoring <110> alignment. It was only fortuitous that the triangular shape of the island was maintained for the $(C/Si)_g$ ratio of 3/10, the necessary condition being some critical balance between the island's expansion rate (the ability of the island to inhibit epitaxial growth) and the rate of Si arrival. A more rapid Si arrival might contain the island within a given surface area, then begin to overlap and give it a roughly circular shape. A slower Si arrival rate would allow the island to spill over. Since the ratio between the Si arrival rate and island formation rate were functions of the respective partial pressures of Si and of the carbon impurities, the results of the present experiments contained examples from both sides of the critical condition. To a first approximation the results seemed consistent.

In the bulk Si, the carbon concentration occasionally exceeds the predicted solubility limit. In epitaxially deposited Si, a controlled carbon excess can be introduced which may be several orders of magnitude greater than the solubility limit. Presumably there is physical trapping of carbon during the rapid growth of an epitaxial deposit if deposition occurs in a carbon-bearing atmosphere (a number of metals are known to trap inert gases) (9, 10). Equilibrium processes dissolve carbon into the Si lattice up to the solubility limit. Any excess trapped carbon is then, for practical purposes, retained interstitially if it fails to (*i*) form SiC, or (*ii*) diffuse and segregate with other carbon atoms. Since neither SiC nor carbon precipitates were observed in deposits which nevertheless contained excess carbon, interstitial accommodation of carbon is inferred.

Conclusions

The carbon content of bulk silicon substrates as measured by the method described here agrees well with those reported by Schink. Epitaxial silicon layers are found to have concentrations of carbon in excess of the substitutional solid solubility limit. These concentrations are determined by the epitaxial growth conditions, *viz.*, partial pressure of methane, and a continuous range of carbon concentration between

pure Si and SiC seems attainable. The crystalline perfection of the epitaxial layer is not affected by the presence of carbon in concentrations up to 10^{18} atoms/cm^3. At levels of carbon concentration near 10^{19} atoms/cm^3 many polycrystalline inclusions are formed with only a small increase in the dislocation density. The presence of a mixture of graphite and Si is observed by transmission electron diffraction from the polycrystalline regions. These regions are converted into SiC by appropriate postdeposit annealing schedules. In the presence of excess methane, thin partially oriented layers of both α and β-SiC are grown. Annealing of epitaxial regions results in the formation of numerous microprecipitates, attributed partly to the precipitation of excess carbon from solid solution. In undoped deposits, an order of magnitude excess of carbon, together with the absence of observable precipitates of carbon or SiC, implies the presence of interstitial carbon. Electrical properties such as resistivity are not affected by increasing concentrations of carbon until the onset of SiC formation.

APPENDIX

Determination of Carbon in Silicon

A new technique is used for carbon analysis in Si. Carbon content is determined by measuring concentrations of CO_2 with a Leco (Laboratory Equipment Corporation) low carbon analyzer. Initially, a Si specimen is burned together with several combustion accelerators in oxygen in an induction furnace. The Si combusts at temperatures greater than 1670°C, all the carbon being oxidized. A catalyst furnace converts residual CO into CO_2. The gas is dried by passing it through anhydrous magnesium perchlorate, then swept into a collection trap. After a predetermined collection interval, the trap is isolated, then heated. The heated CO_2 is swept out of the trap by a stream of helium into a thermal conductivity cell. The output of the cell, amplified and integrated, gives a measure of the carbon content.

The accelerators which are used include lead chromate and iron chip. These are preburned in a ceramic crucible to minimize their inherent content. When the Si sample is to be burned, excess iron chip, of the order of 1.5-2.0g per 0.3g of Si, is added to the preburned accelerators. The excess iron chip yields 12-16 μg of carbon on burning. By assuming conservatively that a 3 μg increase, over the amount introduced by the excess iron chip, can be detected accurately by the apparatus, and by restricting the weight of Si to at least 0.3g, a reasonable lower detection limit of carbon in Si is 20 ppma. The method is reproducible within 10%.

A comparison of results obtained by chemical analysis with those from infrared data (measuring only substitutional carbon) on a Si specimen containing carbon showed the following: carbon (chem) ~ 47 ppma; carbon (I.R.) ~ 13 ppma measured by the Dow Corning Corporation, Hemlock, Michigan; carbon (I.R.) ~ 17 ppma measured in this laboratory at liquid nitrogen temperature using the calibration curve of Newman and Willis.[1]

Technical Notes

RF Sputter Etching—A Universal Etch

P. D. Davidse

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

Photosensitive resists are widely used to define patterns that are to be etched in thin films. The definition obtained depends on the quality and adhesion of the resist film, the nature of the material to be etched, and the etchant used. With materials that are difficult to etch, strong chemicals are needed, which often results in a degradation of the resist adhesion, leading to a high degree of undercutting. In some cases, the adhesion of the resist to the surface can be improved considerably by surface treatments or by applying a so-called conversion coating (1), thus reducing the degree of undercutting. However, because chemical etching proceeds in all directions, there will always be some undercutting. An oversimplified comparison of etching profiles is given in Fig. 1.

D-C sputtering has been used for etching of metals to bring out their grain structure (2). For this, the sample to be etched is made the cathode of a conventional d-c glow discharge. With this method, it is also possible to etch insulators by depositing on the insulator a metal stripe or grid pattern (or by placing a metal grid on the insulator) to which the cathode voltage is applied (2). The spacing between the metal lines has to be small, since neutralization of the accumulated positive charge on the exposed insulator surface takes place by secondary emission from the metal lands. This method is limited also because nonuniform etching of the insulator material takes place due to a focusing effect and because metal sputtered from the metal line patterns can be deposited on the exposed

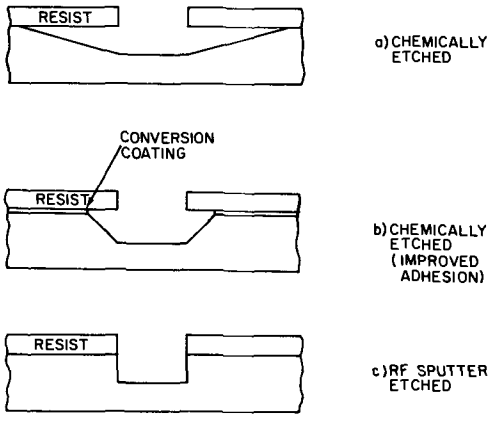

Fig. 1. Etching profiles (simplified)

insulator surface (3). Therefore, this method has been used mainly for the study of the structure of insulators. Similar studies have been made using an ion beam, with which alumina and fused silica were etched (4).

D-C sputtering can be used successfully to etch metal line patterns by using a thicker metal film as a mask. This method's drawbacks are the possibility of arcing between isolated lands and the possibility of dielectric breakdown of insulator films when they are present in the structure to be etched (5). Another disadvantage of the d-c sputtering method is that an extra film deposition and chemical etching step is needed to produce the desired metal mask pattern. These limitations do not exist with the method which is the subject of this publication. With RF sputter etching it is, in principle, possible to etch patterns or holes in any metal, semiconductor, or insulator using standard photoresist materials as masks.

Apparatus

Figure 2 shows a system used for RF sputter etching. The samples are placed on a circular electrode that is mounted on the base plate of a bell-jar vacuum system. This electrode is similar to the electrode used for the deposition of insulator films by RF sputtering (6). After the system has been evacuated, argon is bled in to obtain a pressure of from 2 to 15 x 10^{-3} Torr. A glow discharge is then started by applying RF power to the electrode. The RF power supply is capacitively coupled to the electrode to allow the build-up of a negative d-c bias on the front of the electrode, hereafter referred to as the "cathode." The self-biasing effect is caused by the difference in electron and ion mobility and is necessary to affect sputtering.

The power supply was a crystal-controlled 1 kw amateur radio transmitter with a frequency of 13.56 MHz. The progress of the sputter etching can be followed by observing the removal on a monitor sample or by determining the etch rate or etch time in a trial run.

Although a grounded counter electrode or "anode" parallel to the RF electrode can be used, operation is simplified by its omission, which only slightly lowers the removal rate. Without the "anode," the samples can be more readily observed during the experiment, and the system is easier to load and unload. The basic character of a glow discharge system is not changed because of the presence of many grounded metal parts in the system, *e.g.*, the baseplate and the cathode shield. Because the metal cathode itself is also sputtered, the bell jar will be coated very quickly with a metal film, thus making observation of the samples difficult. This problem can be greatly reduced by placing the samples on a fused quartz plate that rests on the cathode. However, as will be discussed later, it is desirable to keep the samples reasonably cool, which can be more readily achieved when the samples are placed directly on the water-cooled metal electrode. In this case, a fused quartz plate with cut-outs for the samples can be placed on the cathode.

The cathode, which has a diameter of 8¾ in., can hold nineteen 1¼ in. silicon wafers. These wafers are placed in a hexagonal configuration, *i.e.*, one wafer in the center surrounded by two concentric hexagons of six and twelve wafers each. The wafer-to-wafer variation in removal rate was generally less than 2%.

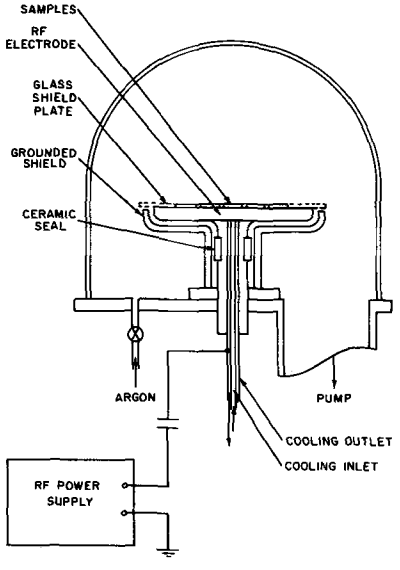

Fig. 2. RF sputter etching system

Experimental

With this etching technique, land patterns or holes have been etched in thin films of the following materials: aluminum, tantalum, Cr-SiO, nichrome, silicon nitride, and RF sputtered and thermally grown silicon dioxide. Film thickness ranged between 500 and 20,000Å.

RF sputter etching has been found to be especially useful for the etching of Cr-SiO films to make thin film resistors. Figure 3 illustrates the procedure to make such resistors. A 1000-2000Å-thick Cr-SiO film is evaporated (7) onto the substrate, followed by the deposition of the contact metallurgy. Next, a photoresist film is applied, the required contact land pattern is developed, and the exposed metal film is etched away (Fig. 3a). Subsequently, a second layer of photoresist is applied, and the resistor pattern is developed (Fig. 3b). At this point, exposed resistive material would normally be etched away chemically. However, chemical etching is difficult with Cr-SiO films, especially when the SiO concentration is high. Very strong chemicals have to be used, which often results in ill-defined edges and attack of the contact metallurgy. These problems do not exist when the exposed cermet is removed by subjecting the sample to RF sputtering (Fig. 3c), after which the photoresist is removed (Fig. 3d).

Figures 4 and 5 illustrate the good definition that can be obtained with this method. The substrates used were 1¼ in. silicon wafers precoated with a 1.5μ-thick film of RF sputtered silicon dioxide. The pattern

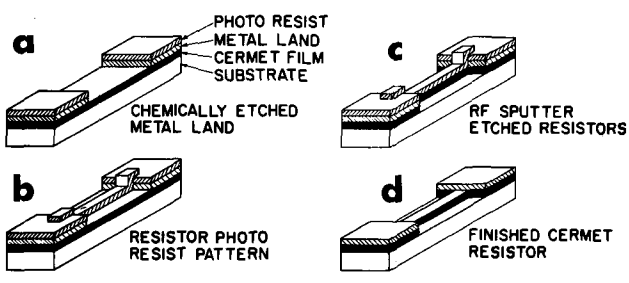

Fig. 3. Sputter-etching of thin-film resistors

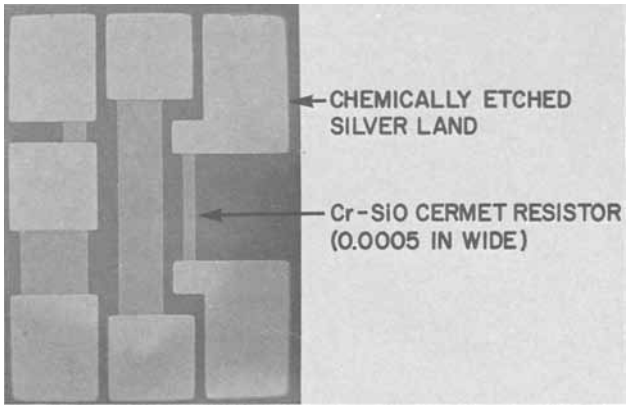

Fig. 4. RF sputter etched Cr-SiO cermet resistors (substrate: silicon wafer precoated with 1.5μ of RF sputtered SiO_2).

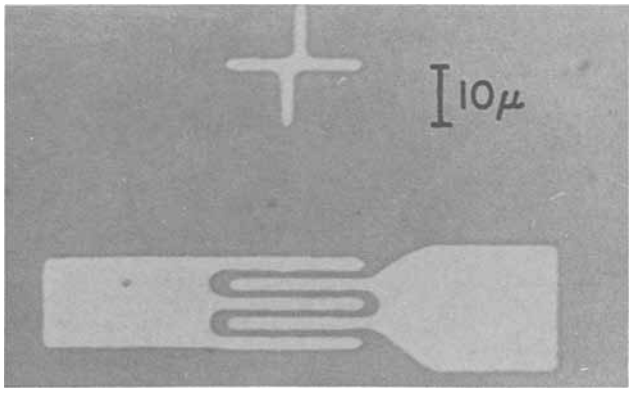

Fig. 5. Fine-line test pattern

shown in Fig. 4 was a unit cell of which there were more than 1200 on each wafer; Fig. 5 shows a fine-line test pattern.

The resist used was KTFR (Kodak Thin Film Resist). Since in RF sputter etching the resist material is also sputtered, it is necessary that the resist film be thick enough to last through the sputter etching. Figure 6 shows the removal rates for various materials as a function of RF power. The KTFR removal rate at a given power level was found to be comparable to the rate for the materials that were etched. As indicated in Fig. 6, this rate is considerably higher for what were believed to be incompletely cured resin films. Later experiments showed that the relatively high removal rate in this case was more likely associated with the presence of relatively high concentrations of reactive gases, such as oxygen and hydrogen, in the sputtering atmosphere. Deliberate addition of these gases was found to give a very high photoresist removal rate with a simultaneous lower removal rate for inorganic materials, thus making this a means for photoresist removal. It has also been found that the photoresist removal rate is strongly dependent on the sample temperature during sputter etching, as expected. The removal rate for a photoresist pattern was generally found to be lower than the rate for a continuous resist film. Similar observations were made when positive resists were used. Removal of the resist after sputtering was found to be somewhat more difficult than usual; however, standard stripping techniques could still be used, *i.e.*, stripping in a J-100 solution followed by rinsing with or without the use of a cotton swab.

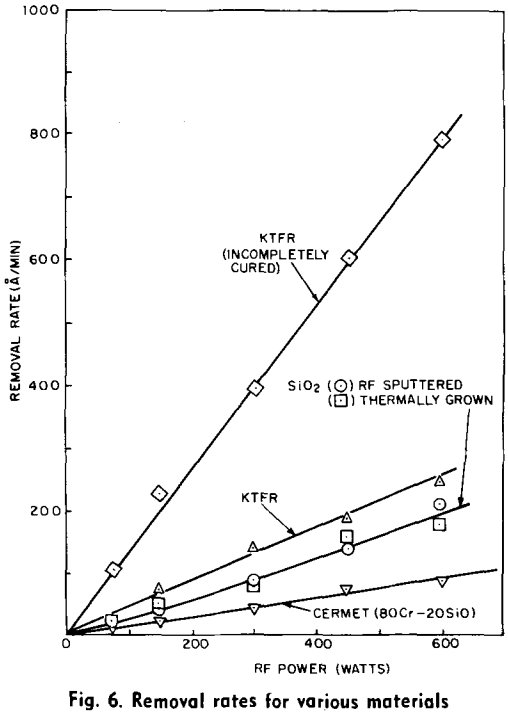

Fig. 6. Removal rates for various materials

In all the experiments, the wafers were mounted on the water-cooled cathode using a high-vacuum grease to provide good thermal contact. Without good contact, extensive degradation of the resist takes place at high power levels. Occasionally, even with good thermal contact, spots have been observed in the resist film after sputtering. However, after removal of the resist, no evidence of spots could be seen on the underlying films.

When the photoresist is incompletely developed, some resist material is left behind at the edges. These "feathered" edges and any debris that is left on the material to be etched are cleaned up during the sputtering operation.

Figure 7 illustrates the sharpness of a step sputter etched in silicon, indicating that absence of undercutting can be achieved. It should also be noted that the polishing marks on the original surface have been smoothed out where material has been removed.

Discussion

The two main advantages of RF sputter etching are, obviously, its universality and the absence of undercutting. The former feature allows the evaluation of new materials for device applications without having to search for suitable etchants first. Once device feasibility has been demonstrated, efforts can be made to find satisfactory chemical etchants. A disadvantage of

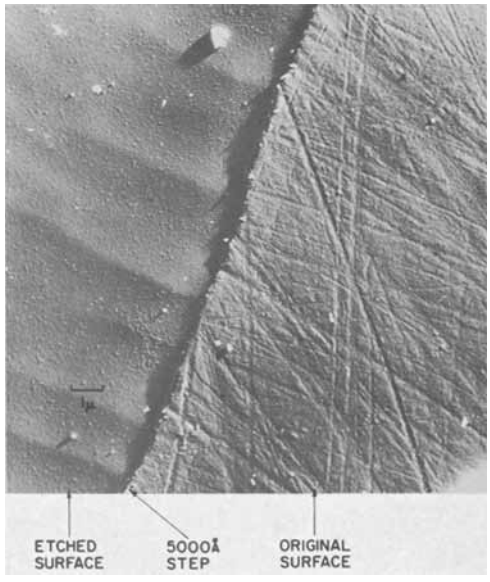

Fig. 7. RF sputter etched step in silicon showing absence of undercutting.

this universality is that the etching continues after the material of interest has been removed. Therefore, careful monitoring of the etching process is necessary. The absence of undercutting is an especially desirable feature where dimensional control is necessary, *e.g.*, precision thin film resistors.

Because the photoresist material is also removed by RF sputter etching, the technique is of practical interest mainly for films that are relatively thin, *i.e.*, several microns or less.

Conclusions

RF sputter etching is a practical technique that can be used in semiconductor and thin film studies. It allows the etching of virtually any material using standard photoresist materials and techniques to define the areas that are to be etched. This characteristic and the absence of undercutting are the attractive features of the technique.

Acknowledgments

The author is greatly indebted to L. R. Koster for his significant contributions in the first phase of this work. He would like to thank Miss M. H. Whitehill for her assistance with the photoresist work and J. J. Van Steenburgh for his assistance with some of the sputtering experiments. He is grateful to C. S. Standley and D. P. Cameron for Fig. 7.

Transmission Electron Microscopy of As-Grown PbSe Single Crystals

H. Abrams* and R. N. Tauber

Department of Metallurgy and Materials Science and the Materials Research Center, Lehigh University, Bethlehem, Pennsylvania

The preparation of thin foils of the compound semiconductor PbSe for transmission electron microscopy has not been reported previously. This note describes the preparation technique and some observations made on as grown thin foils of PbSe.

Single crystals were grown by the Bridgman-Stockbarger technique in an evacuated capsule, containing a molten charge of nominally stoichiometric PbSe. The growth conditions were 6°C/cm temperature gradient through the reported melting point of 1065°C (1) and a lowering rate of 2 mm/hr. These conditions resulted in single crystal PbSe having a dislocation density measured by standard etch pit methods (2) of approximately 6 x 10^6 cm^{-2}. Slices cut with a {100} orientation were thinned for electron microscopy using the following procedure.

Thin foils which may have had surface contamination were prepared using the material removal etch reported by Coates *et al.* (3). After polishing the specimen on both sides with 600 grit silicon carbide to a thickness of about 300μ it was immersed in a solution consisting of 5 volumes of 45% aqueous KOH, 5 volumes of ethylene glycol, and 1 volume of 30% H_2O_2. The solution was maintained at room temperature and agitated with a magnetic stirrer. A relatively uniform bright surface was obtained within a few minutes, and it took from 3 to 6 hr to thin down to a thickness of about 1μ. The polishing rate decreased with time due to depletion of the H_2O_2. However, the solution could be reactivated by the addition of H_2O_2, thereby increasing the polishing rate. When the solution loses its polishing ability it turns a pale yellow color. A highly polished surface and removal of yellow-brown surface stains was achieved by immersing the sample in a 1:1 acetic acid-water solution for a few seconds and then rinsing in deionized water. The 1μ thick sample was then mounted on a Teflon block using apiezon wax and polished for an additional 8 hr. The sample became progressively smaller and thinner until a suitable foil was obtained. The sample was floated off the Teflon holder in reagent grade trichloroethylene, rinsed in deionized water, and mounted on a copper grid for observation in a Hitachi 11B electron microscope, operated at 100 kv.

Figure 1 is a diffraction pattern of a {100} orientation for an as grown PbSe specimen. The most prominent extra diffraction spots (points A and B) correspond to a d spacing of 2.83Å. This value is in error less than 3%, since the PbSe pattern was used as an internal standard. This d spacing corresponds closely to the (111) d spacing (2.855Å) of Pb. Also it could possibly arise from a (200) reflection of Pb_2O_3

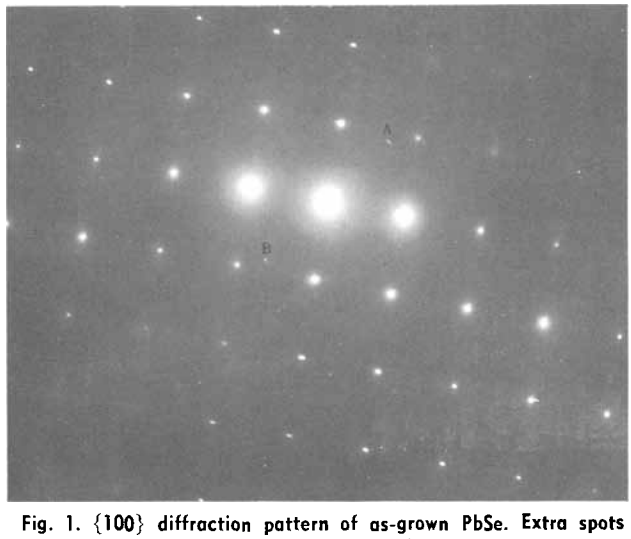

Fig. 1. {100} diffraction pattern of as-grown PbSe. Extra spots at points A and B may be due to precipitated Pb.

* Electrochemical Society Active Member.

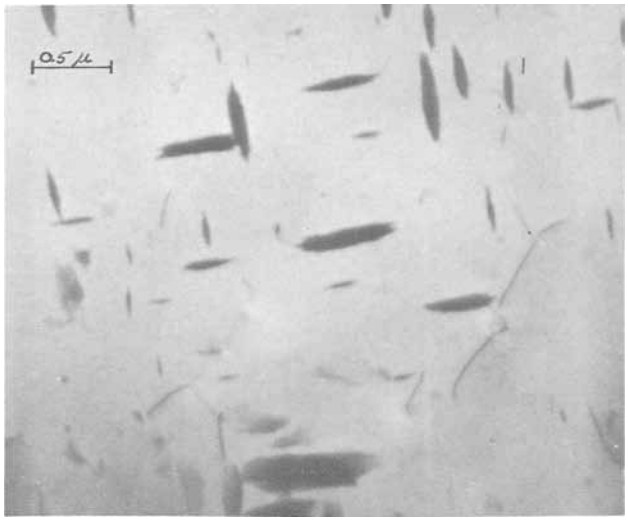

Fig. 2. Transmission electron micrograph of as-grown PbSe. Particles on the order of 0.6 x 0.15 μ, oriented in a <100> direction are observed.

(2.75Å) or a (210) reflection of $PbSeO_3$ (2.735Å), either of which may have deposited on the surface during the thinning procedure. Additional weak spots can be attributed to both Pb and $PbSeO_3$.

An electron micrograph of a region of the as grown PbSe foil is shown in Fig. 2. The micrograph shows about 10 v/o of ellipsoidally shaped particles on the order of 0.6 x 0.15μ, oriented in a <100> direction. It is difficult to determine the exact shape of these particles since they may be inclined to the plane of the foil. The Widmanstatten pattern formed by these particles indicates that they grew by a diffusion limited precipitation process. Relating these particles to the extra diffraction spots reveal they may be due to Pb. Precipitation of Pb can occur in PbSe (4), due to the retrograde nature of the Pb solidus boundary (5). However, in accordance with the PbSe phase diagram near stoichiometry (5, 6) the amount of precipitate should be several orders of magnitude less than that observed here. In order to account for the large volume fraction of second phase observed, either the retrograde solubility is much larger than has been previously reported or the specimen grew nonstoichiometrically. The latter is more plausible since some of the more volatile Se component may have been lost during the growing procedure.

The presence of a two-phase structure has important implications for use of this semiconductor in electronic applications. Further experiments are in progress to ascertain what growth conditions lead to the observed two-phase structure.

Preparation of $Cd_xHg_{1-x}Te$ Crystals by the Vertical-Zone Melting Method

E. Z. Dziuba

Institute of Physics, Polish Academy of Sciences, Warsaw, Poland

The solid solution system $Cd_xHg_{1-x}Te$ has become in recent years an object of intensive scientific research (1) in view of its interesting electrical and optical properties and related theoretical considerations as well as the theory of its energy band structure. A wide range of the variation of the electrical and optical properties makes this material also interesting from a practical point of view (2).

Material obtained by the methods described in the publications (1) does not satisfy the basic requirements of homogeneity of the crystals. Crystals obtained by the Bridgman method have high gradients of composition due to strong segregation into individual components during the solidification process (3). Difficulties in preparing a homogeneous and single-crystalline solid solution $Cd_xHg_{1-x}Te$ are connected with the strong tendency toward segregation and the high mercury vapor pressure.

It is known that the Bridgman method makes it possible to obtain single-crystalline homogeneous material, provided that the segregation can be prevented. Low vapor pressure of the components is not essential in this method, as it is in the horizontal-zone melting method which can also be used for preparing materials which have a tendency toward segregation. It is also possible to use the horizontal-zone melting method for other materials for which the equilibrium condition between vapor, liquid, and solid phases is known (4).

The method of preparing homogeneous single-crystalline $Cd_xHg_{1-x}Te$ alloys described in this work combines benefits of both the Bridgman and horizontal-zone melting methods. This method, although it is very similar to the method used for purification and crystallization of CdTe (5), embodies more complicated phenomena but simpler operating conditions. Both methods consist of pulling the material through a hot zone in a vertically arranged quartz tube. The difference lies in the presence of an empty space in a part of the tube[1] in the method presented in this paper, whereas in the method given in paper (5) the tube is full of charge.

The preparation of homogeneous $Cd_xHg_{1-x}Te$ crystals, the discussion of the operating conditions, and the description of the experimental arrangement are presented in this paper. The $Cd_xHg_{1-x}Te$ solid solutions were prepared from high-purity HgTe and CdTe obtained previously (7, 8). The appropriate quantity of HgTe and CdTe is placed into the quartz container

[1] The method given in paper (9) also contains an empty space in the tube. As the part containing the empty space is kept at room temperature, mercury vapor transport occurs to this part. This method therefore cannot be used with $Cd_xHg_{1-x}Te$.

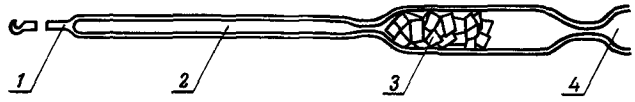

Fig. 1. The quartz arrangement for tightly filling the tube: 1—holder, 2—tube, 3—container, 4—vacuum.

connected to a quartz tube as shown in Fig. 1. After evacuation, both container and tube are sealed off from the vacuum apparatus and put into a horizontal heater having a temperature of about 650°C. The heater temperature is raised to the melting point of the $Cd_xHg_{1-x}Te$ composition in about 24 hr. This process is necessary in order to avoid the danger of explosion due to high mercury vapor pressure which occurs when the liquid phase, rich in mercury component, is present (6).

After the solid CdTe is completely dissolved into the liquid system, the heater, together with the quartz arrangement, is turned to a vertical position to charge the tube. The tube with liquid $Cd_xHg_{1-x}Te$ is removed from the heater for quick solidification and cut off from the container. As an empty space of about 1 cm^3 is present in the tube in the region of the tube-container junction, no other additional operations for cutting off the tube from the container are necessary.

The quartz tube, tightly filled with the macroscopically homogeneous polycrystalline $Cd_xHg_{1-x}Te$, is placed vertically in a furnace having its hot zone wider than the length of the empty part of the tube (Fig. 2). Starting with the tube partly empty, it is lowered through the hot zone.

After the pass of the tube, there are three parts to the ingot: the first part in which the composition of the crystal changes from x' to x_0, the second part (the longest) in which there is a constant composition of $x = x_0$, and the third part in which the composition changes from x_0 to $x = 0$.

Fused at T_0°K in the upper part of the hot-zone, 2 (Fig. 2), the melt flows down and forms the liquid phase, 4. The crystal, 5, grows from this melt.

In the first part, due to segregation (Fig. 3) the crystal with the composition x' grows from the melt

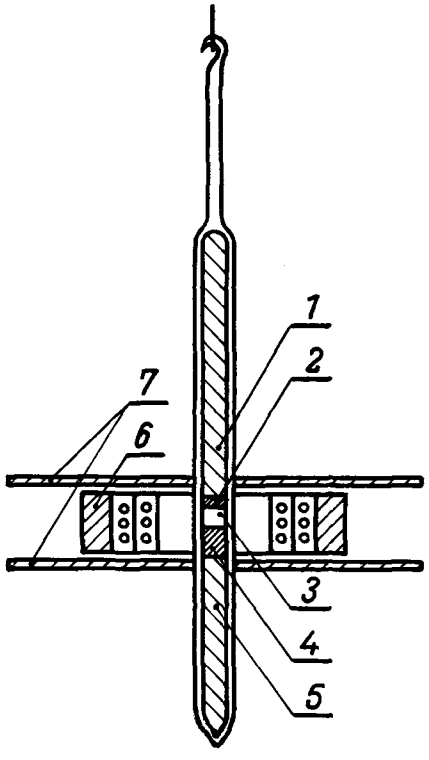

Fig. 2. The principle of arrangement for preparation of single crystals of $Cd_xHg_{1-x}Te$: 1 and 5—solid, 2 and 4—liquid, 3—vapor, 7—ceramic shells, 6—heater.

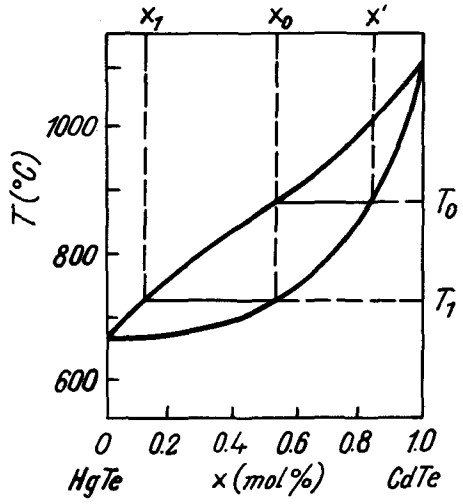

Fig. 3. The solidus-liquidus diagram for $Cd_xHg_{1-x}Te$ (3): x_0, composition in dynamic steady state; x' and $x = 0$, the composition at the start and at the end of the process; x_1, composition of the melt in dynamic steady state; T_0, melting point, and T_1, solidification point in dynamic steady state.

with the composition x_0. This causes the change of the composition of the liquid phase, 4, from x_0 to x_1.

In the second part, in dynamic equilibrium, the composition of the crystal in the lower part of the tube, 5, must be equal to the composition of the material in its upper part, 1, because the melt with the composition x_0 flows down and compensates for the decrease of the value of the components, due to the crystallization process. In this equilibrium condition, the composition of the liquid phase in the lower part of the tube, 4, changes from x_0 at the surface to x_1 at the bottom of the liquid volume.

In the third part, at the end of the crystallization process when the hot zone has reached the upper end of the tube, the liquid phase there is not compensated and, due to segregation, the crystal grows with various compositions from x_0 to $x = 0$.

In the equilibrium condition, in the second part of the ingot, the gradient of the composition of the liquid phase, 4, has constant slopes if all parameters, such as speed of the tube, the temperature of the hot zone, and the transport of the material from the upper, 2, to the lower, 3, part of the tube, are constant. The speed of the tube and temperature of the hot zone are easy to control, but the transport of the material from the upper to lower part of the tube is difficult to control. If the material flows down in the form of large drops, local changes in the composition of the liquid phase, 4, are produced. If, however, the temperature of the vapor phases, 3, are sufficiently high, the transport of the material from the upper to lower part of the tube occurs by small drops or by evaporation. To preserve these phenomena, it is necessary to maintain the high temperature of the hot zone and large gradient of temperature in the upper and lower parts of the hot zone.

The apparatus which was used to obtain the $Cd_xHg_{1-x}Te$ crystals is shown in Fig. 2. The tube, about 12 cm long and having a 7-mm inner diameter and a 10-mm outer diameter, is lowered at a constant rate, 5 mm/hr. The hot zone, about 2 cm long, is produced by resistance heater and two ceramic shells. To maintain the hot-zone temperature constant, the current supplying the heater is controlled. The magnitude of the current was established by direct observation of the melting process when the tube was starting to move. This observation of the melting process is possibly due to the empty part of the tube and required no other additional experiments.

Direct observation of the reflection from the ingot surface in visible light established that the prepared material consisted of several large single crystals. The

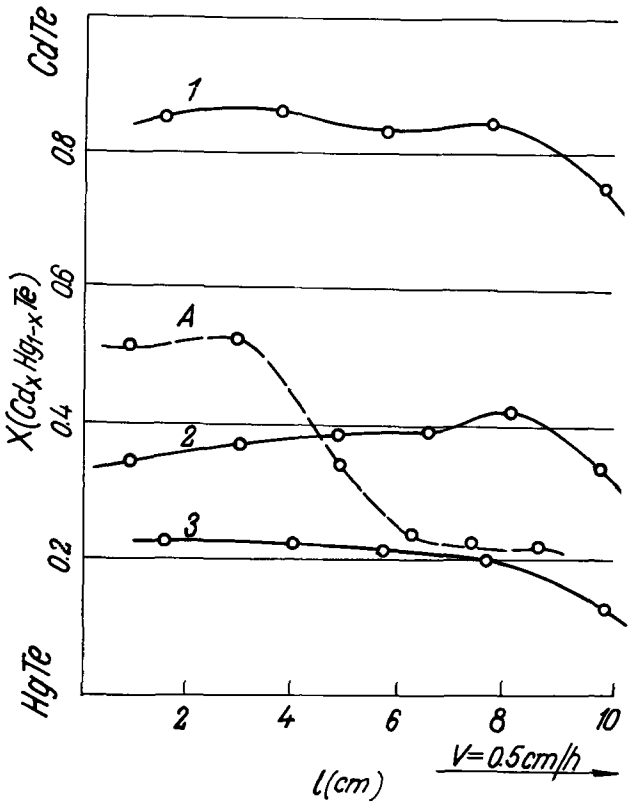

Fig. 4. Distribution of the $Cd_xHg_{1-x}Te$ alloy composition along the ingot.

ingot was cut into samples of about 20 mm length. The average composition of each sample was determined by estimating its density as described in Ref. (8). This method is very simple; and, due to linear variation of the density from $\rho = 8.1$ g/cm³ for HgTe to $\rho = 5.9$ g/cm³ for CdTe, the precision of the measurements is sufficiently high to allow the determination of the composition of the $Cd_xHg_{1-x}Te$ system to within less than 1% (8).

The average composition of the typical samples as a function of their position in the ingot is shown in Fig. 4. It is evident from Fig. 4 that the segregation is not observed over a large portion of the ingots. The change in the composition due to segregation appears only in the third part of the ingot where the liquid phase in the lower part of the tube was not compensated by the material flowing from the top downward. To determine the influence of the fluctuation of the hot-zone temperature on the composition of alloy, the temperature of the hot zone was lowered while pulling the tube. The result is shown in Fig. 4, curve *A*. It can be seen that a large change in the composition occurs in the region grown while the temperature was lowered. It is therefore possible that the fluctuations in the composition along the ingots, as seen from curves 1, 2, and 3 in Fig. 4, are mainly due to the instability of the hot-zone temperature.

Acknowledgments

I wish to express my gratitude to Professor L. Sosnowski for his research guidance and interest and to Drs. J. Baranowski, E. Cruceanu, R. R. Galązka, A. Jendrzejczak, A. Mycielski, and N. Niculescu for their assistance and discussions in the course of this work.

Three-Point Probe Heating Effects in Silicon

P. A. Schumann, Jr.,* J. F. Hallenback, Jr., M. R. Poponiak, and C. P. Schneider

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

The three-point probe (1-9) is a useful tool for the evaluation of the resistivity of semiconducting epitaxial layers deposited on substrates of the same conductivity type. Its main advantage is that it is relatively easy to set up and operate. It also is one of the few "nondestructive" techniques to measure layer resistivity. It has the disadvantage of being imprecise and having a short life.

The short life of the probe is due to the extreme thermal conditions that exist under the probe at breakdown, conditions so severe that the silicon can even be melted. This short life increases the imprecision, of which a major part is due to wear of the probe and resultant drift. The older d-c and a-c methods (1-4) were most severe on the probe. However, newer techniques involving pulse (6) or rapid shut-off (8) systems have improved this situation.

Three-Point Probe Heating Effects in Silicon

P. A. Schumann, Jr.,* J. F. Hallenback, Jr., M. R. Poponiak, and C. P. Schneider

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

The three-point probe (1-9) is a useful tool for the evaluation of the resistivity of semiconducting epitaxial layers deposited on substrates of the same conductivity type. Its main advantage is that it is relatively easy to set up and operate. It also is one of the few "nondestructive" techniques to measure layer resistivity. It has the disadvantage of being imprecise and having a short life.

The short life of the probe is due to the extreme thermal conditions that exist under the probe at breakdown, conditions so severe that the silicon can even be melted. This short life increases the imprecision, of which a major part is due to wear of the probe and resultant drift. The older d-c and a-c methods (1-4) were most severe on the probe. However, newer techniques involving pulse (6) or rapid shut-off (8) systems have improved this situation.

* Electrochemical Society Active Member.

The data presented in this paper were taken with a modified Dumas probe reported on earlier (4), operating at a load of 35 g/point. The points are steel with a radius of curvature of 0.001 in. A description of the measurement electronics is presented in a recent publication (8).

The forming of point contact diodes is a well-known phenomenon (10). Its relation to the three-point probe has not been discussed in the literature. Figure 1 shows the change in the shape of an I-V curve for a three-point probe taken with half-wave rectified 60 Hz power supply. When the current is first applied, the curve looks as shown in Fig. 1a. Then, as the current is increased (1b and 1c), the curve balloons out, increasing the breakdown voltage and decreasing the current necessary to achieve breakdown. This effect can contribute to imprecision if the measurement procedure is not precisely duplicated. Once an appropriate forming

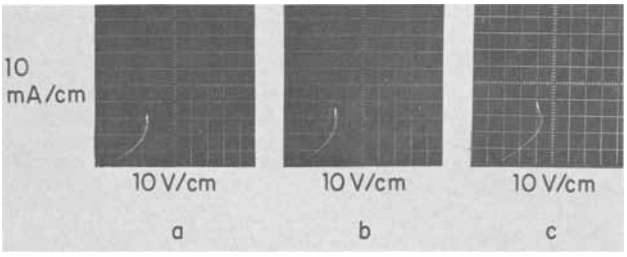

Fig. 1. AC I-V characteristics

action has taken place, the curve may be retraced with no change in the characteristics. If too much current is applied, however, the breakdown will drop to a lower value, and retracing will not bring the voltage up to its original value.

For most of the point radii and loads used (1-7), the silicon under the point is plastically deformed. If an electrical breakdown is achieved and the surface of the silicon is examined, however, a very different effect is observed, depending on the electrical conditions under which the measurement is made. Figure 2 is a micrograph showing the area under all three points after a breakdown has been measured with a d-c system (4). The damage under the voltage probe is purely mechanical, but that under the forward and reverse biased probes is a combination of mechanical and thermal. The diameter of the center damaged area is about 25.0 μm and that of the large ring is about 115.0 μm. The center damaged area has the appearance

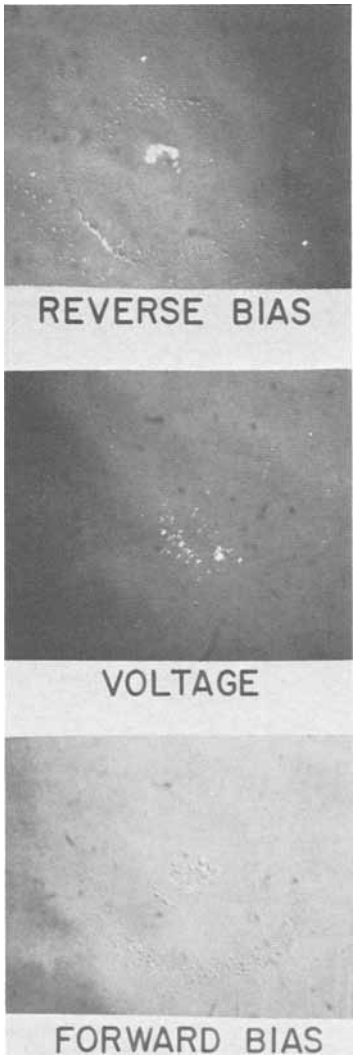

Fig. 2. Damaged area under all three probes after breakdown. Magnification *ca.* 200X.

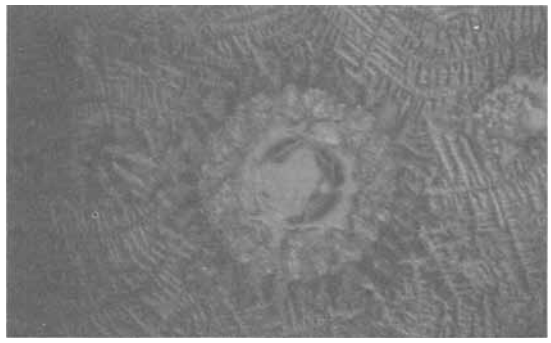

Fig. 3. Melted area under reverse biased probe with d-c breakdown system. Magnification 560X.

of having been melted. There seems to be very little difference between the forward and reverse biased points.

Photographs taken of the damaged area on silicon surface under the reverse biased point can be used to indicate heating effects. Figure 3 shows the melted region under the reverse biased probe for a d-c system, which is the worst offender. This is an extreme case, showing recrystallization of the silicon in a dendrite structure. The diameter of the center hole is 74 μm and that of the larger circle is 46 μm. Figures 4 through 6 show the effect on silicon measured using a d-c ramp with rapid shut-off (8), contrasted with a repetitive-pulse technique with pulse widths of 100 and 1 μs. Figures 7 and 8 show the effect for a single-pulse system, with the same pulse widths as above.

It is easy to see that a reduction in the pulse width or duty cycle reduces the damage to the silicon. Although there is some difference between the single-pulse and repetitive-pulse system, the difference is not great. Also it is clear from the damaged area under the rapid shut-off system that the time spent at breakdown is important. In this case the shut-off occurs in

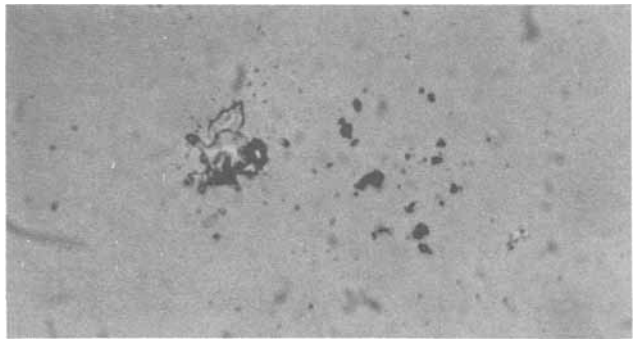

Fig. 4. Damaged area under reverse biased probe on d-c breakdown system with electronic shut off. Magnification *ca.* 225X.

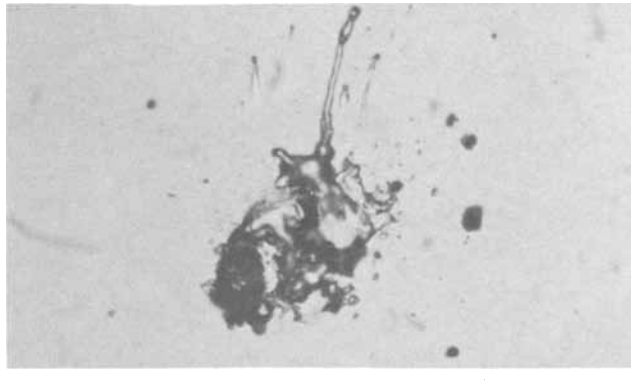

Fig. 5. Damaged area under reverse biased probe by a pulsed three-point probe with a repetition rate of 100 pulses/sec and a pulse width of 100 μsec. Magnification *ca.* 225X.

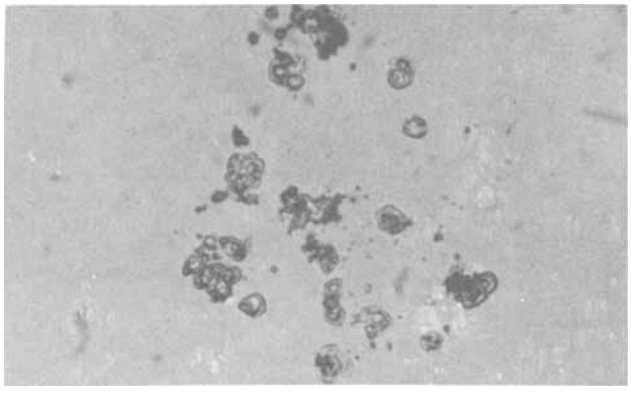

Fig. 6. Damaged area under reverse biased point for repetition rate of 100 pulses/sec with a pulse width of 1 μsec. Magnification ca. 225X.

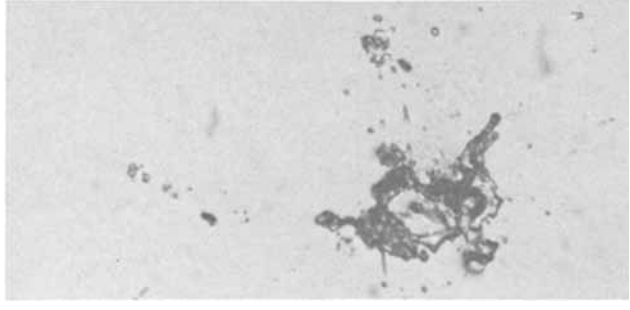

Fig. 7. Damaged area under reverse biased point for single-pulse system with a pulse width of 100 μsec. Magnification ca. 225X.

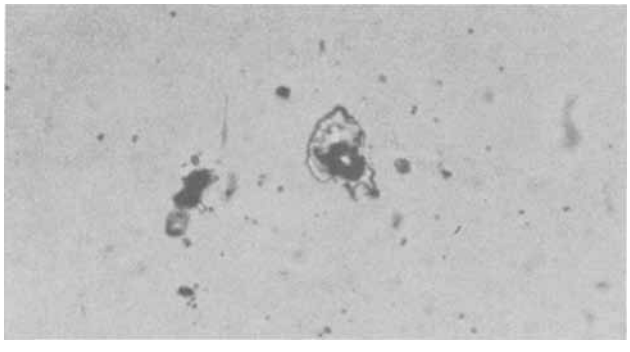

Fig. 8. Damaged area under reverse-biased probe for single-pulse system with a pulse width of 1 μsec. Magnification ca. 225X.

about 1 μ sec after breakdown is reached. The damage for this system is equivalent to that of a pulse system with a pulse width of 1 μsec.

Several breakdown voltage levels are obtained in a typical sample, as shown in Fig. 9. Here the breakdown voltage as a function of time is plotted for a single-pulse system. The structure of the trace is not completely understood, but the second level is probably similar to thermal breakdown and the third level due to melting of the sample. Similar results, although on a larger time scale, were reported by Agatsuma (11) for point contact diodes.

A further complication to the pulse technique is demonstrated in Fig. 10. A repetitive-pulse technique was used with a pulse rate of 15 Hz. A sampling scope was used to read the peak voltage. The oscillator had a peak output of 200v, with a 50 ohm termination. These data were taken on an n/n^+ silicon epitaxial layer with a resistivity of about 0.1 ohm-cm. Note that the readings approach the d-c value but have no apparent upper limit. This type of dependence on pulse width or duty cycle is certainly different than would be expected of a pn junction. These results confirm the trend Allen, Clevenger, and Gupta (6) observed, using their pulse technique.

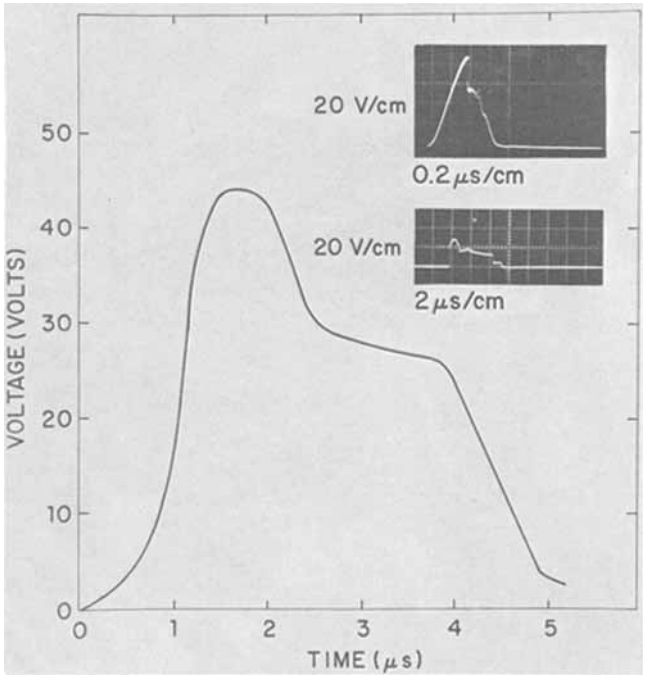

Fig. 9. Pulsed voltage-time characteristics

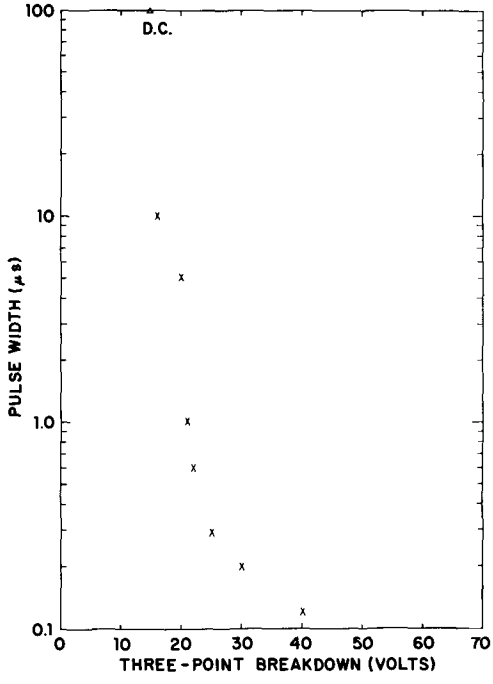

Fig. 10. Effect of pulse width on three-point probe voltage breakdown.

In addition, for a pn junction, the breakdown voltage should increase for an increase in ambient temperature. This is not the case for the three-point probe as shown in Fig. 11. The breakdown voltage is nearly a linearly decreasing function of temperature. The coefficient of temperature variation for this 0.2 ohm-cm n-type sample is 0.0795 v/°C.

Several conclusions can be drawn from these data.

1. It is apparent that the electronics used for the measurement of three-point probe breakdown voltage must be shut off within 1 μsec after breakdown has been reached in order to avoid excessive damage to the silicon and point material. This can be accomplished with either a d-c ramp or pulse technique.

2. Many of the heating phenomena suggest that the three-point probe is not measuring a true avalanche

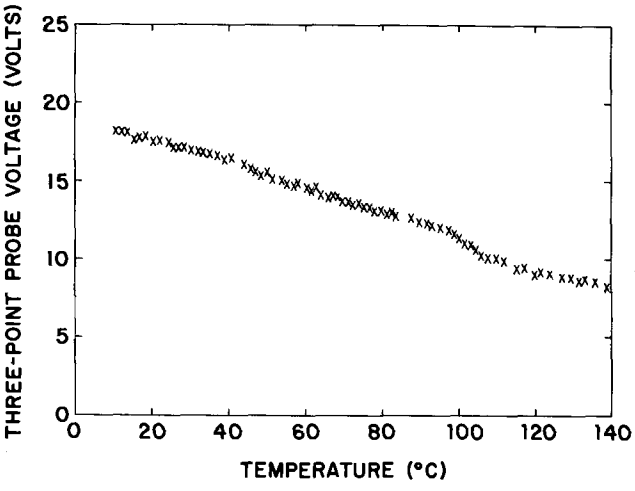

Fig. 11. Three-point probe breakdown voltage as a function of temperature for an n-type silicon sample.

breakdown in its common use but a thermal breakdown effect.

3. The effects of forming and duty cycle are important in determining the breakdown voltage and must be considered in the calibration of a system.

4. The temperature rise under the point is very severe and can lead to an apparent melting of the silicon under the point. The power at breakdown is about 1w, and for the areas of contact normally encountered for these types of probes a power density as much as 10^7 w/cm^2 is possible. This is certainly a high enough power density to melt silicon if it is held at this level for a long enough time.

Acknowledgment

The authors would like to acknowledge the assistance of Miss Lucy A. Pietrogallo for some of the experimental data and of Mr. A. Dupnock for some of the photographs.

Brief Communications

A Deep Donor Level in n-type Silicon Carbide

M. J. Moore

Associated Semiconductor Manufacturers Ltd., Stockport, Cheshire, England

The results of recent investigations (1, 2) on the electro- and photoluminescence of silicon carbide p-n junctions have pointed to the possible presence of a low lying donor state between 0.4 and 0.6 ev below the bottom of the conduction band. The purpose of this note is to present strong evidence for the existence of a group of deep energy states from the measurement of the electrical properties of silicon carbide.

Measurements of Hall coefficient have been made from room temperature to about 1000°C on three n-type single crystals of commercial grade silicon carbide. Details of the experimental arrangements have been outlined in a previous paper (3). The electron concentration n, obtained from the Hall coefficient R, by means of the familiar expression

$$n = 3\pi/8Re$$

is shown as a function of reciprocal temperature in Fig. 1.

From room temperature to about 400°C the variation of carrier concentration is what one would expect with the excitation and eventual exhaustion of electrons from partially compensated nitrogen impurity levels at an energy which, for commercial grade crystals, is generally between 0 and 0.1 ev, depending on the concentration of ionized nitrogen centers. However, beyond 400° and up to 1000°C there is rather unusual behavior of the electron concentration with a rapid rate of increase with increasing temperature. In some semiconductors this behavior is not uncommon and is attributed to the excitation of elec-

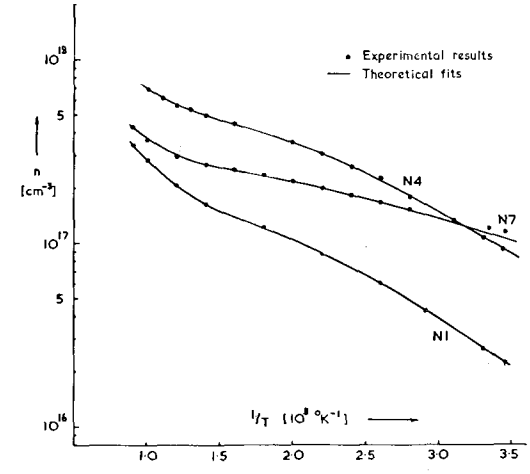

Fig. 1. Reciprocal temperature variation of carrier concentration for three n-type silicon carbide crystals.

trons across the band gap. Hexagonal silicon carbide however, has a band gap of approximately 3 ev and the intrinsic carrier concentration at 1000°K would be of the order of 10^{10} cm^{-3} which is clearly several orders of magnitude less than the concentrations involved at this temperature.

The presence of a second group of donor levels would explain the qualitative features of the experimental data in Fig. 1. A quantitative examination of these results, taking into account the proposed deep levels would begin with the expression for the carrier concentration derived from the condition for electrical neutrality within the crystal, *viz.*

$$n = N_d - N_a - N_d f_d + N_1(1 - f_1) \qquad [1]$$

where the Fermi factors f_d, f_1 are given by

$$f_d = \left(1 + \frac{g_d N_c}{n} \exp -\epsilon_d/kT\right)^{-1}$$

$$f_1 = \left(1 + \frac{g_1 N_c}{n} \exp -\epsilon_1/kT\right)^{-1}$$

with

$$N_c = 2\left[\frac{2\pi m^* kT}{h^2}\right]^{3/2}$$

The concentrations of shallow donor, deep donor, and compensating acceptor centers are, respectively N_d, N_1, and N_a and the corresponding donor activation energies are ϵ_d and ϵ_1. The factors g_d, g_1 depend on the type of binding between an electron and the corresponding ionized donor center. If the binding is unpaired with respect to the electron spin then these factors would be equal to ½ whereas for paired binding they would be equal to 2. For a nitrogen donor we would expect $g_d = ½$.

Because of the nature of the Fermi factors f_d and f_1, the analyses may be carried out in two parts. First, with the effective mass of the electron $m^* = 0.7$ m and $g_d = ½$, N_1 is put equal to zero and N_d, N_a, and ϵ_d are adjusted to give the best fit to the experimental data from room temperature to the temperature at which the point of inflexion is apparent. Following this, g_1 is put equal to ½, and values of N_1 and ϵ_1 are found which explain the dependence of carrier concentration over the remaining range of temperature. The values obtained by this procedure are given in Table I and the theoretical fits are shown in Fig. 1.

Table I. Values obtained

Specimen	N_d	N_a $cm^{-3} \times 10^{15}$	N_1	ϵ_d ev	ϵ_1
N1	2.0	1.78	0.41	0.09	0.50
N4	1.64	1.04	0.85	0.09	0.50
N7	3.40	3.07	0.48	0.04	0.54

The departure of theoretical curves from the experimental results at high temperatures with values of ϵ_1 different from those in Table I gives an indication of the error in ϵ_1. This is such that ϵ_1 is not likely to be greater by a factor of 14% or less by a factor of 7% than the tabulated values. It will also be appreciated that as ϵ_1 is contained with temperature T under the exponential in Eq. [1] then the value of ϵ_1 required for the best fit is quite insensitive to variations in the choice of the other variables. For example, on repeating the second part of the analyses with $g_1 = 2$ it is found that the "best fit" values of ϵ_1 are only 5% greater than those given above.

Depositing Silicon Nitride Layers at Low Temperature Using a Photochemical Reaction

M. G. Collet

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

In the past two years much has been written on the use of silicon nitride in semiconductor technology (1, 2). The subject is of interest because it has appeared that silicon nitride layers can be very dense. This makes them very effective as diffusion masks and less susceptible to ion drift than silicon dioxide layers.

The work of Elgin and Taylor (3) and Emeléus and Stewart (4) on the photosensitized decomposition of hydrazine (N_2H_4) and silane (SiH_4) made us investigate whether it is possible to use a photosensitized reaction between these components to deposit a nitride layer at temperatures as low as room temperature.

We used a closed quartz walled system filled with a mixture of approximately equal quantities of silane and hydrazine with a total pressure of about 5 Torr. Mercury vapor with a partial pressure of 10^{-3} Torr was added to the mixture.

When irradiated with 2537Å uv light the mercury atoms are excited to the $^3P_1$ state. On collision with silane or hydrazine molecules the mercury atoms release the absorbed energy, thereby decomposing the silane or hydrazine. By way of a reaction sequence not yet investigated, the decomposition products form a deposit on the substrate, which may consist for example of silicon or germanium.

In Fig. 1 a comparison is made between the infrared absorption spectra of silicon nitride layers grown at 200°C with uv light and at 900°C with the pyrolytic process ($SiH_4 + NH_3$).

The spectrum for the low temperature process shows an absorption band at 4.7μ, which has also been found for sputtered nitride (5) and has been attributed to Si ≡ N or Si-H bonds. Apart from this band there is no difference with the spectrum for pyrolytic nitride. On this evidence and because the refractive index $n = 2$ we assume the layers to be silicon nitride.

At deposition temperatures lower than 150°C the infrared absorption spectrum showed an Si-O absorption band as well. This is probably caused by contamination of the hydrazine with hydrazine hydrate or water. Ultra dry hydrazine should permit deposition of silicon nitride at room temperature.

Table I compares the properties of pyrolytic nitride and the low-temperature variety. The values given are

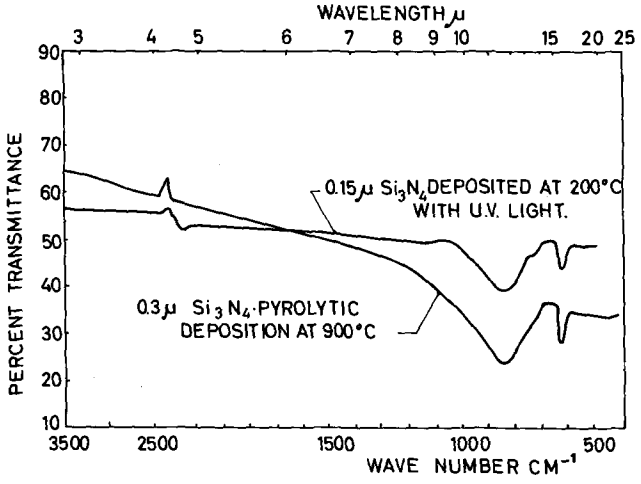

Fig. 1. Infrared absorption spectra of pyrolytic and low-temperature nitride.

only approximate because both processes cover a range of possible values depending on growth conditions.

However, the lower deposition temperature clearly results in less dense layers and with the density all other properties change as well. Thus it is possible to vary the properties of the layers by varying the deposition temperature or by applying various heat-treatments.

At 200°C the photosensitized deposition of silicon nitride on oxidized silicon wafers induces no change in surface states or oxide charge densities. Deposition at a temperature of 450°C influences the oxide-silicon interface in the same way as the well-known hydrogen or wet nitrogen anneal (6).

Table I. Si_3N_4 layers grown at 200°C with uv light and at 900°C from $SiH_4 + NH_3$

	T, °C	Dielectric strength, v cm^{-1}	Dielectric constant, ϵ_r	Etch rate ($NH_4F \cdot HF$) μ min^{-1}
$SiH_4 + NH_3$	900	10^7	6.0	0.001
$SiH_4 + N_2H_4$	200	10^6	5.5	0.1

The most attractive possibilities of the photosensitized process lie in the covering of ready-made devices with a nitride layer impenetrable to air, moisture, Na ions, and other ambient impurities. Some preliminary experiments on this application have given promising results.

Manuscript received Sept. 30, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

High Current Density Chlorate Cell Using Platinized Anodes

J. R. Newberry,*[1] W. C. Gardiner,** A. J. Holmes,[2] and R. F. Fogle[3]

Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

Sodium chlorate was produced in a monopolar cell having platinized titanium anodes and steel cathodes. A high current density was used in order to minimize cell costs. A 144-amp cell was built and tested in a continuous experiment for 31 days. The energy requirements were 6300 kwhr d.c./ton $NaClO_3$. The replacement platinum which may not have been optimized was shown as 5.3 g/ton $NaClO_3$. The cell operated at 1 amp/in.^{2}, and 110°C. The cell feed contained approximately 190g NaCl and 330g $NaClO_3$ per liter. Cell effluent contained 110g NaCl and 580g $NaClO_3$ per liter. The average cell voltage was 3.7. The pH was 6.7. This process is the subject of U.S. Patent 3,043,757. A cell with variable electrode spacings and height was used to indicate that ⅛ in. spacing would be preferred with electrodes 3 ft high in the commercial cell design.

Sodium chlorate is prepared commercially by electrolyzing sodium chloride in an undivided cell to form hypochlorite, which in turn reacts chemically to form chlorate in the cell and/or associated vessels.

The process has been described by Forester (1) and Knibbs and Palfreeman (2). Commercial cells with graphite anodes having become standard practice, the corrosion of graphite has dictated operation generally below 50°C. Current densities below 0.5 amp/in.^{2}, and heat exchange devices to provide cooling, are customary.

About the time that the possibilities for electrolyzing brine with platinized titanium electrodes were indicated (3), Olin had made some interesting observations in chlorate cell studies. The cell voltage with platinized electrodes was lower than expected and, as a result, considerably higher current densities were possible when customary cell voltages were applied. Considering the expected stability of platinum, it was reasonable to explore operation at higher temperature. Increased temperature appeared practical and offered additional advantages involving increased solubility of chlorate. As more chlorate was soluble at higher temperature, the possibility of forming product crystals simply by cooling the cell effluent was apparent. Since cell effluents, relatively concentrated in chlorate, were feasible, it was possible to operate with more sodium chloride in the electrolyte. This increased concentration of NaCl served to reduce both cell voltage and the formation of by-product perchlorate. This process was developed in a series of laboratory cells and when a reasonable approach to economics, competitive with those for conventional cells, was indicated a commercial cell and flow system were designed.

Experimental and Results

After exploratory experiments indicated a high current density might be used to justify the cost of platinized anodes, a 9-amp cell was designed using a 4-liter glass vessel placed on a hot plate with a magnetic stirrer. The vessel was closed with a 1-in.-thick Lucite cover carrying pH electrodes, leads for a level controller, anode and cathode leads, a thermometer, and connections for adding dilute hydrochloric acid and for removing cell gas and water vapor. A condenser separated water vapor from cell gas. The liquid level controller maintained 2.5 liters of electrolyte in the cell by actuating a valve to return condensate to make up for evaporation. A pH controller fed 1% hydrochloric acid to the cell to maintain the electrolyte at pH 7.

The electrodes suspended from the cover by 1/16-in.-diameter metal wires were each 3 in. square and 1/16 in. thick. They were completely submerged in the electrolyte. The anode was platinum-plated titanium and the cathode was either mild steel or platinized titanium. Spacers formed by making saw cuts in small Teflon strips were slipped over the bottom of the electrodes to maintain the distance at ⅛ in.

The cell was charged with a solution containing approximately 750 gpl $NaClO_3$, 100 gpl NaCl, and 2 gpl $Na_2Cr_2O_7$. It was stirred and heated to the boiling point which varied from 105° to 110°C.

Every 24 hr, the electrolyte was analyzed and a portion was removed which contained an amount of chlorate equivalent to the daily production. Solid NaCl was added to the cell at this time to replace the salt that had been consumed. Gas samples were taken daily and analyzed in an Orsat apparatus for Cl_2 and O_2. Current efficiency was calculated from the chlorate analysis and gas analysis. Periodically, current, voltage, temperature, pH, condensate volume, and acid consumption were measured.

Typical data are presented in Table I. The two methods of measuring current efficiency show wide variations. Estimates of the chlorate produced suffer from analytical errors of very concentrated solutions and from any operating upsets that may have occurred during the period. The gas analyses indicate current efficiencies only at the time of sampling.

Perchlorate formation.—The effect of allowing NaCl to be depleted is shown in Table II. Normal practice is to maintain approximately 100 gpl NaCl to minimize formation of perchlorate.

Cathode material.—A platinized titanium cathode was used for much of the test but, in the period 3400-3700 hr, two cathodes lost their platinum. After the second failure, a steel cathode was used and a lower voltage resulted as shown in Table III. The difference seems to be 0.2-0.3v.

Proposed sodium chlorate process.—During the operation of the 9-amp cell with platinized titanium anodes, a processing scheme for recovery of solid chlorate was developed (4). The electrolysis of NaCl to $NaClO_3$ was carried out at temperatures of about 105°-123°C, the boiling range of the electrolyte. Water

was evaporated with cell gas and removed from the cell. The effluent liquor from the cell was cooled; in a plant, this would be done preferably by flashing off further water from the liquor in a crystallizer. Sodium chlorate crystallized out and was separated, washed, and dried. The wash water and filtrate were recycled. Sodium chloride was added as purified brine to the recycle liquor. A flowsheet of this process is shown in Fig. 1.

A larger monopolar cell was built to test the platinized titanium anode further in conjunction with the proposed chlorate process.

144-Ampere monopolar cell.—A second chlorate cell was designed with 144 in.^{2} of anode surface to be operated at 144 amp. It is illustrated in Fig. 2. During an initial run, the platinum plating failed and the anodes were replated with 132 in.^{2} of coated surface. Thereafter, the cell was operated at 132 amp.

The cell was in two parts: a steel cell body with a top flange and a flanged Plexiglas dome. The steel cell body has a perforated steel partition providing a cathode between two anodes. Two platinized titanium anodes are suspended through slots in the dome and are spaced ¼ in. from the cell body and central partition. The anode surfaces were platinized over an area 3 in. x 12 in. (3 in. x 11 in. the second time). Sel Rex Corporation's Platinex L.S.III proprietary plating solution was used. The anodes were weighed before and after plating.

The cell was operated under the conditions of current density, electrolyte concentration, and temperature as proposed for commercial operation. Current was adjusted manually, but an integrating ampere-hour meter was depended on for current efficiency calculations. The cell feed selected was 195 gpl NaCl, 330 gpl $NaClO_3$, and 2 gpl Na_2Cr_2O7. The expected cell effluent was 95 gpl NaCl and 750 gpl $NaClO_3$. The cell effluent was cooled to room temperature and solid $NaClO_3$ crystallized and filtered off. The filtrate was returned to the feed tank along with solid salt and water.

The system was perfected to operate overnight and week ends with the arrangement shown in Fig. 3. Each

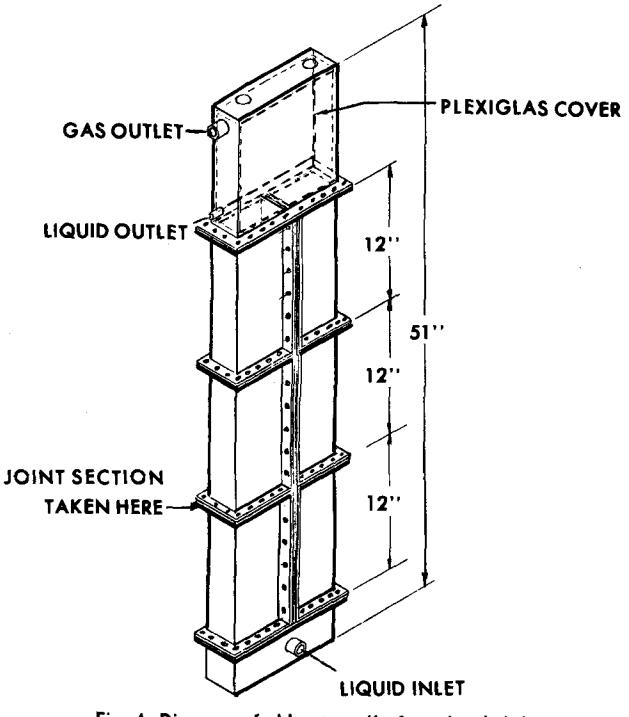

Fig. 4. Diagram of chlorate cell of varying height.

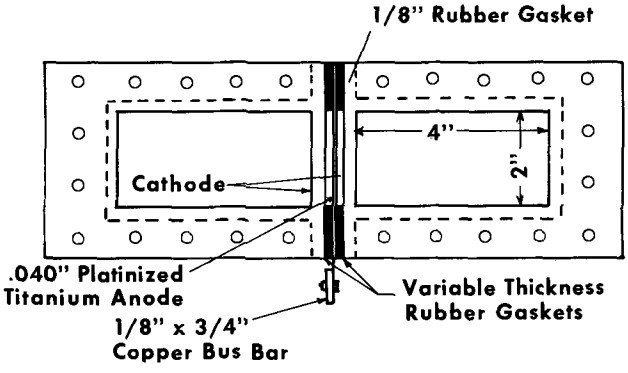

Fig. 5. Cross section of experimental chlorate cell.

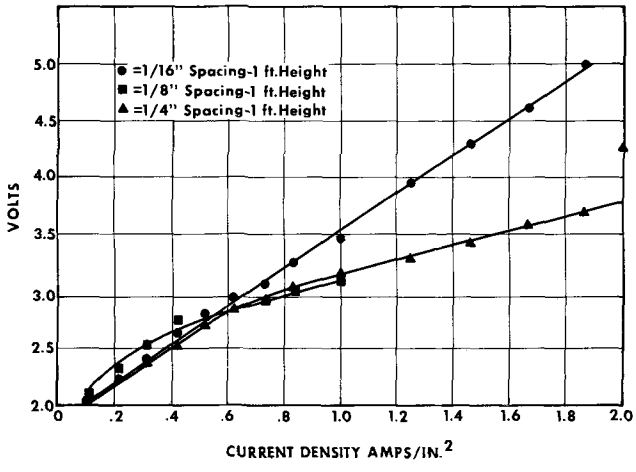

Fig. 6. Effect of anode-cathode spacing on cell voltage.

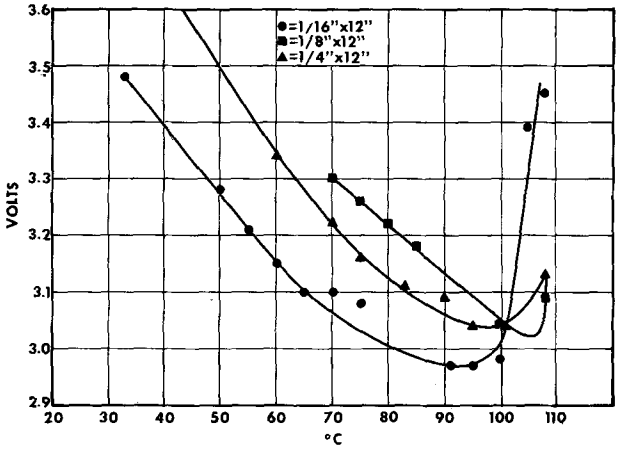

Fig. 7. Effect of temperature on cell voltage.

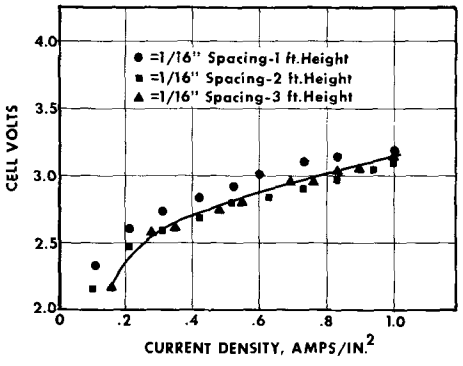

Fig. 8. Effect of electrode height on cell voltage.

feed tank and the cell effluent receiver had 4 days' capacity. The liquor in the cell effluent receiver was weighed and sampled, then cooled and filtered. One feed tank could be prepared while the other was in operation. It was found necessary to pass the cell feed liquor through a glass coil and needle valve immersed in a thermostat to maintain constant flow. The cell temperature was maintained by automatically returning the required amount of condensate to the cell. The *p*H was controlled by passing the cell effluent through a *p*H cell with glass and calomel electrodes. A controller-recorder actuated a valve feeding dilute hydrochloric acid to the cell. It was found that the *p*H electrodes also worked satisfactorily in the cell.

Platinum life.—The anodes were weighed four times to determine platinum loss. The data are given in Table IV. The cell feed failed during one test and resulted in a high platinum loss. If this measurement is excluded, the other three averaged 6.95 g/ton $NaClO_3$.

Operating data for 31 days of continuous operation are given in Table V. There was a short stoppage of cell feed, but the current was not interrupted. The current efficiency based on $NaClO_3$ averaged 81% and energy consumption averaged 6300 kwhr/ton $NaClO_3$.

Electrode height and spacing study.—A companion experiment to the 144-amp process study was made to evaluate the effect of electrode spacing and cell temperature.

A flanged cell was constructed to contain a single pair of vertical electrodes. The cell was arranged so that adjustment in gasket thickness could be employed to provide various interelectrode distances. Additionally, the cell was built in three sections (Fig. 4 and 5), 1 ft high, to study height and spacing with electrodes 1, 2, and 3 ft high. Data taken with this setup are shown graphically in Fig. 6, 7, 8.

Discussion

The data reported in Tables IV and V were collected in a 31-day operation. The data in Table V indicate current efficiencies and energy requirements in kwhr d.c./ton $NaClO_3$ based on the $NaClO_3$ weighed.

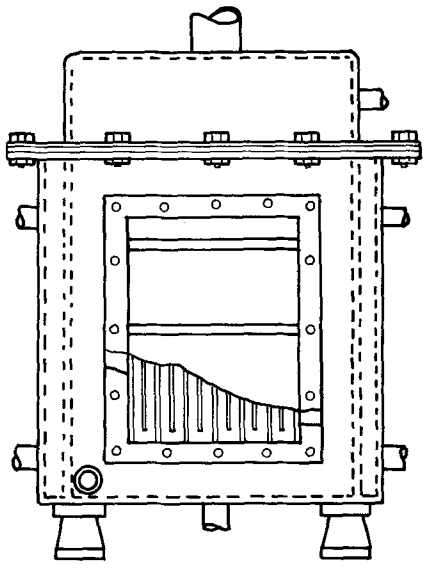

Fig. 9. Diagram of monopolar chlorate cell.

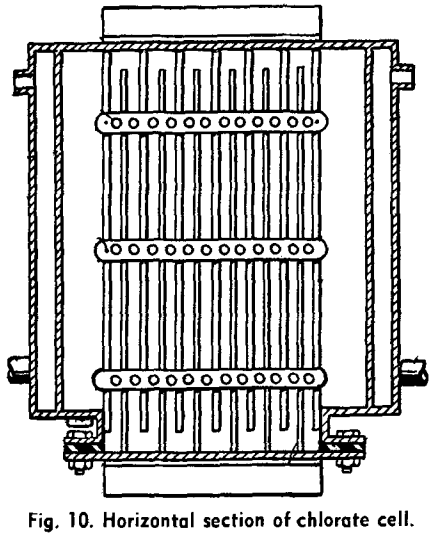

Fig. 10. Horizontal section of chlorate cell.

Experimental work was halted before the platinum loss was fully explored. The operation had become better controlled during the experiment, permitting the hope that platinum losses might be reduced further with increasing skill in operation.

Comparisons of energy requirements reported for various cells and the expectation of improving the operation reported in Table V prompted the design of a commercial cell (5) to operate at 30,000 amp. Study of Fig. 8 indicated that an electrode 3 ft high was workable. An electrode gap of ⅛ in. was chosen from Fig. 6 and 7. A cell was designed as shown in Fig. 9 and 10. As can be seen, the rectilinear cell contained vertical steel cathodes. The sheet anodes were platinized titanium fixed to a titanium header. Twenty anodes, 2 x 2.5 ft, were planned for the 30,000-amp cell. The header and anode assembly slides into the side of the cell and is bolted in position. Teflon spacers are inserted in the cathodes to prevent short-circuiting.

The cell cover is a Fiberglas reinforced polyester dome. Bus connections are made from one cell body to the succeeding anode header by removable bus sections.

Summary

Experiments in bench-scale apparatus established the feasibility of a chlorate cell having platinized titanium anodes and steel cathodes. A 144-amp cell

demonstrated operation for 1 month at 1 amp/in.^{2}. The cell temperature was approximately 110°C. An energy consumption of 6300 kwhr d.c./ton $NaClO_3$ was shown. A commercial cell of 30,000-amp capacity was designed. The process flow visualizes crystallizing by cooling effluent cell liquor. No internal cooling is required for the cell.

Manuscript submitted April 30, 1968; revised manuscript received Sept. 21, 1968. This manuscript was presented at the Chlorates and Perchlorates Symposium at the Boston Meeting, May 5-9, 1968, as Paper 260.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Electrochemical Oxidation of Multicomponent Hydrocarbon Fuels

I. Studies with n-Octane Based Fuels Containing Aromatic, Olefinic, and Naphthenic Components

Eugene Luksha[1] and Eugene Y. Weissman*[,2]

General Electric Company, Direct Energy Conversion Operation, West Lynn, Massachusetts

ABSTRACT

The classes of compounds found in liquid hydrocarbon fuels were studied to determine their effect on the electrochemical performance of direct oxidation anodes. Experiments were conducted on porous platinum black, Teflon electrodes in 95 weight per cent phosphoric acid at temperatures between 150° and 200°C. It was found that the performance of anodes operating on binary mixtures of n-octane and small amounts of hydrocarbon additives depends on the nature of the additive. For aromatic additives, an increase in molecular weight or complexity of the aromatic molecule will result in an increase in anode overvoltage. For olefin additives, there is a distinct relationship between the type of olefins and performance. The anode overvoltage decreases as the number of allylic hydrogen atoms increases. The cyclic olefin (six-membered ring) is aromatic in character due to an apparent dehydrogenation mechanism preceding the oxidation step. Iso-paraffins, in any proportion, do not affect anode performance of normal paraffins having the same number of carbon atoms. Sizable performance gains can be made by increasing cell operating temperatures. If a cell could be operated at 250°C, materials permitting, as much as a ten-fold increase in cell performance could be obtained, based on a linear extrapolation of existing data.

Because of economic necessity, commercial fuels will be used in practical fuel cell devices. While indirect utilizations, such as by steam-reforming, are realizable today, it is the direct electrochemical oxidation process which requires considerably more understanding and improvement. It forms the subject of this paper.

Commercially available fuels generally consist of complex mixtures of hydrocarbons, primarily straight and branched aliphatics, olefins, naphthenes, and aromatics. The aliphatic compounds, both straight and branched-chained, are relatively reactive in fuel cells, while the unsaturated and cyclic compounds are considerably more difficult to oxidize (1) and have been designated as "unreactive." These types of compounds are believed to adsorb on an electrode surface more strongly than aliphatic compounds, forming an inert ad-layer (2). For this reason, it is necessary to know the tolerance of an operating fuel cell anode to these "unreactive" compounds.

Experimental

The model fuel taken into consideration was split into its principal components: paraffins, olefins, naphthenes, and aromatics, as is shown in Fig. 1. The proportions of these components vary widely with the type and origin of the fuel. Normal octane was chosen as the base fuel and various quantities of single unreactive components were added to it. These additives were chosen on the basis that they are all found in relatively high concentrations in various types of hydrocarbon fuels (3-5) and have boiling points lower than 175°C, the practical upper temperature limit of the electrodes used in this work. As a result, compounds containing more than 1 ring, as, for example, indanes, indenes, tetralins, and naphthalenes, were not considered since they all have boiling points in excess of 175°C. Since hydrocarbons with condensed rings were eliminated, only alkylbenzenes, 1-ring naphthenes, in addition to the olefins and paraffins were studied.

The compounds shown in Fig. 1 were added to n-octane in varying concentrations. Polarization curves were taken using the binary solution as a fuel. These polarization curves were measures of the decrease in cell performance caused by the addition of the "unreactive" components.

The experimental equipment has been described elsewhere (6). The following conditions apply to the present work:

1. The electrodes used were 7.6 x 7.6 cm (46 cm^2 active geometric area) platinum-Teflon-screen composites of a type previously described (7). The platinum loading was 35 mg/cm^2 and the composition: 85 weight per cent (w/o) Pt-15 w/o TFE. The current-collecting screen was generally gold-plated expanded tantalum (5 Ta 10 4/0), and sometimes wire-woven platinum (45 mesh).

[2] Present address: Globe-Union, Incorporated, Corporate Applied Research Center, Milwaukee, Wisconsin 53201.

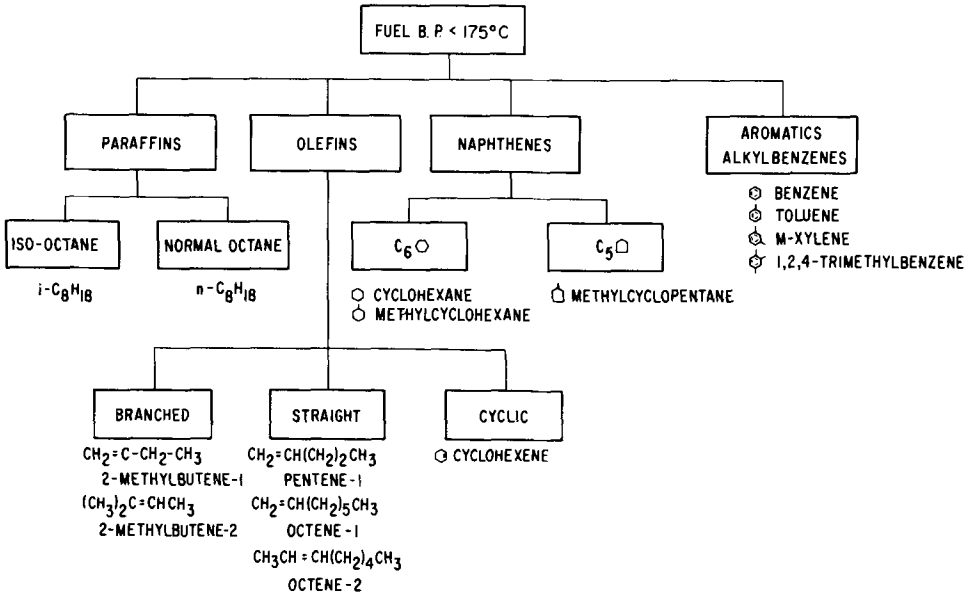

Fig. 1. Principal components of the model fuel.

2. The reference electrodes were hydrogen electrodes in the same electrolyte.

3. The electrolyte was 95 w/o phosphoric acid and, as mentioned above, the maximum practical operating temperature compatible with this electrode structure was found to be 175°C.

4. The counterelectrodes (cathodes) consisted of platinum-Teflon-platinum screen (woven, 45 mesh) composites with the same composition and loading as the anodes.

5. The experimental procedure for obtaining the polarization data was identical for each fuel studied. When the cell reached the desired temperature, the fuel was introduced at a flow rate of 20 μl/min [3] and the O.C.V. was allowed to stabilize for approximately ½ hr. The fuel flow rate was determined by observing the pressure drop across a calibrated capillary.

6. Prior to the start of each run, the anode potential was raised to approximately 1v for 30 sec in order to activate the electrode. The current was then shut off and the potential was allowed to stabilize. This point was recorded as the O.C.V.

7. A Kordesch-Marko bridge was used to control the current through the cell. To determine the initial portion of the polarization curve, small increases in the current were made in the range of 0-1 amp (0-22 ma/cm²). At each current setting, the anode potential was allowed to stabilize, before being recorded. Above 1 amp, the current changes were made in steps of ½ amp until the anode potential reached approximately 0.6v Above this potential, current increases were made in smaller steps as the limiting current was approached. The limiting current was taken as that current at which the anode potential would no longer stabilize. Following each run, the fuel was purged from the anode with nitrogen for 10 min. With the nitrogen purge on, the anode potential was brought up to about 1v to remove traces of fuel from the electrode surface.

Results and Discussion

Binary mixtures.—Aromatic additives.—Anode performance losses for n-octane with up to 5 mole per cent (m/o) additions of benzene, toluene, m-xylene, and 1, 2, 4 trimethylbenzene are summarized in Fig. 2.

There appears to be an effect on anode performance, in terms of molecular weight and degree of complexity of the additive, with the heavier, more complex additives, causing higher anode overvoltages.

The effects are generally small since the concentrations of the additives are small. It is expected that differences may become more pronounced as the concentrations of the additives increase.

In spite of some scatter in the experimental data, certain trends have been observed for the change in anode performance as a function of the additive complexity. Thus, the anode performance penalty for an n-octane fuel containing 3 m/o of various aromatics is shown to increase with an increase in the number of methyl groups in the aromatic molecule. Similar results were obtained with 1 m/o aromatic solutions (Fig. 3).

Naphthene additives.—The naphthenes that were evaluated can be divided into two classes: the six-

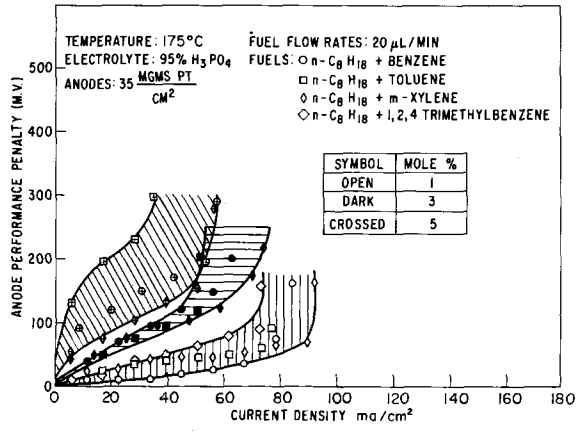

Fig. 2. Anode performance penalty for aromatics at 175°C.

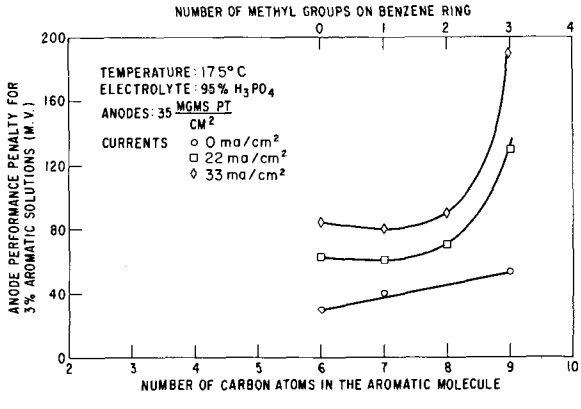

Fig. 3. Anode performance penalty vs. number of carbon atoms on the aromatic additive.

[3] This corresponds to 10 times the theoretical requirement of octane at 30 ma/cm².

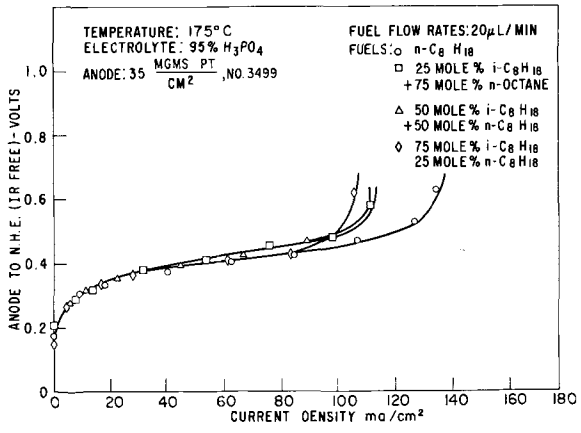

Fig. 5. Anode polarization for n-octane and i-octane mixtures at 175°C.

membered ring types which, under anode operating conditions, may be dehydrogenated to aromatics, and the five-membered ring types which appear to behave like paraffins.

The anode performance losses for n-octane based fuels containing varying amounts of cyclohexane and methylcyclohexane are shown in Fig. 4.

It appears that cyclohexane is more harmful to anode performance than methylcyclohexane, possibly because the presence of the electrophilic methyl group in the latter species would make dehydrogenation to an aromatic structure more difficult, and it is the aromatic structure that would cause the higher anode overvoltages.

In the study of the napthenes, probably the most significant result found was the high tolerance of a fuel cell anode to rather high concentrations of cyclopentyl naphthenes. No performance penalty was observed for these compounds for concentrations of up to 15 m/o and current densities up to 100 ma/cm².

Olefin additives.—The anode performance loss for various n-octane-olefin fuel mixtures is summarized in Table I. There appears to be a relationship between the type of olefin (straight-chained, branched, cyclic) and performance. The straight-chained olefins are apparently the most difficult to oxidize. The chain length of the linear olefin is of little importance to anode performance, except at high current densities, as is evident when one compares octene-1 with pentene-1. Here, at least, the detrimental effect of higher molecular weights is not apparent. The position of the double bond in the olefin molecule also plays a role in determining the anode performance penalty. As the double bond is moved toward the center of the molecule, the anode performance penalty is slightly reduced. This result can be seen by comparing octene-1 with octene-2 in Table I.

The branched olefins do not appear to cause any significant performance penalty when present in concentrations up to 5 m/o.

All these facts may be related to the number of allylic hydrogen atoms that the olefins contain (column 2, Table I). On a qualitative basis, given a series of hydrocarbons containing a single double bond, the olefin containing the largest number of allylic hydrogen atoms will be least harmful to anode performance. This appears to be the case here. An explanation of the phenomenon awaits further clarification.

The cyclic olefins, cyclohexane derivatives, form a separate class of compounds and exhibit higher anode overvoltages than the other types of olefins. These compounds are probably dehydrogenated under anodic conditions (*see* also, negative values of anode performance loss for cyclohexene in Table I) to aromatics, and as a result behave more like aromatics than like olefins. One point that should be emphasized is that an unsaturated six-membered ring is extremely detrimental to anode performance no matter what may be the degree of unsaturation.

Mixtures of normal and branched paraffins.—Polarization curves for cells operating on fuels consisting of mixtures of normal and iso-octanes, with 25-75 m/o iso-octane, show no change in performance as compared to pure n-octane (see Fig. 5). This indicates that branched and straight-chained paraffins having the same number of carbon atoms are very similar in reactivity. This is a useful result since it increases the flexibility of a choice of multicomponent fuels for specific performance requirements.

Multicomponent mixtures.—The above results were for mixtures of n-octane with single "unreactive"

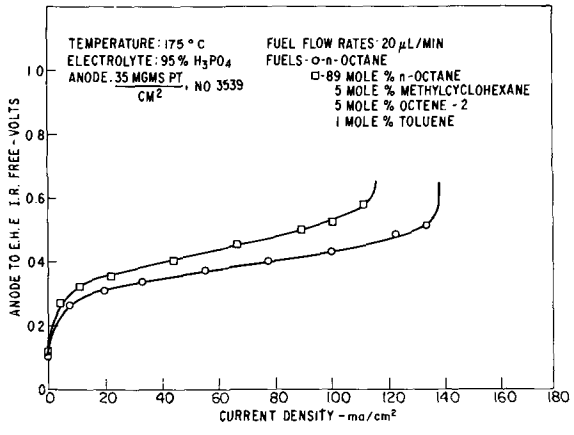

Fig. 6. Anode polarization curves for a fuel mixture consisting of 89 mole % n-octane, 5 mole % methylcyclohexane, 5 mole % octene-2, and 1 mole % toluene at 175°C.

components. Experiments were conducted in which several "unreactive" components were added to n-octane. The polarization curve of an anode operating on a fuel consisting of 89 m/o n-octane, 5 m/o methylcyclohexane, 5 m/o octene-2, and 1 m/o toluene is shown in Fig. 6. The concentrations of each of the additives were determined from binary mix data, so that the anode performance penalty for each of these components is roughly 50 mv at 30 ma/cm^2.

The outstanding feature of these results is that the cumulative effect of the "unreactives" does not appear to be additive. In fact, the performance loss is similar to that obtained for the corresponding binary mixtures, meaning that at these concentration levels each ingredient is not independent of the others present in the mixture.

This seems to suggest that, should a multicomponent mixture be chosen with any combination of ingredients, the performance penalty will be the one roughly corresponding to the "worst offender" in the mixture, as exhibited in a binary mixture with octane.

The main question, then, becomes one of establishing the influence of the other possible performance-determining parameters, such as the fuel flow rate.

Anode performance at other temperatures.—In an effort to determine the magnitude of a performance gain that may be obtained by increasing the operating temperature, several cells containing typical "unreactive" compounds were run at 150°, 175°, and 200°C. The data at 150° and 200°C are given elsewhere (8), while the data obtained at 175°C are given in this paper.

The log of the current at anode potentials of 0.4v for various fuels at 150°, 175°, and 200°C was plotted against $1/T$. From the Arrhenius-type relationship shown in Fig. 7, an approximate activation energy of 13 kcal/gmole is obtained; this is indicative of a strong temperature dependence. Although the data do not form a true straight line, probably because a variety of fuels were used, the trend toward significantly increased anode performance is evident. A linear extrapolation to a cell operating temperature of 250°C, for example, indicates the possibility of obtaining about a tenfold increase in performance, assuming, of course, that compatible electrode structures are available.

Conclusions

The performance of a platinum-activated anode oxidizing binary mixtures of n-octane and various small amounts (generally 1-5 m/o) of hydrocarbon additives in hot concentrated acid electrolytes (95% H_3PO_4 at 175°C) depends on the nature of the additive. Thus:

1. For aromatic additives, an increase in molecular weight or degree of complexity of the aromatic molecule (*e.g.*, number of methyl groups) will determine a corresponding increase in anode overvoltage.

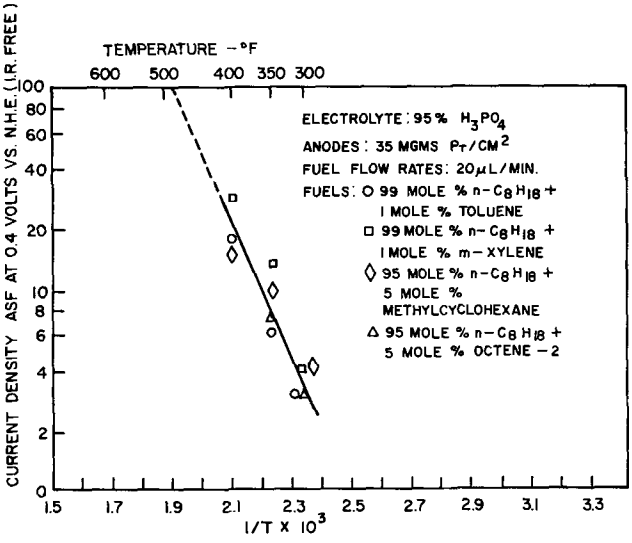

Fig. 7. Current at an anode potential of 0.4v *vs.* $1/T$.

2. For naphthene additives, the opposite appears to be true (when comparing methyl cyclohexane to cyclohexane). These findings are, however, in need of further experimental evidence.

3. For olefin additives, there is a distinct relationship between the type of olefin (straight-chained, branched, or cyclic) and performance; on an over-all basis, the number of allylic hydrogens in the noncyclic additive molecule appears to set a characteristic trend, with the anode overvoltage decreasing as the number of allylic hydrogens increases.

The cyclic olefin is quite aromatic in character due to an apparent dehydrogenation mechanism preceding the oxidation step. Specifically, six-membered cyclic olefins are very harmful to the performance of the anode both on a relative basis (compared to the other types of olefins) and on an absolute basis.

4. Iso-paraffins (in any proportion) do not affect the performance of normal paraffins having the same number of carbon atoms.

The detrimental effects of various additives, as obtained from performance data of binary mixtures (with octane), are not cumulative. Therefore, a multicomponent mixture will not necessarily contribute more to the rise of the anode overvoltage than the single "worst offender" in the mixture.

Sizable performance gains can be made by increasing cell operating temperatures. For example, if compatible materials and electrode structures were available so that a cell could be operated at 250°C, as much as a tenfold increase in cell performance would be possible, based on a linear extrapolation of the existing data.

Electrochemical Oxidation of Multicomponent Hydrocarbon Fuels

II. Long-Term Performance Studies with n-Octane Based Fuels Containing Aromatic, Olefinic, and Naphthenic Components

James F. Lennon, Eugene Luksha,[1] and Eugene Y. Weissman*,[2]

General Electric Company, Direct Energy Conversion Operation, West Lynn, Massachusetts

ABSTRACT

The long-term anode performance with hydrocarbon fuels may be different from what can be predicted from short-term polarization data. This is due to such time-dependent factors as accumulation of inert adlayers on the electrode surface and the progressive structural deterioration of the electrode. A study of the time-dependent aspects of hydrocarbon anode performance was made. The experiments were conducted on practical platinum/Teflon electrodes in 95 weight per cent phosphoric acid at 175°C. Characteristics of extended time *vs.* performance were described for n-octane and n-octane containing various single and multiple additives. It was found that the influence of various hydrocarbon additives on short-term performance of an octane anode cannot necessarily be applied toward prediction of long-term performance. Several additives do not appear to affect performance on a cumulative detrimental basis. However, when a certain total additive limit has been exceeded, the decrease in anode performance can be severe, over extended periods of operation. The cycling characteristics associated with the process of direct electrochemical oxidation of hydrocarbons have been described in terms of several distinct modes of performance fluctuation prior to the establishment of steady-state conditions.

For the most part, studies of the various aspects of direct hydrocarbon oxidation are based on short-term measurements. It is recognized that long-term anode performance with hydrocarbon fuels may be different from what can be predicted from short-term polarization data. This is due to such time-dependent factors as the accumulation of inert ad-layers on the electrode surface. Another important contribution to such performance changes is a progressive structural deterioration of the electrode. A study of the long-term effects that various "unreactive" additives (*e.g.*, aromatics, olefins, naphthenes) may have on the performance of fuel cells operating on n-octane was made in order to determine whether there may be cumulative inhibition of the active sites on the anode as a function of time by these additives.

Other long-term effects of various additives in multicomponent, octane-based fuels, are changes in the characteristics of performance cycling, which is present when hydrocarbons are oxidized directly with phosphoric acid electrolytes.

It is the purpose of this study to provide information and shed some light on these time-dependent aspects of anode performance.

Experimental

The life testing installation has been described earlier (1). The electrodes (both anode and cathode) were of the same types described elsewhere (2) (35 mg Pt/cm^2, 85% Pt-15% TFE, gold-coated Ta screen for anodes, Pt screen for cathodes).

The following experimental procedure was used: After establishing the desired gas flow rates (in general: 20 μl fuel/min; corresponding to 10 times the stoichiometric requirement of octane at 1 amp and 10 times the stoichiometric requirement of oxygen supplied in the air stream to the cathode[3]) and isothermal conditions (175°C), the open-circuit potential was recorded. Thereafter, an initial polarization curve was taken.

After these initial data were obtained, the cell current was maintained in general at 1.5 amp (33 ma/cm^2), by means of Electro-Products, Model EFB, d-c power supply units. The *IR*-included anode *vs.* H_2/H^+ potential and cell current were continuously recorded with Varian two-channel strip chart recorders. *IR*-free potential data were also obtained, by means of a Kordesh-Marko bridge. These data were logged, together with cell potentials and resistances.

The circulating electrolyte concentration was maintained at 95-98% H_3PO_4 by means of controlled-rate addition of water to the electrolyte sump.

At the end of each test (usually caused by excessive electrolyte leakage through the anode), a final polarization curve was taken. The cell was then disassembled and the anode was cleaned. If desired, its surface area was measured by the B.E.T. method.

Whenever time permitted, initial surface area measurements on anodes prior to assembly were also made. The method itself, as applied to whole electrodes, has been described by Weissman (3).

* Electrochemical Society Active Member.

[2] Present address: Globe-Union, Incorporated, Corporate Applied Research Center, Milwaukee, Wisconsin 53201.

[3] These are not the minimum required flow rates; they were selected so as to eliminate any possibility of concentration polarization biases on the life test results but not optimized (in terms of minimum values) since this was outside the scope of the experiment.

Whenever necessary, the polarization curve data points were determined after suitably preactivating the anodes at anode potentials greater than 0.90v *vs.* H_2/H^+, and subsequently waiting for the output to stabilize at what would have been the average anode potential under cycling conditions for a fixed current density. This wait period was usually of the order of 3-4 min. In this way, cycling disturbances were avoided, without affecting the values to be measured.

Interpretation of the Test Data

Characteristics of extended performance vs. time data.—As mentioned above, direct hydrocarbon oxidation in phosphoric acid is characterized by spontaneous performance cycling. One of the objectives of the present work was quantitatively to define differences in the behavior of octane and various octane-based binary and multicomponent fuel mixtures, in terms of the frequency and/or the amplitude of anode potential fluctuations at constant current. The interpretation of such differences can be refined by noting that in each case the time required for the onset of cycling can be divided into four distinctly different periods:

I. The induction period—a short interval of time, normally 1-2 hr, during which there is a large increase in anode potential, from its open-circuit value.

II. The ripple period—follows the induction period and is of short duration; up to 2 hr. During this time interval, the anode potential starts fluctuating at high frequencies (*e.g.*, several times a minute) and low amplitudes (*e.g.*, 10-20 mv).

III. The onset-of-cycling period—sometimes indistinguishable from the actual cycling mode of operation (IV, below). When it occurs, it lasts a few hours, or less, and is characterized by performance cycling at frequencies that are sometimes higher and sometimes lower than during the actual cycling operation that follows; the corresponding amplitudes are always smaller (*e.g.*, 20-80% of actual cycling amplitudes).

IV. The cycling period—characterizes the onset of steady-state anode operation. Here, the performance fluctuations have been established to their full extent, according to the experimental conditions and the species being oxidized.

The anode potential will change from its minimum to its maximum value according to a set pattern. This pattern can be used to define differences in the behavior of various fuels of interest in terms of frequency and amplitude of performance cycling (*see* Results and Discussion).

As time goes on, various modes of degradation occur (*e.g.*, progressive catalyst inhibition by a relatively nonreactive ad-layer, or structural degradation of the anode). These may be responsible for observable changes in the characteristics of performance cycling. It sometimes appears that these changes are auto-compensatory in nature; thus, a certain increase in frequency appears to be associated with a decrease in amplitude and *vice versa*.

Processing and significance of the experimental data.—The high-loading unsupported platinum anodes used in the present work, while sufficiently active catalytically to yield meaningful results, at least on a comparative basis, present the drawback of structural variance with time. This variance is sufficiently severe to make it necessary not to consider the "last-stage" data for comparison purposes since they are often influenced by high rates of electrolyte leakage through the anode.

Two methods of data interpretation were used:

1. Use of available polarization curve data to define various performance points (*e.g.*, anode potential at given current densities) at various chronological stages; say, at the beginning and at the end of a run. These are, essentially, extent-of-degradation data.

2. Averaging of cycling data, from recorder traces, and graphical representation of the resulting changes of performance with time. These are the typical life test curves, supplying information on the total life for a set of predetermined conditions, as well as the individual durations of the various periods of operation (induction, ripple, *etc.*).

Results and Discussion

n-Octane oxidation.—Six anodes were tested with pure n-octane in order to establish a graphical frame of reference for the results obtained with various fuel mixtures. The changes in anode potential with time occupy a band whose boundaries represent the range of anode performance for the electrodes tested (Fig. 2 and 3). The abrupt break in the curve after the initial several hours is an indication of the onset of steady-state operation (cycling).

Figure 1 summarizes the cycling characteristics observed with n-octane. The time to start cycling (periods I + II + III) and the frequency of cycling once it has started are plotted against current density. It is seen that the time to start cycling and the cycling frequency are related to operating current density. No significant trends for the amplitude values could be obtained. Period III of cycling was often indistinguishable from period IV, and period II (ripple) was sometimes negligibly small.

Normal octane with single additives.—The life test data for n-octane containing a single additive indicate

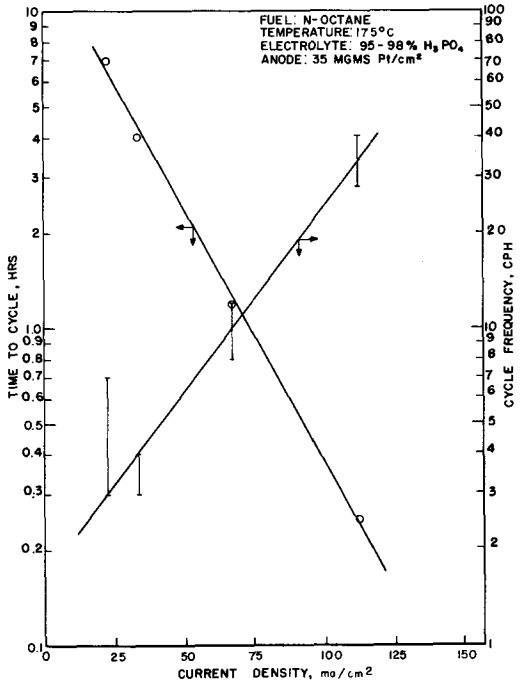

Fig. 1. Anode cycling characteristics as a function of current density.

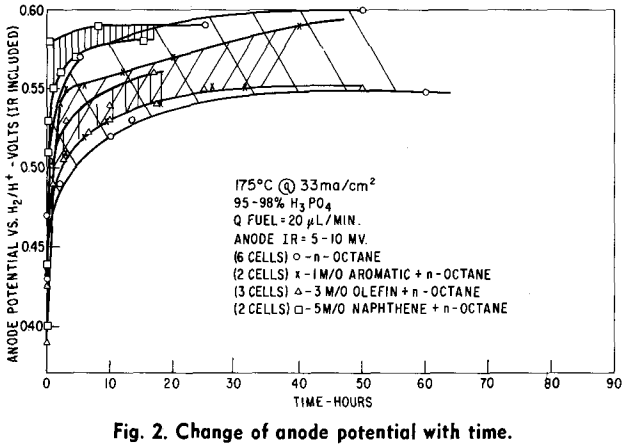

Fig. 2. Change of anode potential with time.

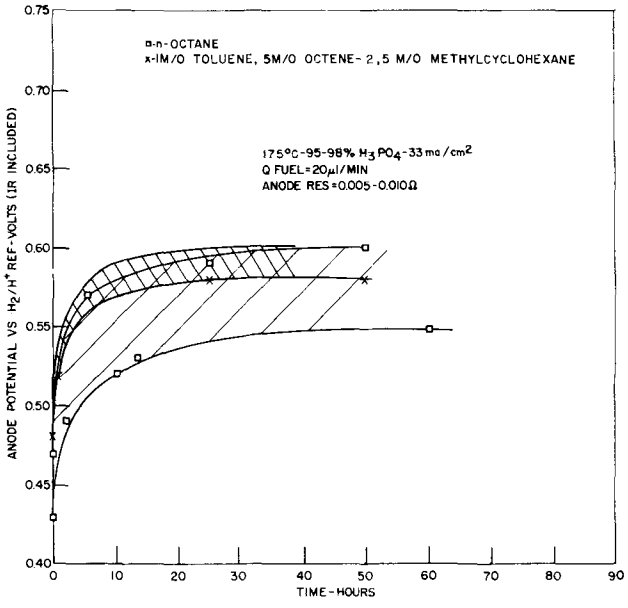

Fig. 3. Change of anode potential with time.

that there were no significant performance differences in the cycling period for the octane + 1% aromatic and octane + 3% olefin data as compared to pure octane. These similarities can be seen clearly in Fig. 2 where the performance-time curves for the fuels containing olefins and aromatics fall within the n-octane band. It can also be seen that anodes operating on octane + 5% naphthene fuels polarize more extensively during a relatively short initial time interval. Even after this brief interval, the performance-time curve is situated within the upper portion of the n-octane band while the latter has most of its data clustered in its lower portion.

The only significant differences in the cycling characteristics of octane plus single additives as compared to pure octane oxidation are the increased cycle frequencies, roughly 3 times higher, for the binary fuels.

Normal octane with several additives.—It has been shown in short-term tests (4) that there are no cumulative effects for multiple additions of "unreactives" up to a total of 11 mole per cent (m/o) additives. It was shown, in fact, that the performance penalty roughly corresponded to the "worst offender."

Figure 3 represents performance-time data for four cells operated on mixtures of 50/50 normal and iso-octane[4] containing 11 m/o additives (1% aromatic, 5% naphthene, 5% olefin). For the purposes of comparison, the experimental n-octane band is superimposed over this curve. A sharp increase in anode potential is first exhibited, up to a value of about 0.575v where the potential finally stabilizes. The multicomponent fuel data fit roughly within the upper portion of the n-octane band. The approximately 40 mv penalty over the performance of pure n-octane, based on the 5% naphthenes being the "worst offender" under these conditions, is substantiated by these graphical representations. This is due to the fact that most of the n-octane results fall within the lower portion of the performance-time band while the multicomponent data are clustered close to the upper limit.

Life test data obtained where increasing amounts of the "unreactive" components were added to n-octane are shown diagrammatically in Fig. 4 and 5. It is evident that sizable performance penalties are paid for concentration levels greater than 11% even to the extent of a 180 mv[5] deviation from n-octane performance, representing approximately 50% of the cell output *IR* included. This performance drop occurs within the first 25 hr of operation, where effects of anode deterioration are minimal. Figure 6 is a graphic representation of the decrease in current density, at a given polarization, with increasing concentrations of the "unreactive" components in n-octane. It should be noted that the current densities are normalized in terms of real B.E.T. surface areas measured on the pure electrodes. The spread of the data increases at higher concentrations of "unreactives."

An analysis of the cycling characteristics of these multicomponent fuels for operation at 33 ma/cm^2 indicated that the frequency and amplitude of cycling did not appear to exhibit any of the trends reported for n-octane and n-octane with single additive mixtures. In fact, there were no appreciable changes of the frequency of cycling with time.

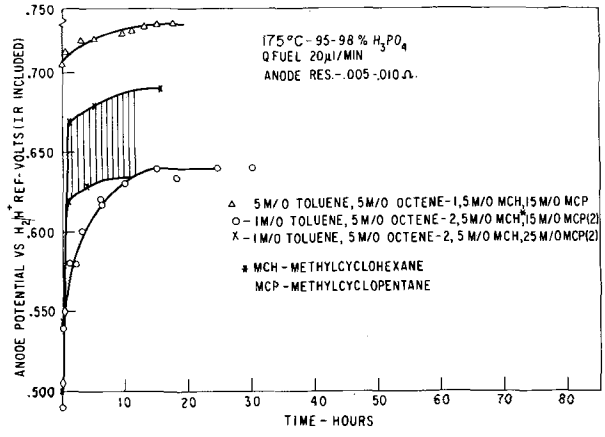

Fig. 4. Change of anode potential with time.

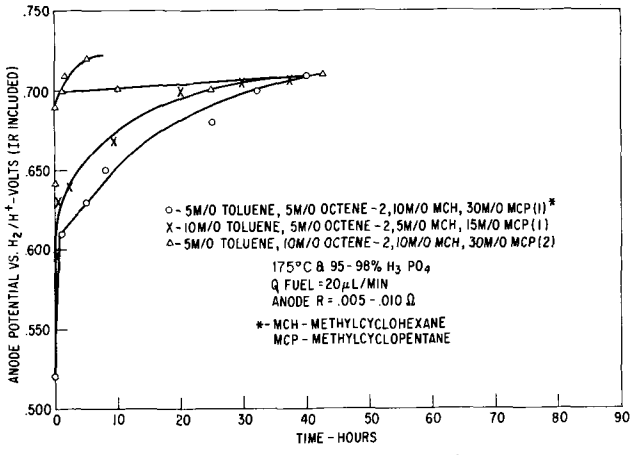

Fig. 5. Change of anode potential with time.

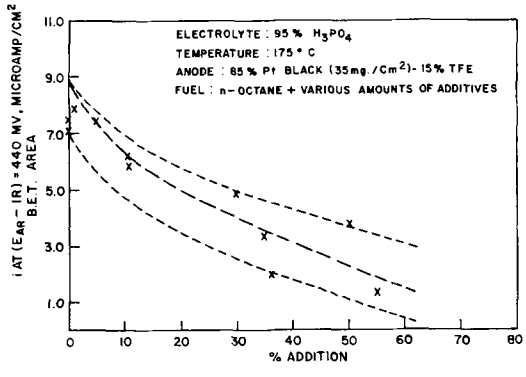

Fig. 6. True current densities as a function of the total amount of additives.

[4] It has been previously shown (4) that there are no performance differences between anodes operating on n-octane and on n-octane + i-octane mixtures.

[5] Note that the detrimental effect of octene-1, as compared to octene-2, is particularly obvious with high amounts of additives (30 m/o).

Conclusions

1. The differences between anode overvoltages for the oxidation of pure octane and of octane with various hydrocarbon additives appear only to be significant in the context of short-term operation, in most cases up to 25 hr.

2. For longer runs, characteristic of real fuel cell operation, differences in anode performance are reduced to practically insignificant levels; this holds true as long as the cumulative amount of additives does not exceed a certain limit. At least for the conditions imposed in the present work, *i.e.* a platinum loading of 35 mg/cm^2, 95% phosphoric acid at 175°C, and excess flow rates of reactants, this limit was found to be 11 m/o.

PbO_2 in the Lead-Acid Cell

I. Formation from Three Typical Oxides

Jeanne Burbank*
Naval Research Laboratory, Washington, D. C.

and Everett J. Ritchie*
Eagle-Picher Industries, Incorporated, Joplin, Missouri

ABSTRACT

Three representative lead oxides for storage battery fabrication were mixed with water and H_2SO_4 to paste consistency. Each of these was hand pasted into antimonial and pure lead circular grids of standard SLI thickness. The plates were cured according to common practice for each oxide. The small circular plates were anodized in an electrolytic cell mounted directly on an x-ray machine, and the diffraction patterns recorded at intervals throughout 72 hr of formation in 1.0585 sp gr H_2SO_4. Beta PbO_2 was identified as the reaction product. At the end of formation, nominally 150% of theoretical requirement, the morphology of the PbO_2 was examined by electron microscopy. The crystals varied from small prismatic individuals to complex spherulitic formations.

Positive plate materials of the lead-acid cell have received intensive study in recent years because of massive failure of nonantimonial submarine cells in which the positive active material suffered catastrophic softening early in life. It was shown that similar cells, pasted with identical materials but having antimonial lead grids, gave longer service life. The difference in performance was attributed to the difference in electron morphology of the PbO_2 crystals, which in the case of the antimonial cells remained characteristically prismatic and dendritic, while those in a softening paste were nondescript spheroids, readily detached from the plate upon gassing on overcharge. These results have led to a systematic examination of the electron morphology of PbO_2 crystals in the lead-acid cell. It has been indicated that the electron morphology is related to the materials originally present in the paste (1-6). As a continuation of the study, the present investigation of positive plate oxides was undertaken.

Materials and Methods

Three representative commercial oxides for storage battery fabrication were used in this study, designated respectively *A*, *C*, and *H*, Table I. These are characterized in Tables II and III which show the particle size ranges and spectrographic analyses.

Pastes of each oxide, water, and sulfuric acid were mixed in a laboratory dough-type mixer in three pound batches, Table IV. Each of the pastes was hand pasted into special grids and cured and dried according to standard practice for each type of oxide. Plates containing pastes of oxides *A* and *H* were racked, and placed in a steam-filled oven to set the paste, followed by drying at about 105°C. Plates containing paste *C* were flashed, rolled, stacked, and cured for 24 hr in an

insulated box, followed by 40 hr in a closed oven at 40.9°C. Conventional square grids for use as counter-electrodes were pasted and cured at the same time, with the same materials.

The special and conventional square grids fabricated for this study were cast from pure lead and nominal 7% lead-antimony alloy. Spectrographic analyses of the grid metals are given in Table V. The special grids were small circles, 47 mm diameter, designed to fit the electrolytic cell mounted directly on an x-ray goniometer, permitting registration of diffraction patterns during anodic treatment (7).

Table VI. Anodization treatments

Oxide	Grid metal	Average plate thickness (mm)	Dry active material weight (g)	Amp-hr (theory)	Amp-hr (actual)	%

	Pb	1.9304	8.7	2.05	3.024	147.51

Radiographs of each of the circular plates were made prior to any electrochemical treatment with a Faxitron 804 table-top radiographic system. The small disk plates were mounted in turn in the electrolytic cell, backed by a circle of pure lead to effect electrical contact, and rotated at 60 rpm throughout the anodization of about 72 hr or less in certain instances, Table VI. A preliminary soak of 20-30 min was given in the electrolyte, 1.0585 sp gr H_2SO_4. Anodic oxidation took place from one side only in the x-ray cell assembly, and the current density was approximately 4 ma/cm^2 on the submerged half of the electrode. Using Cu $K\alpha$ radiation, x-ray diffraction patterns were registered from the cured plate surfaces, and from samples of the paste removed from the grids, ground to pass No. 120 sieve, and mounted in the conventional manner for diffractometric registration. Following the soaking period, and at intervals throughout the anodic oxidation, diffraction patterns of the surfaces of the plates were recorded also. Positive plate polarization was followed continuously by means of a standard Hg, Hg_2SO_4 reference electrode.

Upon completion of anodization, usually about 150% of theoretical requirement on a weight basis, the plates were blotted and dried in air at room temperature. The active material was removed from the grids for electron microscope examination by carbon replication and further x-ray diffraction study by the same methods used in the earlier studies (1-6). All electrochemical experiments were performed at room temperature which varied from 20.0° to 25.2°C.

Results, Discussion, and Conclusions

The radiographic examination of the cured plates showed that, from a practical standpoint, the grids were fairly well filled with paste, and were free of large voids or skips. There were, however, hidden cracks in some pellets, and some areas of the grid bars were not in good intimate contact with the paste. A difference was observed between the radiographic density exhibited by the paste of oxide C and that of the other two oxides. It is seen in Fig. 1 that the paste containing oxide C is markedly more uniformly dense than that of oxide A, which was adopted as a standard for comparison of all plates. While it is true that the plates containing oxide C averaged thicker than the others, Table VI, there were variations among all specimens that eliminate thickness as the sole cause of this difference in radiographic density. Also, it may be observed from the figure that the plate of oxide A is distinctly more grossly porous than the paste resulting from oxide C. This was true of all specimens of pastes A and H when similarly compared with all those containing oxide C. Further, cross-pellet cracking was most prominent in oxide C as a general characteristic, as was poor contact with the grid bars.

Of particular significance is the difference in the relative amounts of small particles in the three oxides, Table II. It is generally accepted that even nonplastic materials such as silica will exhibit plastic behavior if particle size is sufficiently reduced, and even more pronouncedly if the particle shape is also favorable (8). Particles exhibiting plastic behavior are usually 1μ or less in diameter, and the percentage of particles in each oxide falling within this range has been indi-

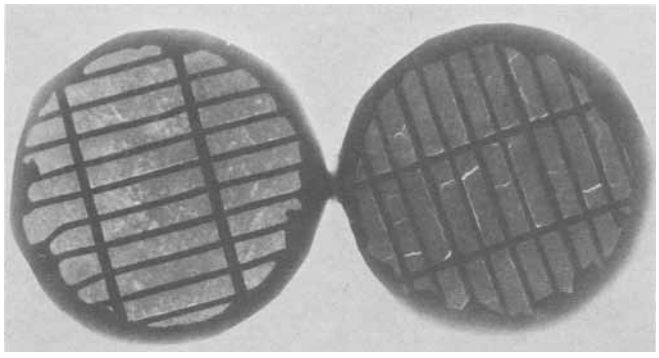

Fig. 1. Representative macroradiographs of unoxidized, cured plates containing pastes from oxide *A (left)* and *C (right)*. The dense packing of oxide C is shown by its greater opacity to x-rays, giving a darker image than that of paste *A*. The distribution of macroporosity in paste *A* is shown by the fairly uniform mottling. Thin white lines are cracks, visible along some grid bars in paste *A*, but larger and more extensive in paste *C* where shrinkage resulted in cross-pellet cracking as well as parting from the grid bars. Similar radiographs from plates containing paste *H* resembled the one shown for paste *A*.

cated as "plastic" and the larger fractions as "granular" in Table II. The handling and curing properties of pastes fabricated from the oxides depend to a large extent on the relative amounts of plastic and granular material present. For example, on the basis of the above radiographic examinations, it is seen that paste *C* suffers greater shrinkage during curing than either paste *A* or *H*. Neglecting the fact that the curing reaction of oxide *C* must include the step of oxidation of the free metallic lead particles present in this type of oxide, and considering only the distribution of particle sizes in the original oxides, Table II, it is to be expected that the oxide containing the lowest percentage of "granular" size particles would undergo the most pronounced shrinkage. The pasting properties, Table IV, of each of the oxides also may be related to the relative amounts of granular and plastic size particles. Oxide *A* contained only 3.6% of plastic material, and gave a paste described as "fair" in pasting quality. Oxides *C* and *H* had 25 and 7.5% plastic material, respectively, and both had "good" pasting properties. This suggests that 3.6% plastic material is too low to impart satisfactory workability to the mix, 7.5% is sufficient, while 25% is excessive, leading to undesirable shrinkage cracking. Investigation of the rheological properties of these and other representative oxides combined with radiographic study of pasting and curing would be of interest. As a result, optimum workability could be realized, and pellet cracking and arcing along grid bars could be minimized and possibly eliminated.

All identifications of solid crystalline materials given in this report were made by x-ray diffraction analyses. Reference diffraction patterns are listed in Table VII giving the card numbers in the standard file (9).

X-ray diffraction patterns from bulk specimens of the cured pastes showed the major component to be tribasic lead sulfate in all three. The surfaces of plates made with oxides *A* and *H* were primarily basic lead carbonate, hydrocerussite, and the surfaces of plates made with oxide *C* were largely tribasic lead sulfate. Residual PbO and, in the case of oxide *H*, Pb_3O_4 were also detected.

When plates containing oxides *A* and *H* came into contact with the dilute H_2SO_4 solution, the gassing of CO_2 was visible, and during the preliminary soaking period all traces of the superficial layers of basic lead carbonate were rapidly eliminated. Crystalline $PbSO_4$ formed on the surface of all three types of plate during the soaking period. At this same time, Pb_3O_4 in paste *H* was converted to PbO_2 and $PbSO_4$ and resulted in a marked purplish coloration in this kind of plate.

Table VII. The x-ray diffraction patterns

Compound	ASTM (9) card number	Remarks
$PbSO_4$	5-0577	Excellent match is obtained for this material; on occasion, the weak line at 5.38 is missing and, with lesser amounts of $PbSO_4$ present, only the strong lines are detected.
β PbO_2	8-185	Excellent match is obtained for this material with the exception of the line at 2.21 which did not appear in the electrochemical products of this study. There was some indication of preferred orientation in some of the electrodeposits, although not to a strong degree.
PbO (tetragonal)	5-0561	Excellent match is obtained for this material. On occasion, preferred orientation causes divergence from the standard intensities.
PbO	5-0570	Excellent match is obtained for this material.
Pb_3O_4	8-19	Excellent match is obtained for this material.
$Pb_3(CO_3)_2(OH)_2$	13-131	This reference card gives the best match for this material when observed as a reaction product on a surface; it arises from an oriented deposit with the basal planes lying in the surface. Because of the strong tendency for this material to form oriented deposits, the lattice parameters given on this card are in error. *See* also card 14-8 and Ref. (10) and (11).
$3PbO \cdot PbSO_4 \cdot H_2O$	6-0282	This reference card gives a fairly good match for identification of this material although weak lines are often missing and relative intensities may vary.
	6-0287	This reference card also gives a fairly good match for this material; however, the preparation contained some $4PbO \cdot PbSO_4$ and lines from this compound must be subtracted from the pattern. Bode and Voss (12) have given a pattern for this compound that compares favorably with the two given above. Comments: Identification of this material by x-ray diffraction in a mixture such as the battery paste is made on the basis of strong lines which fortunately are unique for this material.

The plates were individually anodically oxidized and details of the anodizations are given in Table VI. The positive plate polarization during oxidation followed the expected pattern previously reported by Ikari, Yoshizawa, and Okada (13); one example is

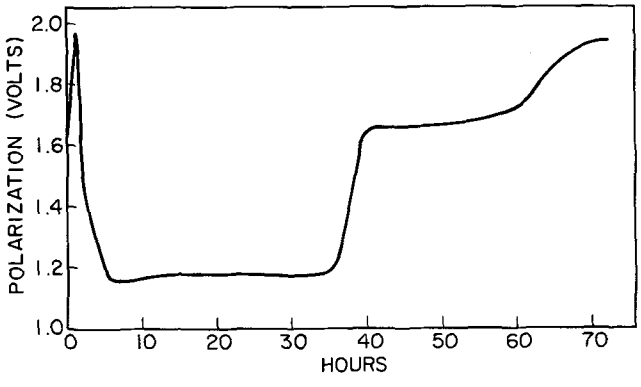

Fig. 2. Plate polarization during anodic oxidation. The polarization is given relative to the standard Hg, Hg_2SO_4 reference electrode, and is a typical example. Theoretically, if the process were 100% efficient, oxidation would have been complete at 48 hr at the constant current of approximately 4 ma/cm^2. The initial rise in polarization is attributed to an initial increase in resistance caused by continued deposition of $PbSO_4$ in the plate. This is followed by a lowering of resistance as the grid metal becomes covered with conducting PbO_2. When sufficient PbO_2 has been formed in the paste mass, between 36 and 40 hr in this case, the potential rises owing to the high oxygen overpotential on PbO_2, and ultimately climbs to the high terminal value when oxygen evolution becomes the major reaction during the final 10 hr of oxidation.

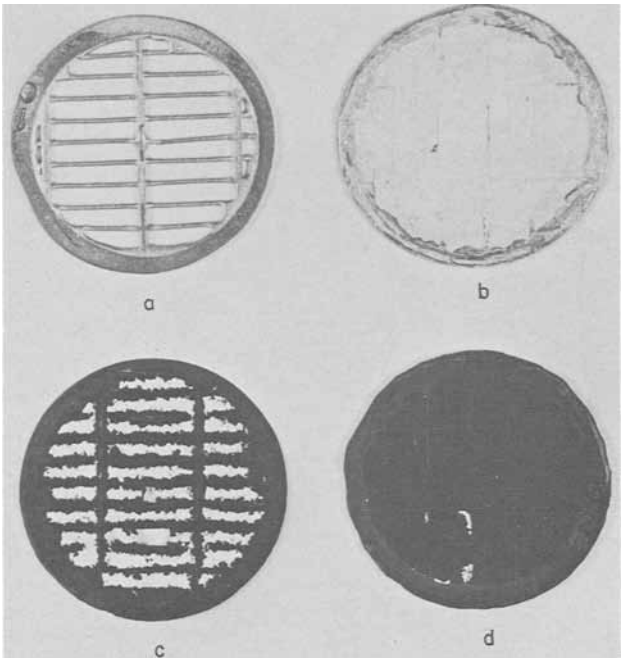

Fig. 3. Small circular plates at various stages of the study: (*a*) Small grid prior to pasting. (*b*) Small plate after pasting and curing. (*c*) Small plate after partial anodization. Black β PbO_2 first appeared adjacent to the grid bars and gradually extended into the central pellet areas as anodization continued. The white areas were $PbSO_4$. In plates containing oxide *A*, a considerable residue of the white layer remained at the outer central surfaces of the pellets after passage of a total of 150% of the theoretical charge requirement. (*d*) Final appearance of small plates containing pastes *C* and *H*. The pastes appeared essentially totally oxidized to β PbO_2. Plates containing oxide *C* were very dark, nearly black, and plates containing oxide *H* were lighter in color. The pockets of white material in the lower left quadrant are residual $PbSO_4$ that were not oxidized possibly because they were not in good electrical contact with the remainder of the pellets. It seems likely that these encrustations would be associated with cracks between the grid metal and paste visible in the radiographs of Fig. 1.

shown in Fig. 2. The actual values of the polarization will, of course, vary with the rate or current density, concentration of the electrolyte, and various *IR* losses in the system such as plate thickness, compactness of the $PbSO_4$ coating on the outer surface of the plates, *etc.*

As the anodic oxidation progressed, dark brown to black β PbO_2 developed near the grid bars, and spread gradually toward the pellet centers. Paste *A* became converted to PbO_2 at the edges and interior of the pellets, but retained a surface coating of $PbSO_4$ at the pellet centers. Pastes *C* and *H* appeared essentially completely oxidized, paste *C* giving a very dark blackish plate while paste *H* was lighter in color. Figure 3 shows the general appearance of the plates at various stages of the work.

After formation, electron microscopy showed a range of morphologies with the individual crystallites varying from about 0.5 to less than 0.1μ. Some prismatic crystals with branching suggestive of multiple twinning were present in paste *A*, and appeared less frequently in the other two pastes. Agglomerates, up to several microns in size, of prismatic crystallites were present in all pastes. Paste *H* gave rise to the largest individual crystallites about 0.5μ diameter. Oxide *C* resulted in many remarkably uniform 0.1μ crystallites arranged in spiraling layers terminated by one central individual crystallite, and forming spheroidal agglomerates, Fig. 4-7. Although not clearly apparent in all of the electron micrographs, it is believed that the aggregates are compound spikes of dendritic growth covered with sessile crystallites of

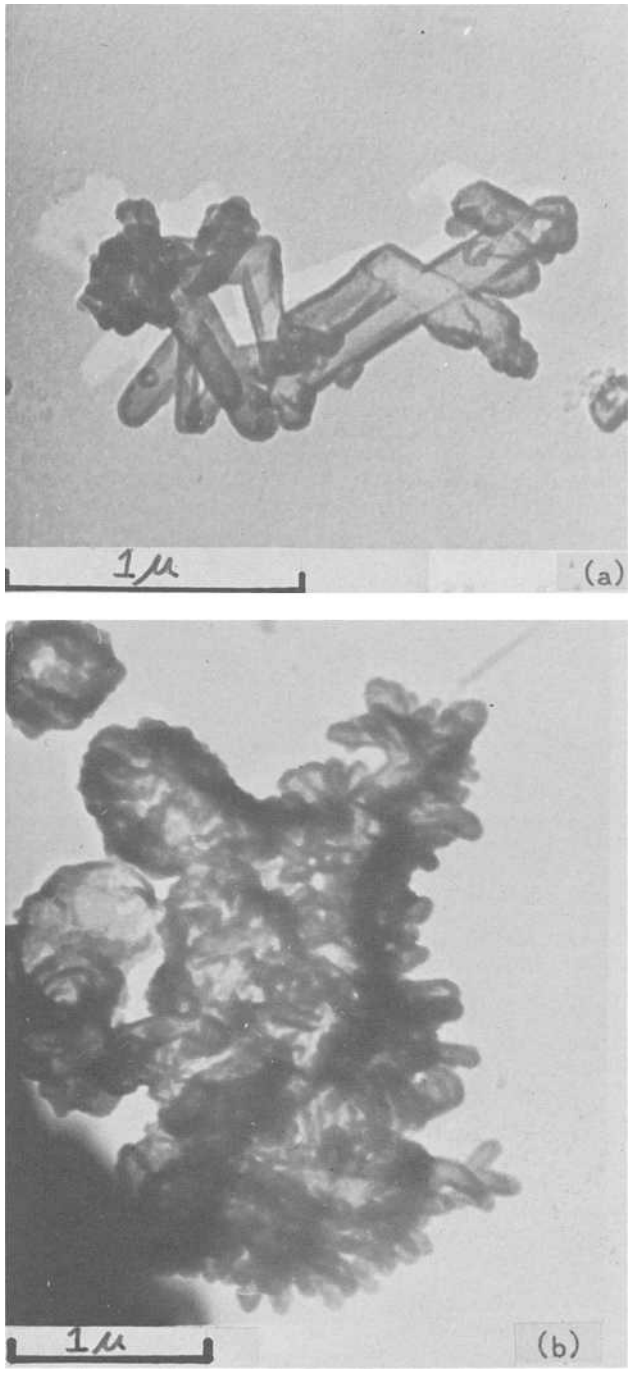

Fig. 4. Prismatic crystals of PbO_2: (*a*) This group of crystals is representative of the type referred to as prismatic individuals with branching suggestive of multiple twinning. They were found more frequently in paste *A* than in *C* and *H*. This is believed to be an early stage in the growth of more extensive clusters of similar prismatic crystals shown in (*b*). (*b*) Christmas tree dendrites of PbO_2 possibly composed of true whiskers. This may be a more advanced stage of growth of clusters of crystals such as shown in (*a*). Markers equal 1μ.

varied size and morphology. It is possible that the agglomerates may arise from the coarse particles present in the original oxides.

Differences in PbO_2 morphology from the three different oxides were recognizable, and the photographs have been selected to illustrate these differences. Paste *A* appeared to give rise to true spherulites, paste *C* produced spheroidal agglomerates of small crystals from which emerged dendritic spikes of somewhat larger crystals, and paste *H* produced irregular-shaped clusters of even larger crystals. Because the largest individual crystals appeared in the paste that

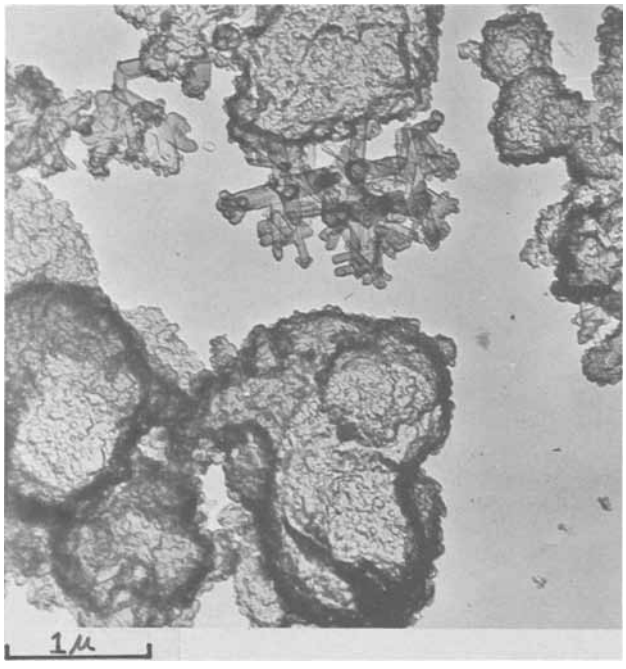

Fig. 5. Spherulites and prismatic crystals which were characteristic of PbO_2 grown from paste A. It is possible that the spherulites originated from dendrites such as shown here and in Fig. 4 through development of overgrowths of sessile crystallites on the originally smooth surfaces of the whiskerlike crystals. Marker equals 1μ.

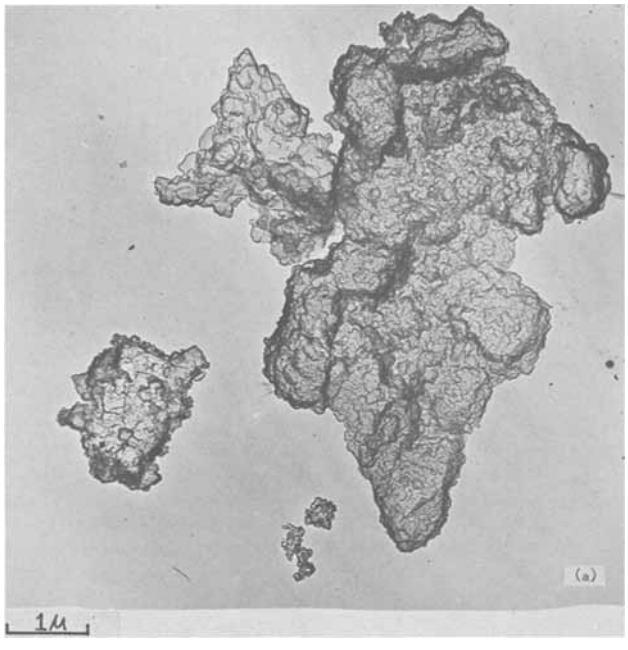
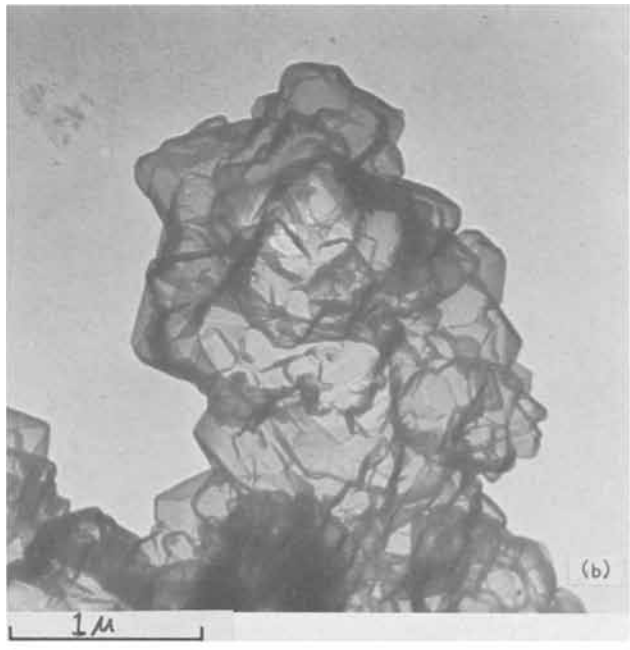
originally contained Pb_3O_4, it seems likely that the PbO_2 particles resulting from chemical reaction with H_2SO_4 acted as growth-promoting nuclei. Despite these differences, it would not be possible to identify any single isolated crystal form as coming from a specific paste, because of the range of individual and agglomerate shapes and sizes in each sample. This is not surprising in view of the fact that all three pastes were primarily composed of the same material after curing, namely tribasic lead sulfate. The morphologies observed in this study are essentially identical with those developed by anodic oxidation of the pure phases examined earlier (5, 6).

It did not appear to make a major significant difference in morphology if the three oxides used in this study were anodized on pure lead or antimonial lead





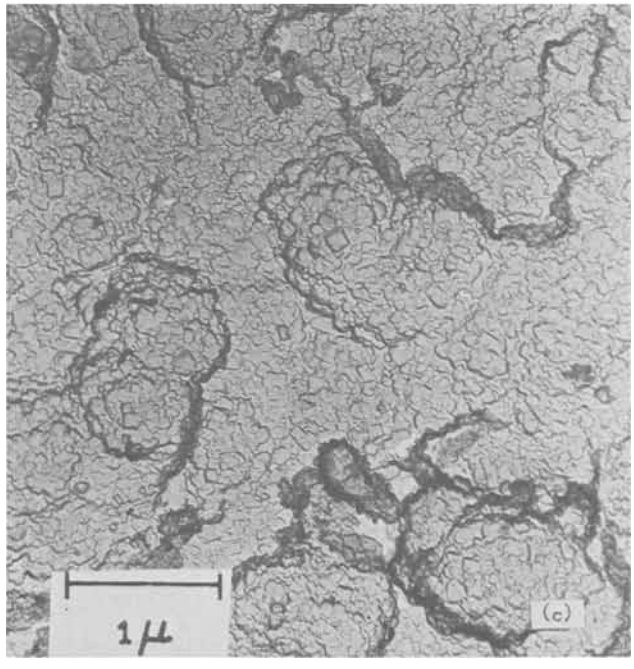


Fig. 6. Spheroidal and dendritic growths fairly typical of PbO_2 from paste C: (a) The similarity in general outline of the emergent dendritic spike to the main body of this nodular mass of crystals is strongly suggestive that the smaller crystals have grown on, and filled in a similar underlying dendritic growth of the larger crystals. This is also suggested by the appearance of the smaller mass at the left which shows a spherulite of larger crystals partially coated with outgrowths of the smaller crystals. (b) Detail of a dendritic spike. (c) Spiraling layers of small prismatic crystals make up the spherical nodules. The uniformity in size of these crystallites indicates that they represent one stage in the PbO_2 growth mechanisms, possibly the final stage. Markers equal 1μ.

grids. This is in contrast to previous observations; however, in the earlier study (4), formation was performed by commercial manufacture, probably under considerably different conditions of current density, temperature, and relative volume of electrolyte to plate area, details not revealed by the manufacturer. Furthermore, the oxides used in this study were of different manufacture, and it may be considered very significant that these gave rise to well-developed prismatic crystallites when formed on pure lead as well

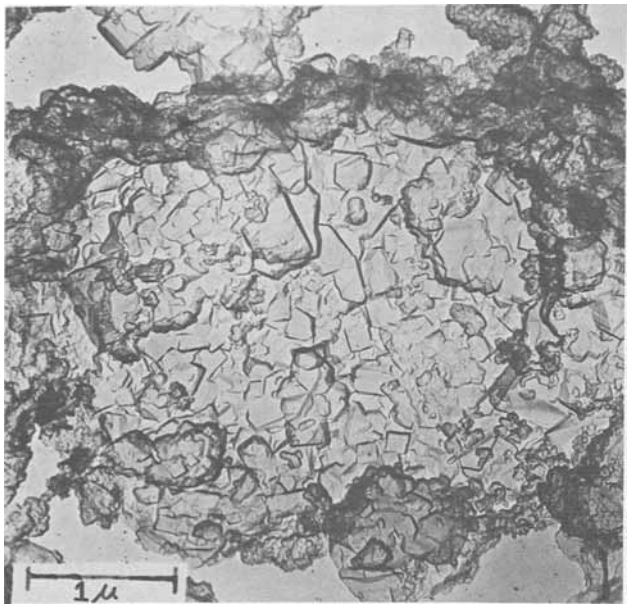

Fig. 7. Clusters of large prismatic crystals like this were characteristic of PbO_2 grown in paste *H*. The clusters took the form of irregular aggregates some approaching ovoids and others, like this one, were rhomboidal in outline. The decoration at the edges with much smaller crystallites was also fairly typical, and again suggests that the small crystals grow on the surfaces of the larger ones, and may represent a final growth stage in the anodic oxidation. Marker equals 1 μ.

as on antimonial lead. Further investigation of the float characteristics of these oxides will be of interest to determine whether the prismatic morphology and attendant paste strength is retained on both antimonial and nonantimonial grids.

The largest crystallites of PbO_2 developed in paste *H* containing Pb_3O_4, suggesting that this oxide may be of particular interest for further investigation. The relatively large agglomerates of these bigger crystals may form a submicroscopic network of considerable strength that may enhance the durability of a plate fabricated from this oxide.

An Electrochemical Method of Preventing Embrittlement in High-Strength Steel Types 1062 and 4037 During Hydrochloric Acid Pickling

A. W. Lui* and R. R. Rogers*

Mines Branch, Department of Energy, Mines and Resources, Ottawa, Ontario, Canada

ABSTRACT

It is shown that a high-strength steel of Type 1062 or 4037, either covered with nonmetallic scale or with the scale removed by blasting with an aqueous slurry of No. 220 aluminum oxide, can be pickled in hydrochloric acid without (*a*) the occurrence of embrittlement, (*b*) the loss of an appreciable amount of metal, or (c) an important change in appearance, when it is maintained within a range of potentials which is specific for each combination of steel and nonmetallic material on the surface of the steel. Any nonmetallic material remaining on the steel after the pickling can be removed by ultrasonic vibration in water. After such treatment, the steel remains unembrittled during plating with cadmium in a stable cyanide bath.

Frequently Type 1010 low-carbon steel, having the specification shown in Table I, is electroplated with other metals to protect it from corrosion, to improve its appearance, *etc.* Prior to plating, the steel ordinarily is degreased and then pickled in hydrochloric or sulfuric acid to remove oxides and other undesirable materials. During the pickling process, metal is dissolved at small anodic areas of the steel, and hydrogen gas is evolved at small cathodic areas.

The situation is different in the case of "high-strength" steels such as Types 1062 and 4037, typical analyses of which are shown in Table I. Such steels absorb part of the hydrogen produced during acid pickling, with the result that they may become severely embrittled. In present-day practice, these steels are baked at a comparatively high temperature after plat-

* Electrochemical Society Active Member.

Table I. Analyses of steel Types 1010, 1062, and 4037 (%)

Constituent	Specification for low-carbon steel (Type 1010)	Analyses of "high-strength" steels used in the present research (%) Steel Type 1062	Steel Type 4037
Carbon	0.08-0.13	0.64	0.40
Manganese	0.30-0.60	1.03	0.76
Silicon	—	—	0.31
Molybdenum	—	—	0.26
Phosphorus	0.04 max.	<0.02	<0.02
Sulfur	0.05 max.	<0.02	<0.02

ing, to eliminate this hydrogen embrittlement. This procedure has certain disadvantages.

Bednar, Dingley, and Rogers (1) already have described a method of pickling high-strength steel of Types 1062 and 4037 without significant embrittlement as indicated by the bend test. This method involves (*a*) removal of oxides, *etc.*, by hydrochloric acid with the use of ultrasonics, (*b*) treatment in copper sulfate solution, (*c*) treatment in a solution of nitric and acetic acids, and (*d*) water rinsing using ultrasonics. Following this procedure, the steels may be plated with a good, very adherent coating of cadmium in a stable cyanide bath [described in an earlier paper (2)] without embrittlement. Equally good results may be obtained when the steels are plated with zinc or copper using stable cyanide baths (3, 4). A new procedure for plating these high-strength steels with silver in a stable bath, without embrittlement, is described in a paper soon to be published.

More recently, this laboratory has become interested in the possibility of pickling high-strength steel without embrittlement by making it anodic in a cell in which the electrolyte is hydrochloric or sulfuric acid. It was assumed that the hydrogen produced would be evolved on the cathode of the cell, *i.e.* at some distance from the high-strength steel. It was believed that such a procedure could be more useful than the one described above (1) under certain circumstances.

The Steels as Received

The high-strength steel pins of Types 1062 and 4037 used in these experiments (chemical analyses in Table I) were 0.4 cm in diameter. Those of Type 1062 were 8.3 cm long and had been austempered in the bainitic range giving a Rockwell C hardness of 52-56. When received, they were covered with a uniform thin blue oxide scale. Those of Type 4037 were 6.7 cm long and had been quenched and tempered giving a Rockwell C hardness of 51-55. When received they were covered with a thin, very porous film of copper together with smutty black material. No attempt was made to pickle more complicated objects made of these steels by the new electrochemical method which has been described here.

Experimental Equipment

The equipment used in these experiments was standard with the following exceptions:

(*a*) Lorco Liquamatte wet-blasting equipment Model 22 using an air-line pressure of 80 psi.

(*b*) Sonogen ultrasonic generator LG-150 (25 kc, 150w) equipped with an LT-60 transducerized tank. (All ultrasonic treatments were performed in distilled water.)

(*c*) Electrical equipment which has been described elsewhere (5).

This included:

1. A glass test cell containing hydrochloric acid as the electrolyte. A high-strength steel pin was used as one electrode, and two platinum sheets connected in parallel as the other electrode.
2. A potentiostat which could be used to maintain the potential of the immersed steel pin at any desired value.
3. A standard saturated calomel electrode which was used in determining either (*a*) the uncontrolled potential of the steel pin, or (*b*) the controlled potential of the steel pin when connected with the platinum electrode.

(*d*) A Hounsfield notched bar bending jig attached to a tensometer machine. During bend testing, the unnotched pin was supported at two points 3 cm apart. Pressure applied to a 0.32-cm-diameter mandrel forced the pin into the gap between these two points until it broke or until a bend of 90° had been produced without breaking. This bending through 90° required 7 min. If the pin remained unbroken, it was arbitrarily assumed to be free of significant embrittlement.

Experimental Procedures and Results

Preventing blasted pins from embrittlement.—During this part of the research, each steel pin was prepared, prior to its use in an experiment, by degreasing in trichlorethylene vapor, blasting with an aqueous slurry of No. 220 aluminum oxide to remove the oxides and other undesirable material from the surface, thorough rinsing with distilled water, and drying.

In the first experiment, a blasted pin of steel Type 1062, free from significant embrittlement, was connected to a standard calomel electrode (SCE) and both were placed in the test cell which contained 250 ml of 0.1*N* hydrochloric acid at room temperature (about 23°C). After 5 min, the potential of the pin *vs.* the calomel electrode was recorded. The pin then was removed from the acid, rinsed with distilled water, and dried in air. Finally, it was bent in the Hounsfield testing machine to determine whether or not it would break due to embrittlement. Four other similar experiments were performed and then the percentage of this set of five pins which had broken during the test was calculated. Five similar experiments were performed with the pins immersed in the acid for only 3 min. The information obtained in this way is given in Table II.

Five additional experiments were performed in each of which a pin of Type 1062 steel was connected with a platinum electrode and the two were immersed in 250 ml of 0.1*N* hydrochloric acid. In each case, the potential of the pin was maintained for 5 min at —1.0v *vs.* SCE by means of the potentiostat. This was followed by rinsing, drying, and testing in the Hounsfield machine as before. The experiments then were repeated using 3 min instead of 5 min.

The procedure described in the last paragraph was repeated using potentials of —0.9, —0.8 . . . 0.3 and 0.4v *vs.* SCE.

The information obtained in the above experiments is summarized in Table II. Similar information, obtained with pins of steel Type 4037, is presented in Table III.

In the case of the pins of steel Type 1062, it is seen that:

1. The potentials of the pins which had been pickled in the acid without any externally applied potential were between —0.56 and —0.54v *vs.* SCE, and 60% of those pins were broken when bend tested regardless of whether they had been 5 or 3 min in the acid.

Table II. Embrittling effect of 0.1*N* hydrochloric acid on blasted pins of steel Type 1062, at different applied potentials and treatment times

Externally applied potential *vs.* SCE (volt)	Pins broken (%) 5-Min treatment	3-Min treatment	Current density at pin surface (amp/sq ft)
−1.0 to −0.9	100	100	−24
−0.8 to −0.7	100	90	−7
−0.6	80	80	−2
(−0.56 to −0.54)*	60	60	—
−0.5 to −0.1	0	0	10 to 20
0.1 to 0.4	0	0	27 to 40

* No external potential applied.

NOTE: The steel pins were anode in the tests in which the externally applied potential was −0.5 or higher.

Table III. Embrittling effect of 0.1N hydrochloric acid on blasted pins of steel Type 4037, at different applied potentials and treatment times

Externally applied potential *vs.* SCE (volt)	Pins broken (%) 5-Min treatment	3-Min treatment	Current density at pin surface (amp/sq ft)
−1.0 to −0.7	100	100	−80 to −4
−0.6	100	80	−2
−0.5	80	80	−1
(−0.50 to −0.47)*	60	40	—
−0.4 to −0.1	0	0	2 to 14
0.1 to 0.5	0	0	24 to 31

* No external potential applied.
NOTE: The steel pins were anode in the tests in which the externally applied potential was −0.4 or higher.

2. All of the pins which had had an externally applied potential of −1.0 or −0.9v *vs.* SCE for 5 or 3 min were broken in the bend test.
3. At least 80% of the pins which had had an externally applied potential of −0.8, −0.7, or −0.6v *vs.* SCE were broken in the test, regardless of the length of pickling treatment.
4. None of the pins which had had an externally applied potential between −0.5 and 0.4v *vs.* SCE were broken in the test, regardless of the length of the pickling treatment.

The results obtained with the Type 4037 pins showed some similarity to those obtained with the Type 1062 pins. Here, none of the pins which had had an externally applied potential between −0.4 and 0.5 were broken, regardless of the length of the pickling.

After pins of both steels had been pickled in 0.2*N* hydrochloric acid (instead of 0.1*N*) for 5 min at an externally applied potential between −0.4 and −0.1v, none of them were broken in the bend test; *i.e.*, no significant embrittlement had occurred. No experiments were performed in which the hydrochloric acid content was below 0.1*N* or above 0.2*N*.

Since acid pickling solutions become less acid and their iron contents increase during use, experiments similar to the above were performed with pickling solutions which were 0.05*N* in hydrochloric acid and 0.05M in ferric or ferrous chloride. It was found that none of the pins were broken after 5 min pickling in these solutions when the externally applied potentials were as follows:

Steel Type 1062

Ferric chloride solution : −0.3 to −0.1v
Ferrous chloride solution : −0.4 to −0.2v

Steel Type 4037

Ferric chloride solution : −0.3 to −0.1v
Ferrous chloride solution : −0.4 to −0.3v

These data show that, even after one half of the hydrochloric acid in a 0.1*N* solution has been changed to ferric or ferrous chloride, there was a range of applied potentials at which no significant embrittlement occurred in pins of Types 1062 and 4037.

The pickling of high-strength steel pins in hydrochloric acid without embrittlement would be of comparatively little importance if a large amount of metal were to be dissolved during the operation, or if even a thin nonmetallic coating were to remain on the surface. Accordingly, the rate of solution of each metal during the pickling, and the appearance of each metal after the pickling, were investigated. As shown in Table IV, the rates of metal loss during 10-min pickling treatments of Type 1062 pins in 0.1*N* hydrochloric acid at applied potentials between −0.5 and −0.1v varied between 0.36×10^{-4} and 3.58×10^{-4} g/cm²/min. The rates for Type 4037 pins at applied potentials between −0.4 and −0.3v varied between 0.33×10^{-4} and 1.75×10^{-4} g/cm²/min. All of these rates are too low to be of importance. The appearance of these metals changed very little during these pickling treatments, as determined by inspection at a magnification of 60X.

Table IV. Rates of metal loss from blasted steel pins during immersion for 10 min in 0.1N hydrochloric acid with various anodic potentials applied

Applied potential *vs.* SCE (volt)	Rate of metal loss (g/cm²/min) Steel Type 1062	Steel Type 4037
−0.5	0.36×10^{-4}	
−0.4	0.94	0.33×10^{-4}
−0.3	1.69	1.75
−0.2	2.64	
−0.1	3.58	

It is important to note that (as shown in Table II), as the applied potential was increased from about −0.5 to about 0.4v, the current density at the steel surface was increased greatly. Although the pins continued to be in the unembrittled condition, the rate of solution of the metal in the acid increased a great deal and the metal surface became considerably rougher. Somewhat similar observations were recorded in Table III.

All of the experiments already referred to were repeated using sulfuric acid instead of hydrochloric acid. Since the results obtained in these experiments were of less practical interest than those obtained with hydrochloric acid, they have not been included in this paper.

Preventing unblasted pins from embrittlement.—In this part of the research, each steel pin was prepared for experiment by merely degreasing in trichloroethylene vapor. No attempt was made to remove or change the nature of the other nonmetallic material originally present on the pins.

It was found that, after pins of steel Type 1062, prepared as described in the previous paragraph, had been pickled for 15 min in 0.1*N* hydrochloric acid at an applied potential between −0.1 and +0.5v, they were free from embrittlement. When the applied potential was between +0.3 and +0.5v and the final surface had been water rinsed and treated ultrasonically, the surface was clean and comparatively smooth (*see* Table V). As shown in the same table, almost the same results were obtained with steel Type 4037.

Electroplating cadmium on steel Types 1062 and 4037 after anodic pickling in hydrochloric acid.—Geyer, Lawless, and Cohen (6) have stated, "Electroplating processes are recognized as the most common source of detrimental hydrogen embrittlement, and cadmium-electroplating processes are considered to be among the most serious offenders." However, in the present research it was found that high-strength steel pins of Types 1062 and 4037 could be plated with adherent cadmium in a stable bath (2) without embrittlement, providing that their surfaces had been given a preliminary preparation consisting of electrolytic treatment in hydrochloric acid, water rinsing, and ultrasonic treatment as described in this paper.

Summary

Degreased high-strength steel of Type 1062 or 4037, covered with oxide or other foreign material produced during previous metallurgical treatment, can be pickled with hydrochloric acid at about 23°C without embrittlement, if it is maintained within a certain range of electrical potentials while the pickling is in progress.

Table V. Effect of applied potential on the embrittlement of unblasted steel and the nature of the surface after water rinsing and ultrasonic treatment (15 min in 0.1N hydrochloric acid)

Type of steel	Potential applied to steel *vs.* SCE	No embrittlement produced	Surface clean and smooth after water rinsing and ultrasonic treatment
1062	−0.1 to +0.2	Yes	No
	+0.3 to +0.5	Yes	Yes
4037	−0.1 to +0.1	Yes	No
	+0.2 to +0.5	Yes	Yes

Any foreign material remaining on the metal surface can be removed by ultrasonic treatment in distilled water. The exact range of electrical potentials giving satisfactory results during the pickling depends on the composition of the metal being treated, the nature of the nonmetallic material on the surface of the metal prior to the pickling, and the length of the treatment time. The metal is dissolved at an insignificant rate and the nature of its surface is practically unaffected during the electrolytic treatment if the proper electrical potential is used.

The following alternate procedure may be used in the case of these steels. After degreasing, the steel is blasted with an aqueous slurry of No. 220 aluminum oxide to remove the undesirable nonmetallic material from the surface, thoroughly rinsed with distilled water, and dried. It then is pickled in hydrochloric acid while being maintained within a certain range of electrical potentials, and the foreign material still adhering after this treatment is removed thoroughly by ultrasonic treatment in distilled water and rinsing.

Steel Type 1062 or 4037 prepared by one of the procedures just described may be electroplated with adherent cadmium in a stable cyanide bath without becoming embrittled.

Since steels of the same type vary somewhat from batch to batch, the most suitable operating conditions for pickling each new batch of steel should be determined before regular production is commenced.

The electrodes used in these experiments were of high-strength steel and platinum. Obviously, in an industrial operation the platinum would be replaced by a cheaper material.

Sulfuric acid was found to be less satisfactory than hydrochloric acid as a pickling agent for the high-strength steels investigated.

Hydride Sources for Diffusion of Dopants into Silicon-on-Sapphire Films

D. J. Dumin

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Mixtures of B_2H_6, PH_3, AsH_3 diluted in H_2 have been used as a source for diffusion into thin silicon-on-sapphire films after the films had been grown. Films 1-2 μm thick of initial resistivity greater than 100 ohm-cm have been reproducibly doped from 0.01 to 1 ohm-cm, both P- and N-type. Films have been doped to resistivities higher than 10 ohm-cm, but not reproducibly. This process has been used to produce either thin heavily doped layers on the surface of the thin film or, after a drive-in step, a uniformly doped film. The doping process was studied as a function of dopant gas flow rate and temperature.

Numerous sources of P- and N-type impurities have been used to dope bulk silicon and silicon epitaxial layers (1). In general, the doping of epitaxial layers of silicon has been performed during growth of the layer (2), allowing for the control of either uniformly doped layers or the production of doping profiles that would be extremely difficult to obtain after growth using diffusion only (3). The solid-solid diffusion process has been found to be both convenient and reproducible, but after diffusion the silicon surface is covered with a doped oxide layer (4).

In general, the techniques used to dope silicon films grown heteroepitaxially on sapphire and spinel have paralleled the techniques used to dope homoepitaxial silicon (5). The use of the gaseous hydrides added to the gas stream during growth of silicon on quartz and beryllium oxide have been reported (6). Fabrication of diodes, transistors, and integrated circuits in silicon-on-sapphire films have used processing steps similar to those used in processing bulk silicon devices (7).

The use of gaseous hydrides in both oxidizing and reducing atmospheres as sources of P- and N-type impurities for the selective doping of silicon has been reported (8). These reports have indicated that the use of an oxidizing atmosphere to provide a doped oxide as the source of impurity tended to produce wafers more uniformly and reproducibly doped than the use of a reducing atmosphere of H_2 or an inert atmosphere of He. Using a hydride in an oxidizing atmosphere results in essentially a solid-solid diffusion process.

During the fabrication of silicon-on-sapphire circuits, it has often been necessary to modify transistor or diode characteristics after the devices had been fabricated. A relatively simple system that we investigated was the use of the gaseous hydrides B_2H_6, AsH_3, and PH_3 in H_2 mixtures as diffusion sources. The silicon surfaces after diffusion were not covered by an oxide layer and uniform doping of layers 0.2-1.0 μm could be obtained in relatively short periods of time. This paper describes the results of experiments performed on the doping of thin silicon films.

Experimental

Wafer preparation.—The wafers used in these experiments were (100) silicon grown on $(1\bar{1}02)$ flame fusion sapphire at temperatures between 1050° and 1100°C using previously described techniques (9).

No dopant was intentionally added to the films during growth, but the films were usually P-type, doped with varying amounts of Al from the Al_2O_3 substrate (10). Previous experiments of growing thin silicon films on 10 ohm-cm P- and N-type bulk silicon wafers indicated that impurities in the SiH_4 source produced silicon doped N-type with carrier concentrations of about $10^{14}/cm^3$. After the Al had been removed from the films by segregation in a thermal oxide (11), the films of silicon on sapphire were N-type with resistivities above 10 ohm-cm and Hall mobilities over 400 $cm^2/vsec$. The films were 1-2 μm thick as determined by using *IR* interference techniques (12).

The diffusion step was carried out by first heating the wafer to the desired hydride deposition temperature in hydrogen. The wafer was held at deposition temperature for 1 min after which the dopant was added to the hydrogen flow. The deposition time in all cases was 5 min. The system was flushed for 1 min in H_2 after deposition from the hydride, and then the temperature was lowered to room temperature. The system used to grow and dope the films has been previously described (9).

At this stage in the processing, the wafers contained both a doped layer on the surface and, because the processing took place in H_2, a somewhat variable amount of aluminum originating from the H_2 reduction of the Al_2O_3 substrate. The aluminum could be removed by segregation in a thermal oxide (11) which also caused redistribution of the desired impurities. Since, in general, P-type impurities tend to segregate in a thermal oxide and N-type impurities do not (13), the redistribution step also caused some reduction in the amount of boron in the films. The presence of aluminum in the films and its removal after the diffusion step complicate the analysis of the data and these complications are discussed below. In the cases where the diffusion was performed at temperatures below 1050°C and only a limited amount of aluminum was introduced into the films, the impurities could be redistributed by heating the wafer in He at 1200°C for 30 min.

P-type doping: boron.—The boron diffusions were carried out using B_2H_6-H_2 mixtures varying in composition from 10^{-6} to 10^{-2} mole per cent (m/o). At B_2H_6 concentrations greater than 10^{-2} m/o, elemental boron was deposited on the wafer surface. At hydride concentrations less than 10^{-3} m/o, the boron apparently diffused into the silicon as fast as it was produced, and a P+ layer of silicon was formed on the surface of the silicon, rather than an elemental boron layer.

Two profiles of resistivity *vs.* silicon thickness are shown in Fig. 1 for two boron layers deposited on a 1 μm-thick silicon film. The boron concentration in the gas stream was $7.5 \cdot 10^{-4}$ m/o at two deposition temperatures of 1050° and 1150°C. The resistivity was measured using a four-point probe using the total film thickness to determine the thickness correction factor (14). The silicon was removed by anodic oxidation involving maximum temperatures of 60°C (15). The aluminum autodoping had been removed from these films, and both films were N-type with resistivities greater than 100 ohm-cm prior to boron doping. In the film doped at 1050°C, a layer of P-type silicon was observed on the surface of the wafer with the N-type silicon remaining below the diffused layer to the silicon-sapphire interface. The depth of diffusion of 0.1 μm is in good agreement with a complementary error function type of diffusion using published values of diffusion constant for boron (16). The wafer diffused at 1150°C was P-type throughout. This was probably due not only to the greater depth of diffusion of the boron at 1150°C but also to the enhanced aluminum autodoping.

A series of plots in Fig. 2 show the variation in carrier concentration in the films due to changes in the

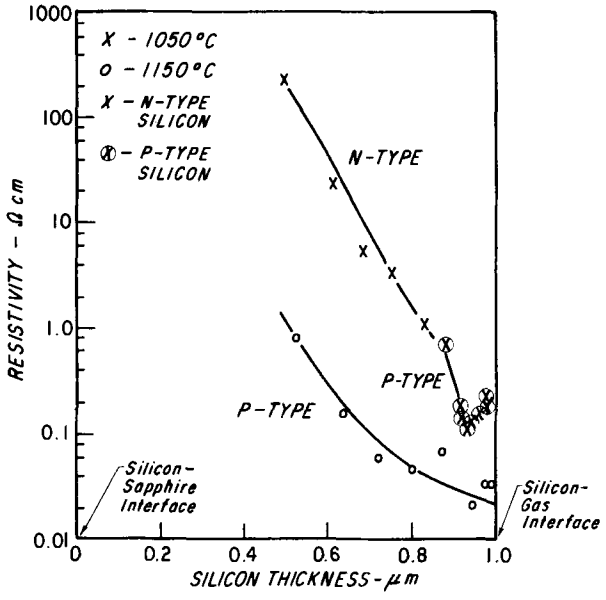

Fig. 1. Doping profiles using B_2H_6 to dope 1-μm-thick, high-resistivity N-type silicon-on-sapphire films. B_2H_6 concentration in H_2 was 2×10^{-5} m/o.

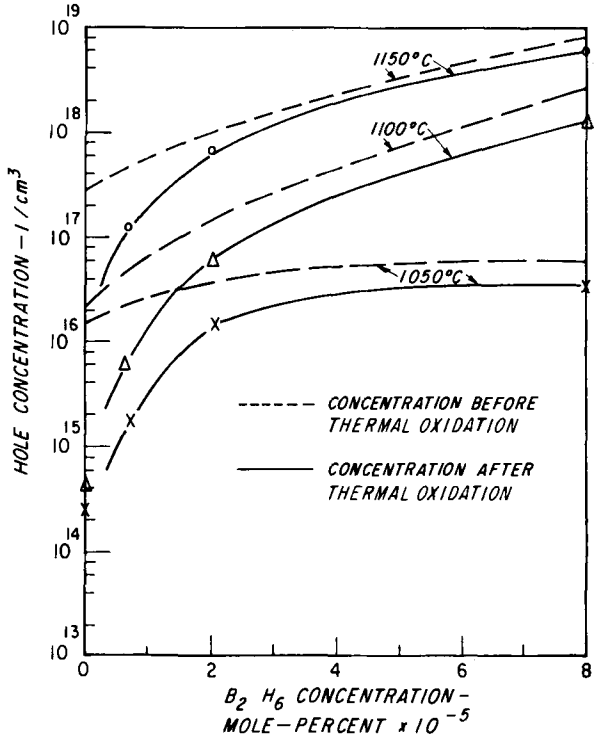

Fig. 2. Carrier concentration in 1-μm silicon-on-sapphire films as a function of gas concentration and temperature. Dashed lines—data taken before aluminum removal by thermal oxidation; solid lines—data taken after aluminum removal by thermal oxidation.

B_2H_6 gas concentration and deposition temperature. These wafers were doped using the cycle: 1 min H_2; 5 min B_2H_6-H_2; 1 min H_2 described above. Hall data were taken both before and after the boron had been redistributed by diffusion in a dry O_2 ambient at 1200°C for 1 hr.

The carrier concentration was determined by using $N = 1/\rho e\mu$ where ρ is the resistivity and μ is the Hall mobility. The ratio of drift to Hall mobility was assumed to be unity. Before oxidation, the wafers contained both the heavily boron doped layer on the silicon surface and any aluminum autodoping that was present. After the oxidation, the boron was redistributed throughout the film and the aluminum was

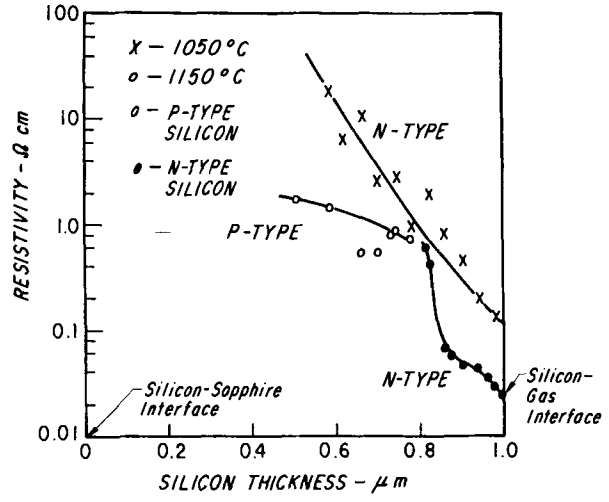

Fig. 3. Doping profiles using PH_3 to dope 1-μm, high-resistivity N-type silicon-on-sapphire films. PH_3 concentration in H_2 was $7.5 \cdot 10^{-5}$ m/o.

removed by segregation in the oxide (11). Some of the boron no doubt also segregated in the thermal oxide (13). Thus, within the error of neglecting the amount of boron that might have segregated in the oxide, the data presented in Fig. 3 represent the amount of boron introduced into the silicon during the deposition step. The hole concentration measured in 2-μm-thick films was about ½ of that shown in Fig. 2 when the 2-μm-thick films were subjected to the same diffusion cycle.

The reproducibility of the boron doping system was tested by attempting to dope several wafers to the same resistivity on successive days. The results of one of these experiments are shown in Table I. The wafers were doped at 1000° and 1100°C for 5 min in $2 \cdot 10^{-5}$ m/o B_2H_6 in H_2. Before thermal oxidation, one set of wafers had resistivities of about 0.14 ± 0.02 ohm-cm. After aluminum removal through the thermal oxidation at 1200°C, the resistivity had risen to 0.23 ± 0.04 ohm-cm. This represents reproducibility to about 30-40%. Wafers doped to resistivities about 1 ohm-cm showed a somewhat larger spread in resistivities with typical values ranging between 1 and 2 ohm-cm after aluminum removal. The resistivity varied over a wafer surface about as much as it varied from wafer to wafer.

Data taken on arsenic doped films are included in Table I and are discussed below.

N-type impurities: phosphorus and arsenic.—Wafers of high-resistivity silicon on sapphire were doped with phosphorus and arsenic *via* the decomposition of PH_3-H_2 and AsH_3-H_2 mixtures, respectively. Two profiles of phosphorus diffusions performed at 1050° and 1150°C are shown in Fig. 3. The PH_3 concentration in H_2 was $7.5 \cdot 10^{-5}$ m/o using the 1-5-1 min cycle described above. These data were taken by measuring the sheet resistance of the films on a four-point probe after successive anodic oxidations. The aluminum introduced into the films was not removed. This accounts for the P-N junction observed in the film doped at 1150°C. At 1150°C, the diffusion length for aluminum is about 0.85 μm and for phosphorus is about 0.5 μm. These numbers predict that a P-N junction should be observed between 0.15 and 0.5 μm below the silicon surface, in reasonable agreement with the observed junction depth of 0.2 μm. The wafer doped at 1050°C was N-type throughout. The resistivity continually rose as the thickness was reduced indicating the effect of the decrease in phosphorus concentration. No layer of P-type silicon was observed at the silicon-sapphire interface in the 1050°C doped film due to the aluminum autodoping. This would be expected from data taken previously on thin silicon-on-sapphire films in this temperature range (10).

Attempts to measure the diffusion profile accompanying arsenic diffusion were unsuccessful for diffusion times of 5 min and temperatures below 1150°C. This reflects the lower diffusion constant of arsenic in silicon. That arsenic was indeed present in the films is however, shown when the carrier concentration data is discussed.

Plots of carrier concentration in the films as a function of hydride gas concentration and deposition temperature are shown in Fig. 4 for both phosphorus and arsenic doped silicon. The data shown in Fig. 4 were taken after a 1-hr oxidation in dry O_2 at 1200°C. Before oxidation, many of the films were P-type with varying resistivity due to the aluminum autodoping. As in the case of the boron doped wafers, increasing either the hydride concentration or the diffusion temperature increased the doping density. The carrier concentration of films doped with arsenic was almost one order of magnitude less than the concentration in the phosphorus doped films, reflecting the fact that the diffusion constant of arsenic in silicon is almost two orders of magnitude lower than the diffusion constant of phosphorus at 1150°C (17).

At diffusion temperatures of 1050°C or below, the diffusion of arsenic into the silicon was sufficiently slow to lead to nonreproducibility in the films doped using the 1-5-1 min diffusion cycle. The reproducibility of the arsenic doping system at an 1150°C deposition temperature is shown in Table I where, under nearly identical conditions, the resistivity of doped silicon layers varied around 0.5 ± 0.1 ohm-cm after aluminum removal. Before aluminum removal, the films were P-type with resistivity about 0.3 ohm-cm. The reproducibility of the phosphorus diffusions was similar to that cited for the boron under similar doping conditions. As in the case of the boron doped films, increasing the initial film thickness decreased the

Table I. Test of doping reproducibility

Resistivity as doped (ohm-cm)	Resistivity after thermal oxidation (ohm-cm)	
0.13	0.20	1100°C B_2H_6 deposition
0.14	0.20	
0.16	0.27	
1.5	2.0	1000°C B_2H_6 deposition
0.75	1.0

P-type	0.44	
P-type	0.42	

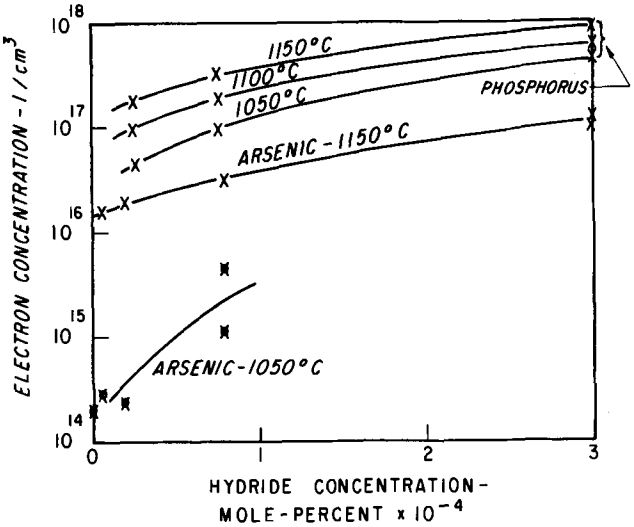

Fig. 4. Carrier concentration of N-type films as a function of hydride concentration and temperature. Many of these films were P-type prior to aluminum removal. Data presented were taken after aluminum removal.

carrier concentration in the films, but the product of carrier concentration and film thickness was approximately constant.

Discussion and Conclusions

The process of using a gas to maintain a constant surface concentration of impurity as a doping source should lead to a diffusion profile which follows the complementary error function (18). The diffusion profiles measured in Fig. 1 and 3 show that a diffusion front was obtained at about the depth of diffusion expected, but the data were not sufficiently accurate to be used as a measure of the diffusion profile. In Fig. 3, a hint of a complementary error function profile might be assigned to the 1150°C diffusion, but any concrete conclusions would be highly speculative. The shallowness of the diffusions precluded accurate measurements of the profile.

The total amount of impurity diffused into the silicon was calculated from the data shown in Fig. 2 and 4 and compared with the amount that would be expected under a complementary error function type of diffusion. For the N-type impurities, phosphorus and arsenic, no segregation of the impurity in a thermal oxide should be observed (13); thus, analyzing the concentration data after impurity redistribution by the 1200°C oxidation step should be valid. In the case of phosphorus in silicon, diffusion is a faster mechanism than thermal oxidation and the ratio $K/\sqrt{D} \approx 0.17$, where K is the parabolic rate constant for oxidation and D is the diffusion constant. This implies that the impurity would diffuse faster than the oxidation front would advance. For arsenic, $K/\sqrt{D} \approx 1.0$ and thus it would be possible for the oxidation front to overtake a portion of the diffusion impurity. This, of course, neglects segregation of the impurity in the oxide or in the silicon. The measured values of carrier concentration accompanying the phosphorus diffusion fit reasonably well the values expected for a complementary error function diffusion. The total carrier concentration varied as the square root of the diffusion constant as would be predicted (18). The carrier concentrations accompanying the arsenic diffusion were lower than predicted and this may have been due to the oxidation front overtaking some of the impurity. The carrier concentrations considered in the case of arsenic diffusion were well below the values needed for degeneracy and thus it has been assumed that the carrier concentration is an accurate measure of the impurity concentration.

The hole concentration measured in the case of the boron diffusions did not fit the error function complement type of diffusion. It appeared as if less boron was being included in the films than was expected. Again, it has been assumed that the hole concentration is an accurate measure of the boron concentration. Since boron segregates in a thermal oxide, the lowering of the hole concentrations measured could be attributed to inclusion of boron in the oxide. Since the boron diffusions were found to be reproducible, the fact that the carrier concentration data did not fit the complementary error function type of diffusion meant that the data shown in Fig. 2 had to be taken at various temperatures before it was possible to use the boron doping system accurately.

One of the purposes of these experiments was to provide a system for the alteration of diode and transister properties after device fabrication. In Fig. 5, the alteration of the characteristics of through-diffused silicon-on-sapphire diodes (19) is shown. Initially, the diodes had reverse breakdown voltages of 220v and forward series resistance of $2 \cdot 10^5$ ohms. The silicon was 10 ohm-cm, N-type, 1.3μ thick. The wafer was broken into several parts. Boron and phosphorus were diffused into the different pieces to produce silicon doped to different levels according to the data presented in Table I and Fig. 2 and 4. After deposition of the thin boron layer and subsequent drive-in, the

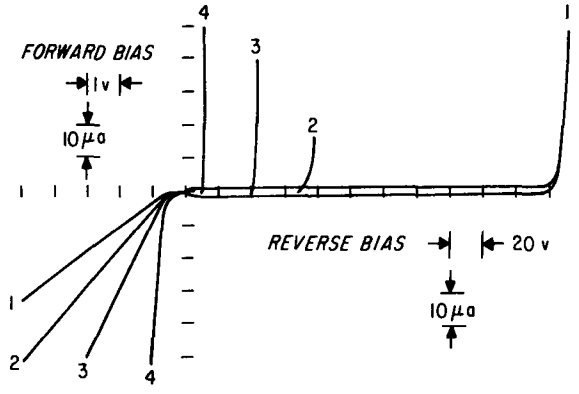

Fig. 5. Alteration of forward and reverse diode characteristics after boron diffusion: 1—Initial characteristics. 2—Portion diffused in $7 \cdot 10^{-6}$ m/o B_2H_6 in H_2 at 1000°C for 5 min. Drive-in was 1200°C dry O_2 for 30 min. 3—Portion diffused in $7 \cdot 10^{-6}$ m/o B_2H_6 in H_2 at 1050°C for 5 min. Drive-in was 1200°C dry O_2 for 30 min. 4—Portion diffused in $8 \cdot 10^{-5}$ m/o B_2H_6 in H_2 at 1150°C for 5 min. Drive-in was 1200°C dry O_2 for 30 min.

diode resistivity had been lowered on one piece of the wafer to 5 ohm-cm, on another portion to 2.5 ohm-cm, and on a third portion to 0.5 ohm-cm with the breakdown voltage being lowered to 70, 40, and 10v, respectively. The phosphorus doped portions of the wafer showed similar changes in diode resistances and breakdown voltages. The gas phase doping of the films did not change the position of the junction, which was determined by microscopically examining the diode under large reverse bias and noting the position of the light emission (20). The breakdown voltages observed in these diodes always correlated well with the breakdown expected on bulk silicon of similar resistivity (21).

Attempts were made to raise the reverse breakdown voltage of diodes made in P-type silicon by partially compensating the material with phosphorus. This has not been reproducibly accomplished.

The surfaces of bulk silicon wafers were doped using the doping schemes described above. Diodes have been manufactured either by uniformly doping the wafer and etching mesas or by diffusion through holes in an oxide mask. P^+N diodes have been produced at deposition temperatures as low as 800°C and N^+P diodes at temperatures above 900°C. The minority carrier lifetime in the starting N-type silicon was of the order of 5-10 μsec and after P^+N diode fabrication was between 1-5 μsec (22). Diffused resistors have also been produced in bulk silicon with values of resistance varying between 10-4000 ohms/sq.

The use of the hydride in hydrogen sources has thus been utilized to dope both thin silicon-on-sapphire films on bulk silicon wafers. The doping of the thin films proved to be reproducible. A sufficient amount of data needed to determine reproducibility on the bulk silicon wafer was not taken; however, the production of diodes with only a small amount of degradation of minority carrier lifetime indicated that the use of the hydride-hydrogen diffusion system may have applications in doping of bulk silicon. At present, the use of the hydride-hydrogen diffusion system appears to be no more reproducible than existing doped oxide systems as sources for diffusion, but the fact that the doped silicon surface is not covered by an oxide after diffusion tends to simplify some device fabrication steps. Helium was used as the carrier gas when it was desirable to avoid oxidation of the silicon surface during the drive-in step.

Preparation and Properties of Boron Carbide Continuous Filaments

J. B. Higgins, A. Gatti, and J. J. Gebhardt

Space Sciences Laboratory, General Electric Company, Missile and Space Division, Space Technology Center, Philadelphia, Pennsylvania

ABSTRACT

Boron carbide filaments are promising reinforcements for use in both resin and metal composites because of their potentially high strength, high elastic modulus, and low density. This paper discusses the preparation and properties of such filaments from the viewpoint of their ultimate usefulness in such applications. Continuous boron carbide filaments were vapor deposited on tungsten substrates having a boron precoat from mixtures of boron trichloride, methane, and hydrogen at 1 atm and temperatures between 1100° and 1200°C. Deposition rates were considerably less than for boron alone; a close relationship was seen between the stoichiometry of the feed gas, filament composition, and mechanical properties. In extended runs, average strengths of 390,000 psi were achieved, with individual values as high as 474,000 psi (1-in. gauge). Elastic modulus values up to 62 x 10^6 psi were also characteristic of the product. In prototype epoxy resin composites of less than optimum uniformity and homogeneity, bend strengths up to 244,000 psi and moduli up to 54 x 10^6 psi were measured at 85 v/o filaments, indicating that efficient transfer of stress to the filaments occurred.

The vapor deposition of refractory high-melting materials on static filamentary substrates was first undertaken on a broad scale by Moers and Agte in 1931 (1). Only within the past few years, however, has this technique been sufficiently well developed to permit preparation of continuous coated filaments on a scale approaching that of pilot-plant production. While both elemental boron and silicon carbide (2, 3) have been prepared in quantity, boron carbide in this form has not been studied in detail, although its bulk mechanical properties mark it as a promising candidate for use in filament reinforced composites.

In order to obtain boron carbide by vapor deposition from easily obtained gaseous species, it is most convenient to reduce a halide and pyrolyze a hydrocarbon simultaneously. Boron can be obtained at reasonable rates by the reduction of boron trichloride with hydrogen at temperatures above about 1000°C (4), while the thermal decomposition of methane can also be brought about, although at lower rates in the same temperature region (5). This temperature requirement necessitates the use of an electrically conductive refractory filament for a substrate, since it must retain sufficient strength at deposition temperatures to be drawn through a continuous deposition reactor. The number of such materials is limited to those in the refractory metal group and since, of these, tungsten is most easily available in quantity, it is the most logical choice. However, because it is very dense (18.9 g/cm^2) and will thus raise the total density of the final filament considerably, only the thinnest available substrate can be used. Thus, the basic outlines of the deposition scheme can be summarized as follows: deposition temperature, above 1050°C; pressure, 1 atm;

reactants, boron trichloride, methane, and hydrogen; substrate, tungsten filament, 0.5-1.0 mil.

Experimental Procedure

Preliminary experiments were carried out using a static filament or hot-wire reactor in which the deposition surface consisted of resistance-heated, vertically suspended tungsten filaments 0.5 and 1 mil thick, spring loaded to compensate for expansion on heating. Data from these experiments were used to obtain preliminary correlations between reaction conditions and the stoichiometry and mechanical and chemical properties of the deposits. These conditions were used as a starting point in the process study for preparing continuous filaments.

In order to prepare continuous lengths of filament, a series of connected 1-in. ID horizontal tubular compartments was arranged to permit the substrate to pass along the common axis while reactant gases were passed at right angles to the filament. The use of connected compartments or stages was required in order to obtain a uniform temperature profile along the filament as it became thicker with the deposit. Gas director plates were also inserted in the compartments parallel to the filament to constrict the gas stream as it passed across the filament and thereby achieve a higher mass flow rate to the deposition surface. Electrical contact to the filament as well as sealing against the atmosphere was achieved by the use of mercury wells located in the dividers between each stage and at each end of the reactor. Prior to entry into the reactor, the filament substrate was heated in an atmosphere of hydrogen to remove impurities and residual lubricant. The filament was unwound from its original shipping reel and through the reactor to the take-up spool by means of a small variable speed motor. Tension was adjusted by means of a simple friction brake on the de-reeling spool. Gas flows and temperatures were independently variable for each deposition stage. Early in the experimental program, it was found advantageous to deposit a precoating of boron on the substrate after cleaning, both for stabilizing the substrate temperature and for increasing the surface area of the substrate during carbide deposition. The bulk of the filament thus consisted of boron with a relatively thin shell of boron carbide on the outside. Figure 1 is a sketch of the deposition apparatus which was evolved during the program and which comprised the final deposition system in which the majority of filament preparation runs was made.

As was stated earlier, conditions used for preparation of continuous lengths of filament were based on those which gave the best deposits in the static hot-wire experiments. Temperatures in the two boron precoat stages of the reactor (*see* Fig. 1) were varied at two levels (1050°-1100°C and 1100°-1195°C). In the boron carbide deposition section of the reactor, temperatures were also varied at two levels, about 790°-1030°C and 1010°-1150°C, along the length of the heated-boron-coated filament. The initial or hydrogen cleaning stage was kept at about 900°C throughout.

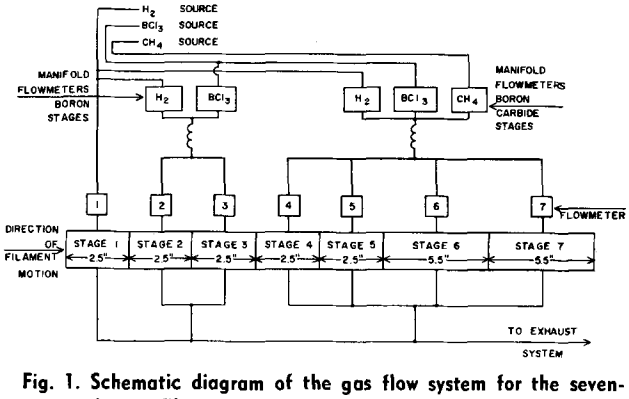

Fig. 1. Schematic diagram of the gas flow system for the seven-stage continuous filament reactor system.

Boron-to-carbon mole ratios in the feed gas were varied from 1.1 to 11.5 in hydrogen, while total gas feed rate to the boron carbide stages was kept between about 1375 and 1630 cc/min. Filament speed was adjusted to produce filaments thicker than 2.5 mils where possible and was usually around 18 in./min. These conditions and associated test data are summarized in Table I.

Typical specimens from each run were tested for tensile strength (1-in. gauge length) and elastic modulus (15-in. gauge length) on a standard Instron Testing Machine at a crosshead speed of 0.020 in./min. Selected specimens were also examined by optical and electron microscopy as well as by x-ray diffraction, while microstructure was studied on smooth unpolished fracture cross sections. To evaluate preliminary composite behavior, epoxy-coated filaments were hand laid by standard techniques developed for making small experimental boron-epoxy (Epon 815) beam composites. These were flexure tested in three-point loading, both before and after a water-boiling treatment, using a span of approximately 0.7 in.

Results

Deposition rate.—Of primary importance in the development of a practical process for manufacturing continuous filament by vapor deposition is the rate at which material is deposited on the substrate. In the deposition of boron carbide filament, the rate, which may be dominated by diffusion processes or by the rate of chemical reaction at the surface, was determined by measuring the filament diameter before and after deposition, and using a geometric averaging procedure to compensate for the increase in substrate surface area during the deposition. In both the static hot-wire and the continuous filament apparatus, the deposition rate for boron carbide was diffusion limited judging from the activation energy derived from Arrhenius plots of deposition rate *vs.* reciprocal temperature (Fig. 2). In the case of the continuous filament reactor, the higher energy of activation is believed to be due to the preliminary coating of boron deposited prior to deposition of boron carbide and which was included in the diameter measurement. This step is known to have been essentially surface reaction controlled from rates measured in the boron deposition stages alone. A pronounced reduction in deposition rate was observed when even small quantities of methane were added to the boron trichloride-hydrogen mixture used to obtain only boron deposits, suggesting the possibility of an interference in the boron deposition mechanism by methane or some of its decomposition products. However, although a num-

ber of mechanisms can be hypothesized which involve, for example, an interaction of hydrocarbon fragments with dichloroborine ($BHCl_2$), a suspected intermediate in the deposition of boron, or a surface adsorption or desorption selectivity for more stable fragments, they cannot easily be tested for validity from the data obtained in the preparative type of experiment.

The experimental variable having the greatest effect on deposition rate, as estimated from filament diameter, was temperature. Variations in the boron-carbon ratios in the feed gas, or in total feed rate, did not produce noticeable differences in filament diameter, nor did changes in the hydrogen content of the feed gas mixture. Certain data in Table I are set off in groups with the identifying code "*H*" and "*L*" representing high and low temperature levels on the average for boron deposition stages and carbide deposition stages. All other experimental factors remained constant throughout this series of runs. Examination of these data shows that high temperature in the second and third (boron deposition) stages, only 5 in. long, and low temperature in the remaining (carbide deposition) stages, 16 in. long (Runs 41, 42 *vs.* Runs 36-39), produced thicker filament than the reverse situation. This is not unexpected since the deposition rate of boron under conditions similar to those prevailing in the second and third stages was controlled by the rate of reduction, while carbide deposition was apparently diffusion limited.

Filament Properties.—Physical properties and morphology. The continuous boron carbide coated boron filaments were between 1.8 and 3.5 mils thick and were dense, hard, and black, exhibiting a somewhat grainy dull surface rather than a shiny smooth appearance (Fig. 3). The formation of isolated islands or patches or a different appearance was occasionally observed (Fig. 4) and appeared to be associated with a perturbation in deposition conditions. Also observed from time to time were isolated nodules believed to be due to the adherence of soot or other solid particles to the substrate. In cross section (Fig. 5), the filaments consisted of a number of concentric rings which resulted from interruption of the deposition process when the filament left one stage, and passed through the mercury contact into the next stage. However, the number of rings was also increased by fluctuations in deposition temperature, which indicates that deposition rate variations due to temperature and perhaps chemical changes can lead to the formation of inhomogeneous deposits. The occurrence of longitudinal cracks or splits (Fig. 6) was also noted in some cases both during and after deposition. These are believed to be due to the relief of asymmetric residual stresses, al-

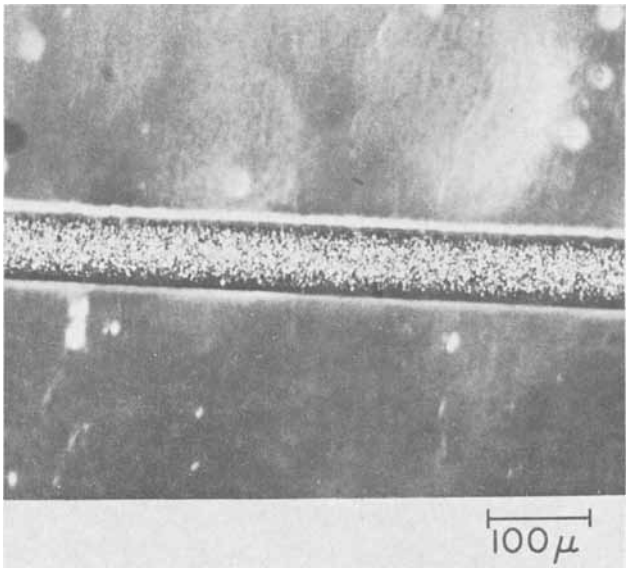

Fig. 3. Surface of boron carbide filament

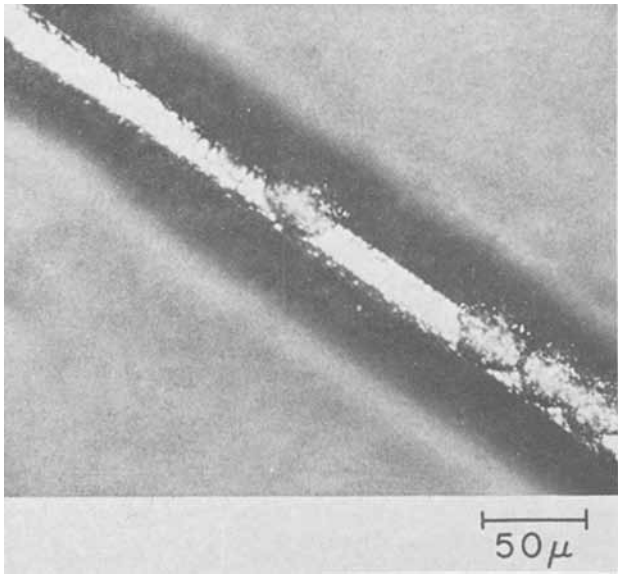

Fig. 4. Isolated regions of nonhomogeneous deposit

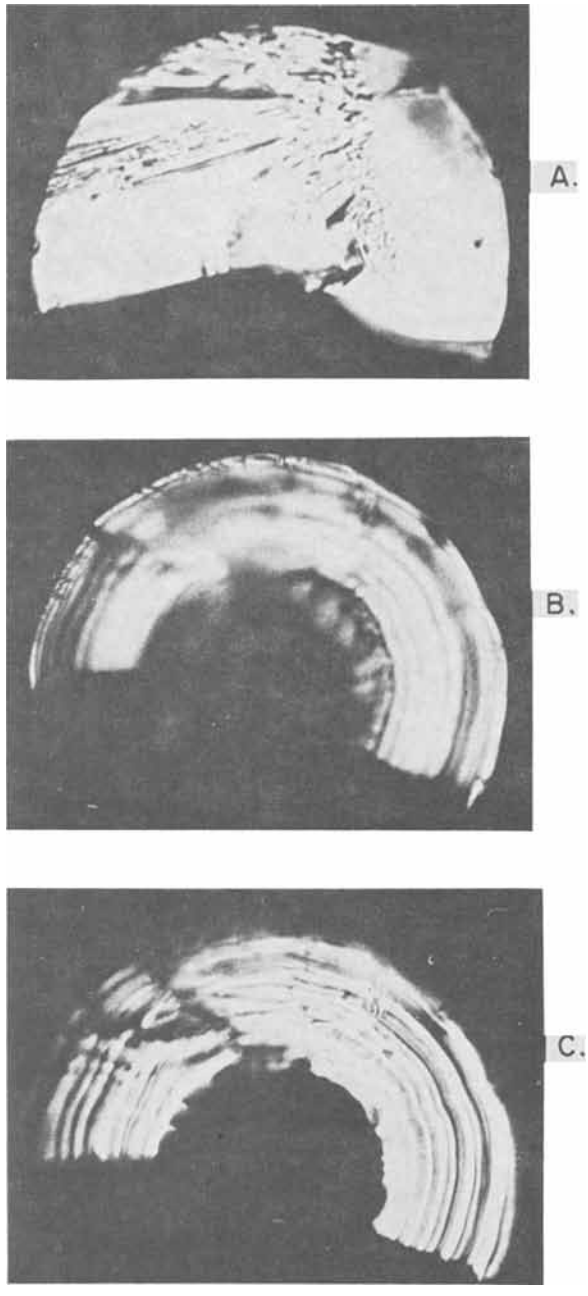

Fig. 5. Cross section of boron carbide filament showing radial structure: (A) before etching; (B) after etching (outer skin in focus); (C) after etching (core and interior in focus). (1210X)

though the probable origins of such stresses (volume expansion of the core due to formation of tungsten borides, differences in thermal expansion coefficients) do not lead in themselves to asymmetry. It can be speculated that the asymmetry was due to the manner in which the gas was fed across the filament, and that temperature gradients and variations in rate as a result of this led to the development of unequal stresses on either side of the filament. Such longitudinal cracks rarely resulted in filament breakage, however, although they tended to cause curvature.

The filament surfaces at higher magnification showed the familiar "corncob" appearance associated with deposition on a tungsten substrate [Fig. 7(*A*)], when the coating was thin (0.1 mil). Thicker coatings obscured the nodule surface as shown in Fig. 7(*B*). On a finer scale, there are significant differences between the filament shown in Fig. 7(*A*) and those made without methane (boron). Figure 8 is an electron photomicrograph of a boron filament, while Fig. 9 is a similar picture of a boron carbide filament. The latter contains isolated nodules which may be boron carbide nuclei. If these inhibit the formation of boron nuclei and in addition grow more slowly because of the more complex chemistry of the boron carbide system, the lower rate of boron carbide deposition may be explained.

Structure, stoichiometry, and mechanical properties. The major differences revealed by x-ray diffraction studies of boron carbide coated boron filaments and elemental boron filaments, both deposited on tungsten substrates at similar temperatures, consisted of (*a*) an alteration of the relative intensities of the lines due to the borided core phases, WB_4 and W_2B_5, denoting a change in phase concentration ratios, and (*b*) the presence of at least one additional diffraction line, indicative of another phase.

The diffraction halos obtained from the boron-carbon filaments were characteristic of a noncrystalline or vitreous structure. Although the diffraction positions (2θ) of the halos appeared to be similar to those produced by vitreous boron, their precise centroid positions could not be determined because of the high degree of overlap with many of the remaining sharp diffraction lines associated with the core phases. Beyond these observations, no direct statement can be

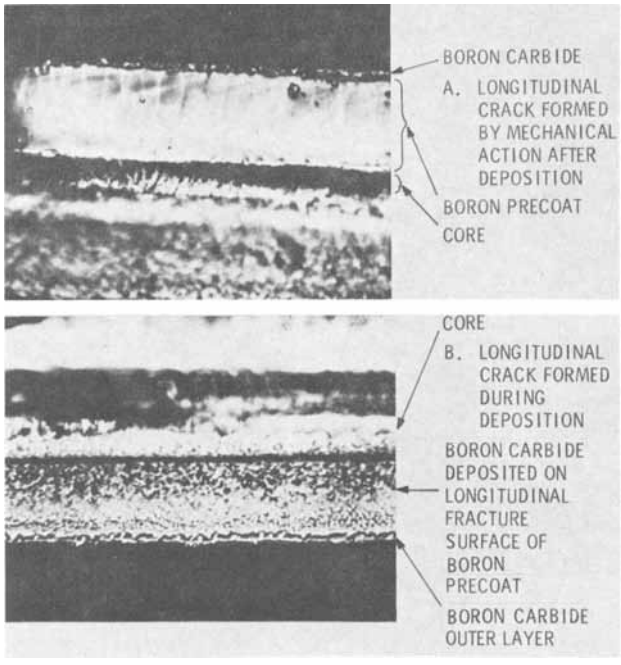

Fig. 6. Detail of longitudinal cracks formed before and after deposition in boron carbide filament (685X).

made from the x-ray data concerning the exact crystallographic structure of the boron-carbon deposits nor about the basic structural unit which comprises it.

Electron microprobe studies did, however, establish that carbon was present in the inner deposit, having most probably diffused in from the outer layer during deposition. Hot 50% hydrogen peroxide attacked this inner layer but not the outer boron carbide layer. Although one may conclude that the as-deposited boron-carbon material is certainly more stable chemically than the inner layer into which carbon had probably diffused, there was no direct way to arrive at specific structures or stoichiometries for these two phases, nor even to establish that the outer layer was boron carbide.

Deposits consisting of only the boron-carbon material with no boron precoated were prepared in the static reactor. These were tested for mechanical properties as well as analyzed chemically for boron and carbon. The correlations which were made are presented in Fig. 10 and 11. Figure 10 shows elastic modulus and tensile strength values as functions of weight per cent (w/o) carbon in the deposit, while Fig. 11 relates feed gas composition to the composition of the deposit. A maximum in both tensile strength and modulus was observed at 27.5 w/o carbon or nearly 25 atomic per cent (a/o). This corresponds to a ratio of three boron atoms to each carbon atom, or a boron deficient deposit from the standpoint of the theoretical boron-carbon ratio of 4 to 1. A mixture of about 2.7 moles of boron carbide (B_4C) per mole of carbon would correspond to the composition observed at the maximum. A composition of 28 a/o carbon was observed by Glaser, Moskowitz, and Post (6) to be the maximum carbon content which can be contained in the so-called boron carbide lattice by filling the holes between boron icosahedra. This was deduced from measurements of density, electrical resistivity, and 2θ values of the (10.4) and (20.1) x-ray reflections as functions of carbon content which showed sudden slope changes or maxima at about 28 a/o. Above this carbon content, free graphite was observed to be present. It would, therefore, appear that the filament material corresponding to the maxima in both tensile

Fig. 9. Electron micrograph of a boron carbide filament

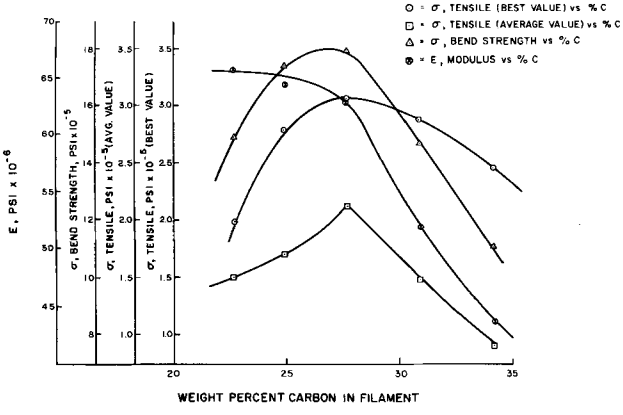

Fig. 10. Strength and modulus data *vs.* carbon content for B_4C filaments.

strength and modulus consisted of boron carbide saturated or nearly saturated with carbon. In view of the heterogeneous character of the filaments submitted for analysis, due to variations in gas composition and temperature along the filament as deposition progressed, a value of 25 a/o may be regarded as being substantially in agreement with the finding of Glaser *et al.* However, no certain evidence could be obtained as to the existence of a carbon phase on the high carbon side of the maximum and further speculation about the phase composition is not warranted.

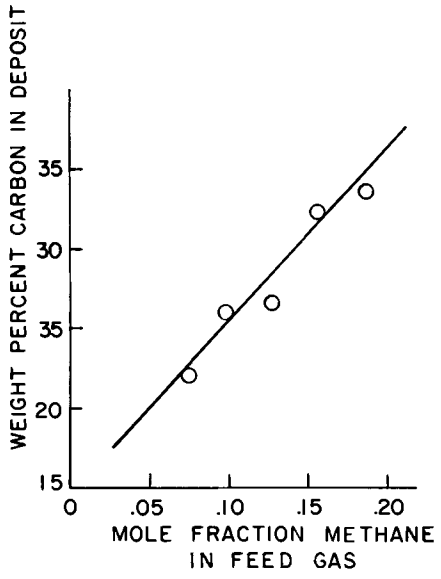

Fig. 11. Weight per cent carbon in deposit *vs.* mole per cent methane in feed gas.

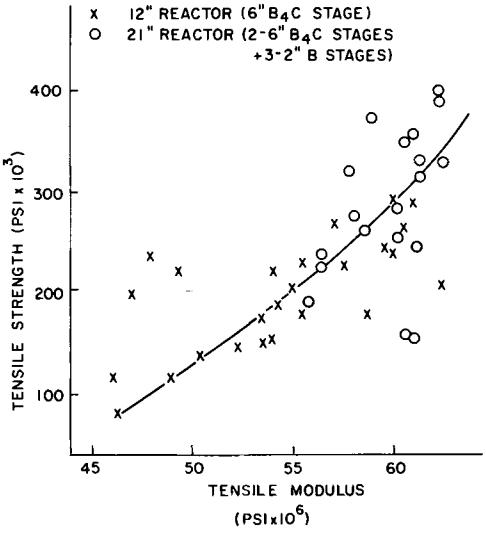

Fig. 12. Relation between tensile strength (psi x 10^3) and modulus (psi x 10^6).

Mechanical test data were obtained for all of the continuous preparative runs which produced filament consisting of a layer of the boron carbide deposited over the boron precoat. Filament diameters varied between 1.8 and 3.6 mils, depending on the deposition conditions. The outer boron carbide layer usually comprised between 4 and 20% of the total filament volume, again depending on the conditions.

Average tensile strengths varied between 150,000 and 390,000 psi with a maximum single value of 474,000 psi. Modulus values lay between 55 and 62 x 10^6 psi and include the contribution of the lower modulus boron precoat layer. Statically prepared filament, with no boron precoat, gave a modulus value maximum of 70 x 10^6 psi. In the continuous filament, although considerable scatter was noted, high tensile and high modulus values appeared to be associated (Fig. 12) as they were in the case of the static filaments (Fig. 10). This lends some support to the contention that the maximum values discussed above in relation to stoichiometry may indeed be structure-related rather than due to deposition conditions.

Composite studies.—In order to obtain preliminary performance data concerning the boron carbide filaments in connection with composite reinforcement, experimental beams were prepared using an epoxy

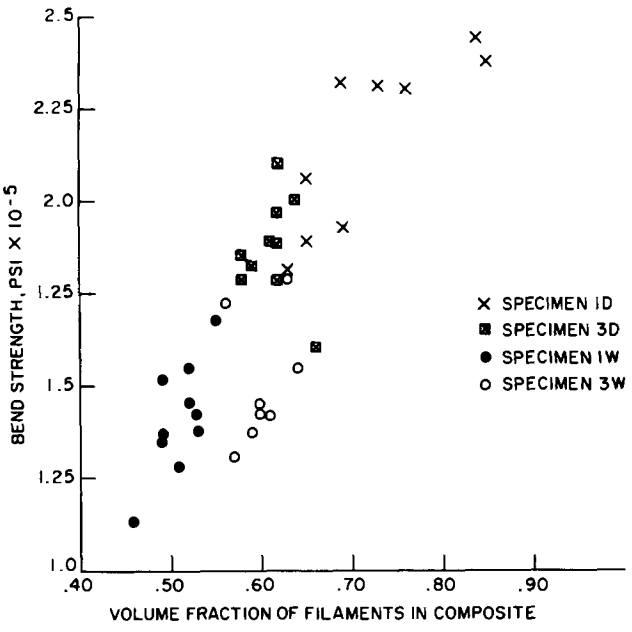

Fig. 13. Bend strength *vs.* volume fraction for B_4C filaments, epoxy microbeam composites.

resin system (Epon 815) cured with methyl nadic anhydride and DMP-30. Incomplete wetting of the fibers was eliminated by refluxing the filaments in methanol prior to formation of the beam. After curing for 2 hr at 95°C and 16 hr at 127°C, the beams measured approximately 23 mils by 40-50 mils in cross section and were tested in three-point bending using a span of about 0.7-0.75 in. Results are shown in Table II for several different volume per cent filament contents. Figure 13 shows these results graphically in terms of bend strength *vs.* volume per cent (v/o) filaments in the composite, before (series 1*D* and 3*D*) as well as after (series 1W and 3W) exposure to boiling water for 2 hr. In both cases, strength was proportional to filament concentration but, while specimen series 1*D* appeared not to have been damaged by the water treatment, specimen series 3*D* had lower strengths at comparable volume fractions. Transfer of the load stress from the resin matrix to the reinforcing filament was efficient, assuming the rule of mixture to be valid for bend test results. A bending modulus of 54 million psi was calculated for a reinforced beam containing 85 v/o filaments having a modulus of 62 million.

Summary

Continuous filaments of boron carbide were prepared on a boron coated tungsten substrate by simultaneous reduction of boron trichloride with hydrogen and decomposition of methane at temperatures between 1050° and 1195°C. Filament thickness varied between 1.8 and 3.6 mils, depending on deposition conditions and filament draw speed.

Deposition rates yielded an activation energy suggestive of a diffusion-controlled mechanism for the over-all rate of the combined reactions, although boron deposition alone was observed to have been surface reaction rate controlled using the same reactor and conditions. An interference effect of methane either in nucleation or in gaseous intermediate interactions may have been responsible.

The boron-carbon deposits were vitreous and noncrystalline, yielding only broad diffuse halos in x-ray diffraction studies. They appeared to consist of a solution or mixture of vitreous carbon in vitreous boron carbide, deduced from chemical behavior and analysis. The boron carbide layer comprised between 4 and 20% of the total filament volume, depending on deposition conditions. Diffusion of carbon into the precoat layer occurred during deposition.

A maximum in the tensile strength and elastic modulus of filaments containing no boron precoat occurred at 27.5 w/o carbon, a composition equivalent to a mole ratio of 2.7 boron carbide to carbon or 7.4 w/o carbon in boron carbide.

Average tensile strengths of the continuous boron carbide filaments with a boron precoat lay between 150,000 and 390,000 psi with a single high value of 474,000 psi. Modulus varied between 55 and 62 million psi. Boron carbide filaments with no boron precoat had modulus values up to 70 million psi.

Flexure test results for epoxy resin beams reinforced with continuous boron carbide filaments both before and after boiling in water indicated that the filaments were well bonded and possibly more resistant to hydrolytic attack than boron filaments. Flexure strengths were proportional to the volume per cent of filaments in the composites.

Acknowledgments

The authors express their thanks to Dr. E. Feingold, Mr. J. M. Berry, and Mr. T. A. Harris, Jr., for assistance during the deposition studies and in characterizing filament structure and behavior. This work was sponsored by the Non-Metallic Materials Division of the Air Force Materials Laboratory, Wright-Patterson AFB, Ohio, under Contract AF33(615)-1644, and the authors wish to extend their appreciation for permission to publish these results.

A Comparison Between the Properties of Anodic Oxide Films on Aluminum Obtained in Different Alkali Nitrate Melts at Various Temperatures[1]

Luigi Campanella

and Arminio Conte
C.S.N. Casaccia, Industrial Chemistry Laboratory (CNEN), Rome, Italy

ABSTRACT

Crystalline form, hardness, kinetic parameters, coating ratio, and resistance to corrosion of the films produced in lithium-containing melts are reported and compared with results obtained in (Na,K)NO_3 fused mixtures at higher temperatures.

The nature and properties of oxide films obtained on the surface of aluminum samples by anodization in fused mixtures of $NaNO_3$-KNO_3 at 300°C have been previously investigated (1, 2). These films were found to be very hard and compact, with a nonporous partially crystalline structure; their corrosion resistance to acid and alkali solutions was found to be higher than the oxides prepared by anodization in aqueous H_2SO_4 solutions; some of their physical properties (specific gravity, flexibility, resistance to high temperatures, adherence, color and appearance, reflectivity, dielectric constant) were also determined and related to the experimental conditions of preparation. The production of oxide films on aluminum surfaces by anodization in the fused eutectic $LiNO_3$-KNO_3, at 160°C, has also been described (3).

In the present communication, the properties of the films produced at lower temperatures in lithium-containing melts are reported and compared with results obtained in (Na,K)NO_3 fused mixtures at higher temperatures.

Experimental

The preparation and purification of the solvent ($NaNO_3$-KNO_3, 59.3% by weight KNO_3 and $LiNO_3$-KNO_3, 59.4% by weight KNO_3) were reported elsewhere (4).

The Ag/Ag^+ reference electrodes were prepared as previously described (4). The test electrodes were cylindrical rods (1 cm) of Al Raffinal AP-O-H 80 (99.99% purity); the samples to be anodized were prepared from the above-mentioned aluminum sheets and their dimensions were 5 x 5 x 0.2 cm. Before immersion in the melt, the specimens were degreased with toluene, chemically polished for 30 min in NaOH solutions (5% by weight), rinsed in distilled water, and air dried. After exposure to the fused nitrates, the samples were cooled in air. The auxiliary electrode was contained in a Pyrex tube with a medium porosity glass frit disk sealed at the bottom end. The Pyrex cell assembly was of the type previously described (4). All the experiments were performed with the cell open to air, at 160° or 300°C according to the melt used. An AMEL 561 Corrograph was used for the electrochemical measurements.

For the determination of the oxide amount, the original oxide was removed without attacking the metal, by immersion in 35 ml/liter 85% H_3PO_4 + 20 g/liter CrO_3 solution, operating at 100°C (Edwards mixture).

The films were stripped from the metal substrate by Treadwell and Obrist's modified method (13).

Results and Discussion

By x-ray analysis, no substantial difference was found between films obtained at 160°C in (Li,K)NO_3, and, at 300°C in (Na,K)NO_3, α, η, γ Al_2O_3 (1), with a prevalence of α and γ, were revealed. The hardness—measured by Brinnell's suitably modified method—of oxide films prepared by anodization at 160°C in (Li,K)NO_3 was found to be approximately 30% lower than that obtained in (Na,K)NO_3 melts at 300°C.

In Fig. 1, potential *vs.* time curves of aluminum electrodes are reported. They were recorded by a recorder electrometer without drawing any current. It can be seen that, without preanodization (curve *a*), the potential, after 10 hr, is not yet stabilized and does not increase to a more positive value, unlike what is observed in (Na,K)NO_3 melts (1). After anodization at +5v for 30 min (curve *b*) and 1 hr (curve *c*), and at +24v for 5 min (curve *d*), the potential decreases slowly to the value observed at open circuit. Only after preanodization at +24v for 5 hr, the potential seems to have attained a constant more positive value.

The equation

$$i = 2\,a\,n\,\nu\,e^{-(W+qaE)/KT} = A\,e^{BE}$$

where i = ionic current, a = activation distance, n = number of mobile ions per unit volume, ν = interstitial ion frequency of vibration in simple harmonic motion, W = potential energy barrier that must be jumped by the ions in order to reach the next site, q = charge on the ion, E = electrical field, K = Boltzmann's constant, and T = absolute temperature, is the key expression for the growth kinetics, if the high-field ionic conductivity approximation ($qaE >> KT$) is applied to the theory of growth mechanism of anodic oxide films.

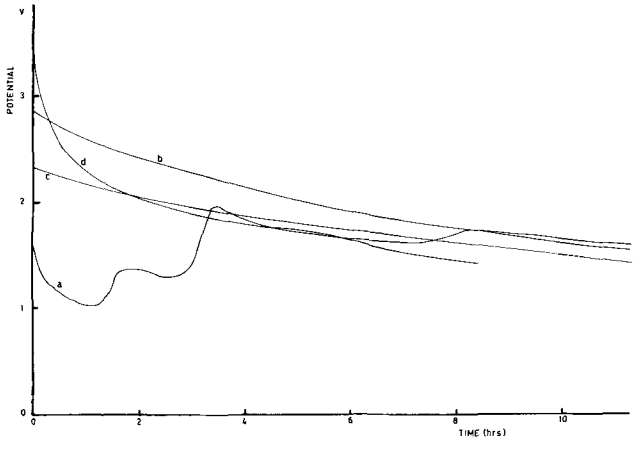

Fig. 1. Potential *vs.* time curves of aluminum electrodes: (a) without preanodization; (b) after anodization at +5v, 30 min; (c) after anodization at +5v, 1 hr; (d) after anodization at +24v, 5 min.

[1] Work carried out with the aid of the Italian C.N.R.

Table I. Corrosion of Al electrodes anodized under the following conditions. (*a*) (Li,K)NO_3, 160°C, +24v; (*b*) (Na,K)NO_3, 300°C, +5v [see Ref. (1)]; (*c*) aqueous H_2SO_4 solution [see Ref. (5)]; (*d*) same as (*a*), electrolysis performed without separated cathodic compartment, Fe as cathode material; (*e*) same as (*d*), 18-8 SS as cathode material

Corroding solution	Time of contact with the corroding solution (hr)	Weight loss (mg/cm²) (*a*)	(*b*)	(*c*)	(*d*)	(*e*)
NaOH 1*N*	1	2.57	1.47	3.68	2.74	3.56
NCl 1*N*	72	0.51	10.46	1.73		0.96
H_2SO_4 1*N*	24	0.11	0.12	0.42		
HNO_3 1*N*	24	0.16	0.23	0.74		
Na_2CO_3 1M	24	0.71	0.18	0.84		

The logarithmic form of the above equation is

$$\log i = \log A + B\,E$$

Values of E, determined by oxide thickness measurements (performed by DERMITRON apparatus manufactured by Unit Process Assemblies Inc., New York, and operating by virtue of eddy currents induced in metallic surfaces) were used for the determination of a and B, that resulted in 1.8Å and 1.5 10^{-6} cm v^{-1}, respectively, for oxides prepared in (Li,K)NO_3. The higher values of a determined in a previous study (2) —7.6Å—, concerning the anodization in (Na,K)NO_3, can be explained if the different values of temperature are considered.

The coating ratio (ratio of coating weight to metal loss) values determined for different anodization times and applied voltages were always found to be 1.8 (theoretical value). The film thickness was remarkably lower as compared to values obtained by anodization in (Na,K)NO_3 melts, ranging from approximately 1μ (1v, 30 min) to 3.9μ (24v, 2 hr).

In Table I, the results of corrosion tests of aluminum samples anodized at +24v, 160°C, in (Li,K)NO_3 melts are reported and compared with those referring to aluminum oxides prepared in H_2SO_4 aqueous solutions (15% w/v) (5) and in (Na,K)NO_3 fused mixtures at 300°C. It can be seen that the corrosion resistance to NaOH and Na_2CO_3 solutions of samples anodized in (Li,K)NO_3 at 160°C is markedly lower than for samples prepared in (Na,K)NO_3 at 300°C, but still high when compared with films obtained in H_2SO_4 solutions. The corrosion resistance to H_2SO_4 and HNO_3 solutions is slightly improved for oxides prepared in (Li,K)NO_3 relative to those obtained in (Na,K)NO_3. The markedly low corrosion in 1*N* HCl may be ascribed to the competition between Cl^- and H_2O, as occurring for oxides prepared in aqueous solutions. Presence of H_2O in our oxides could be postulated if the nature of $LiNO_3$ is considered and is really confirmed by the results of the weight loss (found = 0.1 mg/cm²) determinations of anodized aluminum samples when oven dried at 240°C. The water absorption appears also to be influenced by the presence of lithium in the anodization bath; while no weight change is observed for Al samples previously anodized in (Na,K)NO_3 when contacted with H_2O at 100°C for 30 min (sealing conditions), 0.1 mg/cm² weight gain is observed for samples anodized in (Li,K)NO_3; this is probably due to the higher porosity of the latter films because of the acidity of the electrolyte.

An important point to be investigated also for the purpose of practical application is the influence on the oxide properties of the products of the cathodic reduction of the solvent and of the cathode materials undergoing dissolution. It was shown by calculations (6, 7) and experimentally (8) that the first reduction process of nitrate melts is

$$NO_3^- + 2\,e \rightarrow NO_2^- + O^{2-}$$

Other processes involve oxide ion formation and evolution of various gaseous products. In basic melts, aluminum oxides undergo dissolution (1); therefore, in (Na,K)NO_3, it is worthwhile to operate with separated anodic and cathodic compartments. We have seen that this is unnecessary with (Li,K)NO_3 melts, owing to the more acidic character of Li^+ ions and consequent association with oxide ions (9, 10).

As regards the presence in the melts of species produced by reaction of cathode materials with the reduction products of the solvent (11, 12), no differences were observed in coating ratio values using Pt, Fe, 18-8 stainless steel as cathodes. On the contrary, the corrosion resistance to basic and acid aqueous solutions is lowered, as can be seen from columns (*d*) and (*e*) in Table I, when the oxide films are obtained using Fe and 18-8 SS as cathodes.

On the Mechanism of Anodic Chlorate Oxidation

O. de Nora, P. Gallone,* C. Traini, and G. Meneghini

Oronzio de Nora, Impianti Elettrochimici, Milan, Italy

ABSTRACT

Anodic polarization curves were determined on smooth Pt, Pt-coated Ti, PbO_2-coated graphite, and PbO_2-coated Ti. Operating conditions were typical for industrial perchlorate production, *i.e.* 1.6 moles/liter $NaClO_4$, while $NaClO_3$ concentration was ranging between 0.47 and 4.7 moles/liter, at 50°C, *p*H 6-7. For solutions containing $NaClO_4$ only, the anodic current potential diagram is rectilinear, irrespective of any presence of NaF or $Na_2Cr_2O_7$. If $NaClO_3$ also is present, the diagram shows a strong inflection. For each set of conditions, current efficiency and anode potential were determined *vs.* current density. This allowed two separate curves for ClO_3^- conversion rate and O_2 evolution rate, respectively, to be plotted *vs.* anode potential. Tafel linearity for ClO_3^- conversion is thus obtained on Pt and on PbO_2 under all conditions, with a slope ranging between 0.1 and 0.12. This fact supports the view that ClO_3^- is oxidized through a path involving primary discharge of ClO_3^- with formation of ClO_3 radicals and that charge transfer is in most cases the rate-determining step.

The over-all reaction of anodic chlorate oxidation is

$$ClO_3^- + H_2O = ClO_4^- + 2H^+ + 2e^- \quad E^o = 1.19v \quad [1]$$

The potential-*p*H equilibrium diagram (Fig. 1) runs parallel to that of water oxidation reaction

$$2H_2O = O_2 + 4H^+ + 4e^- \quad E^o = 1.228v \quad [2]$$

Accordingly, the *p*H value affects the thermodynamic equilibrium of both reactions in the same direction and by the same amounts. In other words, it is impossible, on purely thermodynamic arguments and for any established electrode potential, to favor anodic production of perchlorate rather than oxygen evolution, or *vice versa,* simply by changing the *p*H value.

As to the kinetic behavior of oxygen evolution according to reaction [2] on an unreactive electrode such as platinum, a wealth of experimental evidence indicates that oxygen overvoltage is *p*H independent (1). Accordingly, the concern expressed by former authors (2, 9) without any produced evidence about the adverse effect that alkalinity might have on chlorate conversion efficiency, due to the competing reaction involving OH^- discharge, seems unfounded and only based on a prejudice widespread in the past that the charge transfer between the electrode and the electrolyte can involve only ions and not the undissociated water molecule itself or any other uncharged species.

On the other hand, the kinetic independence of the oxygen evolution reaction from *p*H does not necessarily imply a similar behavior of reaction [1]. However, this has also been experimentally evidenced on smooth platinum (3). For lead dioxide anodes, the results are somehow conflicting. This may possibly be explained by the fact that lead dioxide cannot be considered as a perfectly unreactive material, so that different preparative methods, as well as previous performance conditions, may lead to somewhat different results. At any rate, it is to be pointed out that whereas Schumacher (4) finds that current efficiency is not affected by *p*H, according to Narasimham (5) it shows an increase under more alkaline conditions, contrary to what former authors (2, 9) would have expected, in principle, to occur. The equilibrium potentials of reactions [1] and [2] differ by less than 40 mv; therefore, only if the concomitance of all operating conditions that may affect the two kinetics, such as current density, temperature, anode potential, adsorbed discharge inhibitors and catalysts, is such as to bring about a definite increase of the overvoltage proper to reaction [2] over that of reaction [1] will chlorate conversion occur at a satisfactory current efficiency.

* Electrochemical Society Active Member.

As for other oxidation reactions (6), there are two possible pathways along which chlorate conversion may proceed as a preliminary assumption, so that only through experimental verification may conclusions, if any, be drawn about the path that is actually followed by the electrode process. One of these, which we shall call the primary reaction mechanism, would involve a direct electron withdrawal from the chlorate ion, as a first step, followed by a homogeneous reaction of the free radical with water. According to the other possible pathway, which we shall call the secondary reaction mechanism, the water molecule would be involved in the charge transfer step, with the production of surface oxides (or adsorbed oxygen-containing species, *e.g.* OH or O); such entities would then perform as oxidants of the chlorate ion diffusing toward the substrate or being coadsorbed at the electrode surface.

Table I displays in chronological order the several reaction mechanisms that have been proposed so far. A critical review of the several theories has been made by Schumacher (4*a*). It may be observed here that neither the first proposed mechanism (7) nor most of those suggested later (2, 5, 9) are based on any strong experimental evidence, but mainly on speculations, some of which, as noted above, are affected by preconceptions such as the possible role played by a supposed OH^- discharge. Sugino and Aoyagi (8) were, to

our knowledge, the first to investigate the correlation between anode potential and current density. By their method, which was essentially potentiokinetic, they were able to observe two stages of potential in 1.4M $NaClO_3$ at 17°C. Since the first stage, occurring between 1.7 and 1.9v, corresponds (mostly) to oxygen evolution and the second stage, higher than 2.3v, corresponds (mostly) to chlorate oxidation, said authors interpret their results by assuming that chlorate oxidation proceeds through a primary discharge step. However, as will become apparent in further discussion, the two potential stages referred to above do not supply by themselves any evidence in favor of the primary discharge mechanism, as advocated by said authors.

Strangely enough, Grotheer and Cook (10) have been the only investigators that, prior to the present study and as late as 1967, seem to have based their considerations on the most classical and elucidating of all experimental methods, which consists in carrying out intensiostatic current-potential measurements and representing them on a Tafel diagram. By plotting the results thus obtained with two different solutions, which respectively contained sodium chlorate alone and sodium perchlorate alone, they found that both plottings fall on an identical, practically straight, line. The natural conclusion of said authors is that the same anodic process occurs in both cases. This is true because, within the low current density range they have investigated (up to 10 ma/cm^2), the only process that practically does occur is oxygen discharge in either solution, since chlorate conversion efficiency is practically nil at such low current densities. Accordingly such determinations do not seem to supply sufficient experimental evidence in favor of a secondary reaction mechanism between ClO_3^- and adsorbed oxygen as proposed by said authors. Actually, some of the experimental findings disclosed and discussed in the following seem to bring more support to the primary reaction assumption.

Experimental Procedure and Results

The laboratory cell is represented in Fig. 2. The glass container had a capacity of approximately 1 liter and was kept at the desired temperature by a water jacket connected with a thermostat. A top cover provided sufficient tightness to avoid appreciable evaporation losses, which would impair the accuracy of gas volume measurements.

The anodic O_2 gas was collected by a bell hanging over the anode and partially submerged to a depth of approximately 5 cm; from the bell, the gas was drawn into a measuring burette. Current efficiency (C.E.) of O_2 production was determined by comparison with the gas evolved from a standard coulombic cell with Pt electrodes and containing 5% NaOH, connected in

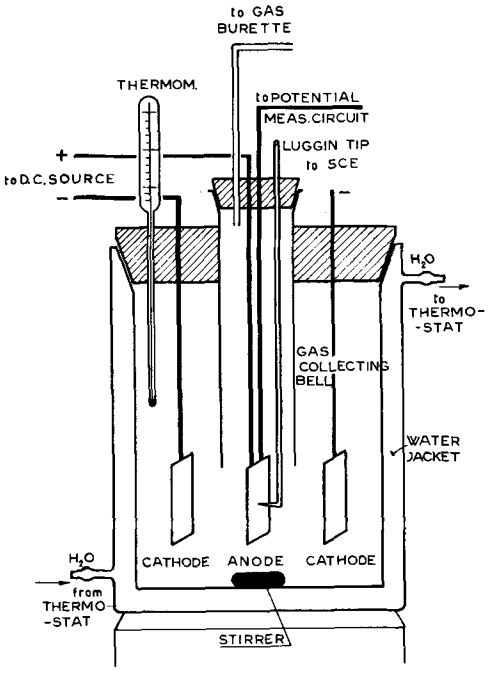

Fig. 2. Experimental cell

series with the laboratory cell. The solution was kept under agitation only during anode potential measurements but not during current efficiency evaluation runs, in order not to facilitate O_2 gas losses. Blank tests were performed with a solution containing $NaClO_4$ only, so that O_2 C.E. had to be 100% and showed that the determination may be affected with a maximum error of ± 1% unit of C.E. The minimum amount of gas collected in any further run was 30 cm^3; each run was repeated at least twice under the same conditions and the average gas volume reading determined. Chlorate conversion efficiency was calculated by subtracting O_2 conversion efficiency from 100.

The several anodic samples were made of 1-x 5-cm rectangular strips suspended in the solution. Both surfaces were made to operate by placing the anode between two counterelectrodes 2 cm apart from the anode. The counterelectrodes used were of nickel, iron, stainless steel, and platinized titanium. With all of these materials, the current efficiency of hydrogen evolution was found to be 100% within the limits of measuring accuracy (±1%). The anodic materials investigated were smooth Pt, platinized titanium, and PbO_2 deposited either on graphite or on titanium (14), the thickness of the deposit being about 5 mm on graphite and 2 mm on titanium. The PbO_2 coating was polished after electrodeposition with fine emery paper of the quality used for metallographic samples. The Pt coating on Ti was of a quality giving very low overvoltage under Cl_2 discharge in NaCl electrolysis. Further tests with this material were discontinued after verifying that chlorate conversion efficiency was very low (less than 10%) also at the highest $NaClO_3$ concentration investigated (4.7 moles/liter). The PbO_2 deposits on graphite and on Ti were found in preliminary tests to have a practically equivalent anodic performance. Accordingly, PbO_2-coated titanium was used throughout the subsequent tests as described in the following. The anode potential was measured by means of a saturated calomel electrode connected with the negative terminal of the electronic voltmeter. The positive terminal of the voltmeter was in direct metallic connection with the anodic structure at a point practically unaffected by ohmic drops. The readings were converted to the NHE scale by conventionally adding 0.25v, whereby any liquid junction effects have been neglected.

The investigation was carried out with particular regard to intermediate conditions that are met with

in industrial $NaClO_4$ production. Accordingly, the temperature was 50°C and the pH value was kept between 6 and 7. $NaClO_4$ concentration was maintained at 1.6 moles/liter (195 g/liter) throughout the tests, after ascertaining that its influence on the kinetics is very small, if any. As to $NaClO_3$ concentration, its effect on the kinetics was investigated between 0.47 and 4.7 moles/liter.

In order to obtain good reproducibility, anode prepolarization was found to be indispensable. This was carried out before every run at 100 ma/cm² on Pt and at 200 ma/cm² on PbO_2. The anode was kept at said C.D. for 30 min, after which the run was started at the lowest C.D. value as shown on the Tafel diagram. Each C.D. value was kept for the time required to collect at least 30 cm³ O_2 for current efficiency determination, whereafter the corresponding anode potential was measured.

Such procedure, besides allowing good reproducibility, brings about as a further consequence a marked decrease of the pronounced hysteresis that would otherwise be observed in the descending branch of the polarization diagram for smooth Pt, when $NaClO_3$ is present in the solution.

Figure 3 represents the Tafel diagrams obtained on Pt and PbO_2 in 1.6 moles/liter $NaClO_4$ with and without NaF or $Na_2Cr_2O_7$ additions. Under all conditions, Tafel linearity is obtained through the C.D. range investigated (0.02-1 amp/cm²). Whereas the presence of 2 g/liter NaF markedly increases O_2 overpotential and the slope on both Pt and PbO_2, the addition of 3 g/liter $Na_2Cr_2O_7$ affects the overpotential substantially only on Pt, and to a definitely minor extent on PbO_2.

Figures 4 and 5 show Tafel diagrams on Pt and PbO_2, respectively, for solutions containing 1.6 moles/liter $NaClO_4$ and $NaClO_3$ in different amounts from 0.47 to 4.7 moles/liter. A comparison with Fig. 3 shows the strong polarization effect of $NaClO_3$ at all concentrations. This effect becomes independent of $NaClO_3$ concentration when the latter approaches 1 mole/liter. However, it is less marked on PbO_2 than on Pt; furthermore, at higher $NaClO_3$ concentrations, the steep potential transition observed on Pt straightens out on PbO_2, so that the polarization curve acquires Tafel linearity, although with a steep slope (0.17).

Figure 6, referring to Pt, shows the strong dependence of chlorate conversion efficiency on current density at all $NaClO_3$ concentrations. Figure 7 represents such dependence for PbO_2. Current efficiency appears to be definitely lower on PbO_2 than on Pt only at relatively low C.D.'s and $NaClO_3$ concentration. The difference, even though still appreciable at 1 amp/cm² and 4.7 moles/liter $NaClO_3$, shows a tendency to level off above these values.

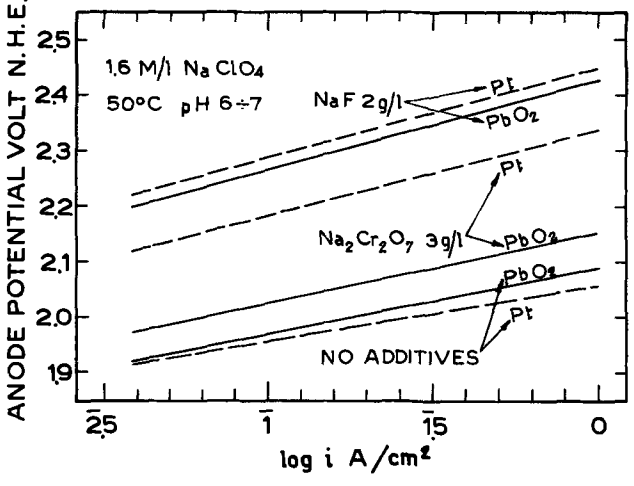

Fig. 3. Polarization curves on Pt and PbO_2 in 1.6 moles/liter $NaClO_4$ at 50°C, pH 6 ÷ 7, with and without NaF or $Na_2Cr_2O_7$.

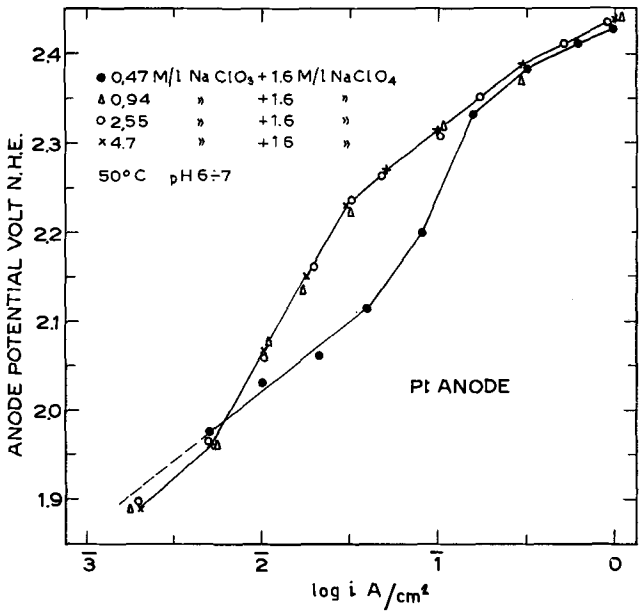

Fig. 4. Polarization curves on smooth Pt at different $NaClO_3$ concentrations.

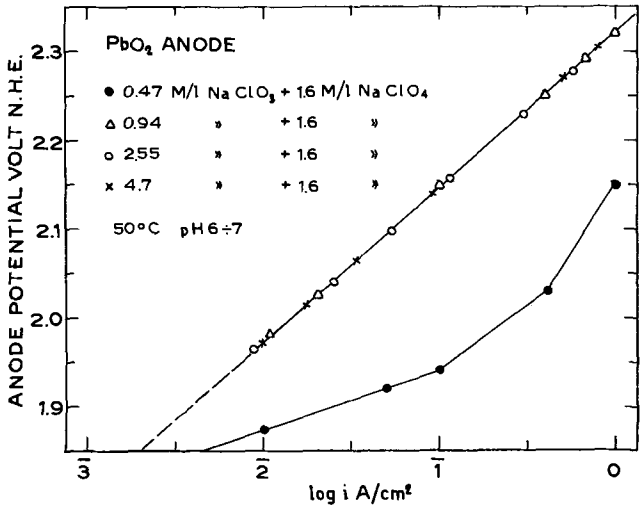

Fig. 5. Polarization curves on PbO_2 at different $NaClO_3$ concentrations.

The effect of NaF or $Na_2Cr_2O_7$ addition on anode polarization and conversion efficiency in a solution containing 0.94 mole/liter $NaClO_3$ and 1.6 moles/liter $NaClO_4$, can be evaluated from Fig. 8 for Pt and Fig. 9 for PbO_2. The presence of 2 g/liter NaF markedly raises polarization on PbO_2 and to a lesser extent on Pt, so that the two corresponding curves become quite close to each other. For both materials, the C.E. is improved throughout the C.D. range, the extent of such improvement being definitely more substantial on PbO_2.

Figure 8 also shows that, by the addition of 3 g/liter $Na_2Cr_2O_7$, polarization and C.E. are decreased on smooth Pt for C.D. lower than 0.1 amp/cm²; at higher C.D., the polarization is slightly increased and this is accompanied by a slight decline in C. E. at equal anode potentials. As regards PbO_2, it can be seen from Fig. 9 that $Na_2Cr_2O_7$ addition lowers the polarization curve throughout the C.D. range, with an associated sharp decline in C.E.

Discussion

The above results, with particular regard to Fig. 3, 4, and 5, show that anodic polarization on Pt and on PbO_2 is strongly influenced by the presence of ClO_3^-

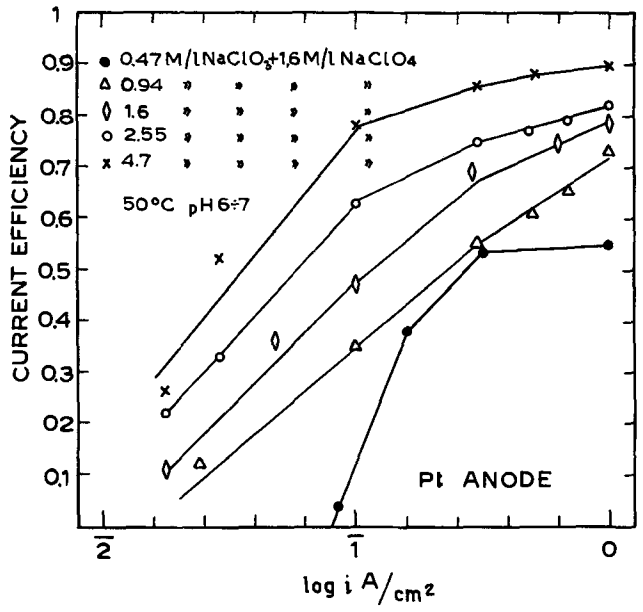

Fig. 6. ClO_3^- conversion efficiency vs. current density on smooth Pt at different $NaClO_3$ concentrations.

ions, on account of their progressive adsorption at the interface as electrostatic attraction increases with potential. Consequently, the water molecules adsorbed at the interface are gradually displaced by ClO_3^- ions, which thus hinder the primary discharge of water and oxygen evolution. This is evidenced, in particular, by the strong inflection generally observed on Pt at all $NaClO_3$ concentrations and also on PbO_2 in the lower concentration range, the somewhat different behavior of the two anode materials being attributable to their different specificity in adsorbing ClO_3^- ions. With regard to the shape of the inflection shown by the curves of Fig. 4, it may be noted that it begins at some potential lower than 1.9v and terminates above 2.3v, which corresponds quite closely to the two stages observed by Sugino and Aoyagi in their potentiokinetic investigation (8). However, this does not provide by itself any evidence in favor of the mechanism of primary ClO_3^- discharge; indeed, besides water displacement from the double layer as postulated above, the further possibility may in principle be visualized that the active sites of high oxygen adsorption energy are progressively blocked by the adsorbed ClO_3^- ions, with a consequent modification of the oxide film and a rise in oxygen discharge overpotential. This could allow the adsorbed ClO_3^- ions to react with oxygen in the modified oxide film, so that ClO_3^- oxidation would occur as a secondary reaction with the chemisorbed oxygen atoms resulting from the primary discharge of water. Such assumption would be in line with the anodic interaction that has been investigated by others (11, 12) between chemisorbed oxygen and ClO_4^- ions in perchloric acid solutions. Evidence of this interaction, which also gives rise to a strong inflection in the polarization curve, has been obtained with experiments conducted in ^{18}O-labeled $HClO_4$ in nonlabeled water (11). In our present case, however, a similar assumption involving interaction between the anion and chemisorbed oxygen seems to be contradicted, in favor of the primary discharge mechanism, by some other experimental evidence discussed here.

Since only the two over-all reactions [1] and [2], *i.e.* ClO_3^- oxidation and O_2 evolution, take place at the anode with complementary current efficiencies, it is possible from the experimental results described above to work out both reaction rates as a function of anode potential and represent them in terms of two partial currents i_1, i_2, respectively, so that $i_1 + i_2 = i$. Such representation, as given in Fig. 10 through 13 for different operating conditions, shows the remarkable fact that the rate of reaction [1] is invariably characterized by Tafel linearity, its slope being generally between 0.11 and 0.12. This provides strong support to the assumption that chlorate oxidation may take place following a pathway that starts with primary discharge of ClO_3^- and proceeds independently of anodic water oxidation throughout the investigated C.D. range. Moreover, since a slope of about 0.12 is typical of an electrode process in which the charge transfer reaction is rate determining, conclusion may be drawn that formation of the ClO_3^- radical is the most likely rate-controlling step in the over-all process leading to ClO_4^- production.

As can be seen in Fig. 10, an increase in $NaClO_3$ concentration c enhances the ClO_3^- conversion rate at a definite constant potential; this is expressed by the positive value of the partial differential coefficient $\delta \log i_1/\delta \log c$, which in the lower potential range is about 0.5, with a tendency to diminish in the higher range. On the other hand, O_2 evolution is strongly inhibited by the adsorbed ClO_3^- ions and depends on the amount of $NaClO_3$ also in the concentration range throughout which the relevant polarization curve remains unaffected (Fig. 4).

Figure 11 illustrates the anodic performance of PbO_2, which is essentially similar to that formerly described for Pt. It is, however, to be noted that the partial differential coefficient $\delta \log i_1/\delta \log c$ is now only about 0.4 in the lower potential range, while O_2 evolution is

inhibited by the presence of $NaClO_3$ to a substantially lesser extent than on Pt.

The influence of additives on the two reaction rates is evidenced by Fig. 12 for Pt and by Fig. 13 for PbO_2. In the case of smooth Pt, the presence of 2 g/liter NaF not only exerts a strong inhibiting action on O_2 evolution, but also slightly improves ClO_3^- conversion in the lower potential range. On the contrary, the addition of 3 g/liter $Na_2Cr_2O_7$ inhibits ClO_3^- conversion on Pt, while catalyzing O_2 evolution. Moreover, while NaF tends to increase the slope of the Tafel line related to ClO_3^- conversion, $Na_2Cr_2O_7$ tends to decrease it. Accordingly, the effects of the two additives are opposite in all respects.

With PbO_2 anodes (Fig. 13), the presence of 2 g/liter NaF inhibits both reaction rates, but O_2 evolution is affected to a much greater extent than ClO_3^- conversion; this explains the improvement in faradic efficiency obtained by NaF addition, which also increases the ClO_3^- conversion slope from the original value of 0.1 to the value of 0.12. As to the effect of $Na_2Cr_2O_7$ on PbO_2 anodes, it is distinguished by the peculiar characteristic that, besides inhibiting ClO_3^- conversion in the C.D. range up to 0.3 amp/cm² and enhancing O_2 evolution rate by a factor that increases with C.D., it markedly lowers the slope of both plottings so that the slope of ClO_3^- conversion is depressed from 0.1 without additives to 0.05 after adding 3 g/liter $Na_2Cr_2O_7$. It ensues that, while persistence of Tafel linearity still provides support to the assumption of the primary discharge mechanism also in this case, the fact that the slope is definitely smaller than 0.1 indicates that the charge transfer would no longer be the rate-determining step and that this is now to be identified with a subsequent step, such as desorption of ClO_3 radicals or a further electrochemical reaction be-

tween radicals and ions. The interaction between a lead anode and chromic acid was originally investigated by Elbs and Nübling (13). They have thus demonstrated that anodic treatment of lead in a chromic acid solution may result in anodic passivation with the build-up of a layer of lead chromate and/or lead dioxide, or else it may cause anode dissolution, depending on chromic acid concentration. Therefore, we wished to carry out some tests to ascertain whether the lead dioxide coating is modified by the presence of CrO_4^{2-} or $Cr_2O_7^{2-}$ ions under the conditions prevailing in our present research. We have accordingly submitted the PbO_2 anode to polarization at 0.3 amp/cm² in 0.1 and 1% chromic acid solution. Electrolysis was conducted for several hours and the tests were repeated in 1.6 moles/liter $NaClO_4$ + 1.6 moles/liter $NaClO_3$ with different $Na_2Cr_2O_7$ additions up to 5 g/liter.

After none of such runs was any anode weight loss measurable. However, after each run the aspect of the anode surface had changed and some pale yellowish hues were visible, which presented interferential characteristics. Such aspect is different from the black metallic luster of a freshly prepared and polished PbO_2 coating, as well as from the gray and dull appearance of anode samples after operating in solutions containing no chromate. It must therefore be concluded that the superficial structure of the PbO_2 substrate is somehow modified by interaction with $Cr_2O_7^{2-}$ ions, with probable build-up of a chemisorbed layer.

Conclusion

The rectilinear character of ClO_3^- conversion rate, when plotted in a current potential diagram, under all investigated conditions, leaves little doubt that ClO_3^- oxidation should be considered as the consequence of a primary discharge reaction involving ClO_3^- ions. It would indeed be difficult to reconcile the constancy of the reaction mechanism throughout the C.D. range with the drastic modification of the chemisorbed oxygen layer that is shown to occur at the same time by the strong inflection of the oxygen evolution curve.

Since the slope of the Tafel line is generally between 0.1 and 0.12, the rate-determining step of over-all reaction [1] should be identified with the charge transfer reaction

$$ClO_3^- \rightarrow ClO_3 + e^-$$

This is in accordance with either one of mechanisms (II) and (IV) in Table I. As to mechanisms (I) and (III), they seem less likely to occur for a number of reasons. First of all, they both involve adsorbed H_2O molecules in a charge transfer reaction;[1] on the other hand, since water is gradually driven out and replaced by ClO_3^- ions in the adsorbed layer, it is difficult to visualize how the reaction rate can thus proceed with Tafel linearity. Moreover, mechanism (I) involves the production and recombination of an unlikely intermediate product such as ClO_2^- according to step (*a*) and, in addition, the production and subsequent reaction rate of chemisorbed oxygen according to step (*b*) should also be affected by the gradual modification of the chemisorbed layer, as observed above; this, again, would be difficult to reconcile with Tafel linearity.

The only slope departure from values between 0.1 and 0.12 has been observed on PbO_2 in the presence of $Na_2Cr_2O_7$. On the assumption of mechanism (II), this would be attributable to a slowing down of the desorption step (*b*). However, the assumption of mechanism (IV) provides an interpretation that is possibly even more in line with the present findings. In fact, the results represented in Fig. 13 indicate that the presence of $Cr_2O_7^{2-}$ ions in the adsorbed layer has the effect of enhancing O_2 evolution by counteracting the tendency of electrosorbed ClO_3^- ions to drive out the H_2O molecules. By supposing, then, that the electrochemical step (*b*), involving adsorbed water, becomes rate determining, a theoretical calculation according to the method used by Bockris (1) would give a slope value of about 0.04, which is quite close to the value of 0.05 as determined in the present investigation.

[1] Step (*d*) in mechanism (III) should obviously be modified as follows: $H_2O \rightarrow H^+ + OH + e^-$.

Catalytic Enhancement of Carbon Monoxide and Reformer Gas Oxidation in Fuel Cells By Sodium Tungsten Bronzes

L. W. Niedrach* and H. I. Zeliger[1]

General Electric Research and Development Center, Schenectady, New York

It has been previously shown that the electro-oxidation of carbon monoxide and reformer gas at platinum black fuel cell anodes can be appreciably enhanced by the incorporation of tungsten oxides into the electrodes (1). The purpose of the present note is to discuss a similar promotional effect that has since been observed with sodium tungsten bronzes.

The tungsten bronzes, which were discovered by Wöhler (2) were so named because of their metallic properties, *e.g.* luster and electrical conductivity. Actually they are neither alloys nor metallic compounds, but, rather, mixed oxides having the general formula M_xWO_3. M is generally an alkali or alkaline earth metal, but other metals can be substituted. The values of x can vary from 0 to 1.0. In the case of the sodium bronzes, compounds covering essentially the full range of x values are known. Other systems are restricted to narrower ranges. While the compounds have been looked upon as containing mixed valences of +5 and +6 tungsten, the physical properties are best interpreted on the basis of an interstitial distribution of the substituent metal and free electrons in a tungsten trioxide matrix (3). The properties of tungsten bronzes have been reviewed in detail elsewhere (4-6).

Experimental

Three approaches were adopted for the preparation of the high area materials desired for use in fuel cell electrodes. All employed high temperatures and, because of the dissociative equilibria involved, were somewhat empirical with regard to the adjustment of the x value.

Fusion of tungsten, tungsten trioxide, and sodium tungstate.—An intimate mixture of the starting materials was heated in a porcelain crucible until a homogeneous melt was obtained (7). After cooling to room temperature, excess Na_2WO_4 and WO_3 were removed by boiling in dilute NaOH. The product bronze was collected over a filter, washed, and dried. One advantage of this method is that one may quickly obtain bronzes with high x values (0.8-1.0) that are otherwise difficult to prepare. A disadvantage is that the bronze powders are attacked slowly by NaOH to liberate hydrogen and form soluble sodium tungstate. The product can be ball milled to obtain a high surface area material (4-6 m^2/g).

Reaction of higher bronzes with WO_3.—One can obtain bronzes with low x values by heating an intimate mixture of a bronze having a high x value with WO_3 either in a vacuum or under an inert atmosphere *e.g.*, argon), at temperatures ranging from 500° to 850°C for durations of from 2 to 66 hr. The reaction occurs *via* a dissociation of the higher bronze to give free sodium which reacts with the WO_3. This reaction is described by Straumanis (7).

Reaction of WO_3 with NaI.—Tungsten trioxide reacts with sodium iodide to form a bronze with the liberation of iodine (7). This reaction can be carried out at 600°-650°C either in a vacuum or under an inert atmosphere (argon). This method is useful for obtaining bronzes of intermediate x values.

The properties of the sodium tungsten bronzes prepared are summarized in Table I. All were examined by x-ray diffraction. Values of x were obtained from the lattice parameters using the data of Straumanis (7).

Teflon-bonded electrodes were prepared with several of the bronzes (surface area 4-6 m^2/g) in admixture with platinum black (surface area, 20 m^2/g) using procedures that have previously been described

* $Na_{0.89}WO_3$ (4 m^2/g) used as starting material.

(8). All the electrodes contained 34 mg Pt/cm^2, 6.8 mg bronze/cm^2, and Teflon binder (DuPont's T-30 Teflon) amounting to 10% of the combined weight of platinum and bronze. A film of 1.6 mg Teflon/cm^2 was used on the gas side of all electrodes.

The electrodes were evaluated in fuel cells at 25°C on both carbon monoxide and a synthetic reformer gas (78% H_2, 2% CO, 20% CO_2, and 0.25% CH_4) fuel. In all cases, the counterelectrode (operated on pure oxygen) was a Teflon-bonded platinum black electrode containing 34 mg Pt/cm^2 and prepared in the same manner as the other electrodes. Both electrodes had a working area of 11.4 cm^2. The electrolyte was 5*N* H_2SO_4. All measurements were made with a Kordesch-Marko bridge (9).

Results and Discussion

Performance data for cells with the bronze-containing electrodes are shown in Fig. 1 and 2 in the form of *IR*-free current-voltage curves obtained with carbon monoxide and synthetic reformer gas fuels, respectively. Included in the figures for reference purposes are similar curves obtained with a fuel electrode containing platinum only, as well as with an electrode containing WO_2 as an additive. This oxide of tungsten had previously been found to be the best among those examined (1).

These data show that the cubic bronze additives result in a considerable improvement over straight platinum, while the tetragonal bronze provides little or no improvement. The data also show that, as the value of x in the cubic bronzes (M_xWO_3) increases, the promotional effect also increases. This parallels the results previously obtained with the tungsten oxides, the lower oxides showing greater catalytic promotion than the higher oxides (1). As is evident, the promotional effect of the bronze with $x = 0.89$ for both carbon monoxide and synthetic reformer gas is only slightly less than the best tungsten oxide (WO_2).

Summary and Conclusions

Relatively high surface area sodium tungsten bronzes (4-6 m^2/g) have been prepared. These materials serve as promoters for the catalytic oxidation of carbon monoxide and reformer gas in fuel cells much the same as the tungsten oxides. The effectiveness of the bronze promoters increases with increasing sodium content.

A Dual Reference Electrode System for Molten Carbonate Cells with Immobilized Electrolyte

E. S. Argano*, [1] and J. Levitan*

Institute of Gas Technology, Chicago, Illinois

The growing interest in the electrochemistry of molten and solid electrolytes brought up the problem of reliable reference electrodes in those high-temperature media.

The corrosivity of molten electrolytes at high temperatures is one of the main problems in the design of reference electrodes and half-cell systems. Reference electrodes reversible to cations such as Na (1-3), Al (4), Pb (5), and Ag (6), and to anions such as the chlorine electrode in chloride melts (7, 8) and the oxygen electrode in borates (9) are being used.

In the case of molten carbonate systems, several types of reference electrodes have been used. The Danner-Rey Ag/Ag^+ electrode (10) has been frequently used in such media and, according to Janz and Conte (11), it has a useful life of about 30 days. Gas

[1] Present address: Istituto di Ricerche Breda, viale Sarca 336, I 20126 Milan, Italy.

reference electrodes are the most reliable in molten carbonate systems because junction potentials are avoided. The Pt/O_2-CO_2 electrode has been investigated by Janz *et al.* (12, 13) and Stepanov *et al.* (14-16) and was found to be thermodynamically reversible and stable with time. This type of gas electrode, using Pt or Au, was used by Schenke and Broers (17) and Borucka (18) for studies in carbonate melts.

When dealing with carbonate fuel cell systems, Moss and Gibbens (19) used a "potential probe" consisting of a Ag wire placed within the immobilized electrolyte, and Trachtenberg (20) used an "idle" electrode consisting of a porous Ag electrode situated in the cathode compartment. The "reference wire" electrode used by Broers and Schenke (21) eliminated the effect of spurious currents by using a carbonate film "bridge" as the liquid junction, but the third electrode was supplied with a mixture of CO_2 and air of unknown composition.

For evaluating properties of individual anodes and cathodes in molten carbonate fuel cells with immobilized electrolytes, the use of proper gas reference electrodes provides reliable and accurate information.

This article reports an improved design for a gas reference electrode for conducting electrochemical studies in molten carbonate cells with an immobilized electrolyte. Two reference electrodes are provided in the same cell assembly.

The present design is shown in Fig. 1.

A pure gold wire (99.999% purity, 0.020 in. in diameter) is enclosed in an alumina tube (*C*) (6 mm in diameter). The lower end of the gold wire is immersed in a closely packed powder of immobilized electrolyte (*D*). An inner alumina tube (OD = 2 mm) situated a few centimeters above the electrolyte level is used to introduce the reference gas mixture. The gas mixture consisting of CO_2 and O_2 (P_{CO_2} = 2/3 atm, P_{O_2} = 1/3 atm) has the most noble potential (14, 15) for this system and was taken as an arbitrary zero point.

The tubes (*C*) of the reference electrodes are located in two symmetrical cylindrical cavities (*G*) containing paste electrolyte.

The electrolyte junction between the reference tubes and the cell electrolyte is obtained through two 0.5-mm-diameter holes: *E* in tube *C* and *J* in ring *H*. The two inner junctions (*J*) were symmetrically located with respect to the electrolyte disk (*I*).

The half-cell housing consists of an outer alumina ring (*H*) (ID = 25 mm) sealed to the bottom alumina tube (*N*) with an alumina-phosphate mixture heated at 1000°C. The electrolyte disk (*I*) (diameter = 25 mm) seated on the bottom tube (*N*) and a similar tube pressed on the top of the electrolyte provide the sealing between the anodic and cathodic compartments of the cell.

The advantage of the present design over the previous three electrode assemblies (19-21) of immobilized electrolyte cells is the ability to maintain a definite and independent atmosphere in the reference chamber. When operated, the reference electrodes and the cell were maintained at 700°C.

An immobilized electrolyte composed of a mixture of inert ceramic and a carbonate ternary mixture (8% Li_2CO_3, 52% Na_2CO_3, and 40% K_2CO_3 melting at 650°C) was used with the present design. The a-c (1000 cps) resistance at 700°C of the reference electrodes *vs.* one of the cell electrodes was found to increase with time from 1 to 2 k-ohm after 30 days of operation. This is probably due to the depletion of carbonates in the pockets (*G*) because of carbonate creeping and decomposition. It can be avoided if tube *C* is sealed to ring *H* but, in this case, the reference tubes are not interchangeable during the operation of the cell. Experiments were conducted for evaluating the long-term stability of the reference electrode. The potential difference at 700°C between the two reference electrodes constructed from the same material and fed by the same gas mixture was ±0.5 mv at the beginning of the test, increased to ±1.5 mv after 10 days of operation, and then did not change during the subsequent 2 months.

A typical polarization curve of a molten carbonate cell with the described reference electrodes (an Au cathode and a porous Ni anode) is shown in Fig. 2.

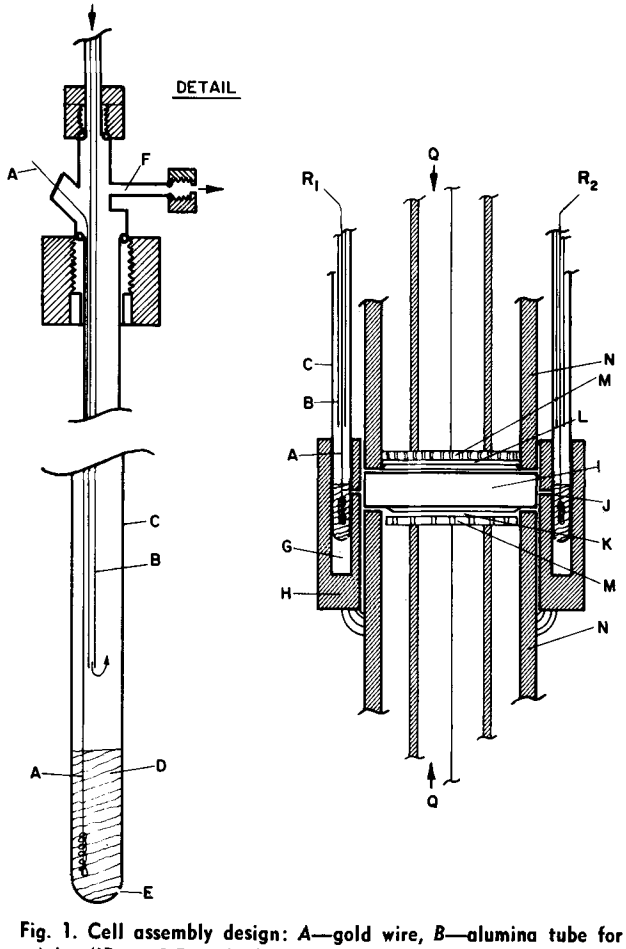

Fig. 1. Cell assembly design: *A*—gold wire, *B*—alumina tube for gas inlet (ID = 1.5 mm), *C*—alumina tube of reference electrode, *D*—paste electrolyte of reference electrode, *E*—hole in tube *C* (diameter 0.5 mm), *F*—gas outlet tube of reference electrode, *G*—paste electrolyte pocket (diameter 6 mm), *H*—alumina ring for reference electrodes, *I*—paste electrolyte disk of cell, *J*—hole for junction with cell electrolyte (diameter 0.5 mm), *K*—cell cathode, *L*—cell anode, *M*—current collector, *N*—alumina tubes of cell assembly, *Q*—gas inlets to cell electrodes.

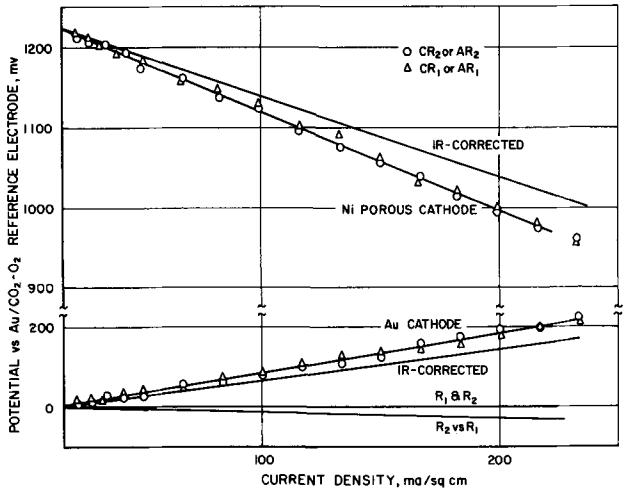

Fig. 2—Typical polarization curve of a molten carbonate cell with an Au cathode and a porous Ni anode.

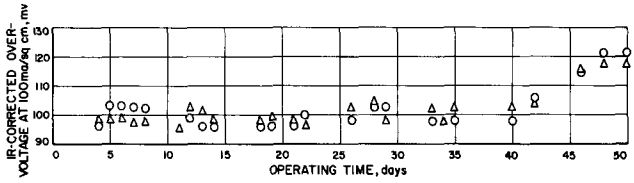

Fig. 3—*IR*-corrected polarization plotted against time of operation.

When the anodic and cathodic polarizations of the cell were measured *vs.* both reference electrodes, the electrode polarization was obtained with ±2 mv accuracy. However, at increased current density, the potential difference between the two reference electrodes increased (15 mv at 200 ma/cm^2). This is presumably due to the nonsymmetrical potential distribution within the electrolyte disk in the vicinity of the inner junctions (*J*) connecting the electrolyte disk (*I*) with the electrolyte pockets where the reference electrodes are located. The single-electrode ohmic components were measured *vs.* both reference electrodes using a standard interruption technique. An *IR*-corrected polarization plotted against time of operation is shown in Fig. 3. The polarization of the porous Ni anode (corrected for *IR* drop) was recorded against both reference electrodes at a current density of 100 ma/cm^2. A mean anodic polarization of 100 ±2.5 mv was measured. The main source of error in this measurement is involved in reading the oscillograms. A failure of the anode was detected after 40 days of operation of that experimental cell.

In conclusion, this design has several advantages:

(*A*) Single-electrode polarization data can be obtained with a known accuracy.

(*B*) The reference electrodes are interchangeable and can be substituted during the operation of the cell without disturbing the cell operation.

(*C*) Long-time stability of the reference electrodes was achieved using immobilized electrolyte in the reference tube and intermediate tubes as well as in the intermediate pocket.

(*D*) The described design can be applied to other electrochemical systems with immobilized and solid electrolytes.

Luminescence of YVO_4:In

S. Faria* and Carl W. Fritsch, Jr.

Sylvania Electric Products Incorporated, Chemical and Metallurgical Division, Towanda, Pennsylvania

Yttrium vanadate, YVO_4, has been activated by most of the trivalent rare-earth (RE) elements (1). The first investigators to activate YVO_4 with another trivalent element, Bi^{3+}, which is not a rare earth, were Toma *et al.* (2) and Datta (3). Their activation with Bi^{3+} resulted in broad-band emission with a maximum at about 550 nm. Although unactivated YVO_4 (1) is in itself a broad-band emitter with a maximum around 435 nm, incorporation of Eu^{3+} (or other RE elements) quenches the matrix emission band and produces characteristic RE line emission.

In this paper, we report that indium, another activator which is not a rare earth, was successfully incorporated in YVO_4 matrix, giving rise to broad-band emission. The emission peak for YVO_4:In is between the matrix emission and Bi emission, *i.e.*, around 470 nm. Some preliminary results on the photoluminescence and cathodoluminescence characteristics of YVO_4:In are presented here.

* Electrochemical Society Active Member.

Phosphor Preparation and Measurements

Procedures similar to those described in the literature for the preparation of YVO_4:Eu (1-3) were followed except for the use of 99.99% In_2O_3 (obtained from Indium Corp. of America). The excitation and emission spectra were measured from phosphor plaques using a Perkin-Elmer spectrofluorimeter and a Hitachi-Perkin-Elmer MPF-2A, respectively. Cathodoluminescence and fluorescent lamp data were also obtained using the conventional techniques.

Effect of In *in* YVO_4

Increasing the In concentration in YVO_4 shifts the emission to longer wave lengths. Figure 1 represents the normalized emission spectra depicting the effect of 0.25 and 5.0 mole per cent (m/o) In substitution

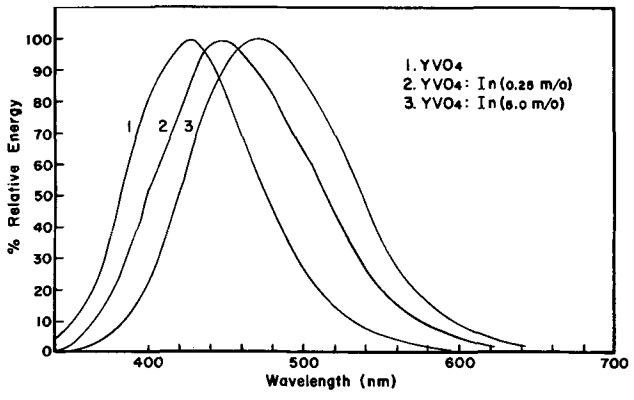

Fig. 1. Emission spectra of: 1—YVO_4, 2—YVO_4:In (0.25 m/o), 3—YVO_4:In (5.0 m/o).

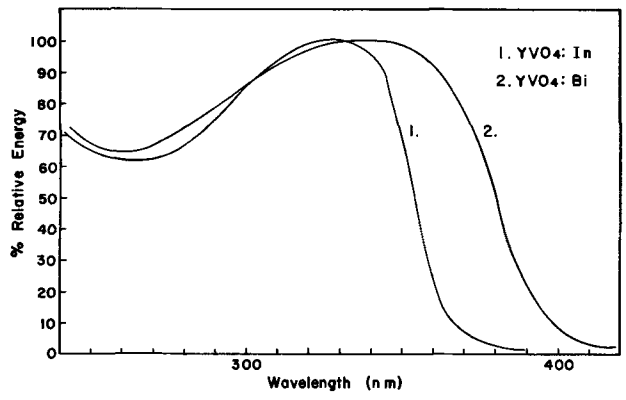

Fig. 2. Excitation spectra of: 1—YVO_4:In (5 m/o) compared to 2—YVO_4:Bi (4 m/o).

for Y^{3+} in YVO_4. Note that 0.25 m/o In shifts the peak of unactivated YVO_4 about 300Å, while 5.0 m/o In shifts it close to 450Å. Per cent plaque brightness with three different ultraviolet mercury excitations at various In concentrations are presented in Table I.

Optimum In concentration for 2537 and 3250Å excitation is about 2 m/o. With 3650Å excitation, however, the maximum was found to be around 7 m/o In.

The blue emission of YVO_4:In was compared to $Sr_2P_2O_7$:Sn and $Ca_5F(PO_4)_3$:Sb, two well-known blue-emitting fluorescent lamp phosphors. Table II shows the lamp brightness results in lumens (mainly 2537Å excitation).

Excitation Spectra of In *vs.* Bi

The normalized excitation spectrum for YVO_4:In was compared to that of Bi and shown in Fig. 2. Note that the excitation peak for In is 330 nm, while for Bi it is around 345 nm. The indium excitation band is much narrower than that of Bi. The excitation spectrum of unactivated YVO_4 is the same as that of YVO_4:In.

In Fig. 3 are plotted the emission spectra of YVO_4, YVO_4:In, and YVO_4:Bi. The separation between the In and Bi peaks is about 100 nm.

0.25	3.8
2.00	5.5
5.00	5.2

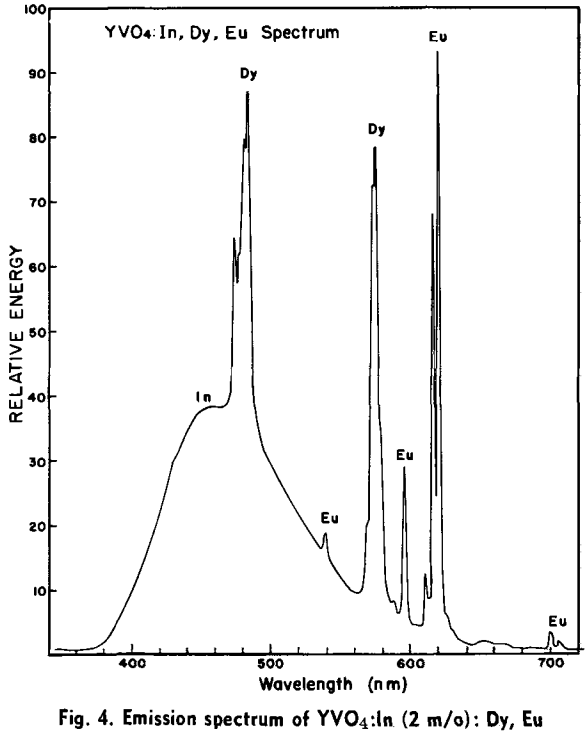

Fig. 4. Emission spectrum of YVO_4:In (2 m/o): Dy, Eu

Cathodoluminescence Properties

Under cathode-ray bombardment, YVO_4:In also showed blue luminescence. Table III shows the brightness results in foot-lamberts (ft-L) for three In concentrations. (About 4.4 mg/cm² of phosphor were settled on 1.5 x 1.5-in. glass slides and bombarded with 12 kv, 6 μa cathode rays.)

The brightness of the 2.0 m/o In sample represents about 60% of the brightness of the normal blue cathode-ray phosphor, ZnS:Ag.

Effect of Eu and Dy

When small amounts of Eu and/or Dy (500 ppm, respectively) were added together with In, we obtained the emission spectrum shown in Fig. 4. Note that the Eu and Dy emission lines are superimposed over the YVO_4:In emission band. Over 1 m/o of Eu or Dy additions tend to quench the YVO_4:In band. On the other hand, high In (1-2 m/o) additions to YVO_4:Eu (5 m/o) do not seem to affect the Eu lines or the Dy lines.

Summary

Indium has been found to activate the YVO_4 matrix, yielding a phosphor with a broad-band emission. The position of the emission peak is dependent on the In concentration. Increasing the In content shifts the emission peak toward longer wave lengths. Optimum ultraviolet-excited and cathodoluminescence brightness appears at about 2 m/o In.

A possible mechanism of energy transfer in YVO_4:Bi has been discussed by Toma (2) and Datta (3). They have assumed that energy absorbed by the matrix is transferred by a radiationless process to the activator center. We suspect that a similar mechanism applies to In-activated YVO_4.

The Luminescence of YVO_4:Dy, YVO_4:Dy,Eu, and YVO_4:Dy,Tb

S. Faria* and D. T. Palumbo

Sylvania Electric Products Incorporated, Chemical and Metallurgical Division, Towanda, Pennsylvania

Rare-earth (RE) vanadate crystals prepared by Brixner and Abramson (1) showed, besides their main host emission, additional luminescent multiplets ascribed to other RE impurities. Similar multiplets were observed by Palilla and co-workers (2) in their extensive luminescence investigation of RE activated YVO_4. Among the RE impurities usually detected were Er, Sm, Tm, Dy, and Eu. The characteristic line emission of these RE and their position in the visible spectrum are easily identified in the vanadate matrix by spectrophotometric measurements.

Dy multiplets in particular are quite evident, even when using yttrium salts of high purity. Concentrations of Dy as low as 1-2 ppm give distinctive lines superimposed over the broad spectrum of YVO_4. The location of the Dy multiplets is centered at about 475 and 575 nm.

Because of its intense emission at low concentrations, we investigated Dy as a primary activator in YVO_4. We also studied the effect other RE's, particularly Eu and Tb, have on the luminescence characteristics of YVO_4:Dy, particularly in fluorescent lamps.

Experimental

YVO_4, YVO_4:Dy, YVO_4:Dy:Eu, *etc.*, were prepared by dry blending high-purity oxides (99.99%) of yttrium, dysprosium, europium, and terbium with excess ammonium metavanadate and firing at 1750°F for 2 hr in open quartz crucibles. After cooling, the phosphors were washed in 10% caustic solution to remove the excess vanadium pentoxide.

Emission spectra were measured with a Hitachi-Perkin-Elmer spectrophotometer, Model MPF-2A. Fluorescence brightness was obtained from both low- and high-pressure (2537 and 3650Å) mercury vapor lamps. The per cent red output from the high-pressure mercury vapor lamps was measured using a Corning red filter #2418 (CS2-62).

Experimental Results

Response of YVO_4:Dy.—Besides being an excellent host for RE activators, YVO_4 is a self-activated phosphor. Its broad band emission spectrum with maximum at about 440 nm has been previously reported (2). Low levels of Dy, as well as other RE's, quench the matrix band and emit their own characteristic lines. We found that the Dy concentration for optimum luminescence ranged between 0.2-0.4 m/o (mole per cent) as shown in Fig. 1. There is a considerable decrease in the emission intensity with Dy content above 1 m/o.

The main Dy transitions are the $^4F_{9/2} \rightarrow {}^6H_{15/2}$ (475 nm) and the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ (575 nm). Other weak transitions are reported at longer wave lengths (3). An unresolved but typical Dy emission spectrum is shown in Fig. 4.

Effect of Eu on YVO_4:Dy.—While maintaining the Dy at 0.3 m/o, Eu was added at various concentrations. No detrimental effect is observed in the Dy intensities until Eu content supersedes the Dy content. The ratio of Eu (619 nm) lines to Dy (575 nm) increases linearly up to about 1500 ppm Eu. Figure 2 shows that a ratio of Eu/Dy emission of 1 is obtained when Eu is approximately 3000 ppm. Amounts of Eu around this concentration improve the color rendition

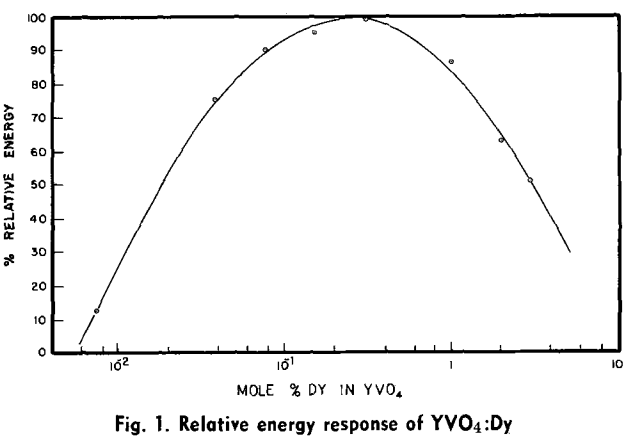

Fig. 1. Relative energy response of YVO_4:Dy

* Electrochemical Society Active Member.

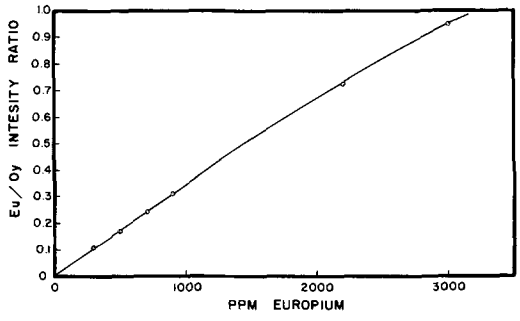

Fig. 2. Ratio of Eu (619 nm) emission to Dy (574 nm) emission

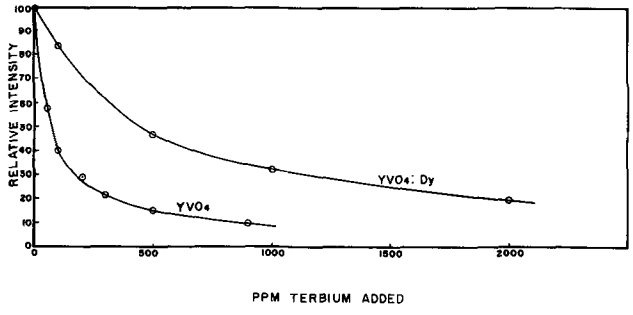

Fig. 3. Effect of Tb on YVO_4 and YVO_4:Dy emission

of the phosphor in high-pressure mercury vapor lamps.

Response of YVO_4:Dy *to* Tb.—Unlike Eu, Tb strongly quenches the Dy emission. At 100 ppm Tb, the YVO_4:Dy emission intensity is reduced to 85% and, at 500 ppm Tb, less than 50% of the original intensity remains as shown in Fig. 3. The strong quenching effect of Tb was even more pronounced in pure YVO_4, 100 ppm Tb reducing the broad band emission intensity of YVO_4 to about 40%.

Fluorescent lamp results.—Figure 4 compares the two broad emission bands of $Ca_5F(PO_4)_3$:Sb (0.06), Mn (0.07), the well-known cool white fluorescent lamp phosphor, with that of the emission of YVO_4:Dy (0.3 m/o). Table I shows the low-pressure mercury vapor lamp data for YVO_4:Dy at various Dy concentrations. An initial brightness of about 76 lpw was obtained with what we consider an optimum Dy concentration; however, there is considerable drop in light output after 100 hr of lamp operation.

YVO_4:Dy was also evaluated in high-pressure mercury vapor (HPMV) lamps. The lumens per watt

Table I. Lumens per watt of YVO_4:Dy in low-pressure lamps

m/o Dy	0 Hr	100 Hr
0.10	62.4	51.3
0.28	75.0	67.2
0.30	75.8	63.5
2.8	30.0	29.0

Table II. Lumens per watt of YVO_4:Dy *vs.* YVO_4:Eu in HPMV lamps

	175w			400w		
	0 Hr	100 Hr	% Red (100 Hr)	0 Hr	100 Hr	% Red (100 Hr)
YVO_4:Dy (0.3 m/o)	57.5	53.3	1.31	63.0	58.1	2.53
YVO_4:Eu (5.0 m/o)	54.0	51.4	14.50	60.8	55.8	15.6

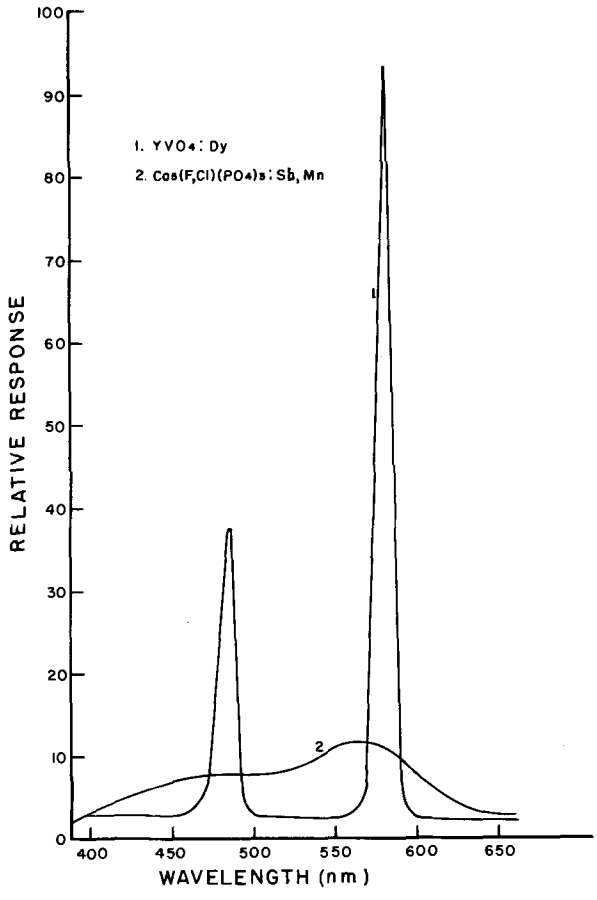

Fig. 4. Comparison of YVO_4:Dy emission with $Ca_5F(PO_4)_3$:Sb, Mn

were compared to that of YVO_4:Eu as shown in Table II. Because of the lack of red emission, this phosphor is not used directly in HPMV lamps. With the addition of Eu, the red rendition of the phosphor is improved. When appreciable amounts of Eu (1 m/o) are added, the red emission intensity increases considerably.

Summary

We have described the effects of Eu and Tb on the luminescence characteristics of YVO_4:Dy. While Eu in moderate amounts (Eu = Dy) does not quench the Dy emission, Tb in very small amounts (Tb << Dy) rapidly quenches the Dy emission.

Lamp data were presented showing that YVO_4:Dy may be used in both low- and high-pressure mercury vapor lamps with interesting results.

Manuscript submitted July 19, 1968; revised manuscript received Sept. 11, 1968. This manuscript was presented at the Boston Meeting, May 5-9, 1968, as Paper 37.

A New Radio-Frequency Inductive Plasma Sputtering Process for Surface Coating

P. Beucherie, M. Block, and J. G. Wurm*

EURATOM, Ispra Establishment of the C.C.R., Chemistry Department, High Temperature Chemistry Section, Ispra, Italy

High-quality thin film coatings are increasingly required in various fields such as the chemical space, nuclear, and electronic industries. The basic cathode sputtering process and the high vacuum evaporation method have both been used extensively for most coating purposes (1). For high-quality coatings, cathode sputtering was preferred, but this method is handicapped by its very low sputtering speed. So, in the last few years, the tendency was to increase the sputtering efficiency with the addition of different auxiliary devices.

In the literature are described several low-energy sputtering devices with two or three auxiliary electrodes and thermionic cathodes (2-4). Furthermore, the addition of a strong magnetic field increased the ion concentration and therefore the sputtering yield. The development of the R-F sputtering, as reviewed by Davidse (5), paved the way to the deposition of thin insulator films. The deposition of Ta metal and Ta_2O_5 by superimposed R-F and d-c sputtering was described by Vratny (6). The increase in sputtering efficiency, obtained from all these improvements, was penalized by more complicated and costly sputtering equipment. It was the purpose of our investigation to find a more compact and simplified device with an acceptable sputtering efficiency for industrial coating applications. It was also thought that the device should be suitable for coating tubes inside. Therefore, the basic cathode concept has been discarded, and the ionized plasma was confined inside an inductive R-F coil made of the material itself to be sputtered. The ions which are created under the impulses of the R-F electromagnetic field bombard the material of the coil and sputter its surface atoms into the surrounding space. Also, a substrate interposed on the trajectories of the sputtered "microparticles" will be coated with a very uniform and dense layer.

Description of the Process

The general schema of the equipment is illustrated by Fig. 1 and 2. The inductor coil, 7, made of the material to be sputtered is placed inside a vacuum enclosure consisting of a metallic base, 4, and a glass bell, 10. Through the base, 4, are inserted: the insulated R-F connections, 6, for the inductor coil and the argon admission line made of a capillary tube, 8, directed toward the axis of the inductor coil. The amount of gas to be admitted is regulated by a precision needle valve, 9. The samples, 5, to be coated are fixed around the inductor coil; however, the preferential position will be in the axis of this latter. The R-F current is supplied to the inductor coil by a R-F generator, 1, S.T.E.L. with an adjustable frequency from 5 to 12 MHz. Between the generator, 1, and the inductor, 7, is switched in a R-F transformer, 3, with a variable capacity, 2. The pumping group consists of a diffusion pump, 12, Leybojet 3000 liters/sec followed by a Roots pump, 14, of 250 m^3/hr and a preliminary pump, 15, of 60 m^3/hr.

Operating Method

The samples to be coated are carefully cleaned in an organic solvent bath; also, an electrolytic attack might be useful in some cases. Then the samples are fixed in their sputtering position. According to their geometrical configuration, a rotation of the samples would be necessary, particularly for the outside coating of tubes. A vacuum of 10^{-5} to 10^{-6} Torr is maintained for some time, until the residual and adsorbed gases are eliminated. Through the needle valve, an argon leak stream about 0.2 Torr liters/sec is introduced into the coil axis by the refractory capillary which is about 5 cm long with a 0.4-mm hole. As soon as the R-F current is switched on, a blue-colored plasma is formed inside the inductor coil (Fig. 3), and the argon line pressure, measured between the needle valve and the capillary, increases from 50 to about 250 Torr. Due to the bombardment by the gas ions, the inductor reaches a temperature of about 600°-1000°C according to the nature of the metal, the geometry of the coil, and the injected R-F power. Example: for a niobium inductor composed of seven turns (wire diameter 3 mm) with a coil diameter of 25 mm, the total consumed power is about 3 kva and the coil temperature around 900°C. The temperature of the sample to be coated depends mainly on its distance from the inductor. A metal sheet fixed at a 10-15 cm distance from

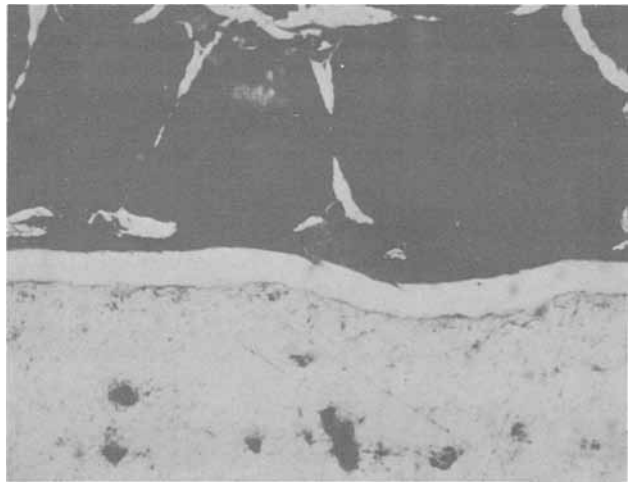

Fig. 5. Photomicrograph of niobium sample coated with 14μ of molybdenum.

the coil can reach a temperature of 60°-100°C. For special coating purposes, a cooling or a heating device for the sample has been set up. The capacity of the pumping group must be calculated in order to maintain inside the enclosure a dynamic vacuum of about 10^{-3} to 10^{-4} Torr despite the permanent argon stream flow through the capillary. As a matter of fact, the pressure inside the vacuum enclosure is less than uniform. In the center of the inductor coil where the plasma takes place, a maximum concentration of the gaseous ions is reached, and the pressure may be estimated to about 10^{-1} to 10^{-2} Torr. Outside the inductor coil a pressure gradient will be established going from 10^{-1} Torr to about 10^{-3} to 10^{-4} Torr at the place where the sample to be coated is fixed. The sputtering rate, which can be defined as the ratio of the sputtered atoms to the number of incident ions, depends on the nature of the metal and the energy of the gaseous ions bombarding it. The coating speed depends on that sputtering rate and, moreover, on the geometry of the system. Coating thicknesses from 0.1 to 0.5 μ/min can easily be obtained. In some special cases, as for instance the inside coating of tubes, a much higher deposition speed can be reached.

Furthermore, the coating speed may be increased by connecting several inductors together, either in series or in parallel. For all refractory metals having a high melting point, the inductor coil is usually composed of a wire. For metals with a melting point lower than 1100°C, it is more advisable to use a water-or air-cooled tube. With inductors made of cooled tubes, it is possible to inject more power and therefore also to increase the sputtering rate. For the sputtering of metals a neutral gas (essentially argon) is preferred, but it is also possible to make use of the reactive gases such as nitrogen or oxygen. In this case, called "reactive sputtering," the sample will be coated with the corresponding nitride or oxide.

Because of the high energy concentration in a restricted volume, delimited by the inductor coil, the microparticles ejected from the latter hit the sample with an appreciable kinetic energy. Consequently, the deposited films are strongly adherent, very dense, and regular in thickness. As there are only two R-F connections to the inductor coil, the effective space in the enclosure is very large and the metallization of samples with various shapes is easy.

Also, this method, well suited for metallizing tubes inside, is of particular interest to the chemical, nuclear, and electronic industries. We have deposited films of various thicknesses up to 20μ of metals such as Nb, W, Ta, Zr, Ti, Fe, Co, Ni, Cu, Al, Pt, Ir, Au, and also alloys of Ni-Cr and stainless steel on all kinds of substrates such as other metals, alloys, ceramics, glass, graphite, plastics, and even paper. As an example: a niobium layer of 8-10μ has been deposited inside of a Zircaloy tube of 50 mm diameter. The film adherence was not altered after a thermal cycling of 250 hr at 500°C (*see* Fig. 4 and 5).

For industrial coating purposes, this new coating process can be compared favorably with cathode sputtering and vacuum evaporation; it is essentially characterized by its great sputtering rate, the excellent quality of the deposits which are obtained, and its extreme operating simplicity.

Manuscript submitted April 11, 1968; revised manuscript received Aug. 8, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Corrosion of Zinc in KOH Solutions

T. P. Dirkse* and R. Timmer

Calvin College, Grand Rapids, Michigan

ABSTRACT

The corrosion rate of zinc in KOH solutions has been measured under a variety of conditions. Amalgamation and the presence of zincate ions lower this rate of corrosion. The effect of increasing KOH concentration on the rate of corrosion is different for nonamalgamated zinc than for amalgamated zinc. The temperature effect is also different for the two types of zinc electrodes.

One of the problems associated with the use of zinc electrodes in alkaline solutions is the reaction of zinc with the electrolyte to produce hydrogen. This reaction has two disadvantages. It uses up the zinc, *i.e.*, it is a self-discharge reaction. Also, the evolution and buildup of hydrogen are undesirable if an alkaline cell containing zinc electrodes is to operate in the sealed condition.

The reaction can be described as a corrosion reaction. Over the years there has been considerable interest in the corrosion of zinc but hardly any work has been published on the corrosion of zinc in alkaline solution.

Snyder and Lander (1) studied the evolution of hydrogen from commercial zinc electrodes containing 2% polyvinylalcohol and encased in a cellulosic separator material. They found that the amount of hydrogen evolved in a given time decreased as the electrolyte changed from 30 to 45% KOH. It decreased with increasing HgO content up to 4%, and it also decreased with decreasing temperature. Furthermore, the presence of zincate in the electrolyte increased the amount of hydrogen evolved.

Ruetschi (2) also studied the corrosion rate of amalgamated zinc in alkaline solutions. His experimental arrangement avoided the use of separators and additives. He used a specified weight of powdered material, but no surface area values were given. Consequently, the rate of corrosion per unit surface cannot be determined from his data. The corrosion of amalgamated zinc was found to increase with increasing temperature. It increased with increasing KOH concentrations, contrary to the results of Snyder and Lander (1). Furthermore, the presence of zincate ions decreased the rate of corrosion except in KOH solutions less than 2*N*. Here the zincate ion appeared to have a catalytic effect.

The main discrepancies between the work of Rüetschi and that of Snyder and Lander are (*i*) the effect of zincate ion and (*ii*) the effect of increasing KOH concentration on the corrosion rate of amalgamated zinc. Some of this difference may be due to the way in which the data were obtained. Snyder and Lander used as the corrosion rate the steady state achieved after about 30 days. Rüetschi started taking measurements less than 24 hr after the zinc and KOH were brought in contact with each other. Thus, in the work of Snyder and Lander, the electrolyte composition at the time measurements were taken was likely somewhat different from that at the time the corrosion began. Furthermore, in the work of Snyder and Lander the corrosion rate was likely also affected by the polyvinyl alcohol and the separator material.

The present work on the corrosion of zinc in alkaline solutions was undertaken for two reasons: (*i*) because so little work has been reported on this matter; and (*ii*) to establish basic information on the effect of KOH concentration, amalgamation, zincate ion, and temperature on this process. These values are needed so that one can determine, with such information as a background, the effect of additives and impurities on the corrosion rate of zinc in a battery system.

Experimental

The apparatus consisted of a sealed glass tube about 2.5 x 20 cm to which a calibrated pipette was attached, Fig. 1. The entire assembly, except for the outlet of the pipette, was immersed in a liquid constant temperature bath. Two pieces of zinc (99.999%) wire, 12.7 x 0.15 cm, were placed in the electrolyte. Thus the surface area exposed to the electrolyte was 12 cm^2.

As hydrogen was evolved, electrolyte was forced into the pipette. Consequently, the rise in the electrolyte level in the pipette was a measure of the rate at which hydrogen was evolved. In each run a blank (containing no zinc wire) was included to correct for minor fluctuations due to changes in barometric pressure. Corrections were also made for vapor pressure, etc., and the results were then expressed as micromoles of hydrogen evolved per square centimeter of electrode area. Measurements were begun within an hour after the apparatus was assembled.

Amalgamation was done by dipping the zinc wire in a $HgCl_2$ solution (50 g/liter) for 30 sec. No work was done to determine the effect of varying degrees of amalgamation.

Results

A typical set of data is shown on Fig. 2. The slope of these lines served as a measure of the rate of corrosion, *i.e.*, rate of hydrogen evolution. This rate was

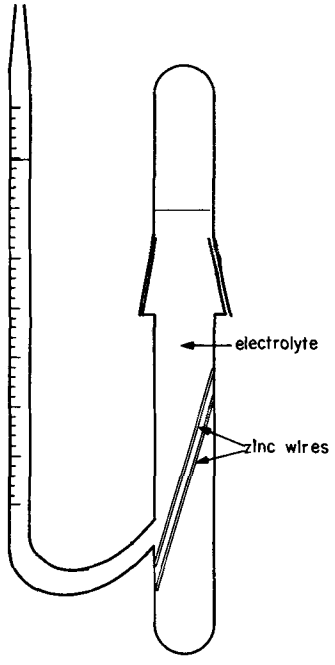

Fig. 1. Experimental arrangement

* Electrochemical Society Active Member.

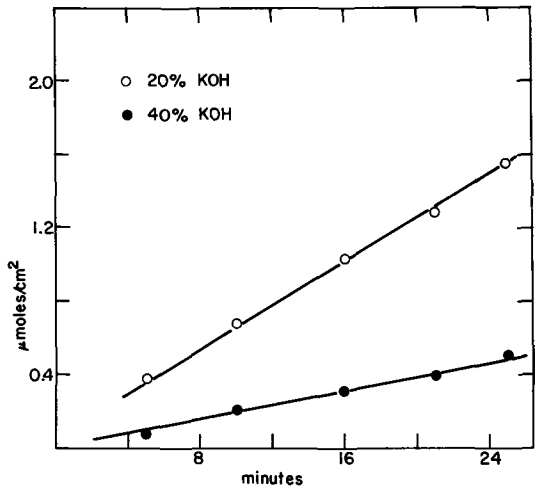

Fig. 2. Rate of hydrogen evolution from nonamalgamated zinc at 25°C.

measured in 20, 30, 35, 40, and 45% KOH and in these same solutions saturated with zinc oxide. Both amalgamated and nonamalgamated zinc electrodes were used and every run was made at two temperatures, 25° and 44°C.

The variation of the rate of corrosion with these differing conditions can be seen on Fig. 3-8. Figure 3 shows the effect of temperature in plain KOH solutions while Fig. 4 shows the effect for solutions saturated with ZnO. On this and other figures, lines are drawn through most of the data points. However, on such lines minor fluctuations are not necessarily significant. Some duplicate runs were made and, especially at the lower rates, the uncertainty may approach ±20%.

In the plain KOH solutions, Fig. 3, temperature seems to have little effect, but, surprisingly, the small difference that there is indicates a lower corrosion rate at the higher temperature. In the zincate solutions, the temperature effect also is small, but here the higher corrosion rate generally occurs at the higher temperature. In any event, the difference in corrosion rates at 25° and 44°C is small.

Figure 3 also illustrates the effect of KOH concentration. Increasing KOH concentrations bring about a reduced corrosion rate as was found by Snyder and Lander (1). When the solutions are saturated with zincate, this regularity does not exist, but rather the

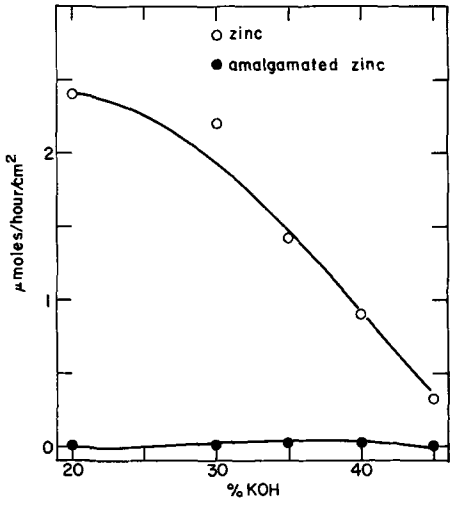

Fig. 7. Rate of hydrogen evolution at 44°C

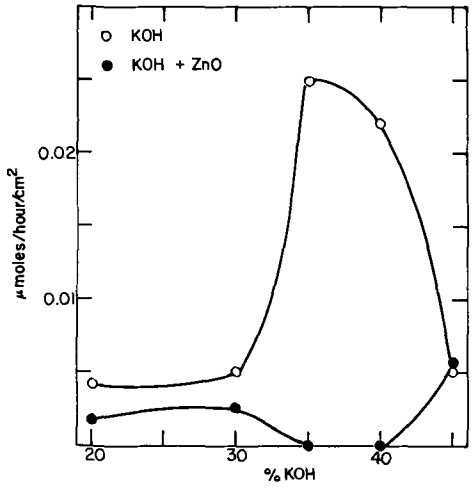

Fig. 8. Rate of hydrogen evolution from amalgamated zinc at 44°C.

corrosion rate increases up to about 35% KOH and then decreases, Fig. 4. Note that the ordinate scale on Fig. 4 is considerably smaller than that on Fig. 3.

The effect of zincate ion can be seen by comparing Fig. 3 and 4, but it is shown more directly on Fig. 5. The solutions designated as KOH + ZnO were all saturated with ZnO so that the zincate concentration increases markedly in going from 20 to 45% KOH. Figure 6 shows the effect of zincate ion at 44°C.

Amalgamation of the zinc electrode also brings about a marked reduction in the corrosion rate, Fig. 7. The amount of amalgamation was not varied so that the effect of increasing quantities of mercury on the corrosion rate cannot be determined from our data.

It is interesting to note that saturating a KOH solution with ZnO has about the same effect in reducing the rate of corrosion as does amalgamation, compare, *e.g.*, Fig. 6 and 7. When both factors are present there is a slight decrease over either one alone, Fig. 8. The effect of temperature and KOH concentration on the corrosion of amalgamated zinc is shown on Fig. 9.

Discussion

No other reported work was found for the corrosion rate of nonamalgamated zinc in KOH solutions except for a few data reported by Snyder and Lander (1). They found, as we have, that the corrosion rate decreased with increasing KOH concentration. Results such as those shown on Fig. 2 and 3 are the basic data against which other factors or conditions can be compared.

A possible mechanism involves the following processes:

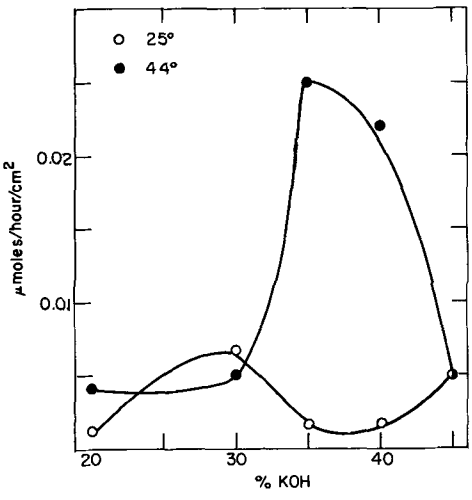

Fig. 9. Rate of hydrogen evolution from amalgamated zinc in KOH solutions.

$$2H_2O + 2e \rightarrow H_2 + 2\,OH^- \qquad E^\circ = -0.828v \quad [1]$$

$$Zn + 2\,OH^- \rightarrow Zn(OH)_2 + 2e \qquad E^\circ = 1.245v \quad [2]$$

$$Zn + 2\,OH^- \rightarrow ZnO + H_2O + 2e \qquad E^\circ = 1.248v \quad [3]$$

Reactions [2] and [3] may each involve several steps as in the anodic treatment of zinc.

Combining [1] and [2], the over-all reaction is

$$Zn + 2H_2O \rightarrow H_2 + Zn(OH)_2 \qquad E^\circ = 0.417v \quad [4]$$

Combining [1] and [3] gives

$$Zn + H_2O \rightarrow ZnO + H_2 \qquad E^\circ = 0.420v \quad [5]$$

For both over-all reactions the driving force, energetically, is favorable and practically the same. The reason the reaction is as slow as it is arises from the overvoltage for the hydrogen evolution, reaction [1]. The initial rate of reaction [4] is

$$\text{rate} = K_4\,(a_{H_2O})^2 \quad [6]$$

while that for reaction [5] is

$$\text{rate} = k_5 \cdot a_{H_2O} \quad [7]$$

A plot of log rate *vs.* log a_{H_2O} should then give a slope of 2 for reaction [4] and a slope of 1 for reaction [5] if these reactions are rate controlling. Making such a plot of the data in ref. (3) gives a slope of 1.6. A similar plot of our data for plain zinc in KOH solutions at 25° gives a slope somewhat larger than 1.5, Fig. 10. This may mean that both reactions [4] and [5] take place. These reactions do agree with the effect of KOH concentration on the rate of corrosion. As KOH concentration increases, the activity of the water decreases, resulting in a lower rate for reaction [1]. This then may be the controlling process.

Amalgamation reduces the corrosion rate of zinc. Our results for amalgamated zinc do agree with other reported work so far as comparisons can be made. The behavior of amalgamated zinc is definitely different from that of nonamalgamated zinc. The corrosion of amalgamated zinc appears to reach a maximum in 30-35% KOH while the rate for nonamalgamated zinc decreases with increasing KOH concentration. Further, the corrosion rate of nonamalgamated zinc decreases in going from 25° to 44° while that of amalgamated zinc increases.

Amalgamating the electrode raises the hydrogen overvoltage considerably and slows down reaction [1] which again limits the over-all corrosion reaction. The value of this overvoltage varies with temperature and KOH concentration (4), and this may partly affect the change of corrosion rate with these conditions. The overvoltage has a minimum value at about 9M KOH.

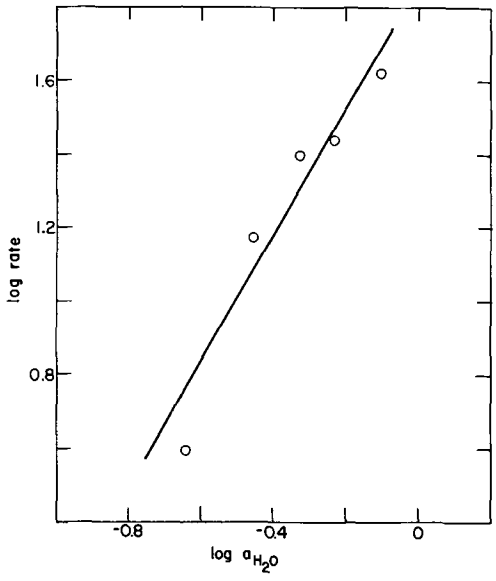

Fig. 10. Log rate vs. log a_{H_2O} plot for hydrogen evolution from zinc in KOH solutions at 25°C.

The corrosion rate appears to have a maximum value at this concentration, Fig. 9.

The presence of zincate ions also reduces the rate of hydrogen evolution. This was observed by Rüetschi (2) but not by Snyder and Lander (1).

When ZnO is dissolved in KOH solutions, reaction [8], the activity of the water is lowered

$$ZnO + H_2O + 2\,OH^- \rightarrow Zn(OH)_4^= \qquad [8]$$

and this should decrease the rate of reaction [1]. However, the rate decrease that was observed, *e.g.*, in 20% KOH, was far greater than could be accounted for by this process alone. Consequently, some other or additional influence of zincate ion must be present.

A more likely explanation is that suggested by Rüetschi (2), *i.e.*, the corrosion rate also depends on the rate of dissolution of interfacial ZnO or $Zn(OH)_2$. In KOH solutions saturated with ZnO, the oxide or hydroxide produced by the corrosion reaction cannot readily dissolve in the electrolyte. Consequently, it remains on the surface of the zinc and protects the zinc underneath from further reaction. The extent to which the zinc is protected depends on the porosity of the corrosion product. This same phenomenon could account for the lack of complete reproducibility in our results. Our solutions were not shaken during the course of a given determination. For the corrosion product to continue to dissolve, it was then necessary for that which had dissolved to be transported away from the zinc surface either by diffusion or convection. Our results then were modified somewhat by the randomness of this material transport.

In conclusion, reactions [1] to [3] serve as a satisfactory mechanism for the initial corrosion of zinc in KOH solutions. With pure zinc the process is controlled by reaction [1]. With amalgamated zinc, reaction [1] is the limiting process because of the higher hydrogen overvoltage. When zincate ion is present other processes, such as dissolution of the corrosion product, may become rate controlling.

Still unaccounted for is the fact that the corrosion rate for nonamalgamated zinc is slightly lower at 44° than at 25°C. This cannot be attributed to decreasing activity of water or to increasing hydrogen overvoltage as the temperature is raised. Further, one would expect the rate of dissolution of ZnO or $Zn(OH)_2$ to be greater at the higher temperature. This leaves as a possible explanation the suggestion that the corrosion product at 44° is more dense than at 25°C. This more dense product affords a more complete covering of the zinc at the higher temperature and lowers the corrosion rate. It has been pointed out (5) that below 35°-40°C a $Zn(OH)_2$ is a stable form while above this temperature ZnO is the stable phase. Gilbert (6) found that the corrosion of zinc is distilled water at 85° produced only ZnO, while at room temperature the product was ZnO + various types of $Zn(OH)_2$. Furthermore, $Zn(OH)_2$ is more soluble than ZnO. Thus it is a possibility that the corrosion of nonamalgamated zinc in alkaline solutions at 25° produces a less dense, and more soluble, product than that which is produced at 44°. Consequently, a more protective covering is formed at the higher temperature giving rise to a lower rate of corrosion.

Controlled Current Deposition of Zinc from Alkaline Solution

S. Arouete,*[1] K. F. Blurton,*[2] and H. G. Oswin*[2]

Leesona Moos Laboratories, Great Neck, New York

ABSTRACT

Electrodeposition of zinc onto foil electrodes from alkaline zincate solutions with direct current results in dendritic or black, porous mossy deposits. Smoother deposits are obtained with a pulsed current source or periodic reversal of current. The nature of the deposit with pulsed charging depends on the current density, the amount of charge passing through the electrolytic cell, the on time, and off time. The optimum values of these parameters are dependent on the cell geometry and the differences between the apparatus used in the present study and a cell containing a secondary zinc electrode are discussed.

Secondary silver/zinc batteries are severely limited in applications where a high energy/weight ratio is desirable because of their limited cycle life at high depths of discharge. In contrast to the insoluble oxidation product formed at other negative electrodes, the oxidation product of the zinc electrode is highly soluble in strong alkali, forming $Zn(OH)_4^{2-}$ as the principal product. This species has the ability to form highly stable supersaturated alkaline solutions (1). In a silver/zinc battery, the concentration of zincate after discharge is estimated at one molar, and where there is restricted diffusion the electrolyte may supersaturate to two or three times this concentration (1). During the subsequent charging cycle, the zincate discharges at the zinc electrode in a nonadherent dendritic or mossy form. This results in a loss of capacity of the secondary zinc electrode.

From the viewpoint of battery technology the three most important morphologies associated with zinc deposition from alkaline solution on foil electrodes are smooth, mossy, and dendritic deposits (2, 3). Smooth deposits are formed at low overpotential with vigorous stirring of the electrolyte. The other two deposits are noncompact. The mossy deposit is black and porous and is formed at low overpotentials, while the dendritic deposits are formed at high overpotentials. The transition from moss to dendrites corresponds to the onset of mass transport control and is characterized by a critical current density which is temperature dependent (2). Thus the overpotential is controlling only to the extent that it determines whether the deposition is mass-transport controlled. Since mass transport plays such an important role in producing dendrites it appeared profitable to follow a previous suggestion and work with interrupted current sources (2), where the concentration gradient is allowed to collapse and reform during metal deposition.

Much of the work to date on improving the capacity of Ag/Zn batteries has been aimed at improving the electrode separators. This has given some success (4) but the cycle life and depth of discharge are still limited by nonadherency of the zinc deposit and dendrite formation. In order to lengthen the cycle life of the Zn electrode, it is necessary to form on the surface an even, adherent, porous deposit during charge. The sole object of the present study has been to investigate the parameters which control the deposit adherency and dendrite formation when charging a zinc electrode with an interrupted current source. Constant current deposition was chosen first because growth of zinc dendrites is controlled by the rate of transport of zincate ions to the electrode surface and second because controlled current charging is a preferred mode of battery charging.

Experimental Procedure

The electrolyte composition was aqueous 43% KOH solution made 1.13M in Zn(II). Reagent grade chemicals were used without further purification. A 130 ml rectangular cell was used which permitted the working electrode to be mounted vertically and parallel to the counter electrode. Sheet zinc was used as the working electrode. Its area was usually 22 cm^2 but this could be varied by coating with epoxy adhesive. In most of the experiments the counter electrode was either gold or platinum foil, but there was no difference in the results when the counter electrode was nickel foil. The temperature was regulated at 30°C in all of the experiments.

A constant current source was developed which provided direct current or pulses of varying on and off times. Current regulation was $\pm 0.25\%$ over the range of 10^{-3} to 1.2 amp, and the pulse rise and fall time was approximately 4 μsec. The quoted values of the current density are those for the on time and are based on the geometric area of the electrode. For the investigation of the periodic reversal of current a constant current source was connected to a time switch.

The deposits were characterized by viewing under a 50X magnification microscope, by preparing cross-sectional photomicrographs of 1000X magnification of the center of the electrode and by measurement of deposit adherency. The adherency of the deposit was determined by essentially the same procedure as Romanov (5). After deposition the electrode was removed from the solution, washed, dried, and weighed. The visible moss was then readily removed by brushing with a tissue. An adherent, compact deposit always remained which could not be removed by the most vigorous brushing. The technique was not precise but it did give an estimate of the amount of nonadherent deposit.

Results

Since the deposit morphology is different above a critical current density from that below it, experiments have been performed at constant current in the two regions. In the present work the value of the critical current density was 21 ma/cm^2.

Charging with a pulsed current source at currents less than the critical current density.—In this series of experiments the deposit was initially compact and adherent, but after a certain time moss usually appeared. Regardless of the extra charge passed thereafter the maximum weight of zinc deposited adherently after the appearance of moss corresponded to only about 6 coulombs/cm^2. This additional weight of zinc cor-

Table I. Adherency of zinc deposit formed at low current densities. Total charge passed in each experiment 18 coulombs/cm²

Current density, ma/cm²	Charge passed before appearance of mossy deposit, coulombs/cm²	Quantity of adherent deposit, coulombs/cm²	Quantity of nonadherent deposit, coulombs/cm²	Mode of charging
4	2.4	3.6	14.4	Direct current
4	3.1	4.0	14.0	Pulsed current 25 msec on, 25 msec off
4	4	5.3	12.7	Pulsed current 2.5 msec on, 2.5 msec off
10	4	6.1	11.9	Direct current
10	9	14.0	4.0	Pulsed current 2.5 sec on, 2.5 sec off
10	15.0	16.5	1.5	Pulsed current 30 msec on, 30 msec off
10	No moss formed	18.0	0	Pulsed current 30 msec on, 45 msec off
10	No moss formed	18.0	0	Periodic reversal of current 12 sec cathodic 8.4 sec anodic

responds to the period during which both compact and mossy deposits form simultaneously. Hence the quantity of adherent deposit is related to the time of appearance of moss. The longer the appearance of moss is delayed the larger the fraction of adherent deposit. Thus in Table I, if charging was continued beyond 18 coulombs/cm² very little extra zinc would have been deposited adherently in the cases where moss had already appeared.

The deposit adherency obtained by pulse charging at current densities less than the critical current density is dependent on the value of the charging current, the ratio of the on to off time and the numerical values of the on and off times (Table I). As expected, the more adherent deposits were produced with the longer off times. In fact, moss was not formed on the electrode when charging at 10 ma/cm² with the on time 30 msec and the off time 45 msec, respectively, until 38 coulombs/cm² of charge had been passed. Presumably moss formation could be eliminated entirely by pulse charging with short pulse lengths and small values of the on to off time ratio, but under those conditions the deposition or charging time would be lengthy.

It has been observed previously (6) that the potential-time variation gives an indication of the formation of dendrites. Similarly the presence of moss is shown by the potential-time curve in the activation control region (Fig. 1). The shape of this curve varied slightly in different experiments, possibly due to impurities in the electrolyte (7), but once moss is formed there is a small, but significant, decrease in the overpotential during the on time. This decrease in overpotential is presumably due to the decrease in the true current density resulting from the increase in electrode surface area. The equilibrium potential of the mossy deposit was 7-10 mv more cathodic than that of a zinc foil

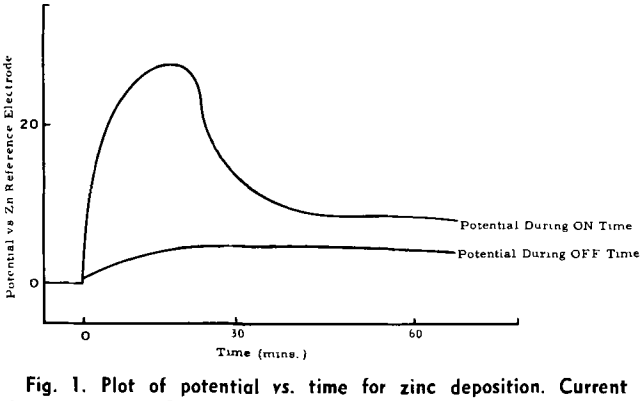

Fig. 1. Plot of potential vs. time for zinc deposition. Current density 10 ma/cm², on time 1 sec, off time 1 sec.

(Fig. 1) in agreement with the work of Bek and Kudryavtsev (8, 9).

Charging with pulsed current source at currents greater than the critical current density.—Preliminary experiments with pulsed current charging at current densities greater than the critical current density indicated that adherent deposits were formed with on and off times of the order of 10 msec, but that dendritic deposits were formed with on and off times of the order of seconds. Subsequent work showed that four factors control the nature of the deposit using a pulsed current source, constant electrolyte composition, and constant temperature. They are current density, the quantity of charge passed, the on time, and the off time. This was confirmed by choosing a set of charging conditions and varying each in turn. For comparison, Fig. 2 shows the deposit obtained with direct current at 40 ma/cm². The current efficiency for deposition in the experiments represented by Fig. 3 to 7 was never less than 85%, whereas the corresponding value in those experiments where dendrites were formed was always very low due to the large amount of hydrogen evolution.

The effect of the pulsed current density is shown in Fig. 3 and 4. The deposit at 40 ma/cm² (Fig. 3) is smoother than that at 80 ma/cm² (Fig. 4). The more even deposits are obtained with the lower current densities, providing these remain above the critical current density. However, due to surface roughening during electrodeposition the true current density may decrease below the critical value causing the formation of nonadherent mossy deposits. The surface roughness increases slightly as the quantity of charge increases (Fig. 5 and 6) and when 200 coulombs/cm² of charge was passed, a small amount of moss formed at the bottom of the electrode. The effect of off time is shown

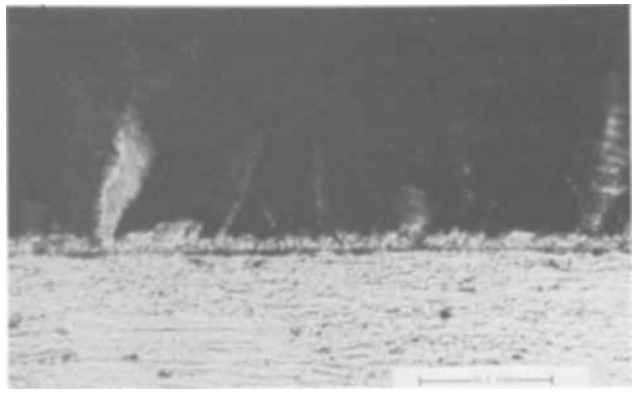

Fig. 2. Photomicrograph of zinc deposit produced by direct current charging. Current density 40 ma/cm², quantity of charge passed 25.8 coulombs/cm².

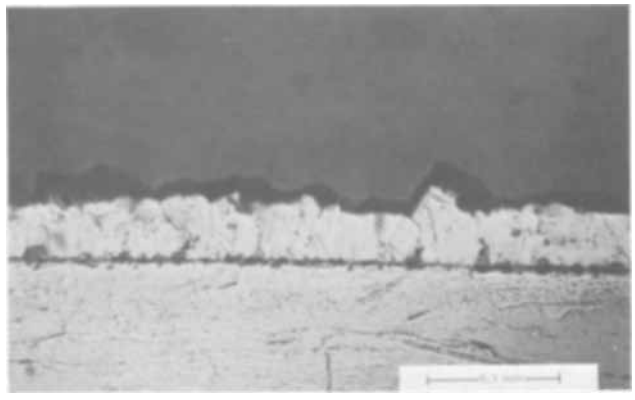

Fig. 3. Photomicrograph of zinc deposit produced by pulsed current charging. Current density 40 ma/cm², time on 10 msec, time off 10 msec, quantity of charge passed 60 coulombs/cm², current efficiency for deposition 85%.

Fig. 4. Photomicrograph of zinc deposit produced by pulsed current charging. Current density 80 ma/cm^2, time on 10 msec, time off 10 msec, quantity of charge passed 60 coulombs/cm^2, current efficiency for deposition 85%.

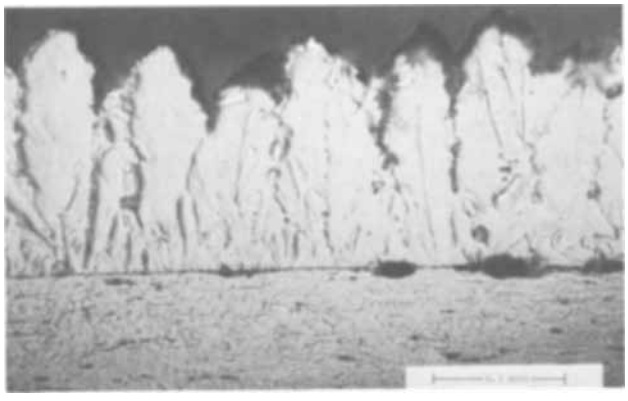

Fig. 5. Photomicrograph of zinc deposit produced by pulsed current charging. Current density 40 ma/cm^2, time on 10 msec, time off 8 msec, quantity of charge passed 200 coulombs/cm^2, current efficiency for deposition 95%.

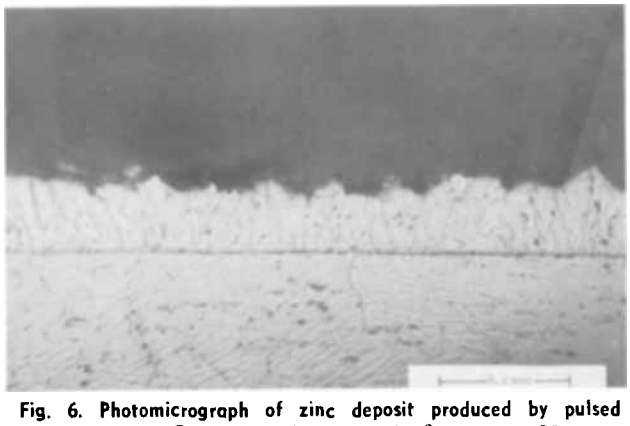

Fig. 6. Photomicrograph of zinc deposit produced by pulsed current charging. Current density 40 ma/cm^2, time on 10 msec, time off 8 msec, quantity of charge passed 60 coulombs/cm^2, current efficiency for deposition 90%.

in Fig. 3, 6, and 7. For a constant on time, the deposit is less dendritic the longer the off time. It is important to note that the ratio of on to off time is not by itself decisive. Thus with a constant current density a more dendritic deposit was obtained with the on and off times both 10 sec than with values of 10 msec. In all cases viewing the deposit cross-sections with polarized light showed that the direction of crystallization of the deposit is independent of the substrate.

At current densities above the critical current density the potential-time curves were similar to those obtained with pulsing under activation control (Fig. 1) but now the overvoltage was approximately 50 mv showing the formation of adherent deposits.

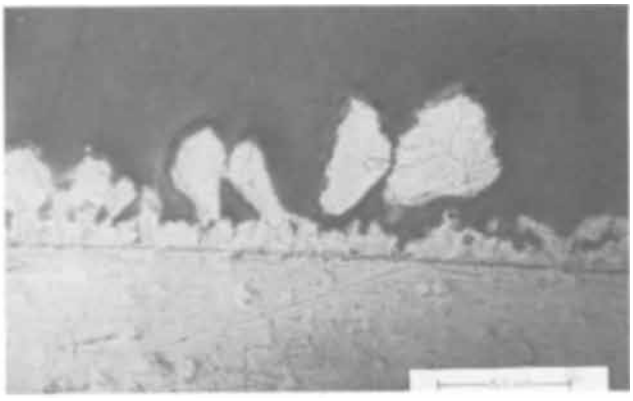

Fig. 7. Photomicrograph of zinc deposit produced by pulsed current charging. Current density 40 ma/cm^2, time on 10 msec, time off 4 msec, quantity of charge passed 60 coulombs/cm^2, current efficiency for deposition 86%.

The dependency of the nature of the deposit on current density, on time, and off time indicates that extremely smooth deposits can be obtained with the current density slightly greater than the critical value for moss deposition, with a short on time (10 msec or less), and an on/off time ratio as small as possible.

Charging with periodic reversal of current.—Deposition with periodic reversal of current was performed with two ratios of the cathodic and anodic period; one of 3.3/2.55 sec, respectively, and the other of 12/8.4 sec, respectively. At a constant current density the deposit was similar with the two charging modes.

Only small quantities of charge were passed when charging at current densities less than the critical current density (*i.e.*, no greater than 30 coulombs/cm^2) and no moss was formed on the electrode (Table I). At higher current densities (greater than the critical current density) larger quantities of charge were passed. Again no moss was formed but the deposit was rough although there was little dendritic growth. With this technique it was found possible to obtain a relatively even deposit with the passage of 900 coulombs/cm^2 of charge at a current density of 100 ma/cm^2. The potential-time curves were similar to the previous cases (Fig. 1) only in this case giving a cathodic overpotential of 100 mv and the current efficiency for electrodeposition was again in the range of 85-95%.

Discussion

Dendritic deposits are formed when the rate of the electrode reaction is controlled by the mass transport of the electroactive species to the electrode surface, *i.e.*, when the surface concentration of the electroactive species is less than the bulk concentration. The beneficial effect of pulsed current charging at current densities greater than the critical current density is probably due to the modification of the ionic concentration gradient during the off period. The transport of ions to the electrode surface during the off period occurs by convection and by diffusion. In the present study the contribution of convective mass transport far outweighed that of diffusive flow due to the relatively large volume of electrolyte.

Convective flow will be limited in a practical cell due to the restricted motion of the electrolyte by the separator. During battery charging, convection may arise from chance vibrations or from changes occurring at the electrode/electrolyte interface, *e.g.*, due to the difference in density between zincate saturated and zincate free KOH solution, due to hydrogen evolution or due to the volume change during the reduction of zinc oxide to zinc. Differentiation between these stirring modes is important for the effect of the former within the battery matrix is probably negligible, whereas stirring at the electrode surface will be more significant.

The less dendritic deposit obtained with pulse charging at 80 ma/cm² and on and off times 10 msec (Fig. 4) than with direct current charging at half the charge rate (Fig. 2) is due to the elimination of the electrostatic force between the electrode and electroreducible anion during the off period. Thus ionic transport by electrical migration is expected in the electrolytes used in the present study during the current on period because the ratio of the concentration of supporting electrolyte to the concentration of zincate ions is very much less than 50, the value considered to be necessary to suppress migratory currents (10). This decreases the rate of mass transport during charge since the transport of an anion to the cathode is involved. Hence during the on period the mass transport of zincate ion to the electrode is hindered and the interfacial concentration of zincate ion is less than it would be when there is no potential applied to the electrode, *i.e.*, during the off period.

Studies on the electrodeposition of copper (11, 12) indicated that the beneficial effect of periodic reversal of current is the delay in the onset of concentration polarization. It is probable that this is also the explanation for the prevention of the formation of zinc dendrites although we have performed insufficient experiments to confirm this hypothesis in detail.

In agreement with the conclusion of Bek and Kudryavtsev (8, 9) we believe that the elimination of the mossy zinc deposit by selected modes of pulse charging and by periodic reversal of current is due to the dissolution of the active mossy deposit during the open circuit or anodic period. This theory is supported by the observations that the equilibrium potential of the mossy zinc deposit is 5-10 mv more cathodic than that of the zinc foil (8) (Fig. 1) and that small quantities of gas are evolved during the current off period. This indicates that the current efficiency for zinc deposition should be less than 100%. However the experimental values of the current efficiency were always high (95-100%) and it was not possible to determine whether this slight departure of the current efficiency from the theoretical value is confirmation of the above theory or merely a measure of the experimental precision.

The numerical values of the current density and on and off times are not directly applicable to a cell consisting of a secondary zinc electrode for in that case, the large surface area of the porous zinc electrode and the restricted transport of the zincate ions must be considered. However this study does indicate the order of magnitude of the parameters, which it is necessary to control, in order to increase the cycle life of a secondary zinc electrode by improving zinc deposit adherency.

ABSTRACT

The current distribution on a short, plane electrode in the wall of a flow channel is calculated at various fractions of the limiting current. Near the limiting current, the current density exceeds the local limiting value near the downstream end of the electrode.

An important geometry in electrochemical industries involves channel flow between two plane, parallel electrodes as shown in Fig. 1. A complicated procedure for treating this problem is outlined in ref. (1). This is based on the concept (2) that concentration variations are restricted to thin diffusion layers near the electrodes, which allows separate treatment of the diffusion layer and the potential distribution outside the diffusion layer. This concept has been applied to the rotating disk electrode (3, 4). However, it is difficult to treat the channel problem, and the present paper is restricted to the consideration of one electrode. If the distance between the electrodes is much greater than the length of the electrodes, each electrode behaves independently. This assumption greatly simplifies the determination of the current and concentration distributions on the electrodes.

The following assumptions will also be made:

1. The electrode is embedded in an infinite, plane, insulating wall.
2. Fully developed, laminar flow prevails, and the velocity can be approximated by a linear profile near the wall, within the diffusion layer.

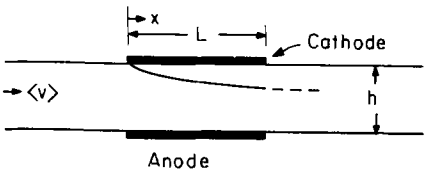

Fig. 1. Plane electrodes in the walls of a flow channel

3. Dilute-solution theory with constant physical properties is applicable.

4. The transport equations used here apply to either the deposition of an ion of a single salt or the reaction of an ion in an excess of supporting electrolyte. The effect of ionic migration for intermediate cases is not considered.

Mathematical Formulation of the Problem

The mode of approach is described in ref. (1-3). The potential in the electrolytic solution outside the diffusion layer satisfies Laplace's equation in two-dimensional form

$$\frac{\partial^2\Phi}{\partial x^2} + \frac{\partial^2\Phi}{\partial y^2} = 0 \qquad [1]$$

where Φ is the potential measured by a reference electrode of the same type as the working electrode. The appropriate boundary conditions are

$$\partial\Phi/\partial y = 0 \text{ at } y = 0 \text{ for } x < 0 \text{ and } x > L \qquad [2]$$

$$\partial\Phi/\partial y = -i/\kappa_\infty \text{ at } y = 0 \text{ for } 0 < x < L \qquad [3]$$

Equation [2] applies to the insulating surface bounding the electrode, and Eq. [3] relates the normal potential gradient to the electrode current density, where κ_∞ is the conductivity of the solution outside the diffusion layer.

Wagner (5) gives the solution of Eq. [1] subject to conditions 2 and 3

$$\Phi = \Phi^* - \frac{1}{2\pi\kappa_\infty}\int_o^L i(x') \ln\left[(x-x')^2 + y^2\right] dx' \qquad [4]$$

where Φ^* is an integration constant reflecting the arbitrary zero of potential. The potential Φ_o near the electrode surface is then

$$\Phi_o = \Phi^* - \frac{1}{2\pi\kappa_\infty}\int_o^L i(x') \ln (x-x')^2 dx' \qquad [5]$$

This should be regarded as the potential of the solution outside the diffusion layer extrapolated to the electrode surface as if the actual current distribution prevails but there is no concentration variation near the electrode.

Another integral equation can be developed for the diffusion layer (1). The limiting current distribution for such a plane electrode is[1]

$$i(x) = -\frac{n\mathbf{F}Dc_\infty}{(1-t)\Gamma(4/3)}\left(\frac{b}{9Dx}\right)^{1/3} \qquad [6]$$

where b, a constant, is the slope of the velocity profile at the wall ($b = \partial v_x/\partial y$ at $y = 0$). We assume here that the concentration variation is confined to a thin region near the electrode surface. Thus the velocity profile within this diffusion layer is linear in y. This approximation is valid when $L < 0.02 \langle v\rangle h^2/D$. Equation [6] applies when the concentration of the reactant is zero at the electrode surface. Application of Duhamel's theorem (9) to Eq. [6] gives a relationship between the current density distribution and the surface concentration, for currents below the limiting current.

[1] This equation is correct for the limiting cases considered here. For a binary electrolyte, D is the diffusion coefficient of the salt. With excess supporting electrolyte, t is zero and D is the diffusion coefficient of the reactant ion or molecule. The indiscriminate use of this equation to describe the effect of migration in intermediate cases is subject to criticism (1, 10, 11).

$$i(x) = -\frac{n\mathbf{F}D}{(1-t)\Gamma(4/3)}\left(\frac{b}{9D}\right)^{1/3}\int_o^x \frac{dc_o(x')}{dx'}\frac{dx'}{(x-x')^{1/3}} \qquad [7]$$

In many cases the electrode kinetics allow the current density and the surface overpotential η_s to be related by an exponential expression

$$i(x) = i_o\left(\frac{c_o}{c_\infty}\right)^\gamma \left[\exp\left\{\frac{\alpha Z\mathbf{F}}{RT}\eta_s\right\} - \exp\left\{-\frac{\beta Z\mathbf{F}}{RT}\eta_s\right\}\right] \qquad [8]$$

where α and β are characteristic parameters of the electrode reaction, and i_o is the exchange current density at the bulk concentration. The exchange current density at the electrode is taken to be proportional to the surface concentration, c_o, raised to the power γ. The surface overpotential is related to the electrode potential V by

$$\eta_s = V - \Phi_o - \eta_c \qquad [9]$$

where η_c is the concentration overpotential and is taken to be (2)

$$\eta_c = -(RT/Z\mathbf{F})\left[\ln (c_\infty/c_o) - t\,(1 - c_o/c_\infty)\right] \qquad [10]$$

where

$$Z = -z_+z_-/(z_+ - z_-) \text{ for a single salt}$$

$$Z = -n \text{ with supporting electrolyte} \qquad [11]$$

If there is an excess of supporting electrolyte, the transference number t will be zero.

Instead of the integral Eq. [7], it might have been possible to treat the diffusion layer with some sort of power series in x, similar to the method used for the rotating disk (3). However, even with the disk, a power series introduces numerical difficulties which can be avoided with an integral equation (4). This is demonstrated in Fig. 2, recalculated for the rotating disk with an integral equation similar to Eq. [7]. Comparison with Fig. 7 of ref. (3) shows that the curves are nearly the same with one important exception. The current density can rise above the limiting current near the edge of the disk and then go through a maximum as the limited supply of reactant becomes decisive. However, it cannot rise again near the edge of the disk as shown in the earlier work. Thus, from a practical point of view, the integral equation is superior to a power series and will be used in the present work.

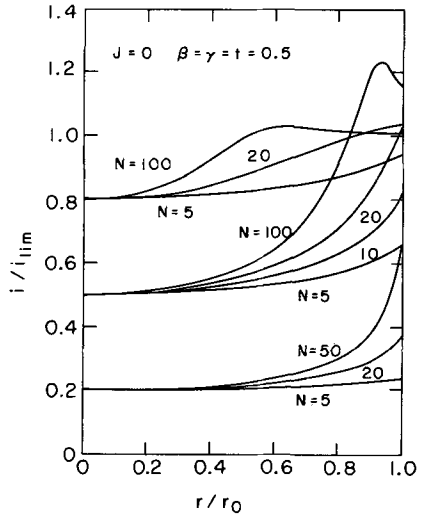

Fig. 2. Current distribution on a rotating disk for Tafel kinetics ($i_o << i_{avg}$). The parameters N and J are the dimensionless limiting and exchange current densities, respectively, as defined in ref. (3).

Numerical Calculations

To determine the current and concentration distributions along the electrode, Eq. [5] and [7] must be solved along with Eq. [8], [9], and [10]. The integral in Eq. [5] was evaluated by Simpson's method. The singularity at $x' = x$ was removed by adding and subtracting $i(x)$ as suggested by Kantorovich and Krylov (6). For a given distribution of total overpotential $\eta_c + \eta_s$, the integral Eq. [7] was solved in conjunction with Eq. [8] and [10] by the method of Acrivos and Chambré (7). It might be noted that Eq. [7] is a special form of a more general equation which can be applied to other flow geometries, for example, the rotating disk electrode.

The number of intervals required to obtain accurate results varied between 50 and 140, depending on the uniformity of the current distribution. The answers were checked by increasing the number of intervals and were considered to be satisfactory if they did not vary by more than 1% with an increase of 20 intervals.

The following iteration procedure was used:

1. The current density was specified at $x = 0$. Since $c_o = c_\infty$ at $x = 0$, this also specifies the total overpotential at $x = 0$. As a first guess, this total overpotential was assumed to apply over the entire electrode.
2. For a given distribution of total overpotential, the current density and surface concentration were determined from Eq. [7], [8], and [10].
3. From the current distribution, new values of the total overpotential were calculated from Eq. [5] and [9]. If the new and old values of the total overpotential differed by more than 0.01%, these values were averaged (usually with unequal weights on the two values) and put back into step 2.

This procedure appears to work well over almost the entire range between the secondary and limiting current distributions. Convergence was always achieved in less than 35 iterations for the cases considered.

Results

The number of parameters required to describe a given situation can be minimized by defining three dimensionless quantities:

$$J = \frac{ZFL}{RT\kappa_\infty} i_o \qquad [12]$$

$$N = -\frac{nZF^2Dc_\infty}{(1-t)RT\kappa_\infty}\left(\frac{L^2b}{D}\right)^{1/3} \qquad [13]$$

$$\delta = \frac{ZFL}{RT\kappa_\infty}|i_{avg}| \qquad [14]$$

These are analogous to those defined for the rotating disk problem (3). J, N, and δ can be regarded as dimensionless exchange, average limiting, and average current densities. The limiting current corresponds to $\delta = 0.807N$. The total number of parameters required to define the problem will now be seven, J, N, and δ, the transference number, t, and α, β, and γ characteristic of the electrode reaction.

The two extreme cases are the primary and limiting current distributions, shown in Fig. 3. The primary current occurs when the electrode is reversible and there are no concentration effects ($N = \infty$ and $J = \infty$). Wagner (5) gives the primary current distribution as

$$i/i_{avg} = (1/\pi)\,[x/L - (x/L)^2]^{-1/2} \qquad [15]$$

When the current is limited solely by the rate of mass transfer through the diffusion layer, the limiting current distribution, obtained from Eq. [6], is

$$i/i_{avg} = (2/3)\,(x/L)^{-1/3} \qquad [16]$$

The secondary current will result when there is a surface overpotential but no mass transfer effects.

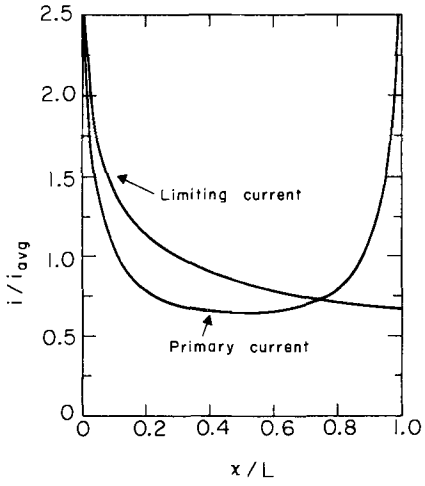

Fig. 3. Primary and limiting current distributions on a plane electrode.

For sufficiently small currents ($\delta << J$), the polarization law 8 can be linearized to

$$i = (\alpha + \beta)\,(ZF/RT)\,i_o\eta_s \qquad [17]$$

Wagner (5) calculated secondary current distributions as a function of the coefficient in Eq. [17]. A linear approximation can also be made if the current distribution is fairly uniform, say $\delta < 0.5$, even if J is small.

If, on the other hand, the average current is much greater than the exchange current ($\delta >> J$), Tafel polarization will apply

$$\eta_s = -(RT/ZF\beta)\,[\ln|i| - \ln i_o] \qquad [18]$$

(For anodic currents, the term in α would be retained.) Gnusin, Poddubnyi, Rudenko, and Fomin (8) determined the secondary current distribution as a function of the average current.

Before considering the case where mass transfer effects are important, we compared our calculated secondary distributions with those in these two papers. Comparison for the rotating disk (3) served as a check on the mass transfer calculations.

Because mass transfer effects occur at higher current densities, we used a Tafel polarization law in subsequent work considering concentration variations. Figure 4 shows the current distribution for $N = 100$

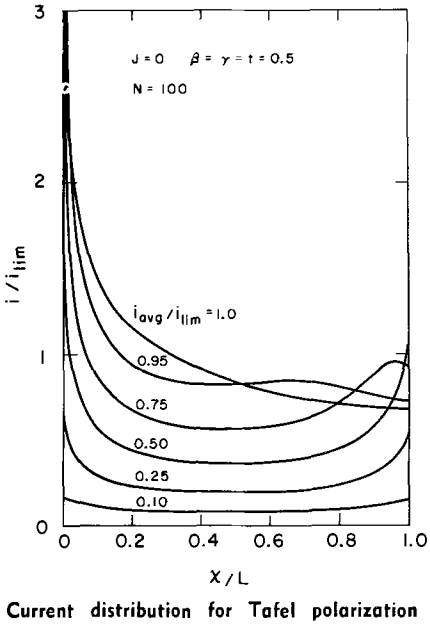

Fig. 4. Current distribution for Tafel polarization at various fractions of the average limiting current.

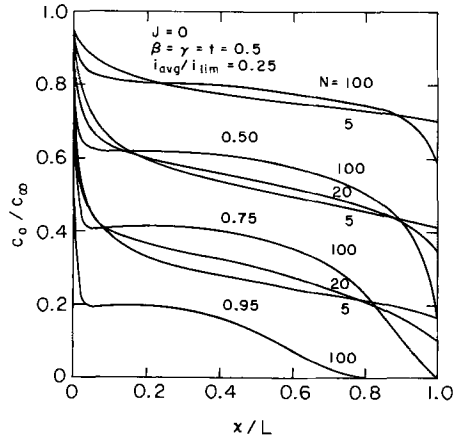

Fig. 5. Surface concentration distribution for Tafel polarization near the limiting current.

and average current densities at various fractions of the average limiting current. At low currents, the distribution is close to the secondary distribution, and mass transfer becomes important only at higher currents. At greater than about 75% of the limiting current, the current cannot continue to increase near the end of the electrode because of mass transfer limitations.

Concentration profiles are shown in Fig. 5 for various values of N. For the case of $N = 100$ at 75 and 95% of the limiting current, there is a slight increase of reactant concentration near the front of the electrode ($x/L \approx 0.1$), resulting from the rapid drop in current density near the front of the electrode. The concentration then has a chance to increase a little before the current density begins to increase.

In Fig. 6 the ratio of the maximum to minimum current density has been plotted against the fraction of the limiting current, giving an indication of the uniformity of the current distribution. At a given fraction of the limiting current, the current distribution becomes less uniform with increasing N. In all cases the effect of mass transfer resistance is to make the current distribution more uniform near the back end of the electrode.

Conclusions

Current distributions on a plane electrode in the wall of a flow channel are calculated while taking into account concentration variations near the electrode, electrode kinetics, and the ohmic potential drop in the bulk of the solution. The procedure is similar to that for a rotating disk, leading to the conclusion that the diffusion layer can be treated by a general method for hydrodynamic situations where the velocity derivative at the electrode surface is known. Thus, for geometric arrangements where the diffusion layer can be treated and where it is also possible to treat the potential distribution outside the diffusion layer, current density calculations can be carried out in the manner illustrated for the plane and the disk.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Nomenclature

b	$= 6 \langle v \rangle / h$, velocity derivative at the wall of the channel, sec^{-1}
c_o	concentration at electrode surface, $mole/cm^3$
c_x	bulk concentration of reactant, $mole/cm^3$
D	diffusion coefficient of reactant or of binary electrolyte, cm^2/sec
$\mathbf{F}$	Faraday's constant, 96,487 coul/equiv
h	height of channel, cm
i	normal current density at electrode surface, amp/cm^2
i_o	exchange current density, amp/cm^2
i_{avg}	average current density, amp/cm^2
i_{lim}	average limiting current density, amp/cm^2
J	dimensionless exchange current density (see Eq. [12])
L	length of electrode, cm
n	number of electrons produced when one reactant ion or molecule reacts
N	dimensionless limiting current (see Eq. [13])
R	universal gas constant, joule/mole-deg
t	transference number of reactant
T	absolute temperature, °K
$\langle v \rangle$	average velocity, cm/sec
V	potential of electrode, volt
x	distance along electrode, cm
y	normal distance from electrode, cm
z_i	charge number of species i
Z	see Eq. [11]
α, β, γ	parameters in kinetic expression (see Eq. [8])
$\Gamma(4/3)$	$= 0.89298$, the gamma function of 4/3
δ	dimensionless average current density (see Eq. [14])
η_c	concentration overpotential, volt
η_s	surface overpotential, volt
κ_x	conductivity of bulk solution, $ohm^{-1}\text{-}cm^{-1}$
Φ	potential in bulk solution, volt
Φ_o	potential in bulk solution extrapolated to electrode surface, volt

Mechanism of Inhibiting Stress Corrosion Cracking of 18-8 Stainless Steel in $MgCl_2$ by Acetates and Nitrates

H. H. Uhlig* and E. W. Cook, Jr.

Department of Metallurgy and Materials Science,
Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Modest additions of sodium acetate, nitrate, iodide, or benzoate to $MgCl_2$ test solution boiling at 130°C are found to increase resistance to or inhibit stress corrosion cracking of 18-8 stainless steel. The critical applied potential in $MgCl_2$ solution (—0.145v) above which, but not below, cracking occurs is shifted in the noble direction by extraneous salt additions. When the shift exceeds the corrosion potential for 18-8 in the same solution, cracking is apparently inhibited. On the other hand, salt additions, *e.g.*, $FeCl_3$, which shift the corrosion potential in the noble direction may induce or accelerate stress corrosion cracking.

The critical potential is interpreted as that value above which but not below Cl^- ions adsorb on imperfection sites of plastically deforming metal in amount adequate to cause failure (stress sorption cracking). The present data do not support an electrochemical mechanism of stress corrosion cracking based on anodic dissolution of metal ions at the tip of a crack, nor the mechanism dependent on continuous cracking of a surface oxide film.

The phenomenon of failure of ductile metals by cracking when stressed in tension and exposed to specific anions is still not well understood. Several theories have been proposed since the time stress corrosion cracking (scc) was first observed, the most important of which are: (*i*) electrochemical, based on dissolution of metal ions at the base of a notch or crack acting as anode in contact with metal elsewhere acting as cathode; (*ii*) progressive cracking of a brittle surface oxide film; (*iii*) reduction of surface energy or weakening of metal bonds by adsorption of specific anions at the root of a notch or crack. There is supporting evidence for each theory, but no general consensus as yet that any one of them can adequately account for the general phenomena of scc (1).

The mechanism by which extraneous salts, when added to damaging solutions, act as inhibitors of scc, and in some instances as accelerators, challenges each of the currently discussed theories and provides the basis for the present paper. The work reported at present began with our observation that a few per cent of a salt, *e.g.*, sodium acetate or sodium iodide, added to the usual boiling concentrated $MgCl_2$ test solution for 18-8 stainless steel effectively inhibited scc. This fact excited curiosity as to how such additions could in principle affect any supposed electrochemical process occurring within the growing crack, particularly when the added salt had no readily discernible major effect on cathodic or anodic polarization behavior, and certainly had little effect on the conductivity of an already good conducting solution [$\kappa = 0.27$ ohm^{-1} cm^{-1} at 146°C (2)]. The cracking of an oxide film, if one construes the passive film to be an oxide, did not seem to be involved in view of the fact that polarization measurements of stainless steels in $MgCl_2$ solution indicated absence of passivity (2, 3). Visible patches of surface oxide, if any, that may form during tests in $MgCl_2$ are equally evident on specimens which do not crack as well as on those which do. And the effect of applied potential to either initiate or to prevent cracking is found whether or not an inhibiting anion is present.

The inhibiting effect of various salts, including NaCl (4), Na_2CO_3 (5, 6), Na_2HPO_4 (6), and others, on the stress corrosion cracking of mild steel in boiling nitrate solutions has been reported previously by several investigators. Nitrates have been reported to act as inhibitors for scc of mild steel in hot NaOH solutions (7). Such additions were used over many years as a practical measure to avoid damage of locomotive boilers containing alkaline boiler waters. Additions of sulfates, fluorides, or nitrates to halide salt test solutions were reported to inhibit scc of a titanium alloy (8% Al, 1% Mo, 1% V) stressed at room temperature (8). Edeleanu (9) reported that 1% $NaNO_3$ added to boiling 20% NaCl solution had an accelerating effect on scc of 18-8 stainless steel. However, the function of nitrates to protect against rather than to stimulate scc of austenitic stainless steels in boiling $MgCl_2$ was reported by Rideout and Mittleberg (10) and more recently by Couper (11). We confirmed the inhibiting effect of nitrates in $MgCl_2$ test solution and showed that several other salts are similarly effective.

Experimental

Specimens 1-3/4 x 3/16 x 0.04 in. (4.5 x 0.5 x 0.1 cm) were sheared from commercial type 304 stainless steel sheet, originally 1/16th in. thick as received and subsequently cold rolled to 0.04 in. (36% reduction of thickness). Longest dimension was in the rolling direction. Some specimens were tested as such; others called "annealed" were heated in argon at 1050°C and water quenched. All specimens were abraded to No. 0 emery paper, degreased in benzene, pickled initially in 25 v/o (volume per cent) H_2SO_4, 25 v/o HCl at 90°C if a tenacious oxide covered the surface, and pickled finally in any event in 15 v/o HNO_3, 5 v/o HF at 90°C for 5 min. Specimens were immediately bent beyond the elastic limit into the shape of a C using a special vise, then transferred to the test apparatus by means of a metal holder adjusting the final span to 1-7/16th in. (3.7 cm), carefully avoiding springback. A compressed spring was used to maintain essentially constant flow stress of the porcelain insulated specimen during the test, and an electric clock recorded time to failure. For polarization measurements, or when a controlled potential was applied throughout the test, usually a type 304 stainless steel wire, 0.025-in. diameter, was spot welded to one end of the specimen. The wire was encased in sections of capillary glass tubing in order to reduce impressed current reaching the wire. Other details of the test apparatus, constructed largely of commercial zirconium, have been described previously (12, 13).

For polarization or controlled potential measurements, the Heathkit or Wenking potentiostats were used. The glass cell for such measurements holding

* Electrochemical Society Active Member.

about 200 ml of test solution was designed with two side arms opposite one another, holding auxiliary electrodes of platinized titanium, and a center arm into which a saturated calomel electrode at room temperature was placed. Glass frit disks separated $MgCl_2$ solution of the arms from the boiling solution in the test cell. Measurements of potential made beforehand showed that IR drop in the $MgCl_2$ solution at the prevailing applied current in the region of the critical potential was so low (approximately 10 $\mu a/cm^2$) that the position of the calomel electrode with respect to the stainless steel specimen made no appreciable difference and hence no correction of potential was needed. Because of accumulating electrode reaction products, polarization runs were usually not extended beyond 50 hr.

The test solution containing 33g anhydrous $MgCl_2$ per 100 ml saturated solution boiled at 130°C, a temperature which was maintained during the test. This solution, which is less concentrated than the usual $MgCl_2$ test solution boiling at 154°C, was chosen in order to allow greater solubility of salts added as inhibitors. Because of variable cracking times characteristic of different batches of $MgCl_2$, originating in large part from variable pH, the reagent salt used for all the tests was a mixture of several 25-pound shipments. Per cent salt additions were calculated on the weight of the $MgCl_2$ solution. When the added salt in the stipulated amount was found to alter the *p*H of the $MgCl_2$ solution saturated at room temperature (measured with a glass electrode), the pH was adjusted to the original value (5.2) by adding NaOH or HCl. The boiling point, which was found to be changed by about 1°C or less by the salt additions, was always adjusted to 130°C by adding a small amount of water.

Results

Almost any salt added to the $MgCl_2$ test solution, if sufficiently soluble, was found to act as an inhibitor of scc, with some salts being more effective than others. The requirement of a salt suited to the present study, other than solubility, included lack of obvious reaction with $MgCl_2$ or with the test specimen. Inhibition was observed in similar degree whether cold rolled or annealed stainless steel was used.

The effects of $NaNO_3$, NaI, and sodium benzoate additions on time to failure of annealed 18-8 stainless steel are shown in Fig. 1, 2, and 3. The effect of sodium acetate on failure times of cold rolled or annealed stainless steel is shown in Fig. 4. A small amount of added sodium benzoate was found to be an effective inhibitor, but maximum inhibition was limited by the small solubility of the salt in the boiling $MgCl_2$ solution, hence time to failure was essentially constant above 0.05%. In Fig. 1, 2, and 4, each point is usually the average time to failure of 2 to 3 specimens. In Fig. 3, each point represents one specimen. A few additional runs in which EDTA was added up to 1.5% showed some degree of inhibition, but the general dissolution rate of the specimen was so high that failure times were not considered reliable.

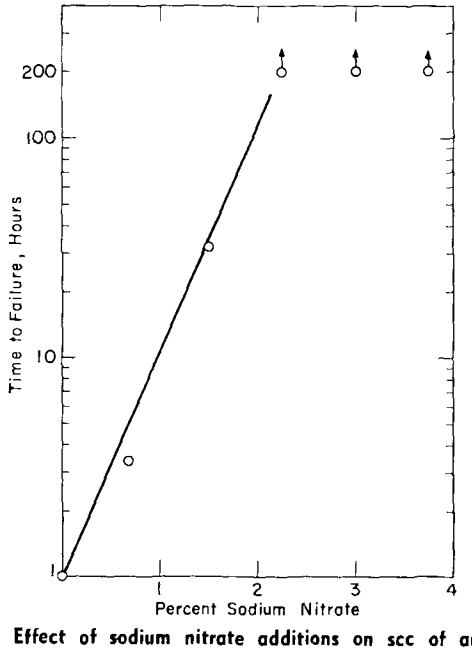

Fig. 1. Effect of sodium nitrate additions on scc of annealed 18-8 stainless steel in $MgCl_2$ boiling at 130°C.

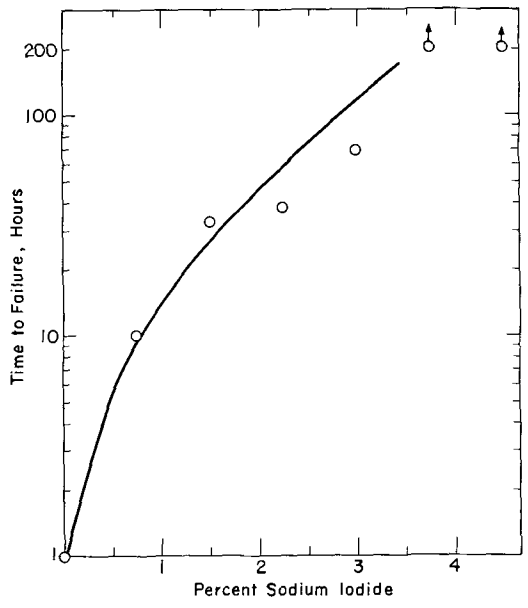

Fig. 2. Effect of sodium iodide additions on scc of annealed 18-8 stainless steel in $MgCl_2$ boiling at 130°C.

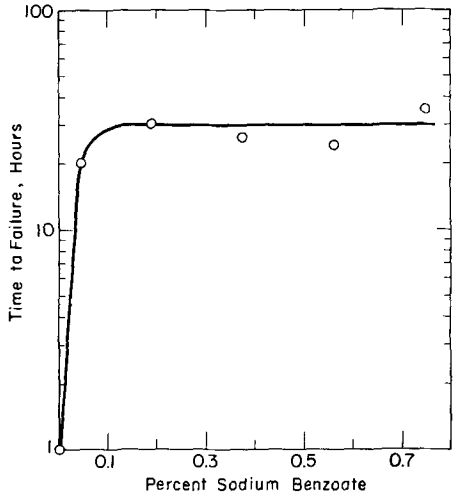

Fig. 3. Effect of sodium benzoate additions on scc of annealed 18-8 stainless steel in $MgCl_2$ boiling at 130°C. (Solution is saturated above 0.05%.)

Consecutive runs using the same test solution demonstrated that the inhibiting salts do not function by gradually reacting with and depleting the test solution. The cracking time, for example, of a second specimen placed in a test solution used for a previous test containing either 1% sodium acetate, or 2% sodium nitrate, or 3% sodium iodide was the same as the first specimen within the usual experimental scatter (14).

Tests under controlled applied potential were carried out in $MgCl_2$ solution both with or without additions of sodium acetate or sodium nitrate at two concentrations (Fig. 5, 6, 7). The lower concentration in each case did not inhibit against cracking in the absence of an applied potential, whereas the higher con-

centration prolonged resistance to failure for at least 50 hr. A definite critical potential was established for each test solution above which cracking occurred in times that decreased with increase of potential (noble direction) and below which cracking did not occur within the maximum test period. The critical potential was sharply defined, usually to within a few millivolts. The value presently obtained for cold rolled 18-8 in $MgCl_2$ boiling at 130°C is —0.145 ± 0.0015v (std. H_2 scale). This value was checked subsequently by H. Lee of this Laboratory. Values reported previously by other investigators fall within the same approximate range, although they are not strictly comparable because of differing test conditions. Barnartt and van Rooyen (2) reported —0.16v for annealed 18-8 in $MgCl_2$ boiling at 146°C. Brennert (15) reported about —0.16v for annealed or cold worked 18-8 in 40% $CaCl_2$ at 100°C; —0.14v for cold worked 18-8 in 24% $CaCl_2$ at 100°C, and —0.18v in 60% $CaCl_2$ at 100°C. Smialowski and Rychik (3) reported a value of about —0.15v for annealed 18-8 type 302 stainless steel in $MgCl_2$ boiling at 125°C.

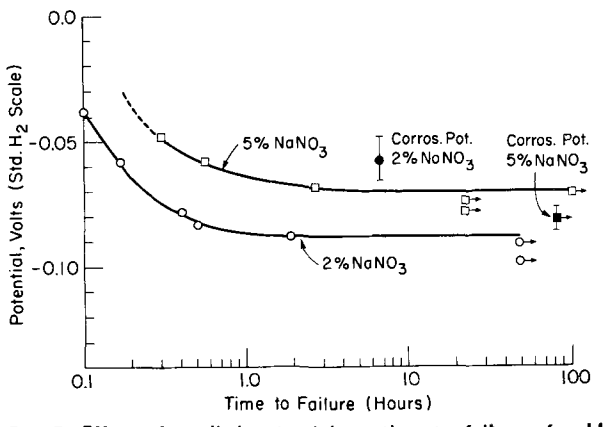

Fig. 7. Effect of applied potential on time to failure of cold-rolled 18-8 stainless steel in $MgCl_2$ solution with sodium nitrate additions boiling at 130°C. (5% $NaNO_3$ addition is inhibiting.)

Data presented in Fig. 6 and 7 show that both nitrates and acetates shift the critical potential in the noble direction. A summary of critical and corrosion potentials is given in Table I.

Discussion

Of considerable importance were observations that the corrosion potential as recorded after several hours was typically more noble than the critical potential for those solutions in which cracking was produced in absence of polarization, but that the reverse situation applied, namely the corrosion potential was more active than the critical potential in solutions in which cracking was not produced. However, in the latter solutions, cracking could nevertheless be induced by anodically polarizing the specimens to any value above the critical potential. The added salts, in other words, become effective inhibitors through their ability to shift the critical potential to a value more noble than the corrosion potential. The added salts may have the supplementary effect of shifting the corrosion potential in either the active direction (as for sodium acetate) or in the noble direction (as for $NaNO_3$). But if cracking is to be avoided in the absence of polarization, the corrosion potential must apparently lie at a value that is consistently active to the critical potential. Whether cracking occurs or not beyond the present maximum test period presumably depends on whether the corrosion potential eventually drifts to a value more noble than the critical value. It also follows that any oxidizing salt which shifts the corrosion potential to more noble values should in general accelerate scc. This is

Table I. Critical and steady-state corrosion potentials (std. H_2 scale) of cold-rolled 18-8 stainless steel in $MgCl_2$ boiling at 130°C

	Critical potential	Corrosion potential
$MgCl_2$	−0.145v	−0.11v
+ 0.1% Sodium acetate	−0.132	−0.12
+ 2% Sodium acetate	−0.116	−0.12
+ 2% $NaNO_3$	−0.090	−0.06
+ 5% $NaNO_3$	−0.070	−0.08

found to be the case, as for example with $FeCl_3$ additions to the $MgCl_2$ test solution as reported by Edeleanu (9).

In carrying out the described tests, it was observed that reproducibility of failure times was much improved under conditions of controlled potential compared to conditions of simple immersion. This observation sets aside previous arguments that tests on stress corrosion cracking lack characteristic reproducibility because of minute irregularities in the specimen surface acting as notches or stress raisers, or because of unknown residual surface stresses varying from specimen to specimen. Variations of either surface or stress are apparently less important in carefully prepared specimens than are variations in the corrosion potential. The latter usually drifts with time in the noble direction probably because of surface alloy composition changes or because of changes in activity of dissolved metal ions, or because of slowly adsorbing Cl^- ions.

The dependence of scc on the relation of the corrosion potential to the critical potential has significant implications with regard to the electrochemical mechanism of cracking based on supposed anodic dissolution of alloy at the tip of an advancing crack, in contact with cathodic areas along the walls of the crack or at the outer surface of the specimen. Were this mechanism to apply, cathodic protection against scc could be expected only if the specimen were polarized to a potential equal to or more active than the open-circuit anode potential representing conditions at the tip of the crack. The critical potential is obviously not such an open-circuit anode potential because the corrosion potential in presence of acetates or nitrates of sufficient concentration to inhibit scc is more active than the critical potential. This order of potentials is impossible for any conceivable operating galvanic cell. Hence the critical potential must have another interpretation.

The cathode reaction, on the other hand, fits the electrochemical model. In view of the fact that cracking occurs in boiling $MgCl_2$ solution in absence of O_2 (12), the cathode reaction must involve hydrogen evolution. The *p*H of $MgCl_2$ boiling at 130°C is 1.17 as presently measured with a platinized platinum electrode over which purified hydrogen was bubbled. Hence the cathode open-circuit potential for 18-8 stainless steel in the $MgCl_2$ test solution is $(-2.3\ RT/F)$ *p*H or —0.094v. For the corresponding galvanic cell, the corrosion potential must always be more active than this value, which in general is observed for $MgCl_2$ and for $MgCl_2$ with sodium acetate additions. For $NaNO_3$ additions, the cathode reaction is expected to involve NO_3^- reduction; hence the corrosion potential in this case is understandably more noble than —0.094v (Table I).

Since the critical potential is not the open-circuit anode potential, it is suggested that it must correspond instead to the potential at which adsorption of Cl^- occurs at metal surface imperfections at the tip of the advancing crack. Only at potentials more noble than the critical value are Cl^- ions adequately adsorbed; at values more active than the critical potential Cl^- ions are desorbed. When the prevailing potential favors Cl^- adsorption, it is supposed that the weakening of metallic bonds or the corresponding reduction of surface energy allows a crack to grow (stress sorption cracking) (16); otherwise in absence of Cl^- adsorption, cracks do not either initiate or grow. When extraneous anions are present which do not of themselves cause cracking when adsorbed on the metal surface, competition between the ions for available sites requires that the potential be made more noble in order to achieve the required Cl^- concentration within the double layer essential for adsorption and cracking. Hence, whenever the competing anion shifts the critical potential to a value more noble than the corrosion potential, adequate adsorption of Cl^- is not possible and the anion acts as an inhibitor.

A parallel situation is found in the critical potential necessary to initiate pitting corrosion in the stainless steels and several other passive metals exposed to chloride solutions. Cathodic protection against pitting consists of polarizing the stainless steel to any value below its critical potential for pitting; it is not necessary to polarize to the open-circuit anode potential which is considerably more active. Additions of extraneous anions, *e.g.*, $SO_4^=$, NO_3^-, ClO_4^-, or OH^- consistently shift the critical potential in the noble direction, presumably by competitively adsorbing with Cl^- for sites on the alloy surface (17). If the shifted critical potential exceeds the corrosion potential or the open-circuit cathode potential, the added salt acts as an effective inhibitor. Here stress is not necessary and adsorption can occur at random on the alloy surface. Rosenfeld and Maximtschuk (18) using radioactive Cl^- showed that Cl^- adsorbs on metallic chromium to an increasing extent the more noble the applied potential (increased anodic polarization). Extraneous anions, *e.g.*, $SO_4^=$ or OH^-, in sufficient concentration prevented adsorption of Cl^- even on anodically polarized chromium. Similar conditions probably apply, although at different potentials, to adsorption of Cl^- on a stainless steel surface either at room temperature leading to pitting or at 130°C leading to stress corrosion cracking.

One distinguishing feature of conditions affecting pitting compared to those affecting scc is that stainless steels are passive in aerated chloride solutions in which pitting may occur, but they show no evidence of passivity when exposed to the $MgCl_2$ test solution. Previously reported potentiostatic anodic polarization curves for 18-8 stainless steel in $MgCl_2$ test solution boiling at 146°C (2) or at 125°C (3) show absence of a passive current density. The 18-8 alloy is also not passive in $MgCl_2$ boiling at 130°C to which sodium acetate is added as shown by polarization curves of Fig. 8. A passive current density is not observed even at relatively noble potentials.

The present measurements, therefore, do not support either an electrochemical mechanism of stress corrosion cracking depending on anodic dissolution of metal ions at the tip of a growing crack or the mechanism depending on continuous cracking of an oxide or passive film. Instead they support a mechanism based on potential-dependent adsorption of Cl^- ions presumably on imperfection sites generated at the surface of the plastically yielding metal. It is predicted that critical potentials for scc of other metals, *e.g.*, carbon steels and Ti alloys, will also be found to lack identity with open-circuit anode potentials and that the critical potentials will be similarly shifted in the noble direction by extraneous anions which act as inhibitors.

An Electrochemical Mass Transport-Kinetic Model for Stress Corrosion Cracking of Titanium

T. R. Beck*

ABSTRACT

The purpose of this work has been to develop a quantitative model for the electrochemical kinetic and mass transport processes in a propagating stress corrosion crack and to use the model to gain insight into manner in which these processes influence propagation. Analysis of the problem led to a system of simultaneous differential equations which with their appropriate boundary conditions were solved by computer implemented numerical methods. Comparison of computed behavior with experimental stress corrosion cracking data for a titanium alloy has guided the development of the model and the specification of critical stress corrosion cracking experiments. Such comparisons indicate that there is a halide ion current to the crack tip with some hydrogen ion discharge in the region downstream from the tip. A significant fraction of the current entering a crack appears to be involved in formation of soluble titanium ions in parallel with oxide formation on the walls.

Stress corrosion cracking (SCC) of Titanium: 8%Al-1%Mo-1%V (Ti: 8-1-1) alloy under potentiostatic conditions in halide salt solutions has previously been described (1). The main features observed were that chloride, bromide, and iodide ions appeared to be the unique SCC agents in aqueous solutions and that SCC velocity and anodic current entering the crack were approximately linearly related to applied potential.

Kinetic data for oxidation of newly generated Ti: 8-1-1 surfaces and hydrogen ion reduction thereon have also been presented (2) and order of magnitude values of the exchange current densities for these reactions determined. Some qualitative ideas about the electrochemical mechanisms in a propagating crack based on the kinetic data were also described (2). However, the influence of mass transport phenomena within the propagating crack in establishing the relationship between potential and propagation velocity has not been seriously examined. The only prior analysis found of potential drop in a stress corrosion crack was that of Hines (3). His analysis is not applicable to titanium and in many other situations, because his assumption regarding uniform wall reactions and absence of any transport restrictions aside from those on current are not consistent with the kinetic data (2).

In the present work an attempt has been made to study more rigorous models for a propagating crack, which account for transport of species involved in reactions at the tip and along the crack walls as well as for the kinetics of the wall reactions. Experimental work continued concurrently with development of the model has provided data for comparison with the model and has guided its development. Some of this experimental work has been reported elsewhere (4), and the salient points are summarized herein.

The model has been derived to be consistent with the experimental findings on crack propagation behavior summarized in Table I and the basic principles of mass transport in electrolytes. The reason for the selectivity to Cl^-, Br^-, and I^-, ions appears to be outside of the scope of the present work, but the model as now formulated appears to be at least in qualitative

* Electrochemical Society Active Member.

Table I. Experimental stress corrosion cracking data for Ti:8-1-1 alloy to which the model must comply (1, 4)

1. SCC occurs only in the presence of Cl^-, Br^-, and I^- ions in aqueous solution.
2. SCC velocity is approximately linearly related to potential over a range of about 2v with zero-velocity intercept at −900 mv (SCE) for duplex annealed Ti:8-1-1.
3. Anodic current flowing into a propagating crack is approximately linearly related to potential with zero-current intercept at about −800 mv.
4. Under potentiostatic conditions SCC velocity is relatively independent of particular alkali or alkaline earth cations present or pH of the bulk solution.
5. Velocity varies with bulk concentration of halide to about the ¼ power becoming asymptotic to a limiting velocity at zero bulk concentration.
6. Activation energy for velocity is about 3.5 kcal/mole.
7. On open-circuiting the current to a propagating crack the initial open-circuit potential is only slightly below the initially applied potential in a range of applied potentials up to +200 mv. At more anodic applied potentials the value of the initial open-circuit potential approaches +200 mv asymptotically. A slow potential transient on open circuit occurs over a period of 10^{-2} to 100 sec with a final approach to about −800 mv.

agreement with the other observations, although its quantitative predictions are dependent on parameter values not all of which can be independently determined. It does not, and cannot, represent nor explain phenomena in the region of atomic dimensions at the very tip of a crack where actual fracture of the metal structure takes place. The effects of mechanical and metallurgical factors (2) are also not considered. These can influence the present results through their effect on the crack opening angle and the electrochemical kinetics parameters.

As will be seen, the model is not in complete quantitative agreement with all of the experimental data, but the source of certain deviations can be inferred. Later modifications to the model may serve to reduce these discrepancies. Nevertheless the model has provided valuable insight into the operation of mass transport phenomena which exert considerable influences on the course of SCC. It has guided our conception of many aspects of the SCC process and has often served to define critical SCC experiments. Further, it is believed that progress in understanding the electrochemistry of stress corrosion cracking can only be achieved by such continuous interplay of theory and experiment.

Model Formulation

The SCC model described here is based on consideration of a straight sided crack in a specimen of sufficient thickness that effects in the transverse direction are not appreciable. As shown in Fig. 1, this crack is subdivided into three basic regions: the "tip zone" ($\delta^t \leq y \leq \delta^p$) where the cleavage process takes place; the inner region or "monolayer zone" ($\delta^p \leq y \leq \delta$) where a first monolayer of oxide is formed on the metal surface; and the outer region or "multilayer zone" ($\delta \leq y \leq l$) where the oxide layer increases in thickness. Based on model studies of several possible reaction mechanisms, some of which are mentioned briefly later, assumptions have been made for the reactions occurring in these three zones which yield model behavior corresponding to experimental SCC measurements.

In the tip zone the reaction

$$Ti + mX^- \rightarrow TiX_m + me^- \qquad \text{Reaction (I)}$$

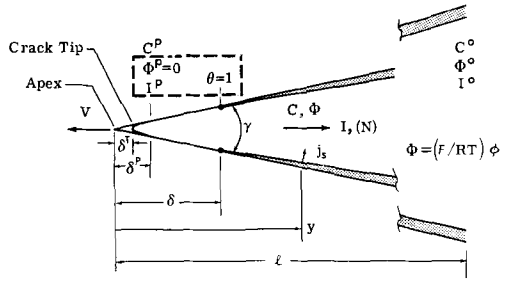

Fig. 1. Mass-transport-kinetic model for SCC

is assumed to take place and is presumably the reaction responsible for SCC. This assumption is based on calculations (described later) indicating the need for a net current of halide ions corresponding to about a monolayer in the tip zone. It is not known whether the halide ion tip current is due to electrochemical reaction or to charging of the electrical double layer, but either can be expressed by reaction (I).

Oxidation of titanium

$$Ti + 2H_2O \rightarrow TiO_2 + 4H^+ + 4e^- \qquad \text{Reaction (II)}$$

is assumed to occur on the walls in both the monolayer and multilayer zones. In the first of these it is assumed to be governed by Tafel-type kinetics (2) and to be accompanied by the displacement of halide ion from the titanium halide or adsorbed halide ion layer formed in the tip zone. This displacement mechanism is required to explain the observed nonlinear relationship of velocity to halide concentration (Table I, Item 5). In the multilayer zone, reaction (II) is governed by high field conduction (2) and thus has considerably different kinetic behavior than in the monolayer zone.

Hydrogen ion reduction

$$H^+ + e^- \rightarrow H \text{ (dissolved in metal)} \qquad \text{Reaction (III)}$$

is also assumed to occur in the monolayer zone where the potential at δ^p appears to be close to the mixed potential in acid solution for reactions (II) and (III). The amount of hydrogen ion reduced is small (on the order of a monolayer), and the hydrogen formed is assumed to go into the metal. Hydrogen ion reduction has been omitted in the multilayer zone because at a potential anodic to the mixed potential the current density would become small relative to reaction (II).

The mass transport and kinetic effects for this model have been analyzed subject to several fundamental assumptions discussed below.

Quasi-steady-state crack propagation.—It is assumed that the time constant for changes in the electrochemical variables is small compared to the period of crack propagation so that the system is essentially at steady state in respect to velocity and to concentration and potential gradients. The velocity, V, is assumed to be either uniform or the stepwise jumps small enough compared to the dimensions affecting mass transport that the velocity can be considered uniform. The mechanism of crack initiation is not considered.

Uniform small-angle crack.—The crack angle observed visually on the sides of SCC specimens and on optical photomicrographs of sectioned cracks to within 10^{-4} cm from the crack tip is on the order of 1-4°. Electron fractography indicates transcrystalline cleavage-type failure of the alpha titanium phase, indicating a curvature of atomic dimensions at the crack tip at a distance δ^t from the apex. There is thus a region of unknown crack angle from the atomic dimensions of the tip to 10^{-4} cm from the geometric apex of the crack, but the simplest assumption regarding shape is that the angle, γ, is uniform from the crack tip to the full length of the crack. Some branching of cracks has been observed on photomicrographs, but the effect will not be considered here.

Electrolyte completely fills crack.—It is assumed that capillary forces are sufficient to fill the crack with electrolyte completely at least to the tip zone.

Continuum treatment is applicable.—The lower boundary for the model is the position, δ^p, where the electrical double layers on the two walls intersect. Continuum mass transport flux equations and electrochemical kinetics data obtained from plane electrodes are assumed applicable at distances larger than δ^p from the apex. The continuum model of mass transport is not entirely applicable at distances close to

δ^p from the apex because of interference by the field of the diffuse part of the double layer. Unfortunately, as will be seen in the solutions, many of the electrochemically significant events in the crack occur not far from δ^p. The breakdown of the continuum conditions is one of the more serious criticisms that can be levied a posteriori against the model.

A one-dimensional representation is applicable.—The width of the small-angle crack is assumed to be small enough that there are negligible concentration and potential gradients normal to the axis of the crack. Actually, because there is no slip at the walls and the relative velocity of electrolyte to walls is on the order of 10^{-3} to 10^{-1} cm/sec, a near-parabolic velocity gradient would be expected. The transverse concentration gradient therefore must be assumed to be leveled by diffusion.

Halide ion is the SCC agent at the crack tip.—As stated earlier, the requirement of a limiting halide ion mass transport rate evolved from the preliminary calculations and was therefore added as a fundamental to the model. This requirement, moreover appeared consistent with the experimental SCC results in Table I. Further justification for elimination of other species is given here.

The other species which might be considered as the SCC agents in aqueous solutions are H_2O, OH^-, H^+, or alkali metal cation. The metal cation can be eliminated because SCC occurs with near equal velocity in the halogen acid solutions. Further, the potential gradient in the crack is in the wrong direction for either H^+ or metal cation to be the primary reactant at the tip. The hydroxyl ion can be eliminated because it is a SCC inhibitor if it is present in high concentration in respect to halide ions (1).

Water is eliminated as the primary SCC agent at the crack tip for several reasons. The reaction consuming H_2O would be the formation of a titanium oxide and hydrogen ions. As will be shown later, ohmic drop with H^+ ion the sole charge carrier cannot account for the large differences between the applied potential and the reversible potential for formation of TiO_2 in acid solutions (—1100 mv vs. SCE).[1] Therefore, this potential difference would have to be explained as activation overpotential. However, this is inconsistent with the linear relationship of velocity to potential and the low activation energy. An exponential velocity-potential relationship and at least an order of magnitude greater activation energy for velocity would be observed.

Tip is at the mixed potential.—It has been found that exchange current densities for reactions (II) and (III) are relatively large on newly generated metal surface so that the short circuit current density is on the order of 1 amp/cm² (2). It was therefore initially assumed that the potential at δ^p was the mixed potential for reactions (II) and (III) (about —800 mv) in the acid solution resulting from reaction (II) on the walls. In later calculations mixed potentials more negative than the —800 mv resulting from reactions (I) and (III) were examined.

Under these basic assumptions the SCC model can be represented mathematically by consideration of the mass transport and kinetic relationships involved.

Kinetic relationships.—The kinetic relationships express local reaction rate (or current) per unit wall area for the reactions enumerated. They consider the dependence of these rates on the potential and species concentrations existing in the electrolyte at the point in question.

In the multilayer zone ($\delta \leq y \leq l$) the formation of oxide through the oxide film is governed by the high-field equation taken in a form modified from Vetter (5).

$$j_s = j_o \exp\left\{\frac{B(\Phi - \Phi_e - \Phi_f - X}{\frac{A}{V}\int_{\delta^p}^{y} j_s\, dy}\right\} \quad [1]$$

This relates the local transfer current density, j_s, to exchange current density, j_o and the potential gradient in the oxide film. The exponential term B is the high-field-conduction constant nondimensionalized in respect to potential, the quantity in parenthesis is the nondimensionalized potential drop across the oxide film, and the denominator is the film thickness. The individual terms are defined under Nomenclature, and values of the parameters used are given in Table II.

In Eq. [1], X represents a surface overpotential defined by the kinetic expression

$$j_s = i_o\, 2 \sinh\left\{\frac{n'}{2} X\right\} \quad [2]$$

This expression was used because the current density spanned both the linear and Tafel overpotential regions, and its use avoided discontinuities in the calculations. The transfer coefficient has been assumed to be one-half. The value of exchange current density, i_o, was assumed to be the same as that for bare metal, i_m, in absence of experimental data for this parameter.

In the monolayer zone ($\delta^p \leq y \leq \delta$), where the surface coverage with oxide is θ, the kinetic equation for reaction (II) has the form (2)

$$j_s = i_m\,(1-\theta)\,2 \sinh\left\{\frac{n}{2}(\Phi - \Phi_e)\right\} + j_o\,\theta \exp\left\{\frac{B(\Phi - \Phi_e - \Phi_f - X)}{t_o}\right\} \quad [3]$$

The first term on the right is the Tafel expression for formation of oxide on bare metal. Mathematically, full coverage of oxide could never be achieved with only this term because this current goes to zero as the oxide coverage, θ, approaches unity. Therefore, it was assumed that formation of oxide on oxide, governed by the high-field equation, has commenced before the first monolayer is complete. The second layer was assumed to shift to the surface and help complete the first monolayer. This procedure gave a smooth transition at $\theta = 1$ from the Tafel to high-field conduction kinetics. The transfer coefficient in the Tafel term was assumed to be one-half in absence of more precise data. Order of magnitude values of the exchange current densities have been obtained experimentally (2).

The oxide coverage, θ, can be related to reaction occurring in the monolayer zone by

$$\theta = \frac{1}{Q_o V}\int_{\delta^p}^{y} j_s\, dy \quad [4]$$

where Q_o is the charge density of a monolayer of oxide.[2]

In the monolayer zone hydrogen ion reduction was considered simultaneously with oxide formation on bare metal (2,4). At open circuit, it appears that hydrogen ion reduction occurs over the whole crack length, resulting in the mixed potential of —800 mv (2). A Tafel expression with a transfer coefficient of one-half was assumed.

$$j_H = i_H \frac{C_H}{C_{H^\circ}} (1 - \theta) \exp \{\tfrac{1}{2}(\Phi - \Phi_H)\} \quad [5]$$

The exchange current density, i_H, was estimated from kinetic studies on new Ti:8-1-1 surface (2). Hydrogen ion reduction in the multilayer oxide region was not considered for the calculations, as there the potential is more anodic to the mixed potential.

The net generation of hydrogen ions is thus defined by

$$j = j_s - j_H \quad [6]$$

Mass transport relationships.—The treatment of mass transport in this model is based upon the one-dimensional assumption discussed above and the use of a coordinate system moving with the propagating crack. Under these conditions there are no convective transport terms, and the fluxes of the significant species along the axis of the crack are (using the Nernst-Einstein approximation for mobilities)

$$N_+ = -D_+ \frac{dC_+}{dy} - z_+ D_+ C_+ \frac{d\Phi}{dy} = 0 \quad [7]$$

$$N_- = -D_- \frac{dC_-}{dy} - z_- D_- C_- \frac{d\Phi}{dy} \quad [8]$$

$$N_H = -D_H \frac{dC_H}{dy} - z_H D_H C_H \frac{d\Phi}{dy} \quad [9]$$

The flux of the alkali cation is zero because it does not participate in reactions (I) to (III).

The current density at any point in the crack can be related to these fluxes

$$i = \mathbf{F} \sum z_i N_i \quad [10]$$

and electroneutrality is assumed to hold at all points

$$\sum z_i C_i = 0 \quad [11]$$

By application of conservation requirements for halide and hydrogen ions in the crack of linearly increasing section

$$\nabla \cdot N_- = \frac{dN_-}{dy} + \frac{N_-}{y} = \begin{cases} \dfrac{2m}{4\mathbf{F}\gamma y} j_s & @ \ \delta^p \leq y \leq \delta \\ 0 & @ \ \delta \leq y \leq l \end{cases} \quad [12]$$

$$\nabla \cdot N_H = \frac{dN_H}{dy} + \frac{N_H}{y} = \frac{2}{\mathbf{F}\gamma y} (j_s - j_H) \quad [13]$$

where the right-hand side terms represent the sources arising in the reactions at the crack walls. No such equation is necessary for the cation as Eq. [7] integrates directly to (with $C_+ = C_+^\circ$ at $\Phi = \Phi^\circ$)

$$C_+ = C_+^\circ \exp \{-z_+ (\Phi - \Phi^\circ)\} \quad [14]$$

If Eq. [7] through [9] are summed after being multiplied by their appropriate charge numbers the diffusion terms can be eliminated by use of [11] to give an equation for potential.

$$\frac{d\Phi}{dy} = -\frac{N_H/D_H + z_- N_-/D_-}{z_-^2 C_- + z_+^2 C_+ + C_H} \quad [15]$$

The side conditions for these equations which correspond to a case of specified propagation velocity (and thus halide flux to tip), tip potential, and external solution concentrations are

At

$$y = \delta^p \ ; \ N_- = N_-^p, N_H = 0, \Phi = \Phi^p$$

$$y = \delta \ ; \ N_- = 0 \ [3]$$

$$y = l \ ; \ C_- = C_-^\circ, C_+ = C_+^\circ, C_H = 0 \quad [16]$$

The model is then represented by the equation system comprising the differential Eq. [12], [13], [14], [8], and [9] together with the kinetic expressions [1], [3], and [5] and the side conditions [16]. Although manipulation can reduce this directly to three second order ordinary differential equations in C_+, C_H, and Φ, the nonlinear nature of these equations precludes analytic solution. In this work a numerical solution of the equation system was developed.

Numerical Procedure

The ordinary differential equations describing the SCC model can be put in the form of five simultaneous first order equations in N_-, N_H, C_-, C_H, and Φ by substitution of Eq. [15] into [8] and [9] and insertion of the kinetic expressions [1], [3], and [5] into [12] and [13].[4] Unfortunately this equation system has boundary conditions on N_-, N_H, and Φ at $y = \delta^p$ and on C_- and C_H at $y = l$ preventing direct solution as an initial value problem.

The method used here was, after suitable nondimensionalizations had been introduced, to assume the values for C_- and C_+ at $y = \delta^p$ (actually of C_- at $y = \delta^p$ and Φ at $y = l$ which is equivalent through [11] and [14]) and solve as an initial value problem, the assumed values being corrected until convergence on the required conditions at $y = l$ was satisfied. The initial value problem was solved at each iteration of this procedure by a Runge-Kutta-Gill integration (8). The selection of successive initial value assumptions followed a Newton-Raphson second order iteration procedure in two variables with the required partial derivative being approximated by first order finite difference representations for steps of 1% (reduced during iteration to 10^{-3}%) in the iteration variables.

This calculational procedure was implemented by a FORTRAN IV program and an IBM 7094 digital computer. The computation became time consuming (convergence of assumed initial values difficult) when conditions approaching a limiting propagation velocity (very high potential drop in the crack) were approached and concentrations C_- and C_H at the tip became very small, but otherwise was quite efficiently converging in about 2 to 4 Newton-Raphson iterations.

The calculation described here allowed evaluation of model performance under any desired set of system parameters and operating conditions.

Results

All calculations were conducted for values of system parameters believed representative of the Ti:8-1-1 halide solution system and for operating conditions corresponding to those for which experiments had been conducted. Values of the parameters used are given in Table II. In the special cases where other values are used it is so stated. The only parameter listed that came from the stress corrosion cracking experiments is the angle, γ. The diffusivities are approximate values. The exchange current densities are order of magnitude values estimated from electrochemical kinetics experiments (2). The value of B in the high-field conduction equation came from Johansen *et al.* (6). The value of A was calculated from the density of bulk rutile. The reversible potentials for oxidation and hydrogen ion reduction were from Latimer (7), converted to the SCE scale. The charge

[2] The charge density of an adsorbed oxide ion layer is assumed for first layer.

[3] This condition results from the fact that there is no net consumption of halide ion in the propagation process.

[4] Equation [15] constitutes the fifth equation, along with Eq. [8], [9], [12], and [13] as modified.

density of a monolayer of oxide is based on one oxide ion per titanium atom in the basal plane.

In the course of the development of the model described above, calculations were also made for several alternative sets of assumed reactions. Two such cases of historical interest in the development will be described; they can be considered as simplifications of the final model as presented. At the time that the model formulation was begun all of the data in Table I were not available. Items 5, 6, and 7 in Table I, for example, resulted from testing the consequences of the models. It was also not recognized initially that the mixed potential for reactions (II) and (III) in acid solution (and the zero-current intercept; item 3) is —800 mv and the tip potential was initially assumed to be —900 mv from the zero-velocity intercept (Table I, item 2).

The failure of these simplified or alternative models for any reasonable parameter values to yield calculated behavior even roughly corresponding to experimental observations led to the model presented in this work and indicated certain important features of the propagation mechanism.

Case I, with no tip current or H^+ reduction.—The first calculations were made before the kinetic data for hydrogen ion reduction on bare metal were available and i_H was in effect assumed zero. The potential of the tip was assumed to be —900 mv based on the zero-velocity intercept. The tip current, being unknown, was assumed to be zero, its importance not yet being recognized. With no tip current, reaction (I) was not considered, and therefore no halide displacement was involved. In test of this model a typical velocity of 10^{-2} cm/sec was chosen for the initial calculation. The experimental values of current and potential for this velocity are, respectively, about 200 μa/cm and —500 mv (1).

Results of the initial calculation are given in Table III. Lower and upper bound levels of j_o of 10^{-12} and 10^{-6} amp/cm^2 (2) were used. It is seen that a 10^6 fold variation of j_o gave only a fourfold change in the current and about twofold change in the potential drop. The reason for this behavior is that for higher values of j_o the resistive oxide layer is built up faster thus limiting the current. Also for faster oxide layer formation, greater rates of generation of hydrogen ion and higher conductivities for the electrolyte will be encountered, and therefore a relatively smaller potential change will result. Calculated currents approach the same order of magnitude as obtained by experiment, but the potential drop is low by more than an order of magnitude. This low potential drop arises in the fact that the hydrogen ion carries most of the current in the model and hydrogen ion concentration increases toward the tip.

Case II, with tip current and H^+ reduction but no halide displacement.—After examination of case I, it became apparent that a lower conductivity must be obtained in the crack in order to obtain potentials compatible with experimental values. A reasonable way to obtain a lower conductivity was to have a mass transport limiting current density of halide ion in the monolayer zone near δ^p such that the ionic concentration at δ^p would become small. Results of

Table III. Comparison of results of calculations to experimental SCC data for V = 10^{-2}cm/sec

	SCC Experiments (1)	Calculations

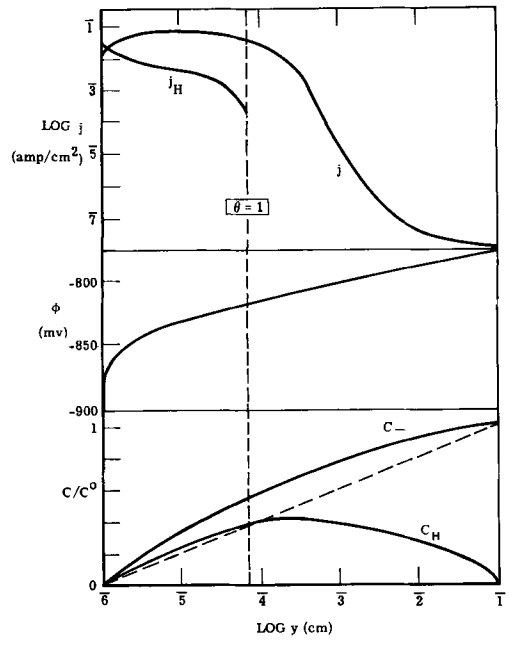

Fig. 2. Calculated current density, potential, and concentration as a function of position in a propagating stress corrosion crack according to model of case II.

the calculation with limiting mass transport are shown in Table III and plots of flux, potential, and concentration *vs.* position in the crack are shown in Fig. 2. It was found that a tip current of 7.2 μa/cm was close to the value of the limiting current, as it gave a concentration of halide ion at δ^p a factor of 10^{-3} times that of the bulk solution. The potential drop now approached the right order of magnitude and could be increased further by approaching the limiting mass transport rate more closely, thus giving a lower concentration at δ^p. The current, I°, was still low (using a value of j_o giving an approximate fit to the experimental kinetic data [2]), but this was considered to be due to the low potential as yet achieved.

It turned out that the limiting tip current corresponds to the order of magnitude for one monolayer of adsorbed halide ions or of titanium dihalide, the thermodynamically stable form at the tip potential (7). The tip current can be defined as $I^p = 2qQ_xV$, which for $I^p = 7.2$ μa/cm, $Q_x = 425$ μcoulomb/cm^2 (for dihalide), and $V = 10^{-2}$ cm/sec, gives $q = 0.85$ of a monolayer. The values of the parameters used in the model are not sufficiently precise that the model cannot distinguish between a monolayer of adsorbed halide ions or a monolayer of titanium dihalide, but it is significant that the order of magnitude of a monolayer is indicated. If the dihalide is formed, it is necessary, however, that it remain adsorbed until it enters the monolayer zone because it is known to be soluble and fully ionized; dissolution would give Ti^{++} as a current carrier, resulting in an increase rather than a decrease in halide ion concentration toward the tip.

The mass transport limiting case was then tested by further SCC experiments in which the bulk concentration of halides was varied. In concentrated solutions (1-10M) the observed velocity (4) was found to correspond to the value calculated for a limiting mass transport rate of halide ions from the bulk solution to the tip zone forming a monolayer therein but with no wall reactions in the region $\delta^p \leq y \leq l$. This calculation is represented by the dashed line in the concentration plot in Fig. 2. Examination of the model shows that this is a limiting case for high concentration electrolytes, thus providing a degree of verification.

On the other hand, the model predicts an approximately linear relation of velocity to concentration,

whereas approximately a 1/4 power relationship was observed, becoming asymptotic to a finite lower limit velocity in distilled water (Table I, item 5). The implication is that unless water molecules are also a stress corrosion agent, halide must be conserved in the crack by displacement or by hydrolysis in order to have SCC in distilled water.[5] Halide displacement tested in a much simplified mass transport model (4) gave results semiquantitatively in agreement with the velocity *vs.* concentration data. The model was therefore modified to include halide displacement.

Case III, with tip current, H^+ reduction, and halide displacement.—In the final form of the model as presented it was assumed that the equivalent of a monolayer of adsorbed halide ion was formed in the tip zone and that this was displaced by oxide on the basis of equal surface coverage. The exchange current densities for oxidation of freshly generated bare metal surface and hydrogen ion reduction thereon (2) were also assumed applicable to the surface covered with adsorbed halogen.

Initial calculations including halide displacement indicated propagation velocities much higher than those observed would be required in order to obtain a limiting mass transport rate and an appreciable potential drop. The reason for this, of course, was that the halide ion was regenerated and built up a higher concentration in the monolayer zone. The simplest change to reduce this discrepancy was to start at a more negative potential at δ^p such that a greater amount of hydrogen ion discharge occurred in the monolayer zone near δ^p, thus lowering the concentration of H^+, and X^- by the electroneutrality condition. This required no change in formulation of the model. It was consistent with the expectation of some oxidation of titanium to Ti^{++} which is the thermodynamically stable oxidized form at negative potentials (7, 9) (E° = −1870 mv), although the amount of Ti^{++} formed would have to be relatively small so as to be neglected in the transport equations. Trial values of tip potential were used until a limiting mass transport rate was achieved at δ^p consistent with velocity and monolayer halide coverage in the tip zone.

Results of calculations for case III are given in Table III and Fig. 3. By starting at the more negative potential the rate of oxidation of titanium was decreased in respect to hydrogen ion reduction. (Further, $j_s = 0$ at potentials more negative than ϕ_e.) This resulted in a lower hydrogen ion concentration in the crack and a larger potential drop. But the potential drop was not large enough to overcome the effect of starting at the more negative potential, and a longer time was required to complete the first monolayer and less total oxide was formed. The total current was therefore also too low as compared to experimental SCC data in Table III. Although there is some hydrogen ion discharge in the monolayer zone the net resulting charge density cannot be greater than $Q_x + Q_o$ in the present formulation. If $Q_x + Q_o$ were exceeded, there would be a net flux of hydrogen ions toward the tip giving a potential gradient in the wrong direction. (It may also be noted that j_H increases initially with distance in Fig. 3 due to increase in hydrogen ion concentration whereas j_H decreased initially in Fig. 2 because the concentration term had not been added to Eq. [5] at the time the calculation was made.)

Although in principle it is possible to achieve as large a potential drop as desired by going to a sufficiently low concentration at δ^p, one very serious problem remains. Examination of the model formulation and results shows that most of the potential drop occurs in the monolayer zone with a very large potential gradient at δ^p. For a concentration at δ^p that is a factor of 10^{-3} times that of the bulk solution (0.6M) the potential gradient at δ^p is over 10^6 v/cm. This is a level at which dielectric breakdown could occur and is higher by at least an order of magnitude than can be supported in continuum electrolyte. Such factors have limited voltage drop calculated by the model to less than about 200 mv while, experimentally, velocity was observed to be linear with potential over a range of nearly 2v. Thus it is apparent that an additional source of a large potential drop must exist.

[5] It is proposed that chloride at a parts-per-million level remaining in the metal from the reduction process is the source in the distilled water experiments. Experiments are underway to test this hypothesis.

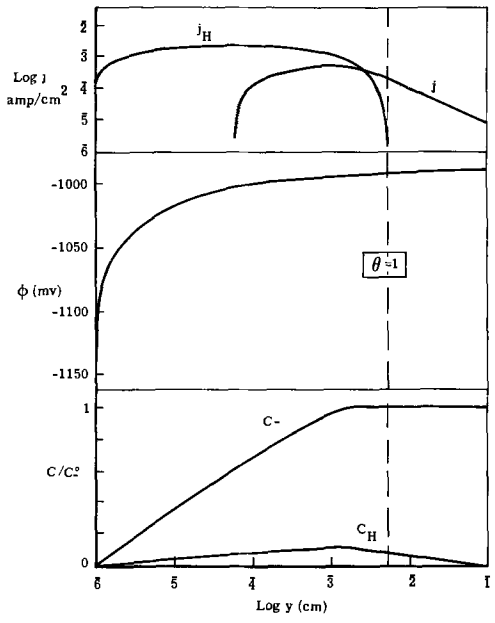

Fig. 3. Calculated current density, potential, and concentration as a function of position in a propagating stress corrosion crack according to model of case III.

It should also be pointed out that where there was some latitude of choice in the exact value of the parameters, values (Table II) were chosen that would tend to maximize the potential drop. For example, $\delta^p = 10^{-6}$ cm which gives a crack width at that point of 5Å is probably about an order of magnitude too small. No experimental value was available for i_o so it was assumed to be equal to i_m, whereas it would be expected to be considerably smaller than i_m. The value of $j_o = 10^{-8}$ used in case II and III is four orders of magnitude larger than the experimental value for titanium (6). The Flade potential was also assumed zero whereas a value of about ½v would be reasonable in comparison to other metals (5). That the model was incapable of producing a potential drop comparable to experiment in spite of this bias shows either that there is a large potential drop in the tip zone or that additional species existing in the electrolyte in the crack must be taken into account. Experiments with a Luggin capillary probe and calculations show that the large potential drop does not occur at the mouth of the crack. As described under limitations, the production of soluble titanium ions in the crack is suspected as the reason for the high potential drop in the SCC experiments.

Comparison of Model Behavior to Experimental Results

We will try to show here to what extent the calculated results for the model developed in this work agree with the experimental data in Table I and thus satisfy our original requirement. In some areas the agreement is quantitative and others qualitative, as an extensive investigation of the effects of all parameters has not yet been made. Some answers are outside of the scope of the present formulation and further experimental work and modeling are required. However, in this comparison, explanations for some observed characteristics of SCC can be obtained.

Only Cl^-, Br^-, *and* I^- *produce SCC in aqueous solution.*—The explanation of this observation is outside of the scope of any transport kinetic model such as the present formulation. Two possibilities are suggested: Perhaps other anions are absorbed in the oxide on the walls of the crack and never reach the tip zone; or they may not have the required surface transport properties to reach the tip within the tip zone.

Linear relation of velocity to potential.—The velocity is apparently limited by mass transport of halide ions in the monolayer zone close to δ^p giving a potential drop which is linear with tip current. The zero-velocity intercept is more cathodic than the mixed potential for reactions (II) and (III) because a cathodic current is required to decrease the halide concentration in the crack to a low enough level to stop propagation.

Linear relation of current to potential.—It can be shown that current flowing into the crack under potentiostatic conditions is linearly related to rate of creation of new surface or to velocity (2). Because velocity is linearly related to potential, current is therefore linearly related to potential. The zero-current intercept is at the mixed potential for reactions (II) and (III) on the crack walls at the acid condition developed in the crack.

Independence of velocity with cation.—The velocity is limited by halide ion transport in the monolayer zone and, with the formation (and reduction) of hydrogen ion that occurs, this phenomena is little affected by the decreased amount of other cations present. (Certain heavy metal chlorides such as cupric chloride, however, give inhibition at open circuit, because they establish a potential in the anodic protection zone for chloride.)

Nonlinear relation of velocity to concentration of halide ions.—This behavior is related to displacement of halide ion by oxide in the monolayer zone, which leads to local circulation of halide ions and a strongly nonlinear relation of halide concentration in the tip region, and thus to bulk concentration of halide.

Activation energy for velocity of approximately 3.5 kcal.—The activation energy for diffusion of species in aqueous solutions is also about 3.5 kcal (10). If the velocity were limited by a chemical or electrochemical reaction, a considerably higher activation energy would be expected. An activation energy of 3.5 kcal for velocity, although not proof of a limiting mass transport, is strong supporting evidence.

Open-circuit transient potential.—The initial open-circuit plateau potential up to an applied potential of +200 mv is only slightly below the applied potential because only the outer IR drop in the crack, which is small according to the model, disappears rapidly. The inner IR drop near δ^p would continue if the velocity remains initially unchanged (at time less than 10^{-2} sec from open circuit) and the tip current for reaction (I) is supplied by local circulation in conjunction with reaction (III), hydrogen ion reduction. There is however, also a need for reduction of other species such as higher valence titanium ions to continue the oxidation on the walls. Further kinetics experiments and model modification need to be done on this aspect.

The time of the potential transient, however, is consistent with the mass transport model. The time constant for a diffusional process is given approximately by $\tau = L^2/D$. The length associated with a diffusivity of 10^{-5} cm^2/sec and transient time of 10^{-2} to 100 sec is 3×10^{-4} to 3×10^{-2} cm consistent with position of peak concentration and value of l in the model. The final potential reached on open circuit is the mixed potential of —800 mv.

Limitations of Model and Calculations

While the mass transport kinetic model is qualitatively, and in some respects quantitatively, in agreement with the experimental stress corrosion cracking data, no real proof of its validity can be claimed. Some of its limitations and areas where it has indicated that further investigation is required are described here.

Mechanisms in tip zone not considered.—As mentioned earlier no continuum model such as this can be applied to the tip zone where distances approach the order of magnitude of atomic spacing. Complete understanding of stress corrosion cracking will require that atomic scale mechanisms at the tip be described. At best the model shows that halide ions disappear into the tip zone but gives no indication of whether electrochemical reaction or only adsorption occur. It also cannot consider the effect of the nature of the metal lattice which is manifested in this region. The transport mechanism within the tip zone itself also remains to be elucidated.

Geometry of crack imprecisely known near tip.—The crack angle, γ, is an important parameter in the model. Although it has been measured for the outer part of a crack to within about 10^{-4} cm from the tip the precise shape in the monolayer zone is not known. This turns out to be an important zone in respect to concentration and potential gradients in the model. The tip radius may be considerably larger than atomic as indicated by Elliott (11), but calculations have indicated that the angle and value of δ^p do not have a large influence on the magnitude of the potential drop near δ^p.

Continuum model breaks down near δ^p *where large changes in potential occur.*—Figures 2 and 3 show that the potential gradient is steepest and most of the potential drop occurs in a zone near δ^p where the applicability of the continuum treatment is doubtful. Originally it was hoped that the model could account for the entire apparent potential drop observed in the experiments; however, these studies have not supported that expectation. A change in the model to include generation and transport of soluble titanium ions as described below may change this situation to some extent, but it is a possibility that at least a part of the potential drop must be assigned to phenomena outside of the continuum region.

Limited accuracy of kinetic data used.—It should be counted as a strength of the model that it forced recognition of the important parameters and a need to evaluate them by independent experiments. Thereby new data were obtained on electrochemical kinetics on newly generated titanium surfaces. It has become evident however, that more data and more precise data are required, including:

(*a*) kinetics of hydrogen ion reduction on bare metal;
(*b*) kinetics of formation of first layer of oxide;
(*c*) kinetics of formation of soluble titanium ions;
(*d*) kinetics of a, b, c on adsorbed halide film;
(*e*) kinetics of formation of oxide on oxide surface;
(*f*) Flade potential (assumed zero in calculations).

Formation and transport of soluble titanium ions not included.—No consideration of possible formation and transport of soluble titanium ions has been included in this model, largely because no kinetic data for formation of Ti^{++} or Ti^{+++} on newly generated titanium surfaces have been available. It has, however, become increasingly clear from the interplay of theoretical model development and experiments that soluble titanium species must be formed. This is implied by need for a potential at δ^p more negative than the mixed potential for reactions (II) and (III) in case III. Also initial open-circuit plateau slightly below the applied potential up to +200 mv (Table I, item 7) suggests a reversible titanium ion couple capable of providing a current to continue crack propagation. Potential-*p*H diagrams (9) for titanium also show that in acid solution the soluble ions are

more thermodynamically stable than the oxide. The oxide apparently owes its existence at all in acid solution to favorable kinetics (*i.e.*, rate of formation much greater than rate of dissolution). Formation of soluble species in parallel with oxide has been reported under certain conditions for iron (12) and for zinc (13). When necessary data are obtained for titanium this mechanism can be included in further model developments.

Conclusions

In this work a quantitative electrochemical mass transport kinetic model has been formulated for stress corrosion cracking of titanium alloy, which has given some new insights into mechanisms in a propagating crack. In particular the model studies have indicated:

1. That the propagation of the crack requires a flux of halide ions to the tip zone. The limiting mass transport rate of these halide ions corresponds to the order of magnitude of one monolayer of halide ions or titanium halide.
2. That a mechanism such as displacement or hydrolysis exists to release of the bound halide from the walls within the crack in order for the model to be consistent with observed velocity *vs.* concentration data.
3. That reduction of hydrogen ions in the crack in the region outside of the tip zone occurs at the negative potential of this zone but the amount must be small to be consistent with the direction of the potential gradient.
4. That the model as now formulated cannot account for the large difference between the applied potential in SCC experiments and the reversible potential for oxidation of newly generated titanium surface. This potential difference either exists outside the region of the model within the tip zone or it must be accounted for in a revised model formulation. Several experimental results point to formation of soluble titanium species in parallel with formation of oxide on new titanium surface which if included in the model may produce the required potential drop.

In addition, as an important general contribution, the model has forced quantitative thinking about the electrochemistry in a crack. This has required obtaining new kinetic data for freshly generated titanium surfaces and suggested key stress corrosion cracking experiments.

Internal Stress of Electroless Metal Films on Single Crystal Silicon

H. E. Austen

Process R&D Department, The National Cash Register Company, Dayton, Ohio

and R. D. Fisher

Materials Research Department, Ferroxcube Corporation, Saugerties, New York

ABSTRACT

The internal stress of electroless nickel and cobalt films on silicon single crystals was measured as a function of thickness and experimental conditions. The internal stress was measured using an interference technique to determine the bending produced by films in the thickness range of 500-5,000Å. The stress was found to be tensile and isotropic for both metals. The stress in electroless nickel films is greater than in similar cobalt films. The stress decreases with thickness which is in contrast to vacuum evaporated nickel and cobalt films which exhibit a stress independent of thickness.

The electroless deposition of nickel, cobalt, and their alloys was reported by Brenner in 1946 (1). Since then, considerable literature on the electroless deposition process has been published, and the physical properties of the deposits have been studied. Graham and coworkers have recently published the results of an extensive investigation of the structure and mechanical properties of electroless nickel (2), and there is increased interest in electroless cobalt, which may be prepared with magnetic characteristics applicable to digital recording media (3).

A property of electroless deposits which has not been extensively studied is the internal stress characteristics. Knowledge of the stress is of theoretical interest due to the relatively small crystalline size and to the inherent phosphorus content of the deposit. Practical interest lies in preparation conditions which may minimize internal stress to promote adhesion and prevent cracking or buckling of the coatings on certain substrates.

In this investigation, the internal stress of electroless nickel and cobalt films were measured as a function of film thickness and experimental conditions.

Experimental

Electroless cobalt and nickel films were deposited on the (111) crystal face of optically polished, single crystal, silicon wafers. The method of determining the internal stress in this investigation was developed by Hoffman and Finegan (4, 5) based on the theory of bending of thin plates (6). The contours of the silicon wafers were determined with, and without, the deposit. From these contours the bending due to the film was determined, and, from this bending and the thickness of the film, the internal stress was calculated.

Electroless deposition conditions.—The silicon substrates were prepared by cleaning ultrasonically in an organic solvent, immersing in hot concentrated nitric acid, rinsing in distilled water, immersing in 30% hydrofluoric acid, rinsing in distilled water, immersing in 20% hydrofluoric acid containing 0.2 g/l $PdCl_2$, and placing in the electroless solution. Two solution concentrations were used to deposit each metal, as follows:

(a) Concentrated Solutions	g/l
$CoCl_2 \cdot 6H_2O$ or $NiCl_2 \cdot 6H_2O$	30
NH_4Cl	50
$(NH_4)_2C_6H_5O_7 \cdot H_2O$ (diammonium citrate)	65
$NaH_2PO_2 \cdot H_2O$	15
NaOH	to *p*H 8.2
Temperature: 84° ± 1°C	

(b) Dilute Solutions	g/l
$CoCl_2 \cdot 6H_2O$ or $NiCl_2 \cdot 6H_2O$	7.5
NH_4Cl	12.5
$H_3C_6H_5O_7$ (citric acid)	19.8
$NaH_2PO_2 \cdot H_2O$	7.0
NH_4OH	to *p*H 8.2
Temperature: 84° ± 1°C	

The time of deposition was varied to obtain deposits ranging in thickness from 500 to 5,000Å out of the four solutions.

Thickness measurement.—The thickness of the electroless films was generally determined by assuming bulk density to be equal to the pure metal, *i.e.*, 8.9 g/cm^3 for both nickel and cobalt, and weighing the deposit on a microbalance. The measurements were checked in thin films by using the Tolansky method (7) and agreed within about 10%.

Stress measurement.—The measurement was made by determining the bending produced in the silicon wafer by the deposit on the face of the wafer. The contour of the face was determined from the interference pattern of sodium light reflected between the face and an optical flat on which the wafer lay. The pattern was photographed, using reference marks, prior to deposition. After deposition, the deposit was stripped from the back of the wafer and the interference pattern again photographed. From these photographs the contours in a line between the reference marks were plotted. Subtraction of the two curves then gave a curve of the bending produced by the deposit. In this investigation, silicon wafers 0.008 in. thick by ¾-⅞ in. diameter were used to give the desired degree of bending. Stress measurements were generally made on five deposits, and the average results were plotted as a function of thickness.

Stress calculation.—The thickness of the deposited film was generally calculated from the weight of deposit and the bulk density of the metal as previously discussed. The thickness of the silicon wafer was measured with a micrometer. Young's modulus and Poisson's ratio were calculated for the (111) plane from the elastic constants.

The curve of bending is normalized by plotting the difference between it and a straight line drawn from one end to the other. The curve is assumed to be a parabola of the form $y = k\,x^2$. At four equally spaced points on the "y" axis, the average x distance to the curve is determined. The values of y *vs.* the square of the average distance $\overline{X}^2$ is plotted, and the straight line fitting these points has a slope whose value is k.

The stress is calculated as

$$\text{Stress} = \frac{E\,h^2\,k}{3\,t\,(1-\mu)}$$

where E is Young's modulus = 1.748×10^{12} dynes/cm^2 calculated from elastic constants, μ is Poisson's ratio = 0.266 calculated from elastic constants, h is thickness of substrate, cm, k is slope of y *vs.* $\overline{X}^2$ plot, cm^{-1}, and t is thickness of deposited film, cm.

Experimental Results

Electroless nickel.—The internal stress of the electroless nickel deposits, parallel to the surface, was found to be tensile and isotropic over the range of 500-5000Å whether deposited from the dilute or concentrated solutions. The tension per unit length, *i.e.*, normalized bending force, *vs.* thickness is shown in Fig. 1.

The tension per unit length from both the dilute and concentrated solutions increases rapidly between 500 and 2000Å, but increases more rapidly for films prepared from the concentrated solution. From 2000-5000Å, the tension per unit length from the dilute solution increases very little, while from the concentrated solution there is a continuous increase.

The internal stress, derived by dividing tension per unit length by thickness, approaches a maximum at about 1000Å from the dilute solution and at about 1400Å from the concentrated solution (Fig. 2). The stress from the dilute solution reached a maximum not much lower than the maximum from the concentrated solution (3.2 *vs.* 3.75 dynes/cm^2 x 10^9). At greater thicknesses the stress appears to decrease to some constant value which is higher for the concentrated solution. However, at 5000Å the deposit from the concentrated solution has a tension per unit length twice that from the dilute solution.

Electroless cobalt.—The internal stress of the cobalt deposits, parallel to the surface, was also found to be isotropic and tensile over a thickness range of 500-3000Å from the dilute or concentrated solutions. The tension per unit length, *i.e.*, normalized bending force *vs.* thickness, is shown in Fig. 3.

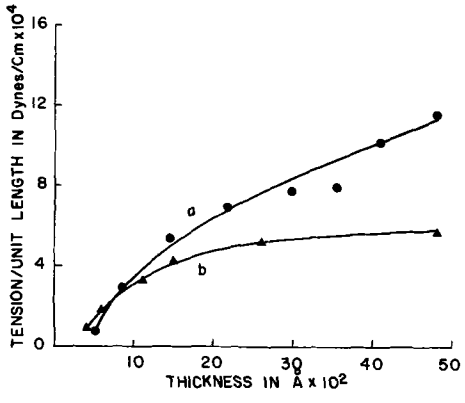

Fig. 1. Tension per unit length *vs.* thickness for electroless nickel: (a) deposits from concentrated solution; (b) from dilute solution.

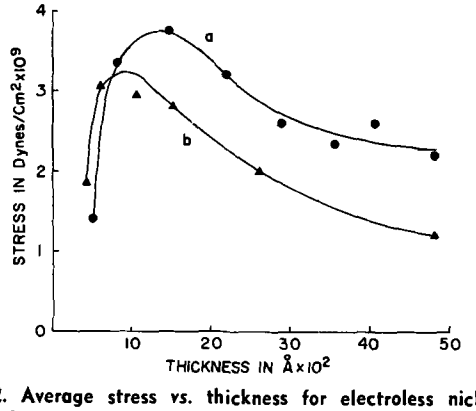

Fig. 2. Average stress *vs.* thickness for electroless nickel: (a) deposits from concentrated solution; (b) from dilute solution.

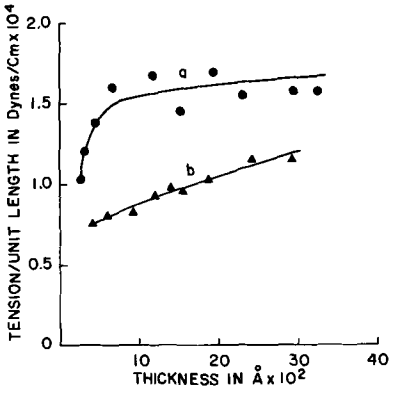

Fig. 3. Tension per unit length *vs.* thickness for electroless cobalt: (a) deposits from concentrated solution; (b) from dilute solution.

The tension increases linearly from 500 to 3000Å when cobalt films are prepared from the dilute solution. However, in the case of concentrated solutions, the tension increases rapidly from 500Å to approximately 1000Å and then remains relatively constant with increasing thickness over the range measured. The tension per unit length is larger for films deposited from concentrated solutions than for films deposited from dilute solutions, regardless of the thickness.

However, the internal stress calculated from the tension per unit length decreases rapidly from a thickness of 500 to 2000Å, and from 2000 to 3000Å is relatively constant (Fig. 4). The stress exhibited by films from the dilute and concentrated solutions is nearly identical at a thickness of 3000Å. However, in thin films, *e.g.*, at 500Å, the stress is much larger in films deposited from the concentrated solution.

Discussion

The method utilized to measure the internal stress detects the presence of anisotropic stresses by producing an asymmetric interference pattern. Previous techniques for measuring the internal stress assumed that the stress was isotropic. Our results show that electroless cobalt and nickel films exhibit an isotropic stress and that the average stress is a function of thickness. These results are in contrast to vacuum evaporated cobalt and nickel films which exhibit a stress independent of thickness (8, 9).

The curves of tension per unit length *vs.* thickness, and stress *vs.* thickness, for nickel, indicate that the initial stress is compressive but rapidly becomes tensile so that the average stress is zero at about 300-400Å. The deposits from concentrated solutions show a rapidly increasing tension per unit length, initially, but then show a smaller, nearly constant rate of change at

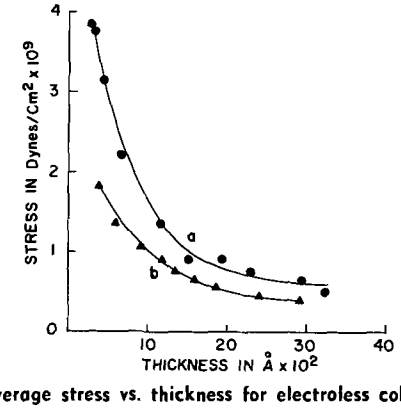

Fig. 4. Average stress *vs.* thickness for electroless cobalt: (a) deposits from concentrated solution; (b) from dilute solution.

thicknesses greater than about 2000Å. The deposits from dilute solutions also show an initially rapid increasing tension per unit length, but the rate of change decreases and becomes nearly constant at a considerably lower tension value, but at about the same thickness.

When the data are plotted as stress *vs.* thickness the stress shows a rapid increase, to a maximum and a gradual leveling off to a nearly constant value of 5000Å or more. Again, it appears that the initial stress was probably compressive. Also, the concentrated solution produces a higher maximum and levels off at a higher thickness value.

The curves for cobalt also indicate a rapidly increasing initial stress, but the data do not indicate that the initial deposit is compressive from either the concentrated or dilute solutions. The deposits from the concentrated solutions reach a higher tension per unit length than those from dilute solutions, and then level off to nearly constant tension at about 1000Å. However, the deposits from dilute solutions show nearly a constant rate of change of tension per unit length with thickness and the rate of increase is greater than for the concentrated solution. Extrapolation of the curves indicates the stresses would be equal at approximately 10,000Å.

In both cases there appears to be a change in the mechanism producing stress at thicknesses between 500 and 1000Å. It is interesting to note that electron transmission micrographs of chemical deposits on "Formvar" have shown that the deposits first become continuous at thicknesses of about 500Å; the observed change in stress mechanism may be associated with such a structural change.

The stress in nickel is much higher than in cobalt at similar thicknesses. Below about 1000Å, there appears to be considerable difference between the two metals. For example, the tensile stress of cobalt below 1000Å is decreasing rapidly with increasing thickness while the tensile stress of nickel is increasing rapidly. While the data for nickel indicate the initial deposit may be compressive, that for cobalt indicates extremely high tensile stress in the initial deposit. It should be noted that there is a possibility that the stress mechanism operates much more rapidly with change in thickness of cobalt and the maxima might be present at thicknesses below that at which measurements were made.

The experimental data on stress in chemically deposited films and on the structure of these films are not sufficient to allow a theoretical explanation as to the origin and mechanism of the stress. However, an explanation for the difference in stress observed for cobalt and nickel might be that the codeposited phosphorus is insoluble in cobalt (10) but in the case of nickel may form a supersaturated solid solution of phosphorus dissolved in crystalline nickel (2). As a consequence, the phosphorus in cobalt films should occur at crystallite boundaries as elemental phosphorus or as a cobalt phosphide which might reduce the generation of internal stress associated with any interaction or crystallite boundary relaxation. In the case of nickel this would not occur due to formation of a solid solution. This mechanism would agree with that proposed by Hoffman (11).

Summary of Results

Electroless cobalt and nickel films exhibit an isotropic tensile stress at thicknesses greater than 500Å whether deposited from relatively dilute solutions or from concentrated solutions. However, deposits from concentrated solutions exhibit higher stress values.

The stress in nickel deposits is greater than in cobalt deposits at equivalent thicknesses by a factor of about four.

A maximum tensile stress in electroless nickel films occurs at a thickness of approximately 1000Å while no maximum in stress was observed for cobalt films over the thickness range investigated.

Effect of Electroless Nickel Substrate on Coercive Force and Microstructure of Certain Co-P Films

V. Morton and R. D. Fisher

Ferroxcube Corporation, Saugerties, New York

ABSTRACT

The influence of electroless nickel as a substrate on the coercive force and microstructure of certain electroless cobalt films was examined. Cobalt films on electroless nickel substrates exhibit (*i*) deposits which may contain a lesser proportion of amorphous or fine grained cobalt, (*ii*) a more pronounced [10$\bar{1}$0] preferred orientation perpendicular to the plane of the deposit relative to similar deposits on a Mylar-adhesive substrate, and (*iii*) higher coercive force values relative to similar deposits on a Mylar-adhesive substrate. The data suggests that the increase in coercive force may be due to a decrease in the amorphous characteristics of cobalt films prepared on electroless nickel in comparison to such films on Mylar.

Chemically deposited cobalt films may exhibit coercive force values from a few oersteds to over one thousand oersteds depending on the experimental conditions (1, 2). In general, investigators have utilized pretreated Mylar (3-5) (polyethylene terephthalate), Mylar with an adhesive (6), glass (7), brass (8), or Be-Cu (1) as a substrate or base material. The influence of the substrate or base material on the coercive force and microstructure of electroless cobalt films has not been extensively studied under given experimental conditions. Consequently, a preliminary study was made as to the influence of the substrate on the coercive force and microstructure of electroless cobalt films. The experimental conditions were fixed and the magnetic properties of electroless cobalt films on nonconductive and conductive substrates were evaluated. The substrates were Mylar-adhesive and Mylar-adhesive coated with electroless nickel. The cobalt film thickness was varied on each substrate from approximately 1000 to 10,000Å and the coercive force and microstructure as a function of thickness were evaluated on each substrate.

Experimental Conditions

Cobalt deposition.—Electroless cobalt films were prepared from the following solution:

$CoCl_2 \cdot 6H_2O$	(cobalt chloride)	0.0315M (Co^{++})
$NaH_2PO_2 \cdot H_2O$	(sodium hypophosphite)	0.03M (H_2PO_2)
NH_4Cl	(ammonium chloride)	0.234M
$H_3C_6H_5O_7 \cdot H_2O$	(citric acid)	0.0934M

*p*H: 8.2 with NaOH
Temperature: 80°C

Nickel deposition.—Electroless nickel was deposited on the Mylar-adhesive substrate from the following solution:

$NiCl_2 \cdot 6H_2O$	(nickel chloride)	0.0315M
NH_4Cl	(ammonium chloride)	0.2338M
$H_3C_6H_5O_7 \cdot H_2O$	(citric acid)	0.0945M
$NaH_2PO_2 \cdot H_2O$	(sodium hypophosphite)	0.0664M

*p*H: 8.2
Temperature: 80°C
Time: 60 sec

Substrates.—Mylar substrates were precleaned and dip coated with an adhesive and cured (3). The Mylar-adhesive substrates were then overcoated in certain instances with electroless nickel from the preceding solution. The Mylar-adhesive surface was sensitized with stannous chloride and activated in the usual manner (3).

Magnetic measurements.—M-H loop measurements were made with an instrument similar to that of Howling (6). A maximum field of 1000 oersteds was applied to measure the M-H loop.

Thickness measurements.—The thickness was generally determined by the weight-density relationship assuming a bulk density for Co-P of 8.6. In general, this method agreed with interference and x-ray techniques which were used to check the thickness estimation from time to time.

X-ray diffraction.—A Norelco x-ray diffractometer was used to determine the crystallographic orientations in the plane of deposit. The specimens were examined in normal reflection geometry using the flat specimen holder. Filtered cobalt Kα radiation was used. A silicon powder standard was used to adjust the instrumental conditions so that they were constant for each specimen examined. The integrated intensities and the proportion of the sum of the integrated intensities attributable to each observed x-ray reflection were determined. The integrated intensities were obtained by integrating the area under each diffraction profile observed.

Experimental Results and Discussion

Magnetic properties.—The coercive force of electroless cobalt as a function of thickness on the Mylar-adhesive and electroless nickel substrates is shown in Fig. 1. The coercive force of cobalt films on both substrates is greatly dependent on the film thickness.

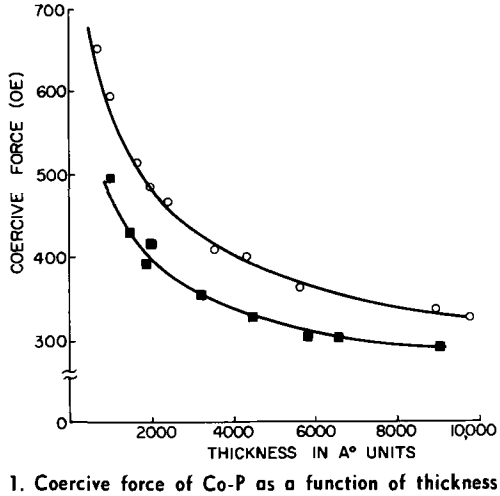

Fig. 1. Coercive force of Co-P as a function of thickness on adhesive coated Mylar, ■, and on electroless Ni-adhesive-Mylar, ●.

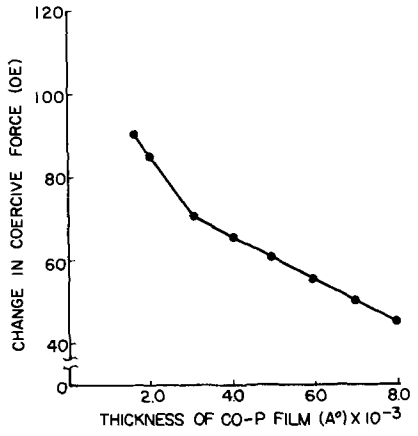

Fig. 2. Change in coercive force of Co-P as a function of thickness due to overcoating the adhesive-Mylar substrate with electroless nickel.

On the Mylar-adhesive substrate, the coercive force decreases from 495 oe at 1000Å to 295 oe at 9000Å. However, on Mylar-adhesive coated with electroless nickel, the coercive force decreases from 660 oe at 600Å to 350 oe at 9000Å. It is apparent that electroless nickel surfaces promote a higher coercive force cobalt deposit than on the Mylar-adhesive base. The increase in coercive force of similar Co-P deposits as a function of thickness due to electroless nickel on Mylar-adhesive substrate is shown in Fig. 2.

Structure

To examine the influence of the electroless nickel substrate on the structure of the Co-P film, deposits prepared on Mylar-adhesive and on the Mylar-adhesive-electroless nickel substrate were examined by x-ray diffraction. The results are shown in Tables I and II.

In the Co-P films on the Mylar-adhesive substrate, only two diffraction peaks were detected; namely, the $(10\bar{1}0)$ and the $(10\bar{1}1)$. Deposits showed a $[10\bar{1}0]$ preferred orientation perpendicular to the plane of deposit but random in the plane. The one-half amplitude peak width of the $(10\bar{1}0)$ reflection remained nearly constant with increasing thickness indicating that the particle size was essentially constant or that any tendency toward peak narrowing due to particle size increase was offset by a tendency to peak broadening caused by micro stress and resultant lattice strain or by lattice imperfections with the net effect being a

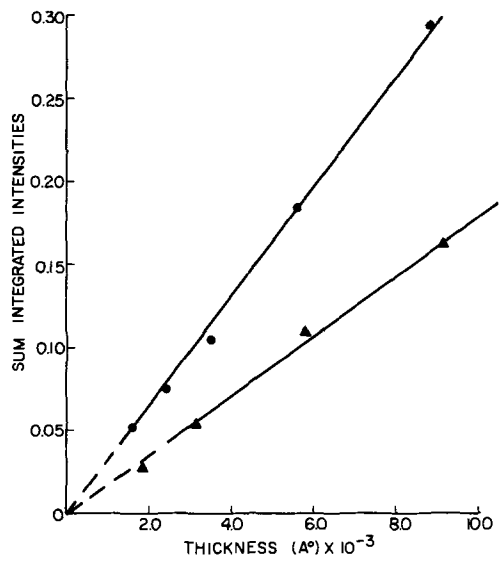

Fig. 3. The sum of the integrated x-ray intensities for all reflections of Co-P as a function of thickness on adhesive-Mylar substrate, ▲, and on electroless nickel-adhesive-Mylar substrate, ●.

constant peak width. However, Co-P films prepared on the nickel substrates exhibited three diffraction peaks, the $(10\bar{1}0)$, $(10\bar{1}1)$, and (0002). The deposits initially exhibit a [0002] preferred orientation perpendicular to the plane of the deposit. As thickness increases, the [0002] orientation decreases and the $[10\bar{1}0]$ orientation becomes predominant. That the diffraction planes indicated were lying preferentially in the plane of deposit but random in that plane was verified by the use of a modified Schulz (9) device. The half amplitude peak width was measured for both the $(10\bar{1}0)$ and (0002) peaks. The $(10\bar{1}0)$ peak width decreases significantly with increasing thickness whereas the (0002) peak width remains nearly constant. Because of the possibility of nonuniform lattice strain or anisotropic lattice defects, definite interpretation of the peak width measurements cannot be made. However, if these factors are assumed to be essentially constant, the data suggests that the particles oriented with $(10\bar{1}0)$ planes in the plane of deposit increases in size with increasing thickness.

A plot of the sum of the integrated intensities of Co-P films as a function of thickness on electroless Ni Mylar-adhesive and Mylar adhesive is shown in Fig. 3.

* Peak breadth in degrees 2θ.

The sum of the integrated intensities, in both cases, is linear with thickness. However, a greater intensity sum is observed for Co-P films on electroless nickel, the difference increasing with thickness. Since all observed x-ray reflections are random in the plane of deposit and the deposits are magnetically isotropic in the deposition plane, the linearity of the intensity sums with thickness would seem to indicate that most of the particles which have a size sufficient for coherent diffraction have one of the orientations observed and as one orientation increases (or decreases) there is a corresponding decrease (increase) in other orientations so that the total reflected x-ray intensity is essentially constant per unit volume in each experimental case. This data would be consistent with an assumption that there may be more amorphous cobalt (very fine grained material below the resolution of the x-ray wavelength used) on the Mylar-adhesive substrate than in the case of an electroless nickel substrate. However, to establish the relative content of amorphous material in the films would require more highly refined x-ray measurements.

Based on a semiparticulate model for the coercive force of cobalt films, it would be expected that a decrease in coercive force would occur in deposits which contained a large number of amorphous or fine particles. This would agree with the experimental observation that cobalt films on Mylar exhibit lower coercive force values than those on electroless nickel substrates.

Conclusion

The influence of an electroless nickel substrate on the microstructure of electroless cobalt is to produce a more pronounced [10$\bar{1}$0] preferred orientation perpendicular to the plane of the deposit.

Cobalt films prepared on electroless nickel Mylar base materials exhibit higher coercive force than similar deposits on Mylar. If a smaller proportion of amorphous (fine grained) cobalt were present in the former, one may reasonably assume that the coercive force would be increased.

Electrochemistry and Photopotentials of Phenazine in Methanol Solutions

David N. Bailey,[1] David M. Hercules, and David K. Roe*[2]

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Linear-potential-scan voltammetry and coulometry have been used to study the electrochemistry of phenazine in methanol solutions. Parallel work (reported elsewhere) was done on the photochemistry of this compound and the combined results led to elucidation of the species involved in the development of photopotentials which occurred upon illumination of phenazine solutions. Acid-base processes dominated the electrochemistry; in acid solution the reactant at a cathode was the diprotonated phenazine, yielding a stable semiquinone radical which was further reduced in a separate step to dihydrophenazine. Oxidation of the products proceeded readily. In buffered solutions of the neutral range, the reactant was monoprotonated phenazine and the over-all rate was strongly influenced by the protonation step; a single reduction wave of two electrons occurred and reoxidation yielded phenazine. Photopotentials in acid solution were due to diprotonated phenazine and photochemically produced semiquinone radical of the same species. In neutral buffered solutions the photochemical product was dihydrophenazine and the photopotential was due to this species and monoprotonated phenazine.

Interest in the redox behavior of phenazine-based compounds stems from their use as dyestuffs as well as from recognition of the biological importance of some phenazine derivatives. Prior to any recorded voltametric measurements of phenazine, it was established that a stable, one-electron reduction product (semiquinone) was formed during potentiometric titrations using suitable solvents. A review of this subject was prepared by Michaelis (1). Following this, Müller (2, 3) showed that the same information about formal potentials and semiquinone intermediates of a number of compounds could be obtained from polarograms. He found (4, 5), however, that some dyes, including several phenazine derivatives, gave an anoma-

[2] Present address: Oregon Graduate Center, Portland, Oregon 97225.

lous wave which preceded the normal or expected reduction wave. Phenazine was included in the survey (5) of compounds but the only information given was that the prewave preceded the main reduction wave by a maximum of 75 mv at a pH of 4.06. Apparently the prewave was not found at a lower pH where the semiquinone was stable. Most of the compounds giving prewaves did so at concentrations of 10^{-5} to 10^{-4} *M*. At higher concentrations the prewave did not increase in magnitude. It is generally accepted now that these anomalous prewaves were due to adsorption of the product of the reduction, as described by Brdicka (6, 7). Somewhat later, Kaye and Stonehill (8) reported the polarographic behavior of phenazine, pyridine, and quinoline. They used 10% ethanol-water solutions with HCl or buffers covering the pH range from 1 to 13 and also 1*M* H_2SO_4. These pH values were measured for nonalcoholic buffers. At pH values below 2, two distinct reduction processes were found; the first wave had an $E_{1/2}$ of +0.09v *vs.* S.C.E. at pH = 0, shifting to −0.02v at pH = 1.93, and the second wave was independent of acidity over this range at −0.18v. Between pH = 3.95 and 13.0, only one wave was found with $E_{1/2}$ values ranging between −0.20 and −0.76v. The interpretation of these polarographic observations is the same as that given by Michaelis (1): when the medium's pH was below pK_a of the protonated semiquinone radical, the latter was a stable intermediate. They calculated pK_a = 3.8 for the radical and 3.2 for phenazinium ion. It was noted that phenazine had no bacteriostatic properties, while several other compounds which gave stable semiquinones at pH of *ca.* 7 were antibacterial. In the series of polarograms given by Kaye and Stonehill there is no clear indication of a prewave at concentrations of 2 to 4 x 10^{-4}*M*. Müller (5) found fully developed prewaves of many compounds, including phenazine, at the same or lower concentration.

Laitinen and Mosier (9) used double layer capacity measurements to survey the adsorption of a number of compounds on the DME. For phenazine, they reported that at −0.8v *vs.* S.C.E. surface adsorption was 50% complete at a solution concentration of 7.6 x 10^{-5}*M*. The solution was 0.1*M* in $NaClO_4$ and neutral (unbuffered). Thus it appears that the adsorbed species was the reduction product of phenazine (dihydrophenazine) since the half wave potential was considerably positive of −0.8v. Müller's study (5) of the concentration dependence of the prewave of phenazine and derivatives is in general agreement with the capacity measurements. He also tried adding ethanol in some cases, the effect of which was to decrease slightly the prewave of α-oxyphenazine. How phenazine's behavior was changed by ethanol was not stated.

Finally, it may be noted that polarographic half-wave potentials for phenazine and 59 of its derivatives have been measured (10).

The occurrence of photopotentials on irradiation of solutions of certain organic compounds has been known for many years (11). Historically, the Becquerel effect, as it is frequently named, was observed as a change in emf measured between two inert metal electrodes immersed in a solution when only one of the electrodes was irradiated by visible or ultraviolet light. Unpoised electrodes would be expected to be subject to relatively large potential changes from impurities, so the majority of such measurements are of qualitative value only. Surash and Hercules (12) found that when proper attention was given to purity of the system, reproducible photopotentials were obtained from a variety of compounds in nonaqueous solutions. Phenazine in ethanol produced a photopotential of −345 mv *vs.* a silver wire coated with silver chloride. Kuwana (13) has recently reviewed the subject of photopotentials and the related photochemistry.

On the basis of the detailed photochemistry of phenazine now available (14), an understanding of the photopotentials produced by products of the photoreduction process is possible. This paper presents the relevant information on the electrochemistry of the system and from this we can deduce what is the potential-determining couple in irradiated phenazine solutions.

Experimental

Details of the preparation of solutions and choice of chemicals have been described (14). Methanol was used as solvent in all cases, except as noted.

All current-potential curves were obtained with a potentiostat based on the details given by Enke and Baxter (15). Depending on the potential scan rate, the curves were recorded either on a Houston Instruments HR-100 X-Y plotter or a Tektronix Type 536 oscilloscope equipped with suitable preamplifiers and Model C-12 camera. Potential scan signals were derived from an internal circuit (15) or from a Wavetek Function Generator.

Polarographic measurements were made with a Heath EUW-19-6 dropping mercury electrode assembly. Maximum possible uncompensated resistance in a 0.1*M* HAc, 0.1*M* NaAc, and 0.1*M* NaCl methanol solution was measured to be 350 ohms near the end of drop life. This resistance was the value measured between counter and indicator electrodes using an Industrial Instruments RC conductivity bridge at 1 kHz. Electrodes were arranged at approximately the three corners of an equilateral triangle so that relatively little solution resistance was compensated. Consequently, concentrations were adjusted so that the maximum iR drop due to uncompensated resistance was less than 2 mv for all curves subject to quantitative interpretation.

Most measurements involving cyclic potential scans were made with a platinum electrode (0.096 cm^2) in an all-glass cell. The counter electrode was a spiral platinum wire enclosed in a porous glass sleeve (Corning 7930 glass). The reference electrode was silver-silver chloride in a 0.125*M* NaCl solution of methanol; isolation from the cell solution was provided by a porous glass plug. Uncompensated resistance was 100 ohms using the same solution referred to in the polarographic case.

Coulometric reduction was done with the same cell with a 1 cm^2 platinum electrode. Potentiostatic control was from a Jaissle Model 300 R potentiostat. Coulombs were measured with a hydrogen-nitrogen coulometer (16). The determination of the number of electrons per molecule, or n-values, was made from a plot of evolved gas volume against peak current at a microelectrode measured by a linear voltage scan. Coulometric electrolysis was stopped during these measurements.

Prepurified nitrogen was used to remove dissolved oxygen.

Hydrogen ion activities were measured in a relative manner with a conventional pH meter and standard electrodes which were normally stored in water. Calibration was routinely performed with aqueous buffers before a measurement; however, the meter reading was occasionally calibrated against a suitable methanol buffer (17-19). Thus, all readings were converted to the pH* scale which is relative to a standard solution of hydrogen ions in methanol. This procedure produced consistent results provided pH* $> \sim 3$. Below this point, the measurements lacked linearity and credibility. Consequently, we resorted to calculation of pH* for all HCl solutions. Activities of HCl in methanol are available (20) and De Ligny *et al.* (18) have calculated chloride ion activities up to 0.1 molal. Since some of our solutions were 0.2*M*, it was necessary to extrapolate the curve, but the probable error from this is <0.1 of a pH* unit. Calculated and measured values of pH* matched with discrepancies of <0.1 unit.

Results and Discussion

Most of the measurements of direct pertinence to the following discussion were made within two pH* ranges: 1 to 2.6 (hydrochloric acid) and 8 to 10 (acetic acid-acetate buffer). Phenazine, denoted by P, exists in the monoprotonated form, PH^+, in acid solution; above pH* of about 6 only the uncharged molecule is found. This information on protonation is based on the results of HCl titrations of phenazine in methanol (containing *ca.* 0.1*M* NaCl). The midpoint pH* of the titration was 4.4, which we take as the logarithm of the reciprocal of the equilibrium constant, pK_{a1}, for the process $PH^+ = P + H^+$ under these conditions. This is a very reasonable value for pK_{a1} in view of the value 3.2 reported (8) for 10% ethanol solutions. Cationic acids typically undergo only small changes in pK_a upon change from aqueous to alcoholic media. Neutral red, a phenazine derivative, was reported (21) to have pK_a values of 7.4 and 8.2 in water and methanol.

Evidence for the occurrence of the reaction $PH_2^{2+} = PH^+ + H^+$ was based on the observation that the yellow color of phenazinium ion was half-changed to an orange color in 65% (10*M*) H_2SO_4 in water. The Hammett acidity function, H_0, has a value (22) of −5 at this concentration of H_2SO_4, but this value cannot apply to a cationic base without major corrections. The factors to be considered are the term log (f_{++}/f_+), where the *f*'s are activity coefficients of the acid and base, association of ions and also the change in dielectric constant to a methanol medium. We estimate pK_{a2} to be more positive than −5, but the order of magnitude is a hazardous guess. A lower limit of pK_{a2} will be discussed later from kinetic measurements.

Cyclic voltammograms of phenazine at low values of pH* are shown in Fig. 1 and 2. Changes of peak potentials with pH*, as identified on the voltammograms, are given by the respective lines of Fig. 3. Up to pH* = 2.6, which was the lowest HCl concentration (0.0041*M*) used, the two reductions and their respective anodic counterparts did not quite meet the criteria (23) of diffusion control at scan rates of about 33 mv/sec or greater: that is, separations of peak potentials ($E_{p4} - E_{p1}$ and $E_{p3} - E_{p2}$) were 62 to 65 mv instead of 57 mv. However, this small deviation,

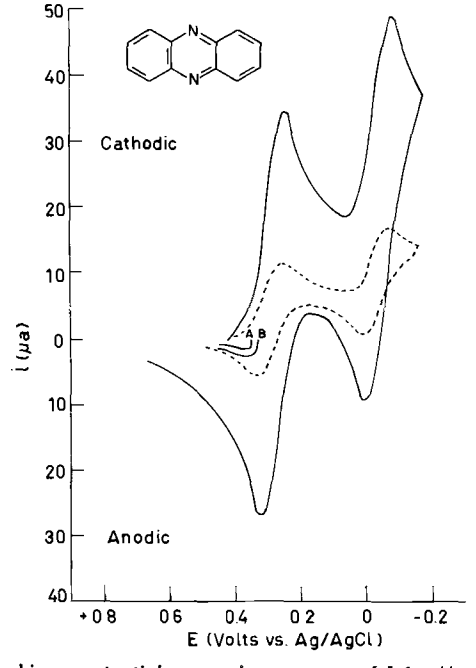

Fig. 1. Linear-potential-scan voltammogram of 1.6 *mM* phenazine in methanol containing 0.1M HCl and 0.1M NaCl. Scan rates are 33 (solid line) and 3.3 (dashed line) mv/sec. Curves A and B are anodic scans initiated from photopotentials.

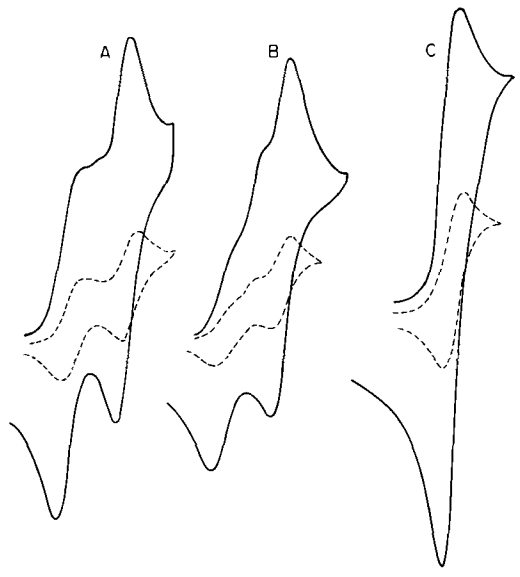

Fig. 2. Linear-potential-scan voltammogram of phenazine in methanol: (a) 0.16 *mM*, pH* = 2.6; (b) 1.6 *mM*, pH* = 2.6; (c) 0.16 *mM*, pH* = 4.9. Solutions (a) and (b) contained 0.0041M HCl and 0.1M NaCl; solution (c) contained 0.067M chloroacetic acid and 0.1M NaCl. Scan rates are 33 (solid line) and 3.3 (dashed line) mv/sec.

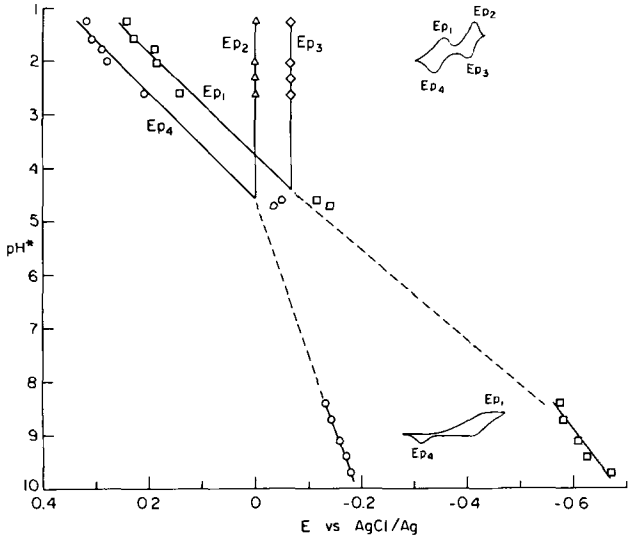

Fig. 3. Peak potentials as a function of pH*. Peaks are identified on inset curves.

corresponding to a heterogeneous rate constant of about 0.01 cm/sec according to the calculations of Nicholson (24) is not very essential at this point. Coulometry at a constant potential of 0.05v with pH* = 1.2 resulted in a value for the number of electrons in the first cathodic peak of $n = 1$. The product of the electrolysis was a stable, green solution which gave an ESR spectrum identical to that reported (25) for the protonated semiquinone radical. Comparison of the relative height of the four peaks leads to the conclusion that each is a one-electron step.

On the basis of the results of pH* dependence and coulometry, the electrode reaction at E_{p1} and E_{p4} involved the sequence

$$PH^+ + H^+ \rightleftarrows PH_2^{2+} \quad [1a]$$

$$PH_2^{2+} + e^- \rightleftarrows PH_2^+ \quad [1b]$$

and at E_{p2} and E_{p3} the reaction was

$$PH_2^{\cdot +} + e^- \rightleftarrows PH_2 \quad [2]$$

The directions of the reactions are to the left for E_{p1} and E_{p2} and to the right for E_{p3} and E_{p4}.

There were, however, two aspects of the first reaction which were subject to analysis by linear sweep methods but not apparent to previous polarographic measurements. Conditions were possible under which the rate of protonation of PH^+, reaction [1a], caused a decrease of the first cathodic current peak and when this protonation rate was made slow enough, a new peak appeared which was apparently the direct reduction of PH^+. Two examples are shown in Fig. 2a and b; note that there is no change in the appearance of the remaining peaks. From an analysis of this behavior of the first cathodic peak, we have set a lower limit on the value of pK_{a2} of phenazine. Table I summarizes the current peaks at three scan rates and for three solutions. These data were processed by the method of analysis given by Nicholson and Shain (23), who found that for the case of a first order chemical reaction preceding a reversible charge transfer the following empirical equation applied

$$\frac{i_k}{i_d} = \frac{1}{1.02 + 0.471\sqrt{a}/K\sqrt{l}} \qquad [3]$$

Here, i_k is the observed, kinetically-influenced current and i_d is the diffusion-controlled current which would be found in the absence of a chemical step; a is $\nu nF/RT$, in which ν is the potential scan rate; K is the equilibrium constant for the preceding chemical reaction, which is equal to $[H^+]/K_{a2}$ for this case; and l equals $(k_f + k_b)$ for a first order chemical reaction, or $([H^+]k_f + k_b)$ for reaction [1a]. We have taken i_d at 3.3 mv/sec to be diffusion controlled since essentially the same value was observed for all values of pH* up to 2.3. At 0.1*M* HCl, $i_d/\nu^{1/2}$ was constant for $\nu < 10$ mv/sec, giving $D = 2.2 \times 10^{-5}$ cm²/sec. For higher scan rates, i_d was calculated from this value; the ratios of i_k/i_d are given in the table and the resulting values of $k\sqrt{l}$. Now if the maximum possible value of k_f is taken to be 10^{10} liters/mole sec, then the upper limit of K_{a2} is found to have an average value of 107 ± 20. More realistically, pK_{a2} appears to be —2, subject also to the accuracy of the estimate of k_f. Since the two reactants in Eq. [1a] have the same charge, a rather low value for k_f was taken. [For purposes of comparison, see the tabulations of Eigen and De Maeyer (26) and of Strehlow (27)].

In solutions in which the ratio of HCl to phenazine was 10 or less, by increasing the phenazine concentration, the additional current peak mentioned previously appeared between the two cathodic peaks at the lowest scan rates, as shown in Fig. 2b. Similar curves were also obtained with buffers prepared with trichloroacetic acid. However, it was found that the effect was greater at a given scan rate with dilute HCl solutions than with high capacity buffers of higher pH*. This additional peak increased with increasing scan rate at the expense of the first cathodic peak; no other changes in the voltammogram were noted. A reasonable interpretation would be that the direct reduction of PH^+ occurred when reaction [1a] became sufficiently slow. In dilute HCl solutions, the decrease in rate was exaggerated because the activity of H^+ was not held as uniform in the diffusion layers as when buffers were present in high concentrations. Thus, pseudo-first-order conditions were not maintained.

With increasing pH* above 2.6, the peak ascribed to direct reduction of PH^+ became dominant and merged with E_{p2} by pH* = 5.0, shown in Fig. 2c. The anodic counterpart, E_{p4}, also shifted negative in potential until it merged into the tail of the wave at E_{p3}. Since pK_a (8) for dissociation of $PH_2^{\cdot+}$ was at least about 0.6 units larger than pK_{a1} of PH^+, E_{p4} persisted to slightly higher pH* values than did E_{p1}. For the curve shown in Fig. 2c, the peak heights corresponded to a two-electron process by comparison with the other curves. Also, the separation of peak potentials was 65 mv at low scan rates in well-buffered solutions.

Further increases in pH* have the significant effect shown in Fig. 4. The cathodic process has shifted negative by nearly 0.5v for a pH* change of 4. Increasing scan rates caused the cathodic curve to flatten and $i_p/\nu^{1/2}$ decreased markedly, as is illustrated by the normalized curves of Fig. 5. Further diagnostic characteristics of the cathodic wave were a negative potential shift with increasing scan rate of both half-peak potential and peak potential (—18 and —40 mv per 10-fold increase in ν, respectively, for rates up to 5 v/sec) and a change of about —70 mv per unit pH* increase, as shown in Fig. 2. Coulometry at —0.7v revealed that two electrons were involved in the overall reduction. As the cathodic current decreased during bulk electrolysis, the anodic wave increased cor-

(a) Phenazine concentration was 0.16 *mM*; methanol solution contained HCl and 0.1*M* NaCl. Diffusion currents are calculated from experimental values at 3.3 mv/sec and pH* = 1.2.

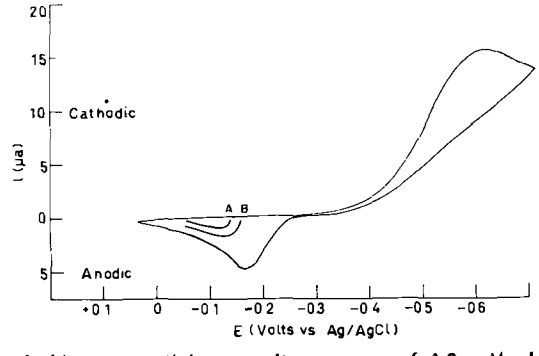

Fig. 4. Linear-potential-scan voltammogram of 1.2 *mM* phenazine in methanol solution of 0.1*M* acetic acid, 0.1*M* sodium acetate, and 0.1*M* sodium chloride; pH* = 9.4; scan rate 33 mv/sec. Curves A and B are anodic scans initiated from photopotentials.

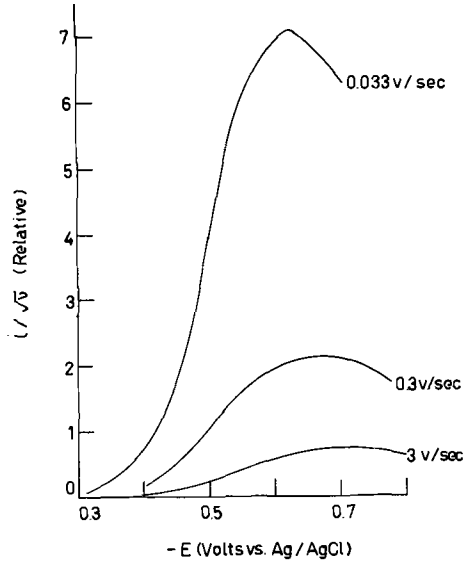

Fig. 5. Normalized voltammograms of phenazine at various scan rates; acetate buffer of pH* = 9.4.

respondingly and no additional current peaks were found.

Several polarographic observations were also made with acetate buffers. Reduction at a DME was a single wave; the rising part of the wave had an average slope of 45 mv when plotted as E *vs.* log $(i_d - i)/i$ for a drop time of about 6 sec. At $pH^* = 8.4$, the diffusion current *vs.* square root of height of mercury column was reasonably linear for drop times greater than 4 sec; below this value the plot curved toward a zero-order dependence on mercury column height.

A diffusion coefficient of the neutral phenazine species was calculated from the polarographic limiting current at $pH^* = 8.4$. Using the Ilković equation and $n = 2$, a value of $D = 3.0 \times 10^{-5}$ cm^2/sec was calculated. This is in fair agreement with the value of 2.2×10^{-5} cm^2/sec calculated from the peak current from a linear scan of 3.3 mv/sec at $pH^* = 5.0$ where the single wave most closely has the characteristic diffusion-controlled shape. Extrapolated to zero scan rate, the value increased to 2.8×10^{-5} cm^2/sec. None of these calculations included a spherical term in the diffusion equation. Also, in anticipation of a one-electron initial step of the over-all process, the term $n^{3/2}$ of the Randles-Sevcik equation was replaced by $(n_1 + n_2)n_1^{1/2}$ in which the subscripts indicate the sequence of electron addition. Nicholson and Shain (28) have shown that this modification is necessary when a single current wave consists of two charge transfers coupled by a chemical reaction; evidence for this assignment of steps is given below. To a certain extent, the diffusion coefficient values given here may appear to be larger than generally reported for similar compounds. However, the difference in viscosity of methanol and water is sufficient to account for the increase. Kaye and Stonehill (8) did not give a diffusion coefficient from their measurements, but assuming they employed the same capillary characteristics for phenazine as for the other compounds investigated, we calculate $D = 8 \times 10^{-6}$ cm^2/sec for phenazine in 1:10 ethanol-water; viscosity of this solvent is 1.32 while that of methanol is 0.55 at 25°C.

Consideration of the above information on the reduction of phenazine over the investigated pH^* range leads to the following four equations as a reaction sequence for solutions giving single cathodic and anodic waves

$$P + H^+ \rightleftarrows PH^+ \qquad [4a]$$

$$PH^+ + e^- \rightleftarrows PH\cdot \qquad [4b]$$

$$PH\cdot + H^+ \rightleftarrows PH_2\cdot^+ \qquad [5a]$$

$$PH_2\cdot^+ + e^- \rightleftarrows PH_2 \qquad [5b]$$

The combination of [4a] and [4b] is based on the marked decrease in $i_p/\nu^{1/2}$ with increasing scan rate (23). If [4b] is not a reversible step, the effect is essentially the same; there appears to be no reason to assume [4b] to be irreversible in view of the results shown for pH^* of 1 to 5. None of the model kinetic systems which have been analyzed shows this characteristic, except a catalytic cycle. We exclude this possibility from having a major role, although it has been found as hydrogen evolution during reduction of many nitrogenous compounds (29), because the diffusion coefficient is constant for a wide range of conditions and the change of the shape of the voltammogram with increasing scan rate of a catalytic reaction (23) is toward that of a peaked, normal diffusion-controlled wave. Figure 5 shows that the opposite was found, in qualitative agreement with the calculated curves (23) for the case of a chemical step preceding charge transfer. There is one important respect in which our measurements deviate from the results of the calculations of Nicholson and Shain (23) for a preceding reaction: with increasing scan rate, the half-peak potential should shift anodic if the sequence is indeed [4a] followed by [4b]; a cathodic shift was found. The explanation can be found in the effect of reaction [5a]. A following chemical reaction shifts E_p (and the half-peak potential) in the cathodic direction (23) with increasing scan rate, becoming constant with increasing scan rate when a/k_f $[H^+]$ exceeds a value of about 10. Here $k_f[H^+]$ applies to reaction [5a], which is considered to be irreversible because of [5b]. The reduction potential of $PH_2\cdot^+$ is positive of the region where [4b] commences, as is evident from the anodic wave of Fig. 4 and further is typical of protonated hydrocarbons, as was shown by Hoijtink *et al.* (30). Thus, at slow scan rates, the effect of [5a] dominates and a cathodic shift amounting to a maximum of −30 mv per 10-fold increase in ν is expected. However, the effect of [4a] at low scan rates also causes a small cathodic shift in E_p (while $E_{p/2}$ moves anodic), as is shown in the calculated current functions (23). It is not known how these criteria, calculated for independent cases, will behave when combined. Certainly the qualitative aspects are correct. As further proof, we found that the half-peak potential became independent of scan rate in the vicinity of 10 to 70 v/sec, in spite of a large ohmic drop in the cell under these conditions. It is interesting to note that no new waves due to intermediates were found at these scan rates.

Calculation of rate constants for reaction [4a] would not be expected to be realistic if the reduction actually occurs as written. Characteristics of peak currents are unique to the boundary conditions assumed for a system and they lose their significance when additional steps occur. We found that the quantity $K\sqrt{l}$ was not constant when Eq. [3] was used; for example, k_f ranged from 10^{12} to 10^{13} liters/mole sec and k_b ranged from 10^8 to 10^9 sec^{-1}. Indications are that k_f of [4a] is a diffusion-controlled constant. The absence of an anodic wave due to the proposed intermediate PH· would require (23) that $a/k_f[H^+]$ for [5a] be less than 0.1. At $\nu \cong 100$ v/sec and $[H^+] = 10^{-8}$ M, this condition gives $k_f \cong 4 \times 10^{12}$ liters/mole sec for [5a].

In the high pH^* range, the anodic wave shifted negative in potential by 31 mv/pH^* unit. Distortion of this curve occurred because of the time lag between reversal of direction of the linear potential scan and the start of the anodic process. There is no doubt that the oxidation is the reverse of the over-all reduction sequence since no cathodic peak was found adjacent to this wave upon a second reversal of direction of potential scan. Also the area of the anodic wave approached the area of the cathodic wave with increasing scan rate.

Since previous investigations (5, 9) indicated that dihydrophenazine was adsorbed on mercury electrodes, it is important to assess the magnitude of this effect under the conditions of our experiments. Due to the many complications causing deviations from simple diffusion control of voltammogram curves, adsorption effects were difficult to locate except at pH^* of about 5. Here the peak anodic wave exceeded the peak cathodic wave by 5% at $\nu = 33$ mv/sec; according to measurements of the curve of Fig. 2c. At low scan rates the difference was too small to measure and at high scan rates (333 mv/sec) the cathodic wave became influenced by the prior chemical step, Eq. [4a]. Wopschall and Shain (31) recently treated the cases of reactant and product adsorption and from their results, one would conclude that the experimental evidence showed that dihydrophenazine was weakly adsorbed from methanol solution.

Photopotentials were measured with 2 mM solutions of phenazine at $pH^* = 1.4$ and also at $pH^* = 9.4$. Cyclic scans were recorded with a platinum electrode and the solution was illuminated at a distance of 15 cm from an AH-6 mercury vapor lamp. In acid solution, the initial potential was 0.45v and unsteady. After a few seconds of illumination the potential moved in a negative direction, first rapidly then more

slowly until a potential of 0.330v was attained after about several minutes. At this point the solution was a definite yellow-green color due to the formation of photoreduced products. Additional curves were measured during illumination; there were no major changes in the curves from those shown in Fig. 1. The potential of E_{p1} shifted about 10 mv negative and the current decreased slightly with time. The other current peaks increased about 5%, an effect most probably due to the thermal convections from the light source. Anodic potential scans started from the photopotential showed a small wave; examples have been added to Fig. 1, lines A and B. These waves increased with time. Using the electrochemical results, the interpretation of these observations is rather direct. The product of photoreduction (14) in acid was the protonated semiquinone radical, $PH_2^{\cdot+}$ and therefore, the potential-determining couple was $PH_2^{2+}/PH_2^{\cdot+}$ (Eq. [1b]), as was clearly shown by the measured potential and current-potential curves. The observed decrease of current of E_{p1} is quite as expected from the gradual conversion of PH^+ to $PH_2^{\cdot+}$, as is the increase in the anodic current wave starting from the photopotential.

The situation with the acetate buffer corresponds more closely to the conditions employed by Surash and Hercules (12) than does the above. Here, the initial potential was about zero volt and also unsteady. After about 10 min of illumination a potential of —0.2v was reached. Again, no marked changes in the voltammogram were noted, except a gradual increase with time of the anodic wave as measured from the photopotential, as shown by curves A and B of Fig. 4. Absence of new current peaks during illumination showed that the photoreduction intermediates were short lived as was established from photochemical studies and the product was PH_2 (14). Thus the potential-determining couple was PH^+/PH_2 since the intermediate oxidation state was not thermodynamically stable. Kuwana (13) expressed the view that photopotentials are due to the fully reduced species and not radical intermediates. This view certainly applies to phenazine in acetate buffer solution. Also, the very slow decay of photopotentials (12) after cessation of illumination is suggestive of diffusional and convective mixing of solution between the exposed and light-baffled parts of the cell.

Finally, it may be noted that the time-rate of change of photopotentials and the anodic waves clearly reflected the large difference in quantum efficiencies (14) of the photoreduction of phenazine in HCl and acetate buffer solutions. In the first solution, the quantum efficiency was 0.094 moles/einstein while in the latter it was 0.011 moles/einstein.

Energy Considerations in Electron Beam Welding

P. G. Klemens[1]

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

An expression is obtained for the depth of penetration of an electron beam in terms of the thermal conductivity of the solid and other parameters of the material. In the case of a moving beam, the penetration decreases with speed; an expression for the decrease of penetration is obtained in terms of the thermal diffusivity. An electron beam technique is described which may be a useful method for measuring thermal diffusivities.

Although electron beams have been used successfully as a tool in cutting and welding materials, and although a large body of empirical information is now available on how this tool can be used to good advantage, our knowledge of the actual processes induced by the electron beam in the target material is incomplete. Ideally we would like to know the details of the atomic processes which govern the penetration of the electron beam (1); however, there is also a prior need to understand the penetration process on a macroscopic level. The present paper considers the energy balance and energy loss mechanisms on a macroscopic basis and shows how these energy considerations govern to a large extent the penetration of the electron beam, although there are some assumptions which have to be made, the validity of which can only be examined on a microscopic basis. It is shown that, provided the beam is sufficiently narrow and its energy content high enough, the penetration in the stationary case is mainly governed by thermal conduction. If the beam is not narrow, a second energy loss mechanism becomes important, the flow of vapor out of the hole made by the beam. In the case of a moving beam, the penetration is reduced by the extra energy requirement of melting the material ahead of the cut, and an expression is found for the decrease of penetration depth as function of the forward velocity of the beam. Finally it is pointed out that since this loss of penetration depth depends on the thermal diffusivity, an electron beam technique may be a convenient way of measuring thermal diffusivity in circumstances when measurements of temperature gradients of temperature variations inside a solid are difficult.

The present treatment depends mainly on energy flow considerations; it applies not only to electron beams, but to any other method which delivers a high flux of energy in a beam of narrow cross section. It may, in particular, apply under appropriate circumstances to laser welding.

Stationary Beam

Consider a narrow electron beam impinging on a surface. Let the voltage be V, the current J, so that the energy flow is $W = VJ$. Suppose in the steady state the beam has cut a deep hole, of depth D, and diameter l, and let $D >> l$. Let T_m be the melting point of the material, and let the vapor inside the hole be of temperature T_v. Presumably there is a sheath of molten material between the vapor core and the surrounding solid; unfortunately, very little is known about what occurs precisely within the hole. But note that by the above definition l is the diameter of the "key hole" formed by the beam and not the width of the molten metal which, by the usual definition, gives the weld width.

The electrons penetrate the hole in an unknown and extremely complicated manner, although some x-ray photographs give information about the spatial distribution of the absorption (2). We shall assume (*a*) that x-rays remove only a negligible fraction of the total power, and (*b*) no matter how the energy loss of the electrons by interaction with the vapor and the walls of the hole is distributed spatially, this energy is rapidly transported within the hole, so that the wall is of uniform temperature.

The energy which is delivered by the beam is dissipated by various mechanisms: by heat conduction into the solid, by energy transported away by vapor, and by radiant energy.

If the hole is deep and narrow, conduction becomes most important. The temperature gradient at the solid-liquid interface is of order T_m/l, so that the heat carried away by conduction is of order $\kappa(T_m/l)\pi lD$, where κ is the thermal conductivity. The heat flow is thus roughly independent of the hole diameter, but proportional to the hole depth D. Therefore, as long as the other energy loss mechanisms are relatively small, the conduction depends on the depth of the hole, which is therefore proportional to beam power; this result is insensitive to the hole diameter, which must be determined by other considerations.

In greater detail, the heat conduction for a length D through a cylinder of inside diameter l and inside temperature T_m, and outside diameter L and temperature T_o is given by (3)

$$W_1 = 2\pi D\kappa \frac{T_m - T_o}{\ln(L/l)} \qquad [1]$$

There is thus a weak dependence on l. We must now choose the radius $L/2$ outside which the material is at the ambient temperature T_o. We find that strictly speaking the process is not stationary and L increases with time. However, as long as the cylinder is not infinitely long but of finite length D, we expect the conduction to be enhanced by the addition of an extra dimension as soon as L becomes comparable to D; at that point a stationary state is more closely approached. We therefore identify $L/2$ with D, noting that any error will only enter into [1] logarithmically, so that

$$W_1 = 2\pi D\kappa \frac{T_m - T_o}{\ln(2D/l)} \qquad [2]$$

In many typical cases, $\ln(2D/l)$ ranges from 3 to 5.

Equating W_1 to the total power of the beam, W, one obtains for the depth of the hole

$$D = \frac{W \ln(2D/l)}{2\pi\kappa(T_m - T_o)} \qquad [3a]$$

$$\simeq \frac{4W}{2\pi\kappa(T_m - T_o)} \qquad [3b]$$

In a typical case of a 15-kw beam and in a metal for which thermal conductivity $\kappa = 1$ watt-cm-deg^{-1}, and $T_m = 1500°C$, one would expect a penetration of the order of 6 cm. If the diameter of the hole is 0.2 cm, this makes $\ln(2D/l) = 4.2$, consistent with our approximation.

Some typical values of D for various materials deduced from [3a] are shown in Table I.

[1] Present address: Department of Physics, The University of Connecticut, Storrs, Connecticut 06268.

Table I. Beam penetration for 15 kw beam, $l = 0.2$ cm:optimum values

Material	T_m, °C	K, watt-cm-deg^{-1}	D, cm
Copper (pure)	1080	4.5	1.5
Copper alloy (20μ ohm-cm)	1080(?)	0.8(?)	10
Iron	1540	0.7	9
Stainless steel	1600(?)	0.14	50*
Tungsten	3380	1.0	2.0
Rocks, various	2000(?)	0.02(?)	400**

* The thermal conductivity of stainless steel is a room temperature value; it may be considerably higher near T_m, resulting in a substantial reduction of D. The value may thus turn out to be closer to that for the copper alloy.

** We have neglected the "dilution" of the beam by electron scattering which causes variations in the temperature of the vapor with depth, and would invalidate the present argument in extreme cases. We have also disregarded the factor of time, which is again of great importance in such extreme cases.

One must recognize that these values are optimum values deduced on the assumption that other heat loss mechanisms are inoperative. Furthermore, it has been assumed that the hole is long and thin and of uniform temperature, and that the solid material which had to be removed to form the hole has been removed without inhibiting the entrance of the beam. In the case of the 400-cm hole calculated for rock, this is certainly a questionable assumption. Limitations due to electron scattering are discussed in an associated paper by Schubert and Schumacher (4).

Let us now consider competing heat loss mechanisms. The material inside the hole is partly in the form of liquid, partly in the form of vapor. The latter probably occupies the major fraction of the volume. The vapor emits electromagnetic radiation and also streams out of the hole, carrying away energy. The black body radiation out of a hole of area l^2 is

$$W_r = 6 \times 10^{-12}\, T_v^4 l^2 \text{ w} \qquad [4]$$

and even if $T_v \simeq 3000$°K, this is clearly negligible.

The energy loss by vapor flow is more important. Let us assume the vapor to emerge with the velocity of sound v, at a temperature T_v. Let d_o be the density of the solid, C its heat capacity per unit volume, and let d be the density of the vapor. The heat capacity per unit volume of the vapor is thus

$$\frac{d}{2d_o} C \qquad [5]$$

the factor 2 being included because the vapor atoms have only translational, not vibrational, energy. The energy flow due to the vapor is thus

$$W_{II} = l^2\, v\, C\, T_v \frac{d}{2d_o} \qquad [6]$$

Invoking the perfect gas law, and assuming that the vapor issues at or near atmospheric pressure

$$\frac{d}{d_o} \simeq 3 \times 10^{-4} \frac{T_v}{300} \simeq 10^{-6}\, T_v \qquad [7]$$

so that

$$W_{II} = \frac{1}{2} \times 10^{-6}\, C\, v\, l^2\, T_v^2 \qquad [8]$$

In a typical case, when $C \simeq 3.5$ joule/cm^3/deg, $T_v = 3000$°K, and $v = 5 \times 10^4$ cm/sec

$$W_{II} \simeq 8 \times 10^5\, l^2 \text{ w} \qquad [9]$$

For beam energies of the order of 10 kw, this loss becomes important when l exceeds say 0.1 cm. In the case of vacuum welding the pressure in the hole is only about ¼ atm (1), and W_{II} is correspondingly decreased.

We now recognize two possible cases: when $W_{II} < W$ and when $W_{II} > W_I$. In the former case the energy balance is

$$W_I = W - W_{II} \qquad [10]$$

where W_I is determined by conduction and proportional to the depth of penetration. The vapor loss W_{II} is proportional to l^2 or the cross-sectional area of the hole. It is thus advantageous to keep l^2 as small as possible.

The factors which control l^2 are obscure, but the minimum requirement is a narrow beam, for l cannot be less than the beam diameter. Another requirement is that the beam does not wander, and that it is not broadened by atmospheric scattering. Alternatively it is desirable to have a large beam power. Inasmuch as it is difficult to concentrate a large beam power into a small area, the condition

$$W > W_{II}$$

is equivalent to a requirement on the beam power density, namely

$$\frac{W}{l^2} > 5 \times 10^{-7}\, C\, v\, T_v^2 \qquad [11]$$

which is the harder to fulfill, the greater the vaporization temperature of the material.

In the typical case quoted above, the critical beam power density below which substantial penetration is certainly impossible is 80 kw/cm^2. In actual practice the beam power density should exceed this value by a substantial factor.

If $W < W_{II}$, we have different conditions altogether. The beam does not drill a deep hole, but eats its way into the material gradually, leaving a relatively wide depression. No vapor cloud forms in that depression, but material is removed until D is comparable to l. Further penetration is governed by the speed with which material can evaporate from a liquid surface of area l^2 kept at some temperature intermediate between the melting temperature T_m and the vaporization temperature T_v. The temperature reached in the steady state depends on the power density W/l^2. Furthermore, since a large amount of liquid is present, the progress of the erosion will depend on how that liquid will flow and possibly refreeze; this in turn depends on the direction of gravity and on surface tension effects.

Moving Beam

It is generally observed that the depth of penetration is less for a moving beam than for a stationary beam, and that this depth decreases as the forward speed of the beam is increased. This is readily understood as a consequence of the additional energy requirement of moving the beam. Since heat is left behind in the wake of the moving beam, less heat needs to be conducted away, so that the penetration decreases.

As the beam is moved forward, material has to be melted at the front of the beam, and material resolidifies at the back. The heat required to do so consists in part of heat required to raise the temperature of the material to T_m, and in part of the latent heat of melting. The latent heat of melting is given up and, as we may assume, completely regained at the back face where the liquid metal resolidifies. The moving hole leaves behind a wake of heat. Originally this heat was concentrated in a small region immediately behind the hole, at a temperature T_m. The fact that it subsequently spreads out does not affect the amount of heat involved. The additional heat required to move the hole is therefore

$$W_{III} = D\, l\, V\, C\, T_m \qquad [12]$$

where D is the depth of the hole, l its diameter, V the forward speed of the moving beam, C the heat capacity per unit volume, and T_m the melting temperature.

The energy balance is now

$$W = A_1 D + A_2 + A_3 D V \quad [13]$$

where $A_1 D$ is W_I of Eq. [2], A_2 is W_{II} of Eq. [6], and $A_3 DV$ is W_{III} of Eq. [12]. The depth of penetration is now given by

$$D = \frac{W - A_2}{A_1 + A_3 V} \quad [14]$$

and in the stationary case

$$D_o = (W - A_2)/A_1 \quad [15]$$

which is given by Eq. [10] and [3] as

$$D_o = \frac{2W - l^2 V\, C\, T_v\, d/d_o}{\pi\, \kappa\, T_m} \ln\left(\frac{2D_o}{l}\right) \quad [16]$$

Strictly speaking, A_1 is not quite constant because it contains the factor $\ln(2D/l)$, but we may approximate this by $\ln(2D_o/l)$, since it varies only relatively weakly.

While [14] and [15] give the magnitude of D and the manner in which it decreases with speed V, it is also of interest to consider the speed V_c for which the penetration is halved. From [14] we obtain

$$V_c = \frac{A_1}{A_3} = \frac{2\pi\,\kappa}{C\, l \ln(2D/l)} \quad [17]$$

In most cases when $\ln(2D/l) = \ln(D_o/l) \simeq 3$

$$V_c = \frac{2\pi\kappa}{3Cl} \quad [18]$$

In the case of a typical metal for which $\kappa/C \simeq 1$ cm^2/sec, taking $l = 0.2$ cm, one finds

$$V_c = 10 \text{ cm/sec} = 240 \text{ in./min.}$$

In stainless steel for which $\kappa/C = 0.04$ cm^2/sec

$$V_c = 0.4 \text{ cm/sec} = 10 \text{ in./min.}$$

In the case of a poor thermal conductor such as concrete, where $\kappa/C = 0.005$ cm^2/sec,

$$V_c = 0.05 \text{ cm/sec} = 1.3 \text{ in./min.}$$

Experimental data on concrete (5) indicate that half the penetration is lost at a forward speed of about 2.5 in./min. The order of magnitude of the agreement is satisfactory; the discrepancy may be due to a number of factors, in particular the crudeness of our theory, but also the variability in the thermal diffusivity of concrete.

Determination of Thermal Diffusivity

The fact that the penetration of the electron beam decreases with forward speed in a manner which depends on the thermal diffusivity of the solid material makes it possible to measure the thermal diffusivity by means of an electron beam. One would have to measure the penetration at two or more forward speeds and determine V_c from the relation

$$D = D_o\,[1 + V/V_c]^{-1} \quad [19]$$

If one also measures the diameter of the cut, l, one can calculate the thermal diffusivity κ/C from [18], or better still, from [17].

The interesting point is that this method of determining κ/C does not depend on the detailed assumptions which we have made. All which is really required is that thermal conduction is the only heat loss mechanism which depends on D, and that the other mechanisms (vapor flow, *etc.*) are independent of D. Then an energy balance equation of the form [13] holds, and V_c is independent of A_2.

If the thermal diffusivity depends on temperature, this method will yield the diffusivity in the vicinity of the melting temperature T_m. Since thermal diffusivity measurements at elevated temperatures are notoriously difficult to carry out, and subject to large and incompletely understood errors, the electron beam method may well be competitive with other methods. Basically, this method is equivalent to a transient method involving a line source of heat, but it avoids the use of thermocouples embedded in the solid.

It would be interesting to attempt quantitative measurements of thermal diffusivity on materials of known properties.

Some Further Problems

Although the present considerations do give an over-all description of the beam penetration which seems to agree with what has been observed, at least in some cases, there are a number of questions which have yet to be answered.

The most important question is to determine the factors which govern the "key-hole" diameter l, an important parameter in our considerations. Clearly the beam diameter sets a lower limit to l, but there could be mechanisms which tend to make l wider than the beam diameter.

A second question is whether the hole is really of uniform diameter and whether the temperature within it is uniform. This has been assumed in our considerations, and although the heat conducted away is not very sensitive to variations in diameter along the length of the hole, there is a need to investigate the mechanism of hole formation in greater detail.

Perhaps the greatest need is to find out what happens when the hole is relatively wide and thermal conduction is only a minor mechanism of heat transport. In that case the present considerations are inapplicable (except possibly that the variation of depth with forward speed is still given correctly). It is unlikely that a simple answer exists in this case but further investigations are clearly needed.

Manuscript received Jan. 24, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 144.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

An Investigation of the Differences Between NaCl and $NaClO_3$ as Electrolytes in Electrochemical Machining

James P. Hoare,* Mitchell A. LaBoda,*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

Constant potential polarization curves were obtained on steel rotating disk anodes in concentrated NaCl and $NaClO_3$ electrolytes, and steady-state polarization curves were obtained on stationary soft iron anodes in NaCl, $NaClO_3$, $NaNO_3$, and $Na_2Cr_2O_7$ solutions. The results show that the metal removal reaction is activation controlled and that $NaClO_3$ electrolytes are reduced to NaCl with extended periods of electrochemical machining. Tests conducted in a flow system showed that up to 50 g/l of NaCl could be tolerated in a concentrated $NaClO_3$ electrolyte (350 g/l) before the excellent machining properties of the electrolyte become impaired. Wild cutting electrolytes (NaCl) do not form protective films on ferrous metals, whereas noncutting electrolytes ($Na_2Cr_2O_7$) form too highly protecting films of γ-Fe_2O_3. The good dimensional control is obtained with electrolytes ($NaClO_3$) which behave in an intermediate way and possess a sharp transition from the passive to the transpassive state.

For a number of years, electrochemical machining (ECM) has been known as a highly effective metal removal method for machining hardened metals at high metal removal rates without producing process-induced stresses and wearing of the machining tool. Until recently, development of ECM as an industrial process has been slow because of the lack of dimensional control when NaCl, $NaNO_3$, or acids were used as the electrolyte. Most developmental efforts (1) have been aimed at improvements in the use of NaCl electrolytes without the required success necessary for industrial usage.

Operating with the concept that satisfactory dimensional control necessitated the uncovering of a new electrolyte, LaBoda and co-workers (2), after an intensive screening effort, reported that $NaClO_3$ electrolyte possesses excellent ECM properties. Metal removal rates were obtained as high as 0.001 in./sec for a hardened Carpenter Ni-Cr steel having a Rockwell hardness of 60C and the finish of the machined surface measured from 1 to 5 μin.

To understand the nature of the processes taking place in the ECM operation, an intense, comprehensive investigation of ECM systems is being carried out at the General Motors Research Laboratories. This report describes the results of some of these studies.

Experimental

Because the experimental conditions for actual ECM (high flow rates, high currents, small distance between anode and cathode, among others) are very complex, the only hope for obtaining meaningful data on such a system is to design experiments in which a minimum number of uncontrolled parameters exist.

Rotating disk studies.—Since the ECM processes take place under conditions of high flow rates of electrolyte, a study of the corrosion process using the controlled hydrodynamic conditions of the rotating disk (3) was carried out.

The rotating disk was made by potting a rod (0.3 cm in diameter) of 5160 steel hardened to Rockwell 60C in epoxy and grinding the face of this assembly to expose a circular area of the steel to the electrolyte. Rotational speeds between 160 and 7550 rpm were employed. A saturated calomel electrode (SCE) served as a reference electrode and a copper cylinder (0.318 cm in diameter) was the counter electrode.

After the anode and cathode were ground, polished and anodically cleaned, the electrodes were mounted in the glass cell shown in Fig. 1 and the anode and cathode were spaced to the desired distance by Lucite spacers. Anodic polarization curves were taken potentiostatically in NaCl (250 g/l) and $NaClO_3$ (350 g/l) electrolytes. Vacuum fusion, electron probe, and electron diffraction techniques were used to study the steel surfaces electrochemically machined in both NaCl and $NaClO_3$ electrolytes.

* Electrochemical Society Active Member.
† Electrochemical Society Student Member.

With the controlled hydrodynamic conditions obtained with the rotating disk technique, an analysis of the system for Cl^- and ClO_3^- ion for a given amount of iron machined was carried out to help answer questions about what happens during ECM over extended periods of time. In this case the rotating disk was composed of a 5160 steel rod insulated from the electrolyte with stopoff tape and held in a neoprene stopper. As the rod was progressively machined away, the experiment was halted and the rod was repositioned in the stopper to expose an additional amount of the rod.

Exactly 3.50 liters of $NaClO_3$ solution (600 g/l) were placed in the cell and the rod was machined at about 35 amp/cm^2 (from a 115v, 15-amp power supply) at 7000 rpm. The amount of charge passed was determined with an electronic coulometer. Samples of the electrolyte were taken at various times by halting the experiment long enough to allow the sludge to settle. At the end of the experiment, the remaining electrolyte was filtered and both the filtrate and sludge were analyzed to obtain an over-all material balance. The Cl^- ion was analyzed by titration with $AgNO_3$ (4) and ClO_3^- ion was reduced with excess $FeSO_4$ and back-titrated with $Na_2Cr_2O_7$. In addition, the sludge was also analyzed for Fe using the Zimmermann-Reinhardt method (6), and for H_2O by weight loss after drying in an oven. The entire cell was thermostated to room temperature by immersion in a large water bath.

Test panel studies.—Since the analytical results indicated that the ClO_3^- ion was degraded to Cl^- ion with time, it seemed desirable to study the effect of the presence of Cl^- ion in the $NaClO_3$ electrolyte on the ECM properties. For this study, a flow system (Fig. 2) was used consisting of a centrifugal pump, a solution reservoir, and a cell fixture (Fig. 3). The cell was a circular cavity (2.5 cm in diameter and 1.15 cm deep) in one side of an epoxy block (5 x 5 x 7 cm) into which extended a copper tube which served as the cathode. The anodes were test panels (2.5 x 7.5 x 0.062 cm) of 1008 steel which were held in place over the face of the cell with a neoprene gasket and Lucite end plate so that the initial gap space between the test panel and the copper tube cathode was 0.0507 cm. After the test panels were cleaned, dried, weighed, and anodically activated, they were electrochemically machined for 1 min at 62 amp/cm^2 at 25°C with an electrolyte flow rate of 4.5 l/min. At the end of each run, the panels were rinsed in water, dried, and reweighed. Each test was run in triplicate.

A topographic microscope (7) was used to examine the profile of the panel surface after ECM. As noted in Fig. 4, the high current density (hcd) region on the panels is an annular ring opposite the annulus of the copper pipe cathode. In $NaClO_3$ solutions virtually all of the metal removal took place in the hcd region.

As NaCl was added to the $NaClO_3$ electrolyte, the anode surface was examined in the low current density (lcd) region for any attack of the surface outside of the hcd region. In one group of experiments, the $NaClO_3$ concentration was held constant at 350 g/l while the NaCl concentration was increased from 0.5 through 15, 30, 45, 60, and 100 to 150 g/l. In a second set of experiments, the ionic strength was kept constant by lowering the $NaClO_3$ concentration by the required amount as the NaCl concentration was increased.

Steady-state polarization studies.—Because the rotating disk studies indicated that the corrosion process at the anode surface was activation controlled, potentiostatic polarization studies were carried out on the more convenient stationary bead electrodes with better control of the parameters affecting the electrochemical properties of the system. From an observation of the curves obtained earlier (2), it was decided that a more careful determination of the polarization curves was required to help in the understanding of the passivating nature of these electrolytes. Since it was observed in the actual ECM operation, for a given set of experimental conditions, that $NaClO_3$ gave excellent dimensional control, $NaNO_3$ gave relatively good control, NaCl gave serious wild cutting, and Na_3PO_4, Na_2CO_3, and $Na_2Cr_2O_7$ gave no cutting at all, these steady-state polarization studies were undertaken to shed light on the ECM behavior of these electrolytes.

To remove any complicating influence of nonferrous components in the anode metal, anodes were fashioned in the form of small beads (~0.13 cm in diameter) melted at the end of soft iron wires plated with soft iron. The iron bead was held in the reducing part of a burning H_2 jet for a few minutes to reduce surface oxides. Tight-fitting Teflon spaghetti was slipped over the wire and pressed against the base

of the bead. Then the bead was imbedded in molten polyethylene so that only a hemisphere of the bead was exposed (8). After mounting three beads in a clean Teflon dual cell (9), they were soaked in triply distilled water for about 24 hr with numerous changes of water to leach out impurities in the system.

The test solutions (made from reagent grade chemicals) were as follows: $NaClO_3$, 350 g/l; $NaNO_3$, 350 g/l; NaCl, 275 g/l; $Na_2Cr_2O_7$, 100 g/l. In a second clean Teflon cell which held about 12 cc of solution, the given electrolyte was preelectrolyzed between removable Pt electrodes for 16 hr. By withdrawing the Pt preelectrolysis electrodes, the circuit was broken and any H_2O_2 formed was removed by saturating the solution with hydrogen gas. A large Pt gauze was used as the counter electrode and a SCE as the reference electrode. After the solution was saturated with nitrogen, the iron test electrodes were removed from the first cell and sealed in the test compartment of the second cell.

The polarization curve was obtained by determining the steady-state current on a Keithley electrometer, Model 600A, and recorded on a Honeywell strip recorder for the stepwise increases and decreases in the potential controlled by a Wenking 61R potentiostat. Although the steady-state value was reached within a few minutes in most cases, periods of time up to 25 min were required in some regions. The solution was stirred by bubbling either purified N_2 or O_2 through the test compartment at a rate of at least 300 cc/min to minimize mass transfer effects, and the temperature was 25° ±1°C.

Results

Rotating disk studies.—A plot of the potential of the steel anode as a function of the log of the apparent current density for various speeds of rotation of the disk in both NaCl and $NaClO_3$ solutions is given in Fig. 5. It is seen that over the range of rotational speeds studied virtually no effect of the rate of rotation was observed on the polarization curves.

Table I contains the results of the analysis for Cl^- ion and ClO_3^- ion for extended periods of ECM in $NaClO_3$ solutions. It is seen that the amount of Cl^- ion builds up in solution while the ClO_3^- ion concentration decreases during the ECM process. There is a linear relationship between the grams of metal removed and the buildup of NaCl in solution as well as between the moles of iron machined and the moles of $NaClO_3$ reduced. The average value of the moles of iron machined to the moles of $NaClO_3$ reduced is 3.95.

The possibility that the reduction of ClO_3^- ion to Cl^- ion takes place at the cathode is the subject of current investigations and is not considered further in this report.

Both vacuum fusion and electron probe analyses indicated a high percentage of oxygen on the surface of disks machined in $NaClO_3$ but none on the surface of those machined in NaCl. Reflection electron diffraction studies confirmed these findings by detecting a film of γ-Fe_2O_3 on specimens machined in $NaClO_3$ but not on those machined in NaCl.

Test panel studies.—The results of these studies are given in Table II and Fig. 6. With NaCl concentrations below 50 g/l in either group A or B tests, the weight of metal removed did not sensibly change compared to the results from the pure $NaClO_3$ control solution. Above 50 g/l of NaCl, the weight of the metal removed increased with each addition of NaCl to the electrolyte but was independent of the amount of $NaClO_3$ in solution. Also associated with the increased metal removal due to the increased NaCl concentration is the

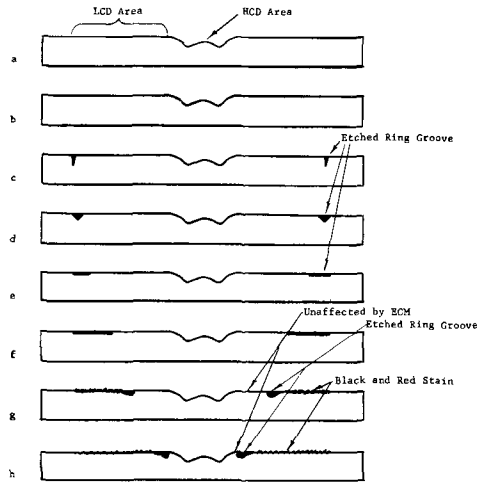

Fig. 6. Profile of hcd and lcd areas after electrochemical machining in a 350 g/l $NaClO_3$ solution with: (a) 0 g/l NaCl, (b) 0.5 g/l NaCl, (c) 15 g/l NaCl, (d) 30 g/l NaCl, (e) 45 g/l NaCl, (f) 60 g/l NaCl, (g) 100 g/l NaCl, and (h) 150 g/l NaCl.

increasingly larger surface area attacked during the ECM process.

Steady-state polarization studies.—A summary of the typical results obtained on soft iron in the various electrolytes is displayed in Fig. 7. Open symbols represent the data for increasing potentials and filled symbols for decreasing potentials. Repeated cycles of polarization gave virtually the same results. All curves shown were obtained in O_2-saturated solutions except one in N_2-saturated $NaClO_3$ solution (x's in Fig. 7). The N_2 and O_2 curves were similar, but the currents in general were lower in the case of N_2-stirring.

A vertical dashed line is drawn arbitrarily at 10 ma/cm² to correspond to the region in which the ECM process takes place. It must be kept in mind that the potentials recorded in Fig. 7 are referred to a reference electrode and are not the total cell potentials commonly reported in the ECM literature. How the potentials in Fig. 7 are related to the reported ECM cell potentials is not important to this discussion since the relative shapes of the polarization curves are the matters of interest.

Discussion

From the rotating disk studies, it is seen that the metal removal process under these conditions is activation controlled rather than limited by a mass transfer step.

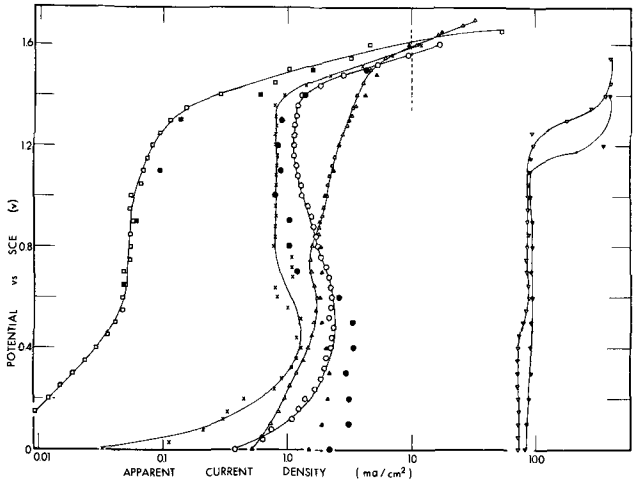

Fig. 7. Steady-state potentiostatic polarization curves of soft iron in concentrated solutions of the following electrolytes: ○, ● — $NaClO_3$; △, ▲ — $NaNO_3$; ▽, ▼ — NaCl; □, ■ — $Na_2Cr_2O_7$. Open symbols indicate data for increasing potentials; filled, for decreasing potentials. All of these solutions were saturated with O_2. A curve in N_2-saturated $NaClO_3$ solution is shown by the x's.

The data of Table I show that $NaClO_3$ is reduced to NaCl with extended periods of ECM operation and the test panel studies confirm that the presence of NaCl in $NaClO_3$ electrolytes produces unacceptable wild cutting above a certain limiting concentration (50 g/l). Since a film of γ-Fe_2O_3 is detected on the surfaces of test samples machined in $NaClO_3$ but not in NaCl electrolytes, it appears, at first sight, that the presence of an oxygen-containing anion (or good oxidizing agent) is required for the electrolyte to have acceptable ECM properties. However, this cannot be the complete story, because electrolytes based on chromates, phosphates, or carbonates produce no cutting under the conditions where $NaClO_3$ gives excellent cutting. Results of the steady-state polarization studies provide data from which a possible explanation for these findings may be made in the light of accepted theories of passivation (10).

Consider first the curve for $NaClO_3$ (circles in Fig. 7). At the lowest potentials, the system is active, and Fe goes into solution as Fe^{++} ions which can then be oxidized by dissolved oxygen to Fe^{+++} ions (11). As the potential becomes more noble, the current increases until a critical current is reached, after which the surface becomes passivated by the formation of a film of γ-Fe_2O_3 and the current falls to smaller values. At still more anodic potentials, the film breaks down, the system becomes transpassive, and the current (rate of reaction) increases rapidly. It is assumed that ECM cutting takes place in this transpassive region.

As a typical example of electrochemical machining (2), currents of the order of 300-1200 amp/in.² were passed between the work sample (anode) and the tool (cathode) at cell potentials between 12 and 15v. With such enormous currents, the iR drop across the anode-cathode gap may assume large values. As machining takes place, the gap between the anode and the exposed face of the tool increased with a resultant increase in iR drop. Consequently, the potential of the surface of the worked piece falls to less noble values where cutting does not occur. Since the difference between cutting and not cutting takes place over a very short gap length, the machined surface is a faithful reproduction of the tool giving the high precision recorded by LaBoda and McMillan (2).

In the case of the $NaNO_3$, which is known to cut with little wild cutting, the polarization curve (triangles in Fig. 7) is similar to the $NaClO_3$ curve except that the transition from passivity to transpassivity is not as sharp. As a result, cutting can take place over a wider gap distance, and the precision with $NaNO_3$ is not as good as with $NaClO_3$. In the transpassive region, the $NaNO_3$ curve lies at more noble potentials than does $NaClO_3$. For a given potential, the rate of cutting (current density) is less for $NaNO_3$ than for $NaClO_3$, in agreement with the observation that $NaNO_3$ cuts slower than $NaClO_3$.

The steady-state polarization curve for NaCl (inverted triangles in Fig. 7) lies in a current density range nearly two orders of magnitude higher than that for $NaNO_3$ and $NaClO_3$. Since cutting can occur even at the lowest potentials given in Fig. 7, the gap space over which cutting is permitted in this case is very large. As reported (2), the undesirable wild cutting obtained with this electrolyte produces a complete lack of dimensional control.

After the polarization curves were obtained, the cell was opened and the electrolyte examined. With $NaNO_3$ and $NaClO_3$, the beads were black or had areas of red rust on them. Rust in the solution was not soluble, so that if the solution was filtered, the filtrate was colorless. With NaCl, the beads were light gray, and the solution was clear but yellow colored. In the NaCl electrolyte, a soluble iron salt is formed instead of a protective film of γ-Fe_2O_3 in the cases of $NaNO_3$ and $NaClO_3$; and this situation keeps iron in a highly active state even in regions of high potential. To have good

Table III. Rest potentials on soft Fe in O_2-saturated, concentrated salt solutions

Salt	Concentration (g/l)	Potential vs. SCE (mv)	Remarks
NaCl	275	−590	Wild cutting
$NaNO_3$	350	−480	Good cutting
$NaClO_3$	350	−350	Excellent cutting
$Na_2Cr_2O_7$	100	−140	No cutting

dimensional control, the electrolyte must passivate the iron surface at potentials below cutting, and the polarization curve must exhibit a sharp transition from the passive to the transpassive region.

To obtain a suitable ECM electrolyte, these data predict that an oxygen-containing anion is a necessary prerequisite to produce the passivating film required for dimensional control. The chromates appear to be likely candidates since a protective film of γ-Fe_2O_3 is formed on Fe in these electrolytes (*e.g.*, 12, 13). However, a solution of $Na_2Cr_2O_7$ did not produce any cutting in the potential range where $NaClO_3$ cuts.

Examination of the steady-state polarization curve obtained in $Na_2Cr_2O_7$ (squares in Fig. 7) shows that the Fe is so well protected that the curve is shifted to current densities about two orders of magnitude lower than those in $NaClO_3$. Although a sharp transition from the passive to the transpassive region exists, the transpassive region for $Na_2Cr_2O_7$ still lies at higher potentials than that for $NaClO_3$. In practice, it is found that cutting with poor surface finishes due to sparking can be obtained with $Na_2Cr_2O_7$ at much higher potentials (above 30v).

Other passivating electrolytes, such as Na_2CO_3 and Na_3PO_4, do not give any cutting. It is likely that their polarization curves are similar to the $Na_2Cr_2O_7$ curve because these electrolytes produce highly protective films of γ-Fe_2O_3 (14, 15).

There is an interesting correlation between the rest potential in O_2-saturated solutions and the ECM properties as shown in Table III. The potentials are the average of three independent determinations. As the potential becomes more noble, one progresses from wild cutting through good dimensional control to no cutting. This correlation, of course, is related to the passivating nature of the electrolyte since the test potentials are mixed potentials (16, 17).

By comparing the polarization curves for Fe anodes in O_2- and N_2-saturated $NaClO_3$ solution, it is seen that the presence of O_2 increases the current density.

Apparently, $NaClO_3$ electrolytes occupy a privileged position. Their polarization curves not only have the sharp transition from the passive to the transpassive region of the highly passivating electrolytes but also have transpassive regions lying at the least noble potentials.

ABSTRACT

An outline is given of an electrolytic process for the production of sodium perchlorate using a pure lead dioxide anode. In this process, a saturated solution of sodium chlorate is electrolyzed batchwise at an anodic current density of 25 amp/dm² at 50°C; current efficiency, about 70% with more than 99% conversion of chlorate to perchlorate; cell voltage, 4.5-5.0v. The process has been operated successfully for more than two years without renewal of the anodes. In relation to the above, the results of basic research on anode potential and current efficiency for perchlorate formation from chlorate are also given.

Although we had perfected a new electrolytic process of producing perchlorate using lead dioxide as the anode about two decades ago in both the laboratory and on a semicommercial scale (1), production using the new process was not carried out in Japan until 1965, when Sanwa began to produce perchloric acid with this process. The principal reason for the delay was the small demand for perchlorate in Japan after the war. When the Pacific Engineering Company of the United States started to produce perchlorate using a lead dioxide anode, we decided to put our

* Electrochemical Society Active Member.

process in practical use. Because of the small demand for perchlorate, we constructed a small-sized perchlorate plant to produce perchloric acid as the final product. This report mainly describes the outline of the process operated in Sanwa Chemical's plant.

Basic Research on Anode Potential and Current Efficiency for Perchlorate Production from Chlorate

In 1953 one of the authors (K. Sugino) and Dr. S. Aoyagi presented a paper entitled "Mechanism of the Electrolytic Formation of Perchlorate" at the New York Meeting of the Society in which the current *vs.* potential curves for the anodic process of chlorate at platinum were shown. The results were subsequently published (2). The curves were obtained by a kind of polarographical technique at a platinum microanode. In a moderately concentrated solution of chlorate two stages of potential were definitely observed on the curves. In the first or lower stage, the potential was between 1.5-1.7v and in the second or higher stage, it was more positive than 2.1v (*vs.* SCE).

As a result of controlled potential electrolysis, it was clarified that the first stage was the potential of oxygen evolution and the second stage was the potential at which the formation of perchlorate occurred.

From the detailed experiments on the above phenomena, it was proved that the first step of this process is the direct discharge of ClO_3^- at a higher potential than that of oxygen evolution.

Recently, from a practical point of view, the current *vs.* potential curves for perchlorate formation were again measured at the platinum and at the lead dioxide anodes by one of the authors (T. Sekine) and his collaborators by using controlled potential electrolyzer (3). They are shown in Fig. 1 and 2.

At the platinum anode curves similar to those of Sugino and Aoyagi were obtained and two potential stages were clearly observed. On the other hand, at the lead dioxide anode, the curves did not indicate such stages. They showed a steep increase of current at around 1.8-1.9v (*vs.* SCE) and were observed as a simple exponential relationship. However, as shown in Fig. 3, when the chlorate solution of *p*H 11.4-12.0 was used, curves having two potential stages were obtained and the lower stage was found to be the potential of oxygen evolution. Accordingly the potential at which the current began to flow in Fig. 2

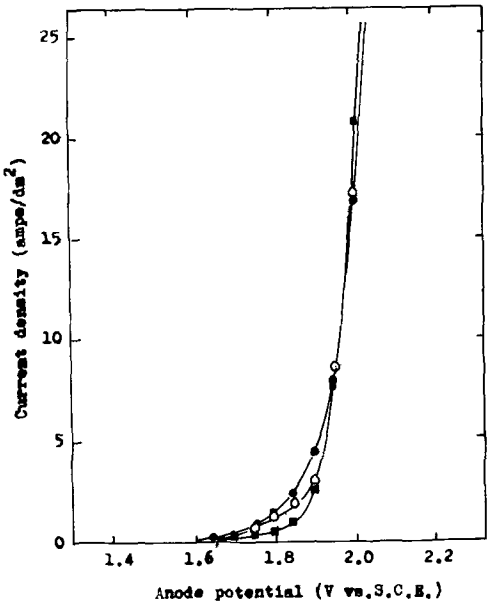

Fig. 2. Current *vs.* potential curves at lead dioxide anode in various concentrations of chlorate solution. ●, $NaClO_3$, 1 mole/l; ○, $NaClO_3$, 3 mole/l; ■, $NaClO_3$, 6.4 mole/l (saturated solution).

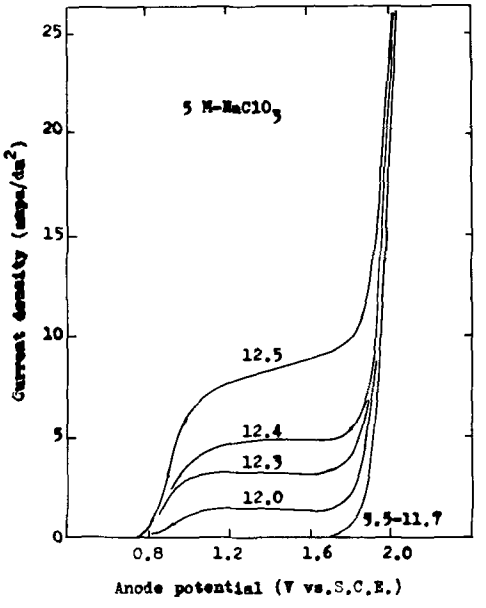

Fig. 3. Current *vs.* potential curves at lead dioxide anode in chlorate solution of different *p*H.

indicated the potential of perchlorate formation at the lead dioxide anode.

The mechanism of perchlorate formation at the lead dioxide anode may be somewhat different from that at the platinum anode. It is presumed to be due to the simultaneous discharge of ClO_3^- and OH^-, followed by the combination of the radicals formed. This was proposed as a possible route by Sugino and Aoyagi in the paper described above.

It was found that the potential at which the current corresponding to perchlorate formation began to flow was about 0.25v lower than that at the platinum anode in the same concentration. In addition, the increase of anode potential with increasing current density was very small up to high current density such as 30 amp/dm^2, but at the platinum anode, the potential increased steadily with increasing current density as shown in Fig. 1. This is an interesting characteristic of the lead dioxide anode and it is the main reason for the smaller cell voltage than that at the platinum cell, especially at high current density.

Table I. Bench scale experiment*

Anode	Lead dioxide
Cathode	18-8 stainless steel
Electrolyte	Saturated solution of $NaClO_3$ containing 2 g/l of NaF
Current	600 amp
Current density, anodic	20 amp/dm²
Temperature	50°C
Conversion	99.5%
Current efficiency	72%

* Data from ref. (1).

It was thought for a long time that the current efficiency for perchlorate formation from chlorate at the lead dioxide anode was not so high when the electrolysis was continued until almost all the chlorate was converted to perchlorate, although a high value could be expected as an instantaneous current efficiency. Therefore, about 2 g/l of sodium fluoride were added to the cell liquor to maintain the over-all current efficiency above 70%. Thus, one of the authors (K. Sugino) and his collaborators reported about 80% current efficiency in a laboratory cell and 72% current efficiency in a 600 amp cell when more than 99% of chlorate was converted to perchlorate (4) as shown in Table I. These results were later confirmed by Schumacher *et al.* (5).

Recently one of the authors (T. Sekine) carried out a detailed study on the current efficiency for perchlorate formation at the lead dioxide anode. From the results, it seems that a high current efficiency could be obtained at the lead dioxide anode without any additive such as sodium fluoride. A few examples are shown below:

Results of controlled potential electrolysis.—Electrolyses at the lead dioxide anode were carried out in various concentrations of chlorate solution (1-6M $NaClO_3$) at a certain potential in the range of 1.85-2.10v (*vs.* SCE). The examples with 6M solution are condensed in Table II. In the table about 90% (87-89%) of current efficiency was marked at the potential of 1.90-2.10v (*vs.* SCE), without addition of sodium fluoride in the electrolyte in the initial stage of electrolysis.

Combining the above results with those obtained at the platinum anode, the influence of anode potential on the current efficiency in 5M solution, for instance, is shown in Fig. 4. From the curve, it is also clear that the potential corresponding to the formation of perchlorate at the lead dioxide anode is about 0.25v more negative than that at the platinum.

Results of almost complete conversion of chlorate to perchlorate by constant current electrolysis (6).—The current efficiencies for perchlorate formation are shown in Table III when more than 80% of the chlorate is converted to perchlorate. A decline in current efficiency was observed in the final stage of electrolysis as shown in the table. The results indicate that with lead dioxide a current efficiency of 65-70% was obtained even when about 99% of chlorate was converted to perchlorate.

However, it should be pointed out that commercial chlorate contains a very small amount of bichromate as a contaminant. As shown in Table III, in the case of the lead dioxide anode, it was found that this contaminant showed a strong negative effect on the current efficiency. It was also found that the addition of sodium fluoride partly compensates the negative effect of bichromate thus contributing to maintain a high current efficiency. Accordingly we are still using this additive.

In regard to the effects of temperature on current efficiency, a remarkable difference was found between platinum and lead dioxide. In the case of platinum, it has been reported that the current efficiency increases with lower temperature. On the other hand it was found that in the case of lead dioxide the current efficiency increased with higher temperature as shown in Fig. 5. This may be a phenomenon suitable from a practical point of view. However, we had operated at 50°C considering another mechanical factor.

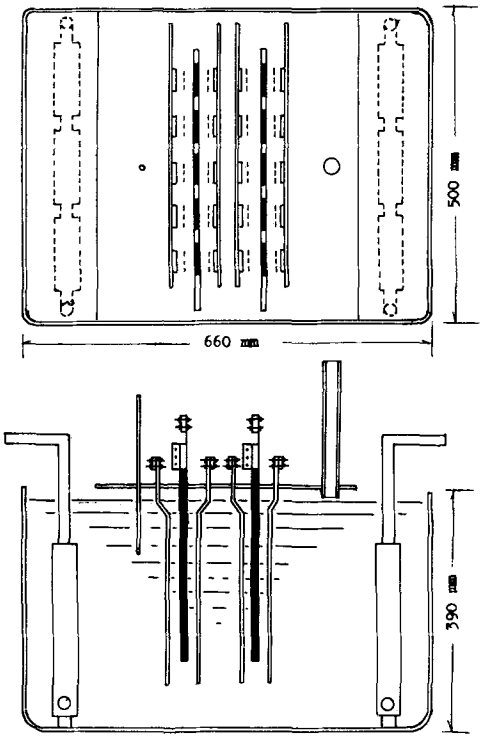

Fig. 6. Cell design

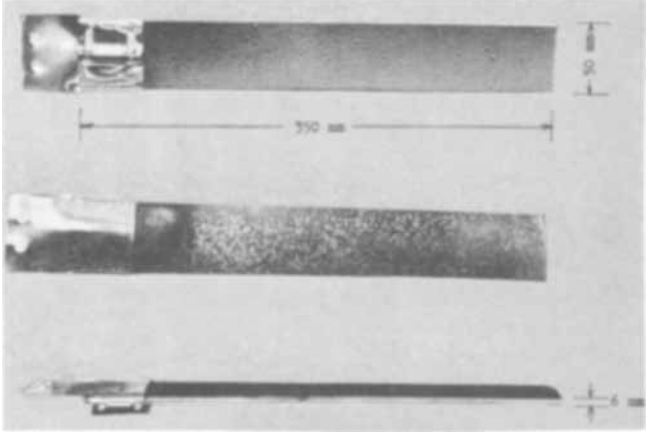

Fig. 7. Lead dioxide anode

Cell Design

The Sanwa perchlorate cell now used is almost the same as that being used in the production of bromate (7). Figure 6 is a diagram of the Sanwa perchlorate cell showing construction and dimensional features.

The cell body is constructed of a sheet iron rectangular tank 660 mm long x 500 mm wide x 390 mm high. The inside surface of the body are all lined with hard polyvinylchloride sheet. A plate of the same hard polyvinylchloride is placed on top of the cell and supports 10 anodes and 20 cathodes. These are arranged in 6 rows running the length of the cover. Down the middle are two rows of 5 anodes and on either side of the rows is a row of 5 cathodes.

The lead dioxide anodes,[1] which are shown in Fig. 7, are 50 mm wide, 6-7 mm thick, and 350 mm long and extend about 65 mm above the cover. The stainless steel cathodes (18-8) are 35 mm wide, 3 mm thick, and 300 mm long. The distance from an anode to the nearest cathode is about 10 mm. Six stainless steel cooling boxes are placed in both ends of the cell and act somewhat as a cathode.

[1] The method used in making the lead dioxide anode was reported in the previous paper (7).

Hydrogen discharged at the cathodes caused sufficient circulation of the cell liquor. It was vented through the roof from each cell.

Although the present cell is operated in a 500 amp capacity, it is possible to bring it up to a 1000 amp cell by doubling the electrode assembly in the container.

A 5000 amp cell can be constructed by combining five unit cells lengthwise. Cells of larger capacities, some 10,000 amp, can also be constructed with lead dioxide anodes of the same size.

The Process

Each cell was filled with 85 liters of a solution of sodium chlorate nearly saturated. Its concentration was 736 g/l $NaClO_3$. To increase the current efficiency, 2 g/l of sodium fluoride was added to the cell liquor. The cells were operated batchwise and each portion of cell liquor was electrolyzed to a final chlorate content of 5-6 g/l before being discharged.

Cell temperature was kept as constant as possible ranging from 47° to 52°C. A current of 500 amp was carried by each cell.

The anodic and cathodic current densities were 25 amp/dm^2 and 35 amp/dm^2, respectively. Current efficiency averaged 70% or a little less based on the analysis of unconverted chlorate. The potential drop across each cell ranged from 4.5 to 5.0v (average 4.7v). Accordingly, energy consumption is estimated to be 3 kw-hr (d.c.) or a little more for each kilogram of sodium perchlorate.

The operation characteristics are listed in Table IV.

The process has been operated successfully for more than two years without renewal of the anodes. It indicated that the loss, if any, may be very small. However, an experiment was made to determine the loss of the anode by using a practical cell. The results are shown in Table V. Conditions of electrolysis are the same as in Table IV.

The data showed that practically no loss resulted after the anode had been used for about three months. A few anodes sustained a very small loss which averaged 8.1 mg/1000 amp-hr.

After electrolysis, the cell liquor was treated with a small amount of calcium chloride to remove fluoride. The resulting solution was then evaporated to a desired concentration. By cooling the concentrated solution at 20°C, about 75-80% sodium per-

Solid Electrolyte Coulometry; Silver Sulfide Bromide Electrolyte

John H. Kennedy and Fred Chen*

Department of Chemistry, University of California, Santa Barbara, California

ABSTRACT

The properties of a coulometer utilizing a highly conductive solid electrolyte have been investigated. The system consists of silver sulfide bromide as electrolyte, between a silver and a gold electrode. A new faster method of preparation for silver sulfide bromide was developd, and the conductivity was re-examined with measurements extending to −60°C. Coulombs of charge are recorded by plating silver on the gold electrode and then recovered by stripping the silver from the gold electrolytically. Under carefully controlled conditions more than 99% of the silver plated on the gold could be stripped off. However, long charging periods gave low results, while idle periods between charging and stripping gave high results.

In a recent paper, the properties of a new type of coulometer using a solid electrolyte were described (1). Silver halides have been found to be of interest as solid electrolytes because of their high conductivity. This conductivity could be increased by the addition of divalent impurities, *i.e.*, $S^=$ (2). More important, however, silver halides react with silver chalcogenides (3, 4), or with alkali halides (5, 6), to produce compounds with ionic conductivities $> 10^3$ higher than the conductivities of silver halides. The aim of this research is to study the properties of a coulometer using a solid electrolyte of high conductivity, specifically using silver sulfide bromide (Ag_3SBr). Although less conductive, Ag_3SBr was chosen over Ag_3SI because of the higher decomposition potential of bromide *vs.* iodide.

Experimental

Preparation.—Ag_3SBr has been prepared by mixing AgBr and Ag_2S (7) and this method (I) was used initially.

(I). Stoichiometric amounts of AgBr (Matheson, Coleman and Bell) and of Ag_2S (A. McKay Inc.) were mixed together and heated at 280°C for several weeks. X-ray powder diffraction patterns showed the absence of Ag_2S, after the mixture was heated for seven weeks.

The long heating time required and often inhomogeneous product led us to studying other possible methods including the following one based on coprecipitation.

(II). 100 ml solution of 1F Na_2S and 1F NaBr (or KBr) were mixed by pouring together into an empty beaker. The mixture was stirred for several minutes, after which 100 ml of 3F $AgNO_3$ was added. The precipitate formed was digested near the boiling point and then allowed to stand for 12 hr. After filtration, it was dried at 200°C for two days. X-ray powder diffraction patterns showed no Ag_2S present. Preparations normally contained some excess AgBr to prevent any presence of Ag_2S which is an electronic conductor.

Key words: coulometer; coulometry; electrolyte, solid; silver sulfide bromide; electrolytic integrator.

* Electrochemical Society Student Member.

For our electrochemical studies, the Ag_3SBr used was prepared by the new procedure (II), because the preparation time was considerably shorter.

Ag_3SBr was found to be stable to air and could be kept at room temperature. Like many silver compounds, it was unstable to light, with the formation of metallic silver. Metallic silver was also formed when Ag_3SBr was heated for long periods at > 200°C.

X-ray diffraction patterns.—For x-ray powder studies a Phillips Electronics X-ray diffraction unit No. 12045 was used with CuKα rays (1.54178Å) at 40 kv.

Values of crystal spacings found for Ag_3SBr were in good agreement with the values reported by Reuter and Hardel (8). The crystal structure of Ag_3SBr is a body center cube with silver atoms on the faces of the crystal. Ag_3SBr has an anti-perovskite structure with the bromine atoms in the corners of the cube and the sulfur atom in the center. The distance between the nearest silver atoms was 4.8073Å and the distance between the nearest bromine atoms was 6.7984Å.

Using Pauling's ionic radii values for Ag^+, Br^-, and $S^=$, the relative volume occupied by the atoms in the cube was 0.262. The large amount of void volume allows for the easy migration of silver ions.

Pellet preparation.—Pellets were prepared with a Perkin-Elmer evacuable die (186-0025), 0.5 in. diameter. As an example, 0.25g powdered silver was pressed at 6000 psi, followed by 0.5g silver sulfide bromide pressed at 6000 psi, and finally 0.5g powdered gold pressed at 6000 psi. The whole pellet was then put under vacuum for 5 min after which it was pressed at 60,000 psi and held under this condition for 1 min. The pressed silver and gold powders served as electrodes for the pellet, and the boundary lines between electrolyte and electrode have been found to be extremely sharp (1). The electrode area of the pellets was 1.27 cm^2.

The pressed material had a density of 6.22 g/cm^3 which is 95% of the theoretical density based on unit cell dimensions (6.52 g/cm^3).

For polarization and cyclic voltammetry studies, pellets with a silver reference electrode were used.

This reference electrode was prepared by cutting the silver electrode into two parts. One silver electrode was operated in the usual manner while the smaller section was used as a reference electrode. The electrode area of the gold electrode remained 1.27 cm^2 for these pellets, but the working silver electrode was approximately 1 cm^2.

Electrochemical measurements.—A Beckman Electroscan 30 was used for cyclic voltammetry and recorded charge-strip cycles at constant current. A Harrison 6112A DC power supply was used for residual current measurements. For long charge-strip cycles at constant current, a Bissett-Berman E-cell digital coulometer was used. A General Radio Inc. 1650A impedance bridge was used for resistance measurements. For studies at temperatures other than ambient, an Associated Testing Lab (SW-5101) Environmental Chamber was used.

Results and Discussion

Resistivity.—Resistance of Ag_3SBr pellets of various thickness were measured using 1000 cycles a-c signal. The resistance of the pellets was found to be proportional to the thickness of the pellets (Fig. 1). The intercept at zero thickness shows little, if any, contact resistance. The resistivity calculated from the slope was 80 ohm-cm at 25°C. This value is an order of magnitude smaller than the value reported by Reuter and Hardel (9). This difference may be attributed to the extremely low contact resistance of compressed powder electrodes.

Addition of AgBr to Ag_3SBr increased the resistance of the pellets proportionally to the amount of AgBr added, up to 20% per mole excess AgBr (Fig. 2). To avoid the possible presence of excess Ag_2S, which is an electronic conductor, most of the preparations contained some excess AgBr in the Ag_3SBr.

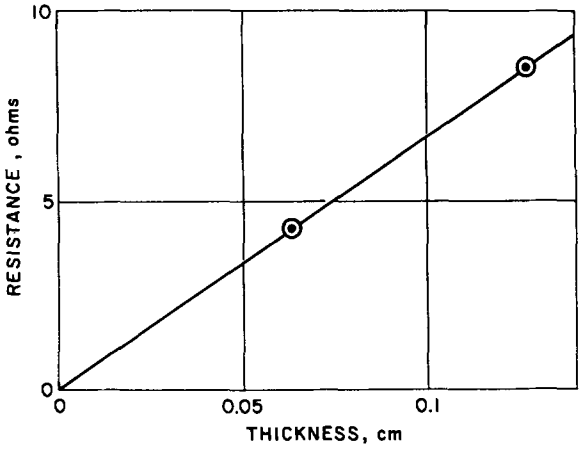

Fig. 1. Resistance of Ag_3SBr pellets

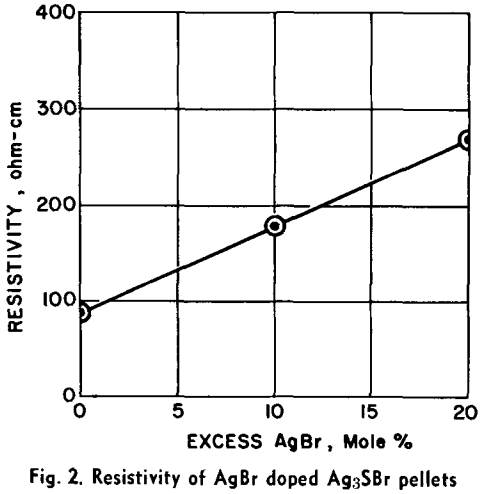

Fig. 2. Resistivity of AgBr doped Ag_3SBr pellets

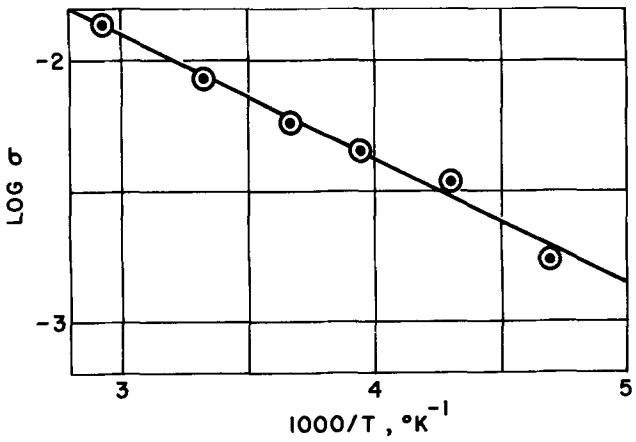

Fig. 3. Temperature dependence for Ag_3SBr conductivity

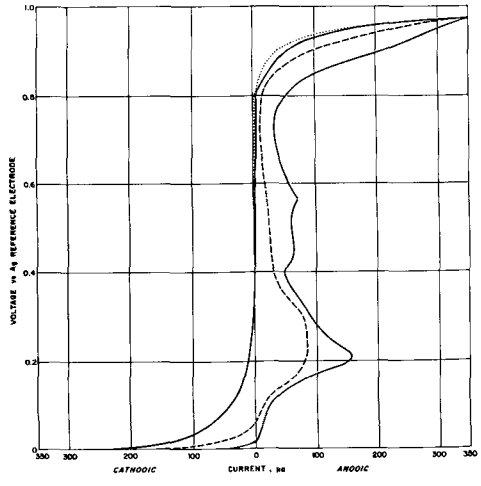

Fig. 4. Cyclic voltammetry of Ag_3SBr. Scan rate = 2 mv/sec; solid line — first sweep, anodic direction first; dashed line — second anodic sweep; dotted line — second cathodic sweep.

Grain boundary conduction, so important to AgBr (1), was not a factor for Ag_3SBr since annealing pellets at 150°C for seven days decreased the conductivity by only 10%.

The conductivity of Ag_3SBr as a function of temperature is shown in Fig. 3. The activation energy was found to be 4.3 kcal/mole. This activation energy is compared with other highly conductive solid electrolytes in Table I.

Cyclic voltammetry.—Cyclic voltammetry was used to examine the electrode reactions which took place on the gold electrode. The potential of the gold electrode was measured *vs.* the silver reference electrode. In general, one anodic peak was observed before the final cut-off, although small peaks between 0.4 and 0.6v were often observed on the first sweep only (Fig. 4). The main anodic peak was observed on the first and succeeding cycles and was about —0.2v *vs.* the silver reference electrode. This peak can be attributed to the following reaction

$$S^{=} \rightarrow S + 2e^{-} \qquad E^{\circ} = +0.203\text{v } vs. \text{ Ag ref.}$$

The final cut-off voltage is probably due to the following reaction

Table I. Activation energy for solid electrolytes

Compound	Activation energy, kcal/mole	Temp. range, K°	(Ref.)
Ag_3SBr	5.5	285-673	(9)
Ag_3SBr	4.3	213-343	Present paper
Ag_3SI	4.0	285-500	(7)
Ag_3SI	3.3	273-373	(4)
Ag_4I_5	2.3	323-523	(11)

$Br^- + Au \rightarrow AuBr + e^-$ $E^\circ = +0.834$v *vs.* Ag ref.

although two other reactions may proceed depending on reversibility and operating current density

$Br^- \rightarrow \frac{1}{2}Br_2 + e^-$ $E^\circ = +0.994$v *vs.* Ag ref.

$3Br^- + Au \rightarrow AuBr_3 + 3e^-$ $E^\circ = +0.910$v *vs.* Ag ref.

The peak positions (corrected for iR drop) were affected by scan rate indicative of irreversibility, and the cathodic reaction was not even observed in the reverse direction although it may have been masked by the reduction of Ag^+ at zero volts. The fact that sulfide can be oxidized at < 0.5v, but the reverse reaction does not proceed forms the basis for a positive error mechanism. It is also important to note that the peak is larger on the first sweep and recovers after a long waiting period.

Charge-strip curves.—The voltage drop during stripping of silver from the gold electrode should remain equal to iR until the gold surface becomes depleted of silver (1), at which time the voltage should rise until it reaches the Ag/Ag_3SBr, AuBr/Au potential plus iR. Figure 5 shows stripping curves for charges of 10 and 36 μa for 1000 sec. The gold surface had been oxidized to 0.5v *vs.* silver before plating. In both cases, the 0.5v end-point voltage was reached at 1000 $\pm$ 1 sec. A three electrode system showed that the end voltage was predominantly a potential developed at the gold electrode as it began to oxidize (Fig. 6).

During the charge cycle, the system is a silver-silver couple and the only voltage drop should be iR. However the voltage drop was higher because of polarization effects, and using a three electrode system, it was found to be predominantly on the silver electrode (Fig. 7). After long charging periods this polarization became significant and increased to the decomposition voltage of the electrolyte. Using a current interruptor circuit almost no change in resistance was found during the charge cycle.

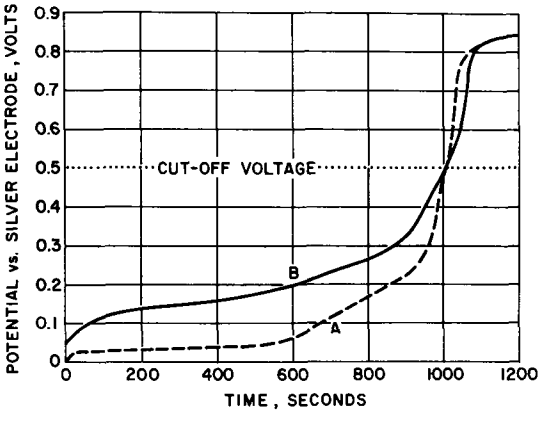

Fig. 5. Stripping curve for Ag_3SBr. (A) Charge: 1000 sec at 10 μa; stripping current: 10 μa; (B) charge: 1000 sec at 36 μa; stripping current: 36 μa.

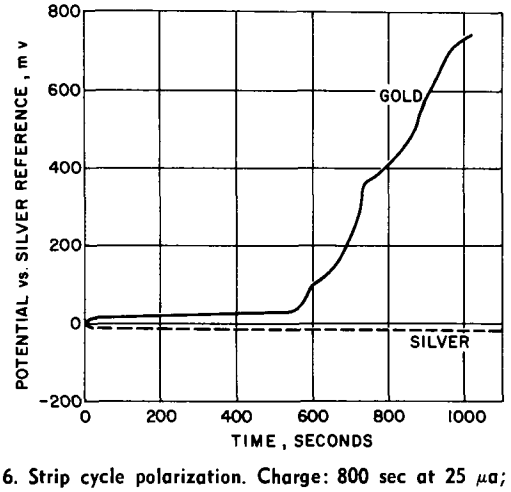

Fig. 6. Strip cycle polarization. Charge: 800 sec at 25 μa; stripping current: 25 μa.

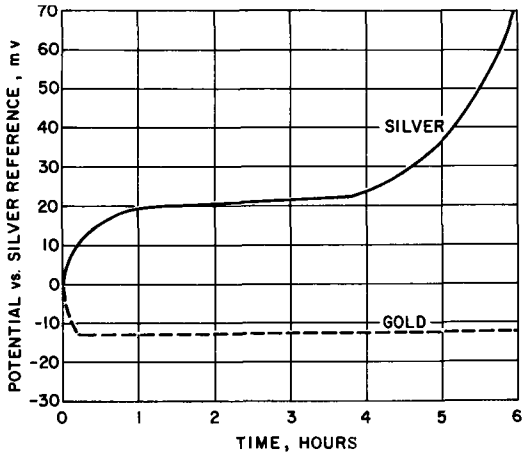

Fig. 7. Charge cycle polarization. Charge: 21,600 sec at 25 μa

Polarization.—The observed polarization (η) on the silver electrode during the charge cycle could be represented by Tafel's equation

$$\eta = a + b \log I$$

For charge, the values of a and b were 63 and 10.0 mv, respectively, and the exchange current density was 5×10^{-7} μa/cm^2.

This value for exchange current is much lower than the Ag/Ag^+ couple in an aqueous electrolyte and may be the result of electrode/electrolyte effects giving rise to much smaller effective areas. A similar situation was observed by Takahashi and Yamamoto (4) who decreased silver electrode polarization by using a silver amalgam electrode.

An increase in polarization on the silver electrode during charge took place after a certain time, and this can also be attributed to a decrease in active area.

Controlled potential electrolysis.—Electrolysis at controlled potential (50-600 mv for 24-72 hr) was carried out to determine the final residual current for the pellets, and the results are shown in Table II. Assuming that no ionic contribution remains after this time the residual current can be used to calculate the upper limit of electronic conductivity contribution. Using the equation of Wagner (10), the electronic conductivity must be less than 0.002% of the total conductivity. Current which flows at cut-off voltage will

Table II. Residual current and leakage current results

Sample	Time o.c., hr	i_R Final residual current, nano-amp	Charge lost, μcoul	i_L Leakage current, nano-amp
Pure Ag_3SBr	1	100	428.7	119.0

	25	3,000	13,221.6	146.0

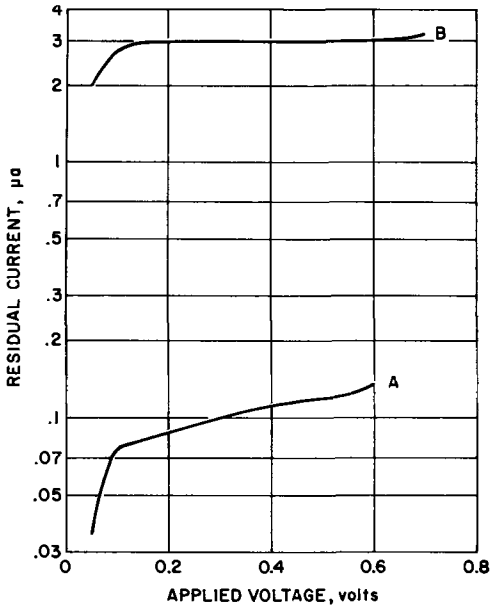

Fig. 8. Residual current. Controlled potential electrolysis. (A) Ag_3SBr; (B) Ag_3SBr containing metallic Ag from decomposition.

also determine the lower limit at which the coulometer can be used.

The residual current of Ag_3SBr pellets, containing metallic silver, (curve B, Fig. 8) was ten times higher than the residual current of pure Ag_3SBr pellets (curve A, Fig. 8). Reuter and Hardel (9) have reported the electronic conductivity of Ag_3SBr as a function of temperature. An extrapolation of their results, shows that at room temperature, the electronic conductivity would be 7.95×10^{-6} (ohm-cm)$^{-1}$. Using this value for electronic conductivity in Wagner's equation

$$i_o = (RT/LF)\ \sigma_o$$

the electronic current would be 3.23 μamp. This value is in good agreement with the residual current we have found for Ag_3SBr containing metallic silver but not for pure Ag_3SBr.

Because the observed residual current may still contain other contributions (note that a strictly flat plateau was not observed) the value of 2.6×10^{-7} (ohm-cm)$^{-1}$ for σ_o is only approximate, but probably represents the maximum electronic contribution.

Leakage current.—After a pellet was driven to a high voltage (0.5-0.6v, the open circuit voltage would decay with time. A number of μcoulombs had to be passed in order to return the pellet to the original voltage. The charge lost can be considered in terms of a leakage current (i_L)

$$i_L = Q/T_{o.c.}$$

where Q is the total charge lost and $T_{o.c.}$ is the open circuit time.

If no electronic shorting existed, the open circuit voltage would not decay and no charge would be lost ($Q = 0$, $i_L = 0$). On the other hand, if all the residual current observed above (i_R) were electronic then i_L would equal i_R. As can be seen from Table II, i_L for Ag_3SBr is initially equal to (or even greater than the final i_R), but decreases to a value about half of i_R. Unfortunately, during this time, the open circuit voltage is decaying, and when it decreases below the plateau value for i_R one would expect the leakage current to decrease. This is what was observed for Ag_3SBr containing metallic silver. Within the first hour at open circuit the voltage dropped to <50 mv and i_L decreased very rapidly (Table II).

Table II shows the results for a number of pellets. Since i_L is significantly lower than the residual current (i_R), i_R must still contain some ionic contributions. Based on the i_L values, the electronic conductivity must be less than 1.2×10^{-7} (ohm-cm)$^{-1}$ or 0.001% of the total conductivity for Ag_3SBr.

Table III. Timing accuracy for Ag_3SBr coulometers

Current μa	Charge time, sec 50 Avg. error	50 Std. dev.	100 Avg. error	100 Std. dev.	250 Avg. error	250 Std. dev.
10	+4.6%	2.3%	+5.8%	1.6%	+3.2%	0.26%
36	−0.2	1.5	−0.1	0.8	−0.6	0.38
100	−1.8	1.3	−0.7	0.6	−0.6	0.30
360	−0.8	0.3	−0.7	0.2	−1.2	0.17

Note: Results represent average of eight determinations.

Timing accuracy.—Timing accuracy for the silver sulfide bromide coulometers was checked for currents of 10-360 μa and for periods of 50-250 sec. The charge ranged from little more than a monolayer (approximately 300 μcoulombs) to about 300 atomic layers on the average. In the current range 36-360 μa, the average error was about —1% in almost all cases, Table III. This error was due to silver remaining on the gold electrode and could be recovered at controlled potential at very low currents.

Results of continued cycling are shown in Fig. 9. Usually the first few cycles gave a relatively large error, due to conditioning effects at the gold electrode surface. In general, less charge was recovered on the first cycles than plated, and could result from either (*i*) reduction of a species during charge that is not re-oxidized during strip, or (*ii*) formation of silver during charge which is not stripped. The latter process, *i.e.*, formation of "inactive" silver, might include migration of silver into the gold via grain boundaries. For fresh pellets possibly containing gold oxide or gold sulfide surfaces, the first mechanism appears more likely.

In general, ten cycles were run and the average of the last eight determinations was used for Table III. This value was usually quite close to the asymptotic value, *e.g.*, in Fig. 9 the average of the last eight cycles was 248.3 sec (—0.68% error) while the asymptotic value was 249.2 sec (—0.32% error). The asymptotic value was not reported in Table III since in several instances the value could not be determined in ten cycles because of random fluctuations.

Charge hold.—The time at open circuit between charging and stripping has been called charge hold (1). Silver sulfide bromide pellets gave positive errors as charge hold time increased. The results are shown in Fig. 10. Two processes are postulated for read-out errors. The first process is the formation of inactive silver (1) on the gold electrode leading to small negative errors (Table III). The second process is the oxi-

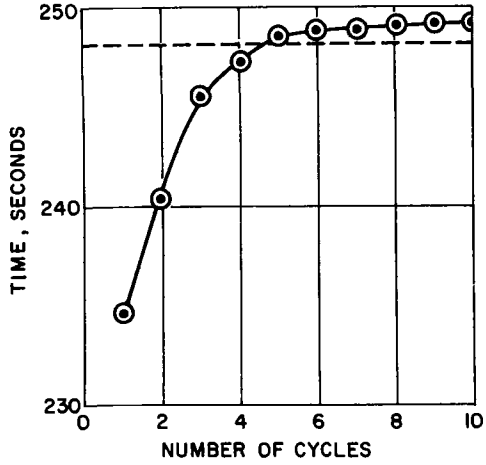

Fig. 9. Timing accuracy results. Charge: 250 sec at 100 μa; stripping current: 100 μa.

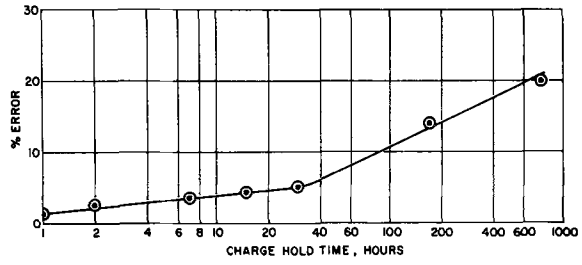

Fig. 10. Charge hold results. Charge: 1000 sec at 50 μa; stripping current: 50 μa.

dation of sulfides on the gold electrode at 0.2-0.4v which leads to a positive error. With a charge hold period, the second process dominates and the net effect is a positive error. The positive error appears because the arbitrarily chosen cut-off voltage (0.5v) was above the potential at which sulfide ion at the gold electrode is oxidized. Thus, additional charge is required before the gold surfaces reach 0.5v. As mentioned earlier, the reaction is not reversible so that positive errors can also be observed on succeeding cycles. Thus, irreversible (*e.g.*, kinetically slow compared to the operating current) processes can give rise to both negative errors for fresh pellets (conditioning) and positive errors after a charge hold period.

Charge capacity.—A practical consideration is the amount of silver which can be transferred to the gold and subsequently stripped without losing accuracy or shorting from silver growth. Table III shows that negative errors of —1.2% were observed with charges of 90,000 μcoulombs, (25 μa-hr). It also shows that negative errors increased as the amount of charge transferred to the gold increased. For large charges (>10 μa-hr) and no charge hold, larger negative errors were observed (Fig. 11). However, most of the high charge studies were carried out with no conditioning (set B on Fig. 11), and the errors were considerably smaller with conditioning (set A on Fig. 11).

One pellet was given a charge of 417.6 μa-hr and a —13% error was observed on stripping. Another possible mechanism for negative errors during stripping of such large charges is that the silver plate may be thick enough to allow under-cutting. That is, silver would be oxidized close to the gold during stripping leaving silver metal in the electrolyte region not connected electrically to the gold electrode. In support of this mechanism, charge lost for these pellets could not be recovered by controlled potential electrolysis.

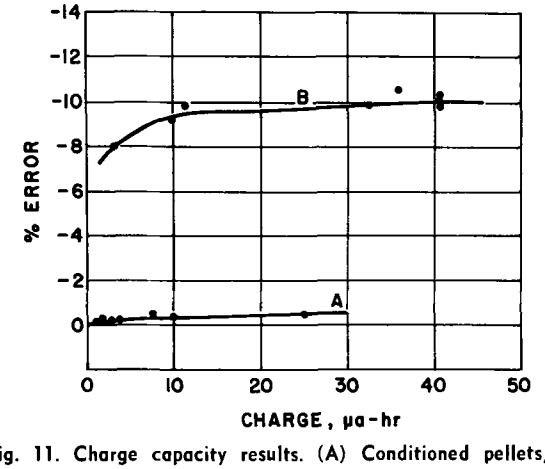

Fig. 11. Charge capacity results. (A) Conditioned pellets; (B) non-conditioned pellets.

Conclusion

Both AgBr (1) and Ag_3SBr have been found to be useful as solid electrolytes for coulometers. Ag_3SBr, because of its much higher conductivity can be used at currents up to 1 ma/cm² (compared to 0.1 ma/cm² for AgBr) and larger amounts of charge could be transferred without shorting by silver dendrites. Also, Ag_3SBr exhibited no room temperature annealing effects, and the resistance was more stable with time. On the other hand, Ag_3SBr showed a significant positive error due to build up of sulfide on the gold electrode when stored for longer than 100 hr while AgBr coulometer showed a negative error.

For highest accuracy, silver coulometers containing silver sulfide bromide as a solid electrolyte must be operated under controlled conditions. These conditions include current densities of 28-280 μa/cm², preconditioning of the gold electrode to the cut-off voltage, charge capacities of 1,400 to 70,000 μcoul/cm², and immediate read-out. Under these conditions coulometer read-out error will be less than 1%.

Linear Sweep Studies of the Oxygen Electrode in Nonaqueous Media

Kinetics Studies on Smooth Platinum Electrodes

Jorge E. A. Toni*[1]

Corporate Applied Research Group, Globe-Union Incorporated, Milwaukee, Wisconsin

ABSTRACT

The electrochemical reduction of oxygen was studied in phenyltrimethylammonium hexafluorophosphate-nitrosodimethylamine solutions. The kinetic effects of different levels of water concentration were also investigated. The electrode studies indicated that the oxygen reduction in nonaqueous media is a complex mechanism. The postulated electrode process in the systems studied includes first, a series of surface processes on the electrode (adsorption, interaction between oxygen and platinum, reduction of the film formed) and second, two partially mass transport dependent steps with chemical kinetics complication (ECE mechanism).

The reduction of oxygen in aqueous media is a classical problem in electrochemistry; nevertheless, new ideas about the electrode process mechanisms are continuously being postulated. However, the study of the mechanism of oxygen reduction in nonaqueous media and particularly in aprotic systems can be considered a relatively recent problem, and perhaps it will receive in the future as much attention by the electrochemists as the study in aqueous solutions.

In an absolutely aprotic solvent, if the reduction of oxygen occurs, it has to be fundamentally different than in water. This condition is difficult to achieve experimentally because moisture (a proton source) is one of the most difficult impurities to eliminate from nonaqueous solvents and water concentrations in the order of 5×10^{-4}M (10 ppm), only one order of magnitude lower than the oxygen concentration, are often present in the best purified solvents.

However, the possibility of eliminating or at least decreasing to a minimum, the effect of protons (without increasing hydroxyl concentration) is a fascinating approach and creates new horizons for the study of the oxygen reduction. Moreover, the study of the oxygen reduction in aprotic media is of interest from the point of view of energy conversion because it permits the study of very high energy couples with alkali metals as anodes (1).

The initial studies of the reduction of oxygen in nonaqueous media were done by Kolthoff and collaborators (2-4). Lately, and in part during the progress of the present research, several other papers have appeared (5-12), and in some cases quantitative data was shown (8, 9, 12). In general, there is agreement that the reduction of oxygen in aprotic media occurs in two principal steps, quasi-reversible and irreversible, respectively. Maricle and Hodgson (5) were the first to postulate that the first step is a one electron reduction of oxygen to superoxide. For the second step the data are not so clear because of difficulties in studying this reduction process. Generally, it is not very reproducible and occurs at such negative potentials that the curve practically is superimposed on the depolarization limiting of the electrodes. However, Sawyer *et al.* postulated first (8) that the reduction corresponds to the reduction of O_2^- to $O_2^=$, and later (12) that OH^- is one of the products. Johnson *et al.* (7) have studied the effect of cations on the E_p of this reduction. Several attempts were made to characterize the superoxide formation. They included chemical (5) and esr (5, 9) experiments. The present discussion summarizes our study on the reduction of oxygen, in a new aprotic solvent, N-Nitrosodimethylamine (NDA) (13). The research was done with smooth platinum electrodes. The technique most frequently used during the present research was linear sweep voltammetry in the direct or cyclic fashion. The diagnostic criteria developed by Nicholson and Shain (14) were a powerful tool for the interpretation of the results. Our conclusions about the mechanism are in some ways different than previous investigations. We have recognized that small (<20 ppm) traces of protons (water) were impossible to remove completely and were always present. We assign an important role to them in the mechanism. The effect on increasing water concentration was also studied and did help in the interpretation of the over-all mechanism.

Key words: oxygen reduction, nonaqueous media, nitrosodimethylamine.

Experimental

The NDA was obtained from Eastman Kodak Company. The two main impurities which generally may accompany the solvent are water and peroxides. The peroxides were eliminated by treatment with Al_2O_3 or Li and the removal of water required a pretreatment and distillation. The solvent was dried for at least twenty-four hours with P_2O_5 or molecular sieves, type 4A; after filtering off the drying agent, the NDA was vacuum distilled from molecular sieves, type 4A, which had been dried previously at 200°C. The distillation was performed at a pressure of 2 mm of mercury and only the fraction which distilled in the range 26°-28°C was collected. If all the previous steps have been performed properly, the only impurity observable by vapor phase chromatography (VPC) is water and its concentration as determined by VPC, is usually reduced to about 20-30 ppm. The gas chromatograph used was an F & M 810 with a thermal conductivity detector as the sensing device. The chromatograph was programmed in the following way: Two 1½ foot copper columns packed with Carbowax (10%) 20 M on Fluoropak 80M were used. Bridge current was 150 ma. Injection post temperature was 160°C. Detector temperature was 180°C. The program temperature scale was 100°C-150°C. Upscale temperature rate of scan was 30°/min. Downscale temperature rate of scan (fixed) was 40°/min. The post injection interval was 0 min, and the upper limit interval was 6 min. The flow rate of helium carrier gas was 40 ml/min. The sample size was 20 μl.

Phenyltrimethylammonium-hexafluorophosphate (ϕMe_3NPF_6) which was used as supporting electrolyte was obtained from K&K Laboratory and dried at 95°C under vacuum for at least 8 hr. Prepurified nitrogen and oxygen were from Airco Company. They were passed through concentrated sulfuric acid and

P_2O_5 or Drierite. The solutions were saturated with oxygen by bubbling the gas through the solution. The concentration of oxygen in the solutions was obtained by applying the volumetric titration method suggested by Coetzee and Kolthoff (2) with slight modifications. The final titration of the excess of Fe(II), which has not reacted with the oxygen present, was performed by a ceric (sulfate) continuous potentiometric titration in order to eliminate the interaction between Ce(IV) and NDA. The concentration of oxygen in a O_2 saturated solution of 0.5m ϕMe_3NPF_6-NDA was 5×10^{-3}M.

The test electrode was a conventional platinum disk electrode which was polished to a 1μ surface finish. Its geometrical area was 7.8 mm^2. The reference electrode was a Ag/AgCl (0.1M KCl), with a salt bridge of 1m $LiClO_4$-NDA which had a potential of —25 mv *vs* SCE (1). A Luggin capillary was used to decrease the uncompensated resistance. Its value, determinated using the conventional study of ratio E_{in}/E_{out} *vs.* frequency was 33 ohms. Simple calculations can show that the IR drop effect is in the experimental error. The counter electrode was a pyrolytic graphite rod. Extreme precautions were taken to eliminate contamination of moisture with the solutions. Vapor phase chromatography of solutions prior to and after electrochemical studies did not show any appreciable increase in water concentration.

The potentiostatic equipment used for this research consisted of combinations of operational amplifier circuits such as originally suggested by DeFord (15) and modified by Shain (16) and co-workers.

Results and Discussion

Figure 1a shows a typical cyclic scan of oxygen in ϕMe_3NPF_6-NDA, and it also shows the base line of residual current which is obtained when the solution is purged free of oxygen by the use of nitrogen. It can be seen that the cyclic voltammogram consists of at least four sections. The scan starts at OV *vs.* the Ag/AgCl electrode and proceeds in a cathodic direction. With oxygen present a prepeak or hump-shaped wave is obtained at approximately —0.4v *vs.* Ag/AgCl. Before this wave has been completed, a well-developed reduction peak occurs at —1.0v *vs.* Ag/AgCl. (In future discussions we will speak of this reduction peak as peak I.) Well beyond peak I a second reduction peak (called in later discussion peak II) is observed just prior to the decomposition potential of the electrolyte at the platinum electrode surface. At this point the scan was reversed and proceeds in the anodic direction. The first observable feature is that there is no anodic peak close to peak II and that an anodic peak occurs at —0.8v *vs.* Ag/AgCl. This anodic peak is related to the first cathodic peak, peak I (Fig. 1b). Figure 1b is typical for the first step in performance of oxygen electrochemically on smooth platinum in the electrolyte system described above. We will label the anodic peak, IA. Since the difference in peak potential between peaks I and IA (Fig. 1b) is approximately 200 mv we cannot consider the reaction to be reversible (14). The criteria for reversibility are such that the peak separation for the cathodic and anodic peaks should be equal to 58 mv/n which is much smaller than the 200 mv observed above. On the other hand, cathodic peak II does not show any signs of reversibility since no anodic peak corresponds to it.

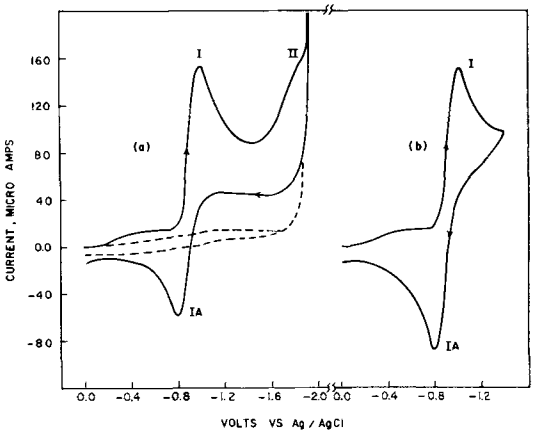

Fig. 1. Typical cyclic voltammogram of oxygen in 0.5m ϕMe_3NPF_6-NDA; concentration 5×10^{-3}M (saturated); scan rate, 100 mv/sec. Two minute hold at 0.0v with agitation; 30 sec rest period prior to scanning; - - - - residual current. (a) complete cyclic voltammogram. (b) cyclic voltammogram of the first step.

The over-all mechanism, as will be shown in the progress of the discussion, is a complex one which includes several steps. They involve a series of surface processes on the electrode and two partially mass transport dependent cathodic steps.

Surface Process

Accumulation of Oxygen on the Surface

In previous work with lithium perchlorate and NDA (1) we had observed that the first cathodic peak current for the reduction of oxygen in that media was dependent on the length of time we held the potential at 0.0v *vs.* Ag/AgCl. This was presumed to be due to a slow adsorption of oxygen on the surface of the platinum electrode. In substantially the same manner we have made studies in the phenyltrimethylammonium hexafluorophosphate-NDA system. It was observed that if we held the potential at 0.0v for longer periods of time, peak I increased in height to a maximum value. Plotting the peak current *vs.* the length of the holding time at 0.0v the peak current reached a maximum value and leveled off as the holding time increased. An auxiliary experiment to demonstrate this effect was also performed in which the solution was stirred and the only change in the form of the curve obtained was that the steady-state value at the maximum peak current was achieved more rapidly. This indicates diffusion control adsorption occurring on the electrode surface since a maximum value would be reached at maximum or saturation coverage. It is therefore suggested that this portion of the mechanism is simply described by the equation:

$$O_2 \text{ solution} \rightleftharpoons O_2 \text{ surface}$$

Interaction between the oxygen and the platinum electrode.—As noted earlier in this paper there appears to be an electroactive species which gives a prepeak or hump before the major oxygen reduction step in cathodic peak I. It is possible that some form of platinum oxide or mixture of platinum oxides are formed on the platinum surface. This is not a new concept since many others have proposed that this occurs with the oxygen electrode in aqueous media. However, we refer to Kolthoff and Tanaka (17) which relates the potential for the reduction of the platinum oxides to the *p*H of the solution and have found that at very high *p*H the reduction of the oxide occurs at a potential region near that of the present hump.

In addition, we have found that the prepeak is observed only after prolonged potentiostatic holds. In the experiments described in the previous section using increasing potentiostatics holds at 0.0v, the prepeak starts to rise after 30 sec of holding. To establish that oxygen was necessary at the surface before this prepeak would be obtained, we ran the following series of experiments all by linear voltammetry. (Fig. 2). One experiment shows the formation of the prepeak when the solution is saturated with oxygen both during the hold and during the scan. The second experiment shows the effect of exposing the electrode to oxygen only during the hold period then purging the solution with nitrogen for 15 min and rescanning. The result of this experiment is that the prepeak shows, but no following oxygen reduction wave (peak I) appears. The third experiment was

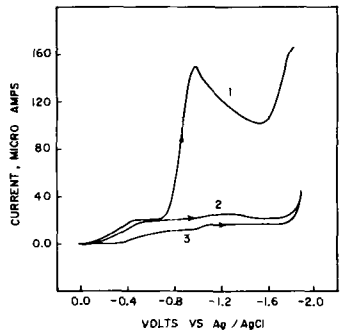

Fig. 2. Relation of the prepeak with the presence of oxygen. Scan rate 100 mv/sec. Curve 1, oxygen saturated solution; 2, oxygen purging only during hold, scan after 15 min purging with N_2; 3, residual current after 15 min hold at 0.0v with N_2 purge.

carried out in the same manner as the first two with the exception that the solution was purged with nitrogen for 15 min, and then the voltammetric scan was carried out. This curve shows neither the prepeak nor the oxygen reduction wave. Thus, it is our conclusion that oxygen is necessary to form the species on the surface which gives the prepeak in a voltammogram. The mechanistic step could be written as follows

$$O_{2ads.} + Pt \rightarrow Pt_xO_y \text{ surface}$$

Other interpretation, suggested by one of the reviewers, is that the prepeak reduction wave "may actually be some other oxidation product such as a free radical formed by the interaction of oxygen with organic impurity or solvent decomposition product."

Reduction of Oxygen

As was explained before (Fig. 1), the electrochemical reduction of oxygen on smooth platinum in ϕMe_3NPF_6-NDA, appears to occur in two steps. They both apparently are irreversible, but since the first cathodic wave peak I has an anodic counterpart, peak IA at potentials close to the cathodic peak, we would, therefore, classify the reaction as quasireversible. The peak potentials are affected by the increase of the scan rate showing a negative shift for the reduction processes and positive shifts for the anodic one. This behavior is also a typical qualitative diagnostic test for cases which do not include a reversible system.

We also knew that the reduction of oxygen is in part mass transport controlled and the reduction current can be considered an additive function of the reduction of oxygen adsorbed and oxygen transported by diffusion from the bulk of the solution. These conclusions were drawn from experiments with stirred solutions. If the solution is stirred during the scan, the reduction current increased greatly. With stirring the anodic peak, IA, decreases, showing that the product of the first reduction is not accumulated on the electrode surface.

To summarize the information we have at this point of the discussion and before passing to more detailed studies, it is believed that after the accumulation and interaction of oxygen with the electrode, the oxygen reduction appears to occur in two steps; one quasireversible, the other completely irreversible. These processes are in part transport controlled. We will pass now to the study of the first step of the reaction.

First step in presence of minimal amounts of water. —The first step of the reaction (that is, peaks I and IA, Fig. 1b) looked promising for a detailed study. It shows both the cathodic and the anodic processes, and peak I is separated well enough in potential from reduction wave, peak II, to give us a chance to study peaks I and IA without interference from the second wave. On the other hand, the second reduction is so close to the depolarization limits of the platinum electrode that it is very difficult to get valid information about peak II.

The main study includes the effect of scan rate on the peak current. The diagnostic techniques of Shain *et al.* (14, 18-21) were studied extensively. Their diagnostic interpretations of appropriate voltammetric experiments can give an enormous amount of information about the mechanism of the reaction. We have run experiments covering a range of practically five orders of magnitude in scan rate (V), from 10 mv/sec to 680 x 10^3 mv/sec. The experiments here were cyclic voltammograms which included only the first step. The scans were run from 0.0v *vs.* Ag/AgCl to an appropriate potential after the peak generally no more negative than 200 mv past the first cathodic peak potential, E_pI. All the experiments had a potentiostatic hold at 0.0v for 2 min with agitation and oxygen passing through the solution for the first minute. Then just prior to scanning the stirring was stopped, the oxygen passed over the surface of the solution, and the solution was allowed to become quiescent for 30 sec. Figure 3 is representative of all the voltammetric studies obtained by this method. It includes experiments run at different times over a period of 6 months. The figure includes the plots of current functions $I_{pI}/V^{1/2}$ *vs.* V. (I_p = peak current, V = scan rate.) The representation of $I_p/V^{1/2}$ is used to normalize the results at different scan rates and relate them with a true reversible case from which the curve has to be a straight line parallel to the abscissa because $I_p = kV^{1/2}$ for a reversible electrochemical reaction. This study includes series without water added. The analysis of Fig. 3 leads to the conclusion that we might interpret the data as diagnosing an ECE mechanism (18) (electron transfer, chemical reaction, electron transfer) exemplified in a general way by

$$A \underset{E_1^o}{\overset{n_1e}{\rightleftharpoons}} B \overset{k}{\rightarrow} C \underset{E_2^o}{\overset{n_2e}{\rightleftharpoons}} D$$

where E^o = formal potential.

For an ECE mechanism $I_p/V^{1/2}$ is larger at low scan rates than at fast scan rates. A similar behavior is only found for reactions with a cyclic (catalytic) reaction (14). However, for these catalytic cases the increase of $I_p/V^{1/2}$ at low scan rate is much greater than was observed in our experiments. Our case only shows a ratio of 2 to 1 between the values obtained at 10 mv/sec and the values over 5.5 x 10^4 mv/sec. This ratio fits perfectly for an ECE mechanism where $n_1/n_2 = 1$ and $E_1^o = E_2^o$ or $\Delta E^o = 0$ (18). These conclusions mean that after the electrochemical reduction of A to B a chemical process takes place which transforms B into C. Then C is electrochemically reduced to D at the same or very close to the same potential at which A is reduced to B. That is why at low scan rates the peak current consists of contributions of both electron transfer reactions. In the slow scan case there is enough time for the chemical interaction of B to C but very fast sweeps do not allow sufficient time for this chemical reaction.

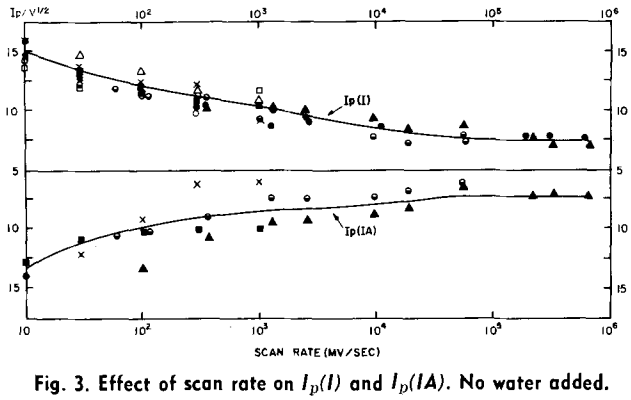

Fig. 3. Effect of scan rate on $I_p(I)$ and $I_p(IA)$. No water added.

Thus, the current observed is only due to the first electron transfer. However, it is well to note that our case must have the same number of electrons transferred in the first case $A \rightleftharpoons B$, n_1 as in the second electron transfer, $C \rightleftharpoons D$, n_2.

An ECE mechanism can have four different cases relative to the reversibility or irreversibility of the individual charge transfers (18) (*R-R*, *R-I*, *I-R*, *I-I*, where *R* = reversible and *I* = irreversible). To characterize the case with $\Delta E = 0$, the effect of scan rate on the anodic peak is important. Only in the case where both electron transfers are reversible will an anodic peak be obtained at all the scan rates over the entire scan rate range. Figure 3 shows that we have that case. Consequently, we can say now that our first step includes two reversible, or at least very close to reversible, equal electron transfers in the ECE mechanism. Our assumption that the first step could be considered quasireversible is thus confirmed.

We consider interesting to include at this point of the discussion a similar type of series of experiments but with 0.25% by volume of H_2O before postulating the mechanism for the first step. Figure 4 shows the results of those experiments. It is notorious a larger spreading of the experimental points and the traced line is only tentative. The concentration of water present is lower than that required for other complicating effects which will be discussed in the next section of this paper. In this case, the peak I current function at low scan rate was always larger and the ratio was slightly over 2. However, the currents at fast scan rates were practically the same as those without water added.

Taking into consideration the data discussed above and the system under study, we think that it is very possible that an ECE case can be postulated. Perhaps a combination of an ECE mechanism and disproportionation reaction occur. The steps may well be related to traces of protons present in the system.

$$A + n_1 e \rightleftharpoons B \xrightarrow{k} C + n_2 e \rightleftharpoons D$$
$$\uparrow \qquad\qquad\qquad\qquad \uparrow$$
$$\underset{k^1}{\longleftarrow}$$

This case has not been studied theoretically yet. It should give larger current functions at low scan rates (because of regeneration of *A*) than a simple ECE mechanism. The latter type of behavior is the type of results which have been observed (especially in the case of addition of low concentration of water) in our experiments.

Summarizing the data available for the first step of the electrochemical reduction of O_2 on platinum we postulate that when no protons are available a one-electron reaction may occur. When protons are available as impurities or at low levels, a ECE mechanism is possible. A disproportionation of O_2^- or HO_2 should be considered in the postulation.

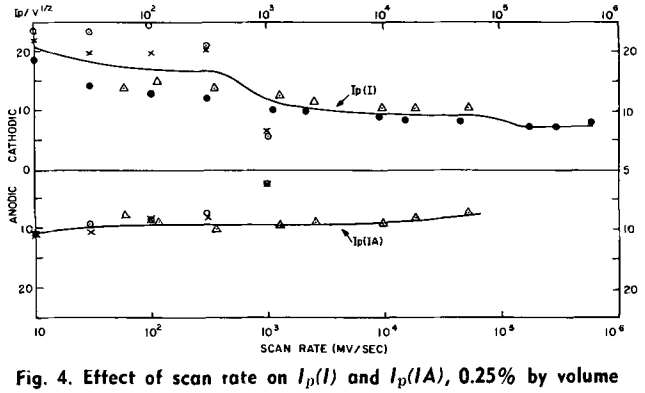

Fig. 4. Effect of scan rate on $I_p(I)$ and $I_p(IA)$, 0.25% by volume of water.

No protons available

$$O_2 + e \overset{E^o}{\rightleftharpoons} O_2^-$$

disproportionation

$$2\,O_2^- \rightarrow O_2 + O_2^=$$

protons available (traces, low concentration)

$$O_2 + e \overset{E_1^o}{\rightleftharpoons} O_2^- + H^+ \xrightarrow{k} HO_2 + e \overset{E_2^o}{\rightleftharpoons} HO_2^-$$

disproportionation

$$2\,O_2H \rightarrow O_2 + O_2H_2$$

Effect of increasing level of water concentration on the mechanisms.—This study of the effect of moisture has given results which permitted us to obtain more information about the second reduction step, peak II, and in this way a better understanding of the over-all oxygen reduction process. We have run several series of experiments with increasing concentrations of water studying simultaneously only the first step, (peaks I and IA) and also the complete reaction (peaks I, IA, and II). Experiments were run at 100 mv/sec and we started with solutions of 0.5m ϕMe_3NPF_6-NDA, which contained low concentrations of H_2O (30-60 ppm) (Fig. 1) and then added appropriate amounts of H_2O (dispensed from a micro syringe) to obtain increases in water concentration. In many cases the unit increase in water concentration was of the order of 0.02%, as was required for the experiments performed. In all other respects the conditions utilized in the experiments with water were the same as in those run without water. With the data thus obtained it has been possible to study the effect of H_2O concentration on both the peak current and peak potential of each of the major voltammetric peaks. The presence of water has affected all the peaks by increasing the current peak heights and has also affected the peak potentials. Figure 5 shows these effects and the curves in the figure should be compared to the curves in Fig. 1 where the amount of water was minimal.

The results are representative of experiments at five different concentration levels of H_2O: 0.006%, 0.20%, 0.40%, 0.80%, and 1.60% by volume, which give a picture of the drastic changes which occur with increasing levels of water concentration. Figures 6, 7, and 8 are the plots of I_p and E_p of the peaks as a function of concentration of water, and cover the

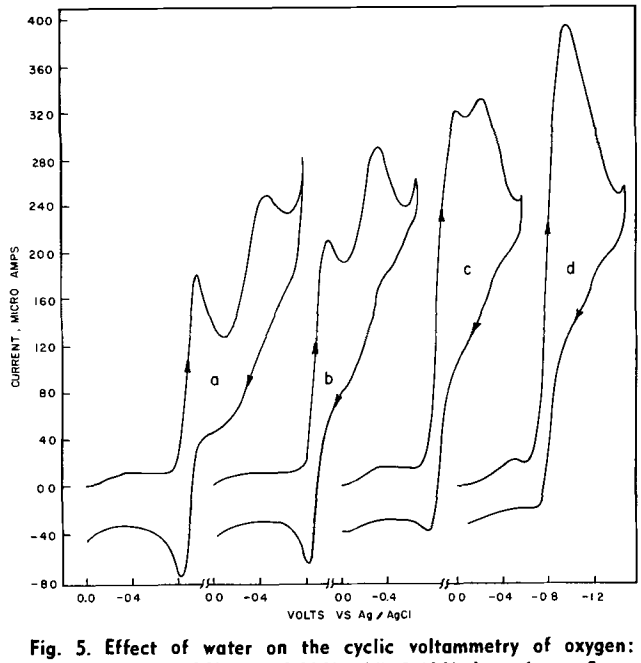

Fig. 5. Effect of water on the cyclic voltammetry of oxygen: (a) 0.20%; (b) 0.40%; (c) 0.80%; (d) 1.60% by volume. Same conditions of Fig. 1.

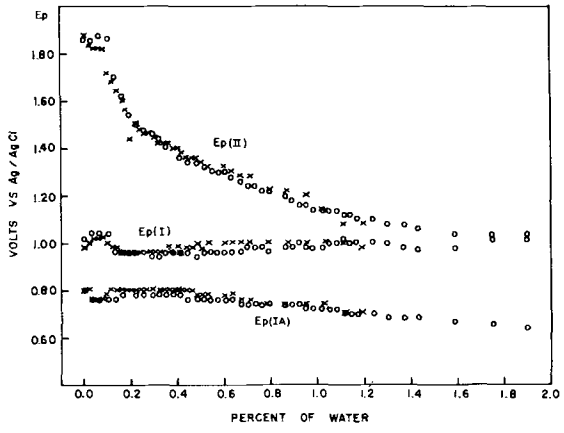

Fig. 6. Effect of increasing concentration of water on peak potentials.

whole range of water concentration levels studied. In Fig. 5 it is noticeable that the prepeak also was affected by the increase in water content of the electrolyte, but this effect has not been fully evaluated.

The effect of water (Fig. 6) on E_pI and E_pIA is not significant but is very pronounced on the second reduction peak, peak II. With increasing water concentration the peak II potential shifts to positive values and finally merges into peak I. It is interesting to note that the peak potential shift follows the following logarithmic equation

$$E_{pII} = -2.15 + 0.06 \log (H_2O) \qquad [1]$$

The value 0.06 would indicate that there is one electron per molecule of water if the reaction is reversible, but as this second step is completely irreversible (Fig. 1), we should include the transfer coefficient α in the equation, which for a value of 0.5 would give two electrons involved in the reaction.

Figure 7 which is the study of I_pI, shows how the peak I current increases until it reaches a steady value. As the figure shows, the increase in current is not continuous and there is an inflection at approximately 0.3-0.4% of H_2O. The current reached at this small plateau is virtually one-half of the maximum current obtained at water concentration levels over 1.2%. This observation can be interpreted as a change in mechanism and perhaps as a change in the number of electrons transferred. We will go back to this observation later during the discussion of the over-all reaction.

Figures 8a and 8b are the same type of study but for I_pII and I_pIA. These experiments possessed larger errors attributable to the difficulty in selecting a realistic base line from which to measure the peak currents. For peak II, it was decided to use the criterion (14) which says that the base line should follow the current-time curve for a potentiostatic hold immediately after the first peak. To obtain the base lines it was necessary to run the experiments at all the concentrations of water studied. For the anodic peak we chose to fix the base line from the base line obtained in the experiments without added water. This criterion possesses larger errors and gave values at high concentrations of water which apparently cannot be realistic from the shape of the peak (Fig. 5d), but it gave some idea about the progressive decrease of the anodic peak until it leveled off or disappeared. The reduction peak II, Fig. 8a, gradually decreases and merges into peak I. It is interesting that the maximum amount of current observed for peak II is of the same order and at the same range of water concentration as the peak current values at the inflection plateau observed for the peak I (Fig. 7). The rise in current of peak II at the beginning of the water additions has to be interpreted carefully because peak II is very close to the potential of the electrolyte decomposition wave at these water concentrations. At this point we prefer to leave the discussion of the results with increasing water concentration to the next section where the over-all mechanistic process is discussed.

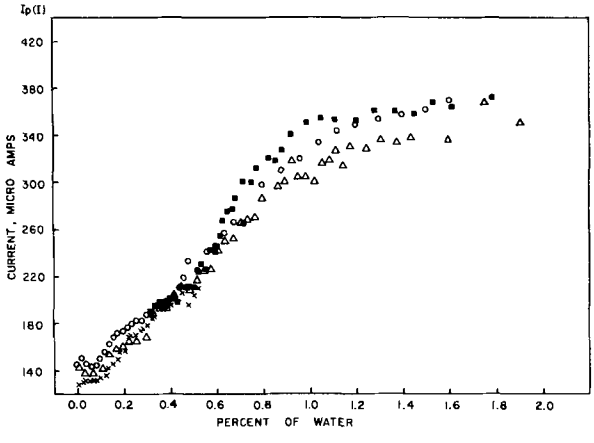

Fig. 7. Effect of increasing concentration of water on I_p (I)

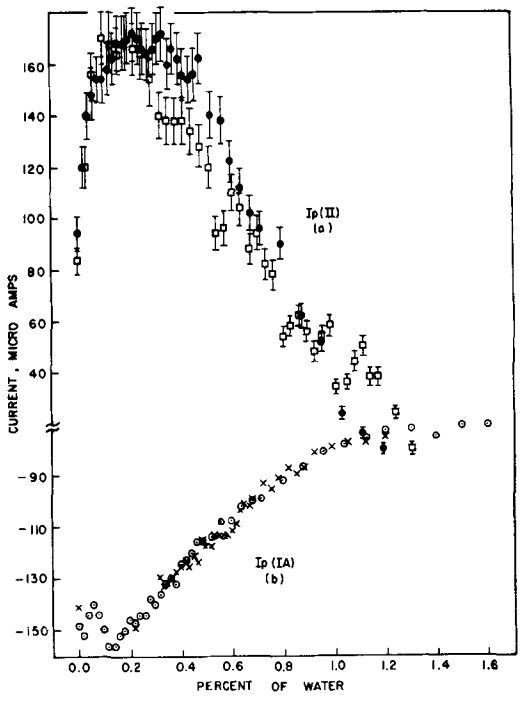

Fig. 8. Effect of increasing concentration of water on (a) $I_p(II)$ and (b) $I_p(IA)$.

Postulation of the complete mechanism.—The experiments described in the last section suggest several conclusions. These conclusions, combined with those obtained in the section of this paper covering step I, permit one to arrive at a hypothetical over-all mechanism for the oxygen reduction. It is believed that the second peak can be the reduction of peroxide to hydroxide, and the strong effect of the presence of water is perhaps an indication of the necessity of proton availability for this latter reduction step.

$$HO_2^- + 2e + H^+ \rightarrow 2\,OH^- \qquad E_3^\circ = f\,(H^+)$$

or following Eq. [1]

$$HO_2^- + 2e + H_2O \rightarrow 3\,OH^-$$

Perhaps in a system completely aprotic this reduction would not occur or is related to the cations which are present (7, 11). The increase in concentration of H_2O has to change the reduction in a way to approximate the reaction in aqueous media. The inflection observed in Fig. 7, the ratio of current between

this point and the maximum amount of current, and the same levels of current at the inflection point for peak I and peak II can suggest that (*a*) at that concentration of H_2O there is the same number of electrons transferred for both reductions (very possibly two), and (*b*) that the inflection for the increase of peak I is obtained when the reaction

$$O_2 + 2H^+ + 2e \rightarrow H_2O_2$$

is predominant.

At a water concentration (0.3-0.4%) the above mechanism would hold. At the other extreme where no protons are available the scheme below would hold.

$$O_2 + e^- \rightleftharpoons O_2^-$$

However, with water or proton concentrations intermediate between aproticity and 0.3 to 0.4% water the reaction could change from a one electron reaction to a two-electron reaction. This can result in a complex intermediate mechanism such as we suggested in the section on step I of the oxygen reduction.

Finally we want to note that at concentration levels over 1.2% H_2O, peak I arrives at a steady value, peak II merges with peak I, and the anodic peak IA disappears or decreases to a minimum. Thus, at 1.2% or higher concentrations of water it can be said that $E_1^\circ = E_2^\circ = E_3^\circ$ since all of the three reactions, having these formal potentials, have now been enclosed and included in peak I. Also, at or above this water concentration (1.2%) the cathodic reduction reaction conforms closely to a four electron reaction of the type postulated below.

$$O_2 + 2H^+ + 4e \rightarrow 2\,OH^-$$

The summary of the electrode process can be now postulated in the following way

$$O_2 \rightleftharpoons O_2 \text{ surface}$$

$$O_2 \text{ surface} + Pt \rightarrow O_xPt_y$$

$$O_2 \rightleftharpoons O_2^- \xrightarrow[k]{e^-,\ (H^+)} HO_2 \rightleftharpoons HO_2^-,\ (H_2O_2) \xrightarrow{2e^-,\ (H^+)} 2\,OH^-$$

(with k^1 on the reverse step; $2e, (H^+)$ over the whole sequence; (H^+) under the first step)

We have postulated our reaction considering the proton as the active specie from the addition of H_2O. We realize that this postulation of the reactions is tentative, because we do not have information about the dissociation of water in NDA and we expect that the mechanism can be expressed using water in place of protons as the active specie.

We also recognize that the postulation has to be confirmed by the determination of the number of electrons involved in the different steps (which from initial experiments looks difficult) or at least by identification of the different species postulated. The lack of time prevented further work covering these two areas.

Technical Notes

Methods for Studying the Solution Chemistry Within Stress Corrosion Cracks

B. F. Brown, C. T. Fujii, and E. P. Dahlberg

Naval Research Laboratory, Washington, D.C.

A major obstacle to a better understanding of the fundamentals of stress corrosion cracking (SCC) has been the almost total lack of information about the nature of the corrodent within a growing stress corrosion crack, particularly near the advancing edge. While it is generally conceded that the local chemistry within the stress corrosion crack differs considerably from that of the bulk solution, the demonstration of this difference has been deterred by inaccessibility and the problems of obtaining representative samples of solution. The present communication describes methods by which the stress corrosion process is interrupted in such fashion as to permit opening the crack without undue mixing of the corrodent within it, and to enable one to analyze the small amount of corrodent present without undue chemical changes in the interval between termination of the SCC test and the completion of the analysis.

The specimens used were for the most part rectangular and about 3 mm thick, with a saw cut at the middle of the long dimension. A metal wedge was pressed into the saw cut using a vise, thus stressing the root of the saw cut in tension. The specimen was then placed in either distilled water or 3½% NaCl solution (*p*H 6.5), with the wedge either paraffin coated or kept above the waterline to prevent galvanic effects. Some of the aluminum alloy specimens were long bars slotted at one end (parallel to the rolling plane) and stressed by opening the slot elastically with a set screw.

After the stress corrosion crack had propagated a suitable distance (a centimeter or so), the specimen was removed from the solution and immersed in liquid nitrogen to freeze the corrodent in the crack in place and also to minimize any side reactions which might alter the composition of the corrodent until the analytical operation could be effected. The specimen was subsequently removed from the liquid nitrogen and broken apart in a vise or with pliers to expose the frozen solution on the SCC surfaces for analysis immediately on thawing. Some of the early experiments were conducted in a glove box filled with dry nitrogen (1), but it was found that in general they can be conducted satisfactorily in the open air.

The inherent difficulties of microanalysis on the microvolume of solution available at the crack tip, the rugged fracture surface, and the obvious requirement of rapid analysis to prevent solution changes suggested a simple *in situ* approach to the problems of determining the solution chemistry of interest, *i.e.*, the acidity and the soluble metallic constituents. (A listing of the acid and ion indicators used for this purpose is given in Tables I and II.) The test method involved the use of indicator-impregnated filter paper or indicator-coated silica gel (60-80 mesh) prepared by saturating the paper or gel with dilute aqueous solutions of indicator, and drying completely. The congo-red and alkacid papers were obtained commercially; the others were all prepared as described above. The silica gel particles were sprinkled on the chilled fracture surface and provided a point-to-point indicator as the specimen warmed up and the corrodent melted. The strips of filter paper were simply pressed firmly on the moist fracture surface, and the color changes over the moist replica of the crack impressed on the paper were observed. In the normal procedure one-half the specimen was used for *p*H determination and the other half for the qualitative test for the ion species of interest. Several specimens of each alloy type were analyzed in this manner to encompass the range of indicators prepared and to bracket the *p*H within as narrow a range as possible.

The results of these test methods on two commercial alloys, 7075 Al alloy and Ti-8%Al-1%Mo-1%V, and a vacuum-melted carbon-deoxidized 0.45%C steel are summarized in Table III. The color changes observed after sprinkling silica gel coated with bromocresol green indicator on the fracture surface of 7075 Al and 8-1-1 Ti alloy specimens suggested local variation in the acidity. The individual silica gel particles ranged in color from the yellow of *p*H 3.8 or lower, through a medium green, to the less acid blue of *p*H 5.4 or higher. Generally, the region of highest acidity was at the advancing edge of the crack with a gradual decrease in acidity in the direction of the initial root

Table I. Acid indicators: ranges and associated color changes

Acid indicator	*p*H range	Color change†
1, Bromocresol green*	5.4-3.8	B-Y
2, Bromophenol blue	4.6-3.0	B-Y
3, Congo red*	5.0-3.0	R-B
4, Thymol blue	2.8-1.2	Y-R
5, Alkacid paper	5.5-3.5	G-Y-O

† B, blue; Y, yellow; R, red; G, green; O, orange.
* Those marked with asterisk used both in paper and on silica gel. All others in paper only.

Table II. Ion indicators: uses and color changes

Ion indicator	Test	Color change for positive test
1, Potassium ferrocyanide	Fe^{+3}	Pale yellow to blue
2, Sodium thiocyanate	Fe^{+3}	Colorless to red
3, Potassium ferricyanide*	Fe^{+2}	Yellow to blue
4, Aluminon reagent	Al^{+3}	Orange to red
5, Alizarin Red S*	Al^{+3}	Yellow to red

* Those marked with asterisk used both in paper and on silica gel. All others in paper only.

Table III. Test results for acidity and metallic ions in solution within the stress-corrosion crack

Alloy	Maximum *p*H detected at crack front	Soluble ions* Al^{+3}	Fe^{+3}	Fe^{+2}
7075 Al	3.5	+	N.T.	N.T.
0.45C Steel	3.8	N.T.	–	+
8-1-1 Ti	1.7	+	N.T.	N.T.

* + present; – absent; N.T. no test.

of the crack. However, within the regions of high or low acidity, local variations of acidity were discernible, *i.e.*, yellow and green silica gel particles were observed at the acid end and yellow, green, and blue particles at the less acid end of the fracture surface.

The pH paper tests permitted more accurate estimates of the acidity. The 7075 Al alloy and 0.45 C steel specimens indicated pH values of 3.5 and 3.8, respectively, near the advancing crack tip. In both cases the pH may actually have been slightly lower, but it was not sufficiently low to yield a positive congo-red test (pH 3.0). The 8-1-1 Ti specimen produced a decidedly positive congo-red test (pH 3.0 or lower), and further testing with thymol blue indicator showed an acidity as low as pH 1.7 at the crack tip.

In all three alloys, the relatively acid condition of the corrodent within the advancing crack suggests that the corrosion products are soluble. For the 7075 Al alloy and the 8-1-1 Ti alloy, positive tests for aluminum ions (Al^{+3}) were obtained with both aluminon and alizarin indicators in the region of highest acidity near the extreme edge of the advancing crack.[1] The 0.45 C steel specimens gave positive tests for the presence of ferrous ion (Fe^{+2}) but showed the absence of ferric ion (Fe^{+3}) in two independent tests, the ferricyanide and thiocyanate papers. Again the blotted imprint of the ferrous ion "blue" from one-half the specimen matched that of the region of highest acidity from the complementary half of the specimen. The results thus indicate that the corrodent is adequately immobilized by freezing, a requirement for the successful application of the test methods. Tests on unchilled, broken SCC specimens indicate that the freezing of the solution does not alter the solution chemistry, *i.e.*, similar indications of acidity were obtained. Thus, it can be concluded confidently that the test results are valid and represent the state of the solution at the termination of the SCC test.

The concurrence of higher acidity with the presence of the metallic ions in the region of the crack root suggests that the acidity is the result of hydrolysis of the metallic constituent released by anodic dissolution. The extreme edge of the advancing crack is generally thought to be anodic to the rest of the specimen and thus is consumed in the corrodent by the electrochemical reaction $M \rightarrow M^{+z} + ze^-$, where M is the metal in question and z the electronic charge involved. Subsequent hydrolysis represented by the general equation.

$$M^{+z} + xH_2O \rightleftarrows M(OH)_x^{(z-x)} + xH^+$$

would produce the increase in acidity observed in all the specimens used in this investigation. Such a mechanism has been offered for reactions within pits protected by an oxide film in the corrosion of Al and Fe in alkaline medium (2). It is likely that the present findings may also be applicable to other alloys which are susceptible to SCC and which contain metals the ions of which are hydrolysis prone. These results would suggest the possibility of SCC control by methods which would inhibit the hydrolysis or neutralize the acidity.

A knowledge of the acidity and the solution chemistry, obtainable by the methods described, would generally be useful in interpreting SCC and specifically be helpful in evaluating the applicability of SCC models such as the film-formation and oxide-rupture model.

[1] The presence of acidity and Al^{+++} ions within stress-corrosion cracks in Ti-Al alloys was predicted by M. Pourbaix in a seminar at NRL in 1967.

Acknowledgments

Much of the experimental work reported herein was conducted by Mr. R. L. Newbegin. This work was supported by the Advanced Research Projects Agency of the Department of Defense as part of the coupling program on stress-corrosion cracking established by ARPA Order 878.

One of the authors (B.F.B.) would like to acknowledge the stimulating value, in planning the present work, of lecture series by Dr. Evans and Dr. Hoar delivered at Cambridge University while he was a postdoctoral guest in Dr. Hoar's laboratory.

Manuscript submitted Aug. 22, 1968; revised manuscript received *ca.*, Nov. 15, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Anodic Voltammetry and Electrolytic Oxidation of Corypalline

G. F. Kirkbright,[1] J. T. Stock,* R. D. Pugliese,[2] and J. M. Bobbitt

Department of Chemistry, University of Connecticut, Storrs, Connecticut

Recent papers on the general (1) and electrolytic (2) oxidation of phenols suggested to us the possible application of electrolytic oxidation to the synthesis of isoquinoline alkaloids. A preliminary communication from this laboratory (3) has outlined the successful electrolytic and photochemical oxidation of one of the simpler isoquinoline alkaloids, corypalline (I). More recently, two studies of the ferricyanide oxidation of corypalline have appeared (4). Qualitatively, the results are similar to those now presented.

This paper describes studies leading to the optimization of conditions for the electrolytic oxidation of corypalline to the "carbon-carbon dimer" N, N'-dimethyl-6, 6'-dimethoxy-7, 7'-dihydroxy-1, 1', 2,2', 3,3', 4,4'-octahydro-8,8'-biisoquinoline (II). The method developed is simple, quite rapid, and relatively efficient. These studies strongly indicate the feasibility of the application of electrochemical oxidation to the synthesis of complex natural products (1, 5). It is especially noteworthy that an aliphatic tertiary nitrogen does not interfere significantly with the reaction.

Experimental

Voltammograms at a platinum wire microelectrode that was rotated at 600 rpm were recorded by an

L&N type E electrochemograph. Preparative electrolyses were carried out with a Wenking potentiostat. The cathode compartment was formed by epoxy cementing a medium-porosity glass filter crucible to the inner wall of the 150-ml beaker used as an electrolysis cell. The semicyclindrical platinum gauze anode had a half-circumference of 82 mm and was 52 mm high. A 50 mm x 80 mm rectangle of platinum foil rolled into a loose spiral was used as a cathode. The anolyte was agitated by a magnetic stirrer bar and by a stream of nitrogen.

Corypalline (6) was prepared (7) from isovanillin by a modification of a general synthesis of 1,2,3,4-tetrahydroisoquinolines (8).

Preparative electrolyses were monitored by thin-layer chromatography (TLC) on microscope slides coated with Merck silica gel GF. Ammonia: methanol (3:100 v/v) was used as developing solvent and the spots were visualized with iodine vapor or Dragendorf's reagent. R_f values were corypalline, 0.65; compound (II), 0.4. A yellow product that awaits identification remained at the origin.

Two grams of corypalline suspended in 100 ml of 0.1M $Na_2B_4O_7$ were placed in the cell, and the cathode compartment was filled simultaneously to the same level with 0.1M $Na_2B_4O_7$. The suspension was stirred rapidly, and nitrogen was slowly bubbled near the anode, which was maintained at a potential of +0.35v. The electrolysis was terminated when all solid had dissolved and the current had fallen by 25% from the essentially constant reading obtained in the presence of solid.

After removal from the cell, the anolyte was allowed to stand for several hours (preferably overnight) to allow precipitation of the first crop of compound (II). This was filtered off and dried. The filtrate was transferred to a 500 ml separating funnel and 20 ml of ammonia (sp gr 0.90) were added. The solution was extracted with four 100 ml portions of chloroform and the extracts were combined, dried over anhydrous $MgSO_4$ and taken to dryness under reduced pressure in a rotary evaporator. The residue was dissolved in 25 ml of chloroform, and the volume was reduced to 15 ml by gentle warming. After cooling in ice water, the recovered corypalline was filtered off. A second crop of compound (II) was obtained from the filtrate by evaporation to dryness, dissolution in 50 ml of ethanol, evaporation to a volume of 10 ml, cooling in ice-water, and filtering. The combined crops were recrystallized from ethanol, to yield (II), mp 235°-236°C, undepressed by the addition of a known specimen of compound 6 (3).

Results and Discussion

Preliminary investigations (9) have shown that, although compound (II) is the major oxidation product of corypalline, a 2-5% yield of an oxygen-linked dimer (III) can also be obtained. No attempts to isolate this minor product were made in the present work.

All potentials are with respect to the saturated calomel electrode.

Voltammetry.—The starting potentials of the single anodic waves given by compounds (I) and (II) were almost identical and, in acid and strongly alkaline media, the drawn-out wave merged into the decomposition wave of the medium. Definition was better in 0.1M $NaHCO_3$ (pH 8.4) or 0.1M $Na_2B_4O_7$ (pH 9.0), and the current approached limiting conditions over the approximate potential range +0.6 to +0.8v (Fig. 1, curve 2). No conditions were found that would permit the oxidation of corypalline without attack on the compound (II) formed by this oxidation. The marked current decay with time observed in $NaHCO_3$ was not significant in $Na_2B_4O_7$, in which a linear current-corypalline concentration relationship could be obtained at any potential in the approximate range +0.2 to +0.5v.

Controlled potential electrolysis.—Preliminary electrolyses of corypalline in CH_3COOH-CH_3COONa (pH 4.6), $NaHCO_3$, $Na_2B_4O_7$, and Na_2CO_3 showed $Na_2B_4O_7$ to be the most promising medium. Conditions finally chosen involved the electrolysis of a suspension of corypalline in 0.1M $Na_2B_4O_7$ at a potential of +0.35v. Partial destruction of compound (II) is then minimized, because the oxidation current of a saturated solution of corypalline is much larger than the current given by a saturated solution of compound (II) Fig. 1, curves 1 and 3). The current remained approximately constant while solid corypalline was present and began to diminish soon after the anolyte had become homogeneous. Experiments with unsaturated corypalline solutions showed that the logarithm of the current decreased linearly with time until the amount of electricity reached approximately 80% of that theoretically required for the oxidation of corypalline to compound (II). Deviation from linearity and fall-off in slope then occurred as shown in Fig. 2, reflecting the increasing competitive oxidation of compound (II). TLC near the deviation point showed the

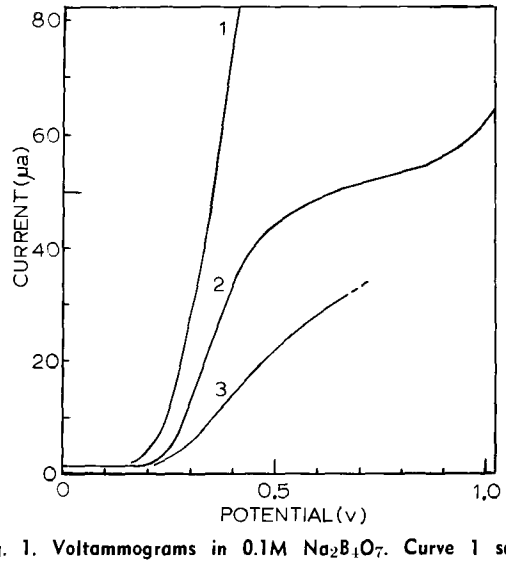

Fig. 1. Voltammograms in 0.1M $Na_2B_4O_7$. Curve 1 saturated with corypalline; curve 2, 0.001M in corypalline; curve 3, saturated with compound II.

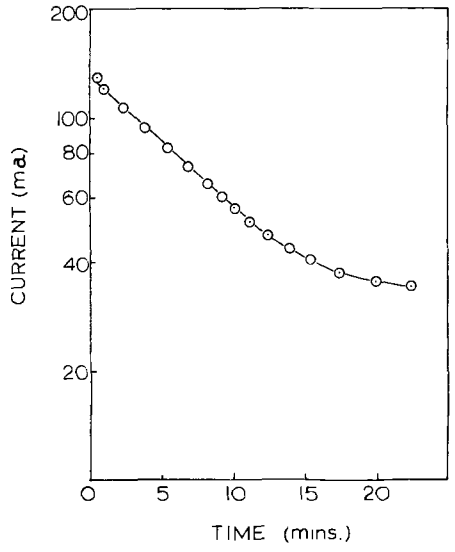

Fig. 2. Current-time relationship for 0.0075M corypalline in 0.1M $Na_2B_4O_7$.

presence of considerable amounts of corypalline and of compound (II). The concentrations of both compounds fell on further electrolysis and buildup of the concentration of a deep yellow further oxidation product proceeded rapidly.

Seven preparative runs with from 0.4 to 3.0g of corypalline gave yields of 44-60% (average 55%), based on recovered corypalline. The current efficiency for the preparation of compound (II) probably exceeds 60%. Differing percentage yields are almost certainly due to variations in the techniques used for isolation and purification of the product.

These studies are being extended to derivatives of corypalline and to other phenolic derivatives of isoquinoline.

Brief Communication

Potential-Wetting Effects of Platinum Electrodes

L. Nanis* and G. F. Rowell

School of Chemical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania

Oxygen on the platinum electrode has been the subject of much attention. Summaries of previous work may be found in recent reviews by Gilman (1) and Hoare (2). The precise nature of the oxygen on the electrode is an issue which is apparently unresolved as yet. The wetting behavior of surfaces is known to be strongly dependent on traces of surface compounds. A critical change in wetting of a platinum anode in 1*N* H_2SO_4 (room temperature) was noted in studies of the oxidation of dissolved hydrogen (3). The apparatus used incidentally permitted rapid (2-3 sec) drainage of a layer of acid 2.4 mm thick from a vertical smooth platinum electrode, 9 x 9 cm, and also permitted observation of the electrode surface. It was noticed that the drainage behavior was influenced by the potential of the electrode. The nature of the draining electrolyte film was correlated with electrode potential by commencement of drainage when the electrode potential was near the hold plateau of 0.74 $\pm$0.02v during transient decay (open circuit) from above 1v.

For drainage beginning above 0.76v (with respect to a reversible hydrogen electrode in the H_2 saturated 1*N* H_2SO_4), total wetting occurred initially. For drainage initiated when the electrode was below 0.70v, the surface was not truly wetted but isolated beads of electrolyte remained. Correspondingly, the total drainage was noticeably more rapid from the poorly wetted surface. In the range between 0.70 and 0.76v, the drainage behavior included mixed features, *i.e.*, initial partial wetting. The wetting behavior noticed here should be added to consideration of the nature of the adsorbed oxygen layer on platinum.

High-Temperature Oxidation of Co-10 w/o Cr Alloys

I. Microstructure of Oxide Scales

P. K. Kofstad[1] and A. Z. Hed

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Oxidation of Co-10 w/o Cr alloy results in an outer CoO layer, an inner CoO layer with inclusions of Cr_2O_3 and $CoCr_2O_4$, and an internal oxidation zone. Both oxide layers contain appreciable porosity and the morphology of the inclusions is a function of temperature. The microstructure of scales formed during oxidation is presented. It is assumed that the rate-controlling step is the solid state diffusion of Co-ions in the CoO phase, while gaseous oxygen is rapidly transported across pores. The pores short-circuit the solid state diffusion process and enhance oxidation, while Cr_2O_3 and Co-Cr spinel inclusions inhibit the oxidation.

Cobalt-chromium alloys serve as a basis material for production of a family of Co-base superalloys for high-temperature applications. To increase the service lifetime and use temperatures of these alloys, an understanding of their chemical stability and, particularly, their oxidation resistance is of paramount importance.

The development of oxidation-resistant alloys has to a large extent been empirical and therefore has failed to provide a detailed understanding of mechanisms of alloy oxidation. The work reported here is a part of a general study on the different mechanisms governing the oxidation behavior of Co-Cr alloys. This paper describes some microstructural and morphological aspects of the scales formed during oxidation of Co-10 w/o (weight per cent) Cr alloys and their influence on the scaling rate.

Oxidation of Co-Cr alloys has been studied by Preece and Lucas (1) in the range 0-40 w/o Cr and by Phalnikar, Evans, and Baldwin (2) in the range 0-48 w/o Cr. Davin, Coutsouradis, and Habraken (3) studied the oxidation behavior of pure cobalt and of Co-Cr alloys containing 10 and 35% Cr.

The study by Phalnikar *et al.*, was the most extensive of these. According to these authors, the main feature of the oxidation behavior of Co-Cr alloys above 900°C is that the oxidation of this system increases with increasing amounts of chromium up to about 10 w/o Cr. Beyond this level, the oxidation rate decreases with increasing chromium content up to 20-30 w/o Cr, after which the oxidation rate again increases up to unalloyed chromium. Their metallographic studies revealed that small additions of chromium cause formation of duplex scales: the outer layer consists mainly of CoO, while the inner layer consists of CoO, Cr_2O_3, and the spinel $CoCr_2O_4$. They found that Cr_2O_3 and the spinel do not form continuous layers but are dispersed in the CoO matrix of the inner layer. They concluded that the rate-controlling process in the oxidation of low-chromium-content Co-Cr alloys is solid-state diffusion of cobalt in CoO. They attributed the continuous increase in the oxidation rate up to 10% Cr to the doping effect of the scale, according to the semiconductor valence approach of alloy oxidation (Wagner theory). However, no detailed analysis was given.

It must be emphasized that, for the Wagner theory to hold, the concentration of the dopant (chromium in this case) must be higher than the native-defect concentration at the ambient oxygen pressure. No data for the solubility of chromium in CoO were reported, either in their work or elsewhere. If we take the solubility of chromium in NiO as a measure of that of chromium in CoO (see below), the use of the semiconductor valence approach in explaining the oxidation of Co-Cr alloy with more than a few per cent chromium does not appear justified.

Meyer and Rapp (4) found that no more than 1% Cr will dissolve in NiO, yet the oxidation rate of Ni-Cr alloys increases continuously up to 5% Cr (5). If the Wagner theory were to be used, a saturation of the NiO scale with Cr would have occurred at 1% Cr, and the oxidation rate should not increase above that chromium percentage. Similar behavior should be expected for the oxidation of Co-Cr alloys. No explanation of the increased rate has as yet been given.

Phalnikar *et al.*, attributed the decrease of the oxidation rate at high chromium concentration to a "blocking" effect by either Cr_2O_3 or spinel. The relative abilities of Cr_2O_3 and spinel to impart oxidation resistance were not evaluated.

This paper reports on the microstructures of scales formed on Co-10 w/o Cr alloy and suggests how these can account for the increased oxidation rate at high temperatures. Thermogravimetric data on this alloy will be given in a following paper (9).

Experimental Procedure

An alloy with the nominal composition Co-10 w/o Cr was prepared in a vacuum furnace and cast into tapered zirconite sand molds. Subsequent analysis showed the actual composition to be 9.62 w/o Cr. After grit blasting, the ingots were heat treated at 1175°C for 2 hr, and then forged. The ingots were cold rolled down to plates of 0.070-in. thickness. After rolling, the plates were reblasted, cut to specimens 1 x 0.75 in., then subsequently ground on emery paper and diamond polished. This procedure removed some 2-4 mils.

Specimens were oxidized in the temperature range 800°-1300°C at oxygen pressures from 0.2 to 760 Torr. A Crusilite furnace was used, with a Mullite tube as a reaction chamber held by a Barber-Coleman controller within 3°C. Weight gains were continuously recorded with a Cahn R-H electrobalance and an AZAR Leeds and Northrup recorder. The balance was used with a full range of 2g, a recording range of 20 mg, and a sensitivity of 0.1 mg. The system could be evacuated to 10^{-5} Torr by a 450-liter CVC diffusion pump and an Edwards mechanical pump. The pressures were measured by CVC-ionization and thermocouple gauges. The polished specimen, washed in water and trichloroethylene, was attached to an annealed Pt-10 Rh wire and dropped into the hot zone by a magnetic device while the system was under high vacuum. Oxygen was then introduced by a Granville-Phillips metering valve to the desired pressure. Below 10 Torr O_2, oxygen was continuously pumped through the apparatus during the run. After oxidation proceeded to the desired extent, the samples were raised into the cool part of the furnace, oxygen was introduced into the reaction chamber, and the specimens were taken out and quenched in molten lead-bismuth

[1] Present address: Central Institute for Industrial Research, Blindern, Oslo, Norway.

alloy, which in turn was rapidly cooled. This was done to prevent spallation of the scale. Some samples were than chosen for metallographic study, x-ray analysis, and electron-probe microanalysis. A Picker x-ray machine was used to determine the different compounds in the scale. A Kenny electron-microprobe analyzer was used for the probe analysis. Since the oxides at room temperature are poor electrical conductors, a layer of carbon 250Å thick was deposited on the specimens. The limit of detection is 0.1%, while the actual resolution is ± 0.5%.

Microstructure of Oxide Scales

The oxidation of the Co-10 w/o Cr specimens results in two-layered scales. The outer layer consists of columnar grains of CoO and the inner of CoO, Cr_2O_3, and the spinel $CoCr_2O_4$. A small area of chromium internal oxidation is present to varying degrees under all oxidation conditions. Various features of the oxide scales are illustrated in Fig. 2 through 15.

Electron-probe microanalyses were performed on a few samples. A typical result is shown in Fig. 1. The outer scale contained less than 0.1 Cr, which is the limit of detection of the apparatus. In the inner layer, no regular gradient of chromium was found, instead, an irregular distribution of high chromium and high cobalt content was found. As described below, the spinel appears as a dispersion in the CoO matrix, and an accurate determination of its composition is not possible by electron-probe microanalysis. We will therefore refer to it as $CoCr_2O_4$, although it must be borne in mind that the actual composition may vary from $Co_{1.3}Cr_{1.8}O_4$ to $CoCr_2O_4$ (11).

Detailed metallographic studies of specimens oxidized under different conditions were performed. Different etching agents were tried to reveal the different constituents of the scale. The following etching agent was found to be most effective: 80 parts lactic acid, 10 parts HNO_3, 10 parts H_2O_2, and 5 parts HCl. This agent completely etched out the Cr_2O_3 and attacked the CoO, to some extent. The spinel is slightly more resistant to the etchant than is the CoO. We were able to determine the distribution of the three constituents in the scale by comparing the metallographic cross section before and after etching.

The only other phase found in the outer layer consists of small Co_3O_4 precipitates within the grains and at the grain boundaries. This confirms the electron-microprobe results, that no measurable Cr_2O_3 is present in this part of the scale.

The deviation from stoichiometry of CoO increases with temperature and partial pressure of oxygen and, at 1200°C and 1 atm O_2, reaches 1.5% excess oxygen (6). When CoO is cooled, the excess oxygen precipitates in the form of Co_3O_4. The concentration of these precipitates should, therefore, increase with increasing temperature and oxygen partial pressure. This effect was not easily observed, however, since the degree of precipitation depends critically on the quenching procedure, which was not accurately reproducible from sample to sample. Nevertheless, a small effect of temperature can be seen in the scales of specimens oxidized at 1000° and 1200°C (Fig. 3 and 4, respectively). Assuming a uniform quenching of the sample, a gradient of these precipitates should be present in the outer scale according to the decreasing oxygen activity. Such an effect is, however, probably masked by the temperature gradients in the samples during cooling and by extensive precipitation at the grain boundaries, which causes a depletion of Co_3O_4 in the grains near these boundaries. In addition, the gradient of excess oxygen in the outer layer may be small compared with that in the inner layer. It may be noted that the appearance of the outer scale is similar to scale formed during oxidation of unalloyed cobalt (7,8).

The interface between the inner and outer layers shows the geometry of the original alloy surfaces (Fig. 2, 3, and 4.). We therefore concluded that this interface in fact represents the original alloy surface. To further substantiate this, a notched specimen was oxidized. The notch dimensions were accurately measured and compared with dimensions of the inner-outer layer boundary at the notch after oxidation. Very good agreement was found.

The microstructure of the inner layer depends largely on the temperature of the oxidation. At low temperatures one can see a general striation with dark and bright layers (Fig. 2 and 3), while at high temperatures the appearance of the inner layer is more uniform. The details of this behavior are described below.

Spinel Morphology

The spinel morphology in the scale depends largely on temperature and to a lesser degree on the oxygen partial pressure of the oxidizing atmosphere. Various

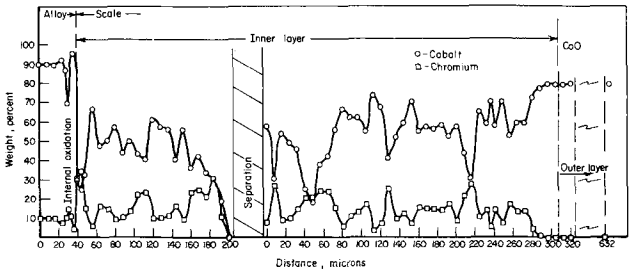

Fig. 1. Profile of cobalt and chromium content in a scale produced on a Co-10 w/o Cr alloy oxidized at 1100°C in air for 17 hr. Note: A slight depletion of chromium followed by an increase is observed at the alloy-oxide interface in the internal-oxidation region. The sum of cobalt and chromium is not constant due to porosity. The outer layer contains only cobalt.

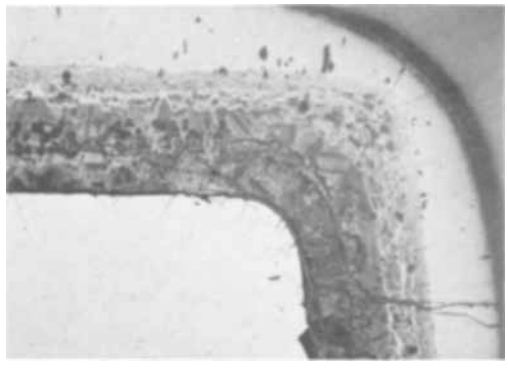

Fig. 2. Corner of a Co-10 w/o Cr specimen oxidized at 900°C in air for 193 hr. Note the decrease in the density of spinel decoration at original alloy grain boundaries from the inner-outer layer interface toward the alloy. Magnification of Fig. 2-4 is *ca.* 50X.

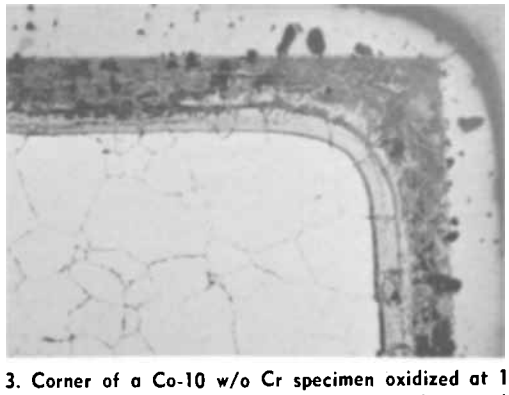

Fig. 3. Corner of a Co-10 w/o Cr specimen oxidized at 1000°C in air for 11 hr. Note the pyramidal pores in outer layer and irregularly shaped pores in the inner layer. Spinel decorations are larger than at 900°C.

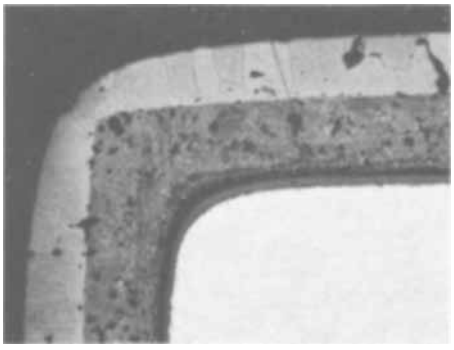

Fig. 4. Corner of a Co-10 w/o Cr specimen oxidized at 1200°C in 100 Torr O_2 for 3 hr. Note: No spinel decoration of the original grain boundaries is present, and irregularly shaped pores are quite evenly distributed.

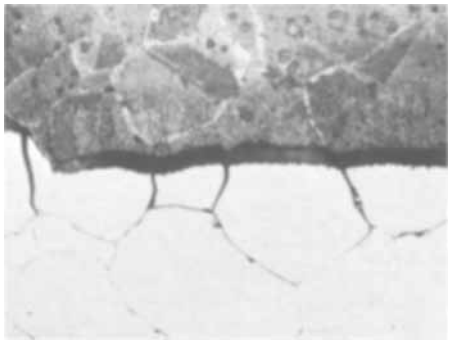

Fig. 5. Alloy-scale interface of specimens of Fig. 2. Note the internal oxidation of alloy grain boundaries and their continuation in the scale as spinel decoration, along with fine dispersion of spinel within the "grains." Magnification of Fig. 5-10 is *ca.* 250X.

features of the spinel growth are illustrated in Fig. 5 through 10.

Figure 5 shows the metal-oxide interface of a sample oxidized at 900°C in air. The grain boundaries in the alloy are etched out, and one can see their continuation in the scale outlined by lighter colored spinel. The etching out of the grain boundaries in the alloy is due to preferential internal oxidation of chromium to Cr_2O_3 at the grain boundaries. Also, fine internal oxidation along the metal-oxide interface occurs, and correspondingly, a fine dispersion of spinel in the CoO inner scale is present. A similar behavior is illustrated in Fig. 6, which shows a specimen oxidized at 900°C and 10 Torr oxygen. Due to the lower partial pressure of oxygen, the internal oxidation is slightly more severe along the metal-oxide interface than along the grain boundaries.

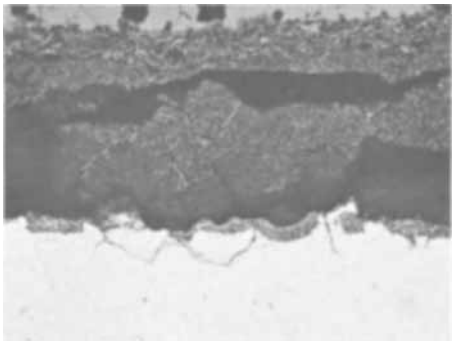

Fig. 6. Alloy-scale interface of a Co-10 w/o Cr specimen oxidized at 900°C in 10 Torr O_2 for 70 hr. Note the more intense internal oxidation at the interface than in air (Fig. 5), and "grain-boundary" decoration by spinel.

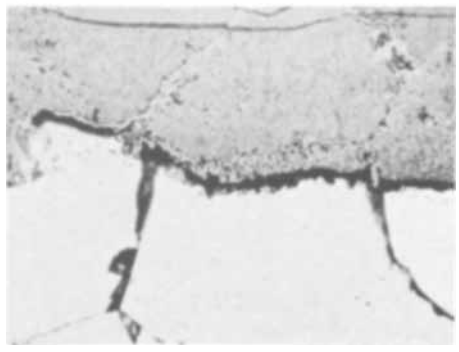

Fig. 7. Alloy-scale interface of a Co-10 w/o Cr specimen oxidized in air at 1000°C for 140 hr. Note the large grains due to annealing during oxidation; spinel decoration is lighter and spinel dispersion coarser than in Fig. 5.

Figure 7 shows the metal-oxide interface of a sample oxidized at 1000°C in air. The grains in the alloy are larger (due to annealing at temperature during oxidation) than in the sample oxidized at 900°C. Furthermore, in the oxide, the spinel decoration along the original grain boundaries in the alloy is less marked and the individual spinel particles are larger in size than those obtained at 900°C.

In Fig. 8 the metal-oxide interface of the specimen oxidized at 1100°C and 100 Torr O_2 is shown. The decoration of the spinel along the original grain boundaries of the alloy has disappeared completely, and the spinel particles are much larger. Figures 9 and 10 show the metal-oxide interface of specimens oxidized at 1200°C in 100 and 10 Torr O_2, respectively. At 100 Torr the spinel has formed relatively large platelets dispersed in a CoO matrix, while at 10 Torr less CoO matrix is left. (The dark background is epoxy that filled a network of pores near the metal-oxide inter-

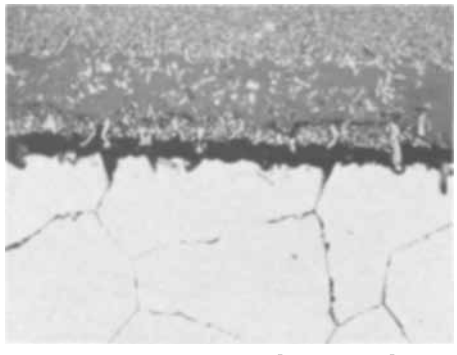

Fig. 8. Alloy-scale interface of a Co-10 w/o Cr specimen oxidized at 1100°C in 100 Torr O_2 for 20 hr. Note: No spinel decorations are present in the scale.

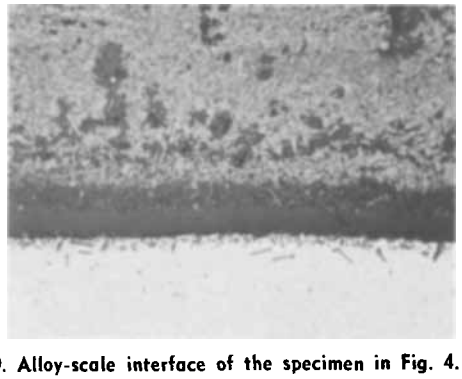

Fig. 9. Alloy-scale interface of the specimen in Fig. 4. Note the line of pores and very coarse spinel. (Spinelization occurs probably partly within the internal oxidation region.)

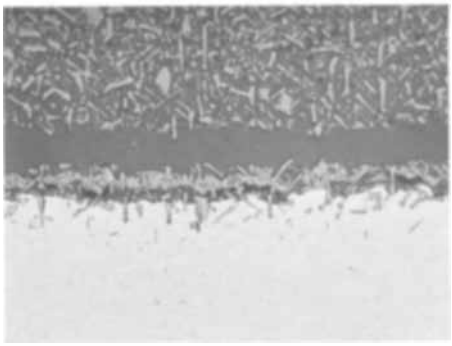

Fig. 10. Alloy-scale interface of a Co-10 w/o Cr specimen oxidized at 1200°C in 10 Torr O_2 for 1.5 hr.

face. The actual pores in this case could be smaller than seen in the photograph.)

From these observations we conclude that the size of the spinel particles and their location in the scale depend largely on temperature. At low temperatures the spinel is finely dispersed and is formed along the original grain boundaries of the alloy. With higher temperatures, the spinel particles grow in size and become more uniformly distributed in the oxide, and the decoration along the original grain boundaries in the alloy disappears.

The distribution of the spinel may also be affected by the history of the oxidizing sample. An example is given in Fig. 11, which shows the scale of a sample oxidized at 900°C in air. The spinel decoration of the original alloy grain boundaries near the outer part of the inner layer shows small "grain" size (which is probably not the oxide grain size), but the size increases as the metal-oxide interface is approached. This feature is due to the fact that the sample was cold rolled and that the grain size before oxidation was relatively small. During oxidation, the alloy is simultaneously annealed, and the grain size in the alloy increases correspondingly. When the temperature is raised, this behavior changes accordingly. In Fig. 3, which shows a sample oxidized at 1000°C, only a very narrow range of small "grains" next to the interface between the inner and outer layers is observed. At and above 1100°C (Fig. 12 and 14) the spinel outlines of the original grain boundaries in the alloy have disappeared.

Porosity in the Scale

Different kinds of pores are observed in the scales. In the outer layer triangular pores are found, the tops of which always point toward the outer oxide surface. This is illustrated in Fig. 13. This kind of pore occurs in almost all of the outer layers (Fig. 2, 3, 11, and 12). To further identify the geometry of these pores, a cross section of the outer layer at a small angle with the outer surface was prepared (see Fig. 14). As

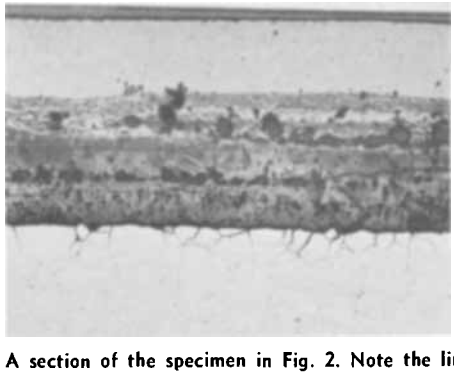

Fig. 11. A section of the specimen in Fig. 2. Note the line of irregularly shaped pores and the behavior of spinel decoration. Magnification ca. 50X.

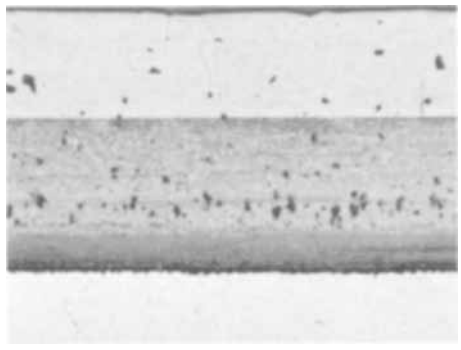

Fig. 12. Section of the specimen in Fig. 8. Note spinel dispersion and slight striation in the inner layer. Magnification ca. 50X.

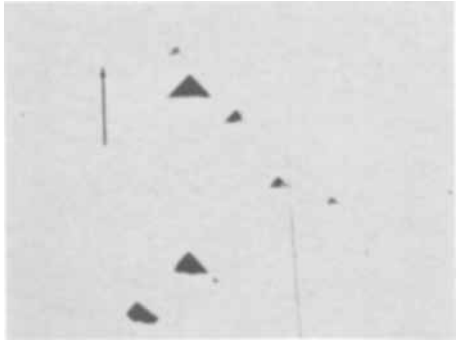

Fig. 13. Perpendicular cross section of the outer layer of a Co-10 w/o Cr specimen oxidized at 1100°C in air for 119 hr. Note the triangular form of the pores in this layer. The arrow is pointing toward the oxide gas interface. Magnification ca. 125X.

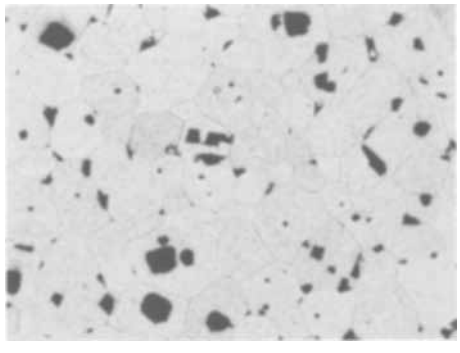

Fig. 14. Tapered cross section of the outer layer of a Co-10 w/o Cr specimen oxidized at 1200°C in 100 Torr O_2 for 35 hr, showing the rectangular shape of the pores parallel to the alloy surface. Magnification ca. 100X.

viewed in this direction, the pores tend to be rectangular. We therefore conclude that these pores tend to be rectangularly shaped pyramids whose tops are pointing toward the outer oxide surface.

The inner layer contains only irregularly shaped pores (Fig. 2, 3, 11, and 12), which may be divided into three groups: (*i*) large pores that sometimes coalesce to form a line of pores, (*ii*) very small pores or micropores distributed evenly throughout the matrix, and (*iii*) pores associated with the chromium oxide in the scale.

The amount of porosity was estimated from the dimensions of the scale and the weight gain of the specimen. In such an estimate one must consider differences in porosities of the inner and outer layers. Assuming that the outer layer is fully dense, the inner layer would be 39% porous. Assuming that the pores are equally distributed throughout both layers, the average porosity would be 27%. The actual values lie

between these limits, and it is estimated that the mean values amount to 33-35% porosity in the inner layer and 3-6% porosity in the outer layer.

In a consideration of the porosity, it is also of interest to estimate the volume change upon converting the alloy to the oxide. Comparisons were made of the thickness of the consumed part of the alloy and the thickness of the inner oxide layer. As an example, in one case the thickness of the consumed alloy was 0.53 mm, while the thickness of the inner layer was 0.93 mm, which amounts to an increase of 75%. As discussed above, the interface between the inner and outer oxide layers reflects the position of the original surface of the alloy. This means that this interface is continuously displaced outward, relative to the center of the specimen during oxidation.

The expanding inner layer puts the outer layer under tension. This tension is probably partially accommodated for by the growth process of the outer layer (involving outward migration of cobalt ions) and partially by plastic deformation and creep. It is proposed that the pyramid-like pores in the outer layer result from mechanical shear and deformation.

The porosity in the inner layer is to a large extent due to the outward migration of cobalt ions to form the outer layer (see Discussion, below). It is not improbable that volume change associated with the oxide formation also causes stresses that in turn may be alleviated by local loss of adherence to the alloy substrate. This may yield porosity in the form of bands observed in some metallographic cross sections.

Discussion

High-temperature oxidation of Co-10 w/o Cr results in the formation of a two-layered oxide scale and a small internal oxidation zone. The over-all oxidation is approximately parabolic (9). In this context only a brief qualitative discussion will be made, while a more detailed treatment of the reaction mechanism is presented elsewhere (9).

The outer layer of the scale consists of CoO and the inner layer consists of CoO with dispersed $CoCr_2O_4$ and Cr_2O_3, while the inner oxidation zone involves formation of Cr_2O_3 in the alloy. The scale, particularly the inner layer, contains appreciable porosity. The demarcation between the outer and inner layers represents the original surface of the alloy.

The parabolic oxidation indicates that the reaction is controlled by solid-state diffusion. However, since the scale is two-layered and consists of several oxide phases, the transport through the scale becomes complex.

When considering the solid-state diffusion processes in the scale, the relative rates of diffusion of cobalt, chromium, and oxygen in CoO, Cr_2O_3, and $CoCr_2O_4$ are of primary importance. Available self-diffusion data show that Co diffusion in CoO (10) is more than three orders of magnitude faster than diffusion of Co or Cr in $CoCr_2O_4$ (11,12) and two orders faster than that of Cr in Cr_2O_3 (13). Oxygen diffusion in CoO (14), Cr_2O_3 (15), and , probably, in $CoCr_2O_4$ is slower than that of the cations. In a discussion of the transport processes in the scale growth, solid-state oxygen diffusion can therefore be neglected, and diffusion of the cations through $CoCr_2O_4$ is negligible compared with that of Co in CoO. As in oxidation of unalloyed cobalt (10,15,16), the solid-state Co diffusion in the CoO phase is probably the predominant process in the oxidation, and the presence of the dispersed $CoCr_2O_4$ particles in the inner layer serves to reduce the effective solid-state diffusion area.

If one neglects the surface oxide formed prior to the start of the actual oxidation run, the initial oxidation at atmospheric or subatmospheric pressures probably involves the simultaneous formation of Cr_2O_3 and CoO. After a continuous film is built up, the oxidation becomes diffusion controlled. The microprobe data (Fig. 1) show that the solubility and /or diffusion of Cr in CoO is low; the continued oxidation thus involves Co diffusion outward through the CoO phase by a vacancy mechanism, and reaction with oxygen takes place at the outer surface. In this manner the CoO phase grows on top of the original alloy surface. Simultaneously, oxygen dissolves in the alloy phase and internally oxidizes the chromium to Cr_2O_3. The Cr_2O_3 is formed as discrete particles in the metal in a zone at the scale-metal interface. At the lower temperatures (*e.g.*, 900° and 1000°C), a marked internal oxidation takes place at grain boundaries in the metal, but this preferential internal oxidation at grain boundaries disappears at higher temperatures. With increasing temperature, the Cr_2O_3 particle size increases. The internal oxidation of chromium depletes the alloy phase in chromium, and the metal at the scale-metal interface probably consists of essentially pure Co. The Cr_2O_3 particles are immobile with respect to cobalt; they serve as internal markers, and the first Cr_2O_3 particles (which subsequently react with CoO to form $CoCr_2O_4$) delineate the original alloy surface.

Considerable porosity is formed as a result of the reaction mechanism. After the outer layer of CoO is formed, with the absence of solid-state oxygen diffusion in CoO, oxygen for the internal oxidation can be obtained only through a decomposition of CoO at the metal-scale interface. While the oxygen is consumed in the internal oxidation, the correspondingly formed cobalt ion diffuses outward through the CoO layer. For each oxygen atom that is consumed through internal oxidation, one CoO molecule is simultaneously removed from the CoO layer at the metal-scale interface. This may result in cavity formation at the inner boundary of the CoO layer. This cavity formation is counteracted by a volume increase of the metal due to the internal oxidation and possibly by plastic deformation of the outer CoO layer.

If physical contact remains between the CoO layer and the metal, the Co metal between internal Cr_2O_3 particles will diffuse outward through the CoO scale. However, the Co supply between the Cr_2O_3 particles is limited. Due to slow diffusion through Cr_2O_3, these particles block the supply of cobalt from underlying areas, and the Cr_2O_3 particles probably serve as sites or areas for cobalt vacancy condensation. As a result, cavities or porosity accumulate at the surface of the Cr_2O_3, particularly the surface facing the outer layer.

This porosity correspondingly reduces the available area for solid-state diffusion of cobalt, but it probably does not limit the oxidation, as discussed in the literature (17). The cobalt oxide on the cavity facing the outer surface decomposes; the cobalt diffuses outward, while the oxygen gas is probably rapidly transferred across the cavity to the inner surface, where it in turn reacts with cobalt. In this manner, CoO is formed beneath the original alloy surface. The Cr_2O_3 particles partially become surrounded by pores and partially by CoO. The Cr_2O_3 and CoO gradually react to form the spinel $CoCr_2O_4$. In all the oxide scales examined in this study, spinel rather than Cr_2O_3 is present, while Cr_2O_3 is observed only next to the metal phase. The inner layer of the oxide scale is formed by the combination of the internal oxidation and the transport of gaseous oxygen across the cavities in the inner layer. The outer layer is formed through outward diffusion of cobalt in the areas where the outer layer is in solid contact with the CoO matrix of the inner layer.

It is difficult to estimate accurately the amount of porosity that is formed in the scale. Part of the porosity stems from the vacancy condensation described above. Some of the porosity is also directly related to the alloy composition. Thus, the flux of cobalt ions that react with oxygen at the outer surface is larger than the cobalt flux reacting with oxygen at the scale-metal interface. Since we have 9.6 w/o or 11.7 a/o (atomic per cent) Cr in the alloy, about 17 a/o of the oxygen at this interface is consumed by chromium to form Cr_2O_3. This means that 17% more cobalt ions react with oxygen at the CoO-gas interface than at the scale-metal interface, leaving a corresponding amount of

porosity in the scale. Other factors affecting the porosity are sintering and plastic deformation, both of which will tend to reduce porosity.

In an over-all consideration of the oxidation rate, the blocking of the transport of cobalt within the scale by the spinel phase and the rapid, short-circuiting transport of oxygen across the cavities must be considered. This will be treated in a separate paper (9).

High Temperature Oxidation of Co-10 w/o Cr Alloys

II. Oxidation Kinetics

P. K. Kofstad[1] and A. Z. Hed

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

Thermogravimetric studies of the oxidation kinetics of Co-10 w/o Cr have been carried out in the temperature range 800°-1300°C at oxygen pressures from 0.05 to 760 Torr. The over-all oxidation is parabolic, and the oxygen pressure dependence of the rate constant can be expressed by $k_p \propto p_{O_2}^{1/n}$, where n varies from 3 at 900° to 2.5 at 1300°C. The oxidation is faster than that of pure cobalt. The oxide scale is double-layered and consists of an outer CoO layer and an inner layer of $CoCr_2O_4$ and Cr_2O_3 particles embedded in a CoO matrix. The inner layer also contains 30-35 v/o (volume per cent) porosity. It is concluded that the oxidation is controlled by Co-vacancy diffusion in the CoO-phase. The spinel inclusions inhibit the oxidation by decreasing the effective diffusion area in the scale. The pores partially short-circuit the solid-state diffusion through the scale due to oxygen transport across the pores; the porosity then serves to increase the oxidation. Semiconductor valence effects due to dissolution of chromium in the CoO phase are concluded to be of minor importance as regards the relative oxidation behavior of pure cobalt and Co-10 w/o Cr alloy.

In the previous paper (1) (hereafter referred to as I) the microstructure of scales formed in oxidation of Co-10 w/o (weight per cent) Cr are described. In this paper the results of thermogravimetric oxidation rate studies in the temperature range 800°-1300°C at oxygen pressures ranging from 0.05 to 760 Torr are reported and discussed.

The oxide phases formed in high-temperature oxidation of Co-10 w/o Cr comprise CoO, Cr_2O_3, and $CoCr_2O_4$ (1). In the following is given a brief survey of reported data on the diffusion in these oxides and of oxidation of cobalt.

Literature Survey

Diffusion in CoO, Cr_2O_3, *and* $CoCr_2O_4$.—CoO is a metal-deficient oxide in which metal vacancy defects predominate. From studies of nonstoichiometry and electrical conductivity of CoO as a function of temperature and partial pressure of oxygen, Fisher and Tannhauser (2) have concluded that the cobalt vacancies may be neutral or singly or doubly charged, depending on the temperature and partial pressure of oxygen. Doubly charged vacancies predominate in a region next to the Co-CoO phase boundary, singly charged vacancies are dominant at higher oxygen pressures, and neutral vacancies are important in a region next to the CoO-Co_3O_4 phase boundary. Accordingly the electrical conductivity at near-atmospheric pressures is proportional to $p_{O_2}^{1/4}$ and the self-diffusion of cobalt in CoO (950°-1350°C and 1-10^{-3} atm O_2) is proportional to $p_{O_2}^{1/3}$ at 1 atm O_2 and to about $p_{O_2}^{1/4}$ at 10^{-3} atm O_2 (2-4). At an oxygen pressure of 5 x 10^{-3} atm, i.e., when the vacancy concentration and diffusion coefficient is proportional to $p_{O_2}^{1/4}$, the Co-tracer diffusion coefficient is given by $D_{Co}^{T} = 1.7 \times 10^{-3} \exp(-38{,}000/RT)$. The observed activation energy of 38 kcal/mole partially represents the activation energy of diffusion of the vacancies

[1] Present address: Central Institute for Industrial Research, Blindern, Oslo, Norway.

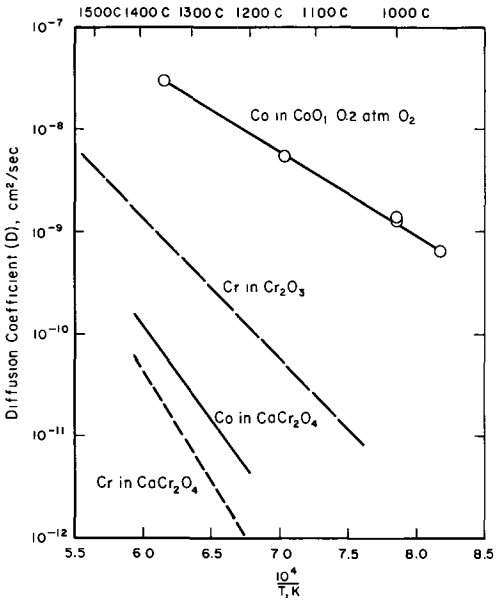

Fig. 1. Comparative plots of cation diffusion in CoO, Cr_2O_3, and $CoCr_2O_4$.

(~30-32 kcal/mole) and partially the heat of formation of the singly charged vacancies (4). The temperature dependence of $D_{Co}{}^T$ at 0.2 atm O_2 is shown in Fig. 1. The oxygen diffusion coefficient in CoO has been found to be three orders of magnitude lower than that of cobalt at high temperature (5, 6).

The defect structure and diffusion mechanism in Cr_2O_3 have not been unequivocally determined (7-14). However, Cr ions are the faster moving ionic species in Cr_2O_3, and the diffusion coefficient of Cr is approximately three orders of magnitude faster than that of oxygen at high temperatures (9, 14). Cr-diffusion is sensitive to pretreatment of the oxide specimens (hot-pressing *vs.* sintering) and probably to impurity content (9). Hagel and Seybolt (9) found that the self-diffusion coefficient of chromium is independent of oxygen pressure. They suggest that the best value for the tracer self-diffusion coefficient is given by $D_{Cr}{}^T = 0.167 \exp(-61{,}100/RT)$ (Fig. 1).

$CoCr_2O_4$ is a normal spinel. It may be nonstoichiometric with its composition ranging from $CoCr_2O_4$ to $Co_{1.3}Cr_{1.8}O_4$ at 1200°-1400°C (15). Although the exact diffusion mechanism is not known, the diffusion coefficients of the cations in the $CoCr_2O_4$ phase are appreciably slower than in Cr_2O_3 (15, 16). This is illustrated in the comparative plot in Fig. 1. As regards potential protective properties in compact oxide scales, the spinel phase is expected to be by far the best oxide.

Oxidation of cobalt.—The oxidation of high-purity cobalt above 950°C results in the formation of a compact scale of CoO (4, 9, 17-20). The oxidation follows a parabolic rate equation

$$\frac{dx}{dt} = \frac{k_p}{x} \qquad [1]$$

where x is the scale thickness, t is time, and k_p the parabolic rate constant. For dense scales x is related to the total weight gain, Δm, through $x = (\Delta m)/YdA$, where Y is the average weight fraction of oxygen in the oxide, d is the oxide density, and A is the surface area.

Through the Wagner theory k_p can be expressed in terms of the diffusion coefficient of cobalt in CoO. Experimental and calculated values of k_p are in good agreement (4). k_p is approximately proportional to $p_{O_2}{}^{1/3}$ at 1-10^{-2} atm. Below 950°C formation of Co_3O_4 takes place at high oxygen pressures. When CoO-

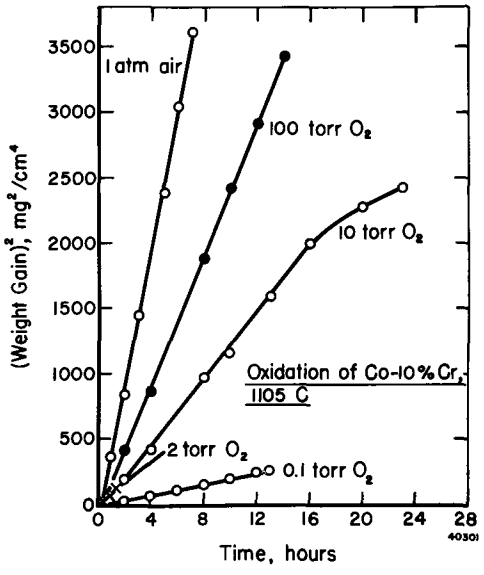

Fig. 3. Oxidation of Co-10 w/o Cr alloys at 1105°C in oxygen at pressures from 0.1 to 100 Torr oxygen. Parabolic plot.

Co_3O_4 scales are formed, k_p becomes independent of the ambient partial pressure of oxygen (4).

Experimental Results

The experimental procedure has been described in I. The results of the thermogravimetric studies are presented in Fig. 2-8. Figures 2, 3, and 4 show parabolic plots of the oxidation of Co-10 w/o Cr at different oxygen partial pressures from 0.1 to 760 Torr at temperatures of 900°, 1105°, and 1200°C, respectively. In all cases the oxidation is well described by a parabolic rate equation. Under some conditions (*e.g.*, at 100 Torr O_2, at 1200°C), one observes breaks or periodic changes within the over-all parabolic oxidation.

The oxidation exhibits a marked oxygen-pressure dependence. This is illustrated in Fig. 5, in which the parabolic rate constant is plotted as function of p_{O_2}. The pressure dependence can be expressed by $k_p \propto p_{O_2}{}^{1/n}$,[2] where n gradually changes from approximately 3 at 900°C to 2.5 at 1300°C. This pressure dependence is similar to that for oxidation of unalloyed cobalt with CoO scales, although for cobalt oxidation the values of n tend to be slightly higher.

In the temperature range 900°-1300°C, the Co-10 w/o Cr alloy oxidizes faster than unalloyed cobalt.

[2] k_p in Fig. 5 is related to k_p in Eq. [1] by the factor $(yd)^{-2}$.

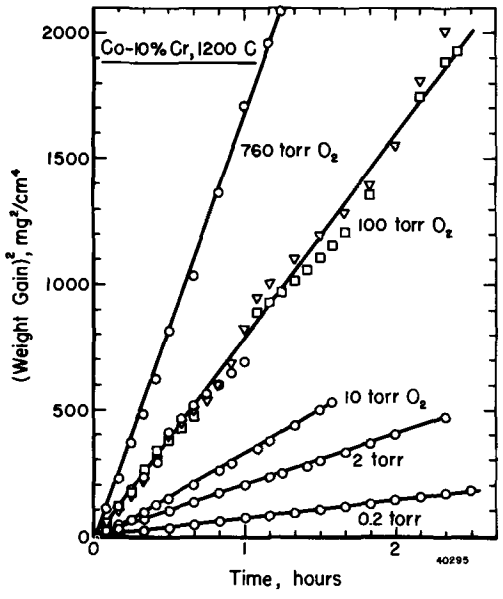

Fig. 4. Oxidation of Co-10 w/o Cr alloys at 1200°C in oxygen at pressures from 0.2 to 760 Torr oxygen. Parabolic plot.

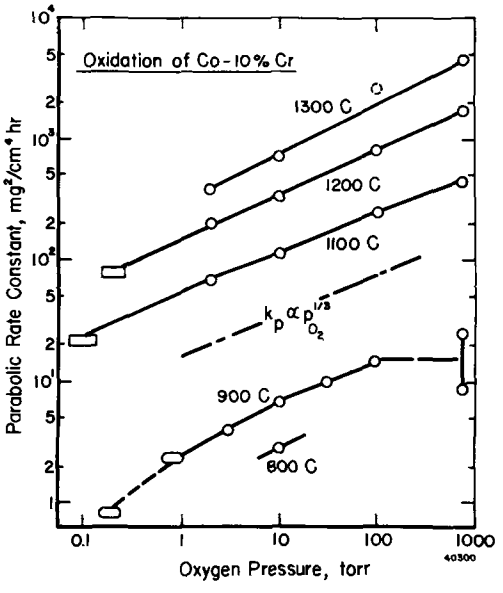

Fig. 5. Parabolic rate constants for oxidation of Co-10 w/o Cr alloys as a function of oxygen pressure at temperatures ranging from 800° to 1300°C.

This is illustrated in Fig. 6, which shows a comparative Arrhenius plot of the parabolic rate constant for oxidation of the Co-10 w/o Cr alloy and of unalloyed cobalt at 100 Torr oxygen. The activation energy for oxidation of the alloy is greater (~46 kcal/mole) than that for oxidation of unalloyed cobalt (35 kcal/mole), and thus the alloy oxidizes progressively faster with increasing temperature as compared with unalloyed cobalt.

At oxygen pressures below 0.1 Torr the oxidation tends to deviate from parabolic behavior during the initial oxidation. This is illustrated in Fig. 7, which shows a linear plot of the oxidation of the Co-10 w/o Cr alloy at 0.05 Torr O_2 at 900°, 1000°, 1100°, and 1200°C, respectively. At the three lower temperatures the oxidation tends to be linear.

After longer periods of oxidation the initial linear oxidation gradually transforms to parabolic oxidation. This is shown in the combined linear and parabolic plot of extended oxidation at 900°C and 0.05 Torr O_2 in Fig. 8.

Discussion

Although the oxidation kinetics of unalloyed cobalt and the Co-10 w/o Cr alloy are similar, they differ in

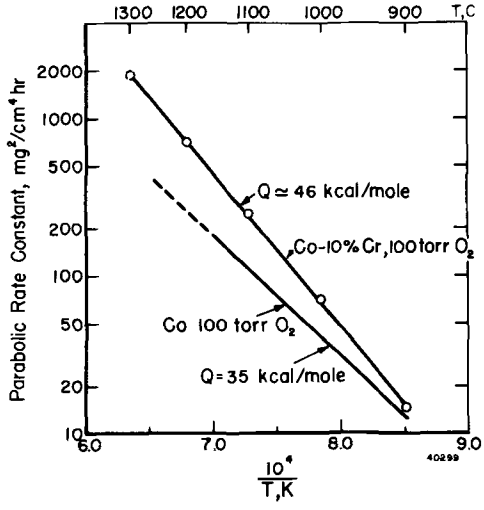

Fig. 6. Arrhenius plot of the parabolic rate constant for oxidation of Co-10 w/o Cr and of unalloyed cobalt at 100 Torr oxygen.

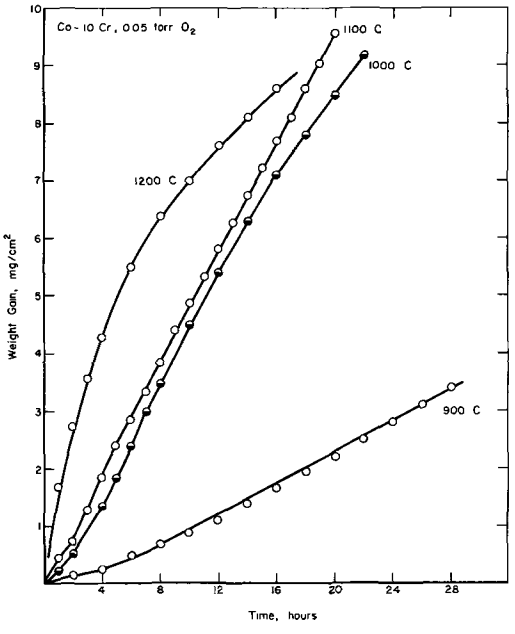

Fig. 7. Oxidation of Co-10 w/o Cr alloys in 0.05 Torr oxygen in the range 900° to 1200°C. Linear plot.

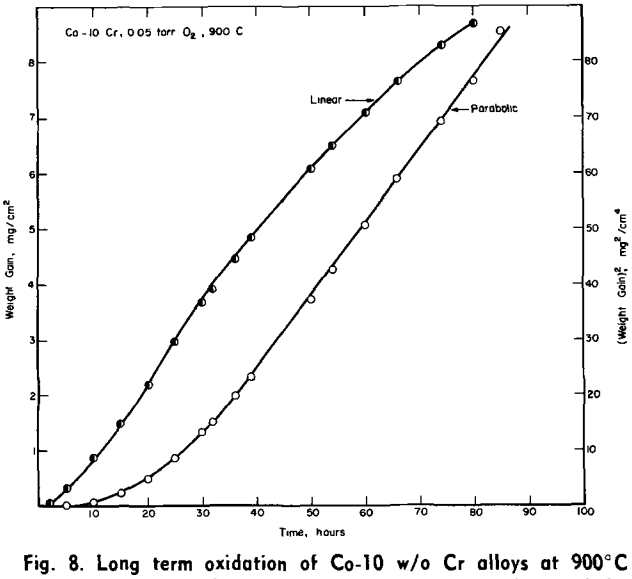

Fig. 8. Long term oxidation of Co-10 w/o Cr alloys at 900°C in 0.05 Torr oxygen. The scale on the right refers to the parabolic plot (circles), the scale on the left refers to the linear plot (half filled circles).

some respects: (*i*) above 900°C the alloy oxidizes faster than does cobalt, (*ii*) the activation energy for the alloy is higher than for cobalt (~46 *vs.* 35 kcal/mole), and (*iii*) the results suggest a slightly higher oxygen pressure dependence of k_p for the alloy than for cobalt.

It is concluded that a cation diffusion in the CoO phase is rate-determining in oxidation of both cobalt and the alloy (1). From this over-all consideration it may be speculated whether the differences in oxidation are completely or partially due to the effect of dissolved trivalent chromium in the CoO phase and the corresponding changes in defect concentrations and diffusion characteristics. If this effect is to be important, the solubility of chromium must be higher than the native cobalt vacancy concentration in pure CoO. The nonstoichiometry amounts to about 1% at 1200°C and 1 atm O_2.

There are no definite data available on the chromium solubility in CoO. However, the microprobe studies on scales of oxidized Co-10 w/o Cr specimens suggest a solubility less than 0.1 w/o Cr. Even if the solubility is higher than this by a factor of ten, it is difficult to explain the results at higher temperatures in terms of the semiconductor valence approach. Such considerations also completely fail to explain a gradual increase of the oxidation rate with increasing chromium concentration from pure cobalt to Co-10 w/o Cr as observed by Phalnikar *et al* (21). We conclude that semiconductor valence effects are of no or of minor importance in explaining the differences in oxidation behavior between pure cobalt and the Co-10 w/o Cr alloy. As noted in I, the same considerations also apply to dilute Ni-Cr alloys. We propose in the following that the differences are due to the differences in composition, microstructure, and porosity of the oxide scales.

The oxide scales on the alloy are double-layered; the outer layer consists of CoO and the inner layer of a CoO matrix with inclusions of $CoCr_2O_4$ (and of Cr_2O_3 near the metal-scale interface) (1). The inner layer, in addition, contains 30-35% porosity. Due to the low diffusion rates in $CoCr_2O_4$ and Cr_2O_3 compared to that of Co in CoO (Fig. 1), the inclusions serve as diffusion barriers and decrease the total cross-sectional area available for transport of the reactants through the scale. The pores, on the other hand, may increase the oxidation, as gaseous oxygen can be transported across the pores, and the gas transport serves to partially short-circuit the solid-state diffusion in the scale (22). When the gas transport is rapid, the oxidation may still be solid-state diffusion-controlled and parabolic, as is found in this work. The blocking of the spinel and the gas transport across the pores are proposed to be the main reasons for the difference in oxidation behavior between cobalt and dilute Co-Cr alloys.

When expressing these effects in terms of a mathematical model, one should as regards the blocking of the spinel consider the morphology, particle size, and distribution of the spinel in the scale. As described in I these factors are a function of temperature, pretreatment of the specimens, and, to some extent, the partial pressure of oxygen. An accurate and detailed description appears to be extremely complicated, and we will at this stage only propose an approximate and general model. The blocking effect of the spinel will depend on the average cross-sectional area of the spinel relative to the total area, and this will in turn depend on the total volume and the particle size of the spinel.

The volume of the spinel relative to that of the entire scale in the temperature range studied is probably only a weak function of temperature. The justification for this statement is that the microprobe studies revealed no marked chromium gradient in the scale and no extensively chromium depleted regions in the alloy at the alloy-scale interface. After the double-layered scale is formed, cobalt and chromium are, as a first approximation, consumed at the same relative rates. Cr_2O_3 is observed as an internal oxide and is present in the scale close to the alloy-scale interface. In the oxide the Cr_2O_3 rapidly reacts with CoO to form the spinel. In the following it will be assumed that the relative amount of Cr_2O_3 and $CoCr_2O_4$ in the total scale is a constant and is independent of temperature.

The size of the spinel particles increases with temperature (1). Their size will partially be governed by the size of the internally formed Cr_2O_3 particles and partially by the subsequent reaction of these with CoO. It is not unreasonable to assume that the processes governing the growth of the spinel particles are thermally activated or diffusion-controlled and that the size is an increasing exponential function of temperature.

Only one plane parallel to the alloy surface needs to be considered for the blocking effect of the spinel; obviously that plane is the one in which the cross-sectional area of the spinel is the largest in the scale. Since all the spinel particles in this plane had a similar history of growth, their size distribution will be relatively narrow. It is not unreasonable, therefore, to describe this dispersion by a sum of equal particles with a single size parameter r. One may then postulate

$$r = r_0 \exp(-Q/RT) \qquad [2]$$

where Q is the activation energy associated with the increase of r with temperature. Q cannot yet be evaluated, since the processes involved in the growth of Cr_2O_3 and spinel are not established.

The total volume of the spinel is proportional to r^3, while the surface area and the blocking cross-section, S, are proportional to r^2. When the total volume is constant with temperature, S can be expressed in terms of r

$$S = \frac{B}{r} = S_0 \exp(Q/RT) \qquad [3]$$

B is a constant which includes the volume of the spinel and a geometrical factor. As a first approximation it is assumed that the shape of the spinel particles do not change with temperature, and S_0 is therefore constant. The available cross-section for diffusion of cobalt through the scale is decreased by the amount S. When this effect is included in the expression for growth of CoO on pure cobalt (Eq. [1]), one obtains

$$\frac{dx}{dt} = k_p \frac{\left[1 - \frac{S_0}{A}\exp\left(\frac{Q}{RT}\right)\right]}{x} = \frac{k_p'}{x} \qquad [4]$$

where the blocking effect is expressed per unit area to retain the units. The effect of the spinel relative to that of cobalt according to Eq. [4] is illustrated schematically in Fig. 9. It should be noted that Eq. [4] does not predcit a straight-line relationship in an Arrhenius plot of the parabolic rate constant k_p', but within experimental errors and reproducibility this deviation may in many cases be difficult to determine. Since many pairs of S_0 and Q can yield the observed behavior, it is impossible at this stage to speculate on the actual values of S_0 and Q.

Although the pores serve as a barrier to the solid state diffusion, it is concluded, as discussed above and in I, that the pores enhance oxidation through rapid gaseous transport of oxygen across the pores. This gaseous transport may be considered to partially short-circuit the solid state diffusion in the scale. In terms of Eq. [4], this means that the total diffusion length x is shortened by the total pore length in a line perpendicular to the surface. If one assumes as a first approximation that the pore volume relative to the scale volume is a weak function of temperature, the reduction in the solid state diffusion length can

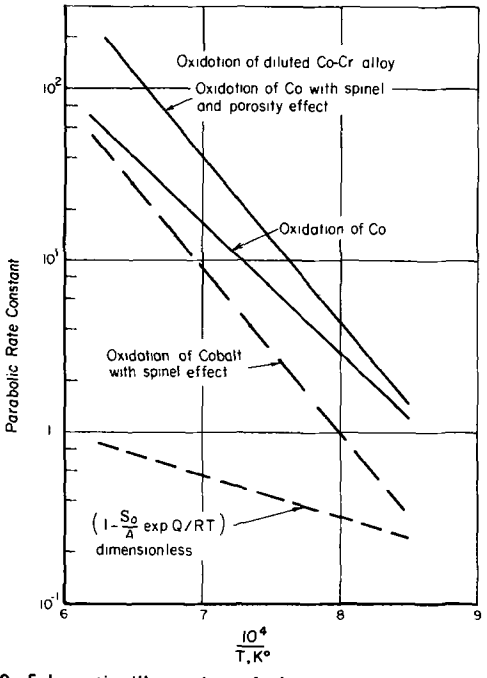

Fig. 9. Schematic illustration of the effects of spinel blocking and gaseous oxygen transport across pores on the oxidation behavior.

be expressed by $x\ (1-\gamma)$. γ is then approximately constant with temperature and depends on pore geometry and is proportional to the cube root of the fraction of the pore volume. With such a correction Eq. [4] takes the form

$$\frac{dx}{dt} = k_p \frac{\left[1-\frac{S_o}{A}\exp\left(\frac{Q}{RT}\right)\right]}{x(1-\gamma)} = \frac{k_p''}{x} \qquad [5]$$

The effect of the gaseous transport is to increase the oxidation rate as illustrated schematically in Fig. 9 ($\gamma = 0.77 = 1.1\ \sqrt[3]{0.32}$). Furthermore, the combined effects of spinel blocking and gaseous transport across scales may explain the oxidation behavior of Co-10 w/o Cr relative to that of cobalt.

At this stage Eq. [5] only represents an approximate phenomenological description of the oxidation of dilute Co-Cr alloys. It is as yet difficult to verify the details of the model through independently measured parameters, but it is believed that the main concepts provide a correct description of the over-all oxidation behavior. Some effects which have been observed experimentally were not accounted for in Eq. [5]. These include the preferential decoration by spinel at the original alloy grain boundaries in the oxide scales (1) at low temperature and low pressures. This effect cannot be dealt with mathematically; however, it is not inconsistent with the kinetic results and the role ascribed to the spinel. We observed in I that the spinel decoration is enhanced at low pressures; this will result in more effective blocking of Co diffusion and therefore lower k_p. This feature can explain the larger n (in $k_p = C\ p_{O_2}^{1/n}$) observed for the oxidation of the alloy.

The origin of this preferential decoration is due to the decreased outward migration of cobalt with decreasing pressure and a corresponding tendency for a preferential oxidation of chromium and a relatively larger amount of the spinel in the scale. For the same reason internal oxidation becomes more pronounced with decreasing oxygen pressure. At very reduced partial pressures of oxygen, *e.g.*, by oxidation in H_2/H_2O atmospheres, selective oxidation of Cr is to be expected as, for instance, observed in Ni-Cr alloys.

The fluctuations around the parabolic behavior, very marked at 1200°C and 100 Torr O_2 (Fig. 4), are probably a side effect. It is not unreasonable to ascribe this to the alleviation of stresses that cause local loss of adherence, producing marked lines of porosity in the scale.

In one of the three runs, the number of marked striations in the scale was found to be equal to the number of cycles in the weight gain. We do not understand, however, why this behavior was so marked at the special conditions, 1200°C and 100 Torr O_2. (Three different runs exhibited the same cyclic behavior, while for other temperatures and pressures this cycling is not so pronounced.

The oxidation of Co-Cr alloys with more than 10 w/o Cr decreases with increasing Cr-content. This is concluded to be due to the fact that an increasingly larger part of diffusion cross-section consists of the spinel, and a minimum in the oxidation rate for Co-Cr alloys are reached when essentially the whole scale consists of the spinel. These features will be discussed elsewhere in connection with the oxidation behavior of Co-25 w/o Cr (23).

With decreasing oxygen pressures it is a general phenomenon in oxidation of metals that phase boundary reactions at the scale surface become increasingly important during initial oxidation, and at very reduced pressures the reaction becomes diffusion controlled only after a relatively thick scale has been built up. This behavior is observed in this study during oxidation at 0.05 Torr (Fig. 7 and 8).

Conclusions

We conclude in this work that the mechanism governing the oxidation of Co-10 w/o Cr at high temperatures is solid-state diffusion of Co cations in the inner layer of a CoO network via a vacancy mechanism. This diffusion is influenced by two factors: (*i*) the porosity of the inner layer, which enhances oxidation, and (*ii*) spinel inclusions, which inhibit oxidation. The first effect is almost temperature independent, while the second effect decreases with increasing temperatures, due to the growth of the spinel particles. The oxygen-pressure dependence of the parabolic rate constants results mainly from the defect structure known in CoO; however, due to enhanced preferential-internal-oxidation grain boundaries at low pressures, the values of n in $k_p = C\ p_{O_2}^{1/n}$ are slightly smaller than those for pure CoO. Semiconductor valence effects due to dissolution of chromium in the CoO phase are believed to have minor or no influence on the oxidation rate of Co-10 w/o Cr alloys. At very low pressures, phase boundary reactions are of great importance for relatively long initial periods.

Preparation, Optical and Dielectric Properties of Vapor-Deposited Niobium Oxide Thin Films

M. T. Duffy, C. C. Wang,* A. Waxman, and K. H. Zaininger

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Thin dielectric films of niobium oxide have been deposited on silicon and quartz substrates by pyrolysis of the niobium alcoholate $Nb(OC_2H_5)_5$ at 450°C in an oxidizing ambient. Optical measurements have been made on these films in the spectral range 0.2-2.6 μm. Information on dispersion, fundamental absorption edge, and absorption coefficient (as related to photon energy) has been obtained. An electrical evaluation of the films has been made, including dielectric properties and MOS behavior.

The recent advances in the technology of microelectronics have led to extensive research on the physical, chemical, and electrical characteristics of MOS structures (1). Studies (2) on the SiO_2-Si system have shown the important role of the insulator-semiconductor interface in determining device behavior. The stringent requirements imposed on thin film dielectrics, including surface passivation, diffusion masking, radiation resistance, and varied applications, have stimulated interest in noncrystalline dielectric materials other than SiO_2 (1).

It is the purpose of this paper to report the preparation, structural, optical, and dielectric properties of niobium oxide thin films, MOS (metal-oxide-silicon) structures using this oxide have been fabricated and evaluated. The results of the MOS characteristics are reported.

Experimental

Thin film deposition.—Thin dielectric films of niobium oxide have been deposited on silicon, germanium, and quartz substrates by the pyrolysis of the niobium-alcoholate, $Nb-(OC_2H_5)_5$, in an oxidizing ambient. The alcoholate vapors were transported to the rf-heated substrates by helium carrier gas. Deposition conditions were optimized by varying the alcoholate vapor pressure, the deposition temperature, and total flow rate of gases. The following deposition parameter values gave uniform coherent films:

Substrate temperature:	450°C
Niobium-alcoholate source temperature:	115°C
Helium carrier flow rate:	325 cc/min
Other gases: helium flow rate:	2500 cc/min
oxygen flow rate:	820 cc/min

Faster flow rates than indicated here favored heavy deposition at the center of the substrate, while slower flow rates favored deposition at the periphery of the substrate.

The deposition apparatus is illustrated in Fig. 1. The reaction chamber is made of quartz and has a length of 20 cm and an internal diameter of 35 mm. A graphite susceptor having a pyrolytic graphite coating was used for heating the substrates. It was cylindrical in shape, 1¼ in. diameter and ¾ in. long. The apparatus was arranged in the vertical position and the vapor path between generator and deposition chamber was kept as short as possible. Air or water was circulated through the outer jacket of the depo-

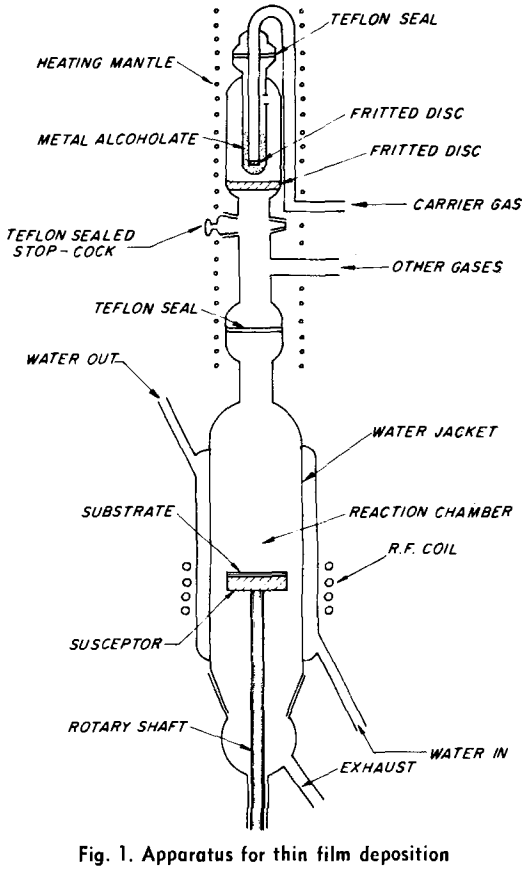

Fig. 1. Apparatus for thin film deposition

* Electrochemical Society Active Member.

sition chamber to cool the inner tube. The susceptor was rotated at 10 rpm during film formation in order to facilitate uniform deposition. Silicon substrates had residual SiO_2 films of about 30Å prior to deposition. This oxide thickness was measured by ellipsometry after the cleaning procedure.

Optical measurements.—Transmission measurements were made on films deposited on quartz substrates in the spectral range 0.2-2.6 μm using a Cary Model 14 spectrometer with a similar quartz substrate in the reference beam. Ellipsometric measurements were made to determine film thickness and refractive index at the mercury wavelength 5461Å in the case of films thinner than 2000Å. Film thickness in excess of 2000Å was determined from the conditions for maxima and minima in the transmittance curves using the refractive index values obtained by ellipsometry. The conditions are (3):

$$T = T_{max} \quad \text{for} \quad n_1 d = (2m + 2)\,\lambda/4$$

$$T = T_{min} \quad \text{for} \quad n_1 d = (2m + 1)\,\lambda/4$$

when $n_2 \gtrless n_1 \lesseqgtr n_0$; where T is the transmittance, n_0, n_1, and n_2 the refractive indices of air, film, and substrate, respectively. The factor m is an integer, d the film thickness, and λ the corresponding wavelength of light.

From the above results, information on optical dispersion, absorption coefficient, fundamental absorption edge, and interband transition has been obtained.

Dispersion data were obtained from the conditions for maxima and minima in transmittance and the calculated thickness of the films. The absorption coefficient has been obtained from transmittance and dispersion curves using the relationship (4)

$$T = I/I_0 = \frac{(1-R)^2}{e^{\alpha d} - R^2 e^{-\alpha d}} \qquad [1]$$

which includes effects of multiple internal reflection but excludes interference effects which cause variation of transmittance with wavelength; T is the transmittance, α the absorption coefficient, R the reflectivity, d the film thickness, and I/I_0 the ratio of transmitted and incident intensities.

MIS measurements.—A variety of methods is available to determine electrical properties of the MIS system such as density, capture cross section and response time of interface states, surface recombination velocity, and surface mobility. We have restricted ourselves to the MIS capacitance (C-V) (5-7) and MIS conductance (G-V) (8) techniques. These are by far the most frequently employed methods due to the simplicity of fabricating test structures, the ease of making (automatic) measurements, and the extent of information that can be obtained.

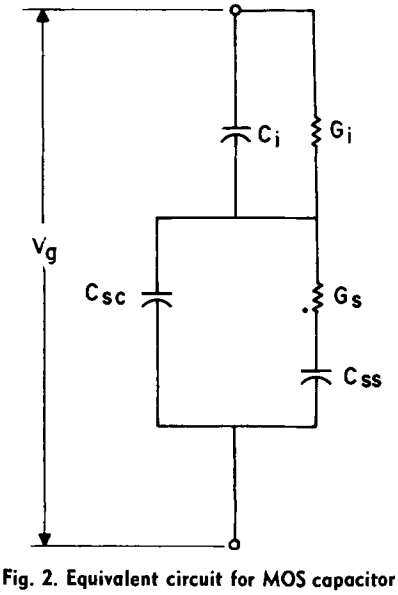

Fig. 2. Equivalent circuit for MOS capacitor

Equivalent circuit of MIS capacitor.—In order to be able to interpret the results of such measurement, a useful equivalent circuit has to be available. The impedance of an MIS capacitor has been derived by several authors (9, 10). However, their equivalent circuits are as complicated as the mathematical models they used and are of little practical use. The circuits have to be simplified considerably if they are to be useful in interpreting experimental results. A generally accepted simplified equivalent circuit that accounts for oxide loss and interface states has been derived and is shown in Fig. 2. C_i and G_i represent the capacitance and conductance of the insulator, C_{sc} is the capacitance of the semiconductor space charge region, and G_s and C_{ss} are the conductance and capacitance, respectively, associated with interface states, all per unit area. For n-type material C_{sc} is given by (11, 12)

$$C_{sc} = \frac{\epsilon_s}{\lambda_n} \frac{\left(1 - e^{+q\psi_s/kT} + \frac{P_B}{N_D} e^{-q\psi_s/kT}\right)}{\left(e^{q\psi_s/kT} - \frac{q\psi_s}{kT} - 1 + \frac{P_B}{N_D} e^{-q\psi_s/kT}\right)^{1/2}} \qquad [2]$$

where ψ_s is the semiconductor surface potential, ϵ_s the semiconductor dielectric constant, k is the Boltzmann constant, T is the temperature, q is the electronic charge, P_B the bulk density of holes, and N_D is the donor concentration. The Debye-length λ_n is defined by (12)

$$\lambda_n^2 = \frac{2(kT/q)\epsilon_s}{N_D q} \qquad [3]$$

The calculation of the a-c conductance for interface states for any type of distribution of states has been derived (13) and yields the following expression:

$$G_s = \frac{\omega^2 q^2}{kT} \int_{E_i}^{E_F} \frac{\tau(E_t) N_{ss}(E_t)\, f(E_t)\,[1 - f(E_t)]}{1 + \omega^2 \tau^2(E_t)}\, dE_t \qquad [4]$$

where ω is the radian frequency of measurement, $N_{ss}(E_t)$ is the density of states/cm²-ev, f is the Fermi function. The expression $\tau(E_t)$ is given by

$$\tau(E_t) = \frac{f(E_t)}{\sigma(E_t) <V_n> n_s} \qquad [5]$$

where $\sigma(E_t)$ is the capture cross section of the states at energy E_t, $<V_n>$ is the thermal velocity, and n_s is the density of electrons at the interface.

The high-frequency MIS capacitance method.—It is quite clear that the performance of the equivalent circuit discussed above is a function of frequency, and that measurements made at an arbitrary frequency could lead to erroneous conclusions. If the measuring frequency is sufficiently high so that surface states cannot follow the applied signal, then the surface state capacitance becomes zero (12), and the MIS capacitance reduces to its high-frequency form, *i.e.*, the series combination of C_i and C_{sc}. When this condition is satisfied, then the MIS capacitance is unambiguously related to the semiconductor surface potential. However, there is a difference between an experimentally determined high-frequency C-V characteristic and one computed for an identical structure without surface states, and that is the voltage due to the total charge in surface states. By finding the difference between the measured voltage for a given capacitance (and thereby ψ_s) and its "ideal" value, ΔV, one can determine the total charge that can be trapped in surface states during the measurement period and the surface state density as a function of ψ_s (or energy). The effective density of surface states, as reflected to the insulator-semiconductor interface, N_{ss},

is then given for any particular value of capacitance (and thereby ψ_s) as

$$N_{ss} = \frac{C_i \Delta V}{1.6 \times 10^{-19}} = \frac{(\epsilon_i \Delta V)}{(1.6 \times 10^{-19} t_i)} \quad [6]$$

where ϵ_i and t_i are the insulator dielectric constant and thickness, respectively. If the experimental curve lies toward more negative voltage than the ideal one, the charge in surface states is positive; if it lies toward more positive voltage, the charge is negative. A typical example of a comparison between experimental and ideal curves is shown in Fig. 3.

For the use of the MIS capacitance technique in the study of surface properties various assumptions and approximations have been made in the past which are not always justified. However, it has been shown (7) that MIS capacitance measurements can yield interesting and meaningful results if the proper experimental conditions are established and care is taken in the interpretation of the experimental results. Thus, we use the C-V technique cognizant of its limitations (7).

The actual measurement of the samples is carried out at a frequency of 1 MHz using an automatic C-V plotter. This system has been described previously (14).

The MIS conductance technique.—An alternate technique which is useful in making quantitative determinations of interface states in MIS structures is the measurement of the dependence of the a-c conductance on measurement frequency and applied bias. As indicated in the equivalent circuit in Fig. 2, interface states contribute an a-c loss due to the inability of charge in the states to follow an applied a-c signal. The lag occurs because of the finite time it takes carriers to move in and out of interface states. The conductance due to this effect is given in Eq. [4]. This equation has the following general features:

1. At any given test frequency, the maximum contribution that a state makes to the conductance occurs when the semiconductor Fermi level is at the energy of the state.
2. At a given surface potential, the expression G_s/ω, that is the ratio of the conductance to the radian frequency, peaks at a radian frequency given by $\omega\tau = 1.98$ and $G_s/\omega = 0.4\ qN_{ss}\ A$ (A is the area).
3. The time constant of the state is inversely proportional to the surface density of electrons at a given surface potential.

The measured a-c conductance can be used in conjunction with the equivalent circuit in Fig. 2 to obtain the dependence of G_s on frequency, at a given voltage. An analysis of the equivalent circuit in Fig. 2 yields the following expression for G_s.

$$G_s = G_m \left(1 + \frac{C_{sc}}{C_i}\right)^2 - G_i \left(\frac{C_{sc}}{C_i}\right)^2 \quad [7]$$

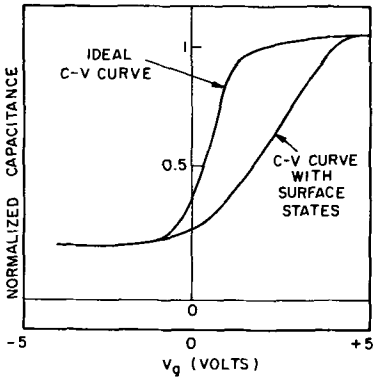

Fig. 3. Comparison between ideal and experimental C-V curves for an n-type MOS capacitor.

where G_m is the measured a-c conductance at a given voltage, and G_i, C_{sc}, and C_i are also determined for this applied voltage.

Since $G_s/\omega = 0.4\ qN_{ss}\ A$ at $\omega\tau = 1.98$, the surface state density can be determined as a function of surface potential and, hence, energy.

The samples are measured using an automatic C-V and G-V plotter which makes use of a phase-sensitive detector. Data can be taken from 10 Hz to 100 kHz. This system has been described elsewhere (15).

Dielectric constant measurement.—The determination of the dielectric constant of an insulating film is normally carried out by determining the capacitance of a parallel plate capacitor made from this material, coupled with a measurement of the capacitor area and insulator thickness. When one of the plates is a semiconductor instead of a metal, the measurement is only then meaningful if it can be assured, by the application of the proper bias, that the semiconductor surface is in heavy accumulation (or inversion).

Our measurements were carried out using the automatic measurement arrangements mentioned above as well as a Boonton Electronics and a GR-1608 Impedance Bridge while maintaining the above conditions. The measurements on adherent contacts of known area were all three-terminal capacitance measurements which yield the direct capacitance between the two plates, excluding all stray capacitances that may exist to other parts of the structure. The thickness of the insulating film was determined by the use of an ellipsometer.

Results and Discussion

Niobium oxide films with thicknesses ranging from 500 to 3000Å have been obtained. The deposition rate was usually ~70-80 Å/min using the flow rates previously mentioned. The films were inert to most acids but could be etched in dilute HF, giving an etch rate of 60 Å/min in 1:4/HF:H_2O.

Structure of films.—The surface structure of the films was examined using the scanning electron microscope. The films have extremely smooth surfaces as shown in the electron micrographs (Fig. 4). No film deterioration was observed as a result of the electron beam. Low glancing angle electron diffraction patterns [Fig. 5(a)] indicated that the films were amorphous. Films, which were annealed in He at 850°C, still showed an amorphous structure as revealed by the electron diffraction pattern [Fig. 5(b)]. However, a film which was removed from the susceptor after heating to >1200°C in inert gas gave an x-ray powder

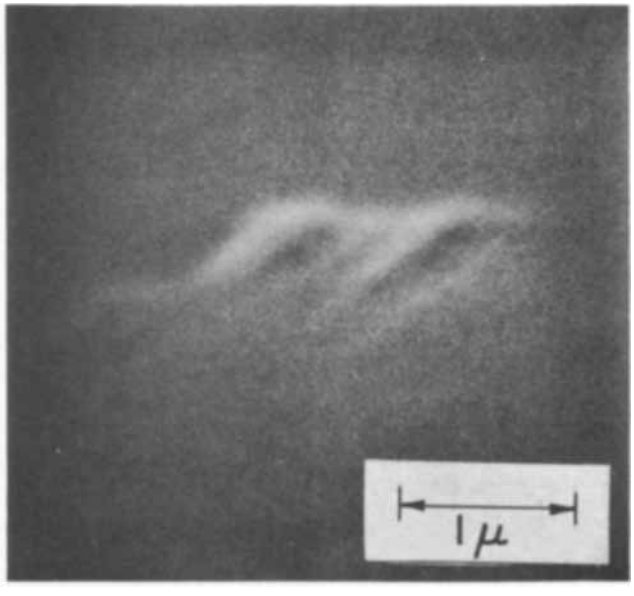

Fig. 4. Scanning electron micrograph of thin film Nb_2O_5

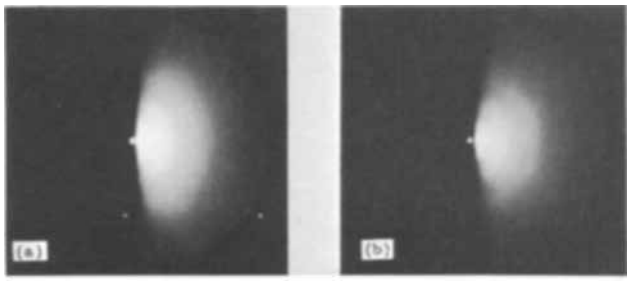

Fig. 5. Electron diffraction patterns of thin film Nb_2O_5: *(a)* before annealing, *(b)* after annealing.

pattern which could be identified as single-phase Nb_2O_5. No other phase was detected. This suggests that the initial material was Nb_2O_5, though the exact formula is not known. The crystallization behavior contrasts with the case of anodic niobium oxide, which has been reported to "recrystallize" at 500°-600°C.

Optical properties.—The dispersion data of the Nb_2O_5 films are plotted in Fig. 6. The data were fitted by the Hartmann equation (16):

$$n(\lambda) = a + b/(\lambda - \lambda_0)^{1.2} \quad [8]$$

where n is the refractive index and a, b, and λ_0 are constants. The experimental points are best fitted by:

$$n_{Nb_2O_5} = 2.0 + 1.1/(\lambda/10^3\,\text{Å} - 1.9)^{1.2} \quad [9]$$

These values are about 15% lower than reported by Young (16) for anodic films and 5% lower than reported by Burgiel *et al.* (17) for sputtered films. These differences may be attributed to differences in preparation.

Optical transmission of an Nb_2O_5 film is illustrated in Fig. 7 showing absorption and interference effects.

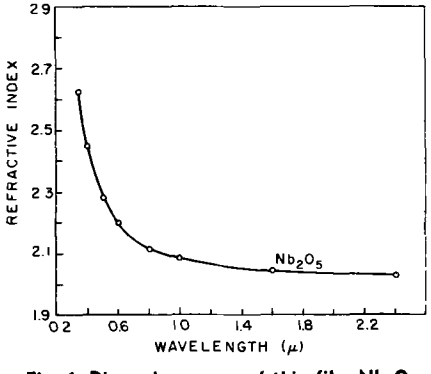

Fig. 6. Dispersion curves of thin film Nb_2O_5

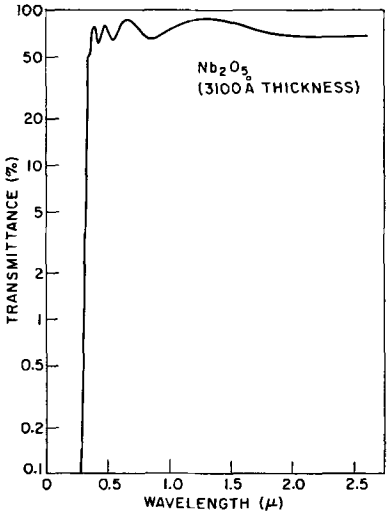

Fig. 7. Optical transmission of thin film Nb_2O_5

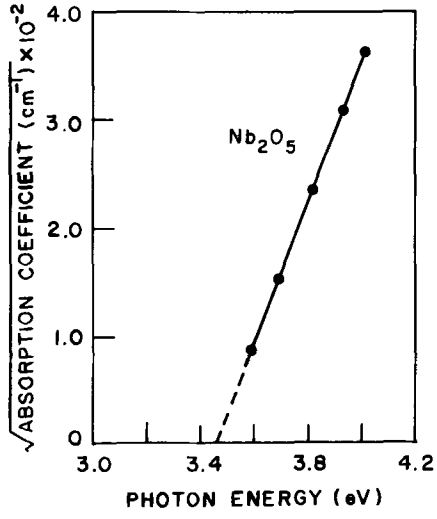

Fig. 8. Square root of absorption coefficient *vs.* photon energy for thin film Nb_2O_5.

Figure 8 is a plot of the square root of the absorption coefficient *vs.* photon energy. The linear nature of this plot suggests that excitation across the bandgap is by indirect transition, even though the magnitude of the absorption coefficient falls within the range expected for direct transition (18). The high value of this coefficient indicates that the absorption is intrinsic rather than by impurities. The intercept in Fig. 8 gives the value of the fundamental absorption edge as 3.48 ev, which is in fair agreement with values reported for oxides prepared by other methods (19-21). However, this value may be influenced by the donor concentration of the oxide as indicated by the work of Vratny and Micale (23). This value, as may be expected, is lower than the values obtained from photoconductivity experiments on anodic oxide films.

MOS behavior of Nb_2O_5*-silicon contacts.—High-frequency capacitance measurements.*—We have fabricated a large number of MOS contacts using Nb_2O_5 as a gate insulator directly on (111) silicon. A 1 MHz C-V curve, obtained with an Hg-probe on a 900Å film, is shown in Fig. 9. From this curve, it can be seen that interface state density and oxide charge can be kept to values which readily allow modulation of the silicon surface potential. We will have more to say about interface state density after we discuss a-c conductance measurements.

Generally, we have found that the positive oxide charge for Nb_2O_5 can be kept below 5 x 10^{11}/cm^2 so that flatband voltages for a 1000Å oxide on 10 ohm-cm, p-type silicon are less than 1v. This number includes oxide charge as well as work function difference due to gate contacts.

The Nb_2O_5-silicon interface generally exhibits a room-temperature hysteresis of the slow trapping

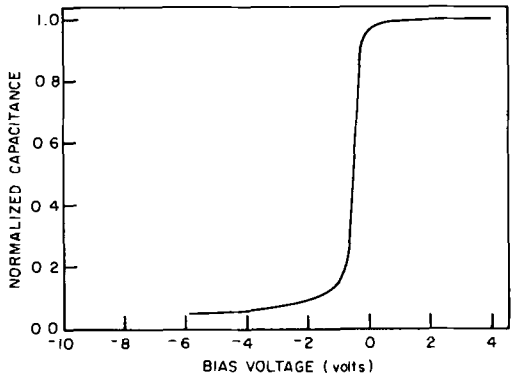

Fig. 9. Normalized C-V curve for an n-type MOS capacitor with 900Å Nb_2O_5 as gate insulator.

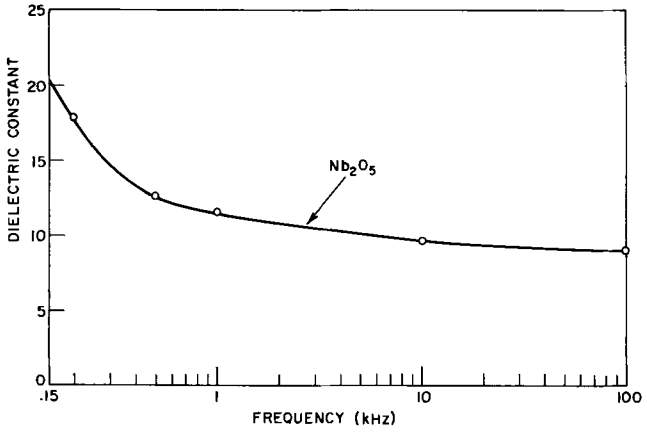

Fig. 10. Variation of oxide dielectric constant with frequency for thin film Nb_2O_5.

type. That is, for increasing negative gate voltage, the flat band voltage shifts to more negative values. Generally, this type of hysteresis is strongly dependent on deposition conditions, but can be reduced by annealing.

Bias-temperature tests at 200°C in an inert ambient show that these films are not an effective barrier against ionic motion. Positive charge is observed to move toward the silicon interface under the influence of positive gate voltage.

The dielectric strength as determined from MOS contacts is about 5 x 10^6 v/cm. The electrode area was 0.11 mm^2.

Frequency dependence of dielectric constant.—During our MOS impedance measurements, we have observed that the dielectric constant of Nb_2O_5 is frequency dependent. A plot of oxide dielectric constant dependence on frequency is shown in Fig. 10. As is seen from this plot, significant changes in dielectric constant can occur over a wide range of frequencies (100 Hz-100 kHz). However, variations in this frequency dependence have been observed as a function of deposition conditions. The value of the dielectric constant of ~11 ± 2 at 1 kHz is unusually low compared to a value of ~40 reported for amorphous anodic oxide films (16). At the present time, no explanation exists for this difference.

A-C conductance in MOS contacts.—A-C conductance measurements as a function of voltage have been made on Nb_2O_5-silicon MOS contacts over a range of frequencies from 100 Hz to 150 kHz. In Fig. 11, the G-V data at two frequencies, 100 and 10 kHz, are shown. The sample consisted of a 1000Å Nb_2O_5 film on 10 ohm-cm p-type silicon. As discussed earlier in this paper, the peak in the conductance is due to the presence of interface states. The peak occurs at the voltage determined by Eq. [7]. The shift of the peak toward positive voltage with decreasing frequency is indicative of a distribution of interface states in energy rather than a single level of states at a discrete energy.

Using Eq. [4] and [7], we have analyzed the G-V data for a number of samples, both p- and n-type. The density of states is found to increase toward both band edges, with a minimum in density occurring near midgap. Typical densities at flat-bands for n- and p-type samples are 1.5-2.0 x 10^{11} states/cm^2-ev. The time constant at flat bands is 3.2 μs and the capture cross section for the interface states is 2.5 x 10^{-17} cm^2. The capture cross section is found to be relatively independent of energy.

In analyzing the G-V data to determine interface states, it is important to note that the variation in frequency of ϵ_i, and hence the oxide capacitance, increases the difficulties in calculating the surface conductance due to interface states. Referring to Eq. [7], the measured a-c conductance is made up of two terms: one due to oxide loss, and the other due to interface states. The oxide loss term must be eliminated to obtain G_s. Equation [7] represents the formula which is used to do this. However, due to frequency dependence of C_i, the term $G_i\ (C_{sc}/C_i)^2$ will not be the same at a given voltage for each frequency. Hence, to determine the interface state density accurately, the dependence of ϵ_i (hence, C_i) on frequency must be determined.

It is also interesting to note the dependence of a-c conductance on voltage beyond accumulation. In Fig. 12, the voltage dependence for two frequencies is shown. It can be seen that the voltage dependence changes as a function of frequency. For example, in the region of —12 to —20v on a 1000Å Nb_2O_5 film on 10 ohm-cm silicon, the a-c conductance changes from being relatively independent at 10 kHz to linear dependence at 100 kHz.

We propose a tentative model to explain this effect. Since the Nb_2O_5 has a relatively narow band gap (3.48 ev) compared to SiO_2, the silicon valence band lies considerably closer to the Nb_2O_5 valence band. Hence, hole injection into the insulator is possible. Under these conditions, the current in the insulator will be space charge limited. In the case where shallower trapping can occur in the insulator, it is well known that d-c current is given by (22)

$$J = \frac{9}{8}\epsilon_i\,\mu_h\theta\,\frac{V^2}{L^3} \qquad [11]$$

where ϵ_i is the insulator dielectric constant, μ_h the hole mobility, θ a factor which describes the relative occupation of the trap and the valence band, and L the insulator thickness.

The a-c conductance will then be proportional to V, and the constant of proportionality related to θ. It is not difficult to show that θ is frequency dependent, with the frequency dependence determined by the

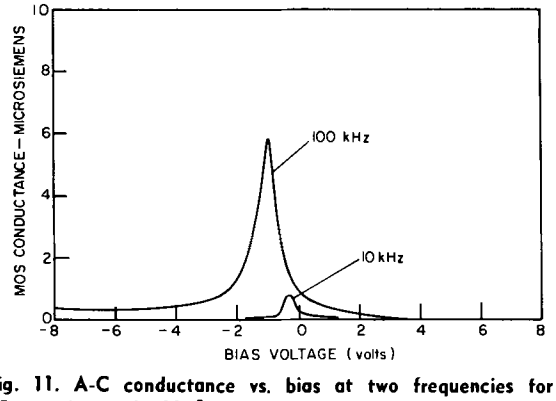

Fig. 11. A-C conductance vs. bias at two frequencies for an MOS capacitor with 1000Å Nb_2O_5 film.

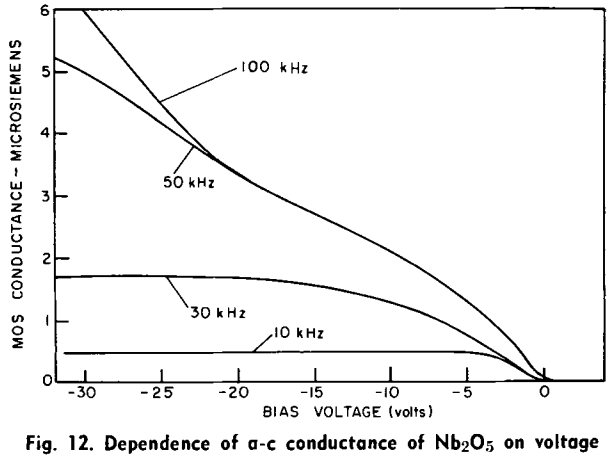

Fig. 12. Dependence of a-c conductance of Nb_2O_5 on voltage at several frequencies.

trap capture cross section and trap location. θ will increase from a low value ($<<1$), to a maximum of one at frequencies above $\frac{1}{2}\pi\,\tau_t$, where $\tau_t = (n_t\sigma_p <v>)^{-1}$ n_t is the density of filled hole traps, σ_p the capture cross section, and $<v>$ the thermal velocity. The exact frequency dependence will be determined by the trap distribution.

In Fig. 12, we see this type of behavior. For 10 kHz the dependence on voltage is very slight, while for 100 kHz the linear dependence is quite apparent. Further work is being done in this area to extend it to the point where information can be determined about trap properties in the insulator.

Acknowledgments

We wish to thank C. Arasim, R. Lenskold, G. Mark, and R. Soltis for assistance in the experimental work, and R. Paff, W. Roth, and B. Seabury for x-ray, electron diffraction, and scanning microscope measurements.

Theory of Dielectric Breakdown in Solids

J. J. O'Dwyer

Physics Department, Southern Illinois University, Carbondale, Illinois

ABSTRACT

A short review is given of current trends in research on the theory of dielectric breakdown in solids; in particular the theory of thermal breakdown is discussed for the case in which the dielectric conductivity is explicitly field dependent. A new possibility for avalanche breakdown is also examined. The field in the dielectric is considered to be nonuniform because of the space charges created by collision ionization, and the enhanced field adjacent to the cathode causes field emission which is many orders of magnitude greater than would be expected from a mean field calculation.

The theory of dielectric breakdown of solids has been divided by custom into three areas (1-3), *viz.*, thermal, intrinsic, and avalanche. Most recent work has been along the lines of developing the theory of thermal breakdown by explicit inclusion of the field strength dependence of the conductivity (4, 5), or of presenting an avalanche theory which takes account of the nonuniformity which will arise in the field strength due to the charges which are the products of collision ionization (6). Theories of intrinsic breakdown would then be seen as yielding a critical field strength of order of magnitude of the field strength at which collision ionization within the material becomes significant, rather than a critical field for direct comparison with the experimental breakdown field.

A brief introduction will first be given to the ideas underlying the various theories of breakdown which have been current for some time; recent developments will then be discussed in more detail.

All theories of thermal breakdown can be derived from the basic equation

$$C_v \frac{dT}{dt} - \text{grad}\,(K\,\text{div}\,T) = \sigma F^2 \qquad [1]$$

where C_v is the specific heat per unit volume, dT/dt is the time derivative of the temperature T, K is the thermal conductivity, F the field strength, and σ the electrical conductivity. Since σ is almost always a strongly varying function of temperature, the solution of [1] is complicated even for the simplest geometry of boundary conditions. The most usual approaches have been to solve [1] for the simple limiting cases: (*A*) Steady state solution in which the time derivative term is set equal to zero. (*B*) Short time solution in which the thermal conduction term is ignored. An alternative approach would be to give a numerical solution to the complete equation for the simple case of plane parallel geometry.

The conclusions of standard thermal breakdown theory have been well tested experimentally; generally speaking they are valid at high temperatures where the ratio of electrical to thermal conductivity is large.

Theories of intrinsic breakdown regarded the breakdown strength as an intrinsic property of the material; the calculation of the critical field strength then corresponded to the failure of some specified process to achieve a stable situation with the conducting electrons. Different physical processes by which an electron can lose the energy it gains from the electric field then specify the various theories of intrinsic breakdown strength. All such theories predict a specific temperature dependence of the breakdown strength but assume that it is thickness independent. This led to much experimental work on the temperature dependence of the breakdown strength, with occasional measurements showing a slight thickness effect.

The simplest theory of avalanche breakdown is based on order of magnitude arguments, which lead to the conclusion that forty generations of collision ionization products will form a critical avalanche (7). If d is the dielectric thickness and $\alpha(F)$ the field dependent mean ionization rate per unit path length, then the critical field strength will be given by

$$\alpha(F_c)\,d = 40 \qquad [2]$$

If we assume that the field dependence of the collision ionization function is given by

$$\alpha(F) = \alpha_0 \exp(-H/F) \qquad [3]$$

where α_0 is a constant ionization rate and H is a field strength characteristic of the material, the thickness dependence of the critical field strength is then given by

$$H/F_c = \ln(\alpha_0 d/40) \qquad [4]$$

This result predicts a monotonic decrease of breakdown strength with increasing thickness of about the magnitude observed over not too great a range of thickness.

The work described in this introduction has been extensively reviewed and discussed in the general references (1-3).

Thermal Breakdown of Thin Films

Recently the breakdown of thin films has been interpreted as thermal; the measured temperature and field strength dependence of the prebreakdown conduction has been used in the equation

$$JFd = \Gamma(T - T_0) \qquad [5]$$

where J is the current density, Γ is the thermal conductance per unit area, T_0 the ambient temperature, T the temperature of the dielectric (which is assumed to be constant throughout the film), F the mean field strength, and d the dielectric thickness. This equation has been fully discussed by Whitehead (7) for the case in which σ is not an explicit function of F, but depends on it implicitly through its temperature dependence.

Various forms for the temperature and field strength dependence of J have been given. Klein and Gafni (4) working on silicon oxide films 3000-50,000Å thick use

$$J = \sigma_0 F \exp\{a(T - T_0) + bF\} \qquad [6]$$

in which both σ_0, a, and b are functions of T_0. They also note a Schottky like expression also fits well to their results, but prefer [6] because of consequent algebraic simplicity. For the same substance in films 1000-10,000Å thick Hartman *et al.* (8) give

$$J = C_1 d \exp\{-(\phi - \alpha_1 F^{1/2})/kT + \alpha_2 F^{1/2}\} \times [1 - \exp\{-F(\alpha_2 + \phi/kT)^2\}] \qquad [7]$$

where C_1 is a constant, d is the dielectric thickness, and α_1, α_2, and ϕ are constants of the material. This is an interesting expression since it contains an explicit dependence on the dielectric thickness, and also a factor which gives an ohmic current for low field strengths. Because of this ohmic dependence [7] leads to $J \propto dF = V$ at low field strengths (V is the voltage); for high field strengths [7] becomes approximately

$$J = C_1 d \exp\{-(\phi - \alpha_1 F^{1/2})/kT + \alpha_2 F^{1/2}\} \qquad [8]$$

so that current density is directly proportional to dielectric thickness for a given mean field strength, but not for a given voltage. Results of this general nature had already been found for silicon oxide in the thickness range 1-4μ by Hirose and Wada (10). Sze (5) working on silicon nitride films found that for high field strengths

$$J = C_2 F \exp\{-(\phi - \alpha_3 F^{1/2})/kT\} \qquad [9]$$

where C_2, ϕ, and α_3 are constants. He also explicitly stated that no thickness dependence was found over the range 500-2900Å.

A wide diversity of choice is, therefore, available for the functional form of the current in Eq. [5], and since the expressions are all empirical it is difficult to find reasons for preferring one to another. We shall use [8], and in making this choice there are three distinct points of difference from other possibilities: (*i*) The explicit field strength dependence is given by an exponential factor in $F^{1/2}$ rather than in F. (*ii*) An explicit thickness dependence is included. (*iii*) The exponential factor in $F^{1/2}$ gives the total explicit field strength dependence of the current; it does not, as in [9], give the field strength dependence of the conductivity. That these two cases may be very difficult to distinguish experimentally has been shown by Hanscomb *et al.* (9) in work on sodium chloride.

Substituting [8] in [5]

$$C_1 F d^2 \exp\{-(\phi - \alpha_1 F^{1/2})/kT + \alpha_2 F^{1/2}\} = \Gamma(T - T_0) \qquad [10]$$

Following Whitehead (7) the critical field strength is found by differentiating both sides of [10] with respect to T and then using [10] to simplify the result. One readily finds

$$kT_c^2/(\phi - \alpha_1 F_c^{1/2}) = T_c - T_0 \qquad [11]$$

which with the use of [10] and the assumption $T_c \simeq T_0$ gives

$$F_c^{1/2} = (\phi - kT_0 \ln C)/(\alpha_1 + kT_0\alpha_2) \qquad [12]$$

where

$$C = C_1 d^2 F_c(\phi - \alpha_1 F_c^{1/2})/\Gamma k T_0^2 \qquad [13]$$

The result is written in this way since ln C is a slowly varying function of F_c and T_0. If $\alpha_1/\alpha_2 >> kT_0$ then

$$F_c^{1/2} = (\phi - kT_0 \ln C)/\alpha_1 \qquad [14]$$

which was derived by Sze (5) using the current form [9]. Equation [14] predicts that $F_c^{1/2}$ decreases linearly with increasing temperature; this has been verified by Sze (5) for the case of silicon nitride. Equation [12] predicts a similar but more rapid decrease of $F_c^{1/2}$ with increasing temperature.

Although the logarithm of the dimensionless quantity [13] varies slowly with any of the variables contained in it, there is a possibility of several orders of magnitude change in dielectric thickness which would lead to a change of one order of magnitude in the logarithm. The square root of the breakdown field strength should vary linearly with the logarithm of dielectric thickness.

Avalanche Breakdown

There have been two principal lines of development to the 40 generations theory of avalanche breakdown described above.

In the first due to Forlani and Minnaja (10) the assumption of uniform field strength between the electrodes is retained, but the electron emission from the cathode is explicity introduced. Although their theory is complicated, the thickness dependence of the critical field strength can be found from an order of magni-

tude argument. The current injected into conduction levels from the cathode will be given by the Fowler-Nordheim expression

$$J_{\text{Inj}} = J_0 \exp\left\{-\frac{4(2m)^{1/2}\phi^{3/2}}{3\hbar e F}\right\} \quad [15]$$

where J_0 is the pre-exponential quantity and ϕ the effective work function. If the lattice vibrations in the dielectric are ineffective in slowing down the electrons in the strong field, then the collision ionization rate per unit length will be given approximately by

$$\alpha = e F/E_g \quad [16]$$

where E_g is the energy required for a collision ionization. Then

$$J(d) = J_{\text{Inj}} \exp(e F d/E_g)$$

$$= J_0 \exp\left\{-\frac{4(2m)^{1/2}\phi^{3/2}}{3\hbar e F} + \frac{e F d}{E_g}\right\} \quad [17]$$

Zero exponent in [17] corresponds approximately to the onset of irreversible changes in the dielectric, and if one takes the breakdown criterion as being that value of F for which the exponent in [17] becomes positive,[1] then the critical field strength is given by

$$F_c^2 = \frac{4(2m)^{1/2}\phi^{3/2}E_g}{3\hbar e^2 d}$$

Inserting values of the appropriate order of magnitude one finds

$$F_c \simeq 3 \times 10^4/d^{1/2}\ V \cdot \text{cm}^{-1} \quad [18]$$

with d measured in cm. Burdenstein and Hayes (11) have verified this result for silicon oxide in the thickness range 10^3-10^4Å. However, the thermal critical field strength of [12] (also alternative avalanche theories to be described below) exhibits a variation of a factor 3 in the breakdown strength for a thickness variation of one decade; measurements over at least several decades of thickness would be required to verify the $d^{-1/2}$ dependence.

The other main line of development of avalanche breakdown theory has resulted from the realization that the space charges caused by the build up of the avalanche should result in a nonuniform field strength distribution. If one drops the assumption of a uniform field, then a natural basic theoretical assumption is constancy of current. A space charge controlled theory of avalanche breakdown was proposed by O'Dwyer (6) assuming that electron current was continuous, and that the collision ionization function was of the form [3]. In this theory it was also assumed that the relatively unmobile holes arranged themselves in such a way that Poisson's equation is satisfied and continuity of electron current is preserved but without contributing to the current themselves. This leads to a relation for the mean critical field strength $\overline{F_c}$ which requires computation, but can be written approximately as

$$H/\overline{F_c} = 8 \cdot 5 \ln(\alpha_0 d) - 2 \quad [19]$$

This theory suffers from a similar defect to the 40 generations theory in that it contains contradictory assumptions; the holes must move to satisfy Poisson's equation, and yet it is assumed that they make no contribution to the current.

A theory of current flow due to collision ionization has been given by O'Dwyer (12). Anode and cathode are assumed to be blocking; both continuity of current and field distribution in accordance with Poisson's equation are strict requirements of the theory. The ionization rate per unit volume per unit time is assumed to be of the form (c.f. Eq. [3])

[1] A weak point in this assumption is that $J_0 \sim 10^7$ amp·cm^{-2}.

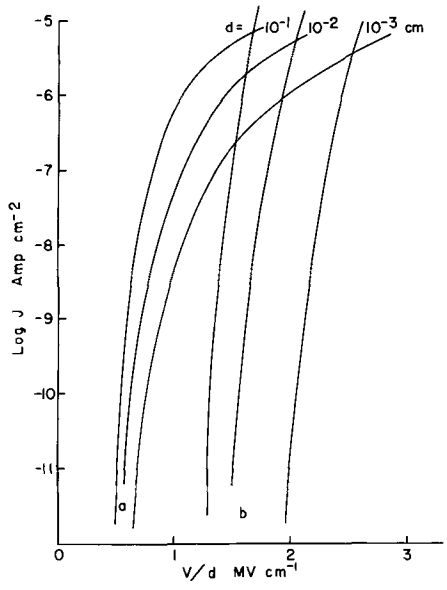

Fig. 1. Double ejection current and cold emission current for various values of the dielectric thickness: (a) double ejection current, (b) cold emission current.

$$I = (\alpha_n n^+ \alpha_p p) \exp(-H/F) \quad [20]$$

where α_n and α_p are constants and n and p are the electron and hole densities. In order to make the equations tractable it is also assumed that

$$\alpha_n/\alpha_p = \mu_n/\mu_p$$

where μ_n and μ_p are the effective electron and hole mobilities.

The computation of the current voltage characteristics is somewhat lengthy, but is given in a dimensionless form in ref. (12). Making the following assumptions about the constants of the dielectric:

$$H = 5 \times 10^6\ \text{V} \cdot \text{cm}^{-1}$$

$$\alpha_n = 2.5 \times 10^7\ \text{sec}^{-1}$$

$$\mu_n = 10^{-3}\ \text{cm}^2\ \text{volt}^{-1}\ \text{sec}^{-1}\ ^2$$

$$\mu_p/\mu_n = 5 \times 10^{-7}$$

one obtains the set of current-voltage characteristics shown in Fig. 1. On the same diagram are plotted the Fowler-Nordheim emission curves for an electrode with 1.50 ev net work function, and subject to a field equal to that caused by the space charge distribution of the double ejection current. The intersection point of these curves corresponds to a mean field strength for which injection from the electrodes can no longer be ignored; the injection would be a most steeply rising function of applied voltage, very much steeper than a Fowler-Nordheim law, and some ten orders of magnitude larger than the injection current as calculated from the mean field strength. If this point of intersection is regarded as the mean critical field strength determining breakdown, then this critical field strength is thickness dependent. The form of this thickness dependence is shown in Fig. 2. Also included on the same diagram for the sake of comparison are thickness dependences for thermal breakdown and the avalanche theories expressed by Eq. [18] and [19], using the same data as above.

Discussion

Since all dielectric breakdown must be in a sense thermal, it is difficult or even impossible to make an ultimate distinction between thermal breakdown and any other type of instability. This is clearly demonstrated by recent work in which the explicit (and strong) field dependence of the conductivity is in-

[2] Collision ionization would not be feasible with such a low value of true mobility. The figure quoted is for effective mobility which may be many orders of magnitude lower than the true mobility.

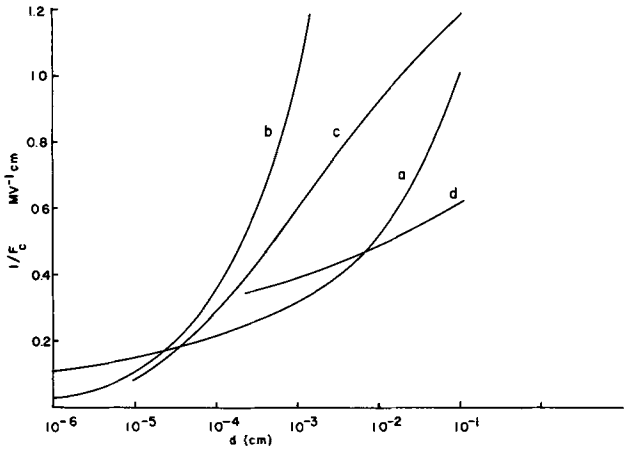

Fig. 2. Thickness dependence of the critical field strength according to various theories: (a) thermal with Schottky field dependence, (b) cathode emission with collision multiplication, (c) cathode emission with collision multiplication and nonuniform field, (d) cathode emission arising from nonuniform field caused by double ejection.

cluded in thermal breakdown theory. However, in the region of so called electrical breakdown the dependence of the conduction current on the electric field still remains; the problem is one of extreme sensitivity. Budenstein and Hayes (11) claim that the conductivity of the breakdown path increases by ten orders of magnitude within 100 n · sec., while Klein (3) mentions current densities of order 10^6-10^{10} amp · cm^{-2} in the discharge path. It is clear that adequate theoretical description of these phenomena faces severe difficulty. Avalanche theories have attempted to give an approximate explanation of the sharp rise in current. As discussed above the basic assumptions of the theory have been either constancy of field strength or constancy of current. The first assumption is self-contradictory in the presence of collision ionization, the second can be made consistent, but the truth is probably somewhere in between. For thin films and consequently few generations of collision ionizations the uniform field assumption should be a reasonable one, provided that the current injected from the cathode is not too great. Distortion of the field depends on the density of charge, and even a single collision ionization between cathode and anode will make this large if the current level is high. On the other hand, it is unlikely that field distortion can ever be ignored in thicker films in which relatively many generations of collision ionization will occur; the constant current assumption will, therefore, be a better starting point, although probably not an adequate one. Recent experimental work by Cooper and Elliott on KBr (14) has supported the assumption of field enhancement in front of the cathode. Measurements of breakdown strength over many decades of thickness will probably not give unambiguous support to one theory or another, since it is likely that the breakdown mechanism will change as the thickness changes.

Measurements of the field strength dependence of the current over many decades of thickness could be more rewarding and may help with the vexing question of identifying the mechanism of the conductivity. Certainly in this situation d-c conductivity measurements must be explained in terms of continuous current, and a change from conditions in which space charge is important to those in which it is not should be clearly manifest.

Manuscript submitted May 15, 1968; revised manuscript received Oct. 31, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 5.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Reactively Sputtered Oxide Films

M. L. Lieberman*[1] and R. C. Medrud

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

Oxide films of eleven metals have been prepared by reactive sputtering. The use of refrigerated substrates resulted in amorphous films in eight of the metal-oxide systems. Crystallization of the amorphous films gave rise to metastable, high-temperature polymorphs of WO_3, Ta_2O_5, and Bi_2O_3, and an unidentified tellurium oxide phase. High-oxidation-state compounds of silver, antimony, and lead were prepared. Optical properties of some films were examined. Films with a high refractive index and low optical absorption were prepared by crystallization of the highly absorbing, amorphous, bismuth oxide films.

Sinclair and Peters (1) have previously shown that it is possible to prepare amorphous metal-oxide films on uncooled substrates by reactive sputtering. They found, however, that lead oxide films prepared in this manner were crystalline and suggested that refrigerated substrates might give rise to amorphous deposits.

For the present investigation, an apparatus has been constructed which has provisions for substrate refrigeration and multicathodic reactive sputtering. Consequently, it is possible to increase the number of

* Electrochemical Society Active Member.
[1] Present address: Sandia Laboratories, Albuquerque, New Mexico 87115.

amorphous single- and mixed-metal-oxide films prepared by reactive sputtering. Secrist and Mackenzie (2) have found that amorphous films, of some systems at least, prepared by a variety of methods can properly be called glasses. If the amorphous, reactively sputtered films are indeed glasses, they should be structurally similar to supercooled liquids. This suggests that the controlled crystallization of such films may give rise to metastable high-temperature phases. Since many oxides have never been prepared as amorphous bulk materials, the crystallization of the amorphous films may produce metastable phases which cannot be prepared by other methods.

The results presented in this paper are limited to single-metal-oxide films.

Experimental

Reactive sputtering.—An apparatus has been constructed which provides for the simultaneous rotation and refrigeration of substrates during reactive sputtering. Substrates are cooled with liquid nitrogen to increase the possibility of obtaining amorphous films. With the present cathode geometry, rotation of the substrates gives rise to films which are more uniform in thickness than could otherwise be obtained. Rotation also serves to aid in the dissipation of heat from the substrate surfaces, since the substrates are only in the plasma region for a small part of each revolution. In addition, rotation permits the preparation of mixed-metal-oxide films by means of the simultaneous reactive sputtering of several independent cathodes. Selection of the various sputtering parameters can be used to obtain some degree of composition control in the mixed-metal-oxide films.

The basic sputtering unit, shown schematically in Fig. 1, is a modified Edwards Evaporation Plant with a 19 in. diameter stainless steel bell jar. The salient feature of the system is a liquid-nitrogen-cooled stainless steel Dewar which was fabricated to specifications by Hofman Laboratories, Inc. The baseplate of the Dewar is a 17 in. diameter, 0.625 in. thick copper plate. The Dewar neck has an outer diameter of 1.5 in. and an inner diameter of 1.0 in. In the region of the rotary seal, the Dewar walls are welded to a stainless steel pipe of the same dimensions.

Substrates (ground and polished Corning Code 7900 glass), typically 1 x 3 x 0.050 in., are supported by screws which go about halfway through the Dewar baseplate. The Dewar is filled with liquid nitrogen to a height of approximately 3 in. above the baseplate before sputtering is initiated. This height is automatically maintained by means of a Hofman P/N 3718 liquid nitrogen level controller (not shown) connected to 200-liter liquid nitrogen supply Dewar.

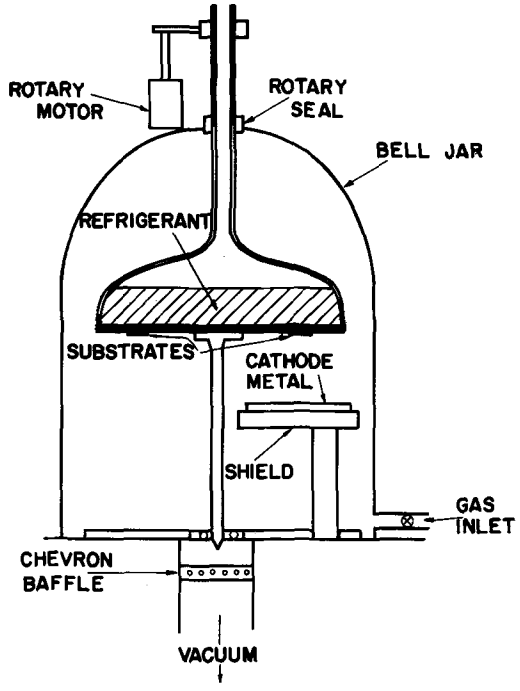

Fig. 1. Reactive sputtering apparatus

A rotary motor, located outside of the vacuum system, turns the Dewar via a V-belt arrangement. The rate of rotation, typically 120 rpm, is regulated by a speed controller. A stainless steel post is screwed to the bottom of the Dewar baseplate; this post fits into a bearing attached to the baseplate of the vacuum system. Since two bearings are also located in the rotary seal area, the Dewar is positioned to within small tolerances. Consequently, the torque applied to the Dewar during its rotation causes only a slight wobble, approximately ± 0.06 in. vertical displacement at the outer edge of the Dewar baseplate.

The rotary seal is a differentially pumped section contained between Viton O-rings which are lubricated with Apiezon H or T grease. The weight of the Dewar is supported by one of the two bearings located in the seal area. With the Dewar rotating prior to refrigeration, a vacuum in the 10^{-6} to 10^{-7} Torr range is typically obtained.

Sector-shaped metal plates with 60° angle and 6.75 in. radius are used as cathodes in the sputtering. Water cooling is provided through the cathode supports. When multicathodic sputtering is performed, the cathodes are positioned adjacent to each other. Separate power supplies are available for three cathodes. Table I lists the manufacturer's reported purity for each of the metals. Except for tellurium, silicon, and cadmium, all metals were purchased in plate form. The tellurium was purchased in lump form and vacuum melted in a graphite mold to obtain a plate. During removal from the mold, the plate broke into several pieces. Since tellurium sputters much faster than aluminum, the cathode support was covered with aluminum foil and the tellurium pieces were fitted together over the foil. An analysis of a tellurium oxide film based on spark-source mass spectrometry indicated about 0.2 w/o (weight per cent) Al. Silicon powder (—325 mesh) was granulated with ~5% sugar, hydrostatically pressed at 15,000 psi, fired in oxygen at 400°C, and then fired in argon from 400° to 1350°C. The resulting plate made a suitable silicon cathode. Purity of the plate was not determined, since residual impurities from the sugar would form volatile compounds during reactive sputtering, most of which would be removed by the pumping system. A cadmium cathode was cast from material of unknown purity.

Reactive sputtering was performed in a nominally 1:1 argon-oxygen gas mixture obtained from the Matheson Co., Inc. Cathode potentials applied to most metals were in the range 1200-2400v, but potentials applied to nickel, silicon, tungsten, and tantalum were in the range 3000-4800v. Total gas pressure was generally in the range 10-30 x 10^{-3} Torr. The cathode-substrate spacing was about 1.4 in., except for the

tellurium cathode in which case it was 1.8 in. Substrates were cleaned with 2-5% HF, distilled water, and Fisher Certified ACS methanol. Filmed substrates were removed from the vacuum system on the day following the reactive sputtering.

X-ray and optical measurements.—All films were examined by x-ray diffraction at room temperature on a General Electric XRD-5 diffractometer equipped with a Hamner detection system and a pulse height analyzer. Cu Kα radiation with a Ni filter was used. Scanning rates of 2.0 and 0.2 deg/min were employed. All phase identifications were made from x-ray diffraction data and, unless otherwise mentioned, the source was the ASTM Powder Diffraction Data File.

Specular reflectance measurements were made in the visible and near infrared by means of Perkin-Elmer Model 350 and Beckman Model DK-2R spectrophotometers. Refractive index n was determined as a function of wavelength from the relation

$$nt = m\lambda/4 \quad [1]$$

where t is the film thickness, λ is any wavelength at which a reflectance extreme occurs, and m is an integer which describes the order of interference. The value of t was determined with a CEJ Multimi 3000D multiple-beam interferometer, values of λ were determined from the reflectance measurements, and values of m could be readily assigned at low orders of interference. Reflectance measurements made with the Perkin-Elmer Model 350 spectrophotometer were corrected for nonnormal incidence, although the 20° incidence resulted in a correction of n of only 1% for a lead oxide film. Reflectance maxima corresponding to optical thicknesses less than $5\lambda/4$ were not used, because of the dispersion errors encountered at low orders of interference (3, 4).

The extinction coefficient k ($\bar{n} = n\text{-}ik$) was determined as a function of wavelength by the method described by Ennos (4). The evaluation of k at any wavelength is primarily determined by the difference in reflectance values measured from filmed and unfilmed areas of an aluminum-backed substrate. This method is particularly suitable for the determination of low k values. For these determinations, all spectrophotometric measurements were made with the Beckman Model DK-2R spectrophotometer.

Results

Film crystallinity.—The as-deposited films were examined by means of x-ray diffraction. Only oxide films of cadmium, nickel, and silver were crystalline. The common cubic forms of CdO and NiO were observed. Both compounds showed a strong (111) preferred orientation. The silver oxide films were black as deposited and became light brown when heated at 100°C. The black films contained AgO, Ag_2O, and a small amount of Ag. The color change on heating was caused by the conversion of AgO to the more stable Ag_2O. These films were prepared under conditions similar to those used by Rollins and Weichman (5). The phases observed confirm their interpretation of resistance measurements being associated with the presence of a higher oxide of silver (Ag_2O_{1+x}, $0 \leq x < 1$).

Crystallization of amorphous films.—Filmed substrates were cut into two or three pieces which were subjected to various thermal treatments in a small furnace. The time of thermal treatment had no apparent effect on whether or not crystallization would occur, but sometimes had an effect on the particular phases obtained when crystallization did occur. Results of various thermal treatments are summarized in Table II. The tabulated thermal treatments are the lowest temperature treatments for which crystallinity was detected by x-ray diffraction. Near the crystallization temperatures, the thermal treatments were generally conducted at intervals of 50°C, although few treatments were carried out below 250°C. The silicon oxide films were not heated above 500°C, at which temperature they were still amorphous.

Crystallization of the oxide films of tin, antimony, and lead produced phases which exist in bulk form at room temperature and pressure. Films of tin oxide crystallized as the rutile analog of SnO_2, as reported by Sinclair and co-workers (6). The antimony oxide films showed either Sb_2O_4 or mixtures of Sb_2O_4 and Sb_2O_5. One of the first lead oxide films, prepared prior to provisions for substrate rotation, crystallized as a mixture of β-PbO_2 and $Pb_{12}O_{19}$. All other lead oxide films crystallized as $Pb_{12}O_{19}$ alone. The diffraction data for $Pb_{12}O_{19}$ obtained in this investigation are in agreement with those given by White and Roy (7), with the exception of the d value for the first and strongest reflection. They reported $d = 3.268$Å which is not consistent with their indexing. The value should be 3.158Å which also agrees with the data obtained in this work. An error of 1° in the scattering angle would account for this difference.

Oxide films of tantalum, tungsten, and bismuth crystallized as metastable, high-temperature phases. The diffraction data for the tantalum oxide films are in good agreement with those reported by Terao (8) and by Sarjeant and Roy (9) for δ-Ta_2O_5. Two different phases occurred in the tungsten oxide films. The first was found in one of the initial tungsten oxide films prepared, and the x-ray diffraction data for it closely resemble the data for $H_{0.5}WO_3$ reported by Glemser and Naumann (10). The formation of a hydrogen-containing compound is not surprising, since Sosniak (11) and Stern and Caswell (12) have shown that hydrogen is a major gaseous impurity in sputtering systems. All other tungsten oxide films resembled the orthorhombic WO_3 structure which, in bulk form, has a stability range from 330° to 720°C (13). To the authors' knowledge, this phase has not been previously obtained at room temperature. The only published diffraction data for this phase are lattice constants as a function of temperature (13, 14). From such data, it is apparent that the diffraction pattern of the orthorhombic form closely resembles that of the room-temperature monoclinic form, except that the former polymorph has no unique $hk\bar{l}$ reflections. A comparison of the authors' diffraction data with the ASTM data for the monoclinic form is given in Table III.

The polymorphic transformations which occur in the bismuth oxide system have been discussed by Gattow and Schütze (15) and Levin and Roth (16). A flow diagram presented by the former authors (15) is shown in Fig. 2. Although the β-modification is metastable, it has been obtained at room temperature by quenching the melt (9, 15, 16). The existence of δ-Bi_2O_3 has been shown by high-temperature x-ray diffraction techniques (15, 16), but an attempt to obtain this polymorph at room temperature by quenching was unsuccessful (16).

Crystallization of the amorphous bismuth oxide films (Table II) occurs readily at 250°C. The Bi_2O_3 polymorph which originally forms is the cubic δ-modification. Whereas Levin and Roth (16) reported a lattice constant of 5.66Å for this polymorph at 750°C, the present authors have obtained a value of 5.53Å at 25°C. If it is assumed that the thermal expansion of δ-Bi_2O_3 is linear over the temperature range 25°-750°C, and Levin and Roth (16) have shown that this is a good assumption for all Bi_2O_3 polymorphs, the calculated coefficient of linear thermal expansion is 24 x 10^{-6}/°C. This value is identical with that reported by Levin and Roth (16) for the temperature range 625°-800°C.

The δ-Bi_2O_3 polymorph undergoes a transformation to the β-modification, accompanied by a color change

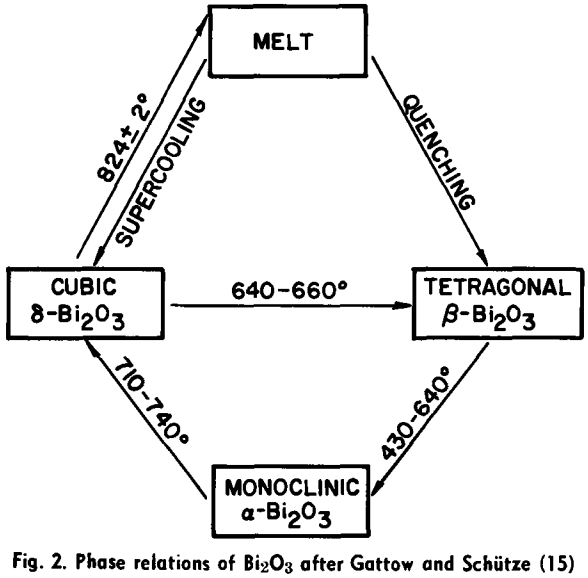

Fig. 2. Phase relations of Bi_2O_3 after Gattow and Schütze (15)

from brown to yellow, if the thermal treatment is extended beyond about 1 hr. Although both modifications are metastable at room temperature, the transformation is in the direction of increasing stability. No further phase transformations occurred when a film was heated at 295°C for 71 hr. Presumably, higher temperatures would result in conversion of the β-modification to the stable α-modification.

Whereas amorphous tellurium oxide films are transparent and nearly colorless, the thermally crystallized films are opaque and white. These features, and the appearance of "splatter" marks, distinguish crystallized tellurium oxide films from other crystallized films. The observations suggest the evolution of gas from the films. Amorphous α-TeO_3 is reported (17) to decompose to Te_2O_5 and then to the stable TeO_2 at 400°C, the temperature at which the films crystallized. Consequently, the presence of large amounts of the higher oxides in the amorphous films is indicated. This was qualitatively verified by observing the effervescent reaction which occurred when amorphous tellurium oxide films were immersed in a 30% NaOH solution. Bulk Te_2O_5, and presumably TeO_3, react in this manner (17), whereas TeO_2 does not yield an effervescent reaction. Such observations only indicate the presence of the higher oxides; the presence of TeO_2 is not excluded. Therefore, the films are designated $TeO_{2+x}(0 < x \leq 1)$.

X-ray diffraction analyses show that crystallization of the amorphous TeO_{2+x} films commences with the formation of an unidentified phase. This phase transforms to tetragonal TeO_2 when heated for a longer period of time or at a higher temperature. It was not possible to obtain a good diffraction pattern of the unidentified phase alone. A comparison of the ASTM data for tetragonal TeO_2 and the data obtained from a representative film containing both phases is given in Table III. High-temperature x-ray diffractometry has shown that bulk TeO_2 undergoes no polymorphic transformations when heated to its melting point in air. The data for the unidentified phase do not suggest formation of the orthorhombic or high-pressure TeO_2 polymorphs (18). The unidentified phase may represent a higher oxide of tellurium, but the diffraction data are not in sufficient agreement with those reported (19) for TeO_3 phases prepared by hydrothermal methods to give definite identification.

Optical properties.—Optical properties of some amorphous films are shown in Fig. 3 and 4. Individual films are identified by numbers which refer to the sputtering run and by letters which refer to the various substrates used in any given run. The order of increasing refractive index is the same as the order of increasing extinction coefficient. The uncertainty in the refractive index of any film is within ± 4% and is primarily due to the uncertainty in the film thickness. For the oxide films of tungsten, tellurium, and tin, $k \leq 0.002$ at $\lambda \geq 450$ mμ. The experimental uncertainty in k is estimated to be within ± 0.003 for the lowest k values.

Few tin oxide films were obtained which were thick enough for optical measurements, because the tin cathode melted unless sputtered at a very low deposition rate. Amorphous bismuth oxide and lead oxide films are brown in transmission, whereas the other amorphous films are nearly colorless. The crystalline oxide films of cadmium, nickel, and silver are all colored; CdO is yellow, and the others are black.

Reactively sputtered bismuth oxide films have long been used as high-refractive-index dielectric films. The main problem associated with such films is the presence of optical absorption. Clapham (20) has examined the effect of gas composition used in sputtering on optical absorption. He found that the absorption is minimized when the ratio of argon to oxygen flow rates is about 100:1. In his work, optical properties were determined for films deposited on glass substrates, while electron diffraction patterns were ob-

tained for films deposited on carbon supports. The films were identified as α-Bi_2O_3.

In the present investigation, both optical and structural properties were determined for films deposited on glass substrates. The refractive index data obtained for the amorphous bismuth oxide films are in excellent agreement (well within experimental error) with those obtained by Clapham (20). The value of the extinction coefficient of the amorphous films at 550 mμ is 0.056, which is in reasonable agreement with the value of 0.07 reported by Clapham for a film prepared with a large excess of oxygen in the gas mixture. Transformation of the amorphous bismuth oxide to the β-modification, however, results in a large decrease in optical absorption without any detectable change in the refractive index. Extinction coefficient values of β-Bi_2O_3 films were determined in the usual manner and are compared with Clapham's (20) minimum-absorption values in Fig. 5. Values presented for the amorphous films are those shown in Fig. 4. The values obtained for β-Bi_2O_3 films are lower than Clapham's minimum-absorption values. These results show that optical absorption in bismuth oxide films is highly dependent on structure. Films of low absorption and high refractive index can be prepared via the crystallization of amorphous- or δ-Bi_2O_3 films of high absorption which have been prepared by reactive sputtering in an excess-oxygen gas mixture. Consequently, gas composition need not be a carefully controlled sputtering parameter.

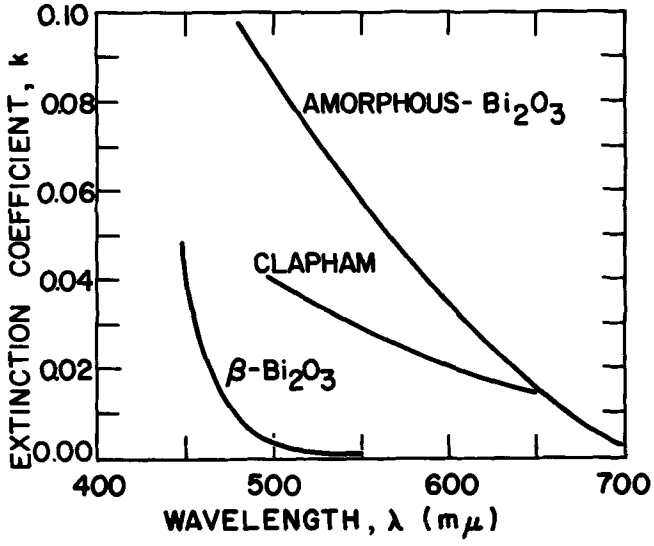

Fig. 5. Comparison of extinction coefficients of Bi_2O_3 films obtained in this investigation with those obtained by Clapham (20).

Discussion

The amorphous metal oxides prepared in this work, with the exception of SiO_2, have not been reported to form bulk glasses. Amorphous films of SiO_2 and SnO_2 have been prepared by reactive sputtering by Sinclair and Peters (1). Those of Ta_2O_5 have been prepared by reactive sputtering by Gerstenberg and Calbick (21). The other amorphous films have apparently not been reported. Only crystalline lead oxide films have been prepared by reactive sputtering by Lappe (22) and Sinclair and Peters (1). Substrate refrigeration was used in this work to maximize the number of amorphous materials prepared. That it had this effect was shown by the preparation of amorphous Bi_2O_3 with substrate refrigeration and crystalline δ-Bi_2O_3 without it.

Sarjeant and Roy (9) have examined the phases of metal oxides obtained from splat cooling and other rapid-quenching techniques. They were unable to prepare amorphous Bi_2O_3, Ta_2O_5, SnO_2, or WO_3 (except in the presence of some crystalline WO_3). In the present investigation, all of these metal oxides were prepared as amorphous films. Consequently, the deposition of reactively sputtered films on refrigerated substrates represents a more effective method of quenching than the techniques employed by Sarjeant and Roy (9).

The crystallization of the amorphous films often produces metastable high-temperature phases which

suggests that such films can be regarded as supercooled liquids. In particular, the formation of δ-Bi_2O_3 on crystallization of the amorphous Bi_2O_3 is good evidence that these films are structurally comparable to supercooled melts (see Fig. 2). If glass is defined as an amorphous, rigid, supercooled melt, such films can be considered to be glasses. Sinclair (23) has expressed the opinion that glass films be defined as those having an amorphous structure and a sufficiently high viscosity so that the structure is rigid. According to this definition, the amorphous films prepared in the present investigation must be regarded as glass films.

Crystallization of the amorphous WO_3 films usually gave rise to the orthorhombic modification rather than the higher-temperature tetragonal modification obtained by Sarjeant and Roy (9). The amorphous films, if supercooled liquids, would have been expected to crystallize initially as the tetragonal modification, and then transform to the orthorhombic modification. The possibility exists that this may have occurred, but the tetragonal to orthorhombic transformation occurred too quickly to be observed.

From the phases observed, it is apparent that the metal atoms of films reactively sputtered in an excess-oxygen atmosphere are frequently in high oxidation states. This is not meant to imply that the highest oxidation states are always obtained. Rather, it indicates that the lower oxidation states, which may be more common in some of the metal oxides prepared by other techniques, are not necessarily to be expected from the highly energetic sputtering process.

Acnowledgments

The authors wish to thank Dr. Peter R. Segatto for supplying some of the sputtering equipment, reading the manuscript, and giving helpful advice throughout the work. Spectrophotometric measurements provided by Mr. Herbert Hoover are particularly appreciated. Finally, the authors gratefully acknowledge the technical assistance of Mr. Oliver W. Kendall and Miss Brenda Boller in the film preparations and x-ray diffraction analyses, respectively.

Optimization of Electroluminescent Efficiencies for Vapor-Grown $GaAs_{1-x}P_x$ Diodes

C. J. Nuese, J. J. Tietjen, J. J. Gannon, and H. F. Gossenberger

RCA Laboratories, Princeton, New Jersey

ABSTRACT

A series of $GaAs_{1-x}P_x$ diodes have been prepared by a vapor-phase growth technique to investigate the effects of current-spreading, absorption, impurity concentrations, and alloy composition on room-temperature electroluminescent efficiencies. It is shown that for maximum efficiencies, a diode structure should be prepared with a p^+ surface layer to enhance current spreading, and a $GaAs_{1-x}P_x$ "window" containing about 10% more GaP than the p-n junction region to reduce absorption losses. It is also shown that the most efficient radiative recombination originates on the p-side of the junction; low acceptor concentrations and high donor concentrations which are required for strong electron injection into the p-side of the junction are thus found to result in highest electroluminescent efficiencies. Slow compositional grading between the GaAs substrate and the $GaAs_{1-x}P_x$ p-n junction also resulted in increased efficiencies. A drop-off in efficiency near the direct-indirect transition for values of x increasing from 0.38 was found to be severe, however, a corresponding increase in the spectral sensitivity of the eye was found to provide a broad maximum in diode brightness at emission wavelengths near 6800Å ($x \approx 0.38$). Planar uncoated diodes have provided brightness values in excess of 300 ft-L at 10 amp/cm^2 with external efficiencies of 2×10^{-4} at 6400Å. Plastic encapsulants can be readily used as domes to increase external efficiencies by a factor of 3, or as directional lenses to provide beam-widths as narrow as 7°.

Several semiconductor compounds have been considered for d-c room-temperature visible-light-emitting diodes, the most promising to date being GaP, $GaAs_{1-x}P_x$, and $Al_{1-x}Ga_xAs$. In GaP, high external efficiencies ($\approx$ 2%) have been measured (1), although much of the radiation is in the infrared. Recent results for solution-grown $Al_{1-x}Ga_xAs$ have also been very encouraging (2) (0.4% for shaped, coated diodes emitting at 6500Å). The work reported here is concerned with determining the potential of the system $GaAs_{1-x}P_x$ for the fabrication of electroluminescent diodes. Such devices have application as small indicating lamps, for alpha-numeric displays, and in various optical systems requiring a particular emission wavelength (*e.g.*, to match a detector or photosensitive device).

In order to optimize $GaAs_{1-x}P_x$ electroluminescent efficiencies, it is desirable to separate the relevant parameters and to determine the importance of each. For this purpose, a vapor-phase growth technique is particularly well-suited. With it, one can individually control such parameters as alloy composition, junction depth, impurity concentration, and compensation, etc.; this is not the case for diffused diodes where many of these parameters are strongly interrelated. In addition, the ease of successively depositing different type layers of $GaAs_{1-x}P_x$ is found to be important for the fabrication of diodes with reduced absorption losses and uniform light emission.

The vapor-phase growth of $GaAs_{1-x}P_x$ p-n junctions has previously been employed for the fabrication of injection lasers capable of pulsed room-temperature (3) or c-w operation at 77°K (4). In addition, vapor-phase growth has been used to clarify the effects of absorption, temperature, and impurity concentrations on the quantum efficiency of GaAs noncoherent diodes (5). For this research, similar growth techniques have been used to prepare $GaAs_{1-x}P_x$ junction structures specifically designed for visible-light-emitting sources operating in the spontaneous mode.

Experimental Procedure

The $GaAs_{1-x}P_x$ used in this study was deposited epitaxially on <100>-oriented n-type GaAs substrates by an open-tube vapor-phase growth technique which has been described previously (6). Briefly, arsine and phosphine are used as the source of arsenic and phosphorus, while HCl gas is used as a transport agent for the gallium. Donor and acceptor doping is accomplished by using hydrogen-selenide gas and Zn vapor, respectively.

The electroluminescent diodes were prepared in an n-p-p^+ structure, as shown in Fig. 1, by grading the phosphorus concentration, x, from zero at the GaAs substrate to about 0.4-0.6 just below the p-n junction. Following junction formation, a further increase in phosphorus concentration was employed to provide a high-energy-gap "window" for the junction radiation. A p^+ layer was used in the outermost portion of the window in order to spread the current laterally from beneath small surface contacts so that the radiative recombination would occur uniformly over the p-n junction. It should be noted that the structure of Fig. 1, consisting of various impurity concentrations and alloy compositions, is prepared in one continuous growth operation and, unlike diffused and (usually) solution-regrown diodes, does not require an additional high temperature process to form or anneal the p-n junction.

Diode fabrication procedures were similar to those used for vapor-grown GaAs electroluminescent diodes (5). An array of small Ag-Mn ohmic contacts (7) was evaporated to the as-grown p-type epitaxial surface, and a continuous Au-Sn contact was evaporated to a lapped surface of the n-type GaAs substrate. Individual chips, 1 mm^2, were cleaved from the wafer, mounted on

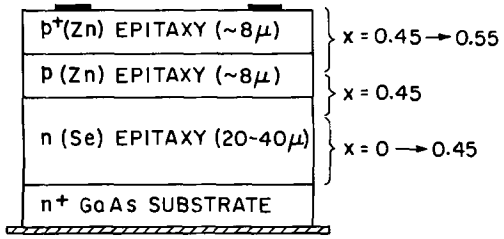

Fig. 1. Vapor-grown $GaAs_{1-x}P_x$ electroluminescent diode structure. Light emission passes through the p and p^+ layers and is emitted from the uppermost p^+ surface.

a transistor header, and contacted with Au leads on an ultrasonic bonder.

The external quantum efficiency was measured with a calibrated, large-area silicon solar cell (Hoffman 2A) placed in close proximity to the uppermost p-type light-emitting surface of the diode. Emission from the four cleaved edges of the diode was not measured by this technique, and therefore, the reported efficiency values are estimated to be low by about 10%. Spectral measurements were taken on a Spex 1700 grating monochromator with an S-1 photomultiplier and associated amplifying and recording electronics. All electrical and optical measurements were taken with applied current densities and/or duty cycles small enough to avoid adverse heating effects.

Donor and acceptor impurity concentrations were approximated by comparison with epitaxial Hall samples prepared under similar growth conditions. $GaAs_{1-x}P_x$ alloy compositions were occasionally determined by x-ray diffractometry, but were usually approximated from the junction emission energy and the known relationship (6) between energy gap and alloy composition.

Results and Discussion

Current spreading and absorption.—To evaluate the performance of the diode structure of Fig. 1, we first examine the importance of the p^+ layer in spreading the current from beneath the dot contacts (Fig. 2). The microphotograph of Fig. (2a) shows an extreme example of current localization beneath the contacts, which is found to occur for diodes without (or with too thin) a p^+ layer. A typical junction acceptor concentration of 3×10^{18} holes/cm^3 ($\rho \approx 10^{-2}$ ohm-cm) is too low to provide adequate lateral conduction between the contacts. Such localization is undesirable because a large fraction of the emission is blocked by the metalization and reflected back into the (absorbing) semiconductor. For Fig. (2b), an 8μ thick p^+ layer of Zn-doped $GaAs_{1-x}P_x$ with $p \approx 3 \times 10^{19}$ cm^{-3} ($\rho \approx 10^{-3}$ ohm-cm) was vapor-grown above a similar p-n junction. Here, the light emission is relatively uniform over the 4 mm^2 junction area, even though less than 6% of the p^+ surface is metalized. A doping concentration of about 3×10^{19} cm^{-3} was found empirically to best enhance the current spreading. This n-p-p^+ structure was then used in all subsequent experiments.

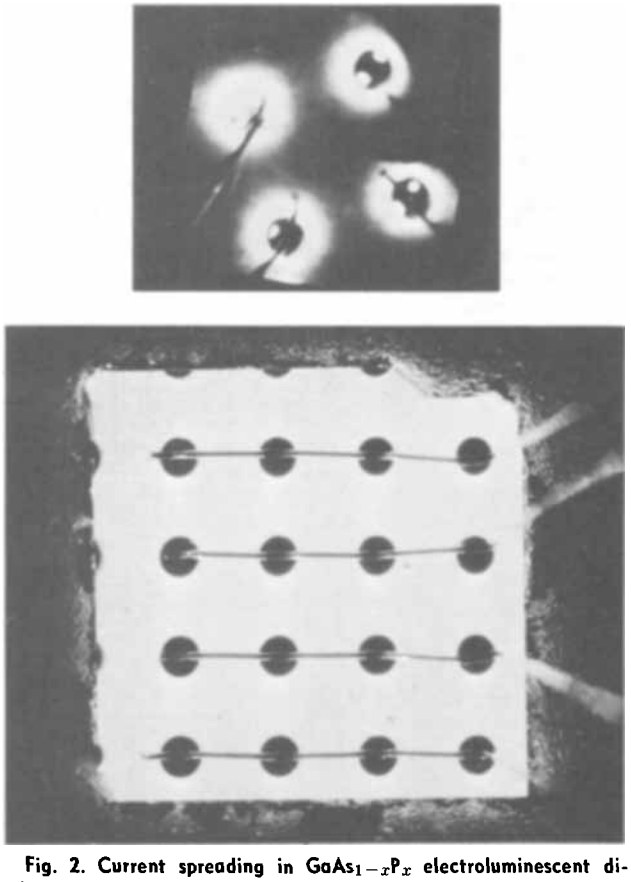

Fig. 2. Current spreading in $GaAs_{1-x}P_x$ electroluminescent diodes. All of the illumination for these microphotographs was provided by the band-gap diode emission. $T = 300°K$. For both photos, ohmic contacts are 0.005 in. diameter dots located on 0.020 in. centers. (a, top) Extreme current localization beneath ohmic contacts, which is caused by absence of p^+ layer. (b, bottom) Uniform light emission enhanced by presence of 8μ thick p^+ surface layer doped to 3×10^{19} cm^{-3}.

It is well known that room-temperature absorption losses significantly limit the external efficiencies of near-band-gap-emitting electroluminescent diodes (5, 8-10). One technique for reducing this absorption is with a higher-energy-gap window adjacent to the p-n junction (11), so that the lower energy junction emission travels to the semiconductor surface with little attenuation. We have previously reported the use of $GaAs_{1-x}P_x$ windows with vapor-grown GaAs electroluminescent diodes (5), and have also found such windows effective for reducing the absorption losses of the $GaAs_{1-x}P_x$ diodes described here.

A series of 6 $GaAs_{1-x}P_x$ wafers were prepared as described above, each with a window of different alloy composition above the p-n junction, but as alike as possible in alloy composition ($x \approx 0.41$) at the junction and in impurity concentrations ($n = 2 \times 10^{18}$, $p = 3 \times 10^{18}$, $p^+ = 3 \times 10^{19}$ cm^{-3}). For these wafers, the p and p^+ layers were each about 8μ thick, and the compositional grading to provide the window was initiated about 2μ beyond the p-n junction, so as not to alter the junction recombination process. The external quantum efficiency of diodes prepared from these wafers is plotted in Fig. 3 as a function of the difference in phosphorus composition, Δx, between the surface and the junction.

The improvement in external efficiency (by a factor of about 3) for windows with $\Delta x = 0.1$ is attributed to reduced absorption losses. The effectiveness of the window for the structure used here is always limited by high free-carrier absorption in the p^+ layer, even at photon energies significantly less than bandgap. Calculations with p-type GaAs (for which room-temperature absorption data are available) indicate that one should expect a reduction in absorption on the order of 3 for a structure similar to that in Fig. 1.

The decrease in relative external efficiency for $\Delta x > 0.1$ is mainly due to inadequate current spreading which is observed for contacts applied to phosphorus-rich $GaAs_{1-x}P_x$. At increased phosphorus concentrations, the surface conductivity of the p^+ layer decreases due to lower hole mobilities, as well as to a reduction in the solubility of Zn in $GaAs_{1-x}P_x$ at the

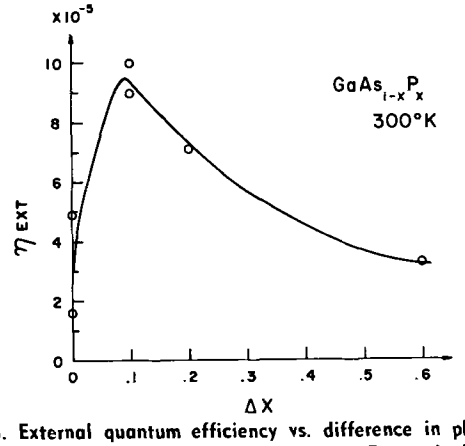

Fig. 3. External quantum efficiency vs. difference in phosphorus composition, Δx, between surface and junction. External efficiencies have been corrected slightly to normalize variations in emission wavelength.

growth temperature (775°C) (14). It is also possible that excessive strain due to lattice mismatch or to differences in thermal expansion coefficients (15) can reduce the junction efficiency whenever the alloy composition in the window is graded too rapidly. The effect of grading on junction efficiencies is again mentioned below.

Impurity concentrations.—After optimizing the p^+ layer to obtain light uniformity and the phosphorus-rich window to reduce absorption, a series of 11 wafers was prepared to determine the effects of impurity concentrations on junction efficiency. For one group of 5 wafers, the doner (Se) concentration was maintained at 2×10^{18} cm^{-3}, and the acceptor (Zn) concentration was intentionally varied from wafer to wafer between 1×10^{18} and 3×10^{19} cm^{-3}. For the second group of 6 wafers, the Zn concentration was held at 3×10^{18} cm^{-3}, while the Se concentration was varied between 6×10^{16} and 5×10^{18} cm^{-3}. For all of the wafers, the p^+ layer was maintained at 3×10^{19} cm^{-3} to ensure good current spreading.

The results of room temperature efficiency measurements for diodes fabricated from these wafers are shown in Fig. 4 and 5. Also included are similar results for GaAs vapor-grown diodes from a previous publication (5). Immediately apparent is the lower efficiencies (by a factor of about 25) for the $GaAs_{1-x}P_x$ diodes as compared to those of GaAs. A reduction in $GaAs_{1-x}P_x$ efficiencies for alloy compositions near the direct-indirect transition has been observed previously (22, 23), and is evaluated further below. However, also interesting in Fig. 4 is the relatively gradual drop-off in efficiency for $GaAs_{1-x}P_x$ diodes that occurs with increasing acceptor concentrations at a value as low as 3×10^{18} cm^{-3}. This effect is probably due to two factors. First, for high acceptor concentrations ($p \approx 10^{19}$ cm^{-3}), the absorption coefficient remains large for photon energies less than bandgap (13), due to large free-carrier absorption. Thus, a high-energy-gap window would then be much less effective in reducing absorption and would result in a reduction in external efficiencies (but not internal efficiencies) at high acceptor concentrations.

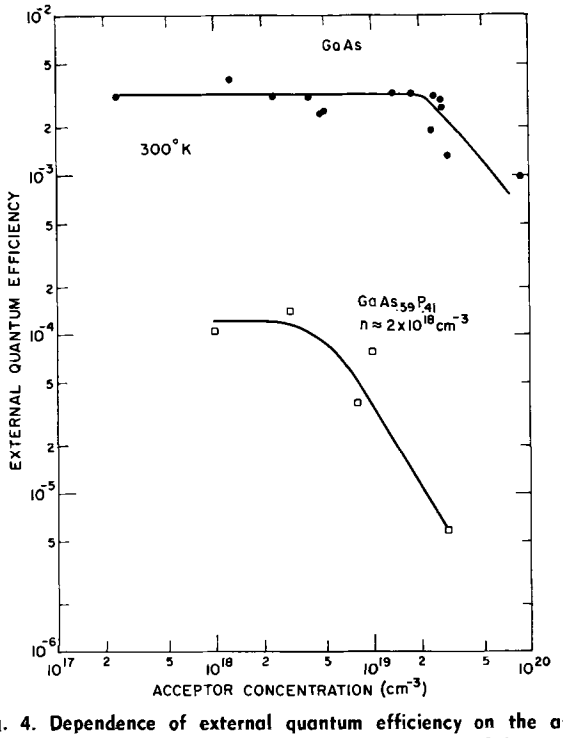

Fig. 4. Dependence of external quantum efficiency on the acceptor concentration on the p-side of the junction. $x \approx 0.41$, $n = 2 \times 10^{18}$ cm^{-3}, $p^+ = 3 \times 10^{19}$ cm^{-3}, T = 300°K. Efficiencies were corrected slightly for small variations in emission wavelength. GaAs data are from previous publication (5).

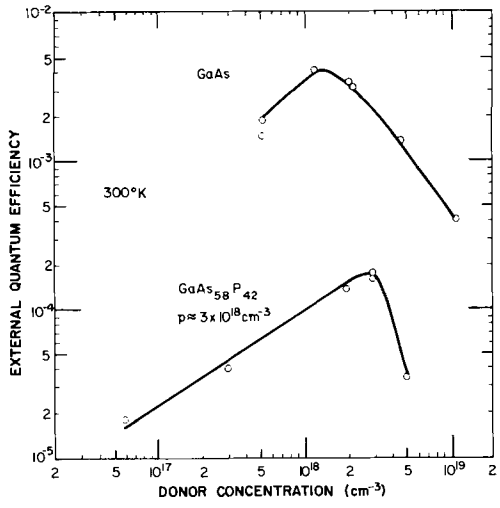

Fig. 5. Dependence of external quantum efficiency on the donor concentration on the n-side of the junction. $x \approx 0.41$, $p = 3 \times 10^{18}$ cm^{-3}, $p^+ = 3 \times 10^{19}$ cm^{-3}, T = 300°K. Efficiencies were corrected slightly for small variations in emission wavelength. GaAs data are from previous publication (5).

Second, the electron injection efficiency into the radiatively efficient p-region, which is given by (16)

$$\gamma_{n\to p} = \frac{1}{1 + \sqrt{\frac{p\mu_p}{n\mu_n}}} \qquad [1]$$

decreases by at least a factor of 3 for an increase in acceptor concentration from 1×10^{18} cm^{-3} to 5×10^{19} cm^{-3}. In general, the electron injection efficiency, $\gamma_{n\to p}$, in $GaAs_{1-x}P_x$ junctions with alloy compositions near the direct-indirect transition ($x = 0.44$) would be expected to decrease (as compared to GaAs junctions) due to the large drop-off in electron mobility, μ_n, from its GaAs value (17, 18). The reduction in μ_n (and μ_n/μ_p) would require a smaller acceptor concentration and/or a larger donor concentration to maintain the electron injection efficiency for $GaAs_{1-x}P_x$ junctions equal to that for GaAs diodes. The fact that the efficiency peaks do occur at lower acceptor concentrations (Fig. 4) and higher donor concentrations (Fig. 5) for $GaAs_{1-x}P_x$ than for GaAs is consistent with this injection process.

In Fig. 5, the initial increase in efficiency with increasing donor concentration is again partly due to increasing electron injection into the p-region, according to Eq. [1]. Over the range of doping studied here, $\gamma_{n\to p}$ would increase by about a factor of 3, somewhat less than the observed efficiency increase in Fig. 5. The peak in efficiency occurs at about $n = 3 \times 10^{18}$ cm^{-3}, higher than that for GaAs, as mentioned previously. The very sharp fall-off in efficiency for $n = 4\text{-}5 \times 10^{18}$ cm^{-3} is not clearly understood, but may be related to metallurgical imperfections (*e.g.*, Se-precipitation) which occur at such high donor concentrations (19).

The electron injection model suggested by Fig. 4 and 5 is based on the assumption of efficient recombination occurring primarily on the p-side of the junction, an assumption which is supported by photoluminescence measurements on bulk n- and p-type epitaxial wafers. Room temperature photoluminescence of p-type wafers consists of a strong near-band-gap peak; however, for n-type wafers such peaks are very weak by comparison.

The fact that the radiation originates primarily from the p-side of the junction is also independently confirmed by examination of the spectral half-widths for these diodes. The half-width, $\Delta\lambda$, plotted in Fig. 6 as a function of the donor or acceptor concentration, remains relatively constant at about 160Å over the entire range of donor concentrations, but increases significantly with increasing acceptor concentration. Such an

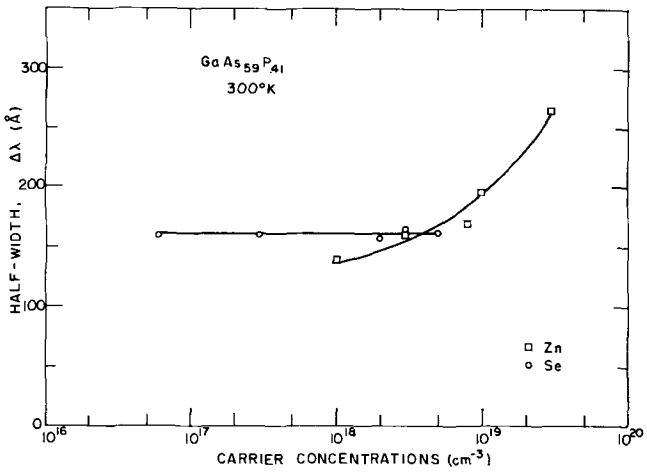

Fig. 6. Spectral half-width, $\Delta\lambda$, vs. donor and acceptor concentrations for $GaAs_{0.59}P_{0.41}$. T = 300°K.

increase is well known to result from impurity band tailing, which demonstrates, in this case, that the acceptor impurity, and therefore the p-side of the junction, is the effective origin of efficient recombination. This is also the case for $GaAs_{1-x}P_x$ diffused p-n junctions (20, 21).

The possibility of the spectral half-widths of Fig. 6 being distorted by a preferential absorption of the high-energy emission edge does exist; however, an expected increase in absorption at high acceptor concentrations would cause a decrease in spectral half-widths, contrary to Fig. 6.

Alloy composition.—For $GaAs_{1-x}P_x$ diodes having compositions near the direct-indirect transition ($x \approx 0.44$), a drop-off in efficiency with increasing phosphorus concentration has been previously noted (22, 23). In Fig. 7, the extent of this effect is clearly depicted, showing a decrease in efficiency by almost 3 orders of magnitude between 6800Å ($x \approx 0.38$) and 6000Å ($x \approx 0.60$). Such behavior is caused by the transfer of electrons from the direct [000] conduction band minimum to the six indirect <100> minima (23),

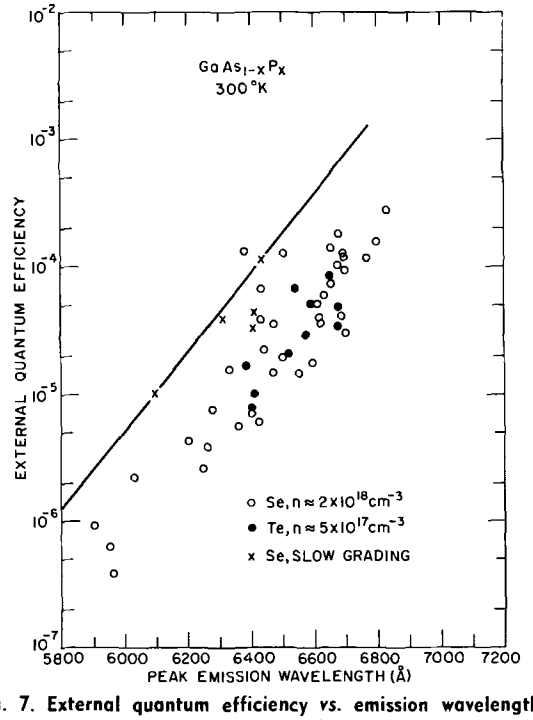

Fig. 7. External quantum efficiency vs. emission wavelength for $GaAs_{1-x}P_x$ junction diodes. T = 300°K. All diodes are planar and uncoated. o Se, n = 2 x 10^{18} cm^{-3}, graded at 2 %/μ; x Se, n = 2 x 10^{18} cm^{-3}, graded at 1 %/μ; o Te, n = 5 x 10^{17} cm^{-3}.

or to "shallow" donor states associated with the indirect minima (24). At 6800Å, planar uncoated diodes yield average efficiencies of 3-4 x 10^{-4}, with best efficiencies anticipated to be at least as high as 1 x 10^{-3} (by extrapolating the best efficiency results at shorter wavelengths, where many more wafers were prepared).

Several of the diodes with highest efficiencies in Fig. 7 were obtained by grading the alloy composition more slowly between the GaAs substrate and the $GaAs_{1-x}P_x$ p-n junction. Whereas typically the phosphorus concentration, x, was graded at a rate of about 2%/μ, most of the highest efficiency diodes were prepared from a few wafers which were graded at a rate of 1%/μ. With the slower grading, not only were efficiencies higher, but a faint dark grid-network (25) (faintly observable in Fig. 2b), which had always been present in the more rapidly graded samples, was not detected. The lower efficiencies and the grid-like array of dark "lines" are believed to be due to strain-induced dislocation arrays caused by rapid grading.

Also note in Fig. 7 that comparable efficiencies have been obtained for $GaAs_{1-x}P_x$ diodes employing either Se or Te as the donor impurity. However, to date, Te donor concentrations in $GaAs_{1-x}P_x$ have been limited by growth conditions to about 5 x 10^{17} cm^{-3}, whereas the Se donor concentrations in Fig. 7 are typically 2 x 10^{18} cm^{-3}. Thus, if the dependence of efficiency on Te concentration is similar to that for Se (Fig. 5), and if Te can be incorporated into the lattice at concentrations comparable to those of Se, then Te should provide still higher efficiencies than those shown in Fig. 7.

Perhaps of greater interest than the external quantum efficiency of visible-light-emitting diodes is their brightness, which takes into consideration the spectral sensitivity of the human eye. The Luminosity Factor (26), F, plotted in Fig. 8, accounts for the eyes' dependence on spectral wavelength, peaking at a value of 1.0 for its maximum response at 5550Å green light, and decreasing rapidly toward zero for near-infrared radiation.

The brightness, B, of a planar electroluminescent diode is proportional to the power radiated per unit area of source, and to the Luminosity Factor of the human eye. For a monochromatic-source approximation, the brightness can be expressed as

$$B \text{ (in ft-L)} = \frac{7.8 \times 10^5 F \eta_{ext} I}{\lambda A} \qquad [2]$$

In Eq. [2], η_{ext} is the external quantum efficiency, λ is the peak emission wavelength in microns, I is the applied diode current in amperes, and A is the observed light-emitting area. The relative brightness of $GaAs_{1-x}P_x$ diodes, also plotted in Fig. 8, is determined primarily by the strong wavelength dependence of F and of η_{ext}, and is seen to peak at emission wavelengths of 6700-6800Å. The dependence of brightness on alloy composition (or wavelength) is much less severe than the efficiency dependence, varying by less than a factor of 3 between 6200 and 7100Å. Highest brightness values at room temperature for these diodes are about 300 ft-L for applied current densities of 10 amp/cm^2. However, these results have been obtained with diodes emitting at 6400-6600Å, which corresponds to those compositions for which the largest number of wafers have been grown. By concentrating on the 6700-6800Å range, only slightly higher brightness values than the 300 ft-L can be expected.

Diode encapsulants.—Thus far we have treated the optimization of material parameters for electroluminescent efficiencies of planar $GaAs_{1-x}P_x$ diodes. However, a simple planar structure is relatively inefficient for diodes of $GaAs_{1-x}P_x$ (and of most other III-V compounds), because of large internal reflections at the semiconductor-air interface. The critical angle,

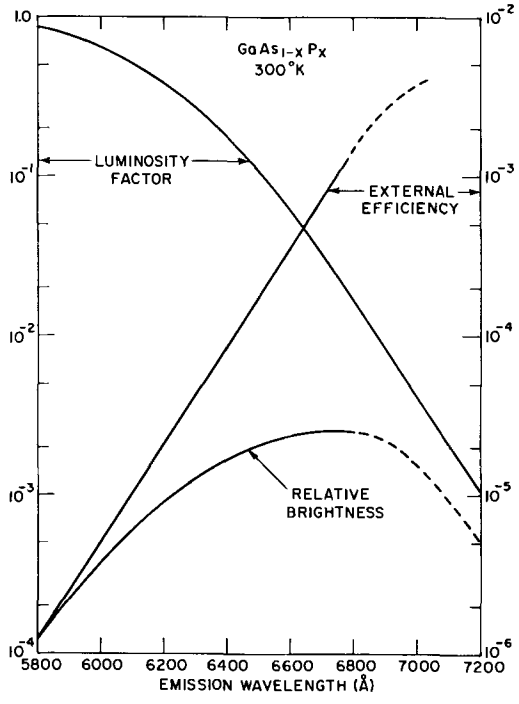

Fig. 8. Luminosity factor, external quantum efficiency, and brightness as a function of $GaAs_{1-x}P_x$ emission wavelength. T = 300°K.

Φc, for total internal reflection (*i.e.*, the largest angle which incident radiation can subtend and still be diffracted from the crystal), is defined by the equation (27)

$$\sin \Phi c = n_o/n_1 \qquad [3]$$

where n_1 and n_o are the refractive indices for the semiconductor and for the surrounding medium, respectively. For a $GaAs_{1-x}P_x$-air interface, the large mismatch in refractive index ($\approx$ 3.6 for $GaAs_{1-x}P_x$, 1.0 for air) defines a critical angle of only 16°, so that a large fraction (about 98%) of the randomly oriented junction radiation is totally reflected back into the semiconductor (28), and efficiently absorbed.

A convenient technique for reducing these reflection losses is by "capping" the planar diode with a transparent material which more closely matches the large refractive index of $GaAs_{1-x}P_x$. Plastic caps (including urethanes, epoxies, lucites, etc.) have been successfully employed for this purpose; however, two requirements are imposed on such caps. The first is, obviously, a high refractive index to increase Φc for radiation at the semiconductor-plastic interface, while the second is appropriate shaping to transmit most of the radiation from the semiconductor into the air without large reflection losses at the plastic-air interface. Theoretically, no efficiency improvement is obtained for a perfectly planar coating, regardless of its refractive index.[1] Actually, improvements of $\approx$ 40% occur for such coatings because of optical inhomogeneities and small deviations from planarity.

One shape which is particularly convenient for improving efficiencies is that of a hemispherical dome, shown in the insert of Fig. 9. For such a shape, the efficiency improvement can be calculated from (28)

$$\frac{\eta_{dome}}{\eta_{air}} = \frac{1 - \cos(\Phi c)_{dome}}{1 - \cos(\Phi c)_{air}} \qquad [4]$$

and is plotted in Fig. 9 as a function of the index of refraction for the coating material.

[1] When a planar plastic coating is deposited on the planar diode, the critical angle of the semiconductor → plastic interface is increased from Φc to Φc'. All of the junction radiation with Φc < Φ < Φc' is diffracted into the plastic, but is incident on the plastic → air interface at an angle greater than its critical angle, and is totally reflected within the plastic. Very thin anti-reflective coatings which utilize interference effects are not considered here.

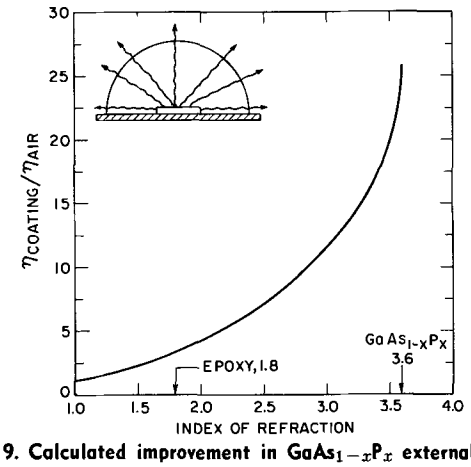

Fig. 9. Calculated improvement in $GaAs_{1-x}P_x$ external quantum efficiencies provided by hemispherical dome with arbitrary index of refraction. Absorption losses are neglected.

It is readily apparent that large improvements can be attained for high-index-of-refraction materials (as much as a factor of 26 for a perfectly matched, non-absorbing, transparent material). However, plastics, etc. which are commercially available to date, have refractive indices no larger than about 1.8, so that caps of these materials can only be expected to improve efficiencies by a factor of about 3. Experimentally, plastic caps have been used which do improve efficiencies by a factor of about 3 (from approximately 0.03 to 0.1%) for $GaAs_{1-x}P_x$ with emission wavelengths near 6500Å. At 6800Å, external efficiencies of at least 0.3% should thus be attainable with such caps. We should add that these efficiency improvements do not lead to similar gains in diode brightness, because the lens-like action of the hemisphere magnifies the observed diode area, thus increasing A in Eq. [2].

Besides improving the external efficiency of a planar electroluminescent diode, a plastic cap also can be used as a spherical lens for applications requiring a source with beam-like directionality. By molding (*e.g.*, in Teflon) a plastic lens to the shape shown in Fig. 10, a diode may be readily located at the primary focal length of the lens so that nearly all of the junction radiation is focused into a narrow beam. Figure 10 shows the experimental far-field radiation patterns for three initially identical $GaAs_{1-x}P_x$ diodes which were capped with plastic lenses of different shapes. The focal length, l, of the lens is calculated from the equation (29)

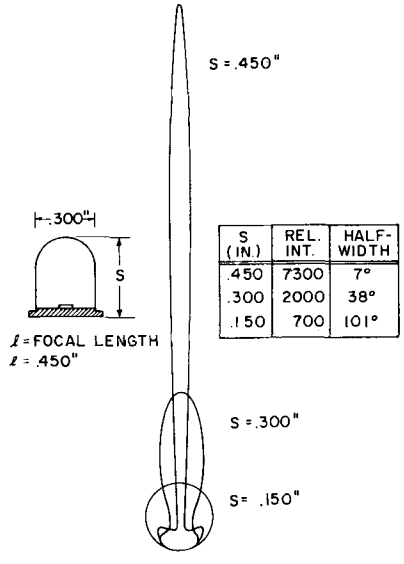

Fig. 10. Far field radiation patterns for $GaAs_{1-x}P_x$ diodes capped with a plastic lens.

$$\frac{n}{l} = \frac{n-1}{r} \qquad [5]$$

where n is the refractive index of the plastic, having a spherical surface of radius r. For the diodes in Fig. 10, $n = 1.5$ and $r = 0.15$ in., yielding $l = 0.450$ in. Particularly significant in Fig. 10 is the very narrow (7° half-width) beam obtained for the diode mounted at the focal length of the lens. Compared with the hemispherically shaped diode ($s = 0.150$ in.), an order of magnitude increase is also noted in its peak intensity. A room temperature electroluminescent source which can be operated on d.c. and provide a narrow beam of efficient visible light could compete with laser diodes in many applications, especially since laser diodes operate only under pulse conditions and at low duty cycles at room temperature.

Conclusions

Room temperature electroluminescent efficiencies of $GaAs_{1-x}P_x$ visible-light-emitting diodes are significantly lower than those of GaAs diodes. It is well known that this is primarily due to electron transfer from the efficient [000] conduction band minimum to the relatively inefficient <100> minima (or to states associated with them). However, in addition to this effect, the present study has revealed that several other parameters must be considered to achieve maximum efficiencies in $GaAs_{1-x}P_x$ diodes. For the diodes studied here, maximum efficiencies were obtained by employing:

(*i*) Strong electron injection into the radiatively efficient p-side of the junction. This is accomplished by using relatively low acceptor concentrations and high donor concentrations ($n \approx p \approx 3 \times 10^{18}$ cm^{-3}) adjoining the p-n junction.

(*ii*) Adequate current spreading at the diode surface to prevent current localization beneath the metallic contacts. This is effected by incorporating a p^+ layer at the surface of the diode.

(*iii*) Slow compositional grading between the GaAs substrate and the p-n junction, resulting in reduced strain and increased efficiencies.

(*iv*) Semi-transparent windows of phosphorus-rich $GaAs_{1-x}P_x$ to reduce absorption. Here, the exact composition of the window is important, with maximum effectiveness being realized with alloys containing about 10% more phosphorus than the junction region. Also, the use of transparent domes of high-index-of-refraction materials can improve both the external quantum efficiency and the directionality of the emitted radiation.

In addition, to achieve maximum brightness in this alloy series, it is necessary to prepare diodes which emit at about 6800Å. At this wavelength, an optimum compromise is obtained between the diode efficiency and the spectral sensitivity of the human eye.

Finally, using a vapor-phase growth method such as that employed in this study, the complex structures dictated by the above considerations can be readily fabricated.

Acknowledgments

The authors would like to thank H. P. Maruska and R. Bednars for preparing some of the wafers used here, and C. W. Benyon for ultrasonically bonding the diodes. We furthermore gratefully acknowledge the helpful discussions and suggestions of L. R. Weisberg. Mechanical Loss and Conduction Mechanism in Iron-Phosphate Glass

R. A. Miller and Kent W. Hansen[1]

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

Mechanical loss measurements were made on an iron-phosphate glass (55% FeO_x-45% P_2O_5 on a mole basis). The activation energy (0.59 ev) determined from the mechanical-loss data compared favorably with those (0.55-0.57 ev) obtained from dielectric-loss and d-c conductivity data on a similar glass. The correlation of these results is consistent with a "hopping" model for electrical conduction in iron-phosphate glasses.

Electrical conduction in semiconducting oxide glasses has been shown to result primarily from electrical charge transfer by electrons and/or holes (1). Two mechanisms have been proposed to explain the conduction. One of these is conduction by band states (2), the other by trapped states (3).

Thermoelectric power measurements made on 55 m/o (mole per cent) FeO_x-45 m/o P_2O_5 semiconducting glasses have been shown to be essentially independent of temperature (4). This would tend to imply that the carrier concentration is insensitive to temperature and, thus, that the conduction cannot be explained on the basis of band states. However, one of the consequences of narrow-band conduction, *i.e.*, conduction in bands of width kT or less, is a thermoelectric power essentially independent of temperature (5). This temperature independence can also be explained on the basis of trapped states by a "hopping" process wherein, for the glass mentioned above, the charge carriers migrate between Fe^{+3} and Fe^{+2} ions. A feature of this hopping process is that the charge carriers are not free to move throughout the glass, but are trapped at cation sites due to the polarization induced by the carriers themselves. In such a process the conduction mobility is a thermally activated process, while the carrier concentration is independent of temperature (6).

A hopping process should show both a mechanical and a dielectric loss with the same activation energy. Furthermore, that activation energy should be equal to the d-c-conduction activation energy. Dielectric loss and electrical conductivity data do exist for semiconducting oxide glasses, but to our knowledge the mechanical loss in a semiconducting oxide glass has never been investigated.

Here mechanical loss will be characterized by internal friction expressed as the logarithmic decrement. Internal friction is a measure of the capacity of a vibrating body to convert some of its mechanical energy of vibration into heat. In a perfectly elastic solid a periodic stress gives rise to a periodic strain in phase with the stress and there is no mechanical energy loss. Real materials are not perfectly elastic, however, and the strain lags behind the applied stress. This results in a loss of elastic energy analogous to the case of dielectric loss. A convenient measure of the mechanical energy loss is the logarithmic decrement which is just π times the phase angle by which the strain lags the stress. Internal friction in glass usually arises from the movement of some of the constituents of the glass, but any process which is capable of causing the strain to lag the applied stress will give rise to internal friction.

Mechanical loss measurements have been made on a glass containing 55 m/o FeO_x-45 m/o P_2O_5, and the results correlated with dielectric loss and electrical conductivity data.

Key words: semiconducting glass, iron-phosphate glass, mechanical loss, modulus relaxation, dielectric loss, d-c conductivity, electron hopping.

[1] Present address: Semiconductor Products Division, Motorola Incorporated, Phoenix, Arizona.

Experimental

The apparatus used to determine the internal friction and Young's modulus for the samples investigated in this work is essentially that described by Marx (7). Briefly, it is a composite oscillator employing two 18.5° x-cut quartz bars; one to drive the system, and one to monitor the amplitude of the strain. Samples were cemented to this driver-gauge combination to form the complete three-component composite oscillator.

The samples themselves were in the form of polished bars of square cross section, ⅛ in. on a side. This is the same cross-sectional size as the quartz and eliminates any question of loss arising from area mismatching at the specimen-quartz interface. The lengths of the samples were determined by the consideration that some multiple of the fundamental resonant length (a half wavelength of the longitudinal stress, strain, or displacement) leaves about a 6-in. dummy section between a half-wavelength sample positioned at the center of the furnace and the driver-gauge combination maintained at or near room temperature outside the furnace. The sample lengths were cut and ground so that frequency mismatching of the samples to the driver and gauge was always less than 0.1% at room temperature.

The samples were heated in a differentially wound vertical tube furnace. To minimize thermal gradients, a silver core was inserted in the furnace, and to minimize convection currents, the top was sealed off completely and the bottom opening made as small as possible. In the center region of the furnace, the maximum temperature variation along the specimens was less than 2°C from room temperature to 500°C. Temperatures were determined by means of a 5-mil chromel-alumel thermocouple placed adjacent to the samples in the furnace.

The composite resonator was driven by a Hewlett-Packard 200T precision oscillator that had been modified to permit fine adjustments of frequency (to within 1 Hz) and to permit operation to 200 kHz. Frequencies were determined by a Hewlett-Packard 5245L electronic counter. The driver and gauge voltages were determined with high-impedance, Hewlett-Packard 400D vacuum tube voltmeters.

The mechanical-energy loss expressed as the logarithmic decrement δ may be defined as the ratio of the energy loss ΔE per cycle in the material to twice the total vibrational energy E stored in the material per cycle

$$\delta = \frac{\Delta E}{2E} \qquad [1]$$

Marx has shown that for a system such as described here, the decrement for the total system (quartz plus sample) is proportional to the ratio of the voltage

applied across the driver V_d to that measured across the gauge V_g

$$\delta = K\frac{V_d}{V_g} \qquad [2]$$

where K is a constant which may be determined initially by measuring the half width of the resonance peak (7). To determine the decrement of a half-wavelength sample, each set of measurements requires two specimens, one a half-wavelength shorter than the other. The decrement δ_s of a half-wavelength sample can be found from the total decrement δ_1 determined with longer sample and δ_2 with the shorter sample by the relation

$$\delta_s = (m_1\,\delta_1 - m_2\,\delta_2)/m_s \qquad [3]$$

where m_1 is the mass of the longer sample plus the mass of the quartz, and m_2 is the mass of the shorter sample plus the mass of the quartz. The quantity m_s is the mass of the extra half wavelength of sample or the difference between m_1 and m_2 if the samples are uniform. Similarly, the resonant frequency f_s of the half-wavelength sample can be found from

$$f_s = (m_1 f_1 - m_2 f_2)/m_s \qquad [4]$$

where the subscripts have the same meanings as before.

The temperature of the furnace was increased at the rate of one degree per minute, and simultaneous readings of the driver voltage, gauge voltage, resonant frequency, and temperature were taken every 5 min. Sets of measurements were made at both 50 kHz and 150 kHz. Strain amplitudes of the order of 10^{-7} were employed at both frequencies. The decrements calculated for each temperature from Eq. [3] are shown as a function of temperature in Fig. 1. The resonant frequency values calculated for each temperature from Eq. [4] were converted to relative Young's moduli Y_T/Y_0 by the relation

$$Y_T/Y_0 = (f_T^2/f_0^2)/(1 + \alpha\Delta T) \qquad [5]$$

and are shown as a function of temperature in Fig. 2. Here Y_T and Y_0 are the high-temperature and room-temperature Young's moduli, respectively; f_T and f_0 are the high-temperature and room-temperature resonant frequencies, α is the linear coefficient of thermal expansion, and ΔT is the temperature difference. For convenience, all values have been plotted at only 20° intervals.

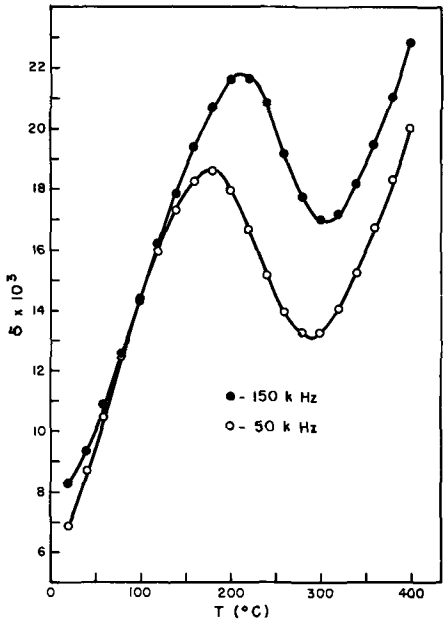

Fig. 1. Logarithmic decrement calculated from 50 kHz and 150 kHz data as a function of temperature for an alkali-free 55 m/o FeO_x-45 m/o P_2O_5 glass with an Fe^{+3}/Fe_{Total} ratio of 0.813.

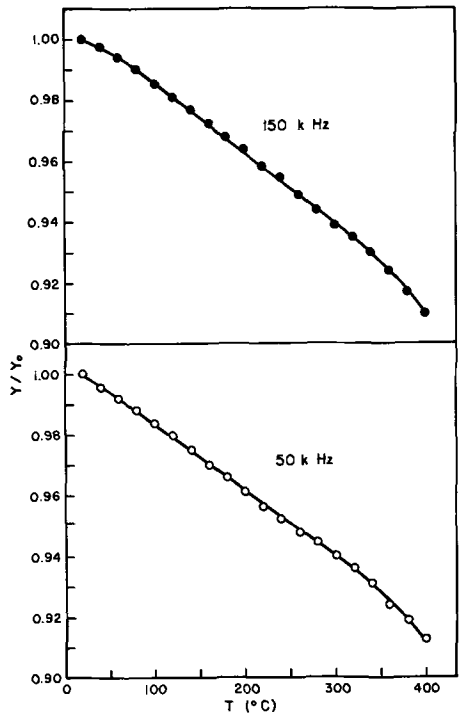

Fig. 2. Fractional change in Young's modulus calculated from 50 kHz and 150 kHz data as a function of temperature for an alkali-free 55 m/o FeO_x-45 m/o P_2O_5 glass with an Fe^{+3}/Fe_{Total} ratio of 0.813.

All measurements were made at atmospheric pressure. Experiments have shown that losses arising from air damping are of the order of 10^{-4}, or an order of magnitude smaller than found in this work, and are in fact on the order of the uncertainty in the measurements. From measurement considerations and reproducibility experiments we feel that the uncertainty in the loss values is of the order of 10% and the uncertainty in the modulus values is of the order of 2%.

Direct-current resistivity and dielectric measurements were made on samples 2 in. in diameter x 2 mm thick. Three-terminal gold electrodes were applied in accordance with ASTM specifications. The resistance was measured with a Beckman Ultrohmeter at a potential of 20v. A detailed description of the conductivity and dielectric loss measurements is given in ref. (8).

Results and Discussion

The material used in this investigation was a 55 m/o FeO_x-45 m/o P_2O_5 semiconducting glass. Chemical analysis gave an $Fe^{+3}/Fe^{+2} + Fe^{+3}$ ratio of 0.813 and a total alkali oxide content of less than 0.05 w/o (weight per cent). The samples were n-type as determined by thermoelectric power measurements. Other pertinent basic data for this glass are a room-temperature Young's modulus of 7.16 x 10^{11} dynes/cm^2 and a linear thermal expansion coefficient of 8.0 x 10^{-6}/°C.

Each of the mechanical-loss curves shown in Fig. 1 is typical of internal friction in glass. First, there is a background loss which increases rapidly at higher temperature and arises from the relaxation of the glass network itself. No attempt has been made to subtract this background loss from the data. Superimposed on this background is a broad loss peak arising from some other relaxation process taking place within the structure. The loss peak at 150 kHz is shifted to a higher temperature than that occurring at 50 kHz, implying that this is a thermally activated relaxation process. Each peak appears to be of the

Debye form

$$\delta = \Delta \frac{\omega\tau}{1 + \omega^2\tau^2} \qquad [6]$$

where Δ is the relaxation strength, ω is 2π times the vibrational frequency, and τ is the relaxation time and is of the form $\tau_0 e^{H/kT}$, where k is Boltzmann's constant, T is the absolute temperature, and H is the activation energy for the relaxation process. The breadths of the peaks indicate that they cannot be explained on the basis of a single relaxation time, and in general one might expect a distribution of relaxation times for a relaxation process occurring in a random network such as glass. Anderson and Bommel have shown that the effects of such a distribution not only broaden the loss peaks beyond that expected from a single relaxation time, but they also thermally broaden them, skew them, and increase the maximum absorption as the frequency is increased (9). All these effects are present here, although it should be noted that the higher loss at 150 kHz can also be due in part to the fact that the background loss itself is larger at the higher temperature.

For a broad distribution such as this, the most probable activation energy in the distribution $\overline{H}$ can be found from the relation

$$\ln \frac{f_2}{f_1} = \frac{\overline{H}}{k}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad [7]$$

where f_2 and f_1 are the resonant frequencies of the two samples at T_2 and T_1, which are the absolute temperatures of the internal-friction peak maxima. The activation energy $\overline{H}$ calculated from Fig. 1 is 0.59 ev, where $T_1 = 177°C$ and $T_2 = 212°C$, corresponding to frequencies of 50 kHz and 150 kHz, respectively. Because the loss peaks are quite broad, the inability to locate the position of the peak maxima to better than $\pm 2°C$ results in an uncertainty of about 12% in this activation energy.

There is good reason for believing that the relaxation strength Δ of Eq. [6] is itself proportional to $(kT)^{-1}$, and one should use the temperature of the maxima from a $\delta \cdot T$ *vs.* $1/T$ plot to find activation energies. This has in fact been done, and the activation energy found is 0.04 ev less than that given above. Since this result is encompassed in the uncertainty of the previous value, and since there is no reason to believe that the background damping should follow such a relation, we prefer not to show this procedure.

The occurrence of internal friction is usually accompanied by a fractional decrease in the modulus of the same order of magnitude as the internal friction. Figure 2 would appear to show only an ordinary decrease in the modulus with temperature. However, closer examination of the 150 kHz values, where the loss peak and, thus, dispersive effects appear at higher temperatures, shows that the initial slope of the curve differs from that seen throughout most of the temperature range investigated. Thus, the modulus *vs.* temperature curve would appear to approach the temperature range considered here with a smaller slope. This is not so evident from the 50 kHz values, but here the dispersive effects due to the relaxation peak would come into play about 35°C lower in temperature, so that the smaller-slope region due to the ordinary decrease in modulus with temperature lies entirely to the left of this curve. At temperatures above 340°C, where one might again expect to see a modulus unaffected by the stress-induced relaxation, the modulus fall-off with temperature due to the gradual softening of the glass is large enough to mask any other effects. In other words, at these frequencies, we are probably able to see only the dispersive region of the modulus in the temperature range over which the measurements were made.

The absence of any significant concentration of alkali in the glass eliminates the possibility that a loss of the magnitude found here is due to the stress-induced movement of alkali ions. Neither can the loss be realistically attributed to the stress-induced diffusion of Fe^{+2} or Fe^{+3} ions or of singly bonded oxygen ions. If these were responsible for this loss, one would expect to find an activation energy more nearly like the 1.3 ev found for the former (10) or the 2-3 ev found for the latter (11) in silicate glasses. Dielectric loss and resistivity measurements yielded similar results. Experiments carried out on a glass of identical composition but with a slightly different $Fe^{+3}/(Fe^{+2} + Fe^{+3})$ ratio of 0.793 [glass 1, ref. (8)] showed a dielectric loss peak with an activation energy between 0.55 and 0.57 ev, and a d-c-conduction activation energy of 0.57 ev. It thus appears that a relaxation associated with the motion of the charge carriers (here localized electrons) is responsible for the observed mechanical loss. The relaxing unit in this case acts as both an elastic and an electric dipole. This behavior is entirely consistent with the model proposed by Heikes and Johnston (6).

The uncertainties associated with the activation energies for both the dielectric and mechanical loss prevent a meaningful comparison of the pre-exponential τ_0 in the expression for the relaxation time. The agreement is, however, order of magnitude ($\sim 10^{-13}$ sec).

Although an activation energy for the mechanical loss was determined on the basis of only two frequencies, it is significant that the activation energy agreed with that found from dielectric-loss and d-c-conductivity data. Equality of activation energies can, of course, be coincidental. The equality of these particular activation energies, however, is certainly as one would expect in a hopping process and would seem to lend strong support to a hopping mechanism for electrical conduction.

Conclusions

1. A mechanical loss and modulus relaxation attributable to the stress-induced movement of electrons in a semiconducting glass has been detected.
2. The similarity of the values of the activation energy calculated from the mechanical loss, dielectric loss, and d-c conductivity suggests that the same mechanism is operative in the two loss processes and quite probably in the d-c conductivity.
3. The ability to detect a mechanical loss associated with the motion of the charge carriers gives further weight to a hopping process of conduction in a semiconducting glass.

Flame Emission Analysis for Sodium in Silicon Oxide Films and on Silicon Surfaces

J. E. Barry, H. M. Donega, and T. E. Burgess

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

A flame emission spectrophotometric method has been developed for the determination of ultramicro amounts of sodium present in thin silicon oxide films and on cleaned silicon surfaces. Ultrapure 5% hydrofluoric acid is used as the solvent and the sodium measured directly in the solution by flame emission analysis. This method, which has a sodium detection limit of 0.2 ppb, is used in place of the more contamination-prone neutron activation analysis to determine sodium distribution profiles in thin silicon oxide films as well as to measure the sodium contamination level of cleaned silicon surfaces. Sodium contamination on the surface of a single silicon wafer, having a surface area of approximately 16 cm^2, can be detected down to 8×10^{11} Na atoms/cm^2.

The presence of trace impurities in silicon oxide films grown on silicon surfaces has recently been the subject of many investigations. Field-effect measurements made on metal-oxide-semiconductor structures have indicated that the number of surface charges per cm^2 at the silicon-silicon oxide interface are directly related to the presence of certain impurities (1). Further studies have confirmed the fact that the presence of alkali metal impurities, especially sodium, both in the silicon oxide film and at the silicon-silicon oxide interface contribute significantly to the instability of the metal-oxide-semiconductor structure (2-4).

Previous studies of the distribution of sodium in silicon oxide films grown under a variety of conditions have been made by neutron activation analysis (5-7). The flame emission method not only offers the high sensitivity necessary for this application, but at the same time essentially eliminates the obvious inherent shortcomings of activation analysis.

The flame emission method has also been successfully applied to the determination of the sodium contamination level of cleaned silicon surfaces for which neutron activation analysis is most seriously limited.

Experimental

Flame photometry.—Flame photometric analysis consists essentially of the emission of characteristic radiation by a metallic element as the result of atomization of a solution of the element into a flame of sufficient thermal energy to excite the metal atom. The intensity of the emitted radiation is directly proportional to the number of atoms excited by the flame and therefore to the concentration of the element in solution. The light emitted is resolved by a monochromator into specific wavelengths, and the radiation intensity in the selected spectral region measured using a suitable detector system. The instrument is calibrated with standard solutions of the element of interest in order to establish a relationship between the measured emission intensity of a known characteristic spectral line and the concentration of the element in solution. Similar intensity measurements are made on the sample solutions and converted to concentrations by comparison to the calibration curve.

The spectral emission line used for the determination of sodium is the unresolved doublet at 589.0/0.6 mμ. This is the most sensitive of all lines employed in flame photometry (8). Its use results in an extremely sensitive method for sodium and calibration curves which are linear even at extremely low concentrations.

Equipment.—For this work a Beckman Model DU spectrophotometer was used equipped with the following Beckman accessories: (*i*) 9200 flame attachment, (*ii*) a-c power supply, (*iii*) 4020 atomizer-burner assembly, (*iv*) W128719 oxygen burner sheath, (*v*) 4310 multiplier phototube (1P28), (*vi*) 100 megohm phototube resistor.

The purpose of the oxygen burner sheath was to shield the flame from the ambient air and air-borne dust. Use of the sheath reduced any turbulence, improved the stability of the flame, and as a result increased the detection limit by approximately a factor of two.

Only polyethylene ware was used throughout this study for all sample handling and storage of solutions to eliminate possible contamination by leaching of sodium from glass. Polyethylene cups were used as sample containers in the spectrophotometer and standard solutions were stored in polyethylene bottles. All of the equipment was cleaned immediately prior to use by rinsing first in distilled water and finally distilled-deionized water.

Preparation of standards.—Two calibration curves covering the ranges 0-100 ppb Na and 0-10 ppb Na in 5% HF were prepared from standards made by diluting a water solution containing 1000 ppm Na (as sodium chloride). The final hydrofluoric acid concentration was adjusted to 5% in all standard solutions to coincide with the use of 5% HF to etch the silicon surfaces.

Figure 1 shows the sodium calibration curve covering the range 0-10 ppb Na in 5% HF. The instrument was adjusted for 0% transmission with the dark current control using a 5% HF blank. The 100% transmission was set using the sensitivity controls and a 10 ppb sodium standard in the same 5% HF. This procedure was repeated each time a measurement was made. Based on the data obtained in preparing this curve, the optimum precision of the method was determined to be ± 0.2 ppb Na and the limit of detection 0.2 ppb Na corresponding to 2.6×10^{13} atoms of sodium.

Method of analysis.—The scope of this study included not only the measurement of the sodium contamination level of cleaned silicon surfaces but also the determination of the distribution of sodium in

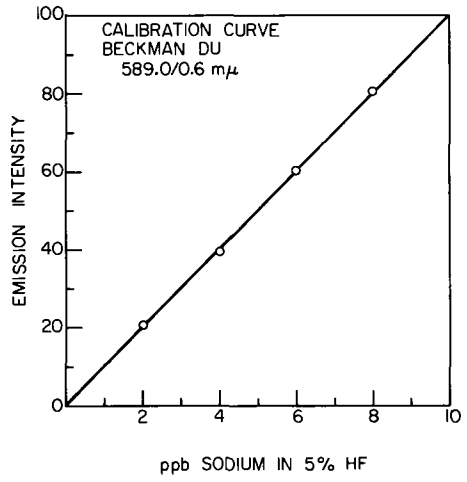

Fig. 1. Calibration curve for Beckman DU flame spectrophotometer at 589.0/0.6 mμ.

silicon oxide films grown on silicon wafers. Generally, the silicon wafers were treated to a dissolution step designed to remove the sodium and isolate it in a measured volume of 5% HF. The sodium content of the hydrofluoric acid was then determined by flame emission analysis. From this data the sodium concentration of the oxide film or the sodium contamination level of the silicon surface was calculated. The 5% HF solution which dissolves silicon oxide films at a fairly uniform rate of 300 Å/min was prepared by volumetric dilution of an ultrapure reagent grade (minimum 40%) hydrofluoric acid manufactured by E. Merck Inc., Darmstadt, Germany, and distributed by Brinkmann Instruments Inc. Silicon wafers were cleaned before analysis by exposure to a 10% HCl-90% H_2 atmosphere at 1250°C for 30 min. This treatment removed 15μ of silicon from the surface. The sodium remaining on these surfaces or distributed in 6000Å oxide films thermally grown in a dry oxygen atmosphere on similarly prepared surfaces was measured.

To determine the level of sodium contamination on cleaned silicon surfaces, each wafer was placed in a clean polyethylene beaker and 5 ml of 5% HF added. After a 2-min exposure time, the hydrofluoric acid was transferred to a photometer cup and the sodium measured directly by flame emission analysis. The same process was repeated with additional hydrofluoric acid for either a maximum of four rinses or until the sodium content was reduced to a value equivalent to the detection limit. The total sodium determined was then related to the individual wafers on a surface area basis. The surface area of each wafer was approximately 16 cm^2.

A similar procedure was used to determine the distribution of sodium in thermally grown silicon oxide films on silicon surfaces. In this case, the individual wafers were placed in clean polyethylene beakers and 5 ml of 5% HF added. After a predetermined period of time, the hydrofluoric acid was transferred to a polyethylene photometer cup and the sodium measured directly by flame emission analysis. Immediately after transfer of the acid, the wafer and the beaker were rinsed several times with distilled-deionized water, the washings discarded, and an additional volume of hydrofluoric acid added. This process was repeated until the oxide film was completely removed in several increments. The sodium determined was then related to the thickness of the oxide removed on a concentration basis.

Results and Discussion

The results of a study of the distribution of sodium in thermally grown silicon oxide films are given in Table I. Eighteen silicon wafers were used having an oxide thickness of 6000Å and a surface area of 16 cm^2.

Table I. Distribution of sodium in thermally grown silicon oxide films

Silicon oxide removed (Å)	Sodium atoms: Group A (Avg. 4 wafers)	Sodium atoms: Group B (Avg. 14 wafers)
50	3.4×10^{14}	4.5×10^{14}
1200	7.5×10^{13}	
1200	3.0×10^{13}	
1200	5.6×10^{13}	
1200	5.6×10^{13}	
900	1.3×10^{14}	
250	2.8×10^{14}	3.9×10^{14}
5700	3.5×10^{14}	4.4×10^{14}

For the study, the wafers were divided into two groups. Group A represents the average data from four individual wafers in which the oxide was removed in several small increments. Group B represents the average data from 14 wafers in which the initial 50Å of oxide at the surface and the final 250Å at the silicon-silicon oxide interface were removed in identical fashion to group A. However, the intermediate 5700Å was removed in a single step rather than in several small increments.

The data show excellent agreement between the two studies. For the initial 50Å of oxide at the surface an average of 3.4 x 10^{14} atoms of sodium in group A and 4.5 x 10^{14} in group B are found. For the intermediate 5700Å of oxide, the total number of sodium atoms in group A, 3.5 x 10^{14}, compares favorably with a corresponding value of 4.4 x 10^{14} atoms for group B. In the final 250Å of oxide, which essentially represents the level of sodium contamination at the silicon-silicon oxide interface, group A has an average of 2.8 x 10^{14} atoms of sodium and group B, 3.9 x 10^{14} atoms.

The results of this study show, first, that the average sodium profile for group A is generally in good agreement with the average distribution of sodium determined for group B. Second and most important, the average sodium content determined for the intermediate 5700Å of oxide in group A, which is based on five separate acid cuts and includes five individual flame measurements, agrees well with the comparable data determined for group B, which involves only a single acid cut and a single flame measurement. This excellent agreement eliminates contamination during the analysis as a source of error since group A involved five times as much handling as group B.

Figure 2 is a comparative study of the distribution of sodium in thermally grown oxide films made by both neutron activation analysis and flame emission analysis. The lower curve represents the average data taken from four individual profile studies made by flame emission analysis of silicon wafers having an oxide thickness of 6000Å. The upper curve, represented by a

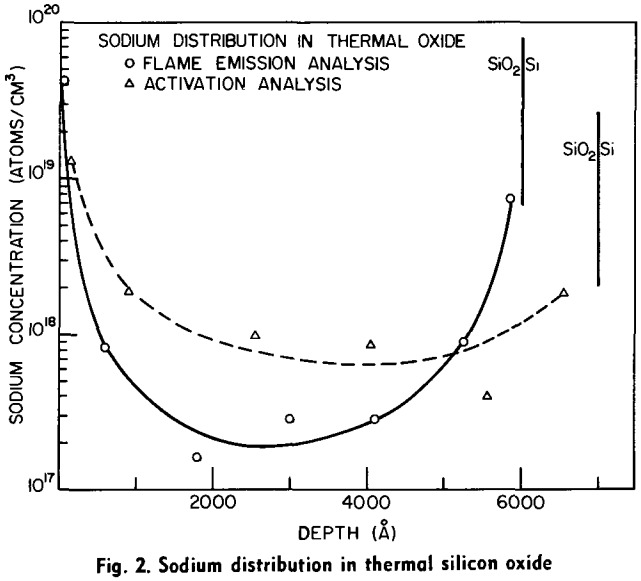

Fig. 2. Sodium distribution in thermal silicon oxide

Table II. Sodium on the surface of HCl vapor-etched silicon wafers

Lot No.	Wafer No.	Sodium atoms/cm²
1	1	$<8.2 \times 10^{11}$
	2	$<8.2 \times 10^{11}$
	3	1.4×10^{13}
	4	$<8.2 \times 10^{11}$
	5	$<8.2 \times 10^{11}$
2	1	$<8.2 \times 10^{11}$
	2	$>9.1 \times 10^{13}$
	3	$>1.6 \times 10^{14}$
	4	$>3.3 \times 10^{14}$
	5	$<8.2 \times 10^{11}$
3	1	4.2×10^{13}
	2	7.7×10^{12}
	3	4.3×10^{12}
	4	1.1×10^{13}
	5	5.4×10^{12}

broken line, is a plot of the average data from two individual profile studies made by neutron activation analysis of silicon wafers having an oxide thickness of 7000Å. Except for a slight difference in thickness, the oxide films were prepared in an identical manner by thermal oxidation in a dry oxygen atmosphere, in the same furnace but not at the same time. The shapes of the two sodium distribution curves are the same and the only difference between the two curves is the slightly higher concentration of sodium both at the surface and the silicon-silicon oxide interface in the 6000Å films analyzed by the flame emission method.

In general, the sodium profile obtained by flame emission is in relatively good agreement with that obtained by neutron activation analysis. The slight difference between the two profiles is no more than would be observed if both studies had been made by activation analysis alone.

Besides the study of the distribution of sodium in thermally grown oxide films, flame emission analysis has one other significant application; this is in the measurement of the level of sodium contamination on silicon surfaces prior to oxide formation. This is of importance since it is related to the level of sodium contamination found in the oxide grown on such a surface.

Table II shows the results of a study to determine the level of surface contamination on silicon wafers after HCl vapor-etch cleaning. The surface sodium remaining after cleaning was removed by dissolution in a measured volume of 5% HF and quantitatively measured by flame emission analysis. The data was obtained from three lots of silicon wafers cleaned at different times. The results are reported as atoms of sodium per square centimeter based on a total surface area of 16 cm².

The data show considerable lot-to-lot variation in the level of surface sodium contamination as well as some piece-to-piece variation within the same lot. Lot No. 2, for example, had contamination levels ranging from below the analytical detection limit, 8.2×10^{11} sodium atoms/cm², to greater than 3.3×10^{14} sodium atoms/cm².

No direct comparison between these results and results obtained by other methods of analysis such as spark source mass spectroscopy is available; however, the values measured compare favorably with the 8×10^{14} silanol (Si-OH) groups per square centimeter found on fully hydrated silicon dioxide surfaces (9). This suggests that at least a portion of the protons of these silanol groups on the natural oxide which would form on the HCl-etched surface in air would be replaced by sodium in the presence of this contaminant to give Si-O-Na. This oxide and the sodium contaminant is easily removed by 5% HF (10).

Summary

Flame emission spectrophotometry has been successfully applied to both the study of the distribution of sodium in thermally grown silicon oxide films and to the measurement of the level of sodium contamination on silicon surfaces.

The limit of detection for the method is 0.2 ppb Na, corresponding to 2.6×10^{13} atoms of sodium. When applied to a silicon surface having an area of 16 cm², the detection limit is 8×10^{11} atoms/cm².

The sensitivity and detection limit of flame emission spectrophotometry is approximately equivalent to that obtained by neutron activation analysis and comparable results have been obtained by both methods in determining the distribution of sodium in silicon oxide films.

Metallic Inclusions and Cellular Substructure in $Pb_{1-x}Sn_xTe$ Single Crystals

J. F. Butler and T. C. Harman

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

Electrolytic etching has revealed metallic inclusions and a cellular substructure in a number of $Pb_{1-x}Sn_xTe$ single crystals. The existence of metallic inclusions and cellular substructure in the interior of some Bridgman-grown crystals is explained by the mechanism of constitutional supercooling. Metallic surface inclusions, which are possibly due in part to reaction with the quartz growth vessel, were observed on as-grown surfaces of Bridgman- and vapor-grown crystals. Growth conditions have been found which result in $Pb_{1-x}Sn_xTe$ crystals free of bulk metallic inclusions and cellular substructure.

There has recently been considerable interest in fabricating infrared devices of $Pb_{1-x}Sn_xTe$ because its bandgap can be reduced, probably to zero width, by adjusting the Pb:Sn ratio (1). This offers the promise of intense radiation sources and intrinsic photodetectors covering the wavelength region between about 5μ and the far infrared. So far, injection laser action (2) has been observed to 28.1μ and photovoltaic detection (3) has been demonstrated to 30μ in $Pb_{1-x}Sn_xTe$ diodes. Metallic inclusions and cellular substructure are highly undesirable in these semiconductor devices, causing, for example, sinks for nonradiative recombination of electrons and holes, leakage paths across p-n junctions, and nonplanarity in diffused p-n junctions. Such metallic inclusions and cellular substructure have been observed in some single crystals of $Pb_{1-x}Sn_xTe$. This paper describes the method used to identify these macroscopic defects and presents growth conditions that can be used to avoid them. It is shown that the occurrence of metallic inclusions and cellular substructure in various $Pb_{1-x}Sn_xTe$ crystals grown from different liquidus compositions is consistent with a model of constitutional supercooling at the growth interface between liquid and solid.

Experimental Procedure and Results

Single crystals of $Pb_{1-x}Sn_xTe$ were grown by the Bridgman technique and by closed tube vapor transport. These methods have been described in detail elsewhere (2, 4). For Bridgman growth a mixture of the elements is sealed in a carbonized evacuated fused silica ampoule and reacted at a temperature 50°C above the liquidus. The ampoule is then lowered out of the high temperature region of the vertical furnace at a rate of 1 cm/day. The temperature gradient in the furnace is approximately 10°C/cm. Bridgman-grown single crystals are commonly 15 cm long and 2.5 cm in diameter. Vapor growth is carried out in a special fused silica ampoule using a vapor source consisting of a two-phased alloy of composition $(metal)_{0.51}(Te)_{0.49}$. The evacuated, sealed ampoule is placed in the furnace at approximately 825°C in a small temperature gradient of about 0.25°C/cm. Nearly stoichiometric crystals with linear dimensions up to several millimeters are formed on the walls. Before opening the growth ampoules the vapor grown crystals are usually annealed for lengthy periods at temperatures between 400° and 600°C.

The presence of metallic inclusions and cellular substructure is revealed by microscopic examination of samples electrolytically etched in a solution of 20g KOH, 45 ml H_2O, 35 ml glycerol, and 20 ml ethanol. This is a well-known polishing etch for PbTe (5). The samples are biased anodically and are thoroughly rinsed in distilled water after etching. The stirred solution is used at room temperature. At a current density of 0.5 a/cm^2 the $Pb_{1-x}Sn_xTe$ crystal is polish-etched at a rate of approximately 30 μ/min. Metallic inclusions, if present, acquire an orange film but otherwise remain intact. They remain as protuberances on the deeply etched semiconductor surface. At a current density of approximately 0.05 a/cm^2, the solution is suitable for obtaining dislocation density measurements or, in the present case, showing cellular substructure.

Figure 1 shows the surface of a sample cut from the last-to-freeze end of $Pb_{1-x}Sn_xTe$ crystal A-2 which was grown from a liquid with excess metal and etched at a current density of 0.5 a/cm^2. The weighed out proportions corresponded to the composition $(Pb_{0.70}Sn_{0.30})_{0.5063}Te_{0.4937}$. For the 400g ingot, it was estimated that at the growth temperature about 7 mg of Te was present in the vapor space above the liquid. Thus, the weighed out composition and actual liquidus composition are very nearly identical. The first-to-freeze solidus composition of A-2 was determined to be approximately $(Pb_{0.80}Sn_{0.20})_{<0.50}Te_{>0.50}$ from electron microprobe and Hall coefficient measurements (4). This photomicrograph, which shows an unusually large number

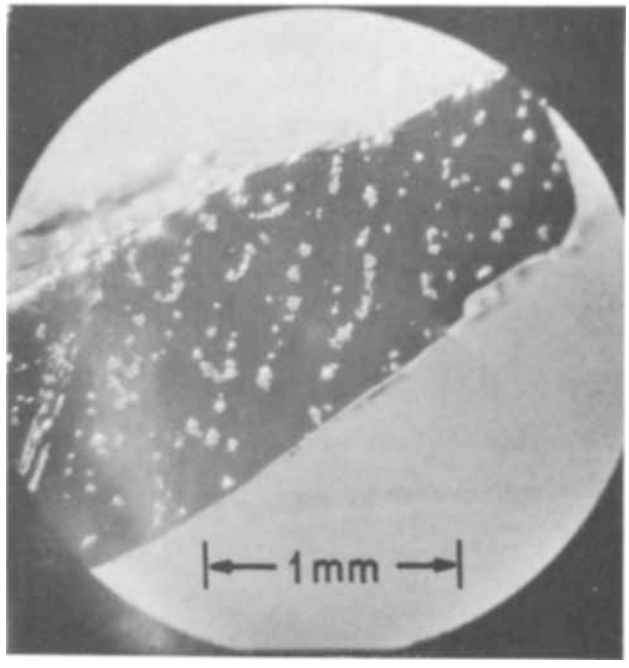

Fig. 1. Etched sample from last-to-freeze end of $Pb_{1-x}Sn_xTe$ crystal A-2 containing a large number of metallic inclusions. Unannealed.

[1] Operated with support from the U.S. Air Force.

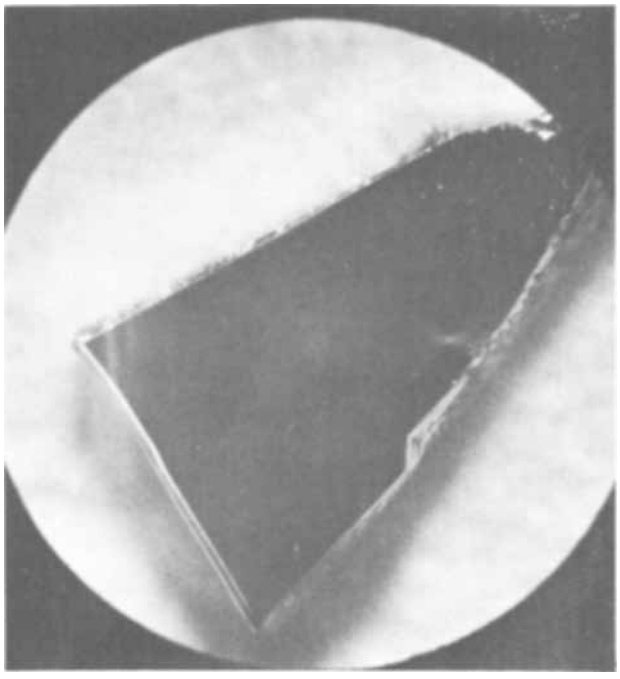

Fig. 2. Etched unannealed sample of $Pb_{1-x}Sn_xTe$ crystal A-4 in which no bulk metallic inclusions are observable; magnification is same as in Fig. 1.

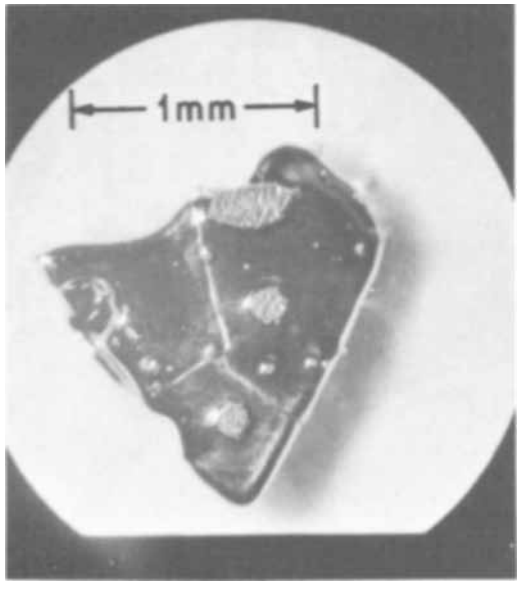

Fig. 3. Etched crystal from last-to-freeze end of $Pb_{1-x}Sn_xTe$ crystal A-2 after 850°C anneal for seven days.

of light spots, presents an extreme example of the presence of bulk metallic inclusions in Bridgman grown crystals. The inclusions observed range in size from a few microns to over 0.1 mm in diameter. The 100% metallic composition (Pb-Sn alloy) of the inclusions was determined by chemical and electron microprobe analyses.[1] Figure 2 shows for comparison purposes a sample of crystal A-4, which was grown from a Te-rich melt of composition $(Pb_{0.70}Sn_{0.30})_{0.49}Te_{0.51}$ and etched in the same manner. No metallic inclusions were observed in this crystal.

A section of the sample cut from the last to freeze end of A-2 is shown in Fig. 3 after isothermally annealing for seven days at 850°C in the presence of a metal-rich powder of composition $(Pb_{0.8}Sn_{0.2})_{0.5125}Te_{0.4875}$. The inclusions have apparently migrated and coalesced, forming larger metal

[1] Electron microprobe analysis was carried out by M. C. Finn.

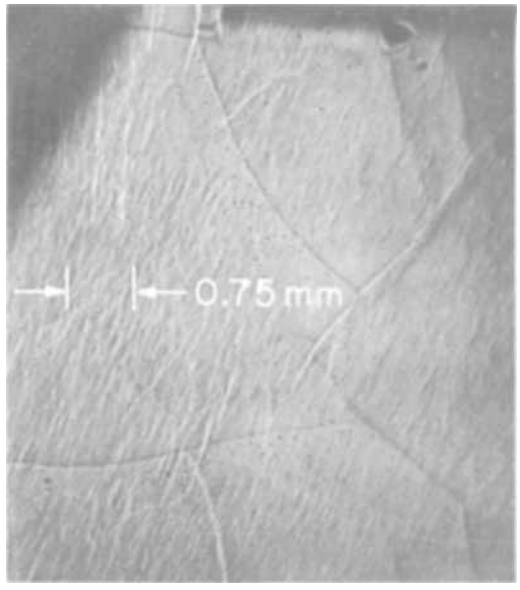

Fig. 4. Slowly etched sample from the first end to freeze of Bridgman grown $Pb_{1-x}Sn_xTe$ crystal A-2 containing cellular substructure. Unannealed.

regions with a smaller number density. A photomicrograph of the surface of a specimen obtained near the first end to freeze of a crystal A-2 is shown in Fig. 4. This sample was etched at the slower rate to show the cellular substructure. At the fast rate, only a few metallic inclusions were observed in a 1 cm^2 area. The pronounced mosaic pattern evident in Fig. 4 was found throughout the crystal and is believed to be due to preferential etching at the cell boundaries.

Table I indicates the presence or absence of metallic inclusions and cellular substructure in several crystals of $Pb_{0.8}Sn_{0.2}Te$. Bulk metallic inclusions, when present, varied in number from essentially zero at the first end to freeze to a maximum at the opposite end of each crystal. The density of bulk inclusions in the as-grown solid decreased as the composition of the melt became richer in Te. Surface metallic inclusions, which had physicochemical characteristics identical to the bulk metallic inclusions, were observed rather uniformly distributed over the exterior surfaces of the crystals. A second $M_{0.49}Te_{0.51}$ crystal was grown which was free of both bulk and surface metallic inclusions. The inner surface of the silica growth ampoule for this crystal had been carbonized by the reduction of acetone, whereas the former crystal was grown in an ampoule carbonized by the reduction of natural gas.

A number of the vapor grown crystals were etched by the technique previously described. No evidence for the presence of either metallic inclusions or cellular substructure was found in the bulk of these

crystals. However, metallic inclusions in the surface layers of crystals vapor grown from metal-rich sources were observed in all crystals. In the case of crystals vapor grown from a Te-rich source, no metal inclusions were evident in the surface layers directly exposed to the vapor. However, even in this latter case, metallic inclusions were seen on surfaces in contact with the inner walls of the quartz growth capsule. This result indicates that surface inclusions may be due at least in part to a chemical reaction of $Pb_{1-x}Sn_xTe$ with the surface of the silica growth tube.

Discussion

We believe the bulk metallic inclusions and cellular substructure are due to constitutional supercooling during growth. The mechanism of constitutional supercooling has been previously used to explain cellular growth and other defects in various crystals (6). In the present case, segregation of excess metal (relative to the composition at the maximum melting temperature) at the liquid-solid interface of the growing crystal is postulated to be the basic cause of the observed macroscopic imperfections. Figures 5 and 6 illustrate the relationships between the phase diagrams of $Pb_{1-x}Sn_xTe$ and the pertinent parameters which are usually employed in standard discussions of constitutional supercooling phenomena (6). Figure 5 shows an idealized equilibrium phase diagram for $Pb_{1-x}Sn_xTe$ near the stoichiometric composition. It is well established that the position of the maximum melting point is on the Te-rich side of the binary phase diagram in both the Pb-Te (7) and Sn-Te (8) systems. Furthermore, the data presented in ref. (4) give strong evidence that the maximum melting point is on the Te-rich side for the pseudobinary alloys, $Pb_{1-x}Sn_xTe$. As evident from data given in ref. (4), for $x = 0.2$ the maximum melting temperature is approximately 890°C, and the intersection of the solidus line with the stoichiometric line occurs at about 525°C. Figure 6a shows schematically the variation of the metal-Te ratio across the interface between the melt and solid of a growing crystal. The buildup of the metal-Te ratio in the liquid at the interface depends on the growth rate and would be absent for an infinitesimally slow rate. Pertinent compositions are shown at the liquidus and solidus temperatures in Fig. 5. It is evident that the equilibrium freezing temperature in the liquid will vary with position as a result of varying the metal-Te ratio. The variation of freezing temperature is shown schematically in Fig. 6b. Also shown are two possible actual temperature gradients. For the less steep line there is a region of instability where the liquid is locally supercooled. Rapid quenching will occur in this region causing spurious nucleation and leading to cellular substructure. In addition, the rapidly quenched solid material should

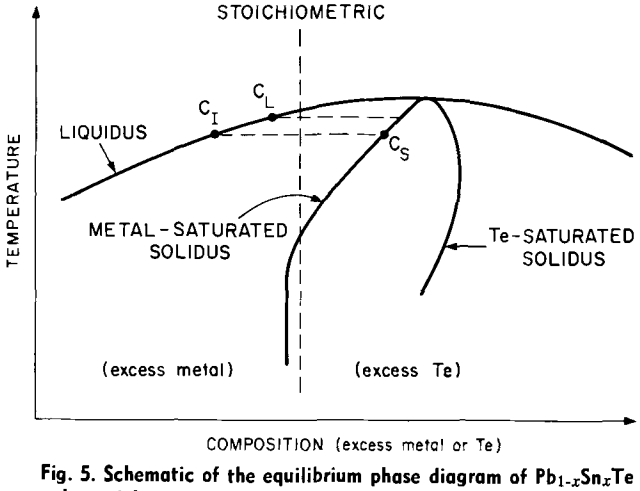

Fig. 5. Schematic of the equilibrium phase diagram of $Pb_{1-x}Sn_xTe$ near the stoichiometric composition.

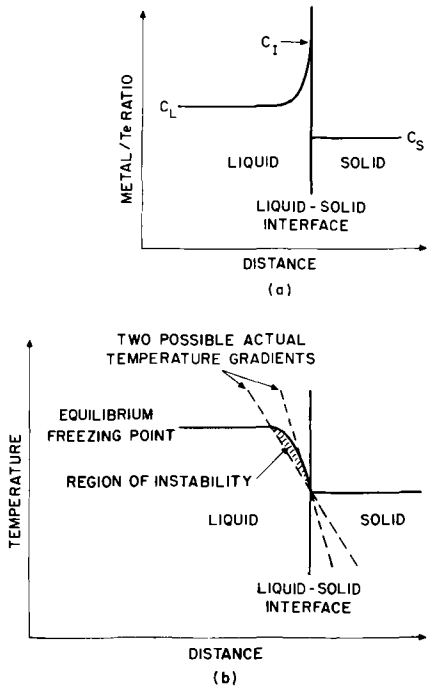

Fig. 6(a) Schematic of Metal-Te ratio near the freezing interface of a growing crystal of $Pb_{1-x}Sn_xTe$. C_L, C_I, and C_S are the Metal-Te ratios in the liquid at the interface and in the solid, respectively. (b) Schematic of equilibrium freezing temperature variation near freezing interface along with two possible gradients of the actual temperature and a region of instability.

contain metal-rich liquid as a second phase at the higher temperatures and two solid phases at lower temperatures, *i.e.*, $Pb_{1-x}Sn_xTe$ and metal.

This qualitative explanation for the occurrence of macroscopic defects suggests some practical methods of avoiding them. As may be seen from Fig. 5, C_I, C_L, and C_S will be identical at the maximum melting point composition; hence, growth from a liquid of this composition should eliminate constitutional supercooling. Crystal growth from a melt composition richer in Te than the maximum melting point composition should also yield crystals free of metallic inclusions. We believe the $M_{0.49}Te_{0.51}$ crystals mentioned previously were grown from a melt near or on the excess Te side of the maximum melting point composition. These crystals were free of bulk metallic inclusions and cellular substructure. According to Fig. 6b, constitutional supercooling can also be prevented by imposing a steep enough temperature gradient or by reducing the slope of the freezing temperature curve by decreasing the growth rate.

The Solution of Aluminum Phosphide in Aluminum

Sylvan Z. Beer*[1]

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

The solubility of aluminum phosphide in molten aluminum was measured over the temperature range of 900°-1200°C. This was done by equilibrating molten aluminum with solid aluminum phosphide, pouring off and quenching the aluminum, and analyzing the quenched metal. The heat of solution is calculated to be 18.1 kcal. From the measured solubility, approximate dissociation pressures at different temperatures were calculated.

The physical properties of AlP are the least known of the family of III-V intermetallic compounds possessing the zinc blende structure. This is largely due to the difficulties encountered in preparing and handling single crystals. Of the various applicable methods for growing single crystals of AlP, growth from solution in aluminum stands out because it presents the possibility of accurate control of impurity levels. To grow single crystals from molten aluminum under optimum conditions, requires a detailed knowledge of the solubility of AlP in aluminum as a function of temperature. Such data could also provide a means for roughly estimating some thermodynamic properties of AlP, which are at present almost totally lacking. For these reasons the solubility of AlP in molten aluminum was measured and is presented in this publication.

Experimental

The solubility was measured by holding the molten aluminum in contact with aluminum phosphide in an equilibration crucible until equilibration and then inverting the furnace to cause the molten aluminum to fall into a cold catch crucible, thus quenching-in any dissolved phosphorus.

The aluminum phosphide was prepared by the method described previously (1). Briefly, aluminum (Alcoa, 99.999%) was etched in a 96% phosphoric acid-4% nitric acid mixture and air dried. It was then placed in an alumina boat (Morganite) in one end of a closed-end mullite tube which had a borosilicate glass extension at the open end. Red phosphorus (United Mineral, 99.999%) was placed about midway along the length of the mullite tube. The tube was pumped at less than 10^{-6} Torr for 24 hr and sealed off. It was then placed in a horizontal two-zone furnace with the hot end kept at 1450°C while the glass end, to which the phosphorus distills, was kept at about 450°C. The tube was withdrawn from the furnace at a rate of about 6 mm/day keeping the phosphorus end at constant temperature. The larger crystals of AlP which grew this way were extracted (2) and used for these experiments.

For the solubility measurements, the aluminum phosphide was placed in a high purity alumina crucible (Morganite), previously baked out at 900°C for at least 24 hr. In this was also placed a 2g piece of aluminum (Alcoa, 99.999%) which had been etched with a mixture of 96% phosphoric acid-4% nitric acid and air dried. The crucible was then placed vertically in a quartz vessel with the catch-crucible (a long closed-end alumina tube) placed in inverted position against the equilibration crucible. The two were held tightly together by means of a spring compressed in the cold end of the quartz tube. The lower end of the tube was inserted into the furnace. The upper end of the catch crucible was kept at room temperature by means of muffin fans. The quartz tube was sealed at the top with a wax-sealed ground joint. It was then evacuated and heated slowly to the equilibrating temperature. The temperature was held constant to ±1°C for 20-24 hr to attain equilibration. After equilibration, the vessel was inverted and molten aluminum was dropped into the catch crucible and quenched. On solidification, the aluminum was removed, etched with the phosphoric-nitric mixture and analyzed for phosphorus by the colorimetric phosphovanadomolybdate method (3).

Analytic procedure.—About one gram of the metal was dissolved in a dilute aqua regia solution. Because the method was found to be sensitive to acidity, the solution was then heated almost to dryness, rediluted, and transferred to a 100 ml volumetric flask. To this was added 5.0 ml of 70% perchloric acid, 10 ml of 0.75M sodium sulfate solution, and 10.00 ml of a vanadium stock solution prepared in the following manner. To a mixture of 400 ml of water and 25 ml of 8*N* perchloric acid, 1.17g of ammonium metavanadate was added. The mixture was then diluted to 500 ml with water.

The unknown mixture in the 100 ml flask was stirred and to it was added 20.00 ml of a molybdenum stock solution. The latter was prepared by dissolving 35g of ammonium molybdate tetrahydrate in one liter of water. The unknown mixture was then diluted to the 100 ml mark. The absorbance was determined one hour later with a Cary spectrophotometer at 390μ against a similar solution containing no phosphorus. This was converted to concentration through the use of a calibration curve prepared as above using potassium dehydrogen phosphate as the phosphorus source. The over-all precision of the method was found to be within 3%. It was found to be insensitive to aluminum in the range encountered here.

Discussion of Results

The results of the measurements are shown in Fig. 1. It can be seen that the solubility as a function of the inverse absolute temperature falls on a straight line. The line was extrapolated to low temperatures for reasons to be discussed later. The slope of the line is equivalent to a ΔH solution of 18.1 kcal.

It is most convenient to analyze these results according to the method of Wagner (4), as further developed by Schottky and Bever (5), Hall (6), Vieland

The Solution of Aluminum Phosphide in Aluminum

Sylvan Z. Beer*[1]

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania

ABSTRACT

The solubility of aluminum phosphide in molten aluminum was measured over the temperature range of 900°-1200°C. This was done by equilibrating molten aluminum with solid aluminum phosphide, pouring off and quenching the aluminum, and analyzing the quenched metal. The heat of solution is calculated to be 18.1 kcal. From the measured solubility, approximate dissociation pressures at different temperatures were calculated.

The physical properties of AlP are the least known of the family of III-V intermetallic compounds possessing the zinc blende structure. This is largely due to the difficulties encountered in preparing and handling single crystals. Of the various applicable methods for growing single crystals of AlP, growth from solution in aluminum stands out because it presents the possibility of accurate control of impurity levels. To grow single crystals from molten aluminum under optimum conditions, requires a detailed knowledge of the solubility of AlP in aluminum as a function of temperature. Such data could also provide a means for roughly estimating some thermodynamic properties of AlP, which are at present almost totally lacking. For these reasons the solubility of AlP in molten aluminum was measured and is presented in this publication.

Experimental

The solubility was measured by holding the molten aluminum in contact with aluminum phosphide in an equilibration crucible until equilibration and then inverting the furnace to cause the molten aluminum to fall into a cold catch crucible, thus quenching-in any dissolved phosphorus.

The aluminum phosphide was prepared by the method described previously (1). Briefly, aluminum (Alcoa, 99.999%) was etched in a 96% phosphoric acid-4% nitric acid mixture and air dried. It was then placed in an alumina boat (Morganite) in one end of a closed-end mullite tube which had a borosilicate glass extension at the open end. Red phosphorus (United Mineral, 99.999%) was placed about midway along the length of the mullite tube. The tube was pumped at less than 10^{-6} Torr for 24 hr and sealed off. It was then placed in a horizontal two-zone furnace with the hot end kept at 1450°C while the glass end, to which the phosphorus distills, was kept at about 450°C. The tube was withdrawn from the furnace at a rate of about 6 mm/day keeping the phosphorus end at constant temperature. The larger crystals of AlP which grew this way were extracted (2) and used for these experiments.

For the solubility measurements, the aluminum phosphide was placed in a high purity alumina crucible (Morganite), previously baked out at 900°C for at least 24 hr. In this was also placed a 2g piece of aluminum (Alcoa, 99.999%) which had been etched with a mixture of 96% phosphoric acid-4% nitric acid and air dried. The crucible was then placed vertically in a quartz vessel with the catch-crucible (a long closed-end alumina tube) placed in inverted position against the equilibration crucible. The two were held tightly together by means of a spring compressed in the cold end of the quartz tube. The lower end of the tube was inserted into the furnace. The upper end of the catch crucible was kept at room temperature by means of muffin fans. The quartz tube was sealed at the top with a wax-sealed ground joint. It was then evacuated and heated slowly to the equilibrating temperature. The temperature was held constant to ±1°C for 20-24 hr to attain equilibration. After equilibration, the vessel was inverted and molten aluminum was dropped into the catch crucible and quenched. On solidification, the aluminum was removed, etched with the phosphoric-nitric mixture and analyzed for phosphorus by the colorimetric phosphovanadomolybdate method (3).

Analytic procedure.—About one gram of the metal was dissolved in a dilute aqua regia solution. Because the method was found to be sensitive to acidity, the solution was then heated almost to dryness, rediluted, and transferred to a 100 ml volumetric flask. To this was added 5.0 ml of 70% perchloric acid, 10 ml of 0.75M sodium sulfate solution, and 10.00 ml of a vanadium stock solution prepared in the following manner. To a mixture of 400 ml of water and 25 ml of 8*N* perchloric acid, 1.17g of ammonium metavanadate was added. The mixture was then diluted to 500 ml with water.

The unknown mixture in the 100 ml flask was stirred and to it was added 20.00 ml of a molybdenum stock solution. The latter was prepared by dissolving 35g of ammonium molybdate tetrahydrate in one liter of water. The unknown mixture was then diluted to the 100 ml mark. The absorbance was determined one hour later with a Cary spectrophotometer at 390μ against a similar solution containing no phosphorus. This was converted to concentration through the use of a calibration curve prepared as above using potassium dehydrogen phosphate as the phosphorus source. The over-all precision of the method was found to be within 3%. It was found to be insensitive to aluminum in the range encountered here.

Discussion of Results

The results of the measurements are shown in Fig. 1. It can be seen that the solubility as a function of the inverse absolute temperature falls on a straight line. The line was extrapolated to low temperatures for reasons to be discussed later. The slope of the line is equivalent to a ΔH solution of 18.1 kcal.

It is most convenient to analyze these results according to the method of Wagner (4), as further developed by Schottky and Bever (5), Hall (6), Vieland

(7), and others. Based on the quasi chemical approach and on the assumption that the solution is regular and that the excess free energy is given by $F^E = -wX(1-X)$, where w is the interaction parameter and X is the mole fraction of the solute, an equation determining the solubility was derived. It is given in the form

$$-\ln[4X(1-X)] = \frac{\Delta S^f}{R}\left[\frac{T_m}{T} - 1\right] - \frac{w}{4RT}(1-2X)^2 \quad [1]$$

where ΔS^f is the entropy of fusion and T_m is the melting point of the compound. The value of w is the only quantity which cannot be readily estimated. It has been shown for other III-V compounds to be a function of temperature (8). The evaluation of w as a function of temperature can be accomplished using Eq. [1] over the range of measured solubility. To do this requires the evaluation of both T_m and ΔS^f.

In order to obtain an estimated melting temperature, the melting temperatures of the other III-V's were plotted as a function of the atomic number. In Fig. 2 this was done utilizing the gram atomic number in accordance with the method of Lichter (9). The gram atomic number is simply the average atomic number of each III-V compound. Plotting the relationship in

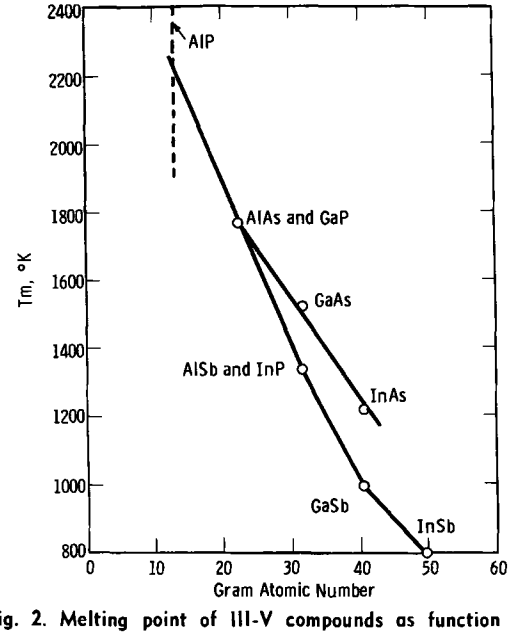

Fig. 2. Melting point of III-V compounds as function of gram atomic number.

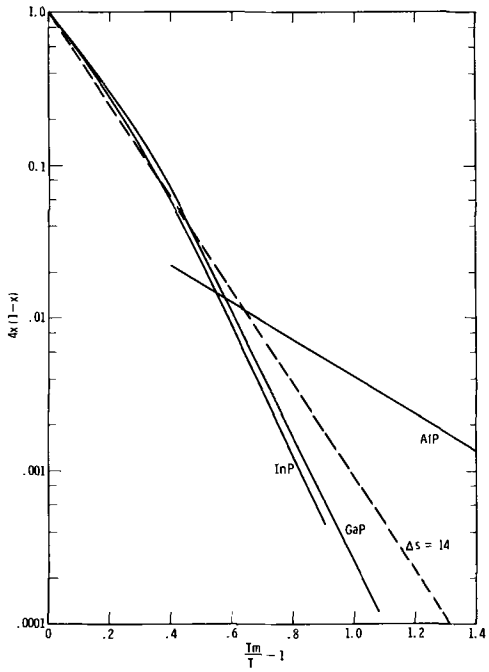

Fig. 3. Plot of ln $4X(1-X)$ as a function of $T_m/T-1$ for III-V phosphides. The $\Delta S = 14$ line is the average of many compounds plotted by Hall (6).

this way has the particular advantage in that all the compounds can be placed on the same graph conveniently, From this plot it can be seen that fairly reasonable straight lines can be drawn for the arsenides, the gallium compounds, and to some extent the antimonides. On this basis the AlP melting point can be estimated to be 2200°K.

The value of ΔS^f can be calculated directly from a plot of $\ln[4X(1-X)]$ against $T_m/T-1$. At low temperature, where the solubility is also low, a straight line relationship can be expected as a first order approximation. This plot is shown in Fig. 3. The relationship is seen to be fairly linear with a slope determined to be 5.9 eu. This is rather small compared with the other III-V phosphides and the other III-V compounds which average around 14 eu. Estimating the entropy of melting according to the method used by Thermond (8) for GaP and GaAs yields a value of about 16 eu. The experimental value is however close to that of the elements Ge and Si. The small value found experimentally may perhaps be attributed to the highly ionic nature of aluminum phosphide and its low solubility and low degree of dissociation in the metallic aluminum.

Utilizing the calculated values of ΔS^f and T_m in Eq. [1], the temperature dependence of w can be approximately determined. The relationship plotted in Fig. 4 is given by

$$w = 2.131 - 1.167T \quad [2]$$

As in the case of other III-V compounds (8), the value of w is found to follow closely a linear function of temperature.

Basic to the regular solution-quasi chemical approach the partial free energy of the V-species of compound is given as

$$\bar{F}^E = RT \ln \gamma_V = w(1-X)^2 \quad [3]$$

Rewriting this in terms of pressure, the vapor pressure of phosphorus in equilibrium with aluminum phosphide can be calculated from the relationship

$$p^{1/2}{}_v = p^{1/2}{}_{ov}\, X\, e^{(1-X)^2 w/RT} \quad [4]$$

where p_v is the equilibrium pressure of the P_2 species of phosphorus and p_{ov} is the pressure of pure phosphorus at temperature T. The equation cannot be used

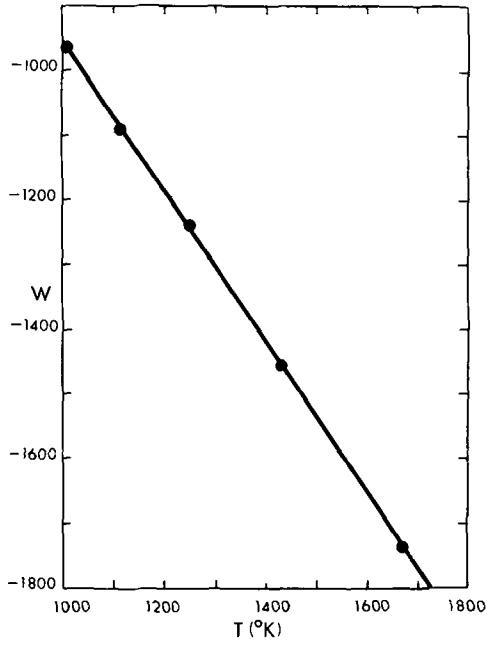

Fig. 4. Interaction parameter w as a function of absolute temperature.

directly because as can be seen from Fig. 1, the measurements are well above the critical temperature of phosphorus, 695°C (10). However, by utilizing the solubility data of GaP in Ga and by rewriting the equation in the form

$$\frac{p^{1/2}_{AlP}}{p^{1/2}_{GaP}} = \frac{X_{AlP}}{X_{GaP}} \frac{e^{(1-X)^2 w/RT}}{e^{(1-X)^2 w/RT}} \qquad [5]$$

the useful temperature range of the equation can be extended. Solution of this equation requires both the solubilities of the GaP in Ga and the solubility of AlP in Al over the same temperature range as well as the value of w for each compound over the same range. An equation for w for GaP has been given by Thurmond (8). Thus, the pressure ratios in Eq. [5] over the range of 800° to 1200°C is found to be 1.9 x 10^{-6} to 8 x 10^{-7}. From the known pressure-temperature relationship of GaP (11), the pressure of phosphorus in equilibrium with aluminum phosphide is found to lie in the range of 5 x 10^{-10} to 3 x 10^{-6} Torr over the same temperature range.

Because of the exponential dependence of the calculated pressure on the solubility of phosphides in the molten metals, the errors in the calculated pressures can be rather considerable. The values so obtained must, therefore, be regarded as first approximations.

The Determination of Phase Boundaries and Thermodynamic Functions in the Iron-Oxygen System by EMF Measurements

H. F. Rizzo,[1] R. S. Gordon, and I. B. Cutler

Division of Materials Science and Engineering, University of Utah, Salt Lake City, Utah

ABSTRACT

Coulometric titration in a high-temperature cell employing a stabilized zirconia electrolyte was used successfully in the determination of phase boundaries and related thermodynamic data in the iron-oxygen system. The standard free energy of formation of oxygen-deficient wüstite was determined between 540° and 1200°C. Values agree to within 500 cal of the most critically reviewed data. The free energy of reaction for the formation of magnetite from wüstite and oxygen was determined between 900° and 1200°C. The composition of the iron-rich boundary of wüstite was found to decrease very slightly in oxygen content with increasing temperature. For all practical purposes, however, the composition of the boundary can be considered constant at $FeO_{1.05}$. The compositions of oxygen-rich wüstite agreed fairly well with existing data. Evidence was presented, however, for the existence of additional phases in the region of the Fe-O diagram between the presently reported oxygen-rich wüstite and magnetite. The temperature for the Fe, Fe_xO, Fe_3O_4 three-phase equilibrium was found experimentally to be 610° ± 10°C. Extrapolation of low temperature ($T < 900$°C) Fe_zO-Fe_3O_4 equilibrium data resulted in lower transformation temperatures.

The use of emf measurements on galvanic cells, utilizing solid electrolytes such as stabilized zirconia, yttria, and thoria has led to the production of valuable thermodynamic data in numerous oxide systems. The standard molal free energies of formation of oxides such as FeO (1, 2), Fe_3O_4 (1), CoO (1, 2), Cu_2O (3), NiO (1, 2), and MoO_2 (4) have been determined at elevated temperatures in numerous studies.

The high-temperature galvanic cell is especially suited for studying the thermodynamic properties of defect oxide phases. By employing the technique of coulometric titration, which involves varying the composition of the oxide phase electrochemically, it is possible, in principle, to measure the activity of oxygen as a continuous function of composition over the entire phase field of a nonstoichiometric phase (5-9). Thus information such as thermodynamic activities, phase boundaries, and the existence of defect phases is readily obtained by this method.

It is the purpose of this paper to explore the feasibility of employing a solid electrolyte galvanic cell in conjunction with the technique of coulometric titration in the determination of phase boundaries in an oxide system. The iron-oxygen system was selected since there is considerable information on the phase boundaries in the literature, principally that of Darken and Gurry (10).

Experimental

Two kinds of experimental cells were employed: (*i*) closed-end tube cell, and (*ii*) three electrode cell. The electrolyte in the former cell is a closed-end, 10 in. long, 13/16 in. diameter calica-stabilized zirconia tube (0.85 ZrO_2 + 0.15 CaO). The basic arrangement of this cell is shown schematically in Fig. 1. The open end of the zirconia tube, which was exposed to air, was the oxygen reference potential used as the cathode. The outside of this tube was exposed to a purified argon (10-25 cm³/min) or helium atmosphere.[2] The FeO sample electrode was held in place by an alumina disk supported by a molybdenum wire. A 1-mil thick platinum electrode separated the FeO sample from the alumina. A Pt, Pt-13Rh 10-mil thermocouple was attached to the bottom of this platinum electrode. The platinum wire was also used to measure the cell voltage and as the lead wire for the titrating current. A ½-in. platinum electrode was placed around the outside of the zirconia cell within ¼ in. from the bottom of the cell. This electrode was used to monitor the oxygen pressure within the inert cell atmosphere using the air electrode (cathode) as the oxygen reference potential. The platinum electrode used in the cathode (the open end exposed to air) also had a 10 mil Pt, Pt-13Rh thermocouple attached and was used in the same manner as described for the anode. A spring-loaded mullite tube ensured good contact between the platinum electrode and the air cathode.

Three compositions were studied in the closed-end tube cell

$$\text{Pt, Fe-Fe}_x\text{O} \;\Big|\; \begin{matrix}0.85\ ZrO_2\\ +\\ 0.15\ CaO\end{matrix} \;\Big|\; \text{air } (P_{O_2} = 0.18 \text{ atm}), \text{Pt} \qquad \text{(I)}$$

$$\text{Pt,Fe}_2\text{O}^3\text{-Fe}_3\text{O}_4 \;\Big|\; \begin{matrix}0.85\ ZrO_2\\ +\\ 0.15\ CaO\end{matrix} \;\Big|\; \text{air } (P_{O_2} = 0.18 \text{ atm}), \text{Pt} \qquad \text{(II)}$$

$$\text{Pt,FeO}_y{}^4 \;\Big|\; \begin{matrix}0.85\ ZrO_2\\ +\\ 0.15\ CaO\end{matrix} \;\Big|\; \text{air } (P_{O_2} = 0.18 \text{ atm}), \text{Pt} \qquad \text{(III)}$$

$$\frac{1}{x} < y < \frac{1}{z}$$

The cell potentials are given by Eq. [1] and [2] in which $\bar{F}'_{O_2}$ and $\bar{F}''_{O_2}$

$$E = [(\bar{F}''_{O_2} - F^\circ_{O_2}) - (\bar{F}'_{O_2} - F^\circ_{O_2})]/4\mathbf{F} \qquad [1]$$

$$= \frac{RT}{4\mathbf{F}} \ln \frac{P''_{O_2}}{P'_{O_2}} \qquad [2]$$

are the partial molal free energies of oxygen at the anode and cathode, respectively, $F^\circ_{O_2}$ is the standard molal free energy of (ideal gas at one atmosphere pressure) oxygen, P'_{O_2} and P''_{O_2} are the partial pres-

[1] Present address: Air Force Weapons Laboratory, Kirtland Air Force Base, New Mexico.

[2] The gas was purified by passing it in succession over anhydrous magnesium perchlorate, ascarite, heated copper or titanium-zirconium turnings, and ascarite.

[3] Evidence will be presented that indicates the presence of more than one wüstite-type defect phase between $FeO_{1.05}$ and $FeO_{1.33}$. Therefore, reference to the Fe_zO-Fe_2O_4 two-phase region corresponds to the most oxygen-rich wüstite-type phase in equilibrium with Fe_3O_4 or an over-all composition slightly less oxygen-rich than $FeO_{1.33}$ (*i.e.* Fe_3O_4).

[4] FeO_y is used to denote the composition within the single phase region because the O/Fe ratio ($=y$) is used to describe the composition.

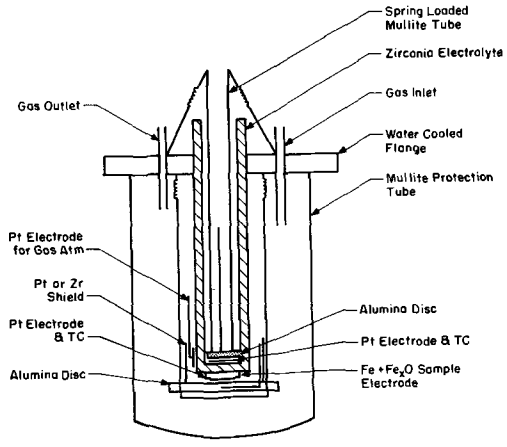

Fig. 1. Schematic of galvanic cell with zirconia electrolyte closed-end tube.

sures in atmospheres of diatomic oxygen at the anode and cathode, respectively, and **F** is the Faraday constant.

In these experiments the oxygen pressure at the cathode (P''_{O_2}) was always a constant (P_{O_2} [air] ≈ 0.18 atm), the partial pressure of oxygen in the atmosphere at Salt Lake City, Utah. Thus, from a measured emf, the oxygen pressure (P'_{O_2}) was calculated for the two phase mixtures, Fe-Fe$_x$O (I) and Fe$_z$O-Fe$_3$O$_4$ (II). In addition, the oxygen pressure was obtained for any arbitrary composition (y) in the wüstite phase (FeO$_y$) by coulometric titration in cell III. Isothermal titration experiments were conducted at temperatures between 800° and 1200°C in both directions across the wüstite phase. In addition to the titration experiments, heating and cooling experiments were performed with cells I and II. From these experiments, the oxygen activity was determined as a function of temperature (500°-1200°C) in the two-phase equilibrium mixtures Fe-Fe$_x$O and Fe$_z$O-Fe$_3$O$_4$.

The three-electrode cell consists of three electrodes in a cylindrical zirconia electrolyte (1 in. diameter, 0.75 in. high) as can be seen in Fig. 2. In the coulometric titration studies, one of the bottom Fe-Fe$_x$O electrodes was used to titrate oxygen in or out of the top electrode, while the other bottom electrode was used to record the open-circuit emf.

A mullite tube was fitted inside the top wüstite electrode so that incoming gas would flow from the cathode to the anode and thus lower the possible reduction of wüstite *via* the gas phase from the anode which is at a lower oxygen partial pressure. The entire asembly was spring loaded to insure good electrical contacts. The top sample electrode and one Fe-Fe$_x$O reference electrode were instrumented with Pt, Pt-13Rh thermocouples.

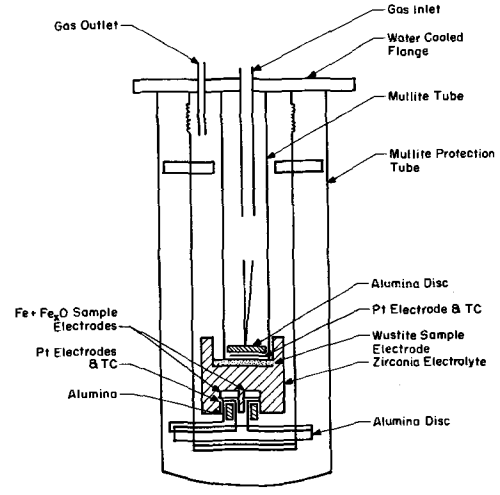

Fig. 2. Schematic of galvanic cell with three-sample electrode cylindrical shaped zirconia electrolyte.

Two compositions were studied with the three-electrode cell.

$$\text{Pt, Fe-Fe}_x\text{O} \left| \begin{matrix} 0.85\text{ZrO}_2 \\ + \\ 0.15\text{CaO} \end{matrix} \right| \text{Fe}_z\text{O-Fe}_3\text{O}_4\text{, Pt} \qquad \text{(IV)}$$

$$\text{Pt, Fe-Fe}_x\text{O} \left| \begin{matrix} 0.85\text{ZrO}_2 \\ + \\ 0.15\text{CaO} \end{matrix} \right| \begin{matrix} \text{FeO}_y\text{, Pt} \\ (y \text{ variable}) \end{matrix} \qquad \text{(V)}$$

Isothermal titration experiments were conducted in both directions with cell V across the entire wüstite phase. Heating and cooling studies were conducted on cell IV. From the emf measured as function of temperature, the activity of oxygen (P_{O_2}) in the Fe$_z$O-Fe$_3$O$_4$ system was evaluated between 700° and 1200°C. In order to calculate the pressure of oxygen at the cathode (Fe$_z$O-Fe$_3$O$_4$), the pressure at the anode must be known. The oxygen potentials for the Fe-Fe$_x$O equilibrium are reasonably well known (10, 11-16). These potentials were also measured with the closed-end tube cell (I) described previously. Since this paper will concern itself primarily with the determination of the phase boundaries in the Fe-O system, the description of the experimental details connected with coulometric titration within single phase wüstite, FeO$_y$, are given elsewhere (5, 17).

The electrolytes used in this study, with the exception of one of the closed-end tubes which was made by Zircoa Corporation, were fabricated in this laboratory. The zirconia was —325 mesh Wah Chang "S" Reactor Grade which is 99.9% pure and hafnia free. Reagent grade CaCO$_3$ (Baker's 1288) was the principal source of CaO. The complete description of the fabrication of the electrolyte can be found elsewhere (17). Each electrolyte was subjected to a vacuum test (1-2 x 10^{-3} mm Hg) to insure that it was impervious. It is noted here that the real test for an impervious electrolyte was the absence of any sample oxidation (emf drift with time) during an experiment.

The closed-end tube electrode samples used in this study varied from pure iron (less than 25 ppm impurities) to samples containing 85.5% iron and 14.5% oxygen by weight. The pure iron sample electrode was prepared at Battelle Memorial Institute by zone melting in a hydrogen atmosphere. Compositions containing 85.5 and 82 w/o (weight per cent) iron were prepared by dry mixing reagent grade Fe$_2$O$_3$ (99.0% minimum) with iron powder (GAF HP carbonyl 99.6-99.9%). Samples were dry pressed in ½ in. steel dies and heated in a tungsten vacuum furnace between 950°-1000°C for 19 hr at a pressure of 2 x 10^{-5} mm Hg. A sample containing 77 w/o iron was prepared by oxidation of iron wire (99.96%) in a H$_2$O/H$_2$ atmosphere at 900°C. This powdered sample was used in the three-electrode cell for the variable wüstite electrode. The other Fe-Fe$_x$O reference electrodes were powdered samples containing 85% iron. The sample weights and thicknesses varied between 0.0922 and 0.3385g and 0.023 and 0.10 cm, respectively.

Platinum electrodes were perhaps not the best choice to use with wüstite because of the solubility of iron in platinum. The predominant effect would be loss of iron in the wüstite electrode. Darken and Gurry (10) determined that there was zero solubility of platinum in any wüstite or magnetite composition. The solubility of iron in platinum at 1300°C is about 13%, based on the measurements of Taylor and Muan (18) for a partial pressure of oxygen corresponding to the Fe$_z$O-Fe$_3$O$_4$ equilibria. Therefore, in the lower temperature range (1057°-1200°C) of this study, it is very doubtful that the solubility of iron in a 1-mil thick platinum electrode will affect the results.

Results

In this paper only results connected with the phase boundaries are reported. The presentation and analysis of the titration data in single phase wüstite can be found elsewhere (5, 17).

Fe-Fe_xO *equilibria.*—The reaction for cell (I) is

$$x\,Fe + \tfrac{1}{2}\,O_2\,(0.18\,atm) = Fe_xO;\ \Delta F_3 \qquad [3]$$

When reaction [4] is added to reaction [3]

$$\tfrac{1}{2}\,O_2\,(1\,atm) = \tfrac{1}{2}\,O_2\,(0.18\,atm);\ \Delta F_4 \qquad [4]$$

the desired reaction [5], *i.e.*, the formation of Fe_xO from the elements in their standard states, is obtained.

$$x\,Fe + \tfrac{1}{2}\,O_2\,(1\,atm) = Fe_xO;\ \Delta F_5 \qquad [5]$$

Using Eq. [5a] the standard free energy of formation of Fe_xO (ΔF_5) was

$$\Delta F_5 = \Delta F_3 + \Delta F_4 = -n\mathbf{F}E_I + RT \ln (0.18)^{1/2} \qquad [5a]$$

evaluated from temperature profiles of cell I for the two-phase mixture (Fe, Fe_xO) between 540° and 1200°C. A linear least squares analysis of 156 data points obtained from six separate experiments resulted in Eq. [6].

$$E_I\ (mv) = 1354.0\ (\pm 1.0) - 0.36488\ (\pm 0.00109)\ T\ (°K) \qquad [6]$$

The actual data are tabulated elsewhere (17). In Fig. 3 a portion of these data is presented in addition to those for the Fe_zO-Fe_3O_4 region (cell II). The results substantiated that the fit was linear between 540° and 1200°C. Substitution of Eq. [6] into [5a] gave Eq. [7] for the standard free energy of formation of Fe_xO in calories

$$\Delta F_5 = -62{,}452 \pm 46 + 15.127\ (\pm 0.05)\ T\ (°K) \qquad [7]$$

The partial pressure of oxygen in equilibrium with the phases Fe and Fe_xO as a function of temperature is given by Eq. [8]. The standard enthalpy and entropy for reaction [5] were evaluated from the temperature dependence,

$$\log P_{O2} = \frac{-27{,}295 \pm 20}{T} + 6.6115 \pm 0.0218 \qquad [8]$$

of ΔF_5 and are $-62{,}452 \pm 46$ cal/mole and -15.127 ± 0.05 cal/mole deg, respectively.

These results agree well with the data of other workers (10, 12-16, 19) and should be more accurate since the use of air as a reference electrode eliminates one of the principal sources of error, namely, the thermodynamic properties of gaseous phases or other two-phase coexistence mixtures which are used to establish the partial pressure of oxygen at the reference electrode. The results of this study for the standard free energy of formation of iron-rich wüstite are compared with previous data in Table I. Any errors due to thermal emf's caused by possible temperature gradients across the electrolyte would be minimized, since the primary temperature-measuring thermocouple was attached to the Pt electrode in contact with the Fe-Fe_xO sample electrode. The use of air as an electrode does result in a higher cell potential across the electrolyte which could result in greater electronic conduction. However, there was no evidence of this behavior since the data were reproduced from heating and cooling profiles and also from a number of experiments in which different zirconia tubes were employed. The reported transference number data on the zirconia-base electrolytes (20, 21) indicate that there are practically no measurable electronic or other charge-carrying species other than oxygen ions in the oxygen partial pressure range covered in this study.

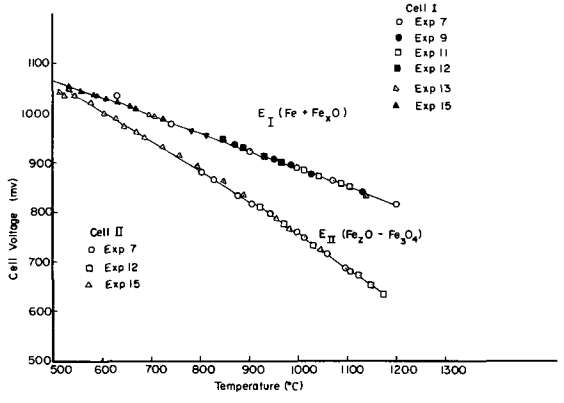

Fig. 3. Cell potentials for Fe-Fe_xO, Fe_zO-Fe_3O_4 equilibria closed-end tube.

Table I. Comparison of the standard free energy of formation of $Fe_{0.95}O$ obtained from this and previous studies

Investigators	Temperature $-\Delta F_f$ ($Fe_{0.95}O$) in calories 1000°K	1500°K
This study	47,325	39,752
Chipman (13)	47,600	39,800
Kleman (12), Vallet and Raccah (16)	47,230	39,743
Humphrey, King, and Kelley (14)	47,850	40,000
Wicks and Block (15)	47,350	39,050
Ackerman and Sandford (19)	47,761	39,850

Fe_zO-Fe_3O_4 *equilibria.*—The reaction for cell (II) is

$$\frac{3}{4z-3}\,Fe_zO + \tfrac{1}{2}\,O_2\,(0.18\,atm) = \frac{z}{4z-3}\,Fe_3O_4;\ \Delta F_9 \qquad [9]$$

Combining Eq. [4] and [9] results in Eq. [10].

$$\frac{3}{4z-3}\,Fe_zO + \tfrac{1}{2}\,O_2\,(1\,atm) = \frac{z}{4z-3}\,Fe_3O_4;\ \Delta F_{10}$$

$$\Delta F_{10} = -n\mathbf{F}E_{II} + RT \ln (0.18)^{1/2} \qquad [10]$$

The reaction for cell (IV) is:

$$x\,Fe + \frac{z}{4z-3}\,Fe_3O_4 = Fe_xO + \frac{3}{4z-3}\,Fe_zO;\ \Delta F_{11} \qquad [11]$$

Using established data for the Fe-Fe_xO equilibria (ΔF_5), the free energy of reaction [10] is given by Eq. [12].

$$\Delta F_{10} = -\Delta F_{11} + \Delta F_5 = n\mathbf{F}E_{IV} + \Delta F_5 \qquad [12]$$

Voltage-temperature profiles for cells (II) and (IV) are plotted in Fig. 3 and 4. The emf values for cell IV (Fig. 4) were obtained after titration into the Fe_3O_4 single-phase region at 1000° and 1100°C after which the sample was reduced to a composition slightly more oxygen deficient than magnetite. The reduction of the sample was apparently achieved through the gas phase by the lower oxygen potential of the two other Fe-Fe_xO sample electrodes. The cell voltage was recorded continuously and, after a steady-state constant voltage was achieved, emf-temperature profiles were made. Cell voltages were reproduced both on cooling and on heating to within ± 1 mv above 950°C. Another measure of the accuracy and reproducibility is to compare the emf difference between cell (I) and (II) with that of cell (IV). The agreement between 800° and 1100°C was within ± 2 mv.

An analysis of the emf-temperature curves in Fig. 3 and 4 indicates that the partial molal enthalpy of oxygen for the Fe_zO-Fe_3O_4 equilibria is not constant over the temperature range 700°-1200°C. A linear least squares fit was performed over several temperature ranges and the results are presented in Table II. A linear least squares analysis of all the data above

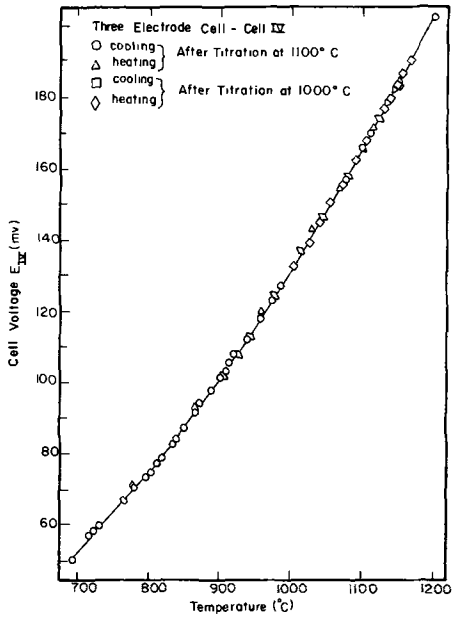

Fig. 4. Cell potentials for cell (IV) at different temperatures

900°C for the free energy of reaction between Fe_xO and Fe_3O_4 in Eq. [10] is given by Eq. [13].

$$\Delta F_{10}(\text{cal}) = -75{,}985 \pm 194 + 30.550 \pm 0.15\,T(°K) \quad [13]$$

The partial pressure of oxygen between 900° and 1200°C for the reaction is given by Eq. [14] and corresponds to the most oxygen-rich wüstite phase (Fe_xO) in equilibrium with Fe_3O_4. Excellent agreement exists between

$$\log P_{O_2} = \frac{-33{,}210 \pm 85}{T} + 13.354 \pm 0.064 \quad [14]$$

Eq. [14] and Darken and Gurry's data at 1100° (10). However, above 1200°C the partial pressure of oxygen is less than that reported by Darken and Gurry. The partial molal enthalpy and entropy of oxygen for the Fe_xO-Fe_3O_4 equilibrium are −75,985 ± 194 cal/mole and −30.550 ± 0.15 cal/mole deg, respectively. It is emphasized again that the data for the Fe_xO-Fe_3O_4 equilibria correspond to compositions containing an

over-all oxygen to iron ratio between 1.25 and 1.31. Equation [14], giving the equilibrium oxygen pressure for the equilibrium between magnetite and the most oxygen-rich phase of wüstite, is compared with the equations of other workers in Table III. Included also in the table are the Fe, Fe_xO, Fe_3O_4 transformation temperatures obtained by equating the oxygen pressure for the Fe_xO-Fe_3O_4 equilibrium with that for the Fe-Fe_xO equilibrium (Eq. [8]).

Iron-rich boundary of wüstite.—The composition of wüstite in equilibrium with iron as a function of temperature is well established. The phase boundaries for wüstite determined by Darken and Gurry (10) are widely accepted by most investigators. A compilation of these data along with more recent data on the Fe-O system is presented in Table IV. The data for the Fe-rich boundary support the selection of $FeO_{1.05}$ as the composition.

The change in composition with temperature of the boundary was studied by determining the temperature coefficient of oxygen pressure at constant composition for a series of compositions close to the boundary. The three-electrode cell was employed. The cell voltages (E_V) for compositions between $FeO_{1.0536}$, $FeO_{1.058}$, and $FeO_{1.067}$ as a function of temperature are shown in Fig. 5.

It is noted that the temperature coefficients of cell voltage at constant composition decreased from 0.06 mv/°C ($FeO_{1.067}$) to 0.02 mv/°C ($FeO_{1.053}$), which if extrapolated to $FeO_{1.05}$ would be 0.003 to 0.01 mv/°C. If the composition of Fe_xO in equilibrium with Fe_xO + Fe was $FeO_{1.05}$ at 800°C and invariant, the temper-

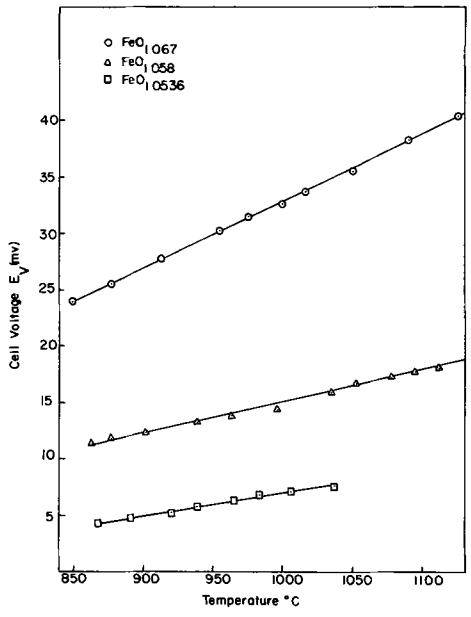

Fig. 5. EMF vs. temperature for compositions $FeO_{1.0536}$, $FeO_{1.058}$, and $FeO_{1.067}$ in cell (V).

ature coefficient for $FeO_{1.05}$ in this cell would be zero. Therefore, assuming that the extrapolated coefficient of 0.01 mv/°C is real and that the composition $FeO_{1.05}$ is not invariant, the true composition of wüstite in equilibrium with iron at temperatures greater than 800°C would be more iron rich. From a knowledge of the ratio of cell voltage per coulomb which was determined from the titration experiments, the change in composition over a 300° temperature rise was calculated to be + 0.00077 using a slope of 0.01 mv/°C. This decrease in O/Fe ratio corresponds to $FeO_{1.04923}$. Thus the assumption that $FeO_{1.05}$ is constant over the temperature range between 1057° and 1200°C has been well substantiated.

Oxygen-rich boundary of wüstite.—The oxygen-rich boundary of wüstite was determined by the technique of coulometric titration. The boundary is readily identified by a plateau in either a P_{O_2} or emf *vs.* composition (O/Fe) plot. In Fig. 6 a plot of P_{O_2} *vs.* O/Fe is given which is representative of the titration experiments in both cell configurations. This particular experiment was conducted at 1139°C in the three-electrode

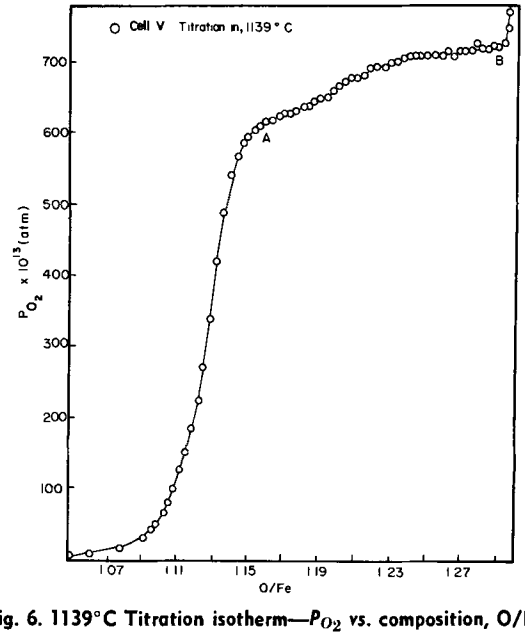

Fig. 6. 1139°C Titration isotherm—P_{O_2} vs. composition, O/Fe

cell. It is noteworthy that the oxygen pressure (activity) is a continuous function of composition until an O/Fe ratio of about 1.15 (composition A on Fig. 6) is reached. This composition corresponds to the oxygen-rich wüstite boundary presently reported on the phase equilibrium diagram (refer to Table IV). The oxygen pressure at composition B (O/Fe ~ 1.29) corresponds to the Fe_zO-Fe_3O_4 equilibrium value measured in this study (5, 17) and by other investigators (10, 12, 16). The rapid increase in oxygen potential at a composition (O/Fe) of 1.29, which is less than the magnetite composition (1.33) is due probably to the presence of a polarizing layer of magnetite at the electrode.

The fact that the oxygen potential at composition A is lower than that at B indicates tentatively that the composition of wüstite at A is not in equilibrium with magnetite. Between compositions A and B a series of single- and two-phase regions was observed. These were detected by a series of composition ranges with variable and constant oxygen activity, *i.e.*, variable and constant cell emf. If the composition range between A and B was a single two-phase region, as is now believed, the equilibrium oxygen activity (cell emf) should not vary with the composition as observed in this study but be constant until the magnetite composition is reached.

It is important to emphasize that the composition where the first two-phase region (A on Fig. 6) was observed corresponds to the presently accepted oxygen-rich boundary of wüstite. These compositions are listed at different temperatures in Table IV. It is also noted that the difference in oxygen pressure between points A and B corresponds to differences in cell voltage of ≈ 5-10 mv. These small differences in partial pressure (~ 1 x 10^{-11} atm) would be difficult to determine in normal gas equilibration techniques. For example, ratios of P_{CO_2}/P_{CO} (~8) in this oxygen pressure region are difficult to control precisely. A plot of the log P_{O_2} *vs.* 1/T for the oxygen pressure corresponding to the first two-phase region (composition A) observed in the titration studies at different temperatures led to Eq. [15].

$$\log P_{O_2} = \frac{-33{,}633 \pm 230}{T} + 13.567 \pm 0.176 \qquad [15]$$

This equation is very close to that reported earlier (Eq. [14]) for the true Fe_zO-Fe_3O_4 (*i.e.*, O/Fe at 1.33) potential and compares well with reported data (10, 12, 16). The small difference between Eq. [14] and [15] easily illustrates how the difference in oxygen potential between compositions corresponding to A and B in Fig. 6 could be overlooked in the less precise gas equilibration studies.

In order to justify further the results of this study in connection with the oxygen-rich boundary of wüstite, it is informative to review briefly the results of previous workers in establishing the oxygen-rich boundary of wüstite.

The phase boundaries corresponding to the Fe_zO + Fe_3O_4 equilibrium are not well established, and considerable difficulty was experienced by many investigators working in this region of the Fe-O system (10-12, 19, 25, 26). It is believed by the authors that this difficulty stems from the fact that there is a series of two-phase regions existing between the commonly accepted oxygen-rich wüstite boundary and Fe_3O_4. One of the principal reasons frequently given for failure to determine this boundary sharply is that nucleation of magnetite is the slow or rate-determining step. This explanation is difficult to understand when one considers the following:

1. At temperatures such as 1100°-1200°C diffusion of iron is fairly rapid (27, 28).
2. The crystal structures of FeO_y and Fe_3O_4 are basically the same, at least with respect to the anion packing.

3. Lattice parameter measurements indicate that the Fe_3O_4 structure can be derived by continuous removal of iron cations from the wüstite structure (29).

4. Oxygen potential measurements by Barbi (30) made during the reduction of Fe_2O_3 to Fe + Fe_xO did not indicate any evidence of a phase boundary between Fe_3O_4 and FeO_y.

5. A good epitaxial relation exists between FeO_y and Fe_3O_4, with a coherent boundary between the two phases (31, 32).

6. The rate of decomposition of FeO_y to Fe_3O_4 is very fast and a low activation energy process (33).

7. The single crystal structure is not destroyed by repeated reduction and oxidation of Fe_3O_4 to FeO (32).

8. Experimental evidence (neutron and high-temperature x-ray diffraction) has been found for clusters of defects present in wüstite which basically have the structure of magnetite (34, 35). Libowitz (36) has derived a relationship between oxygen pressure and composition based on the model proposed by Roth, wherein the principal defect in wüstite is assumed to be a Fe^{3+} interstitial associated with two iron vacancies. This model predicted correctly the P_{O_2} *vs.* composition (O/Fe) dependence in single-phase wüstite between 1057° and 1200°C (5).

In summary, ample evidence exists that magnetite-type clusters of defects are always present in wüstite, especially oxygen-rich wüstite. These defects may be responsible for the number of two-phase regions observed in this study. The presence of these defects should not only provide sites for nucleation but should also enhance its rate as well. Considering the difficulties encountered by other investigators in determining the Fe_zO-Fe_3O_4 equilibrium boundary, it is very difficult to rationalize that the principal cause is the slow nucleation of magnetite. In summary, one might expect from these facts to find a continuous solid solution between $FeO_{1.05}$ and $FeO_{1.33}$ (Fe_3O_4).

A summary of the two-phase regions observed in the P_{O_2} composition isotherms (5, 17), which were obtained from the coulometric titration experiments, is presented in Table V. In this table the oxygen-rich compositions to which titration was extended in addition to the compositions where two-phase regions were observed are listed. Compositions listed without a range for the two-phase region correspond to the composition at which there was a definite break in the oxygen activity-composition curve. The partial pressure of oxygen corresponding to the most oxygen-rich composition titrated is also listed.[5] A plot of the Fe-O phase diagram with selected reference data showing the oxygen-rich boundary of wüstite is presented in Fig. 7. The compositions where two-phase regions were noted are included in this figure.

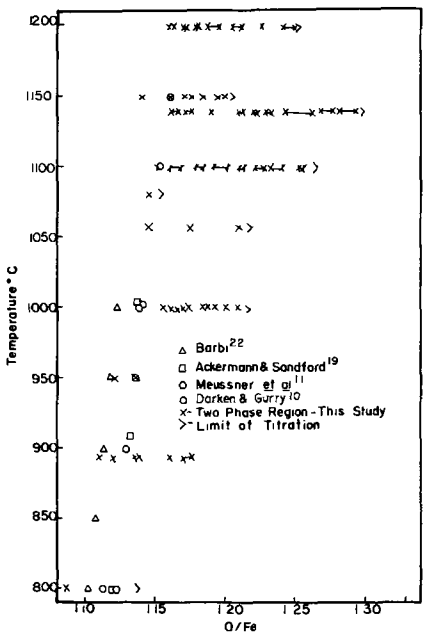

Fig. 7. Two-phase regions observed between oxygen-rich wustite and magnetite.

The results of the coulometric titration studies indicate the presence of as many as eight different two-phase regions between oxygen-rich wüstite and magnetite at temperatures between 1100° and 1200°C. The principal proof was the constant oxygen potential, *i.e.*, cell emf, observed over a finite composition range. These phases were found to exist over a narrow pressure range corresponding to a total cell voltage change from 5 to 10 mv with differences of 0.3 mv between some two-phase regions. The emf-temperature coefficient for cells III and V in the oxygen pressure range between FeO_y and Fe_3O_4 is 0.67 and 0.36 mv/°C, respectively. Thus, the duplication of isotherms would require very accurate temperature measuring and control equipment. Since this equipment was not available, the experimental technique employed was to use a constant voltage supply and then correct the cell emf to a particular temperature. Temperature measurements were made frequently between cycles to ensure a constant temperature. Fluctuations were normally within ± 1°C. Although differences (~ 0.3 mv) between successive two-phase regions were diffi-

[5] This study was not initially intended to determine phase boundaries in the iron-oxygen system so that many of the titration experiments used to establish the isotherms were stopped once a partial pressure of oxygen determined from the cell emf corresponded to the reported value for the Fe_zO-Fe_3O_4 two-phase equilibrium.

Table V. Compilation of two-phase regions observed in wüstite regions determined from coulometric titrations

cult to reproduce, the gradual increase in cell emf (5-10 mv) between compositions represented by points A and B on Fig. 6 was easily reproduced and was well within experimental error.

The initial evidence for additional two-phase regions was obtained by observing the cell emf as a function of time under reducing conditions. In Fig. 8 the cell emf as a function of time for a closed-end tube cell operating at 1150° is plotted. Titrations were carried out at 1057° and 1075°C; then the temperature was increased to 1150°C, and the change of emf with time was recorded. The reducing potential was either a zirconium getter or molybdenum wire used in the cell assembly. In cell (V) it was most likely the Fe-Fe_xO electrodes. Similar reduction data were obtained in both cells at other temperatures.

Tare and Schmalzried (37) used the reverse of this technique to determine the oxidation rate constant for the phase-boundary reaction in the oxidation of iron to wüstite. For the phase-boundary reaction to be controlling, no concentration gradients can exist in the sample so that equilibrium is established throughout. The rate-controlling mechanism is the transfer of oxygen from the surface of the sample to the gas phase. This transfer would be expected to be a low activation energy process and perhaps might explain why the general shape of the reduction curves in this study (17) remains the same for different temperatures (1090°-1200°C). The important conclusion to draw from these reduction studies is the presence of several constant emf regions in reducing Fe_3O_4 to wüstite. These constant emf regions indicate the presence of two coexisting phases which are being reduced providing the reduction is phase boundary controlled. Linear reduction rates have been observed in wüstite by a number of workers (37-41).

An example of a titration experiment at 1139°C into magnetite followed by a reduction on the same sample can be seen in Fig. 9. The titration portion corresponds to the last 60 cycles (60 out of the total of 87 hr of titration) in which the titration current varied from 1.50 to 1.25 ma with titration and emf measuring times of 26.5 and 35.5 min, respectively. With the rapid rise of cell emf at $FeO_{1.316}$ the titrations were stopped, and the resultant cell emf as a function of time during reduction is plotted on this same figure. There is a good correlation between these curves for the two-phase regions. The wavy portions in the reduction curves are most likely due to the temperature variations. A similar plot for reduction after titration to composition $FeO_{1.186}$ at 1100°C is shown in Fig. 10. It is noteworthy that a constant emf was recorded in some cases up to 200 min. A summary of additional reduction and titration results for two-phase regions is given in Table VI.

Similar reduction experiments were conducted in which oxygen rich magnetite was reduced into the Fe_zO-Fe_3O_4 coexistence region. The data from these experiments conducted in both cell configurations are shown in Fig. 11. The reduction reaction for the closed-end tube (exp. 12) started within 1 mv of the Fe_3O_4-Fe_2O_3 two-phase region. It is clear that in this composition range ($1.33 < O/F < 1.5$) the absence of any emf-time plateaus indicates that only single phase Fe_3O_4 is being reduced. However, in the FeO_y-Fe_3O_4 composition range (*i.e.*, $1.15 < O/F < 1.33$) numerous plateaus were observed.

In summary, it has been demonstrated that a number of two-phase regions exist between oxygen-rich wüstite and magnetite. They can be reproduced within experimental accuracies of measuring the temperature and cell emf's between different cells. The actual delineation of the phase regions will require greater precision and accuracies in controlling the temperature in addition to better control of the partial pressure of oxygen existing in the cell atmosphere.

Transformation temperature for decomposition of wüstite to magnetite.—The temperature corresponding to the decomposition of wüstite into magnetite has been reported to be between 565° and 620°C (16, 19, 42). This temperature can be uniquely determined by the triple point where iron, magnetite, and a particular composition of wüstite are in equilibrium. At this temperature the phase boundaries merge and the oxygen pressure is unique. Thus, extrapolations of Eq. [8] and [14], which relate the partial pressure of

E_T for experiments 7 and 12 (closed-end tube cell) was determined from the relationship, $E_T = E_I$ (Eq. [6]) $- E_{III}$.

oxygen in equilibrium with Fe-Fe_xO and Fe_xO-Fe_3O_4 to the temperature where the pressure of oxygen is the same and unique, should define the transformation temperature. The extrapolation of Eq. [8] for the Fe + Fe_xO equilibrium is valid in this temperature range. However, Eq. [14] describing the Fe_xO + Fe_3O_4 equilibrium should not be extrapolated below 900°C (per previous discussion in the section Fe_xO-Fe_3O_4 equilibria). The transformation temperatures obtained from a linear extrapolation of the equation for log P_{O_2} of the Fe_xO-Fe_3O_4 equilibrium are presented in Table VII. The transformation temperatures listed were determined as a function of the temperature range from which the equation describing the Fe_xO-Fe_3O_4 equilibrium was derived. The resultant temperatures (417°-547°C) obtained from extrapolation of low-temperature data appear unrealistic and are hard to explain. This same behavior was also noted by Vallet and Raccah (16). The transformation temperature of 614° ± 7°C derived from the extrapolation of high-temperature data (900°-1200°C) indicates good agreement with the results of Vallet and Raccah.

* The temperature range in which the equation, $-\log P_{O_2} = A + B\,(1/T) \times 10^4$, for the Fe_xO + Fe_3O_4 equilibrium was derived and used with the Fe-Fe_xO equilibrium (Eq. [8]) to calculate the triple point.

The transformation temperature was measured experimentally by the use of cell (V) with the composition $FeO_{1.08}$ as the cathode. The cooling and heating profiles (1050°-450°C, 19 hr each) are shown in Fig. 12, as the X-Y plot of a Pt, Pt-13Rh thermocouple emf vs. E_V (mv) for the cell reaction. When the cell emf is zero, both electrodes have the same oxygen potential corresponding to the Fe-Fe_3O_4 equilibrium. The temperatures obtained were 620° and 599°C for cooling and heating, respectively. The 620°C obtained upon cooling was extrapolated to a point where the slope, $dE_V/dE_{Pt,\ Pt\text{-}13Rh} = 0$.

Conclusion

The usefulness of a solid electrolyte galvanic cell in determining phase boundaries and thermodynamic functions in the iron-oxygen system has been demonstrated. Tentative evidence for the existence of more than one defect phase between wüstite and magnetite has been presented from coulometric titration experiments.

Technical Notes

Luminescence of Some Bismuth-Activated Oxides

S. Z. Toma* and D. T. Palumbo

Sylvania Electric Products, Inc., Chemical and Metallurgical Division, Towanda, Pennsylvania

Y_2O_3 has the so called C-type structure with two yttrium sites characterized by C_2 and S_6 symmetry. The cations are 6-coordinated in both sites. Bismuth luminescence in this and several other matrices has been studied (1-3). Broad absorption and emission bands are usually observed with energies quite dependent on the particular environment of Bi^{3+} ion. The present work concerns further study of bismuth luminescence in Y_2O_3 and the isomorphous oxides of scandium and gadolinium.

* Electrochemical Society Active Member.

Experimental

Samples of Y_2O_3:Bi were prepared from luminescent grade yttrium oxide (~99.99%). Appropriate amounts of bismuth and yttrium oxalates were acetone blended and dried. The mix was ignited to the oxide for 1 hr at 700°C and refired for 3 hr at 1100°C. A sample of

$(Y_{0.99}E_{0.01})_2O_3$ was prepared by firing coprecipitated oxalates at 1200°C for 3 hr.

All spectra were obtained at room temperature with a Hitachi-Perkin-Elmer MPF-2A spectrophotofluorimeter. This instrument, although uncorrected, provided better separation of the excitation and emission bands due to its grating optics. Minimum excitation and emission slit widths possible were used, consistent with the sample brightness. The excitation monochromator bandpass was 10Å in most measurements, while that for the emission monochromator was 10-20Å. An HTV-R213 photomultiplier was used.

Results and Discussion

Figures 1 and 2 show the emission spectra of Y_2O_3:Bi (0.5 a/o) for a number of different excitation wavelengths. The excitation spectra for the two emissions

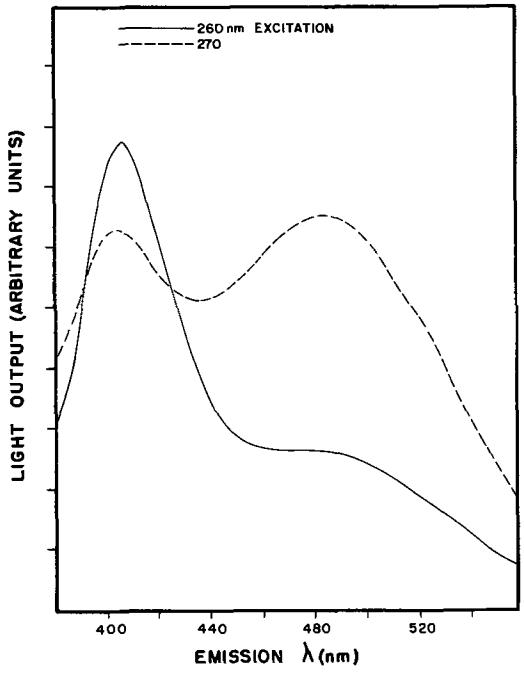

Fig. 1. Emission spectra of Y_2O_3:Bi with short uv wavelength excitations.

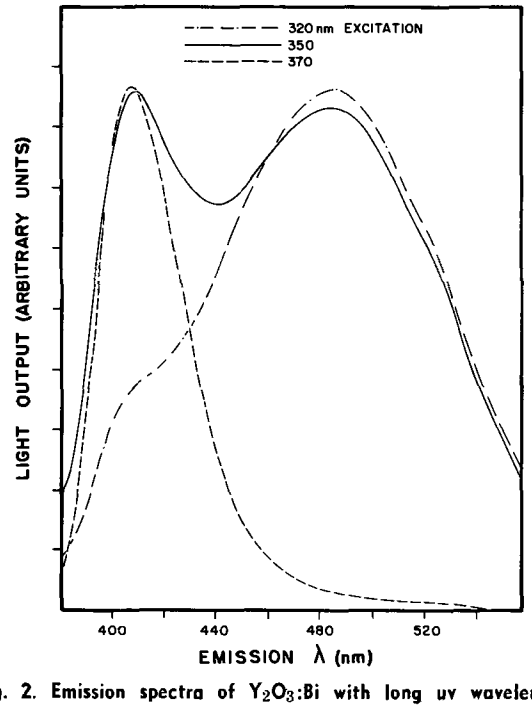

Fig. 2. Emission spectra of Y_2O_3:Bi with long uv wavelengths excitations.

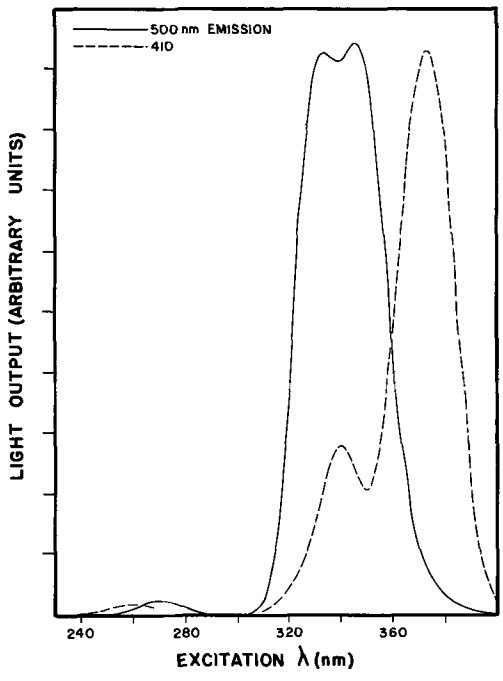

Fig. 3. Excitation spectra of Y_2O_3:Bi for the two emissions

are shown in Fig. 3. A sample formulated with 1 a/o bismuth *i.e.*, $(Y_{0.99}Bi_{0.01})_2O_3$, gave similar results. Comparison of the band maxima in the spectra of Sc_2O_3, Y_2O_3 and Gd_2O_3 activated with bismuth appears in Table I.

Incorporation of an activator ion with $6s^2$ electrons in a matrix allows a number of new electronic states, *e.g.*, $s^2 \rightarrow sp$ transitions, activator-matrix states, and "dimer" states resulting from the proximity and interaction of activator ions. "Dimer" absorption in thallium-activated alkali halides is the subject of recent works (4, 5). Activator-matrix states, those not characteristic of the free ion levels, have been considered in bismuth activated YVO_4, $YNbO_4$, Y_2WO_6 (3), and Y_2O_3 (2). The free ion $s^2 \rightarrow sp$ transitions give rise to four excited states, which for L — S coupling, are $^3P_0$, $^3P_1$, $^3P_2$, and $^1P_1$. With j — j coupling the levels are $(j_1, j_2)_J = (1/2, 1/2)_0$, $(1/2, 1/2)_1$, $(3/2, 1/2)_2$, $(3/2, 1/2)_1$. Selection rules imply the transitions to J = 1 levels to be strongest, and symmetry considerations predict complete splitting of all degenerate levels in C_2 symmetry. Within the limits of instrumental resolution (10Å) we were not able to detect any structure in the observed bands.

The electronic transitions responsible for the observed excitation and emission bands are difficult to ascertain from the present work. However, since two emissions are observed with bismuth addition, each having characteristic excitation bands, two distinct emitting centers may be present and be associated with the two sites in these oxides. Evidence for Eu^{3+} absorption (6) and emission (7) from both sites of Y_2O_3 has been reported. The two sites of Eu^{3+} can give differing, broad excitation bands and this is shown in Fig. 4 where the band for the 582.3 emission (7) extends to

	272	270	270

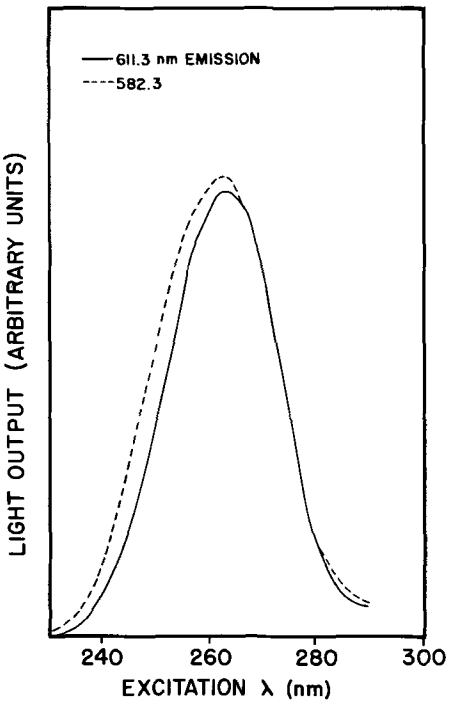

Fig. 4. Broad excitation bands for the 611.3 and 582.3 nm line emissions in Y_2O_3:Eu.

shorter wavelength than that for the 611.3 nm line. Analogously, the excitation and emission spectra of Y_2O_3:Bi may be understood by assuming that bismuth occupies both sites in Y_2O_3, each having characteristic excitation and emission.

The possible effect of long or short distance interaction between two bismuth centers would complicate the assignment of the observed excitation bands. For example, since the green emission overlaps the excitation band of the blue emission, the latter's excitation bands may have some contribution from the green band excitations. Such interactions can occur to some extent due to this overlap (8) and bismuth concentrations and spectral measurement conditions were selected to minimize such effects.

Although narrow band emissions due to trivalent rare earths are well studied in Y_2O_3, much less has been reported about activators with broad absorptions and emissions in this matrix. These are of some interest in studies of the general questions of two sites and activator-matrix states in Y_2O_3. We have observed that pure Y_2O_3 and Y_2O_3:Tl(2a/o), prepared in air, have broad emissions under x-ray and 254 nm excitations, respectively (9). The emission color is yellow for Y_2O_3:Tl and uv-blue for the pure matrix.

Epitaxially Grown Guard Rings for GaAs Diodes

C. M. Wolfe* and W. T. Lindley*

Lincoln Laboratory,[1] Massachusetts Institute of Technology Lexington, Massachusetts

In this paper we present a technique for fabricating guard rings for GaAs p-n junction and Schottky barrier avalanche diodes. To obtain uniform avalanche diodes it is necessary to prevent breakdown at the edges of the diodes. Although this can be done by etching mesas, GaAs diodes fabricated in this manner often show surface leakage, deterioration with time, or even complete failure at the surface. Even when the diodes are hermetically sealed in an inert atmosphere, or the surfaces are coated with pyrolytic silicon dioxide or silicon nitride, these problems are not completely eliminated. Edge breakdown has been prevented in silicon devices by using diffused guard ring structures (1). To avoid the problems involved in diffusing guard rings in GaAs, we have developed a method for growing guard rings in an epitaxial reactor which is compatible with current GaAs epitaxial technology.

These epitaxially grown guard rings have been used for both p-n junction and Schottky barrier diodes (2) on <100> orientated GaAs. The two diode configurations are shown in Fig. 1. For the Schottky barrier diode the Au or other high work function metal must extend out over the n^- regions. In this guard ring structure edge breakdown is suppressed by utilizing two diodes in parallel: an annular outer diode of lightly doped material (guard ring) and an inner diode of heavier doped material (diode). Since the same voltage is applied across both diodes, the heavier doped inner diode breaks down first in reverse bias. The space charge region of the annular guard ring isolates the junction interface of the inner diode. Due to the smaller area of the annular guard ring, it does not contribute significantly to the reverse leakage current.

The mesas for these diodes are etched and the guard rings are grown in an epitaxial reactor utilizing the $AsCl_3$-Ga-H_2 flow system (3) by a technique previously described (4). With this system the mesa etching can be carried out in a high-purity gaseous ambient, and relatively uncompensated GaAs guard rings with doping levels in the 10^{14}-10^{15} cm^{-3} range can be grown. Higher resistivity, more heavily compensated n-type material can be obtained by introducing trace amounts of O_2 into the reactor during growth.

The process used for making the guard rings around p-n junctions is illustrated in Fig. 2. Figure 2(a) shows the initial p^+-n-n^+ layer structure with an etch mask consisting of an array of SiO_2 disks on the p^+ region and a layer of SiO_2 on the n^+ region. The layer structure is produced by growing an epitaxial n-type layer (10^{15}-10^{17} cm^{-3}) on an n^+ substrate ($\sim 10^{18}$ cm^{-3}) and then either diffusing Zn into the n layer or growing a Zn-doped ($\sim 10^{19}$ cm^{-3}) epitaxial layer on the n re-

Epitaxially Grown Guard Rings for GaAs Diodes

C. M. Wolfe* and W. T. Lindley*

Lincoln Laboratory,[1] Massachusetts Institute of Technology Lexington, Massachusetts

In this paper we present a technique for fabricating guard rings for GaAs p-n junction and Schottky barrier avalanche diodes. To obtain uniform avalanche diodes it is necessary to prevent breakdown at the edges of the diodes. Although this can be done by etching mesas, GaAs diodes fabricated in this manner often show surface leakage, deterioration with time, or even complete failure at the surface. Even when the diodes are hermetically sealed in an inert atmosphere, or the surfaces are coated with pyrolytic silicon dioxide or silicon nitride, these problems are not completely eliminated. Edge breakdown has been prevented in silicon devices by using diffused guard ring structures (1). To avoid the problems involved in diffusing guard rings in GaAs, we have developed a method for growing guard rings in an epitaxial reactor which is compatible with current GaAs epitaxial technology.

These epitaxially grown guard rings have been used for both p-n junction and Schottky barrier diodes (2) on <100> orientated GaAs. The two diode configurations are shown in Fig. 1. For the Schottky barrier diode the Au or other high work function metal must extend out over the n^- regions. In this guard ring structure edge breakdown is suppressed by utilizing two diodes in parallel: an annular outer diode of lightly doped material (guard ring) and an inner diode of heavier doped material (diode). Since the same voltage is applied across both diodes, the heavier doped inner diode breaks down first in reverse bias. The space charge region of the annular guard ring isolates the junction interface of the inner diode. Due to the smaller area of the annular guard ring, it does not contribute significantly to the reverse leakage current.

The mesas for these diodes are etched and the guard rings are grown in an epitaxial reactor utilizing the $AsCl_3$-Ga-H_2 flow system (3) by a technique previously described (4). With this system the mesa etching can be carried out in a high-purity gaseous ambient, and relatively uncompensated GaAs guard rings with doping levels in the 10^{14}-10^{15} cm^{-3} range can be grown. Higher resistivity, more heavily compensated n-type material can be obtained by introducing trace amounts of O_2 into the reactor during growth.

The process used for making the guard rings around p-n junctions is illustrated in Fig. 2. Figure 2(a) shows the initial p^+-n-n^+ layer structure with an etch mask consisting of an array of SiO_2 disks on the p^+ region and a layer of SiO_2 on the n^+ region. The layer structure is produced by growing an epitaxial n-type layer (10^{15}-10^{17} cm^{-3}) on an n^+ substrate ($\sim 10^{18}$ cm^{-3}) and then either diffusing Zn into the n layer or growing a Zn-doped ($\sim 10^{19}$ cm^{-3}) epitaxial layer on the n re-

Guard ring fabrication process for p-n junction diodes: (a) initial p^+-n-n^+ layer structure with an etch mask of SiO_2 disks on the p^+ region and a layer of SiO_2 on the n^+ region; (b) removal of the excess p^+ layer before insertion in the furnace to avoid contamination of the epitaxial reactor; (c) high-temperature furnace etching step to ensure clean mesa surfaces; (d) growth of the lightly doped guard rings over the etched mesas.

gion. The SiO_2 is then deposited on both sides of the epitaxial structure by the pyrolytic decomposition of SiH_4 in the presence of O_2 at 300°C. Islands of SiO_2 are defined by standard photolithographic techniques. To prevent severe undercutting during the subsequent high-temperature furnace etching, there must be good adherence between the SiO_2 and the p^+ layer. This can be attained by ensuring a clean and oxide-free GaAs surface before SiO_2 deposition. Circles of SiO_2 as small as 2 mils in diameter on <100> orientated material have been cycled from room temperature to 900°C to room temperature with no loss of adherence. The n^+ side of the wafer must be coated with SiO_2 to reduce autodoping of the initial growth. When the n^+ side of the wafer is not coated with SiO_2, the resulting diodes

or avg. cooling rate (800°-750°C)	5°C/min

exhibit premature reverse breakdown which is characteristic of a heavily doped region at the n-n^- interface.

Before inserting the layer structure into the epitaxial reactor, the excess p^+ layer is removed [Fig. 2(b)]. A solution of $5H_2SO_4$-$1H_2O_2$-$1H_2O$, allowed to cool for about 5 min before use, can be used to controllably remove p^+ layers several microns thick. This step in the process is necessary to avoid reactor contamination from the heavily doped p^+ layer. When the excess p^+ layer is removed by high-temperature furnace etching, it is difficult to obtain lightly doped n-type material for the guard rings in the growth step. For the Schottky barrier diode configuration this pre-etch is not necessary.

To ensure a clean n-n^- interface the exposed mesas of the layer structure are re-etched in the high-purity atmosphere of the epitaxial reactor [Fig. 2(c)]. This step is performed by inserting the layer structure in a flat temperature region of the furnace at a temperature somewhat higher than the temperature that is used for growth. After thermal equilibration, the H_2 through the $AsCl_3$ is turned on and the furnace is allowed to cool to the growth temperature. Etching occurs during the cooling of the furnace. The conditions we have used to obtain etch depths from 1 to 5μ are listed in Table I. Larger amounts can be removed by initiating the etch cycle at higher temperatures. Etch conditions, however, will vary from one system to the next due in part to differences in furnace cooling rates. We have found that at an etching temperature of 800°C, compared to higher temperature etching, the etch depth is very temperature dependent. Thus, good temperature control is required to reproducibly remove small amounts of material. This furnace etching process undercuts the SiO_2 at about the same rate that it etches into the sample. Caution must also be taken to avoid etching through to the n^+ layer. When this occurs, the resulting diodes exhibit premature breakdown due to autodoping of the n-n^- interface.

In the next step [Fig. 2(d)] the n^- guard ring is grown over the etched mesas. The growth of lightly doped n^- material in this system has previously been discussed in some detail (3-5). Growth must be obtained by a surface catalyzed reaction to prevent nucleation of the GaAs on the SiO_2. Unlike the small area {100} growth through holes in an oxide (6), where it is difficult to terminate growth before the oxide is overgrown, this essentially large area {100} growth is sufficiently slow to make growth termination noncritical. The requirements on the doping level of the n^- guard ring are also not critical. We have found that it is only necessary that the doping level of the n^- guard ring be about a factor of five below that of the doping level of the n region of the diode. The approximate doping level of the guard ring is determined from Hall measurements on layers simultaneously grown on high-resistivity substrates.

Schottky barrier diodes with the structure which was shown in Fig. 1(b) have been fabricated by electroplating a semi-transparent gold film (~100Å) onto the active diode area and over part of the epitaxially grown guard ring. By looking at the visible light emission (7) from these diodes when they are biased into reverse breakdown, the uniformity of the avalanche breakdown can be observed. For diodes fabricated on this same material with no guard ring, the breakdown light emission is entirely at the perimeter. Figure 3 shows the light emission from one diode of an array of 3.5-mil diameter diodes which have epitaxial guard

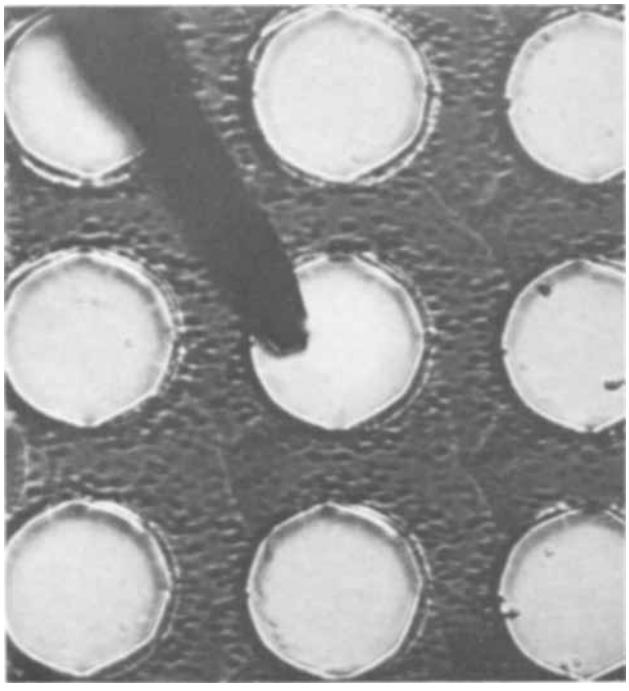

Fig. 3. An array of 3.5 mil diameter semitransparent Au-GaAs Schottky barrier diodes with epitaxial guard rings. Reverse bias visible light emission pattern is shown for the center diode.

rings. The breakdown voltage of these diodes is higher than those without a guard ring and the breakdown is entirely in the center active region. The slight nonuniformity in the light emission is due to material inhomogeneity. These diodes have also been used as avalanche photodetectors and show a gain in excess of 100 when biased near their reverse breakdown.

We believe that this epitaxial process for the formation of GaAs guard rings provides a useful and efficient technique for eliminating surface problems and suppressing edge breakdown in GaAs p-n junction and Schottky barrier avalanche diodes.

Properties of Ion-Implanted GaAs Diodes

P. E. Roughan and K. E. Manchester

Research and Development Center, Sprague Electric Company, North Adams, Massachusetts

GaAs p-n junction diodes have been produced by the implantation of 80 kev singly charged zinc ions into n-type GaAs substrates of carrier concentration 2.4 x 10^{16} cm^{-3}. The implantation was carried out at room temperature, into wafers cut parallel to the <110> direction. The apparatus employed has been previously described by Manchester *et al.* (1).

After implantation, the wafers were covered with an evaporated layer of SiO_x and annealed at 650°C in argon for various periods of time. The protective oxide layer was then removed, the wafer diced into squares approximately 20-25 mils on a side, and the dice bonded to standard headers. Measurements were then carried out on the forward and reverse current-voltage characteristics, the capacitance-voltage relationship, and the light emission properties of the diodes.

The annealing behavior of implanted GaAs does not, at present, appear to be as consistent as that for silicon. In the latter case, relatively mild anneal cycles (*e.g.*, a minimum of 600°C for 10 min in the case of phosphorus implants) are sufficient to produce diodes with excellent characteristics. However, for GaAs, we have found that, in some cases, brief anneals (30 min to 3 hr) are sufficient to produce diode properties, while, in other cases extended annealing periods, of the order of 10 hr and longer, appear to be necessary before diode properties are obtained. This behavior appears to be related to ion dose; for example, all of the samples implanted with 10^{16} ions cm^{-2} required only brief annealing periods, while most, but not all, of the samples implanted with 10^{15} ions cm^{-2} required long anneals. Furthermore, extended annealing (up to 15 hr) of high dose samples produced no significant changes in diode properties, while those low dose samples which required long anneals displayed quite different diode properties.

Figure 1 shows curve tracer displays of the I-V characteristics for two typical diodes, one of each type. Part (a) of this figure shows the characteristics for a diode obtained by the implantation of 10^{16} Zn^+ ions cm^{-2}, followed by an anneal for 3 hr at 650°C. A good thermally diffused diode produced in background material of similar carrier concentration would show the same characteristic. Part (b) of this figure illustrates the diode characteristic obtained for a sample implanted with 10^{15} Zn^+ ions cm^{-2}, then annealed for 18 hr at 650°C. The most significant difference here is the extremely large value of reverse breakdown voltage, ~115v. The forward characteristic also indicates a higher series resistance. Schroeder and Dieselman (2) have presented I-V data on Zn-implanted GaAs diodes which exhibit rather large reverse currents and soft breakdown characteristics. A maximum anneal temperature of 250°C, however, was employed by these authors, which is probably insufficient to remove the radiation damage.

Figure 2 illustrates the capacitance-voltage relationships, again for two typical diodes. Linear dependencies are obtained for C^{-2} and V for diode C8-11,

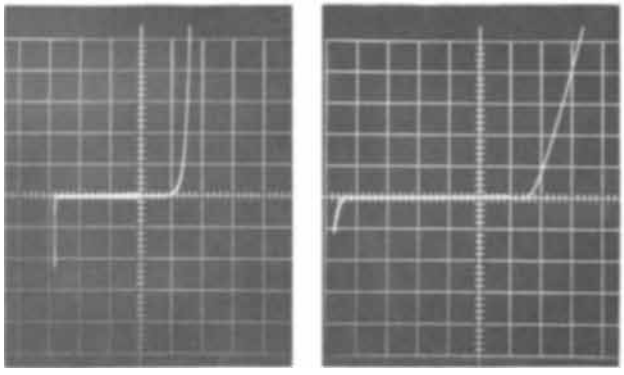

Fig. 1. Curve tracer displays of I-V characteristics of Zn-implanted diodes: a (left) dose 10^{16} ions cm^{-2}, anneal 3 hr, 650°C, in Ar (scales: vertical, 0.01 ma/div.; horizontal, 10 v/div. reverse, 0.5 v/div. forward); b (right) dose 10^{15} ions cm^{-2}, anneal 18 hr, 650°C, in Ar (scales: vertical, 0.05 ma/div.; horizontal, 20 v/div. reverse, 1 v/div. forward. Origin has been shifted one division to the right.)

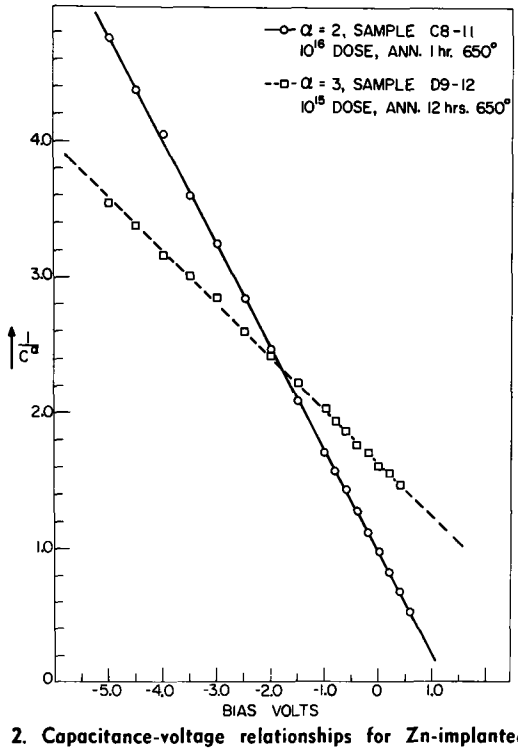

Fig. 2. Capacitance-voltage relationships for Zn-implanted diodes.

which had been annealed for 1 hr at 650°C, and between C^{-3} and V, for diode D9-12, an 18-hr anneal. Thus, the high dose units, for which only a brief anneal is required, exhibit the characteristics of a typical abrupt junction, while the low dose units, annealed for longer periods, show graded junction behavior. In fact, if one calculates an impurity grading coefficient from the slope of the C^{-3} *vs.* V plot, the rather low value of a $\simeq 10^{20}$ cm^{-4} is obtained, as opposed to the typical value of a $\geqslant 10^{22}$ cm^{-4} for normal graded junctions.

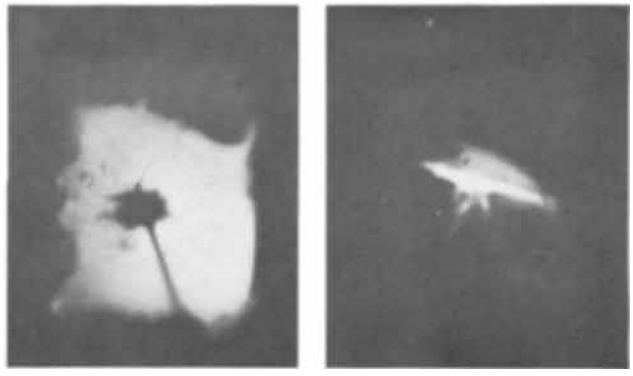

Fig. 3. Infrared emission for an implanted GaAs diode: a (left) top view of diode; b (right) side view of diode.

Both types of diodes emit light when biased in the forward direction. As might be expected, however, power outputs and efficiencies are considerably higher in the case of the abrupt junction types. Figure 3 shows the light emission characteristics of an implanted GaAs diode, as observed on the screen of an image converter. The best emitters have shown power outputs of 0.7-0.8 mw at external efficiencies of ~0.5% at room temperature. Spectral measurements indicate that the peak of the emission occurs at $\lambda = 0.92$ μm.

Summary

GaAs diodes have been fabricated by room-temperature implantation of 80 kev Zn^+ ions. Preliminary data indicate that, by suitably altering implantation conditions, two types of diodes can be obtained, *i.e*, abrupt junction units, formed using a high-dose implant and brief annealing periods, or graded-junction units formed with a low dose implant after extended annealing. The former display I-V and light emission characteristics comparable to good thermally diffused diodes. The latter exhibit high forward resistances and large reverse breakdown voltages; they are perhaps more appropriately described as p-i-n structures, produced by smoothing out the implanted profile (assumed to be Gaussian) by thermal diffusion during the long annealing periods.

Manuscript submitted Feb. 20, 1968; revised manuscript received Oct. 23, 1968. This paper was presented at the Chicago Meeting, Oct. 15-19, 1967, as Paper 172.

Brief Communications

Measurement of Anodic Oxide Film Thickness by Electroreflectance Interferometry

B. J. Holden and F. G. Ullman*

Electrical Materials Laboratory, Department of Electrical Engineering, University of Nebraska, Lincoln, Nebraska

In this Communication, we describe a new spectrophotometric method for the measurement of the thickness of oxide films on tantalum and niobium[1] with which the wavelengths of reflectance maxima and minima can be measured with a precision of better than 0.1%.

In a study of room temperature electroreflectance from tantalum oxide films on tantalum by the electrolyte method (1), oscillatory spectra, extending from just inside the oxide absorption edge (about 4.4 ev) to photon energies less than the edge by more than a factor of two, were observed (2). It was apparent that the measured response was proportional to the slope of the reflectance spectrum since the wavelengths of the zero crossings corresponded closely to the reflectance maxima and minima. However, the mechanism responsible for the observed electric field-induced modulation was not immediately obvious. Calculations of the Franz-Keldysh effect, using Aspnes' theory (3), showed it to be too small at photon energies much less than the absorption edge to account for the observed modulation which ranged from about 0.01 to 1.0%. However, at the field strengths used in these experiments, about 10^6 v/cm, an electrostrictive compression of the oxide of the order of 0.001% can be expected for an assumed linear compressibility of the oxide of about 10^{-12} cm^2/dyne. The calculated changes in reflectance for thickness changes of this order are in good semiquantitative agreement with the observed changes. (We are indebted to B. O. Seraphin for suggesting electrostriction to be the mechanism responsible for our observations.)

The change in reflectance resulting from such small thickness changes is directly proportional to the slope of the reflectance spectrum if dispersion in the optical constants of the film and substrate is small. Using phase-sensitive detection, we found that the wavelengths of the zero crossings could be determined with a reproducibility of better than 0.1%. These results suggested that film thicknesses could be measured by this new technique, which we have termed "electroreflectance interferometry," with a precision approaching that obtainable by multiple beam interferometry (4) or shearing interference microscopy (5). However, our method has the additional advantage of being nondestructive, *i.e.*, no steps, scratches, or metallic overlays are required. Further, since the effect can frequently be observed in a region of low film absorption, the calculation of film thickness, in this case, is straightforward.

Taking into account the phase shift on reflection at the film-substrate interface, and neglecting film absorption ($k_1 = 0$), the film thickness, s, for normal incidence, is

$$s = (m\lambda/4n_1)\{1-(1/m\pi)[\tan^{-1}(2n_1k_2/(n_2^2-n_1^2+k_2^2))]\} \quad [1]$$

where λ = wavelength of zero crossing, n_1 = real part of refractive index of film, n_2 = real part of refractive index of substrate, k_2 = imaginary part of refractive index of substrate, and m is an integer, odd for minima and even for maxima, if the refractive index of the film is less than that of the substrate. The appropriate values of the interference order, m, are obtained by first estimating the film thickness, without the phase correction, from the photon energy increment between adjacent maxima or minima. An incorrect choice of m is then readily detected since this will result in a monotonic variation in calculated thickness with increasing m instead of a random variation about an average value.

A block diagram of our instrumentation is shown in Fig. 1 and typical spectra obtained from samples of tantalum oxide on tantalum and niobium oxide on niobium are shown in Fig. 2. The samples were anodized in 2% boric acid solution buffered to a pH of 6-7 with NH_4OH.[2] The measurement conditions are given in the figure caption. The calculated tantalum oxide thicknesses, their mean, the mean deviation, and the sources of constants used in the calculation are shown in Table I. For niobium oxide, consistent results are obtained only for obviously incorrect, or nonintegral, values of the interference order, m. Apparently, the refractive indices of our films differ significantly from the published values (6) used for these calculations.

Because of the electrolyte, this method is limited to wavelengths longer than the vacuum ultraviolet which, at best, imposes a short wavelength cutoff of about 1800Å. Consequently, this technique is limited to films sufficiently thick for at least the first reflectance minimum to be at greater than 1800Å. For such thin films there would be only one observable zero crossing; consequently, it is more accurate to use the wavelength of the electroreflectance maximum to calculate the film thickness in this case. This is accomplished by calculating numerically the wavelength

[1] Other materials have not yet been tried.

[2] One sample of niobium was anodized in 0.2*N* H_2SO_4 with no change in results.

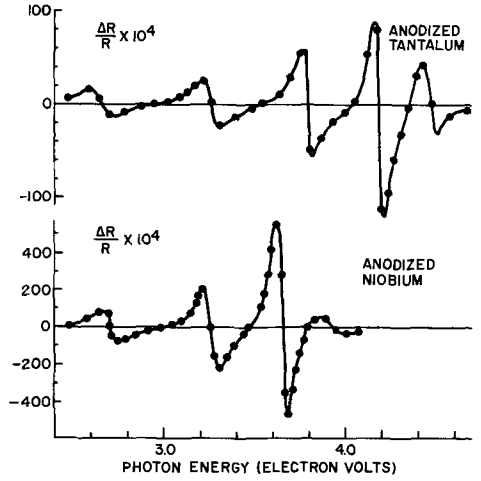

Fig. 2. Electroreflectance spectra of anodized tantalum and niobium. Upper curve, one mil tantalum foil anodized to 200v. Measurement made in boric acid electrolyte (1.0M KCl solutions were also used with no change in results) with 160v d-c bias and 35 Hz, 50v peak-to-peak sine wave modulation. Lower curve, one mil niobium foil anodized to 118v. Measurement made in boric acid (0.2*N* H_2SO_4 was also used) with 35v d-c bias and 35 Hz, 70v peak-to-peak sine wave modulation.

of the maximum in the ratio of the derivative of the reflectance with respect to thickness to the reflectance, $(dR/ds)/R$, as a function of thickness in the appropriate spectral range for comparison with the experimental result. We have been able to measure electroreflectance maxima for tantalum oxide films estimated to be as thin as about 70Å as shown in Fig. 3. The vertical bars in the figure indicate the width of the noise in these measurements. The measurement conditions are given in the caption. Photomultiplier shot-noise and the inherently lower precision in locating a maximum, rather than a zero crossing, limit the precision in this case to values as poor as 10%. Calculation of film thicknesses from these and similar data await the determination of the refractive index for this spectral region.

The results in Table I indicate a precision for thickness determination of about 0.6% (0.3% is more typical of other measurements) whereas the reproducibility in the determination of the zero crossing wavelengths was better than 0.1%. Since the applied field varied from zero to its maximum value in these measurements, the measured change in reflectance is not directly proportional to just the first derivative of reflectance with respect to film thickness but may depend on higher derivatives as well. To determine if

neglect of these higher order derivatives in the thickness calculations was contributing to the apparent experimental error, we calculated the magnitude of the second derivative term. The effect of including the second derivative on the calculated thickness was less than 0.05%, and therefore only the first derivative term is significant. The most likely explanation for the observed error is the choice of the optical constants used in the thickness calculations. The optical constants of tantalum and niobium oxide are not known at all wavelengths of interest and particularly, at wavelengths shorter than 3000Å. In any case, reported values vary by as much as 10% (7-9) and seem to depend on methods and conditions of preparation. The optical constants of tantalum and niobium are also not known except at a few wavelengths (10, 11). However, these appear only in the phase correction term which is nearly constant and therefore, the error resulting from assuming these to be the same for all wavelengths is significant but less serious.

We are carrying out ellipsometer measurements on anodic and reactively sputtered films on various substrates. With the optical constants obtained from these results, we hope to achieve the ultimate precision of better than 0.1% that is expected with this technique.

YPO_4:Ce Phosphor Sensitized by Thorium Ions

Kenzo Awazu and Katsutoshi Muto

The Central Research Laboratories, Mitsubishi Electric Corporation, Amagasaki, Japan

The efficient uv emitting phosphor, $BaSi_2O_5$:Pb is well known and commercially used (1, 2). Recently Ropp has described YPO_4:Ce as the uv phosphor which has two emission peaks near 3500Å (3, 4). The photoluminescent material had an integrated output of only 36% of the commercial $BaSi_2O_5$:Pb phosphor when excited by 2537Å.

In the present communication, we report on the YPO_4:Ce phosphor sensitized by Th ions. The sensitized phosphor is 150% more efficient than $BaSi_2O_5$:Pb phosphor when excited by the low pressure mercury discharge lamp. The result may be explained by energy transfer from Th to Ce ions.

The phosphor was prepared by precipitating solution of yttrium with a dilute solution of phosphoric acid. Mixture of the ions was made, including soluble salts of the activator Ce ions and the sensitizer Th ions, before precipitation. The material as produced was then fired to form the phosphor composed of the desired solid solution of phosphates. Firing was accomplished in air or in a slightly reducing atmosphere at 1200°C.

Measurements of fluorescent spectra were made employing a Beckman model DU spectrometer with 1P28 photomultiplier. The spectra were not corrected for the sensitivity of the tube.

The emission spectra of $BaSi_2O_5$:Pb and YPO_4:Ce phosphors are given in Fig. 1. As a photoluminescent material, YPO_4:Ce sensitized by Th ions, the most efficient phosphor, had an integrated output of 150% of the commercial $BaSi_2O_5$:Pb phosphor when excited by a low-pressure mercury discharge lamp and measured under identical condition as shown in Fig. 1. YPO_4:Ce and one which contained a trace of Nd^{3+} ions and other rare earth ions had an integrated output of only 60 and 20%, respectively. It is clear that Nd^{3+} ions and other impurities reduce the emission intensity of YPO_4:Ce phosphor, whereas Th ion sensitizes the phosphor.

The excitation spectra of YPO_4:Ce phosphor and the Th-sensitized phosphor are given in Fig. 2. The peak of the new excitation band in the Th-sensitized

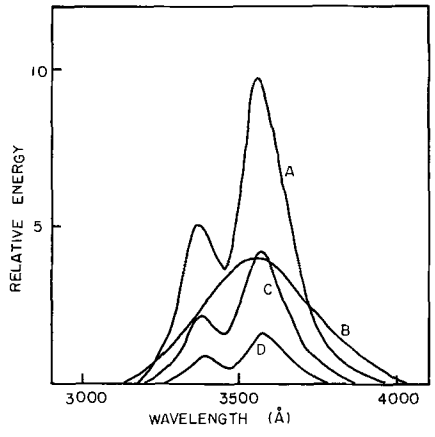

Fig. 1. Radiometric comparison of uv emitting phosphors: A, YPO_4:6.3 a/o Ce 0.1 a/o Th; B, Ba Si_2O_5:Pb; C, YPO_4:6.3 a/o Ce; D, YPO_4:Ce which contained a trace of Nd^{3+} impurity.

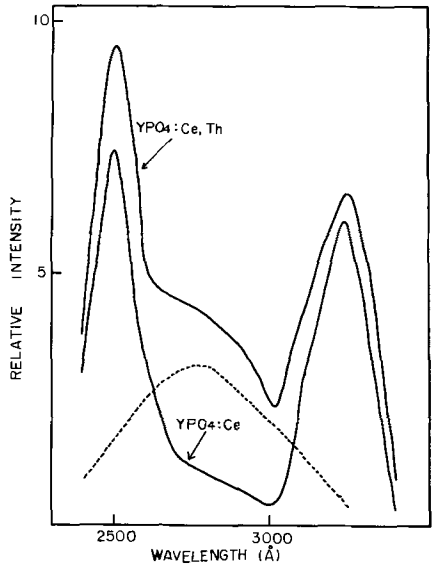

Fig. 2. Excitation spectra of YPO_4:Ce and Th sensitized phosphors.

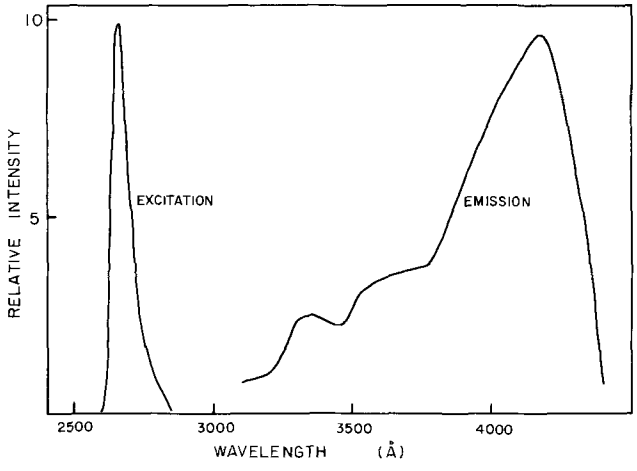

Fig. 3. Emission and excitation spectra of YPO_4:Th

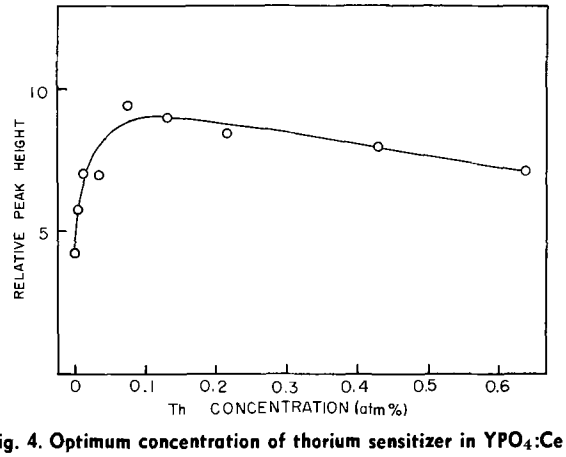

Fig. 4. Optimum concentration of thorium sensitizer in YPO_4:Ce

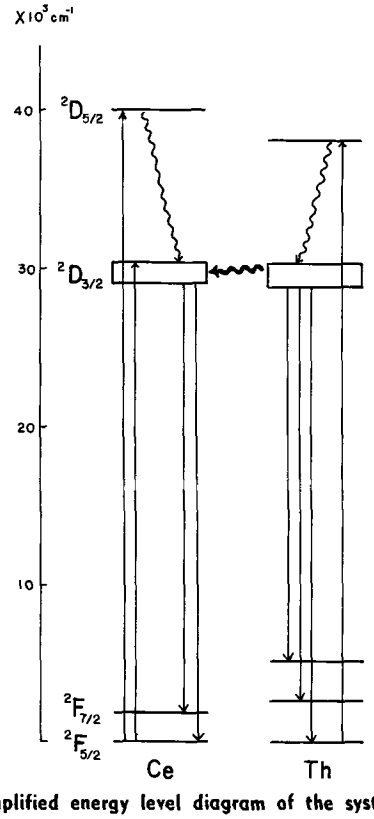

Fig. 5. Simplified energy level diagram of the system YPO_4:Ce, Th.

phosphor is near 2750Å, whereas in YPO_4:Th phosphor, the excitation peak is near 2650Å as shown in Fig. 3. Thus one is led to the conclusion that the new excitation band is probably due to the excitation of thorium ions in YPO_4:Ce, which are disturbed by Ce ions.

As shown in Fig. 4 for photoluminescence, the optimum sensitizer concentration for the YPO_4:6.3 a/o Ce composition is about 0.1 a/o.

The trivalent ion, Ce^{3+}, has an electronic structure containing one 4f electron. The allowed multiplet terms for $4f^1$ configuration are $^2F_{7/2}$ and $^2F_{5/2}$. The energy separation of these two levels is about 1800 cm^{-1}, from which one may obtain the spin-orbit coupling coefficient for a 4f electron in cerium; ξ 4f (Ce) = 514 cm^{-1}, in fair agreement with other estimates (5). The 5d levels $^2D_{3/2}$ at 40,000 cm^{-1} and $^2D_{5/2}$ at 30,860 cm^{-1} are 9140 cm^{-1} apart, from which ξ 5d (Ce) = 3656 cm^{-1}. The value is different from the other estimate (5).

The simplified energy diagram of the system Ce, Th:YPO_4 is shown in Fig. 5. It is considered that the excitation energy is transferred from the fluorescent level of Th ion to the $^2D_{3/2}$ level of Ce ion.

Quantum Efficiency Spectra of Photoluminescent Materials

W. A. Thornton*

Advanced Development Department, Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

A method for synthesizing accurate quantum efficiency spectra of luminescent materials, over a range of exciting wave length and temperature, is described. By (*a*) using pure monochromatic exciting radiation, (*b*) correcting for changes, with temperature and exciting wave length, of the spectral energy distribution, (c) correcting for inconstancies in response of the standard excitation material, and (*d*) using measured absolute diffuse reflectance data for a standard material, the method removes the rather drastic assumptions usually made in such optical measurements to reduce the labor involved but which often introduce large errors. New data on the quantum efficiency spectra of some important phosphors are presented, together with new data on the dependence of spectral energy distribution, excitation spectrum, and diffuse reflectance on exciting wave length and temperature; subordinate data on chromaticity and luminosity are included.

One of the important intrinsic characteristics of a phosphor is its quantum efficiency; the determination of quantum efficiency spectra (1) as exciting wave length or temperature varies involves the measurement of emission, excitation, and reflectance spectra, any one of which is a demanding task if accuracy is necessary. There are three major requirements for the accurate determination of the variation of quantum efficiency with exciting wave length and temperature: (*a*) The emission spectrum must be measured against that of a source of known spectral energy distribution, and the variation of this emission spectrum with exciting wave length and temperature must be determined. If variation of emission spectrum is neglected, errors of as much as 50% in the resulting quantum efficiency values can occur. (*b*) The excitation spectrum must be measured against that of a phosphor of known excitability, since it is usually highly inconvenient and often impossible to measure the incident exciting intensity directly. The assumption, for example, that the excitability of sodium salicylate is independent of wave length may result in a 20% error (2). In the excitation measurements, the emission of the phosphor must either be measured by means of a photon detector which is independent of wave length, or must be sampled at a chosen wave length and corrected to total photon output by the emission spectrum data of (*a*). Only the second alternative seems to be practical. (c) The reflectance spectrum must be measured against that of a reference sample of known absolute reflectance (3). Neglect of phosphor reflectance altogether can, of course, result in errors of a factor of ten in the quantum efficiency values, while assumptions concerning the reflectance of some standard sample can, at least in the 200-300 nm region, be in error by tens of per cent. Because there is so much labor involved in the correct determination of a spectrum of quantum efficiency, the usual procedure is to neglect many of the above factors with the result that such spectra are so rough as to give only a general idea of the behavior of a phosphor with change of exciting wave length or temperature. The usual excitation spectrum or temperature dependence curve is also a rough approximation for the above reasons. Useful as these approximations may be in the absence of more accurate data, there is the danger of being seriously misled. The objective of this paper is to provide a method of obtaining emission, excitation, reflectance, and quantum efficiency spectra, as exciting wave length and temperature vary, by avoiding the usual assumptions and approximations which introduce sizable errors in the results, and to provide examples of the spectra obtained. These examples constitute, in addition, much new data on the luminescent materials described.

The luminescent materials for which data are included are listed in Table I with approximate raw molar composition and preparation conditions.

Key words: phosphor, luminescence, quantum efficiency, spectrum, excitation, temperature, reflectance, chromaticity, luminosity.

Procedure

Spectral energy distributions.—Equipment.—Adequate precision in the spectral energy distribution (SED) is obtainable if well-known procedures are used with care. Here, two Bausch and Lomb 500-mm 33-86-45-01 grating monochromators were used. High-pressure or medium-pressure (4) mercury lamps, quartz-iodine (5) incandescent lamps, or 1000-w water-cooled Hanovia 771B-32 hydrogen lamps (6) were used; in some cases synthetic quartz (7) lenses were used to fill the entrance aperture of the first monochromator with source radiation. The first monochromator had a 600 groove/mm grating blazed for 150 nm in order to favor transmission around 200 nm wave length. The rejection factor (ratio of transmission in pass band to transmission outside the pass band) of this monochromator was more than 10^4; some trace of mercury line emission other than the excitation wave length nevertheless leaks through and is identified, used as an accurate check on the wave length scale, and then removed from the data to be analyzed. For comparison, a 2-mm thick Corning 9863 filter shows a measured rejection ratio of 22, and a typical metal-dielectric interference filter shows a measured ratio of about 40 in the ultraviolet (254 nm) and about 500 in the visible.

The intermonochromator optics (Fig. 1) provided about a 0.3 magnification on the phosphor sample of the slit image; this results in two favorable effects, intensification of the exciting radiation on the sample (photons/sec-cm^2) and increase of the collecting solid angle of reflected or emitted radiation from the sample into the second monochromator. It will be seen that for optimum throughput the input and output optical arrangement must be symmetrical; *i.e.*, the magnification must be the same, and as great as optical registry problems will allow. Focus and alignment are done arbitrarily at 254 nm; aberrations at other wave lengths are not harmful because calibration is always done by accurate substitution of the appropriate reference sample at the normal sample position.

The total useful range of wave length is 190-850 nm, the short wave length cut-off due to air absorp-

tion and the long wave length cut-off due to reduction in photomultiplier sensitivity. The accessible range of temperature of the phosphor sample is approximately −170° to +300°C, although the upper limit is uncertain, and sample temperature is maintained by helium at 1 atm. The sample can is shown in Fig. 2. The synthetic quartz window between the monochromator space and the sample space is necessary to confine the helium atmosphere to the latter,

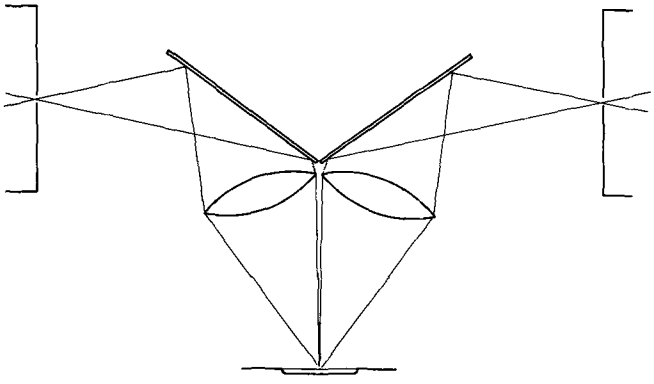

Fig. 1. Optics between the two monochromators showing symmetrical arrangement for incoming and outgoing radiation at the sample position.

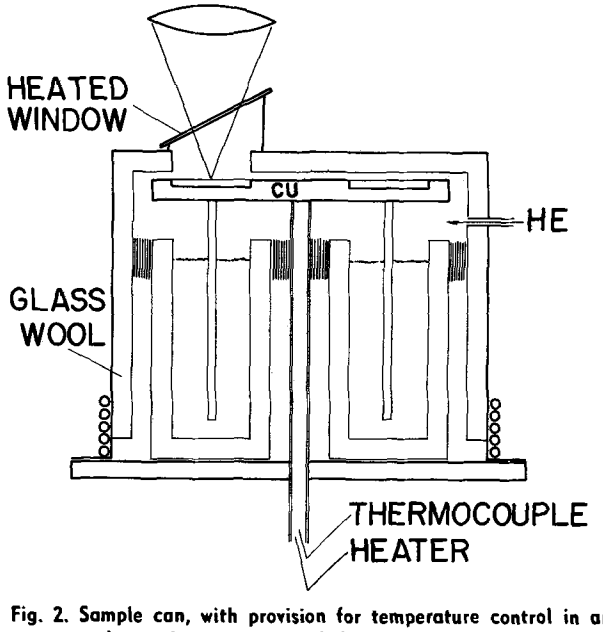

Fig. 2. Sample can, with provision for temperature control in an inert atmosphere, showing sample holder at focus of lens, liquid nitrogen Dewar, copper cooling vanes.

is slightly heated to prevent frosting when the sample is held at low temperature, and is mounted at an angle to avoid reflections from input into output monochromators. The second monochromator is identical to the first except that its grating is blazed for 300 nm radiation. Typical slit width was 2 mm, equivalent to resolution (line width at half maximum) of 6-7 nm. Detector was a 2-in. diameter end-on EMI 9558 photomultiplier (8), of which the sensitivity [amperes output per watt of input radiation per ampere of dark current (9)] is extremely high.

In the work covered by this paper the intention was to use phosphor powder layers so thick that transmission of both exciting and emitted radiation is negligible. The phosphor samples were made by filling bright aluminum dishes, 2 mm deep by 1¼ in. diameter. The transmission of strongly absorbed radiation is certainly nearly zero and for radiation which is only moderately or weakly absorbed the reflectance of the aluminum is about the same as an infinitely thick phosphor layer (≈90%), so the net result must be quite representative of a powder layer which is infinitely thick. With a little practice the top surface of the phosphor in the filled dish can be made visually flawless. The smooth phosphor surface is made by a gentle wiping action with a glass plate, using only light pressure. This method does produce some orientation of the phosphor crystals which can be detected as anisotropy in emission and reflection, as the azimuthal angle is varied and the angle of elevation fixed. The variations, however, are fortunately of the order of 1%. All phosphors and reference materials were sieved through 200 mesh, which did not cause a particle size separation but removed agglomerates.

Calibration.—Accurate calibration of the monochromator-photomultiplier combination requires a radiant source of known emission spectrum which should have the size, shape, and diffuseness of the phosphor samples to be measured subsequently, in order that identical geometry may be used and optical apertures filled in exactly the same way. This ideal situation was achieved as follows. A smoked and bleached MgO sample which had been calibrated accurately for absolute diffuse reflectance (by the partial sphere method mentioned later) was placed in the sample position; the size and shape of this reference sample is the same as that of typical phosphor samples. Radiation from a National Bureau of Standards calibrated quartz iodine incandescent lamp QL-33 (operated at the standard 6.50-amp condition) shone directly onto this reference MgO sample. NBS states that no atmospheric absorption takes place between 250-1100 nm, that 100 hr of operation causes less than 1% variation in output, and that absolute errors in calibration of the incandescent lamp output are less than 8% near 250 nm and less than 3% in the visible and infrared; this does not imply that one

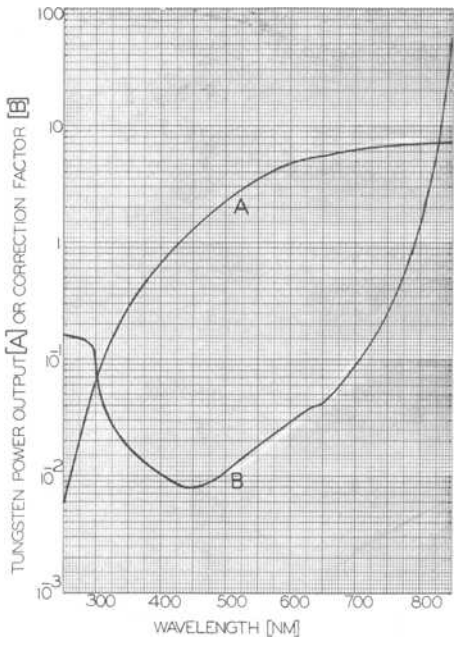

Fig. 3. Power output (A) of standard tungsten lamp per unit area per unit wave length, at a given distance, and correction factor (B) of analyzing monochromator obtained with the standard lamp.

visible region is in error with respect to another by as much as 3%.

The NBS values for the emission of this incandescent lamp (microwatts per square centimeter per nanometer at 43 cm distance) are given in Fig. 3, curve *A*. These values were corrected by the measured absolute reflectance of the MgO sample even though this reflectance varied only between 95 and 97%. The product of these factors was taken to be the radiation intensity entering the optics of the monochromator. The output of the monochromator, scanned through the range 250-850 nm, was used to calculate the final correction curve:

$$\frac{\text{NBS intensity (Reflectance of MgO)}}{\text{(Monochromator Signal)}}$$

shown in Fig. 3, curve *B*, and it is seen that the correction factor becomes as large as 10^4 in the near infrared region, into which the emission of some phosphors extends. The magnitude of this correction factor, even with the excellent S-20 photosurface, together with the requirement of good accuracy in correction over this range, makes the use of a correcting device unallowable, in the writer's opinion. The use of a computer for this step is, on the other hand, satisfactory, particularly since other spectra and integrated quantities in addition to the usual spectral energy distribution are computed at the same time.

Data analysis.—For each combination of exciting wave length and temperature, a recorder trace is used as the baseline, obtained from an inert material of similar reflectance to that of the phosphor sample in the sample position. The oxide or carbonate of magnesium is suitable. This baseline is normally quite flat and gives the signal level due to stray light, photomultiplier noise, and bias settings of the amplifier and recorder. However, it is absolutely indispensable to determine this baseline and to use it as the reference for the desired emission spectrum, rather than to assume that the "zero" level is independent of wave length, since under some conditions there are at least traces of visible components from the source leaking through the first monochromator, as well as second-order effects and peculiarities of grating reflectance. These nonuniformities in the baseline are usually small but often not negligible. From this raw spectrum, data are taken every 10 nm if the spectrum contains only the usual broad emission bands; otherwise the wave length interval is chosen narrow enough to sample adequately whatever structure is in the spectrum. For example, if the SED of zinc silicate:Mn is analyzed both at 2-nm and at 8-nm intervals, computed values of integrated quantities such as chromaticity, total watts, total lumens, *etc.*, vary by ½ to 2 parts per thousand. The computer program makes use of the quadrature formula known as Simpson's Rule (10).

These data are punched into a computer program in which are stored the tristimulus values for spectrum colors (11) and the correction data described in the preceding section. The total computation may be summarized as follows:

Spectral distributions (relative and normalized)
  Energy
  Photons
  Lumens
Total energy E
Total photons Q
Tristimulus values X, Y, Z
Trichromatic coefficients x, y, u, v
Color temperature, mean wave length, luminosity factor (Y/E)

For each phosphor, 30 or more spectral energy distributions were determined, by correction against the NBS standard lamp; five temperatures (—160°C, —60°C, room temperature RT = 25°C, 100°C, 200°C) and six or more pure exciting wave lengths were used. All of the measured spectra are used in determination of other data to be presented. Examples of SED variation with temperature or exciting wave length are given in Fig. 4-11 for "cool white" calcium halophosphate:Sb,Mn, strontium magnesium phosphate:Sn, magnesium fluorogermanate:Mn, and magnesium tungstate; each of these SED's is normalized to constant peak height. Some integrated quantities calculated from the SED which are independent of phosphor efficiency are, for example, chromaticity and luminosity factor. In Fig. 12 and 13 of trichromatic coefficient data, the dashed lines are contours of equal exciting wave length and the solid lines of equal temperature; the arrows indicate dominant wave length (11) in nanometers. Figure 12 shows the peculiar behavior of the chromaticity of the calcium halophosphate phosphors due to different dependence on exciting wave length of the blue antimony band and the yellow manganese band. Figure 13 shows the large chromaticity variation of strontium magnesium phosphate:tin due to the strong dependence of the ratio of violet to orange band output on both temperature and exciting wave length. Figures 14-16 are contour plots,

of luminosity factor Y/E for three phosphors, over the range of excitation wave length in which the material is appreciably excited. These figures demonstrate the importance of such changes in the SED, in that, unless one uses a detector with equal response to photons of all wave lengths, corrections which are both large and accurate must be made for these changes.

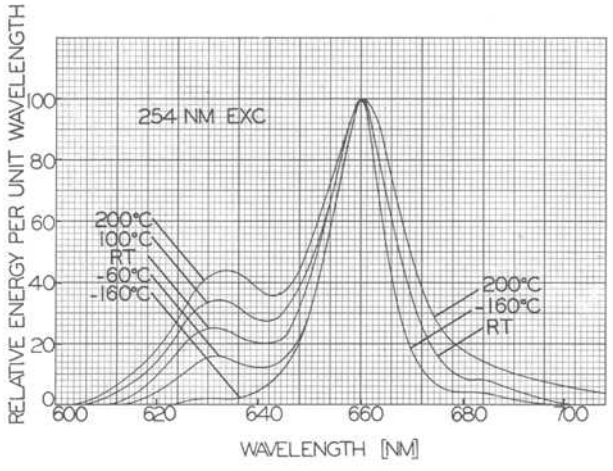

Fig. 8. Spectral energy distributions of magnesium fluorogermanate:Mn phosphor excited at 254 nm and at various temperatures.

It is convenient to define the quantity Q_w as the number of emitted photons within a certain wave length "window" as defined by Fig. 17, in which the total area under the curve is total photons Q. Thus the ratio Q/Q_w is characteristic of the SED of a phosphor at a given combination of exciting wave length and temperature (λ,T) and is used later in the calculation of the quantum efficiency spectra. The window may be specified anywhere on the SED but is usually taken

near one or another emission peak, for maximum signal as will be seen, and then retained as a constant of the phosphor; for example the chosen window wave lengths of the halophosphate phosphors are 480 or 580 nm and that of zinc silicate:Mn is 528 nm. Plots of Q/Q_w as this ratio depends on exciting wave length and temperature appear in Fig. 18 for a bluish white calcium halophosphate phosphor for window wave length of 580 nm, for strontium magnesium phosphate:tin at 600 nm (Fig. 19), and for zinc silicate:Mn (Fig. 20) at a window wave length of 528 nm. In each case the window width is 8 nm at half maximum.

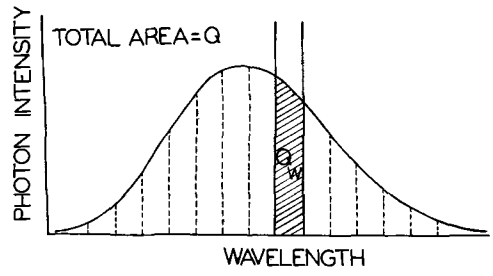

Fig. 17. Definition of the quantity Q_W, the number of photons detected in an interval at "window wave length" W chosen near the peak of a major emission band.

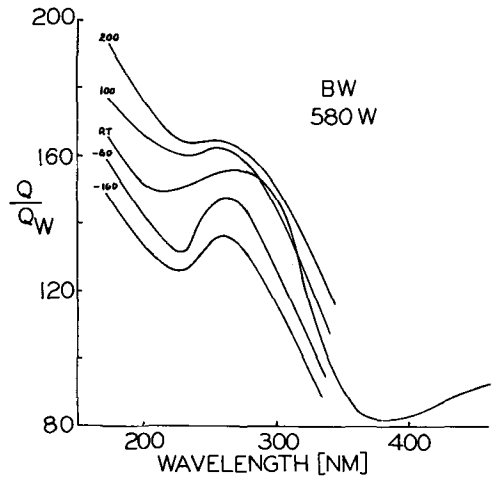

Fig. 18. The variation of Q/Q_W with wave length and temperature for bluish white calcium halophosphate phosphor when the chosen "window wave length" is 580 nm and window width is 8 nm at half maximum. When 480 nm is chosen for this phosphor (near the peak of the blue band) the Q/Q_W curves which result bear a rather inverse relationship to those pictured here. The dependence shown is of course due to the varying excitability of the blue and yellow emission bands, and to shifts in position of these bands.

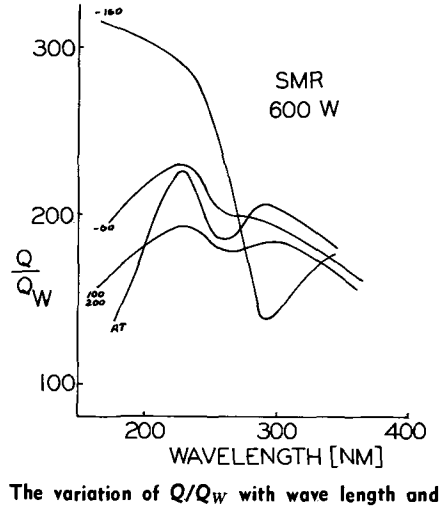

Fig. 19. The variation of Q/Q_W with wave length and temperature for strontium magnesium phosphate:tin. The large variation at —160°C is due to the appearance of the strong violet emission band at low temperature and short-wave excitation.

Excitation spectra.—Equipment.—The equipment described in the preceding section is used also for obtaining excitation spectra. Since phosphors of known excitability were used in the normal sample position as excitation standards, it is necessary neither to determine the transmission of the first monochromator as a function of wave length nor to know the output of the various source lamps *vs.* wave length. The 1000-w hydrogen lamp or the quartz-iodine incandescent lamp

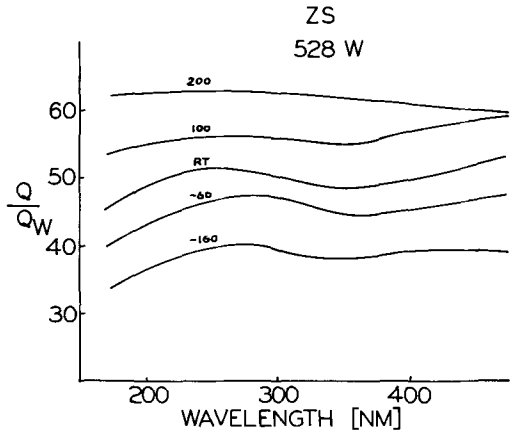

Fig. 20. The variation of Q/Q_W with wave length and temperature for zinc silicate:Mn. The predominant variation with temperature is due to broadening of the single emission band with increasing temperature (the window width, or monochromator resolution which is a function of slit width, remaining constant at 8 nm width at half maximum.

was used in the source position and the first monochromator was scanned over the appropriate wave length range with either the standard or unknown phosphor in sample position. The second monochromator was set at the chosen, constant window wave length W characteristic of each phosphor in turn. The standard phosphor was always measured at room temperature (and remeasured at short intervals) and removed before the unknown phosphor(s) were exposed to other temperatures; it was assumed and verified that the source lamp output and standard phosphor behavior changed very little between calibrations.

Calibration.—A standard phosphor is used so that the visible light emitted by this standard can be simply related to the intensity of ultraviolet radiation incident upon the phosphor. The ideal standard would be a phosphor which emitted some constant number of visible photons for every 100 u.v. photons incident, independent of the wave length of the incident radiation, and of the temperature of the phosphor. No phosphor is known, at present, to have such a "flat" response even over a limited wave length region, although a number of phosphors approach this condition closely enough to be very useful. For accurate work, it is best simply to measure the characteristics of the phosphor which is to be used as the standard, and to correct for the deviations from constant output. Sodium salicylate has been used as the primary standard in the present work, and much use has been made of the University of Rochester data (2, 12) on this material. Kristianpoller and Knapp (2) measured the visible quantum output per ultraviolet quantum incident from 175 to 350 nm; this curve is used in the present work as a correction curve from which to obtain the incident ultraviolet intensity with good accuracy. These authors showed that the quantum efficiency is about 20% higher at liquid nitrogen temperature and that its dependence on wave length at low temperature is very similar to that at room temperature.

Before using the above data for correcting the response of sodium salicylate, it is necessary to make sure that there is no appreciable change in emission spectrum as incident wave length varies from 175 to 350 nm. (If such a change in spectrum occurs, it would mean that the University of Rochester data quoted above would be valid only for their particular phototube; another phototube with a different wave length sensitivity would yield a different correction curve.) Fortunately, it turns out that at room temperature the emission spectrum of sodium salicylate is quite independent of excitation wave length (Fig. 21). At 200°C, however, there is an appreciable shift toward the green. In the present work, this standard phosphor is used only at room temperature where the University

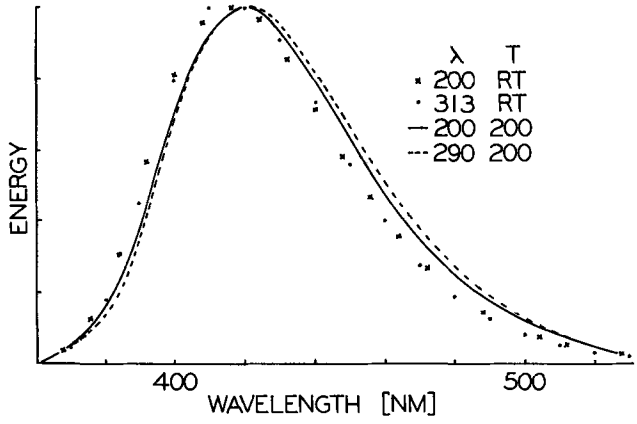

Fig. 21. Spectral energy distributions of sodium salicylate excitation standard, at various exciting wave lengths and temperatures.

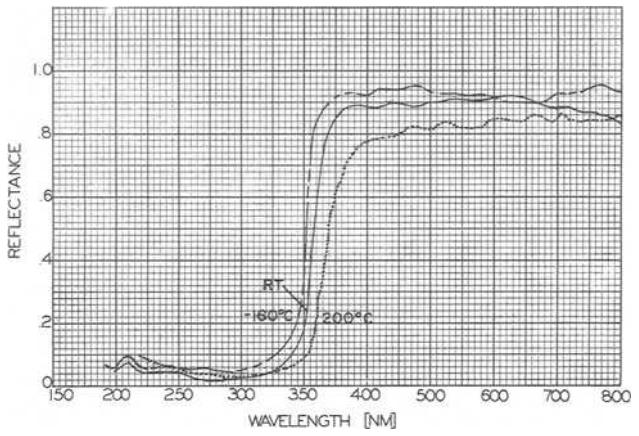

Fig. 22. Absolute diffuse reflectance of sodium salicylate excitation standard, at various exciting wave lengths and temperatures.

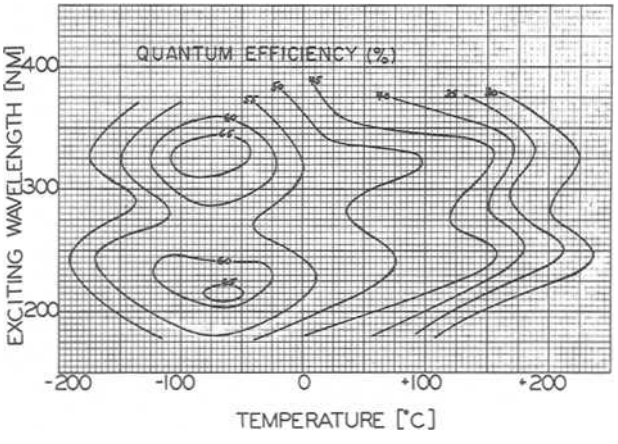

Fig. 23. Quantum efficiency of sodium salicylate excitation standard, at various exciting wave lengths and temperatures.

of Rochester data should be completely applicable. Sodium salicylate emits with good quantum efficiency (12-14) (≈50%, *see* remarks below), is easily deposited (15) on glass slides or directly on the phototube, and is stable in air or vacuum. Allison, Burns, and Tuzzolino (16) find that quantum efficiency values for lots of sodium salicylate from four different suppliers differ by no more than 3% at 254 nm; the implication is that the dependence of quantum efficiency on wave length will be about the same also for samples of different origin. The fluorescent yield of sodium salicylate is stable for long periods of time in dry air or clean vacuum and under 254 nm radiation (17).

There is disagreement concerning the absolute quantum efficiency of sodium salicylate, no doubt due to errors in interpretation of data. In 1964 papers were published which gave the quantum efficiency at room temperature and an exciting wave length of 254 nm as 0.99 (16), 0.50 (13), and 0.25 (18). Nygaard (13) measured the quantum efficiency as a function of layer thickness and obtained a maximum efficiency of 0.50 ± 0.05 at 1-2 mg/cm², defined as visible photons emitted per ultraviolet photon *incident*. Sodium salicylate reflects roughly 5% of the 254 nm radiation, so Nygaard's value defined as quanta emitted per quantum absorbed would be about 0.53. Studer (14) has measured the absolute quantum efficiency under the same conditions and obtained a value of 0.60 + 0.05. Kristianpoller (12) arrives at a value of 0.64. The writer, by comparison to the absolute quantum efficiency of $MgWO_4$ (NBS No. 1027; *see* section on Synthesis of quantum efficiency spectra—Quantum efficiency standard) and to standard calcium halophosphate phosphors,[1] repeatedly obtains a value of about 0.5 for sodium salicylate. It seems that the extreme values quoted above are incorrect, and in any case such a range of values emphasizes the pitfalls in a measurement of absolute quantum efficiency.

As a matter of possible interest, the reflectance and quantum efficiency spectra of sodium salicylate are given in Fig. 22 and 23; procedures for obtaining these are described later.

In some cases the incident ultraviolet intensity may be needed at wave lengths longer than the 350 nm limit to which sodium salicylate may be used. Another organic compound, dihydroxynaphthalazine (DHN), has been measured by the University of Rochester group (19) to have almost constant quantum efficiency between 200 and 470 nm. We have used corrected values for DHN as the excitation standard between 350 and 470 nm, usually in the form of a thick powder layer; it is also easily evaporated and has similar properties in layers equal to or greater in thickness than about 2μ.

Finally, we have used the smoked and bleached MgO reference sample in the sample position, and the calibration of the second monochromator, to determine the intensity of exciting radiation, particularly in the visible, from the quartz iodine lamp.

Data analysis.—When a phosphor exhibits more than one emission band in its spectral energy distribution, the response or excitability of one band (that is, the intensity of emission within the band) generally depends on exciting wave length and temperature in a different manner than that of another band. For example, it is well known that the yellow emission band in halophosphates activated by manganese and antimony is much more strongly excited by near-ultraviolet wave lengths, say 365 nm, than is the blue band in the same phosphor even when the bands are equally excited at shorter wave lengths. Actually, if one chooses two wave lengths present in the same emission band of a given phosphor, emission at one wavelength will in general exhibit a different dependence on exciting wave length and temperature than emission at the other wave length. These two phenomena are of course related to the shifts with exciting wave length and temperature in spectral energy distribution, chromaticity, and luminosity already mentioned. It is sometimes of practical interest to determine the excitability of one emission band relative to another. The method adopted here is to assign a "window wave length" denoted by W to each emission band of interest; W is approximately the wave length of the peak of the emission band at $\lambda = 254$ nm and room temperature. In obtaining the excitation data the detector could "see" only the emission at window wave length W as exciting wave length and temperature were varied. The excitation data are corrected to equal numbers of incident exciting photons and are normalized to unity at 254 nm.

[1] Which, from fluorescent lamp performance, must have a quantum efficiency in the neighborhood of 0.80-0.85.

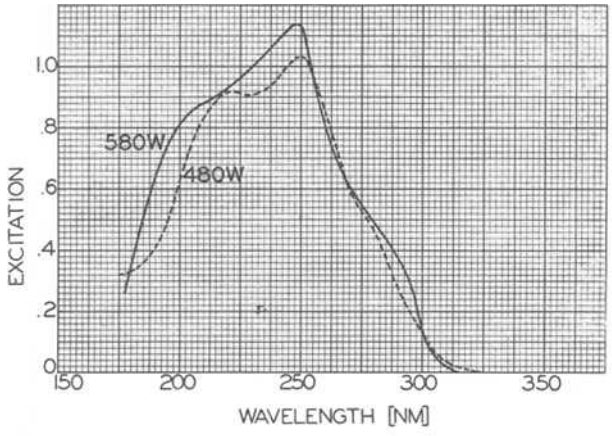

Fig. 24. Excitability of the blue antimony band (480W) and the yellow manganese band (580W) in bluish white calcium halophosphate phosphor at room temperature. Normalized at 254 nm.

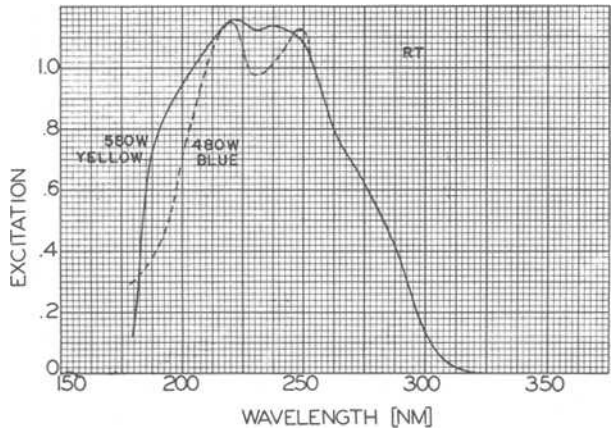

Fig. 25. Excitability of the blue antimony band (480W) and the yellow manganese band (580W) in warm white calcium halophosphate phosphor at room temperature. Normalized at 254 nm.

Figures 24 and 25 show, for example, the excitability of the blue antimony band (480W) and the yellow manganese band (580W) at room temperature in a "bluish white" and a "warm white" calcium halophosphate, and indicate the increased relative excitability at 220 nm of both blue and yellow bands in the latter phosphor with the higher manganese activator content; Fig. 26 shows excitabilities of the former phosphor at more extreme temperatures. Figure 27 demonstrates the different violet and orange band excitability at room temperature in strontium magnesium phosphate:

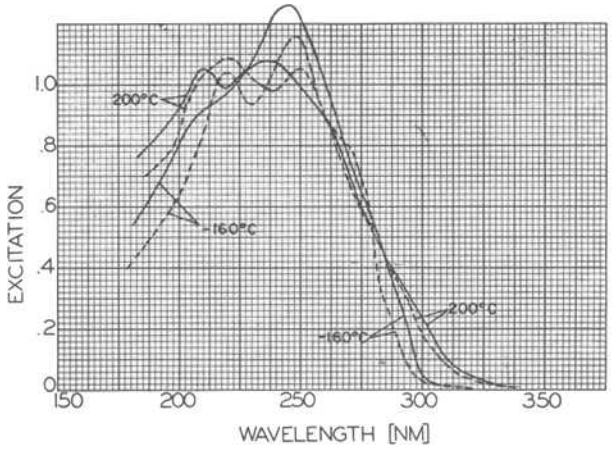

Fig. 26. Excitability of the blue band (dashed curves) and yellow band (solid curves) of the phosphor of Fig. 24 at more extreme temperatures.

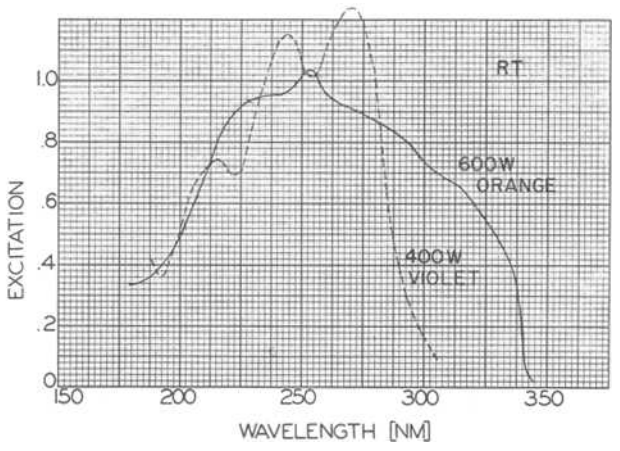

Fig. 27. Excitability of the violet band (400W) and the orange band (600W) in strontium magnesium phosphate:Sn phosphor at room temperature.

tin; Fig. 28 does similarly for calcium silicate:Mn,Pb. In these figures, the ordinate is proportional to Q_w/Q_{INC} where Q_{INC} is the number of photons of wave length λ incident upon the phosphor sample.

Reflectance spectra.—Equipment.—The equipment described in the section on Spectral energy distributions—equipment is used also for obtaining reflectance spectra. A material of known reflectance was used as standard, in the normal sample position. Either the hydrogen lamp or the tungsten lamp was used as source. The wave length drives of the two monochromators were connected and the two scanned together over the appropriate wave length range with either the standard reflecting sample or the unknown phosphor in sample position. The standard reflecting sample was always measured and maintained at room temperature as in the case of the excitation standard.

Calibration.—The reflectance of a layer of phosphor for various wave lengths of incident radiation must be measured absolutely; that is, the actual ratio of total radiation reflected to total radiation incident, ordinarily given in per cent, must be determined. A smoked layer of MgO, which appears to be the best standard known, is quite stable in the visible region of the spectrum, but at wave lengths shorter than 300 nm varies in reflectance depending on the time, wave length, and intensity of radiation to which it is exposed (3). The solution seems to be to form such a layer, bleach it thoroughly with short-wave ultraviolet radiation, measure its reflectance on an absolute basis throughout the spectrum of interest, and immediately compare it to that of a secondary standard of which fresh samples can easily and repro-

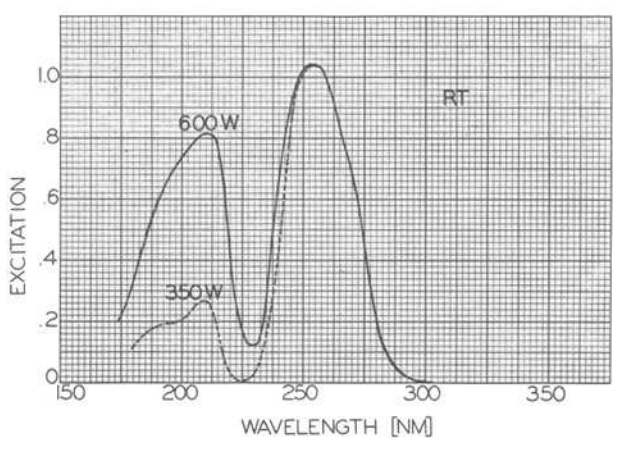

Fig. 28. Excitability of the ultraviolet band (350W) and the orange band (600W) in calcium silicate:Mn,Pb phosphor at room temperature.

ducibly be made. This procedure has been carried out as follows.

The "partial sphere" method (3) is a convenient and very accurate determination of the diffuse reflectance of a layer of material, provided the reflectance of that material at wave lengths of interest is greater than 0.5, and preferably greater than 0.8. On the other hand, the entire inside surface of a sphere must be uniformly covered with an opaque coating of the material of which the reflectance is desired, so it is a technique suitable for calibrating a standard diffuse reflector, but too time consuming and difficult to use for routine determination of reflectance. A section (cap) of about 0.1 of the area is cut out of the sphere but coated in the same way as the remainder of the sphere. The measurement consists of introducing a beam of radiation of the required wave length into a small port in the sphere and measuring the radiation escaping from the same or another port under two conditions: (*a*) with the cap in position, completing the sphere, and (*b*) with the cap removed, and radiation also escaping through the cap area. The ratio of intensities at the exit port with and without the cap in position, together with the dimensions of the sphere, cap, and ports, determines the absolute diffuse reflectance of the sphere coating.

Sections were cut from 500-ml spherical Pyrex boiling flasks, the edges ground, and matched sets of the parts were obtained. A single slot about 8 by 32 mm was cut in the hemisphere at the focus of the slit image from the first monochromator; the same slot served as exit port into the symmetrical optics of the second monochromator. Light-sensitive paper on the sphere surface was used to find the image position. It is necessary that the incoming radiation not strike the cap area. A reversible motor and screw moved the cap in and out of position; in the "out" position only a flat black surface was visible through the cap area from the interior of the sphere. The Pyrex sphere parts were carefully cleaned and aluminized inside, a precaution which almost completely corrects, apparently, for the fact that usable thicknesses of materials are not completely opaque; the highly reflecting aluminum throws transmitted radiation back into the material layer in much the same way as would added thickness of the material to be measured. A number of aluminum disks were mounted flush on the inside surface of the hemisphere, to be removed finally and used as the standard samples. All glass parts were smoked by burning magnesium ribbon (Mallinckrodt, 0.125 x 0.006 in.) in air; the parts were assembled in hemispheres and rotated about an axis roughly 45° to the horizontal, 2 or 3 in. above the burning Mg ribbon, until the MgO coating on the inside of the sphere parts was about 0.5 mm in thickness. The sphere and cap were then mounted in position in the sample can of the double monochromator (Fig. 29).

In the present equipment, the inside sphere diameter with the coating in place was 97.2 mm and the cap diameter was 52.0 mm. The equation (3) relating the ratio of the signal N_0 with the cap off to the signal with the cap on reduces to

$$\frac{N_0}{N} = \frac{1 - R\ (1.0089)}{1 - R\ (1.088)}$$

where R is the absolute diffuse reflectance of the coating. The "sensitivity" of the method, *i.e.* ratio of per cent change in N_0/N to per cent change in R, varies from 10 at $R = 0.95$ to 1.0 at $R = 0.78$ to 0.15 at $R = 0.5$. It is for this reason that the method becomes inaccurate for materials of low reflectance. A calculation showed that the sphere and cap dimensions used resulted in approximately optimum sensitivity. Reflectance measurements were made between 200 and 700 nm, followed by bleaching of the coating by a bare quartz LPMV lamp for different intervals, and remeasurement of reflectance. The results are shown in Fig. 30. Reflectance in the visible was reproducible

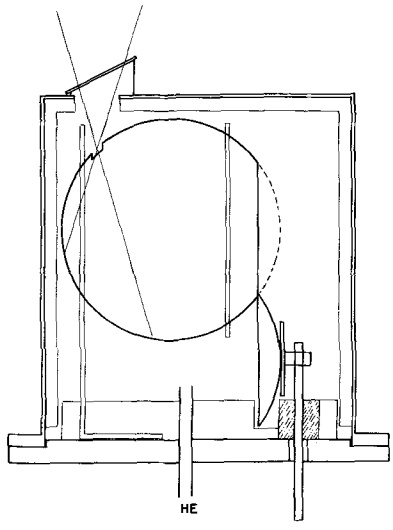

Fig. 29. Assembled attachment for measuring by the "partial sphere" method the absolute reflectance of the inner sphere wall coating; *cf.* Fig. 2.

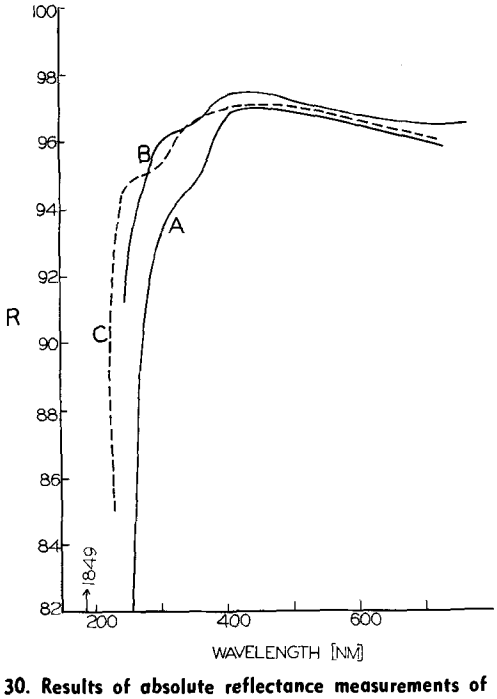

Fig. 30. Results of absolute reflectance measurements of smoked MgO on aluminum. (*A*) As deposited. (*B*) After 115-hr bleach under unfiltered quartz LPMV lamp. (*C*) After 250-hr bleach under same conditions.

to about 0.004. Bleaching increased the reflectance at 254 nm, for example, from 0.82 to 0.95. It appears that reflectance remains relatively low in the region of 200 nm.

The detachable samples were removed from the inside of the sphere wall and immediately used to calibrate the reflectance of samples of fired MgO and of magnesium carbonate block, which were then used as secondary standards. The $MgCO_3$ block (20) was found to have the same reflectance values within 1% as those reported by Taylor (21) in 1931.

Data analysis.—The proportion of radiation reflected from a thick layer of phosphor in per cent of incident radiation is plotted against exciting wave length and temperature. The ordinate in the figures to follow is $r_P R_S / r_S$ where r_P is the signal due to the reflected radiation from the unknown phosphor P, R_S is the absolute reflectance of the standard reflecting sample, and r_S is the signal from this standard sample, all measured at a given wave length λ. Figure 31 for zinc

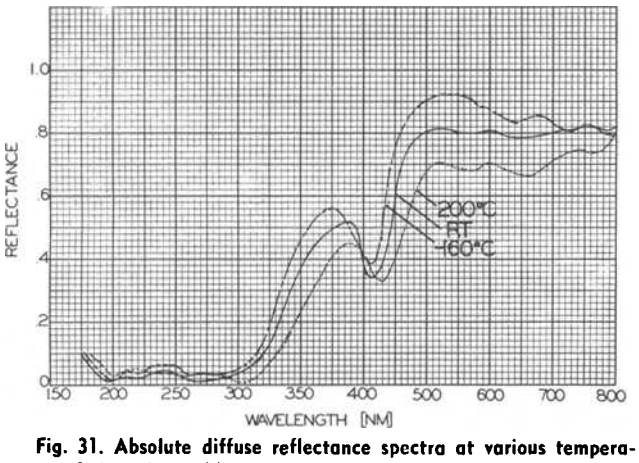

Fig. 31. Absolute diffuse reflectance spectra at various temperatures of zinc silicate:Mn.

silicate:Mn and Fig. 32 for magnesium fluorogermanate:Mn are representative of the results, and Fig. 33 for cool white halophosphate is an example of a contour plot of similar data.

Synthesis of quantum efficiency spectra.—Quantum efficiency standard.—We have not yet in this laboratory attempted measurement of absolute quantum efficiency. The alternative is to choose a value of absolute quantum efficiency from the literature, for a particular phosphor under particular conditions, upon which some reliance can be placed. It is a fortunate circumstance that the National Bureau of Standards has accumulated a number of phosphors in sufficient quantity that they are available for distribution in small lots. Many groups concerning themselves with phosphor comparison now have sets of these standard phosphors in their possession, and thus have common standards to which reference may be made. Bril (22) has made what appear to be careful measurements of the absolute quantum efficiencies of a number of the NBS standard phosphors. Such measurements must specify exciting wave length and temperature, however. To obtain adequate intensity, Bril used a HPMV lamp and filter combination which, rather than constituting a monochromatic source, rendered his spectrum of exciting wave lengths peculiar to his equipment. If a given phosphor shows appreciable difference in excitability by the wave lengths incident upon it, the resulting quantum efficiency value will be ill defined. However, magnesium tungstate (NBS 1027) is about equally well excited by 254 nm and by all the wave lengths present in Bril's measurement (245-280 nm) and for this reason Bril's value of 0.84 ought to be quite reliable and is assumed for reference purposes in this paper.

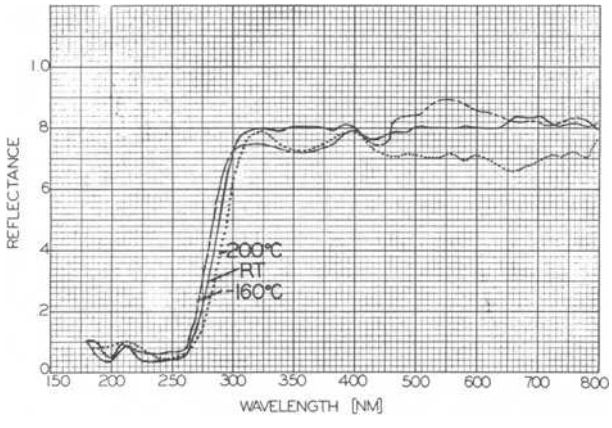

Fig. 32. Absolute diffuse reflectance spectra at various temperatures of magnesium fluorogermanate:Mn.

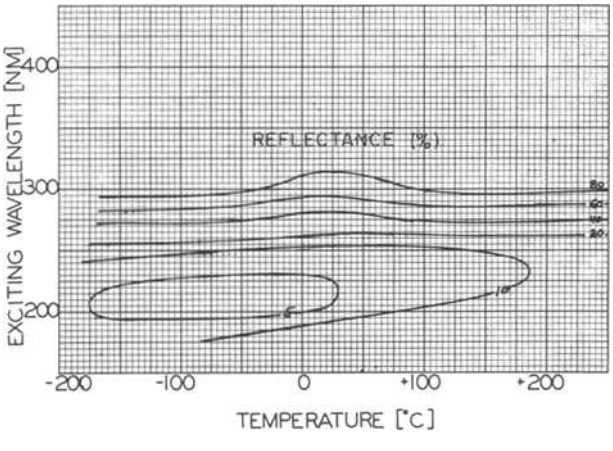

Fig. 33. Contour plot of absolute diffuse reflectance at various wave lengths and temperatures of cool white calcium halophosphate phosphor.

Calculation procedure.—We define quantum efficiency as the total number Q of quanta emitted by the phosphor divided by the total number of (exciting) quanta absorbed by the phosphor Q_{ABS}. We recognize that the number of photons absorbed by the phosphor Q_{ABS} is equal to the number incident Q_{INC} multiplied by the fraction absorbed, which is $(1 - R)$ if R is the fraction reflected and the phosphor layer is thick enough that no transmission occurs. Therefore,

$$QE = \frac{Q}{Q_{\text{INC}}(1-R)} = \frac{Q/Q_W}{(1-R)} \cdot \frac{Q_W}{Q_{\text{INC}}} = \frac{Q/Q_W}{(1-R)} \cdot X \qquad [1]$$

The quantum efficiency of a phosphor thus depends on three measurable quantities: (*a*) the factor Q/Q_W which is a measure of the emission spectrum, and which will change when the spectrum changes; (*b*) the factor Q_W/Q_{INC} which is a measure of the excitability of the phosphor and for which we use the symbol X; (*c*) the diffuse reflectance R. The great difficulty lies in the determination of the excitability Q_W/Q_{INC} since the actual total number of photons, either incident upon the sample or emitted at the window wave length, is extremely difficult to measure. The problem is dealt with as follows. Returning to Eq. [1], and discarding Q_W temporarily, we can write for two phosphors

$$\frac{QE_1}{QE_2} = \frac{Q_1}{Q_2} \frac{Q_{INC_2}(1-R_2)}{Q_{INC_1}(1-R_1)} \qquad [2]$$

For phosphor 2 we use magnesium tungstate (NBS 1027) and Bril's quantum efficiency value of 0.84 for 254 nm excitation at room temperature. We measure Q_1 and Q_2 at the same incident intensity, 254 nm wave length, and room temperature. Then for unknown phosphor P

$$QE_{P,254,T_R} = 0.84 \left(\frac{Q_P}{Q_{1027}} \right)_{254,T_R} \left(\frac{1 - R_{1027,254,T_R}}{1 - R_{P,254,T_R}} \right) \qquad [3]$$

and this is the method used for comparing quantum efficiencies of two phosphors at a given excitation wave length and temperature. The procedure is to measure the emission spectra of the two phosphors under identical conditions (same intensity and wave length λ of incident radiation, same monochromator slit widths, same photomultiplier gain), convert to the photon spectrum, and integrate by computer; this determines Q_P/Q_{1027}. Absolute diffuse reflectances R_P and R_{1027} are also determined, and then the unknown quantum efficiency calculated.

In comparing quantum efficiencies of phosphors at different exciting wave lengths (λ) and/or temperatures (T), one cannot in general hold the incident

intensity constant, or at least it is inconvenient to do so. It is also inconvenient to measure the total quantum output $Q_{P,\lambda,T}$ of the unknown and reference phosphors at each combination of wave length and temperature, primarily because the emission spectrum of the unknown and the standard must be measured under identical conditions, and the total quanta computed. The next logical step is, therefore, to remove these restrictions. First we rewrite Eq. [3] to read

$$QE_{P,254,T_R} = 0.84\left[\frac{(Q/Q_W)'_P}{(Q/Q_W)''_{1027}}\left(\frac{Q_{W_P}}{Q_{W_{1027}}}\right)'''\right]_{254,T_R}\left(\frac{1-R_{1027,254,T_R}}{1-R_{P,254,T_R}}\right) \quad [4]$$

If we assume that emission spectra are independent of intensity, then the three factors in the square brackets may be measured at arbitrary intensities of incident radiation, as indicated by the primes. Second, the ratio of quantum efficiency of unknown phosphor P at arbitrary wave length λ and temperature T to that under the standard conditions is, from Eq. [1],

$$\frac{QE_{P,\lambda,T}}{QE_{P,254,T_R}} = \frac{(Q/Q_W)_{P,\lambda,T}}{(Q/Q_W)_{P,254,T_R}}\,\frac{1-R_{P,254,T_R}}{1-R_{P,\lambda,T}}\,\frac{X_{P,\lambda,T}}{X_{P,254,T_R}} \quad [5]$$

By definition,

$$\frac{X_{P,\lambda,T}}{X_{P,254,T_R}} = \frac{\left(\frac{Q_W}{Q_{INC}}\right)_{P,\lambda,T}}{\left(\frac{Q_W}{Q_{INC}}\right)_{P,254,T_R}} = \left[\frac{\left(\frac{Q_W}{Q_{INC}}\right)_\lambda}{\left(\frac{Q_W}{Q_{INC}}\right)_{254}}\right]_{P,T} \times \left[\frac{\left(\frac{Q_W}{Q_{INC}}\right)_T}{\left(\frac{Q_W}{Q_{INC}}\right)_{T_R}}\right]_{P,254} \quad [6]$$

Since only phosphor P is involved, for which window wave length W is assigned, the raw signal S_W is proportional to Q_W; S_W is the detector output with the second monochromator set at window wavelength W. The last factor in [6], if incident intensity Q_{INC} is held constant, is essentially a normalized temperature dependence factor.

Substituting [6] in [5] and multiplying by [4] results in the final expression

$$QE_{P,\lambda,T} = 0.84\,\frac{\left(\frac{Q}{Q_W}\right)'_{P,\lambda,T}}{\left(\frac{Q}{Q_W}\right)''_{1027,254,T_R}}\left(\frac{Q_{W_P}}{Q_{W_{1027}}}\right)'''_{254,T_R}\left(\frac{1-R_{1027,254,T_R}}{1-R_{P,\lambda,T}}\right)\left[\frac{\left(\frac{S_W}{Q_{INC}}\right)_\lambda}{\left(\frac{S_W}{Q_{INC}}\right)_{254}}\right]_{P,T}\left(\frac{S_{W_T}}{S_{W_{T_R}}}\right)_{P,254} \quad [7]$$

$$a\,\frac{b}{c} \qquad d \qquad \frac{e}{f} \qquad \frac{g}{h} \qquad j \quad [7a]$$

This expression for quantum efficiency makes the experimental work reduce to a series of independent measurements which can be carried out for the most part at arbitrary lamp intensity, arbitrary signal amplification, and in an order which suits the convenience of the experimenter rather than is dictated by the requirement of equivalent conditions.

Factors (a), (c), and (e) in Eq. [7a] are constants of the standard magnesium tungstate phosphor. Factor (d) is the ratio of "photons out the window" for the unknown and standard phosphors, determined once at 254 nm and room temperature by measuring the window signals S_W and correcting them to photons by the same correction factors used by the computer in calculating a photon spectrum. Factors (b), (f), and (g) are the only three factors which vary with λ and T, and correspond of course to the emission, reflectance, and excitability of the unknown phosphor at λ and T. To determine factor (b), a series of emission spectra is measured, ordinarily at the five temperatures −160°, −60°, +25° (T_R), +100°, and +200°C, and at six or seven exciting wave lengths including 200, 230, 254, 280, 313, 365, 405, 436, and 546 nm or others depending on the results of the excitation measurements; Q and Q_W are read off from the computer results and Q/Q_W plotted and smoothed as λ and T vary, as in Fig. 18-20. From this family of curves $(Q/Q_W)_{P,\lambda,T}$ is read off for every 10 nm at each of the five temperatures. Factor (f) is, in the computer program, actually

$$1 - \frac{r_P R_S}{r_S}$$

Q_{INC} in factors (g) and (h) is the raw signal S_W, derived from sodium salicylate, which is multiplied by a correction factor (2) at each wave length. Factor (g/h) is the excitability X of Eq. [1] normalized to that at 254 nm. Factor (j) is the ratio of window output of phosphor P at temperature T to that at room temperature T_R, excited at 254 nm.

The computer program corresponding to Eq. [7] is

$$QE = PT\,\frac{[(Q/Q_W)_{P,\lambda,T}]}{\left(1-\left[\frac{r_P}{r_S}\right]R_S\right)_{P,\lambda,T}}\,\frac{[S_{W_\lambda}]}{ISH} \quad [8]$$

where

$$P = 0.84\,\frac{(Q_{W_P}/Q_{W_{1027}})_{254,T_R}}{(Q/Q_W)_{1027,254,T_R}}\,(1 - R_{1027,254,T_R})$$

a constant which relates the output of phosphor P to that of the standard,

$$T = \left(\frac{S_{W_T}}{S_{W_{T_R}}}\right)_{P,254}$$

a constant for a given temperature,

$$IS = Q_{INC_\lambda}$$

and consists of a deck I of stored data of $S_{W\lambda,T_R}$ for sodium salicylate and a deck S of stored data from Ref. (2) which correct data I to actual incident intensity. Deck I is related to source output and is checked periodically and changed if necessary.

$$H = \left(\frac{S_W}{Q_{INC}}\right)_{P,254,T}$$

and is a normalizing factor comparing all excitabilities to that at 254 nm. The three bracketed quantities in Eq. [8] are fed to the computer at 10-nm intervals over the entire wave length range. Constants P, T, H are fed in on the title card. R_S, I, and S are stored in permanent card decks, I being changed only when the source is changed. The computer readout provides, for every 10-nm wave length interval, the computed value of quantum efficiency, the absolute reflectance, and the normalized excitability.

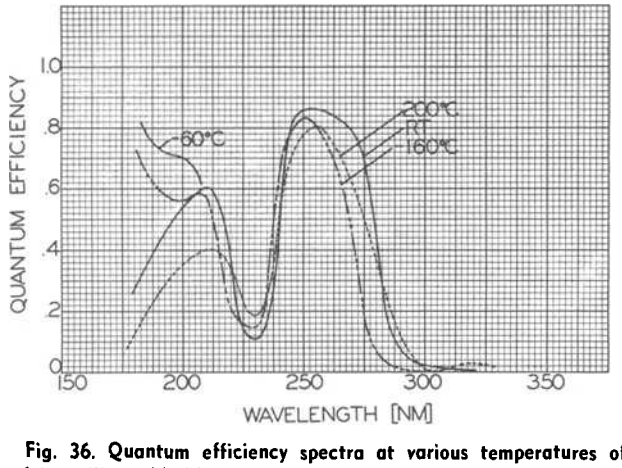

Fig. 36. Quantum efficiency spectra at various temperatures of calcium silicate:Mn,Pb.

Resulting QE spectra.—Figure 34 is an example of the final computed quantum efficiency spectra, for zinc silicate:Mn. Although the *QE* at 350 nm increases strongly near liquid nitrogen temperature, the output of this phosphor will remain low because reflectance (Fig. 31) remains high; obviously this is a case where such complete measurement is necessary in order to understand the phosphor behavior; Fig. 35 shows the same data presented as a contour plot. Figure 36 shows the *QE* spectra of calcium silicate:Mn, Pb and their similarity to the excitation curves of Fig. 28. Figure 37 shows a contour plot which is rather typical of calcium halophosphate:Sb,Mn.

Lumen output.—This calculated quantity represents the relative number of lumens one should expect

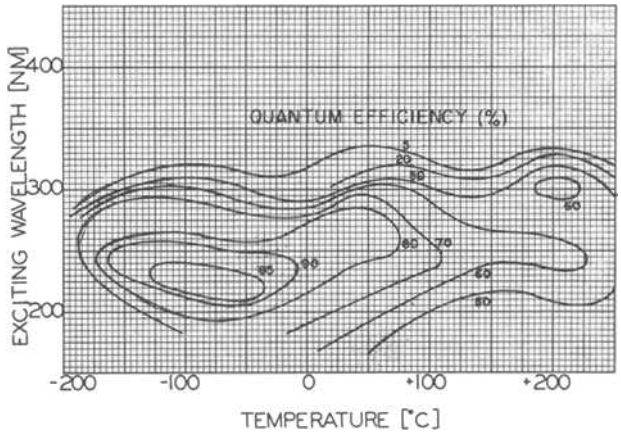

Fig. 37. Contour plot of quantum efficiency as a function of exciting wave length and temperature of white 3500K calcium halophosphate phosphor.

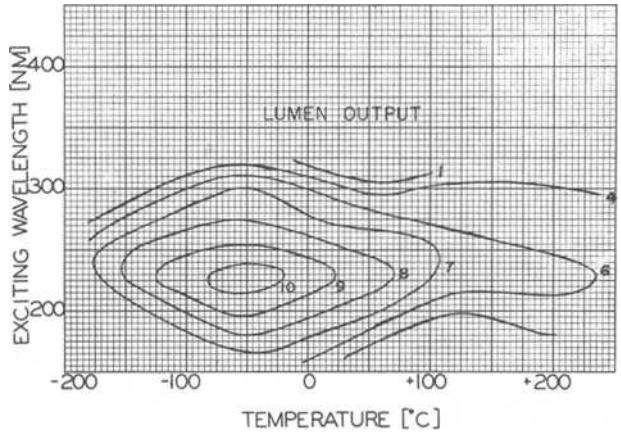

Fig. 38. Lumen output (lumens emitted per exciting photon absorbed) contours *vs.* exciting wave length and temperature, of warm white calcium halophosphate phosphor.

from a lamp made with the given phosphor at optimum coating weight, excited by a discharge generating a certain constant number of (ultraviolet) photons at a single wave length λ, and operating at bulb wall temperature T. "Lumen output" is defined here as (Y/Q) QE, where Y/Q is the ratio of lumens emitted to total photons emitted by the phosphor at λ, T and is derived from the relative quantities Y and Q calculated by the computer for each spectral energy distribution. "Lumen output" is thus simply lumens emitted divided by photons absorbed and is plotted as

equal-lumen-output contours against exciting wave length and temperature. Figure 38 represents warm white halophosphate and Fig. 39 magnesium fluorogermanate: Mn.

Acknowledgments

It is a pleasure to acknowledge the helpful contributions of many associates. Many thanks are due G. R. Hagen for the computer programs and assistance with their use, D. A. Larson for some useful source lamps, J. W. McNall and H. F. Ivey for helpful comment, and especially E. J. Ham, R. J. Mahalik, and W. R. Wheatley for much good assistance.

Manuscript submitted July 23, 1968; revised manuscript received Nov. 7, 1968. This paper was presented at the San Francisco Meeting, May 9-13, 1965, as Paper 38.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Particle Size and Morphology of Zinc Sulfide

II. Thermal Recrystallization Effects

R. A. Brown*

Radio Corporation of America, Electronic Components and Devices, Lancaster, Pennsylvania

ABSTRACT

The action of heat on ZnS:0.015% Ag, 2% sodium chloride flux results in rapid intra-aggregate coalescence, followed by the subsequent growth of the primary zinc sulfide particles. At temperatures between 700° and 1100°C, the rate of growth of the particles during the initial, fast recrystallization follows the empirical equation $D^{4/5} = kt$, where D is the average particle diameter at a firing time t. An Arrhenius activation energy of 13 ± 2 kcal was obtained for this stage of the growth process. An inverse relationship exists between the initial zinc sulfide aggregate size and the particle size of the resultant phosphor. This suggests that the agglomerate structure does not collapse completely during the period of coalescence.

Luminescent zinc sulfide phosphors are usually prepared by firing zinc sulfide precipitate with a suitable activator and flux at moderately high temperatures. Although the mechanism of flux action in initiating thermal recrystallization is not always clearly understood, it is well known that the presence of a flux has a marked influence, not only on luminescent emission (1, 2), but also on crystal structure (3) and particle size (4). Common fluxes employed in zinc sulfide type phosphors include the halogen salts of ammonium, the alkali metals, and the alkaline earth elements.

Leverenz (5) has shown that during firing particle volumes may change by a factor of 10^8. The data of Bube (6) indicate that, in the presence of a flux, a limiting particle size of about 6μ is attained, irrespective of the temperature employed, whereas in the absence of a flux, and at temperatures of 900°-1350°C, the particles continue to grow. Smith (7), following earlier work by Gugel (8), has studied the chemical nature of the flux and has suggested that, since the alkali or alkaline earth halides are liquid at normal firing temperatures, solid solution may occur with the zinc sulfide. Contrast this with the work of Houben (9) who studied the ZnS-NaCl system and found no zinc sulfide in the fused sodium chloride phase. The activator may also be responsible for changes in morphology or crystal structure. For example, Gashurov and Banks (10) have demonstrated that the wurtzite-sphalerite transition in the ZnS:Cu system is initiated by a separate phase of cuprous sulfide.

Recently, Bodi (11) and Bodi and Tufts (12) have attempted to give a more detailed description of the changes in particle size and morphology which occur during the thermal recrystallization of zinc sulfide containing a sodium chloride flux. Bodi (11) found that particle sizes obtained from air sedimentation rates were much larger than those given by gas adsorption measurements. From this he concluded that during the early stages of heating zinc sulfide has a highly porous structure. Electron microscopic studies carried out by Bodi and Tufts (12) supported this observation. On the basis of these results, the latter workers showed that rapid coalescence of intra-aggregate grains occurs within the first few minutes of firing.

* Electrochemical Society Active Member.

A previous paper (13) examined the influence of various preparative conditions on the particle size and habit of zinc sulfide obtained by precipitation methods. Of the parameters studied, pH had a marked effect on particle size. In addition, the size varied inversely with the rate of precipitation. Preparation of the zinc sulfide in strongly acid solution resulted in the formation of aggregates, of the order of 1 to 5μ, which were irregular, globular masses. If the precipitation was carried out in the presence of certain additives, such as ammonium acetate or ammonium formate, irregularly shaped platelets resulted. In all cases, zinc sulfide obtained from strongly acid, neutral, or alkaline solution was precipitated in the sphalerite form, although occasionally a small amount (<2%) of wurtzite was also detected.

The object of the present work was to investigate thermal recrystallization effects in zinc sulfide precipitate. With this object in mind, attempts have been made to: (*a*) obtain a phenomenological description of the changes in morphology and particle size which occur during heating; (*b*) determine what relationship, if any, exists between the initial zinc sulfide particle size and that of the final phosphor; (c) obtain quantitative data on the rate of growth of the particles during the initial stages of recrystallization. Most of this work was carried out with ZnS:0.015% Ag, 2% sodium chloride flux, and 1% sulfur as the starting material. Note that these are weight per cent values.

Experimental

A detailed account of the precipitation of zinc sulfide by the addition of gaseous hydrogen sulfide to an aqueous solution of zinc sulfate has been given elsewhere (13). In order to obtain reproducible results in the firing series, phosphor samples were prepared by a dry-blending process, following the usual procedures. By way of example, a typical experiment involving the firing of zinc sulfide at 700°C is described below.

Test samples of 3.5g of ZnS:0.015% Ag, 2% sodium chloride, containing 1% sulfur, were fired in air at 700°C using 10 cm^3 covered "Vitreosil" crucibles. During the heating, samples were removed at regular intervals of time from periods of 1 min up to 4 hr. Subsequently, specimens were examined by electron microscopy and Coulter counter methods, for the determination of the size and shape of the particles, and by x-ray powder and electron diffraction procedures, to ascertain the crystal structure.

Firings were carried out at temperatures in the range 700°-1100°C. In addition, different "types" of precipitate (for example, zinc sulfide obtained at various rates of precipitation and in the presence of conventional buffering agents) were used as the starting material. For comparison, 3.5g specimens of pure zinc sulfide containing no flux or activator as additives were fired for various lengths of time at 700° and 800°C. It should be pointed out that the thermal effects depend on factors such as the sample size, configuration of the firing vessel, and rate of cooling. Consequently, the results obtained should be regarded as relative.

Results and Discussion

A typical firing sequence at 700°C for a ZnS:0.015% Ag phosphor containing 2% sodium chloride as flux and 1% sulfur is illustrated in Fig. 1. The original precipitate was prepared from 1M zinc sulfate solution at 25°C, using a hydrogen sulfide flow of 0.82 liter/min. Initially, the precipitate is in the form of highly aggregated, globular masses approximately 2μ in size, as shown in Fig. 1 (*a*). After firing for 2.5 min [Fig. 1(*b*)], there is a roughening in the surface texture and some coalescence of adjacent grains has taken place. At 4.5 min [*see* Fig. 1(*c*)], rapid intra-aggregate coalescence occurs, resulting in the formation of many, small particles having a size of the order of 0.2μ. Following this coalescence, the large particles grow at the expense of smaller ones by normal growth processes (14, 15). This is demonstrated in Fig. 1(*d*) to 1 (*h*) which show the gradual assimilation of the zinc sulfide particles during the 4-hr firing period. After 4 hr, the final size attained is approximately 4μ; the particle has lost all traces of the globular form, and instead shows evidence of crystal facets. These results agree with the observation of Bodi and Tufts (12).

A summary of the particle size measurements obtained for the firing series, together with the crystal structure as determined by x-ray powder diffraction methods, is given in Table I. Note that the particle sizes obtained by the Coulter counter procedure differ widely from those given by electron microscopic examination. This confirms the findings of Bodi (11). Apparently, the size given by the Coulter counter represents that of the zinc sulfide aggregates, whereas electron microscopic observation provides the size and shape of the primary zinc sulfide particles which compose the agglomerates. During the early stages of heating, the aggregate size does not change appreciably. In contrast to this, the primary zinc sulfide particles grow very rapidly within an agglomerate.

The data of Table I also show that during the recrystallization an appreciable amount of wurtzite may be formed. Higher firing temperatures made this even more evident. For example, after heating for 10 min the amount of wurtzite present was 14% at 700°C and 27% at 900°C. During the remainder of the 4-hr heating cycle, the quantity of hexagonal phase present gradually diminishes at each of these temperatures.

240	3.3	7.0	14.0				1.4	6	100

NOTE: The Coulter counter values represent the median point by number of particles.

Brown (13) has shown that the initial zinc sulfide precipitate is poorly crystalline and essentially cubic, although it may contain a small amount of wurtzite. Apparently, during the period of coalescence that occurs in the first few minutes of firing, the hexagonal form grows more rapidly than the cubic. However, since sphalerite is the more stable form at temperatures below the transition point of 1020°C (16), the initial rapid crystallization is followed by a slower rearrangement during which the wurtzite present is gradually converted to sphalerite.

Since it was desirable to obtain a more quantitative understanding of the thermal recrystallization processes, an attempt was made to determine whether the rate of increase in particle size at a given temperature would obey the same type of relationship as that observed during grain growth in ceramic systems. For many systems, grain growth is observed to follow the empirical equation (17, 18)

$$D^n = kt$$

where

D = average diameter of the grains
n = a constant
k = the rate constant
t = time

On the basis of this equation, a plot of log D *vs.* log t should be a straight line with a slope of $1/n$. Nicholson (19) has shown that an activation energy for the growth process can be obtained directly from a plot of —log t against 1/T, where T = temperature (°K), for an arbitrarily selected constant D.

Figure 2 shows the relationship between log D and $1/t$ at temperatures of 700°, 900°, and 1100°C. Since the particle sizes were estimated from an electron microscopic examination, the values should, perhaps, be regarded as relative rather than absolute. For comparison, the particle growth observed in the same system by Bodi (11) at 1200°C, determined from surface area measurements, is also given. These results confirm that a linear dependence does, in fact, exist. Since the measured slope of these lines is 5/4, the relationship between average particles size D at a firing time t may be expressed by the empirical equation $D^{4/5} = kt$. A plot to determine the Arrhenius activation energy for the growth processes was derived from the data of Fig. 2, with the use of an arbitrarily chosen constant D of 1μ. From this plot, given as Fig. 3, the activation energy for the thermal recrystallization of zinc sulfide, 2% sodium chloride flux during the initial stage of firing was calculated to be 13 ± 2 kcal. Secco (20) and MacKinnon *et al.* (21) have studied the self-diffusion of ions in polycrystalline zinc sulfide. Although the movement of the zinc ions was found to be the rate-determining step, the results obtained were not straightforward to interpret. An apparent activation energy of 30.5 kcal was derived for a mechanism involving the interstitial diffusion of zinc; for a bulk diffusion model, a value of 61.5 kcal was obtained. A detailed discussion of the activation energy in terms of rate processes and mechanisms is not within the scope of this paper. However, the value of 13 kcal obtained for the recrystallization processes is considerably lower than that of 30.5 kcal calculated for interstitial diffusion, or 61.5 kcal given for self-diffusion of the rate-controlling (zinc) ion. This result could be interpreted in terms of a boundary diffusion model, as suggested by the work of Nicholson (19).

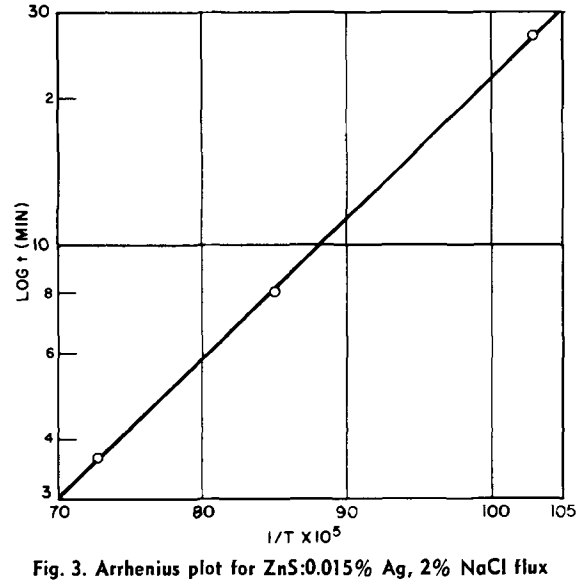

Fig. 3. Arrhenius plot for ZnS:0.015% Ag, 2% NaCl flux

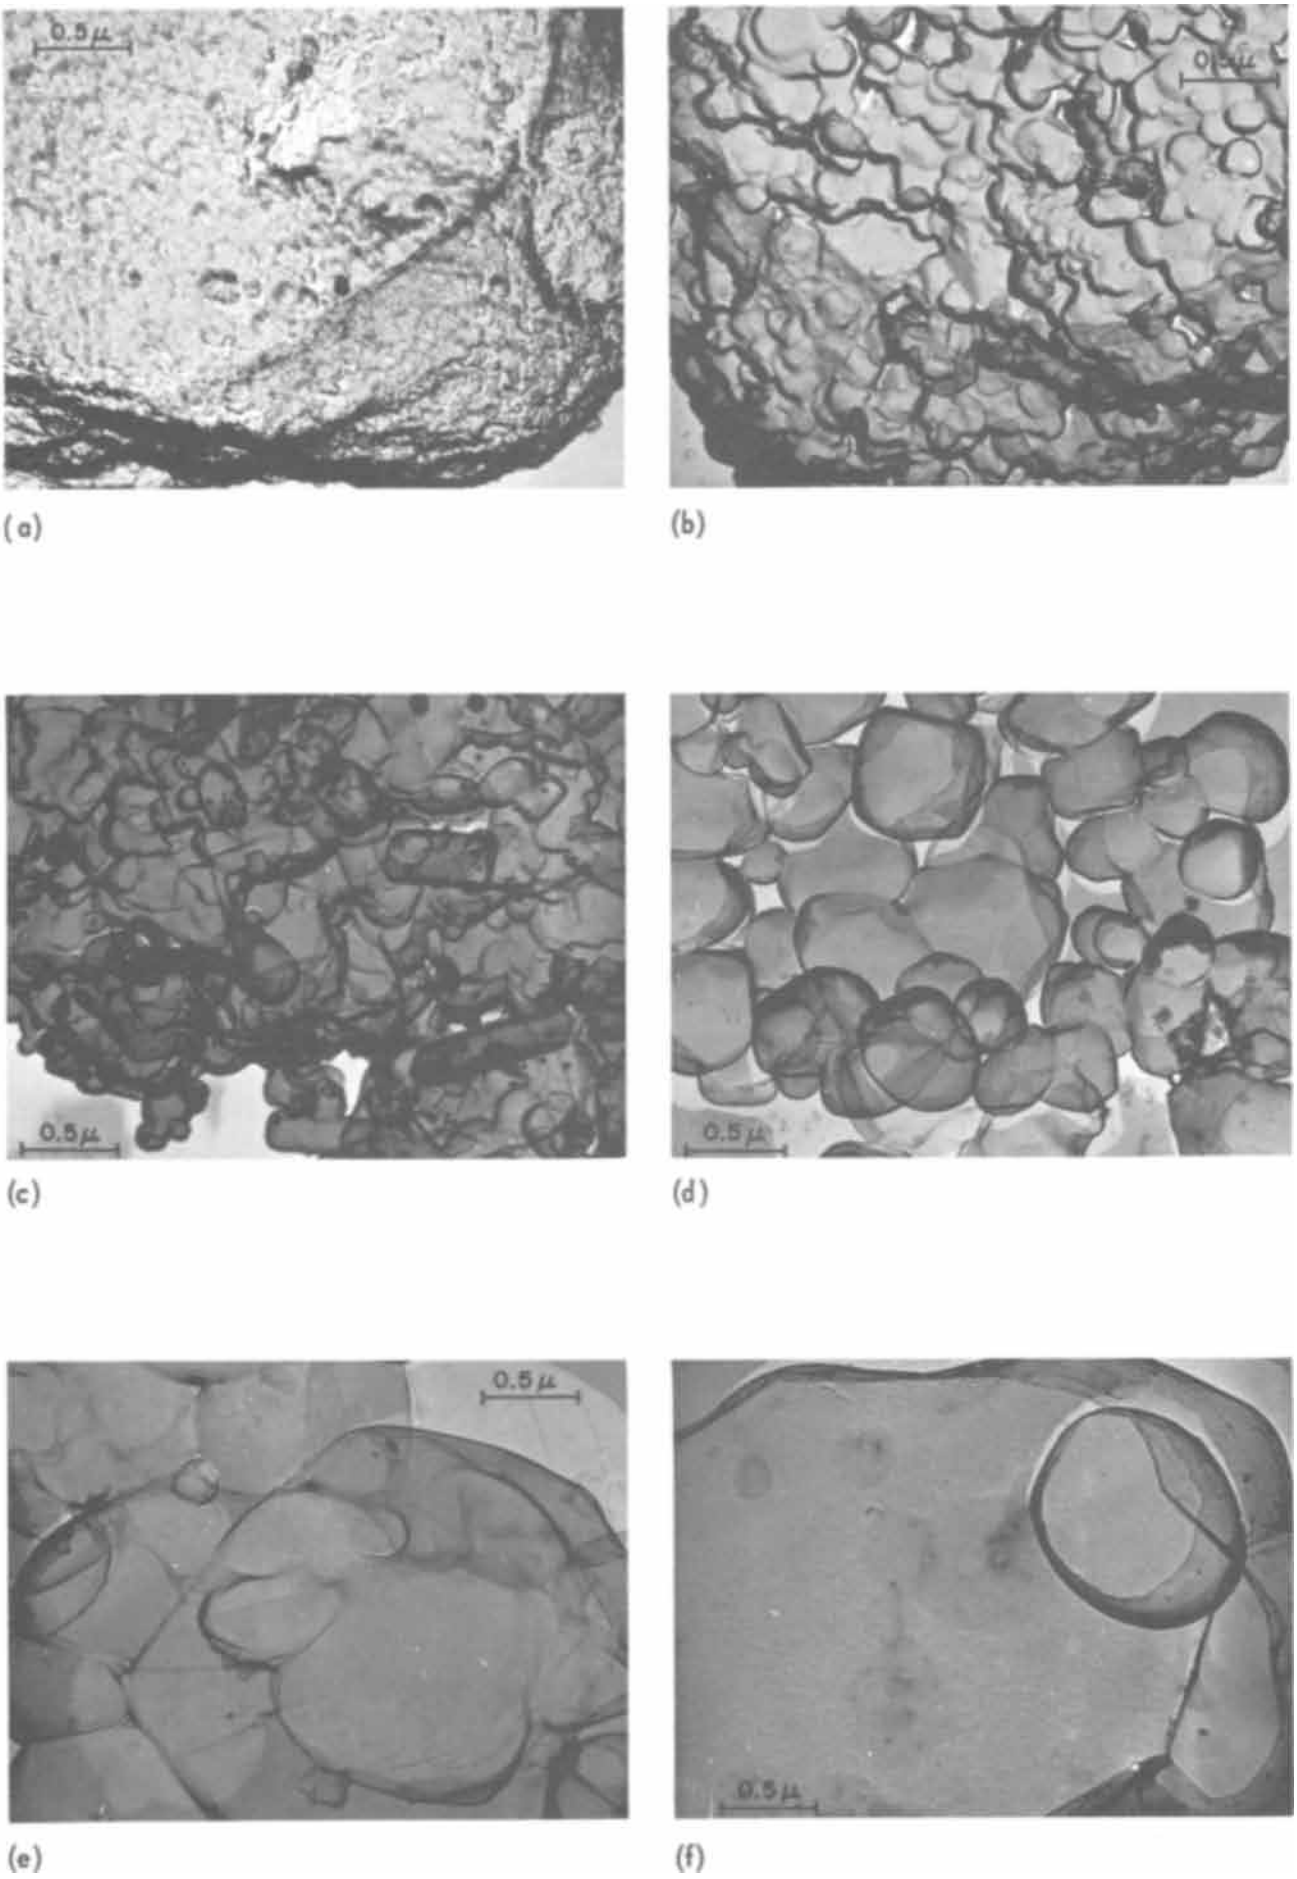

Fig. 4. Firing sequence at 700°C for ZnS:0.015% Ag, 2% NaCl flux: *(a)* 1 min, *(b)* 5 min, *(c)* 10 min, *(d)* 15 min, *(e)* 3 hr, *(f)* 4 hr. Initial ZnS precipitated from $ZnSO_4$-ammonium formate with H_2S.

Figure 4 illustrates a firing sequence at 700°C for a different zinc sulfide powder. In this case, the starting material was precipitated with hydrogen sulfide from a zinc sulfate solution containing an ammonium formate buffer. As such, it would consist of smaller particles with a tendency to aggregate as platelets. In general, the recrystallization follows the same pattern as that noted above, namely intragrain coalescence followed by the growth of the fundamental zinc sulfide particles. The composition of the phosphor is again ZnS:0.015% Ag, 2% sodium chloride flux with 1% sulfur. An interesting type of behavior is demonstrated in Fig. 4(c). A new crystalline phase is observed to form from an apparently amorphous precipitate. Electron diffraction analyses of the two areas showed that they were both hexagonal zinc sulfide, in spite of the fact that the unheated precipitate was essentially cubic. This confirms the observation made above, that during the rapid thermal recrystallization comparatively large amounts of wurtzite may result.

All of the zinc sulfide precipitates examined so far, irrespective of the initial size or morphology of the particles, have follwed this same pattern of recrystallization. Note that this applies only to zinc sulfide containing sodium chloride as a flux. In the absence of additives, pure zinc sulfide showed no noticeable changes, either in particle size and morphology, or in crystal structure, even when heated at temperatures up to 800°C for periods of 2-4 hr.

Another aspect of this work was the determination of any relationship that might exist between the aggregate size of the initial zinc sulfide precipitate and the particle size of the resultant phosphor. Previous work (13) (summarized above) has shown that the size of the zinc sulfide aggregates can be controlled most readily by varying the rate of precipitation. Consequently, zinc sulfide obtained at different precipitating rates was used as the starting material in the preparation of ZnS:0.015% Ag phosphors. A summary of the results obtained is presented as Fig. 5, which shows an inverse relationship between aggregate size of the precipitate and phosphor particle size. Thus, the relatively small zinc sulfide aggregates, such as would be obtained by rapid precipitation, show considerable particle growth on heating [Fig. 5(*b*)]. On the other hand, the larger aggregates prepared at a slow rate of precipitation do not grow to the same extent [Fig. 5(*a*)]. It is well known that fine particles are more "reactive" than coarse ones, owing to their higher surface energy. The behavior of the zinc sulfide precipitates is in accord with this general observation. This finding, together with Coulter counter measurements reported above, suggests that the aggregate structure does not collapse completely during the thermal recrystallization. Apparently, following the intragrain coalescence, the submicron particles are still held together within the framework of the original zinc sulfide agglomerate.

In summary, this work has confirmed that the thermal recrystallization of zinc sulfide, in the presence of a sodium chloride flux, proceeds by coalescence within an aggregate followed by fusion of the primary zinc sulfide particles. During heating, very pronounced changes occur in particle size, morphology, and crystal structure within a period of a few minutes. Contrast this with the fact that, during the preparation of zinc sulfide luminophors, firing times up to several hours in duration are frequently employed. During the early stage of recrystallization, the rate of particle growth can be expressed by an equation similar to that used in describing grain growth in metals or ceramic systems, namely $D^{4/5} = kt$, where the symbols have the meanings given above. In addition, it was shown that there is an inverse dependence between initial aggregate size and the particle size of the resultant phosphor. Consequently, these studies have led to a clearer understanding of the relationship between the physical properties of zinc sulfide precipitate and those of the phosphor, and have shown some of the factors which are important in controlling the particle size of zinc sulfide phosphors.

Diffusion Pipes in Silicon NPN Structures

F. Barson,* M. S. Hess,* and M. M. Roy

Components Division, International Business Machines Corporation, East Fishkill Laboratory, Hopewell Junction, New York

ABSTRACT

Diffusion pipes in silicon NPN structures were investigated both by electrical measurements and by microsectioning. It was found that certain crystalline defects, specifically stacking faults and edge dislocations, can act as sites for the formation of such pipes. The presence of gold doping at these lattice defects greatly increases the incidence of pipes, apparently by offering a path of enhanced diffusivity for phosphorus from the emitter.

"Pipes" in NPN transistor structures may be defined as localized n-type regions extending through the p-type base. They appear electrically as a low resistance path, or near short circuit, between the emitter and collector and can be a significant cause of yield loss in device fabrication. Although these defects have been known for years, little has been reported in the literature as to their cause and cure. Goetzberger and Stephens (1) showed that localized diffusion pipes could result from small bits of impurities, specifically phosphorus, on the wafer surface. Enhanced diffusion along dislocations has also been reported (2, 3), although not actually correlated to pipes in device structures.

The scarcity of references on pipes is perhaps partly due to the fact that their incidence has been minimized by dust control in the diffusion areas, and also by the availability of silicon crystals with relatively few imperfections. However, with the advent of complex integrated circuit fabrication, the perfection of the silicon may be degraded by the increased number of high-temperature epitaxial and diffusion cycles required (4). Also, in most cases, a greater total area of the silicon wafer contains active device structures, which increases the probability of a defect occurring in an area which is susceptible to damage by such defects. Hence, the possibility arises once again that yield loss due to pipes can be quite severe.

In the present work, the effects of various process steps and of certain crystalline defects have been investigated as to their influence on the incidence of diffusion pipes. It has been found that stacking faults and edge dislocations can act as sites for pipes, and that the probability of the occurrence of pipes is greatly increased when the wafers are doped with gold.

Electrical Measurements

During development of a specific integrated circuit, a situation did arise in which yields suffered severely from an incidence of pipes. Electrical tests indicated emitter-to-collector shorts, even though the base widths were not abnormally narrow, and it was sometimes possible to demonstrate the presence of diffusion pipes by microsectioning. The process at that time employed epitaxial silicon wafers, a capsule boron base diffusion process (5), and an open-tube, gaseous source phosphorus emitter diffusion similar to that described by McDonald *et al.* (6). The wafers were gold-doped for lifetime control, and the total emitter area (the area susceptible to pipes) was about 60 sq mils per chip.

Variations in several of the process parameters were made in an attempt to discover a particular operation or operations which caused the large incidence of pipes. The results are shown in Table I. In the "standard" gold process, gold from a metallic film deposited on the back of each wafer was diffused during an 1150°C reoxidation following the boron base diffusion.

Experiment 1 in the table consisted of varying the surface concentration (C_0) of the emitter diffusion. The highest concentration was obtained with a two-zone P_2O_5 diffusion, and the lower ones were done with the usual gaseous source. The phosphorus surface concentrations listed in the table were computed

Table I. Effect of process parameters on junction yield

Experiment No.	Parameter	Variable	No. of wafers	Yield (%) Range	Yield (%) Avg
1	Emitter diffusion (std Au process)	$C_0 = 1.5 \times 10^{20}$ cm^{-3}	6	0-2	0.6
		$C_0 = 6 \times 10^{20}$ cm^{-3}	7	0-1	0
		$C_0 = 3 \times 10^{21}$ cm^{-3}	7	0-4	0.5
2	Boron source powder (std Au process)	"*A*"	7	0-30	7.0
		"*B*"	6	0-30	10.0
		"C"	5	0	0
3	Au *vs.* no Au	Abraded/Au	4	0-2	1
		Etch/Au	4	0-16	4
		Abraded/no Au	5	28-57	42
		No Au	5	5-56	35
4	Au diffusion	970°C Au/post-emitter depn.	5	0	0
		970°C Au/post-emitter reoxn.	5	25-42	35

* Electrochemical Society Active Member.

from the measured junction depths and sheet resistivities by use of Irvin's curves (7). No improvement in yield resulted from changing either the surface concentration or the impurity source. Experiment 2 compared the results of using three separately prepared boron-doped silicon powders as the impurity source for the sealed-capsule base diffusions. The small differences in yield shown in the table probably are not significant, particularly since source "*A*" was used in the previous experiment.

The third experiment involved the gold diffusion process, and wafers with and without gold were compared. An additional variation included chemical etching *vs.* abrasion as a cleaning technique before evaporating gold on the back of the wafers. Here it can be seen that a dramatic increase in yield (*i.e.*, a decrease in pipes) was obtained by omitting gold from the process. The method of surface preparation before gold deposition had little, if any, effect.

Although it improved the junction yield significantly, the omission of gold was not acceptable in this particular process, since lifetime control was necessary. Hence, experiment 4 in Table I was performed to learn whether gold added later in the process might be less harmful. Indeed, it can be seen that, if the gold is added after the final reoxidation (but not before), the yield approximates that of wafers without gold. It should be noted that the gold diffusions in both parts of experiment 4 were done at 970°C. Hence, it is the point in the process, rather than the temperature, at which gold is introduced which is significant in affecting the incidence of pipes. Although the addition of gold as a final process step seems to be an effective cure for pipes, it is a practical one only if the gold diffusion cycle is compatible with the previous diffusions. In Table I, for example, gold was necessarily added at a lower temperature in experiment 4 than in the "standard" gold process. In general, the impurity profiles (base width, *etc.*), as well as the amount of gold doping required, must be considered for any specific design before such a process can be applied.

Microsectioning Studies

In order to study any influence of crystalline defects on the formation of pipes, and also to attempt to get a more quantitative measure of pipe densities, microsectioning techniques were employed. Figure 1 illustrates the use of a conventional bevel section. To examine a large area of the base region, where pipes are visible, a low-angle bevel of about 1° was used. The diffusions were done over a large area, or even over the entire wafer, and were adjusted to produce abnormally wide bases. By such techniques, and by making several microsections across each wafer, a total base area of perhaps a tenth of a square centimeter could be scanned for pipes and counts of pipe densities could be made semiquantitatively. A copper staining technique, which plates out copper on n-type regions, was used to make the pipes and the junctions visible. Incidentally, it is noted that in a bevel section (Fig. 1) a pipe is observed as a small n-type spot in the p-type base region.

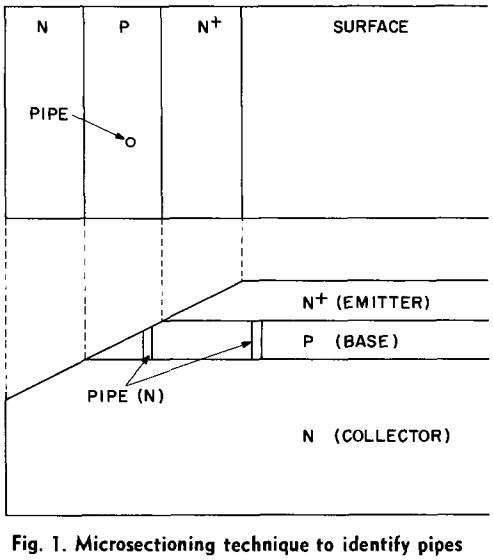

Fig. 1. Microsectioning technique to identify pipes

Table II. Pipe densities for various substrates and gold diffusions

	Nonepitaxial	Epitaxial, low stacking fault count	Epitaxial, high stacking fault count
A. No gold	3×10^3/cm²	0.4×10^3/cm³	7×10^3/cm³
B. Au at 970°C after final reoxidation	0.8×10^3	0.8×10^3	9×10^3
C. Au at 1150°C during postboron reoxidation	8×10^3	5×10^4	$>10^5$

Crystalline Defects as Sites for Pipes

To make a correlation between pipes and crystalline defects, it is advantageous to use wafers with very high defect densities. For example, it was possible to grow epitaxial silicon films with very high stacking fault counts by repeated oxidation and heat cycling of the substrate prior to epitaxial growth. Although this is not a completely reproducible effect, some wafers with over 10^5 stacking faults per square centimeter were obtained for this work.

In addition to wafers with very high stacking fault densities, epitaxial wafers with much greater perfection, and also nonepitaxial wafers, were diffused and microsectioned to investigate pipe densities. Three variations were made with regard to gold doping in this experiment, based on results of the electrical measurements previously made: (*a*) no gold at all was used; (*b*) gold was added at 970°C, following final reoxidation, to minimize pipe formation; and (c) gold was added at 1150°C, before the emitter diffusion, to enhance pipe formation.

Table II lists the resulting pipe densities as determined by microsectioning. It can be seen that these results completely verify the electrical measurements. Gold added after final reoxidation is essentially equivalent to the omission of gold entirely, so far as pipes are concerned. The addition of gold earlier in the process increases the incidence of pipes by approximately an order of magnitude.

Of equal interest is the observation that the epitaxial material with very high stacking fault densities contained many more pipes than did the more perfect material. Good quality epitaxial material appeared equivalent to nonepitaxial material with respect to pipe formation. In the case of highly faulted epitaxial material with gold added prior to emitter diffusion, the density of pipes was found to be on the same order as the stacking fault density, *i.e.* over 10^5/cm². Figure 2 is a photomicrograph of a bevel section illustrating

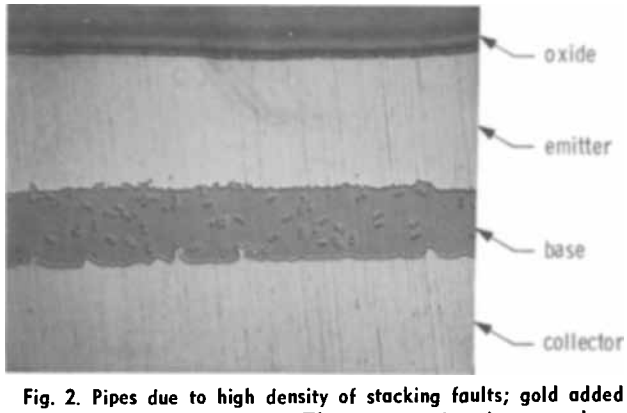

Fig. 2. Pipes due to high density of stacking faults; gold added during boron reoxidation cycle. The apparent junction raggedness is principally due to scratches introduced in lapping. This is aggravated by the low angle of the bevel in microsectioning.

this extremely high incidence of pipes. Since the wafer was (111)-oriented, the appearance of pipes in pairs showing a three-fold symmetry is particularly significant. The appearance of the pipes, plus the statistical correlation with stacking faults, suggests strongly that there may be a one-to-one correspondence of the pipe pairs and stacking faults.

To test this hypothesis, similar structures were produced in which the phosphorus was diffused through an oxide mask having an irregular shape. The corners of this masking pattern could then be used as fiducial marks to locate specific stacking faults prior to microsectioning, as well as the pipes themselves after beveling and staining. Figure 3 illustrates that an almost one-to-one correlation does in fact exist. The location of the base region from Fig. 3(*b*) is indicated on the original wafer surface in Fig. 3(*a*). A comparison of the figures shows the correspondence between the stacking faults, as indicated by the triangular figures on the surface, and the pipes, which appear as small n-type spots in the base region of the microsection. A few exceptions are at the stacking faults lettered *A,B,C* in the figure, which do not have any corresponding pipes. The converse has also been observed in other such studies, *i.e.*, a few pipes which correspond to no visible stacking faults. Thus, in spite of the good correlation, stacking faults alone are neither a completely necessary nor a completely sufficient condition for the formation of pipes.

A significant observation in Fig. 3(*b*) is that pipes occur only under the phosphorus-diffused, or "emitter," region and not in the remainder of the base region. This leads to the conclusion that the pipes are a result of enhanced phosphorus diffusion along the crystalline defects, rather than simply some sort of impurity precipitation at these sites. It may also be noted that the depth to which this diffusion extends is appreciable. In the microsections shown, the emitter depth is slightly over 1μ and the base width is also almost 1μ. In spite of this excessively wide base, some pipes can be seen extending at least this far beyond the emitter diffusion front. It is also interesting that, in nearly all cases, there are pipes at two, rather than at all three, corners of the triangular traces of the stacking faults. Actually, of course, the faulted area is in the shape of an inverted tetrahedron with its apex at the substrate-epitaxy interface. Possibly one face of this tetrahedron is a multiple fault, which would result in a more complex defect along two edges of the tetrahedron than the stair-rod dislocations ordinarily anticipated.

Since in many cases the edges of stacking faults act as sites for pipe formation, it might be expected that edge dislocations extending through the base region would act the same. It is more difficult to demonstrate a one-to-one correspondence here, since it is not easy to locate either pipes or dislocations nondestructively with high precision. By analogy to the results above with stacking faults, however, one might hope to use

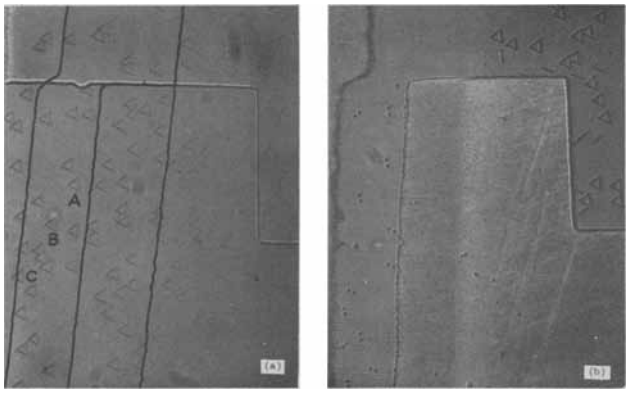

Fig. 3. Correlation of stacking faults and pipes: *(a)* top view showing stacking faults, *(b)* microsection showing pipes.

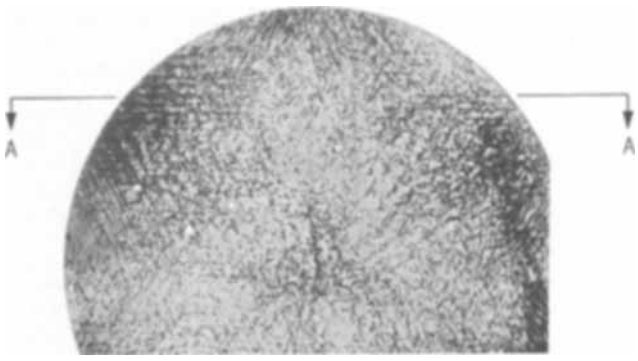

Fig. 4. Topograph of highly dislocated wafer. Microsection location is indicated at *A-A*.

gold-doped wafers with high dislocation counts in order to produce enough pipes that at least a statistical correlation could be found.

Silicon wafers from a crystal grown by the floating-zone technique, and containing a very high dislocation density, were used for this work. The dislocation array in one such wafer is shown in Fig. 4, which is an x-ray transmission topograph made by use of the scanning oscillator technique (8). The wafer is once more (111)-oriented, so that the rows of dislocations run in <110> directions. This wafer was diffused, with gold included, and microsectioned to search for pipes.

In preparing the wafer for microsectioning, it was cleaved, *i.e.* broken precisely along a <110> direction, parallel to the rows of dislocations. The approximate location of the microsection is shown in Fig. 4, with "*A-A*" indicating the cleaved edge. Figure 5 is a photomicrograph of the stained section itself. The arrangement of diffusion pipes in straight rows, following the dislocation array, is quite striking. This plus the fact that the pipe density was highest near the wafer edge, where dislocations were also most dense, is taken as an indication that edge dislocations can indeed act as sites for pipe formation.

Although it is perhaps an obvious point, it should be recalled that these dislocations were grown in the crystal and extend generally from top to bottom of the wafer. Dislocations parallel to the surface, such as might result from high concentration impurity diffusions (9), would not normally extend through the base region and would not be expected to cause pipes.

Summary and Conclusions

It has been demonstrated, both by electrical measurements and by microsectioning techniques, that stacking faults and dislocations can act as sites for diffusion pipes in double-diffused silicon npn structures. The presence of such defects alone is not sufficient to cause pipes; however, the addition of gold doping to the crystal greatly increases the probability of pipe formation at such sites. Since pipes so formed occur only under the emitter, or phosphorus-diffused region, it is concluded that an enhanced diffusion effect is involved rather than simply a precipitation of impurities about the crystalline defects. It seems most likely, however, that a clustering of gold about the

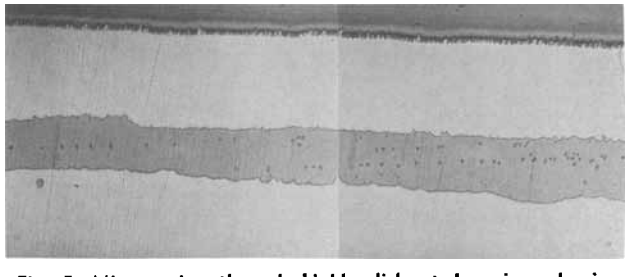

Fig. 5. Microsection through highly dislocated region, showing pipes along <110> direction.

dislocations or stacking faults produces this path of easy diffusion.

Although it has not been demonstrated experimentally, it is tempting to speculate that other fast-diffusing impurities might act in a manner similar to gold in causing these diffusion pipes. Copper, for example, which is known to segregate at crystalline defects (10-12), would seem to be a likely suspect. Thus, the experimental observation that heavily faulted material exhibits an increased incidence of pipes, even without the deliberate addition of gold, may be due to the inadvertent presence of a similar impurity through contamination.

When the use of gold is necessary for lifetime control, its effect in causing pipes can be minimized by adding it at the end of the process, following emitter reoxidation. However, this assumes that the heat cycle for gold diffusion is compatible with the completed device structures. Otherwise, some compromise may be required in the gold diffusion temperature and, hence, in the amount of gold doping used.

Acknowledgments

Electrochemically Controlled Ion Exchange

I. Mechanism

S. Evans,* M. A. Accomazzo,* and J. E. Accomazzo

Rocketdyne, A Division of North American Rockwell Corporation, Canoga Park, California

ABSTRACT

The results of coulometric and mass balance analyses have been used to elucidate the mechanism of this demineralization process. Essentially, undissociated fixed groups (*e.g.*, weak acid or weak base) that are ionized as a result of the electrochemical reactions partake in an ion exchange process. The properties of weak acid and weak base ion exchange resins are incorporated into the electrodes. The simultaneous removal of anions and cations is undertaken in neutral solution. Regeneration of the electrodes is accomplished by polarity reversal.

The exchange of cations at chemically oxidized carbon electrodes that were coupled to Ag-AgCl electrodes has been previously discussed (1,2). Essentially weak acid groups that were present on the surface of the treated carbons were ionized as a result of electrochemical reactions, and took part in an ion exchange process.

The objective of this effort was to investigate the feasibility of electrochemically controlling ion exchange at electrodes that contained commercial weak acid and weak base, ion exchange resins, respectively.

Experimental

The mixtures used for electrode preparation were made by the addition of graphite, Norit, and ion exchange resin to a xylene solution of Kraton binder (Shell Chemical Co.). The cation-responsive mixture consisted of: 20% Kraton, 30% acid-treated Norit (1), 15% graphite, and 35% Amberlite CG-50 (weak acid, ion exchange resin). The anion-responsive mixture consisted of: 20% Kraton, 15% untreated Norit, 15% graphite, and 50% Amberlite CG-4B (weak base, ion exchange resin). Mixtures were painted onto one face of a graphite backing with an artist's paintbrush; the area covered by the mixture was 1.5 cm^2. Generally, five layers were applied; each layer was allowed to dry (about 1 hr) before subsequent painting.

The cell (Fig. 1) was a small glass vial in which the three electrodes were fixed in the positions shown.

[e] Current: 2.0 ma.

The potential at each of the ion-responsive electrodes was detected through a Luggin capillary which contained a silver wire coated with silver chloride. This Ag-AgCl electrode was in contact with the electrolyte (*e.g.*, 1200 ppm NaCl). The electronic instrumentation has been described previously (3).

All of the test solutions were analyzed for sodium with a Beckman DU Spectrophotometer with flame attachment, and were titrated potentiometrically for chloride ion. The solution *pH* was determined with a digital *pH* meter (E. H. Sargent and Co.).

Results and Discussion

Several hundred electrodes were prepared and evaluated. The tabulated results of representative experiments with one pair of electrodes are shown in Table I. Each run involved pipetting 10 cc of 1200 ppm NaCl solution into the vial which contained the electrodes (Fig. 1). After passage of a constant current through the cell, the solution was analyzed for sodium and chloride ions, and the *pH* was determined. The efficiency for each run was determined from the ratio of the measured change in sodium or chloride ion concentration to the change calculated by Faraday's law.

When current was passed such that the polarity of the cation-responsive electrode was negative, sodium and chloride ions were efficiently removed from the solution with little change in *pH* (demineralization cycles, Table I). Sodium and chloride ions were efficiently released to the solution during regeneration. Regeneration was accomplished by reversing the polarity.

Cation-responsive electrode potentials (Fig. 2) recorded during demineralization and regeneration showed some dependence on the sequence of cycles. Regeneration followed by demineralization (Fig. 2, Run 5) occurred at lower potentials than consecutive regeneration cycles (Run 6). Demineralization undertaken after regeneration occurred at lower potentials than consecutive demineralization cycles. This has been discussed previously (1, 2). Similar cyclical dependence was observed at the anion-responsive electrode.

The cell potential (total potential) recorded during demineralization and regeneration is shown in Fig. 3. The cyclical behavior of the individual electrodes is reflected in these curves. Most of the total cell potentials for demineralization and regeneration at 1.0 ma were less than 1.0v (Fig. 3). Increasing the current to 2.0 ma did not result in doubling the potential.

The processes occurring in complete cells are shown in Table II. During demineralization, the electrochemical reactions involve the generation of OH^- and H^+ at the cation- and anion-responsive electrodes, respectively. Demineralization (removal of NaCl) occurs to the extent that the generated OH^- and H^+ are utilized in the ionization of acidic and basic groups, respectively. The reactions occurring at the cation-responsive electrode have been elucidated (1,2) with the results of coulometric experiments wherein the cation-responsive electrode was coupled to an Ag-AgCl electrode (half-cell studies).

The rate of exchange of weak acid groups (or weak base) is dependent on the *pH* within the resin; the *pH* determines the ratio of ionized to un-ionized groups. In the electrochemical process, it is the localized *pH* generated at the electrode interface that

$RCOO^- + Na^+ \rightarrow RCOONa$	Exchange	$RNH_3^+ + Cl^- \rightarrow RNH_3Cl$
	Regeneration	
Cation-responsive-electrode (Anode)		Anion-responsive electrode (Cathode)
$H_{ADS} - e^- \rightarrow H^+$	Electrochemical	$H_2O + e^- \rightarrow H_{ADS} + OH^-$
$RCOONa + H^+ \rightarrow RCOOH + Na^+$	Exchange	$RNH_3Cl + OH^- \rightarrow RNH_3OH + Cl^-$

dictates the ratio of ionized and un-ionized groups. The ion exchange groups are in close proximity to this interface.

The polarity is reversed to achieve regeneration (Table II). The hydrogen which was adsorbed on the cation-responsive electrode during demineralization is oxidized during regeneration, resulting in the formation of a localized high concentration of hydrogen ions; the low pH results in regeneration of the spent form (1). Additionally, water is oxidized; the resulting low pH is favorable to regeneration. At the anion-responsive electrode, the OH^- formed results in a localized high pH that is favorable to regeneration. In accordance with the mechanism presented, there is no change in pH during efficient demineralization or regeneration.

The ion exchange capacities of electrodes have been evaluated chemically (2). During consecutive demineralization experiments, it has been possible electrochemically to achieve about 90% of the chemically determined value. The capacity of the electrodes evaluated was of the order of 2.0×10^{-4} equiv. of NaCl.

The electrochemical process is undertaken in neutral solution; negligible exchange was found to take place chemically at these electrodes in neutral solution. The anion- and cation-responsive electrodes are regenerated simultaneously; chemical regeneration must be undertaken with each electrode individually.

Electrochemically Controlled Ion Exchange

II. Transport Processes

M. A. Accomazzo* and S. Evans*

Rocketdyne, A Division of North American Rockwell Corporation, Canoga Park, California

ABSTRACT

At present, the highest current density that has resulted in the efficient removal of ions is approximately 1.5 ma/cm^2. Chemical ion exchange rates were determined at ion exchange sheets prepared in a manner similar to electrode fabrication. It was concluded that transport through the binder limited the rate of exchange. A simple model was used to predict the critical current density for the process.

The mechanism and feasibility of the electrochemically controlled ion exchange process has been previously discussed (1-3). Essentially, undissociated fixed groups (*e.g.*, weak acid or weak base) that are ionized as a result of the electrochemical reactions partake in an ion exchange process. The properties of weak-acid and weak-base ion exchange resins are incorporated into the electrodes. The anion-responsive electrode (ARE) consists of a weak base ion exchange resin, carbons, and a binder. The cation-responsive electrode (CRE) contains a weak acid ion exchange resin, carbons, and a binder.

During demineralization (ARE is made positive), acid is generated electrochemically at the ARE.

$$H_2O - 2e^- = 2H^+ + O_{ADS} \qquad [1]$$

Key words: electrochemically controlled ion exchange, cation-responsive electrodes, anion-responsive electrodes, anion exchange studies, cation exchange studies, ion exchange kinetics.

* Electrochemical Society Active Member.

The resulting low pH, localized in the vicinity of the weak-base ion exchange resin favors exchange.

$$\frac{RNH_3OH}{resin} + HCl = \frac{RNH_3Cl}{resin} + H_2O \qquad [2]$$

The electrochemical generation of base at the CRE

$$H_2O + e^- = OH^- + H_{ADS} \qquad [3]$$

results in a localized high pH which favors ion exchange at the weak-acid ion exchange resin.

$$\frac{RCOOH}{resin} + NaOH = \frac{RCOONa}{resin} + H_2O \qquad [4]$$

Polarity reversal results in regeneration of the anion and cation resin to the free base and acid form, respectively.

At present, the highest current density that has resulted in the efficient removal of ions is approximately 1.5 ma/cm^2. A current density of 15 ma/cm^2 has been passed between the electrodes, but the resulting current efficiency for ion removal was low. Under these conditions, the acid and base produced at the electrodes was being released to the solution; interaction between acid and base and the ion exchange resins was thus obviated. Hence, at present, it appears that the current density for this process is being limited by the ion exchange kinetics of the electrodes.

Ion Exchange Kinetics

Although theories of ion exchange kinetics are still being developed, a recent paper by Helfferich (4) is helpful in describing the ion exchange kinetics that could be expected at the electrodes.

During demineralization, the ion exchange reactions at the electrodes are given by Eq. [2] and [4]. It has been long known that ion exchange kinetics is controlled by diffusion. Two types of diffusion control are considered; namely, film diffusion and particle diffusion.

Film Diffusion

Film diffusion, which occurs in the solution, is the mechanism by which ions are transported to the ion exchange surface. In the preceding reactions, NaOH and HCl must diffuse to the weak-acid and weak-base resin surfaces, respectively. Film diffusion control is well understood. If an ion exchanger of surface area A is placed in a solution of volume V with an initial concentration C_o, the concentration of the solution, C, as a function of time is given as

$$C = C_o\, e^{-ADt/V\delta} \qquad [5]$$

Particle Diffusion

Particle diffusion is the mechanism by which ions are transported in the resin phase. Particle diffusion in strong-acid and strong-base ion exchangers is very rapid (4). Consequently, at low concentrations the ion exchange process at strong ion exchangers would be under film diffusion control. Weak-acid and weak-base ion exchange kinetics, however, can be many orders of magnitude lower (than strong). This results from the fact that most of the fixed ionogenic groups are undissociated. The concentration of mobile ions is therefore low; this results in slowing the diffusion process greatly. If the solution in contact with the resin can cause ionization (*e.g.*, Eq. [4], weak-acid resin in contact with NaOH), the limiting kinetics are controlled by the particle diffusion of the co-ion, namely OH^-. This is quite an unusual situation in ion exchange kinetics; the rate of ion exchange would be dependent on the solution concentration of the co-ion. Analytical expressions have been developed for the rate of reaction of weak-acid and weak-base ion exchangers (4). For a slab of thickness x_o placed in an infinite volume of solution at concentration C_A^o, the fractional attainment of equilibrium is given by

$$F = \left(\frac{2\,\overline{D}_A\,\overline{C}_A^o\,t}{x_o^2\,\overline{C}} \right)^{1/2} \qquad [6]$$

For a limited volume of solution, V, the surface concentration would decrease with time. This would result in slowing the diffusion rate. Under these conditions, the fractional attainment of equilibrium can be represented by

$$F = \frac{x}{x_o} \qquad [7]$$

where x is related to time by the following expression

$$t = \frac{V^2}{\overline{D}_A\,\overline{C}\,A^2} \left[\overline{C}_A^o \ln \frac{\overline{C}_A^o}{\overline{C}_A^o - A\overline{C}x/V} - \frac{A\overline{C}x}{V} \right] \qquad [8]$$

The expression for time, t, obtained when the logarithm is expanded is

$$t = \frac{\overline{C}x^2}{\overline{C}_A^o\,\overline{D}_A} [1/2 + 1/3\,yx + 1/4\,(yx)^2 + 1/5(yx)^3 + \ldots] \qquad [9]$$

where

$$y = \frac{A}{V}\frac{\overline{C}}{\overline{C}_A^o} \qquad [10]$$

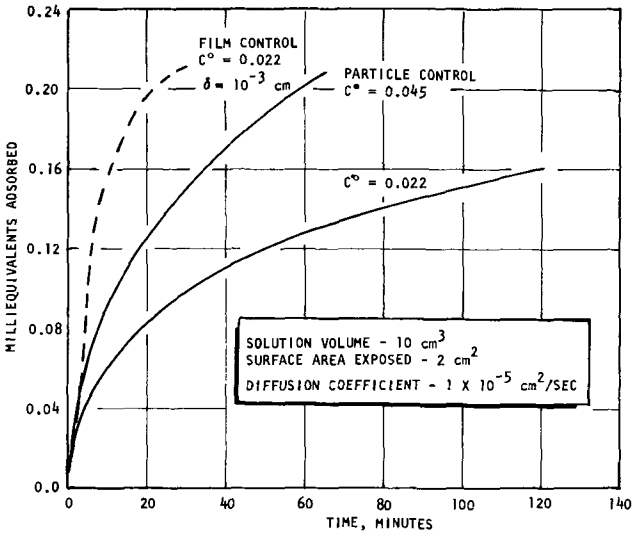

Fig. 1. Theoretical rate of ion exchange assuming particle or film diffusion control.

Figure 1 is a plot of Eq. [9] for two different initial concentrations. The concentrations chosen (C^o) were those described. The capacity value ($\overline{C}$), represents an experimentally determined capacity for the coupons. The best possible diffusion coefficient was assumed. Also shown is the rate of ion uptake for coupons under film diffusion control with adequate agitation.

Experimental

Chemical ion exchange rates were determined at ion exchange sheets prepared in a manner similar to electrode fabrication (3). Ion exchange resin in fine powder form was mixed with a binder (46% Kraton 101, 46% Nujol, 8% Piccotex) that was initially dissolved in xylene. The solution was then poured onto glass and the xylene was allowed to evaporate. The remaining sheet (approximately 1 mm thick) was peeled from the glass and cut into 1 cm squares. The resulting coupons were spent and regenerated before being used in kinetic studies.

Ion uptake as a function of ion exchange resin, solution concentrations, and time was determined by placing the coupon in 10 cc of solution for a given length of time. Depending on the resin used, the solution was analyzed for change in sodium or chloride ion concentration, using a Beckman DU Spectrophotometer with flame attachment or by potentiometric titration, respectively.

Results and Discussion

Weak-base ion exchange.—Coupons containing a weak-base resin in the hydroxide form (Amberlite CG-4B) were studied in 10 cc of HCl test solution (two concentrations). The results presented in Fig. 2 clearly indicate particle diffusion control. In fact, the data closely follow the curves predicted from the theoretical model (Fig. 1).

Similar tests were conducted with the weak-base resin in the chloride form and a test solution of Na_2SO_4 (two concentrations). According to theory, the rate of ion uptake should be under film diffusion control. However, the data in Fig. 2 clearly show particle diffusion control.

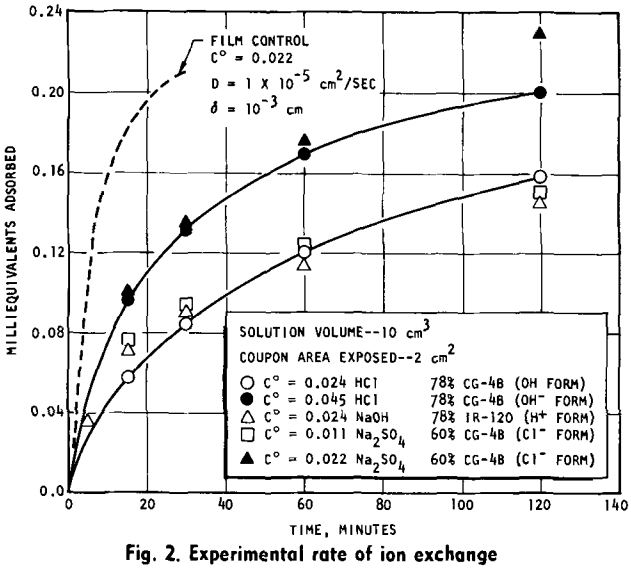

Fig. 2. Experimental rate of ion exchange

Strong-acid ion exchange.—Coupons containing a strong-acid resin in the hydrogen form (Amberlite IR-120) were studied in 10 cc of NaOH test solution. At the concentration used (0.024*N*), the coupons' kinetics should be under film diffusion control. However, again the data shown in Fig. 2 indicate particle diffusion control.

Critical current density.—The results of the chemical rate studies clearly indicate that ion exchange kinetics at sheets prepared in a manner similar to electrode fabrication is severely limited. Apparently, the method of preparation causes the ion exchange particles to be separated or coated by the binder system. Hence, it is the diffusion through the binder which controls the rate of ion uptake. Since the ionic concentration between the particles is low, the diffusion process is slow.

Now consider an electrode (CRE) placed in an NaCl solution (Fig. 3). Inside the electrode, OH^- ions are being produced electrochemically at carbon sites according to Eq. [3]. For 100% demineralization efficiency, based on Faraday's Law, the OH^- ion must be involved in ion exchange by Eq. [4]. This means that current must be carried across the electrode-solution interface solely by the transport of Na^+ and Cl^- ions; if OH^- does aid in current transport across the interface, good efficiencies cannot be obtained. Hence, it is the transport of NaCl inside the electrode that limits the rate of the process because it is at a low concentration (~0.02*N*). However, that portion of the electrode that has been converted to the Na^+ form contains a high concentration (~2*N*) of mobile sodium ions. If the ion exchange resin beads were in contact with each other, this would provide a path for rapid transport of sodium ions. However, the chemical rate studies previously described clearly indicated that the ion exchange particles were separated.

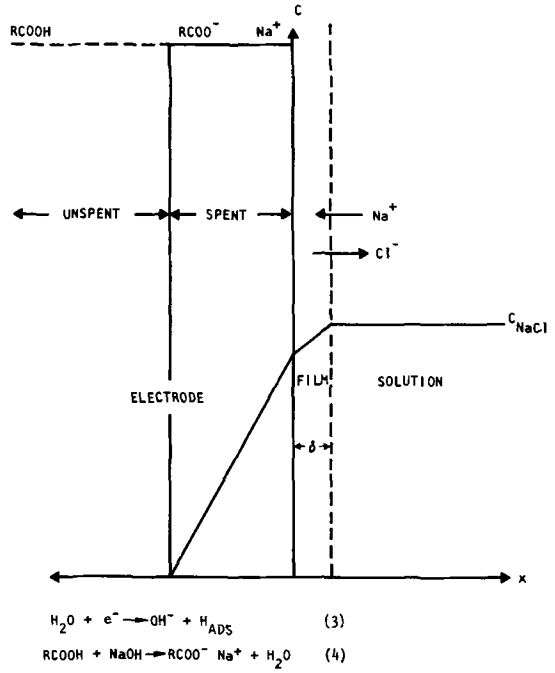

Fig. 3. Concentration profile at cation-responsive electrode

With the above considerations in mind and realizing that the application of a homogeneous model for an electrode is a poor assumption and only a first approach, one can write the usual critical current density expression

$$(I/A)_{crit} = \frac{\mathbf{F}D\bar{C}_s}{x(1-t^*)} \qquad [11]$$

The above equation shows that the critical current density is directly proportional to the surface concentration of the transported ion and inversely proportional to the depth of penetration. For a reasonable depth of 0.25 mm, a transport number of 0.5, a diffusion coefficient of 1 x 10^{-5} cm^2/sec, and a surface concentration of 0.02*N*, one obtains a critical current density of 1.5 ma/cm^2. This is in agreement with previous experimental results (1-3). However, if one could utilize the mobile ions in the ion exchange resin which are at a concentration of approximately 2*N*, one would calculate a critical current density of 150 ma/cm^2. Of course, solution transport would now limit the current density.

Research is now focused on methods of electrode fabrication which will allow rapid transport in the resin phase to occur.

In the past, there has been a fluctuating interest in solid state batteries (1). The interest waned primarily because of lack of any high-conductivity solid electrolyte. A material that was frequently utilized as a solid electrolyte was AgI; the highest specific conductivity reported for compressed powdered AgI was nominally 10^{-4} (ohm-cm)$^{-1}$ at 25°C (2, 3). The compound Ag_3SI was reported to have an ionic conductivity of 10^{-2} (ohm-cm)$^{-1}$ at 25°C (4). Because of the high ionic conductivity of this material, it appeared attractive as a solid state electrolyte, and Takahashi and Yamamoto (5-8) have extensively investigated cells of the type $Ag/Ag_3SI/I_2$.

The present investigation was carried out to determine the feasibility of developing a solid state battery, utilizing the electrolyte Ag_3SI, that could be operated at elevated temperatures. However, the system was found to exhibit a considerable amount of instability at the elevated temperatures. This note reports the degradation of the electrolyte by the cathode according to the reaction

$$I_2(g) + Ag_3SI(s) \rightarrow 3\,AgI(s) + S(s) \qquad [1]$$

Reaction [1] has not been reported in the papers on the $Ag/Ag_3SI/I_2$ solid-electrolyte cell.

Experimental

Reagent-grade or 98% pure materials were used in these experiments. The Ag_3SI was prepared by the combination of AgI and Ag_2S, following Takahashi's procedure (7).

Cells of the type $Ag/Ag_3SI/X$, where X represents the electroactive cathode material, were fabricated in the configuration reported by Takahashi and Yamamoto (7). In addition to I_2 cathodes, a number of other materials, including $CuBr_2$, V_2O_5, S, NiO_2, and MnO_2, were also investigated.

The reactivity of Ag_3SI with I_2 gas was determined by measuring the change in weight of powdered samples of Ag_3SI after these solid samples had been exposed to controlled atmospheres of Ar, equilibrated with I_2 at pressures of 0.18 Torr (65°C) or 8.2 Torr (70°C). The iodine pressures were maintained at the indicated values by having present in the reaction vessel excess solid I_2 at T = 70°C or a mixture of RbI and RbI_3 at T = 65°C. Vapor pressures of I_2 were calculated from literature data (9, 10). A sample of Ag_2S was also run for comparative purposes.

Results and Discussion

Table I shows initial open-circuit voltages observed for the cathode systems investigated. Cell voltages were obtained as a function of temperature for the resultant electrochemical couples. All of the solid state cells underwent an irreversible loss in voltage at elevated temperatures (100°-400°). This property of the cells suggested that the chemical components were not compatible and therefore the stability of the electrolyte to I_2 was investigated.

The results of the weight gain experiments are given in Table II. It was assumed that the weight changes were due to the addition of I_2 to the samples and that no volatile products were formed. All of the samples gained weight, and in an amount consistent with 1 mole of I_2 per mole of solid reactant. The data are in agreement with Eq. [1] for Ag_3SI and with the reaction

$$I_2(g) + Ag_2S(s) \rightarrow 2AgI(s) + S(s) \qquad [2]$$

for the Ag_2S. The powder patterns of the products confirmed that AgI and S were formed and no significant difference (other than relative intensities) was detected in the x-ray patterns of the products of the two reactions.

No thermodynamic data have been reported in the literature for Ag_3SI and, consequently, the free energy change for reaction [1] is not known. However, reaction [2] has a standard free energy change of −22 kcal at 25°C (for solid components). Therefore, unless the reaction

$$AgI + Ag_2S \rightarrow Ag_3SI \qquad [3]$$

has a free energy change more negative than −22 kcal, reaction [1] would be expected to be thermodynamically favored.

The results show that reaction [1] readily occurs. In view of this instability of Ag_3SI in the presence of I_2 vapor, it is necessary to re-evaluate the usefulness of this material as a solid state battery electrolyte, and to reconsider the results of Takahashi's investigations. In the cells that Takahashi fabricated, the iodine was present in the cathode as crystalline I_2 rather than any complex with reduced activity, and the observed cell emf was 675 mv at 20°C, slightly below the calculated $Ag-I_2$ potential of 687 mv. In addition, it was reported that the emf was unchanged by storage of

Table I. Cathodes for the $Ag/Ag_3SI/X$ solid state cells

Cathode (X)	Measured voltages at 25°C[a]
	v

the cells for over 1 yr. This would infer that elemental I_2 is in stable contact with the Ag_3SI electrolyte layer.

Based on the results of the present investigation, it seems unlikely that a cell $Ag/Ag_3SI/I_2$ would be stable unless some means of preventing the I_2-Ag_3SI reaction were in effect. Upon fabrication of the indicated cell, degradation of the Ag_3SI at the electrolyte-cathode interface should occur according to reaction [1]. The product of this degradation is predominately AgI which can function as a Ag^+ conducting solid electrolyte. However, the internal resistance of such a cell should increase as the electrolyte-cathode reaction occurs. If the products of the electrolyte-cathode reaction form in a sufficiently dense layer, impermeable to I_2, then the resulting cell

$$Ag/Ag_3SI/AgI, S/I_2,C$$

could function in the manner observed by Takahashi. The cell is now essentially a

$$Ag/AgI/I_2$$

cell with the electrolyte phase now consisting of a bilayer of Ag_3SI and AgI-S.

An alternate method in which the bilayer electrolyte could be fabricated *in situ* would be to discharge the cell immediately upon its fabrication. The cell reaction product AgI would then form at the electrolyte-cathode interface, without the concurrent formation of the S.

It therefore appears that, although the compound Ag_3SI has a high ionic conductivity, its application to solid electrolyte cells involving the combination

$$Ag + \tfrac{1}{2} I_2 \rightarrow AgI$$

is quite limited. In this type of cell, the effective electrolyte must be AgI rather than Ag_3SI. Lower emf cells such as

$$Ag/Ag_3SI/S$$

would be thermodynamically stable. However, they would have the disadvantages of low emf, low power density, and possibly kinetic restrictions in the current densities that could be attained.

Acknowledgments

The authors wish to thank Drs. James E. Oxley, Leo E. Topol, and Samuel Yosim for helpful discussions during the course of this investigation.

Improved Methods for Deposition of Thin-Film Zn_2SiO_4:Mn Phosphors

George M. di Giacomo

Westinghouse Defense and Space Center, Aerospace Division, Baltimore, Maryland

In this paper, two methods are described for the deposition of Zn_2SiO_4:Mn in a polycrystalline thin-film form: (*a*) vapor phase reaction; (*b*) vacuum evaporation. Vapor phase reaction is a chemical process in which the reactant is transported as a compound to the sample surface. The resultant product is then obtained by thermal decomposition and hydrogen reduction by maintaining the sample surface at a higher temperature than the source of reactant vapors (1).

In the vapor reaction process, the halides of the constituent materials were used to form zinc orthosilicate by the following reaction:

$$SiCl_4 + 2\,ZnCl_2 + 4\,CO_2 + 4\,H_2 = Zn_2SiO_4 + 8\,HCl + 4\,CO$$

Manganese was added in the form of $MnCl_2$ as a dopant.

A metered flow of 50 cc/min CO_2 and 40 cc/min H_2 was bubbled through a room-temperature bath of $SiCl_4$. The evaporation rate of $SiCl_4$ was controlled by diverting some of this gas flow around the liquid. The small part of the gas bubbled through the $SiCl_4$ bath carried 1-2 ml of liquid into the reaction.

Mixing with the solid constituents and the deposition took place in a two-zone reaction furnace lined with a quartz tube. The solid constituents, 3g $ZnCl_2$ and 0.1g $MnCl_2$, were placed in a crucible in the first zone, the mixing zone. These solids were vaporized by heating this zone at 550°-600°C. An orifice at the end of this zone caused turbulence in the flow and resulted in mixing of constituents before they entered the reaction zone.

In the reaction zone, the substrates were held on a large flat quartz plate to insure even heat distribution. This section was heated to 1100°-1200°C. By-product gases were exhausted.

The substrates used were quartz, sapphire, and silicon wafers with an oxide thickness of 1μ.

The second method of depositing $ZnSiO_4$:Mn phosphor material in a thin-film form involves the vacuum evaporation technique developed by Feldman (2). This is a two-step process. First, a commercial Zn_2SiO_4:Mn phosphor is evaporated onto a substrate. During the evaporation, the phosphor decomposes into its more stable molecular components and condenses on the substrate as a film composed of a mixture of these materials. The second step then involves the recombination of these components into the crystalline phosphor on the substrate by firing the layer in air. The problem encountered using this method was that it was difficult to cover a given substrate with an even film. It seemed to be a matter of chance whether a smooth, even film condensed as various cleaning techniques and substrate conditions were used. In order to increase the

affinity between the evaporated material and the substrate, a seeding technique was developed. The substrate was first coated with a film of ZnO of about 200-300Å thickness. The method used to deposit the ZnO was first to "nucleate" the substrate with a few seconds' exposure to evaporating Ag. Over this, metallic zinc was evaporated to a thickness of about 200-300Å. The seeding with silver promotes a smooth, even film of Zn. The Zn-coated substrate was then removed from the vacuum and placed in an air or O_2 atmosphere furnace at 200°C in order to oxidize the Zn film completely. After the process, the conventional evaporation and baking process described by Feldman (2) was used to develop the zinc orthosilicate film.

Films resulting from both these techniques luminesced green under 2537Å u.v. and glow discharge bombardment excitation. When compared to powder Zn_2SiO_4:Mn excited by the same technique, the best films were from ¼ to ½ as bright as the powder. The thicknesses of the layers were from 0.2 to 0.5μ. Thicker films could have been deposited. The quality of the film varied from foggy to clear. The best clear films were highly transparent (est 75%) but not as bright as some of the foggy films.

The advantage of using the vapor deposition technique was that the film could be deposited on different substrate shapes such as a cylinder of curved surface. This technique could also be used where a vacuum chamber is not available. The advantage of the vacuum evaporation techniques was that a smooth, even film of this difficult-to-deposit material was condensed with much greater regularity.

Dependence of the Composition of the Anodic Layer on the Oxidation Potential of Lead in Sulfuric Acid

D. Pavlov, C. N. Poulieff, E. Klaja, and N. Iordanov

Institute of Physical Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

ABSTRACT

Potentiostatic oxidations of lead in 1*N* H_2SO_4 were performed in the potential range between −900 and +1400 mv (with respect to the mercury/mercury sulfate electrode). The anodic layer was subjected to x-ray diffraction and chemical analysis. According to the phases present three potential ranges are discerned. From −956 to about −300 mv only $PbSO_4$ is present. From −300 to +900 mv large amounts of $PbSO_4$ and PbO-tet are formed, as well as small amounts of $PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, $5PbO \cdot 2H_2O$ or PbO orthorhombic and α-PbO_2. Above +900 mv the divalent lead compound content decreases, while that of α-PbO_2 rapidly increases. Above +1200 mv β-PbO_2 is formed.

Many of the processes taking place during anodic oxidation of lead in sulfuric acid can be elucidated by identifying the compounds which constitute the anodic layer.

X-ray and electron diffraction methods (1-4) as well as electrochemical techniques (5-9) have been used for the identification of the phases occurring in the anodic layer. In the potential range between the equilibrium potentials of the $Pb/PbSO_4$ and $PbSO_4/PbO_2$ electrodes diffraction lines of tetragonal PbO were found by Lander (1) and Burbank (2). Lander explained the formation of this compound in terms of solid-state reactions between lead and lead dioxide. Later, Rüetschi and Cahan (3) found lines of α-PbO_2 in the anodic layer. The coincidence of diagnostic diffraction lines of alpha lead dioxide with those of tetragonal lead oxide caused some workers to deny the formation of tetragonal lead oxide (3, 7).

If diffraction methods alone are used the identification of the individual phases is ambiguous owing to the overlapping of numerous diagnostic reflections, brought about by close similarities in the crystal structures of the various lead oxides and hydroxides.

In two previous papers (8, 9) one of us studied the behavior of the $Pb/PbSO_4$ electrode in H_2SO_4 upon anodic polarization. It was established that it behaves first as a lead sulfate electrode, then, over a large interval, as a lead oxide one, and, lastly, at very high polarizations, as a lead dioxide electrode. However, the potentiometric identification of the compounds formed (8, 9) is also somewhat uncertain because of the very close values of the equilibrium potentials of lead oxides, hydroxides, and basic sulfates. Furthermore, not every compound present in the anodic layer is potential determining at open circuit.

These difficulties in the identification of the phases of the anodic layer inherent in the diffraction and electrochemical methods led to differences in the model of the structure of the anodic layer (4, 6).

The purpose of the present paper is to study the changes in the phase composition of the anodic layer at different oxidation potentials of the lead electrode in H_2SO_4. In the present investigation the x-ray analysis and electrochemical techniques were supplemented by appropriate chemical determinations which make it possible to eliminate the ambiguities resulting from the limitations of these techniques.

Results and Discussion

Electrochemical measurements.—High-purity 99.9999% lead electrodes with dimensions 16 x 11 x 1 mm were subjected to oxidation in electrolytically purified, analytical-grade 1*N* H_2SO_4. The oxidation was performed by means of an electronic potentiostat in the cell described in previous works (8, 9). The mercury/mercury sulfate electrode was used as reference. All potentials are given with respect to this electrode. Between −900 and +900 mv the oxidation was carried out during 72 hr, while above +900 mv the oxidation time was only 24 hr. After each oxidation run the quantity of electricity was determined graphically from the i/t curves. Figure 1 gives the calculated quantities of electricity at the various potentials. The steep rise of the curve above +1300 mv must be ascribed to oxygen evolution reaction proceeding parallel to the oxidation of the metal.

The potential change of the electrode was recorded during several minutes after the interruption of the polarization in order to study the electrochemical behavior of the anodic deposit. The results of these measurements are shown in Fig. 2. The equilibrium potentials of the tetragonal lead oxide (PbO-tet) and normal lead sulfate electrodes in 1*N* H_2SO_4 are also shown in the figure. Three regions of behavior can be discerned on the potential/time curves: lead sulfate, lead oxide, and lead dioxide (8, 9).

X-ray diffraction studies.—After performing the electrochemical measurements the electrodes were washed, dried, and introduced in the sample holder of the Müller-Mikro 111 diffractometer. The diffraction patterns were recorded with filtered copper radiation and the following goniometer settings: goniometer speed $2°2\theta$/min, and slits 1°/1°/0.1 mm. The intensity of the strongest line of each pattern was taken as 100. The diffractometer traces were measured down to $d = 1.60$Å.

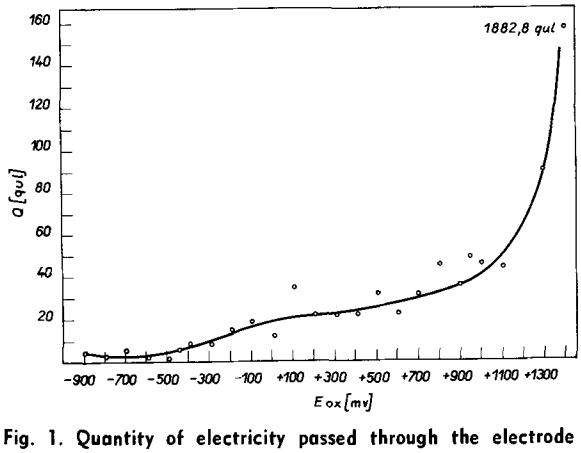

Fig. 1. Quantity of electricity passed through the electrode at different oxidation potentials.

Key words: x-ray diffraction, lead oxide, lead sulfate, anodic oxidation of lead.

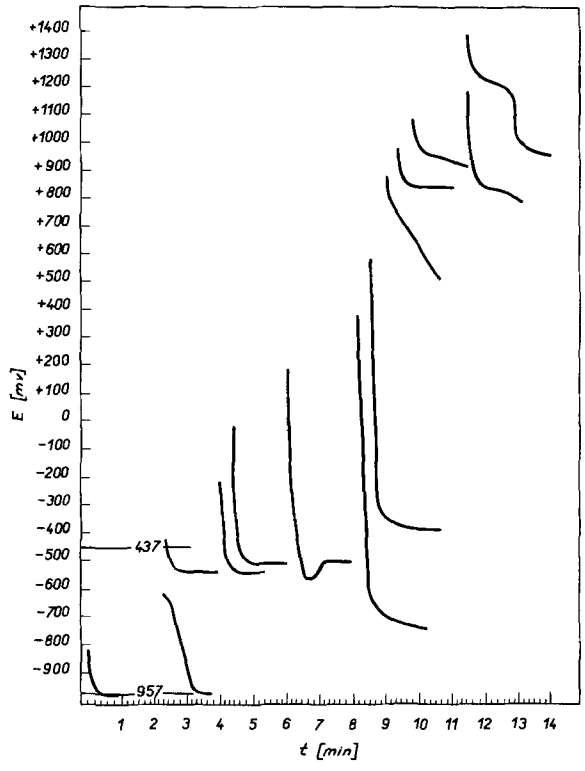

Fig. 2. Change of the electrode potentials with time on open circuit: E = —437 mv, PbO-tet/Pb; E = —957 mv, $PbSO_4$/Pb.

The following method was adopted in order to insure an unambiguous assignment of each diffraction line. For each diffraction line the dependence of the relative intensity (I) of each reflection was plotted against the oxidation potential (E); that is, it was referred to a non-x-ray parameter. Thus each diffraction line was assigned to a particular compound both on the basis of its interplanar spacing and of the shape of its I/E curve. The diffraction lines were then separated into groups having an identical or closely resembling shape of the I/E curves over the whole potential range. This was done under the assumption that normally the relationships between the intensities of the diffraction lines of the various compounds are preserved in mixtures. Therefore, the resemblance in the curve I/E should indicate that they belong to the same compound. Differences in the I/E curve of a given reflection can be due either to texture effects or to coincidences with reflections belonging to other compounds. The appearance of new lines in the x-ray diffraction patterns or a drastic change in the I/E curve are brought about by the formation of additional phases in the anodic deposit at some oxidation potentials.

The diffraction patterns of the electrodes contained all lines belonging to $PbSO_4$ and to lead from 4.24 to 1.60Å (16). The I/E curve for $PbSO_4$ is illustrated in Fig. 3 by the diffraction line with d = 3.00Å.

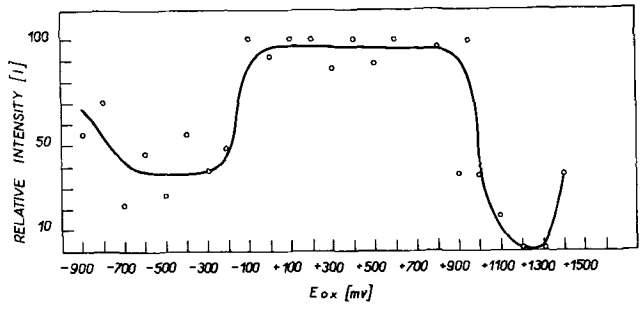

Fig. 3. Intensity of the d = 3.00Å reflection of $PbSO_4$ at different oxidation potentials.

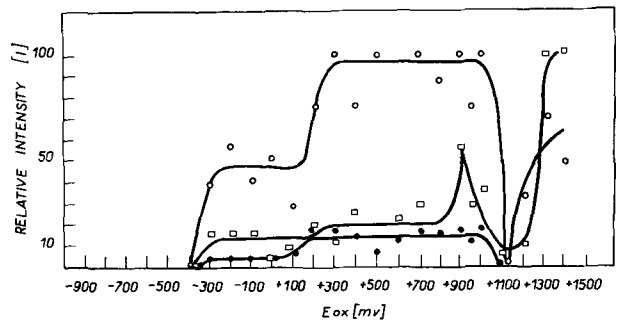

Fig. 4. Intensity of the diffraction lines, □ d = 3.12Å, ○ d = 2.80Å, ● d = 1.67Å, at different oxidation potentials.

In the diffraction patterns of electrodes anodized at potentials more positive than —300 mv additional strong lines were recorded with interplanar spacings 3.49, 3.12, 2.80, 2.12, 1.85, and 1.67Å. The relative intensity changes of the 3.12, 2.80, and 1.67Å lines are given in Fig. 4, while the potentials at which the remaining lines occur are given in Table I. The line with d = 3.12Å is notably broadened. It coincides with the strongest reflections in the x-ray patterns of α-PbO_2 (10) and of tetragonal PbO (11). On the other hand, both PbO-tet and β-PbO_2 show reflections with d = 2.80Å, the relative intensity being 62 for the former and 100 for the latter. The coincidences between these diffraction lines have been the cause of the discussion which has originated during the last years concerning the formation of PbO-tet. This problem can be unambiguously solved only by applying additional non-x-ray identification techniques. Alpha- and β-PbO_2 are both strong oxidizing agents, while PbO-tet possesses no oxidizing properties. We made use of this difference in behavior of the above compounds in order to assign the diffraction lines with d = 3.12 and 2.80Å. After recording the x-ray pattern the anodic deposit was removed from the surface of the electrode. The powder thus obtained and the electrode were placed in an iodine determination flask and the amount of lead dioxide was determined iodometrically, using the method described by Diehl and Toph (12). These determinations were duplicated on a sec-

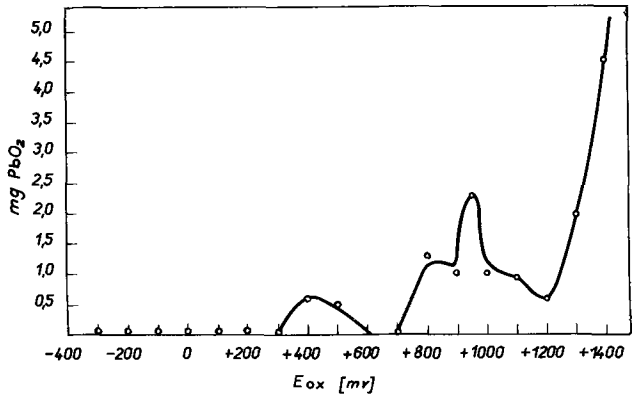

Fig. 5. Amount of lead dioxide in the anodic layer at different oxidation potentials.

ond series of electrodes by photometric determinations of lead dioxide with o-tolidine (13). The results of both series of measurements were in agreement. Figure 5 shows the iodometrically determined amount of PbO_2 contained in the anodic layer of the electrodes oxidized between —200 and +1400 mv. The anodic layer does not contain lead dioxide up to the oxidation potential +400 mv, nor between +600 and +700 mv. However, the 3.12 and 2.80Å reflections already occur at —300 mv. The relative intensity of the latter is nearly equal to that of $PbSO_4$ between +300 and +1000 mv. It can be assumed therefore that these diffraction lines indicate the presence of tetragonal PbO in the anodic layer.

The 3.12 reflection at potentials up to +800 mv is due to PbO-tet. Only at +400 and +500 mv does the reflection of alpha dioxide coincide with that of the tetragonal oxide. In the standard x-ray diffraction pattern of tetragonal oxide this reflection is strongest (relative intensity 100), while in the PbO-tet it appears as a very weak line. In the standard x-ray diffraction pattern the 2.80 reflection has a relative intensity of 62. In the diffraction pattern of anodically obtained PbO-tet in sulfuric acid its intensity is considerably enhanced. This change in the intensities of these lines may be ascribed to preferred orientation. In order to test this assumption a series of oxidations was performed between —200 and +900 mv on wire electrodes, x-ray diffraction photographs of which were subsequently taken in a conventional 57.3-mm Debye-Scherrer camera. The diffraction ring corresponding to the 110 reflection of PbO-tet (d = 2.80Å) exhibited marked orientation texture effects. This indicates that the tetragonal lead oxide crystals are preferentially oriented with the texture axis [110] oriented along the axis of the wire. In the x-ray diffraction pattern the remaining lines of PbO-tet in the interval considered are the following: d = 2.51 (I = 11); 2.12 (1); 1.99 (8); 1.87 (37); and 1.67 (24). The lines with d = 2.51 and 1.99Å were not recorded in our diffraction pattern. The 1.87 reflection coincides with a normal lead sulfate line. Reflections with d = 2.12 and 1.67Å are observed in the potential range between —300 and +1000 mv. Up to potential +1000 mv the 1.67Å reflection shows the same shape of the I/E curve as the 2.80Å reflection, indicating formation of PbO-tet.

Figure 2 shows that following anodization between —400 and +800 mv, on interrupting the polarization, the electrode potential at open circuit is arrested in the interval between —450 and —750 mv. According to the x-ray data, PbO-tet is formed in the same potential range. Consequently, the potential arrest observed under open-circuit conditions should be ascribed to the presence of lead oxide in the anodic layer.

A comparison between Fig. 4 and 5 indicates that the increase in relative intensity of the 3.12 reflection above +900 mv is due to the alpha dioxide formed during anodization. The strong intensities at potentials above +1300 mv (Fig. 4) show that the major part of the anodic layer above this potential is constituted by alpha lead dioxide. From the diffraction lines of the standard x-ray pattern of alpha lead dioxide which do not overlap with lead sulfate reflections only those with d = 2.73 and 1.64Å are absent. In some oxidation runs minor amounts of α-PbO_2 occur in electrodes anodized at —100, 0, and +200 mv. This shows that between —200 and +900 mv the formation of α-PbO_2 is determined by fortuitous factors.

The diagnostic diffraction lines of β-PbO_2 are those with interplanar spacings 3.49, 2.80, and 1.85Å. The remaining reflections coincide with those of lead and lead sulfate. The 3.49 reflection occurs at potentials more positive than +1200 mv (Table I). The increase in relative intensity of the 2.80Å reflection (Fig. 4) for electrodes anodized at potentials above +1200 mv is also brought about by the presence of β-PbO_2. The 1.85 line is due both to beta and to alpha dioxide.

Apart from these reflections the diffractometer traces of electrodes anodized at potentials more positive than —400 mv contained some very weak lines. These are given in Table II together with the oxidation potentials at which they appear. The reflection with d = 3.25Å coincides with the strongest line of $3PbO \cdot PbSO_4 \cdot H_2O$ (14). The reflection with d = 3.06Å coincides with the strongest line of orthorhombic PbO (10) and with the 3.05Å reflection of $5PbO \cdot 2H_2O$ (relative intensity I = 70) (15). It is thus impossible to differentiate these two compounds only by means of the x-ray diffraction pattern. The reflection with d = 2.95Å coincides with the strongest line of $PbO \cdot PbSO_4$ (15), Pb_2O_3 (I = 90) (17). However, the remaining strong lines of Pb_2O_3, 3.03 (I = 70), 2.85 (40), 2.31(80), and 1.78(50), do not occur in the diffraction patterns of the electrodes, thus clearly indicating that this compound is not formed in the anodic deposit. Consequently the observed reflection with d = 2.95Å should be assigned to $PbO \cdot PbSO_4$.

On the basis of the x-ray data and of the electrochemical behavior of the electrode the potential range investigated can be divided into three regions according to the composition of the anodic layer:

(A) Lead sulfate region: from —956 to —300 mv. The deposit is built up by $PbSO_4$ crystals.

(B) Lead oxide region: from —300 to about +900 mv. Apart from lead sulfate the deposit contains substantial amounts of tetragonal lead oxide. Minor amounts of $PbO \cdot PbSO_4$, $3PbO \cdot PbSO_4 \cdot H_2O$, and $5PbO \cdot 2H_2O$ or PbO-orthorhombic are also formed. At some potentials small amounts of orthorhombic α-PbO_2 also occurs. In previous electrochemical investigations (8, 9) it was established that the lead oxide region begins between —450 and —500 mv. The x-ray data yield a more positive value for the beginning of the second region. This difference is probably due to the lower sensitivity of the x-ray diffraction technique.

(C) Lead dioxide region. It lies at potentials more positive than +900 mv. However, the composition depends strongly on the oxidation potential and changes with the oxidation time. The major component of the anodic layer in this region is α-PbO_2. Beta-PbO_2 begins to form at potentials more positive than +1200 mv.

The present experimental results show that both tetragonal PbO and α-PbO_2 are formed in 1N H_2SO_4 although it is known that these compounds originate in alkaline media. Obviously the mechanism of the alkalinization of the lead electrode during anodic oxidation must be elucidated in order to explain this contradiction.

Such a mechanism for the alkalinization of the solution in the near-electrode potential was suggested in previous work (8). This mechanism is based on the hindered diffusion of SO_4^{2-} in the intercrystalline spaces of $PbSO_4$.

The composition of the anodic layer depends not only on the oxidation potential but on the quantity of

electricity passed at each potential as well. Any attempt to elucidate the mechanism of the processes which take place in the anodic oxidation of lead should take into account these two parameters.

Acknowledgments

Thanks are due to I. Tomov and Z. Iordanova, of the same institute, for x-ray diffraction measurements.

The Influence of Ternary Alloying Additions on the Galvanic Behavior of Aluminum-Tin Alloys

D. S. Keir, M. J. Pryor,* and P. R. Sperry

Metals Research Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

The effect of a series of ternary alloying additions on the galvanic behavior of Al-Sn base alloys has been investigated. A group of soluble ternary elements including Bi, Zr, Mg, and Ag expands the aluminum lattice, stabilizes the Al-Sn solid solution and either maintains or enhances the high galvanic currents observed in an aluminum alloy-steel couple in sodium chloride solution. A group of soluble ternary elements including Si, Zn, Cu, and Mn contracts the aluminum lattice, rejects tin from solid solution, and markedly decreases the galvanic current. A group of comparatively insoluble ternary alloying additions including Co, Ni, Fe, and As has little effect on galvanic current but reduces the anodic efficiency of the Al-Sn base alloy anodes.

A previous study (1) of the galvanic corrosion characteristics of aluminum alloyed with group IV metals showed that alloying aluminum with as little as 0.1% tin resulted in a major change in corrosion and galvanic corrosion characteristics in chloride solutions. For instance, the corrosion potential in 0.1*N* NaCl was debased from around —0.5 to —1.2 volts[1] while the current in a galvanic couple with an equal area of mild steel was enhanced by a factor of around fifty times. Other group IV alloying additions including germanium, silicon, titanium, and zirconium did not result in a similar major change in corrosion characteristics.

The dramatic effect of tin as an alloying addition was attributed to its ability to enter the surface oxide film as Sn^{4+} ions thereby creating additional cation vacancies. It was shown experimentally that the a-c resistivity of the surface oxide film on the aluminum-tin alloy in sodium chloride solution was almost two orders of magnitude lower than that of similar films on pure aluminum; this effect was attributed to lowered ionic resistance.

The galvanic behavior of dilute aluminum-tin alloys was not particularly reproducible unless the alloy castings were subjected to a thermal treatment designed to insure maximum retained solid solubility of tin in aluminum. This involved soaking the alloys at around 620°C followed by quenching in still water. This treatment was effective because of the existence of a small but significant solubility loop in the aluminum tin equilibrium diagram at this temperature where a maximum of around 0.1% tin may be dissolved (2, 3). When the maximum amount of tin was retained in metastable solid solution by this homogenizing treatment, the corrosion potential and a-c resistivity of the surface oxide film were debased to the maximum degree, and galvanic current output was maximized. A lower temperature thermal treatment at 400°C resulted in precipitation of most of the tin retained by homogenizing. Such precipitation treated (heterogenized) aluminum-tin alloys showed much more noble corrosion potentials, significantly higher film resistivity, and greatly reduced galvanic corrosion currents. These results demonstrated that tin in the alloy could not pass effectively into the surface oxide unless it was retained in solid solution.

In view of the foregoing, it was felt important to determine the effects of ternary alloying additions on the galvanic behavior of aluminum-tin alloys. Such effects might well be related to the influence of the ternary alloying addition on the solid solubility of tin in aluminum. No information appears to exist on this point in the literature partly because of the difficulty of studying changes in small solid solubilities by conventional metallurgical methods. However, in the aluminum-tin system the measurement of galvanic current provides an accurate means of locating the phase boundary (1). The particular ternary alloying additions investigated included iron, magnesium, bismuth,

* Electrochemical Society Active Member.
[1] All potentials in this paper are expressed on the standard hydrogen scale.

zirconium, zinc, manganese, copper, silver, nickel, arsenic, and cobalt. Iron and silicon were also investigated both singly and in combination because these are common impurities in aluminum.

Experimental and Results

Material preparation.—Alloys were prepared from superpurity (99.992%+) aluminum, high-purity tin, and high-purity elemental ternary alloying additions. Ternary alloys containing magnesium, bismuth, zirconium, zinc, manganese, copper, silver, iron, nickel, arsenic, and cobalt were prepared using a constant tin content of 0.2 w/o (per cent by weight). The ternary alloying additions were added in amounts varying from 0.012% to approximately 1.0% depending on their solubility in aluminum. The alloys were prepared as small chill castings measuring 1.25 x 1.4 x 10 cm using the technique described previously (1). The chemical compositions are given in Table I. Similar castings of selected binary alloys were also prepared, Table II.

Aluminum-tin-iron-silicon alloys were likewise prepared from 99.992% pure aluminum with high-purity iron, silicon, and tin as alloying additions. The nominal tin content of these alloys was 0.14 w/o. A variety of iron and silicon contents of up to about 0.3 w/o was investigated, Table III. The castings were prepared by the direct chill method. The ingots measured 7.5 x 15 x 100 cm. The pouring temperature of the melt was 720° ± 5°C, with an initial drop rate of 7.5 cm/min during the start-up, being succeeded by a final constant drop rate of 11 cm/min. The molten metal head was held constant in the mold at a value of 6 cm. Gaseous chlorine at a flow rate of 2500 cc/min was passed through each melt from 8 to 13 min before casting to insure a low hydrogen level in the ingots. Each ingot was cut into 7.5 cm long sections for use in the galvanic corrosion studies.

Thermal treatment of castings.—All castings were homogenized to insure uniform distribution of tin and of the other alloying additions. A homogenizing temperature of 620° ± 3°C was employed. Most alloys were held for 16 hr and were then quenched in still water. The alloys containing zinc, magnesium, and arsenic were homogenized for a reduced time of 6 hr in order to minimize loss of volatile ternary alloying additions.

Experimental method.—Specimens were machined from the castings in the form of square rods having dimensions of 0.5 x 0.5 x 8.0 cm. In the galvanic experiments only 5 cm of the rod (10 cm^2) were immersed in the electrolyte. The machined specimens were degreased in benzene, etched in 1*N* NaOH for 5 min, washed, dried in acetone, and exposed to dry air over phosphorus pentoxide for 24 hr and weighed.

Mild steel cathodes had an area of 10 cm^2. Their chemical composition and method of preparation was described earlier (1).

Galvanic couples of 10 cm^2 of the appropriate aluminum alloy coupled to 10 cm^2 of mild steel in 0.1*N* NaCl at 25° ± 0.05°C were investigated using the cell and experimental method described earlier by two of the authors (4). Galvanic currents and cell potentials were recorded continuously for 48 hr, the standard duration of all galvanic experiments in this paper. After each experiment had been terminated the aluminum anode was freed from corrosion product by treatment in 2% chromic-5% phosphoric acid at 85°C, after which it was rinsed, dried, and reweighed. The steel cathode was cleaned in 1:1 HCl inhibited with 3% of rhodine 41, rinsed, dried, and reweighed. All steel cathodes were effectively protected against corrosion.

Results.—The results of the galvanic experiments on homogenized Al-Sn alloys containing a variety of ternary alloying additions are shown in Table I. The experimental data include the numbers of coulombs flowing in 48 hr, the closed-circuit cell potentials, and the anodic efficiencies.

From Table I, only bismuth caused a major increase (more than 50%) in the galvanic corrosion current. A group of alloying additions comprising Mg, Ag, Zr, Co, and Fe, had little effect on the galvanic current and cell potential, although the iron addition caused a large drop in anodic efficiency. The remaining alloying additions caused a reduction in galvanic current together with an ennobling in cell potential with the major effects stemming from the addition of Cu, Zn, or Mn. The closed-circuit cell potentials for these three elements are in the range obtained from homogenized binary Al-Sn alloys with tin contents in the range of 0.04-0.06% (1).

Table II shows the number of coulombs flowing in galvanic couples with pure aluminum and selected binary alloys including tin. With the exception of tin, all other elements (Bi, Zr, As, and Si) reduced galvanic output in binary alloys.

Iron and silicon are major impurities found in commercial grades of aluminum and, hence, were investigated in more detail. Table III lists the galvanic data obtained from a range of homogenized Al-Sn alloys with varying amounts of iron and silicon.

The data from Table III are plotted in Fig. 1 and 2 as the individual effects of iron and silicon, at approximately constant silicon and iron levels, respectively. It may be seen that increasing iron results in a modest decrease in galvanic current together with decreasing efficiency as $FeAl_3$ accumulates in the alloy. Figure 3 shows that the cell potential change is relatively insensitive to the presence of iron up to 0.2%. Alloying with silicon (Fig. 2) results in a major decrease in galvanic current accompanied by a drastic displacement in cell potential in the noble direction

Discussion

It was previously found that tin in aluminum can enter the surface aluminum oxide film only if it is initially dissolved in the aluminum solid solution. A ternary alloying or impurity element could conceivably modify the effect of tin on the galvanic properties in one of two ways:

(*i*) it could also enter the oxide and further change its defect structure, or

(*ii*) it could affect the solid solubility of tin in aluminum so that it influences the effectiveness of tin in an indirect manner.

If (*i*) was true, it would be expected that an element such as bismuth, which enhances the effect of tin would increase the galvanic current in a binary alloy. Table II shows that this is not so. Furthermore, it is well known that binary zinc additions to aluminum shift the potential in the active direction and yet this element annihilates the effect of tin (Table I). Clearly ternary alloying effects in Al-Sn base alloys cannot be related to the influence of the ternary alloying additions themselves on the surface oxide films.

Since (*i*) above is not a valid explanation of the results in Tables I and III, the tin solubility considerations outlined in (*ii*) can be examined. In an earlier paper (1) it was demonstrated that only the tin retained in solid solution in the alloy could enter the surface oxide film and modify its conductivity. Tin retained in an aluminum solid solution is recognized as being a strong expander of the FCC lattice with the expansion being reported as +0.0045 Å/w/o of tin in solution (2). This is a surprisingly large effect which is comparable with the effect of magnesium in also expanding the aluminum lattice (+0.0052 Å/w/o).

Since tin expands the aluminum lattice, it would appear that it should be compatible with other solid solution elements which are also lattice expanders. By contrast, lattice contractors could well result in the rejection of tin from solid solution which would reduce the galvanic corrosion current and ennoble the potential of the alloy. Insoluble elements should have no effect on the solubility of tin, but if present as electronically conducting second phase particles should reduce anodic efficiency.

The available data required to support or reject these contentions is summarized in Table IV (5-7). This

Table IV. Solubility and lattice changes due to alloying aluminum

Element	Solubility in w/o at 600°C*	Change in Al lattice, Å/w/o*	Goldschmidt atomic radius A**

* Data for solubility at 600°C and change in lattice from ref. (5); other solubility data from ref. (6).
** Data from ref. (7).

table contains solubility limits at 600°C for the various ternary elements[2] together with what quantitative information is available relative to their effect in expanding or contracting the aluminum lattice (5). Complete information is not available on this point for all the ternary elements; in such cases, the Goldschmidt atomic radius has been used (7). This number normalizes the atomic radius for a coordination number of 12 which is applicable to aluminum. Where lattice expansion or contraction data is also available, the agreement between the values quoted and the Goldschmidt atomic radius is good.

The elements in Table IV are organized into three groups, as follows:

1. Elements which are soluble at the quantity added and which expand the aluminum lattice. These include Bi, Mg, Zr, and Ag.
2. Elements which are soluble at the quantity added and which contract the aluminum lattice. These include Zn, Cu, Mn, and Si.
3. Elements which are insoluble at the quantity added.

If the groupings in Table IV are compared with the electrochemical results in Tables I and III, an excellent correlation is found to exist. The lattice expanders Bi, Zr, Mg, and Ag do not degrade the electrochemical properties normal to binary Al-0.2% Sn alloys. Indeed the very large bismuth atom results in a major enhancement of galvanic current and a further debasement in cell potential. Silver slightly enhances the galvanic current, whereas magnesium and zirconium have essentially no effect on the electrochemical behavior. These results can be interpreted as meaning that the presence of ternary lattice expanders either permits the binary solid solubility of tin to be maintained at around 0.11% or else, in the case of bismuth, to be enhanced.

The lattice contractors, Zn, Cu, Mn, and Si, all have the opposite effect on galvanic characteristics. They reduce to a major degree the galvanic corrosion current and ennoble the cell potential. The effect is greatest for manganese, which, at the quantity added, results from Table IV in the largest total lattice contraction. Clearly as the ternary element contracts the aluminum lattice tin is rejected from solid solution and the logical (1) reduction in galvanic corrosion current results. Comparison with earlier work on binary aluminum-tin alloys suggests that in the ternary Al-Sn-Mn system less than 0.05% tin is retained in solid solution.

The insoluble elements, Co, Fe, As, and Ni, generally have a small effect on galvanic current. Up to their small solubility limits they are all lattice contractors (Table IV) so should slightly reduce galvanic current. This effect is in fact found in Table I with the greatest current decrease being found with nickel which also has the largest solid solubility. As these elements are added over and above their solubility limits, they form intermetallic compounds. Since these are usually good electronic conductors, they can act as good local cathodes and so can promote local action on the alloy anodes. Accordingly, the effect over and above the solid solubility limit is principally to reduce anodic efficiency without further affecting galvanic current. This effect is elucidated in Tables I and III and also in Fig. 1 for iron.

The combined effect of silicon (a lattice contractor) and iron (an insoluble element) is of greatest interest because these are common impurities in aluminum. The individual effects of these elements are shown in Fig. 1 and 2. Their combined effect is shown in Table III which shows that the galvanic current is controlled by the silicon content and the anodic efficiency by the iron content.

This work provides further support of the contention that only the tin retained in solid solution can enter the surface oxide film and modify its conductivity and through this means, the electrochemical behavior of the alloy. Accordingly, the effects of ternary alloy additions follow closely the effects of these elements on the solid solubility of tin in aluminum.

[2] Information on arsenic is not available, but its solubility should be very low.

Anodic Polarization of Titanium and Titanium Alloys in Hydrochloric Acid

Milton Levy* and Gilbert N. Sklover

Army Materials and Mechanics Research Center, Watertown, Massachusetts

ABSTRACT

Commercially pure titanium and the alloys studied exhibited active to passive transitions in HCl. Increasing the acid concentration increased the critical current density for passivity and the dissolution current density in the passive range and shifted the critical potential for passivity in the noble direction. Increasing the temperature served only to increase the critical current density for passivity and the dissolution current density in the passive range. Activation energies for the anodic polarization process were the right order of magnitude for a reaction controlled by reactivity at the metal surface. For the α-β alloy 6Al-6V-2Sn the critical current density for passivity increased as the ratio of amounts of beta to alpha phase decreased with increasing strength level. The dissolution is accelerated probably, by the galvanic effects and the unfavorable area ratio. Ti 75A, a commercially pure metal, had a smaller critical current density for passivity value than did the alloys, which was expected. Secondary current density increases were observed for all the alloys at potentials above +1.0v. For the 13V-11Cr-3Al alloy such behavior was attributed to transpassivity. For the other alloys the phenomena was attributed to pitting or localized corrosion. The commercially pure metal remained passive in this potential range. The addition of Fe^{3+} and Cu^{2+} (0.03M) to the HCl facilitated passivation of the metal and its alloys. Pitting of several of the alloys occurred in HCl but not in H_2SO_4.

The anodic behavior in acid media of pure titanium and titanium alloyed with selected amounts of noble elements has been reported by several investigators (1-7). Relatively few data on the anodic behavior of commercial titanium alloys are available (8-10).

In previous work (8) the anodic behavior of α-β titanium alloy 6Al-6V-2Sn was studied in sulfuric acid as a function of temperature, acid concentration, selected ion additions to the electrolyte, yield strength level, and microstructure of the alloy. For comparison, commercially pure α titanium and a β alloy containing 13V-11Cr-3Al were also studied. The present investigation extends this study to hydrochloric acid media, additional commercially available titanium alloys, and considers the directionality of the metal specimen.

Experimental Procedure

The metal and alloys studied were commercially pure α Ti75A in the annealed condition, α-β titanium 6Al-6V-2Sn heat-treated to strength levels of 140, 160, and 180 ksi, β titanium 13V-11Cr-3Al in the as-received mill anneal condition, α-β titanium 8Al-1Mo-1V in both the single and duplex annealed condition, and annealed α-β titanium 6Al-4V alloy.

The potential sweep method of potentiostatic polarization (sometimes called potentiodynamic polarization) was used. The electrode potential was continuously changed at a constant rate of 5000 mv/hr (83.3 mv/min) and current simultaneously recorded. A Wenking potentiostat in conjunction with a motor potentiometer for automatic programming of the operating potential and an x-y recorder were employed to automatically record current *vs.* voltage. The automatic potential sweep technique (as opposed to potential step) yields the most reproducible results because of the high resolution offered by continuous recording. The critical potentials for passivity determined by the potential step method agree within ±10 mv of those obtained from the potential sweep technique at the same traverse rate. The critical current densities for passivity are greater when the potential sweep technique is used. The polarization cell and general procedure have been described previously (8).

Polarization measurements were made in 5, 12, and 20% hydrogen saturated hydrochloric acid electrolytes at temperatures of 35, 50 and 65°C ±1°C. Reproducibility was within experimental error (<3%).

For the directionality studies cylindrical specimens of 1 cm^2 surface area were machined both parallel (longitudinal) and perpendicular (transverse) to the working direction. Because of the many similarities in behavior, a number of the polarization curves obtained are not presented.

Results and Discussion

Polarization of Ti-6Al-6V-2Sn

Effect of concentration of electrolyte.—Figure 1 shows the anodic behavior of Ti-6Al-6V-2Sn (180 ksi strength level) at 65°C in 5, 12 and 20% HCl. Increasing the acid concentration increases the critical current density for passivity or maximum dissolution current density and the critical potential for passivity is shifted in the noble direction. The dissolution current density in the passive range was highest in 20% HCl. The higher the value of the corrosion current in the passive state, the less stable the passive state. Similar behavior was observed at other strength levels and temperatures except at the lowest temperature (35°C) where the curves were characterized by the

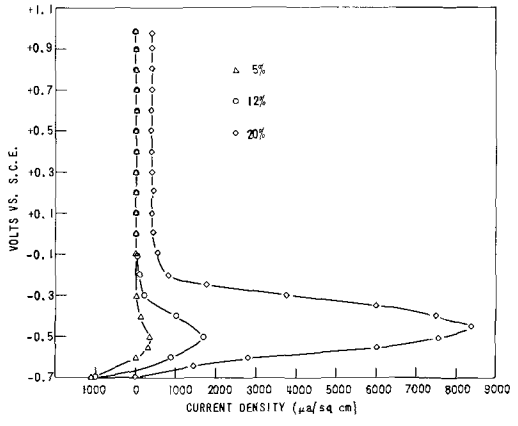

Fig. 1. Effect of concentration of HCl on polarization of Ti-6Al-6V-2Sn (180 ksi) at 65°C.

* Electrochemical Society Active Member.

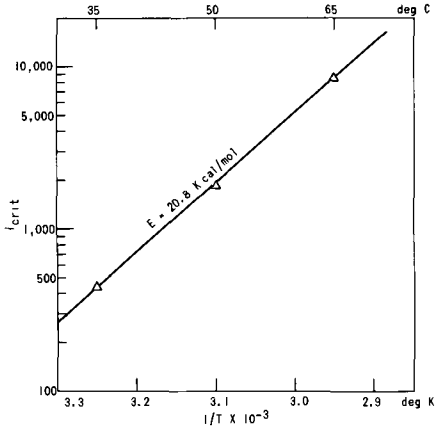

Fig. 2. Arrhenius plot for Ti-6Al-6V-2Sn (180 ksi) in 20% HCl

extremely small currents required to passivate the alloy and the negligible extent of their active regions.

Effect of temperature.—The critical current density for passivity for the alloy (140, 160, 180 ksi strength levels) in 5, 12, and 20% HCl increases considerably as temperature is increased from 35° to 60°C. The critical potential for passivity is unaffected. Figure 2 shows log critical current density for passivity plotted against the reciprocal of absolute temperature. The result is a linear dependency which can be expressed by the Arrhenius equation and an activation energy of 21 kcal/mol calculated. This activation energy is the right order of magnitude for a reaction controlled by chemical reactivity at the surface rather than a diffusion controlled reaction.

Effect of strength level.—Anodic polarization curves for Ti-6Al-6V-2Sn at strength levels of 140, 160 and 180 ksi in 20% HCl at 65°C are shown in Fig. 3. The critical current density for passivity increases with increasing strength level. The dissolution current density in the passive range also increased at the higher strength levels. The critical passive potential shifts in the more noble direction at the 180 ksi strength level. X-ray diffraction analysis showed that the β phase content decreases from 36 to 23 to 17% with a corresponding increase in α phase as the strength level increases from 140 to 160 to 180 ksi. It is probable that the alloying additions in the alloy produce a significant potential difference between the α and β phases which causes the relatively high dissolution currents. The dissolution current increases as the ratio of amounts of β to α phases decreases with increasing strength level. Dissolution may be accelerated both by the galvanic effects and the unfavorable area ratio.

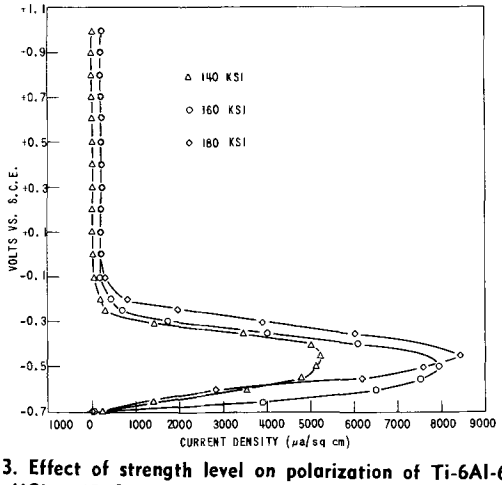

Fig. 3. Effect of strength level on polarization of Ti-6Al-6V-2Sn in 20% HCl at 65°C.

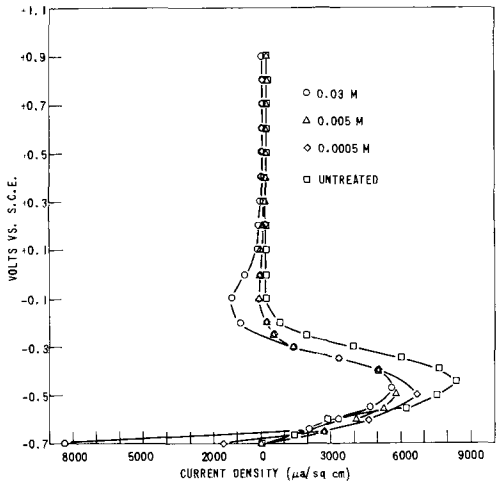

Fig. 4. Effect of $FeCl_3$ concentration on polarization of Ti-6Al-6V-2Sn (180 ksi) in 20% HCl at 65°C.

Effect of Fe *and* Cu *additions.*—Fe^{3+} and Cu^{2+} were added to the HCl electrolyte in the form of $FeCl_3$ and $CuSO_4$. Figure 4 shows the effect of the Fe addition on the polarization behavior of Ti-6Al-6V-2Sn (180 ksi) in 20% HCl at 65°C. The critical current density for passivity decreases with increasing Fe concentrations. At all concentrations of Fe there is some inhibition of the anodic reaction. At the maximum Fe concentration (0.03M) the polarization current density becomes negative and recrosses the zero current to a positive value at some point in the passive range. According to Mueller (11) this behavior indicates that passivity is stable and a stable passive potential exists. The lower value for the corrosion current density in the passive range at the 0.03M Fe concentration also indicates a more stable passive state. The electrochemical process associated with the cathodic currents is probably hydrogen ion reduction, particularly because the cathodic current occurred at a potential more active than the hydrogen electrode value of the electrolyte. Similar cathode currents have been reported for other metals by Greene *et al.* (12) and Myers *et al.* (13) who suggested they were related to the chemical reduction of hydrogen ions. The effect of cupric ions on the polarization behavior of the alloy in 20% HCl at 65°C is shown in Fig. 5. The Cu^{2+} ion reduces the critical current density for passivity. The reduction increases with increasing Cu^{2+} concentration. At 0.03M concentration the maximum dissolution current is approximately one-third that of the untreated solution. The Cu^{2+} ion achieves greater inhibition than the Fe^{3+} ion. Cobb and Uhlig (4) and Levy (8) reported that ferric and cupric ions are effective inhibitors for the corrosion of titanium and several titanium alloys in other acid media.

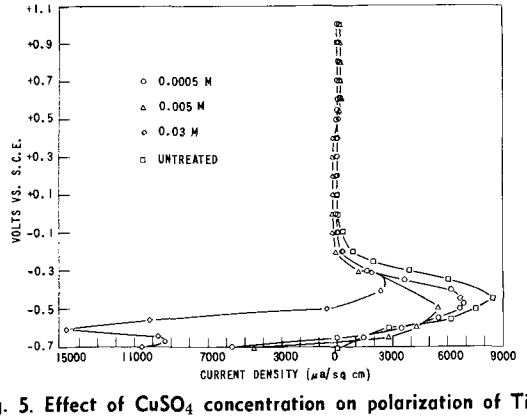

Fig. 5. Effect of $CuSO_4$ concentration on polarization of Ti-6Al-6V-2Sn (180 ksi) in 20% HCl at 65°C.

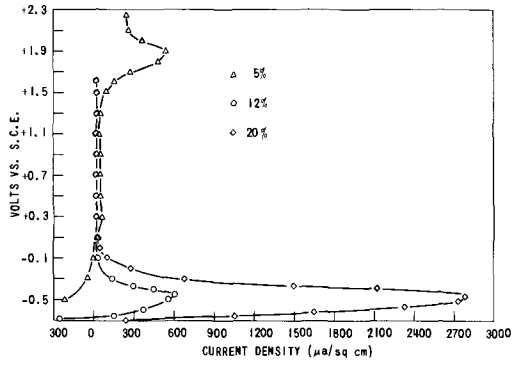

Fig. 6. Effect of HCl concentration on polarization of commercially pure Ti 75A at 65°C.

Polarization of Commercially Pure Ti 75A

Effect of concentration of HCl.—Figure 6 shows anodic polarization curves for Ti 75A in 5, 12, and 20% HCl at 65°C. The maximum dissolution current density increases with increasing HCl concentration. The critical potential for passivity is essentially the same in both 12 and 20% solutions. At the lowest HCl concentration, the curve is characterized by the negligible extent of the active region and a very small current is required to passivate the metal. At a potential of +1.5v different behavior is observed in 5% HCl solution. A secondary active-passive transition is observed. Although Levy (8) reported transpassive behavior for Ti 13V-11Cr-3Al in H_2SO_4, transpassivity has not been reported for commercially pure titanium. Why it should occur only in 5% HCl is not understood. Perhaps it does not represent true transpassive behavior but rather is an artifact.

Effect of temperature.—Figure 7 shows the effect of temperature on the polarization of the metal in 20% HCl. Paralleling the effect of concentration, the critical current density for passivity increases with increasing temperature. The rate of increase corresponds to an activation energy of about 20 kcal/mol. At 35°C, even at the 20% acid concentration, a relatively small current is required to passivate the metal. The dissolution current density in the passive range is of very low order of magnitude at all temperatures. Of course, the lower the value of the corrosion current in the passive state, the more stable the passive state.

Effect of Fe^{3+} *additions.*—Figure 8 shows the effect of $FeCl_3$ additions on the polarization behavior of Ti 75A in 20% HCl at 65°C. $FeCl_3$ in concentrations of 0.005 and 0.0005M accelerates anodic dissolution, 0.03M $FeCl_3$ reduces the maximum dissolution current density slightly. At this concentration cathodic current densities are observed in the passive range which indicates a more stable passive potential exists.

Polarization of Ti 8Al-1Mo-1V

Concentration of HCl.—Figure 9 shows anodic polarization curves for the alloy as a function of HCl

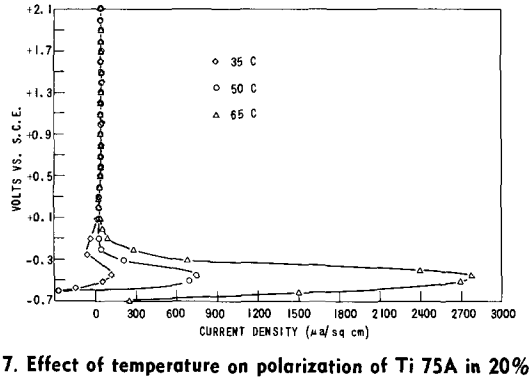

Fig. 7. Effect of temperature on polarization of Ti 75A in 20% HCl

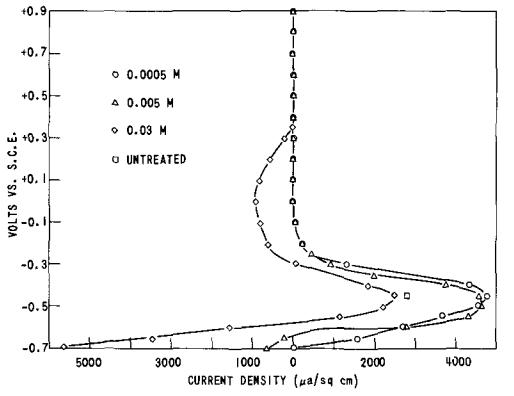

Fig. 8. Effect of $FeCl_3$ concentration on polarization of Ti 75A in 20% HCl at 65°C.

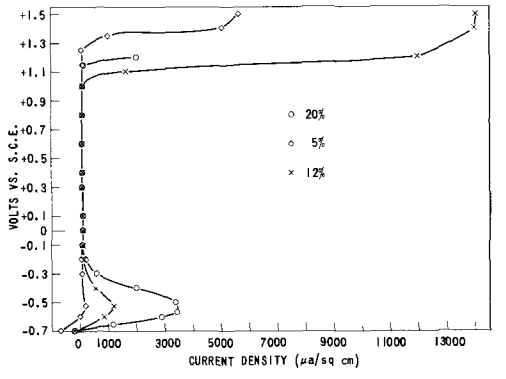

Fig. 9. Effect of concentration of HCl on polarization of Ti-8Al-1Mo-1V (duplex annealed) at 65°C.

concentration at 65°C. The maximum dissolution current density increases with increasing concentration. The critical potential for passivity remains essentially the same. Note the negligible extent of the active region in 5% HCl even at 65°C. At potentials between +1.0 to +1.25v, depending on the concentration, a secondary anodic reaction occurred. Such behavior is usually attributed to transpassivity. However, pitting occurred at these potentials indicating that the reaction was not one involving general dissolution or transpassivity.

Effect of temperature.—Figure 10 shows anodic polarization curves for the alloy in 20% HCl as a function of temperature. The critical current density for passivity increases with increasing temperature at a rate corresponding to an activation energy of about 20 kcal/mol. At 65°C the passive state is less stable since the value for the dissolution current density in the passive state is greater. There is no significant change in the critical potential for passivity. Pitting occurred at all temperatures at potentials above +1.1v where

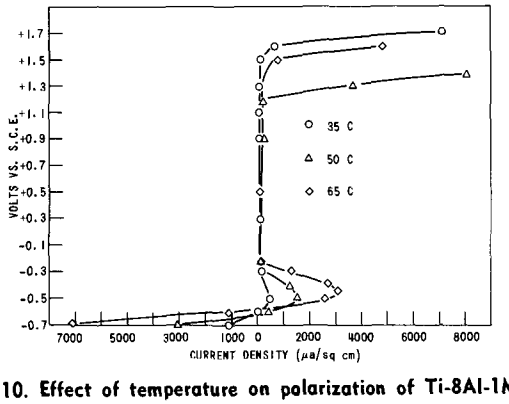

Fig. 10. Effect of temperature on polarization of Ti-8Al-1Mo-1V (single anneal) in 20% HCl.

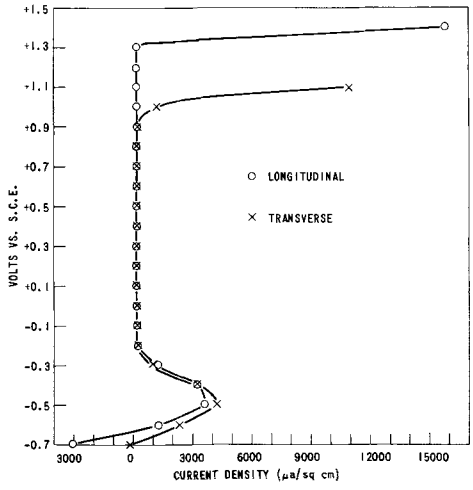

Fig. 11. Effect of directionality on polarization of Ti-8Al-1Mo-1V (duplex anneal) in 20% HCl at 65°C.

the current density increased appreciably. The potential at which pitting occurred varied with temperature.

Effect of directionality.—The anodic behavior of the alloy in both longitudinal and transverse directions in 20% HCl and 65°C is shown in Fig. 11. The maximum dissolution current density for the specimen fabricated in the transverse direction (machined normal to the working direction) was greater than that fabricated in the longitudinal direction (parallel to the working direction). Pitting occurred in both transverse and longitudinal specimens but at a more noble potential in the longitudinal specimen (+1.3v *vs.* +0.9v).

Effect of heat-treatment.—The effect of heat-treatment on the polarization of Ti 8Al-1Mo-1V in 20% HCl at 65°C is shown in Fig. 12. The critical current density for passivity and the critical potential for passivity are essentially the same for the alloy in the single and the duplex annealed condition. Localized corrosion (pitting) of the single and duplex annealed alloy occurred at potentials of +1.0 and +1.3v, respectively.

Polarization of Ti 13V-11Cr-3Al

Effect of concentration of electrolyte.—Figure 13 shows the polarization behavior of the alloy in 5, 12, and 20% HCl solutions at 65°C. The critical current density for passivity increases with the increasing HCl concentration, and the critical potential for passivity shifts in the more noble direction. Although not shown in Fig. 13, above +1.0v a secondary reaction was ob-

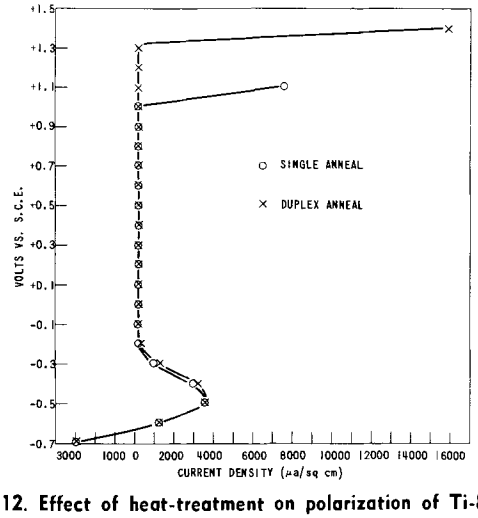

Fig. 12. Effect of heat-treatment on polarization of Ti-8Al-1Mo-1V in 20% HCl at 65°C.

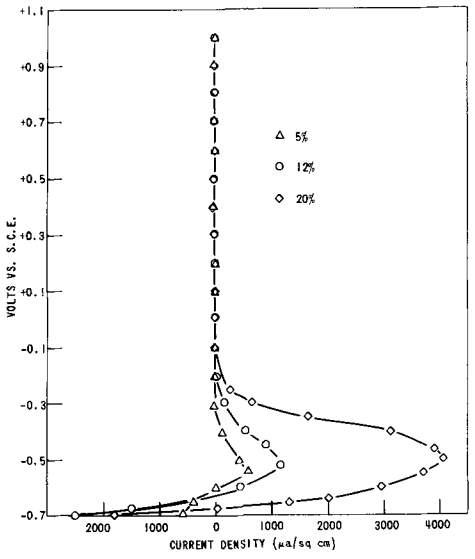

Fig. 13. Effect of HCl concentration on polarization of Ti-13V-11Cr-3Al at 65°C.

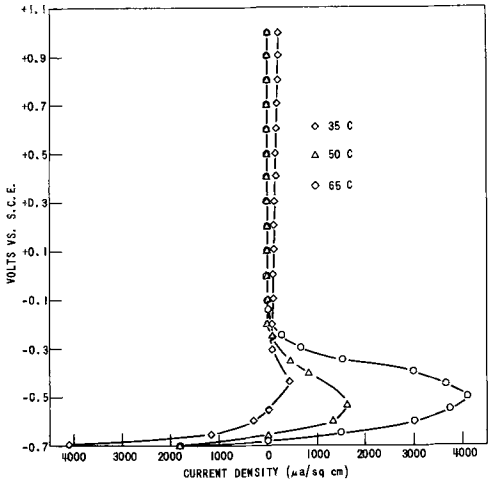

Fig. 14. Effect of temperature on polarization of Ti-13V-11Cr-3Al in 20% HCl.

served at all HCl concentrations and was characterized as transpassive behavior due to the 11% chromium content of the alloy.

Effect of temperature.—Figure 14 shows that the critical current density for passivity increases with increasing temperature. The activation energy for the polarization process (about 20 kcal/mol) is the right order of magnitude for a reaction controlled by chemical reactivity at the surface The alloy exhibited transpassive behavior at all temperatures at potentials above + 1.0v (not shown).

Effect of Cu^{2+}.—Figure 15 shows the effect of $CuSO_4$ on the polarization of Ti-13V-11Cr-3Al in 20% HCl at 65°C. Corrosion is accelerated by the addition of $CuSO_4$ in concentrations of 0.005 and 0.0005M. The anodic reaction is markedly stifled in 0.03M solution. Note the cathodic currents in the passive range which indicate that the passivity is stable.

Polarization of Ti-6Al-4V

Effect of temperature.—The temperature dependence of the anodic polarization process is shown in Fig. 16. The critical current densities for passivity and the dissolution current densities in the passive range increase with increasing temperature. Again the activation energy is the right order of the magnitude for a chemical controlled reaction rather than diffusion controlled. Paralleling the effect of temperature, in-

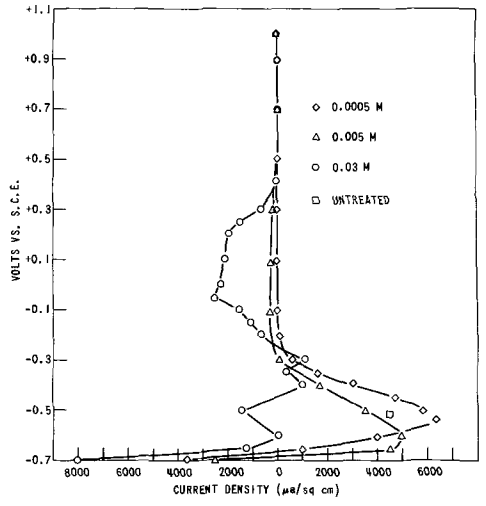

Fig. 15. Effect of $CuSO_4$ concentration on polarization of Ti-13V-11Cr-3Al at 65°C.

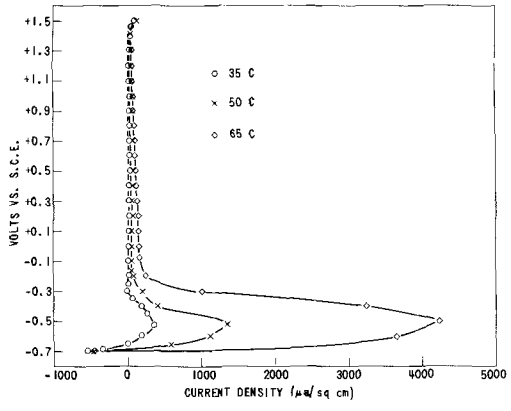

Fig. 16. Effect of temperature on polarization of Ti-6Al-4V in 20% HCl.

creasing the HCl concentration increased the critical current for passivity.

Comparison of Polarization Behavior of Titanium and Alloys

The anodic behavior of commercially pure titanium and several alloys in 20% HCl at 65°C are compared in Fig. 17. Based on maximum dissolution current, α-β Ti-6Al-6V-2Sn shows the least corrosion resistance followed by β Ti-13V-11Cr-3Al, α-β Ti-6Al-4V, α-β 8Al-1Mo-1V (10%β), and α Ti75A, in order of increasing corrosion resistance. Since the anodic polarization process was shown to be controlled by reactions occurring at the surface, metal composition and structure should achieve their greatest effect. Composition gradients in a metal create galvanic cells causing accelerated attack of anodic areas. A pure metal or homogeneous single phase alloy, therefore, is usually more corrosion resistant than an impure or multiphase alloy which appears to be the case here. The critical potential for passivity is essentially the same for the metal and the alloys which means that the alloying does not significantly alter the critical potential for passivity. The dissolution current densities in the passive range were of very low order of magnitude for all alloys indicating stable passivity. The commercially pure Ti 75A remains passive throughout the potential range (from —0.2 to +2.3v). All the alloys exhibit secondary reactions above potentials of +1.0v. The secondary reaction for the Ti-13V-11Cr-3Al alloy (+1.1v) is attributed to transpassivity. In this region of potential, chromium becomes oxidized to its hexavalent soluble state. The secondary current increase associated with the remaining alloys Ti-6Al-6V-2Sn,

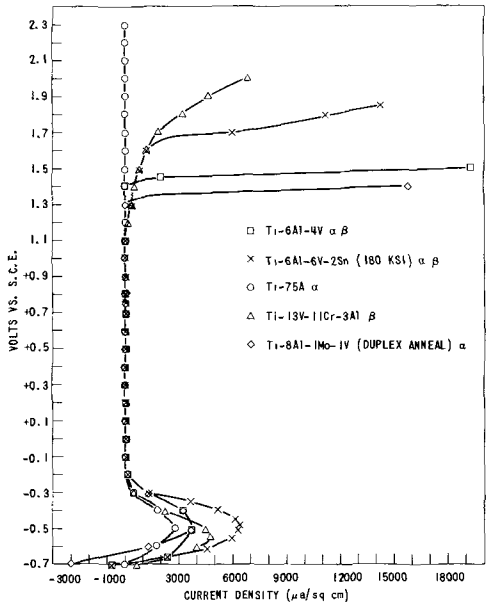

Fig. 17. Comparison of polarization behavior of titanium and alloys in 20% HCl at 65°C.

Ti-6Al-4V, Ti-8Al-1Mo-1V is attributed to localized corrosion or pitting. It should be noted here that the pitting observed in HCl solutions was not observed in H_2SO_4 solutions.

Summary

Commercially pure titanium and the alloys studied exhibited active to passive transitions in HCl. Increasing the acid concentration increased the critical current density for passivity and the dissolution current density in the passive range and shifted the critical potential for passivity in the noble direction. Increasing the temperature served only to increase the critical current density for passivity. Activation energies for anodic dissolution in the active region were the right order of magnitude for a reaction controlled by reactivity at the metal surface. For the α-β alloy 6Al-6V-2Sn the critical current for passivity increased as the ratio of amounts of beta to alpha phase decreased with increasing strength level. The dissolution is accelerated probably, by the galvanic effects and the unfavorable area ratio. Ti 75A, a commercially pure metal had a smaller critical current for passivity value than did the alloys, which was expected. Secondary current density increases were observed for all the alloys at potentials above +1.0v. For the 13V-11Cr-3Al alloy such behavior was attributed to transpassivity. For the other alloys the phenomena was attributed to pitting or localized corrosion. The commercially pure metal remained passive in this potential range. The addition of Fe^{3+} and Cu^{2+} (0.03M) to the HCl facilitated passivation of the metal and its alloys. Pitting of several of the alloys occurred in HCl but not in H_2SO_4.

Two-Dimensional Nucleation in Electrocrystallization

R. D. Armstrong and J. A. Harrison

Department of Physical Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, England

ABSTRACT

The transient and steady-state responses of electrodes under conditions where two-dimensional nucleation is rate determining are considered.

The suggestion that the formation of two-dimensional nuclei was rate determining in electrocrystallization was first made by Erdey-Gruz and Volmer (1). This view was subsequently not accorded much attention since (*i*) no experimental evidence could be obtained to support it, and (*ii*) it was thought by analogy with crystal growth from the vapor phase that the presence of large numbers of screw dislocations in real surfaces would control the kinetics of electrocrystallization. More recently it has been demonstrated that two-dimensional nucleation can be experimentally observed in situations where the number of dislocations is drastically reduced, *e.g.*, the deposition of Ag on to Ag single crystals (2), the formation of anodic films on Hg and Hg amalgams (3-9), the deposition of Ni on to Hg (10), and the formation of a monomolecular layer of pyridine, also on Hg (11).

It is the purpose of this communication to formulate the transient and steady-state responses of unbounded electrodes[1] under conditions where two-dimensional nucleation occurs, and to consider the significance of the results.

Potentiostatic Conditions

For the formation of a single layer of a phase on an unbounded electrode surface, the *i-t* transient under potentiostatic conditions (where the rate constants V and A are time independent) has been shown to be (3, 12)

$$i = q_{mon}\,\pi V^2 A t^2 \exp\left(-\frac{\pi t^3 V^2 A}{3}\right) \qquad [1]$$

for a nucleation rate (A) constant in time, or

$$i = q_{mon}\,2\,\pi V^2 N_0 t \exp\,(-\pi t^2 V^2 N_0) \qquad [2]$$

for a fixed number of nuclei (N_0) formed at $t = 0$. The symbols are defined near the end of the paper. [1] and [2] thus give the transient and steady-state responses for the special case of the formation of a single layer. Experimentally this situation often arises in the formation of anodic phases on mercury electrodes, but in general the process will not stop after the formation of the first layer. A derivation of the *i-t* transient for the formation of successive layers under conditions of progressive nucleation has been attempted by computer simulation (3). A much simpler approach in which the dependence of the transient on the rate constants for successive layers can be seen more clearly is as follows.

A patch of the n^{th} layer (dS_n) formed at time u, will generate a current due to the succeeding layer at a time t given by

$$di_{n+1} = q_{mon}\,3\beta_{n+1}(t-u)^2 \exp\,[-\beta_{n+1}(t-u)^3]\,dS_n$$

so that the total current due to the formation of the $(n+1)$ layer is

$$i_{n+1} = q_{mon}\int_0^t 3\beta_{n+1}(t-u)^2 \exp\,[-\beta_{n+1}(t-u)^3]\,\frac{dS_n}{du}\,du$$

$$= \int_0^t 3\beta_{n+1}(t-u)^2 \exp\,[-\beta_{n+1}(t-u)^3]\,i_n\,du \qquad [3]$$

Since i_1 is known [1] the current contributions from successive layers can be evaluated by numerical integration using a calculating machine. For the case where $\beta_1 = \beta_2 = \ldots \beta_n$ (which is the case expected for metal deposition) the resulting *i-t* transient with the component layer currents are shown in Fig. 1. It is apparent that in the steady state the current is constant and is the same magnitude as the maximum current due to the first layer, *i.e.*

$$i(t \to \infty) \approx q_{mon}(\pi V^2 A)^{1/3}\,(2)^{2/3} \exp(-2/3) \qquad [4]$$

(obtained by differentiating [1]).

Thus evidence for two-dimensional nucleation can only be obtained at short times, by observation of the rising section and subsequent damped oscillation of the current. The *i-t* transient for three dimensional nucleation when overlap effects are included (6) (Fig. 2) differs significantly from that for two-dimensional nucleation only in that damped oscillations are not observed before the steady state is reached. It should be stressed however that the model used for the evaluation of the *i-t* transient for three-dimensional nucleation is somewhat unrealistic, differing essentially from that for two-dimensional nucleation only in that it does not recognize the finite size of atoms. It is for this reason that oscillations due to the formation of individual atom layers are not predicted. We should generally expect to observe three-dimensional nucleation in deposition on to heterogeneous substrates where the spreading of a monomolecular layer over the surface may be inhibited so that the outward growth becomes comparable with the lateral growth.

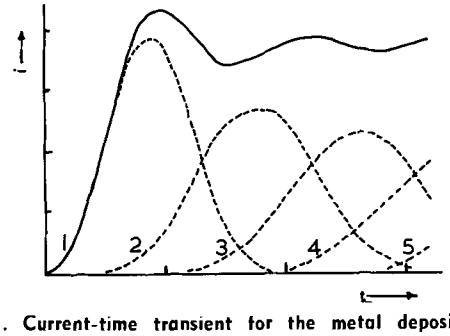

Fig. 1. Current-time transient for the metal deposition case, together with currents for individual layers.

[1] These are taken to be electrodes where edge effects are negligible.

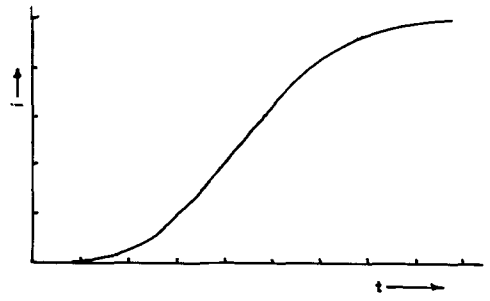

Fig. 2. Current-time transient for three-dimensional nucleation, taking into account overlap.

The present results extend the computer simulations (3) which were not taken to sufficiently long times to show the damping of the current oscillations, and which also showed an artifact in that the curves depended separately on V and A which is not substantiated by the present analysis.

The steady state i-E relationship is given by [4]. The prediction of the i-E curve demands a knowledge of the potential dependence of V and A. The dependence on potential[2] would be expected to be the same as that of a normal electrochemical rate constant, *i.e.*

$$V = V_{\eta=o}\left[\exp\left(\frac{\alpha z\mathbf{F}\eta}{RT}\right) - \exp\left(\frac{-(1-\alpha)z\mathbf{F}\eta}{RT}\right)\right] \quad [5]$$

provided that average potentials (7) are of significance in determining the rate.

The potential dependence of A is of the form (1, 2, 12)

$$A = \text{const.}\exp\left(-\frac{\text{const}}{\eta}\right) \quad [6]$$

Neither [5] nor [6] can be regarded as proved although [6] has been in some measure substantiated (2). [In the earlier work (3-5) on the formation of anodic films on mercury and mercury amalgams the potential dependence of V and A for individual layers is obscured by ohmic overpotential effects.]

Galvanostatic Conditions

For the formation of a single layer from N_o instantaneously nucleated centers under galvanostatic conditions $V(t)$ is given by

$$S_{ex} = N_o\pi\left(\int_0^t V(t)\,dt\right)^2 \quad [7]$$

where

$$S_{ex} = -\ln\left(1 - \frac{it}{q_{mon}}\right) \quad [8]$$

[7] and [8] use the relationships given by Avrami (13).

Solving [7] gives

$$V(t) = \frac{1}{2(\pi N_o)^{1/2}}\frac{i}{(q_{mon}-it)}\left[\ln\left(\frac{q_{mon}}{q_{mon}-it}\right)\right]^{-1/2} \quad [9]$$

The form of V as a function of t is given in Fig. 3. This has a minimum at a time

$$t = \frac{q_{mon}(e^{1/2}-1)}{ie^{1/2}} \quad [10]$$

If an exponential dependence of V on η is assumed the corresponding η-t relationship can be derived.

For the growth of successive layers with a time dependent rate of nucleation the transient condition cannot be solved. However the steady-state i-E relationship for the metal deposition case is again given by [4]. For a crude approximation to the nonsteady-state condition we can assume that as one layer is

[2] It is important that η is referred to the appropriate monolayer reversible potential (7).

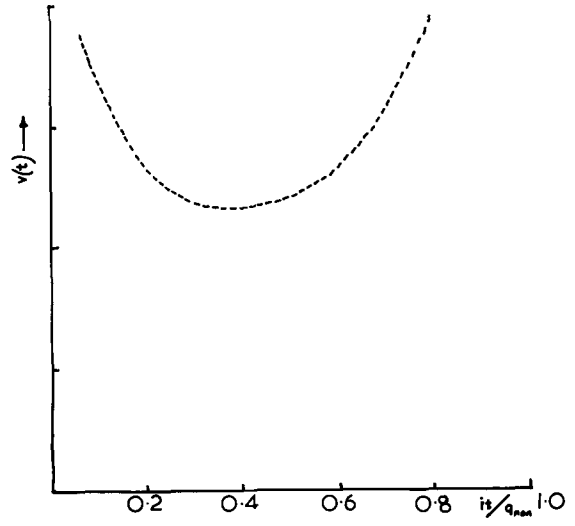

Fig. 3. Dependence of the rate of advance of an edge (V) on time for instantaneous nucleation under galvanostatic conditions.

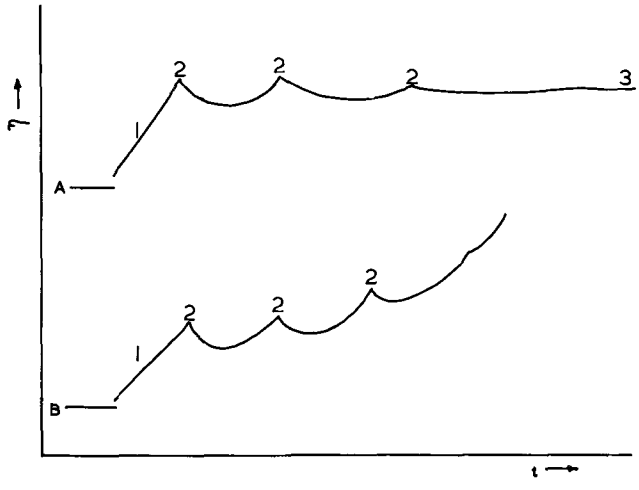

Fig. 4. Schematic η-t transients: A, metal deposition case; B, anodic film case. 1, double layer charging; 2, period of high nucleation rate; 3, steady state.

completed the potential rises to a high value for a short time to produce effectively N_n nuclei instantaneously. The η-t relationships are shown in Fig. 4, and such transient conditions have been observed for the electrodeposition of Ag on to Ag[2] (although on a bounded electrode, where the steady state given by [4] is not expected) and for the formation of calomel on Hg (14, 15).

Diffusion Effects

A situation which is very likely to arise in metal deposition is that a transport process either on the surface or in the solution procedes incorporation into the nucleus. A completely rigorous solution of the problem is difficult. However the problem can be simplified by calculating two limiting cases: (*i*) the diffusion zones are confined to individual nuclei; and (*ii*) the diffusion zones have overlapped so that only a concentration gradient at right angles to the surface exists.

Case (i).—The calculation of the current-time characteristic for the formation of a single layer can be achieved by relaxing the condition that V is time independent. The rate of advance of the radius is assumed to be controlled by hemicylindrical diffusion symmetrically about an axis at right angles to the 2D nucleus. The exact solution for the simple growth of one nucleus has been given by Frank (16).

$$R(t) = S\sqrt{Dt} \quad [11]$$

S is a constant which depends on $\frac{(C^* - C^o)M}{\rho}$ and can be obtained from equations or calibration curves given in the paper.

Application of the Avrami theorem (13) gives analogues of [1], [2]

$$i = q_{mon}\pi S^2 D \exp(-\pi S^2 D N_o t) \quad [12]$$

$$i = q_{mon}\pi S^2 D A t \exp\left(\frac{-\pi S^2 D A t^2}{2}\right) \quad [13]$$

The forms of [12] and [13] are shown in Fig. 5 and 6. It is to be noted that the form of Fig. 6 is the same as that of Eq. [2] and experimentally indistinguishable from it.

Case (*ii*).—This limiting situation is likely to arise when a large number of nuclei are formed initially and the individual diffusion zones soon disappear. When the growth is controlled by linear diffusion, with Nernst equilibrium only at the growing patches the current-time curve can be calculated as for the adsorption of organic molecules (17, 18). The expression assuming a linear isotherm is (19)

$$i = \frac{zFA'C^*D^{1/2}}{\pi^{1/2}t^{1/2}} - \left\{\left(\frac{zFA'^2C^{*2}D}{m}\right)\left(\exp - \frac{z\mathbf{F}\eta}{RT}\right)\right.$$
$$\left.\exp\left[\frac{C^{*2}DA'^2t}{m^2}\left(\exp - \frac{2z\mathbf{F}\eta}{RT}\right)\right]\right.$$
$$\left.\operatorname{erfc}\left[\frac{C^*D^{1/2}A't^{1/2}}{m}\left(\exp - \frac{z\mathbf{F}\eta}{RT}\right)\right]\right\} \quad [14]$$

which is to be compared with the well-known situation

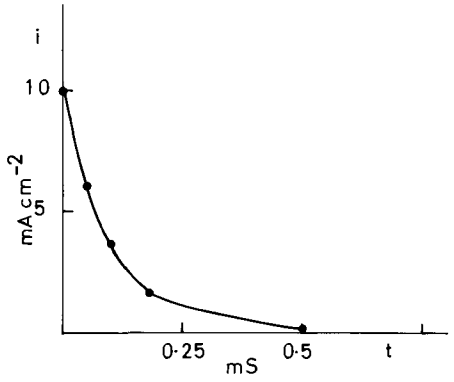

Fig. 5. Current-time transient for instantaneous two-dimensional nucleation with diffusion control.
$\pi S^2 D q_{mon}$ = 10 ma cm^{-2}
q_{mon} = 1.0 mcoul cm^{-2}
N_o = 10^6

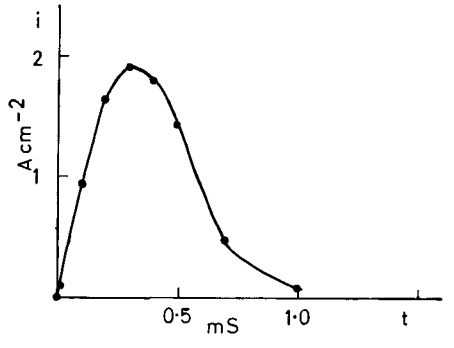

Fig. 6. Current-time transient for progressive two-dimensional nucleation with diffusion control.
$q_{mon}\pi S^2 DA$ = 10^7 ma cm^{-2} sec^{-1}
A = 10^6 sec^{-1}
q_{mon} = 1.0 mcoul cm^{-2}

when the whole of the surface appears to be active to cations approaching the surface

$$i = zFAC^*\left[1 - \exp\left(-\frac{z\mathbf{F}\eta}{RT}\right)\right]\frac{D^{1/2}}{\pi^{1/2}t^{1/2}} \quad [15]$$

Conclusions

Since the steady-state response for metal deposition under conditions where the formation of two-dimensional nuclei is rate determining has no remarkable features, evidence for 2D nucleation must be obtained from transient experiments. An exact time dependent analysis is only possible under potentiostatic conditions because two potential dependent parameters are involved.

Due to the presence of (*i*) a large number of bounded areas and (*ii*) large numbers of dislocations (possibly screw dislocations) which act as growth sites, in real metallic surfaces it may not be possible to observe the predicted i-t or η-t oscillations even if 2D nucleation occurs. However there are certain other indications that 2D nucleation and growth control the rate of metal deposition, *e.g.*, the successful prediction of change of orientation with potential based upon the equilibrium orientation of a 2D nucleus (20).

and Arnulf Muan

Department of Geochemistry and Mineralogy, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

A "double-cell" involving a combination of ZrO_2-CaO and ThO_2-Y_2O_3 solid electrolytes has been developed for emf measurements at elevated temperatures. The cell utilizes the desirable properties of the ZrO_2-CaO electrolyte at relatively high oxygen pressures and the desirable properties of the ThO_2-Y_2O_3 electrolyte at very low oxygen pressures to make it operative over a considerably wider range of oxygen pressures than has been possible with previously described cells.

Galvanic cells involving solid electrolytes with oxygen-ion conductivity are being used widely in investigations of thermodynamic and kinetic properties of materials at elevated temperatures (1, 2). Such cells also have potential applications as fuel cells (3).

The most commonly used electrolyte is a solid solution of zirconia and lime [85 m/o (mole per cent) ZrO_2, 15 m/o CaO], which at moderately high temperatures (*e.g.*, 700°-1400°C) is a practically pure ionic conductor over a wide range of oxygen pressures (P_{O_2}). This electrolyte performs well even at oxygen pressures above 1 atm. For instance, a preliminary investigation (4) has shown that appreciable hole conductivity at 1000°C appears only if $P_{O_2} > 100$ atm. However, the 85% ZrO_2 15% CaO electrolyte is not suitable at very low oxygen pressures because of the appearance of electronic conductivity according to the reaction

$$O_O \rightarrow \tfrac{1}{2} O_2\,(g) + V_O^{\cdot\cdot} + 2e' \qquad [1]$$

where O_O is an oxygen atom in a regular oxygen site, $V_O^{\cdot\cdot}$ is a doubly ionized oxygen vacancy, and e' is an excess electron. Applying the method of coulometric titration, Tretyakov (5) found that the average value of the ionic transference number, $\bar{t}_i$,[3] was $\geqq 0.99$ (and hence the average value of the electronic transference number, $\bar{t}_e$, $\leqq 0.01$) if

$$\log_{10} P_{O_2} \geqq -\frac{60.5 \cdot 10^3}{T} + 23.5 \qquad [2]$$

Thoria-yttria solid solutions (with 5-10 m/o Y_2O_3) (7, 8) have been found to be a more satisfactory electrolyte than ZrO_2-CaO at very low oxygen pressures. However, the ThO_2-Y_2O_3 electrolyte has the serious disadvantage of developing a significant hole conductivity at moderate oxygen pressures. This hole conductivity has been shown (9) to be strongly temperature dependent.

The present work has two main objectives: (*a*) to design a galvanic cell which combines the desirable properties of the ThO_2-Y_2O_3 electrolyte at very low oxygen pressures and the desirable properties of the ZrO_2-CaO electrolyte at relatively high oxygen pressures; (*b*) to determine the conditions of appearance of electronic conductivity in the ThO_2-Y_2O_3 electrolyte of this cell as a function of temperature.

Description of the Cell

The design of the cell is shown schematically in Fig. 1. The feature of main interest is the two concentric, impervious tubes, an outer 85 m/o ZrO_2 15 m/o CaO tube[4] and an inner 92 m/o ThO_2 8 m/o Y_2O_3 tube,[4] each closed in one end. The two tubes separate the electrode to be investigated, located inside the inner tube, from the reference electrode, located outside the outer tube, allowing only transport of oxygen ions through the double electrolyte. In the space between the two electrolyte tubes there is a partially oxidized Co strip which acts as a buffer, keeping the

[1] Contribution No. 67-80 from College of Earth and Mineral Sciences, The Pennsylvania State University, University Park, Pa.

[2] At the time of this work, Dr. Tretyakov was a visiting scientist at the Pennsylvania State Unversity under the 1967-1968 U.S.S.R.-U.S.A. exchange scholar program.

[3] According to Wagner (6)

$$\bar{t}_i = \frac{\int_{\mu_O'}^{\mu_O''} t_i \, d\mu_O}{\mu_O'' - \mu_O'}, \qquad [3]$$

where t_i is the true value of the ionic transference number, and μ_O' and μ_O'' are the oxygen chemical potentials on the two sides of the solid electrolyte.

[4] The tubes were manufactured by the Zirconium Corporation of America. The dimensions and impurity levels of the tubes (in wt. %) are approximately as follows: ZrO_2-CaO tube (12″ long, ½″ O.D., ⅜″ I.D.): Aluminum, 0.09%; Iron, 0.07%; Magnesium, 0.15%; Titanium, 0.07%; Silicon, 0.29%. ThO_2-Y_2O_3 tube (12″ long, ⅜″ O.D., 9/32″ I.D.): Aluminum, 0.02%; Boron, 0.002%; Calcium, 0.001%; Cobalt, 0.003%; Copper, 0.002%; Iron, 0.03%; Magnesium, 0.005%; Molybdenum, 0.001%; Nickel, 0.001%; Potassium, 0.001%; Silicon, 0.06%; Sodium, 0.003%.

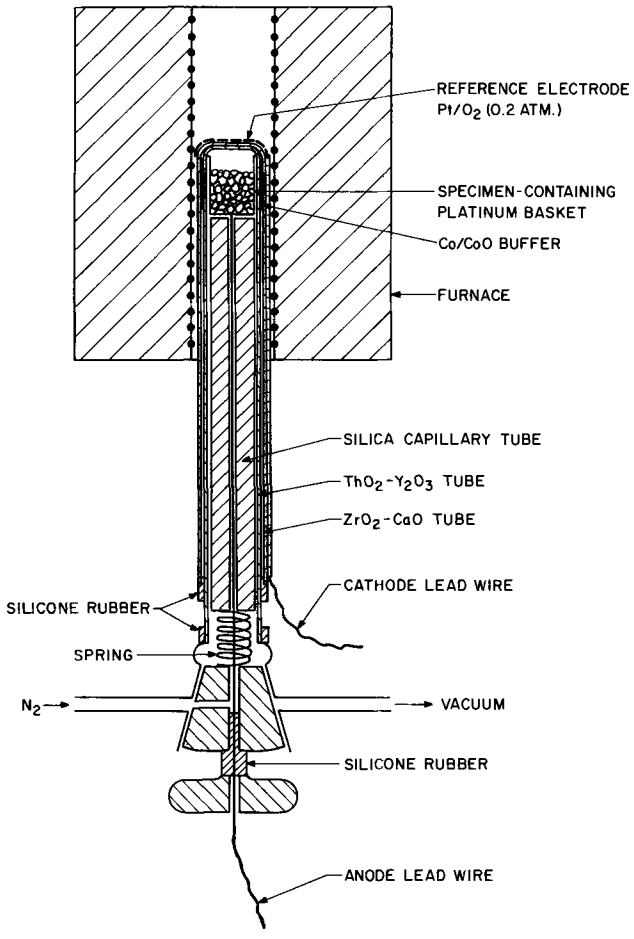

Fig. 1. Schematic diagram showing main features of new cell combining ThO_2-Y_2O_3 and ZrO_2-CaO electrolytes for electrochemical studies at elevated temperatures (compare text).

oxygen pressure in this space equal to that of the Co/CoO equilibrium at a given temperature. The rest of the space between the tubes is filled with nitrogen gas, and the two tubes are attached to each other with a gas-tight silicone rubber seal which is indifferent to the gaseous phase up to 200°C. The same sealing technique is used to attach the ThO_2-Y_2O_3 tube to the ground-glass joint at the lower end of the apparatus.

The material to be investigated is contained in a small platinum basket (~7 mm OD, ~15 mm long) near the closed end of the ThO_2-Y_2O_3 tube. A silica-glass capillary tube occupies the major part of the remaining volume inside the ThO_2-Y_2O_3 tube. The remaining, free volume inside the ThO_2-Y_2O_3 tube is small and accurately known [the method of precise determination of free volume of such a chamber has been described elsewhere (10)]. The tip of the inner surface of the ThO_2-Y_2O_3 tube, as well as the outer surface of the tip of the ZrO_2-CaO tube, is coated with a porous platinum film. Good contact is ensured between the specimen-containing platinum basket and the ThO_2-Y_2O_3 electrolyte by means of a spring at the lower end of the apparatus. This spring exerts pressure on the silica-glass capillary tube inside the ThO_2-Y_2O_3 tube. A platinum wire attached to the specimen-containing basket goes through the silica-glass capillary tube, through the male part of the ground-glass joint (silicone rubber sealing), and to a very sensitive potentiometer. The reference electrode consists of platinum gauze in contact with air (P_{O_2} = 0.21 atm) and wired firmly to the platinum film at the outer surface of the tip of the ZrO_2-CaO tube. A platinum lead wire is attached to the platinum gauze. The wire as well as the Pt-Pt 10% Rh thermocouple wires used to measure temperature are insulated from the electrolyte by alumina capillary tubes. The cell is heated by a Kanthal-wound microfurnace (15 mm ID, 150 mm long) with low heat capacity. The EMF of the cell is measured with a Guildline 9160-1 potentiometer assembly, which includes a narrow galvanometer combined with a photocell amplifier.

Experimental Procedures Used in Testing the Performance of the Cell

The platinum basket with the material to be investigated is introduced into the ThO_2-Y_2O_3 tube. The latter is evacuated, heated to 50°-60°C, and filled with nitrogen at pressure slightly in excess of 1 atm. The ThO_2-Y_2O_3 tube is then closed by turning the glass graded seal, and the cell is heated to the maximum temperature of the experiment (in the present case usually 1100°C). In order to maintain the electrolyte tubes impervious as long as possible, it is important to change the temperature of the cell slowly—in no experiments did the rate of heating or cooling exceed 300°C/hr.

The emf's of the following cells were measured in order to check the performance of the apparatus under various experimental conditions:

$$\text{air } (P_{O_2} = 0.21 \text{ atm}) \,|\, \text{Pt} \,|\, ThO_2(Y_2O_3) \,|\, ZrO_2(CaO) \,|\, \text{Pt} \,|\, \text{air } (P_{O_2} = 0.21 \text{ atm}) \quad (A)$$

$$O_2(P_{O_2} = 1 \text{ atm}) \,|\, \text{Pt} \,|\, ThO_2(Y_2O_3) \,|\, ZrO_2(CaO) \,|\, \text{Pt} \,|\, \text{air } (P_{O_2} = 0.21 \text{ atm}) \quad (B)$$

$$\text{Fe,Fe}_{1-x}\text{O} \,|\, \text{Pt} \,|\, ThO_2(Y_2O_3) \,|\, ZrO_2(CaO) \,|\, \text{Pt} \,|\, \text{air } (P_{O_2} = 0.21 \text{ atm}) \quad (C)$$

$$\text{Mn,MnO} \,|\, \text{Pt} \,|\, ThO_2(Y_2O_3) \,|\, ZrO_2(CaO) \,|\, \text{Pt} \,|\, \text{air } (P_{O_2} = 0.21 \text{ atm}) \quad (D)$$

The electrode $Fe,Fe_{1-x}O$ was prepared by sintering a pelletized mixture of high-purity metal and Fe_2O_3 (molar ratio 4:1) in an evacuated and sealed silica tube at 1000°C for 24 hr. The electrode Mn,MnO was prepared by sintering a pressed mixture of Mn metal and Mn_3O_4 (molar ratio 5:1) in an alumina container in a nitrogen atmosphere at 1100°C for 24 hr. Measurements of the emf's of the cells were made over the temperature range 700°-1100°C.

Results of these measurements for the four cells are shown in Fig. 2. The results presented are typical of the more extensive sets of data which were obtained; for sake of clarity the number shown has been reduced. Cell (*A*) produces the emf of zero ±0.5 mv over the entire temperature range, showing that there is practically no emf developed in our apparatus in addition to that created by the different oxygen potentials on the two sides of the double solid electrolyte according to the equation

$$E = \frac{1}{2\mathbf{F}} \int_{\mu_o'}^{\mu_o''} t_i \, d\mu_o \qquad [4]$$

where **F** is Faraday's number, t_i is the transference number of oxygen ions, and μ_o' and μ_o'' are the oxygen potentials on the inner surface of the ThO_2-Y_2O_3 electrolyte and on the outer surface of the ZrO_2-CaO electrolyte, respectively. The emf of cell (*B*) is in good agreement (deviations $\leqq$ 0.7 mv) with the value calculated from Eq. [4], assuming $t_i = 1$, *i.e.* $E = 1/2\mathbf{F}\ (\mu_o'' - \mu_o') = RT/4\mathbf{F} \ln P_{O_2}''/P_{O_2}'$. This is remarkable, in view of the fact that a ThO_2-Y_2O_3 solid electrolyte, when used alone, has considerable hole conductivity under similar conditions. For instance, Wimmer, Bidwell, and Tallan (9) have shown that in the cell

$$O_2(P_{O_2} = 0.08 \text{ atm}) \,|\, \text{Pt} \,|\, ThO_2(Y_2O_3) \,|\, \text{Pt} \,|\, O_2(P_{O_2} = 1 \text{ atm})$$

the average ionic transference number is as low as ~0.7, independently of temperature in the range of 900°-1500°C.

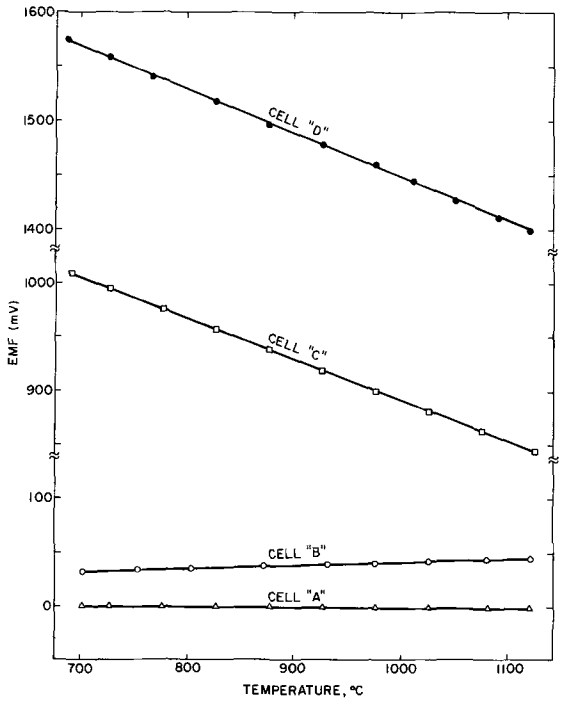

Fig. 2. Experimentally determined emf values as a function of temperature for cells "A," "B," "C," and "D" as described in the text.

In the double solid electrolyte shown in Fig. 1, practically pure ionic conductivity is maintained also at low oxygen pressures. Thus, the Gibbs free energies ΔG^o for the reaction Me + 1/2 O_2 = MeO (M = Fe,Mn) calculated from the emf's of cells (*C*) and (*D*) are in good agreement with the data of Chipman (11) and of Coughlin (12).

Determination of Conditions for Occurrence of Electronic Conductivity in the ThO_2-Y_2O_3 Electrolyte of the Present Cell

Theoretical background.—The occurrence of electronic conductivity at low oxygen pressures, and its pressure dependence according to

$$[e'] = K' P_{O_2}^{-1/4} \qquad [5]$$

are to be expected on the basis of reaction [1] (*see* p. 331). The corresponding mass-action expression is

$$P_{O_2}^{1/2}[V_o^{\cdot\cdot}][e']^2 = K \qquad [6]$$

For the ThO_2-Y_2O_3 electrolyte, $[V_o^{\cdot\cdot}] = \frac{1}{2}[Y'_{Th}] = Y_2O_{3_{total}}$ = constant. The ionic transference number may be written

$$t_i = \frac{\sigma_i}{\sigma_i + \sigma_e} = \frac{1}{1 + K''[e']} \qquad [7]$$

assuming that electronic conduction σ_e is proportional to $[e']$. Inserting Eq. [5] into Eq. [7], one obtains

$$t_i = \frac{1}{1 + (P_{O_2}^*/P_{O_2})^{1/4}} \qquad [8]$$

where $P_{O_2}^* = (K' \cdot K'')^4$. It is seen from Eq. [8] that $P_{O_2}^*$ is the oxygen pressure which corresponds to $t_i = 0.5$. Inserting Eq. [8] into Eq. [4] and taking into account that $\mu_o = \mu_o^o + RT \ln P_{O_2}^{1/2}$, one obtains (3) the following expression

$$E = \frac{RT}{F} \ln \frac{(P_{O_2}^*)^{1/4} + (P_{O_2''})^{1/4}}{(P_{O_2}^*)^{1/4} + (P_{O_2'})^{1/4}} \qquad [9]$$

If $P_{O_2'} << P_{O_2}^* << P_{O_2''}$, Eq. [9] yields the expression

$$P_{O_2}^* = P_{O_2''} \exp\left(-\frac{4E_sF}{RT}\right) \qquad [10]$$

where E_s is the potential of a galvanic cell in which the equilibrium oxygen pressure on one side of the solid electrolyte is determined by the self-dissociation of the electrolyte ($P_{O_2}^* >> P_{O_2'}$), leading to the occurrence of electronic conductivity.

Experimental.—The method of coulometric titration was used in the present investigation to measure E_s over a wide temperature range. In cell (*A*) (*see* p. 332) oxygen was removed from the inner compartment of the ThO_2-Y_2O_3 tube by the application of a suitable external voltage. The titration current varied between 0.2 and 2 ma, and every charge consisted of 0.5-1 coulomb. After every charge, the external circuit was disconnected, and the emf was measured. High and very unstable emf values, resulting from polarization of the electrolyte, were followed by stable emf values corresponding to equilibrium states of the system. One of the curves showing emf as a function of charge at 900°C is presented in Fig. 3. It is seen that the emf increases during the initial stage of the coulometric titration and then reaches a practically constant value. Results of the determination of the free volume of the inside of the cell show that the titration curves of Fig. 3 are consistent with a complete removal of the oxygen which was originally present in this compartment of the cell. If the solid electrolyte is stable under similar conditions and is impervious to oxygen, the curve emf = $f(q)$ would go toward infinity. Stability of the maximum emf value proves gas-tightness of the solid electrolyte tube. The stable, fixed plateau-value of the emf results from proper dissociation of the ThO_2-Y_2O_3 electrolyte, *i.e.* emf = E_s in Eq. [10]. The results of the determination of E_s as a function of temperature, as shown in Fig. 4, can be expressed by the following equation:

$$E_s(V) = 2.87 - 7 \cdot 10^{-4} T (\pm 0.02, 1000°\text{-}1400°K)$$

From this equation and Eq. [10] it follows that for the ThO_2-Y_2O_3 electrolyte

$$\log_{10} P_{O_2}^* = -\frac{56.25 \cdot 10^3}{T} + 13.36 \ (1000°\text{-}1400°K) \qquad [11]$$

Assuming that the range of applicability of the ThO_2-Y_2O_3 electrolyte is limited by the oxygen-pressure range in which the average value of the ionic transference number t_i is $\geqq 0.99$, and taking into account the analysis of Vetcher (14), one obtains

$$\log_{10} P_{O_2}^{**} = -\frac{56.25 \cdot 10^3}{T} + 17.36 \ (1000°\text{-}1400°K) \qquad [12]$$

where $P_{O_2}^{**}$ is the minimum value of the oxygen pres-

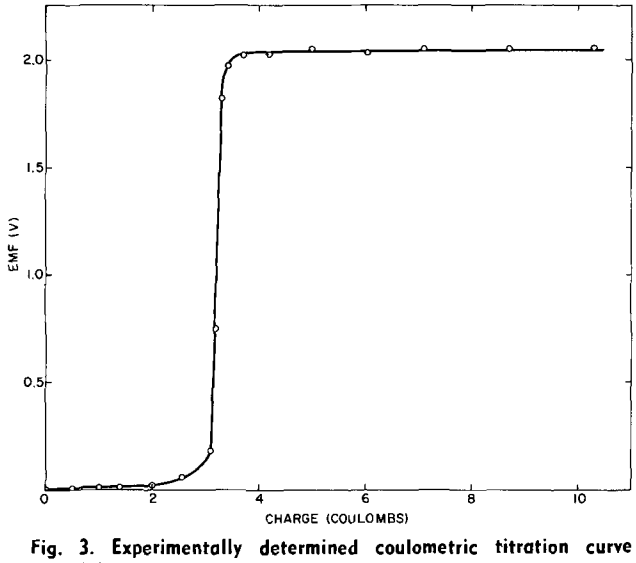

Fig. 3. Experimentally determined coulometric titration curve for cell "A" (compare text).

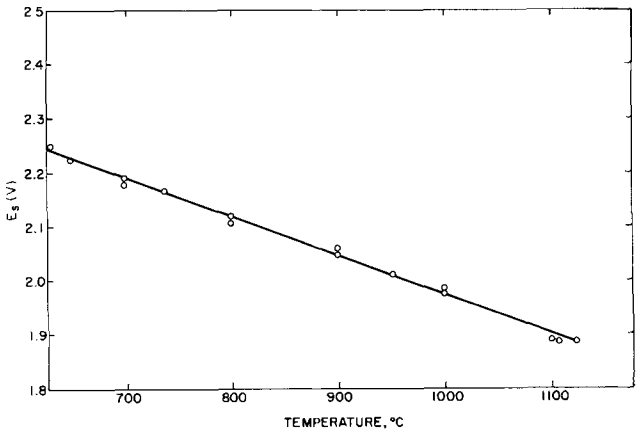

Fig. 4. Experimentally determined values of E_s as a function of temperature for ThO_2-Y_2O_3 electrolyte of the present cell (compare text).

sure for which electron transport in the solid electrolyte causes an error in the determination of the thermodynamic emf not exceeding 1% (the usual limit of accuracy in such measurements).

General Considerations and Conclusions

In applying the ThO_2-Y_2O_3 solid solution as electrolyte in galvanic cells, one must take into account that direct contact between the electrolyte and the electrode to be investigated may result in considerable decrease of the emf because of polarization effects (15), surface contamination, oxidation of the electrode, or reaction between the electrolyte and the adjacent solid phases. Hence, it would be more correct to consider Eq. [11] as the condition of applicability of the ThO_2-Y_2O_3 solid electrolyte only if there is no direct contact between the electrolyte and the solid phases of the electrodes, *i.e.* if equilibrium between electrolyte and solid phases is established through the gas phase only.

Studies of Electrooxidation of Dextrose in Neutral Media

M. L. B. Rao[1] and Roger F. Drake*

Monsanto Research Corporation, Boston Laboratory, Everett, Massachusetts

ABSTRACT

Electrooxidation of dextrose on platinized platinum electrodes has been studied in phosphate buffer at *p*H 7.4. Rest potentials are interpreted as mixed potentials. Galvanostatic curves have been observed to exhibit oscillatory voltage behavior. In the range of potentials investigated gluconic acid is observed as the reaction product and is found to inhibit oxidation of dextrose due to adsorption on the electrode surface. From the measurements of the adsorption characteristics of the acid, the oscillatory voltage behavior of the galvanostatic curves have been ascribed to kinetic effects of formation of the product and the potential dependence of its adsorption.

Anode-cathode couples based on redox components of the blood are under investigation in a program to study the feasibility of an implantable fuel cell for an artificial heart (1). The possibility of utilizing the dextrose in blood as fuel for this purpose is contemplated. Therefore, tests are carried out at the blood *p*H of 7.4.

Literature on the electrochemistry of dextrose is limited. Polarographic reduction of the carbohydrate was treated by Delahay and Strassner (2). Bockris, Piersma, and Gileadi (3) reported electrooxidation of dextrose in aqueous alkali at high temperature. Mention is made of dextrose oxidation in acid media by Bagotsky and Vasilyev (4). In contrast to previous investigations, this paper is devoted exclusively to a detailed analysis of the electrooxidation of dextrose in neutral media.

Experimental

Electrodes.—The working electrode is a 3 cm^2 platinized platinum sheet spot welded to a platinum wire, which is embedded in a glass tube. Before platinizing, the electrode surface is cleaned in concentrated nitric acid and flamed. It is then platinized at 10-20 ma/cm^2 for 10-20 min in a H_2PtCl_6 platinizing solution.

The counter electrode is a platinized platinum gauze of apparent area 10 cm^2.

A standard calomel electrode (SCE), immersed in the electrolyte through a Luggin capillary situated at the working electrode, serves as the reference for the measurement of potential.

Electrolyte and cell.—Reagent grade chemicals and distilled water are used to prepare the solutions. The electrolyte is a 1M phosphate buffer (19.85g K_2HPO_4, 22g $Na_2HPO_4 \cdot 12H_4O$, and 29g NaCl per liter) of pH 7.4. Known amounts of dextrose or gluconic acid or both are added to the electrolyte as required. Measurements are carried out at room temperature employing freshly deaerated solutions. An H-type cell with a fine sintered glass frit separating the two compartments is used in the experiments.

Measuring procedure and equipment.—The rest potential of the working electrode is first determined in the deaerated dextrose solution. The electrode is then set at the value of the rest potential by means of a potentiostat. At predetermined time intervals, the potentiostat circuit is switched off and a constant anodic current is passed by means of a galvanostatic circuit and a mercury wetted relay switch. On application of the galvanostatic current, the working electrode assumes more positive values. When the electrode potential exhibits a point of inflection in the range of 0 to +0.25v (*vs.* SCE), the galvanostatic current is switched off, and the electrode is returned to the control of the potentiostat. Between measurements, the electrolyte is stirred by bubbling nitrogen for 40 sec. When the gas is turned off, an additional 60 sec is allowed to obtain minimum turbulence. The galvanostatic pulse is again applied, and the sequence of operation is repeated for further measurements. In the absence of the potentiostatic circuit, it is observed that the decay of the electrode potential subsequent to anodization to the initially observed rest potential is slow and is not reproducible, possibly due to formation of platinum oxides or sorption of the reaction product. By utilizing the potentiostatic circuit, either the reduction of platinum oxide or the desorption of the product is accomplished, and thus reproducible surface conditions are established.

A 610A Keithley Electrometer, Wenking Potentiostat, Tektronix Oscilloscope Model 545 with Type-L Plug-in unit, a strip chart recorder, 6200-B Harrison D.C. power supply, and a mercury relay (Potter & Brumfield JM1-121-11) are used in the experiment. The circuitry is conventional.

Product analysis.—In order to determine the product, anodization is carried out at constant current employing small volumes of 0.5M dextrose solution and a large area working electrode. The potential of the electrolysis is restricted to $<+0.2$v (*vs.* SCE). The spent solution is analyzed for products by thin layer chromatography.

Results

Open-circuit behavior of dextrose half-cell.—On bright platinum electrodes immersed in a 0.01-0.5M dextrose solution in the deaerated electrolyte, the rest potential is in the range of -0.1 ± 0.05v. Platinized platinum electrodes, however, attain rest potentials of -0.65 ± 0.05v. Experiments reveal that the rest potential of the electrode is sensitive to the previous history of the electrode and impurities in the solution. This behavior is illustrated from data in Table I.

Dextrose oxidation.—Typical galvanostatic curves observed during the anodization of platinized platinum electrodes in 0.5M dextrose solution in the saline phosphate buffer are illustrated in Fig. 1. Curves 1 through 5 are for apparent current densities 4.26, 3.26, 2.6, 1.86, 1.3, and 0.66 ma/cm². The roughness factor of the electrode as determined by electrochemical hydrogen coverage is in the range of 80-150.

The total coulombic charge required to reach the point of inflection A in Fig. 1 varies with current density and is quantitatively represented in Fig. 2, curve 1. Voltage oscillations are observed in the current density region 2.6-1.3 ma/cm². At current densities of 0.66 ma/cm², voltage oscillations are not observed except just prior to occurrence of the point of inflection (*cf.* Fig. 1, curve 5).

Table I. Open-circuit potential established on platinized-platinum electrode in 0.5M dextrose solution in phosphate buffer (pH = 7.4)

Experimental condition	Observed open-circuit potential (volts *vs.* calomel)
Just after immersion of the electrode in the solution	−0.56
Solution deaerated with N_2 for 20 min	−0.65 ± 0.05
Subsequent to subjecting to cathodic pulse at 1 ma for 2 min	−0.66
Subsequent to subjecting to anodic pulse at 10 ma for 1 min	+0.15v
3 min after the anodic pulse	−0.55
20 min after the anodic pulse	−0.65 ± 0.05
On stirring the solution by introducing air	−0.1
Unstirred solution saturated with air	−0.56
Electrode potential subsequent to potentiostating at −0.66v (potentiostat requires ± <0.01 ma to maintain the potential)	−0.66

In order to understand the dextrose oxidation behavior, further experiments were carried out in the electrolyte solution containing 0.01, 0.05, 0.10M of the active material. The nature of the galvanostatic curves obtained in these experiments was similar to those represented in Fig. 1. However, at lower concentrations of dextrose, no oscillatory behavior was observed.

Considering the time (t or τ) required to attain the transition point A as the termination of oxidation of dextrose, the data are analyzed for constancy in it and $i\tau^{1/2}/c$, as in the measurement of coulometric adsorption coverage and in chronopotentiometry, respectively. The results indicate that neither it nor $i\tau^{1/2}$ is constant.

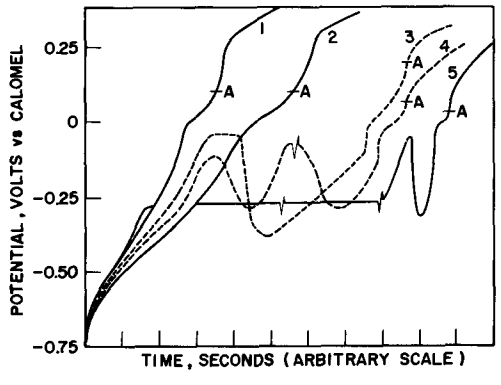

Fig. 1. Nature of dextrose curves. Curves 1 to 5 are for current densities 4.26, 3.26, 2.6, 1.86, 1.3, and 0.66 ma/cm², respectively. Electrolyte: 0.5M dextrose in phosphate buffer (pH = 7.4); electrode: (Roughness factor 150).

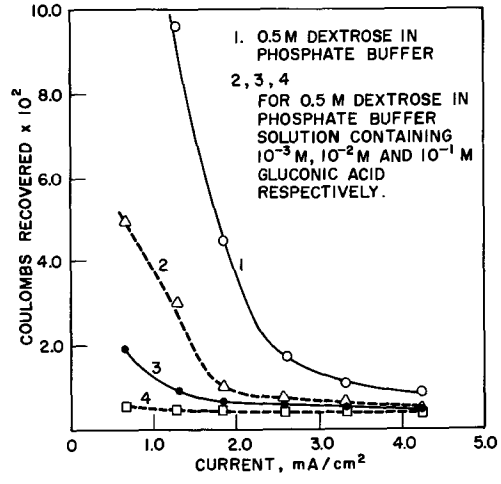

Fig. 2. Effect of gluconic acid on oxidation of dextrose. Curve 1, 0.5M dextrose in phosphate buffer. Curves 2, 3, and 4 are for 0.5M dextrose in phosphate buffer solution with 10^{-4}M, 10^{-2}M, and 10^{-1}M gluconic acid, respectively.

Under experimental conditions gluconic acid is observed as the product of dextrose electrooxidation. Stirring as well as increasing the temperature of the solution favors the requirement of higher charge coulombs to attain the transition point A in the galvanostatic curves.

Evaluation of the effect of the products of oxidation of dextrose on the behavior observed in Fig. 1 is made by obtaining polarization curves in 0.5M dextrose solution containing 0.001, 0.010, and 0.100M gluconic acid. The nature of the curves obtained in these experiments is similar to the ones in Fig. 1, except that the current density at which voltage oscillations occurred decreases with an increase in the concentration of gluconic acid. The charge coulombs required to reach the point of inflection A in Fig. 1 decreases at all current densities with increasing gluconic acid concentration in the dextrose solution. The results are represented in Fig. 2, curves 2, 3, and 4.

The platinized platinum electrodes used in the above experiments assume open-circuit voltages of +0.05 ± 0.05v in deaerated gluconic acid solution (10^{-4} to 10^{-1}M) in the saline buffer electrolyte. Anodic charging curves on the platinized platinum electrodes are taken in the electrolyte with and without gluconic acid in order to examine whether there is evidence for the oxidation of gluconic acid. These experiments are carried out from the open circuit voltage as well as from —0.65v (*vs.* SCE). The latter potential is chosen since it is the open-circuit voltage of dextrose solution. It is observed that in either case, the nature or coulombic charge required to reach the point of inflection on the anodic curve was not significantly different in the two solutions. This suggested gluconic acid does not undergo further oxidation in the voltage range of investigation.

In order to understand the mechanism of inhibition of dextrose oxidation induced by gluconic acid (*cf.* Fig. 2, curves 2-5), the adsorption characteristics of the acid were studied. The method of investigation consisted of taking cathodic charging curves of platinized platinum electrodes immersed in the saline buffer of the electrolyte at various levels of gluconic acid content. Taking the charging curves from different initial potentials, Q_H, the hydrogen coverage was determined as a function of potential. In this procedure, the difference in Q_H observed in the two solutions at any given potential would reflect the number of hydrogen adsorption sites which are occupied by gluconic acid. This procedure and method of computation of θ, the fraction of total surface covered by gluconic acid, is similar to that employed by Breiter and Gilman (5) for obtaining the potential dependence of adsorption of methanol in acid electrolyte. For example, the hydrogen coverage of an electrode was 83.3 mc/cm² at —0.2v. This value was observed to have changed to 73.3, 61.7, and 51.3 mc/cm² in the presence of 0.0001, 0.01, and 0.5M gluconic acid concentration, respectively. Based on the results the θ_{GA} values of 0.12, 0.26, and 0.38, respectively, were calculated. Similar computation of observed data yielded the variation of θ_{GA} with potential at different concentrations of gluconic acid and this is shown in Fig. 3. θ_{GA} for gluconic acid is potential dependent, and the maximum adsorption occurs in the region of —0.35 to —0.2v (*vs.* SCE).

Discussion

The open-circuit potentials in Table I, exhibited by oxide-free platinized platinum electrodes immersed in dextrose-containing saline phosphate buffer solution, may be considered as mixed potentials of the following reactions

$$O_2 + 4H^+ + 4 \rightarrow 2H_2O$$
$$E^o_{pH7.4} = +0.55v \text{ } vs. \text{ calomel} \quad [1]$$
$$R\text{-}CHO + H_2O \rightarrow R\text{-}COOH + 2H^+ + 2e$$
$$E^o_{Dextrose,\ pH7.4} = -0.625v \text{ } vs. \text{ calomel (6)} \quad [2]$$
$$2H^+ + 2e \rightarrow H_2 \quad E^o_{pH7.4} = 0.68v \text{ } vs. \text{ calomel (7)} \quad [3]$$

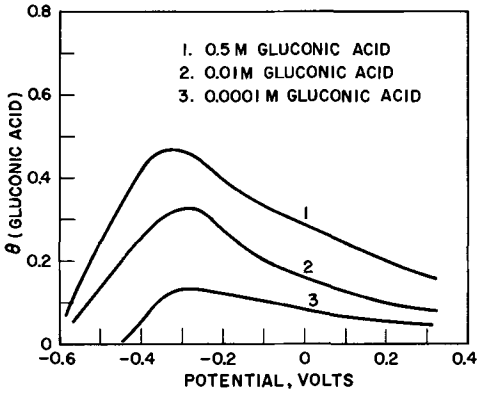

Fig. 3. Variation of surface coverage of gluconic acid with electrode potential.

where R- represents the $CH_2OH(CHOH)_4$ group of the dextrose molecule.

Considering the facts that (*i*) the open-circuit potentials are sensitive to the presence of oxygen; (*ii*) gluconic acid has been identified as reaction product; and (*iii*) the open-circuit potentials are close to the reversible hydrogen electrode potentials; it is suggested that the rest potentials are mixed potentials of reactions represented in Eq. [1], [2], and [3]. In thoroughly deaerated solutions, the effect of reaction in Eq. [1] is negligible because of very low partial pressure of oxygen.

The electrooxidation products of dextrose in the electrolyte obviously depend on the polarization voltage of the electrode. In the voltage range of investigation, *i.e.*, from —0.65 to +0.2v (*vs.* SCE) gluconic acid is found as a reaction product. It is also noted that gluconic acid does not seem to undergo further oxidation in this voltage region, and has a tendency to adsorb on the electrode (Fig. 3). In the presence of gluconic acid, dextrose oxidation was noticed to be inhibited (cf. Fig. 2, curves 2 to 4). These facts suggest that production of gluconic acid and its tendency to adsorb on the electrode results in a decrease in active surface area for dextrose oxidation and, hence, the inhibition of the oxidation reaction. The low material efficiency observed for the reaction is thus explained.

The oxidation curves of dextrose are complicated as shown from the oscillatory voltage behavior represented in Fig. 1 and also from the analysis of the results which revealed lack of constancy in the computed values of it or $i\tau^{1/2}/c$. The complexities seem to arise due to kinetic effects of potential-dependent adsorption-desorption phenomena associated with the product, gluconic acid. The behavior may be explained phenomenologically.

Curves 1 through 5 in Fig. 1, observed for the dextrose oxidation reaction, may be grouped into three categories: (*i*) high current density region wherein no oscillatory voltage behavior is observed [*cf.* curves 1 and 2]; (*ii*) intermediate current density region for which oscillatory voltage behavior is observed as in curves 3 and 4; and (*iii*) the low current density region for which the oscillatory behavior is observed only prior to the attainment of the point of inflection A. As indicated, gluconic acid is the oxidation product. Since gluconic acid has been found to inhibit the oxidation of dextrose (Fig. 2, curves 2, 3, and 4), and since the extent of inhibition depends on the concentration of gluconic acid, it is of interest to consider the effect of pseudoequilibrium of adsorption of the electrogenerated acid in the system. The quantity of gluconic acid present under kinetic conditions in the diffusion layer and on the electrode depends upon the rate of production of the acid, *i.e.*, current density, and the rate of desorption and diffusion of the acid into the bulk of the solution. The experiments carried out under stirred electrolyte condition favor the pas-

sage of higher charge coulombs until attainment of the inflection point in comparison to unstirred solution. Based on this information it is inferred that both desorption and diffusion processes contribute to the removal of gluconic acid from the vicinity of the electrode, the latter being rate limiting. In the high current density region, presumably, the rate of production of the acid exceeds the rate of diffusion of the product into the bulk of solution, and hence a large concentration of the acid predominates at the electrode. The presence of a large concentration of gluconic acid at the electrode decreases the active area of the electrode, due to the pseudoequilibrium for the adsorption of the acid. Thus, the transition point A may be said to be reached soon because of a large decrease in active surface area. The potential dependence of adsorption is probably of secondary importance on curves 1 and 2 in Fig. 1 as they are inferred to be operating under the influence of a high concentration of adsorbable species. Because of the changes in active surface area of the electrode during the measurement, neither it or $it^{1/2}/c$ would be constant.

At medium current densities, the rate of production of gluconic acid and the rate of diffusion of the species away from the electrode are hypothesized to be approximately equal. This results in a steady concentration of gluconic acid in the diffusion layer. Under these conditions, for the pseudoequilibrium of adsorption of the acid, the potential dependence as observed in Fig. 3 becomes important. Thus, during anodization, when the electrode crosses the potential of maximum adsorption of the acid, desorption of the adsorbed species is favored. At this point, the effective surface area for dextrose oxidation increases, resulting in a decrease in the reaction overpotential, and the reversal of potential occurs. As the reaction proceeds, once again the accumulation of gluconic acid occurs; adsorption takes place, resulting in a decrease in surface area for dextrose oxidation. The latter process increases the reaction overpotential. Repetition of the aforementioned sequence results in oscillatory voltage behavior. The voltages at the turning point of the oscillatory voltage behavior observed for Fig. 1, curves 3 and 4, correspond reasonably well with the potential dependence of adsorption observed in Fig. 3, and thus the mechanism is substantiated.

In the low current density region, the rate of production of gluconic acid is presumed to be less than the rate of diffusion of the acid into the bulk of the solution, and hence a low concentration of the acid exists in the vicinity of the electrode. Under this condition the decrease in surface area due to adsorbed gluconic acid is small and the reaction proceeds uninhibited.

Termination of the dextrose oxidation at medium and low current density regions possibly occurs because of slow accumulation and adsorption of impurities. The impurities may be oxidation products of gluconic acid, and may have been generated from the very low partial currents effective for such reactions. This suggested that the oxidation products of gluconic acid would also effect the inhibition of dextrose oxidation. The effect of temperature to favor higher charge coulombs during electrooxidation of dextrose may be understood in terms of increased rate of removal of gluconic acid from the vicinity of the electrode, due to an increase in the value of diffusion coefficient of the species.

In earlier studies on small amplitude voltage oscillations, the behavior was observed for the oxidation of formaldehyde in sulfuric acid by Koch (6). The author has proposed the accumulation and desorption of a polymer product as the cause for the oscillatory behavior. Based on the results of this paper, the mechanism of the formation of a polymer product is an unlikely cause for the oscillatory voltage behavior observed in the case of dextrose oxidation.

It is recognized that the carbohydrate under investigation exists in two optical isomers. In the dextrose reduction reaction on mercury it is shown that only the open chain aldehyde form of the material is the electroactive species. Because of the inhibiting effect of the product of oxidation observed in the present experiments, it is not clear whether the activity of dextrose for oxidation at platinum depends on the structural and configurational parameters. Further insight into the problem has to come subsequent to the development of electrocatalysts capable of oxidizing the carbohydrate without the complication of adsorption of the product.

Acknowledgment

The authors wish to thank Dr. David L. Williams for helpful discussions, Mr. A. R. Doig, Jr., for providing the thin layer chromatographic analysis, and Mr. P. W. Orthmann and Mr. W. P. Brissette for technical assistance. This work was sponsored by the National Heart Institute, United States Department of Health, Education, and Welfare, contract PH43-66-976.

Manuscript submitted Aug. 9, 1968; revised manuscript received Nov. 20, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 184.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Electroosmosis in Ion-Exchange Membranes

N. Lakshminarayanaiah

Department of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

ABSTRACT

Application of an electric field to the system, electrolyte solution ⇌ membrane ⇌ electrolyte solution, gives rise to unidirectional flow of solvent phenomenologically called electroosmosis. The volume of this transference depends primarily on membrane water content and the concentration of the electrolyte solution bounding the membrane on either side. For the passage of 1**F** of electricity, the quantity of electroosmotic flow in dilute solutions is shown by some investigators to be dependent on current density, while others claim it to be independent of current density. Recent measurements indicate that membranes with low water contents (less than about 14%) produce water flows independent of current density, while those with higher water contents show current dependence. However, at external concentration greater than 0.1*N*, the current dependence of water flow disappears and the flow decreases with increase in external concentration. These results and others are discussed in terms of existing theories of electroosmosis in charged membranes.

Application of an electric field to the system, electrolyte solution ⇌ membrane ⇌ electrolyte solution, causes not only transference of ions but also flow of liquid through the membrane. The number of moles of ions and of water transported for the passage of 1**F** of electricity are called ion transference number ($\bar{t}_i$) and water transference number ($\bar{t}_w$), respectively (overbar refers to membrane phase). The total water transport composed of two components—water of ion hydration and water transported electroconvectively—is designated purely phenomenologically by the well-known term electroosmosis. The flow of water usually takes place in the direction in which the counterions move and as a result the counterions move faster than coions, since they experience less resistance to movement than coions.

Electroosmosis is observed with all types of membranes. It is due to the presence of charged groups arising either by adsorption of one or more ionic species from solution onto the walls of the pores or by fixation to the membrane matrix by an appropriate chemical process. Presence of these fixed groups in an aqueous electrolyte medium leads to the type of ionic distribution associated with the electrical double layer.

All electrokinetic phenomena have been attributed to interactions between flow of electricity and flow of liquid in the double layer (1). A slipping plane between the fixed charges and the diffuse part of the double layer of opposite total charge density is usually envisaged and the electrical potential in this plane is identified with the zeta (ζ) potential. The classical theory of electroosmosis centers round the parameter ζ which cannot be measured directly. Without using this concept of ζ potential, Schmid and Schwarz (2-8) have dealt with the different electrokinetic phenomena in detail considering the membrane as a system composed of fine pore capillaries in which solution of fixed charges and their counterions existed. Disregarding this membrane structure, electrokinetic phenomena have been treated by the methods of thermodynamics of irreversible processes by Staverman (9) and Kedem and Katchalsky (10). Spiegler (11), on the other hand, using a pore model, has given a very illuminating treatment "in generality falling between Schmid's and Staverman's."

Some of our new results and those already existing in the literature are reviewed in the light of the equations developed by Schmid, Spiegler, and others (12, 13).

Key words: double layer, electroconvection, electroosmotic permeability, friction coefficient, ion transport number, membrane conductance, membrane fixed charge density, membrane porosity, surface charge density, water transport number, zeta potential.

Experimental

A number of investigators have measured water transport through various ion-selective membranes using different ions and a variety of techniques and cell designs (12-48). Basically two methods, one based on weight changes (12, 16, 34, 35, 44) and the other based on volume changes (13, 16-22, 24-30, 33, 36-39, 41-43, 45-48) have been used to measure total transport of water through ion-exchange membranes. Weight method is accurate with flexible membranes which are likely to move back and forth during electrolysis. It has the other advantage that volume changes due to salt transport, electrode reactions, and small temperature fluctuations need not be considered seriously. It calls for meticulous care in transferring solutions and washing the apparatus. In contrast, experiments by the volume method are easy to perform, provided temperature fluctuations are well controlled by a thermostat held constant to ± 0.01°. Its chief advantage is the innumerable number of experimental runs that may be carried out by simply reversing the direction of current flow in each succeeding run. The membrane movement may be controlled by the techniques described elsewhere (18, 39). All our new results given in this paper and those results referred to herein are obtained by the volume method (13, 18, 25, 27, 36, 39, 42, 46).

Results and Discussion

The work relating to electroosmosis in permselective membranes has been recently reviewed by Lakshminarayanaiah (49). Since then a few more papers dealing with different aspects of electroosmotic water flow have appeared (38-48). These and some of our new results are examined to emphasize the effects of different membrane parameters on $\bar{t}_w$.

Effects of various factors on $\bar{t}_w$.—Two major factors which act directly to control the amount of electroosmosis (*i.e.*, $\bar{t}_w$) in membranes are the water content of the membrane and the concentration of the external electrolyte solution. Normally $\bar{t}_w$ is found to decrease with decrease in the water content and to increase with the decrease in the electrolyte concentration. The data of Lakshminarayanaiah (42) realized for phenolsulfonate (PSA) membranes and given in Table I illustrate these effects. It should be noted that $\bar{t}_w$ values are determined by both the electrolyte concentration and the water content. To isolate the influence of one on $\bar{t}_w$ from the influence of the other is difficult. Recently, we have measured $\bar{t}_w$ keeping the external electrolyte concentration constant at 0.01*N*

Table I. $\bar{t}_w$ values for phenolsulfonate (PSA) membrane as functions of external NaCl concentration and water present in the membrane (42)

External electrolyte normality	Water content g H_2O/g wet membrane	Current density ma/cm²	$\bar{t}_w$
0.10	0.622	0.5-10.1	37.2
0.50	0.606	0.5-10.1	18.2
1.00	0.602	0.5-10.1	11.0
2.00	0.568	0.5-10.1	6.1
3.00	0.558	0.5-10.1	3.9
5.20	0.540	0.5-10.1	2.1

Table II. $\bar{t}_w$ values for AMF C-104 membrane with 0.01*N* solution

Current density ma/cm²	Li^+	Na^+	K^+	Rb^+	Cs^+
0.32	10.0	5.8	4.5	4.0	4.3
1.58	9.5	6.3	3.7	3.6	4.1
3.15	10.1	6.2	4.0	3.7	4.3
15.75	10.0	6.4	3.4	4.1	4.4
Water content: g H_2O/g wet membrane	0.132	0.121	0.118	0.115	0.112

but varying the nature of the cation. These new results obtained for AMF C-104 membranes and shown in Table II indicate that, besides showing the effect of the nature of the cation on $\bar{t}_w$, $\bar{t}_w$ does decrease with decrease in the membrane water content. The independent demonstration of the effect of the other factor, *i.e.* at constant water content increase of electrolyte concentration will decrease $\bar{t}_w$, is quite difficult, as electrolyte invasion of the membrane following increase in external concentration will always affect the membrane water content.

There are a few other factors which also affect $\bar{t}_w$ rather indirectly by affecting the water content of the membrane. They are, the temperature, the degree of crosslinking of the membrane, the fixed charge density of the membrane, and the current density employed in the measurement of $\bar{t}_w$.

Recently George and Courant (43) examined the effect of temperature and found $\bar{t}_w$ to decrease slightly with increase in temperature in the range 10°-40°C. Usually increase of temperature decreased the membrane water content and so the observed $\bar{t}_w$ variation with temperature was in accordance with the change in the water content of the membrane.

The effect of crosslinking on $\bar{t}_w$ depends on the way crosslinking affects again the membrane water content. The data of Lakshminarayanaiah (13) obtained for differently crosslinked polymethacrylic acid (PMA) membranes in contact with 0.01*N* NaOH solution are shown in Fig. 1. At any given current density, $\bar{t}_w$ value is greater the lower the crosslinking, because the membrane with the lower degree of crosslinking has higher water content.

The effect of fixed charge density on $\bar{t}_w$ is quite complex. No systematic study of this effect exists in the literature. Its effects may, however, be inferred from studies made on a number of membrane systems. In Table III are given the values of $\bar{t}_w$ derived by Lakshminarayanaiah and co-workers (27, 36, 39) for three membrane systems. In the case of PMA membrane whose water content is greater than PSA membrane, the $\bar{t}_w$ value is less than that of the PSA membrane. This follows from the fact that the water associated with an equivalent of counterion in PMA membrane is less than that of the PSA membrane. But the same is not seen in the case of untreated collodion membrane which in spite of an internal molality of 10.4 is still cation selective giving a water flow of 7.4 moles in the direction of the cation flow. These facts by themselves are acceptable but taken together

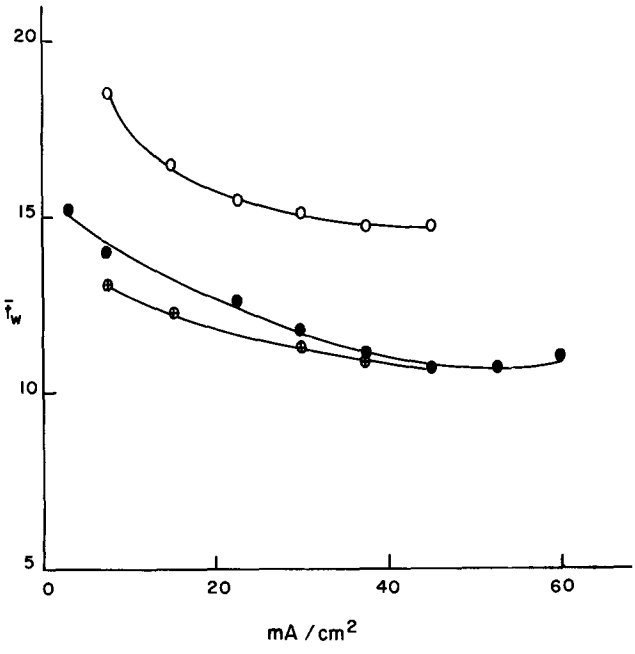

Fig. 1. $\bar{t}_w$ plotted as a function of current density for PMA membranes differently crosslinked with 5% (○), 10% (●) and 15% (⊕) ethylene glycol dimethacrylate. Data taken from Ref. (13).

belie belief in generalizations about membrane behavior.

Studies of the dependence of $\bar{t}_w$ on current density using dilute solutions (0.01*N*), in whose environment there is little invasion of the membrane by the coion, are not definitive. Mackay and Meares (24) in 1959 reported complete independence of $\bar{t}_w$ on current strength employing NaCl solutions in the concentration range 0.01-1.0*N*. Carr *et al.* (29) obtained the same current independence of $\bar{t}_w$ with 0.02*N* KCl solution. Similar results have been obtained by others (30, 34) using higher concentrations and moderate current densities. At very high current densities, however, $\bar{t}_w$ decreased (30) and this decrease was attributed to membrane polarization. In contrast, Lakshminarayanaiah (13, 18, 42, 46, 49, 50) for the first time in 1956 using 0.01*N* solutions showed (Fig. 1 and Table IV) that $\bar{t}_w$ depended on current density displaying two main characteristics: (*a*) at low current densities $\bar{t}_w$ rose to a high value, and (*b*) at high currents it attained a limiting value. Subrahmanyan and Lakshminarayanaiah (25, 26, 42) showed later that these relationships changed as the concentration of external electrolyte was increased to 0.1*N* and above when $\bar{t}_w$ became independent of current density (see Table I). The results for Na^+ ion (0.01*N*) obtained by Lakshminarayanaiah (13, 18, 46) for three different mem-

Table III. Membrane characteristics

branes at different current densities are given in Table IV. These results are further confirmed by the work of George and Courant (43) who used leached membranes (Nepton CR-61) in 0.01N NaCl solution. The water content of PMA, PSA, and AMF C-103 membranes were 0.68, 0.59, and 0.18g H_2O/g wet membrane, respectively. Lakshminarayanaiah and Subrahmanyan (46) used AMF C-103 membrane in 0.01N RbCl or CsCl solution and obtained values for $\bar{t}_w$ shown in Table V. It is seen that $\bar{t}_w$ is completely independent of current density. The water contents of the membrane in Rb^+ and Cs^+ forms were 14 and 13%, respectively (46). This pointed to the fact that water content of the membrane controlled current dependence of $\bar{t}_w$; that is, at water contents greater than 14% $\bar{t}_w$ depended on current density, whereas at lower values it did not depend on current density. To check this further, we measured $\bar{t}_w$ with AMF C-104 membrane which has a low water content in 0.01N solutions. The results of Table II confirm the independence of $\bar{t}_w$ on current density where the water content of membrane in different ionic forms is less than 14%.

Evaluation of Schmid's theory of electroosmosis.— All of the results obtained by different investigators under a variety of conditions cannot be explained by any one of the existing theories of electroosmosis. Let us consider the theory of electroconvection in fine capillary membrane systems proposed by Schmid and Schwarz (4, 6). They related the ratio of convection current Δi (*i.e.*, $\Delta i = i - i'$ where i is current flowing through the membrane in presence of an applied field and i' is current flowing in absence of solvent flow) to total current to the fixed ion concentration and radius r of the membrane pores. Thus

$$(i - i')/i = \Delta i/i = (\mathbf{F}^2\bar{X}^2r^2)/(8\bar{\eta}\bar{k}_i) \quad [1]$$

where $\mathbf{F}$ is faraday, $\bar{X}$ is fixed charge density of the membrane expressed in moles/liter, $\bar{\eta}$ is viscosity of pore liquid, and $\bar{k}_i$ is specific conductance of pore liquid. Despic and Hills (17, 51) have cast this into the form

$$\bar{\lambda} - \bar{\lambda}' = (10^3\mathbf{F}^2\bar{X}r^2)/(8\bar{\eta}) \quad [2]$$

($\bar{\lambda}$ is equivalent conductance measured electrically and $\bar{\lambda}'$ is equivalent conductance derived from self-diffusion coefficient) and found it inapplicable to PMA rods (17).

To make a critical check of Eq. [2], we measured the equivalent conductance ($\bar{\lambda}$) and self-diffusion coefficient $\bar{D}$ of ^{22}Na using PSA and AMF membranes in the usual way (52). These results are given in Table VI. From $\bar{D}$ values, $\bar{\lambda}'$ values were derived using the Nernst-Einstein relation

$$\bar{D} = (RT)/(z\mathbf{F}^2)\bar{\lambda}' = 2.66 \times 10^{-2}\bar{\lambda}' \quad [3]$$

$$\text{for } z = 1$$

Using the bulk viscosity value for water in Eq. [2], values for r, the radius of membrane pores, were calculated. These calculated values are compared in Table VI with the values derived by water flux measurements described by Lakshminarayanaiah (53). The agreement in the case of tight membranes (AMF C-103 and C-104) is good, whereas with PSA membrane the agreement is bad. From these results, it is thus concluded that Schmid's theory of electroconvection is applicable to tight membranes of low water content.

Another equation of Schmid's theory which involves $\bar{t}_w$ may be used to make a further check on the validity of the pore model chosen by Schmid who in developing the theory of electroosmosis has used the equations derived by Bjerrum and Manegold (54) and Manegold and Solf (55). He showed that electroosmotic permeability D_i per ampere is given by

$$D_i = \frac{\mathbf{F}\bar{X}D_h d}{\bar{k}} \quad [4]$$

where D_h is permeability defined as the volume of solution transferred in unit time through unit membrane area under unit pressure difference, d is membrane thickness, and $\bar{k}$ is specific conductance of the membrane.

Some of the data derived again for the three membranes (PSA and AMF C-103 and C-104) by Lakshminarayanaiah (18, 46, 53) are used here to check Eq. [4]. Values of $\bar{t}_w$ calculated according to Eq. [4] and those obtained by direct measurement are shown in the last two columns of Table VII. The agreement between the calculated and measured values is poor in the case of PSA membranes and very good in the case of AMF membranes. This check also goes to show that the Schmid theory is applicable to tight

** New results except $\bar{t}_w$ and D_h values for AMF C-103 membrane which are taken from Ref. (46, 53).

membranes whose water contents are about 14% or less. The capillary model therefore seems to be quite realistic for evaluating both electroconvection and total water transport.

Evaluation of surface charge density of membrane pore liquid.—In order to explain the current dependence of $\bar{t}_w$, Lakshminarayanaiah (13, 49) assumed a capillary model for the membrane and derived the relation

$$\bar{t}_w = (r\mathbf{F})/(36\sigma) \qquad [5]$$

where σ is the surface charge density per square centimeter of the pore liquid. For any i^{th} pore in the membrane, a value of r_i/σ_i can be assigned. If the membrane was "heteroporous," it was postulated that at low currents liquid in pores of larger radii and lower surface charge became mobilized and gave a larger value for $\bar{t}_w$. In most cases, it is possible, unless the membrane is very homogeneous, $\sigma_i \neq \sigma$ and $r_i \neq r$ where σ and r are the average values for all the n pores in the membrane. These averages, which can be written as $\sigma = \sum_i \sigma_i/n$ and $r = \sum_i r_i/n$ $(i = 1,2 \ldots n)$, become effective at high currents and gave limiting values for $\bar{t}_w$.

The average values of r given in Table VI for PSA and AMF membranes and the values of $\bar{t}_w$ given in Tables II and IV may be used in Eq. [5] to derive values for σ. Some of these values are shown in Table VIII in which are included some values derived by Frumkin (56) by directly measuring the current flowing (*i.e.*, the charge) from a dropping mercury electrode to a pool of mercury containing the electrolyte solution. The agreement is surprisingly good and, if this is genuine, it seems to give credence to the reality of the capillary model chosen for the membrane. This is the first time water transport values have been used to derive values for the surface charge density of the pore liquid in a membrane.

Effect of friction between membrane parameters on $\bar{t}_w$.—In contrast to the capillary model approach, Winger *et al.* (12) made a phenomenological approach and wrote the following relationship for an ideal system in which there were no interactions between the different membrane components.

$$\bar{t}_w = (\bar{t}_1\bar{n}_1/z_1) - (\bar{t}_2\bar{n}_2/z_2) \qquad [6]$$

where $\bar{n}_1$ and $\bar{n}_2$ are the numbers of moles of water associated with cation and anion, respectively. When valencies $z_1 = z_2 = 1$, Eq. [6] becomes

$$\bar{t}_w = \bar{t}_1\bar{m}_w - \bar{n}_2 \qquad [7]$$

Table VIII. Surface charge in different systems

System	(μcoulomb/cm²)
PSA + 0.01*N* NaCl : Eq. [5]	40.5
AMF C-103 + 0.01*N* NaCl : Eq. [5]	38.3
AMF C-104 + 0.01*N* NaCl : Eq. [5]	34.1
1*N* NaCl saturated with Hg_2Cl_2 (Frumkin)	47
1*N* H_2SO_4 saturated with Hg_2Cl_2 (Frumkin)	39

where $\bar{m}_w = \bar{n}_1 + \bar{n}_2$. According to Eq. [7], Winger *et al.* (12) found a linear relationship between $\bar{t}_w$ and $\bar{t}_1$. On the contrary, Kressman *et al.* (35) and Lakshminarayanaiah and Brennen (39) found no such linear behavior although the latter found a linear relationship between $\bar{t}_w$ and $\bar{m}_w$ for untreated collodion membrane. The straight line relationships between $\bar{t}_w$ and $\bar{t}_1$, and $\bar{t}_w$ and $\bar{m}_w$ never gave, on extrapolation according to Eq. [7], agreeing values for $\bar{n}_2$ for any given anion. Further, the data of Lakshminarayanaiah (39, 42) showed that it was impossible to interrelate different membrane parameters by simple relationships. The observation that ions and water moved through the membrane with the same linear velocities noted by Kressman *et al.* (35) has not been observed by other workers. However, Eq. [7] predicts that this would take place only when $\bar{t}_1 = 1$ and $\bar{n}_2 = 0$ (*i.e.*, complete absence of coions). These conditions reduce Eq. [7] to

$$\bar{t}_w = \bar{m}_w \qquad [8]$$

This equation has been deduced by Lakshminarayanaiah and Subrahmanyan (46) assuming a capillary model for the membrane in the form

$$\bar{t}_w = 55.56/\bar{m}_1 \qquad [9]$$

where $\bar{m}_1$ is the molality of the counterion in the membrane.

Although the data of Table IV are obtained under these conditions, the values of $\bar{t}_w$ in the case of PSA membrane are higher than $\bar{m}_w$ ($\bar{m}_w \approx 40$) at 0.32 ma/cm² and at higher currents lower than $\bar{m}_w$. In the case of the other two membranes, the values of $\bar{t}_w$ are lower than $\bar{m}_w$ ($\bar{m}_w$ for PMA membrane $\approx$ 17.6 and for AMF C-103 $\approx$ 11). This deviation of $\bar{t}_w$ from values predicted by Eq. [8] is due to omissions of interactions between different components—membrane matrix, counterion, and water—of the membrane system. Spiegler (11) has considered these interactions in detail and has shown that the ratio of the fluxes of free water (J_3) and mobile counterion (J_1) is given by

$$J_3/J_1 = \bar{C}_3/[\bar{C}_1 + \bar{C}_3(\bar{X}_{34}/\bar{X}_{13})] \qquad [10]$$

where $\bar{C}_1$ and $\bar{C}_3$ are the concentrations of counterion and water in the membrane and $\bar{X}_{34}$ and $\bar{X}_{13}$ are the friction coefficients between water-membrane matrix and counterion-water, respectively. Equation [10] shows that only when $\bar{X}_{34}/\bar{X}_{13} = 0$ both ions and water move with the same linear velocity. For the condition $J_1 = 1$ (*i.e.*, $\bar{C}_2 = 0$ and $J_3 = \bar{t}_w$) Eq. [10] takes the form in which it has been derived by Dorst *et al.* (57)

$$viz., \quad 1/\bar{t}_w = (\bar{C}_1/\bar{C}_3) + (\bar{X}_{34}/\bar{X}_{13}) \qquad [11]$$

The relevant data from the work of Tombalakian *et al.* (30) have been used by Dorst and Staverman (58) to derive values for the ratio $(\bar{X}_{34}/\bar{X}_{13})_{HCl}/(\bar{X}_{34}/\bar{X}_{13})_{NaCl}$,

i.e. $(\bar{X}_{13})_{NaCl}/(\bar{X}_{13})_{HCl}$. They found this ratio to be approximately constant and to lie between 5 and 6 for a number of membranes. The results of similar calculations made for a variety of membranes and for different alkali metal ions but containing the same anion (except in the case of 10% PMA which contained OH^- ion) are shown in Table IX. For different combinations of cations, the ratio $(\bar{X}_{13})_{M_1^+}/(\bar{X}_{13})_{M_2^+}$ lies between 1 and 2. In view of this constancy Eq. [11] can be written for two electrolytes M_1 and M_2 as

$$[(1/\bar{t}_w) - (\bar{C}_1/\bar{C}_3)]_{M_1} = \text{Constant}\,[(1/\bar{t}_w) - (\bar{C}_1/\bar{C}_3)]_{M_2} \quad [12]$$

and from this, as pointed out by Dorst and Staverman (58), $\bar{t}_w$ for M_2 may be inferred, provided all the required data for M_1 and the values of $\bar{C}_1$ and $\bar{C}_3$ for M_2 are known. Since $\bar{C}_2 = 0$ for the membrane phase, the nature of the anion should have little effect on the ratio $(\bar{X}_{13})_{M_1^+}/(\bar{X}_{13})_{M_2^+}$.

Conclusions

1. Effects of various factors have shown that $\bar{t}_w$ is primarily controlled by the membrane water content and the concentration of the electrolyte solution surrounding it. $\bar{t}_w$ values decrease with decrease in water content and increase in electrolyte concentration.

2. $\bar{t}_w$ is independent of current density at external concentrations greater than 0.1*N*. In dilute solution (0.01*N*) it depends on current density if the water content of the membrane is greater than about 14%. This dependence disappears if the water content is less than about 14%.

3. The Schmid theory of electroconvection and electroosmosis has been tested and found to be inapplicable to membranes of high water content and applicable to membranes of low water content.

4. For the first time the surface charge density of moving pore liquid has been estimated from $\bar{t}_w$ data and found to be about 35 μcoulombs/cm^2.

5. That ions and water move through the membrane with the same linear velocity has been found to be an exception rather than the rule.

6. The value for the ratio of the friction coefficients $(\bar{X}_{13})_{M_1}/(\bar{X}_{13})_{M_2}$ has been found to lie between 1 and 2 for all the alkali metal ions in dilute solution contrary to the value of about 5.5 found by Dorst and Staverman for $(\bar{X}_{13})_{NaCl}/(\bar{X}_{13})_{HCl}$.

Acknowledgments

Some of the original experimental work described in this paper was supported by a grant from the Office of Saline Water, U. S. Department of the Interior.

Manuscript submitted May 17, 1968; revised manuscript received Oct. 25, 1968. This paper was presented at the Boston Meeting, May 5-9, 1968, as Paper 240.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

NOMENCLATURE

Subscripts 1, 2, 3, and 4 refer to counterions, coions, water, and membrane, respectively. Often, subscript w is used instead of 3 for water. Terms with bars on top refer to the membrane phase.

$\bar{C}$	Concentration (mole cm^{-3})
d	Thickness of membrane (cm)
$\bar{D}$	Self-diffusion coefficient (cm^2 sec^{-1})
D_h	Hydraulic permeability (cm^3 dyne^{-1} sec^{-1})
D_i	Electroosmotic permeability (cm^3 amp^{-1} sec^{-1})
Δ	Difference
$\bar{\eta}$	Viscosity of pore liquid (g cm^{-1} sec^{-1})
$\mathbf{F}$	Faraday's constant (coulomb equiv.$^{-1}$)
i	Current flowing through the membrane (amp)
i'	Current flowing through the membrane in absence of solvent flow (amp)
J	Flux (mole cm^{-2} sec^{-1})
$\bar{k}$	Specific conductance of membrane (ohm^{-1} cm^{-1})
$\bar{k}_i$	Specific conductance of pore liquid (ohm^{-1} cm^{-1})
$\bar{\lambda}$	Equivalent conductance measured (ohm^{-1} cm^2 equiv.$^{-1}$)
$\bar{\lambda}'$	Equivalent conductance derived (ohm^{-1} cm^2 equiv.$^{-1}$)
$\bar{m}$	Molality (mole/1000g H_2O)
$\bar{m}_w$	Moles of water associated with 1 equiv. counterion
n	Number of pores in the membrane per unit area
$\bar{n}$	Number of moles of water associated with an ion
N	Normality (equiv./liter)
R	Gas constant (erg deg^{-1} mole^{-1})
r	Radius of membrane pore (cm)
σ	Surface charge density (coulomb cm^{-2})
T	Absolute temperature
$\bar{t}_i$	Ion transference number (i = 1, 2)
$\bar{t}_w$	Water transference number (moles/**F**)
$\bar{X}$	Fixed charge density (mole cm^{-3})
$\bar{X}_{ij}$	Friction coefficient between components i and j (dyne sec cm^{-1} mole^{-1})
z	Valency
ζ	Zeta potential (v)

Technical Note

Limitations of the Determination of the True Surface Area of Spongy Metals with the Help of A-C Polarization Measurements

Carl Wagner*

Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

Pickering (1) has recently used a-c impedance measurements in order to determine the change in true surface area of Cu-Au samples subject to anodic dissolution of Cu with a sponge of Au-rich alloy surrounding the core of the sample. Impedance measurements were conducted in 1M H_2SO_4 with a negligible a-c component of the faradaic current. In this context the question has been raised under which conditions the ohmic resistance of the electrolyte in the sponge of Au-rich alloy affects the impedance measurements. The following elements of a model of the sponge may be considered (*i*) channels of uniform width and finite length whose axes are normal to the surface of the sample, (*ii*) wedgelike grooves, and (*iii*) conical pits.

The a-c impedance of each of these elements has been calculated by de Levie (2, 3). His equations can be used directly with suitable modifications for the special conditions considered in this paper.

The following general symbols are used

$j = (-1)^{1/2}$
κ double layer capacity per unit true surface area,
ρ resistivity of the electrolyte,
ω angular frequency of the alternating current.

(*i*) For the impedance Z_1 of a single channel of radius r and depth $L >> r$ de Levie (4) has derived an expression involving the ohmic resistance of the electrolyte in the pore per unit length ($=\rho/\pi r^2$) and the impedance of the double layer capacity in a pore of unit length ($=\frac{1}{2}\pi r j\omega\kappa$)

$$Z_1 = \left[\frac{\rho}{\pi r^2 \cdot 2\pi r j\omega\kappa}\right]^{1/2} \cdot \coth\left[\left(\frac{\rho}{\pi r^2} \cdot 2\pi r j\omega\kappa\right)^{1/2} L\right] \quad [1]$$

For the following calculation, it is expedient to introduce the real parameter

* Electrochemical Society Active Member.

$$u_1 = (2\omega\kappa\rho r^{-1})^{1/2} L \quad [2]$$

and to rewrite Eq. [1] as

$$Z_1 = \frac{j^{1/2}u_1 \cdot \coth (j^{1/2}u_1)}{2\pi r L j\omega\kappa} \quad [3]$$

Using a series expansion (5) for $j_1^{1/2}u_1 \cdot \coth j^{1/2}u_1$ one obtains

$$Z_1 = \frac{1}{2\pi r L j\omega\kappa}\left[1 + \frac{1}{3}(j^{1/2}u_1)^2 - \frac{1}{45}(j^{1/2}u_1)^4 + \frac{2}{945}(j^{1/2}u_1)^6 - \frac{1}{4775}(j^{1/2}u_1)^8 + \dots\right]$$

$$= \frac{1 + \frac{1}{45}u_1^4 - \frac{1}{4775}u_1^8 \dots}{2\pi r L j\omega\kappa} + \frac{\frac{1}{3}u_1^2 - \frac{2}{945}u_1^6 + \dots}{2\pi r L\omega\kappa} \quad [4]$$

The surface area of the wall of the channel is $2\pi rL$. The contribution of the bottom of the channel is disregarded since $L >> r$. Thus the admittance of the double layer capacity C_1 is

$$2\pi r L j\omega\kappa = j\omega C_1 \quad [5]$$

In view of Eq. [5], one may rewrite Eq. [4] as

$$Z_1 \cong \frac{1 + \frac{1}{45}u_1^4 - \frac{1}{4775}u_1^8 - \dots}{j\omega C_1} + \frac{\frac{1}{3}u_1^2 - \frac{2}{945}u_1^6 + \dots}{\omega C_1} \quad [6]$$

(*ii*) The impedance Z_2 of a groove of width $2b$ and depth L per unit length has been calculated by de Levie (3) as

$$Z_2 = \frac{\rho}{\tan\beta}\frac{I_0(\lambda)}{\lambda I_1(\lambda)} \quad [7]$$

In Eq. [7] $\beta = \sin^{-1}(b/L)$ is half the angle between the walls at the bottom of the groove, I_0 and I_1 are the modified Bessel functions of zero and first order, respectively, and the variable λ is defined as

$$\lambda = 2(\rho L/\zeta \sin\beta)^{1/2} \quad [8]$$

where $\zeta = (j\omega\kappa)^{-1}$ is the double layer impedance per unit true surface area. In a metal sponge as present in Pickering's experiments, L is much greater than b and accordingly $\beta << 1$. Hence

$$\sin\beta \cong \tan\beta \cong b/L \quad [9]$$

Thus Eq. [8] may be rewritten as

$$\lambda = 2j^{1/2}u_2 \quad [10]$$

where the dimensionless real parameter u_2 is defined as

$$u_2 = (\omega\kappa\rho b^{-1})^{1/2} L \quad [11]$$

The modified Bessel function of order ν is represented by the series expansion (6)

$$I_\nu(\lambda) = (\tfrac{1}{2}\lambda)^\nu \sum_{k=0}^{k=\infty} \frac{(\tfrac{1}{2}\lambda)^{2k}}{k!(\nu + k)!} \quad [12]$$

Further, one has the auxiliary formula

$$\frac{1}{1+\epsilon} = 1 - \epsilon + \epsilon^2 - \epsilon^3 + \dots \quad \text{if } \epsilon < 1 \quad [13]$$

Substituting Eq. [9], [10] and [12] in Eq. [7] and using Eq. [13], one obtains

$$Z_2 = \frac{1 + \frac{1}{12}u_2^4 + \dots}{2j\omega\kappa L} + \frac{\frac{1}{2}u_2^2 + \dots}{2\omega\kappa L} \quad [14]$$

The surface area of the walls of a narrow groove ($\beta << 1$) per unit length is $2L$. Thus the admittance of the double layer per unit length of the groove is

$$2bj\omega\kappa = j\omega C_2 \quad [15]$$

where C_2 is the double layer capacity per unit length of the groove. Thus Eq. [14] may be rewritten as

$$Z_2 = \frac{1 + \frac{1}{12}u_2^4 + \dots}{j\omega C_2} + \frac{\frac{1}{2}u_2^2 + \dots}{\omega C_2} \quad [16]$$

(*iii*) The impedance Z_3 of a conical pit with the radius r at its opening and the depth L has also been calculated by de Levie (3)

$$Z_3 = \frac{2\rho}{\pi r \tan\beta}\frac{I_1(\lambda')}{\lambda' I_2(\lambda')} \quad [17]$$

where $\sin\beta = r/L$ and

$$\lambda' = 2(2\rho L/\zeta \sin\beta) = 2j^{1/2}u_3 \quad [18]$$

and the dimensionless real parameter u_3 is given by

$$u_3 = (2\omega\kappa\rho r^{-1})^{1/2} L \quad [19]$$

Substituting Eq. [12], [18], and [19] in Eq. [17] with $\tan\beta \cong r/L$ if $r << L$ and using Eq. [13], one obtains

$$Z_3 = \frac{1 + \frac{1}{72}u_3^4 + \dots}{j\pi r L\omega\kappa} + \frac{\frac{1}{6}u_3^2 + \dots}{\pi r L\omega\kappa} \quad [20]$$

The surface area of the wall in a conical pit ($r << L$) is πrL. Thus the admittance of the double layer of the pit is

$$\pi r L j\omega\kappa = j\omega C_3 \quad [21]$$

where $C_3 = \pi rL\kappa$ is the double layer capacity of the pit. Thus Eq. [20] may be rewritten as

$$Z_3 \cong \frac{1 + \frac{1}{72}u_3^4 + \dots}{j\omega C_3} + \frac{\frac{1}{6}u_3^2 + \dots}{\omega C_3} \quad [22]$$

The solutions in Eq. [6], [16], and [22] are very similar. Thus they may be discussed jointly. If u_1, u_2, or u_3 is much less than unity, the value of Z_n for $n = 1, 2, 3$ is given by $(j\omega C_n)^{-1}$ as the limiting value for negligible ohmic resistance. The total impedance of a sample is given by the reciprocal of the sum of the individual admittances $j\omega C_n$. Thus, if the contribution of the metal surface between channels, grooves, or pits is disregarded, the total impedance Z of a sample involving a large number of channels, grooves or pits may be written as

$$Z \cong \frac{1 + \beta_n u_n^4}{j\omega C} + \frac{\alpha_n u_n^2}{\omega C} \quad \text{if } u_n << 1 \quad [23]$$

where C is the total double layer capacity, the parameters u_n for $n = 1, 2, 3$ are given by Eq. [2], [11], and [19], and the coefficients α_n and β_n for the three models are

$$\alpha_1 = \frac{1}{3}; \quad \alpha_2 = \frac{1}{2}; \quad \alpha_3 = \frac{1}{6} \quad [24]$$

$$\beta_1 = \frac{1}{45}; \quad \beta_2 = \frac{1}{12}; \quad \beta_3 = \frac{1}{72} \quad [25]$$

It is noteworthy that according to Eq. [23] even for $u_n = 1$ the change in the imaginary term is relatively small. The predominating effect is due to the second real term in Eq. [23]. Therefore, if u_n is not much less than unity, the bridge used by Pickering can be balanced only if during dissolution of Cu from a Cu-Au sample with increasing depth L corresponding to an increasing value of u_n in the model one adjusts not only capacitor C_5 but also resistor R_2 shown in Fig. 2 of Pickering's paper (1). Numerical estimates show that in most runs reported by Pickering values of u_n for each model were sufficiently small so that use of the limiting relation

$$Z = (j\omega C)^{-1} \quad [26]$$

is appropriate. This is in accord with Pickering's (1) observation that values of C calculated from Eq. [26] for measurements of Z with different frequencies do not differ to a large extent.

The ratio of the real part to the amount of the imaginary part of the impedance calculated in Eq. [23] is in essence proportional to u_n^2, *i.e.*, according Eq. [2] [11], and [19], proportional to the resistivity ρ of the solution, the square of the depth L, and the angular frequency ω, and inversely proportional to the width of the channel, groove, or pit expressed either by r or b. Thus the effect of a finite ohmic resistance of the electrolyte in the sponge is quite low if the depth L is small. In most of Pickering's experiments, L was less than 10^{-4} cm. Care, however, must be exercised if L is greater. Eventually, it is recommendable to use a low rather than a high a-c frequency if one intends an evaluation of measurements with the help of Eq. [26].

Since no model represents adequately the odd geometry of a metal sponge, Eq. [23] cannot be used for a quantitative evaluation of experimental data obtained for a metal sponge. Equation [23], however, can be used in order to estimate the limits for the applicability of a-c impedance measurements and their evaluation with the help of Eq. [26] for an approximate determination of the true surface area. In this context it is important to notice that an estimate based on Eq. [23] gives in essence the same result for all three models.

Crystal Growth and Properties of Mica-Like Potassium Niobates

K. Nassau, J. W. Shiever, and J. L. Bernstein

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Large single crystals of KNb_3O_8 and $K_4Nb_6O_{17}$ can be grown by Czochralski pulling from the melt. In the case of KNb_3O_8 a small amount of excess K_2O is used to avoid incongruent crystallization. Both materials show pronounced cleavage very similar to that of mica. The electrical properties of KNb_3O_8 are also very similar to those of mica, making this material a possible mica substitute as well as being an interesting new dielectric material in its own right. KNb_3O_8 is orthorhombic $Pmmm$, with $a = 8.91 \pm 0.01$Å, $b = 10.66 \pm 0.01$Å, $c = 3.77 \pm 0.01$Å, not the previously reported perovskite structure. Other characteristics determined include optical, mechanical, and chemical properties. When exposed to atmospheres between about 25 and 85% relative humidity, $K_4Nb_6O_{17}$ becomes a trihydrate, with higher hydration above about 85% relative humidity. Optical, electrical, and structural properties of all three forms of $K_4Nb_6O_{17}$ are described.

A total of nine compounds between Nb_2O_5 and K_2O have been discussed in recent studies. Reisman and Holtzberg (1) reported K_3NbO_4, $KNbO_3$, $K_4Nb_6O_{17}$, KNb_3O_8, and "$K_6Nb_{44}O_{113}$" in their equilibrium phase diagram based on differential thermal analysis. Guerchais (2) added to these $K_4Nb_2O_7$ and $K_2Nb_8O_{21}$ from his formation reaction powder x-ray diffraction study and found two other phases instead of "$K_6Nb_{44}O_{113}$." Whiston and Smith (3) in their single crystal x-ray diffraction study added the unit cell dimensions of $K_{12}Nb_{14}O_{41}$, "$K_4Nb_6O_{17}$," KNb_3O_8, "$K_2Nb_8O_{21}$," and $K_6Nb_{44}O_{113}$ to the well known perovskite structure of $KNbO_3$. Several of these identifications must, however, be questioned.

Since KNb_3O_8 is stated to melt incongruently (1), the platy crystals obtained by Whiston and Smith from a melt of the composition are expected to be the adjacent compound $K_6Nb_{44}O_{113}$ (1) or $K_2Nb_8O_{21}$ (2). It is indeed possible to index the $K_2Nb_8O_{21}$ pattern of Guerchais (2) with the Whiston and Smith KNb_3O_8 cell parameters thus confirming the probable identity of these two compounds. The cell parameters given by Whiston and Smith for acicular $K_4Nb_6O_{17}$ do not apply to any of the three platy forms of that composition described below, but do fit the diffraction lines of Guerchais' "third compound" in the $K_2Nb_8O_{21}$-$K_6Nb_{44}O_{113}$ region. There are other inconsistencies which are however not relevant to the present study. Except for $KNbO_3$, none of the crystals obtained in these studies was analyzed or characterized other than by x-ray diffraction and sometimes brief statements of crystal morphology, nor could the powder x-ray diffraction patterns be indexed.

Reisman and Holtzberg (1) state that crystals of $K_4Nb_6O_{17}$ and KNb_3O_8 are birefringent, the former being similar in appearance to mica, the latter occurring as rectangular plates. The growth of $K_4Nb_6O_{17}$ crystals by slow solidification of the melt has also been reported by Kestigian *et al.* (4), who gave extensive analysis details and some electrical measurements. They observed moisture absorption, but it appears that all measurements and analyses were performed on freshly dried material and accordingly the hydrates described below were not observed.

Among the factors which produce confusion in this system may be mentioned incongruent melting, extreme metastability (5) with excessive annealing times needed to obtain the final equilibrium compounds, as well as extensive hydrate formation, again probably including some metastability. The growth and detailed study of single crystals provides one way of avoiding many of these difficulties. We have grown crystals of KNb_3O_8 and $K_4Nb_6O_{17}$, and have characterized these, as well as the hydrates of $K_4Nb_6O_{17}$, by chemical analysis, x-ray diffraction, optical, and electrical measurements.

Crystal Growth of KNb_3O_8 *and* $K_4Nb_6O_{17}$

Niobium oxide (Kawecki Chemical Company, optical grade, highest impurity Ta < 100 ppm) and potassium carbonate (Fisher Scientific Company, reagent grade, highest impurity Na < 200 ppm) were ground together in stoichiometric amounts and fired overnight and reground three times at 500°, 700°, and 800°C. This material was melted in a platinum crucible heated by a 450 kHz radio frequency generator. In the case of KNb_3O_8 a small amount of excess K_2CO_3 was added at this point to avoid the incongruent melting point. The addition of 1 w/o (weight per cent) K_2CO_3, corresponding to approximately 2 m/o (mole per cent) excess potassium was found to be suitable. The temperature was controlled with a platinum sheathed platinum/platinum 10% rhodium thermocouple immersed in the melt. Growth was performed by the Czochralski pulling technique as previously described (6). The uncorrected optical pyrometer temperature of the melt during growth was about 1275°C for KNb_3O_8 and 1220°C for $K_4Nb_6O_{17}$, as usually, somewhat higher than the melting temperatures.

Crystals could readily be nucleated at the end of a platinum wire. Growth rates of ½-1 in./hr gave crystals of satisfactory size and quality. These crystals were oriented and cut into seed crystals which were used for further pulling experiments. Growth in a direction perpendicular to the cleavage was difficult due to the easy separation along the cleavage in both materials.

The orientation of crystals could be rapidly determined by the observation of a cleavage fragment between crossed polarizers. Figure 1 shows the observed biaxial interference figures, and their relation to the crystallographic axes of both materials. Growth along a, c, and intermediate directions yield crystals with

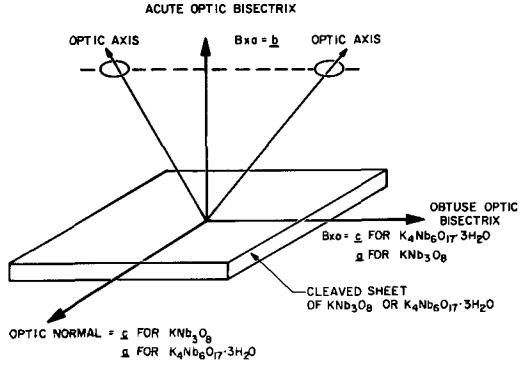

Fig. 1. Relationship of optical and crystallographic axes in KNb_3O_8 and $K_4Nb_6O_{17}\cdot 3H_2O$.

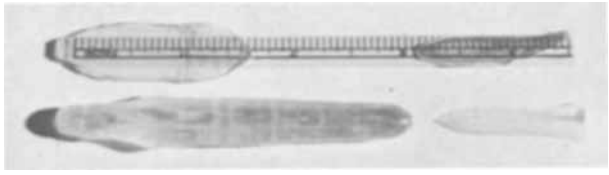

Fig. 2. Crystals and cleaved sheets of KNb_3O_8 (left) and $K_4Nb_6O_{17}\cdot 3H_2O$ (right).

oval cross-sections, the cleavage plane always lying in the widest part. Growth approximately half-way between a and b also proceeded readily. As-grown and cleaved c-axis grown crystals are shown in Fig. 2. The growth of crystals up to 4 in. in length and 7/8 in. diameter from a crucible 1½ in. diameter and 1½ in. deep indicates that this process should present no difficulties if performed on a larger scale. There was a pronounced tendency of crystals to twin with parallel growth at relatively small angles close to the cleavage plane, but this could be avoided by the choice of undeformed seeds and by maintaining a steady growth temperature.

Satisfactory crystal growth of KNb_3O_8 was also obtained in a single Bridgman-type experiment, by lowering a 3½ in. long tapered crucible at a rate of 1 in./day through a furnace having a 20°/in. temperature gradient. Even without refinements, crystals up to ⅜ in. in size were obtained.

Measurement Techniques

Powder x-ray diffraction patterns were obtained in a Phillips 114.6 mm Debye-Scherrer Camera with V filtered CrKα radiation. Single crystals were examined by means of a precession camera using Zr filtered MoKα radiation.

Differential thermal analysis was performed in a Dupont 900 machine in platinum cups in flowing air at a heating rate of 20°/min. Densities were determined by flotation in a thallium formate-malonate-water mixture at 60°C, and pycnometrically in alcohol at room temperature, with estimated accuracies ±0.2 and ±0.05 to 0.1, respectively.

Refractive indexes were determined by measuring the real and apparent thickness of parallel cleavage sheets under the microscope in white light. Optical transmission curves (unpolarized) were determined on a Cary Model 14 double beam spectrophotometer and a Perkin-Elmer Model 421 double beam grating spectrophotometer. Electrical measurements were performed on a General Radio Type 1620A capacitance measurement assembly. Electrodes were applied with silver conducting paste.

Water absorption studies were performed by storing about 0.5g samples in small Teflon cups over constant humidity reagents in 500 ml screw-capped jars. The specimens were weighed every day until constant weight was reached, usually after two days. At least two samples were run at each humidity.

Properties of KNb_3O_8

Crystal data.—The unit cell dimensions obtained on a single crystal of KNb_3O_8 are shown in Table I, together with the calculated and observed densities. The Laue symmetry and systematic absences indicated the possible space groups *Pmmm*, *Pmm*2, or P222. The absence of response in a laser-induced single crystal harmonic generation experiment (7) demonstrated the probable presence of a center of symmetry, thus indicating the space group to be *Pmmm*. The previously reported perovskite structure (3) does not appear to refer to the KNb_3O_8 compound as discussed in the first part of this paper. The powder x-ray diffraction pattern is shown in Table II, with indexing based on the single crystal unit cell parameters. The observed d spacings are generally similar to those of Guerchais (2), except that we do not observe his very strong line at 8.44Å (for which there would be no index) but instead observe the 110 reflection to occur at 6.83Å.

The similarity of mechanical behavior, also shown in Table I, with that of mica suggests a similar structure. Mica type materials, using muscovite $KAl_2(AlSi_3O_{10})(OH)_2$ as representative, contain (8) triple layer sheets composed of alumina octahedra (sharing edges) with alumino silicate tetrahedra sheets (sharing corners) on each side. These triple layers are held together by K^+ ions. A somewhat similar

structure with similar mechanical properties (9), is observed for potassium tetrafluo-aluminate, $KAlF_4$, where sheets of aluminum octahedra, sharing corners, are again held together by K^+ ions. An analogous structure consisting of single or multiple sheets of niobium-oxygen octahedra, held together with K^+ ions is accordingly suggested for KNb_3O_8. Detailed structural work is however expected to be difficult due to the easy deformation of the material due both to the cleavage as well as the flexibility.

Mechanical and optical properties.—The mechanical and optical data are also included in Table I. The relationship of the optical to the crystallographic directions is shown in Fig. 1.

The most notable characteristic of KNb_3O_8 is the highly developed cleavage. In this it greatly resembles mica, except that KNb_3O_8 is appreciably more flexible than mica. Delamination occurs on bending, with separations down to one micron. The crystal is colorless and highly transparent with essentially no absorption in the 0.5-5μ region as shown in Fig. 3 and with the remarkably high refractive indices shown in Table I.

Chemical properties.—Chemical analysis using x-ray spectrochemical analysis on an HF-HNO_3 solution shows the crystals to have the composition KNb_3O_8 as shown in Table III. Differential thermal analysis indicates no phase changes occur below a melting point of 1205° ± 10°C, compared to the reported value of 1234° (to <1213)°C (1).

KNb_3O_8 does not show any detectable reaction with water, in contrast to the closely related $K_4Nb_6O_{17}$. It dissolves in hot HF, but is not attacked by other acids or alkalies either cold or hot. A number of impurities at the 1 to 2 m/o level were added to the melt and the distribution coefficients (ratio of concentration of impurity in crystal to concentration of that impurity in the melt) determined. Most of these contained two ions at one time. Distribution coefficients and colors are shown in Table IV. More than one color is listed when the material is strongly dichroic or trichroic. In the cases of chromium (yellow-green) the impurity was predominately physically trapped, possibly due to too rapid growth, the clear crystal remaining colorless; distribution coefficients were not determined in this case.

Electrical properties.—The dielectric constant (D) and loss tangent (tan δ) were determined as a function of frequency at room temperature as shown in Fig. 4 and 5, and the dielectric constant as a function of temperature at 10^4 Hz as shown in Fig. 6.

The room temperature dielectric constant of 9.5 and loss tangent of less the 0.0005 at 10^6 Hz may be compared with the equivalent values of 6.5-9.0 and 0.0003 for highest quality natural muscovite mica (10). Further electrical measurements will be reported by J. F. Puluka, who has observed a dielectric breakdown strength of greater than 3 kv/mil as compared to 3 to 6 kv/mil for mica (11). KNb_3O_8 appears to be highly resistant to radiation damage; exposure to 20 Mrads of 1 meV electrons produced only approximately twice the change in loss tangent produced in mica (11).

In view of the importance of natural mica and the relative lack of success in growing synthetic mica as a substitute (12) despite extensive work at the Bureau of Mines and elsewhere (10), there is still a need for a comparable dielectric material which can be grown in large crystals in a controlled manner. KNb_3O_8 shows considerable promise in this respect.

Properties of $K_4Nb_6O_{17}$

Crystals of $K_4Nb_6O_{17}$ become completely brittle and develop many small cleavage cracks after a number of days at ambient conditions. This is caused by re-

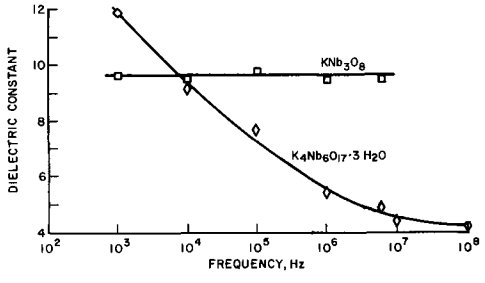

Fig. 4. Dielectric constant variation with frequency of KNb_3O_8 and $K_4Nb_6O_{17} \cdot 3H_2O$.

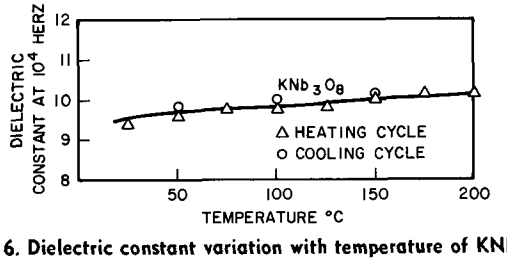

Fig. 6. Dielectric constant variation with temperature of KNb_3O_8

action with moisture as described in the next section. All of the water is driven off by heating to 150°-200°C. Because of this reaction only a limited number of properties were determined. The dielectric constant and the loss tangent show small peaks at 148°C, as shown in the curves of Fig. 7 and 8. They do not, however, show up on the differential thermal analysis curve of Fig. 9, which also indicates a melting point of 1155°C; the value given by Reisman and Holtzberg is 1163°C. The only measurement reported by Kestigian, who grew thin plates by the slow solidification of a nonstoichiometric melt, was a dielectric constant of 10.7 at 10^3 Hz which was reported not to change appreciably over the range —50° to 400°C, not really inconsistent with the data of Fig. 7.

Lattice parameters of $K_4Nb_6O_{17}$ were obtained from selected area electron diffraction during examination in a Siemens electron microscope operating at 111 kv. The data is given in Table I and was used to index the powder x-ray diffraction pattern given in Table V. The powdered and well-dried crystal sample was sealed into a capillary tube with wax.

This pattern does not agree with any of Guerchais' patterns (2), nor can it be indexed using the $K_4Nb_6O_{17}$ parameters of Whiston and Smith (3). It had been suggested that the structure is complex and of monoclinic symmetry (4); we find it to be orthorhombic.

Occurrence of $K_4Nb_6O_{17}$ Hydrates

In view of the changes occurring in $K_4Nb_6O_{17}$ on exposure to the atmosphere, the reaction with both CO_2 and H_2O was investigated. No reaction with CO_2 was observed, but absorption of water occurred readily. This had been noted by Kestigian *et al.* (4), who did not however observe the formation of hydrates.

Experiments on the water absorption of sintered powders did not yield reproducible results, presumably due to the presence of metastable intermediates (5). The use of powdered single crystal material completely avoided these problems and gave the data of Table VI. By transferring samples to higher and lower humidities, the water absorption was found to be reversible; all the water could also be removed again by storage in a desiccator over Drierite. Reproducibility was poor only in the 98% humidity atmosphere, where water condensation occurs very readily.

As shown in Fig. 10, the stable compound between about 25 and 85% relative humidity is $K_4Nb_6O_{17}\cdot 3H_2O$, which is therefore the composition normally encountered in the laboratory. Above about 85% humidity the fully hydrated compound is probably $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$, although more water may be involved.

The differential thermal analysis curve of $K_4Nb_6O_{17}\cdot 3H_2O$ is shown in Fig. 9. The occurrence of the water loss in three steps is not significant, since the shape of the pattern changes with the heating rate. At all heating rates there is no water remaining above

Table VI. Variation of composition of $K_4Nb_6O_{17}\cdot XH_2O$ with humidity

Chemical*	Relative humidity, %	PH_2O, mm Hg	x
Drierite	~0	~0	0.0

150°C, and subsequent heating cycles retrace the lower curve of Fig. 9, now pertaining to anhydrous $K_4Nb_6O_{17}$.

Properties of $K_4Nb_6O_{17}$ Hydrates

The composition $K_4Nb_6O_{17} \cdot 3H_2O$ is the stable form below 65°C and between about 25 and 85% humidity. The crystals produced from $K_4Nb_6O_{17}$ by atmospheric water absorption are colorless, clear in thin layers, but with a silver sheen due to internal delamination, perhaps at grain boundaries at low angles to the cleavage plane in thicker sections. They cleave readily but show great brittleness, resembling the brittle micas. The addition of chromium to the melt produced yellow crystals; microscopic examination however showed that the color was due to trapped melt, the crystal remaining in fact colorless.

The optical transmission curve is shown in Fig. 11. The strong absorption near 3μ is consistent with either OH-bonded water or water of crystallization. The intensity of this absorption corresponds only to about 0.1 moles H_2O/mole $K_4Nb_6O_{17}$, because a freshly grown sample of $K_4Nb_6O_{17}$ with a short exposure to the atmosphere had been used. The optical constants listed in Table I were somewhat variable, presumably dependent on the humidity. The dielectric constant and loss tangent variation with temperature and frequency is shown in Fig. 4, 5, 7, and 8. The strong dispersion at 10^7 Hz in Fig. 5 presumably originates in the water content.

The single crystal parameters of $K_4Nb_6O_{17}\cdot 3H_2O$ are given in Table I. The Laue symmetry and systematic absences indicate the most probable space group to be $P22_12_1$. Due to the low quality of the diffraction patterns arising from the bent crystals, the space group $P22_12$ cannot be completely eliminated.

The b parameter was found to be slightly variable, again presumably dependent on the humidity, and

the value of 37.9Å was used in the indexed powder x-ray diffraction pattern of Table VII. This, as well as the pattern of $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$ in Table VIII, is based on traces taken on a General Electric XRD 3 diffractometer with Ni filtered CuKα radiation at a rotation rate of 0.2°/min. The sample consisted of a slurry of powdered $K_4Nb_6O_{17}$ crystal in water on a microscope slide covered with tape. As the water evaporated, the pattern changed slowly from that given in Table VIII ($K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$) to that in Table VII ($K_4Nb_6O_{17}\cdot 3H_2O$).

In the presence of water $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$ spontaneously separates into thin laminations. A single crystal of $K_4Nb_6O_{17}$ surrounded by a thin walled glass tube partially filled with water gave the fully hydrated compound, presumably $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$. The single crystal parameters are given in Table I. As in the case of $K_4Nb_6O_{17}$ the probable orthorhombic space group is $P22_12_1$ or $P22_12$. Neither of the two hydrate diffraction patterns or unit cell dimensions were the same as any of those listed by Guerchais (2) or by Whiston and Smith (3).

The change in unit cell volume in going from $K_4Nb_6O_{17}$ to the hydrates is 28.6Å^3/H_2O for $K_4Nb_6O_{17}\cdot 3H_2O$ and 27.6Å^3/H_2O for $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$. These values are in the range observed in inorganic hydrates (*e.g.*, 24.7 for $KAl(SO_4)_2\cdot 12H_2O$, and 30.0 for $Ca_2Al(OH_2)Br\cdot 2H_2O$) and confirm the hydrate formula for $K_4Nb_6O_{17}\cdot 4\frac{1}{2}H_2O$.

Only the b spacing changed appreciably with the variation in water content of the $K_4Nb_6O_{17}$ hydrates. Mica and related materials consist of layers of single or multiple sheets of linked octahedra and/or tetrahedra with alkali ions between the sheets. A similar structure composed of sheets of linked NbO_6 octahedra, with K^+ ions between the sheets, appears likely for the $K_4Nb_6O_{17}$ compounds. On this basis the water molecules would probably occur as a hydration sphere about the potassium ions.

Solid State Properties of Some Valve Metal Oxides

Ashok K. Vijh*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Lattice energies and heats of atomization have been calculated for HfO_2, ZrO_2, Al_2O_3, Nb_2O_5, and Ta_2O_5 from thermochemical (see text, however) data by the use of the appropriate Born-Haber cycles. An attempt has been made to explore the relation of these quantities to certain fundamental properties, *e.g.*, melting points, boiling points, heats of formation, dielectric constants, forbidden gaps, *etc.*, which are a measure of the general physical and chemical nature of substances. Average bond energy values as well as MO bond dissociation energies for these oxides have also been calculated and discussed. Possible relation of these and related matters to heats of hydration and solution, and, heat capacities and thence temperature coefficients of band gaps have been briefly indicated.

On anodization in suitable electrolytes, Ta, Nb, Al, Zr, and Hf form thick (*ca.* > 1000Å) oxide films (1) which are of considerable interest as dielectric materials in electrolytic capacitors. It is of some importance, therefore, to attempt to obtain quantities which, in general, are diagnostic of a variety of mechanical, thermal, chemical, and electrical properties of these substances. In case of ionic compounds, such a quantity is lattice energy whereas the corresponding parameter for covalent compounds is the heat of atomization (2). Like many other materials of technological interest, these oxides are partially ionic and partially covalent (1). Here, an attempt has been made to calculate both the lattice energies and heats of atomization and compare each with various fundamental properties of these oxides, *e.g.*, heats of formation, melting points, and dielectric constants, etc.

Lattice Energies and Heats of Atomization

The lattice energies have been calculated from thermochemical data[1] by use of the appropriate Born-Haber cycle (3). The values obtained as well as the thermochemical data used in these calculations, together with the source references for these data, have been shown in Table I. The only previous value available in the literature is for Al_2O_3 (3). Our value for lattice energy per mole (at 25°C) for Al_2O_3 in Table I (3651.5 kcal) compares favorably with the older value (3663 kcal/mole), also obtained by Born-Haber cycle, quoted by Waddington (3). The heats of atomization have also been obtained from the thermochemical data listed in Table I, by means of the shorter Born-Haber cycle.

In Table II, lattice energies per equivalent as well as heats of atomization per equivalent for these oxides have been compared with the corresponding dielectric constants, melting points, boiling points, and heats of formation per equivalent. In order to explore the significance of these data in more detail and to permit discussion of these properties individually, each one of these properties has been plotted separately against the corresponding lattice energies per equivalent and heats of atomization per equivalent in the various graphs shown here. It may be concluded from Table II and from Fig. 1-4, that, in general, with increasing heat of atomization per equivalent, melting point (Fig. 1), heat of formation per equivalent (Fig. 2), boiling point (Fig. 3), all increase and dielectric constant decreases (Fig. 4). Again, lattice energy, in general, may be concluded to be related to these quantities in a way opposite to that of heat of atomization.

It may be noted that the comparisons are not entirely satisfactory, *e.g.*, shaded points in Fig. 1, 3, and 4 do not really follow a relation either with the heats of atomization or lattice energies. All these points, it may be mentioned, represent Al_2O_3. This is probably not entirely unexpected, since the heat of sublimation for aluminum, which makes a substantial contribution to heat of atomization of aluminum oxide and some contribution to the lattice energy of Al_2O_3 is, in the present context, unusually low. The reason being that, aluminum, unlike Ta, Nb, Zr, and Hf, is not a transition metal. For improved estimates one must invoke

* Electrochemical Society Active Member.

[1] Values of the heat of formation of O^{2-} from O cannot be obtained by thermochemical measurements, since O^{2-} ion is unstable. An estimate of this quantity is usually made by first calculating the theoretical lattice energy of an oxide by a Madelung type computation (assuming 100% ionicity) and then applying the Born-Haber cycle. One of the referees is thanked for pointing this out to us.

Table I.*

Oxide	$-\Delta H°_{form.}$ (kcal · mole^{-1}, 25°C)	Successive ionization potentials of the respective metals, kcal					$A_{O^{-2}}$,† kcal · mole^{-1}	$\Delta H_{diss}O_2$, kcal/g atom	$(\Delta H_{Sub})_{metal}$‡ kcal/g atom	U, 25°C kcal · mole^{-1}
		1	2	3	4	5				
HfO_2	271.5 (5)	160 (6)	344 (6)	485 (7)	715 (7)		156 (8)	59.5 (9)	163.2 (9)	2569.7

* The numbers in the parentheses indicate the reference from which a particular value has been obtained.
† $A_{O^{-2}}$ is the energy required to form O^{-2} from O atom.
‡ The values of $[\Delta H_{Sub.}]_{metal}$ have been taken as the same as the heats of formation of gaseous atoms of the respective metal from its standard state, *i.e.*, crystalline form of element. In general, $[\Delta H_{Sub.}]_{metal} = [\Delta H_{fusion}]_{metal} + [\Delta H_{Vap.}]_{metal}$ and hence the values used are valid since metals usually evaporate to monoatomic gases [see ref. (4), pp. 82, 86].

a "correction factor" to take into account the lack of unfilled d orbitals and thence low cohesive energies of aluminum. This, of course, is not very straightforward.

In case of Fig. 3, no data seem to exist for the boiling point of Ta_2O_5.

Significance of Various Graphs (Fig. 1-4)

Since melting points increase systematically with heats of atomization and not lattice energies (Fig. 1), it may be concluded that the solid-state cohesion of these oxides is determined predominantly by covalent aspects of their bonding (2; *cf.* 1). Identical qualitative conclusions would also follow from Fig. 2-4 (2). No quantitative estimates, however, can be made regarding partial ionicity and covalence in these oxides. This is because the various procedures for estimating the nature of bonding in solids often yield widely different results (4). Further, since the Born-Haber lattice energies are not true thermochemical values for the case of oxides, it is not valid to compare them with the theoretical lattice energies for the purposes of obtaining per cent ionicity. It has been recently pointed out to us that Pauling's criteria for per cent ionic character (*cf.* 1) are not applicable to solids (4a).

It may also be stated, by analogy with some previous work (2), that the magnitude of various other properties diagnostic of the general stability of these oxides would be largely determined by the covalent aspects of their bonding. Some of these properties are: heats of fusion and evaporation, dielectric strengths, activation energies for the creation of dislocations and other physical "faults," and band gaps.

Band Gaps and Their Temperature Dependence

It may be noted that no attempt has been made in the foregoing discussion to relate heats of atomization or lattice energies of these oxides, to the corresponding values, ΔE, of the forbidden gaps. Since relation to the heats of formation per equivalent has already been examined (Fig. 2), it follows that the relation to the energy of the forbidden gap, ΔE, would exhibit the same trend. This is because, recently, it has been shown that, for a great variety of semiconducting compounds, especially ones with high ΔE values and specifically for Al_2O_3, Ta_2O_5, Ga_2O_3, In_2O_3, TiO_2 (and,

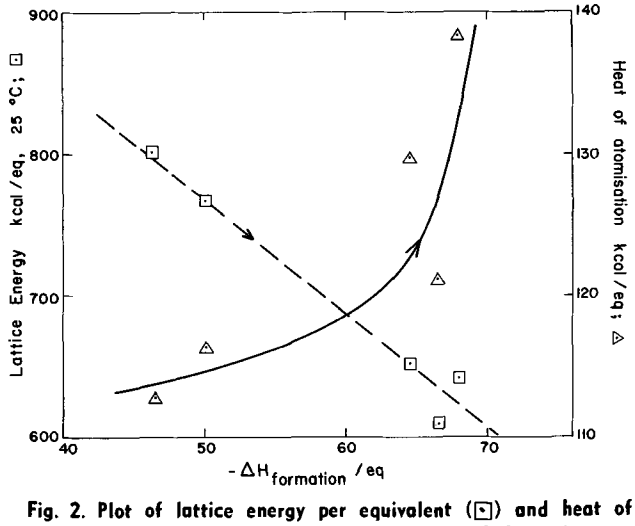

Fig. 2. Plot of lattice energy per equivalent (⊡) and heat of atomization per equivalent (△) against heats of formation per equivalent.

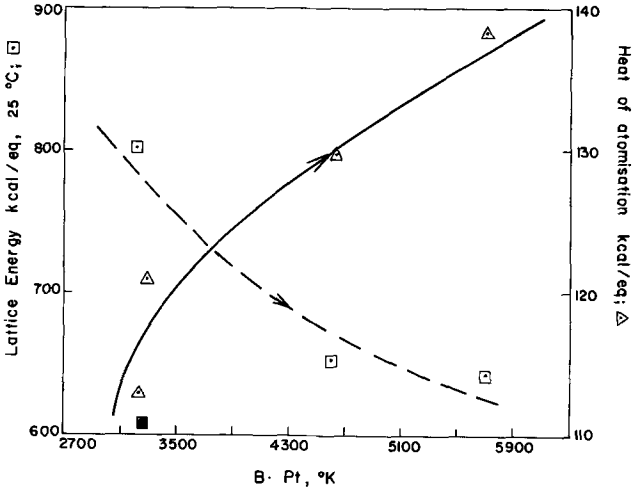

Fig. 3. Plot of lattice energy per equivalent (⊡) and heat of atomization per equivalent (△) against boiling points.

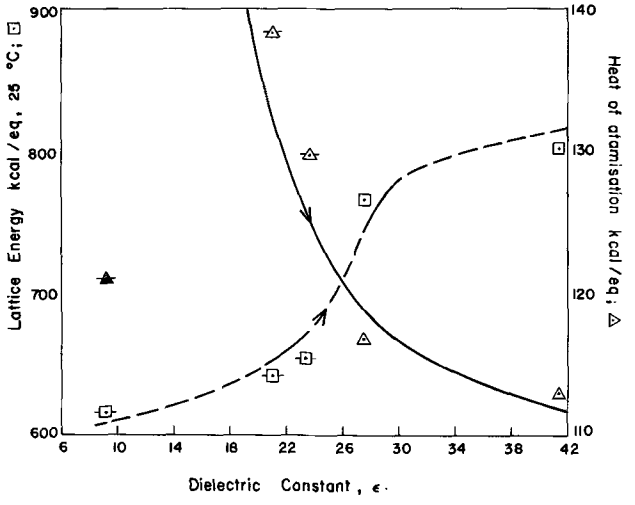

Fig. 4. Plot of lattice energy per equivalent (⊡) and heat of atomization per equivalent (△) against dielectric constants for various oxides.

presumably, other polyvalent oxides), $\Delta E \simeq 2$ x heat of formation per equivalent (14).

The values of heat capacity at constant pressure, C_p, available in the literature (15) are for Nb_2O_5, Ta_2O_5, and Al_2O_3 only. For these three substances, C_p has a value 3.13 ± 0.1 cal/deg equiv. (15). Since C_p is directly related to $\partial(\Delta E)/\partial T$, the temperature coefficient of the band gap, it follows that the change in the band gap with changing temperature for these three substances is approximately the same (16).

It has been tacitly assumed in the foregoing discussion that concepts valid for crystalline substances can also be applied to amorphous oxides as indeed would be obtained on anodization. This is essentially valid, though approximately so, since the short range structure and crystalline order is still maintained intact in amorphous substances and even in melts; *e.g.*, band theory of solids can be applied to these states (*i.e.*, amorphous and molten) exactly the same way as to the crystalline substances, except that the bands tend to be diffuse and thence the consequent approximations (17).

Relation of Lattice Energies to Heats of Hydration and Solution

The lattice energies of compounds are also related to their heats of hydration and heats of solution (18). In fact, Lattice energy = Heat of hydration — Heat of solution.

Heats of solution are usually a small fraction (*ca.* 5%) of heats of hydration, and, experimental values are unknown for the present oxides. It may be concluded, therefore, that the lattice energies reported in Table I are also an approximate measure of the heats of hydration of the corresponding oxides. This is confirmed by a direct theoretical estimation of standard free energies of hydration for oxides and their comparison with the lattice energies calculated in Table I. These estimations have been carried out as follows (19).

The molal free energy changes associated with the conversion of the lattice into individual ions in the ideal gas state at one atmosphere pressure may be represented by $\Delta\mathring{G}_L$, which is related to the lattice energy U (see, Table I) by the equation (19)

$$\Delta\mathring{G}_L = -U - 7.4\,(a + c) \qquad [1]$$

where a is the number of anions and c that of cations in one molecule of the given oxide, *e.g.*, Al_2O_3.

The standard free energies of hydration for a cation and anion may be estimated semi-empirically by the equations (19)

$$(\Delta\mathring{G}_h)_{Cat} = -164\,Z^2 + /(r+ + 0.75) \qquad [2]$$

and

$$(\Delta\mathring{G}_h)_{An} = -164\,Z^2-/(r- + 0.35) \qquad [3]$$

Where $Z+$ and $Z-$ are the respective cationic and anionic charges and $r+$ and $r-$ are the crystallographic radii of the cation and anion, respectively; the factors 0.75 and 0.35 are in Angstroms and are the empirical corrections that must be made to the crystallographic radii to make the latter agree with the radii as determined by the Born equation, which are presumably equivalent to the gas phase ionic radii (undefinable and unknown). The $\Delta\mathring{G}_L$, $(\Delta\mathring{G}_h)_{Cat}$, $(\Delta\mathring{G}_h)_{An}$ and $(\Delta\mathring{G}_h)_{oxide}$, determined, per mole, by this procedure for every one of the five oxides have been shown in Table III.

It may be emphasized that no corrections for per cent ionic character are necessary in the lattice energies used here since if the oxides were entirely covalent, one would replace the lattice energy by heat of dissociation into ions (*e.g.*, for HCl) and not corresponding heats of atomization (18).

Bond Energies and Bond Dissociation Energies

If the spin correlation stabilization energies, which are usually small, are ignored (20), the heats of atomization (Table II) per equivalent would be identical

Table III.

Oxide	$\Delta G°_L$*	$(\Delta G°_h)_{cat}$†	$(\Delta G°_h)_{An}$†, ‡	$(\Delta G°_h)_{oxide}$*
HfO_2	2598	1701	393	2487
ZrO_2	2642	1690	393	2476
Al_2O_3	3688	1170	393	3519
Ta_2O_5	7722	2866	393	7697
Nb_2O_5	8070	2752	393	7469

* Values are kcal mole^{-1}.

† Values are kcal g-ion^{-1}.

‡ For the hypothetical ion O^{-2}; hypothetical because the ultimate anion formed for, *e.g.*, Al_2O_3 would depend on the pH of the solution, *e.g.*, AlO_2^- in certain alkaline solutions.

Notes:

All values in this table are approximate since no rigorous procedures are available for calculating $\Delta G°_h$ of individual ions; approximations become particularly serious for the polyvalent ions as in the present case [see ref. (18) and (19)].

Data on ionic radii have been obtained from ref. (5), p. F-89.

Values of $(\Delta G°_h)_{cat}$ are much more reliable than $(\Delta G°_h)_{An}$, since empirical corrections to Born's radii have been shown to give much more accurate results in case of cations than in case of anions (19).

Table IV.

Oxide	Heat of atomization, kcal/equiv. of oxide	MO bond energy, kcal · mole^{-1} of the bond	MO bond dissociation energies, kcal · mole^{-1} 25°C		
			1	2	3
HfO_2	138.4	148	184	—	—
ZrO_2	129.8	142	173	182	151
Al_2O_3	121.2	132	158	116	120
Ta_2O_5	116.6	123	167	215	195
Nb_2O_5	113	122	115	181	93

Notes:
MO bond dissociation energies under 1 have been calculated by us from Pauling's equation

$$D_{MO} = \tfrac{1}{2}\,(D_{MM} + D_{OO}) + 23.06\,(X_M - X_O)^2,$$

in kcal · mole^{-1} of MO (21); Pauling calls it bond energy. However, since he assumes an isolated diatomic molecule in his procedure, MO in this case, these bond energies are bond dissociation energies and in case of a diatomic molecule are equal to bond energies.

MO bond dissociation energies under 2 above have been obtained from ref. (22) and have been determined by a variety of experimental and theoretical procedures. See ref. (22) for the assessment of accuracies of these values.

MO bond dissociation energies under 3 were obtained from ref. (23) and were determined by different procedures of widely differing accuracies.

The quantity of interest in the present discussions is MO bond energy, an average value obtained by Howald's method and represents the average strength of MO bond as it occurs in the oxide of interest; MO bond dissociation energies refer to isolated MO bonds and are not relevant to the arguments developed here. They have been presented here, however, for the purposes of comparison and for emphasizing the distinction between bond energies and bond dissociation energies.

to the average bond energies (not bond dissociation energies for particular bonds). An attempt has also been made here to calculate the MO (metal-oxide) bond energies for these oxides, by taking into account spin correlation stabilization energies (20). The values obtained have been compared with the values of heats of atomization in Table IV. This procedure for the calculation of bond energies involves reference to Howald's (20) "valence state atoms" [see Table III in ref. (20)] and an assumption that, $\alpha = Q$, since Q values are not available. This assumption amounts to ignoring the contribution of coordinate valence to the bonding. It may be noted in Table IV that the bond energies are consistently slightly higher than the corresponding values for heats of atomization per equivalent.

It is clear from Table IV, however, that replacing heats of atomization by bond energies in various plots (Fig. 1-4) would not change the nature of arguments presented here.

In Table IV, values of (last) bond dissociation energies estimated by us by Pauling's method (21) and experimental values of other workers have also been shown for the sake of comparisons with bond energies. The relative significance of various quantities in Table IV has been explained in the notes to that Table.

Acknowledgments

The author would like to thank Dr. R. S. Alwitt and Dr. D. M. Smyth for some general discussion on matters related to the content of this paper. Thanks are also due to Professor R. A. Howald of Montana State University for a personal communication on the procedures for calculation of bond energies. A recent personal communication from Dr. M. Tosi of Argonne National Laboratory [ref. (4a)] and the helpful comments of the referees are gratefully acknowledged.

Manuscript submitted Sept. 9, 1968; revised manuscript received Nov. 18, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

The Electrical Conductivity and the Crystal Structure of Silver Iodide

Takehiko Takahashi,* Katsumi Kuwabara, and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

The electrical conductivity of silver iodide pressure moulded into pellets at 2.0 tons/cm^2 was measured and the crystal structure of γ-AgI was investigated by means of x-ray diffraction. The conductivity of γ-AgI decreases gradually as the heating and cooling operations are repeated. The decrease is attributed to the phase transition of γ- to β-phase. In the case of β-AgI the conductivity is not changed by the heating procedure. The activation energies of conduction for γ- and β-AgI at near room temperature are about 7.0 and 9.5 kcal/mole respectively. The crystal structure of the compressed γ-AgI differs from the ideal zinc blende structure. The modified structure has been suggested to be the average one which has silver ions distributed randomly over the ideal position of the ideal zinc blende structure and the four positions surrounding the ideal position.

Studies on high ionic conductive solids have been carried out in our laboratory for several years and some compounds have been found to have high ionic conductivity (1-6). These compounds, such as Ag_3SI (1) and $Ag_4HgSe_2I_2$ (3), were synthesized using silver iodide as a main material. Silver iodide is, therefore, of interest as a mother compound of the high ionic conductivity solid electrolytes.

A number of reports (7-13) have shown polymorphism in silver iodide. At atmospheric pressure, three forms of silver iodide are said to exist: face-centered cubic, hexagonal, and body-centered cubic forms. The third, α-phase, is famous for typical "average structure."

The electrical conductivity of α-phase is the order of 10^0 ohm^{-1}cm^{-1}, which is 10^4 or 10^6 times larger than that of the γ- or β-phase. It is known that the charge carrier in the α-phase is the silver ion.

Silver iodide is usually precipitated by the reaction between silver nitrate solution and potassium iodide solution at room temperature. It is, however, impossible to prepare a single crystal stable at normal pressure, and silver iodide is generally a mixture of γ- and β-phase (14). Accordingly, the electrical conductivities reported were mean values.

The purposes of the present study were to measure the electrical conductivity of γ- and β-phase silver iodide separately, to survey the conductivity change with time, and to make clear the correlation between the electrical conductivity and the crystal structure of silver iodide.

Experimental

Preparation of the starting materials.—Silver iodide is precipitated by the following reaction in the low cubic form under the condition that silver is in excess of the stoichiometric proportion (15)

$$AgNO_3 + KI \rightarrow AgI \downarrow + KNO_3$$

By the addition of KI (aq) into excess $AgNO_3$(aq) with constant stirring, γ-AgI containing a small amount of β-AgI was obtained. In order to get as pure γ-phase as possible, the dried precipitate was gently ground in a mortar.

Electrical conductivity and x-ray diffraction measurements were performed with a pellet type specimen. The γ-AgI pellets, 13 mm in diameter and about 2 mm thick, were formed by a hand press. It is known that the β-phase tends to precipitate if iodide ion is in excess (15). However, in this study, β-AgI was prepared by heating the compressed γ-AgI for a long time at 200°C.

* Electrochemical Society Active Member.

Conductivity measurement.—Apparatus for conductivity measurements is shown in Fig. 1. To measure the conductivity change with time and temperature, the apparatus was placed in an electrical oven, the temperature of which was changed from room temperature to 160°C. An impedance bridge at 1 kHz was used to measure the electrical conductivity.

X-ray diffraction.—A copper anode tube was operated at 15 ma and 35 kv. The goniometer scan speed was selected to 1°/min in the qualitative analysis.

A sample holder made in our laboratory was used to follow the change in structure at higher temperatures.

In the structure analysis, the goniometer scan speed was reduced to ¼°/min. The observed intensities discussed later are the mean values of the diffraction lines obtained from twelve samples.

Results and Discussion

Stability of γ-AgI.—The structure of silver iodide changes with temperature and pressure (16-22).

As a first step, the dependency of the conductivity on pressure was examined. The pellet type samples made at 0.5 to 6.0 tons/cm^2 were used to measure the electrical conductivity σ. The results are shown in Fig. 2. Up to about 2.5 tons/cm^2, σ increases; between 2.5 and 4.0 tons/cm^2, σ is nearly constant; and in the range above 4.0 tons/cm^2, the curve has a descending plateau. These three parts of the curve should be compared with the phase relationship of AgI drawn by Davis and Adams (23) which reveals agreement with the phases found by them at room temperature. The low pressure part in Fig. 2 corresponds to the II' phase (low fcc) in their diagram, the middle part to the IV

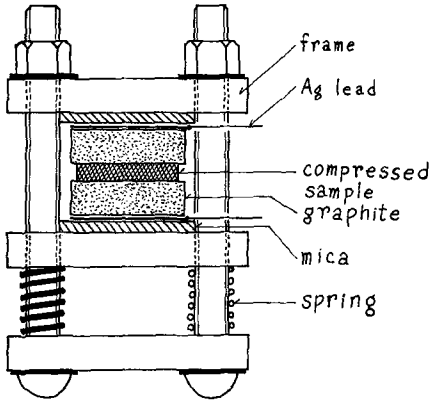

Fig. 1. Apparatus for conductivity measurement

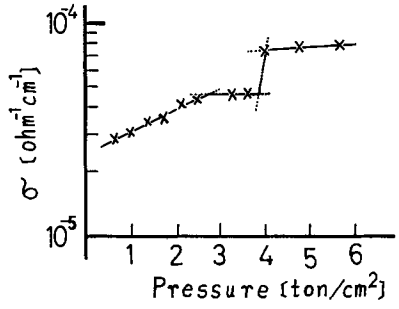

Fig. 2 Conductivity of γ-AgI compressed at various pressures at room temperature.

phase (ortho), and the higher pressure part to the III phase (fcc).

It has been reported that γ-AgI is metastable and β-AgI transforms to γ-AgI when being ground in a mortar or strongly pressed. In the second part of this report, therefore, the change of the conductivity with time was followed at room temperature. σ remains essentially constant and there is no change in the x-ray pattern with time.

From these facts it is suggested that the γ-AgI pellet is stable at room temperature.

Conductivity.—γ-AgI.—As mentioned above, γ-AgI has been found to have a high stability at room temperature, but it is affected by heating. Initial experiments showed that when the specimen was annealed for 10 hr at 60°C, σ was observed to be lower than the initial value by about one order of magnitude. After being annealed for several hours at 100°C, σ decreased considerably.

Thus, the conductivities were measured at several temperatures in the range between room temperature and 100°C. The temperature of the specimen was kept constant for one or two hours in conductivity measurement.

The results are shown in Fig. 3. Curve A was obtained with the initial heating operation. Curve B shows the result for the cooling operation after the initial heating. Curves C, D, and E correspond to the results for successive heating operations. These curves are fairly linear and the conductivity tended to decrease as the operations were repeated. The activation energy of conduction is obtained from these slopes to be about 7.0 kcal/mol.

The repetition of heating and cooling in the range of room temperature to 160°C makes the slope larger and the linearity poorer. Curve F in Fig. 3 shows the result in the case where the heating operation was done after the heating procedure represented by Curve E had been performed. The σ values are found to decrease by about one order in the cooling operation next to the heating. Finally, σ values are fixed to the positions shown by the open circles.

β-AgI.—It is ordinarily very difficult to prepare pure β-AgI. Even if the pellet type specimen is heated over 10 hr at 200°C, it is not possible to completely prevent γ-AgI forming. The sample so treated may be regarded as pure β-AgI so far as the conductivity measurement is concerned. In practice, the conductivity change of β-AgI with time is not observed and the presence of a trace of γ-AgI has been neglected in this experiment.

Two kinds of electrodes, graphite and silver plates, were used to check the effect of electrode materials, but no effect was detected.

Figure 4 shows the conductivity curve of β-AgI. There exists a slight displacement between the curves for temperature descending and ascending. This may be due to supercooling of the α-phase. This hysteresis was observed in every measurement extended to 160°C. The activation energy is calculated from the slope of the linear portion of the curve near room temperature and is found to be about 9.5 kcal/mole, which is larger than that of γ-AgI.

Conductivity and phase transition.—The electrical conductivities of a number of solid electrolytes are known to be changed by phase transition. For example, the electrical conductivity of Ag_2HgI_4 (24, 25) is about 10^{-7} ohm^{-1} cm^{-1} at room temperature, the phase of which is demonstrated as β-Ag_2HgI_4. When it transforms to α-Ag_2HgI_4 at 50°C which has an "average" structure (26), the conductivity becomes about 10^{-3} ohm^{-1} cm^{-1}.

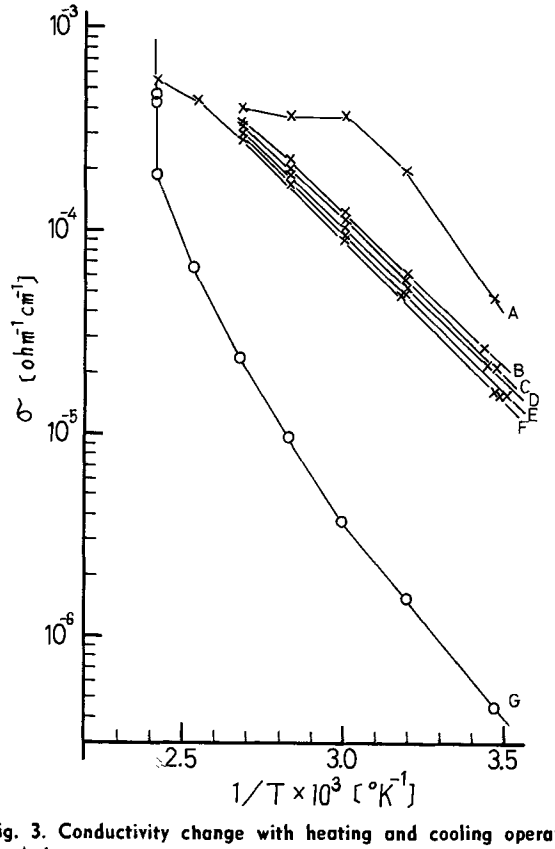

Fig. 3. Conductivity change with heating and cooling operation for γ-AgI.

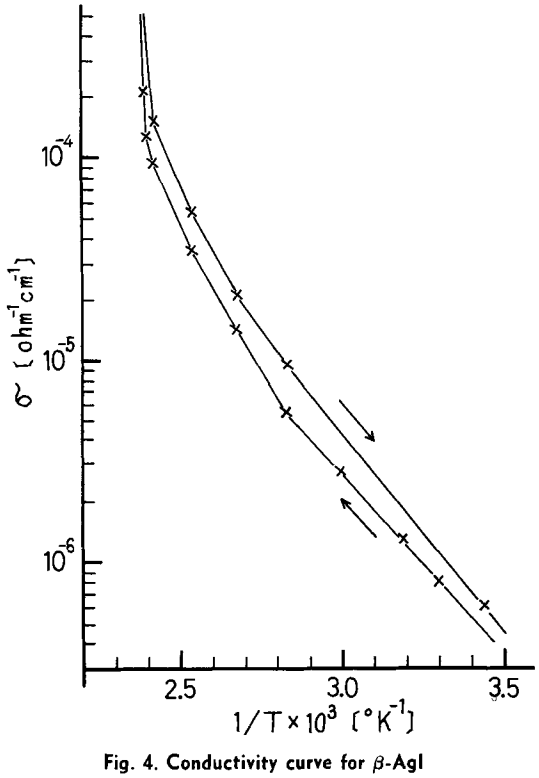

Fig. 4. Conductivity curve for β-AgI

The polymorphism or phase transition of AgI has been investigated by many authors. Mrgudich (27) studied pellet type AgI. In his study on solid electrolyte batteries, he measured the conductivity of compressed AgI powder pellets. According to his results, the presence of a deformed hexagonal phase was an important factor in determining the conductivity, and the face-centered cubic phase, i.e., γ-phase, gave some resultant decrease in conductivity.

On the other hand, different phenomena were observed in the present investigation. X-ray diffraction patterns were taken in order to find the reason why the conductivity change was observed when the heating and cooling operations were repeated with pellet type γ-AgI. The results are shown in Fig. 5. The profile (a) is that of the sample immediately after the conductivity was measured at room temperature. The three peaks are fairly broad. The pattern (b) was taken at 120°C. In addition to the three peaks in (a), a few small peaks which belong to β-AgI are seen. They grow moderately as the heating operation is repeated. At 170°C which is above the transition temperature 147°C, four peaks are obtained as are seen in (c). This pattern is typical for the body-centered cubic lattice. After being annealed for 1 hr at 170°C, the sample was cooled to room temperature, and the x-ray diffraction pattern was taken again. The more complex peaks shown in (d) are those of β-AgI which have been identified by the help of ASTM card. The ratios of their intensities differ slightly from the data indicated in ASTM data. This difference suggests that the lattice distortion is induced by heating of the pellet.

To compare the diagram of the pellet with that of the powder sample, x-ray diffraction profiles were taken at room temperature, 100°, and 170°C. The results with powders shown in Fig. 6 agreed approximately with those of the pellet. The (d) in Fig. 6 differs from (d) in Fig. 5. The agreement of the intensity ratios in Fig. 6 with ASTM data is better than that in Fig. 5.

From these results it is confirmed that the face-centered phase transforms to the hexagonal phase in the course of repetition of heating and cooling. This consideration coincides with Burley's study (13).

Thus, the change of conductivity in γ-AgI can be attributed to the phase transition. The decrease in

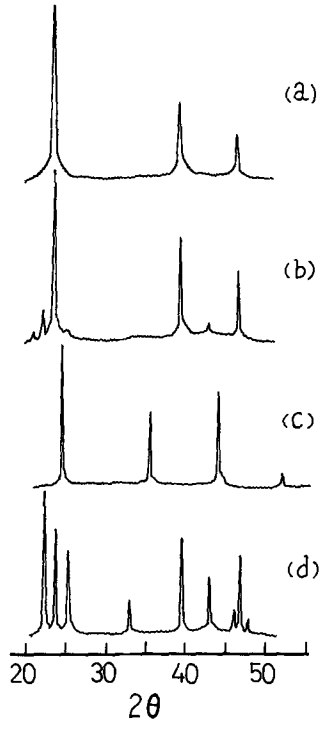

Fig. 5. X-ray diffraction of compressed γ-AgI at various temperatures.

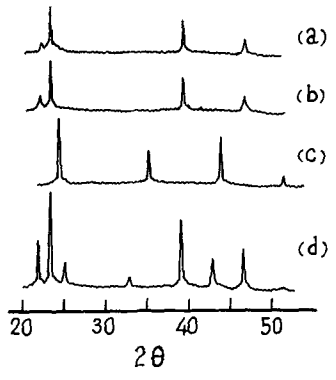

Fig. 6. X-ray diffraction of γ-AgI powder at various temperatures

conductivity of the γ-phase is not due to the presence of the face-centered cubic phase, but to the transition of the γ- to β-phase.

Structure of compressed γ-AgI.—The crystal structure of γ-AgI was analyzed by Wilsey (28) in 1921 and confirmed by Davey (29) in 1922. According to their powder x-ray diffraction studies, γ-AgI has a face-centered cubic lattice of zinc blende type. On the other hand, a hexagonal structure of wurtzite type was reported as a result of the optical studies with relation to iodyrite by Aminoff (30) in 1922. In addition, the fact that the silver atoms in β-AgI are distributed at random among four positions situated tetrahedrally around the ideal position in the wurtzite structure was found on the basis of oscillation studies by Helmholz (31) in 1935.

As can be seen in the previous sections, pellet type γ-AgI gives a hundred times larger conductivity than that of β-AgI at room temperature, and its activation energy of conduction is comparatively low. Moreover, a little breadth in x-ray diffraction peaks is observed and separation of the peaks corresponding to $CuK\alpha_1$ and $K\alpha_2$ is insufficient. These data suggest that compressed γ-AgI may have some structural peculiarity.

In fact, our observed intensities did not agree with the expected. Thus, a modified structure model may be introduced like (b) in Fig. 7, which differs from that of ideal zinc blende (a). The intensities of the diffraction lines were calculated by the following formula in order to compare with the experimental data

$$I = A \cdot \frac{1 + \cos^2 2\theta}{\sin^2\theta \cos\theta} \cdot P \cdot |F|^2 \qquad [1]$$

where I is the relative intensity, A the absorption factor, the second term the Lorentz-polarization factor containing the Bragg angle θ, P the multiplicity of lattice plane, F the structure factor. The last term F is expressed by the following relation

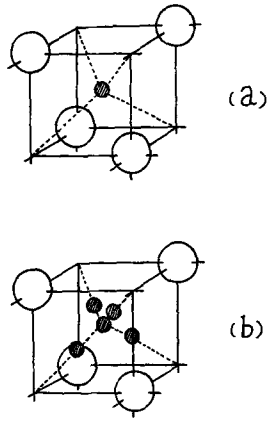

Fig. 7. Crystal structure of γ-AgI showing 1/8 of unit cell, (a) ideal zinc-blende structure, (b) proposed average structure.

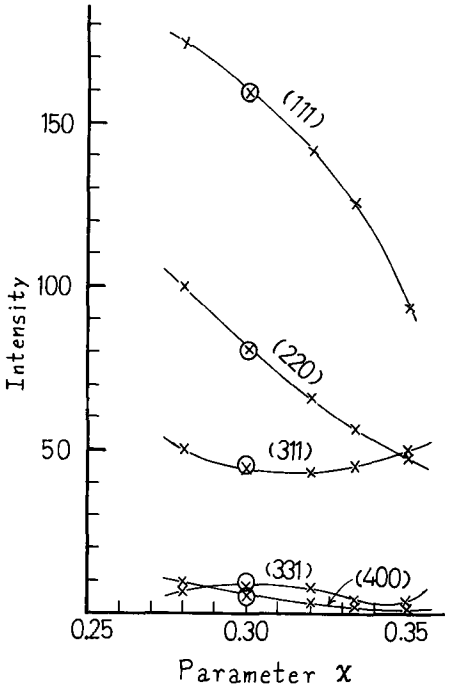

Fig. 8. Calculated intensity as a function of the parameter x 16 (e) of F $\bar{4}$3m.

$$F = F(hkl) = \sum_i f_i \exp 2\pi i\,(hx_i + ky_i + lz_i) \quad [2]$$

$$= A(hkl) + iB(hkl) \quad [3]$$

$$A(hkl) = \sum_i f_i \cos 2\pi\,(hx_i + ky_i + lz_i) \quad [4]$$

$$B(hkl) = \sum_i f_i \sin 2\pi\,(hx_i + ky_i + lz_i) \quad [5]$$

$$f_i = f_{io} \exp\,(-\bar{B} \sin^2\theta/\lambda^2) \quad [6]$$

where h, k, l are the Miller's indices, f_i the modified atomic scattering factor of the i-th atom related to the atomic scattering factor f_{io} and the Debye factor $\bar{B}$ by Eq. [6], x_i, y_i, z_i the parameters of the i-th atom.

The ideal lattice of γ-AgI is that of the zinc-blende type and the space group is F $\bar{4}$3 m (32). A parameter in 16(e) is 0.25 in ideal zinc blende but it may be changed in the compressed γ-AgI.

In this calculation, the Debye factor plays an important role in an attempt to conform to the experimental intensities. Therefore both x in 16(e) and $\bar{B}$ were roughly examined and then the range of x was limited to 0.28-0.35, and $\bar{B}$ was kept constant at 5.0. This $\bar{B}$ is somewhat larger than that of the ordinary compound at room temperature, but reasonable for the "average structure" like α-AgI (33).

Figure 8 shows the intensities as a function of x. The open circles are the observed intensities. The agreement of the calculated intensities with the observed ones is the best when $x = 0.30$.

In addition, the reliability index R was computed with the aid of next equation

$$R = \frac{\Sigma||F_{obs}| - |F_{calc}||}{\Sigma|F_{obs}|} \quad [7]$$

where F_{obs} and F_{calc} are the observed and calculated structure factors respectively. The obtained R is 0.115 which suggests that the above calculation of the intensity is highly reliable.

From these results, a new average structure is confirmed in which silver atoms are randomly distributed over four possible sites placed tetrahedrally around the ideal site in zinc blende, similarly over the ideal position. The distance between the ideal and the tetrahedral sites is 0.60Å, which is greater than the amplitude of the simple oscillation of a silver atom.

The low activation energy in conduction, the large ionic conductivity at room temperature, and the insufficiency of the separation between $K\alpha_1$ and $K\alpha_2$ in x-ray diffraction may be obviously interpreted by the disordered or averaged structure in compressed γ-AgI.

Manuscript submitted Sept. 30, 1968; revised manuscript received Nov. 19, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

Thermal Cycling and Surface Reconstruction in Aluminum Thin Films

C. J. Santoro

Motorola Semiconductor Products Division, Phoenix, Arizona

ABSTRACT

The appearance of "annealing hillocks" on heat treated aluminum films has been previously reported. Thin films of Al, deposited on passivated wafers, were annealed for various lengths of time in the temperature range 200°-500°C. The effects of grain size, alloying and surface passivation on hillock formation, were studied. It is the purpose of this report to summarize the effect of thermal cycling on similar films and to show in more detail the size and appearance of the hillocks. Aluminum was deposited on oxidized silicon substrates in a vacuum of about 10^{-8} Torr. Grain sizes at the deposition temperature were on the order of $<1\mu$, 1μ, and 5μ. Manual cycling was carried out between a hot stage in N_2 and a room temperature heat sink. Control samples were annealed (uncycled) for equivalent times-at-temperature. Photomicrographs of the surface at its various stages of reconstruction were taken and scanning electron micrographs provided a more detailed view of individual hillocks and their surroundings. At the higher temperatures (425°C) thermal cycling increases the number of hillocks by factors of 2 or 3, with the typical hillock density estimated to be approximately $10^6/cm^2$. Cycling also increases the size of the protrusions, and hillocks as high as 3.5μ have been observed growing out of a 0.7μ film. Experiments employing glass passivation confirm earlier results that surface reconstruction can be eliminated.

Aluminum thin films have found wide application in the semiconductor industry. As interconnections on a semiconductor device or integrated circuit the aluminum, usually in contact with a thin layer of SiO_2 on a Si wafer, may be subject to forces tending to change its structure. This is especially true if thermal excursions are encountered. If an aluminum film on an oxidized silicon substrate is heated sufficiently above its deposition temperature abnormal localized growths, "annealing hillocks," appear (1, 2). This effect has also been reported for lead, tin, and indium films (3) on substrates of lower thermal expansivity. Paddock and Black (1) have reported increases in hillock density with increasing time, temperature, and impurity content for aluminum films on silicon held at elevated temperatures. Similar features exist for the other metal films.

d'Heurle *et al.* (2) do not attempt an explanation of the growth phenomena for their aluminum on silicon films; Paddock and Black (1) attribute this growth to increased grain boundary diffusion. Caswell *et al.* (3) feel that the presence of cross slip in their film provides evidence for plastic deformation but find it difficult to explain the presence of sufficiently large strains even though the films are on low expansion coefficient substrates.

It is the purpose of this report to summarize some experiments studying the effect of thermal cycling on this surface reconstruction phenomena and to comment further on the mechanisms responsible for the size, density, and external morphology of the hillocks.

Experimental

The aluminum films used in this investigation were vacuum deposited at less than 10^{-8} Torr using 99.999% pure aluminum wire on a braided tungsten filament. The filaments were outgassed with a high temperature anneal before each evaporation. The substrates, p-type silicon with 1μ of thermally grown oxide on a polished surface, were thoroughly cleaned and dried before deposition. A dehydration and final surface cleaning were accomplished by heating the wafers to several hundred degrees centigrade while under vacuum. Both cleaning and deposition temperatures were achieved with a tungsten wound radiation heater and monitored with a Pt-Pt 10% Rh thermocouple, mounted on a "dummy" wafer. Three deposition temperatures were used to produce 7000Å thick films of various grain sizes; room temperature (28°C), 200°C, and 400°C. The average grain sizes of the films deposited at these temperatures were in the range less than 1μ, 1μ, and 5μ, respectively.

Thermal cycling was performed manually between a hot stage in a tube furnace and a massive aluminum block held at room temperature. Temperature control was ±2°C and a N_2 atmosphere was used. A 15 min cycle time was selected. Control samples were run for the same time-at-temperature as the cycled ones.

Observation of the surface reconstruction was accomplished in three ways. During anneal (*i.e.*, after each cycle) surfaces were examined by standard optical microscopy (up to 2000X). This enabled estimates of hillock density at various stages of development to be made. Three stage replication and shadowing permitted the use of an electron microscope (10,000X to 20,000X) for viewing individual hillocks. Employment of a scanning electron microscope (up to 20,000X) with its large depth-of-field allowed examination of individual hillocks from a variety of incident directions and yielded much information about the details of hillock morphology.

Results

The effect of thermal cycling on surface reconstruction is rather dramatic. Figures 1 and 2 illustrate this for 7000Å aluminum films deposited at 200°C having a grain size of about 1μ. Both films were annealed in a dry N_2 atmosphere at 430°C and hillock growth was apparent in either case. The uncycled film (Fig. 1) has had a continuous 2½ hr anneal and the "uncycled hillock density" (ρ_u) is about $5 \times 10^5/cm^2$. This includes hillocks of base diameter about 1μ or larger whose typical height is close to 1.5μ.

Figure 2 shows an identically prepared film which has undergone ten 15 min cycles at 430°C (equivalent time-at-temperature as the film of Fig. 1). The "cycled hillock density" (ρ_c) is $1.5 \times 10^6/cm^2$ while the average height has increased to almost 3μ.

Similar experiments (*i.e.*, 430°C anneal) have been carried out for films deposited at room temperature and also at 400°C. The corresponding hillock densities are given for all these films in Table I and sample data is plotted in Fig. 3. A nearly logarithmic dependence on deposition temperature is indicated. For

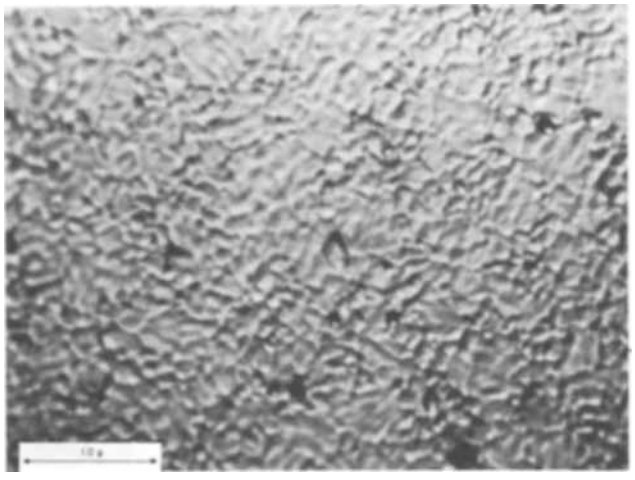

Fig. 1. Optical micrograph of 7000Å Al film annealed 2½ hr at 430°C, 4360X.

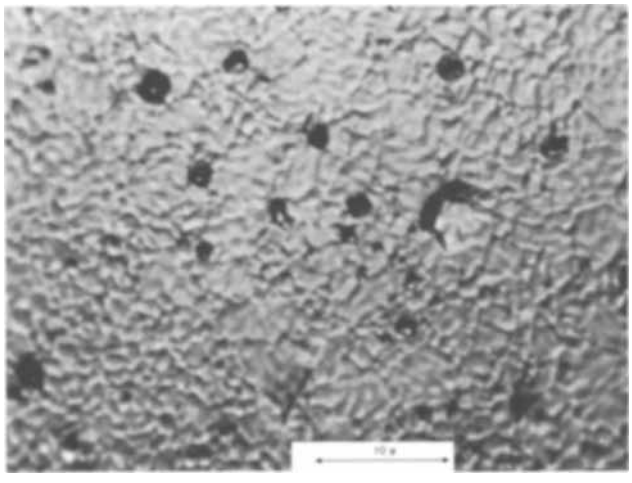

Fig. 2. Optical micrograph of 7000Å Al film annealed in ten, 15 min cycles at 430°C, 4360X.

the room temperature films densities are high and the sizes were generally just greater than 1μ. For the films deposited at 400°C densities are considerably lower. In all cases the estimates of hillock number are rough since the relatively low number (especially in the larger grained specimens) prevents obtaining good counting statistics.

Both large and small grain films were annealed at temperatures below that of deposition. In the case of large grains (5μ) no hillock formation was observed at anneal temperatures of 175°C, and 237°C for either cycled or uncycled samples. For the smaller grained (1μ) films deposited at 200°C some hillocks were observed for an anneal at 179°C. Here the densities are $\rho_c \approx 5.2 \times 10^5/cm^2$ and $\rho_u \approx 2.8 \times 10^5/cm^2$. These data are included in Table I.

Several films were passivated by depositing films of SiO_2 at 150°C with thickness 1000Å to 1μ. As was reported for constant temperature anneals (1), thermal cycling produced no hillocks in the passivated state.

Table I. Hillock densities for films deposited at room temperature and 400°C

T_e, °C	T_a, °C	ρ cycled	ρ uncycled	ρ_c/ρ_u
R.T.	430	$8.7 \times 10^7/cm^2$	$4.0 \times 10^7/cm^2$	2.2

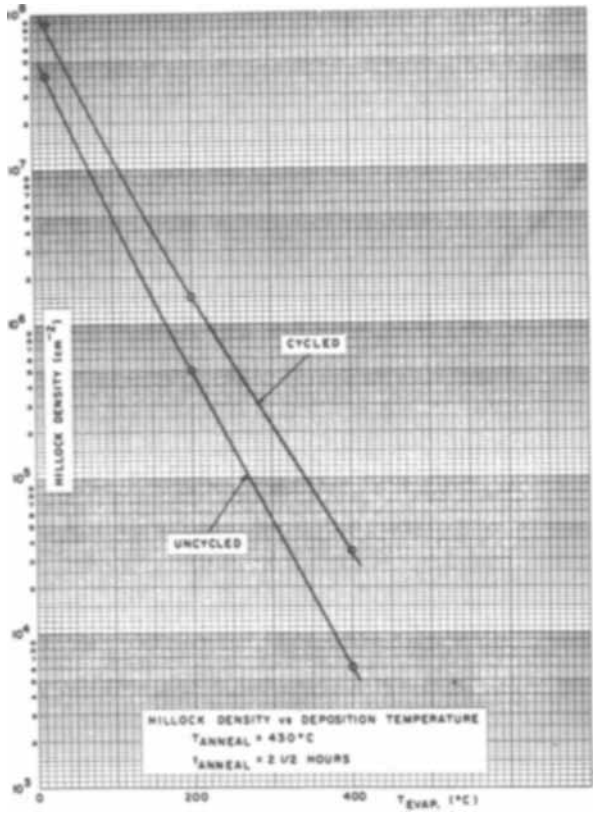

Fig. 3. Dependence of hillock density on deposition temperature for films annealed at 430°C.

The shape of the hillocks is determined by the granular structure of the film. The hillocks may be divided into three general classes based on the grains from which they originate. Figure 4 shows the three grain patterns present in these films. Growth from a configuration similar to 4a can result in an "edge" hillock such as shown in Fig. 5. Configurations 4b and 4c yield hillocks such as the flat-topped one shown in Fig. 6 and the spire-like one shown in Fig. 7. Edges corresponding to the surrounding boundaries are apparent in both of the latter types.

Discussion

The primary reason for hillock development is the disparity in linear expansion coefficient between the silicon substrate ($\alpha_{Si} = 3.3$ ppm/°C) and the deposited Al film ($\alpha_{Al} = 23.6$ ppm/°C). The film is in "size equilibrium" with the substrate at the temperature of evaporation (T_e) whereas at the anneal temperature (T_a) a strain, ϵ, is introduced on the film given by

$$\epsilon = \frac{L_{Al}(T_a) - L_{Si}(T_a)}{L(T_e)}$$

where $L(T_e)$ is the size (diameter) of the substrate and film at deposition and $L_{Al}(T_a)$ and $L_{Si}(T_a)$ are the sizes of each if they are allowed to expand freely from T_e to T_a. To a first approximation, then, this

strain can be expressed

$$\epsilon = [\bar{\alpha}_{Al} - \bar{\alpha}_{Si}]\ (T_a - T_e)$$

where the $\bar{\alpha}$'s are some appropriate average values (in a linear approximation α is a constant) of the coefficients of thermal expansion of the layers. In the cases where $T_a > T_e$ the Al film is placed under a compressional ($\epsilon > 0$) stress proportional to ϵ and hence to $[\bar{\alpha}_{Al} - \bar{\alpha}_{Si}]$ and $\Delta T = T_a - T_e$. Using the aforementioned coefficients of expansion, a $\Delta T = 250°C$, and an elastic modulus of 9×10^6 psi for aluminum, we have obtained a rough estimate of this stress to be about 40,000 psi. Paddock (1) has calculated a value of 60,000 psi for similar conditions. A more elaborate calculation (6) employing the appropriate stress function (7) for axially coupled cylinders yields a value on the order of 25,000 psi with a slight radial dependence. It is to relieve this compressional stress that mass transport forming the hillocks occurs at the elevated temperature. In an uncycled anneal the hillock growth continues until equilibrium at the higher temperature is achieved. When a specimen undergoes thermal cycling, however, there is a reversal of the stress patterns during the cooling cycle. Since hillock formation relieves some of the compressional stresses present on heating, and since the aluminum atoms are mobile at temperatures above the recrystallization point (150°C) one expects some relief of the tension stresses, present during cooling, while the film is above the recrystallization temperature, and the aluminum atoms are still mobile. Because one does not expect a reversibility to exist in the mass motion causing hillock formation, this relief is probably accomplished by gross thinning of the film or by grooving or separation at grain boundaries. The film then approaches the higher temperature equilibrium, except in a thinner, "hillocked" state. The reapplication of heat, in a subsequent heating cycle, once again causes compressional forces to rise, and new hillocks as well as the growth of older ones are promoted. Hence one anticipates the increase in both hillock size and number when films are thermally cycled.

It is noteworthy that this relief-upon-cooling may also explain the growth of hillocks in the cases where $T_a < T_e$. In one such case where $T_e = 200°C$, and $T_a = 179°C$ a sparse but nevertheless significant hillock population was seen (Fig. 8). Since cooling in a vacuum after evaporation is generally slow there may have been sufficient time for reordering and hence the establishment of a film which appears to have been deposited at an "effective T_e," lower than the anneal temperature. This reordering is certainly present in all the films deposited at higher temperatures and hence any quantitative evaluation of stresses which would certainly involve a knowledge of T_e requires an assumption about this effective value.

In one model for hillock formation, grain boundary diffusion is postulated as the controlling mass transport mechanism. It is assumed that films containing a high grain boundary density relieve the compressional forces by diffusion down these boundaries to nucleat-

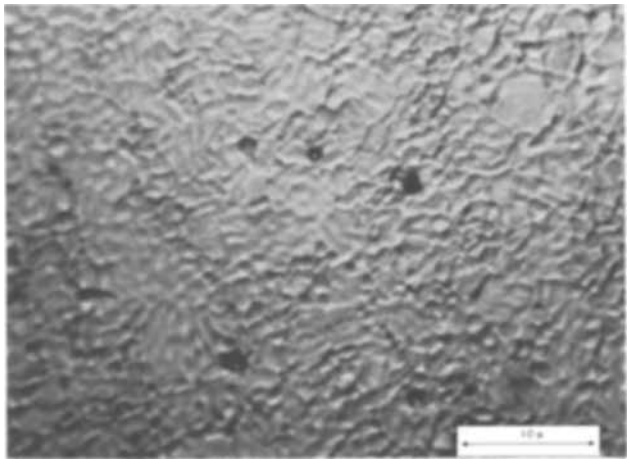

Fig. 8. Hillocks formed in an anneal below the deposition temperature, 4360X.

ing sites when the hillocks form. The evidence of higher hillock density on the "cold-deposited" small grain films, and films doped with silicon is pointed to in support of this mechanism.

It is presently felt that the formation and growth of hillocks is a creep (4) phenomenon. Although primarily diffusion controlled, this is a lattice rather than a boundary process in which the surface is plastically deformed due to atomic motion in the bulk of the film. Dorn (5) has shown that creep occurs in bulk aluminum at temperatures above 400°C for stresses as low as 3000 psi. The calculations above estimate the stress levels in these films to be greater than 25,000 psi. Hence it is not unreasonable to consider reconstruction of the film as being due to creep under the influence of this rather high compressive stress. No experiments have been performed during this investigation to try to determine which mechanism of creep is operating during the reconstruction process.

It is interesting to postulate the effect of many thermal cycles on the aluminum. Hillock growth is highly anisotropic, this random thickening of the film takes place as mass is locally "piled-up" during the heating cycle. The hillock formation is not reversible, however, and hence some "thin-spots" are likely to occur after many cycles. The stress levels in these less thick regions may be considerably higher than the remaining films—high enough, perhaps to cause separation along a grain boundary. This is expected to occur during cooling at temperatures below 150°C where the mobility of Al atoms is restricted and tension forces of sufficient magnitude to pull grains apart, may exist.

Summary

In summary, then, the presence of high compressive stresses and elevated temperatures, coupled with the observation of creep in bulk aluminum, lends evidence to the creep mechanism of hillock formation.

The effect of thermal cycling is seen to increase the over-all hillock density since a renewed compressive stress accompanies each heating cycle. This is due to the fact that some relief of the tensile stress, present during cooling, must occur above the recrystallization temperature. This relief is not simply the reverse of the hillock formation but is most probably a bulk reordering of the film accompanied by some grain boundary separation. The repeated cycling of the film, then, produces hillocks as well as enlarging those already formed. In the extreme case of many cycles, grain boundary separation leading to "opens" may be expected to occur.

Acknowledgments

Electrically Conducting Photoluminescent ZnSe Films

Alvin M. Goodman

RCA Laboratories, Princeton, New Jersey

ABSTRACT

Electrically conducting photoluminescent ZnSe films have been prepared by evaporation onto suitably cleaned, heated sapphire ($1\bar{1}02$ orientation) substrates. The presence of electrical conductivity is shown to be correlated with (*a*) the degree to which the (111) planes of the films are parallel to the substrate surface, and (*b*) preferred orientation of these planes about the normal to the substrate. Crude electroluminescent comb cells utilizing these films have been fabricated.

The purpose of this paper is to describe a technique for producing electrically conducting photoluminescent (PL) ZnSe films of micron thickness. This type of film should be useful for the fabrication of electroluminescent (EL) devices (1, 2). With one possible exception,[1] it has not been feasible in the past to produce such films although much effort has been expended toward this objective (4-6). The method used here is basically that developed by Fonger (4-6) to produce photoluminescent insulating ZnSe films; it was found, however, that by proper selection and preparation of the substrate material, electrically conducting films could be produced.

[1] The one possible exception to this is in the work reported by Dobbs (3) in which the films were heavily doped with Cu to a concentration of from 500 to 5000 ppm. It seems probable that in that work the conductivity was due to metallic Cu which had precipitated along grain boundaries.

Film Preparation

A series of ZnSe films were produced using an evaporation technique developed by Fonger (4-6). Since that work has been described in great detail, only the essentials will be described here.

A cross-section view of the multiple arm evaporation chamber used in this work is shown in Fig. 1. The evaporation chamber and the associated heaters and heat shields are mounted inside the bell jar of a Kinney evaporation system equipped with a 4 in. diffusion pump and a liquid nitrogen trap. The system ordinarily pumped down to pressure in the range $10^{-6} = 10^{-5}$ Torr. The evaporation chamber is constructed of quartz and has five arms extending from its bottom. Three of the arms are short, closed at the lower end, and inclined (at an angle of 13° with respect to the vertical) to point toward the center of the substrate.

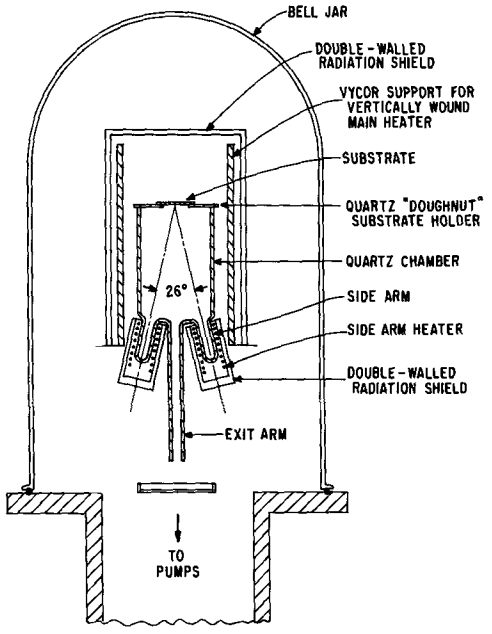

Fig. 1. Cross-section schematic view of the multiple-arm evaporation chamber.

They are intended for use with high-evaporation-temperature materials and were used in the present work. The other two arms are long and vertical. One of these (not shown in Fig. 1) is closed at the lower end and is intended for use in evaporating material at a relatively low temperature; it was not used in this work. The remaining arm emanating from the center of the chamber bottom is open and serves to evacuate the chamber to the bell jar and the pumps.

Each of the evaporating arms has its own tungsten coil heater and radiation shield. There is also a heating coil and radiation shield which surrounds the main chamber. The power to each of the heaters is individually controlled and metered. A thermocouple between the main heater and the chamber was used to monitor the chamber temperature and thus the substrate temperature. Various substrates and substrate preparation procedures were used and these are discussed in detail in the following section. The substrate holder was a quartz plate with a beveled hole in the center through which the evaporants reached the substrates.

The usual procedure for the deposition of a film was the following:

1. The chamber and substrate holder were thoroughly cleaned in aqua regia and rinsed in distilled water. The weight of the substrate was measured.

2. A measured amount of ZnSe powder was placed in one of the short inclined arms of the chamber and a similar amount of NaCl was placed in another. The amount was in each case typically ~ 100 mg. The ZnSe powder[2] was prefired in a reducing atmosphere (H_2 or forming gas) at ~ 1000°C to remove volatile impurities and to increase the crystallite size. The larger crystallite size is desirable to decrease "rocket flights" of the particles due to self-propulsion as they volatilize nonuniformly. The use of the coevaporant NaCl was shown by Fonger to result in much greater reproducibility of PL in ZnSe films (6). The probable effect of the use of NaCl as a coevaporant is the introduction of Cl as a coactivator for the red-orange "self-activated" luminescence of ZnSe.

3. Loosely packed plugs of quartz wool were inserted over the ZnSe and NaCl to prevent spattering during evaporation.

4. The chamber was placed in the vacuum system and the substrate holder and the substrate were positioned as shown in Fig. 1. The arm heaters and the chamber radiation shield were placed as shown in Fig. 1.

5. After putting the bell jar in place, the system was pumped down and baked by applying power to all heaters. The power to the main heater was adjusted to obtain the desired chamber temperature. The power to the arm-heaters was adjusted to keep the arms hot (hopefully near the chamber temperature) but much below the temperature at which rapid evaporation occurs.

6. When the chamber temperature stabilized, the power to the arms containing the NaCl and the ZnSe was increased and the evaporation was started. Typical evaporation times were ~ 15 min. After this, the power to all heaters was turned off and the system was allowed to cool. The film was then removed from the vacuum system and the weight gain of the substrate was determined. Typically the deposit weights were of the order of 1 mg.

[2] "Luminescent grade" ZnSe powder obtained from the General Electric Company.

Table I. Photoluminescence, conductivity, and electroluminescence in ZnSe evaporated films

Substrate material	Substrate preparation	Substrate temperature, °C	PL	Conducting	EL
Quartz	Unknown	400	No	No	No

[a] Cleaned in 1:1 mixture of H_2O_2 (30% solution) and H_2SO_4 (~96% solution) followed by a thorough rinse in distilled water. [b] Washed in Calgonite, thoroughly rinsed in distilled water, boiled in trichlorethylene, and air dried.

Film Properties

The films were tested for photoluminescence by illuminating them with near-uv light (3660Å) and visually observing the resulting visible (red-orange) luminescence. The photoluminescent efficiency was not measured; however, the visually observed brightness (of the films which exhibited luminescence) appeared to be approximately equal to that of films grown by Fonger (6) at similar substrate temperatures. The quantum efficiency of those films was of the order of 3%.

The films were tested for conductivity by measuring the resistance between two In-Ga electrodes painted on the films or between Pt electrodes which had been evaporated onto one of the sapphire substrates before deposition of the ZnSe film.

A variety of substrates, substrate preparation procedures, and temperatures were used; the most significant results are summarized in Table I. The only combination that resulted in an electrically conducting, photoluminescent film was that of (*i*) a $1\bar{1}02$ oriented sapphire substrate prepared by washing in Calgonite,[3] rinsing thoroughly in distilled water and boiling in trichlorethylene, and (*ii*) use of a high substrate temperature during film deposition. The observed conductivity between "painted-on" In-Ga electrodes was non-ohmic and light was observed emanating from the periphery of the negative electrode. Between two Pt contacts which had been evaporated onto one sapphire substrate before deposition of the ZnSe, the conductivity was ohmic and no luminescence was observed. The current-voltage plots for these cases are shown in Fig. 2.

[3] Calgonite is a laboratory cleaning agent for glassware obtained from Fisher Scientific Company. It contains soap, carbonates, silicates, and a water conditioner, i.e., glassy sodium phosphate.

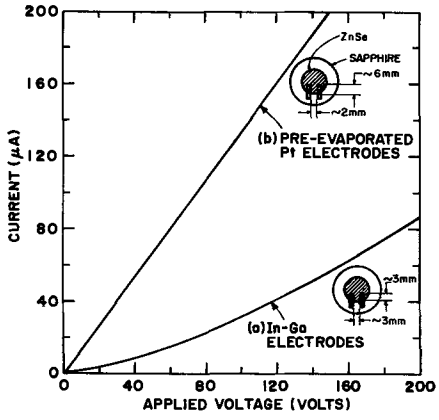

Fig. 2. Current-voltage characteristics of a ZnSe film between identical electrodes: (a) In-Ga "painted-on," (b) previously evaporated Pt.

An order of magnitude estimate of the resistivity of the conducting films is about 300 ohm-cm. Detailed studies of the electrical characteristics of the films were not carried out.

A crude electroluminescent comb cell using a conducting, photoluminescent ZnSe layer is described in the Appendix.

In an effort to determine why only the films grown on sapphire which had previously been cleaned using procedure b of Table I were conducting and the others were not, the films were examined using high magnification light microscopy, x-ray methods (Laue and diffractometry), and electron diffraction. The results are discussed below.

In Fig. 3 are shown 4 micrographs of ZnSe films for different growth conditions. In (a) the substrate was quartz at 400°C. There is no granularity apparent; the film is smooth though slightly cloudy.

In (b), the substrate was also quartz but at 670°C. The granularity here is apparent; the maximum grain dimension is about 2μ with the average probably somewhat smaller than 1μ. In (c) the substrate was sapphire at 670°C. The maximum grain size may be slightly larger than for (b) but the difference is certainly not striking. In (d) the substrate was an evaporated layer of Pt on sapphire. The grain size is not significantly different from either (b) or (c). In other cases (not shown) with different substrates and substrate preparation procedures but using the same substrate temperature (670°C) during deposition, the film grain size was not noticeably different from (b), (c), or (d). To summarize, the grain size was larger when deposition of the ZnSe occurred on higher temperature substrates but was relatively independent of the substrate material and cleaning procedure.

The x-ray results on the same samples showed that all were either predominately or entirely cubic ZnSe but that there were significant differences in crystallinity and orientation (7). These results are summarized in Table II.

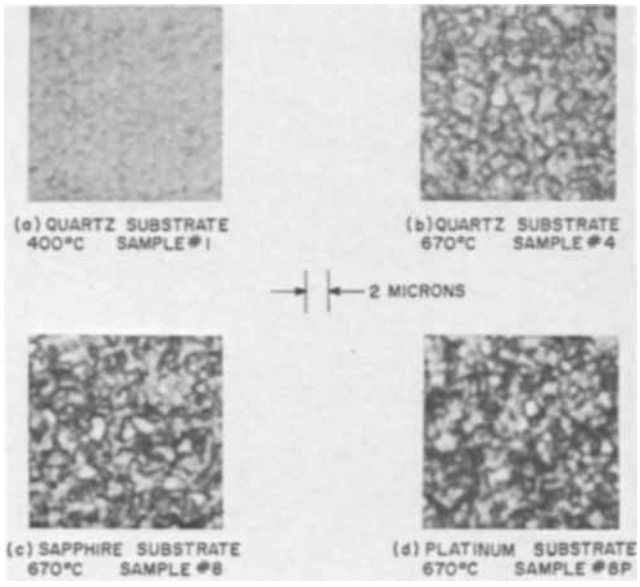

Fig. 3. Photomicrographs of ZnSe films for 4 different growth conditions: (a) quartz substrate 400°C, sample No. 1, (b) quartz substrate 670°C, sample No. 4, (c) sapphire substrate 670°C, sample No. 8, (d) evaporated platinum layer (on sapphire) at 670°C, sample No. 8P.

The back-reflection Laue pattern showed the presence of polycrystalline rings for all samples. In each case, the rings were continuous, indicating no detectable azimuthal ordering in planes not parallel to the surface. The rings were sharp and resolved ($K\alpha_1$-$K\alpha_2$) except for sample No. 1; this was interpreted as being due to a smaller particle size in sample No. 1. Sample No. 8 produced sharp continuous rings but fewer of them indicating a higher degree of preferred orientation; *i.e.*, more planes were parallel to the surface (111) and fewer planes were oriented at an angle to the surface.

Diffractometry indicated that all of the samples were single phase ZnSe (cubic) and had preferred orientation in the (111) direction relative to the substrate. There was, however, a difference in degree. Sample No. 8 was most highly oriented and showed only (111) reflections and higher orders. Samples No. 4 and No. 16 were less highly oriented in the (111) direction than No. 8. Sample No. 1 gave the poorest crystalline pattern and was only slightly oriented in the (111) direction. Sample No. 8P was the most randomly oriented ZnSe of the lot.

"Omega scans" (rocking curves) were obtained for each of the samples by keeping the detector stationary on the 111 reflection and scanning through the θ angle. The width at half maximum intensity was measured for each sample and is given in Table II. The important observation here is that the smallest half-width (3.1°) was obtained for sample No. 8 and that

Table II. Results of x-ray and electron diffraction analyses of ZnSe evaporated films

Sample	Substrate	Temp, °C	X-ray results	Peak half-width in omega-scan	Electron diffraction results
1	Quartz	400	Gave poorest crystalline pattern (relative to other samples) and was only slightly oriented in (111) direction. Had smallest crystallite size	>10°	Polycrystalline rings with little if any orientation in reflections other than (111). The (111) reflection shows some orientation. Some hexagonal phase ZnSe can also be identified
4	Quartz	670	Somewhat higher degree of crystallinity than No. 1 and slightly more highly oriented in (111) direction than No. 1	5°	Similar to sample No. 1 except that no hex phase is present
8	Sapphire (cleaning procedure b of Table 1)	670	Most highly oriented in (111) direction and only the (111) peak and its higher orders were observed on the trace	3.1°	Sample gives pattern of rings showing preferred orientation about the normal to the surface for all rings with the (111) most highly oriented. All rings are cubic ZnSe
8P	Pt on sapphire	670	Most randomly oriented ZnSe of the lot	—	—
16	Sapphire (cleaning procedure a of Table I)	670	Results very similar to those for sample No. 4	4°	Similar to sample No. 1

Fig. 4. Electron diffraction patterns of ZnSe for different growth conditions.

this is still much greater than the value which might be expected for a good single crystal ($\sim 0.1°$).

Four of the samples were also examined by reflection electron diffraction using 100 kev electrons at near grazing incidence (8). The diffraction patterns are shown in Fig. 4 and a summary of the interpretation is given in Table II. The significant point here is that the (111) planes are highly oriented about the normal to the film surface for sample No. 8 and that they are not for the other samples.

Discussion

The results of the last section show clearly that electrical conductivity of the film is correlated with a high degree of crystalline grain orientation. This result tends to support the following speculation of Fischer on the reason for lack of conductivity in polycrystalline ZnSe films (9). Fischer suggests that depleted Schottky barriers form between grains of a polycrystalline ZnSe layer thus causing it to be insulating. It follows then that a high degree of crystalline orientation of the grains should give rise to less disorder and thus fewer electronic interface states along the grain boundaries. This is illustrated in Fig. 5 where in (a) the high density of electronic interface states gives rise to larger depletion regions and a higher barrier than in (b) where the interface state density is low. While the foregoing reasoning is not "a proof," it does constitute a strong plausibility argument.

In order to determine how the procedure for cleaning the substrates affected the crystallinity of the deposited films, two sapphire substrates were examined by scanning electron microscopy (10). One of these had been prepared using cleaning procedure "a"—"cleaned" in 1:1 mixture of H_2O_2 (30% solution) and H_2SO_4 ($\sim$ 96% solution) followed by a thorough rinse in distilled water. The other was prepared using cleaning procedure "b"—washed in Calgonite, thoroughly rinsed in distilled water, boiled in trichlorethylene, and air dried. The substrate prepared using cleaning procedure "a" showed considerably more contamination remaining on the surface than the other substrate although both were relatively clean. Two more or less typical areas are shown in Fig. 6.

The work described thus far has (hopefully) answered one question about the nature of conductivity (or lack of it) in ZnSe films. It leads, however, to many more questions. It is appropriate to set the stage for possible future work by explicitly asking some of these questions:

1. What are the electronic properties of these films? carrier density? carrier mobility?
2. What would be the effect of using other crystalline substrates? For example, spinel, GaAs, Ge, etc.
3. What would be the effect of doping on the electrical conductivity and luminescence of these films?
4. Are these films useful for device purposes?

To give a definitive answer to any of these questions is beyond the scope of the present work. However, a first and admittedly very crude step toward an answer to the last question is described in the Appendix.

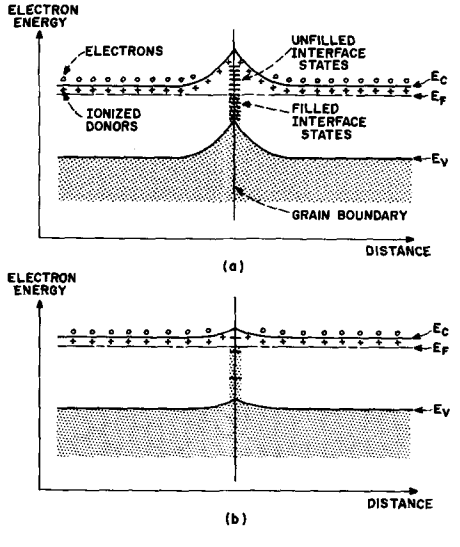

Fig. 5. Models of the energy-band-diagram at a grain boundary: (a) high electronic interface-state density, (b) low electronic interstate density.

Conclusion

Electrically conducting photoluminescent ZnSe films have been prepared by vacuum evaporation onto suitably cleaned, heated sapphire ($1\bar{1}02$ orientation) substrates.

The presence of electrical conductivity has been shown to be correlated with (*a*) the degree to which the (111) planes of the film are parallel to the substrate surface, and (*b*) preferred orientation of these planes about the normal to the substrate.

The results are in agreement with and tend to confirm a model suggested by Fischer for explaining the lack of conductivity in other ZnSe films.

Acknowledgment

Any discussion of this paper will appear in a Discussion Section to be published in the December 1969 JOURNAL.

APPENDIX

An Electroluminescent Comb Cell

A crude electroluminescent cell using the comb structure illustrated in Fig. 7 was fabricated on each of two conducting luminescent ZnSe layers by evaporation of metal electrodes through appropriate masks. The current voltage characteristics of the two devices were similar though not identical; one of these is shown in Fig. 8. The observed light when viewed through the microscope appeared to come principally from the edges of the negative electrode regardless of whether it was Pt or In. The mechanism was probably that of impact ionization described by Fischer (2). When the Pt lines were positive, however, some light did appear to come from their edges and was probably due to hole injection. At a power input of 5w the light from the cell was visible in dim room light. No further work has been done to improve the performance of these devices or to analyze the radiative mechanisms involved.

Photoexcitation and Luminescence in Redox Processes on Gallium Phosphide Electrodes

K. H. Beckmann and R. Memming

Philips Zentrallaboratorium, Hamburg, Germany

ABSTRACT

The mechanism of the charge transfer between energy states of electrons in GaP electrodes and redox systems was studied. Measurements of the photoexcitation of electrons in GaP have shown that not only the conduction and valence band but also surface states are involved in the charge transfer at the interface. Electroluminescence is observed if minority carriers are injected into the electrode. The corresponding recombination process is compared with that of the photoluminescence. Quenching effects are discussed.

In a recent paper (1) we reported on some electrochemical properties of GaP-electrodes. In connection with those studies we already discussed the reduction mechanism of certain oxidizing agents. Some results indicated that not only the conduction and the valence band but also surface states are involved in charge transfer reactions. This assumption is based mainly on investigations of redox reactions in which minority carriers are consumed. In this case the reaction rate may be controlled by light excitation. In the present paper the corresponding excitation mechanism is reported.

In connection with those studies, measurements of the luminescence produced by light or current injection give valuable information about the charge transfer mechanism on GaP surfaces. As mentioned in a previous paper we observed electroluminescence in GaP after addition of an oxidizing agent (1). Similar effects were observed with ZnS electrodes in electrolytes containing oleum (2). In this paper the corresponding recombination mechanisms are reported.

Experimental

All experiments were performed with single crystals of GaP oriented in the <111> direction. Whereas the n-type material was doped with tellurium, the p-type crystals contained zinc and oxygen. In both cases the density of free carriers was about $10^{17}/cm^3$. Before each measurement the electrodes were etched in HCl.

The current-potential curves were measured using a Wenking potentiostat. In the electroluminescence experiments the electrolyte was streaming along the surface in order to increase the supply of oxidizing agent near the surface. In this case the electrode potential was modulated by square wave pulses (28 Hz) leading to current peaks up to 100 ma/cm². The photoluminescence was excited by chopped radiation (12.5 Hz) from a mercury arc or a tungsten lamp. Schott glass filters BG 18 and a copper sulfate solution in the incident and RG 5 in the emitted beam were used. The spectral distribution was measured using a Leiss monochromator and a photomultiplier or a PbS-cell. The corresponding signal was amplified (lock-in amplifier) and displayed on a recorder.

Results and Discussion

Photoexcitation mechanism.—The charge transfer between a semiconductor electrode and an electrolyte may occur via the conduction or the valence band of the semiconductor. From current-voltage curves it can generally be concluded which band is involved in the corresponding charge transfer. Typical curves of the interfacial current *vs.* electrode potential for n- and p-type GaP-electrodes are plotted in Fig. 1 and 2. In the anodic region the current increases exponentially at a p-type electrode whereas a saturation current was observed with an n-type electrode. This means that only the valence band is involved in the corresponding process (anodic dissolution). The mechanism of the anodic dissolution itself will not be discussed here; it was recently published elsewhere (1).

When polarizing the GaP-electrode cathodically hydrogen evolution occurs. Since the cathodic current does not increase at cathodic potentials for a p-type electrode obviously only conduction electrons are involved in this process. The number of electrons available for the evolution of hydrogen and consequently the interfacial current may be increased by illuminating the electrode (see Fig. 2).

If $K_3[Fe(CN)_6]$ is added as an oxidizing agent to a solution of 3*N* NaOH a cathodic current was observed also with p-type material without illumination (Fig. 2). From this result it may be concluded that the reduction of $[Fe(CN)_6]^{3-}$ in alkaline solutions proceeds mainly via the valence band.[1] As shown in Fig. 2, however, not only the valence band is involved since the reduction current is slightly increased by illumination of the electrode. As we reported recently (1) in acid solution the dark current is much lower and the light effect stronger than in alkaline solutions, *i.e.*, in this case only few electrons from the valence band are consumed.

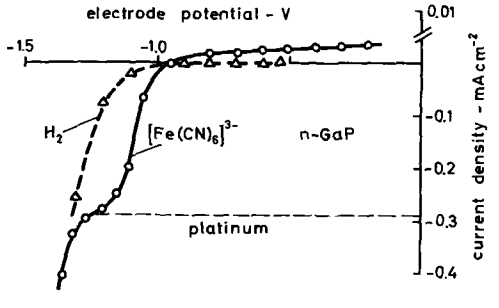

Fig. 1. Interfacial current *vs.* electrode potential for an n-type GaP-electrode in 3*N* NaOH before and after addition of 10^{-2}M $K_3[Fe(CN)_6]$ (electrode potential measured against saturated calomel electrode).

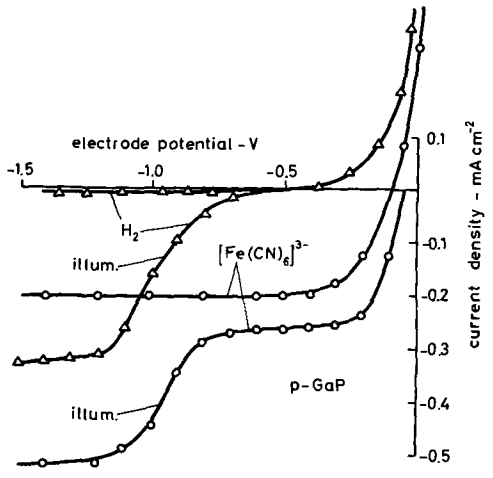

Fig. 2. Interfacial current *vs.* electrode potential for a p-type GaP-electrode in 3*N* NaOH before and after addition of 10^{-2}M K_3 $Fe(CN)_6$.

In order to study this reduction process more accurately the following experiment was performed. A p-type GaP electrode was illuminated by monochromatic light. The change of the cathodic current normalized to unit intensity of the incident radiation was then measured at weak cathodic polarization as a function of the wavelength of the incident light. As shown in Fig. 3 the photocurrent in 1*N* H_2SO_4 due to hydrogen evolution starts to rise near 2.0 ev and reaches a maximum at about 2.75 ev (curve a). Figure 4 shows the absorption spectrum of GaP as it was measured by Subashiev and Abagyan (3). Comparing the increase of the photocurrent with the absorption spectrum it is quite obvious that electrons by a band-band transition are consumed for the discharging of hydrogen ions. With $K_3[Fe(CN)_6]$ present in the solution we observed an additional broad peak in the excitation spectrum at an energy of about 1.6 ev (curve b in Fig. 3). This is a very weak current peak, since its maximum value differs from the main peak at 2.75 ev by about four orders of magnitude.

Similar experiments have been performed with other oxidizing agents, such as persulfate and ceric ions. In these cases we also observed a small current peak in the same energy range around 1.6 ev as it is demonstrated for $K_2S_2O_8$ in Fig. 3 (curve c). The experimental results differ only in so far as the maximum value of the current at 1.6 ev depends on the type of oxidizing agent used for these measurements.

Since the current peak at 1.6 ev appears at an energy smaller than the band gap of GaP (2.25 ev) it has to be concluded that surface states are involved in the charge transfer for the reduction of certain oxidizing agents. As shown in Fig. 5 surface states may be filled by optical excitation with electrons from the valence band. In this figure the energetic positions of the conduction and valence band, of surface states and of the electronic states of the oxidizing agent are indicated. The model for the latter states has been developed by Gerischer (4). According to it these states

[1] It should be mentioned that the large shift of the rest potential occurring for n- and p-type electrodes in opposite directions after addition of the oxidizing agent is due to the formation of electron-hole pairs. The mechanism of this effect was described previously (1).

within the electrolyte show an appreciable broadening so that overlapping with states of different energetic positions in the solid electrode is possible. Charge transfer between the solid and those states within the electrolyte occurs horizontally, *i.e.*, at constant energy. Thus transitions of electrons from surface

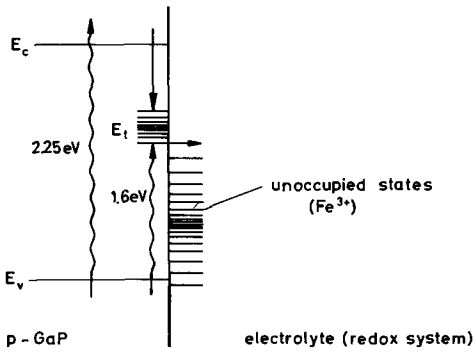

Fig. 5. Schematic energy diagram of p-GaP and redox system (photoexcitation model).

states into the electrolyte lead to the increase in the reduction current. An excitation of an electron from a surface state into the conduction band can be ruled out since in that case the hydrogen evolution should also be excited through photons of 1.6 ev, which is not the case (see Fig. 3 curve a).

As mentioned above in the case of $[Fe(CN)_6]^{3-}$ ions a charge transfer also occurs (see Fig. 2) via the valence band. Consequently the unoccupied states (Fe^{3+}) of this system overlap with the energy levels of the valence band and of the surface state as indicated in Fig. 5, *i.e.*, in alkaline solutions more with valence band and in acid solutions more with the surface states. According to Fig. 3 the reduction current is also increased by exciting electrons directly from the valence into the conduction band. From this fact it can be concluded that electrons are also transferred directly from the conduction band into the unoccupied state of the redox system. Since the band gap of GaP is quite large it seems to be rather unlikely that the unoccupied states of the redox system also overlap with the energy levels of the conduction band. We therefore prefer to assume that electrons excited into the conduction band are trapped by the surface states and then transferred to the Fe^{3+} states. The quantum efficiency for the latter possibility is much larger than for the transition from the valence band into the surface state because of the large absorption cross section for a band-band transition.

Electroluminescence.—As mentioned above the reduction of $[Fe(CN)_6]^{3-}$ ions proceeds partly via the valence band of GaP, *i.e.*, holes are injected. For similar studies with germanium and silicon electrodes the injection current was quantitatively determined using the "thin slice" method (5), *i.e.*, the number of holes was detected by a pn-junction alloyed on the reverse side of the electrode. Since the diffusion length of minority carriers in GaP is only about 1μ (see below), it was impossible to apply this method. Another possibility to detect minority carriers injected from the electrolyte into the crystal is given by luminescence measurements.

GaP is a semiconductor with relatively good luminescence properties. The electroluminescence produced by passing a current through a forward biased pn-junction of GaP was studied by several authors (6). In order to produce electroluminescence by injecting holes during the reduction process we had to take an n-type GaP-electrode. The electroluminescence spectrum obtained with $K_3[Fe(CN)_6]$ as an oxidizing agent is plotted in Fig. 6. Since no electroluminescence was observed without ferricyanide ions it is proved that the electroluminescence is indeed produced by the charge transfer during the reduction process. The same spectral distribution was obtained with a variety of other oxidizing agents such as ceric ions, hydrogen peroxide, and persulfate.

In the spectral distribution of the electroluminescence two peaks are visible, at 1.2 and 1.55 ev. Ac-

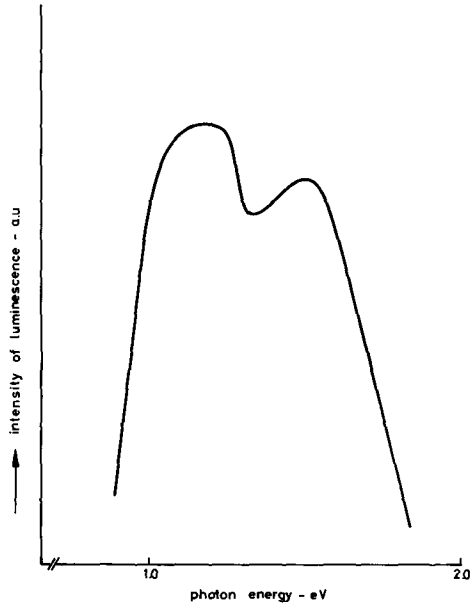

Fig. 6. Electroluminescence spectrum of n-GaP in 1*N* H_2SO_4 + 1M $K_3[Fe(CN)_6]$.

cording to the literature only one luminescence peak was found with pn-junctions. In this case the peak appeared in the range of 1.4-1.9 ev depending mainly on the spatial separation of the Zn and O which participate in this recombination (7). This could lead to the assumption that at least one of our peaks (1.55 ev) would fit into this range and could be explained by the same recombination mechanism as it was found for pn-junctions. This assumption, however, may be ruled out by two arguments: (*A*) According to investigations with pn-junctions (8) the luminescence is due to a corresponding transition between an oxygen and a zinc level within the p-type material. Since we studied the luminescence in n-type electrodes we could not observe the same type of luminescence. (*B*) In the case that still small traces of zinc and oxygen in our n-type material were responsible for the 1.55 ev peak one should expect at the same wavelength a peak in the luminescence spectrum produced by photoexcitation. We performed corresponding measurements with n-type electrodes immersed into an electrolyte free from ferricyanide or any other oxidizing agent. As demonstrated in Fig. 7 only one peak at 1.2 ev appears in the photoluminescence spectrum. At 1.55 ev practically no luminescence was observed.

Comparing the spectrum in Fig. 6 and 7 it is quite evident that the photoluminescence coincides in the spectral distribution very well with low energy peak (1.2 ev) of the electroluminescence. Consequently the luminescence at 1.2 ev may be attributed to one and the same recombination transition within the bulk of n-type GaP independent from the excitation mechanism. The levels within the forbidden zone involved in this transition mechanism are not known. For demonstration only we marked in Fig. 8 the corresponding recombination as a transition between a level within the band gap and the valence band. Whether this is the case or a transition occurs between the conduction band and a certain level or between two levels within the forbidden zone is open for discussion. In order to interpret the appearance of the second peak in the electroluminescence spectrum we have to consider the boundary conditions for the excitation process of the photo- and electroluminescence. In both cases minority carriers are injected. Since the photoluminescence is very weak in n-type GaP we had to use light for the excitation covering a greater spectral range between $\approx$2 ev and higher energies. For all energies of the exciting light below 2.75 ev the penetration depth is large compared with the diffusion length (1μ) of the minority carriers. In the case of the excitation of the electroluminescence, however, holes are injected directly at the surface. Consequently, the probability for a recombination near the surface is much higher. From this consideration it may be concluded that the second peak (1.55 ev) is due to a radiative transition via surface states. This assumption is supported by the fact that a current peak in the excitation spectrum of the photocurrent (see Fig. 3) was observed at practically the same energy (1.6 ev). Since we related this current peak with the optical excitation of an electron from the valence band into a surface state (see Fig. 5) we have to postulate that the electroluminescence is due to a transition from the same surface state into the valence band (Fig. 8).

As mentioned above the luminescence is very weak. The quantum efficiency amounts to about 10^{-6}. Since p-type GaP has much better luminescence properties it seems to be much more favorable to study injection luminescence with p-type instead of n-type electrodes. In the case of p-type electrode we had only to take a redox system with which it is possible to inject electrons. Principally such an experiment could be performed using a strong reducing agent (4). We tested a variety of corresponding redox systems, but we did not find any reducing agent with which it was possible to inject electrons into the conduction band. Probably the position of the conduction band in the absolute energy scale is so high so that it does not overlap with the occupied energy states of a corresponding reducing agent.

Quenching effects.—In the preceding chapters we described the mechanisms of the excitation and the radiative transition via surface states. Now we want

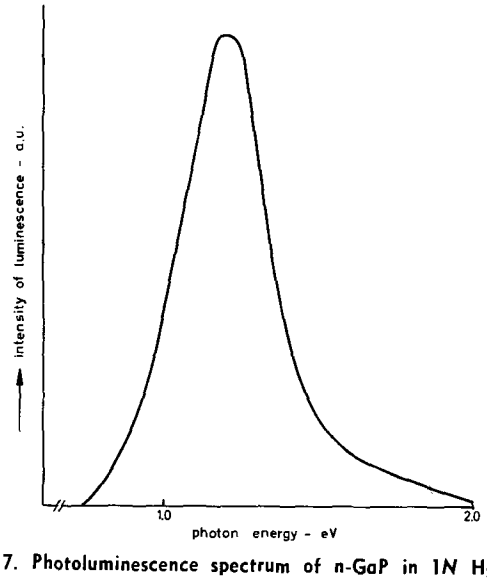

Fig. 7. Photoluminescence spectrum of n-GaP in 1*N* H_2SO_4 at rest potential.

to discuss the influence of interfacial properties on the bulk photoluminescence.

As mentioned before the quantum efficiency for photoluminescence in appropriately doped p-type GaP is much larger than in n-type material. According to the literature the red luminescence at 1.8 ev is due to a transition between an oxygen donor and a zinc acceptor term as demonstrated in Fig. 9. In the case that minority carriers recombine via surface states or are consumed for a surface reaction one should expect that the quantum yield of the bulk luminescence depends on the penetration depth of the exciting light.

We performed corresponding measurements with a p-type electrode keeping the electrode potential constant at the rest potential. The result is plotted in Fig. 10 (circles). Values for the penetration depth were taken from the absorption curve in Fig. 4. In order to get some quantitative information from the curve presented in Fig. 10 we derived a simple relationship between luminescence intensity and surface parameters as follows. The recombination rate is given by

$$U = \frac{\delta n\,(x)}{\tau} \qquad [1]$$

$\delta n\ (x)$ is the density of charge carriers excited at a certain distance x from the surface and $1/\tau$ is the rate constant for the luminescent transition. The intensity I of the light emitted from the whole specimen is obtained by integrating Eq. (1)

$$I = \frac{\alpha}{\tau}\int_0^\infty \delta n\,(x)\,dx \qquad [2]$$

(α is a factor which includes the quantum efficiency of the corresponding transition).

The relationship between the generation and recombination process is given by the continuity equation:

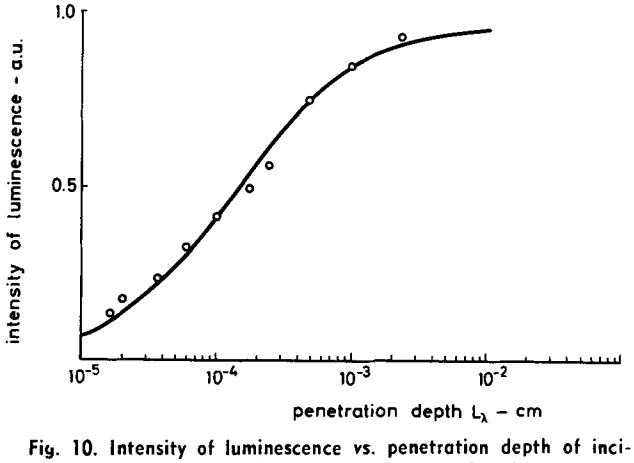

Fig. 10. Intensity of luminescence vs. penetration depth of incident light for p-GaP in 1N H_2SO_4 (values for L_λ obtained from Fig. 4).

$$D\frac{\partial^2 \delta n}{\partial x^2} - \frac{\delta n}{\tau} + g(x) = 0 \qquad [3]$$

$g(x)$ is the generation rate and is related to the number of incident photons P by

$$g\ (x) = \frac{P}{L_\lambda} e^{-x/L_\lambda} \qquad [4]$$

(L_λ = penetration depth of incident light and D = diffusion constant).

The surface parameters may be introduced via the boundary conditions. We assume that minority carriers recombine via surface states or are consumed for a charge transfer into the electrolyte, s and k are the corresponding rate constants. Under stationary conditions the transition rate at the surface equals the diffusion current toward the surface

$$(s + k)\ \delta n = D\frac{\partial\, \delta n}{\partial x}\Big/_{x=0} \qquad [5]$$

Solving the continuity Eq. [3] one obtains using Eq. [1]-[5]

$$I = \frac{I_0}{L_n + L_\lambda}\left(L_\lambda + \frac{D}{s + k + D/L_n}\right) \qquad [6]$$

(L_n = diffusion length of minority carriers). This equation is already normalized in so far as I_0 is the intensity of the photoluminescence if no quenching at the surface occurs. Moreover it should be mentioned that Eq. [6] is valid only in this simple form for the case that the penetration depth is smaller than the sample thickness. As soon as the penetration depth is of the order of the sample thickness we actually observed a decrease of the luminescence intensity (not plotted in Fig. 10).

According to Eq. [6] the diffusion length may be determined easily provided that $s + k >> D/L_n$. Then

$$L_n = L_\lambda \quad \text{for} \quad I = \frac{I_0}{2}$$

The theoretical function of I *vs.* L_λ calculated for large values of s and k ($L_\lambda >> D/s + k$) is also plotted in Fig. 10 (solid line). The best fit was obtained with $L_n = 1.5\mu$. According to this result it has to be concluded that $s + k > 10^5$.

Since according to the Shockley-Read model the surface recombination velocity s depends on the position of the Fermi level at the surface (9, 10) it should be possible to vary the luminescence intensity by changing the band bending, *i.e.*, the electrode potential. This effect, however, turned out to be very small. In order to measure those small variations of the luminescence intensity we increased the sensitivity of our experimental arrangement by modulating the electric field at the surface. This differential method has the advantage that scattered exciting light is not detected. The differential potential dependence of the luminescence ($d\,I/d\,U_E$) ("differential luminescence") as measured by superimposing a 50 mv a-c signal on the external d-c voltage is plotted in Fig. 11a. For comparison the interfacial d-c photocurrent (hydrogen evolution) measured in the same potential range is shown in Fig. 11b. Since the maximum of the differential luminescence coincides with the inflection point of the interfacial photocurrent curve obviously the charge transfer of minority carriers across the interface is responsible for the potential dependence of this luminescence. An influence of the surface recombination velocity s on the differential luminescence may be ruled out because then, according to the bell shaped potential dependence of s[10], two peaks of different signs should have appeared.

This experiment does show the quenching of the red luminescence by charge transfer across the interface. The quenching efficiency is very low and the lumi-

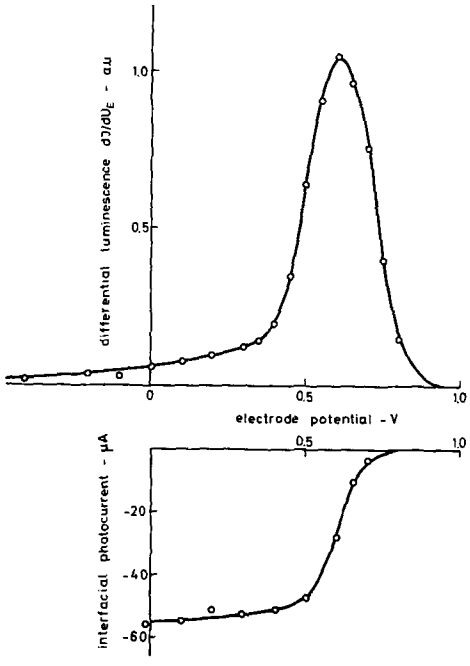

Fig. 11. Differential luminescence (a, top) and photocurrent (b, bottom) as a function of the electrode potential for p-GaP in 1*N* H_2SO_4.

nescence is varied by only few per cent of its total intensity in the corresponding potential range. Since we observed, on the other hand, a strong dependence of the luminescence intensity on the penetration depth of the incident light (Fig. 10) we have to conclude that surface recombination is chiefly responsible for the quenching. This is in agreement with results obtained by Gershenzon and Mikulyak (11) who performed similar measurements with dry surfaces. Why the surface recombination is not changed by varying the electrode potential remains a problem. Since at low depth of penetration the intensity of the luminescence is considerably reduced compared to its value obtained by exciting with radiation of greater penetration depth, the only possible explanation is given by the assumption that not only one discrete but a whole spectrum of energy levels of the surface states on GaP exists. This assumption is supported by the fact that also in the photocurrent spectrum (Fig. 3) the current peak due to the excitation of electrons from the valence band into surface states is very broad. Moreover, other measurements have shown that the quantum yield for the cathodic photocurrent determined at low penetration depths is very low (10^{-2}). This result also indicates that surface recombination is the dominant factor in the luminescence quenching.

The charge transfer by which the luminescence is partly quenched is a cathodic process (cathodic photocurrent in Fig. 11b), *i.e.*, electrons are consumed for discharging hydrogen ions. From the thermodynamic point of view hydrogen evolution is expected to occur only below −0.27v and not at such a high anodic potential as +0.8v. On the other hand, electrons and holes are not in thermodynamic equilibrium under illumination because the number of electrons excited by light is by several orders of magnitude larger than that in the dark ($n_o \approx 10^{-16}$ for $p_o = 10^{17}$). Moreover, according to capacity measurements flat band position is obtained with p-type GaP at +0.1v in 1*N* H_2SO_4, *i.e.*, below +1.0v the energy bands are bent downward at the surface. In the corresponding electric field within the space charge region the electron-hole pairs created by light are separated: electrons move toward the surface and holes in the opposite direction which leads to a reduction of the electric field (surface photovoltaic effect). On the other hand we kept the electrode potential and consequently the potential drop within the space charge region constant. In this case the electrons excited by light are forced to pass the interface. This leads to a cathodic reaction process, *i.e.*, the hydrogen evolution.

In the derivation of Eq. [6] we introduced the charge transfer as a diffusion determined term. This is not correct, of course, if the photovoltaic effect is responsible for the charge transfer. This fact, however, has no influence on the qualitative description of the quenching by charge transfer.

Growth of Zinc-Doped Gallium Phosphide by the Water Vapor Transport Method

Lars C. Luther

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Large Zn-doped GaP crystals have been grown epitaxially on GaAs and GaP substrates. The presence of oxygen as an uncontrolled and perhaps major impurity is inferred from photoluminescence data. Carrier concentrations and total Zn concentrations were obtained from electrical measurements and analytical techniques. The variation of the room-temperature hole concentration with the Zn partial pressure of the growth ambient is in qualitative agreement with a calculated curve using an estimated value of the intrinsic carrier concentration at the growth temperature.

Frosch (1) has described a water vapor transport method for epitaxial deposition of GaP. The purpose of this paper is to describe the application of this technique to the preparation of large-area Zn-doped GaP crystals and to present data on the Zn incorporation.

Experimental

A schematic diagram of the apparatus is given in Fig. 1. Wet hydrogen is passed over a GaP source heated to 1100°C. The source reacts with the water producing phosphorus, Ga_2O, and hydrogen. As these gases are carried over a GaAs or GaP seed crystal placed in a temperature gradient of 6°-10°C/cm and centered at 1075°C, the decomposition reaction is reversed and GaP is deposited on the seed as well as the walls of the furnace tube. The Zn vapor is introduced into the growth ambient by passing dry hydrogen over a heated source of Zn and mixing the gas into the wet hydrogen at 900°C upstream from the GaP source. At this temperature no zinc oxide will precipitate out. The flow rate of the hydrogen carrier gas ranged from 130 to 450 cm^3/min but generally was held at 300 cm^3/min. A constant water vapor pressure of around 3 Torr was used in the majority of the runs; however, pressures as high as 10 Torr and as low as 0.3 Torr were tried. The source temperature was varied between 1100° and 1150°, while that of the seed ranged from 1020° to 1100°C. The average growth rate was 15 μ/hr. A wide range of Zn partial pressures (0.09-34 Torr) was used, the limitation on the high-pressure side being the voluminous Zn deposits which rapidly blocked the gas flow before significant epitaxial growth was achieved.

Gallium was obtained from Alcoa or Alusuisse and had a purity of 99.9999%. United Minerals and Chemical Company was the supplier of 99.998% pure Zn. The GaAs substrates obtained from the Monsanto Chemical Company in the form of <111> oriented slices were cut from undoped, boat-grown ingots. The carrier concentration was 10^{15} cm^{-3} and the dislocation count 10^5 cm^{-2}. The arsenic (B) faces of the slices were polished with bromine in alcohol on rotating Pellon cloth. The GaP seeds were made from epitaxial layers grown on GaAs substrates in the same manner as the Zn-doped material described below. Immediately before a run the GaAs substrate was etched in a mixture of 3 parts conc sulfuric acid and 1 part each of "Superoxol" (30% H_2O_2) and water. GaP seeds were etched in *aqua regia* or a methanol solution of chlorine. Polycrystalline source GaP was prepared by a method developed by Frosch (2), in which gaseous phosphorus was passed over gallium in a quartz boat placed in a temperature gradient of 1000°-1130°C.

Epitaxial growth of gallium phosphide on gallium arsenide under the conditions employed was reproducible only when a phosphorus pressure higher than the decomposition pressure of GaP was maintained over the GaAs seed during the heat-up period (10
