In addition to the insensitivity of the emf measurement at low temperature, the multiplicity of phases in the bismuth-tellurium alloys makes any study on the phase equilibrium of the system very difficult. Establishment of the phase diagram is also complicated by the necessity of excessively long annealing times to obtain thermodynamic equilibrium. Attainment of equilibrium may require annealing for periods in excess of 6 months (17). This problem appears to be more serious for alloys having a tellurium content of 5-50 m/o. Reported phase diagrams may reflect the differences in the alloy preparations, particularly in the range of 5-50 m/o tellurium.

X-Ray Diffraction Study

The Debye-Scherrer powder method of x-ray diffraction was employed. The x-ray radiation of wavelength $\lambda = 2.29092$Å was obtained from a chrome target, and a vanadium filter was used to eliminate the Kβ radiation in the camera. The alloy was converted by filing and grinding into powder which would pass through a 325 mesh screen. The film was exposed from 7 to 10 hr.

Our results of the x-ray powder diffraction study show that the alloy electrodes used in our galvanic cells have a rhombohedral structure. Francombe (18) gives detailed diffraction data on Bi_2Te_3, and his result is in excellent agreement with our investigation.

But our observations indicate no obvious difference in the patterns obtained from alloys in the β-phase region, the $\beta + \gamma$ region, and the γ-phase region. The dimensions of the unit cell of alloys in different phase regions are essentially identical. The average values of the lattice dimensions given by Brown and Lewis are $A_o = 4.38$Å, and $C_o = 30.49$Å, which are in excellent agreement with our values of $A_o = 4.38$Å and $C_o = 30.487$Å. Brown and Lewis give the difference in dimensions of the unit cells between 33 and 60 m/o tellurium as 0.09Å in A lattice and 0.8Å in C lattice. The x-ray study performed by Glatz on the bismuth-tellurium compounds with a tellurium content of 56-62 m/o gives the lattice parameters of the compound Bi_2Te_3 as $A_o = 4.384$Å and $C_o = 30.495$Å which also agree well with those reported by Brown and Lewis and by us. But the differences in the lattice parameters between the compounds in the $\beta + \gamma$ two-phase region and the γ single phase region, namely, between the compounds having a tel-

lurium content of 58.7 and 59.7 m/o reported by Glatz, are extremely small: $A_o = 4.386$Å, $C_o = 30.48$Å for compound with 58.7 m/o tellurium, $A_o = 4.384$Å, $C_o = 30.48$Å for compound with 59.7 m/o tellurium. Thus, the change in lattice dimensions between alloys of varying composition is difficult to detect, especially around the compound Bi_2Te_3, where the change in composition between the β and the γ phases is only 2 m/o.

Differential Thermal Analysis

Differential thermal analysis was used to investigate the phase transitions in the lower temperature range in which the emf measurements became less valid. In our study, a duPont Model 900 analyzer was employed. Alumina was used as the reference material. The sample cell was heated from room temperature up to 873°K at a heating rate of 20°K/min and was then cooled naturally. Differential thermal analyses were performed on various bismuth-tellurium alloys which were all prepared the same as the electrodes in the emf measurements. The tellurium-rich samples lost Te rapidly, and we were unable to obtain any useful information from the samples. For all alloys having a tellurium content up to 65 m/o, a strong endothermic effect was observed at 533°K corresponding to the bismuth-rich eutectic temperature. Glatz also reported that an endothermic effect was observed at 539°K in his differential thermal analyses, and he argued that this phase transition can be eliminated by long time annealing of the alloy. However, the characteristics of the bismuth-tellurium alloy at lower temperature, *i.e.*, below 573°K, in our opinion still have not been fully clarified.

Coulometric Titrations

One of the main interests is to clarify the discrepancy in the phase diagram near the compound Bi_2Te_3; this necessitates an accurate determination of the phase boundaries for the single γ-phase region. To this end, coulometric titrations were performed.

Coulometric titrations were first introduced by Grower (19), and the theory and technique are reviewed elsewhere (20, 21). In our application of the technique, the bismuth ions were transferred from the pure bismuth electrode to the bismuth-tellurium electrode. This method is applicable to a transference of as little as a hundredth of a microgram or even less. This small change in composition allows a close definition of the boundaries of the phase boundaries.

However, the equilibrium potential, *i.e.*, the emf after the titration had been performed, was established very slowly. This low rate of attaining equilibrium was presumably due to the slow rate of diffusion of the bismuth within the alloy. It was unfortunately impractical to increase the rate of attaining equilibrium by increasing the temperature because of the high vapor pressure of $BiCl_3$. Cubicciotti (22) estimated that the vapor pressure of $BiCl_3$ at 850°K might be as high as 70 atm. In this study, coulometric titrations were performed at 766°K, and true equilibrium was successfully established.

The preparation of the experimental cell and the procedure of recording data were similar to those in the conventional emf measurements. The current used in the titration ranged from 0.6 to 70 mA. The emf's of the cell were recorded after the titration had been performed; usually it required 36 hr or more for the system to reach equilibrium. After equilibrium was reached the procedure was repeated. A sequence of titrations performed in the same cell allowed us to scan the concentration easily. The reproducibility of the emf measurements and their agreement with the earlier conventional emf runs is exceptionally good and is shown in Fig. 8. As discussed earlier, a possible loss of up to 0.2 m/o tellurium may occur in the process of preparing the alloy. This loss also may occur in the coulometric titration. From the results obtained, taking into account the loss of the tellurium, the

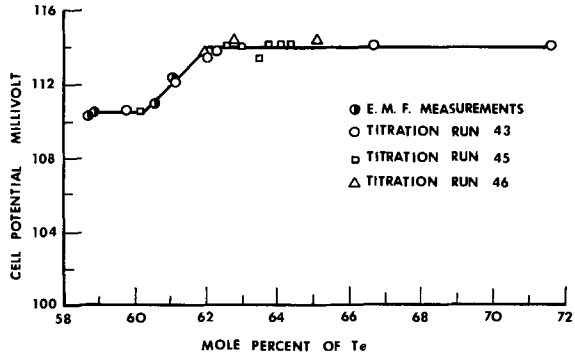

Fig. 8. Relation between cell potential and composition as determined by coulometric titrations and conventional emf measurements.

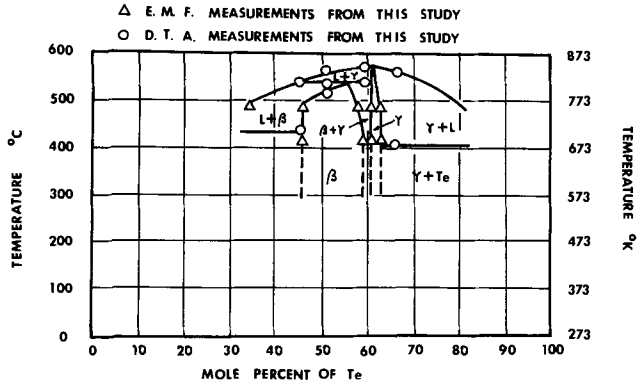

Fig. 9. Proposed phase diagram for the Bi-Te system

boundaries of the single γ-phase region are 60.5 ± 0.1 to 61.9 ± 0.1 m/o tellurium. The close correspondence between the phase boundaries indicated by the coulometric titrations and the conventional emf runs is further confirmation that the bismuth valence is +3. See especially run 43 in which a rather large amount of Bi was transferred.

Proposed Phase Diagrams

Basically, the data obtained from emf measurements, coulometric titrations, and the differential thermal analyses provide sufficient information for the construction of the phase diagram of the bismuth-tellurium system. However, the characteristics of the bismuth-tellurium alloys at lower temperature, *i.e.*, below 573°K, still have not been fully clarified. As mentioned before, an endothermic effect was observed at 533°K, corresponding to the bismuth-rich eutectic temperature, in the differential thermal analyses for all alloys having a tellurium content up to 65 m/o; this phenomenon results in many difficulties in interpreting the data at low temperatures.

In view of the uncertainty in defining the characteristics of the bismuth-tellurium alloys at lower temperature, we restrict our interest to temperatures higher than 673°K and in the composition range of 35-75 m/o tellurium. A phase diagram so constructed is presented in Fig. 9. This phase diagram is based on our emf measurements, coulometric titrations, and differential thermal analyses. Both qualitatively and quantitatively, this phase diagram agrees very well with those proposed by Glatz and by Abrikasov and Bankina. These phase diagrams show a narrow single phase region, the γ-phase region, existing near the compound Bi_2Te_3. At 766°K, the boundaries of this γ-phase region are defined by us as 60.5 ± 0.1 to 61.9 ± 0.1 m/o tellurium, while Glatz defines them as 59.7 to 60.1 m/o and Abrikasov and Bankina give a value of 60.2 to 61.0 m/o tellurium. The differences between the definition of the boundaries is approximately 1 m/o in composition. The agreement between us and Abrikasov and Bankina regarding the location of the boundaries is excellent.

Conclusions

1. The thermodynamic properties of the bismuth-tellurium alloy have been obtained by emf measurements. The activity, relative partial molar free energy, relative partial molar entropy, relative partial molar enthalpy of the bismuth and the tellurium in the alloy, and the relative integral properties of the alloy were obtained. It appears that the electronic state has a significant effect on the thermodynamic properties of the alloy; this effect is similar to that in the silver-tellurium system.

2. The heat of formation of Bi_2Te_3 is -46 ± 10 kcal/g mole at 766°K.

3. The phase diagram of the bismuth-tellurium alloys has been investigated by emf measurements, coulometric titrations, x-ray diffraction, and differential thermal analyses. From these experimental results, the discrepancies between reported phase diagrams of the bismuth-tellurium system have been clarified. We conclude that a very narrow single γ-phase region exists near the compound Bi_2Te_3, in agreement with the work of Glatz and Abrikasov and Bankina. The boundaries of this single phase region have been defined by us as 60.5 ± 0.1 and 61.9 ± 0.1 m/o tellurium at 766°K.

Acknowledgments

One of the authors (JCA) would like to thank R. Fredrick for many long and interesting discussions of the phase equilibrium in the Bi-Te system. Another author (CCL) would like to express his gratitude to The Electrochemical Society for a summer fellowship. The financial support from the Selenium-Tellurium Development Association, Inc. is also gratefully acknowledged.

The Carbon Monoxide, Carbon Dioxide and Carbon Monoxide Electrodes in Molten Alkali Carbonates

P. K. Lorenz* and G. J. Janz*

Rensselaer Polytechnic Institute, Department of Chemistry, Troy, New York

ABSTRACT

The potentials of cells Au|CO,CO_2|$CO_3^=$|CO_2,O_2|Pt and Au|CO|$CO_3^=$|CO_2, O_2|Pt have been determined in the ternary eutectic Li_2CO_3-Na_2CO_3-K_2CO_3 between 510° and 800°C. At 800°C the potential resulting from the Au|CO, CO_2|$CO_3^=$|CO_2,O_2|Pt cell indicated that the reaction occurring at the Au electrode was $CO_3^= + CO - 2e \rightleftarrows 2CO_2$. At 700°C and lower, the cell potential confirmed that the reaction $CO_3^= + C - 2e \rightleftarrows CO_2 + CO$ dominates the high CO partial pressure range. At lower temperatures the reaction $CO + 2\,OH^- \rightleftarrows CO_3^= + H_2$ was observed to proceed to the right, consuming part of the incoming CO stream so that the cell potential appeared to deviate from the Nernst slope (corresponding to the reaction $CO_3^= + CO - 2e \rightleftarrows 2CO_2$). The Nernst slopes and cell potentials follow the thermodynamic prediction for the electrochemical reactions occurring at the Au electrode.

The potentials resulting from the Au|CO|$CO_3^=$|CO_2,O_2|Pt cell were in agreement with the thermodynamically calculated potential for the reaction $CO_3^= + 2C - 2e \rightleftarrows 3CO$ occurring on the Au electrode between 510° and 670°C. At low CO flow rates over the entire temperature range and at all flow rates at higher temperatures the cell potential differed considerably from the predictions for the above reaction. The reaction $CO_3^= + 2H_2 - 2e \rightleftarrows CO + 2H_2O$ is seen as a possible explanation for this behavior.

Reactions occurring in fused alkali carbonates are of interest for their potential applications in (*i*) a practical reference electrode, (*ii*) oxygen regenerative systems, and (*iii*) the carbonate fuel cell.

The Au|CO, CO_2 electrode has been advanced as a reference electrode for the (Li, Na, K)$_2CO_3$ system between 700° and 800°C (1, 2). The behavior of this electrode below 700°C and at high partial pressures of CO is unexplained. Reduction of CO_2 can be utilized to regenerate O_2 from electrolysis in carbonate systems (3, 4). Since the absence of CO is a requirement for most O_2 regenerative systems, it is of interest to establish the temperature regions in which CO is not produced. Relative to the carbonate fuel cell, electrochemical investigations are of interest in order to explore the question of thermodynamic control and to observe possible interfering reactions (5, 6).

The present investigation was undertaken to determine the reactions occurring on a Au electrode immersed in the molten (Li,Na,K)$_2CO_3$ eutectic while the electrode was subjected to CO and mixed CO,CO_2 atmospheres.

Experimental Technique and Apparatus

Chemicals.—Lithium, sodium, and potassium carbonates (reagent grade) were vacuum dried at 250°C under a CO_2 atmosphere. The dried carbonates were stored in a desiccator over $Mg(ClO_4)_2$ until required for use. In order to avoid contamination by H_2O, the eutectic mixture (Li_2CO_3-Na_2CO_3-K_2CO_3, 43.5-31.5-25.0 m/o [mole per cent] mp 397°C) (7) was weighed out in a dry-box. The mixture was then placed in the furnace and melted under a constant atmosphere of predried CO_2. The CO_2 atmosphere above the melt served to minimize the carbonate dissociation and to remove OH^- from the melt by virtue of the reaction (8)

$$CO_2 + OH^- \rightleftarrows CO_3^= + H_2O \qquad [1]$$

Apparatus.—The gastight electrochemical cell assembly is illustrated in Fig. 1. The cell potential was monitored with a high input impedance electrometer which was connected between the test and reference electrodes. The electrometer output was connected through a series of decade resistors to a potential-time recorder. The recorder functioned to indicate when the system had reached equilibrium; the potential registered on the electrometer was then noted.

A Pt wire bathed in a flow of CO_2,O_2 (mol ratio, 2/1) served as the reference electrode. The behavior of this electrode has been thoroughly investigated (9-12). Carbon dioxide and oxygen were passed through drying trains containing $Mg(ClO_4)_2$, monitored on flowmeters, and mixed before entering the reference elec-

* Electrochemical Society Active Member.

trode compartment. Flow rates of 40 and 20 cm³/min were used for CO_2 and O_2, respectively.

The test electrode consisted of a Au wire (0.8 mm diameter) dipping into the melt. The Au wire was housed inside two concentric pythagoras sheaths; the inner served to supply the desired atmosphere over the electrode, the outer contained this atmosphere and exhausted it to the connecting gas chromatograph for analysis.

Periodic analysis of the spent gases, "on-stream," was accomplished with a gas chromatograph. Two columns consisting of silica gel and molecular sieve were connected in series across the detector elements. The purpose of the gas chromatographic determination was to identify the spent gases and to yield the relative ratios so as to compare with input flow measurements.

The furnace temperature was controlled to ±0.6°C over the 2-in. working zone by means of appropriate adjustment of variable resistors connected to each of the five separately wound furnace windings. Two sets of baffle systems, one above and the other supporting the crucible (Fig. 1), functioned to minimize temperature gradients by halting convective currents. The lower baffle system, mounted on a thermocouple rod, could slide freely in the alundum core. The thermocouple rod was seated on a variable platform jack; the melt, thus, could be raised or lowered to any desired position in the furnace. A Pt-Pt 10% Rh thermocouple, insulated with an alumina sheath, was fitted into a Au casing and rested on the bottom of the 80-20 Au-Pd alloy crucible.

Measurements.—The potential resulting from the cell

$$\text{Au} \mid \text{CO},\text{CO}_2 \mid \text{CO}_3^{=} \mid \text{CO}_2,\text{O}_2 \mid \text{Pt} \qquad [2]$$

was monitored over the partial pressure ranges of CO (0.05-0.95 atm) and CO_2 (0.05-0.95 atm). At a constant temperature, the cell potential for a high partial pressure CO_2 stream was recorded. Stepwise, the CO partial pressure was increased at the expense of the CO_2 partial pressure and the potential recorded until the influence of the entire range of partial pressures was investigated. The measurements were then continued to complete the cycle from the high CO to the high CO_2 partial pressure region. At each gas composition, the potential was recorded until the value was invariant with time, and the latter value was noted as the equilibrated value. The results are in Table IA.

In studying the cell

$$\text{Au} \mid \text{CO} \mid \text{CO}_3^{=} \mid \text{CO}_2,\text{O}_2 \mid \text{Pt} \qquad [3]$$

predried and metered flows of CO were passed through the test electrode compartment. The resultant potentials were monitored as a function of the CO flow rates, starting with flows of 230 cm³/min and decreasing to 10 cm³/min in 30 cm³/min decrements. At each flow rate the potential was observed until the equilibrated (time-invariant) value was gained. The measurements were continued with increasing flow rates and the same increments until the initial flow rate (230 cm³/min) was attained. The results of this series of measurements established that the cell potentials were independent of the CO flow rates in the region of higher CO flows. Accordingly the temperature dependence of the cell potential was investigated in the region of high CO flows, with a fixed flow rate of about 200 cm³/min. The equilibrated values thus established are in Table IB, and are shown in Fig. 5 with the limits of uncertainty for each potential given by the double headed arrows.

Results

The electrochemical cell

$$\text{Au} \mid \text{CO},\text{CO}_2 \mid \text{CO}_3^{=} \mid \text{CO}_2,\text{O}_2 \mid \text{Pt} \qquad [2]$$

was investigated over the temperature range 510°-800°C.

The reactions occurring on the Au electrode, predicted from thermodynamic calculations, are

$$\text{CO}_3^{=} + \text{CO} - 2e \rightleftarrows 2\text{CO}_2 \qquad [4]$$

and

$$\text{CO}_3^{=} + \text{C} - 2e \rightleftarrows \text{CO}_2 + \text{CO} \qquad [5]$$

The Nernst equation for reaction [4], assuming unit carbonate activity, reduces to

$$E = E^{\circ} + 2.303\frac{RT}{2F}\log\frac{P_{CO}}{P_{CO_2}^2} \qquad [6]$$

For reaction [5], the Nernst equation, at unit C and carbonate activity, reduces to

$$E = E^{\circ} - 2.303\frac{RT}{2F}\log P_{CO_2}P_{CO} \qquad [7]$$

The contributions of reactions [4] and [5] to the cell potential can be evaluated by constructing graphs of the cell potential *vs.* log $P_{CO}/P_{CO_2}^2$ and log $P_{CO_2}P_{CO}$. The experimental results were treated in this manner and are illustrated in Fig. 2 and 3. Figure 4 shows the oxidation potentials for reactions [4] and [5], calculated from thermodynamic data (13), as a function of temperature. The experimental and calculated Nernst slopes for reactions [4] and [5] are summarized in Table II.

The electrochemical oxidation of carbonate and C to CO was investigated with cell [3]

$$\text{Au} \mid \text{CO} \mid \text{CO}_3^{=} \mid \text{CO}_2,\text{O}_2 \mid \text{Pt}$$

over the temperature range 510°-830°C. The result of this investigation is illustrated in Fig. 5 where the cell potential is shown as a function of temperature along

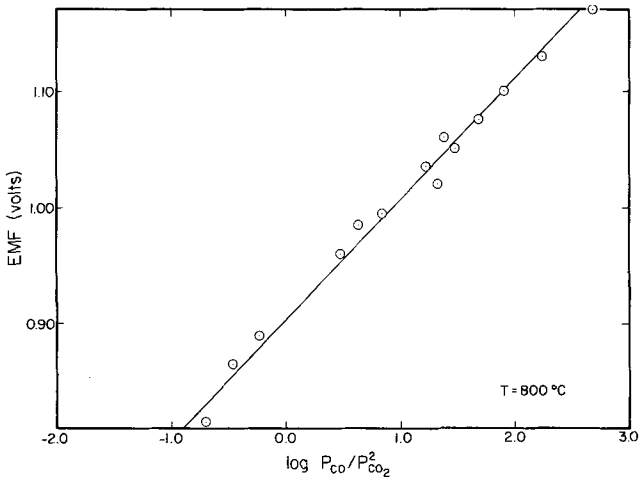

Fig. 2. Potential *vs.* log $\frac{P_{CO}}{P_{CO_2{}^2}}$ for the CO-CO_2 cell at 800°C in the ternary eutectic. The solid line is theoretical prediction for the Nernst equation: $E = E° + 2.303\ RT/2F \log (P_{CO}/P_{CO_2{}^2})$; the circles are the observed values.

with the thermodynamically calculated oxidation potential-temperature curve for the reaction

$$CO_3{}^= + 2C - 2e \rightleftarrows 3CO \qquad [8]$$

Discussion

In using a mixture of CO and CO_2 to supply the Au electrode in the cell

$$Au \mid CO,CO_2 \mid CO_3{}^= \mid CO_2,O_2 \mid Pt$$

due note must be taken of a possible change in the composition of the metered input mixture due to the Deville equilibrium

$$2CO \rightleftarrows C + CO_2 \qquad [9]$$

The maximum rate of CO decomposition to C and CO_2 is known to occur between 500° and 600°C (14, 15). Walker, Rakszawski, and Imperial (16, 17) studied this process [9] extensively, and observed that H_2 plays an important role as a catalytic agent. Neville and Taylor (18) found the forward reaction to be accelerated in the presence of alkali carbonates. This acceleration is undoubtedly due to a series of simultaneous processes possible in molten carbonates, such as: (*i*) CO_2 reacting with the oxide from the dissociated carbonate; (*ii*) CO_2 dissolving in the melt; (*iii*) CO reacting with H_2O vapor yielding CO_2 and H_2; (*iv*) CO reacting with hydroxide in the melt producing H_2 and carbonate; and (*v*) the H_2, thus produced, catalyzing the conversion of CO to CO_2. The contributions of (*iii*), (*iv*), and (*v*) would be the dominating factors after equilibrium has been achieved between the melt and CO_2. The preceding considerations, while somewhat speculative, leave little doubt that the composition of the spent gas stream from the Au electrode should be monitored in order to determine the contribution from reaction [9]. This was investigated accordingly. Gas chromatographic analyses of the spent gas streams for pure CO input streams established that a maximum of 1% CO_2 was formed via reaction [9] at CO flow rates of 10 cc/min. At the more rapid flow rates used for the cell potential studies (150 cc/min), the CO conversion rate was found to be less than 0.5%. The conversion of CO to C and CO_2 due to the Deville equilibrium [9] is thus a slow process under the experimental conditions of the present studies, and, unless otherwise indicated, one may justifiably assume that the compositions of mixtures of CO and CO_2 about the Au electrode were essentially the same as established via the input flowmeters.

Table II. Theoretical and observed Nernst slopes

T, °K	Theoretical Nernst slope	A* observed slope	B* observed slope
783	0.078	0.080	−0.086

973	0.097	0.102	−0.098
1073	0.106	0.104	—

* A: for $CO_3{}^= + CO - 2e \rightleftarrows 2CO_2$.
* B: for $CO_3{}^= + C - 2e \rightleftarrows CO_2 + CO$.

Inspection of Fig. 2 clearly illustrates that reaction [4] controls the cell potential over the entire range of gas compositions at 800°C. As seen in Fig. 3, at temperatures of 700°C and lower, the cell potential deviates from that expected for reaction [4] in the high and low CO partial pressure ranges. The deviation at high CO partial pressures may be due to reaction [5] becoming thermodynamically more favored than reaction [4]. This receives support from the thermodynamic considerations summarized in Fig. 4, where the theoretical oxidation potentials for reaction [4] and [5] are plotted as a function of temperature along with the calculated shift of the cell potentials obtained from the Nernst equations at various CO partial pressures. It is evident, from inspection of the results, that the observed cell potentials follow the thermodynamic predictions. The expected inversion of reaction [4] to reaction [5] at high CO partial pressures is within the experimental accuracy of the measurements at temperatures of 625°C and above. The low cell potential at 510°C and the consequent greater range of CO partial pressure where reaction [4] was observed can be understood as due to possible traces of moisture in the reference gas stream. The deviation of the cell potential from reaction [4] at low CO partial pressures may be due to a loss of CO from the gas stream. The following series of reactions are seen possible

$$2CO \rightleftarrows C + CO_2 \qquad [9]$$

$$CO + 2\ OH^- \rightleftarrows CO_3{}^= + H_2 \qquad [10]$$

$$CO + H_2O \rightleftarrows CO_2 + H_2 \qquad [11]$$

$$CO + H_2 \rightleftarrows C + H_2O \qquad [12]$$

$$CO + 3H_2 \rightleftarrows CH_4 + H_2O \qquad [13]$$

The equilibria for these reactions thermodynamically favor the formation of the products (displacement to the right) at temperatures less than 800°C. Exploratory studies in this laboratory have shown that reaction [10] is the major source of CO consumption. The Au electrode, thus, undoubtedly experienced a CO partial pressure lower than the metered inputs (used for the abscissae in Fig. 2 and 3, respectively). This receives additional support from the results of the gas chromatographic analyses of the spent gas streams. An increase of H_2 at the lower CO partial pressures and the lower temperatures was observed.

Borucka (1, 2) investigated reaction [4] on Au electrodes using a concentration cell of the type

$$Au \mid CO,CO_2 \mid CO_3{}^= \mid CO,CO_2 \mid Au \qquad [14]$$

At 780° and 800°C, the cell potentials were in agreement with Nernst predictions, and use of the Au| CO,CO_2 electrode as a practical reference electrode in the carbonate eutectic in this temperature range was recommended. It was suggested (1, 2) from thermodynamic considerations, that the Deville reaction [9] sets a limit on the application of the proposed reference electrode. The results of the present study show that additional considerations must be taken into account in evaluating the limits of applicability of this reference electrode. Thus it follows from the present study that: (*i*) reaction [9] is kinetically so slow that the potential created by a change in the composition of the dynamic inlet stream is negligible; (*ii*) the dominant CO consuming process appears to be reaction [10] and

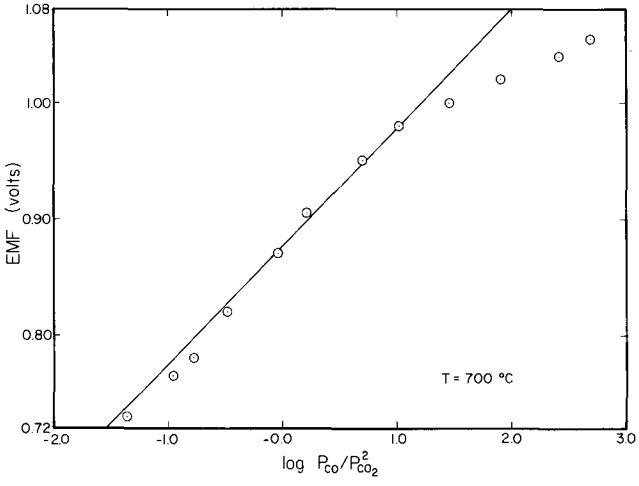

Fig. 3A

Fig. 3. Potential vs. log $\frac{P_{CO}}{P_{CO_2}^2}$ and log $P_{CO_2}P_{CO}$ for the CO,CO_2 cell in the ternary eutectic. The solid lines are the theoretical predictions for the two Nernst equations: $E = E^\circ + 2.303\ RT/2F$ log $(P_{CO}/P_{CO_2}^2)$ and $E = E^\circ - 2.303\ RT/2F$ log $(P_{CO_2}P_{CO})$, respectively, at 700°, 625°, and 510°C; the circles are the observed values.

not the Deville reaction (unless the melt is completely void of moisture, and this is very difficult to attain in practice); and (*iii*) reaction [5] becomes thermodynamically favored at lower temperatures and may overshadow any effect of a shift in the inlet stream composition due to the Deville equilibrium.

The emf from cell [3]

$$Au \mid CO \mid CO_3^= \mid CO_2,O_2 \mid Pt$$

indicated that reaction [5]

$$CO_3^= + 2C - 2e \rightleftarrows 3CO$$

proceeded at the Au electrode between 510° and 670°C. The correspondence between the thermodynamic values and the cell potentials, shown in Fig. 5, is support for this viewpoint. The deviation from the theoretical slope in the higher temperature range (700°-830°) has not been explained, but appears due to other electrochemical processes. Thus it readily follows from thermodynamic considerations the theoretical reduction

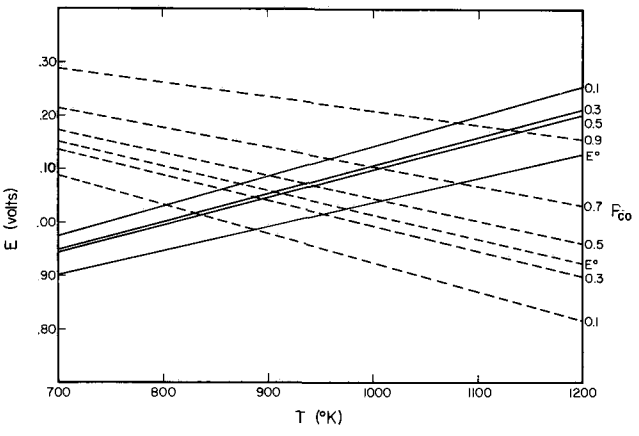

Fig. 4. Theoretical emf temperature dependence of the CO, CO_2|molten carbonate cell at various CO partial pressures. Variation of the thermodynamically predicted oxidation potentials with temperature for the two electrode reactions: $CO_3^= + CO - 2e \rightleftarrows 2CO_2$ and $CO_3^= + C - 2e \rightleftarrows CO_2 + CO$ (solid and dashed lines, respectively).

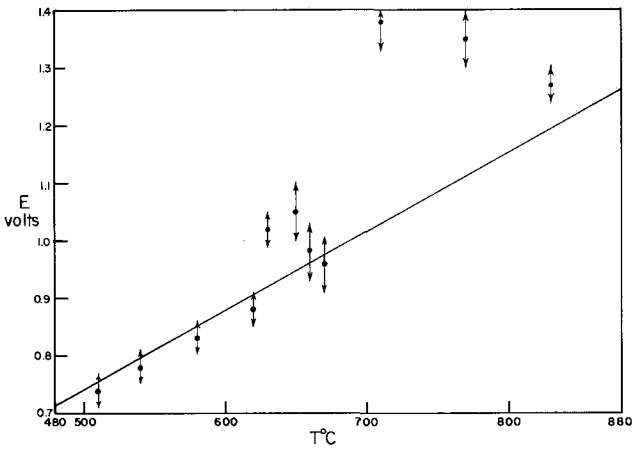

Fig. 5. Graph of the potential vs. temperature for the CO cell in the ternary eutectic. The solid line is the thermodynamically predicted value for the process: $CO_3^= + 2C - 2e \rightleftarrows 3CO$. The limits of uncertainty of the equilibrated potentials are indicated by the double-headed arrows.

potential of reaction [5] can be shown to intersect a number of electrochemical reactions (involving CO_2, CO, OH^-, and H_2) at 670°C. Under appropriate conditions these can become thermodynamically more favorable than reaction [5]. For example, one may use the Nernst equation to calculate the partial pressures of CO, CO_2, and H_2; from this approach it appears that a very plausible explanation for the higher potentials above 700°C is the reaction

$$CO_3^= + 2H_2 - 2e \rightleftarrows CO + 2H_2O \qquad [15]$$

for which the Nernst equation is

$$E = E^\circ + 2.303\frac{RT}{2F}\log\frac{[CO_3^=]\,P_{H_2}^2}{P_{CO}\,P^2_{H_2O}} \qquad [16]$$

The calculated P_{H_2}/P_{H_2O} ratios are 74.0 and 32.5 at 800° and 1100°K, respectively, so that this process, as well as

$$CO + 2\,OH^- \rightleftarrows CO_3^= + H_2 \qquad [10]$$

would contribute directly to deviations (higher values) than would be predicted from a consideration of reaction [5] as the only potential-controlling process in this electrochemical cell.

Acknowledgments

Concentration Changes in Operating Fuel Cells

J. T. Lundquist, Jr., and W. M. Vogel*

Advanced Materials Research and Development Laboratory, Pratt & Whitney Aircraft, Middletown, Connecticut

ABSTRACT

The high current densities at which fuel cells operate give rise to large concentration changes across the porous matrix employed in most of these cells. These changes were measured in cells especially constructed for these determinations using aqueous potassium hydroxide and phosphoric acid as electrolytes. Part of the resulting voltage losses of the fuel cells, due to pH changes and liquid junction potentials, were measured. A theoretical treatment is presented which accurately describes the experimental data.

The electrolyte in H_2/O_2 fuel cells is frequently a highly concentrated solution of a strong acid or base. In these solutions only one kind of ion participates in the electrode reaction, *i.e.*, either H^+ or OH^- ions. The cells often contain a porous matrix between the electrodes which greatly reduces convection in the electrolyte. A necessary consequence of these conditions is that, in the steady state, an ionic concentration gradient exists which counteracts by diffusion the electrical migration of the inert ions, while it enhances the transport of the reactive ions. This concentration gradient affects the cell operation through changes in the vapor pressure and in gas solubilities. A direct result of the electrolyte variation is the existence of an ionic concentration overvoltage η_d, a liquid junction potential ϵ_D, and a change in the ohmic polarization $\Delta\eta_{ohm}$. The latter two are sometimes combined as resistance polarization (1), but for the purpose of this study this definition is impractical since, although it is possible to measure the sum $\eta_d + \epsilon_D$ and also $\Delta\eta_{ohm}$, it is impossible, even in principle, to accurately determine η_d or ϵ_D separately.

The concentration overvoltage was first considered by Williams and Gregory (2) who measured the total electrode polarization but not the concentration changes. Because of the complex nature of the polarization of porous fuel cell electrodes, one cannot accurately separate the portions due to ionic changes from such data.

In a recent paper Beltzer (3) discussed ionic concentration overvoltages at fuel cell electrodes emphasizing buffer electrolytes. In contrast to our findings the author did not observe any effects of concentration changes in 30% H_2SO_4 or 3M KOH at current densities up to 200 mA/cm^2. Due to the lack of experimental details we cannot speculate as to the reasons for this discrepancy.

While the present paper was being prepared, a paper by Miller and Fornasar (4) appeared, in which actual concentration gradients were measured in KOH fuel cells. The results obtained by these authors were strongly influenced by the flow pattern of the gases in their cells and, therefore, do not lead easily to an understanding of the fundamental process involved.

In view of the incomplete and contradictory nature of these results it was felt that a theoretical and experimental treatment of concentration gradients in fuel cells would be of value. This paper presents the results of studies whereby ionic concentration changes were measured in special fuel cells and the resultant voltage losses were determined with hydrogen concentration cells with liquid junction.

Experimental

The electrochemical cell consisted of four cylindrical Plexiglas sections. The porous membrane and the two fuel cell electrodes were inserted between these sections as shown in Fig. 1. The whole assembly was held together with bolts (not shown) inserted into holes in the Plexiglas walls. Electrolyte leakage through the porous bodies was prevented by means of rubber gaskets and by applying a rubber cement along the outside perimeter of these porous parts. Anolyte and catholyte were stirred separately by means of external pumps.

It was necessary to overcome the large iR drop in the cell with an external power source, for which purpose a potentiostat (Anotrol, Model 4100) was used in galvanostatic circuit.

The electrodes were porous Teflon/platinum black fuel cell electrodes of Pratt & Whitney Aircraft manufacture. The matrix was made of porous hydrophilic Teflon sheet (American Cyanamid, Type TA-1). For the experiments with KOH 10 mil asbestos sheet was used (Johns-Manville, Fuel Cell Asbestos). Both electrodes as well as the membrane had the same effective diameter of 4.15 cm.

Anolyte and catholyte both had the same volume of 95 cm^3. The cell was positioned in a Plexiglas tank with the membrane in horizontal position (any other position leads to liquid circulation through the membrane due to density differences). The temperature in the cell was maintained at 60°C. Reagent grade chemicals were used without further purification.

The hydrogen in the anode was not vented. The oxygen, after being preheated and humidified, was passed through the space behind the cathode and vented to remove the reaction water. The degree of humidification and the flow rate were adjusted to maintain a constant total electrolyte volume in the cell. For this purpose preliminary experiments were done, so that during the main experiment only minor adjustments had to be made. At certain times equal and small electrolyte samples were withdrawn, weighed, and titrated potentiometrically. The experiment was continued in a few cases until no further concentration change was observed. In the majority of the cases

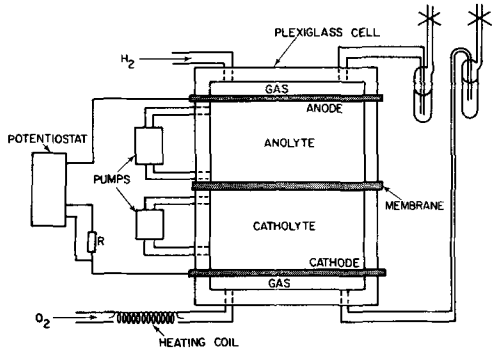

Fig. 1. Apparatus used to simulate a fuel cell under load. (Electrolyte KOH; with acid electrolyte positions of anode and cathode reversed so that more dense electrolyte is always on the bottom.)

* Electrochemical Society Active Member.

the experiment was terminated after the data allowed a sufficiently accurate extrapolation to steady state. This extrapolation was made by plotting log $(1 - \Delta C/\Delta C_\infty)$ *vs.* time according to Eq. [5], where ΔC_∞ was chosen to obtain a straight line. This procedure was checked with the data from those runs where steady state was obtained and found to be actually more accurate (because of the averaging) than the direct determination of ΔC_∞.

The efficiency of the stirring was studied by observing the boundary layer at the membrane when the electrolyte, colored with a dye, was slowly pushed through the matrix into the other half of the cell. This boundary layer was not exactly uniform but it was less than 0.03 cm over more than 90% of the membrane area.

The equilibrium voltage of concentration cells of type Eq. [8] was measured using platinized platinum wires as electrodes around which H_2 was bubbled. Freshly made solutions of electrolyte were used. The two solutions were separated from each other by a porous plug of glass wool or of asbestos. Voltages were measured with a vacuum tube voltmeter with a precision of approximately 1%.

Theoretical

A rigorous theoretical treatment of the experiments would be a matter of considerable complexity. However, by introducing a number of reasonable assumptions an approximate theory can be derived which describes the experiments rather well. The equations are derived for phosphoric acid as electrolyte. Analogous equations for bases are given without derivation.

Let V be the volume of liquid in either of the two chambers of the cell and let C_A and C_C denote the concentrations of anolyte and catholyte, respectively. Before reaching the stationary values these concentrations are continually changed by the migration and back diffusion of electrolyte through the matrix. In the actual experiments liquid flow through the matrix was prevented and the electrolyte in both chambers was stirred, thus confining the concentration gradient to the matrix and the associated liquid boundary layers.

We assume that, because the rate of change in C_A and C_C is very small (see Fig. 2) and because the porous matrix is thin, the concentration distribution in the matrix is at any time very similar to the stationary distribution which would prevail if the momentary values for C_A and C_C were kept constant. We assume further a constant concentration gradient through the matrix and neglect the effect of the liquid boundary layers at the matrix. Under certain conditions this last assumption can introduce serious inaccuracies. The experimental evidence shows, however, that this was not the case (see, *e.g.*, Fig. 6). Assuming finally that the transference numbers n and the diffusion coefficient D of the electrolyte do not depend on the concentration, we have as transport equations for a matrix of area q and thickness l

$$VdC_A/dt = in_-/\mathbf{F} - Dq\Delta C/l \quad [1]$$

$$VdC_C/dt = -in_-/\mathbf{F} + Dq\Delta C/l, \ \Delta C = C_A - C_C \quad [2]$$

The indices A and C refer to anolyte and catholyte, respectively, i is the current through the matrix, and n_- is the effective anion transference number. From the sum of Eq. [1] and [2] we obtain

$$d(C_A + C_C)/dt = 0 \text{ or } C_A + C_C = 2C_O \quad [3]$$

The concentrations are divided symmetrically around the initial concentration C_O. The difference of [1] and [2] yields

$$Vd\Delta C/dt = 2in_-/\mathbf{F} - 2Dq\Delta C/l \quad [4]$$

the solution of which is

$$\Delta C = [1 - \exp(-2Dqt/Vl)]\, in_-l/\mathbf{F}Dq \quad [5]$$

The initial slope is given by

$$(d\Delta C/dt)_{t=0} = 2in_-/V\mathbf{F} \quad [6]$$

and depends on the current but is independent of the particular matrix used. The steady state concentration difference is given by

$$\Delta C_\infty = in_-l/Dq\mathbf{F} \quad [7]$$

and depends on the geometry of the matrix as well as on the current but is independent of the amount of electrolyte V surrounding the electrodes.

The polarization $\eta_C = \eta_d + \epsilon_D + \Delta\eta_{ohm}$ due to concentration changes would be very difficult to measure directly on a fuel cell under load, because of the complicated interaction between it and other kinds of polarizations. A partial measurement of $\eta_d + \epsilon_D$ at $i = 0$ also would be unsatisfactory because of the difficulties encountered in making reversible O_2-electrodes. We, therefore, determined the sum $\eta_d + \epsilon_D$ indirectly from the emf ΔE_t of the cell with junction

$$(Pt)H_2/C_A/C_C/H_2(Pt) \quad [8]$$

which is given by

$$(\Delta E_t)_{H_2/H_2} = n_-RT/\mathbf{F} \ln a_A/a_C \quad [9]$$

where a is the activity of phosphoric acid in anolyte and catholyte, respectively. Writing $(\Delta E_O)_{O_2/H_2}$ for the thermodynamic voltage of the fuel cell at $C_A = C_C = C_O$ and $(\Delta E_t)_{O_2/H_2}$ for $C_A \neq C_C$ we have, for the difference

$$\eta_d + \epsilon_D = (\Delta E_O)_{O_2/H_2} - (\Delta E_t)_{O_2/H_2} =$$
$$RT/2\mathbf{F} \ln (H_2O)_C/(H_2O)_O + n_-RT/\mathbf{F} \ln a_A/a_C \quad [10]$$

Here (H_2O) is the water activity in the catholyte and in the original electrolyte. By combining Eq. [9] with [10] we obtain

$$\eta_d + \epsilon_D = (\Delta E_t)_{H_2/H_2} + RT/2\mathbf{F} \ln (H_2O)_C/(H_2O)_O \quad [11]$$

From data for the emf of cell [8], which can be easily and accurately measured, and vapor pressure data we can determine the direct voltage loss due to ionic concentration changes across the matrix. The total loss of the cell is greater because of the neglected $\Delta\eta_{ohm}$, because of similar effects within the porous electrode structures and because of other effects neglected here.[1]

For KOH as electrolyte an analogous derivation yields

$$\Delta C = [1 - \exp(-2Dqt/Vl)]\, in_+l/Dq\mathbf{F} \quad [5a]$$

$$(d\Delta C/dt)_{t=0} = 2in_+/V\mathbf{F} \quad [6a]$$

$$(\Delta C)_\infty = in_+l/Dq\mathbf{F} \quad [7a]$$

$$\eta_d + \epsilon_D = RT/\mathbf{F} \ln (H_2O)_C^{1/2} (H_2O)_O^{1/2}/(H_2O)_A$$
$$+ 2n_+ RT/\mathbf{F} \ln (a_\pm)_A/(a_\pm)_C \quad [10a]$$

$$\eta_d + \epsilon_D = (\Delta E_t)_{H_2/H_2} + RT/2\mathbf{F} \ln (H_2O)_O/(H_2O)_C \quad [11a]$$

Calculating the voltage losses from pH differences alone (*i.e.*, only η_d), as was done by others [Ref. (2) and (3)], leads to partial results because ϵ_D is being neglected. The data presented below indicate that ϵ_D is rather large but has the opposite sign of η_d.

Results and Discussion

The experimental results are reproduced in Tables I, II, and IIIa (column 3). In Fig. 2 the concentrations of anolyte and catholyte are plotted against time for three typical experiments. We see that, in agreement with Eq. [6], the initial slope is independent of the geometry of the matrix although the steady state values C_∞ are quite different (curves 1 and 2). This initial slope also is approximately proportional to the

[1] *E.g.*, changes in gas concentration overvoltages due to changes in the water vapor pressure.

current i as required by Eq. [6]. The anolyte and catholyte concentrations in Tables I and II approximately average to the initial concentration, as per Eq. [3]. The small remaining difference reflects the accuracy with which we were able to match the water removal rate to the rate of production. (This is rather difficult especially during unattended night runs.)

In Fig. 3 we have plotted log $(1 - \Delta C/\Delta C_\infty)$ against time for three experiments. According to Eq. [5] we have

$$\log (1 - \Delta C/\Delta C_\infty) = -2Dqt/2.3Vl \qquad [12]$$

We see that the slopes in Fig. 3 indeed do not depend on i. The steady state concentrations C_∞ are plotted against the current density I through the matrix (Fig. 4). ΔC_∞ is proportional to I as required by Eq. [7].

One could calculate the transference number $n_\pm$ from the initial slopes of the curves in Fig. 2 using Eq. [6]. A more accurate way of obtaining $n_\pm$ is indicated by combining Eq. [7] and [12]. We thus obtain for the anion in H_3PO_4

$$n_- = -(2.303VF\Delta C_\infty/2i)\, d \log (1 - \Delta C/\Delta C_\infty)/dt \qquad [13]$$

From the slopes of the lines in Fig. 3 and 4 we calculated the values for $n_\pm$ at 60°C given in Table IV. A direct comparison with the published data listed in Table IV is not possible mainly because of the difference in temperature. We feel, however, that, in spite of these differences, these figures afford a check into the validity of our results.

We calculated the voltage loss $\eta_d + \epsilon_D$ from our data using Eq. [11] and [11a]. The values of the water activities were calculated using the well known ther-

modynamic relationship, from vapor pressure data from ref. (7) and (8). The results are given in Table IIIa and IIIb and also in Fig. 5. In Table IIIa results are included which were obtained from activity data for 25°C from ref. (9) using Eq. [10a]. The temperature dependency of the activity ratio in Eq. [10a] is small. For this reason we calculated the losses $\eta_d + \epsilon_D$ for KOH which are plotted in Fig. 5 from the same data (9).

The magnitude of the liquid junction potential ϵ_D could be determined if it were possible to measure thermodynamic pH values of the respective solutions. Although this is not possible, we can estimate some values from the difference between the sums $\eta_d + \epsilon_D$ in Table IIIb and the values for η_d which were calculated from published data according to Eq. [14] for H_3PO_4

Table V. Values calculated from Eq. [14]

C_A/C_C (mole/l)	$\frac{RT}{2F} \ln \frac{(H_2O)_O}{(H_2O)_C}$, mV	$\Delta pH_{25°C}$	$(\eta_d)_{25°C}$ (Eq. [14]), mV	$(\eta_d + \epsilon_D)_{60°C}$ (Table IIIb), mV
7.38/5.70	−1.0	−0.3	−20.8	−5.8
8.44/4.79	−1.6	−0.67	−45.8	−11.8
9.13/4.22	−2.2	−0.92	−62.9	−16.3

$$\eta_d = RT/2F \ln (H_2O)_O/(H_2O)_C + [(pH)_A - (pH)_C]\, 2.3\, RT/F \quad [14]$$

Values calculated in this fashion using data of ref. (8) and pH data of ref. (10), together with those of Table IIIb, are given in Table V.

The increase of ΔC_∞ with the matrix thickness is shown in Fig. 6. The extrapolated line goes almost through the origin, demonstrating that the influence of the liquid boundary layers at the matrix is small. These boundary layers are the essential difference between our cell and actual compact fuel cell. Our results thus can be directly applied to fuel cells.

The Decomposition of AgO in Alkaline Solutions

Aladar Tvarusko[*1]

Research Center, ESB, Inc., Yardley, Pennsylvania

ABSTRACT

The gassing rate, r, of powder AgO samples, made by the chemical oxidation of $AgNO_3$, was measured in gassing pipettes. The mean r of 52 AgO samples at 200 hr (AgO content $\geq 95\%$, $r_{200} \leq 35$ μl/day/g) was 23.0 μl/day/g. Gassing rates at different times and in different solutions, respectively, are correlated. r increased with increasing NaOH concentration, temperature, and pelletizing pressure, and with ball milling. r of AgO samples made in the presence of transition elements (added as compounds) were, in general, larger than r of samples with nontransition elements. The effect of Co and Ni is especially catastrophic. Pb suppressed r of highly gassing AgO samples regardless of the method of addition.

Silver(I)-silver(III) oxide, commonly designated as AgO, is thermodynamically unstable in alkaline electrolytes (KOH, NaOH) but has a reasonable degree of metastability (1). Oxygen evolution is the end result of the decomposition reaction

$$2AgO \rightarrow Ag_2O + \tfrac{1}{2} O_2 \qquad [1]$$

Denison (2), however, claimed that AgO is stable in 20-40% KOH solutions.

Oxygen overvoltage of the local cell action and formation of a protective Ag_2O film on the AgO is thought to be the reason for its metastability (1, 3). The decomposition of AgO (*a*) is light sensitive (4, 1), (*b*) increases with increasing temperature (1, 3, 5-8), and (c) increases with increasing KOH concentration (1, 7, 8). The decomposition of "Ag_2O_3" (a reaction product of $AgNO_3$ and $K_2S_2O_8$) in KOH ($< 1N$) was found by Stehlik (6) to be a first order reaction with an activation energy of 22 kcal/mole.

The stability of AgO seems to depend on its mode of preparation (9) and the various AgO samples were found to decompose at different rates (1, 5, 7). Unoxidized silver metal increased the rate of decomposition of AgO (3, 7) whereas Ag_2O did not affect the stability of AgO (3). Boer and Ormondt (10) found that the incorporation of Mn, Cu, and Co into AgO during its preparation decreased its stability, whereas Cd increased the stability of $(Ag_3O_4)_a \cdot AgSO_4$ (where a varies from 2 to 2.5). The presence of carbon in AgO battery plates is claimed to have no adverse effects (11), whereas CO_2 decomposes AgO (10).

The addition of Al_2O_3 to alkaline electrolytes is said (12) to inhibit the oxygen evolution. The addition of ZnO to KOH electrolytes decreases the decomposition rate of AgO to Ag_2O (1, 5) and prevents the reduction of Ag_2O to Ag (5). According to Amlie and Rüetschi (1), the addition of zincate ions has little influence because the addition of ZnO to KOH electrolyte reduces its OH^- activity and this causes the decrease of the decomposition rate. Cahan (13) showed that the addition of PbO to 40% KOH (and other electrolytes) markedly reduced the gassing rate of AgO; 1% PbO was found to be the optimum.

Yoshizawa and Takehara (14) have shown that the formation of AgO was retarded by Te and Sb which lowered the oxygen overvoltage or made the decomposition of AgO easier.

The effect of intentionally added inorganic additives on the electric resistivity of AgO was described in a previous paper (15). It was found that the AgO content of samples was very low in the presence of small amounts of Co and Ni indicating either an inhibited formation or an accelerated decomposition of AgO during its preparation in alkaline medium. Since AgO is mainly used in sealed cells, it is very important to know its gassing rate in the absence or presence of beneficial or detrimental additives.

The gassing, *i.e.*, decomposition rate of AgO samples (prepared by chemical oxidation of $AgNO_3$) was determined in alkaline electrolytes as a function of time, NaOH concentration, temperature, porosity, surface area, pelletizing pressure, and intentionally added inorganic additives.

Experimental

The AgO samples were prepared by the chemical oxidation of $AgNO_3$ with alkaline $K_2S_2O_8$ (16). The inorganic additives were incorporated into AgO during its preparation (15), initially at one concentration level: 1000 parts (element) per million parts of Ag, *i.e.*, 1000 ppm (Ag). Subsequently, some of the beneficial and detrimental impurities were studied as a function of concentration.

The amount of oxygen evolved in contact with alkaline solutions was determined in a modified Amlie-Rüetschi microvolumetric apparatus (1), "gassing pipette." The ground glass joint of their apparatus was replaced by an 18/7 O-ring joint (Pyrex, Buna N rubber ring) to eliminate "freezing" of the joint. Furthermore, filling of the gassing pipette (0.2, 0.5, or 1.0 ml capacity) with the electrolyte and joining of the two parts is easier with an O-ring than with a ground glass joint. Loose AgO powder (0.5000 $\pm$ 0.0002g) was used for the determinations unless otherwise mentioned.

The assembled gassing pipettes were placed in a constant temperature oil bath and allowed to equilibrate for 1 hr. The position of the meniscus of the electrolyte column after this time is considered as the zero hour reading; at least two parallel measurements were made on each sample at 37.78 $\pm$ 0.02°C (100°F) unless otherwise mentioned. The measurements were made in the presence of light.

The gassing rate is calculated at various time intervals from the volume of the evolved gas. This gassing rate is a cumulative average gassing rate and is not corrected for water vapor pressure.

The decomposition of AgO was measured in two alkaline electrolytes, unless otherwise mentioned. One of them contained 8.6N NaOH and 2.2N Na_2ZnO_2, whereas the other had 9.7N KOH and 2.8N K_2ZnO_2.

The data were subjected to statistical analysis. The "mean" parameter refers to the average of the samples the distribution of which tends to normality. The least square method was used for regression and curve fittings. If the coefficient of correlation, R of linear regression was low, the data were subjected to polynomial regression analysis.

Results and Discussion

Gas evolution as a function of time.—Figure 1 shows the gas evolution and the gassing rate of an AgO sample (98.1% AgO content) as a function of time in

* Electrochemical Society Active Member.
[1] Present address: Engineering Research Center, Western Electric Company, Inc., Princeton, New Jersey.

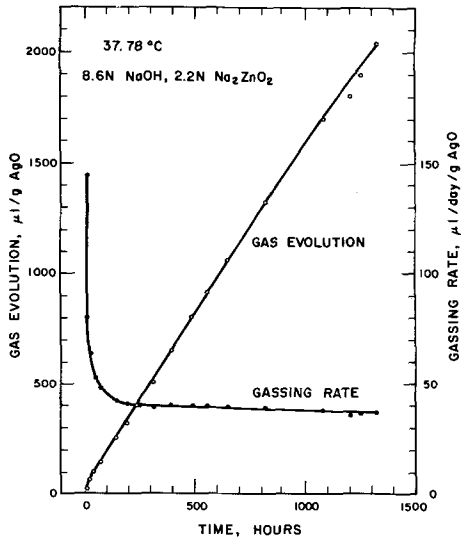

Fig. 1. Gas evolution and gassing rate of AgO as a function of time

8.6*N* NaOH and 2.2*N* Na_2ZnO_2 electrolyte. It can be seen that gas evolved almost linearly with time. The initial nonlinearity shows up clearly in the rapid decrease of the gassing rate. After approximately 200 hr the decrease of the gassing rate is small. On the basis of these results and other considerations, the minimum duration of the gassing test was chosen to be about 200 hr and this is the gassing rate, r_{200}, given, unless otherwise mentioned.

This test is time consuming (200 hr) and the long delay in obtaining the gassing rate is not well suited for routine testing. It was observed that the gassing rate-time curves were more or less parallel to each other. Figure 2 shows an approximately linear relation ($R = 0.896$) between the gassing rates of 114 AgO samples at 20 and 200 hr (samples with $r_{20} > 150$ μl/day/g are not shown in Fig. 2 but were taken into the consideration in the regression analysis). The analysis of variance for a quadratic regression reveals that the linear term is dominating (degree of freedom, $df = 1$, mean square, $MS = 13{,}791$), the increase due to the quadratic term is negligible ($df = 1$, $MS = 24.58$), and the deviation about regression is small ($df = 111$, $MS = 30.18$). Because of low R, the gassing rate at 20 hr (approximately overnight) and the linear regression equation in Fig. 2 can be used only for semiquantitative prediction of the gassing rates of AgO samples. This test, however, may be useful in the production of AgO and in testing a new batch of chemicals for sealed-cell electrolytes.

The mean gassing rates, $\bar{r}_{200}$, of AgO samples (AgO content ≥ 95.0%) were calculated for arbitrarily chosen

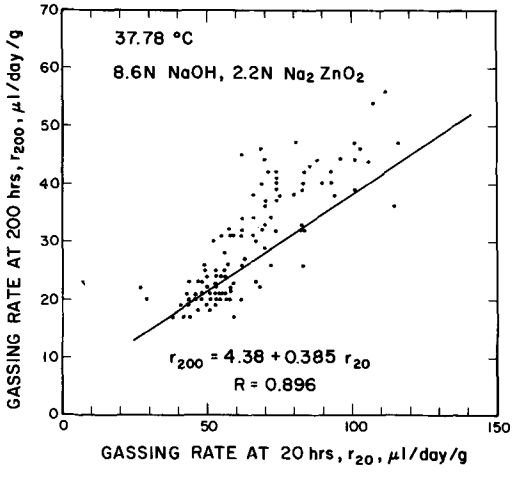

Fig. 2. Gassing rates of AgO samples at 20 and 200 hr.

Table I. The mean gassing rate of AgO samples in 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 solution

r_{200}, μl/day/g	Number of samples	Mean $\bar{r}_{200}$, μl/day/g	Mean AgO content, %	Standard deviation r_{200}, μl/day/g	Standard deviation AgO content, %
≤35.0	52	23.0	98.1	4.62	0.82
≤25.0	37	20.6	98.2	2.32	0.75
≤20.0	15	18.3	98.1	1.23	0.64
≤18.0	5	16.8	97.8	0.82	1.00

levels and are shown in Table I. The majority of the considered AgO samples had $r_{200} \leq 25.0$ μl/day/g which clearly shows up in mean gassing rates. The standard deviation of $\bar{r}_{200}$ becomes smaller mainly due to the narrower gassing rate levels. These results support the observation of several workers (1, 5, 7, 9) that various AgO samples decompose at different rates.

It can be seen in Table I that the mean AgO content of the AgO samples did not change appreciably with the gassing rate. No correlation was found between the gassing rate and AgO content down to 60%.

According to Eq. [1], ½ mole oxygen gas is obtained from 2 moles of AgO at its complete conversion to Ag_2O. Thus, 50,483 μl O_2, a, would evolve per gram AgO (98.1% AgO content) at 37.78°C and 760 mm Hg. If the decomposition is a first order reaction

$$\log \frac{a}{a-x} = \frac{k}{2.303} t \qquad [2]$$

should be linear. In this equation x is the volume of the evolved gas/g AgO at time t and k is the rate constant. Figure 3 shows this to be the case with $R = 0.9988$. The rate constant is calculated from the slope to be 3.09 x 10^{-5}/hr, *i.e.*, 0.271/year in 8.6*N* NaOH and 2.2*N* Na_2ZnO_2 solution at 37.78°C. It should be mentioned that others consider the decomposition to be zero (7, 8), pseudo zero (7), or first order (6) reaction.

Influence of concentration and temperature.—Figure 4 shows the gassing rate of AgO at 42 hr (98.4% AgO content) to increase with increasing NaOH concentration at all temperatures (these solutions do not contain ZnO). This is in agreement with the results in KOH (1, 7, 8). In view of the large gassing rates at 60°C, r_{42} was chosen instead of r_{200} even though some uncertainty may exist (see Fig. 1), mainly at lower temperatures. Linear regression analysis of the data in Fig. 4 ($R \geq 0.983$) yielded physically incorrect nega-

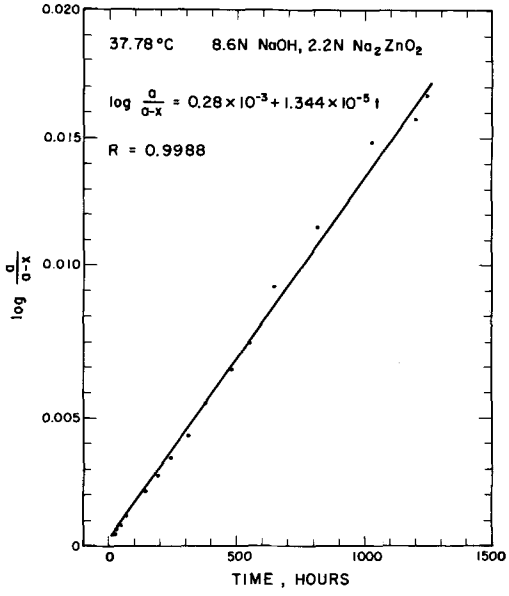

Fig. 3. First-order reaction plot of the decomposition of AgO in alkaline solution.

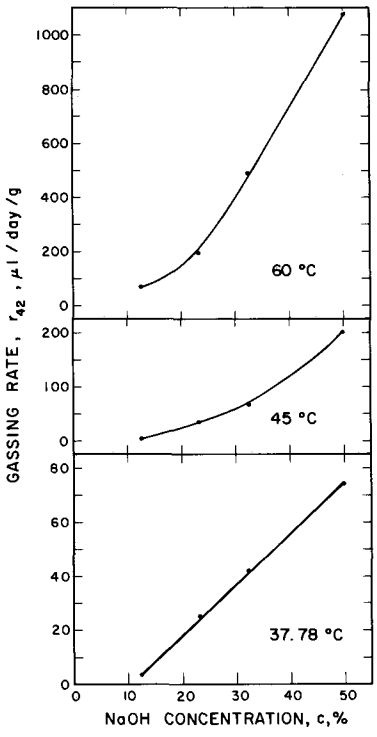

Fig. 4. Gassing rates of AgO as a function of NaOH concentration at various temperatures.

tive intercepts, *i.e.*, no gassing would take place below a certain NaOH concentration. This would be contrary to the results obtained by others in KOH (6-8). Polynomial regression analysis revealed that the curves in the investigated concentration range are predominantly linear and the increase due to the quadratic and cubic terms is slight. The slope of the log r_{42} — log c curve was found to be 2.2, 2.7, and 2.0 at 37.78°, 45°, and 60°C, respectively ($R \geqq 0.973$).

Figure 4 reveals also the known temperature dependence of the gassing rate in alkaline solutions (1, 3, 5-8); the gassing rate increased with increasing temperature. The rate constants, k in various NaOH solutions were calculated by the half-life method from r_{42} and r_x, the gassing rate at the longest available time ($x \geqq 42$ hr). The activation energies, E were calculated from the slopes of log k *vs.* $1/T$ curves. The activation energy of the complex decomposition reaction of AgO (1, 3, 5, 7, 8, 17) was calculated from all data to be 26 kcal/mole. E calculated from r_{42} was found to be 24 kcal/mole whereas E from r_x is 28 kcal/mole. These results are close to the following values obtained by other workers: (*a*) 28.4 kcal/mole in 10-50% KOH solutions (8), it was calculated from gassing rates at approximately 35 hr; (*b*) 22 kcal/mole for "Ag_2O_3" in solutions up to 1*N* KOH (6); and (c) 30 kcal/mole for the decomposition of AgO in air (18).

Calculating E from Otto's gassing rates in 11.6*M* (44%) KOH solution [(7), Table I] through the half-life method, one obtains 18.9 kcal/mole. This is considerably lower than the aforementioned E values for AgO. If the gassing rate at 100°C, *i.e.*, r at approximately 20 hr is neglected, 17.2 kcal/mole is obtained from gassing rates at approximately 200 hr and more. The difference in activation energies of the two groups is probably due to the decrease of gassing rate with time, mainly in the beginning of the test.

Figure 5 shows log k *vs.* $1/T$ in two zincate-containing electrolytes. The E values calculated from their slopes are: 21.0 and 23.6 kcal/mole in 9.7*N* KOH, 2.8*N* K_2ZnO_2 and 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 solutions, respectively. The k values were obtained from gassing rates at 100 hr and more. These lower E values seem to support the aforementioned explanation for the difference of E.

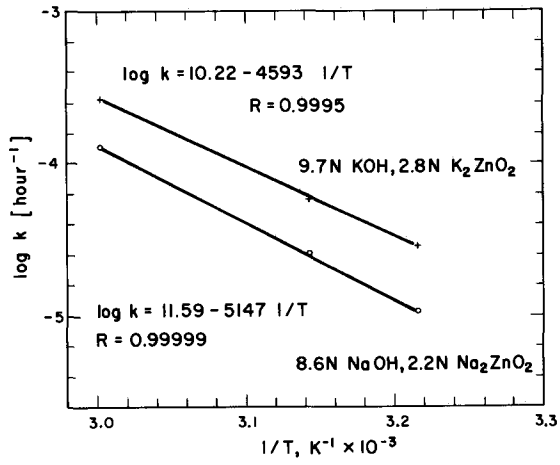

Fig. 5. Rate constants as a function of temperature

Correlation of r in various solutions.—The composition of the electrolyte in AgO cells is varied and the gassing rates are usually determined in each of them. This is, however, time consuming. Figure 6 shows the correlation of the gassing rates (r_{200}) in two frequently used battery electrolytes. It can be seen that the gassing rate in 9.7*N* KOH, 2.8*N* K_2ZnO_2 solution is approximately three times larger than in 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 solution. Even though the data are scattered ($R = 0.887$), the linear relation allows a semi-quantitative prediction of the gassing rate in one of the solutions if r is known in the other one.

Amlie and Rüetschi (1) found that the decomposition rate is larger in 10*N* KOH (40%) solution than even in 13.8*N* (40%) NaOH. This could be explained by the different activities of KOH and NaOH. The activity, a is given by $a = \gamma m$ where γ is the mean molal activity coefficient and m is the molality of the solutions. Since $m_{KOH} = 8.96$, $m_{NaOH} = 12.71$, $\gamma_{KOH} = 4.82$, and $\gamma_{NaOH} = 6.12$ [obtained by linear interpolation of the published values (19)], activities are: $a_{KOH} = 43.2$, $a_{NaOH} = 77.8$. It can be seen that the activities are opposite to the gassing rate values and thus, the activities of KOH and NaOH cannot account for the difference in gassing rates. Unfortunately, the individual ionic activities are not available for correlation.

Effect of pressure.—The gassing rate of loose AgO powder samples is measured in this work. AgO, however, is usually compressed in actual cells and therefore it was of interest to investigate the gassing rate of AgO as a function of pelletizing pressure. Figure 7 shows the increase of the gassing rate with increasing pelletizing pressure in both cases. It is evident that

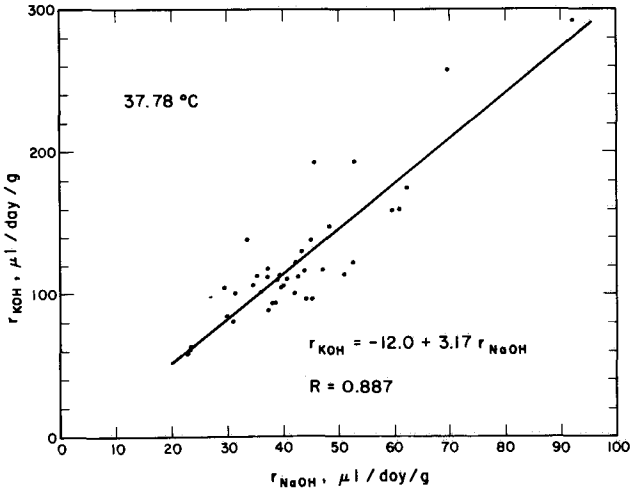

Fig. 6. Gassing rates of AgO samples in 9.7*N* KOH, 2.8*N* K_2ZnO_2 (r_{KOH}) and 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 (r_{NaOH}) solutions.

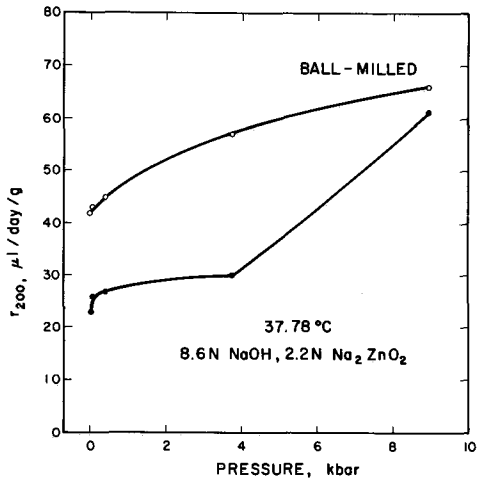

Fig. 7. Gassing rate of AgO as a function of pelletizing pressure

ball-milling of the AgO sample is detrimental. The gassing rate of pellets made from ball-milled AgO was markedly higher than that of unmilled AgO sample at pressures up to approximately 4 kbar; at the highest pressure the difference became small. In view of these results and the pressure dependence of resistivity (15), the pressure of the pelletizing of AgO should be kept to an optimized minimum.

Influence of surface area.—The BET surface area of AgO samples did not correlate with gassing rate of AgO samples contrary to the observation of Amlie and Rüetschi (1) who found a slight correlation. The mean surface area of 13 AgO samples is 1.12 m^2/g (standard deviation, $s = 0.39$) and the $\bar{r}_{200}$ is 22.8 µl/day/g ($s = 3.2$). The surface area increased with decreasing AgO content of the samples (0.86 to 1.79 m^2/g between 98.8 and 71.8%, respectively) and with increasing rate of $AgNO_3$ addition during the preparation of AgO (0.63 to 0.99 m^2/g between 4.25 and 34g $AgNO_3$/min). The surface area increased by *ca.* 50% in the presence of 1000 ppm (Ag) Pb (1.62 m^2/g) but Sn and Hg did not influence it.

The pore volume of AgO samples (determined by mercury intrusion in an Aminco-Winslow porosimeter) showed no correlation with the gassing rate. The mean pore volume of 43 AgO samples ($\bar{r}_{200} \leq 35.0$ µl/day/g) was found to be 0.57 ml/g ($s = 0.05$) at a mean gassing rate of 23.7 µl/day/g ($s = 4.5$). The pore volume (0.525 ml/g) of Otto's AgO sample (7) is close to the mean pore volume. The gassing rates of this section were measured in the 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 solution.

Effect of inorganic additives.—The influence of various inorganic additives on the resistivity of AgO samples was described separately (15). Here, their effect on the gassing rate of AgO samples is described. Tables II and III show the results for the investigated elements (added as compounds) at a concentration of 1000 parts by weight per million parts of silver used for the preparation of AgO, *i.e.*, 1000 ppm (Ag). The AgO content should not decrease due to this small amount of additive unless it is detrimental. The AgO contents of samples made in the presence of nontransition elements varied slightly but all were > 96.0%. Samples with transition elements had, in general, lower AgO contents and Co and Ni caused the largest drop.

AgO samples made in the presence of nontransition elements had, in general, low gassing rates (Table II). Sb leads the list with a gassing rate of 46 µl/day/g and only samples with Mg, Ba, and Sn show gassing rates above 30 µl/day/g. On the other hand, AgO samples with Pb, Al, Cd, and Zn have gassing rates ≤ 20 µl/day/g.

The incorporation of Cd was found (10) to increase the stability of $(Ag_3O_4)_a \cdot AgSO_4$ (where *a* varies from 2 to 2.5) and the addition of Al_2O_3 (12) and PbO (13)

to alkaline electrolyte, to inhibit and markedly reduce, respectively, the oxygen evolution from AgO. The corresponding low gassing rates of Table II support these findings. The decrease of gassing rate of AgO in the presence of large amounts of ZnO (1, 5) is said (1) to be due to the decrease of OH^- activity of the alkaline solution and the zincate ions have little influence (1). The 20 µl/day/g gassing rate in the presence of 1000 ppm (Ag) Zn is only slightly below the mean gassing rate and the addition of Zn seems to have little influence. Yoshizawa and Takehara (14) found that the AgO formation is retarded on a silver alloy anode containing 2% Te or Sb because the oxygen overvoltage is decreased or the decomposition of AgO is easier in their presence. Table II shows that the sample with Sb has the highest gassing rate. According to Amlie and Rüetschi (1), the decomposition rate of AgO must depend on the oxygen overvoltage. Yoshizawa and Takehara (14) measured the anode potential of silver and its alloys (2% alloying element) during oxygen evolution and found the oxygen overvoltage to decrease by *ca.* 100 mV according to following series (20): pure Ag > Cd > Au > Pb > In > Cu > Te > Sb. The corresponding gassing rates are: 16.8,[2]

[2] The lowest $\bar{r}_{200}$ used (Table I).

16, —, 17, 27, 65, —, 46 μl/day/g in 8.6*N* NaOH, 2.2N Na_2ZnO_2 at 37.78°C. It can be seen that the gassing rate increases with decreasing oxygen overvoltage of silver alloys mainly in the second half of the aforementioned series.

Table III shows the gassing rates of AgO samples made in the presence of transition elements (15) to be, in general, larger than the gassing rates of samples with nontransition elements. The presence of 1000 ppm (Ag) Co, Ni, and Zr is catastrophic from the viewpoint of gassing rates. Samples with Ce, Pd, and W have intolerably large gassing rates. On the other hand, AgO samples made in the presence of the common V, Cr, and Mo have low gassing rates because they were oxidized and washed out from the precipitate as meta-vanadate, chromate, and molybdate, respectively. When Mn was incorporated, part of it was oxidized to permanganate (red-wine colored mother liquor) and part of it precipitated with AgO. This supports the similar observation of Boer and Ormondt (10). The large gassing rates support their observation (10) that the incorporation of Mn, Cu, and especially Co into AgO during its preparation decreased its stability, *i.e.*, increased the amount of oxygen evolved at 20°C and 77% relative humidity.

Gassing rate as a function of additive concentration.—In view of the aforedescribed, mainly detrimental, effects of the additives, it was of interest to determine the effect of additive concentration. Their influence on the resistivity of AgO and other pertinent information were described elsewhere (15). It should be emphasized that reagent-grade chemicals and additives were used for the preparation of AgO samples without recrystallization or other purifying treatments.

Figure 8 shows the gassing rate of AgO samples as a function of additive concentration. This concentration represents the metal content of the additive used in the preparation of AgO and does not necessarily correspond to its content in the sample (15). It can be seen that the gassing rate of AgO samples increased with increasing additive concentration. The gassing rate in the presence of Cd (not shown) increased only slightly to 34 μl/day/g at 10^5 ppm (Ag) Cd.

The resistivity of AgO samples decreased in the presence of Pb, Sn, Hg, and Bi (15). The gassing rate increased slowly with increasing Sn concentration and it went through a small minimum in the presence of Pb. The latter supports Cahan's similar observation (13). In the presence of small amounts of Hg, the gassing rate was small but started to rise rapidly above 10^4 ppm (Ag) Hg. The gassing rate of AgO samples with Bi was high already at moderate Bi concentrations. Sb and As yielded samples of high gassing rates without beneficially affecting their resistivity.

Ni and Co, which are common trace impurities in most chemicals, drastically increased the gassing rate

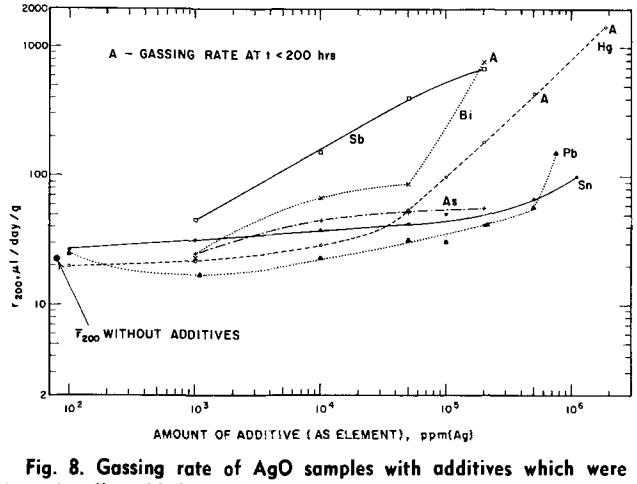

Fig. 8. Gassing rate of AgO samples with additives which were intentionally added in various amounts during their preparation.

Table IV. Gassing rate and AgO content of AgO samples made in the presence of Ni, r_5 in 8.6*N* NaOH, 2.2*N* Na_2ZnO_2 solution

Ni, ppm (Ag)	AgO content, %	r_5, μl/day/g
1000	38.0	8900
100	83.1	8300
10	96.2	1150
1	98.2	176

of AgO samples at 1000 ppm (Ag) concentration (Table III). Therefore, it was of interest to determine the gassing rate at lower Ni concentrations. Table IV shows the gassing rates at 5 hr to be still intolerably high even at 1 ppm (Ag) Ni addition. The volume of the evolved gas increased linearly with time up to 5 hr except at 1 ppm (Ag) Ni where a break occurred after 2 hr.

The explanation of the effect of these inorganic additives cannot be ascertained on the basis of the performed experiments. A correlation of the gassing rates with some meaningful parameters may shed some light on the influence of these additives. This, however, will not be attempted here. The possibilities are numerous. According to Amlie and Rüetschi (1), the gassing rate depends on the oxygen overvoltage and the physical characteristics (structure and porosity) of the surface Ag_2O film. The BET surface area of AgO sample with 1000 ppm (Ag) Pb was *ca.* 50% higher than the mean surface area of AgO samples without additives. In view of the smaller gassing rates in the presence of small amounts of Pb and higher surface areas, the porosity does not seem to be a controlling factor. Cahan (13) ascribed the decrease of gassing rate to the presence of a silver plumbate surface film. The limited number of oxygen overvoltage data on silver alloys (14, 20) seem to correlate with the gassing rates but not without exception.

The effect of transition metal additives, mainly Ni, Co, Zr, and Ce, on the gassing rate seems to point to catalytic action. The thermodynamic, but more likely the kinetic metastability of AgO in alkaline solution can be also affected by their presence. The charge transfer may take place in the bulk or at the surface of AgO by several possible mechanisms (injection, tunneling, transition state).

Suppression of gassing.—In order to determine the effect of beneficial additives (from the viewpoint of resistivity and gassing rate) as gassing suppressors, AgO samples were made in the presence of 5 ppm (Ag) Ni with and without 10^4 ppm (Ag) Hg, Sn, and Pb. The results are shown in Table V. Hg increased the gassing rate by the same amount whether the $Hg(NO_3)_2$ was added to the $AgNO_3$ or to the alkaline persulfate solution. Sn decreased the gassing rate moderately, whereas Pb decreased it markedly neutralizing the affect of Ni to some degree. Replacing part of Pb by Hg, the gassing rate increased indicating the aforementioned detrimental effect of Hg. The resistivity of

GeO_2	147	209
PbO	105	209

AgO samples containing Pb, Sn, and Hg are lower as found earlier (15). The AgO content of the samples are generally lower due to the presence of Ni. The addition of Pb to AgO during its preparation is beneficial not only from the viewpoint of electric resistivity but also of gassing rate. Thus, it is advantageous to have Pb as one of the components in any combination of beneficial additives.

In view of the aforementioned beneficial affect of Pb, etc. on the gassing rate and Cahan's results with PbO (13), it was of interest to determine their influence on the gassing rate when they are incorporated in the alkaline solution. An AgO sample with high gassing rate was chosen (98.2% AgO content). The results of Table VI show that Hg increased, Sn did not influence, and Ge and Pb decreased the gassing rate of the AgO sample. Since the trend of the gassing rates in Table V and VI is nearly the same, the effectiveness of the additives is due to their presence and is independent of the method of incorporation.

Summary

The volume of the oxygen evolved from AgO samples in contact with alkaline solutions was measured in a modified microvolumetric appartus of Amlie and Rüetschi (1) and the gassing rates (cumulative average) were calculated. The AgO samples were prepared by the chemical oxidation of $AgNO_3$ with alkaline $K_2S_2O_8$ (16) in the absence or presence of intentionally added metal additives (as compounds). The gas evolved almost linearly with time and the decrease of gassing rate, r after 200 hr was small. In view of the approximately linear relation between the gassing rates at 20 and 200 hr, r_{20} can be used for the rapid semiquantitative prediction of gassing rates. The gassing rates varied somewhat and the mean r_{200} of 52 AgO samples (AgO content $\geq 95\%$, $r_{200} \leq 35$ μl/day/g) was 23.0 μl/day/g. Assuming the decomposition of AgO to be a first order reaction, 0.271/year was obtained for the rate constant in 8.6N NaOH, 2.2N Na_2ZnO_2 solution at 37.78°C.

The gassing rate increased with increasing NaOH concentration and temperature. With NaOH concentration, r_{200} increased approximately linearly. The activation energy for the complex O_2 evolution reaction was calculated from all data to be 26 kcal/mole. The correlation of the gassing rates in two solutions of different composition was found to be approximately linear. The gassing rate of AgO powders increased with ball milling and increasing pelletizing pressure. No correlation was found between the gassing rate and surface area or porosity.

The gassing rates of AgO samples made in the presence of transition elements were, in general, larger than the gassing rates of samples with nontransition elements. The presence of 1000 ppm (Ag) Co, Ni, and Zr is catastrophic from the viewpoint of decomposition and samples with Ce, Pd, and W have intolerably large gassing rates. The gassing rate of AgO samples increased with increasing additive concentration with the exception of Pb at small concentration. The addition of Pb is advantageous also from the viewpoint of electric resistivity (15).

Sn, Ge, and especially Pb suppressed the large gassing rates of AgO samples regardless whether they were incorporated with 5 ppm (Ag) Ni during their preparation or only added to the alkaline solutions.

Electrical Properties of Electrodeposited PbO_2 Films

W. Mindt

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Resistivity, Hall effect, and optical absorption of electrodeposited α- and β-PbO_2 films have been investigated. Films of both crystalline modifications show low resistivities (α-PbO_2: 10^{-3} ohm-cm, β-PbO_2: 10^{-4} ohm-cm) and electron densities of about 10^{21} cm^{-3}. Free electrons are due to nonstoichiometry or to incorporation of hydrogen. As a result of the high carrier densities, the absorption edge is shifted to higher photon energies. The band gaps of intrinsic α- and β-PbO_2 are about 1.4 eV.

Lead dioxide has a high electrical conductivity, comparable with that of some metals. This property is important for its use as positive active material in the lead acid battery as well as for other applications, *e.g.*, as an inert anode material in several electrolytic processes.

In the past two decades, very little experimental work on the electrical properties of PbO_2 has been published. Most of the information we have today originates from papers of Palmaer (1), Kittel (2), and Thomas (3). The latter two authors carried out Hall effect measurements on electrodeposited samples. They found n-type conduction with electron densities between 10^{20} and 10^{21} cm^{-3} and mobilities of the order of 100 cm^2/Vsec. It was assumed that the free electrons are due to an effective deficiency of oxygen, which is generally found in PbO_2 regardless of the method of preparation (4-6). According to Thomas, the temperature coefficient of the resistivity is positive in the temperature range between —200°C and +100°C and the sign of the thermoelectric power negative.

At the time these studies were made, only the tetragonal (β) modification of PbO_2 was known. Conductivity measurements on both orthorhombic (α) and tetragonal PbO_2 were carried out by White and Roy (7) and Aguf *et al.* (8). Unfortunately, pressed powder samples were used, which have the disadvantage of being extremely sensitive to experimental parameters such as grain size and applied pressure, particularly since the thermal instability of PbO_2 does not allow heat treatment of the powder samples. The resistivity values obtained by the two groups of authors differ by more than three orders of magnitude. There are, as far as we could determine, no Hall effect measurements reported on the pure α-PbO_2 phase.

PbO_2 films prepared by reactive sputtering of lead in an oxygen atmosphere were investigated by Lappe (9). The films were several hundred angstroms thick and consisted of a mixture of α- and β-PbO_2. An electron density of 10^{21} cm^{-3} and a relatively low mobility of 0.6 cm^2/Vsec were found. The latter value was probably influenced by the low film thickness. From the optical absorption spectra of these films the band gap of PbO_2 was estimated to be 1.5 eV. At lower photon energies free electron absorption occurs.

In the present work resistivity, Hall effect, and optical absorption of electrodeposited PbO_2 films were investigated. Since α- and β-PbO_2 can be obtained in pure forms by electrodeposition (1-6, 10-16), a separate study of the two modifications was possible. A better knowledge of the difference of their electrical properties is desirable in problems concerning the lead acid battery, in which both crystalline forms occur.

Experimental

Deposition of PbO_2 *films.*—Electrolytic deposition of PbO_2 is possible on electrochemically inert substrate electrodes. In the present investigations, Pt and SnO_2 coated glass were used as anodes.

To obtain a uniform and continuous deposit of PbO_2, it was necessary to nucleate some PbO_2 on the substrate electrode prior to the deposition. This was done by briefly applying a high anodic current density in an acid solution of 10^{-4}M/l lead perchlorate. Electron photomicrographs of a Pt surface treated in this way showed a uniform distribution of PbO_2 clusters with an average diameter of about 100Å. No crystalline structure could be detected in these clusters by electron diffraction. Lead dioxide films subsequently deposited grew uniformly and without leaving uncovered spots or pores visible by electron microscopy. The crystalline modification of the PbO_2 films was not affected by the pretreatment, as could be seen by comparison with PbO_2 deposited on clean, un-nucleated Pt electrodes.

The solutions were prepared by dissolving PbO (yellow, Fisher Certified) in $HClO_4$. It is generally believed that under acid conditions β-PbO_2 is obtained. We found, however, a considerable amount of the α-modification in deposits obtained even from strong acid solutions (pH $\leq$ 0). The intensities of the x-ray lines of α-PbO_2 were in some cases stronger than those of the β-lines. A similar observation has recently been reported by Duisman and Giauque (6). In general, high Pb^{++}-concentrations and low current densities seem to promote the formation of α-PbO_2 in this pH region. The conditions under which a good crystalline and pure β-PbO_2 deposit was obtained involved the use of a solution of 20 mM/l PbO in 0.165 M/l $HClO_4$ (pH 1) and a current density of 0.1 mA/cm^2. α-PbO_2 was deposited from a saturated solution of PbO in 0.2M $HClO_4$ (pH 5.5) at the same current density. Under alkaline conditions, Pb_3O_4 is likely to be formed as a second phase. For this reason, only studies on α-PbO_2 obtained from neutral solutions are reported here. The solutions were slightly stirred. The temperature was always 25°C.

After deposition the samples were rinsed with distilled water and dried at room temperature. The thickness of the films was calculated from the amount of charge passed, using x-ray densities and current efficiencies determined by weight gain measurements on 20 cm^2 Pt electrodes under equivalent conditions of deposition. In most cases the current efficiencies were close to 100%.

Electrical measurements.—The substrate electrode used for the resistivity and Hall effect measurement is shown in Fig. 1. A 500Å Pt film was evaporated on a glass slide with a 200Å Ti underlayer for better adherence. A geometrical form was chosen which is commonly used for Hall effect measurements: Two contacts on the same side are used to measure the ohmic voltage drop, V^R, and two contacts on opposite sides to measure the Hall voltage V^H. The contacts to the Pt were made with silver flake and covered with epoxy to isolate them from the electrolyte during deposition.

The principle of the method was to determine V^R and V^H before and after deposition of the PbO_2 films

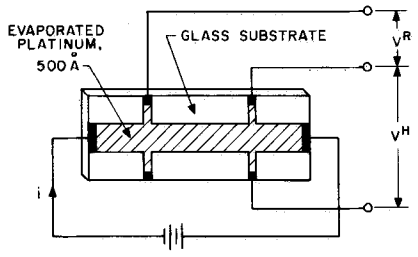

Fig. 1. Electrode arrangement for Hall effect and resistivity measurements.

and to calculate resistivity and Hall coefficient of PbO_2 from these data. To be able to do this, the contact resistance between Pt and PbO_2 must be low and not rectifying. We made, for this reason, some studies of the contact resistance between PbO_2 and Pt as well as some other metals. The current-voltage characteristic of the contacts was nonlinear in most cases where an insulating oxide can be formed between PbO_2 and the metal, *e.g.*, in the case of Ag, Cu, Al, or Ga. On precious metals like Au or Pt the contact resistance was sufficiently low and ohmic.

The Hall voltage of a sandwich type sample as used here, consisting of two conductors with different resistivities ρ_1 and ρ_2 and thicknesses d_1 and d_2, can be derived straightforwardly from elementary considerations of the Hall effect (31) and is given by

$$V^H_{1+2} = -\frac{i \cdot B}{e_0} \frac{\left(\frac{\rho_1^2}{n_2 d_1} + \frac{\rho_2^2}{n_1 d_2}\right)}{\left(\frac{\rho_1}{d_1} + \frac{\rho_2}{d_2}\right)^2 d_1 d_2} \qquad [1]$$

where i is the current, B the magnetic field strength, e_0 the electronic charge, and n_1 and n_2 the carrier densities. The indices 1 and 2 refer to Pt and PbO_2, respectively. Since the Hall voltage of one of the layers, 1, can be measured separately, a simplification is possible. If the same current and magnetic field strength are applied to measure the Hall voltage of layer 1, V^H_1, and of both layers together, V^H_{1+2}, the Hall coefficient of layer 2, $\mathcal{R}^H_2$, is given by the relation

$$\mathcal{R}^H_2 = \frac{-d_2}{B \cdot i}\{(1+\gamma)^2 V^H_{1+2} - \gamma^2 V^H_1\} \qquad [2]$$

γ is the ratio of the resistances, R_2/R_1, which was in most cases smaller than 1. The carrier concentration, n_2, and the mobility, μ_2, can be calculated from the Hall coefficient in the usual way

$$n_2 = \frac{1}{e_0 |\mathcal{R}^H_2|}; \mu_2 = \frac{|\mathcal{R}^H_2|}{\rho_2} \qquad [3]$$

Optical measurements.—As the substrate electrode, commercial tin dioxide coated glass was used (resistance 15 ohms/in.^{2}). Deposition of PbO_2 was carried out in the same way as on Pt, following the nucleation pretreatment described above. The thickness of the PbO_2 films was 3000Å.

Transmission spectra of the systems α-PbO_2-SnO_2-glass, β-PbO_2-SnO_2-glass, and SnO_2-glass were determined in the wavelength interval from 4600 to 15,000Å with a Cary 16 spectrophotometer. The transmission of PbO_2 was calculated from the ratio

$$\frac{\text{transmission of } PbO_2\text{-}SnO_2\text{-glass}}{\text{transmission of } SnO_2\text{-glass}}$$

The error involved by not taking into account reflections at the various interfaces is low in the spectral region in which the transmission of PbO_2 is low.

Results

Electrical measurements.—In Fig. 2, the resistivity of a β-PbO_2 film is plotted against the film thickness.

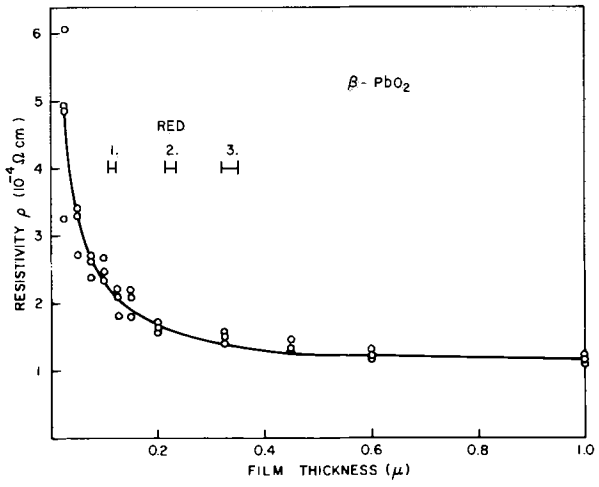

Fig. 2. Resistivity of β-PbO_2 vs. film thickness. The positions of the first three red interference colors are indicated.

The form of the curve is characteristic of metal or semiconductor films. At low values of the film thickness, surface scattering or inhomogeneities in the film are mainly responsible for a higher resistivity. With increasing thickness the resistivity approaches a nearly constant value. In the present case, deposition was continued up to a thickness of 50μ. The resistivity increased slightly but was no more than a factor of 1.2 higher than at 1μ. This shows that the properties of PbO_2 films in the thickness range studied here are very similar to bulk properties of electrodeposited PbO_2. Resistivity values of electrodeposited β-PbO_2 bulk samples reported in the literature (1-3) are mostly close to the value of 10^{-4} ohm-cm obtained here. The films show bright interference colors which can be seen up to the fifth order. The approximate positions of the first three red interference colors are marked in Fig. 2.

A comparison of data obtained on α- and β-PbO_2 is given in Fig. 3. The resistivity of α-PbO_2 films is almost one order of magnitude higher. This is mainly the result of a lower electron mobility in α-PbO_2, which overcompensates the effect of a higher electron concentration in this phase. It may be noted, in the right of Fig. 3, that the electron concentration in α-PbO_2 is only about a factor of 20 smaller than the concentration of lead ions in the lattice.

In general, these curves are fairly reproducible under different plating conditions. In the case of α-PbO_2, a variation of the pH between 4 and 6 and a variation

of the lead perchlorate concentration between 20 mM/l and 2 M/l had only a small influence on the positions of these curves, no more than 20%. The influence of the anion in this pH range is of the same magnitude. Besides perchlorate, nitrate and acetate were also used. In acid solutions, the conditions under which a pure β-PbO_2 deposit is obtained are critical, as was described above. An increase in the lead ion concentration or a lowering of the pH caused the formation of some α-PbO_2 in the deposit. The resistivity of the mixed films was slightly higher than of the pure β-PbO_2 films.

The electrical measurements described to this point were carried out within an hour after deposition of the films. With longer storing at room temperature in air the properties, mainly of the β-PbO_2 films, change, as is shown in Fig. 4. The carrier concentration in a 1μ thick film increases from 5×10^{20} to 8.7×10^{20} cm^{-3} after 12 days. The mobility decreases by a factor of 3 in the same time. X-ray diffraction studies of the samples after this time showed no changes in the crystalline structure.

The increase in the carrier density suggests that a change in stoichiometry in the direction of a lower oxygen content or by the incorporation of hydrogen occurs under these conditions as will be discussed below. The amount of oxygen which corresponds to the observed increase in carrier density is large enough to be detected by simple manometric techniques if larger quantities of PbO_2 are taken. For this purpose, several grams of α- and β-PbO_2 were deposited under the conditions described above, powdered, and placed into a Summerson differential manometer. To study the effect of humidity, the experiments were carried out in dry air and in air saturated with H_2O. In the latter case the wells in the two reaction flasks of the manometer were filled with water. The results are shown in Fig. 5. Both modifications lose oxygen; however, α-PbO_2 far less than β-PbO_2. Humidity causes a considerable increase in the amount of liberated oxygen. Under humid conditions, 5 mm^3 O_2 per gram β-lead dioxide are obtained in 30 days. This amount is equivalent to a change in carrier concentration of $1.7 \times 10^{18} cm^{-3}$, if it is assumed that each liberated oxygen atom provides two free electrons. This increase in electron concentration is far less than that observed by Hall effect measurements on a β-PbO_2 film (Fig. 4). The reason for this difference is probably the larger size of the crystallites used for the manometric measurements, which results in a lower decomposition rate because of the smaller surface to volume ratio.

Optical measurements.—In Fig. 6, absorption coefficients of α- and β-PbO_2 films are plotted as a function of the photon energy. The absorption edges of α- and β-PbO_2 (curves a and b) differ by 0.2-0.3 eV. Extrapolation to zero absorption indicates values of the "optical" band gap, ΔE_0, of 2.0 and 1.7 eV for α- and β-PbO_2, respectively. At photon energies below 1 eV free electron absorption begins. This type of absorption is stronger in the α-modification which has the higher carrier density. Since free electron absorption also occurred in the SnO_2 substrate, the measurements could not be extended to lower photon energies. The waves in the curves in the region of low absorption are due to interference effects.

The values of ΔE_0 obtained here are not identical with the band gap, ΔE_g, of intrinsic PbO_2. As a result of the high electron concentration, the energy states in the bottom of the conduction band are occupied and electrons have to be excited to higher energy levels for absorption to occur. The shift in photon energy due to this effect is, for a degenerate semiconductor (17)

$$\Delta(h\nu) = \Delta E_0 - \Delta E_g \cong \left(1 + \frac{m_e^*}{m_h^*}\right) \cdot E_f \qquad [4]$$

where m_e^*, m_h^* are the effective masses of electrons and holes and E_f the Fermi energy. The Fermi energy of an ideal degenerate Fermi gas is

$$E_f = \left(\frac{3}{\pi}\right)^{2/3} \frac{h^2}{8m_e^*} \cdot n^{2/3} \qquad [5]$$

In β-PbO_2, a shift of the absorption edge could be observed when the sample was exposed to air for several days (curve c in Fig. 6). The experiment described previously showed that under these conditions an increase in carrier concentration occurs. With the two pairs of values of n and ΔE_0, a rough estimation of the effective electron mass, m_e^*, in β-PbO_2 is possible from Eq. [4] and [5]. Using values obtained shortly after deposition and 30 days later

$$n_1 = 5 \times 10^{20}\,cm^{-3}; \quad \Delta E_{0.1} = 1.7\,eV$$

$$n_2 = 9 \times 10^{20}\,cm^{-3}; \quad \Delta E_{0.2} = 1.84\,eV$$

and assuming that $m_e^* << m_h$,* an effective electron mass of 0.8 m_o is obtained. This leads, according to Eq. [4], to a band gap for intrinsic β-PbO_2 of $\Delta E_g = 1.4$ eV.

No change of the absorption curve with time could be detected on α-PbO_2. However, if the same effective mass is used as in β-PbO_2, a value of $\Delta E_g = 1.45$ eV is obtained.

These results are similar to the values of the band gap determined by Lappe (9) (1.5 eV) and Shapiro (18) (1.85 eV). A different value of 4.45 eV was obtained by Arai (19). The author described the method by which he prepared PbO_2 films as similar to the spraying technique commonly used for preparing conductive SnO_2 films. Since the substrate temperatures usually applied in this technique are between 500° and 800°C (20), these films may have contained lower lead oxides, because PbO_2 decomposes at temperatures above 270°C (21). This assumption is supported by the fact that the films were insulating.

Discussion

Lead dioxide belongs to a group of n-type metal oxides which show high electron mobilities. Other oxides of this type are ZnO, In_2O_3, and SnO_2. The electronic configurations of these compounds indicate that the conduction bands are formed from s-orbitals of the metallic species rather than from unfilled inner shells as, for example, in transition metal oxides. The mobilities in oxides of the latter type are, in general, several orders of magnitude smaller. The conduction band in PbO_2 arises, to a first approximation, from the 6s levels of Pb^{4+} and the valence band from the 2p levels of O^{2-}.

The presence of free electrons in PbO_2 can be due to the following effects: deviation from stoichiometry, incorporation of hydrogen, and presence of other impurities.

It is well established that lead dioxide exists in a wide range of nonstoichiometry, which was determined by Katz (22) as $PbO_{1.87\text{-}2.00}$. Other authors give different values for the lower limit of the composition which vary between $PbO_{1.95}$ (23, 24) and $PbO_{1.66}$ (25). It is not certain whether the nonstoichiometric composition is due to interstitial lead ions or to oxygen vacancies. The observations that the density of electrodeposited PbO_2 is lower than the x-ray value (1) and that oxygen appears to have a high mobility in PbO_2 (26) promote the assumption that oxygen vacancies are predominant.

Rüetschi and Cahan (4) suggested that free electrons in PbO_2 may be due in part to OH groups substituting for oxygen in the lattice. This is supported by the observation that an appreciable amount of bound hydrogen is found in electrodeposited PbO_2 (4, 5, 6, 15). A similar role of hydrogen is known in other oxide semiconductors, *e.g.*, in ZnO (27). The presence of hydrogen is, however, not necessary to explain high electron concentrations. This was shown by experiments with sputtered PbO_2 films by Lappe (9), which did not contain hydrogen and also had a carrier density of 10^{21} cm^{-3}.

The influence of impurities other than hydrogen is presumably small, since high concentrations are necessary to cause significant relative changes in the carrier concentration. For the same reason, doping of PbO_2 with 3- or 5-valent ions will not have a similar influence on the conductivity as, for example, in SnO_2.

It is in the frame of the present investigations not possible to decide whether electrons in electrodeposited PbO_2 are due mainly to nonstoichiometry or to incorporation of hydrogen. The carrier concentration of 1.4×10^{21} cm^{-3} found in the α-PbO_2 films corresponds to a composition of $PbO_{1.971}$ if electrons are due only to ionized oxygen vacancies, and to $PbO_{1.942}(OH)_{0.058}$ if they are due only to OH-groups substituting for oxygen. Chemical analytical methods are probably not sufficiently exact to distinguish between the two cases. In particular, the determination of hydrogen involves a large error (5), and it is difficult to distinguish between hydrogen bound in OH-groups in the lattice and hydrogen which is part of adsorbed water.

The decomposition of electrodeposited PbO_2 at room temperature can be interpreted in terms of the generation of oxygen vacancies or the incorporation of hydrogen due to oxidation of water. In both cases, oxygen is evolved and the electron concentration increased. The over-all reactions may be written as

$$(2\,O^{2-})_{latt} \rightarrow (2\,\square\,O + 4e^-)_{latt} + (O_2)_g \qquad [a]$$

$$(4\,O^{2-})_{latt} + 2H_2O \rightarrow (4\,OH^- + 4e^-)_{latt} + (O_2)_g \qquad [b]$$

The result that moisture in the air increases the decomposition rate makes reaction [b] more probable. However, a similar effect may result if adsorbed water increases the rate of one step of reaction [a].

The different electron mobilities in α- and β-PbO_2 are the result of several factors. The lower mobility in the α-PbO_2 films may be due in part to the smaller size of the crystallites in this modification. The average size of the α-PbO_2 crystallites was about 2000Å, compared to 5000Å for the β-modification. There is certainly also an influence of the higher carrier density in α-PbO_2, since this corresponds to a larger number of lattice defects at which electrons are scattered. Since the α-PbO_2 films have a high degree of orientation [the (100) axis is perpendicular to the substrate], an anisotropy of the mobility in α-PbO_2 could also influence the results.

There is, finally, the influence of the different crystalline structures of α- and β-PbO_2. α-PbO_2 has the structure of columbite, which is orthorhombic and has the space group Pbcn (V_h^{14}). β-PbO_2 has the tetragonal rutile structure, which belongs to the space group P4/mnm (D_{4h}^{14}). It was shown first by Pauling and Sturdivant (28) that a close relationship exists between the two lattices. In both cases, each metal ion is in the center of a distorted octahedron. The essential difference is in the way in which the octahedra are packed, as is illustrated in Fig. 7. In β-PbO_2, neighboring octahedra share opposite edges, which results in the formation of linear chains of octahedra. Each chain is connected with the next one by sharing corners. In α-PbO_2, neighboring octahedra share nonopposing edges in such a way that zig-zag chains are obtained. Each chain is connected with the next one also by sharing corners. The oxygen positions have actually been determined only in the case of β-PbO_2 (29), however, the Pb-O distances are thought to be the same in both modifications (30). Since the difference in the crystal structures results mainly from the

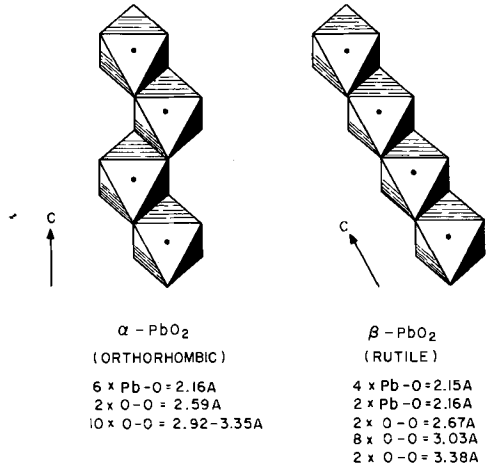

Fig. 7. Packing of oxygen octahedra in α- and β-PbO_2. Lead-oxygen and oxygen-oxygen distances as determined by (29) and (30).

different packing of octahedra of similar dimensions, large differences in the band structure and mobility are not expected.

Acknowledgments

The author wishes to thank U. B. Thomas and P. C. Milner for helpful discussions and interest in this work. He is also indebted to H. C. Montgomery and J. D. E. McIntyre for provision of facilities and to G. W. Kammlott for the careful accomplishment of all the x-ray, electron diffraction, and electron microscopic work involved in this study.

Manuscript received March 14, 1969. This was Paper 362 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Active and Passive Corrosion States in the High-Temperature Aqueous Corrosion of Mild Steel

John B. Moore, Jr.,[1] and Robert L. Jones*

Naval Research Laboratory, Washington, D. C.

ABSTRACT

In static high-temperature (300°C) corrosion tests of mild steel in dilute NaOH solutions, both the corrosion rate and morphology of the generated oxide film were observed to vary in a reproducible and presumably correlatable fashion as the NaOH concentration increased. A transitory corrosion rate minimum was found *circa* 2 g/l NaOH; there was at this same point a change in the structure of the oxide film, with a compact, randomly oriented, apparently continuous film giving way to a crystallographic surface oxide as the critical concentration was exceeded. The activation energy for corrosion differed depending on which oxide type prevailed, being 5-8 kcal/mol for the noncrystallographic oxide and 16 kcal/mol for the crystallographic. The transformation is thought to be basically a transition between passive and active corrosion states.

Although alkalization of the feed water is generally found to be beneficial in the operation of steam generating boilers (1), actually very little is known of the specific effects of this treatment on the corrosion processes occurring within the boiler. One discernible result of raising the feed water pH is the growth of larger crystallites in the oxide film on the boiler's interior, and it has been thought that these larger crystallites may provide increased corrosion protection because they are more resistant to erosion by the flowing streams present in a dynamic boiler system. Berl and Van Taack's research (2) suggests that alkalization has effects beyond just this, however, for they found that the corrosion suffered by mild steel in 310°C NaOH solution was relatively independent of alkali concentration up to about 0.7 g/l, at which point a rather sharp, localized reduction in corrosion was observed. The corrosion rate subsequently rose again, increasing smoothly with concentration for

solutions up to 200 g/l NaOH. This region of minimum corrosion was later reinvestigated by Bloom and coworkers (3) who confirmed its existence. Their longer term studies revealed, however, that the minimum, while real, appeared to be only transitory, and that after 25 days the corrosion rate increased monotonically with pH from zero concentration NaOH onward.

Recent work at this laboratory (4) indicated that the corrosion rate of steel in high-temperature aqueous media may be related to the morphology of the oxide film concurrently produced, and that the rate data are at least partially understandable in terms of certain transitions which occur in the oxide film with time. To test this notion further, and perhaps to elucidate the pH dependency of the corrosion of mild steel in high-temperature alkaline waters, experiments were undertaken to determine both corrosion rates and oxide film morphologies for specimens at 300°C in NaOH solutions with concentrations spanning both sides of the corrosion minimum.

Experimental

The rates of oxide film formation were measured using a hydrogen effusion technique devised by Bloom and Krulfeld (5). With this method, the test specimen is a sealed capsule which is filled completely with the solution under study. The corrosion reaction takes place on the capsule interior, and its progress is monitored by measuring the hydrogen which diffuses through the hot capsule wall, that hydrogen having originated in a reaction which can be written over all as

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2$$

Our capsules were fabricated and filled as described previously (5). Simple vacuum vessels as shown in Fig. 1 were used to measure the rate of hydrogen evolution. The working volume of an individual vessel runs about 32 cm^3 and the interior area of a capsule about 12.5 cm^2 so that the growth of 100Å of oxide film corresponds to a pressure increase within the vessel of 0.85 Torr. The use of a cathetometer allows film growth of as little as 20Å to be readily detected. A constant voltage transformer was used as the power source for the block oven, and the oven temperature remained constant to ±1-2°C over a two-week run.

As the corrosion rate data were being accumulated, specimen capsules were withdrawn at appropriate times and the oxide films on their interiors detached and examined by electron microscopy, either directly by observation of the film itself or indirectly by observation of replicas of the upper oxide surface. The microscopy specimens were prepared as previously described (4).

The seamless mild steel tubing used here was 0.25 in. OD with 0.022 in. wall thickness and contained 0.15% C, 0.09% Si, 0.66% Mn, 0.22% Cr, 0.09% Ni, 0.026% S, 0.011% P, and 0.013% N. Pretreatment consisted of degreasing in trichloroethylene and then duPont Freon TF solvent, followed by vacuum annealing at 875°C and 10^{-5} Torr for 1 hr. The annealed specimens were stored in a closed container over anhydrous $CaSO_4$.

The NaOH solutions were prepared fresh in Pyrex glassware from A.R. NaOH and distilled water, with the less concentrated solutions being made up by dilution. The solution pH was measured before and after each run to determine any change in basicity.

Results

In Fig. 2, we have plotted curves showing total corrosion as a function of NaOH concentration from 0.006 to 10.24 g/l NaOH (approximately 9.5-13.3 pH at 25°C) for progressively increasing times at 300°C. A minimum corrosion region is found once again, although the minimum here appears to be slightly displaced, falling at 2-4 g/l rather than at 0.7 g/l as found by Berl and Van Taack. The points in Fig. 2 represent the arithmetic means of data from groups of 4-5 capsules, where individual capsules could vary by ±10% from the mean for a 312-hr run. Some uncertainty in the positioning of the corrosion minimum therefore exists; however in each of three separate runs, the minimum fell sufficiently closer to 2-4 than 0.7 g/l as to suggest that something more than experimental error may be involved.

With time, the corrosion rates for the individual NaOH solutions change and they become monotonic functions of concentration, *e.g.*, at 204 hr, the instantaneous rates are 0.58, 1.1, 1.2, 1.7, 1.9, 2.3, 2.8, and 3.3 $\mu g\ Fe_3O_4\ cm^{-2}\ hr^{-1}$ for the concentrations 0.006 through 10.24 g/l, respectively. This concentration-dependent progression of instantaneous corrosion rates is observed from about 200 hr onward, and it is evidently a persistent effect since Bloom has found the same trend in capsules heated 25 days. The inflections shown in Fig. 2 would therefore ultimately disappear

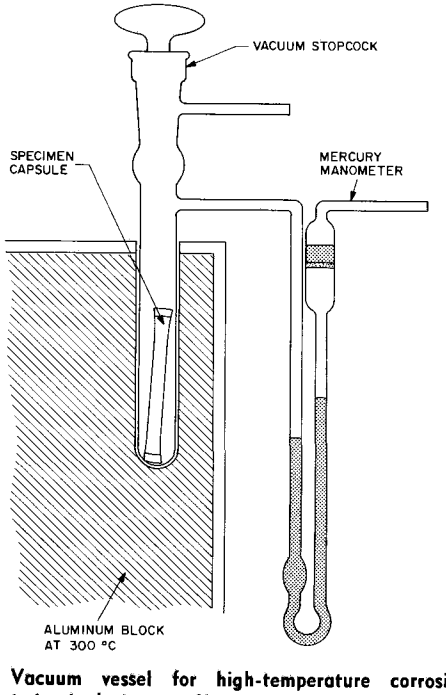

Fig. 1. Vacuum vessel for high-temperature corrosion rate measurements by the hydrogen effusion method.

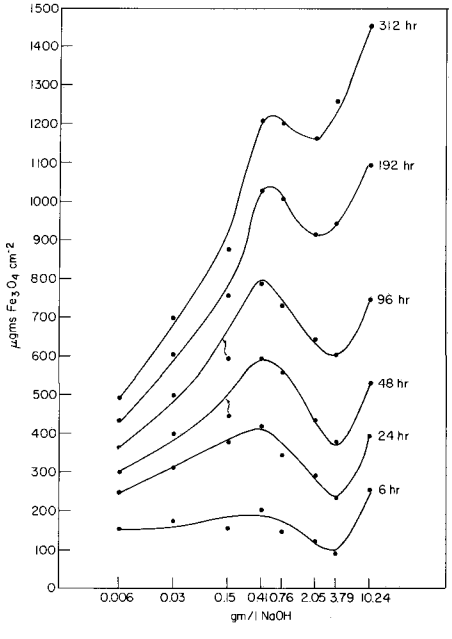

Fig. 2. Aqueous corrosion of mild steel as a function of NaOH concentration with increasing time at 300°C.

entirely and measurements taken at longer time intervals would fail to show the corrosion minimum either in terms of total corrosion or instantaneous corrosion rate.

Electron microscopy of oxide films grown during these runs shows that there is a distinct difference in the oxide morphology from one side of the minimum to the other. With 10.24 and 3.79 g/l NaOH solutions, the oxide film in its earlier stages of formation is strongly oriented and apparently in epitaxial relationship with the various substrate grains, *i.e.*, it is crystallographic (Fig. 3a). This tendency to orientation appears to persist, moreover, through the development of the film. Although crystals of considerable size come into being with time (Fig. 3b), the oxide film over the rest of the metal surface remains comparatively thin and can be seen to consist of small rectilinear crystallites. These crystallites continue to be well oriented with the orientation differing from point to point on the surface, an indication that the growth of the innermost oxide is still influenced by epitaxial forces from the substrate.

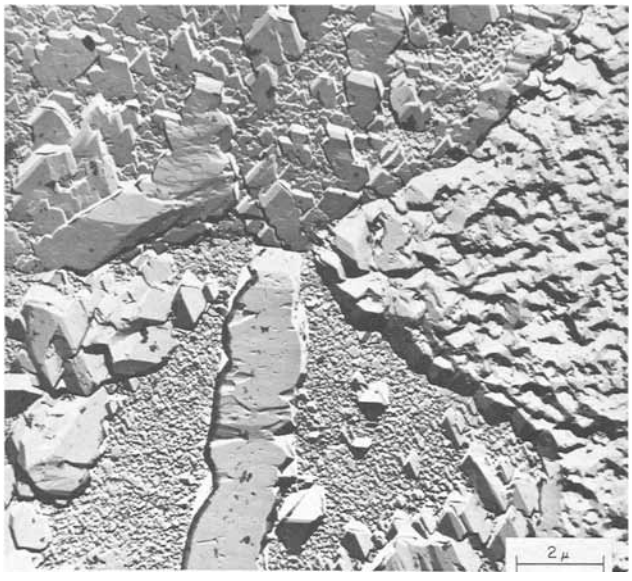

Fig. 3c. 0.76 g/l NaOH, 4 hr at 300°C

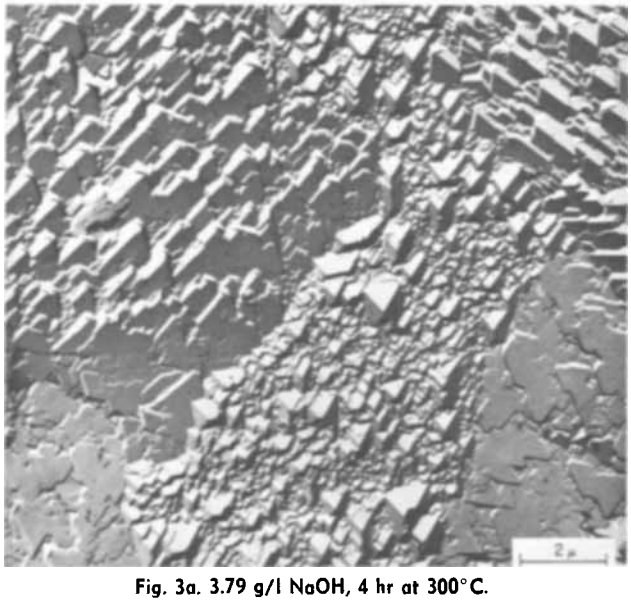

Fig. 3a. 3.79 g/l NaOH, 4 hr at 300°C.

On the other hand, while the oxide corrosion film also grows at first with epitaxial orientations in 0.76 g/l and lower solutions, it soon undergoes a degeneration, as described previously (4), to an apparently duplex film structure consisting of a thin, continuous innermost layer of very small, randomly oriented crystallites partially covered in turn by much larger, faceted crystals. The innermost film is noncrystallographic; it is not oriented to the substrate and its appearance is the same at every point at which it is visible on the metal surface. In Fig. 3c, three different orientations of the oxide film (as identified by the morphology of the residual oriented crystals) are shown at an intermediate state of degeneration. The orientation at the bottom of Fig. 3c is almost completely transformed, the orientation at the upper left partially transformed, while the oxide at the right remains virtually unchanged. This latter oxide is in the (001) orientation (4) which evidently represents one of the most stable epitaxial relationships under these conditions since it resists transformation longest. Eventually all of the oriented oxide is transformed, however, and the resultant oxide film has the structure shown in Fig. 3d. Note that the base oxide film has a distinctive pebblelike texture which is easily identified and quite different to that seen in

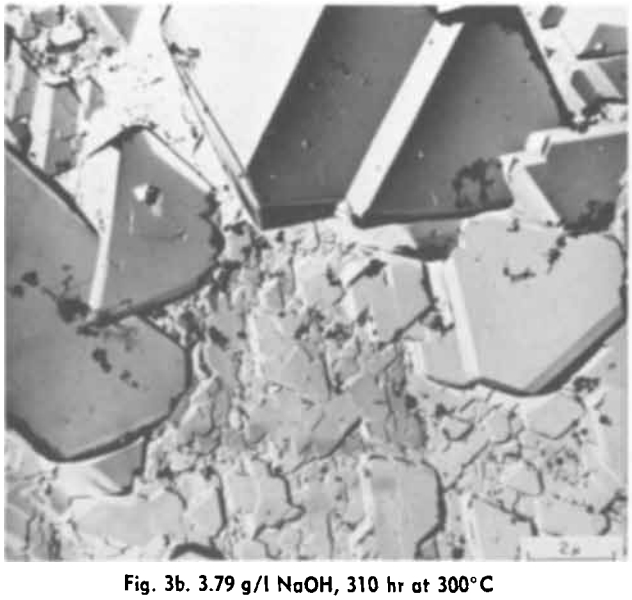

Fig. 3b. 3.79 g/l NaOH, 310 hr at 300°C

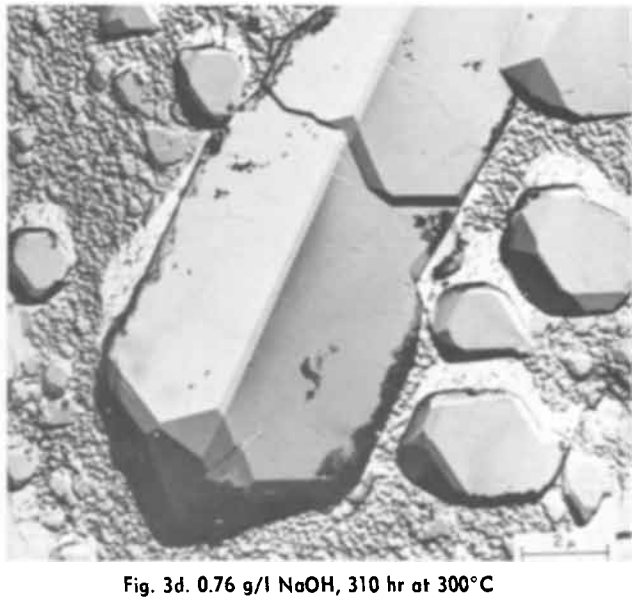

Fig. 3d. 0.76 g/l NaOH, 310 hr at 300°C

Fig. 3b. The NaOH concentration representing the point of transition between these two modes of film development lies evidently near 2.05 g/l NaOH, where degeneration of the epitaxial oxide occurs slowly. Oxide films at this concentration are still strongly oriented after 4 hr at 300°C, although they do eventually develop the duplex film structure, being completely transformed by 96 hr.

In very dilute NaOH, *e.g.*, 0.030 g/l NaOH, which gives approximately pH 11 at 25°C, degeneration to the duplex oxide structure does not proceed to any great extent, at least over our periods of investigation. [This is contrary to our earlier findings with pH 11 LiOH (4), where the transformation went freely.] Areas of randomly oriented base film are found, but much the greater part of the oxide remains oriented for both short (Fig. 3e) and long (Fig. 3f) heating intervals. The crystallographic nature of the oxide here is not as apparent from its morphology as it is with oxides produced in more concentrated solutions, but selected area diffraction, the final criterion, readily confirms that in both instances the oxide in question is strongly oriented. Oxide films grown in capsules containing just water are also crystallographic and virtually identical in appearance to Fig. 3e and 3f, except that evidences of the fine-grained base film are even more sparse.

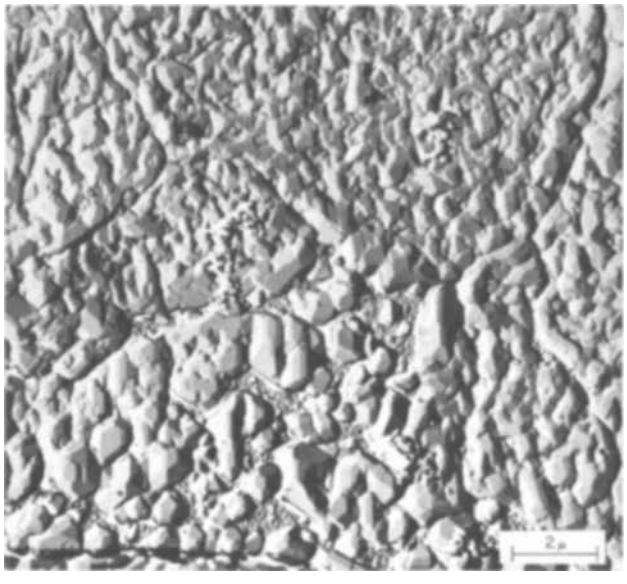

Fig. 3e. 0.03 g/l NaOH, 4 hr at 300°C

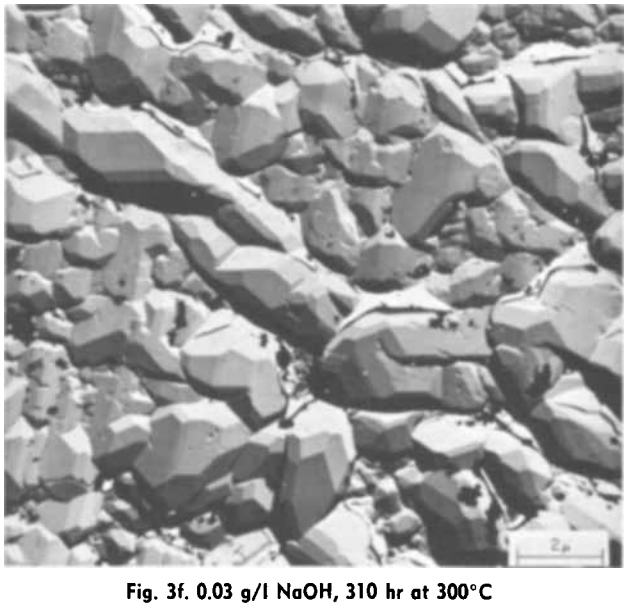

Fig. 3f. 0.03 g/l NaOH, 310 hr at 300°C

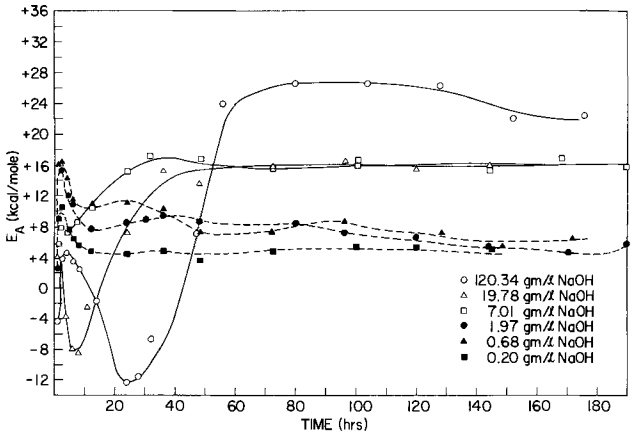

Fig. 4. Time dependence of activation energies (E_a) for corrosion in NaOH solutions above and below the corrosion rate minimum concentration.

On the assumption that the different oxide morphologies reflect a change in the oxide growth mechanism at the corrosion minimum point, we measured activation energies (E_a) of corrosion in NaOH solutions on both sides of the corrosion minimum to see if a simultaneous change in activation energy could be detected. The results are shown, plotted as a function of time, in Fig. 4. These are apparent activation energies only; they were calculated from a plot of the logarithm of the reaction rate at a given time *vs.* $1/T$ for three different temperatures (nominally 250°, 275°, and 300°C, in the main). The linearity of the points in the individual plottings was not particularly good, and the energy values obtained should probably be considered semiquantitative and suited mostly for purposes of comparison. Nonetheless, although there are early time fluctuations, a trend becomes discernible after about 72 hr in the activation energies in Fig. 4. As the NaOH concentration increases successively from 0.20 to 0.68 to 1.97 g/l, that is, as we cross the concentration range yielding the noncrystallographic duplex oxide film, the activation energies remain relatively constant at 5-8 kcal/mol. The next factor of 3 increase, however, brings us past the corrosion minimum point into the region where the crystallographic oxide predominates, and the activation energy jumps to 16 kcal/mol. A final concentration increase to 19.78 g/l yields an almost identical 16 kcal/mol value. Presumably then, the apparent activation energy for corrosion in NaOH solutions through this concentration range is not a first order function of the hydroxide concentration, but depends primarily on whether or not the point of transition for the oxide growth mechanism has been exceeded.

The activation energy with 120 g/l NaOH was measured so that comparison could be made with an energy value reported earlier by Potter and Mann (6) for 13% NaOH at 250°-355°C; their figure was derived from an Arrhenius plot of parabolic rate constants and was originally given as 15 ± 2 kcal, but subsequently corrected to 30 ± 2 kcal (7). If our rate data for 120 g/l NaOH after say 80 hr at temperature are recalculated, assuming parabolic kinetics, then an E_a of about 28 kcal is obtained (with the usual reservation that the linearity of the points is not good). However, the significance of this agreement is obscured by the fact that the corrosion behavior of our specimens was appreciably different here than with the less concentrated solutions (see Table I). The capsules containing 120 g/l NaOH corroded very rapidly and with nearly equal rates for all three temperatures up to about 24 hr, at which time the corrosion in the 275° and 300°C capsules dropped off sharply, and then settled down to rates showing an approximately appropriate temperature dependency. The 250°C capsules continued to corrode at a disproportion-

ately high rate for perhaps another 24 hr before dropping to what appears, in context of Table I, an abnormally low rate. The result of this is that at 80 hr, when the "steady state" has been reached, the total corrosion is actually greater at 250° than 300°C.

Discussion

We concluded earlier (4) that the thin, pebble-textured base film of the duplex oxide structure is a high-temperature passive oxide film which exists in an equilibrium state of formation and dissolution, and that the large, faceted crystals occurring on its upper surface are formed by precipitation of iron species put into solution by that process. Our present experiments support this theory by showing that the stability range of this particular oxide morphology (from 0.006 to 2 g/l NaOH, or about 9.5 to 12.5 *p*H at 25°C) agrees with that predicted by Pourbaix (8) for passive iron oxides in aqueous media. That this is so even though our experiments were at 300°C whereas Pourbaix's calculations are based on 25°C thermodynamic data may indicate that the relative stabilities of the pertinent species are not extensively affected in going from 25° to 300°C. Beyond these concentration limits, *i.e.*, when the specimen is in the active corrosion state, the morphology of the oxide film is changed, its distinguishing feature now being that it is crystallographic.

West (9) and Hoar (10) have offered mechanistic reasons as to why the physical structure of the surface oxide should differ depending on whether the corroding metal is in the active or passive state. According to Hoar, a metal may corrode, as determined by prevailing electrochemical conditions within the system, either by direct reaction of water molecules adsorbed at the metal surface to form the oxide essentially *in situ* or by dissolution with the formation of metal ionic species which subsequently deposit as the least soluble salt or hydroxide. (At the temperatures involved in our experiments, any iron hydroxide would be converted to magnetite by the Schikor reaction.) The first process yields the so-called passive oxide film and it is noncrystallographic since the generating reaction is as likely to occur at one point on the metal surface as another. The fundamental step in the alternative process, however, is the removal of an ion from the metal lattice, a feat most easily accomplished at certain specific crystal sites, and so the corrosive attack here will tend to be crystallographic in nature (and presumably the deposited oxide films also). West postulates, on the other hand, that a noncrystallographic oxide is produced on a metal undergoing passivation when the rate-determining factor comes to be diffusion through the passivating oxide film itself.

Morphological changes consistent with a passive-active corrosion state transition have not been reported previously for oxide films on mild steel, although there have been findings in studies of stainless steel corrosion in high-temperature water which appear in accord with this hypothesis. Maekawa *et al.* (11) observed that AISI 304 stainless steel corroded in high-temperature deaerated water (less than 0.1 ppm O_2) with the formation of a "crystalline" oxide corrosion film, but in undeaerated water (approximately 5 ppm O_2) with the formation of a noncrystalline film. Moreover, they found, just as we have, that the corrosion rates were effected differently by temperature in the two circumstances. In deaerated water, the corrosion rate increased strongly from 200° to 300°C but then decreased as the temperature was raised further to 350°C. With undeaerated water, the temperature effect was considerably less, and there was no corrosion maximum, the rate increasing smoothly from 200° to 350°C. They identified the films by infrared adsorption measurements as consisting of magnetite and chromite in deaerated water (with the chromite content increasing at higher temperatures) and γ-Fe_2O_3 in undeaerated water.

A transformation of the surface oxide, perhaps similar to the one observed here, has been found by Nakayama and Oshida (12) during the early stages of oxidation of an 18-8 stainless steel in 300°C water containing 8 ppm O_2. They showed by electron diffraction that a corundum type oxide film was generated on the stainless steel in the initial heating but that this converted with further heating (within 24 hr) to a spinel-structured surface film. The film was not identified as γ-Fe_2O_3 however, as in the works cited above and below, Nakayama and Oshida concluding rather that the film was probably $NiO\cdot(Cr, Fe)_2O_3$ and/or $NiFe_2O_4$ because electron probe microanalysis showed it to contain nickel and chromium as well as iron. (Since these authors were not able to show quantitative stoichiometries, it seems possible that the film could still in fact be γ-Fe_2O_3 with the foreign elements being present in occlusions or by ion substitution.)

A noncrystallographic-crystallographic transition in the mode of oxide growth can be induced not only by the presence of oxygen but also by increased *p*H. Francis and Whitlow (13) found differing oxide morphologies on AISI 304 stainless steel in 300°C aqueous corrosion tests depending whether the oxide is grown in neutral or alkaline (*p*H 12) waters, the *p*H 12 oxide being, from their description, essentially crystallographic and the oxide grown at *p*H 7 noncrystallographic. Their diffraction measurements (14) indicated the noncrystallographic *p*H 7 film to be γ-Fe_2O_3 and the crystallographic *p*H 12 film to be a Fe_3O_4-type spinel.

In terms of passivation phenomena, our interpretation of these observations would be that (*i*) 304 stainless steel is brought from an active to passive corrosion state (although it corrodes appreciably at these temperatures even while "passive") by 5 ppm O_2 in neutral water (Maekawa *et al.*); (*ii*) stainless steel may corrode in water by the "active state" mechanism for some time (perhaps depending on how the specimen was prepared) before converting to the passive growth mode even when O_2 is present (Nakayama and Oshida); and (*iii*) a passive-active transition can also be produced by raising the solution *p*H beyond a certain upper limit, as the Pourbaix diagram for the iron-water system would predict (Francis and Whitlow). There is an apparent contradiction here though, since Francis and Whitlow find a passive oxide morphology under nominally the same experimental conditions (300°C, O_2-free water) in which Maekawa *et al.* re-

port an active-type surface oxide. These conditions represent a point very near the boundary between active corrosion and passivation (in Pourbaix diagram reference) however, and only very slight increases of *p*H or minute traces of oxidizing impurities would be required to bring the passivation found in Francis and Whitlow's studies. The particular composition of the steels used may also be a factor here since Leckie (15) has shown that the *p*H at which a stainless steel spontaneously passivates is a function of its composition. In general, with consideration of all that is involved in high-temperature aqueous corrosion experiments, it would not be expected that the point of transition between active and passive corrosion would be precisely reproducible in every instance. And it is probably not noteworthy therefore that the minimum in the corrosion *vs.* NaOH concentration curve seems to fall in our experiments *circa* 2 g/l, whereas Berl and Van Taack, and later Bloom *et al.*, placed it at 0.7 g/l NaOH.

Iron oxide passive films in aqueous media are generally considered to consist of a nonstoichiometric oxide which is essentially Fe_3O_4 at the film's metal/oxide interface and γ-Fe_2O_3 at its oxide/solution interface (16). If this is so, then γ-Fe_2O_3 should be present in the high-temperature corrosion films which we have termed "passive" in this discussion. Of the three papers cited, one reports the detection of γ-Fe_2O_3 in such films by electron diffraction (14), the second finds γ-Fe_2O_3 identifiable by infrared adsorption, but not by electron diffraction (11), while the third describes the film's diffraction pattern as only spinellike and does not try to differentiate between the γ-Fe_2O_3 and Fe_3O_4 structures (12). Warzee *et al.* (17) have also tried to distinguish γ-Fe_2O_3 and Fe_3O_4 and failed because sufficiently good diffraction patterns could not be obtained. Selected area diffraction patterns from our "passive" films fail to show any rings beyond the Fe_3O_4 pattern to indicate the presence of γ-Fe_2O_3. However, Fe_3O_4 and γ-Fe_2O_3 have very similar diffraction patterns (18) and, if the proportion of γ-Fe_2O_3 is small, its pattern might well remain undetected. We believe therefore that more sensitive tests are required before concluding that γ-Fe_2O_3 is absent.

Only a limited analysis of the corrosion rate data can be made, but the corrosion minimum at 2-4 g/l NaOH would seem to have the following significance. If the only cathodic reaction is the reduction of hydrogen, then the rate of hydrogen effusion must be equivalent to the rate of anodic reaction and therefore proportional to the anodic current. Moreover, considering that passivation occurs here, and that the corrosion values given in Fig. 2 represent in a sense then passivating anodic currents, we can compare Fig. 2 with Pourbaix's (8) plot of minimum current densities for iron passivation as a function of solution *p*H. And we find that the minimum in the critical current density for passivation occurs at almost exactly the *p*H (12.5-13) at which the corrosion minimum occurs. This happens most likely not from coincidence, but because the point of emergence from the region of passive oxide stability has been reached in both instances; in our case, we can actually see the change from a passive to an active oxide morphology.

On the other hand, while Pourbaix's passivation current densities decrease linearly from *p*H 2 through *p*H 12.5-13 (although it appears that he made no current measurements in the 8-12 *p*H region), the corrosion values in Fig. 2 increase over *p*H 9 to 12 before dropping to their minimum *circa* *p*H 12.5. This is contrary to the corrosion behavior of iron in 25°C water where increasing *p*H beyond 9.5 brings decreasing corrosion rates up to *p*H 12 where the rate begins to rise once again (19), the *p*H-dependency here being essentially the same as shown by the passivation current densities. The early-time maximum near *p*H 12 in our 300°C corrosion data is evidently not spurious, however, for a similar maximum has been observed by Bloom *et al.* (3), and it is probably associated with the active to passive-type oxide transformation which occurs during the initial hours of capsule heating. Little can be said at present of the actual mechanism of transformation, but apparently competing effects are involved, for, as the *p*H is raised, the active state oxide which develops first grows thicker and persists longer until finally as the corrosion minimum concentration is exceeded, it becomes the stable surface oxide species and degeneration to the passive oxide morphology no longer takes place. The passivation experiments of Cartledge (20) with iron in molybdate solutions are interesting in this conjunction because they show that a prepassivation (active state) corrosion film is displaced by a second surface film as passivation occurs, and, moreover, that near this point of transition the surface film becomes highly oriented and gives single crystal diffraction patterns very similar to those found in our previous experiments (4).

Ultimately, however, our corrosion rates come to show a monotonic increase with alkali concentration from 0.006 to 10.24 g/l NaOH. This agrees with earlier findings by Bloom who also used the capsule system (3), but not those of Warzee *et al.* (17) who found that boilerplate steel corroded at 300°C, under dynamic flow conditions, at decidedly lower rates in *p*H 10 LiOH solutions than in *p*H 7 water. These authors also demonstrated that the outer layer of magnetite crystals in iron corrosion films grows by precipitation from solution by exposing strips of AISI 304 and 410 steels simultaneously in water in an autoclave at 250°C and showing that the 304 specimen which would ordinarily have only a very thin oxide coating at these temperatures now became covered with magnetite crystals similar to those on the 410 steel. And their conclusion was that raising the *p*H to 10 gave a more protective film because it induced the deposition of a thicker, more adherent outer crystal layer by decreasing the solubility of ferrous hydroxide. It may be therefore that, while the early corrosion rates in the capsules depend on the structure, *i.e.*, active or passive, of the innermost oxide film, the long-term rates are finally determined by how the precipitated secondary crystals germinate and grow, our having observed that the lower concentration solutions give more complete surface coverage than the high concentrations which yield larger crystals, but leave more areas of "base" film exposed.

In the time-plot of activation energies in Fig. 4, the solutions which give passive state corrosion show early activation energies up to 16 kcal before dropping to apparently stable 5-8 kcal values. These initial high energies most likely reflect the active state corrosion which the specimens experience before they become passive. Conversely, the solutions giving true active state corrosion exhibit negative activation energies during the first hours of heating. These "negative" energies really only indicate a maximum in the temperature-corrosion rate relationship, however, and may be related to similar maxima found with 304 and 410 stainless steels when these steels were also presumably corroding in the active state. Maekawa *et al.* (11) believe that the temperature-corrosion maximum occurs with 304 stainless because the corrosion film is transformed from magnetite to chromite with increasing temperature. On the other hand, according to Warzee and co-workers (17), 410 stainless steel dissolves giving ferrous hydroxide which subsequently decomposes to produce a magnetite surface film. The two reactions have different temperature dependencies, however, with the latter reaction being accelerated more rapidly at the higher temperatures, and there is therefore a temperature (about 250°C) at which maximum solubility and corrosion occurs. Unfortunately, although our x-ray diffraction measurements seem to indicate that there is no change in structure of the Fe_3O_4 outer layer here, it has not been possible yet to

show the cause of the E_a time dependence shown for active state corrosion in Fig. 4.

The change in activation energy from 16 to 8 kcal/mol may be characteristic of the active-passive transition for iron and perhaps certain other metals as well in neutral to alkaline pH regions. Leach and Nehru (21) have found, for instance, a sharp 7-16 kcal/mol rise in E_a during the cathodic polarization of uranium in pH 9.7 buffer solutions under circumstances where a passive-active transition might be possible, uranium being known to be passivatable (22) and to show a different oxide morphology in the passive and active states (23). It may ultimately be feasible to use this characteristic E_a change as a substitute criterion for passivation in cases where electrochemical measurements cannot be made.

Summary

Our experiments reconfirm the existence of a minimum in the corrosion rate/alkali concentration relationship for the high-temperature corrosion of iron (mild steel) in NaOH media.

The morphology of the oxide film produced in the corrosion reaction is a function of the NaOH concentration of the generating solution; concentrations below the corrosion minimum point (about 2 g/l) give a noncrystallographic oxide, those above, a crystallographic oxide.

That these morphological differences reflect two distinct growth mechanisms is shown by the fact that different activation energies are obtained with each, 5-8 kcal/mol for the noncrystallographic oxide and 16 kcal/mol for the crystallographic.

Drawing from these observations and the literature, we have concluded that the underlying phenomenon is a transition between passive and active corrosion states as described by Hoar (19), albeit at 300°C.

Acknowledgments

The authors are indebted to E. D. Osgood and R. W. Scott for their assistance in specimen preparation and to Dr. M. C. Bloom for a stimulating critique of the first draft of this paper.

Electrochemical Reduction of 6-Substituted Purines Correlation with Structural and Energetic Characteristics

Borivoj Janik and Philip J. Elving

The University of Michigan, Ann Arbor, Michigan

ABSTRACT

The electrochemical reduction of 6-substituted purines has been examined over the available *p*H range by direct- and alternating-current polarography, and the effects of substitution evaluated in respect to significant electrochemical characteristics. Where the 1,6 and 3,2 N=C bonds are available in the pyrimidine moiety, a four-electron polarographic wave due to hydrogenation of these bonds is observed; purine itself and 6-methylpurine give two two-electron waves. The energy-controlling step involves reduction of the protonated 1,6 N=C bond. The current is essentially diffusion controlled at low *p*H where the wave is relatively constant in height and kinetically controlled at higher *p*H where it begins to disappear. Correlation of the ease of reduction, as measured by $E_{1/2}$, with total polar substituent constant (σ_p) and polar substituent constant (σ^*) indicates either an absence of mesomeric and steric effects due to the substituents or their transmittal by an inductive mechanism and, further, that none of the substituents exerts any specific effect different from those exerted by the other substituents. Substitution in the 6-position influences mostly the N(1)-C(6) bond order and the electronic charge distributions on N(1) and N(3), which, in turn, largely determine the reducibility; $E_{1/2}$ correlates linearly with the quantum mechanically calculated magnitudes of these quantities, but not with other bond orders and charges. $E_{1/2}$ also correlates linearly with electron-acceptor properties as represented by the calculated energy of the lowest empty molecular orbital (k_i coefficients) and with pK_a for proton acquisition (the protonation, which occurs prior to electron transfer, seems to have no significant role in the potential-determining step except in the region where the wave has nearly disappeared). Isoguanine generally deviates from the various correlations. Adsorption involving an uncharged site in the molecule is markedly greater with derivatives having bulky substituents.

The polarographic behavior of purine and some of its derivatives at the dropping mercury electrode, D.M.E., has been investigated (1-14). However, no systematic study of the electrochemical reduction of 6-substituted purines has been made in spite of their importance; the naturally occurring purines are, with few exceptions, substituted in that position, including major and minor purine constituents of nucleic acids.

Among the reasons for investigating the electrochemical behavior of biologically important compounds are the development of possible correlations based on the implicit or explicit postulation that the mechanistic paths involved and the characteristic potentials associated with them, *e.g.* half-wave potentials ($E_{1/2}$), are a function of electron density and other factors, which are also relatively simply related to some biological, clinical, physical, or chemical property and activity (15, 16). The resulting frequently linear relationship between $E_{1/2}$ for a series of more or less closely related compounds and a suitably selected mathematical function of the values of the given property for that series of compounds permits (*a*) prediction of the magnitude of the property of a compound from its readily measured $E_{1/2}$ and (*b*) the rapid comparative evaluation of a property based on comparison of $E_{1/2}$ values. Furthermore, correlation of $E_{1/2}$ with structural, reactivity, and other characteristics may provide a better understanding of the effect of structure on the redox behavior of purines and related heterocyclic compounds (17).

The present study covers purine and nine 6-substituted purines (*cf.* Fig. 1 for structure and numbering), largely involving amino functions, since only those 6-substituted purines were investigated whose substituent is unlikely to remove by tautomeric shift the 1,6 N=C bond, which is the more readily reduced of the two possible electrochemical reduction sites (1,6 N=C and 3,2 N=C) in purines (18). The objectives of the study were to gather sufficient information to define the essential features of the electrochemical behavior of the series and the effect of structure on such behavior, and to examine the validity of using potential data obtained under comparable conditions for correlation purposes in view of the somewhat complex set of factors involved in the electrochemistry of purines at mercury electrodes.

Experimental

Chemicals.—Purines from the sources indicated were used: adenine, 6-methylpurine and 6-methylaminopurine (A grade), and 6-n-hexylaminopurine and 6-methoxypurine (C grade) from Calbiochem; 6-benzylaminopurine, 6-phenylaminopurine, 6-dimethylaminopurine, and isoguanine sulfate monohydrate (the latter two in M.A. grade) from Mann Research Laboratories; the reported analytical data indicated sufficient purity for polarographic study. Stock solutions (0.5-5 mM in distilled water) were stored in a refrigerator; where ultraviolet absorptivities were available, the concentration was checked spectrophotometrically.

The following buffer systems, prepared from analytical grade chemicals (J. T. Baker), were used at an ionic strength of 0.5 (*p*H regions in parentheses): KCl + HCl (1-2); Na_2HPO_4 + citric acid + KCl, *i.e.* constant ionic strength McIlvaine buffers (19), (2.5-7.8); NaOAc + HOAc (3.9-5.9); NH_4Cl + NH_3 (8.5-9.1); K_2CO_3 + KOH (9.2-10).

Nitrogen used for deoxygenating was purified and equilibrated by bubbling it successively through vanadous chloride solution in dilute HCl containing heavily amalgamated mossy zinc (20), NaOH solution, and water.

Apparatus.—Polarograms were recorded on a Sargent Model XV Polarograph, using capillary A and a water-jacketed H-cell, maintained at 25.4° ± 0.1°C and containing in one leg a saturated calomel reference electrode (S.C.E.), which was separated from the test solution by a glass frit and agar plug. The height of mercury reservoir, *h*, was 64 cm, unless otherwise

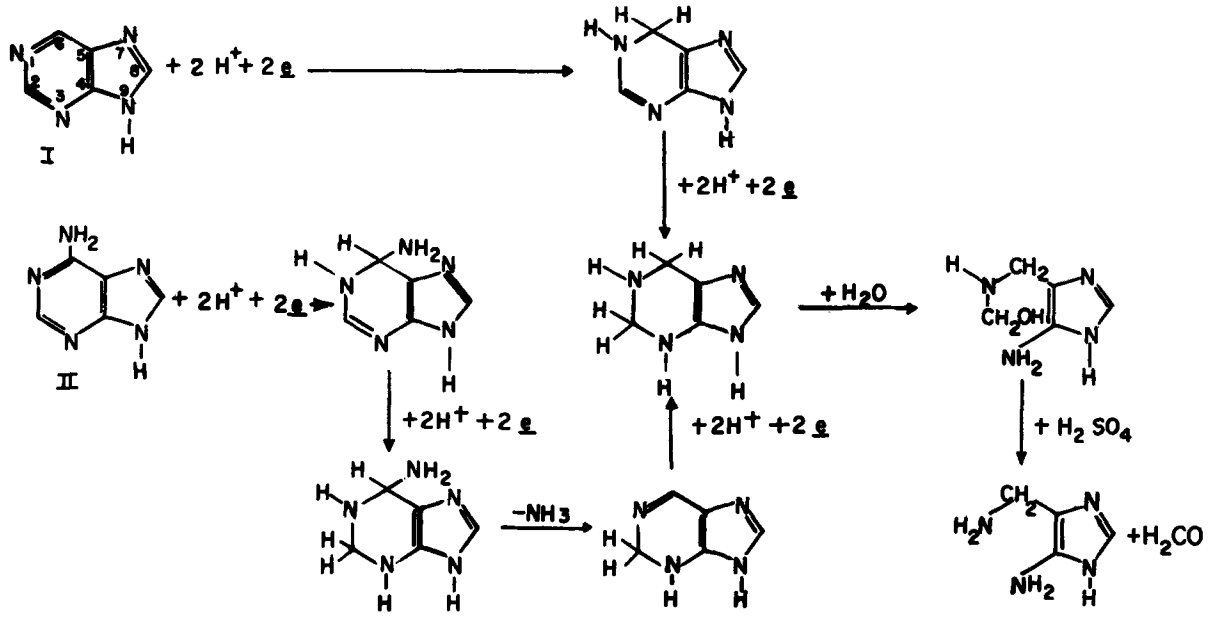

Fig. 1. Interpretation of the electrochemical and chemical behavior observed on polarographic reduction of purine (I) and adenine (II). Protonation, dissociation, and other acid-base and keto-enol equilibria, which may be involved, are not shown. Numbering is that of Chemical Abstracts.

stated. Capillaries (marine barometer tubing) had m values in distilled water (open circuit, 25°C) at 64 cm Hg of (A) 2.69 and (B) 2.22 mg/sec. Drop-times, measured at potentials of interest, were generally between 3 and 4 sec.

Current-time curves on a single drop, obtained with capillary B (h = 64 cm), were observed with a Tektronix Type 502 oscilloscope, whose traces were photographed on a Tektronix C-12 camera using 3000 speed Type 47 Polaroid film.

An operational amplifier-based polarograph (21) was used for alternating current polarography in conjunction with capillary B and an alternating voltage of 50 Hz and 4 mv rms amplitude.

pH was measured with a Beckman Model G pH meter.

Procedures.—Conventional procedures were used to obtain the experimental data; potentials are *vs.* S.C.E. The d-c polarographic measurements were made on 0.125 mM depolarizer solution except for isoguanine (0.25 mM) or as otherwise noted. Test solution pH was measured after diluting stock solutions to the desired depolarizer and buffer concentrations, and after polarographic measurement.

Polarographic data for purine were taken from Ref. (8) and (22).

A-C polarographic measurements were made on 0.25 mM purine solutions in pH 2.5 McIlvaine buffer. Current magnitudes given in Fig. 7 correspond to those measured at the end of the drop-life or before an abrupt current increase just previous to the fall of the drop. Current attenuation was 10%.

Observed Behavior

D-C polarography.—All 6-substituted purines examined show polarographic behavior comparable to those of the parental compounds, purine and adenine. Purines having substituted amino or methoxy groups at the 6-position exhibit a fairly well defined reduction wave similar to adenine (Table I); the diffusion current constants recorded under similar conditions are equal within ±8% and correspond to those of a four-electron (4e) faradaic process. 6-Methylpurine, similar to purine, shows two nearly equal waves, the sum of whose diffusion current constants equals that of the other 6-substituted purines. The diffusion current constant of isoguanine, whose behavior generally differs from that of the other 6-substituted purines, is about one-half of that of the latter.

Effect of pH and buffer components.—$E_{1/2}$ becomes more negative with increasing pH (Table I), while the wave height (sum if two waves appear) is relatively constant to about pH 5-6, when it sharply decreases, to vanish by pH 7-8 (Fig. 2-4), except for isoguanine, whose wave height remains practically constant up to

Table I. Diffusion current constants and variation with pH of $E_{1/2}$ for polarographic reduction of 6-substituted purines

Substituent (pK_a)	Potential variation[a]			
		pH	$E_{1/2}$, V	I^k
6-Hydrogen (purine; 2.30)	I	2-6	−0.697-0.083 pH	10.1[i]
	II	2-6	−0.902-0.080 pH	
6-Methyl (2.50)	I	1.0-3.9	−0.820-0.079 pH	8.5[i]
		3.9-6.0	−0.745-0.091 pH	
	II	2.5-6.0	−0.915-0.082 pH	
		3.9-5.9	−0.765-0.162 pH[b]	
	III	6.0-7.4	−0.785-0.095 pH	
		7.4-7.8	+0.080-0.209 pH	
6-Methoxy (2.17)		2.5-4.2	−0.825-0.105 pH	8.5

		7.2-9.6	−1.210-0.055 pH	
		8.5-9.1	−0.705-0.104 pH[g]	

[a] Roman numbers indicate successive polarographic waves: potentials are *vs.* S.C.E. Data for purine taken from Ref. (8) and (9).
[b] Acetate buffer.
[c] Very ill-defined wave, which merges with background above pH 4.5.
[d] Since the normal and abnormal waves almost merge, only $E_{1/2}$ corresponding to their total height can be estimated.
[e] Maximum on the rising portion of the wave. $E_{1/2}$ is not changed after the maximum is suppressed by Triton X-100 addition.
[f] Maximum on the crest of the wave in pH range indicated. $E_{1/2}$ is not changed after the maximum is suppressed by Triton X-100 addition.
[g] Ammonia buffer.
[h] Diffusion current constant, $I = i_l/Cm^{2/3}t^{1/6}$, was calculated from average current data in that pH region, usually between pH 2.5 and 4.5 in McIlvaine buffer, where i_l varied least with pH.
[i] Calculated from the total current of the two reduction waves.

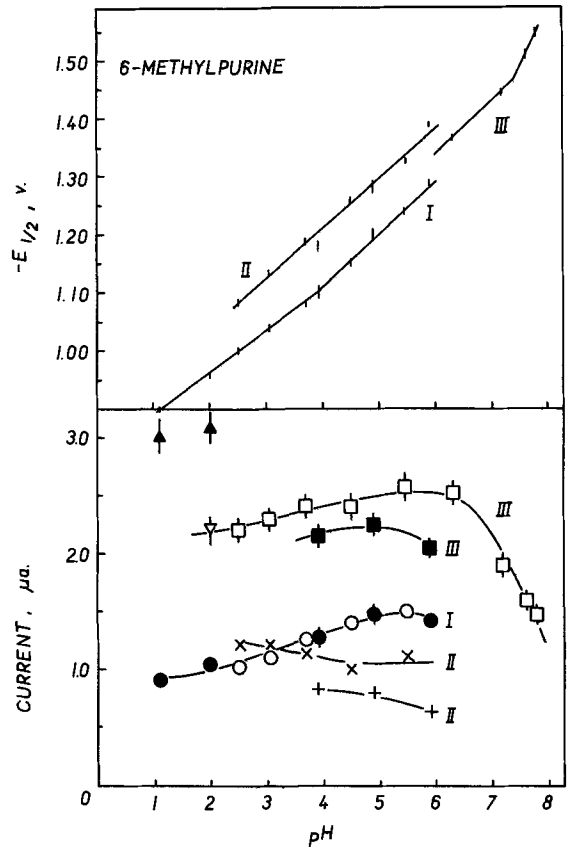

Fig. 2. Variation with pH of $E_{1/2}$ and limiting current of polarographic waves of 6-methylpurine (0.125 mM). (I) First reduction wave: circles, McIlvaine buffer; solid circles, chloride and acetate buffers. (II) Second reduction wave: crosses, McIlvaine buffer; pluses, acetate buffer. (III) Sum of I and II or third wave, which appears as a result of I and II merging: squares, McIlvaine buffer; solid squares, acetate buffer; solid triangles, II with a maximum on II; reversed triangles, III after suppression of maximum on II by Triton X-100 addition. Currents and potentials are plotted with a range of ± 5% and ± 5 mV, respectively, *i.e.* estimated average experimental errors.

pH 9, at which pH it suddenly drops (a small depression occurs in the *i*-pH plot at *ca.* pH 3.5) (Fig. 5). Plots of $E_{1/2}$ *vs.* pH for the normal reduction wave (two waves in case of 6-methylpurine) generally consist of two or three linear segments; 6-methylaminopurine gives a single line. The heights of the two 6-methylpurine waves are pH-dependent; wave I increases and wave II decreases with increasing pH; the waves merge at pH 6 to form wave III and their total height, which has been essentially constant, now decreases with increasing pH.

Buffer composition either has no influence on wave height, *e.g.* 6-methoxypurine and 6-methylpurine wave I, or shifts the descending part of the *i*-pH plot to lower pH in acetate than in McIlvaine buffer, *e.g.* 6-methylamino-, 6-n-hexylamino-, 6-phenylamino-, and 6-dimethylaminopurines.

$E_{1/2}$ values recorded in chloride and acetate buffers generally fall on the $E_{1/2}$-pH plot for McIlvaine buffer. In the alkaline region, $E_{1/2}$ values for isoguanine in McIlvaine and carbonate buffers fit the same line, while those in ammonia buffer are more positive.

Effects of concentration and drop-time.—The wave heights of 6-benzylamino-, 6-phenylamino-, and 6-n-hexylaminopurines are directly proportional to concentration (0.01-0.15 mM) in pH 4.9 acetate buffer, in which their $E_{1/2}$ values are independent of concentration while the diffusion current constants decrease by 10-20%; the ratio of $i_l/h^{1/2}$, where h is the mercury column height, increases slightly with increasing h. The $i_l/h^{1/2}$ ratio for 0.25 mM 6-methylaminopurine at pH 2.5 is roughly independent of h, and for isoguanine is independent of h at pH 2.5-3.7 and decreases slightly with increasing h at pH 1.1.

More extensive mercury height dependency studies were not made in view of the uncertainties in the case of waves close to background discharge, particularly in the presence of another more negative wave.

Maximum and its suppression.—All compounds examined, except 6-methylpurine, produce between pH 1 and 2 a maximum on the rising part of the wave, which more or less affects the wave plateau; the maximum decreases and finally disappears with increasing pH. 6-Dimethylamino- and 6-phenylaminopurines also produce maxima in McIlvaine but not in acetate buffer, below pH 4.3 and 4.7, respectively.

Triton X-100, even in concentration below 0.001%, completely suppresses the maxima and is more efficient at higher pH. $E_{1/2}$ of a wave with a just suppressed maximum is up to 10 mV more negative with the exception of 6-methoxypurine, whose $E_{1/2}$ shifts up to 20 mV more positive. The 6-phenylaminopurine wave height, which can be measured even in presence of the maximum above pH 2, is not altered on addition of just sufficient Triton to suppress the maximum; higher Triton concentrations, however, depress the wave height. In the absence of a maximum, Triton addition shifts $E_{1/2}$ 20-30 mV more negative and depresses the wave height by 0-20% per 0.001% Triton; these effects are less at higher pH.

Additional wave.—In addition to the normal reduction wave described, 6-methylamino-, 6-hexylamino-, and 6-benzylaminopurines exhibit, similar to adenine (22), a more negative wave in a limited pH region (the former two compounds below pH 3.7; the latter in pH 2.0 chloride buffer only), which is usually hard to define due to its merging either with background discharge, *e.g.* at pH 1.0, or with the normal wave at higher pH. Isoguanine forms a second more negative wave below pH 5, which is readily defined and decreases sharply with increasing pH.

The height of the normal reduction wave of 6-methylaminopurine, 6-n-hexylaminopurine, and isoguanine is depressed in the pH region where the second wave exists.

0.0006% Triton X-100 completely removes the second 6-benzylaminopurine wave without altering the normal wave, but decreases both 6-n-hexylaminopurine waves by 25 and 60% at pH 1.0, and 0 and 20% at pH 2.5. Triton is more effective at higher pH, *e.g.* 0.0012% completely eliminates the second 6-methylaminopurine wave in pH 3.7 buffer; in pH 2.5 and 3.0 buffer, it decreases the second wave by 20 and 50%, and the normal wave by 35 and 8%, respectively. $E_{1/2}$ of the first and second waves of 6-n-hexylamino- and 6-methylaminopurines are shifted *ca.* 10 mV and 0-5 mV more negative, respectively, per 0.0006% Triton, consequently, the waves first merge with each other and then with background discharge as the Triton concentration increases.

This additional wave is apparently due to streaming of the solution past the D.M.E. and reduction of a depolarizer, which is produced by the normal wave reduction product in a chemical step (23). This wave is, consequently, not specifically discussed except insofar as it affects the prior normal purine reduction wave. The second isoguanine wave, as indicated by its large current-concentration ratio and marked increase with decreasing pH (Fig. 5), is probably due to a catalytic hydrogen discharge.

Calculation of αn_a and p.—Values of αn_a (product of transfer coefficient and number of electrons involved per molecule of reactant in the rate-determining step of the electrode process) and of p (number of hydrogen ions involved per molecule of reactant in the rate-determining step) were calculated on the basis of Eq. [1] and [2] [*cf.* Chapter 4 of Ref. (20) for justification] and are summarized in Table II:

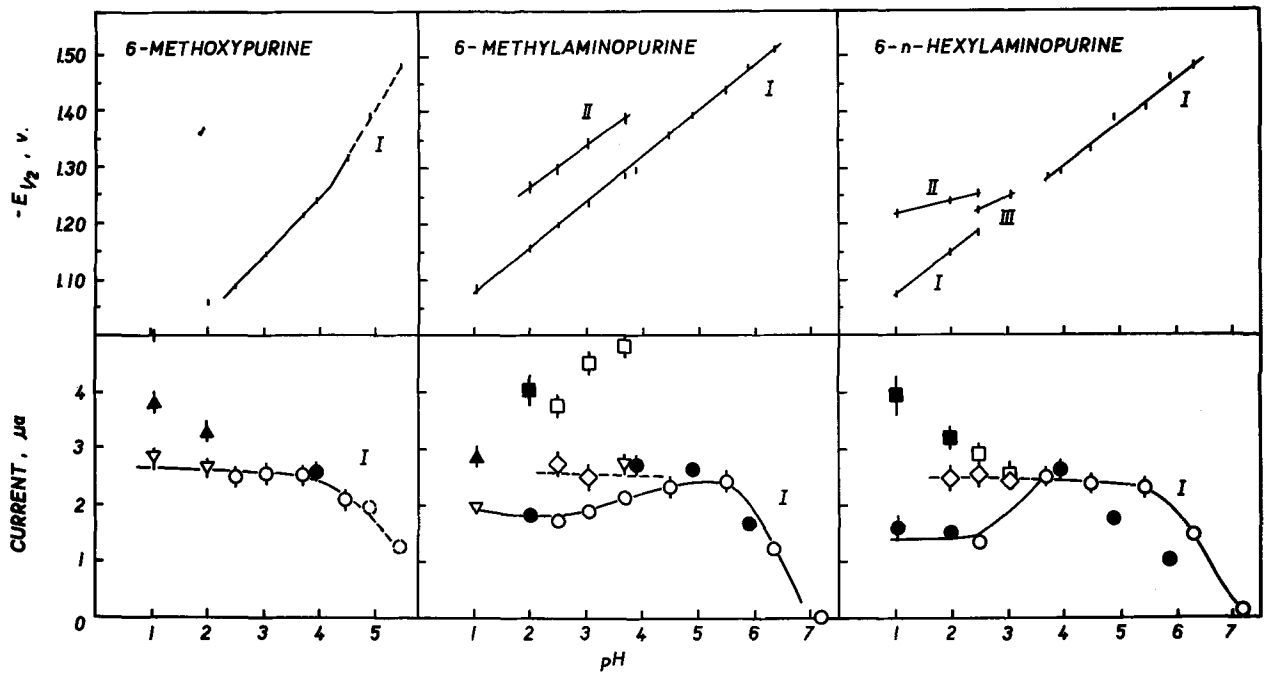

Fig. 3. Variation with pH of $E_{1/2}$ and limiting currents of polarographic waves of 6-methoxypurine, 6-methylaminopurine, and 6-n-hexylaminopurine (0.125 mM). (I) Normal reduction wave: circles, McIlvaine buffer; solid circles, chloride and acetate buffers; solid triangles, maximum in chloride buffer; reversed triangles, suppressed maximum or abnormal wave by Triton X-100 addition. (II) Abnormal reduction wave. (III) Sum of I and II: squares, McIlvaine buffer; solid squares, chloride buffer; diamonds, III suppressed to a constant height or III with I and II merging due to Triton X-100 addition (up to 0.002%). Currents are plotted with a range of ± 5% (I) and ±7% (III), and potentials with a range of ± 5 mV (I) and ± 10 mV (II), *i.e.* estimated average experimental errors, unless the deviation exceeds the average.

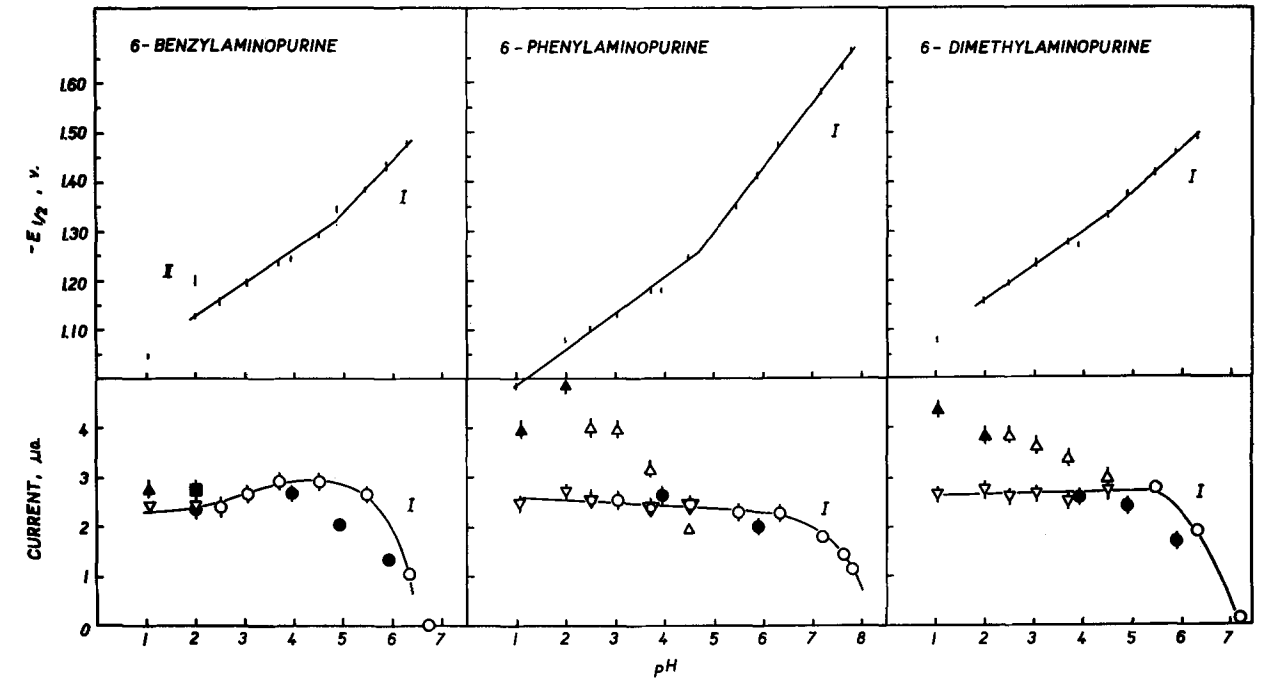

Fig. 4. Variation with pH of $E_{1/2}$ and limiting currents of polarographic waves of 6-benzylaminopurine, 6-phenylaminopurine, and 6-dimethylaminopurine (0.125 mM). (I) Normal reduction wave: circles: McIlvaine buffer; solid circles, chloride and acetate buffers; triangles, maximum in McIlvaine buffer; solid triangles, maximum in chloride buffer; reversed triangles, suppressed maximum or abnormal wave by Triton X-100 addition. (II) Abnormal wave. (III) Sum of I and II: solid squares, chloride buffer. Currents are plotted with a range of ± 5% (I) and ± 7% (III), and potentials with a range of ± 5 mV (I) and ± 10 mV (II), *i.e.* estimated average experimental errors, unless the deviation exceeds the average.

$$E_{1/4} - E_{3/4} = 0.0517/\alpha n_a \qquad [1]$$

$$d(E_{1/2})/d(\mathrm{pH}) = -0.05915\, p/\alpha n_a \qquad [2]$$

Values of αn_a, calculated for adenine and 6-methylaminopurine from the following equation, proposed by Oldham and Parry (24),

$$\frac{0.0592}{\alpha n_a} \log \left[\frac{2x(3-x)}{5(1-x)} \right] = E_{1/2} - E \qquad [3]$$

where x is the ratio of the current at potential E to the limiting current, are identical within experimental error with those obtained from Eq. [1].

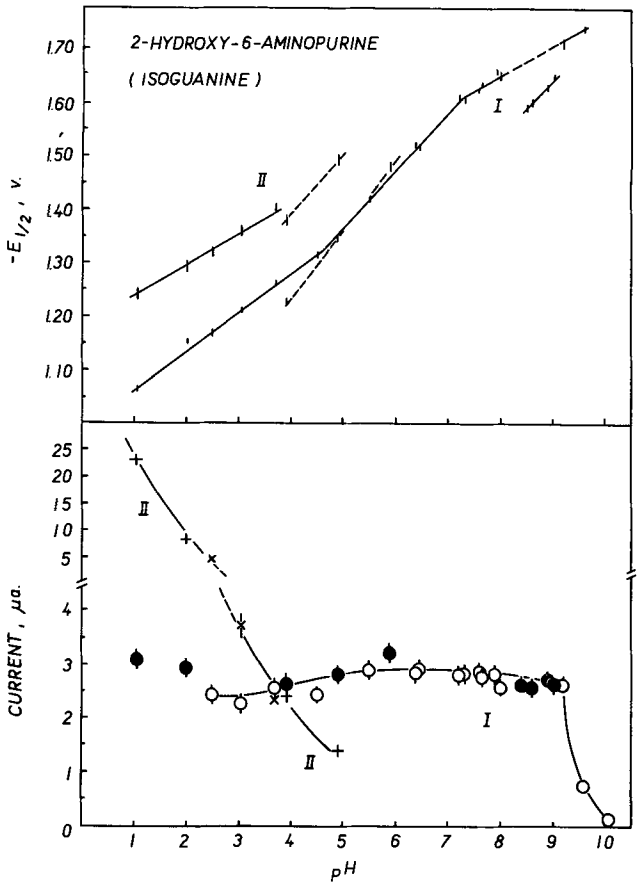

Fig. 5. Variation with pH of $E_{1/2}$ and limiting currents of polarographic waves of isoguanine (2-hydroxy-6-aminopurine) (0.25 mM). (I) Normal reduction wave: circles, McIlvaine and carbonate buffers; solid circles, chloride, acetate, and ammonia buffers. (II) Abnormal wave: crosses, McIlvaine buffer; pluses, chloride and acetate buffers. Currents are plotted with a range of ± 5% (I) and ± 7% (II), and potentials with a range of ± 5 mV (I) and ± 10 mV (II), *i.e.* estimated average experimental errors.

Values of αn_a and p cannot be meaningfully calculated for 6-benzylaminopurine below pH 2.5 and for 6-phenylaminopurine; in the former case αn_a sharply decreases with increasing pH up to *ca.* pH 2.5, probably due to the concomitant presence of an additional wave current in the normal reduction wave; in the latter case, maxima are present (up to pH 4.5), which cannot be suppressed by Triton X-100 addition without a change in wave slope. The high αn_a values for 6-methylpurine wave I may be due to the proximity of wave II ($E_{1/2}$ values are only 85 mV apart). Similarly, the normal and abnormal waves of 6-n-hexylaminopurine almost merge at pH 2.5-3.7.

Table II. Effect of pH on the rate-determining step in the polarographic reduction of 6-substituted purines

Substituent		pH	αn_a[a]	p[a]
6-Methyl	I	1.0-6.0	1.64 ± 0.08	2.33 ± 0.08
	II	2.0-6.0	0.99 ± 0.12	1.46 ± 0.10
		3.9-4.9[b]	1.11 ± 0.05	2.01 ± 0.09
	III	6.0-7.5	0.80 ± 0.02	1.20 ± 0.03
6-Methoxy		1.0-3.9	1.18 ± 0.16	2.10 ± 0.30
		3.9-4.5	0.77 ± 0.01	1.35 ± 0.01
6-Amino		2.0-2.5	1.36 ± 0.09	1.91 ± 0.14
		2.5-6.5	1.09 ± 0.07	1.54 ± 0.08
		3.9-4.9[b]	0.86 ± 0.08	1.22 ± 0.10
6-Methylamino		2.0-3.8	1.52 ± 0.08	2.07 ± 0.12
		3.8-6.5	1.00 ± 0.09	1.36 ± 0.12

6-Dimethylamino		1.0-6.4	1.25 ± 0.10	1.60 ± 0.16
2-Hydroxy-6-amino		1.0-4.2	1.05 ± 0.04	1.35 ± 0.06
		4.2-7.2	1.11 ± 0.16	1.96 ± 0.17
		7.2-9.6	1.22 ± 0.13	1.13 ± 0.13

[a] Data consist of mean and standard deviation. See text for method of calculation and discussion of experimental error.
[b] Acetate buffer only.

The data need to be interpreted with caution in view of the normal variation in measuring wave slopes; the standard deviations in Table II for αn_a, which also affect p, are of the order of 5-12%, due—at least in part—to the experimental error in estimating potential (*cf.* captions to Fig. 2-5). However, certain regularities are apparent, *e.g.* αn_a decreases with increasing pH, which may indicate decreasing reversibility and/or a decreasing number of electrons involved in the rate-determining step; however, since n_a is probably 1 or 2, the latter is unlikely. The apparent increase for wave II of 6-methylpurine is within experimental error; isoguanine, as usual, differs.

All 6-substituted purines examined, with the exception of isoguanine, seem to have two protons involved in the rate-determining step below *ca.* pH 4 with generally a lesser number at higher pH.

Current-time curves.—The variation of current with time during the life of a single drop (i-t curves) was recorded for sequential drops from a vertical capillary. Due to the depletion of the solution surrounding the drop (25), i-t curves obtained under such conditions produce log i *vs.* log t plots, which are convex to the time axis so that the choice of the slope is ambiguous. Such i-t curves cannot be used to estimate the extent of diffusion control; however, the instantaneous current would be expected to show a depression for an adsorption process (25, 26). Curves recorded at the limiting portion of the normal wave for 0.25 mM solutions of purine derivatives at pH 2.5 do not show any such depression.

Curves of i-t taken at the top of the maximum formed on the rising portion of the 6-phenylaminopurine reduction wave are very distorted (Fig. 6) and cannot be analyzed. Undistorted i-t curves are obtained on the limiting portion of the normal wave at potentials more negative than the foot of the maximum. The distorted shape of the i-t curve at a potential on the 6-phenylaminopurine maximum is usual for maxima of the second kind (25), while the position of the maximum on the rising portion of the polarographic wave corresponds to a maximum of the first kind (20); at present, this anomaly cannot be explained.

Distorted i-t curves, which are also obtained on the limiting portion of the second adenine and 6-methylaminopurine waves at drop times varying from 2 to 4.5

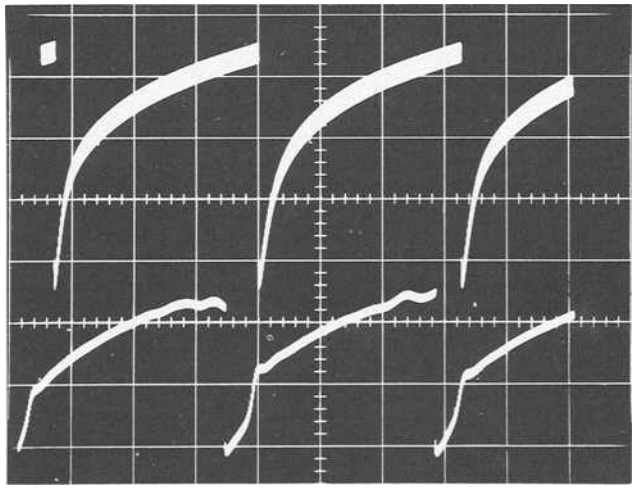

Fig. 6. Current-time curves for 0.25 mM 6-phenylaminopurine in pH 2.5 McIlvaine buffer. Upper curves taken at —1.25V (on limiting current portion of the normal reduction wave) with capillary B: x axis, 1 sec/(large) division; y axis, 2 μa/div. Lower curves taken at —1.17V (on maximum appearing on the normal reduction wave): x axis, 1 sec/div; y axis, 5 μa/div.

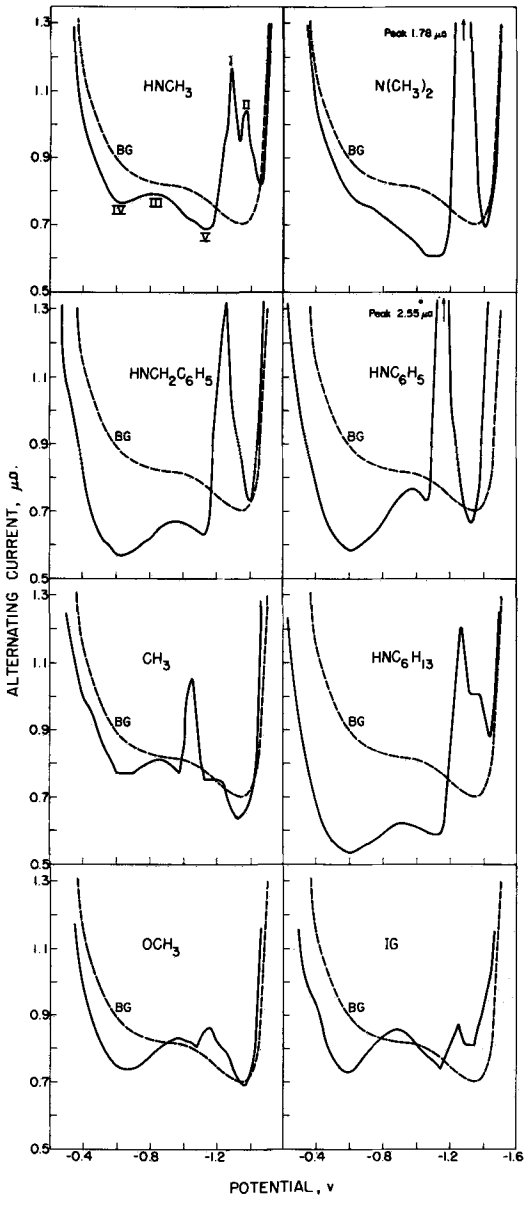

Fig. 7. Alternating current polarograms for 0.25 mM 6-substituted purines in pH 2.5 McIlvaine buffer; substituents are indicated. IG = isoguanine. Background electrolyte base current is marked BG.

sec (h = 36-81 cm), indicate that these waves are not diffusion controlled.

Alternating-current polarography.—A-C polarograms of all derivatives examined (Fig. 7) show a common pattern. A reduction peak (I) is seen in the potential region corresponding to that of the normal polarographic wave (Table III). In the case of 6-methylaminopurine, a new peak (II) appears at more negative potential than peak I with a height about 0.5 of that of peak I; 6-n-hexylaminopurine and 6-methylpurine exhibit a shoulder on the negative side of peak I. The base current is depressed below that of the supporting electrolyte at potentials more positive than that of peak I and usually forms two minima (IV and V) at about —0.6 and —1.1V, which are separated by a broad peak (III) at about —0.9V.

Depression of the base current below that of the background at potentials more negative than E_s of peak I was observed only with 6-phenylaminopurine and, more pronouncedly, with 6-methylpurine.

Peak III overlaps the background base current only in the cases of 6-methoxypurine and isoguanine. In the potential region where peak I appears and at more negative potentials, abnormal current increases are observed, when the mercury drop is about to fall, which could be due to hydrogen ion discharge catalyzed by the reduced form of the purine and/or streaming of the solution past the D.M.E. surface.

Reduction Mechanism and Structural Factors

The two *p*H-dependent polarographic waves of purine itself are due (8) to 2*e* reduction of the 1,6 N=C double bond to 1,6-dihydropurine, followed by a further 2*e* reduction, probably to 1,2,3,6-tetrahydropurine, which hydrolyzes to a 4-aminoimidazole (equations in Fig. 1). Under the conditions of macroscale electrolysis, the electrolytic reduction of adenine parallels that of purine for an over-all 6*e* reduction: 2*e* hydrogenation of the 1,6 N=C bond at a potential more negative than that of both purine waves is immediately followed by 2*e* reduction of the 2,3 C=N bond, slow deamination at the 6-position, further 2*e* reduction of the regenerated 1,6 N=C bond, and hydrolytic cleavage at the hydrogenated 2,3 position to give the same product as the over-all 4*e* purine reduction; however, at the D.M.E., the extent of deamination of the reduced adenine is negligible, resulting in a single *p*H-dependent 4*e* wave (8) (equations in Fig. 1).

The present results confirm the preceding; polarographic reduction of purines generally involves 4*e* hydrogenation of the 1,6 and 3,2 N=C bonds in the pyrimidine moiety, when such double bonds are not removed from the ring due to tautomeric shifts, which favor oxygen in a keto form and amino nitrogen in the amino form (27, 28). 6-Methylpurine resembles the parental purine in being reduced in two separate 2*e* waves, while 6-alkylamino-, 6-dialkylamino-, 6-phenylamino-, and 6-methoxypurines behave similarly to adenine (6-aminopurine).

Current control.—Diffusion as the principal factor controlling the reduction wave current is supported by the $i_l/h^{1/2}$ *vs.* h plots, which are generally independent of h, and by temperature coefficients, which range from 1.5 to 2.5%, *e.g.* for adenine and 6-methylaminopurine in *p*H 3.0 McIlvaine buffer. However, dif-

Table III. Comparison of a-c and d-c polarographic data for 6-substituted purines[a]

Substituent		Normal wave			Abnormal wave		Minimum[d]	
		i_s, μa	$-E_s$, V	$E_{1/2} - E_s$, mV	$-E_s$, V	$E_{1/2} - E_s$, mV	$-E_{min}$, V	i_{min}, μa

[a] Measured on 0.25 mM depolarizer solution in pH 2.5 McIlvaine buffer.
[b] Shoulder.
[c] A minimum, whose current is about 0.1 μa higher than the background base current.
[d] Minimum in the a-c curve indicated as IV in Fig. 7; current given is that below background electrolyte current.

fusion is not the only factor involved; a minor amount of kinetic control is present, *e.g.* the normal reduction wave is almost fully kinetically controlled in the *p*H region where the limiting current decreases and reaches about one tenth of the original value.

Effect of substituent nature.—$E_{1/2}$ of the 6-substituted purines becomes more negative in the following order (substituent in 6-position indicated; since $E_{1/2}$ is *p*H-dependent, data at *p*H 2.5 and 4.0 were chosen for reasons subsequently discussed): H, CH_3, CH_3O, C_6H_5NH, $C_6H_5CH_2NH$, (isoguanine), n-$C_6H_{13}NH$, $(CH_3)_2N$, NH_2, and CH_3NH at *p*H 2.5, and H, CH_3, C_6H_5NH, CH_3O, $C_6H_5CH_2NH$, (isoguanine), $(CH_3)_2N$, n-$C_6H_{13}NH$, CH_3NH, and NH_2 at *p*H 4.0.

Substitution in the 6-position with electron-repelling groups decreases the ease of reducibility of the parent purine with the magnitude of the effect increasing with increasing electron repellency (basicity) of the substituent; the effect of the amino group can be counterbalanced by electron-withdrawing substituents on that group. This is generally consistent with the order of electron-repellent groups, *e.g.* methyl < methoxy < arylamino < amino $\gtrless$ alkylamino (29), which increases the electron density at neighbor atoms due to the inductive effect (29), and with the order of increasing basicity of amines, *e.g.* $C_6H_5NH_2$ (pK_a for dissociation of the protonated amine = 4.6), NH_3 (9.24), $C_6H_5CH_2NH_2$ (10.33), $C_6H_{13}NH_2$ (10.56), CH_3NH_2 (10.66), and $(CH_3)_2NH$ (10.73) (30).

The presence of an amino or substituted amino group in the 6-position seems to be a necessary but not sufficient factor for the appearance of the abnormal polarographic wave mentioned, which may involve the adsorbed reduced form of the purine, *e.g.* Ref. (8) and (9); other factors involved are now under study (23).

Nature of reducible species.—The need for protonation prior to reduction, *i.e.* the presence of the conjugate acid of the purine as the polarographically reducible species, and the probability of the proton being intimately connected with N(1) of the pyrimidine moiety, are supported by the following:

(*A*) The reducibility, represented by $E_{1/2}$, is inversely proportional to pK_a for the addition of a proton to the purine (cf. below).

(*B*) Plots of limiting current *vs.* *p*H (Fig. 2-4) exhibit a sigmoidal decrease in current centering at a *p*H generally 2-3 units greater than the pK_a value of the purine. The current also shows kinetic control in this *p*H region. Such behavior is characteristic of the polarographic reduction of the acid form of a conjugate acid-base equilibrium as a result of the recombination of the nonprotonated form with protons. A depression, observed below *p*H 4 on the *i*-*p*H plot for 6-methylamino- and 6-n-hexylaminopurines, is due to the presence of the second (abnormal) wave, whose rising portion masks the limiting portion of the normal wave, so that its measured height is lower than the actual one.

(*C*) In a series of related compounds, reduction may be expected to be more difficult as the electron density at the reduction site increases. The fact that $E_{1/2}$ does become more negative as the net negative charge on N(1) and the pK_a value increase (cf. below) supports the association of the energy-controlling step of purine reduction with the 1,6 N=C bond (8) and with the site of protonation which is N(1); the latter is the most basic nitrogen in adenine (15, 16, 27) and presumably in other closely related 6-substituted purines. Correlations of reducibility with negative charge on N(1) and pK_a are also valid for the protonated species, since the net positive charge on N(1) is inversely proportional to the net negative charge of the nonprotonated form.

Adsorption of reactant and product.—All 6-substituted purines examined exhibit an a-c reduction wave at *p*H 2.5, whose summit potential, E_s, is 50-90 mV more negative than the corresponding $E_{1/2}$ (Table III; Fig. 7), which indicates that the oxidized and reduced forms of the depolarizer are not equally strongly adsorbed in the $E_{1/2}$ potential region (31). The similarity in d-c polarographic behavior of purine and 6-methylpurine, *e.g.* both give 2*e* waves, is also observed under a-c conditions; purine gives two a-c peaks (21, 32) with the smaller more negative peak corresponding in potential to a shoulder on the negative side of the main 6-methylpurine peak.

In general, the base current is deeply depressed at potentials positive to the a-c peak, indicating strong adsorption of the oxidized form, whereas at more negative potential, *i.e.* on the limiting current portion of the d-c wave, the depression of the a-c current is very small or zero; however, the lack of such depression need not mean that the reduced form is not appreciably adsorbed. Since the main a-c peak is located at moderately negative potential, the background discharge could begin before the main peak current drops below the background base current. The shift of background discharge to more positive potential in the presence of some 6-substituted purines (Fig. 7) and the second (abnormal) wave process of 6-amino-, 6-methylamino-, and 6-n-hexylaminopurines and isoguanine may contribute to the masking of the depression on the negative side of the main peak. Only 6-methylpurine, whose E_s is 0.1-0.2V more positive than those of the other purines, shows such depression on both sides of the main peak, which indicates that the oxidized and reduced forms are adsorbed to a comparable extent.

The base current for 6-substituted purine solutions in the potential range more positive than the a-c reduction peak forms two minima (Fig. 7), the more positive of which is near the potential of zero charge of the D.M.E., indicating that an uncharged species is predominantly adsorbed. Since pK_a for the 6-substituted purines fall in the range of 2.2-4.5, the protonated, *i.e.* positively charged, species is predominant at *p*H 2.5 and, consequently, an uncharged portion of the purine molecule is involved in the strong adsorption at —0.6V. The broad desorption peak and the consequent adsorption minimum, which indicate first decreasing effect due to adsorption and then increasing effect with increasing negative potential, are probably caused by the adsorbed molecule gradually rearranging its position on the surface so that the positively charged site of the molecule is now attached to the D.M.E. surface, rather than being due to an uncharged form of the molecule being desorbed and replaced by a protonated form.

Only in the cases of methoxypurine and isoguanine, whose desorption peaks exceed the base current of the supporting electrolyte itself, is the rearrangement apparently accompanied by complete desorption of an adsorbed species. Absence of the desorption peak and presence of the deep minimum at —1.1V in 6-dimethylaminopurine are likely due to the protonated form being relatively stronger adsorbed than the uncharged form.

The order of uncharged site-controlled adsorbability of 6-substituted purines [cf. depths of the more positive minima (Table III)] indicates that purines with more bulky substituents are more extensively adsorbed and/or cause greater changes in the double layer capacity, probably due to decreased aqueous solubility; the three derivatives, which exhibit by far the greatest adsorbability, are extremely insoluble in water, *i.e.* their saturated solutions are *ca.* 0.5 mM.

The abnormal d-c wave of 6-methylamino- and 6-n-hexylaminopurines has its a-c counterpart in a peak and in a shoulder, respectively, at potentials more negative than E_s of the main peak (Table III) at the same *p*H. The second, presumably catalytic, d-c wave of isoguanine has no a-c counterpart; however, the base current of isoguanine solutions at potentials

more negative than the main a-c peak is considerably elevated above the background base current and the latter is shifted to considerably more positive potential (Fig. 7), while the base current for solutions of other derivatives drops at least to the background base current; this may indicate a second faradaic process taking place at more negative potential than E_s of the main peak.

The derivatives, which exhibited a maximum on the d-c normal wave at pH 2.5 (6-dimethylamino- and 6-phenylaminopurines) also give an unusually high peak current (Table III).

Correlation of $E_{1/2}$ with Structural and Electronic Indexes

Half-wave potential data.—Since $E_{1/2}$ for 6-substituted purines is pH-dependent, data at pH 2.5 and 4.0 were compared for the following reasons: (*a*) Both pH values are available in the same buffer type (McIlvaine); (*b*) the purines are largely protonated at pH 2.5 and to a much lesser extent at pH 4, (even though the polarographic current is practically constant in the pH interval of 2.5-4); (*c*) values of $d(E_{1/2})/d(pH)$ are generally within the relatively narrow span of 0.067-0.084 V/pH in the pH range of 2-4; and (*d*) maxima do not appear above pH 2 except for 6-dimethylamino- and 6-phenylaminopurines, whose maxima at pH 2.5 are easily suppressed at only about 0.0007% Triton X-100.

In the case of purine and 6-methylpurine, which give two 2*e* waves, $E_{1/2}$ for the first wave was used on the basis that the initial energy-determining process both in the first 2*e* waves and in the 4*e* waves involves the identical reaction: attack on the 1,6 N=C double bond of the pyrimidine ring [*cf.* subsequent discussion and the initial 1*e* reduction observed for pyrimidine by d-c and a-c polarography (18, 33)].

The reliability of correlations of $E_{1/2}$ with experimental and calculated parameters, particularly the latter, depends on the calculations and measurements having been made on identical molecular species and for the proper reaction site. Theoretical calculations are generally based on an idealized gas-phase molecule and a reversible electron-transfer process. The assumption is made that, while solvation, irreversibility, and adsorption are complicated factors, they may be expected to operate uniformly in a closely related series; the usefulness of such correlations has been emphasized, *e.g.* Refs. (34) and (35). Thus, $E_{1/2}$ values for over-all irreversible polarographic reductions have frequently been correlated with MO and free energy indexes, *e.g.* Ref. (36) and (37).

In general, correlations of calculated MO and structure-reactivity indexes with experimental electron affinity values, *e.g.* $E_{1/2}$, and other properties, *e.g.* ultraviolet absorption maxima, must—for the time being —be considered as semiempirical, since there are no exact methods for calculation of MO and other parameters which involve all possible intra- and intermolecular effects. In any event, comparison of calculated values with $E_{1/2}$ for a series of related compounds may provide information on whether effects of the types mentioned operate with all individual derivatives to comparatively the same extent and on whether differences in $E_{1/2}$ due to structural changes have a counterpart in differences in MO and other indexes, and *vice versa.*

Linear free energy relations.—The physical basis for using $E_{1/2}$ values in linear free energy relations, *e.g.* the Hammett-Taft equations, is the fact that $E_{1/2}$ is a simple function of the logarithm of the heterogeneous rate constant for irreversible electrode processes or of the equilibrium constant for reversible electrode processes (17). Since the application of free energy relationships to the polarographic behavior of 6-substituted six-membered heterocyclic compounds analogous to the pyrimidine ring in which purine

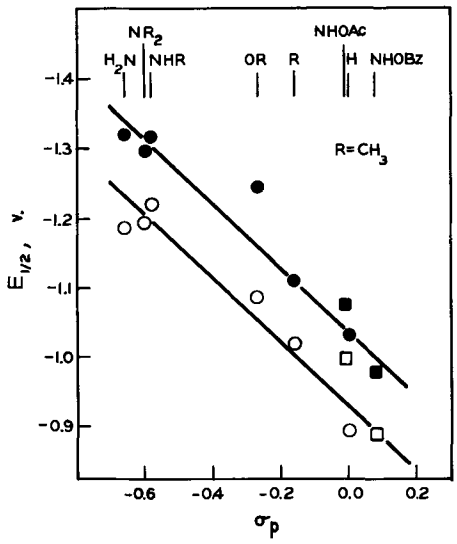

Fig. 8. Variation of $E_{1/2}$ of 6-substituted purines with the total polar substituent constant, σ_p (substituent indicated). $E_{1/2}$ determined in McIlvaine buffer (circles, pH 2.5; solid circles, pH 4.0); purine data from reference (8); 6-acetylamino- and 6-benzoylaminopurine data (squares, pH 2.5; solid squares, pH 4.0) from Ref. (14) (background not indicated). Slope, ρ, is 0.46V at pH both 2.5 and 4.0.

reductions occur has not been previously reported, a trial and error approach was used. Polar substituent constants were selected from the literature (38, 42); unfortunately, as was also true for the other parameters investigated, complete data are not available for all of the purines studied.

A fairly linear correlation is obtained in a plot (Fig. 8) of $E_{1/2}$ against total polar substituent constant, σ_p, which is dependent on the kind and position of the substituent, as well as to some extent on the nature of the aromatic ring, but is presumably independent of reaction and reaction conditions (17). Plots of $E_{1/2}$ against other constants, which are frequently used in modifications of the Hammett equation (17, 34, 42), do not result in reasonably linear correlations.

In the 6-substituted alkylaminopurines, the 1,6 N=C bond initially reduced polarographically is separated by an —NH— group from an alkyl or aryl group in a series of 6-alkylamino- or 6-arylaminopurines. As a rough approximation, the —NH— group may be considered analogous to the —CH_2— group in the sense of an additional atom being between the substituent and the reaction site, and $E_{1/2}$ may be plotted against polar substituent constant, σ^* (17, 39, 42); a linear relation is obtained (Fig. 9).

The positive ρ values (Fig. 8 and 9) indicate that the mechanism of the potential-determining step is a

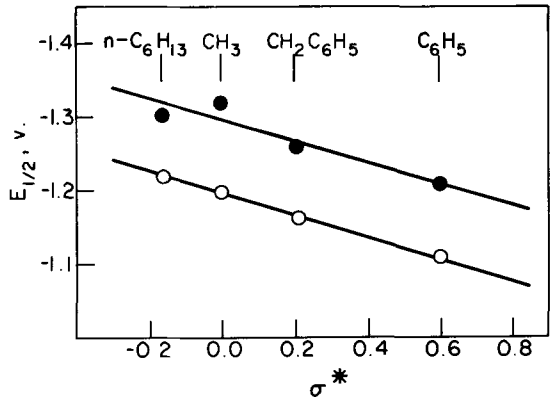

Fig. 9. Variation of $E_{1/2}$ of N'-substituted 6-aminopurines with the polar substituent constant, σ^* (substituent indicated). $E_{1/2}$ determined in McIlvaine buffer (circles, pH 2.5; solid circles, pH 4.0). Slope, ρ, is 0.14V for pH 4.0 and 0.15V for pH 2.5.

nucleophilic one (39), with an electron being the most probable nucleophilic agent. Thus, any primary electrophilic attack, *e.g.* protonation prior to electron-transfer, has no significant role in the potential-determining step (43). Since the protonated form is the species believed to undergo electroreduction, the protonation must be very rapid and, hence, not potential determining. The value of ρ depends on the charged state of the depolarizer and on the transfer coefficient (43). The similar values of ρ at pH 2.5 and 4.0 indicate that the same species is reduced at both pH values by the same mechanism.

In agreement with the polarographic behavior, the correlation of $E_{1/2}$ with σ_p (Fig. 8) places 6-methylpurine closer to purine than to the 6-amino derivatives. The small change in the polarographic reducibility of purine produced by introducing the 6-methyl group also corresponds to small differences in LEMO energies and other electronic indices (Fig. 10-12).

Support for the fact that the mechanisms for the polarographic reduction of the 6-substituted purines studied are essentially the same as those of the parental compounds, purine and adenine, is apparent from the data in Fig. 8 and 9; *i.e.*, the linear correlations of $E_{1/2}$ with the polar substituent constants for the series of 6-alkylamino purines and with the total

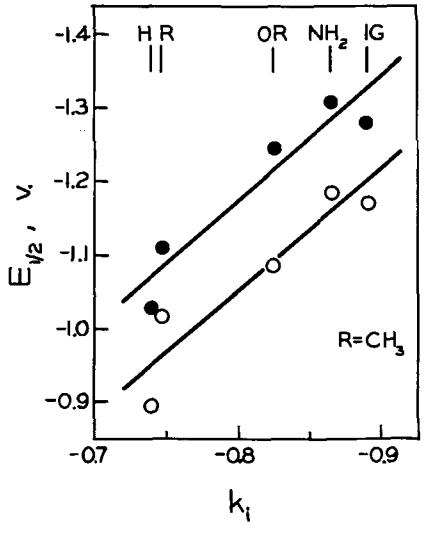

Fig. 10. Variation of $E_{1/2}$ of 6-substituted purines (substituent indicated) with LEMO energies (k_i). IG = isoguanine. $E_{1/2}$ determined in McIlvaine buffer (circles, pH 2.5; solid circles, pH 4.0).

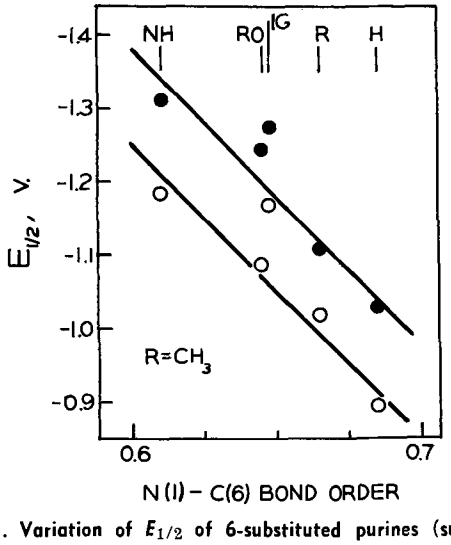

Fig. 11. Variation of $E_{1/2}$ of 6-substituted purines (substituent indicated) with calculated N(1)-C(6) bond order. IG = isoguanine. $E_{1/2}$ determined in McIlvaine buffer (circles, pH 2.5; solid circles, pH 4.0).

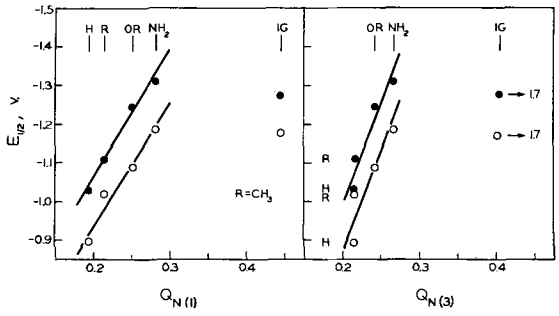

Fig. 12. Variation of $E_{1/2}$ of 6-substituted purines (substituent indicated) with net negative charges on N(1) and N(3). IG = isoguanine. $E_{1/2}$ determined in McIlvaine buffer (circles, pH 2.5; solid circles, pH 4.0).

polar substituent constants for 6-substituted purines indicate either that no mesomeric and steric effects due to the substituents are involved or that they are transmitted by an inductive mechanism (17, 39, 42); the correlation also indicates that none of the substituents exerts any specific effect different from those exerted by the other substituents (42).

Quantum mechanically calculated electronic indexes. —Correlations of MO calculations with $E_{1/2}$ data generally involve the energies for adding an electron to the lowest empty MO (LEMO) or removing one from the highest occupied MO (HOMO), based on calculation of the energies of the molecular orbitals of the mobile or π electrons, which are of the form

$$E_i = a + k_i\beta \qquad [4]$$

where a is the coulomb integral and β the resonance integral (15). For a homologous series, the smaller the absolute value of LEMO k_i, the greater the electronegativity and, consequently, the greater the electron acceptor properties of the molecule and, in turn, the easier should be the polarographic reduction.

In addition to correlation of $E_{1/2}$ with LEMO values, correlations were investigated between $E_{1/2}$ and bond orders for selected pairs of atoms, and between $E_{1/2}$ and net charges on certain atoms in order to see whether such correlations could be used to identify the electroactive sites in the molecules [*cf.* Refs. (15) and (44) for discussion of concepts of *bond order* and *net charge*]. Methods of calculation of the MO parameters used for the purines are described by Pullman and Pullman (15), from whose book the data were taken.

Fairly linear relationships (Fig. 10) are obtained between $E_{1/2}$ and the LEMO energy (k_i coefficient) for purine, 6-methylpurine, adenine, and 6-methoxypurine (data calculated for the hypoxanthine lactim form were used for the latter). The deviant behavior of isoguanine is subsequently discussed.

Correlation of $E_{1/2}$ data with LEMO and HOMO energies is of special interest. Since the latter have been correlated with chemical and biochemical activity for a variety of molecules, *e.g.* Ref. (15), a successful correlation with $E_{1/2}$ will facilitate correlation of such activity with polarographic data. It is clear, however, as previously mentioned, that the effects of adsorption, electron-transfer reversibility, and solvation must be considered, since these may alter the potentials associated with the redox processes and perhaps even the mechanistic route.

Substitution in the 6-position influences mostly the N(1)-C(6) bond order and the electronic charge distributions on N(1) and less on N(3), which, in turn, largely determine the reducibility; $E_{1/2}$ correlates with these (Fig. 11 and 12), but not with the C(2)-N(3) bond order and the charges on C(6) and C(2). These results are in accord with the association of the initial purine and adenine reduction steps with the 1,6 N=C bond, which bond, moreover, seems to be more acces-

sible for reduction than the 2,3 C=N bond; *e.g.*, isoguanine (2-hydroxy-6-aminopurine) produces a well-defined wave, while hypoxanthine (6-hydroxypurine) gives only an ill-defined inflection on the background discharge (8) and guanine (2-amino-6-hydroxypurine) is polarographically reducible only at potentials more negative than background discharge by a mechanism different than that for other purine derivatives (8, 11, 12, 45).

A least-square calculation for the $E_{1/2}$-bond order data at *p*H 2.5, omitting the isoguanine point, gives $E_{1/2} = -3.474 + 3.727$ (B.O.) with the standard error of estimate for $E_{1/2}$ being 0.018V.

Acid dissociation constants.—Since only the protonated 6-substituted purine is apparently polarographically reducible, correlation of $E_{1/2}$ with acidic dissociation constant (pK_a) for the protonated form might be expected on the basis that (*a*) the initial potential-determining reduction step is associated with N(1); (*b*) adenine—and presumably other 6-substituted purines—is protonated first at N(1), *i.e.* at the most basic nitrogen (15, 16, 27); and (*c*) the electron density at N(1) would affect both $E_{1/2}$ and pK_a; $E_{1/2}$ does become more negative as the net negative charge on N(1) increases. Although the electronic density on the ring nitrogen cannot be taken alone as a measure of its basicity (15), as a first approximation, the reducibility should be inversely proportional to the basicity represented by pK_a. Actually, six of the seven purines, for which pK_a data are available, do give a reasonably linear $E_{1/2}$-pK_a plot (Fig. 13). A least-square calculation for the data at *p*H 2.5, omitting the point for methoxypurine, gives $E_{1/2} = -0.653 - 0.128$ pK_a with the standard error of estimate for $E_{1/2}$ being 0.042V and $E_{1/2} = 0.562 - 0.916$ $pK_a + 0.118$ $(pK_a)^2$ with a standard error of 0.020V. Equilibrium constants (pK_a values) for the acid-base system involving the uncharged purine (P) and its conjugated acid,

$$HP^+ \rightleftharpoons H^+ + P \qquad [5]$$

were selected from the most reliable compilations available (30, 46).

$E_{1/2}$ for 6-methoxypurine, which is between those of 6-methyl- and 6-aminopurines as predicted by the order of electron-repelling groups, falls on the linear plot of $E_{1/2}$ *vs.* the net electronic charge at the reduction site; its deviation from the $E_{1/2}$-pK_a plot may be due to the pK_a value in the literature (30) being too low.

Anomalous behavior of isoguanine.—As previously mentioned, $E_{1/2}$ for the isoguanine reduction deviates markedly from the linear correlations of $E_{1/2}$ for other 6-substituted purines with net negative charge on N(1) and N(3), but only slightly from the linear plots of $E_{1/2}$ *vs.* LEMO energy and N(1)-C(6) bond order (Fig. 10-13). This behavior may be correlated—at least to some extent—with the reduction site and the effect of protonation on the latter.

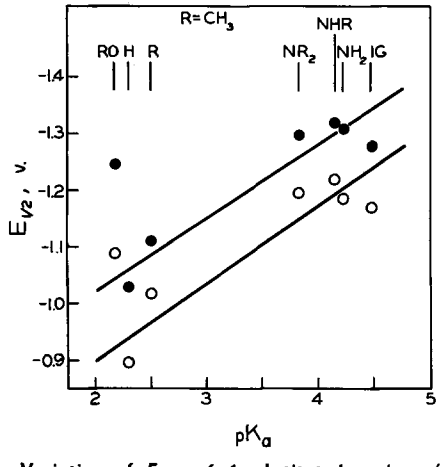

Fig. 13. Variation of $E_{1/2}$ of 6-substituted purines (substituent indicated) with acid dissociation constant (pK_a). IG = isoguanine. $E_{1/2}$ determined in McIlvaine buffer (circles, *p*H 2.5; solid circles, *p*H 4.0).

The diffusion current constant of isoguanine (Table I) is consistent with a 2*e* process based on only the 1,6 N=C bond being reducible since the 2,3 C=N bond is unavailable due to the stability of the keto form. Even though $E_{1/2}$ seems to fit the $E_{1/2}$-pK_a plot (Fig. 13), protonation of isoguanine at the reduction site does not seem to play a decisive role in its polarographic reduction; *i.e.*, the inflection point in the *i*-*p*H curve (Fig. 5) is at least 5 *p*H units higher than its pK_a compared to 2-3 units for other 6-substituted purines, and the most probable protonation site, based on comparison of N-charges (15), is N(7). The agreement of $E_{1/2}$ with LEMO energy and N(1)-C(6) bond order may then be ascribed to the connection of the latter with the reduction site.

Electrochemical Oxidation of 6-Thiopurine at the Pyrolytic Graphite Electrode

Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma

ABSTRACT

The electrochemical oxidation of 6-thiopurine (6-TP), which gives three well defined voltammetric waves at the pyrolytic graphite electrode (PGE), has been investigated by linear sweep and cyclic voltammetry, macroscale controlled electrode potential electrolysis at the PGE in aqueous 1*M* acetic acid (*p*H 2.3), ammonia buffer *p*H 9 and carbonate buffer *p*H 9, and by determination of reaction products and possible intermediates. The electrochemical oxidation of 6-TP appears to follow a pathway quite different from the major enzymatic oxidative route. The first *p*H dependent wave is an adsorption wave due to oxidation of 6-TP to give an adsorbed layer of product bis(6-purinyl) disulfide (PDS). The second *p*H-dependent wave is a 1*e* process to give PDS both at *p*H 2.3 and *p*H 9; however at *p*H 2.3 further slow chemical oxidation to a disulfone or disulfoxide occurs, while in ammonia *p*H 9 the PDS decomposes rapidly to 6-TP, purine-6-sulfinic acid (P-6-Si) and purine-6-sulfonamide (P-6-Sm), with possibly some purine-6-sulfonic acid (P-6-So), with the over-all result that somewhat in excess of 4*e* are transferred. The third *p*H dependent wave in carbonate *p*H 9 gives P-6-So as the final product; in ammonia *p*H 9 wave III gives rise to a mixture of P-6-Si, P-6-Sm and possibly some P-6-So; PDS appears to be an unstable intermediate in these oxidations at high *p*H capable of being chemically oxidized by dissolved atmospheric oxygen.

6-Thiopurine (6-TP) is widely employed for the treatment of acute leukemia. The action of 6-TP as an anticarcinogen is not understood, although it is known that it inhibits *de novo* synthesis of nucleic acids, probably by blocking the conversion of inosinic acid into other purine ribonucleotides (1). Studies have also indicated that 6-TP ribonucleotide inhibits the normal enzyme conversions of inosinic acid (2-4).

The mechanism of metabolic breakdown of 6-TP in man and other systems is also incompletely understood. However, various studies in man have revealed that 6-TP is at least partially biologically oxidized to 6-thiouric acid, although inorganic sulfate and other unidentified products are produced (5, 6). Xanthine oxidase catalyzes formation of 6-thiouric acid as a major urinary metabolite from 6-TP in bacteria, mice, and men (7).

Bergman and Ungar (8) have shown that 6-TP is attacked by xanthine oxidase first at C-8 and then at C-2. However, in the purine oxidizing system of *pseudomonas aeruginosa* 6-TP is apparently attacked first at C-2 and then at C-8 and subsequent further oxidation occurs (9). The biochemical effects of 6-TP have been summarized by Silberman and Wyngaarden (7) and Elion and Hitchings (10).

Relatively little work has been reported on the chemical oxidation of 6-TP. In sodium carbonate (11) solution or phosphate buffer *p*H 7.6 (12), it is oxidized by aqueous iodine-iodide to bis(6-purinyl)disulfide (PDS). Treatment of this disulfide with oxygen in alkaline solution or oxidation of 6-TP with excess iodine in alkaline solution yields purine-6-sulfinic acid (P-6-Si). Oxidation of 6-TP with alkaline permanganate gives purine-6-sulfonic acid (P-6-So) (12). Oxidation of 6-TP with chlorine in the presence of methanol, potassium fluoride, and hydrofluoric acid gives purine-6-sulfonyl fluoride which on further treatment with methanol and ammonia at 0°C yields purine-6-sulfonamide (P-6-Sm) (13).

Because of the importance of electron transfer processes in biological systems, and the close similarity between the conditions of enzymatic and biological

transformations and electrochemical reactions, it is likely that information obtained from the study of electrochemical processes regarding the potentials of the electron transfer step and associated electrode and subsequent chemical reaction mechanisms will prove helpful in understanding complete biological transformations. In view of the incomplete knowledge of the metabolism of 6-TP, the electrochemical oxidation of this compound was studied.

There are only two detailed studies of the electrochemical oxidation of the purines. Struck and Elving (14) found that uric acid (2,6,8-trioxypurine) is oxidized at controlled potential at a graphite electrode in 1*M* acetic acid in a process which was essentially identical to that observed for the enzymatic oxidation of uric acid. Dryhurst and Elving (15) showed that adenine (6-aminopurine) is electrochemically oxidized at a graphite electrode in 1*M* acetic acid by a pathway that was initially very similar to that observed for oxidation with xanthine oxidase, but further oxidation and fragmentation occurred and a complex over-all mechanism was obtained.

The work reported here of the electrochemical oxidation of 6-TP at controlled electrode potential over a wide *p*H range at the pyrolytic graphite electrode (PGE) indicates a mechanism whereby 6-TP is oxidized in three distinct steps; the first step is an adsorption process due to oxidation of 6-TP to give an adsorbed layer of product, PDS. The second step is a 1*e* process to give PDS both at *p*H 2.3 and *p*H 9; at *p*H 2.3 further slow chemical oxidation to a disulfone or disulfoxide occurs, while in ammonia background *p*H 9 the PDS decomposes rapidly to 6-TP, P-6-Si, P-6-Sm, and possibly some P-6-So, the over-all result being that slightly more than 4*e* are transferred.

The third process in carbonate buffer *p*H 9 is due to oxidation to P-6-So; in ammonia *p*H 9 the oxidation product is a mixture of P-6-Si, P-6-Sm, and possibly some P-6-So; PDS appears to be an unstable intermediate in these oxidations at high *p*H capable of being chemically oxidized by dissolved atmospheric oxygen.

Experimental

Chemicals.—6-Thiopurine was obtained from Calbiochem. Bis(6-purinyl) disulfide, purine-6-sulfinic acid (sodium salt), and purine-6-sulfonic acid (potassium salt) were prepared according to Doerr *et al.* (12), the latter compound being most conveniently prepared from 6-chloropurine (Calbiochem). Purine-6-sulfonamide was supplied as a gift from Dr. Roland K. Robins (University of Utah).

Buffer solutions were prepared from analytical reagent grade chemicals.

Argon (Linde) used for deoxygenating purposes was equilibrated with water; no other purification was necessary.

Apparatus.—Polarograms and voltammograms were recorded on a Sargent Model XV Polarograph, using a water-jacketed three-compartment cell maintained at 25° ± 0.1°C and containing a saturated calomel reference electrode (SCE), and a platinum counterelectrode in saturated potassium chloride solution. All potentials are referred to the SCE at 25°C.

The dropping mercury electrode had normal *m* and *t* values.

The preparation of the large PGE and the coulometric cell have been described earlier (15).

Cyclic voltammetry was performed with the apparatus described by Dryhurst, Elving, and Rosen (26); voltammograms were recorded on either a Moseley Model 7001A X-Y recorder or a Tektronix Model 502A Dual Beam Oscilloscope in the X-Y mode equipped with a C-27 polaroid camera.

Controlled potential electrolyses were carried out using a Wenking Model 66TA1 Potentiostat. Potentials of interest were measured with either a Sargent Laboratory Potentiometer or a Heathkit Model EUW-24 vacuum tube voltmeter. The *p*H was measured with a Beckman Zeromatic *p*H meter.

Current integration during coulometry utilized a titration coulometer as described by Lingane and Small (27) and Lingane (28).

Ultraviolet absorption spectra were obtained with a Beckman Model DB recording spectrophotometer using 1.00 cm stoppered quartz cells.

Lyophilization was accomplished using a Kinney Model KC-2 vacuum pump; cooling traps contained 2-propanol-dry ice; the lyophilization vessel was a round bottomed distillation flask of an appropriate size on whose walls the solutions were shell frozen.

Voltammetric procedure.—Test solutions were prepared by diluting appropriate quantities of stock solutions (0.8 m*M* in 6-TP in water was the maximum concentration attainable) with suitable background solution. The *p*H of the solution was measured. Solutions were deaerated for at least 10 min with water-saturated Argon. Once in position the PGE was allowed to stand for about 30 sec without applied potential; the starting potential was then applied for 5 sec (usually 0.00V) and the voltammetric scan commenced. The PGE was resurfaced before every run by polishing on a 600-grade silicon carbide paper disk mounted on a motor driven rotating disk. The electrode was then washed thoroughly with water and the surface wiped free of any loose or adhering graphite particles with a clean paper tissue.

Coulometry.—A measured volume of background solution was electrolyzed at the appropriate potential in the working electrode compartment until the coulometer gave a small constant titration rate. Then sufficient sample was introduced to give up to a 1 mM solution and the electrolysis continued until the current decayed to the background level or to a constant small value. In many studies 0.5 ml aliquots of the electrolysis solution were removed at appropriate time intervals and, after suitable dilution, the u.v. spectrum was immediately recorded. Completion of the electrolysis was always confirmed by the disappearance of the characteristic 6-TP absorption peak. The solutions were not normally deaerated during these electrolyses; in the cases where deoxygenation was performed appropriate reference is made in the text.

Determination of purine-6-sulfinic acid.—P-6-Si was determined at the completion of the electrolysis by transferring about 20 ml of the electrolysis solution to the polarographic cell, deaerating, running a polarogram between 0.0 and —2.0V, and comparing the height of the wave at —1.20V with a calibration curve prepared from authentic P-6-Si.

Determination of purine-6-sulfonamide.—P-6-Sm was determined in the same way as for P-6-Si except that since only a very small quantity of P-6-Sm was available a known volume of a standard solution of P-6-Sm was added to a known volume of the electrolysis solution and by measuring the increase in height of the polarographic wave at —1.03V the concentration of P-6-Sm could be computed utilizing the method of standard additions. A detailed account of the analytical procedures will appear elsewhere (25).

Results and Discussion

Voltammetry.—6-Thiopurine exhibits up to three distinct anodic waves at the stationary pyrolytic graphite electrode (PGE) (Fig. 1). The two more negative waves appear over the range *p*H 1-8, above which the first wave disappears; the most negative wave (wave I) only appears intermittently, and is never observed at some *p*H values. The most positive of the three waves (wave III) is often masked by background discharge and is only observed in 1*M* HOAc *p*H 2.3, acetate *p*H 5.4, ammonia *p*H 9.1, and hydroxide *p*H 10 buffer solutions. In 1*M* HOAc and occasionally at *p*H 3.7 a small postwave appears after

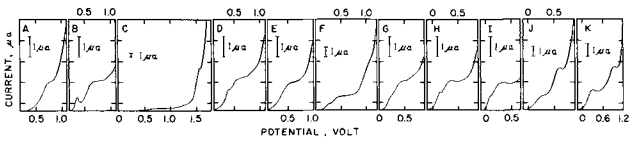

Fig. 1. Voltammograms of 0.4 mM 6-thiopurine at the PGE. A. 2M H_2SO_4 background; B and C. 1M acetic acid pH 2.3; D. pH 3.5 acetate buffer; E. pH 4.4 acetate buffer; F. pH 5.4 acetate buffer; G. pH 6.0 McIlvaine buffer; H. pH 6.9 McIlvaine buffer; I. pH 8.1 McIlvaine buffer; J. pH 9.1 ammonia buffer; and K. pH 9.9 chloride buffer.

wave II. This appears only at the highest concentration levels studied.

The peak potentials for all three waves become linearly more negative with increasing pH (Fig. 2): E_p = 0.51-0.047 pH for wave I, E_p = 0.805-0.052 pH for wave II, and E_p = 1.88-0.136 pH for wave III.

Waves I and II appear together most clearly in 1M HOAc, and waves II and III in ammonia or carbonate-bicarbonate background pH 9.0-9.2. Accordingly, the respective reactions were studied in detail at these pH values. Voltammetric studies were supplemented by coulometry and exhaustive electrolysis at large electrodes.

Examination of the changes in the composition of a 6-TP solution after the electrochemical oxidation at appropriately controlled anode potentials allowed qualitative identification and, at times, quantitative determination of the ultimate products as well as characterization of intermediate species.

Examination of the peak current for the three anodic waves of 6-TP at the 0.434 mM concentration level (Table I) indicates that for wave I the current density is 0.127 μA mM^{-1} mm^{-2}, for wave II 0.24 μA mM^{-1} mm^{-2}, and for wave III 0.65 μA mM^{-1} mm^{-2}. By comparison with previous data (15, 16) this indicates that wave I involves considerably less than 1e per 6-TP molecule. Wave II probably involves 1e, and wave III involves somewhat greater than 2e. In order to gain more insight into these ratios a concentration study was carried out in ammonia buffer pH 9.15 and 1M HOAc (Table II). At pH 2.3 wave I shows, an average, an almost constant current between 0.08 and 0.25 mM (Table II) although considerable variation was observed between replicate runs. At the 0.42 mM concentration level in this series of experiments wave I appeared as a very poorly defined inflection on the rising portion of wave II. Wave II showed a constant

[a] At least three replicate runs were carried out at each concentration level.
[b] In this series of runs a well-defined peak was not obtained but a rather indistinct inflection on the rising portion of wave II.
[c] At these concentration levels wave II was too indistinct and drawn out to allow accurate measurement of the peak current.

i_p/C ratio over the range of concentration examined of 3.4 μA/mM.

Wave I does not appear at pH 9.1 although waves II and III do. At the concentration ranges where waves II and III are sufficiently well-defined to allow accurate measurements, both have constant i_p/C ratios; for wave II i_p/C is 3.9 and for wave III i_p/C is 11.3 μA/mM. This data suggests that about three times as many electrons are involved in wave III as are involved in wave II.

The concentration independence of wave I is characteristic of an adsorption wave. Because the adsorption wave appears prior to the diffusion controlled wave it is probable that the product of the wave II process is adsorbed since its activity would be lower in the adsorbed state than in solution, hence facilitating the oxidation of 6-TP (17). As a result of the very low current for wave I it was not possible to study its behavior at concentrations where 6-TP would be oxidized in a diffusion controlled process to the adsorbed product and where surface coverage was not complete.

Wave II must therefore be due to oxidation of 6-TP to the dissolved form of the oxidation product. The i_p/C ratio for the sum of wave I and wave II currents in 1M HOAc is the same as for the single wave II ratio at pH 9.1 where wave I does not appear which again indicates that wave I is a small adsorption wave.

Cyclic voltammetry.—Cyclic voltammetry supports the view that the wave I and wave II processes give

identical products since at a scan rate of 20 mV·sec^{-1} reversing the anodic voltage scan after scanning wave I or wave I and wave II gave essentially identical cathodic voltammograms (Fig. 3 and 4). Usually the cathodic wave produced from the anodic adsorption wave alone appears at slightly less negative potential than that obtained when both anodic processes were scanned (Table III). This was particularly so at polarographic scan rates (2 mV·sec^{-1}) when the cathodic peak observed after scanning only anodic wave I was about 0.2V more positive than when both wave I and wave II were scanned (Table III).

The peak potential of this cathodic wave shifted linearly more negative with increasing *p*H.

At a scan rate of 20 mV·sec^{-1}

$$E_p = -0.085\text{-}0.0386\ pH$$

Recently Wopschall and Shain (18) have presented an elegant theoretical treatment of adsorption effects in stationary electrode polarography. Attempts were made in the present study to apply the various diagnostic criteria outlined by these authors, although their calculations were based on model systems where the electrochemical reaction was perfectly reversible. Oxidation of 6-TP at the PGE is not electrochemically reversible as evidenced by the separation of the anodic and cathodic peaks obtained by cyclic voltammetry.

[a] Only wave I was scanned.
[b] Both wave I and wave II were scanned.
[c] Only a single wave appeared; for discussion see text.

At *p*H 2.3 wave I shifts more anodic as the scan rate increases. At a scan rate of 2 mV·sec^{-1} wave I is almost always less than one half the height of wave II (Table II); at 20 mV·sec^{-1} scan rate wave I is of about the same height or slightly larger than wave II, whereas at 200 mV·sec^{-1} only wave I appears. Such effects are characteristic of an adsorption wave where the product of the electrochemical reaction is strongly adsorbed (18). It was rather difficult to obtain accurate data on the actual ratio of the peak current for waves I and II because of the somewhat variable height of wave I even on replicate scans. The cause of this irreproducibility was traced to variations in the electrode surface area under the conditions that were normally employed to prepare the PGE. Normally, the electrode was resurfaced before each voltammogram was run (see Experimental section) and, after washing the electrode with water, any loose graphite particles on the surface were removed by wiping the surface with a soft paper tissue. Experiment showed that if the surface were merely washed with water, but not wiped free of loose adhering graphite particles, the current for wave I was about three times larger than if the electrode were prepared in the usual fashion. Clearly the height of an adsorption wave such as wave I would be expected to increase as the surface roughness, hence surface area, increased. It is unlikely that either of these electrode preparation procedures would result in highly reproducible data for an adsorption process, although not apparently affecting a normal diffusion controlled process, hence the rather erratic behavior of wave I is not unusual.

At 200 mV·sec^{-1} scan rate in 1*M* HOAc the cathodic wave (E_p = −0.24V) has a greater slope on the rising portion of the wave than for the corresponding anodic wave, and the cathodic current is somewhat larger than the anodic current. Such behavior is characteristic of a process where the product of the initial electrochemical reaction is adsorbed (18-20).

The shift of the cathodic peak potential to more negative values with increasing scan rate is in accord with the expected shift for a process involving reduction of an adsorbed reactant (18). The fact that no post-peak is obtained may be associated with the rather irreversible nature of the over-all process.

Coupled with the very low current magnitude for wave 1 at polarographic scan rates (~2 mV·sec^{-1}), then wave I must be an adsorption wave due to adsorption of the product of the first electrochemical reaction.

Macroscale Electrolysis

Since wave I was shown to be due to an adsorption process, coulometry, and macroscale electrolysis were only carried out at potentials corresponding to waves II and III.

Coulometry at wave II in 1M acetic acid.—Electrolysis of 6-TP in 1*M* HOAc at a potential on the crest of anodic wave II gave an average coulometric n value of 0.98 (average of 0.94, 1.04, and 1.00). After the electrolysis had proceeded for some time a very pale yellow precipitate formed.

The ultraviolet absorption spectrum of the dissolved product differed considerably from that of 6-TP (1*M* HOAc λ_{max} = 324 mμ) having λ_{max} = 287-288 mμ.

The involvement of a single electron in the wave II process suggested that 6-TP was forming a dimer species similar to the disulfide species which are commonly encountered on mild oxidation of many alkyl and aryl thiols. Comparison of the ultraviolet absorption spectrum of the electrolysis product with that of authentic bis(6-purinyl)disulfide (PDS) showed them to be identical (12). The product of the electrolysis in 1*M* HOAc was isolated by lyophylizing the solution. The product was pale yellow and only very sparingly soluble in water. It gradually decomposed after turning orange at about 300°C [literature value 245(d) (12)]. Subsequent work indicated that this product was an impure sample of PDS and KCl (from the reference electrode and salt bridges) along with some disulfone and disulfoxide (*vide infra*). A suspension of this material in 1*M* acetic acid gave three distinct polarographic waves, $E_{1/2}$ = —0.03V, —0.26V, and —1.06V. Authentic PDS gave only two waves at $E_{1/2}$ = —0.05V and —1.05V. However, standing PDS in 1*M* HOAc for several hours (or warming the solution for a few minutes) resulted in the appearance of a new wave at $E_{1/2}$ = —0.30V with a decrease in the height of the most anodic wave. The wave at $E_{1/2}$ = —0.26V for the electrolysis product was only small when the electrolysis solution was polarographed immediately at the end of the electrolysis; it grew steadily in height over the course of several days or upon lyophylization of the solution. Hence the product giving rise to the wave at $E_{1/2}$ = —0.26V is due to chemical decomposition of PDS and is not due to a primary product of the electrochemical reaction.

Cyclic voltammetry of the electrolysis product solution at a scan rate of 20 mV·sec^{-1} showed that both anodic wave I and wave II had been eliminated and that a large cathodic wave, E_p = —0.15V had appeared along with a smaller wave at $E_{1/2}$ = —0.80V; the latter wave grew steadily over the period of several days. After scanning these cathodic peaks the original anodic waves I and II were observed on the subsequent anodic scan.

Once the nature and identity of the electrochemical oxidation reaction product had been ascertained (*i.e.*, PDS), a rate study of the oxidation was carried out by monitoring the rate of disappearance of 6-TP, the rate of appearance of PDS, and the rate of charge passage. The current and 6-TP concentration decreased exponentially with time and the PDS concentration increased exponentially at the same rate as predicted theoretically for a process which is diffusion controlled and free of long lived chemical or electrochemical intermediates (22).

Coulometry at wave II in ammonia background pH 9.1.—Electrolysis of 6-TP at a potential on the crest of anodic wave II gave an average coulometric n value of 4.08 (average of 4.00, 4.08, and 4.12).

As the electrolysis proceeded the ultraviolet absorption spectrum showed that the 6-TP peak (λ_{max} = 312 mμ) decreased in height and a new peak appeared at λ_{max} = 277-281 mμ. At completion of the electrolysis a peak λ_{max} = 277 mμ was observed.

The current did not decrease exponentially throughout the course of the electrolysis, but decreased fairly rapidly over the first hour or so and then decreased in a linear fashion until the completion of the electrolysis. Such behavior indicated the formation of an unstable intermediate, the breakdown of which to an electroactive species becomes the rate limiting step, although other kinetic explanations are possible.

On completion of the electrolysis, which was about three to four times as long as that in 1*M* HOAc, polarography of the solution showed five and, occasionally, six cathodic waves, $E_{1/2}$ = —0.41V, —1.02 to —1.05V, —1.18 to —1.20V, —1.39 to —1.43V, —1.50 to —1.55V and occasionally an even more negative wave of ill-defined potential at $E_{1/2}$ about —1.70V (Fig. 5). The wave at $E_{1/2}$ = —0.41V was always very small and on occasion was not even detected. The 6-TP wave II oxidation product solution showed a single well formed anodic wave at the PGE E_p = 0.87V and cathodic wave E_p = — 1.22V.

Since the height of voltammetric wave II at the PGE was approximately the same in both 1*M* HOAc and ammonia pH 9 (*i.e.*, same number of electrons involved) it seemed likely that PDS, the known product in 1*M* HOAc, was decomposing in alkaline solution to yield some further electro-oxidizable material. Accordingly, the stability of authentic PDS in ammonia pH 9.1 was examined. It was found, by ultraviolet spectrophotometric studies that 1 mole of PDS rapidly decomposed to give approximately 1.5 mole of 6-TP; no other easily observable spectrophotometric absorption peaks were observed. Polarograms of PDS in ammonia solution pH 9 after 6 hr at room temperature were qualitatively identical to those observed after complete electrolysis of 6-TP at wave II in the same background, except that the anodic wave of 6-TP was also observed, $E_{1/2}$ = —0.40V (23). Earlier workers have shown that PDS decomposes in alkaline solution to give 75% of 6-TP and 25% of the appropriate salt of purine-6-sulfinic acid (P-6-Si) (12). Authentic P-6-Si in ammonia pH 9.1 gave two polarographic waves $E_{1/2}$ = —1.20V and —1.70V (Fig. 6). Spectrophotometry of P-6-Si at pH 9.1 showed λ_{max} = 277 mμ and ϵ_{max} = 8.8 x 10^3 in agreement with earlier data (12). Voltammetry of P-6-Si at the PGE at pH 9.1 showed a well-formed anodic wave, E_p = 0.86V and a cathodic wave E_p = —1.21V.

Purine-6-sulfinic acid was found to be stable in ammonia pH 9.1 open to the atmosphere or with oxygen bubbling through the solution for at least 24 hr as evidenced by the almost constant height of its polarographic waves and absorption spectrum.

Doerr *et al.* (12) have reported that P-6-Si is converted to hypoxanthine in 95-100% yield in 0.1*M* hydrochloric acid. Treatment of the wave II electrolysis product solution (λ_{max} = 277 mμ) with hydrochloric acid resulted in the formation of two absorption peaks λ_{max} = 325 and 249 mμ, the latter being about three times as large as the former; in strongly acid solution λ_{max} 6-TP = 324 mμ, λ_{max} hypoxanthine = 248 mμ (24). This data therefore strongly supports the presence of P-6-Si in addition to other

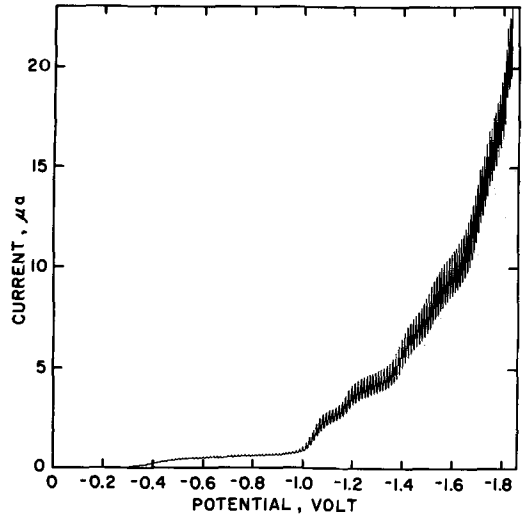

Fig. 5. Polarogram of 6-thiopurine wave II oxidation product in ammonia buffer pH 9.1. Solution originally 0.63 mM in 6-thiopurine.

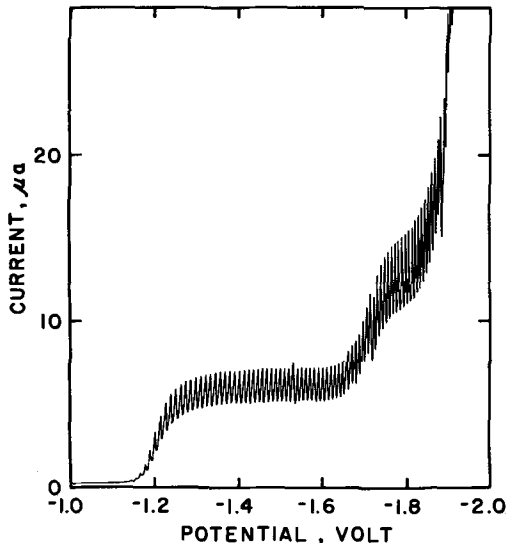

Fig. 6. Polarogram of approximately 1 mM purine-6-sulfinic acid (Na salt) in ammonia background pH 9.1.

products capable of regenerating 6-TP upon acidification.

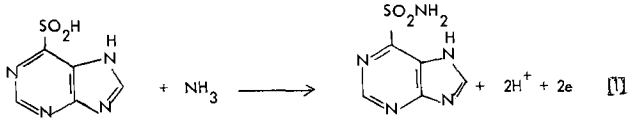
It was thus fairly obvious at this stage that the primary electrochemical oxidation of 6-TP at potentials corresponding to wave II at pH 9.1 was a 1e process to give PDS, but that subsequent decomposition of this product leads to formation of 6-TP and P-6-Si along with other products. The nature of these other products became more obvious when the mechanism of the anodic wave III at pH 9.1 was studied. Further discussion will therefore be continued under Mechanism.

Coulometry at wave III in ammonia background pH 9.1.—Electrolysis of 6-TP at a potential on the peak of anodic wave III gave an average coulometric n value of 4.3 (average of 4.2, 4.4, 4.7, and 4.0).

The ultraviolet absorption spectrum of the electrolysis product differed quite considerably from that of 6-TP (λ_{max} = 313 mμ) having λ_{max} = 280 mμ. At no point in the electrolysis did the 313 and 280 mμ peaks appear together; rather there was merely a pronounced broadening of the peak in the intermediate stages of the electrolysis. The electrolysis was completed in less than one fourth the time required for complete electrolysis of 6-TP at wave II at pH 9.1.

Voltammetry of the product solution at the PGE showed a small rather poorly defined wave at E_p = 0.85V.

Polarography of the product solution showed five or possibly six waves cathodic $E_{1/2}$ = —0.49 to —0.50V, —1.03V, —1.20V, —1.43V, —1.55V, and possibly an ill-defined wave at —1.7 to —1.75V. The wave at $E_{1/2}$ = —0.49V was always extremely small and on occasion was not observed at all. The waves at —1.20 and —1.70V were also considerably smaller than observed in the electrolysis solution from wave II electrolysis in ammonia. The spectral data, voltammetry, and polarography indicated that P-6-Si was present in the electrolysis solution. However, the fact that the P-6-Si voltammetric anodic wave and polarographic cathodic waves ($E_{1/2}$ —1.20V and —1.70V) were lower than observed in the wave II electrolysis solution suggested that P-6-Si might itself be oxidized at wave III potentials (0.64V). A voltammogram of P-6-Si at pH 9.1 indicated that at 0.64V some oxidation would indeed occur. When a 1 mM solution of P-6-Si was electrolyzed at the PGE at 0.64V for 4 hr at pH 9.1, it was found that the original polarographic waves at $E_{1/2}$ —1.20V and —1.70V decreased in height and three new waves appeared at $E_{1/2}$ = —1.03V, —1.43V, and —1.54V and the polarogram had, qualitatively, the same form as that of the wave II and wave III electrolysis product solutions at pH 9.1. By altering the applied potential to 0.80V the polarographic waves at $E_{1/2}$ = 1.20V and —1.70V could be completely eliminated leaving only four waves at $E_{1/2}$ = 1.03V, —1.28V, —1.43V, and —1.56V; the wave at —1.28V was very small. Coulometry of P-6-Si at 0.8V in ammonia buffer pH 9.1 gave an average coulometric n value of 1.9. This at first suggested that the oxidation product was purine-6-sulfonic acid (P-6-So). However, polarography of authentic P-6-So at pH 9.1 gave waves at $E_{1/2}$ = —1.31V, —1.46V, and —1.56V indicating that the main product of the oxidation was not P-6-So. The only alternative therefore was that P-6-Si was being oxidized in a 2e process to purine-6-sulfonamide (P-6-Sm) (Eq. [1]).



[1]

The spectra of P-6-Si, P-6-So, and P-6-Sm are so similar λ_{max} = 277 mμ, 279 mμ, 281 mμ, and ϵ_{max} = 1.09 x 10^4, 8.8 x 10^3, and 8.9 x 10^3, respectively, at pH 9, that it is impossible to determine or distinguish then in the presence of each other. However, polarography of P-6-Sm at pH 9.1 at about the same concentration as the product showed three distinct waves at $E_{1/2}$ = —1.03V, —1.43V, and —1.55V. P-6-Sm was stable in aerated ammonia pH 9 for several hours. Polarograms of P-6-Sm, P-6-So, and the solution of oxidized P-6-Si in ammonia buffer pH 9.1 are presented in Fig. 7. The mechanisms of the polarographic reduction of all these compounds have been elucidated (25). Clearly P-6-Si is oxidized in ammonia pH 9 predominately to P-6-Sm.

By preparation of suitable calibration curves for P-6-Si, and P-6-Sm it proved possible to determine quantitatively each of these electrolytic oxidation products of 6-TP wave III at pH 9. A 0.94 mM solution of 6-TP gave 0.35 mM P-6-Si and 0.50 mM P-6-Sm with possibly a very small quantity of P-6-So, *i.e.*, less than 0.1 mM. This represents better than 90% of the original 6-TP accounted for. It did not prove possible to identify the product which gave rise to the first small polarographic wave at $E_{1/2}$ = —0.40 to —0.50V.

Coulometry of 6-TP at wave III in carbonate buffer pH 9.—In carbonate-bicarbonate background pH 9, 6-TP shows two well-formed anodic waves at PGE at E_p = 0.3V and 0.82V. The average coulometric n value at an applied potential of 0.8V was 5.0 (average of 4.73 and 5.28). At completion of the electrolysis the ultraviolet absorption spectrum was quite different from that of 6-TP, having λ_{max} = 277-278 mμ. Polarography of the product solution showed that two waves were produced $E_{1/2}$ = —1.42V and —1.58V (6-TP showed no polarographic waves in this background). The involvement of 5e suggested that P-6-So might be an ex-

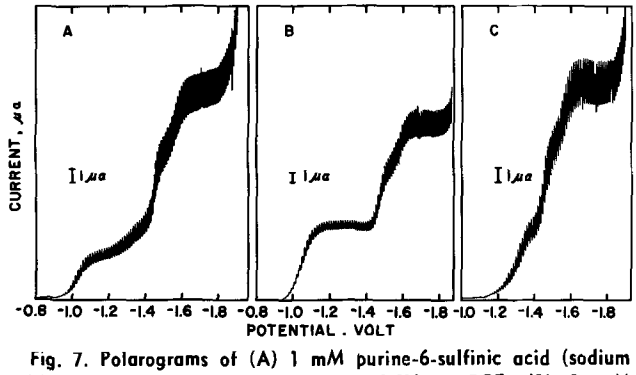


Fig. 7. Polarograms of (A) 1 mM purine-6-sulfinic acid (sodium salt) after exhaustive electrolysis at 0.8V at PGE, (B) 1 mM purine-6-sulfonamide, and (C) 1 mM purine-6-sulfonic acid (potassium salt) in ammonia buffer pH 9.1.

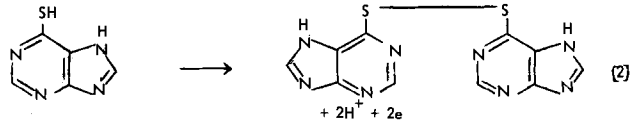
pected oxidation product, and indeed it was found that P-6-So gave an identical polarogram. Because of the involvement of only 5 electrons and the known instability of PDS in alkaline solution it was thought that the oxygen present in the electrolysis solution might chemically oxidize a small amount of some intermediately produced PDS. Coulometric electrolysis of 6-TP with argon bubbling through the solution gave an n value of 6.2. Analysis of a product solution after electrolysis of 1.02 m*M* 6-TP gave 1.10 m*M* P-6-So, which bearing in mind slight evaporation losses, accounts satisfactorily for the total 6-TP initially present.

Mechanism of Oxidation of 6-Thiopurine

The characteristic ultraviolet absorption spectrum of 6-TP is due mainly to the —C(4) = C(5) — C(6) = N(1) — chromophoric group, the fact that the u.v. absorption peak remains after oxidation, although λ_{max} is shifted slightly, indicates that the C(4) = C(5) — bond remains intact. Thus the electrochemical oxidation of 6-TP at the PGE must obviously involve attack at the exocyclic sulfur atom rather than attack on the purine nucleus unlike other purine electrochemical oxidations (14, 15). This at first sight is rather surprizing in view of these latter studies and the known partial biological oxidation of 6-TP to 6-thiouric acid.

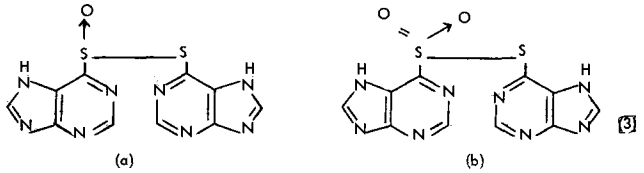
Wave I of 6-TP is undoubtedly an adsorption wave due to adsorption of bis(6-purinyl)disulfide on the electrode as evidenced by the very low current observed for this wave, its dependence on surface roughness, and its behavior on both cyclic and linear sweep voltammetry.

Wave II of 6-TP is a true faradaic oxidation process involving 1*e* per mole of 6-TP to give bis(6-purinyl)-disulfide according to reaction



[2]

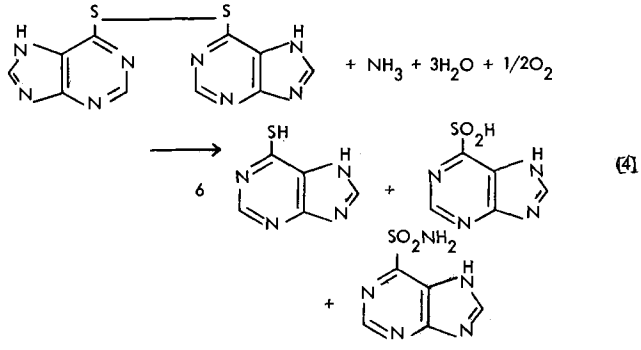
In 1*M* HOAc, PDS slowly decomposes to a product which is not 6-TP, P-6-Si, or P-6-So. The nature of this decomposition product is not definitely known but since its polarographic reducibility is somewhere intermediate between PDS and P-6-Si it is suggested that the decomposition product is either a disulfone [3a] or disulfoxide [3b].



[3]

There is considerable evidence for the formation of these types of oxidized disulfides. For example oxidation of organic disulfides with cold nitric acid (31) or sulfuric acid (32) gives a disulfoxide as has oxidation with hydrogen peroxide (33-35). Disulfones have been formed by oxidation of the corresponding disulfide with perbenzoic acid (33, 34, 36). Many other references and data on these oxidized disulfide species are presented by Reid (37).

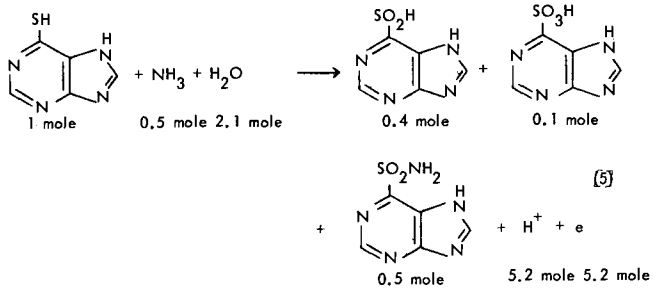
In ammonia buffer pH 9 PDS, the primary electrooxidation product, decomposes in a complex series of reactions to yield 6-TP, purine-6-sulfinic acid, purine-6-sulfonamide and possibly a small amount of purine-6-sulfonic acid according to a reaction of the type shown in Eq. [4].



[4]

The involvement of this reaction in the over-all process is evidenced by the very slow nondiffusion controlled electrolysis and the fact that authentic PDS itself decomposes to the same products.

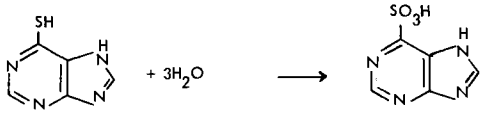
Wave III of 6-TP in ammonia background pH 9 is due to the oxidation of 6-TP to a mixture of P-6-Si and P-6-Sm and possibly a small amount of P-6-So according to reaction [5].



[5]

The fact that considerably less than 5.2*e* per mole of 6-TP are transferred may be interpreted as being due to intermediate formation of PDS which may either undergo further electrochemical oxidation, or may undergo chemical oxidation in the presence of dissolved oxygen to the same products via a route similar to reaction [4].

In the absence of ammonia and air in carbonate background pH 9 the wave III process involves 6*e* and 6-TP is quantitatively electrochemically oxidized to P-6-So according to Eq. [6].



[6]

Since in the presence of atmospheric oxygen less than 6*e* are involved in the oxidation, it again seems reasonable to postulate that an intermediate species such as PDS may be partially chemically oxidized to P-6-Si or P-6-So.

Conclusions

Unlike the electrochemical oxidation of uric acid and adenine, which closely parallel enzymatic oxidations, 6-thiopurine is oxidized in a manner similar to chemical oxidation. These electrochemical mechanisms might however, aid in understanding the complete enzymatic mechanism, and not only suggest metabolites not previously suspected but provide the basis for selective analytical determinations of these compounds in complex mixtures.

The ease with which bis(6-purinyl)disulfide, purine-6-sulfinic, and sulfonic acids and particularly purine-6-sulfonamide are electrochemically prepared recommends further study of the utility of these findings in electrosynthetic chemistry, particularly in view of the difficulty with which P-6-Sm, for example, is prepared chemically (13).

High Speed Non-Faradaic Resistance Compensation in Potentiostatic Techniques

A. A. Pilla,* R. B. Roe, and C. C. Herrmann*

Power Sources Division, Electronic Components Laboratory, USAECOM, Fort Monmouth, New Jersey

ABSTRACT

The general problem of the incorporation of IR compensation in a potentiostatic circuit is considered. The manner in which the number of time constants needed to describe the system affect the amount of stable positive feedback at short times or high frequencies is discussed and a theoretical model developed for present state of the art potentiostats and operational amplifiers. It is shown that the use of a model in which all series nonfaradaic resistance has been removed to establish a reference for complete IR compensation indicates that stable overcompensation cannot take place in any practical system. The use of positive feedback in pulse and a-c techniques is compared and it is concluded that great caution must be exercised in the latter with regard to the proper detection of optimum compensation. Interpretation of results using IR compensation is considered and it is shown that the use of frequency domain conversion to obtain the impedance of the system under, *e.g.*, pulse conditions allows potentiostat parameters to be eliminated such that meaningful results may be obtained at times of the order of 10 nsec.

The study of rapid or complex electrochemical reactions by means of the potentiostatic method is well known (1-5). One of the major limitations in the use of this technique is the presence of a nonfaradaic resistance across the potential control points in the potentiostat circuit. This may be caused by the presence of a relatively low conductivity electrolyte between the reference and working electrodes or to the resistivity of the particular working electrode configuration. The effect of the nonfaradaic resistance may be conveniently analyzed by considering the electrochemical system as linear. In this case the concept of impedance may be employed which allows the electrochemical system to be represented by an aperiodic equivalent electric circuit (6, 7). For most systems a circuit may be constructed such that the double layer capacitor, C_d, is shunted by a faradaic impedance, Z_F, the complexity of which depends on the actual reaction mechanism. The nonfaradaic resistance, R_e, is placed in series with the above elements. The total circuit is shown in Fig. 1. In order to provide a mathematical description of this circuit, Laplace transformation (8) will be used, as well as in the remainder of this study, since this allows simple algebraic expressions to be obtained which are sufficient to describe the frequency response of the system. Thus, the impedance, $Z(s)$, of this circuit is given by

$$Z(s) = R_e + \frac{1}{1/Z_F(s) + C_d s} \qquad [1]$$

where s is the Laplace transform variable. Note that s is a complex number given by $s = \sigma + j\omega$, where σ is the real part, and ω the angular frequency and $j = \sqrt{-1}$ define the imaginary part. The dimension of s is reciprocal time. Inspection of this equation indicates that evaluation of the faradaic portion of the impedance (*i.e.*, electrode kinetic constants) necessitates a knowledge of R_e and C_d, as well as Z_F. Of prime importance, then, is the establishment of experimental conditions such that R_e is not so large as to obscure the remaining electrode impedance during electrolysis times significant with respect to the faradaic time constant(s). In addition, the classical treatment of the potential step method (1) requires that constant potential conditions be achieved across C_d essentially at the beginning of electrolysis. Clearly a large R_e will not allow this. An elegant discussion of the effect of R_e on the time domain response of relatively simple systems to a variety of potential input signals has recently been presented (9). This study clearly shows that elimination of the effect of R_e would be highly desirable.

The potentiostatic technique lends itself readily to the use of the generally applicable positive feedback method for the reduction of the effect of R_e. Thus if a current-proportional voltage signal of the same sign as that of the input signal is appropriately fed back into the potentiostat input it is clear that the potential function desired across the interphase region of the working electrode will be more closely approximated. The positive feedback technique has long been employed by electrical engineers in amplifier design (10, 11), but has only recently been used in electrochemical studies. Several workers have given circuits devised to achieve compensation (*i.e.*, reduce the effect of R_e) in some cases (12-23), but frequency limitations and phase instabilities have been the major causes of the lack of generality of these techniques. Further, there appears to be a rather major misconception about what the oscillations (whether damped or undamped) caused by too much positive feedback mean in terms of the degree of compensation. For example, recent analyses (23-25) of the frequency behavior of some potentiostats with IR compensation appear to show that stability conditions can be such that what has been

* Electrochemical Society Active Member.

called overcompensation can occur in some cases before the system becomes unstable. It will be shown below that if the reference point for complete compensation is correctly chosen then overcompensation cannot occur in any practical system.

The most versatile potentiostat-IR compensation system is that which can achieve the lowest effective R_eC_d time constant without the onset of severe ringing or oscillations which would render potential control impossible. The basic criteria for the realization of such a system are considered in detail and it is shown that a potentiostat and positive feedback amplifier are presently available which allow these criteria to be closely met.

Theoretical

In order to discuss the requirements for the proper design of a potentiostat which is able to operate effectively, and therefore with sufficient stability at short times (or high frequencies) with the incorporation of positive feedback IR compensation, it is appropriate to review the stability criteria for the transfer function of a feedback amplifier. The circuit description of a feedback amplifier is well known (26) and can be represented as shown in Fig. 2. The transfer function is defined as the ratio of the transform of the output voltage $O(s)$ to that of the input voltage $V(s)$. This ratio can be readily shown (26) to be given by

$$\frac{O(s)}{V(s)} = \frac{G(s)}{1 + G(s)\,H(s)} \qquad [2]$$

where $G(s)$ is the open loop gain function of the potentiostat and $H(s)$ is the function (often complex) representing the output voltage which is fed back to the input of the potentiostat.

Consideration of Eq. [2] will indicate in a straightforward fashion whether or not a given system can exhibit instabilities. For this the denominator of the r.h.s. of [2] need only be considered. It is clear that if

$$1 + G(s)\,H(s) = s + a \qquad [3]$$

where a is the inverse of the time constant, then the system, which can now be described as first order, will be inherently stable. This is so since its time domain behavior can only be a decreasing exponential function for real and positive a. Thus the voltage output of the potentiostat will be given in general by

$$O(t) = A \exp - at \qquad [4]$$

where A will depend on the explicit forms of $V(s)$, $G(s)$, and $H(s)$. However, if

$$1 + G(s)\,H(s) = s^2 + as + b \qquad [5]$$

then the system is now second order and may exhibit severe instabilities. This may be seen by considering the roots of the r.h.s. of [5]. If these roots are real, *i.e.*, $a^2 - 4b$ is real and positive, the time domain response will be of the form

$$O(t) \propto \frac{\exp(-at/2)\,\sinh(\sqrt{b - a^2/4}\,t}{\sqrt{b - a^2/4}} \qquad [6]$$

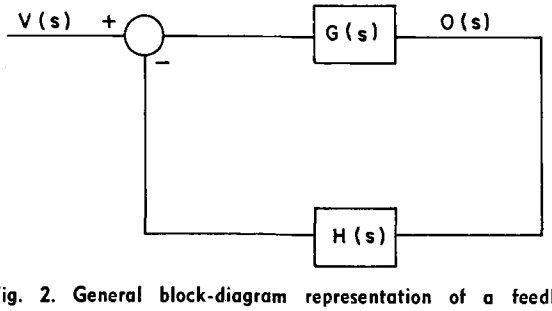

Fig. 2. General block-diagram representation of a feedback amplifier.

which is clearly a stable response function. However, for the case in which the roots are complex, *i.e.*, $4b - a^2$ real and positive, the system will exhibit damped oscillations (or ringing) since the response will be of the form

$$O(t) \propto \frac{\exp(-at/2)\,\sin(\sqrt{b - a^2/4}\,t}{\sqrt{b - a^2/4}} \qquad [7]$$

It is obvious from the above considerations that it is sufficient to consider the transfer function (which is therefore in the complex frequency domain) to obtain adequate information concerning the stability of the system. This is a simple matter in the second order case, but more complex for higher order systems. For these, the various stability criteria (*e.g.*, Routh-Hurwitz) have been adequately discussed elsewhere (27). It is to be noted, however, that the higher the system order the more difficult it will be in general to achieve smooth and stable response over a wide frequency range and to have sufficient gain at high frequencies for high speed applications. It is therefore of importance to have the minimum possible system order. That this is so can clearly be seen from the fact that a first order system will never oscillate, whereas second and higher order systems can and do indeed oscillate necessitating stabilizing networks which can increase the order of the system. It is to be noted that increasing the order of the system [*e.g.*, by the addition of zeros (28) to $G(s)\,H(s)$ in Eq. [2]] can increase the amount of positive feedback which can be tolerated before the onset of ringing. However, this is generally accomplished with a decrease in the power bandwidth of the system and therefore a decrease in maximum frequency at which a given degree of IR compensation can be obtained. Thus it may be advantageous when using a-c methods to increase the order of the system since this can allow a greater degree of compensation in the low frequency range of operation (23). In the case of pulse techniques, however, a maximum power bandwidth is desired since, *e.g.*, in the classical potential step method the object is to charge C_d in as short a time as possible (*i.e.*, minimum $R_e\,C_d$ time constant) under stable conditions.

The first step toward achieving minimum system order is therefore to employ a potentiostat which has the simplest possible gain function [$G(s)$]. The ideal potentiostat would be that for which $G(s) = K$, *i.e.*, a flat response in the frequency range of interest. Unfortunately this range is such that even the best practical potentiostats can rarely fulfill this condition simply because it has a finite rise time. A potentiostat frequently used for electroanalytical applications is constructed with three operational amplifiers (15), all of which are in the control loop and, at least two of which must be described by a minimum of a first order function for the respective $G(s)$, *i.e.*

$$G(s) = \frac{K}{s\tau + 1} \qquad [8]$$

where K is the open loop d-c gain and τ the open loop time constant of the potentiostat. A completely flat response [$G(s) = K$] is not attainable to the highest frequencies of interest in electrochemical applications. However, operational amplifiers which are adequately characterized by Eq. [8] are attainable and those having higher order gain functions should be avoided, if possible, for high speed applications.

An additional note should be made concerning the aspect of stabilizing a potentiostat both with and without IR compensation. If an operational amplifier is employed which has the desirable first order gain function (Eq. [8]) then every attempt should be made to assure that the process of stabilization does not increase the basic order of the system. Thus the incorporation of stabilizing networks in the control loop (23) normally increases the system order at high

frequencies. It is possible, however, to obtain stabilization through the use of operational amplifiers which have provision for external phase compensation. This is effectively an internal adjustment which does not change the essential gain function, merely its magnitude. Thus τ may be varied while Eq. [8] is still obeyed. This is a more desirable method of obtaining stabilization and it is recommended that all amplifiers employed in the potentiostat control loop be provided with external phase compensation when high speed applications are desired. It can now be seen that the use of two operational amplifiers in a standard potentiostatic circuit leads at least to an undesirable second order system even before the electrolytic cell characteristics are considered and also leads, as will be seen below, to a system of even higher order when IR compensation is employed. It is thus more advantageous to use a single operational amplifier for the potentiostat. This can be done through the use of a high impedance input differential amplifier. The basic circuit describing this approach is shown in Fig. 3 where R_o represents the output impedance of the amplifier to which eventually can be added a current sampling resistor. The necessary measurements of potential and current can easily be carried out by amplifiers which are not within the control loop and which therefore will not affect the stability of the control system. A possible arrangement is shown in Fig. 4 where R_C is the resistor across which a voltage proportional to the total current may be sampled, A_1 is the potentiostat, A_2 is a wideband differential amplifier, and A_3 is a high input impedance wideband voltage follower necessary only if reference electrode loading is unavoidable.

The incorporation of IR compensation in the single amplifier potentiostat described here can be achieved by voltage feedback of part of the signal appearing across a current sampling resistor to the noninverting input (+) of the potentiostat. This signal must be supplied by an additional amplifier which is now in a control loop and therefore must be considered when evaluating over-all system stability.

In order to evaluate the performance of the single amplifier potentiostat with IR compensation the circuit shown in Fig. 5 will be considered. Here A_1 and A_2

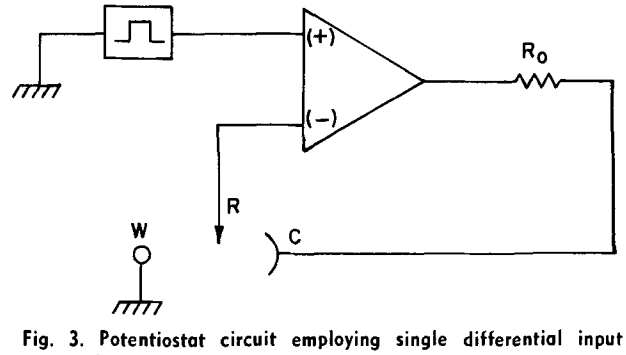

Fig. 3. Potentiostat circuit employing single differential input operational amplifier.

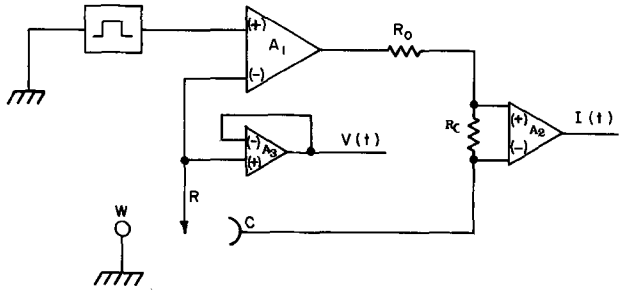

Fig. 4. Single amplifier potentiostat circuit with incorporation of potential and current measurement.

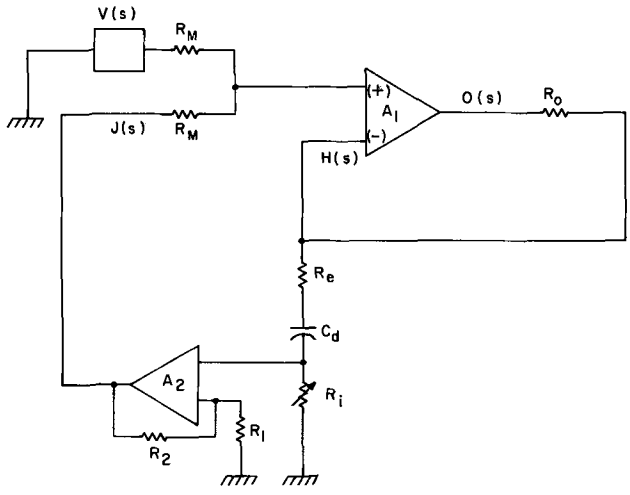

Fig. 5. Positive feedback potentiostat circuit with compensation outside the negative feedback loop.

are the potentiostat and IR feedback amplifiers respectively; R_e and C_d represent the electrochemical cell (a relatively accurate analog for high frequencies and low amplitude input signals); R_1 a resistor placed external to the cell for sampling the current-proportional IR voltage feedback signal, $J(s)$; $O(s)$ and $V(s)$ are defined in Eq. [2]; R_1 and R_2 fix the closed loop gain of the feedback amplifier; and R_M represents the mixing resistors for the addition of $V(s)$ and $J(s)$.

The over-all transfer function of this system may be written by considering Eq. [1] and taking into account $J(s)$. Thus

$$\frac{O(s)}{V(s)} = \frac{G_1(s)}{1 + (H(s) - J(s))\, G_1(s)} \qquad [9]$$

It will be considered here, that a potentiostat is available for which the gain function $G_1(s)$ is given by Eq. [8]. As indicated earlier it will be difficult to obtain a potentiostat which will have a zero order gain function for the variety of electrochemical cell conditions normally encountered. Since $H(s)$ is defined as the fraction of the output voltage which is fed back to the noninverting input of the potentiostat, it is given by

$$H(s) = \frac{(R_e + R_i)\, C_d s + 1}{(R_e + R_i + R_o)\, C_d s + 1} \qquad [10]$$

$J(s)$ is the voltage feedback ratio at the output of the IR feedback amplifier and is given by

$$J(s) = \frac{R_i\, C_d s\, G_2(s)}{(R_e + R_i + R_o)\, C_d s + 1} \qquad [11]$$

where $G_2(s)$ is the gain function of the IR feedback amplifier. Since the total order of the system is to be kept as low as possible, it is desirable that $G_2(s)$ be effectively given by K_2 which is simply the closed loop gain magnitude of the positive feedback amplifier. This can be accomplished if an operational amplifier, which is used merely as a voltage and not a current amplifier, can be obtained with a unity gain crossover point at least one order of magnitude above that which is possible with the potentiostat. If, in addition, the amplifier is employed at a relatively low ($\approx$10) closed loop gain, its closed loop time constant becomes small enough such that $G_2(s) = K_2$.

In order to use the above considerations to develop an expression which may be used to evaluate the stability of the system, it is convenient to define the quantity $E(s)/V(s)$ where $E(s)$ is the voltage function actually appearing across the potentiostat control points and $V(s)$ is the voltage function of the perturbation applied at the potentiostat input as defined earlier. $E(s)/V(s)$ can be regarded as an ideality ratio mea-

suring the degree to which the potentiostat can apply the input driving function across its control points. $E(s)$ is related to $O(s)$ by

$$E(s) = O(s) - i(s)\, R_o \qquad [12]$$

where $i(s)$ is the total output current. Using [9], [10], [11], and [12] the following expression for $E(s)/V(s)$ may be obtained

$$\frac{E(s)}{V(s)} = \frac{K}{K+1}\left[\frac{(R_e + R_i)\, C_d s + 1}{\left[\frac{(R_e + R_i + R_o)\, Cd\, \tau\, s^2}{K+1} + \left\{\frac{(R_e + R_i + R_o)\, C_d}{K+1} + \frac{K(R_e + R_i - R_i K_2)\, C_d}{K+1} + \frac{\tau}{K+1}\right\} s + 1\right]}\right] \qquad [13]$$

The system as chosen is thus second order and consideration of the expression between brackets in the denominator of the r.h.s. of [13] is, as indicated earlier, sufficient to evaluate the stability conditions for this particular electrochemical cell analog.

In order to analyze these conditions in terms of a real electrochemical system, it is convenient to define the following quantities

$$\tau_c = (R_e + R_i + R_o)\, C_d \qquad [14]$$

$$\tau_u = (R_e + R_i - R_i K_2)\, C_d \qquad [15]$$

$$\tau_e = \frac{\tau}{K+1} \qquad [16]$$

where τ_e is an experimentally obtainable quantity. Thus for any given potentiostat for which the open loop gain, K, is known (the manufacturers value may usually be relied upon), evaluation of the closed loop time constant, τ_e, under unity gain conditions on a purely resistive load allows relation [16] to be obeyed. This evaluation should be carried out at the power level of the particular experiment with IR compensation employed. The manufacturer's value of τ should not be used since this is usually obtained under essentially no-load conditions.

Using Eq. [14] to [16] the critically damped behavior allowable in terms of [13] is then

$$\tau_u + \frac{\tau_c}{K+1} + \tau_e = \sqrt{4\, \tau_c\, \tau_e} \qquad [17]$$

Equation [17] then allows the experimentally useful minimum time constant τ_{min} of the system at maximum stable positive feedback to be established

$$\tau_{min} = \sqrt{\tau_c \tau_e} \qquad [18]$$

Consideration of [18] indicates that the larger the cell time constant or the longer the closed loop potentiostat rise time, the larger the minimum time constant of the system. This means that, *e.g.*, for a given C_d, the larger R_e is, the larger τ_{min} will be at critical damping. The same reasoning holds true for every component of τ_c. Note that, in general the larger R_o is, (*i.e.*, the more resistance between counter and reference electrodes or the use of a large current sampling resistor), the larger τ_e will be since more power is thereby demanded of the potentiostat and τ_{min} is thus increased. It is therefore quite obvious that experimental conditions should be chosen to achieve minimum τ_e. This is of great importance in the choice of the manner in which IR compensation is carried out. Thus for maximum speed of compensation R_i should be placed in the working electrode circuit, *i.e.*, outside the negative feedback loop as opposed to being placed in this loop thereby effectively increasing R_o.

It is now appropriate to discuss what the minimum time constant, τ_{min}, signifies in terms of the degree of compensation of a given system. To do this it is necessary to establish what is actually meant by complete IR compensation. In the ideal case, for a perfect potentiostat, the current $i(s)$ required to charge C_d is given by

$$i(s) = V(s)\, C_d s \qquad [19]$$

where $V(s)$ is the input voltage function to the potentiostat. From a practical point of view this relation can of course never be satisfied for a voltage step or relatively high a-c frequencies, since it would require that the potentiostat be an infinite source of current. The charge of C_d will then always occur in some finite time and, for the model used in this study, the time for critically damped charging will be given by τ_{min}. In terms of Eq. [19], therefore, overcompensation can never take place due to the existence of the quantity τ_{min}. In fact, complete compensation can never take place even with a potentiostat which is several orders of magnitude better than the present state of the art models.

What then is meant by overcompensation? To understand the significance of this, it is sufficient to examine how τ_{min} is defined in terms of both the cell and potentiostat parameters. Using [17] and [18] τ_{min} may be defined as

$$\tau_{min} = \sqrt{\tau_c\, \tau_e} = \frac{\tau_u}{2} + \frac{\tau_c}{2(K+1)} + \frac{\tau_e}{2} \qquad [20]$$

Equation [20] shows that τ_{min} is a function of the amount of positive feedback τ_u as well as of both the cell and potentiostat time constants. Complete compensation in terms of previous definitions (23, 25) occurs when $\tau_u = 0$. It is quite clear that under these conditions τ_{min} still contains terms involving both the electrochemical system and the potentiostat. For the condition $\tau_u = 0$, Eq. [20] may be satisfied in a physically meaningful fashion only for the condition

$$\tau_c \geq 4\, \tau_e\, (K+1)^2 \qquad [21]$$

which means that the time constant of the cell has to be considerably larger than that of the closed loop potentiostat in which case the minimum time constant contains only electrochemical parameters.

Further examination of [20] indicates that, provided [21] is satisfied, it is possible for τ_u to become negative. This, however, does not mean that overcompensation has taken place since the system still has a finite time constant, but merely means that Eq. [20] is satisfied at the critical damping point of the system. The difficulty then essentially lies in the interpretation of the experimental results. If, as in the potential step method, it is desired merely to charge C_d as rapidly as possible in order to unmask faradaic current at the shortest possible times, then it is immaterial what constants τ_{min} is composed of. The only requirement is that the experimental conditions be arranged to achieve the smallest possible value for τ_{min}. However, it is often desirable to evaluate C_d using IR compensation. When this is so Eq. [20] clearly shows the conditions under which τ_{min} is appropriately determined by the electrochemical cell parameters, which then allow an unambiguous evaluation of C_d. Obviously there are cases in which this will not be possible.

In order to avoid the difficulty of determining C_d when employing compensation, it is possible to obtain results such that the quantity $Z(s)$ as defined by Eq. [1] may be evaluated. Equation [1] shows that $Z(s)$ is determined only by electrochemical cell parameters. For the model used in this study $Z(s)$ is given by

$$Z(s) = R_e + \frac{1}{C_d s} \quad [22]$$

Obtaining $Z(s)$ from experimental measurements necessitates a knowledge of the total current $i(s)$ flowing through the system. This quantity is related to $O(s)$ by the expression

$$O(s) = i(s)\,[R_o + R_i + R_e + 1/C_d s] \quad [23]$$

which states that the total output voltage of the potentiostat is the product of the current and the total impedance. Using [9], [10], [11], and [23] the following expression for $i(s)$ can be obtained

$$i(s) = \frac{K}{K+1} \frac{V(s)\,C_d s}{\tau_c \tau_e s^2 + (\tau_u + [\tau_c/K + 1] + \tau_e)s + 1} \quad [24]$$

where τ_c, τ_u, and τ_e are again defined in [14], [15], and [16], respectively.

The voltage appearing across the potentiostat control points (*i.e.*, between the reference and working electrodes) has been previously defined as $E(s)$ which is given in Eq. [13] for the case in which IR compensation is carried out in the working electrode circuit. The desired quantity $Z(s)$ is now obtained simply by dividing Eq. [13] by Eq. [24]. The result is

$$Z(s) = \frac{E(s)}{i(s)} = R_e + R_i + \frac{1}{C_d s} \quad [25]$$

This expression differs from Eq. [22] in the presence of the additional term R_i. This is to be expected since for this type of compensation R_i now appears between the potentiostat control points (see Fig. 5) and must be added to the electrochemical cell impedance. Inspection of [25] shows that the potentiostat characteristics, K and τ_e, as well as the time constant resulting from any degree of positive feedback, have been eliminated allowing only the desired electrochemical parameters to be obtained. Thus $Z(s)$ is a characteristic only of the quantities existing between the potentiostat control points and may be obtained no matter what the quality of the potentiostat is, or the type of perturbation, $V(s)$, applied to the system. $Z(s)$ is also obtained at any degree of compensation, however, the experimentally accessible information content at short times of both $E(s)$ and $i(s)$ becomes progressively better as the degree of positive feedback approaches critical damping, and for τ_{min} as small as possible. Thus, if R_e is large enough to effectively mask C_d at the short times of interest in this study ($s >> 1$), and if the system is such that the difference between τ_{min} and τ_c is only 10%, the evaluation of $Z(s)$ would still essentially allow only R_e to be evaluated at short times. This point is especially important when it is desired to determine C_d in the presence of a relatively fast faradaic reaction.

The impedance function $Z(s)$ may be obtained from either pulse or a-c measurements. For the former it is necessary to perform either real axis ($s = \sigma$) or imaginary axis ($s = j\omega$) Laplace transformation on both the total time domain (*i.e.*, experimentally measured) current, $i(t)$, and voltage $E(t)$ appearing across the potentiostat control points. This effectively converts the time domain results into the frequency domain as defined by the Laplace variable, s. The manner in which this may be performed has been discussed elsewhere (7, 29).

In the case of a-c measurements the results are obtained directly in the frequency domain since in this case, when steady-state is achieved, $s = j\omega$. The evaluation of the quantity $Z(s = j\omega)$ can then be carried out in a manner exactly analogous to that for pulse measurements. The experimental measurements, when a potentiostat is employed, are usually carried out either by direct measurement of the impedance magnitude and phase angle or by direct measurement of the real and imaginary parts of the impedance using phase sensitive detectors. Thus, in order to obtain $Z(s = j\omega)$ the a-c voltage across the potentiostat control points and the total a-c current must be employed. As in the pulse case, the information content at higher frequencies is increased when more positive feedback is employed and when τ_{min} is as small as possible. When measurements are performed in this way the phase angle will be the same at a given frequency independent of the amount of positive feedback employed (except of course when the stability conditions are exceeded). This is so since proper positive feedback merely changes the signal amplitude and not its phase relation provided that the voltage reference for phase is taken across the potentiostat control points as it must be in order to obtain $Z(s = j\omega)$.

The question of detection of optimum compensation conditions may now be examined. When a pulse or triangular voltage waveform is employed the onset of ringing is usually the most convenient manner to evaluate τ_{min}. In the a-c case phase angle measurements or phase sensitive detection cannot normally be used (this point will be discussed further below). However, the onset of nonlinearity caused, *e.g.*, by excitation of the ringing frequency may certainly be employed. This would probably necessitate the use of a distortion analyzer. As in the pulse or triangular waveform case complete IR compensation may not be achieved in a practical system. It is thus experimentally impossible to achieve either a phase angle of —90° or a zero in-phase component over the complete frequency range desired (*e.g.*, 1 Hz to 1 MHz) when the reference a-c voltage employed is that in the absence of compensation (*i.e.*, the total a-c voltage appearing across the potentiostat control points minus the compensation signal). The most convenient way to measure phase in this way would appear to be to use the voltage applied at the input of the potentiostat, $V(j\omega)$.

In order to determine what parameters have to be taken into account when the phase reference is taken as $V(j\omega)$, Eq. [24] may be employed. For the condition $s = j\omega$, and at critical damping, the following equation may be written

$$Z_A(j\omega) = \frac{V(j\omega)}{i(j\omega)} = \frac{1 + \omega^2 \tau_c \tau_e}{\omega C_d} e^{-j\pi/2}\, e^{j\theta} \quad [26]$$

where

$$\theta = \tan^{-1}\left[\frac{2\sqrt{\tau_c \tau_e}}{1 - \omega^2 \tau_e \tau_c}\right] \quad [27]$$

and $Z_A(j\omega)$ is the apparent complex electrochemical cell impedance.

Equation [26] may be compared to the expression for the ideal impedance $Z_I(j\omega)$ which would be obtained if the system behaved as though all series resistance ($R_e + R_i$) had been removed. This is given by

$$Z_I(j\omega) = \frac{1}{C_d} e^{-j\pi/2} \quad [28]$$

Comparison of [26] and [28] shows that in certain frequency ranges both the measured impedance magnitude and phase angle may differ substantially from that which would be obtained if all R_e and R_i were effectively removed. Thus, minimum magnitude error is obtained only for the condition $\omega << 1/\sqrt{\tau_c \tau_e}$, which means that only at frequencies much lower than the corresponding minimum time constant τ_{min} will the error be tolerable (two orders of magnitude lower for 1% error). Higher frequencies may of course be achieved as τ_{min} becomes lower and lower (*i.e.*, as the potentiostat employed for a given system becomes faster the higher is the minimum amplitude error frequency).

Evaluation of the minimum phase angle error may be carried out if the following equation, valid for small phase errors (≈1°) is employed

$$\theta = \frac{2\omega\sqrt{\tau_c \tau_e}}{1 - \omega^2 \tau_e \tau_c} \quad [29]$$

Using [29] the frequency ω_o at which the phase error is 1 degree is found to be

$$\omega_o = \frac{1.4 \times 10^{-3}}{\sqrt{\tau_c \tau_e}} \text{ Hz} \quad [30]$$

This again indicates that the minimum phase error frequency is substantially lower than τ_{min} and is one order of magnitude lower than the minimum amplitude error frequency. Conclusions identical to those for minimum amplitude error concerning the effect of a faster potentiostat prevail for minimum phase error.

The above considerations indicate that the evaluation of electrochemical parameters from a-c measurements must be carried out with extreme caution when IR compensation is employed particularly when phase angle measurements or phase sensitive detection are employed using $V(j\omega)$ rather than $E(j\omega)$ as phase reference.

Experimental and Results

In order to illustrate and test the model developed above for high speed ohmic drop compensation in the case of the potential step method, the basic circuit shown in Fig. 5 was employed. The potentiostat, A_1, is the ultrafast rise Tacussel Model PIT-20-2A provided with external phase compensation, the gain function for which is given by Eq. [8]. The IR feedback amplifier, A_2, is an Optical Electronics Inc. Model 9186 chosen for its unity gain cross-over point of 1 GHz and its provision for external phase compensation. This amplifier is the fastest known of the operational type having sufficient voltage and current range for the present application. Its low input impedance and limited current output (5 mA) prohibit its use as a potentiostat of the single amplifier type. For the present application the resistors in the loop of the OEI 9186 are chosen for appropriate closed loop gains to obtain sufficient positive feedback. For this $R_1 = 1$ k-ohm and R_2 is variable from 5 to 30 k-ohms in 5 k-ohm steps. Note that in general low value metal film resistors should be used for high speed operational amplifier applications (*e.g.*, R_1 and R_2 should not be tenfold larger, nor should they be wirewound). The step voltage source $V(s)$ is the Monsanto 300A pulse generator correctly mated to the potentiostat. The mixing resistors, R_M, are chosen in this case to be 1 k-ohm. Note that the best possible signal mixing should be carried out using a 50 ohm system. Unfortunately, however, an operational amplifier, having the characteristics of the OEI model, able to supply at least 5V into 50 ohms is not available at the present time. Thus in order to be able to obtain the required 5V from the OEI model, it is necessary that $R_M = 1$ k-ohm, which enables the time constant of the mixing network to be kept acceptably small.

Special attention must be given to the manner in which the amount of positive feedback voltage is adjusted. In the early applications of this technique R_i was simply a GR decade resistor box which enabled the feedback voltage to be increased to critical damping value by a stepwise augmentation of R_i. This approach has two inherent disadvantages if maximum compensation speed is desired. Thus as the critical damping point is approached τ_c becomes progressively larger because R_i is increased rendering τ_{min} larger than it need be. In addition, the residual inductance of these resistors is high enough ($\approx$1 μH) to cause considerable error at the frequencies attainable in this work. The use of, *e.g.*, a carbon potentiometer either in place of the decade resistor or at the output of A_2 is also not acceptable for high speed work since these are even more inductive and have high capacitance associated with them. The optimum manner found to attenuate the positive feedback signal with adequate resolution was to employ a fixed resistance for R_i and place a step-wise high frequency attenuator in series with the input to A_2. The attenuator chosen for this work is the Texscan Model RA-535 which allows 11 db of voltage attenuation in 0.1 db steps and is linear to 500 MHz. Use of this attenuator requires that it be terminated with 50 ohms which then restricts R_i to this value. In order to obtain sufficient positive feedback for values of R_c generally encountered in high speed kinetics studies (10-1000 ohms) the gain of A_2 was rendered adjustable in fixed steps from 6 to 30. The oscilloscope employed in this study was the Tektronix 556 equipped with two 1A5 preamplifiers. All voltage measurements were made using Tektronix P6045 probes at the input of the preamplifiers. These probes allow measurements to be made at nanosecond times with little or no perturbation on the system. In addition they can be matched to better than 0.5%.

In order to illustrate the affect of compensation on the observed current response to a potential step initial measurements were performed on an equivalent circuit with $R_e + R_i = 266$ ohms, $R_o = 0$, and $C_d = 0.15$ μF. Note that measurements performed on electrical analogs at the frequencies attainable in this work require that the components be suitable for high frequency work. Thus only metal film resistors and glass capacitors are used in this study. The photographs shown in Fig. 6 are oscilloscopic traces of the current-time curves experimentally obtained using the above components. The amplitude of the input voltage signal, $V(s)$, was chosen in each case so as to obtain 0.4 mA per major division on the vertical axis.

The validity of the model employed to evaluate the performance of the system employed in this study may readily be determined by evaluation of τ_{min}. This quantity is experimentally obtainable by determination of the time required for C_d to achieve 99% charge at critical damping. The results in Fig. 6b show that the experimental τ_{min} is 2.76 μsec. The closed loop potentiostat time constant τ_e for this circuit is 0.06 μsec and $\tau_c = 120$ μsec. Using these quantities τ_{min} is calculated from Eq. [18] to be 2.68 μsec. This is satisfactory agreement. In order to more fully test the theory a variety of equivalent circuits having τ_c from 15 to 350 μsec were examined. The results are shown in Table I. It may be seen that the average error between calculated and observed τ_{min} is approximately 5% which is sufficiently low to consider that the model considered in this study for IR compensation satisfactorily describes the actual experimental system.

An attempt was made to evaluate C_d from the time domain current response at critical damping for each of the circuits used above. The results in almost every case were ambiguous since a straight line plot of log i *vs.* t which would normally be valid for the series RC circuit used here was not obtainable over a sufficiently large time range. It is considered that a plot of this type over at least two orders of magnitude of t should be obtained for unambiguous results. In addition, this condition must be achieved at sufficiently short times if C_d is to be evaluated in the presence of a relatively fast faradaic reaction.

As was indicated earlier in the theoretical analysis, evaluation of the quantity $Z(s)$ from a knowledge of both $E(t)$ and $i(t)$ should alleviate the above difficulty. It will be remembered that $Z(s)$ is a characteristic only of the parameters existing between the potentiostat control points (in this case R_e, R_i, and C_d). Thus the actual shape of the current and voltage time curves is immaterial (*i.e.*, it does not matter whether or not the potential step has actually achieved its plateau value for meaningful results to be obtained). For this reason data points for both $E(t)$ and $i(t)$ as close to $t = 0$ as is experimentally possible may be utilized. In these experiments the first data point was normally obtained at 10 nsec to enable accurate real axis transformation to be accomplished for large σ values (29).

The evaluation of $Z(s)$ was carried out on a cell analog in which $R_e + R_i = 1050$ ohms and $C_d = 0.15$ μF.

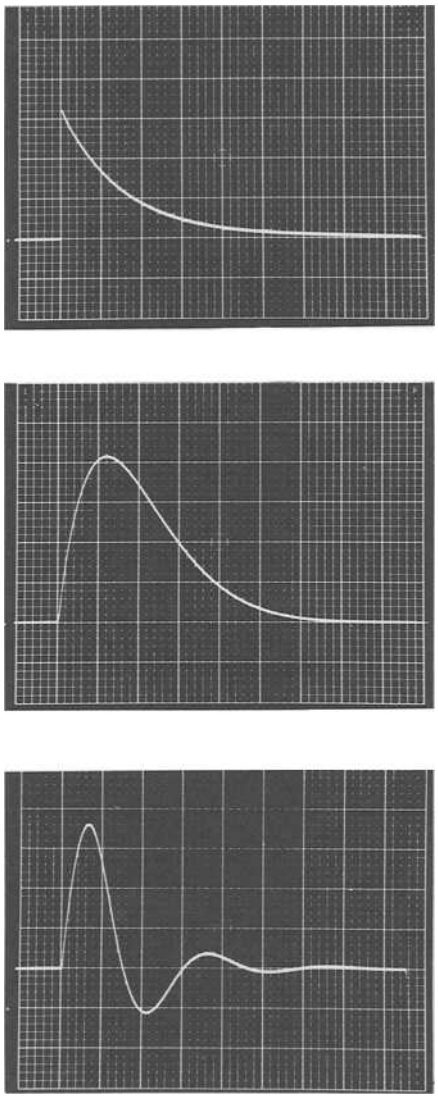

Fig. 6. Oscilloscope traces of current-time response curves to voltage step input. In each case the vertical axis (current) is 0.4 mA per major division and the horizontal axis is time as indicated below: (a) uncompensated system, 50 μsec per major division: (b) compensation at critical damping, 2 μsec per major division: (c) compensation exceeding critical damping, 10 μsec per major division.

Real axis ($s = \sigma$) Laplace transformation was performed with the aid of a digital computer (Burroughs 5500) on both $E(t)$ and $i(t)$. Results were obtained in the absence of compensation and at critical damping. In both cases $Z(s = \sigma)$ should be given by

$$Z(s = \sigma) = R_e + R_i + \frac{1}{C_d \sigma} \qquad [31]$$

Thus a plot of $Z(s = \sigma)$ *vs.* $1/\sigma$ should result in a straight line, the slope of which contains C_d while the intercept gives $R_e + R_i$. This plot is shown in Fig. 7 which shows the variation in $Z(s = \sigma)$ over two orders of magnitude in σ. This figure indicates that significant results are obtained in this time (frequency) range only when significant compensation is employed. Thus in the uncompensated case $R_e + R_i$ are overwhelmingly responsible for the current response and the experimental results reflect this condition enabling only the series resistance to be detected in the range $\sigma = 10^6 - 10^7$ and causing gross inaccuracies in the results down to $\sigma = 10^5$. It can then be seen that the use of compensation results in greatly increased experimentally accessible information content in the short time data enabling detection of, *e.g.*, double layer charging in the presence of a faradaic process. Particular attention should be paid to the fact that meaningful results have been obtained for σ values as large as 5 x 10^7 (see Fig. 7) which corresponds to a frequency of 50 x 10^6 rad/sec. This is a relatively high frequency necessitating certain experimental precautions. At these frequencies the major error is caused by the presence of inductance, *e.g.*, in the external electrical leads. For these experiments lead length could be kept to substantially less than 3 cm. However, in an actual electrolytic cell longer lead length is a necessity. In this laboratory cells requiring connecting leads of only 2-10 cm have been constructed which allow satisfactory results to be obtained at frequencies of up to 10^7 rad/sec. The description of this cell and results obtained with it will be reported elsewhere.

Table I. Comparison of theoretical and experimental τ_{min} values*

Conclusion

The analysis presented in this study of the requirements for high speed IR compensation in potentiostatic techniques has enabled some basic criteria for the application of this technique to be established. The results indicate that the choice of a fast system should be predicated on achieving the lowest possible order for its transfer function which may be accomplished through the use of present state of the art potentiostats and operational amplifiers. However, the best that can presently be achieved is a second order system which by definition may exhibit instabilities if excessive positive feedback is employed. Examination of the stability criteria for this system allows the minimum time constant, τ_{min}, achievable at critical damping to be determined. The fact that τ_{min} is always a finite quantity implies that overcompensation in the absolute sense (*i.e.*, achieving the proper response to charge C_d in the absence of any series resistance) is a physical impossibility. Consideration of τ_{min} indicates that it is generally the sum of time constants involving both the electrochemical cell and the potentiostat, and it becomes difficult in some cases to evaluate unambiguously both the uncompensated resistance and the double layer capacitance. This problem may be overcome if the total cell impedance $Z(s)$ is determined

which effectively eliminates the potentiostat characteristics and τ_{min}. When compensation is employed, the experimentally accessible information content of the experimental data at critical damping is increased roughly by the percentage that τ_{min} differs from τ_e allowing more accurate results to be obtained at shorter times or higher frequencies thus allowing $Z(s)$ to be evaluated more precisely. This is of great importance when R_e is very large and it is desired to evaluate C_d in the presence of a relatively fast faradaic reaction. The detection of optimum compensation is straightforward for the case of the potential step technique, however, it becomes much less straightforward when a-c techniques are employed. For the latter, it is shown that the use of phase sensitive detection employing the potentiostat driving voltage, $V(j\omega)$, as phase reference can lead to severe errors in the interpretation of experimental data.

Double Layer Capacitance on Platinum in 1M H_2SO_4 from the Reversible Hydrogen Potential to the Oxygen Formation Region

Murray Rosen,[1,*] David R. Flinn,[1,*] and Sigmund Schuldiner*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C.

ABSTRACT

Improved design and electronics which gave maximum oscilloscopic screen sensitivities of 5 mV and 5 nsec/div permitted measurements with single, relatively high intensity galvanostatic pulses of short duration so that the net perturbation of the system from equilibrium or steady state was small. This arrangement gave accurate separation of double layer, faradaic, and adsorption/desorption processes at times less than 200 nsec. The double layer capacitance at a clean, bright Pt electrode in 1M H_2SO_4 was measured from the reversible H_2/H^+ equilibrium potential to 1.2V *vs.* N.H.E. The double layer capacitance of the normal equilibrium hydrogen electrode on Pt was found to be 17 ± 1 μF/cm^2 (all measurements were on a true area basis). The double layer capacitance increases to 30 μF/cm^2 at 0.15V and uniformly decreases to 17 μF/cm^2 at 0.7V. Above 0.9V, the formation of highly polarized oxygen atoms on the Pt causes the capacitance to increase. The exchange current density for the $H \rightleftarrows H^+ + e$ reaction was found to be 0.44 A/cm^2. No "ideally" polarized potential region was found.

The measurement of the double layer capacitance on Pt has been complicated by impurities, fast faradaic reactions, and adsorption/desorption processes (1-3). At the reversible H_2/H^+ potential, double layer capacitance measurements have previously been masked by the pseudocapacitance which resulted from the fast hydrogen oxidation/reduction process occurring in parallel with the double layer charging. In the present work, the pseudocapacitance, adsorption/desorption, and impurity effects have been virtually eliminated, and the double layer capacitance *vs.* potential relation-

ship has been determined from the equilibrium H_2/H^+ potential (N.H.E.) to 1.2V positive. The technique used examined the potential response of a Pt electrode/solution interface to a constant current pulse at very short times just after the perturbation time (4, 5). The latter phenomenon was shown to occur in 1M sulfuric acid solution in the first 38 nsec immediately after the application of a pulse.

Improvements in the cell design and electronic equipment used at this Laboratory to identify and to investigate the perturbation time have permitted a more precise separation of the faradaic, nonfaradaic, and double layer processes at times less than 200 nsec. A sensitivity of 5 mV/div on the oscilloscope potential axis and 5 nsec/div on the time axis of a single galvanostatic pulse has been achieved. As previously pointed out (6), high precision is required for double layer measurements on the non-ideally polarized Pt electrode.

Experimental

The electrochemical cell is shown in Fig. 1 and primarily varies from those used in past short pulse techniques (4, 5) by having a solution compartment above the coaxial arrangement of electrodes. The new cell permitted any arrangement of gas, a pre-electrolysis electrode, an α-Pd-H reference electrode, and a glass reference electrode to be introduced or removed at will.

In the circuitry shown in Fig. 2, the combination of resistor R_T and diode 1N914B are required to isolate the small d-c current which is always present at the output of the EH132A pulse generator. The value of resistor R_1 was such that the total pulse generator load exactly matched its output impedance, which was 50 ohms. The use of the Tektronix P6046 differential probe enabled potential measurement between the reference electrode and the grounded working electrode with *IR* compensation accomplished at the measurement point. This differential probe has a rise time of 3.5 nsec for all gain positions, with a maximum sensitivity of 1 mV/div. The Tektronix 454 oscilloscope also has a rise time of 3.5 nsec and has a maximum sweep rate of 5 nsec/div. A single sweep pulse was

recorded with a Tektronix C-31 Camera (f/1.2 lens) using Polaroid 10,000 ASA film. In order to maintain a useful relative perspective, most double layer capacitance measurements were made using a vertical sensitivity of 10 mV/div and a horizontal sweep rate of 20 nsec/div. The capacitance values at these sensitivities were the same as those determined at the maximum sensitivities of 5 mV/div and 5 nsec/div.

The working Pt electrode has a true area of 0.329 cm^2 as determined from measurements to be discussed later. All current density and area measurements reported in this paper are on the true area basis (2). The Pt reference electrode had slightly less area and was mounted parallel to the working electrode. These electrodes were surrounded by a large cylindrical Pt gauze counter electrode, approximately 0.5 cm in diameter and 2 cm in length. The circuit shown in Fig. 2 has been checked by substitution of the cell with several different equivalent circuits containing carefully calibrated components. Two differential probes were shown to have the same response and agree within experimental error when used with the equivalent circuits and the real cell.

The method of gas purification and distribution through a gastight, glass pipe system has been previously described (2). In addition to these pure gas sources, an electrolytic hydrogen-oxygen generator was placed directly in the He gas line. By the use of this generator, the partial pressure of hydrogen or oxygen passing through the cell could be varied from 0 to about 0.2 atm.

The method of cell cleaning has been previously described (5). In addition to this cleaning, the cell was later inverted while steam produced from triply distilled water was passed through the cell for at least 24 hr. The cell was then placed upright and allowed to fill with condensed water. The proper amount of ultrapure H_2SO_4 (E. Merck A. G., Darmstadt, containing impurities at generally less than the 10^{-7}% level) was then added to the cell.

Carefully cleaned shrinkable Teflon was used to couple short pieces of regular Teflon tubing to the cell. Concentric pieces of Teflon tubing were used for gas inlet and exit, giving the cell some flexibility when it was coupled into the regular glass pipe system. Gas entering the cell passed through the center Teflon tubing, while exit gases moved in the outer tube. This method effectively prevented appreciable oxygen leakage into the cell through the Teflon walls, as was shown by the fact that upon removing hydrogen from the cell and substituting helium the potential never rose above about 0.2V. Also, the seals made with the shrinkable Teflon tubing were gastight when checked with a leak detector sensitive to less than 0.1 ft^3/yr.

After the cell was cleaned and filled with solution, a pre-electrolysis treatment was performed. In this procedure, all of the Pt electrodes in the cell were made the anode with respect to a removable Pt cathode. A current of about 1 mA was passed through the cell for a 24-hr period in He-saturated solution. The removable cathode was then replaced by a clean glass

electrode, again coupled to the cell using several layers of clean, shrinkable Teflon tubing. Hydrogen was then introduced into the cell and the electrodes were left at open circuit for several hours to remove the last traces of oxygen.

A Pd wire was then introduced into the solution through the gas exit tube and was charged with hydrogen at 2 mA for ½ hr giving a stable reference electrode (7). This electrode was used for potentiostatic control of all further cell electrolytic purification and made it possible to control the electrolysis potential in the presence or absence of hydrogen. Electrolytic purification was repeatedly carried out between measurements using the working, reference, and counter electrodes as the anode and a small Pt wire mounted in the upper part of the cell as the cathode. It was necessary to remove the Pd wire from solution contact during capacitance measurements, since it was in effect an antenna which introduced sufficient noise in the reference electrode circuit making measurements impossible. The potential of the working electrode during electrolysis and during capacitance measurements was monitored by the use of the glass electrode, using a Keithley model 630 potentiometric electrometer. Cleanliness tests, which are discussed below, indicated that oxidation of organic impurities was more successful when done in the presence of a small amount of hydrogen mixed with helium than when done in pure helium. The hydrogen partial pressure during electrolytic purification was normally about 0.1 atm. The temperature was maintained at 25° ± 1°C.

Two tests were used for cleanliness. First is the shape of the anodic charging curve in H_2-saturated solution (2). In a clean system, the small breaks seen along the charging curve in the H atom ionization region are very distinct, as is the sharp transition from the H atom ionization to atomic oxygen formation region. Also, the O atom adsorption region is very linear in a clean system. The fact that an electrode remained at open circuit for many hours in a solution and still exhibited the same anodic charging curve was taken as good evidence of a clean system. The amount of charge required to move through the various regions had to remain invariant; that is, the charge required for hydrogen ionization and oxygen atom formation had to remain fixed.

The second check for cleanliness was less direct but was shown to parallel the first method. The capacitance at the N.H.E. potential was not strongly dependent on impurities. However, at potentials positive to 0.1V, the capacitance depended quite strongly on impurity adsorption at the electrode. This effect could be observed by first employing an anodic pulse to clean the electrode, followed by capacitance measurements made every few minutes for an hour or more. In an unclean solution the capacitance would slowly fall, while in a clean system the capacitance remained constant for times as long as 3 or 4 hr.

Results

The current density, i, is determined by measuring the time, t, required to generate one monolayer of O atoms, assuming that 456 $\mu C/cm^2$ is the charge required (2, 8). A pulse which represents a clean system and is used to determine current density is shown in Fig. 3a. The current density thus obtained is used to determine the double layer capacitance, C, from the potential response of the working electrode over a known period of time; hence,

$$C = i\frac{\Delta t}{\Delta E} \qquad [1]$$

The $\Delta t/\Delta E$ ratio at very short time and low polarization is considered to approach dt/dE, so that the true differential capacitance is virtually determined. For each measurement, a single, short, high current density galvanostatic pulse was applied to the working electrode which was at a steady-state potential prior to application of the pulse. The measured capacitance was independent of the galvanostatic pulse current density from 1 to 6 A/cm^2. Most of the data were taken using a 2.60 A/cm^2 pulse current.

A typical response of the working electrode to a single, constant current pulse is shown in Fig. 3b. This picture includes an approximately 0.4V solution IR drop and shows about 35 nsec of time from the initiation of the pulse to the point after which meaningful capacitance measurements may be taken. Because of experimental requirements, the cell used was not as compact as those previously used to determine perturbation time. The additional inductance and capacitance of the cell leads and components caused electrical disturbances which masked the perturbation region (4, 5).

The pulse current flow between counter and working electrode measured by use of a Tektronix P6020 probe placed around the working electrode lead wire is shown in Fig. 3c. The current is seen to be constant after about 30 nsec, and remained constant to 500 μsec.

In Fig. 3d, the response of the working electrode to a galvanostatic charging pulse of 2.60 A/cm^2 is shown on a more sensitive range of the differential probe with the solution IR drop fully compensated. The initial indeterminant electrode response has been shifted 40 nsec to the left on the oscilloscope screen. By measuring the initial linear potential response of 60 nsec, the capacitance may be calculated. The 40 nsec before capacitance measurements can be made does not appear to be as serious an experimental problem as might be thought, as was shown by the following experiment. By deliberately adding length to the connection between the cell and pulse generator, it was possible to produce an even longer indeterminate response, first up to 60 nsec and finally up to as long as 80 nsec, yet the initial capacitance determined after these longer times was the same, as was the over-all appearance of the curve. These results show that small electrical disturbances and inductive and capacitive time constant changes, which may delay the charging of the double layer up to 80 nsec, have no significant effect on double layer capacitance measurements.

The curvature present in the electrode response shown in Fig. 3d after the first 60 nsec does not appear to be due to a faradaic reaction. In the double layer capacitance *vs.* potential curve in Fig. 4, the capacitance is shown to increase with potential in the region from 0 to 0.15V, and it is possible to account for about 90% of the curvature observed in Fig. 3d by the changing capacitance. At more positive potentials, the response tends to become more linear as the capacitance becomes less potential dependent, but never becomes absolutely straight. This behavior seems to indicate rapid faradaic or adsorption/desorption processes at more positive potentials.

The potential of the working electrode as measured *vs.* the glass electrode was adjusted by four different procedures. In the first method, the amount of hydrogen in a helium gas stream was set to yield a given steady potential, after which the capacitance measurement was made. This procedure worked well in the region of 0 to 0.15V *vs.* N.H.E. In the second method, low concentrations of oxygen were introduced into the helium flow *via* the electrolytic generator. Potentials from equilibrium to about 1V *vs.* N.H.E. were set by this method. The rate of change of potential during oxygen addition could easily be controlled to less than 1 mV/min. In the third method, the working electrode was polarized by the use of repetitive short pulses, and the electrode was allowed to come to a steady potential for several minutes with continuous polarization. By this procedure, it was possible to collect capacitance data at any point over the entire potential range studied. Finally, in a few cases over the potential region between 0.3 and 1V, single, long pulses were employed to change the potential over a significant range, and the capacitance was determined as the electrode slowly

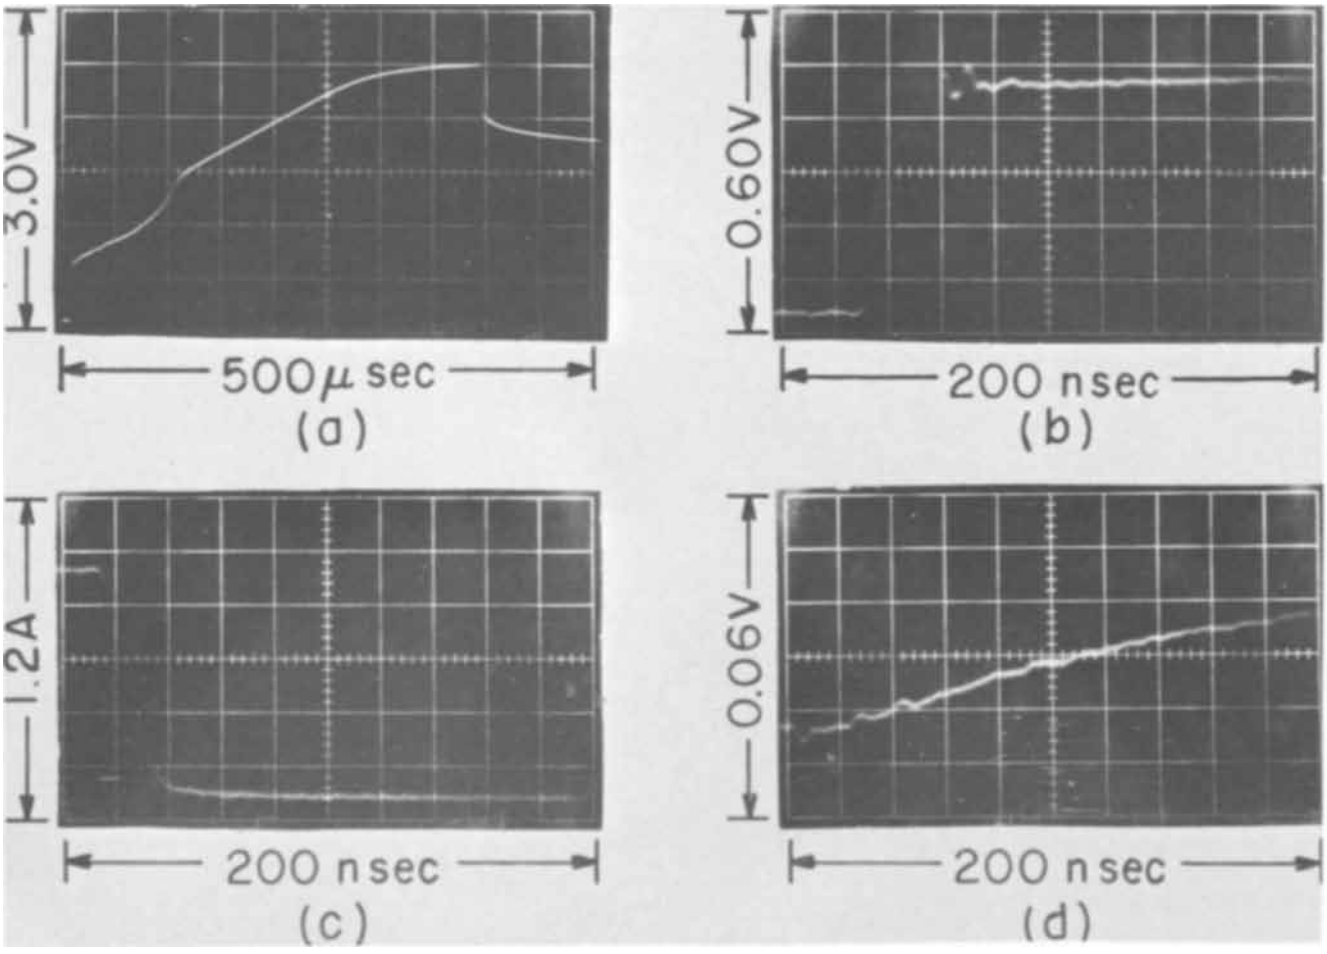

Fig. 3 (a) Typical anodic charging curve (i = 2.60 A/cm^2); (b) working electrode response at low sensitivity for 2.60 A/cm^2 constant current pulse without IR compensation; (c) pulse current flow between counter and working electrode measured with current probe; (d) working electrode response at high sensitivity for 2.60 A/cm^2 constant current pulse with IR compensation.

decayed through the desired potential. Within the ±5% experimental reproducibility, all of the above methods yielded the same result for the same measured potential from 0 to 0.95V *vs.* N.H.E. For the cases in which the electrode was made more positive than 1V for short times, and then allowed to decay to some less positive value, the measured capacitance would be too high for several minutes, indicating the presence of oxygen which is slowly removed from the electrode.

The double layer capacitance of Pt in 1M H_2SO_4 as a function of potential is shown in Fig. 4. The capacitance of 17 ± 1 μF/cm^2 measured at equilibrium appears to be the first accurately experimentally determined value of the double layer capacitance of an equilibrium hydrogen electrode. The capacitance is seen to pass through a maximum at about 0.15V *vs.* N.H.E. The scatter in the data was numerically largest in the region of the maximum, and this region was seen to be the most strongly influenced by organic impurities. In a clean system, the scatter of any point from the curve shown was about ± 5%. However, in the case of the presence of adsorbed impurities, an impurity level which reduced the capacitance at 0V by less than 1 μF/cm^2 reduced the capacitance by about 8 μF/cm^2 at 0.15V.

Discussion

The increase in capacitance noted above 0.9V has been cited and discussed (2, 9, 10) and is attributed to the presence in this region of a highly polarized chemisorbed oxygen-atom layer. The hysteresis noted here in capacitance measurements when the potential was reduced from above 1V down to some less positive potential has been observed by Laitinen and Enke in 0.01 and 1M $HClO_4$ solution (9). Near equilibrium, the potential response of the working electrode to the constant current pulse can be explained on the basis of the change in double layer capacitance with potential. This change means that the faradaic current component within the first 200 nsec is no more than about 5%, the average experimental error observed in these measurements. Consider the total applied anodic charging current density, i, to be divided between capacitive charging and a faradaic process, i_f(H = H$^+$ + e), then (11, 12)

$$i = C\frac{d\eta}{dt} + i_f \qquad [2]$$

$$i_f = \frac{i_o\,\mathbf{F}\eta}{RT} \qquad [3]$$

where η is the overvoltage, i_o is the equilibrium exchange current density, and R, T, and $\mathbf{F}$ are the gas constant, Kelvin temperature, and Faraday, respectively. Equation [3] assumes a linear current *vs.* overvoltage relationship over the low overvoltage region considered. Equations [2] and [3] may be integrated to yield

$$\eta = \frac{iRT}{i_o \mathbf{F}} \left\{ 1 - \exp \left[- \frac{i_o t \mathbf{F}}{CRT} \right] \right\} \qquad [4]$$

Equation [4] can be solved graphically to yield an i_o for the faradaic process, but care must be taken to assure that the experimental error does not override the faradaic contribution. For example, using a high current density pulse, we found $t = 100$ nsec, $\eta = 15.3$ mV, and $C = 17$ μF/cm^2. However, since the linear response found over the first 60-100 nsec shows that the contribution of the faradaic process to the measured capacitance is not detectable within the experimental limits of measurements, the above experimental results will not yield a solution for i_o. A necessary approach is to lower the amplitude of the applied current density pulse so that longer times are required to achieve comparable polarization, *i.e.* allow a significant faradaic component. To determine i_o, the amplitude of the galvanostatic pulse was reduced to 0.419 A/cm^2 causing a polarization of 13.6 mV in 800 nsec. Applying these values, along with $C = 17$ μF/cm^2, to the graphical analysis of Eq. [4] gave $i_o = 0.44$ A/cm^2.

An estimate of the experimental error involved in double layer capacitance determinations due to a faradaic component can now be made. If one assumes that the overvoltage in the typical high current density measurement given above ($t = 100$ nsec, $\eta = 15.3$ mV, and $C = 17$ μF/cm^2) is in error by 5% at the end of 100 nsec, η may be as small as 14.6 mV. Substituting into Eq. [4] gives $i_o = 0.1$ A/cm^2. If the error were 6%, i_o would be 0.4 A/cm^2. Therefore, even if i_o is of the order of 0.5 A/cm^2, the faradaic contribution to the calculated capacitance at times less than 100 nsec will be an insignificant portion (<5%) of the total capacitance. For longer times or higher polarizations, the faradaic component becomes a large portion of the total charging current.

In a paper by Schuldiner and Roe (2), the capacitance at Pt in 1M H_2SO_4 was determined using single 0.022 A/cm^2 current density pulses of 5 μsec duration. By this method, the measured capacitance near equilibrium was very erratic and varied from 100 to 300 μF/cm^2. These high capacitance values may now be explained on the basis of Eq. [4] and $i_o = 0.44$ A/cm^2. Schuldiner and Roe's measurement included pseudocapacitance, and they used Eq. [1] to calculate the net capacitance. For example, for a determined capacitance of 100 μF/cm^2, they observed an η of 1.1 mV. Using the correct capacitance value of 17 μF/cm^2, the 0.022 A/cm^2 current density and the 0.44 A/cm^2 i_o, Eq. [4] gives an η of 1.3 mV for a 5 μsec pulse. Thus, an $i_o = 0.44$ A/cm^2 satisfactorily predicts the observed overvoltage at the end of such a 5 μsec pulse. This observation means that an average of 80% of the applied current went into the faradaic reaction over this time. The possibility of the reaction of H_2 gas contributing to the total charge consumption at the low current density used should not be neglected. At higher current densities, contribution of H atoms from H_2 in solution is insignificant (8).

Schuldiner and Roe's (2) determination of double layer capacitance at potentials 0.1V positive to N.H.E. using 5-μsec pulses gives values about twice as high as those found in the present paper. These high capacitance values also have been found by others using similar techniques. The interesting feature of these measurements is that even those in the so-called double layer region (0.55-0.88V) require submicrosecond, high current density pulses to separate adequately double layer charging from faradaic and adsorption/desorption processes. In short, there is no "ideally" polarized potential region on Pt.

Measurement of the equilibrium capacitance also was made using the charge-step method. The current density was varied from 1 to 2.6 A/cm^2 and the time of charge input was varied from 60 to 140 nsec, so that q varied from 1 to 4 x 10^{-7} C. The decay responses, measured at 200 nsec/div, yield a linear log η against time curve. The initial overvoltage measured from these curves gave the same value as that measured directly from the oscilloscope pictures at pulse cut-off. The capacitance was found to be 17 $\pm$ 1 μF/cm^2 for all q values, so that decay and charging measurements result in the same capacitance value for the equilibrium case. Also, the slope of the log η *vs.* t curve yields a value of $i_o = 0.40$ A/cm^2 for the faradaic process, which is in good agreement with the low current-density pulse result.

The identical galvanostatic and charge-step results obtained at 0V indicates that adsorption-desorption processes are either of virtually infinite rate or that they are slow compared to the time periods of measurement used here. That the latter seems to be the case is supported by the high capacitance values found by Schuldiner and Roe (2) in the double layer region discussed earlier.

The agreement of the capacitance values determined by the use of both charging and decay techniques is, of course, important in itself. Moreover, the use of the charge-step technique is of interest for future work in dilute solutions in order to determine the potential of zero charge on a clean platinum electrode. Burshtein, Pshenichnikov, and Skevchenko (3) reported the presence of this capacitance minimum in 0.01N H_2SO_4 at 0.230V *vs.* N.H.E. and found its position to be pH independent.

Manuscript submitted March 24, 1969; revised manuscript received May 5, 1969. This was Paper 213 presented at the New York Meeting, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

The Rotating Split Ring-Disk Electrode and Applications to Alloy Corrosion

B. Miller*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The rotating ring-disk electrode technique has been extended to a split-ring design in which the half rings may be maintained at independent potentials. Availability of two detecting surfaces has facilitated studies in anodic dissolution of alloy or pure metal disks where two components or oxidation states can be simultaneously monitored. The construction of the split ring disk and operational amplifier circuitry for control of the three active electrodes (with disk potentiostatic or galvanostatic) are outlined. Applications to the anodic behavior of copper-zinc alloys in ammoniacal solution are discussed.

The utility of the rotating ring-disk system for observing both stable and unstable products of disk reactions has been well established since the original work of Levich, Frumkin, and Nekrasov (1-3). No studies of the dissolution under applied potential of metal disks appear to have been made to the time of Riddiford's review (4) but some such investigations (5-11) have been performed recently with ring-disks. Spontaneous reaction with disks (chemical corrosion or etching) has been studied [see (4)] where the solution is analyzed to determine the extent of reaction. The potential value of rotating disk studies for understanding metal and alloy corrosion processes is considerable, particularly with the addition of the ring to observe the products. To the measured corrosion behavior of the metal or alloy disk is added simultaneous information from the ring on the nature and amount of the species dissolving and, as the detectability of such ions varies with disk conditions, the results may be further interpretable in terms of film formation, change of mechanism, or chemical reaction in transit.

In many situations, *e.g.*, changing oxidation states in the anodic polarization of pure metals or multiple products in alloy dissolutions, the number of variables may make the combination of ring current and geometric collection efficiency (ratio of ring current to disk current for equal number of electrons transferred in the respective electrode reactions) insufficient to define the mass distribution adequately in a single experiment. In theory repetition of the experiment enough times or maintenance of a constant disk anodic reaction so that the ring can be adjusted to all necessary potentiostated conditions would give the total extractable information for that ring electrode. This requires that the experiment either be exactly duplicable or held in a constant state, conditions that may not be available when the surface of the disk or the composition of the solution is altered by the experiment. Particularly in the case of alloys where possible preferential dissolution of components may itself be the point of interest, repeated anodization experiments may well vary since the newly generated surface must necessarily be different from the original state when the effect is observed. In addition, holding all other experimental conditions constant may be difficult.

To extract more data from a single run and to measure reliably two oxidation states or components simultaneously, a split ring design has been constructed and investigated. This modification of the ring-disk system involves the use of a ring which is mechanically and electrically divided in half by two thin insulating regions 180° apart. Such a configuration extends the ring-disk method not simply through the more rapid accumulation of data numerically inherent in two simultaneous half-ring measurements, but more importantly for disk anodization, introduces the possibility of differentiating events in time (*e.g.*, selectivity in alloy dissolution and passivation) or distinguishing the details of simultaneous processes (*e.g.*, combined oxidation state changes and formation of solid phases for pure metals).

The construction of electrodes and the associated electronics based on operational amplifiers necessary to exploit the technique will be outlined. The degree of independence of the half rings and their alternate use when shorted as equivalent of a conventional ring are discussed. Applications to electrochemical problems and the various operating modes of the system will be illustrated in this paper by selected results from an investigation of the corrosion of copper-zinc alloys in ammoniacal media and its relation to stress cracking. The solutions employed were the NH_3-$(NH_4)_2SO_4$ mixtures one molar in total nitrogen of the type found by Mattson (12) to give very rapid cracking in the neutral pH range with 0.05M $CuSO_4$ present as oxidant. In our work initial Cu(II) concentration is replaced by anodic current. Potentiostatic and corrosion potential measurements in Mattson-type solutions on tensile-stressed 70/30 brass have been reported by Hoar and Booker (13). Ring-disk experiments addressed to the question of preferential dissolution of zinc in brass have been made in other media by Pickering and Wagner (5) and Feller (6) who found absence of selectivity beyond experimental error in the 70/30 alloy.

Experimental

Electrodes.—The fabrication of the split-ring design follows from a conventional ring-disk construction utilizing epoxy adhesive bonding and insulation of a concentric rod (disk) and tube (ring) similar to that of Albery and Bruckenstein (14). The working end of the completed split ring disk electrode is shown in Fig. 1 and the necessary steps in the procedure are schematically given in Fig. 2. For both rod and tube

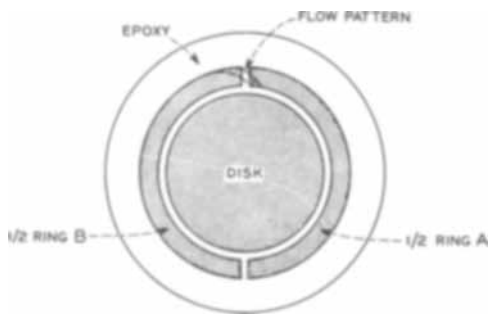

Fig. 1. Diagram of split-ring disk electrode surface showing insulating division of conventional ring. Flow pattern of electrolyte on rotation indicated over epoxy gap.

* Electrochemical Society Active Member.

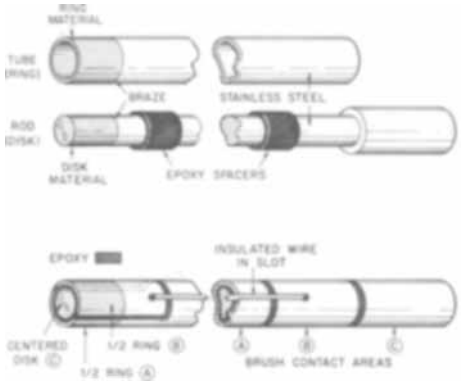

Fig. 2. Construction for split ring disk electrode (see text)

approximately ¼ in. length of the desired material is brazed or adhesively bonded with conductive silver-epoxy cement to one end. If the disk is not to be consumed in use, 50 mil thickness (*e.g.*, for platinum) suffices; for corrosion-oriented work ¼ in. provides a long period of use for disk electrodes that require polishing (to a final 0.3μ Linde A stage) intermittently to retain coplanarity of the surfaces in Fig. 1. Machining the attached materials to the rod diameter and inner and outer tube diameters (see Fig. 2) provides a standard method leading to nominal duplication of the geometry of all completed electrodes. Epoxy resin is applied and cured on two separate bands on the rod and then carefully machined to the ID of the tubes (epoxy spacers, Fig. 2).

Since the assembled electrode will rotate about the ring axis when the tube is eventually spindle-mounted for driving, errors in centering the disk affect both the ring geometry and the disk eccentricity. Bonding (and insulation) of the concentrically-aligned tube and rod is completed with fresh epoxy; particular care is taken with use of vacuum to fill the void at the working end of the electrode to avoid bubbles that would later appear as holes in the epoxy ring. The epoxy system (Union Carbide ERL 3794 resin and ERL 2807 curing agent, 5:1 by weight) has shown adequate chemical stability in both strongly acidic and basic aqueous environments and is essential to maintain the structural integrity of the electrode during subsequent division of the ring.

For a conventional ring-disk, the construction described to this point requires only an application of epoxy to the outside of the lower end of the electrode and machining to give an epoxy insulating region over the immersed portion with thickness about 50 mil. Normally heat-shrinkable polyethylene tubing is placed on the outer tube from about ¼ in. from the end to the point at which the electrode fits into its lower nylon collet on the driving spindle.

To obtain the split ring configuration, the adhesively bonded tube is appropriately sawed through both radially and axially along its length in the areas shown in Fig. 2 to expose the epoxy. These slots are then filled with epoxy for permanent insulation. A circular saw blade of 4 mil width is used for the ¼ in. ring material end to provide a minimal insulating gap division; for the further cutting areas 10 mil or wider blades may be employed for their greater rigidity and easier use. An approximately 15 x 15 mil slot is cut in the tube for the recessed insulated wire joining half ring B to its brush contact area. The slot and mounted wire are also back-filled with epoxy to the original diameter for further insulating protection (not shown in Fig. 2).

At the completion of these steps the half ring indicated as *B* is thus electrically isolated from the tube (half ring *A*) and the three active electrodes as specified in Fig. 1 have their appropriate brush contact areas at the top of the electrode. The body of the electrode sits in nylon collets in a side driven spindle and the projecting top of the electrode along with three pairs of silver-graphite electrode-radiused brushes in an acrylic mount are insulated from the mechanical rotating assembly. The final product corresponding to Fig. 1 has the nominal diameters of disk and inner and outer rings of 0.1875, 0.206, and 0.253 in., respectively, with the insulating epoxy gaps in the ring each less than 1% of the inner ring perimeter. Modification to provide different dimensions is readily performed. For example, to provide the thinner gap-thinner ring electrode of utility in various kinetic studies (15) the disk tip of the rod may be machined to diameters closer to the inner ring 0.206 in. diameter and then, when concentric bonding is complete, the ring tipped portion of the tube may be machined to the desired thinness.

The particular electrode employed for the experiments in this paper has a 70:30 Cu-Zn atom ratio α-brass disk and gold half rings. For runs with one mercury half ring, one of the gold surfaces was amalgamated with a drop of mercury with the excess carefully removed by either wiping off with twill cloth or by high speed rotation with the other gold surface-coated temporarily by an acetone soluble lacquer.

Circuitry.—The requirements for the operating circuitry of the split ring-disk system were chosen as the following:

1. Disk to be operable either under controlled potential or current with linear sweep of either variable if desired.
2. Half rings to be operable at controlled potentials independent of each other and the disk control scheme; with external short they provide the equivalent of a conventional ring using one of the two independent ring circuits. Linear potential sweeps of the rings for steady-state disk conditions are to be available.
3. One reference electrode and one counterelectrode should serve all three working electrodes.

Figure 3 is a schematic of the operational amplifier circuitry which, with addition of routine switching, satisfies the above; disk, reference, and auxiliary (counter) electrode configurations are shown for both potentiostatic and galvanostatic configurations. Only one half ring is shown connected; the other would have identical circuitry.

The operating configurations of the disk are conventional; inputs E_s from an integrator sweep generator provide the scanning modes. In both potential and current control schemes the disk is maintained at virtual ground by the control amplifier and thus the reference electrode follower output has the same relation to ground in both, whether it is controlled (potentiostat)

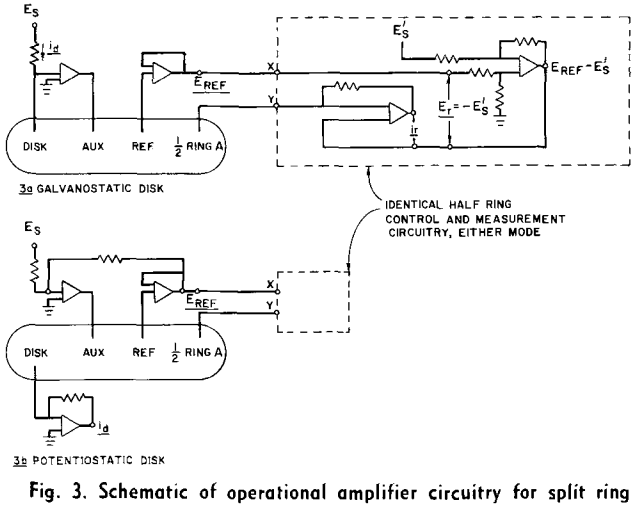

Fig. 3. Schematic of operational amplifier circuitry for split ring disk. (a) Disk galvanostatic control; (b) disk potentiostatic control (see text).

or measured (galvanostat). When a signal E_s', from a constant or linearly scanning source, is applied to the negative input of a unity gain difference amplifier whose positive input signal is the reference electrode potential, E_{REF}, the amplifier's output is $E_{REF} - E_s'$. The second amplifier serves to hold the half ring at this potential while converting the half ring current, i_r, into a corresponding voltage drop. The potential applied to the half-ring, E_r, is thus $-E_s'$ *vs.* the reference. The circuits are completed in each case by the disk control amplifier through the single counterelectrode. Switching from disk potentiostatic to galvanostatic modes is accomplished through a multipole wafer switch not involving the half ring control configuration. Capacitive damping is employed across the disk control and current follower amplifiers as required for stability; normally this involves capacitors of 10^{-3}-10^{-2} μf or less. The ring current followers need parallel capacitance across the load resistor to give RC time constants in the millisecond region.

All six variables of interest, E_d, i_d, E_{rA}, i_{rA}, E_{rB}, and i_{rB}, the potentials and currents at disk, half ring *A*, and half ring *B*, respectively, are available for recording from low impedance amplifier outputs as indicated in the schematic. Both E_r and i_r, the half-ring parameters, are measured differentially (all other outputs and signals are with respect to ground). In recent practice these differential outputs have been fed into a unity gain difference amplifier identical to that shown for subtracting E_s' from E_{REF} to produce a ground referenced output for convenience with conventional recorders which do not normally have true differential inputs. When any of the six quantities are held constant their values are obtained from calibrated controls. Booster amplifiers (Burr-Brown 1634A or 3069) provide a counterelectrode capability of 0.5A at $\pm$10V. The electrode potentials are all in some degree of error due to the uncompensated resistance between the electrode plane and the reference capillary tip. Most applications of a ring involve holding a constant potential at the limiting current of a disk product's reaction at the ring which normally allows for minor potential errors with minimal effects on the measured current of interest.

The first use of a current-measuring and voltage-controlling fourth electrode amplifier configuration was made by Anderson and Reilley (16) for thin layer studies. A ring-disk operational amplifier circuit involving the use of two balanced potentiostatic configurations of the type employed here for the disk circuit was recently described by Johnson, Napp, and Bruckenstein (17) and a circuit schematic offering disk current control was outlined by Tindall and Bruckenstein (18).

Data display for the split-ring system normally involves an *X* Y_1 Y_2 presentation which is obtained on a Honeywell 580 recorder or a Tektronix 564 Storage Oscilloscope equipped with a 3A3 dual differential vertical amplifier and either a 3B4 time base-amplifier or a 2A63 amplifier for horizontal axis. Choice of displayed variables depends on the experiment and will be illustrated in the results section.

Results

Interaction of half rings.—The typical flow pattern in the ring region of disk produced material, as derived, *e.g.*, from photographs of ring plated copper originating from a copper disk, is indicated in Fig. 1 for the insulating region between the half rings. As noted the two gaps produced by the construction technique outlined amount to 1-2% of the outside circumference. Interaction between the half rings is possible to the extent that a reaction at half ring *A* with a current i_A produces a change Δi_B in the current at half ring *B* if *B* is set at a limiting current region potential to detect the product of *A*. From the geometry of flow the maximum fraction of the area of *A* from which products could reach *B* is about 0.02 and this will be reduced by loss to the solution bulk. Experimental measurement of the quantity $\Delta i_B/i_A$ defining the interaction collection efficiency N_{INT} was made with the following pairs of reactions:

A	B	Solution
$Fe(CN)_6^{-4} \xrightarrow[ox]{} Fe(CN)_6^{-3}$	$Fe(CN)_6^{-3} \xrightarrow[red]{} Fe(CN)_6^{-4}$	0.1M $K_4Fe(CN)_6$, 1M NaOH
$Cu(II) \xrightarrow[red]{} Cu(I)$	$Cu(I) \xrightarrow[ox]{} Cu(II)$	Cu(II), pH 9 NH_3 buffer

In both cases a value of $N_{INT} = 0.004 \pm 0.001$, independent of rotation speed, was obtained. Measurement of N_{INT} where the *A* reaction is of a disk generated, rather than bulk solution transported, product is more difficult than the above but it does correspond to the true experimental situation of interest. For sequence 2 this corresponds to an initially copper-free NH_3 buffer and a copper disk polarized to Cu(II) generation. From such measurements and from results for Cu(I) generated at the disk with comparison of the equality of the 1 electron ring reactions I → II(ox) and I → O(red), where II can be cross-detected by the ring set for I → O, it is also seen that 0.004 is a reasonable measure of the interaction.

For the continuous ring form of our electrode the theoretical value of the defined collection efficiency, $N = i_r n_d/i_d n_r$ where n_d and n_r are the number of electrons transferred in disk and ring reactions, respectively, is 0.34 from the table of Albery and Bruckenstein (14). Typical values found for the quantities i_A/i_d and i_B/i_d are 0.165 for these electrodes in satisfactory agreement with the theory and the 1-2% loss due to the insulating gaps. With a half ring *N* of 0.165, the effect of interaction is to increase i_B to $0.165(1.004\ r)i_d$ where 1.004 is the contribution of N_{INT} and *r* is the ratio of electrons in the reaction producing Δi_b to that producing i_b in the particular case. The factor 0.004 implied by the computed interaction is negligible for practical purposes and means that each half ring may be treated independently of whether the other half ring is operating or off and further, that shorting the half rings at the cell gives conventional ring-disk operation with $N_A + N_B = N_{shorted}$, $N_{shorted}$ being the value 1-2% less than the continuous ring collection efficiency and which we shall henceforth abbreviate as *N* with that understanding.

Because of construction alignment and symmetry limitations, the values of N_A and N_B may not be exactly equal. The ratio of N_A and N_B is measured readily by looking at the same reaction simultaneously at both half-rings and measuring the ratio of i_A to i_B which becomes a permanent calibration factor. Alternatively the inequality may be cancelled in an experimental use of the ratio N_A/N_B by repeating a given split-ring experiment with half rings interchanged and averaging the two ratios (8). Assuming unchanged chemistry no requirement is placed on reproducing disk current exactly since the individual half-ring collection efficiencies should be independent of that value. For the brass disk-gold split-ring electrode the half-ring equality is shown experimentally in the oscilloscope picture of Fig. 4 in which both half rings are held at +0.5V *vs.* S.C.E. for the limiting current oxidation of Cu(I) generated at a linear current scan at the brass disk in pH 7.47 ammonia-ammonium sulfate. The slopes (collection efficiencies) of both are within os-

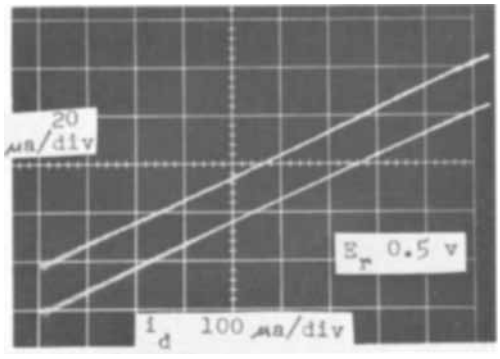

Fig. 4. Oscilloscope trace of split-ring currents *vs.* disk current with both half rings at +0.50V in pH 7.47 ammonia-ammonium sulfate. Current sensitivity; half rings 20 μA/major division, disk 100 μA/major division. Rotation speed 1580 rpm. Brass disk, gold half rings.

cilloscope accuracy of each other (0.089 ± 0.001). The linearity of the plots indicates no change in disk reaction in this region of current density.

Brass disk behavior.—The experimental data on brass will be presented in terms of the operating mode being used, for the purpose of demonstrating the information obtainable through the split-ring technique. Sufficient examples are included to cover most practical configurations. Inferences for brass anodization chemistry in neutral ammoniacal media will be collected in the discussion section.

Disk galvanostatic: ring potential sweep.—In this configuration a potential scan is applied to the ring(s) at constant disk current, suitable where E_d has acquired a steady value indicative of an unchanging composition of the flux reaching the rings. A special feature of the split-ring system in this mode is the ability to operate with two different electrode materials. Thus, with one gold and the other mercury, the anodic potential range of the former and the cathodic of the latter can be attained in single or successive scans. Figure 5 is a composite of a pair of scans with such an electrode; brass disk, gold and mercury half rings. The dissolving brass shows at gold the anodic wave due to Cu(I) → Cu(II) and the corresponding cathodic wave for Cu(I) → Cu(O). The absence of a Cu(II) → Cu(I) wave indicates essentially no Cu(II) is present. The anodic range is to +1V *vs.* S.C.E. (scan to +0.6V shown). For mercury positive potentials *vs.* S.C.E. yield electrode dissolution; for the negative potential scan from about —0.1V are seen Cu(I) → Cu(O) and Zn(II) → Zn(O) waves with effective range to —1.6V *vs.* S.C.E.

By offsetting one half-ring potential by 0.8V with respect to the other (*i.e.*, to the reference), the full 2.6V range can be scanned in a single run with simultaneous display from both electrodes. Corrosion studies, as commonly involved with solutions of H^+, OH^-, Cl^- and many complexing agents, are particularly amenable to observation over a wide potential range of the distribution of the anodized disk products, since interfering redox reactions from the electrolyte at the rings are minimized. Sweeps of the type shown in Fig. 5 indicate the feasibility of, and the proper ring potentials for, the potentiostatic monitoring of limiting currents due to individual components and states or the sum of two (or more) as a function of changing disk conditions. Where a steady-state condition obtains at the disk, a single ring scan can display the product distribution: a second surface might then be useful in extending the potential region available.

Disk potential sweep: ring(s) controlled potential.—This configuration serves the monitoring function discussed above for one or two potentials at the rings at limiting currents for selected reactions with an X Y_1 Y_2 display where X will be E_d or i_d as best suited to the experiment. Comparison of conventional and split-ring data for the distribution of the oxidation states of dissolved copper from the α-brass is shown in Fig. 6, 7, and 8. Ring oxidation current at +0.4V *vs.*

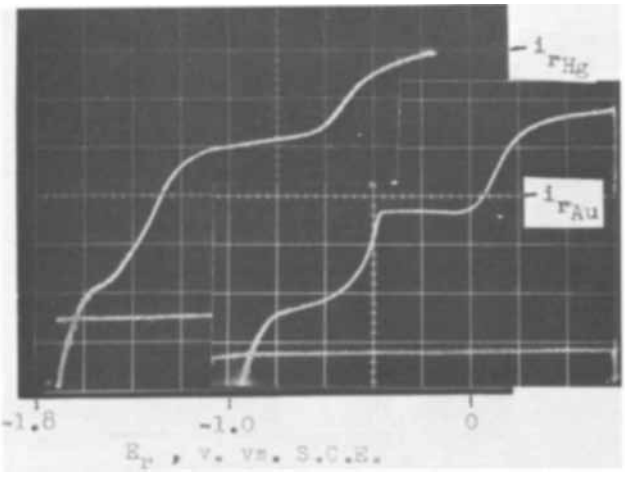

Fig. 5. Mercury half ring (upper trace) and gold half ring (lower trace) scanned at 20 mV/sec and plotted on common ring potential axis. Zero current indicated for each trace, sensitivities 50 μA/major division (Hg), 20 μA/major division (Au). Disk current 1 mA(Hg), 200 μA(Au) with brass disk at 2000 rpm. (Horizontal traces are disk potential monitored during ring scan.)

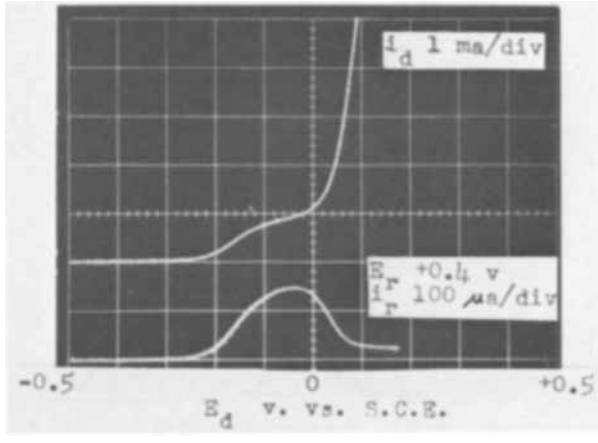

Fig. 6. Upper trace is i_d and lower trace is i_r, both *vs.* linear E_d scan of 20 mV/sec at 1000 rpm. Current sensitivities and anodic ring potential as indicated. Brass disk, gold half rings (shorted) in pH 7.45 ammonia-ammonium sulfate.

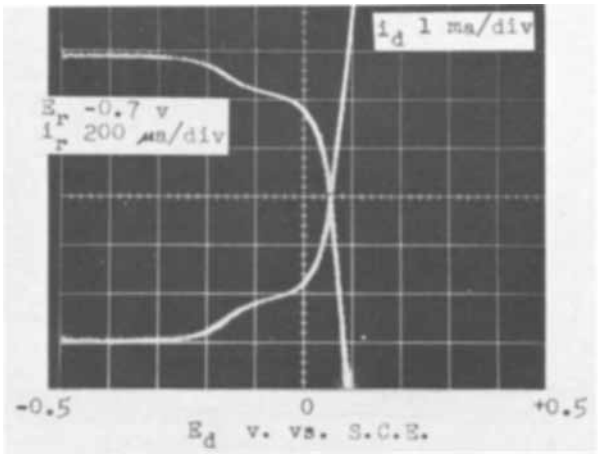

Fig. 7. Conditions of Fig. 6 except shorted half rings set for cathodic reaction at —0.7V and 200 μA/major division (ring trace beginning upper left).

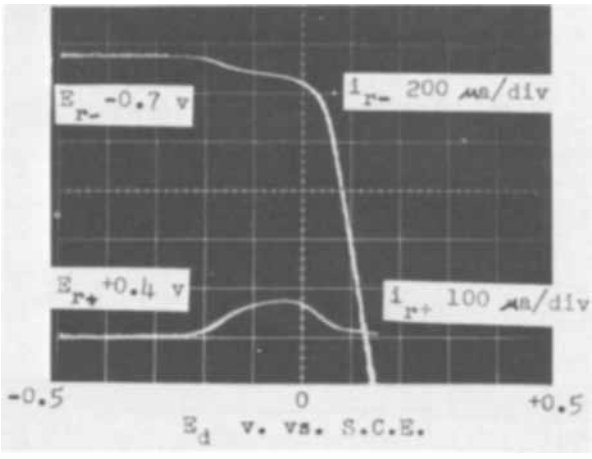

Fig. 8. Split-ring currents for solution-rotation conditions of Fig. 6 with cathodic (—0.7V., 200 μA/major division) and anodic (+0.4V., 100 μA/major division) half rings recorded against disk potential.

S.C.E. measures Cu(I) → Cu(II) while reduction at —0.7V is negative enough to measure limiting currents for both Cu(II) and Cu(I) reduced to Cu(O). Figures 6 and 7 show shorted rings operated at these potentials, respectively, and the corresponding disk current with its region of polarization and changing reaction. Figure 8 shows the split ring simultaneous measurement of both oxidation (i_r+) and reduction (i_r-) reactions from which it is then possible to calculate the ratio of copper product in (I) and (II) states at any time (or disk potential) from $(I)/(II) = i_r+/\left(\frac{i_r- - i_r+}{2}\right)$. Such a determination is independent of the assumption required in two conventional runs or a ring sweep of one that the value of i_d or E_d chosen for the measurement of the ring currents represents an exactly duplicable or steady-state experimental situation. The split-ring ratio thus determined is experimentally independent of both geometric collection efficiency and the fraction of disk current going to copper dissolution. This polarization of the anodic reactions of copper can then be referred to the disk potential; further, with the geometric collection efficiency and the corresponding value of the disk current, the selectivity of dissolution (ratio of zinc to copper dissolving compared to their atomic ratio in the alloy) can also be established. The zinc current is obtained by difference, $i_d - i_r-/N_-$, where i_r- is the cathodic current at one half ring for the copper species reduced to metal and N_- the geometric collection efficiency of that half ring. The utility of simultaneous monitoring of the two oxidation states or elements as described in this and the preceding section is even more clearly illustrated under circumstances where passivation (filming reactions) also occurs. Here the sequence of steps and transient selective dissolution (19) are of interest. Such processes, where transitions undergone by two components rather than steady states are under investigation, cannot be satisfactorily reconstructed by superposition of separate conventional single-ring scans.

The generation of Cu(I) at low currents and the polarization plateau region in the $i_d - E_d$ plots is evident for brass anodization under neutral Mattson buffer conditions in Fig. 6 and 7. No indication of filming reactions (no i_d peak, agreement of ring-determined copper with free nonselective disk dissolution) is seen, only a shift of soluble copper species from I to II as the surface concentration of the former becomes nearly comparable to the free ammonia available at pH 7.45. In the region of transition, the relative amounts of the products can be taken by current measurements as indicated; an experimentally more convenient technique with respect to data reduction is to use the split rings with controlled current sweep, as below.

Disk linear current sweep: ring(s) controlled potential.—This mode is that employed in Fig. 4 in testing the equality of the half rings. With the same solution conditions and half rings set for oxidation to Cu(II) [E_r+ + 0.5V *vs.* S.C.E.] and reduction to Cu(O) [E_r- — 0.7V *vs.* S.C.E.], the results are as in Fig. 9. The disk current is swept to 0.9 mA which is at the region of the peak of Cu(I) production (Fig. 6). The straight lines of the ring currents *vs.* disk current indicate a constant disk anodic chemistry up to about 0.5 mA (2.8 mA/cm²). The numerical values of the straight slopes are 0.089 for —0.7V reduction and 0.088 for +0.5V oxidation, equal within 1% of their average. This fact, independent of N and the concomitant zinc dissolution, within the single scan defines the oxidation state of the copper product as Cu(I), which gives equal current magnitudes for one electron oxidation to Cu(II) and one electron reduction to metal. The technique has been elsewhere applied to unstable intermediate states (8) and anodization complicated by film formation (10).

If the disk current scan is extended from the 100 μA/div of Fig. 9 to 1 mA/div (Fig. 10) the polarization of the Cu(I) reaction is seen as i_r+ changing from linear increase to decline as a function of disk current. The initial 100% current efficiency of Cu(I) generation indicated by the Ni_d relation decreases to 2% at 9 mA (50 mA/cm²). The split-ring scale sensitivities are different by a factor of 10 for reduction and oxidation in Fig. 10 (200 and 20 μA/div). The independence of the

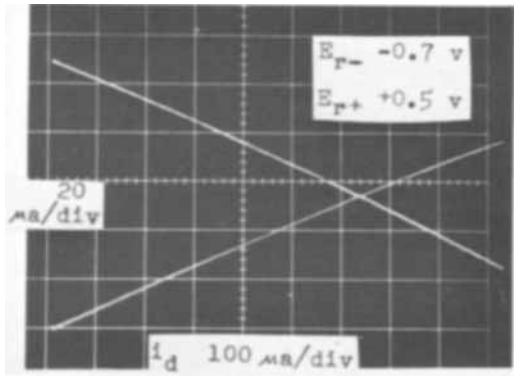

Fig. 9. Split-ring currents recorded *vs.* linearly scanned disk current; both half ring sensitivities 20 μA/major division. Cathodic trace (E_r- —0.7V) begins at upper left, anodic trace (E_r+ +0.5V) at lower left. Solution-rotation conditions of Fig. 4.

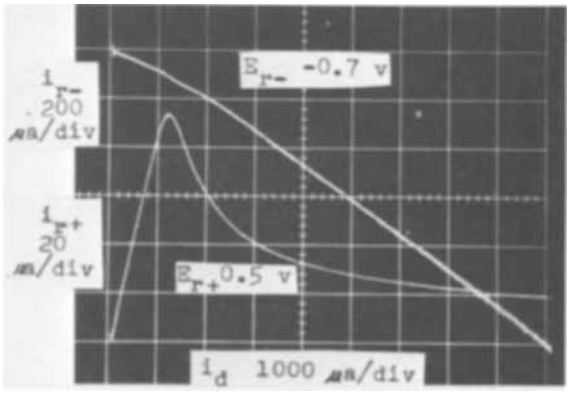

Fig. 10. Split-ring currents recorded *vs.* linearly scanned disk currents with half ring potentials and solution condition of Fig. 9 but with cathodic half ring current sensitivity changed to 200 μA/major division and disk current sensitivity changed to 1000 μA/major division. Rotation speed 2000 rpm.

half rings with the high absolute sensitivity and wide product ratios that are normally accessible make feasible the detection of low fractions of one state in the presence of large fluxes of a second state or identification of species in low concentrations at passivated surfaces.

Anodic dissolution of copper from the brass disk, as seen in Fig. 10, shows in the ring reduction trace two linear regions corresponding to the nearly quantitative appearance first of Cu(I), then of Cu(II), with an intermediate curved region of change. The first line at lower currents is amplified in Fig. 9 or with opposite sign in the linear oxidation region of either Fig. 9 or 10. The two linear regions offer either a means of analyzing the composition of binary alloys, or, knowing the composition, determining whether preferential dissolution is occurring independent of zinc measurements or of geometric collection efficiency. This feature, unique to ring-disk measurements, follows from considering collection efficiency for copper as a function of brass composition.

Copper may dissolve quantitatively under our neutral ammonia conditions with either 1 or 2 electrons, ignoring the mixed dissolution region. Thus we have, considering only a cathodic ring reaction at —0.7V *vs.* S.C.E.

Disk

$$Cu \rightarrow Cu^{+n} + ne \qquad n = 1 \text{ or } 2$$

$$Zn \rightarrow Zn^{+2} + 2e$$

Ring

$$Cu^{+n} + ne \rightarrow Cu$$

If no preferential dissolution occurs, as by the possible dezincification due to the more active metal, redeposition or filming reactions involving selective formation of an oxide, then the fraction of anodic disk current due to copper is proportional to na, where a is the atomic fraction of copper, and the fraction for zinc is proportional to $2(1 - a)$. Assuming further no complications in transit, the apparent (measured) collection efficiency for copper at the ring, N_n, will be related to the geometric collection efficiency by

$$N_1 = \frac{a}{2(1-a) + a} N = \frac{a}{2-a} N \qquad \text{when } n = 1$$

and

$$N_2 = \frac{2a}{2(1-a) + 2a} = aN \qquad \text{when } n = 2$$

Then the ratio N_2/N_1 is simply $2 - a$, the limiting cases being pure Cu, $a = 1$ and $N_2/N_1 = 1$ (no change in slope) and $a \rightarrow 0$ when $N_2/N_1 \rightarrow 2$. Chemical analysis of the disk material gave $a/1 - a = 2.34$ or $2 - a = 1.30$. The ring-disk determination of N_1 and N_2 individually requires knowledge of N. An experimental value of 0.320 for N (0.160 per half ring) was obtained by overplating the brass with pure copper from an acid sulfate bath, then, with linear anodic disk current scan and copper plating at the ring in fresh copper-free acidified sodium sulfate, determining the $i_r - i_d$ slope. From Fig. 9 anodic and cathodic measures of N_1 in pH 7.45 ammonia averaged 0.0885; predicted from $(a/2 - a)$ N is (0.70/1.30) (0.160) = 0.0862, less than 3% difference. This agreement is not reflected in the slope for N_2 from higher current measurements of the type shown in Fig. 10; the calculated aN is 0.112, whereas experimental values run 10-20% higher with reproducibility reduced partially by the fact that the i_r trace increases from linear to upward curvature. The source of the discrepancy may be involved in this latter effect. However, separately obtained values of N_1 and N_2 with the same electrode in media such that the 1 or 2 electron reactions were quantitative from "zero" current are within 4% of the theoretical nonselective dissolution ratio. The neutral ammonia value of N_1 was duplicated in a pH 5 acetate-buffered chloride solution and N_2 was determined in copper-free acidified sodium sulfate (technique comparable to that used to measure N).

Further work in this area is continuing to establish the reliability of the ratio method when applied to experimental situations like copper-ammonia where the reaction can be polarized. However, it is notable that the property of the ring-disk system of a fixed geometric collection efficiency that allows such ratio analysis to be made, either with or without knowledge of the N value, is not equivalently available for an anode alone, rotating disk or otherwise.

Disk open or zero external current: ring (s) controlled potential.—These configurations provide for the study of chemical corrosion by means of the ring current measurement of either the flux of corrosion product or the decrease in flux of corrodent. Operation of the disk at open circuit with ring potential controlled is simply done by using the regular disk potentiostat connection on the ring and leaving the disk open. More convenient and electrically equivalent is to use the ordinary galvanostatic configuration at zero applied current where the rings will operate as previously described.

Data in this type of study were obtained for copper etching in Mattson-type solutions, first as a function of added Cu(II) at pH 4-5, and then as a function of pH at constant Cu(II). Results are shown in Fig. 11, where ring potential of —0.6V *vs.* S. C. E. corresponds to the reduction of Cu^{+n} to metal, and +0.4V is limiting for oxidation of the etching product, Cu(I), to Cu(II). The etching reaction is Cu(II) + Cu(O) → 2Cu(I) with equilibrium shifted with pH mainly because of the concomitant alteration of the free NH_3 concentration. For example, the equilibrium constant of the reaction shifts approximately from 10^{-6} to 10^{3} from free ions to unit free NH_3 concentration. The constant in 0.2M H_2SO_4 was found to be 5.6×10^{-7} from a ring-disk electrode determination by Tindall and Bruckenstein (11). These authors also give a general treatment of heterogeneous equilibria involving oxidation of a metal by a soluble oxidant under mass transfer rate control.

For the present solutions, at the lower pH end, increments of Cu(II) are reflected in linear increase of ring reduction current at —0.6V but a negligible etching rate is found (very low +0.4V ring current, left side of Fig. 11). A sharp increase in the neutral region then occurs and the rate of etching becomes transport-limited above pH 8. Experiments with Matt-

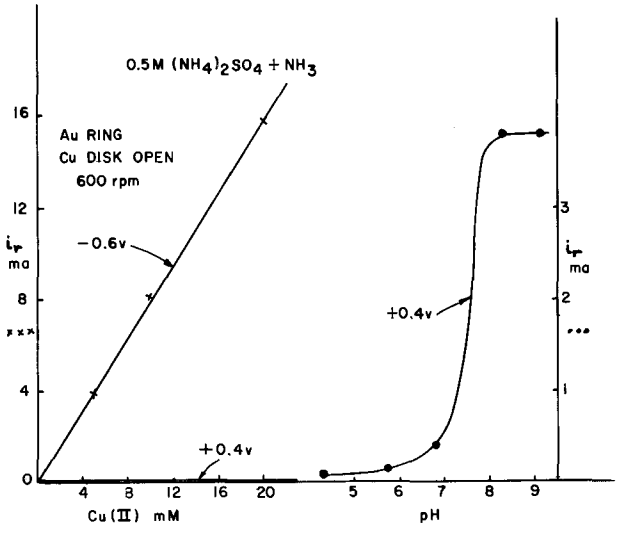

Fig. 11. Left side: initial solution of 0.5M $(NH_4)_2SO_4$, pH 5.4 with Cu(II) as sulfate added incrementally. Final pH 4.3 at 20 mM Cu(II). Ring currents for —0.6 and +0.4V plotted *vs.* [Cu(II)]. Right side: pH of 20 mM Cu(II) final solution at left raised incrementally with NH_3 with +0.4V ring current plotted *vs.* pH.

son's 0.05M Cu(II) solutions have indicated the 50% of maximum rate point to be about pH 7.6. These data complement well the above observations on brass dissolution under anodic current where the pH 7.45 reaction initially produces Cu(I) which shifts in favor of Cu(II) at higher currents (higher surface concentrations of dissolved copper and therefore equivalently reduced concentrations of free ammonia).

The other variation, when redox potentials and rates are suitable, of measuring the decrease of ring current resulting from a decrease in corrodent flux rather than a product reaction would be exemplified in the copper case by a discrete Cu(II) → Cu(I) wave at higher pH values in ammonia solution. Direct measurement of a product, as is available in the anodic determination of Cu(I), is preferable to the second, or difference, method.

Summary

The utility of the applications demonstrated for the split ring as an adjunct to conventional ring-disk observation in the study of anodic and corrosion reactions may be generalized in the following areas. In the dissolution of pure metals the split ring may be used to identify oxidation states (including relatively unstable intermediates), transition regions (reaction changes), and the determination of total material distribution even when such reactions are complicated by passive ⇌ active processes. In all these cases the ring and split-ring offer the distinct advantage of observing the solution products corresponding to what may be a thoroughly mixed system as viewed by disk current-potential curves alone. With a sufficiently versatile apparatus to take advantage of the optimum method of viewing a particular effect, the split-ring system in its power to identify oxidation states adds direct chemical information to supplement what can usually only be guessed at from the corresponding surface's current-potential behavior. For alloys direct simultaneous observation of more than one component is feasible as well as dual measurements made according to the techniques outlined on reactions of a single metal constituent whose dissolved state is in question. These techniques will also hold for film forming conditions where it may be possible, for example, to define the time dependency of the reactions of the components that contribute to passivity of the system or preferential dissolution.

Chemical corrosion of disks may be investigated as to rates and selectivity of constituent removal. Mixed anodic and cathodic reactions at the disk (*e.g.*, concurrent H^+ reduction) may in many cases be unscrambled if disk products are detectable. True corrosion rates may then be interpreted through ring currents which would be proportional to actual weight losses.

In the brass system the above techniques have shown the neutral ammonia-ammonium salt solutions to correspond to the pH region in which Cu(II)-ammonia complexes begin to etch copper (and zinc) with Cu(I)-ammonia complexes as product. The anodization of the brass produces the Cu(I) species at low current densities and Cu(II) at higher currents, the polarization being a function of free ammonia concentration and therefore of pH. Although precipitation of a Cu_2O film is not observed in these experiments it is not unlikely that accumulation of product would lead to such filming under anodic conditions with less vigorous mass transport (13). Split-ring experiments (10) with pure Cu in basic solution show Cu_2O films form in that medium without detectable supersaturation. More experiments in the ammonia system are in order to observe whether cracking reactions and media sensitivity correlate with film formation dependent mechanisms.

The Mechanism of Operation of the Teflon-Bonded Gas Diffusion Electrode: A Mathematical Model

J. Giner*

Tyco Laboratories, Inc., Waltham, Massachusetts

and C. Hunter

Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

A mathematical analysis of the working mechanism of the Teflon-bonded gas diffusion electrode, based on the concept of "flooded agglomerates," is discussed. This model is used to predict the performance of the electrode as a function of such measurable physical characteristics as intrinsic activity of catalyst, agglomerate size, internal porosity, real surface area, etc. The alkaline oxygen electrode is taken as an example for the discussion.

The theory of porous electrodes has been the object of many publications. A general discussion of the behavior of fully flooded and gas diffusion porous electrodes, both for steady state and transient responses, can be found in a recent monograph by De Levie (1). The present paper is concerned only with the steady state behavior of gas diffusion electrodes which, although studied less than flooded electrodes, has also been the subject of attention in the last few years.

Four main models have been currently used to explain the behavior of the gas diffusion electrode: the simple pore model, the thin film model, the surface migration model, and the dual scale of porosity model.

Two comments should be made at this point. First, the applicability of a certain model will depend on electrode structure; thus it can be expected that a model which applies to a Teflon-bonded electrode will not apply to a Bacon sintered electrode and vice versa. Second, many of the models are microscopic models concerned with one element of the electrode producing the current (such as a thin film or a finite contact meniscus, etc.). While the relationship between theory and the results obtained with an experimental model system (such as half immersed wires, slit cells, etc.) is straightforward, the way in which the electrode is composed by the simple elements is usually not clear at all. Thus a comparison between theory and results obtained with an actual electrode is virtually impossible. A few models, on the other hand, are macroscopic and treated as continuum systems. The application of these models is limited by their abstract nature. From this point of view, the model to be discussed in this paper is a hybrid, with a microscopic division of the electrode in elements (flooded cylinders) and a macroscopic treatment of these elements.

The simple pore model.—This model as developed by Austin *et al.* (2), is a modification of the old theory (3) of the three-phase boundary and has been studied in some detail by Srinivasan, Hurwitz, and Bockris (4). It has also been proposed as the working mode of the Teflon-bonded electrode by Austin and Almaula (5), who state that only 2-5% of the electrode area is wetted. This is in contrast to our experiments (6) which show almost 100% wetting of the electrode surface area.

The thin film model.—The thin film model was introduced by Will who treated it mathematically (7) for the case of diffusion and ohmic control and has experimentally (8) confirmed his conclusions using a prewetted, half immersed Pt-wire in H_2SO_4 under H_2 atmosphere.

In a more recent publication (9) Will has made confirming measurements using horizontal electrodes with rather thick (1 mm) electrolyte films. He concludes that considerable stirring ought to exist to explain the lower than predicted concentration gradients along the film. It is questionable, however, whether the conclusions reached with these rather thick films can be scaled down to thin films. In addition, concentration gradients can be explained by a "distillation mechanism" [see ref. (15) and assumption No. 4 of this paper], which would cause, in its turn, only little convection.

The thin film model has been generalized by other authors (10-12) who have considered activation polarization in addition to concentration and ohmic polarization.

Lindstrom (13) and Lindholm *et al.* (14), have applied the thin film model to porous electrodes of the Bacon type. An important contribution of this work is the consideration of transport limitations in gas phase.

Bennion and Tobias (15) have studied the O_2-electrode according to the thin film model taking into consideration axial diffusion of electrolyte. These authors also considered the possibility that water transfer from one end of the film to the other may occur through the gas phase.

Variants to thin film model.—Models considering the shape of a meniscus can be considered as half-way between the thin film model and the simple pore model. An example is to be found in the work of Cahan (16) and Borucka and Agar (17).

The surface migration mechanism.—Migration of hydrogen on the surface of electrodes has been suggested by several authors (18-20).

Double scale of porosities model.—Burshtein and coworkers (21) have treated the Bacon type electrode, assuming that there is a spectrum of porosities, so that small pores are flooded, a model initiated by Markin (22, 23). Flooding of small pores increases the ionic conductivity across the electrode and results in a deeper utilization than with the thin film model. It should be noted that the experimental results of Brown and Rockett (20) with so-called "flooded electrodes" and the effect of pressure on activity observed by Lindstrom (13, 14) could be used to confirm the "double scale of porosity model," although these authors give a different interpretation.

A quantitative treatment for a somewhat related model has been given by Grens II (24). Grens considers gas filled macropores and electrolyte filled micropores. The electrode is represented by two one-dimensional continuum systems (a macro- and micropore system) which are joined by a series of "linking pores," the length of which is short compared with the length of the micropores. Some limitations of this treatment are as follows: (*a*) Diffusion is assumed to

* Electrochemical Society Active Member.

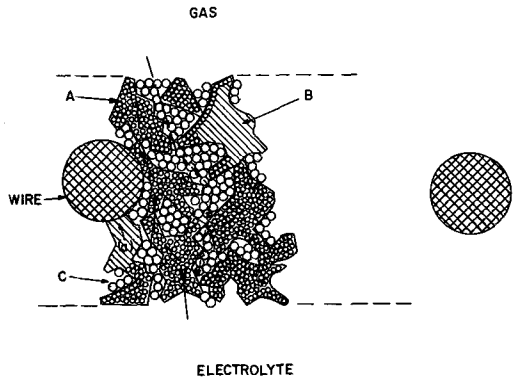

Fig. 1. Schematic representation of a hydrophobic, porous electrode made of Teflon-bonded platinum black. A, Catalyst particle; B, agglomerate; C, Teflon particle.

be linear. (b) It is implicitly assumed that concentration equalization in the micropore phase is not possible by evaporation and condensation; *i.e.* Q-term of ref. (15) is unity. (c) The diffusion of reactant gas and the ionic conductivity process in the micropore phase (*i.e.*, excluding linking pores) are considered along the same coordinate. (*d*) The thickness of flooded areas does not appear in the treatment. (*e*) Linking pores are assumed, the dimensions of which are arbitrarily selected.

The Flooded Agglomerate Model of the Teflon-Bonded Electrode

Qualitative Description

The Teflon-bonded electrode seems to us an ideal case of structure with a double scale of porosity. According to a qualitative description by Giner (25, 26) the working mechanism of this structure can be explained by assuming, as shown in Fig. 1, that the catalyst particles form porous (and electronically conductive) agglomerates which, under working conditions, are flooded with electrolyte. The catalyst agglomerates are kept together by the Teflon binder which creates hydrophobic gas channels. As current is drawn from the electrode, reactant gas diffuses through the channels, dissolves in the electrolyte contained in agglomerates and, after diffusing a certain distance, reacts on available sites of catalyst particles.

This qualitative explanation of the working mechanism based on the flooded agglomerate is confirmed by our own measurements which show (*i*) that the catalyst area in contact with electrolyte is the same when the Teflon-bonded electrode is working as a gas diffusion cell electrode as it is when it is completely flooded with electrolyte,[1] and (*ii*) that the microporosity of the agglomerates can be as large as 90%, *i.e.*, 10% catalyst and 90% electrolyte. [Microporosities of about 80% have also been measured by Horowitz (27), who also assumes the same qualitative model.]

Mathematical Treatment

One way of quantitatively treating this working mechanism is to substitute a column of flooded agglomerates perpendicular to the electrode surface by a porous cylinder of radius r_o and length h (as shown in Fig. 2), in which catalyst particles and electrolyte are homogeneously dispersed as a continuum. (Microporosity, θ, is defined as the volume of electrolyte per total volume of cylinder.) During operation, gas arrives at the lateral surface of the cylinder and diffuses radially to its center, with simultaneous reaction on catalyst particles in the diffusion path. Ionic current is conducted in the axial direction of the cylinder.

Assumptions.—For the mathematical treatment we assume that:

[1] This is conflict with the value of 2-5% reported by Austin and Almaula (5).

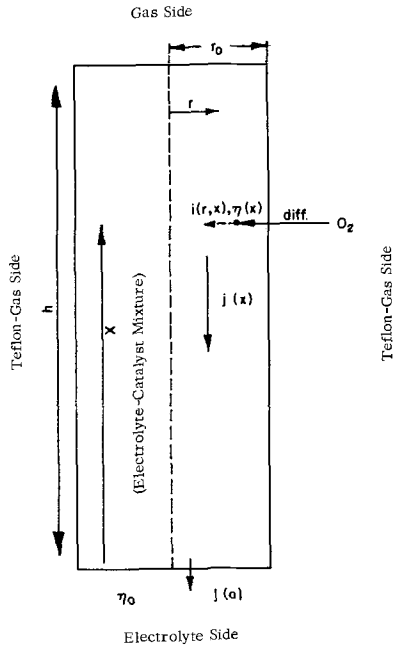

Fig. 2. Schematic representation of flooded cylinder

1. The electrode is made up of a number of porous cylinders of catalyst flooded with electrolyte. These cylinders are perpendicular to the external surface of the electrode.
2. Electrolyte and catalyst are homogeneously mixed as a continuum.
3. The intrinsic activity of the catalyst is constant throughout the cylinder.
4. Equilibration of electrolyte concentration in cylinders occurs efficiently via an evaporation-condensation process.
5. The local current density is directly proportional to the local concentration of reactant; *i.e.*, an expression such as Eq. [1] is pertinent.
6. The voltage in the cylinder changes only in the axial direction and diffusion of dissolved gas occurs only in the radial direction.
7. There are no transport limitations in the gas phase.
8. There are no kinetic limitations in the process of gas dissolution.
9. There is no electronic iR-drop in the cylinders.
10. Convection inside of the cylinders is low and has negligible effect on current.

In order to extend the theory of a single cylinder to the complete electrode we will further assume at this point that:

11. The radius of all porous cylinders has the same value. [Under these conditions the number of cylinders per square centimeter of electrode (N) is related to a measurable macroscopic factor, which we will call macroporosity (β), by the expression $\beta = 1 - N\pi r_o^2$].

General treatment.—The local current density $i(r, x)$, *i.e.*, current per unit of "real area," at a point (r, x) in the cylinder is assumed to be expressed by equation

$$i = i_o \left[\frac{C(x,r)}{C_o} \exp\left[\alpha z \eta(x)/\phi\right] - \exp\left[-(1-\alpha)\, z\, \eta(x)/\phi\right] \right] \quad [1]$$

The diffusion of the gas in the cylinder (with a simultaneous bulk consumption given by $i\gamma/n\mathbf{F}$, γ = surface to volume ratio) follows the second Fick's law for cylindric diffusion that for steady state can be written

$$\bar{D}\frac{\partial^2 C(x,r)}{\partial r^2} + \bar{D}\frac{1}{r}\frac{\partial C(x,r)}{\partial r} - \frac{i\gamma}{n\mathbf{F}} = 0 \quad [2]$$

and therefore

$$\bar{D}\left\{\frac{\partial^2 C}{\partial^2}+\frac{1}{r}\frac{\partial C}{\partial r}\right\} \quad [3]$$
$$=\frac{\gamma i_o}{n\mathbf{F}}\left\{\frac{C(x,r)}{C_o}\exp\frac{\alpha z\eta(x)}{\phi}-\exp\frac{(\alpha-1)z\eta(x)}{\phi}\right\}$$

Boundary conditions

$$\frac{\partial C}{\partial r}=0 \text{ at } r=0,\ C=C_o \text{ at } r=r_o$$

The solution of this equation for the r-variation of C under the boundary conditions is

$$C=C_o\exp\left(-\frac{z\eta}{\phi}\right)+C_o\left[1-\exp\left(-\frac{z\eta}{\phi}\right)\right]\frac{I_o\left(q\frac{r}{r_o}\right)}{I_o(q)} \quad [4]$$

where I_o is the modified Bessel function of zero order and

$$q=\left[\frac{\gamma i_o r_o^2}{n\mathbf{F}\bar{D}C_o}\exp\frac{\alpha z\eta}{\phi}\right]^{1/2} \quad [5]^2$$

Thus Eq. [4] gives the variation of C with the radius of the cylinder (agglomerate) at a given value of x. A similar equation relating i and r can be obtained from [1] and [4].

As assumed above, E (or η) is only a function of x (coordinate in the axis direction) according to Ohm's law

$$\frac{d\eta}{dx}=-\frac{j(x)}{\pi r_o^2\bar{\kappa}} \quad [6]$$

At the same time

$$-\frac{dj(x)}{dx}=2\pi\gamma\int_o^{r_o} irdr \quad [7]$$

while from Eq. [3], [6], and [7]

$$\frac{d^2\eta}{dx^2}=\frac{2n\mathbf{F}\bar{D}}{\bar{\kappa}r_o}\left(\frac{\partial C}{\partial r}\right)_{r=r_o} \quad [8]$$

or using solution [4]: The equation for η is

$$\frac{d^2\eta'}{dx'^2}=\frac{2n\mathbf{F}\bar{D}C_o h^2}{\eta_o\bar{\kappa}r_o^2}\left[1-\exp\left(-\frac{z\eta_o}{\phi}\eta'\right)\right]\frac{qI_1(q)}{I_o(q)} \quad [9]$$

Boundary conditions $\eta'=1_1$ at $x'=0$, $d\eta'/dx'=0$ at $x'=1$. (I_1 is the modified Bessel function of order 1, $\eta'=\eta/\eta_o$, $x'=x/h$ where η_o is the measurable overvoltage at the electrolyte side of the electrode.)

It can be seen that Eq. [9] expresses η' only as a function of x' and a series of measurable constants. This equation can be solved with a relatively simple computer program which will tell us the effect of parameters on the following: (*a*) The radial distribution of the local current at constant x. This is a measure of the depth utilization of the cylinder (or agglomerate), which is controlled mainly by diffusion. (*b*) The current production at different values of x'. This is a measure of the depth of utilization of the electrode, which is controlled mainly by ohmic drop. (*c*) The current density per unit area of electrode, *i.e.*, the measurable current density.

[2] The physical meaning of q can be understood by defining $I_{act}=\gamma i_o r_o\exp\frac{\alpha z\eta}{\phi}$ and $I_{diff}=\frac{n\mathbf{F}\bar{D}C_o}{r_o}$ so that $q=\left(\frac{I_{act}}{I_{diff}}\right)^{1/2}$

I_{act} is the current that would be obtained under exclusive activation control from a block with a 1 cm² surface and r_o thickness, made of the catalyst of bulk area γ, and I_{diff} is the diffusion limiting current density if the reactant were to be consumed at one of the surfaces of the same porous block after diffusing through it. Obviously q will be large when diffusion control is more important than activation control.

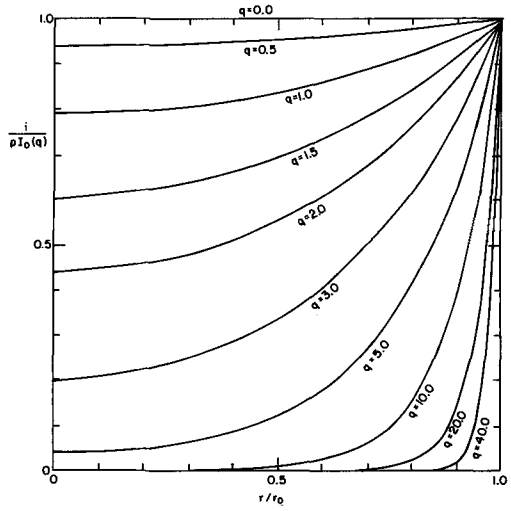

Fig. 3. Radial distribution of current in cylindric agglomerate as function of second distribution parameter of Eq. [5] and [10].

Depth utilization of cylinder.—The local current can be obtained from Eq. [1] since we know $C(x,r)$ and $\eta(r)$ from Eq. [4] and [9], respectively. Thus the equation relating i and r can be written as

$$i=pI_o\left(q\frac{r}{r_o}\right) \quad [10]$$

where p and q, which we will call distribution parameters, are suitably defined. From q the utilization of the catalyst as a function of r for a given x can be obtained, as shown in Fig. 3.

Depth utilization of electrode.—Other information of a pertinent nature is the current production for different cross sections of the cylinder. This current is, of course, $dj(x)/dx$. The total current per cylinder across the surface x = constant, is

$$j(x)=-\frac{\pi\bar{\kappa}r_o^2\eta_o}{h}\frac{d\eta'}{dx'} \quad [11]$$

Electrode current density.—The current density per unit area of electrode surface $I(o)$ can be obtained from the total current of a cylinder $j(o)$ by

$$I(o)=j(o)\frac{1-\beta}{\pi r_o^2} \quad [13]$$

or

$$I(o)=\frac{-\bar{\kappa}\eta_o(1-\beta)}{h}\left(\frac{d\eta'}{dx'}\right)_{x'=0} \quad [14]$$

Application of the model to oxygen electrode.—In the first application of the model we have used the computer program to calculate (*a*) radial distribution of current at constant x, (*b*) current generated at different planes perpendicular to cylinder axis, and (*c*) measurable electrode current density.

We have fixed the following data which we feel is realistic for a Teflon-bonded platinum electrode operating as oxygen electrode at 80°C in 30% KOH:

η_o = 0.3V
α = 0.5
n = 4 equiv/mol.
D = 2 x 10^{-5} cm²/sec[extrapolated from ref. (28)]
$\bar{\kappa}$ = 1.3 ohm^{-1}cm^{-1} (29)
S = 20 m²/g (6)
w = 20 x 10^{-3} g/cm² (6)
h = 0.02 cm (6)
C_o = 5.5 x 10^{-8} mol/cm³ (30)
z = 1
ϕ = 0.032
ρ = 20 g/cm³

The current derivative

$$\frac{dj}{dx} = -\frac{\pi\bar{\kappa}r_o^2\eta_o}{h^2}\frac{d^2\eta'}{dx'^2} \qquad [12]$$

Indirect structural parameters are

$$\gamma = S\rho(1-\theta) = 2 \times 10^5 \text{ cm}^2/\text{g} \times 20 \text{ g/cm}^2 (1-\theta) = 4 \times 10^6 (1-\theta) \text{ cm}^{-1}$$

$$\beta = 1 - \frac{w}{\rho h(1-\theta)}, \text{ macroporosity, and}$$

$\bar{D} = \theta D$ and $\bar{\kappa} = \theta\kappa$. (The tortuosity factor is taken as unity for the purpose of the present example.)

As variables we have taken microporosity θ, cylinder radius r_o, and exchange current i_o.

For a set of values of θ, i_o, and r_o computer tabulations have been obtained by varying x' from 0 to 1 at increments of 0.05. These tables were obtained for $\theta = 0.5$, 0.7, and 0.9, $r_o = 10^{-3}$, 10^{-4}, and 10^{-5} cm, and $i_o = 10^{-6}$, 10^{-7}, and 10^{-8} A/cm².[3] The columns of these tables showed (*a*) position $= x/h$; (*b*) relative potential $= \eta/\eta_o$; (*c*) current in amps flowing through a plane x of single cylinder; (*d*) current derivative, *i.e.*, current produced at the plane x of single cylinder; and (*e*) distribution parameter p, (see Eq. [10]), and distribution parameter q (see Eq. [5] and [10] and Fig. 3). At the end of each tabulation the measurable current density for the electrode (in A/cm²) was printed. Figure 4 shows a summary of effect of θ, r, and i_o on electrode current density. In all cases, decreasing the radius from 10^{-3} to 10^{-4} cm has a large effect on current, but a further decrease below 1μ has little effect on performance. This finding, of course, applies only under the diffusion conditions of this example.

According to Fig. 4 current densities higher than 150 mA/cm² are obtained for $i_o = 10^{-6}$ A/cm² and $r_o \leq 10^{-4}$ cm. For $r_o \leq 10^{-4}$ and $i_o < 10^{-7}$ the current density is proportional to i_o. These conditions correspond to high radial Pt utilization (small values of q).

When the Pt is well utilized, the current is also independent of microporosity (θ). This is due to the fact that in this range the current from the cylinder is directly proportional to $(1-\theta)$, and the number of cylinders is inversely proportional to $(1-\theta)$.

[3] Our own work with smooth platinum in KOH shows $i_o = 5 \times 10^{-7}$ A/cm² at 80°C (31, 32).

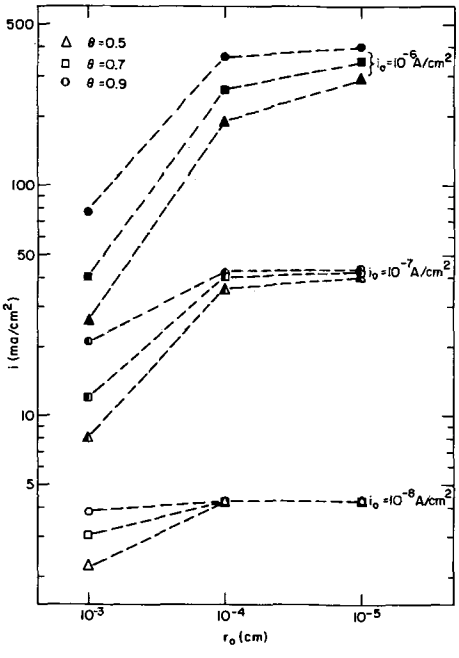

Fig. 4. Effect of r_o, i_o, and θ on measurable current density at 300 mV polarization.

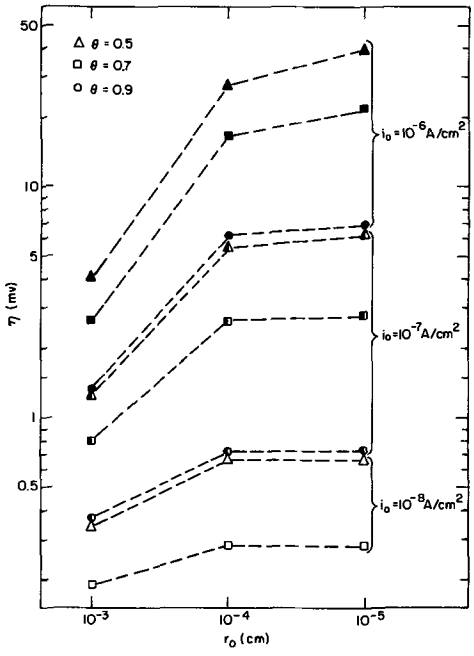

Fig. 5. Effect of r_o, i_o, and θ on internal drop (η) at 300 mV polarization.

A summary of the internal voltage drop as a function of θ, i_o, and r_o is given in Fig. 5 which shows that in all cases the internal voltage drop is small. For $\theta = 0.9$ $r_o = 10^{-5}$ and $i_o = 10^{-6}$ A/cm², a voltage drop of only 7 mv between front and back electrode is observed, even if the current density is 400 mA/cm². Correspondingly, the current produced at the plane $x' = 1$ is only 10% lower than the current at $x' = 0$. For $\theta = 0.5$, on the other hand, the internal voltage drop is 40 mV and the current produced at the plane $x' = 1$, 46% lower than at the plane $x' = 0$. This relatively poor transversal utilization of the electrode with $\theta = 0.5$ explains in part why, for instance, at $i_o = 10^{-6}$ and $r_o = 10^{-4}$ the current for this value of θ is only half of the current when $\theta = 0.9$. The obvious solution of using electrodes of a high degree of microporosity has to be re-examined after considering limitations of gas phase diffusion. Increase of microporosity (θ) at constant electrode loading (w) and thickness (h) results in a decrease of macroporosity (β) and therefore in a decrease of the residual volume. This volume includes volume of gas channels, of Teflon particles, and of wire screen, as shown in Table I. The fraction of gas volume in the residual volume is immaterial in the present treatment because we have assumed that diffusion in the gas phase is fast. But this assumption applies only under certain conditions of electrode structure, reactant gas concentration, and current drain.

Table II shows the value of the second distribution parameter (q) which is a measure of the radial utilization of the agglomerates. As shown in Fig. 3, the radial distribution is reasonably good for $q < 1$. Comparing the values of q in Table II with the curves of Fig. 3

Table I. Volume distribution in Teflon-bonded electrode ($w = 20$ mg/cm², $h = 0.02$ cm, $\theta = 0.9$, and 30% Teflon)

Component	Volume × 10^3 cm³/cm²
Total electrode	20
Platinum	1
Wetted agglomerate	10
Residual volume (gas, Teflon, screen)	10
Teflon (density ~ 2.3)	3
Screen	2
Gas	5

Table II. Effect of θ, r_o, and i_o on radial distribution parameter q of Eq. [5] and [10] for $x = 0.5$ at 300 mV polarization

		Cylinder radius, r_o (cm)		
	i_o (A/cm²)	10^{-3}	10^{-4}	10^{-5}
$\theta = 0.5$	10^{-6}	$3.12 \times 10^{+1}$	2.72	2.52×10^{-1}
	10^{-7}	1.00	9.79×10^{-1}	9.75×10^{-2}
	10^{-8}	3.19	3.19×10^{-1}	3.19×10^{-2}
$\theta = 0.7$	10^{-6}	$2.06 \times 10^{+1}$	1.90	1.84×10^{-1}
	10^{-7}	6.59	6.52×10^{-1}	6.51×10^{-2}
	10^{-8}	2.09	2.09×10^{-1}	2.09×10^{-2}
$\theta = 0.9$	10^{-6}	$1.06 \times 10^{+1}$	1.03	1.02×10^{-2}
	10^{-7}	3.36	3.36×10^{-1}	3.36×10^{-2}
	10^{-8}	1.07	1.07×10^{-1}	1.07×10^{-2}

we see that for $r_o \leq 10^{-4}$ and $i_o \leq 10^{-6}$ radial utilization of catalyst in agglomerate is reasonably good.

Discussion based on approximations.—When applying the model to the oxygen electrode, the potential changes very little along the cylinder in most cases (Table II). The current derivative is almost constant, a related result since this is a function of η'.

This result could have been anticipated from the fact that the right hand side of Eq. [9] is small for the range of values of i_o and r_o of interest to us.

Under these conditions the total current per unit area is

$$I(o) = \frac{2n\mathbf{F}\bar{D}C_o h(1-\beta)}{r_o^2}\left[\frac{qI_1(q)}{I_o(q)}\right] \quad [15]$$

(the exponential term is neglected)
where now

$$q \sim \left(\frac{10^{15}(1-\theta)i_o r_o^2}{\theta}\right)^{1/2} \quad [16]$$

Further analysis can be made in the two following extreme situations.

1. For q small, which is a good approximation when $r_o = 10^{-5}$, $i_o = 10^{-7}$ though not for $r_o = 10^{-3}$, $i_o = 10^{-6}$, we can use the approximation

$$\frac{qI_1(q)}{I_o(q)} \simeq \frac{q^2}{2}$$

Hence

$$I(o) \sim Swi_o \exp\left(\frac{\alpha z\eta_o}{\phi}\right) \quad [17]$$

The electrode current density is independent of r_o though it depends on C_o through i_o.

Total current increases linearly with i_o, S, and w, and is independent of θ.

The Tafel parameter b for the porous electrode is the same as for the smooth electrode.

The basic situation is one in which C is roughly uniform across the electrode, and the I_o Bessel function is roughly $=1$ everywhere.

2. For q large, as is the case when $r_o = 10^{-3}$, $i_o = 10^{-6}$ for instance, the Bessel function's arguments vary widely across the cylinder. C is then much larger near the outer surface than in the center, and the catalyst is not being so well utilized. Now we have

$$\frac{qI_1(q)}{I_o(q)} \simeq q$$

and hence

$$I(o) = \frac{2w}{\rho(1-\theta)r_o}(\gamma i_o n\mathbf{F}\bar{D}C_o)^{1/2}\exp\left(\frac{\alpha z\eta_o}{2\phi}\right) \quad [18]$$

$I(o)$ does depend on r_o, increasing when r_o decreases. It increases like $C_o^{1/2}$ and $i_o^{1/2}$, (over-all then current is proportional to C_o).

The Tafel parameter b for the porous electrode is twice that for the smooth electrode.

Also

$$I(o) \propto \frac{\theta^{1/2}}{(1-\theta)^{1/2}}$$

i.e., increasing θ increases current.

Analysis of Assumptions

The consideration of a Teflon-bonded electrode with flooded agglomerates as a bunch of parallel flooded cylinders consisting of a continuum mixture of catalyst and electrolyte is a very simplified treatment of a very complex structure. Therefore, the applicability of the assumptions used is restricted to relatively narrow limits. It is necessary to know these limits in order to use the model safely in the pertinent cases and/or to modify the assumptions when we want to extend the model to other cases. An exact discussion of the assumptions and an extension of the application of the model by using less restrictive assumptions should be the object of future work. A preliminary discussion however will be given in the following:

Cylindric configuration.—The difference between a cylindric surface and any other surface as gas/agglomerate interface is reflected mostly on the accessibility of the interior of the agglomerate to diffusion. For comparison let us consider a porous planar agglomerate of a thickness $2\,r_o$ perpendicular to the external surface of the electrode.

Now instead of Eq. [3]

$$\frac{\partial^2 C}{\partial r^2} = \frac{\gamma i_o}{n\mathbf{F}D}\left\{\frac{C(x,r)}{C_o}\exp\frac{\alpha z\eta}{\phi} - \exp\frac{(\alpha-1)\eta}{\phi}\right\} \quad [19]$$

Boundary conditions

$$\frac{\partial C}{\partial r} = 0 \text{ at } r = 0,\ C = C_o \text{ at } r = r_o$$

With Eq. [6] converted to

$$\frac{d\eta}{dx} = -\frac{j(x)}{2r_o\bar{\kappa}} \quad [20]$$

and Eq. [7] converted to

$$-\frac{dj(x)}{dx} = 2\gamma\int_o^{r_o} i\,dr \quad [21]$$

Under these conditions one obtains

$$\frac{d^2\eta'}{dx'^2} = \frac{n\mathbf{F}\bar{D}C_o h^2}{\eta_o\bar{\kappa}r_o^2}\left[1 - \exp\left(-\frac{z\eta_o\eta'}{\phi}\right)\right]\frac{q\sinh q}{\cosh q} \quad [22]$$

The only difference between this and the case of cylindric geometry is the absence of the factor 2 on the right hand side of the ratio of hyperbolic functions instead of Bessel functions.

The approximations are similar as before: (*i*) q small, the expression for the $I(o)$ *vs.* η_o relationship is identical with the previous result for the cylindrical geometry, which is a consequence of the full utilization of the electrode material. (*ii*) q large.

$$I(o) \sim \frac{h(1-\beta)}{r_o}(\gamma i_o n\mathbf{F}\bar{D}C_o)^{1/2}\exp\left(\frac{\alpha z\eta_o}{2\phi}\right) \quad [23]$$

There is a factor 2 difference between this result and the previous one for cylindric diffusion due to the geometry.

Continuum distribution of catalyst and electrolyte.—Such an assumption is acceptable if (*a*) the dimensions of the particles and pores making up the agglomerate are small compared with the radius of the agglomerate and (*b*) the dimension of the region where most of the current is produced is large compared with the dimensions of the catalyst particles and of the micropores. This second condition is, of course, more restrictive than the first and should suffice. For large values

of q (*i.e.*, for large values of i_o) the current is produced almost exclusively in the periphery of the cylinder; therefore, the continuum assumption cannot be used in the case of the hydrogen electrode.

As a consequence of the continuum distribution, a diffusion limiting current for an electrode of very high i_o, such as the hydrogen electrode, cannot be obtained mathematically with our model. This is easy to understand because assuming a continuum distribution of electrolyte and catalyst even on the external surface of the cylinder there are active catalyst sites which can be reached by the reactant gas without the hindrances of any diffusion path in the electrolyte.

Formally this problem can be solved by introducing a thin film of pure electrolyte around the cylinder. The model converts then for very high i_o to a thin film model with the reaction localized on the surface of the cylinder. Diffusion is through the thin film as in the thin film model, but with ionic current flowing mostly through the porous cylinder

If the thickness of the thin film is δ and we now call C_o' the concentration of the reactant on the interface cylinder thin film to differentiate from C_o solubility of gas, all the previous equations apply if C_o is substituted by C_o'. In addition we will have the following relation between C_o and C_o'.

$$-\frac{dj(x)}{dx} = \frac{n\mathbf{F}\bar{D}(C_o - C_o')2\pi r_o}{\delta} \qquad [24]$$

A computer program with an additional equation could, of course, be easily written. The merit of this approach is doubtful, however, since δ is not known. This correction will be necessary when $C_o' - C_o$ is large. $C_o' - C_o$ is large when δ/r_o and/or $dj(x)/dx$ are large.

For the oxygen electrode example treated with $C_o = 5.5 \times 10^{-8}$

$$\frac{C_o'}{C_o} = 1 - \frac{4 \times 10^5}{\theta} \cdot \left(\frac{\delta}{r_o}\right) \cdot \frac{dj(x)}{dx} \qquad [25]$$

Equation [25] can be used with $dj(x)/dx$ as printed out by computer to estimate for what values of δ/r_o there is a significant difference between C_o and C_o'.

Constant intrinsic activity of the catalyst throughout the cylinder.—This assumption seems reasonable, although it is possible that under certain conditions a larger amount of bulk area is located in the core of the agglomerate. This could be handled mathematically by an expression relating γ to r_o.

When large values of q exist (*i.e.*, high values of i_o, r_o, and η and/or low values of D and C_o), it may be advisable to form agglomerates with porous noncatalytic cores. This will result in significant savings of the catalyst.

Equilibration of electrolyte concentration in cylinder via gas phase.—Due to the small diameter of the cylinder compared with its length, this assumption seems more reasonable than the assumption [implicit in ref. (24)] that concentration equalization occurs only via ionic migration in the axial direction of the flooded micropore system.[4] As a consequence of evaporation and condensation, electrolyte transport to the gas side of the oxygen electrode should be expected. A compensating counterflow of electrolyte from the gas side to the electrolyte side can be expected also. Indeed, the often observed "weeping" of oxygen electrodes could be explained at least partially by this mechanism.

Absence of convection.—Convection caused by local heating has been found to occur at the meniscus of partially immersed electrodes (16). It seems unlikely that this type of convection occurs to an appreciable degree inside a highly porous and thermally conductive agglomerate. However, the evaporation-condensation process postulated in assumption 4 will cause convection. This convection should be negligible if the electrolyte, which tends to accumulate in the back side (gas side) of the electrode, returns to the front side (electrolyte side) through the very large pores always present as imperfections in a Teflon-bonded electrode.

All cylinders have the same radius.—This assumption is to some extent justified by the high degree of lateral interlocking of the agglomerates. The effect of having a spectrum of agglomerate radii on the calculation of total electrode current densities should be investigated in subsequent work.

With regard to the other assumptions, it seems that assumption 6 will apply in most cases since h is very large compared with r_o. Assumptions 5, 7, 8, and 9 can cease to apply under more severe conditions of operation of the porous electrode. When this happens or is expected to happen, the mathematical treatment can be suitably modified, without essential changes of the proposed model.

Conclusions

A working mechanism of the Teflon-bonded electrode is proposed in which the catalyst agglomerates are completely flooded and are surrounded by hydrophobic channels. The reacting gas diffuses through the hydrophobic channels, dissolves in the electrolyte in the agglomerate, and diffuses to the center of the agglomerate with simultaneous reaction along this diffusion path. For the mathematical treatment the model is further simplified by assuming cylindric flooded agglomerates with a continuous distribution of catalyst and electrolyte. The following conclusions have been obtained with this model:

1. The model allows one to predict not only the utilization of the catalyst across the thickness of the electrode (transversal utilization), but also the utilization of the catalyst along the radius of the flooded agglomerate. As a consequence, in addition to often studied variables such as porosity (macro- and micro-) bulk area, etc., the importance of agglomerate size is shown. A parameter (q) which determines the radial current distribution in agglomerate is introduced and quantitatively defined as a function of diffusion coefficient, microporosity, solubility of reactant gas, exchange current, bulk surface area, local potential, and agglomerate radius.

2. For the specific example of the oxygen reduction on Teflon-bonded Pt electrodes in 30% KOH at 80°C, a good radial distribution is obtained for agglomerate sizes below 1μ and polarizations up to 300 mV. Under similar conditions the transversal utilization of the electrode is very good (very low internal iR drops).

3. For the same example, both the radial utilization of agglomerates and the transversal utilization of the electrode become poor at higher current drains ($i >$ 300 mA/cm^2), and with poor structures (low microporosity and large agglomerate size).

4. For good transversal utilization of the electrode and good radial utilization of the agglomerate, the Tafel plot is obviously the same as that obtained with a smooth electrode. If, on the other hand, the transversal utilization of the electrode is good but the radial utilization of the agglomerate is very poor, a linear relationship is predicted with a Tafel slope twice that of the smooth electrode.

5. The present model and, more specifically, the parameter of radial distribution (q) introduced here can be used to design more efficient hydrophobic gas diffusion electrodes by predicting the maximum agglomerate size tolerable. When due to a high ratio of diffusion to activation control for a certain electrode reaction, high values of q are obtained for all reasonable agglomerate sizes, the model suggests the use of porous, conductive, but catalytically inactive agglomerates which have been activated with catalyst only on their periphery.

[4] This is independent of the fact that our assumptions greatly simplify the mathematical treatment.

6. The proposed model cannot be used without further modification to predict quantitatively the performance of electrodes with high exchange current as the hydrogen electrode in acid electrolyte, because the parameter q becomes too large and the assumption of a continuum distribution of catalyst and electrolyte does not apply.

This work was carried out under Contract No. NASW 1233. The authors would like to thank Mr. Ernst Cohn for his interest in this work.

Manuscript submitted Nov. 19, 1968; revised manuscript received May 6, 1969. This was Paper 327 presented at the Montreal Meeting, Oct. 6-11 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

LIST OF SYMBOLS

$C,C(r,x)$	Concentration of reactant gas at a point (r, x) (mol x cm^{-1})
C_o	Solubility of reactant gas (mol x cm^{-1})
D	Diffusion coefficient of reactant gas in liquid (cm^2 x cm^{-1})
$\overline{D}$	Effective diffusion coefficient of reactant gas in liquid; affected by microporosity and tortuosity
$\mathbf{F}$	Faraday constant
h	Thickness of electrode, cm
$i,i(r,x)$	Local real current density (A x cm^{-2})
i_o	"Real" exchange current density (A x cm^{-2})
I_o	Bessel function of order zero
I_1	Bessel function of order one
$I(o)$	Electrode current density (A x cm^{-2})
$j,j(x)$	Current flowing through plane x of cylinder (A)
$j(o)$	Total current produced by cylinder (A)
N	Number of cylinders in 1 cm^2 of electrode
n	Number of electrons involved in electrode reaction
p	First distribution parameter (see Eq. [15] and Fig. 3)
q	Second distribution parameter (see Eq. [15] and Fig. 3)
R	Gas constant
r	Radial coordinate in cylinder (cm)
r_o	Radius of cylinder (cm)
S	Surface area of catalyst (m^2 x g^{-1})
T	Absolute temperature (°K)
w	Catalyst load in electrode (g x cm^{-2})
x	Axial coordinate in cylinder (also in electrode) (cm)
x'	Scaled axial coordinate
z	Stoichiometric number
α	Transfer coefficient
β	Macroporosity
γ	Surface to volume ratio, (cm^{-1})
δ	Electrolyte outer layer, (cm)
$\eta, \eta(x)$	Overvoltage at plane (x), (V)
η_o	Measured overvoltage, at plane $x = 0$ (V)
η'	Scaled overvoltage ($\eta' = \eta/\eta_o$)
θ	Microporosity
κ	Ionic conductivity, ($ohm^{-1}cm^{-1}$)
$\overline{\kappa}$	Effective ionic conductivity, affected by microporosity and tortuosity, (ohm^{-1} cm^{-1})
ρ	Catalyst density (g x cm^{-3})
ϕ	$RT/\mathbf{F}$(V)

An Electrochemical and Electron Microscopic Study of Activation and Roughening of Platinum Electrodes

T. Biegler

Division of Mineral Chemistry, CSIRO, Port Melbourne, Victoria, Australia

ABSTRACT

The factors which govern the behavior of platinum electrodes during anodic-cathodic cycling in 1M H_2SO_4 are examined. Cyclic voltammetry with linear potential sweep is found to be a sensitive criterion of the state of the electrode surface. With a new electrode, the shapes of these voltammograms change during the first few hundred cycles of any potential program in which a layer of adsorbed oxygen is periodically formed and reduced. These changes are considered to represent activation of the electrode and electron microscopy suggests that they are accompanied by surface structural changes in the form of shallow pitting. Further roughening occurs if the electrode is treated with a potential program fulfilling the conditions that (*a*) the amount of adsorbed oxygen after the anodic cycle exceeds the equivalent of one oxygen atom per platinum atom and (*b*) the reduction cycle is fast. The rate of roughening is proportional to the amount of adsorbed oxygen. Smoothing occurs when a program which does not fulfill conditions (*a*) and (*b*) is applied to an already roughened electrode. After extensive roughening, platinum can be detected in solution. The nature of the roughening process and also of the effects produced by flaming the electrode is examined by electron microscopy. It is suggested that activation and roughening occur through weakening of platinum interactions due to formation of the strong platinum-oxygen chemisorption bond. This allows rearrangement of platinum surface atoms and dissolution of a platinum-oxygen species. High energy platinum sites are probably lost in the initial activation process while a roughening program provides sufficient energy to dislodge atoms in more stable sites.

Electrochemical roughening of platinum surfaces subjected to anodic-cathodic treatments is now a well established phenomenon (1-6), although there is no general agreement as to the mechanism or the significant controlling factors. The main controversy concerns the roles played by successive formation and dissolution of adsorbed hydrogen- and oxygen-containing films at or in the electrode surface. Hoare (3, 7) based his mechanism on the concept of dermasorbed hydrogen, claiming that absorption and then removal of such hydrogen caused alternate lattice expansions and contractions and hence breaking up of the platinum surface. Gilman (4) disputed this explanation since he observed roughening under conditions where the presence of hydrogen would not be expected at any stage of the potential programs used. He considered (4) that the formation and reduction of surface oxide are the critical processes. On the basis of experiments in which sequences of sawtooth and rectangular potential pulses were applied to a platinum electrode in 85% phosphoric acid at 120°, Gilman also concluded (4) that fast reduction of surface oxide caused roughening, while slow reduction caused a decrease in the surface roughness. This seems to be the first report of such smoothing effects, although losses of area have been observed for platinized electrodes (8, 9) and are to be expected from the sintering behavior of high area unsupported catalysts.

There is a close connection between the questions of roughening and the well known activation of platinum electrodes by anodic-cathodic treatments. This connection arises, first, because one of the contending theories to explain electrochemical activation (10) invokes the idea that a kind of platinized layer is produced at the electrode surface and is responsible for the activity, and, second, because there are no adequate criteria for distinguishing between surface cleaning and true roughening as measured by the usual electrochemical methods of area determination (hydrogen adsorption, oxygen adsorption, double layer capacity). A convincing demonstration that activation produces surface changes which differ only in degree from the blackening found by Anson and King (2) and Hoare (3) is still lacking. As the following work will show, it is possible by means of cyclic voltammetry to make certain clear distinctions between activation and roughening but in several ways the processes are similar.

A second group of theories for the activation process (11-13) contains the notion of a structurally distinct active surface layer without necessarily implying that the electrode area increases at the same time. A third theory, that activation is essentially a cleaning process, has been gaining wide acceptance (14-16) and is based mainly on observations of deactivation as a function of factors such as solution purity and stirring rate. Interpretation of these experiments in terms of surface contamination seems indisputable, but it is doubtful whether their design could permit detection of any activation effects due to surface structural changes in view of the inadequate attention paid to electrode prehistory. The work presented here will show that both effects must be considered when explaining the activation of a platinum electrode by anodic-cathodic treatments.

Experimental

Glass cells (2 or 3 compartments) of conventional design were used. One compartment contained the reference electrode, mercury/mercurous sulfate in 1M H_2SO_4. Its potential was 0.68V with respect to a reversible hydrogen electrode in 1M H_2SO_4, to which all potentials are referred. In some experiments the platinum counter electrode was in the main compartment and in others it was placed in a third compartment separated from the working electrode by a fine sinter. No effects could be attributed to the placement of the counter electrode.

Platinum electrodes of 34 or 38 gauge wire were sealed into soft glass. Foil electrodes (~0.04 mm thick) of geometric areas around 1 cm^2 were spot welded to short lengths of 28 gauge platinum wire sealed into soft glass. Electrodes cut from one sheet of foil were found to contain a significant impurity, probably gold, and subsequent work was carried out with another sample of 99.99% purity. Apart from certain differences found during the initial activation process, which will be described below, the behavior of elec-

trodes from different sources was similar. None of the platinum used in this work had previously been employed in electrochemical experiments.

Two kinds of pretreatments were used before electrochemical runs were commenced. Those electrodes designated as "heat-treated" were subjected to the following sequence: (*i*) washed in cold chromic acid; (*ii*) rinsed in distilled water; (*iii*) held for several seconds at yellow heat in the oxidizing part of a coal gas/air flame; (*iv*) washed in cold chromic acid; (*v*) rinsed in distilled water; (*vi*) inserted in cell containing degassed electrolyte and held at open circuit during final degassing (5-10 min); (*vii*) connected into potentiostatic circuit during a cathodic sweep at the moment when the control potential reached the open circuit potential. The other pretreatment without heating the electrode started at step (*iv*).

All experiments were carried out using 1M H_2SO_4 as electrolyte. This solution was prepared from water redistilled from alkaline permanganate and reagent grade sulfuric acid purified by distillation under reduced pressure. Nitrogen for degassing the solution was first passed over heated copper turnings and then through a cold trap (liquid oxygen). Except where otherwise stated, experiments were carried out at 25°C.

Instrumentation was similar to that described earlier (17) except that in most experiments a Tacussel GSTP2 function generator was used to program the electrode potential. The main kinds of programs used are shown in Fig. 1.

Electrode area measurements were carried out by integrating the current due to deposition of adsorbed hydrogen atoms during the cathodic portion of a triangular cyclic voltammogram. Integration using the corrections for double layer charging and hydrogen evolution current shown in Fig. 2 was assumed to give the hydrogen monolayer charge, Q_H^S, and the real electrode area was calculated using $Q_H^S = 210$ μcoul/real cm². Area measurements were always carried out in carefully deoxygenated solutions.

A two stage replica technique was used in the electron microscope studies. The primary plastic replica (Bexfilm) was shadowed with platinum/carbon at an angle of 20° and the plastic dissolved in acetone. The platinum/carbon replica was examined in a Philips EM200 electron microscope at 100 kV.

Results

Activation of electrodes.—The initial changes in behavior of electrodes on anodic-cathodic cycling will be referred to as activation for reasons which will become apparent below. Figure 2 shows the shapes of triangular sweeps at various stages of the activation of an electrode by triangular cycling between 0.05 and 1.54V. Between the stages shown, cycling was speeded up by a factor of 10 faster than the sweeps in Fig. 2 so that the large number of cycles needed for activation could be completed in a reasonable time.

The most notable changes with activation are (*i*) development of the peaks in the hydrogen region, (*ii*) steepening of the current rise corresponding to the start of the "oxide region" at about 0.82V in the anodic sweep, (*iii*) development of two distinct peaks at 0.95

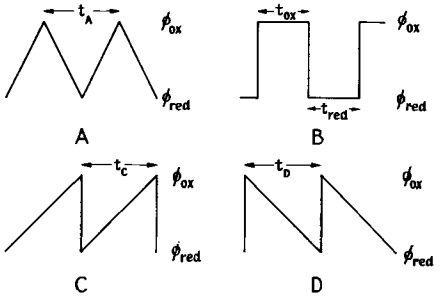

Fig. 1. Anodic-cathodic programs used in this work

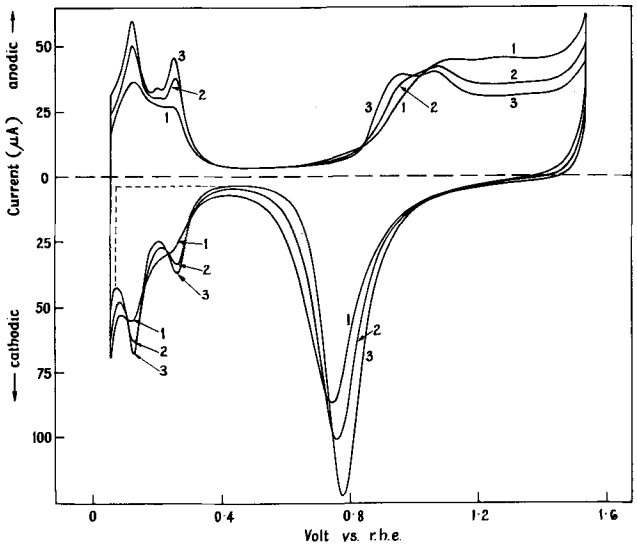

Fig. 2. Cyclic voltammograms during activation of Pt wire electrode by triangular cycling between 0.05 and 1.54V. 1, 2nd cycle; 2, 5th cycle; 3, 200th cycle. No significant changes between 200th and 500th cycle. Sweep rate 40 mV/sec. Boundaries for integrating Q_H^S are shown for curve 3.

and 1.07V, (*iv*) lowering of the current plateau in the region 1.1-1.5V, and (*v*) an increase in height and decrease in width of the oxide reduction peak in the cathodic sweep. Breiter (15) found similar changes in cyclic voltammograms during activation.

Detailed behavior depended somewhat on the source of the platinum and on the pretreatment. A series of electrodes made from one sample of foil consistently gave a steep anodic current rise between 1.3 and 1.5V and also a small peak at 1.16V on the cathodic sweep. These features gradually disappeared over about 300 cycles but returned after heat treatment. Comparison with curves given by Breiter (18) for platinum-gold alloy electrodes suggests a gold impurity in this sample of platinum foil and indicates further that this impurity accumulates preferentially at the platinum surface. Anodic-cathodic cycling removes the gold from the surface and after such activation the behavior is indistinguishable from that of purer electrodes.

The main effect of heat pretreatment is to produce an electrode which is initially more active than unheated platinum by the above criteria. Thus, hydrogen peaks are well developed in the early cycles, and the portions of the curves corresponding to "oxide" formation and reduction show smaller changes during the activation period than found with unheated electrodes.

Activation by triangular cycling takes some 200 to 500 cycles after which the rate of change in the shapes of voltammograms becomes negligible. It is this behavior which distinguishes activation from the electrode roughening to be described below. Activation is induced by any periodic program extending well into the "oxide" region, while, for example, triangular cycling between 0.08 and 0.88V (just at the start of the "oxide" region) does not produce the changes characteristic of activation. This is to be expected from the idea that alternate formation and reduction of the "oxide" film are responsible for activation.

The roughness factor reached on activation depends on the source of platinum and the pretreatment. Heat-treated electrodes from all sources had roughness factors in the range 1.10 to 1.20. Unheated foils varied between 1.22 and 1.45. An unheated wire had a roughness factor of 2.8 which fell to 1.13 after heating.

Deactivation by contamination.—Severe poisoning of the electrode occurs if it is left in the electrolyte for long periods (hours) at open circuit or held at potentials below about 0.9V. On the first cycle after such treatment, the peaks in the hydrogen region are low-

ered or disappear completely and large anodic currents are seen in the "oxide" region. The curves return to normal within about five triangular cycles, in agreement with the results of Breiter (15). Thus, the loss of activity through adsorption of impurities from 1M H_2SO_4 is easily reversed and seems to be quite different from the low activity of a new platinum electrode.

Activated electrodes held at potentials between about 1.1 and 1.6V retain their activity indefinitely, the first cycle showing full development of hydrogen peaks. An active electrode can be removed from the cell, washed in chromic acid, rinsed, and returned to the cell without change in activity or area. However, if the electrode is wiped with a paper tissue, some loss of activity occurs, and a considerable amount of cycling is needed to restore the hydrogen peaks to their former shape.

Roughening and smoothing of electrodes.—Once an electrode has been activated, its response to anodic-cathodic cycling depends on the kind of potential program used. Thus, as noted above, no further changes occur when a triangular sweep is employed. In agreement with the conclusions of Gilman (4), it is found that roughening occurs only with programs which cause fast reduction of surface "oxide." Rectangular pulse (B) and sawtooth (C) programs fall into this category, although such programs are roughening only under certain conditions which will be outlined below. The inherently nonroughening programs A and D leave an activated surface unaltered but will smooth a surface which has previously been roughened. These generalizations emerge from large numbers of experiments with 25 different electrodes, and their validity is independent of the prehistory of the electrode and of the order in which several programs are applied.

Prolonged application of a smoothing program brings the roughness factor down to about the value characteristic of an unroughened, activated electrode. The following example gives the history of an electrode which illustrates this effect. This electrode was roughened with program B from an initial roughness factor of 1.36 to a value of 4.90 and was then smoothed using program D, with ϕ_{ox} = 1.48V, ϕ_{red} = 0.48V, and t_D = 3.8 sec. After 2000 cycles the roughness factor had decreased to 1.97. ϕ_{ox} was then changed to 1.68V and further decreases in roughness factor to 1.63 (1000 cycles) and 1.44 (2500 cycles) occurred, after which there were no changes within 17,000 cycles. The final roughness factor was thus only 6% above the initial value. Similar smoothing effects are also found with programs A or D when ϕ_{red} is in the hydrogen region.

As observed previously (6), area changes are accompanied by changes in the shapes of the triangular cyclic voltammograms used to monitor the platinum surface properties. In the hydrogen region the more cathodic peak (0.12V) generally increases faster with roughening than the peak at 0.26V; at the same time the third peak, found only in anodic sweeps between the two main peaks (6, 19) increases in height and with extensively roughened surfaces (roughness factor >4) it becomes comparable to the peak at 0.26V. Roughening is also found to produce rather more subtle changes in the small peaks at the start of the "oxide" region (Fig. 2), the relative heights of which change in a manner roughly comparable with the two main hydrogen peaks. Thus, on roughening, the peak at 1.07V increases with respect to the peak at 0.95V. All these changes are reversed on smoothing.

Visible darkening of the surface is found to occur when the roughness factor exceeds about 7. Similar electrode blackening was also found by Anson and King (2) and Hoare (3), but roughness factors for their surfaces are not available. Gilman (4) observed only slight dulling of the electrode surface under conditions where the roughness factor did not exceed 4.

Roughening as a function of oxide coverage.—In the early stages of this work it was found that roughening with sawtooth program C occurred only when ϕ_{ox} was sufficiently anodic and then increased with increasing ϕ_{ox}. For example, with ϕ_{red} = 0.48V and t_c = 2.3 sec, the roughening rates (RR) for various ϕ_{ox} were: ϕ_{ox} = 1.54V, RR = 0; ϕ_{ox} = 1.67V, RR = 0.006% per cycle; ϕ_{ox} = 1.78V, RR = 0.012% per cycle. This observation led to the idea that the amount of "oxide" present on the surface just before rapid reduction occurred was important in determining the roughening rate.

The "oxide" coverage (the term will be used here to denote the total charge due to adsorbed oxygen-containing species) can be varied by changing the time and/or the potential of anodization. The dependence of roughening rate (measured over several hundred cycles) on both factors is shown in Fig. 3, all values being obtained with one electrode. Program B was used, ϕ_{ox} and t_{ox} were varied and ϕ_{red} and t_{red} kept constant at 0.48V and 3.7 sec, respectively. It can be seen that the roughening rate increased approximately linearly with ϕ_{ox} for each value of t_{ox} used.

In order to establish a quantitative relationship between roughening rate and "oxide" coverage, the charge needed to reduce the surface after a period of anodization was determined by the appropriate program of Fig. 4. For $\phi_{ox} \leq$ 1.28V program E was used. For higher ϕ_{ox} it was thought desirable to introduce the step down to 1.28V to ensure that no extra surface oxidation occurred during the first part of the cathodic sweep. In fact this precaution was later shown to be unnecessary, programs E and F giving identical results when ϕ_{ox} is in the range 1.28-1.7V. Program G, in which the solution was vigorously purged with nitrogen for about 10 sec while the electrode was held at 1.28V, was used whenever ϕ_{ox} was high enough to cause oxygen evolution. The limiting current due to dissolved oxygen was then undetectable in the double layer region. Slow cathodic stripping rates, around 40 mV/sec, were used with these pro-

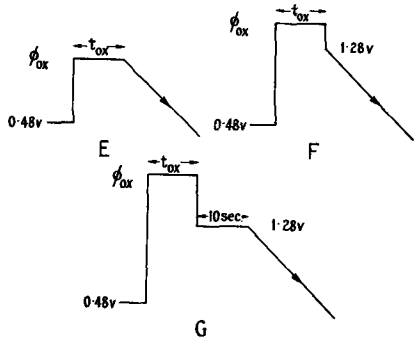

Fig. 4. Programs used to determine "oxide" coverage

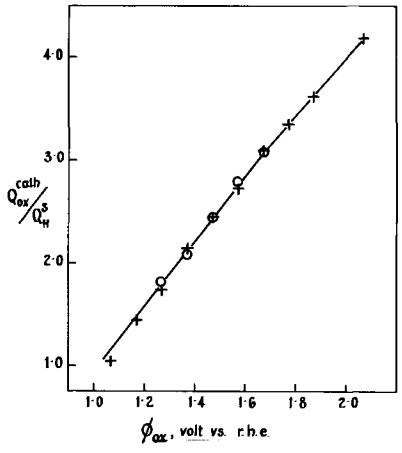

Fig. 5. Potential dependence of "oxide" coverage, expressed in terms of Q_H^S, for a constant oxidation time of 5 sec. Results for two different electrodes are shown.

grams. From the resulting curves, which resembled the cathodic sweep of Fig. 2, the amount of adsorbed oxygen, Q_{ox}^{cath}, was determined by integrating the cathodic "oxide" reduction peak. An arbitrary choice of base line is involved in this integration (here, the current at 0.48V was used as the double layer charging correction) but the error cannot amount to more than about 10%. The dependence of Q_{ox}^{cath} on potential for t_{ox} = 5 sec is shown in Fig. 5. The values are in reasonable agreement with the results of Becker and Breiter (20) and Gilman (21); discrepancies with other work on "oxide" coverage are discussed elsewhere (22).

Combination of results such as those shown in Fig. 3 and 5 gives Fig. 6 in which the roughening rate is plotted as a function of "oxide" coverage. Program B was used for roughening, t_{ox} and t_{red} kept constant at 5 sec, ϕ_{red} maintained at 0.48V and ϕ_{ox} varied. Results for two electrodes are given and the roughening rates for a variety of electrodes used in other aspects of this work are found to fit reasonably well onto this plot. The rather wide scatter reflects the generally poor reproducibility found in this study, not only for different electrodes but also for successive runs on a single electrode. However, Fig. 6 clearly shows that a minimum amount of "oxide" is required for roughening with a square wave potential program. This minimum value corresponds to one adsorbed oxygen atom per surface platinum atom and at higher coverages the roughening rate tends to increase linearly with oxygen coverage, although anomalies seem to be present at the highest potential examined (ϕ_{ox} = 2.08V).

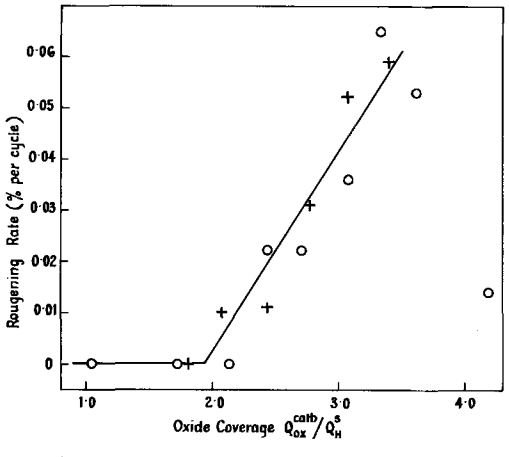

Fig. 6. Dependence of roughening rate on "oxide" coverage. Program B used for roughening, with t_{ox} = t_{red} = 5 sec, ϕ_{red} = 0.48V. Results for two electrodes shown.

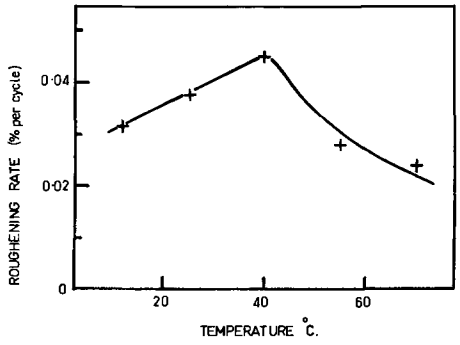

Fig. 7. Effect of temperature on measured roughening rate

Effect of temperature.—Roughening rate was measured over a range of temperatures using a constant roughening program (program B, t_{ox} = t_{red} = 5 sec, ϕ_{ox} = 1.68V, ϕ_{red} = 0.48V). Results are shown in Fig. 7. Contrary to Gilman's view (4) that roughening is appreciable only at the elevated temperatures used in hydrocarbon oxidation work, the roughening rate is seen to depend only slightly on temperature and shows a tendency to decrease at higher temperatures.

Effect of reduction potential.—The foregoing results with program B were all obtained using a reduction potential (ϕ_{red}) of 0.48V, *i.e.*, in the so-called double layer region. When ϕ_{red} was changed to 0.08V, all other factors being held constant, the roughening rate fell to about 20% of its former value. Thus, with the potentiostatic square wave program used here, the presence of hydrogen on the surface after reduction of the "oxide" layer inhibits the roughening process rather than initiating it as proposed by Hoare (3, 7).

Other factors.—Heat pretreatment produced no significant changes in the roughening rate although the scatter of results would not have allowed detection of an effect less than about 25%.

Stirring the solution with nitrogen appeared to produce a significant decrease in roughening rate compared with that in a quiescent solution. In a vigorously stirred solution the roughening rate was 50-75% of its value in unstirred solution, poor reproducibility once again making a more accurate assessment impossible. All of the previous results were obtained in quiescent solutions or with slow nitrogen bubbling, under which conditions the roughening rates are not significantly different.

In view of an earlier observation (6) that addition of methanol increased the roughening rate, a similar comparison was made under the somewhat different conditions of pretreatment and potential program used in the present study. Roughening with program B (ϕ_{ox} = 1.58 or 1.68V, ϕ_{red} = 0.48V, t_{ox} = t_{red} = 3 or 5 sec) was found to be 1.5-2 times faster in 1M H_2SO_4 containing 0.5M methanol than in 1M H_2SO_4 alone. Attempts to locate the source of the increased roughening by using programs C and D and by varying the ratio of t_{ox} to t_{red} in program B were inconclusive.

At several stages during this work, notably after extensive roughening or smoothing, cyclic voltammograms showed a small, stirring dependent cathodic current in the "double layer" region. The presence of dissolved platinum was suspected and confirmed using the stannous chloride test [*e.g.*, (23)]. The highest concentration found was about 1 ppm (5 x 10^{-6}M) which is close to the detection limit for this test. In the majority of runs, the absence of significant current indicates platinum concentrations less than about 2 x 10^{-6}M.

Electron microscopic observations.—Replicas of a number of foil electrodes at various stages of activation and roughness were examined in the electron microscope. Considerable variation from sample to sample, not directly attributable to the electrode treatment, was evident, especially in those electrodes sub-

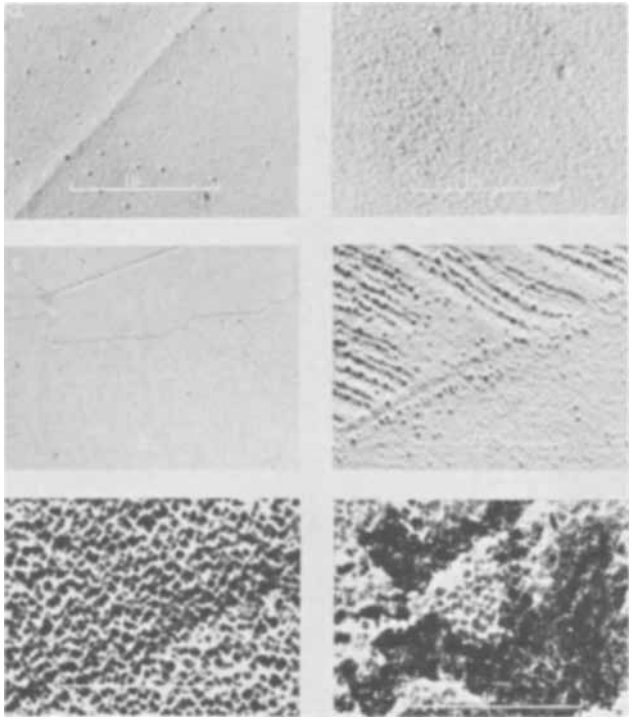

Fig. 8. Electron micrographs of shadowed replicas of platinum foil surfaces. (a) Heat pretreated electrode (no electrochemical treatment) showing grooved grain boundary and pitting. (b) Unheated electrode roughened with program B to roughness factor 1.62. (c) Heat pretreated electrode roughened with program B to roughness factor 2.55. (f) Same electrode as (e) showing platinum particles stripped off with replica.

jected to heat pretreatment. The main observations are as follows and are illustrated by some representative micrographs in Fig. 8.

1. Electrodes which are subjected to no pretreatment except washing in cold chromic acid appear fairly smooth at high magnification.

2. The heat pretreatment used here produces three kinds of visible effects; grooving along grain boundaries (Fig. 8a and c), faceting (Fig. 8c and d), and development of pits uniformly distributed over the surface (Fig. 8a). Faceting, which gives a terraced appearance to the surface, is rather variable from sample to sample, a result probably due to the lack of close control of flaming conditions. On a given sample the extent of faceting depends strongly on grain orientation and at grain boundaries the change in direction and density of facets is clearly visible. The pits are of the order of 200Å in diameter.

3. Electrodes which have been subjected to an electrochemical treatment leading to an increase in the monolayer hydrogen coverage are also rough when examined by electron microscopy. In the roughening process the pits increase in diameter and depth; at high roughness the pit diameters reach about 800Å. Preferential enlargement of pits occurs at the edges of the facets. There are some indications that the pits assume an angular shape as the electrode roughens.

4. On surfaces which have darkened through roughening, some of the platinum is stripped from the surface with the plastic replica and its structure can be examined by electron diffraction. Distinct diffraction spots indicate that the particles originate from a single crystal. A number of such particles scattered over the surface of a grain all have the same orientation.

Considerable attention was paid to the question of whether or not activation by triangular anodic-cathodic cycling produced any surface structural changes. Unfortunately, any such changes were difficult to detect with certainty because of the limitations in resolution of the replica technique, the variability from sample to sample, and the problems in choosing truly representative fields under the microscope for purposes of comparison. There were however some indications that, on an unheated electrode, activation is accompanied by slight surface roughening and that on the pitted surface of a heat pretreated electrode some enlargement of the pits occurs on activation.

Discussion

Electrode activation.—The activation criteria adopted here are, to an extent, arbitrary in that a direct connection between the development of specific features on the cyclic voltammograms and the activity of the electrode to electrocatalytic processes in general has not yet been established. For the extreme cases, such as electrodes which have had no activation at all or are clearly contaminated in some way, there is general agreement that the corresponding voltammograms should be regarded as typifying lack of activity; in particular, the small activity toward hydrogen and oxygen electrosorption can be cited. However, with the more subtle changes which occur later during cycling, such as slight increases in the hydrogen peaks or steepening of the current rise at the start of the "oxide" region, the term activation will be used here as defining such changes rather than implying a relation to electrode activity in the practical sense.

Electron microscopy suggests that activation by anodic-cathodic cycling involves structural alteration of the surface. This is a slow process requiring several hundred cycles whereas cleaning of a contaminated surface occurs in fewer than ten cycles. The observation of a time-, stirring- and purity-dependent decay of electrode activity after anodic treatment is certainly good evidence for the role of contaminant adsorption in deactivation (14, 16) but does not exclude the possibility of structural changes being important in the initial activation. Several authors (10-13) have proposed that the time-dependence of electrode activity indicates the decay of an unstable layer of surface platinum atoms in a hypothetical active state. In fact, the activated structure is shown in the present work to possess long term stability and the deactivation found by these authors must be attributed to the inevitable contamination of the surface by dissolved impurities. The active structure can, however, be disrupted by mild mechanical means such as gentle wiping with a paper tissue as described above. Of course, more vigorous methods such as chemical attack or annealing will also disturb the active structure produced by anodic-cathodic cycling.

The mechanism of electrode activation (as distinct from cleaning) seems to involve some kind of redistribution of surface platinum atoms during anodic-cathodic cycling. The freedom of movement needed to bring about such a redistribution presumably arises from the periodic formation and breakage of platinum-oxygen bonds, since this work has shown that neither adsorbed nor absorbed hydrogen plays a part in the activation process. These observations suggest the following mechanism for electrode activation. After rolling or drawing during manufacture, a platinum surface probably contains a large proportion of high index crystal faces and many defects. There is a correspondingly large number of high energy surface platinum atoms with low co-ordination to the underlying lattice. Such a surface is essentially unstable to the formation of an electrochemically generated layer of adsorbed oxygen and when the strong Pt-O chemisorption bond forms [see (22) for discussion of the nature of the adsorbed oxygen layer], the further weakening of the co-ordination of the high energy platinum atoms allows rearrangement of the atoms or complete separation of the Pt-O entity from the surface. Repetition of this process using one of the nonroughen-

ing programs eventually removes most or all of the high energy platinum atoms and leaves a stable surface exposing predominantly low index, high co-ordination faces. It is presumably within the pits that such planes are exposed, an idea supported by the angular appearance which the pits assume on further roughening. From the electrochemical point of view, the featureless hydrogen adsorption curve which results from a large spread of energetically different kinds of sites gives way to well-defined peaks which, if the association of hydrogen peaks with crystal faces (19) is accepted, correspond to the smaller number of types of low index faces produced by cycling. Heat treatment in an oxidizing flame affects surface structure and activity in a manner similar to cycling because of the greater volatility of platinum oxide formed at high energy sites.

A clear analogy exists between this process and the recently proposed explanation (24, 25) for changes in surface properties of silver powder exposed to cyclic oxygen adsorption and reduction (*i.e.*, at gas/solid interface). Czanderna (24, 25) suggests that surface silver atoms rearrange by a small amount each time a layer of oxygen atoms is chemisorbed until finally a stable surface of minimum free energy, *i.e.*, low index planes, is generated; the driving force for the movement of the silver atoms is supplied by the bond energy between silver and oxygen. A similar mechanism was proposed earlier for the roughening of platinum electrodes (6). Note however that the possibility of complete removal of platinum atoms from the surface is now introduced.

Two arguments provide indirect support for a theory involving actual loss of surface platinum during activation. First, the tendency for platinum to dissolve under mild anodic conditions is becoming increasingly recognized (16, 26-29). Second, the assumption of such a dissolution process can provide a ready explanation for the difficulty in obtaining charge balance in the oxidation and reduction of a platinum surface [see ref. (30) for discussion of this problem]. Although impurity adsorption is undoubtedly an important factor, the loss of a species such as Pt-O to the solution at some stage during the cyclic process can help to explain some of these observations. For example, Breiter (15) measured the charges involved in oxidizing (Q_{ox}^{an}) and reducing (Q_{ox}^{cath}) a platinum surface during the first 110 cycles of an activation process (triangular cycling between 0.2 and 1.5V) similar to that used here. He found that the ratio of these charges decreased as the number of cycles increased and was still about 1.4 at the 110th cycle. The total difference between the two charges during the course of cycling was about 40 mcoulomb/cm^2 which is much greater than can reasonably be attributed to impurity adsorption but can be explained by assuming that, as cycling proceeds, a decreasing fraction of platinum atoms can leave the surface bound to an oxygen atom.

If the structural concept of platinum electrode activation is correct, then the various common pretreatments might differ in the way they alter either the platinum surface structure and/or its ability to respond to cathodic-anodic treatment. It is suggested that to obtain comparable electrode surface states it is necessary not only to use identical activation procedures but also to precede activation with an annealing step which will tend to produce similar types of surfaces on samples of different origin. However, the initial bulk platinum structure will also depend on the amount and nature of the cold working received during fabrication. Annealing is not expected to eliminate preferred grain orientations arising from different kinds of cold work so that unless a uniform and sufficiently vigorous cold work pretreatment is given to the platinum this factor will remain a variable of as yet unknown importance to activity. It should be mentioned that wire and foil electrodes used in this work gave slightly different ratios of the two main hydrogen peaks, supporting the idea (19) that grain orientation is important in determining the shape of the hydrogen adsorption curve.

Electrode roughening.—Roughening occurs when platinum atoms which are stable to triangular cycling (presumably those in low index planes) acquire sufficient energy to diffuse over or break away from the surface. The two conditions for roughening are:

(*a*) Surface oxygen : surface platinum atom ratio > 1. This suggests that sufficient weakening of Pt-Pt interactions occurs only when chemisorption bonds form between a Pt atom and more than one O atom. An explanation in terms of dissolution of a particular platinum oxide phase, *e.g.*, PtO_2, is less likely in view of the chemisorptive nature of the oxygen layer on Pt electrodes (22).

(*b*) Fast reduction of surface oxygen. This condition indicates that a concerted effect is needed to allow these Pt atoms to move to new positions or to leave the surface. The simultaneous reduction of a large amount of adsorbed oxygen provides the necessary activation energy for mobility of some of the surface Pt atoms. It is not clear in what form these atoms leave the surface but, as with activation, some kind of platinum-oxygen species is favored.

Adsorbed or dermasorbed hydrogen (3, 7) is not a causative factor in the roughening process which is actually inhibited in a program where the electrode is reduced at a potential in the hydrogen region. One can speculate that this is due to the rapid replacement of adsorbed oxygen with adsorbed hydrogen so that at no stage does the platinum surface energy rise to the same level as in the absence of chemisorbed species (in the double layer region).

The single crystal platinum particles present where an electrode is visibly darkened probably arise through undercutting of the metal surface due to lateral expansion of the pits. The alternative possibility that an epitaxed layer forms on redeposition of platinum which has entered solution is considered less likely in view of the fact that no platinum particles are stripped off with the replica until high roughness factors are reached.

As an electrode roughens, changes in shape of the cyclic voltammograms indicate changes in the state of the electrode surface. Thus, if the two main hydrogen peaks represent two major kinds of platinum surface sites, changes in relative peak heights indicate a greater stability of one type of site to the roughening program. The facts that parallel changes occur in the heights of the two small peaks near the start of the "oxide" region and that the separation of these peaks and the hydrogen peaks is similar suggest that the peaks in the "oxide" region correspond to adsorption of the OH radical and that adsorption of the species H and OH occurs with similar relative energies on the two main kinds of platinum sites. If this conclusion is correct, then one of the main effects of activation is to lower the potential at which adsorption of the more strongly bound OH radical commences, as indicated by the increase in steepness of the current rise at the start of the "oxide" region. In view of the role which adsorbed OH is supposed to play in the electro-oxidation of organic compounds [*e.g.*, (32, 33)], a correlation between the arbitrary activation criteria used here and the actual electrocatalytic activity can be expected.

Technical Note

The Oxygen Electrode in Molten Alkali Metal Nitrates

II. Standard Potentials as a Function of Na^+/K^+ Ratio

R. N. Kust*

Department of Chemistry, University of Utah, Salt Lake City, Utah

In the last several years an increased interest in the study of molten salt systems has occurred, not only in terms of the numerous applied industrial processes which utilize such solvents but also because of the increased need for fundamental knowledge of systems containing no protons.

Numerous workers have postulated the existence of the oxide ion in several such melts (1). Some of the investigations have involved the assay of small concentrations of oxide ion potentiometrically with an oxygen gas-oxide ion electrode in a sodium nitrate-potassium nitrate equimolar melt. The standard potentials of the oxygen electrode have been defined in this melt with a 1.0M silver nitrate reference electrode (2).

Several workers (3) have indicated that equilibrium constants and rate constants for some acid-base reactions in molten alkali metal nitrates are influenced to some degree by the ratio of cations present in the melt. Recent studies (4) suggest that solvation of anions by the alkali metal cation constitutes an important part of this influence. In order to investigate potentiometrically the changes in various acid-base equilibria when the cation ratio of the solvent is changed, the variation in the standard potential of the oxygen electrode with cation ratio must first be determined. This paper is a report of the evaluation of the standard potential of the oxygen-silver nitrate electrode system in sodium nitrate-potassium nitrate melts as a function of temperature and cation ratio.

Experimental Section

All chemicals used were of reagent grade. The sodium nitrate and potassium nitrate were dried for 24 hr at 140°C before being used to prepare the various solvents. Bulk quantities of solvent containing 22.9 m/o (mole per cent) sodium nitrate-77.1 m/o potassium nitrate and 82.6 m/o sodium nitrate-17.4 m/o potassium nitrate were made by fusing together the proper quantities of the salts, mixing well, filtering through a medium porosity fritted glass disk, molded into slugs of about 100g and stored over magnesium perchlorate. Melts of intermediate cation ratios were made by mixing suitable quantities of these two bulk solvents.

The reaction vessel and electrodes were similar to those previously described (2). An oxygen-platinum electrode was used as the indicator electrode and a silver-silver nitrate (1.0m $AgNO_3$ in equimolar $NaNO_3$-KNO_3) electrode enclosed in Pyrex glass was used as the reference electrode. Potential measurements were made with a high impedance potentiometric network as has been previously described (2).

The standard oxide ion solutions used were made by dissolving small quantities (*ca.* 10^{-4}m) of anhydrous sodium carbonate in equimolar sodium nitrate-potassium nitrate solvent. These solutions were held under a vacuum of less than 10μ for over 48 hr. The oxide in these solutions was then assayed by titration with hydrochloric acid. Titration of the oxide solutions with permanganate indicated that there were no oxidizable impurities and consequently that nitrites, peroxides, and superoxides were not present in significant quantities.

Results

The electrochemical cell used in this study can be described

$$\text{Pt, } O_2(g) \;\Big|\; \begin{matrix} x_{NaNO_3} \\ 1-x_{KNO_3} \end{matrix} \;\Big\|\; \underset{NaNO_3\text{-}KNO_3,}{\text{equimolar}} \; 1.0\text{m } AgNO_3 \;\Big|\; \text{Ag}$$

Pyrex

* Electrochemical Society Active Member.

where x is the mole fraction of sodium nitrate in the indicator electrode compartment, and where the vertical dotted lines indicate the Pyrex glass membrane, about 0.1 mm thick, which encloses the reference electrode compartment. The cell reaction can be written

$$2Ag^+ + O^{2-} \rightleftarrows 2Ag + \tfrac{1}{2} O_2 \qquad [1]$$

for which the Nernst equation is

$$E = E^\circ - \frac{2.3RT}{2F} \log \frac{P_{O_2}{}^{1/2}}{[O^{2-}][Ag^+]} \qquad [2]$$

The standard potential for this cell was determined in four different sodium nitrate-potassium nitrate solvents which had the following compositions expressed in mole per cent: 23% $NaNO_3$, 77% KNO_3; 44% $NaNO_3$, 56% KNO_3; 64% $NaNO_3$, 36% KNO_3; 83% $NaNO_3$, 17% KNO_3. The concentration of oxide ion in these solvents was varied from about 5 x 10^{-7}m to about 5 x 10^{-5}m. The temperature was varied from 290° to above 360°C. The reversible nature of the electrode system was checked in each of the different solvents at each temperature. The criteria used to determine whether or not the electrochemical cell was reversible were (*i*) adherence to the Nernst equation when the O^{2-} ion concentration and the oxygen pressure were independently varied, and (*ii*) lack of hysteresis in micropolarization plots of current *vs.* voltage when the voltage was scanned through ± 100 mV of the equilibrium potential. In all cases, the tests indicated the cell was reversible within experimental limits.

Standard potentials were calculated from the observed potentials with the aid of the Nernst equation [2]. Experimental data obtained in the various solvents at a temperature of 320° are indicated in Table I.

The variation of standard potential with temperature and composition is graphically represented in Fig. 1 and 2. The previously determined temperature dependence of the standard potential for the oxygen electrode in a melt of equimolar $NaNO_3$-KNO_3 is also shown in Fig. 2 for reference purposes.

Discussion

According to the data in Fig. 1 and 2, there is evidently a small but definite dependence of the standard potential of the oxygen gas-silver ion electrode system on the ratio of sodium nitrate to potassium nitrate in the solvent. The E°, in volts, can be calculated for any temperature between 290° and 360°C and for a sodium nitrate-potassium nitrate melt of any cation ratio from the equation

$$E^\circ(t, x_{Na}) = [0.6730 - 0.000130(t - 290^\circ)] - [0.0830 + 0.000275(t - 290^\circ)]x_{Na} \qquad [3]$$

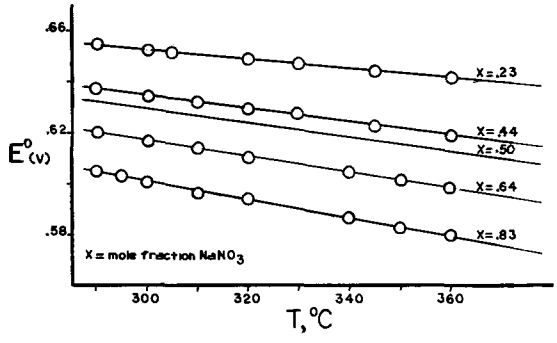

Fig. 2. Variation of standard potential of the oxygen electrode with temperature in sodium nitrate-potassium nitrate melts at different Na^+/K^+ cation ratios.

where t is the temperature in °C and x_{Na} is the mole fraction of sodium nitrate. The standard deviation is estimated to be ± 0.0009V.

The lower temperature limit of 290°C was dictated by the observation that melts containing 23 m/o $NaNO_3$ froze a few degrees below 290°C. However, for other salt mixtures melting at lower temperatures, a linear extrapolation of Eq. [3] would be reasonable, at least to temperatures down to 250°C since the above equation can be used to calculate standard potentials in equimolar sodium nitrate-potassium nitrate solvents which are within the error of experimentally determined values in melts of this composition (2).

The decrease in standard potential with increase in sodium nitrate concentration suggests that the activity of the oxide ion decreases as the sodium ion activity increases. An even more pronounced decrease in standard potential would be expected if lithium ion were substituted for the sodium ion. However, it cannot be claimed that this solvation process is the sole explanation for the variation in standard potential with cation ratio. The temperature dependence of the standard potential is negative in all of the melts studied, and, furthermore, becomes more negative as the sodium nitrate/potassium nitrate ratio increases. The negative temperature dependence indicates a negative entropy of reaction for the cell reaction. Since the oxide ion is a reactant in the cell reaction, more effective solvation of the oxide ion should cause the entropy change and hence the temperature coefficient of the standard potential to become less negative as the ratio of sodium nitrate to potassium nitrate is increased.

There are several features of this particular electrode system which are not well understood and which may contain the explanation for the temperature dependence of the standard potential. One such feature is the Pyrex glass membrane which is used to separate

the anode and cathode compartments of the cell. It has been shown (5) that in highly ionic nitrate melts, the behavior of the Pyrex glass membrane is most adequately described by an ion exchange model. Membrane potentials for Pyrex in sodium nitrate-silver nitrate systems have been approximately evaluated (5b) and generally are small, on the order of 8 to 10 mV. Similarly, membrane potentials in lithium nitrate-silver nitrate, sodium nitrate-silver nitrate, and potassium nitrate-silver nitrate systems have been evaluated (5c) and again are small. However, in both of these studies, potentials were measured when a finite activity of Ag^+ was present on both sides of the Pyrex membrane. In the electrode system presented in this article, the silver ion activity in the anode compartment is essentially zero. Hence the actual membrane potential of this system cannot be inferred from these other studies.

Another feature which is not completely understood and which may have bearing on the situation is the actual chemical process occurring at the platinum electrode. It has been shown (6) that in molten carbonate melts, platinum electrodes can function as electrodes reversible to the oxide ion, but that in so doing, platinum oxides are formed. Although these studies in nitrate melts have been carried out at much lower temperatures, formation of platinum oxides might still be possible and might lead to a complex relationship with the cations in solution.

More information regarding these systems is needed. An investigation of the cation and temperature dependence of the oxygen electrode when a reference electrode which substitutes an asbestos wick or glass frit for the glass membrane should contribute more information on what role the glass membrane plays. Also extension of the investigation to the lithium ion should prove interesting.

Solid Solubility and Diffusion Coefficients of Boron in Silicon

G. L. Vick and K. M. Whittle

Instrument/Controls Division, Conrac Corporation, Duarte, California

ABSTRACT

The solid solubility and diffusion coefficients of boron in silicon have been determined as a function of temperature over the range of 700°-1151°C, by anodically sectioning diffused layers. The solid solubility was found to vary from 1.6×10^{19} atoms/cm^3 at 700°C to 2.4×10^{20} atoms/cm^3 at 1151°C. The diffusion coefficients for impurity levels below 10^{18} atoms/cm^3 may be represented by $D = 6.0 \times 10^{-7} \exp(-38600/RT)$. The diffusion coefficients above 10^{18} atoms/cm^3 were found to be dependent on the impurity level.

In view of the importance of boron as a dopant in the technology of silicon electronic devices, there is a remarkable paucity of information regarding the solid solubility of boron in silicon. In Trumbore's review of solid solubilities of elements in germanium and silicon (1), boron is represented by only two points, a eutectic point and a single point based on diffusion data.

This paper describes a series of experiments in which boron is diffused into silicon at a number of different temperatures between 700° and 1151°C from an effectively infinite source. The resulting diffusion profiles are anodically sectioned to determine the solid solubility of boron in silicon as a function of temperature. The diffusion coefficients of boron in silicon are also calculated as a function of temperature and boron concentration.

Experimental Procedure

A boron rich glass (B_2O_3) is pyrolytically deposited on the surface of 3.0 to 6.5 ohm-cm n-type wafers at relatively low temperature (688°C). The wafers are then diffused at higher temperatures in an nonoxidizing atmosphere (N_2). Under these conditions the boron glass is reduced by the silicon, making elemental boron available for diffusion into the silicon. The deposition and diffusion systems have previously been described by Whittle and Vick (2). The reduction of the B_2O_3 makes boron atoms available at a rate greater than the rate at which they are diffused away into the silicon. This results in a thin layer of a boron-rich phase such as that discussed by Busen *et al.* (3). This boron rich phase will act as an effectively infinite source of boron for diffusion into the silicon. Similar phases may be observed in phosphorus diffusion and have been used by Kooi (4) in determining solubility of phosphorus in silicon.

Experiments have been performed which show that the surface concentrations are independent of all deposition parameters over a wide range [ref. (2)] and are independent of diffusion time for all the different values of diffusion time reported in this paper and are dependent only on diffusion temperature. The work of Owen and Schmidt (5) could be interpreted as predicting a surface concentration independent of time under certain conditions. This work is not directly applicable here, however, because the rate of chemical decomposition of the B_2O_3 controls the rate at which boron is made available for diffusion. This is demonstrated by the fact that the doping will be inhibited by the presence of oxygen in the atmosphere. The presence of the boron-rich phase ensures an adequate supply of boron so that surface concentration will be determined by the solid solubility.

In view of the departures from complementary error function form of the profiles obtained at the higher temperature diffusions, experiments were performed to determine whether there was precipitation of the boron such as that found for phosphorus by Tannenbaum (6). Diffused wafers were cooled from 1150°C to room temperature in times ranging from 1 min to 1 hr without preceptible change in profile, leading to the conclusion that precipitation was not occurring to any measurable amount.

Sectioning of the diffused impurity profiles was accomplished by anodically growing and then removing layers of silicon dioxide. Anodic oxide growth was carried out in a solution consisting of 3 parts ethylene glycol and 1 part phosphoric acid at 100V. The oxide was removed with HF and the anodization repeated. After every fifth anodization-HF cycle a measurement was made of sheet resistivity and depth of silicon removal. Sheet resistivity was measured by a standard 4-point probe method. Silicon removal was measured by masking off a region of the wafer during anodization-HF cycles and measuring the height of the resulting plateau by means of interference fringes. Irwin's (7) plot of resistivity *vs.* impurity concentration was used to determine the impurity concentration of successively removed layers of boron concentration.

Accuracy

The diffusion temperatures were controlled to ±2°C and diffusion times were controlled to ±0.05 min.

The 4-point probe measurements on a given sample were consistent from reading to reading within 1%.

The depth of silicon removal was determined by calibrating the silicon removal per anodization cycle against depth measurements made by means of interference fringes. The calibration was made to a depth of 4μ with an accuracy of ±¼ fringe, giving a possible consistent error of about 7%. In addition, the random errors, represented as deviations of data points from the calibration curve amounted to about ±5% rms.

The plots of impurity concentration *vs.* depth shown in Fig. 1 and 2 involve the first derivative of the curve of conductivity *vs.* depth which was experimentally determined. The deviation of data points from complementary error functions in Fig. 1 and from the best smooth curves in Fig. 2 are ± 13% rms.

A significant source of inaccuracy in the values of diffusion coefficient at temperatures above 1000°C lay in graphical integration and differentiation of the impurity profiles. These procedures are somewhat subjective in nature and it was found that variations in diffusion coefficient as large as ±100% could be achieved by differing estimations of the slopes. The values reported in Fig. 4 represent the best judgment of the authors as to the interpretation of existing data. At temperatures less than 1000°C, the diffusions are too shallow to justify accuracy greater than ±100%.

Solid Solubility

In Fig. 1 and 2 are plotted the curves of impurity *vs.* depth. The curves for diffusions below 1018°C are

Key words: Solid solubility, diffusion coefficient, boron, silicon.

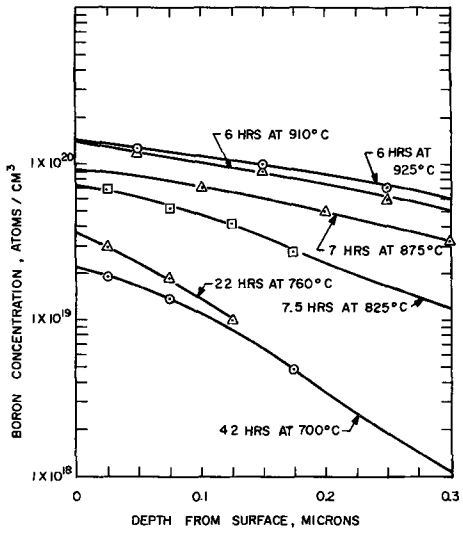

Fig. 1. Boron concentration vs. depth from surface

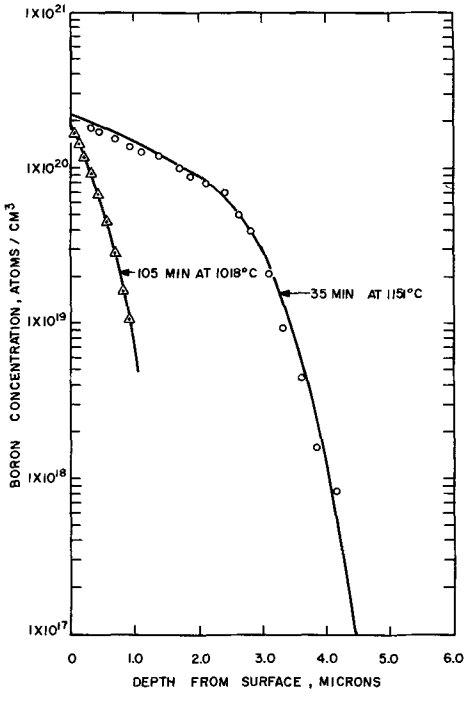

Fig. 2. Boron concentration vs. depth from surface

found to fit well the complementary error function. For diffusion at 1018°C and higher the curves are simply the smooth curve which best fits the data. Solid solubilities are obtained by extrapolating the diffusion profiles to zero depth and are plotted *vs.* temperature in Fig. 3.

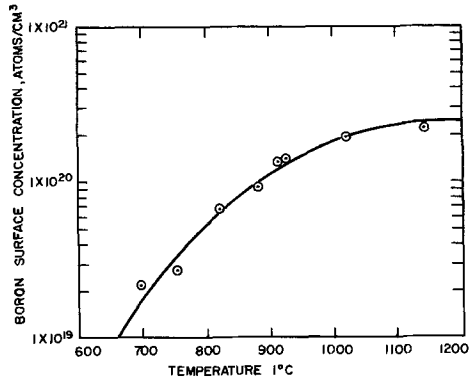

Fig. 3. Boron solid solubility vs. temperature

The solid solubility data indicate a lower solubility of boron in silicon than had previously been reported. There is, however, little actual data to support a higher value of solubility. Diffusion profiles having larger surface concentrations have been reported. These, however, have been calculated on the assumption of a complementary error function distribution which is shown to be false for temperatures above 1000°C.

Diffusion Coefficients

For those diffusion profiles which may be represented by the familiar complementary error function, $C_x = C_s\text{erfc}\ (x/2(Dt)^{1/2})$, calculation of diffusion coefficients is straightforward since C_x is the concentration of the diffusant at distance x after time t and C_s is the extrapolated surface concentration. All the necessary data can be obtained from the diffusion profiles in Fig. 1.

The profiles which do not fit a complementary error function must be dealt with differently. The possibilities of source depletion or of impurity precipitation as explanations for the shape of these curves have been ruled out as described earlier. It may be assumed, then, that the profiles result from a concentration dependent diffusion coefficient similar to that found by Tannenbaum (6) for phosphorus. The diffusion coefficients may be calculated as a function of impurity concentration by a method presented by Crank (8) using the equation

$$D_{c=c_1} = \frac{1}{2t}\frac{dx}{dc}\int_0^{c_1} x\,dC$$

where D is the diffusion coefficient at a concentration C, and x and t are depth and time, respectively.

Applying this equation to the curves in Fig. 2 results in the dependence of diffusion coefficient on impurity concentration shown in Fig. 4. The slope dx/dc and the area $\int_0^{c_1} x\,dc$ were determined graphically so that the curves in Fig. 4 should be considered to show a qualitative trend only. An accurate determination of diffusion coefficient as a function of impurity concentration could be made by subjecting the impurity profile data to computation by a computer. These curves in Fig. 4 are seen to approach a minimum value of the diffusion coefficient at each temperature at which the diffusion coefficient is independent of impurity concentration.

A plot of the logarithm of the diffusion coefficient *vs.* inverse temperature should yield a straight line since the temperature dependence of the diffusion coefficient follows the form

$$D = D_0 \exp\ (E_a/RT)$$

where E_a is the activation energy for diffusion, R is the gas constant, and T is the absolute temperature.

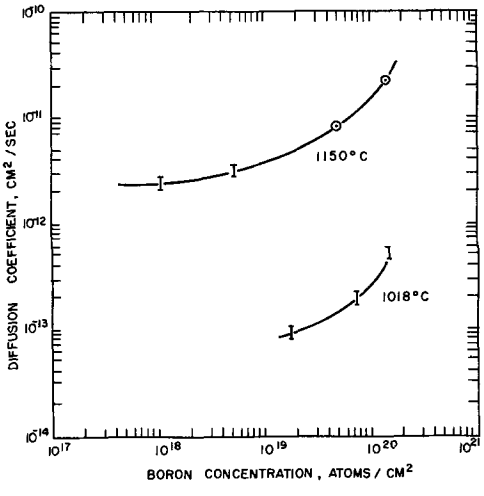

Fig. 4. Diffusion coefficient vs. boron concentration

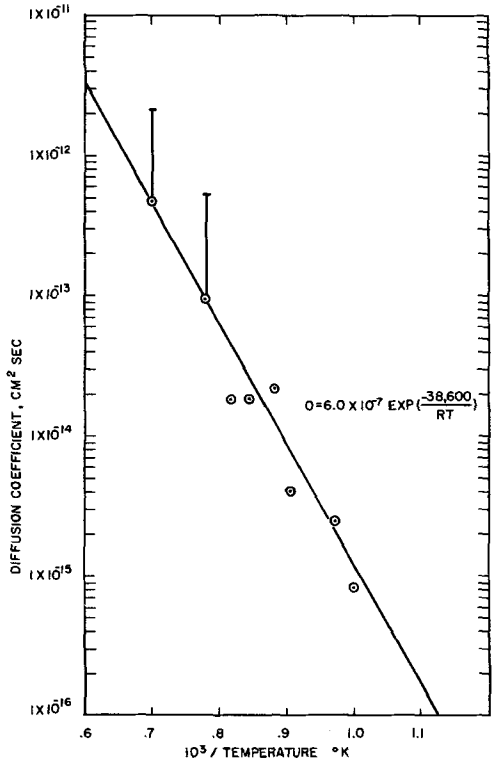

Fig. 5. Boron diffusion coefficient vs. temperature

The diffusion coefficients are plotted against the inverse of temperature in Fig. 5 and can be shown to follow the equation $D = 6.0 \times 10^{-7} \exp(-38600/RT)$.

Those diffusion coefficients (above 1000°C) for which the coefficients are dependent on impurity concentration are represented on Fig. 5 by a data point indicating the value of the concentration independent coefficient, together with a vertical line indicating the range of values which hold at higher concentrations.

Summary

Values for the solid solubility of boron as a function of temperature in silicon are presented in this paper for the first time.

Values of diffusion coefficients for boron in silicon are given over a range of temperature almost 300°C greater than was previously available (700°-1150°C) (9-11). Concentration dependent diffusion coefficients of boron in silicon are reported.

Technical Notes

The Estimation of Bending Stresses from Flexure Measurements

R. E. Pawel*

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

The flexure technique, based on the physical deformation observed when a suitably prepared specimen is reacted on one side, has recently been employed in several investigations in which the characterization and measurement of stresses induced by surface or near-surface reactions were of interest. Originally the tool of the electroplater, this technique is now being used in other disciplines to collect special types of information which are otherwise difficult to obtain. Since the principal experimental measurements in flexure studies are ones of strain, the problem of transforming or assigning appropriate stress values must be faced. The general methods for doing this have existed in the literature for some time, but some uncertainty has arisen recently concerning the extent and importance of the Poisson (transverse) contributions during flexure experiments on various kinds of specimens. (This particular problem is, of course, entirely separate from the usually more tedious one of inferring the complete stress distribution from the bending stress values.) While it might be argued that this uncertainty is not a serious drawback because of the many other sources of error involved with the technique, such a possibility nevertheless warrants consideration, and it is the intent of the present note to express some thoughts and the results of an experiment which appear pertinent to the manner in which bending stresses are determined from bending strains.

Since the stress system imposed on the specimen may be considered to be uniform, it is helpful for purposes of this problem to think only in terms of bending stresses and to visualize the surface reaction that creates them, whatever it may be, as resulting in simple

* Electrochemical Society Active Member.

sets of bending moments rather than in the complex stress distribution which may actually exist. It is reasonable to do this, for uniform surface stresses, because the problem actually involves only the mutual transverse effects of the bending stresses.

The stress-strain relationship for a state of plane, biaxial elastic stress in a plate (which is an applicable approximation for most flexure experiments) is given by the following general equation

$$\sigma_x = \frac{E}{1-\nu^2}(\epsilon_x + \nu\epsilon_y) \qquad [1]$$

where σ and ϵ are the stress and strains in the indicated orthogonal directions, x is considered the "long" direction for strips, ν is Poisson's ratio, and E is Young's modulus. A similar expression can be written for the transverse, y, direction.

If a specimen is uniformly bent about a major axis, the maximum bending strain, located in the concave and convex surface layers of the plate, is given by the "flexure formula"

$$\epsilon_x = \pm\frac{t}{2\rho_x} \qquad [2]$$

where t is the plate thickness and ρ_x is the radius of curvature in the x direction.

In the analysis of the data obtained in a given flexure experiment, there are several possible configurations which need to be considered when relating the bending stresses to the measured flexure or strain by means of Eq. [1] and [2]. The relative applicability of each of these cases is dependent on the specimen geometry.

1. If equivalent surface forces result in the bending of a thin, rectangular specimen equally in the two directions, then $\epsilon_y \cong \epsilon_x$, and Eq. [1] yields $\sigma_x = (1/1-\nu)E\epsilon_x$. This is a "high-energy" situation for thin plates requiring that the specimen assume the shape of a part-surface of a sphere. Only comparatively "thick" specimens might be expected to exhibit this behavior for measurable curvatures.

2. Simple beam theory considers no stress to act in the y direction. Thus, if this condition exists, $\sigma_y \cong 0$, $\epsilon_y \cong -\nu\epsilon_x$, which leads to $\sigma_x = E\epsilon_x$, the relationship for uniaxial stress and strain. The specific assumption here is intuitively not an attractive one for bending in rectangular plates where bending is caused by a uniform surface reaction of some sort.

3. If, during bending, sufficient distortion occurs so that the bending strain is limited essentially to a single direction, then $\epsilon_y \cong 0$ and the pertinent equation becomes $\sigma_x = (1/1-\nu^2)E\epsilon_x$. Timoshenko (1) considered this to be the most likely condition for the bending of thin strips, although a correction for the specific geometry of the specimen was also included in his analysis. As indicated below, the corrections for specimen geometry typically employed in flexure experiments were in a direction and of such magnitude so as to make the "simple beam solution," condition 2, accurate within a few per cent.

While direct examination of thin strips which have undergone flexure as a result of either external forces or surface reactions seems to indicate that the geometric requirements for condition 3, above, are reasonably well met, a set of interesting experiments which more graphically supports the validity of Timoshenko's conclusion for bending due to surface reactions is as follows. Several 4- and 6-cm disk shaped specimens were cut from 0.015- and 0.010-in. tantalum sheet; they were annealed in vacuum at 1600°C and chemically polished. A thin layer of aluminum was vapor-deposited onto one side and the specimens then oxidized for various times at 500° and 550°C to yield a range in the observed degree of flexure.

The nature of the deformation exhibited by these specimens as a result of this reaction was informative. Although the disks were prepared carefully so that there would be no obvious mechanical axes, the deformation which occurred during oxidation at these temperatures was in all cases approximately uniaxial, cylindrical bending, resulting in the configuration shown in Fig. 1a. Please note that Fig. 1 is drawn with an exaggerated degree of bending to preserve clarity. While there are no long and short dimensions in disk-shaped specimens which would predetermine the axis of bending, the presence of any kind of flaw would be sufficient to influence the initial flexure of an otherwise perfect disk. Once started in a given direction, it is energetically favorable for elastic bending to continue in uniaxial fashion, and this shape will persist, even for a considerable degree of plastic deformation. Therefore, even for the case of biaxial stresses acting on one surface of a thin disk, flexure can result in bending about a single axis.

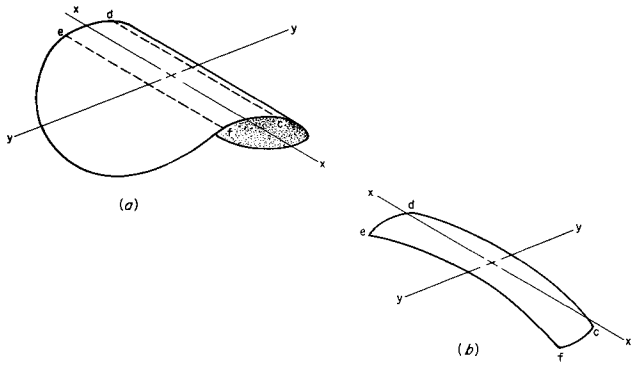

Fig. 1. Schematic drawing of the flexure behavior of a thin, disk-shaped specimen after oxidation of its upper side. The degree of bending shown here is exaggerated compared to that observed in most of our experiments concerning tantalum oxidation. (a) As-oxidized specimen; flexure has occurred predominantly in a single direction. (b) Section cdef, cut as indicated from original specimen after oxidation. The stresses, which also existed in (a), have now caused flexure in the x direction.

It should not be forgotten, however, that even though no bending takes place in the x direction in Fig. 1a, there should still be stresses present. The total stress existing in this direction would be composed of the same surface forces which caused bending in the y direction, plus the Poisson contribution from these associated bending stresses. For an elastic stress system, the stresses in the x direction might be allowed to exert themelves if a suitable change in specimen geometry were made after the initial bending was terminated. The results of such a change were determined for the deformed disks. Several of the bent oxidized specimens were cut parallel to the x direction to remove a rectangular strip of heretofore almost unstrained (in that direction) material. In all cases, the excised portion of the specimen then exhibited curvature in the x direction as illustrated in Fig. 1b. The geometry was then favorable for flexure in this direction and the stresses could manifest themselves accordingly.

While a strict quantitative analysis of these experiments was not attempted, it was observed that for experiments in which the total flexure was kept small (*i.e.*, the bending stresses were completely elastic), the subsequent bending of the cut strip was essentially the same as that observed originally for the disk in the transverse direction. On the other hand, several experiments obviously involved significant amounts of plastic strain and, in these cases, the flexure of the cut strip was only a fraction of that exhibited by the disk. Clearly, only the elastic components could contribute to the postoxidation distortion along the x direction. It was not practical to attempt to obtain the exact Poisson contribution or correction from these "excision" experiments. However, the behavior exhibited by these specimens establishes the deformation character-

istics and helps to ascertain the relevant stress-strain relationships during flexure.

A thin rectangular flexure specimen will generally bend along its long dimension and be constrained from similar bending along its short one. (One should be aware, however, that unless the specimen is carefully prepared, bending is likely to take place about a mechanical, rather than a geometric axis. For example, if a slight degree of curvature existed across the short dimension of a rectangular specimen prior to reaction, it very probably would continue to bend in this direction with virtually no curvature observed in the long dimension.) Although some distortion exists, the state of limited strain in the transverse direction does appear experimentally to be described best by the condition $\epsilon_y \cong 0$.

The above reasoning supports the use of the equation

$$\sigma_x = \pm \left[\frac{1}{1-\nu^2} \right] \frac{tE}{2\rho_x} \qquad [3]$$

to relate the maximum bending stress to the measured radius of curvature. However, Timoshenko, for only a slightly different set of conditions and a more sophisticated analysis, used a modified factor $(1-\nu^2 k)/(1-\nu^2)$, where k is a function of the strip dimensions and its radius of curvature. Typical dimensions for flexure specimens yield k-values only slightly less than unity. In other words, the simplest expression

$$\sigma_x = \pm \frac{tE}{2\rho_x} \qquad [4]$$

may also be the most appropriate. The best choice of the particular equation to represent the stress-strain relationships in a real system thus depends on the physical system itself, particularly the geometrical aspects. Recently, there have been several instances brought to our attention where an apparently arbitrary, or at least not fully justified, choice of the $1/(1-\nu)$ (case 1), correction was made. While there will be instances where this will be correct, it should be pointed out, as we have tried to do in this note, that this is not necessarily a straightforward choice, and a comparatively large absolute error in stress values may result if it is the incorrect one.

Acknowledgment

Thanks are extended to Drs. R. O. Williams, M. H. Yoo, H. E. McCoy, and J. V. Cathcart of the Metals and Ceramics Division, ORNL, for their helpful discussions. Research was sponsored by the United States Atomic Energy Commission under contract with Union Carbide Corporation.

Reduction of Radiation Sensitivity in MOS Structures by Aluminum Doping of Silicon Dioxide

A. G. Revesz,[1] K. H. Zaininger, and R. J. Evans

RCA Laboratories, Princeton, New Jersey

The resistance of metal-insulator-semiconductor (MIS) devices against high energy electron bombardment or similar irradiation is important in several applications. Unfortunately, the metal-silicon-dioxide-silicon structures commonly used in many circuits are adversely affected by ionizing radiation and exhibit a shift of their device characteristics toward more negative voltage values. The extent of the shift and possible deformation of the surface capacitance *vs.* voltage (C-V) curve (compared with the ideal one) depend on the oxidation conditions and postoxidation treatments (1, 2). In the case of dry oxygen oxidation followed by high temperature helium-annealing, for example, it was found that irradiation by 1 MeV electrons under + 10V bias (fluence = 10^{14} e/cm^2) results in a shift of the C-V curve by 40-60V (for 1000Å thick oxide); this corresponds to the introduction into the oxide of positive surface electronic charges of the order of 10^{13}/cm^2. MIS structures using Al_2O_3 on Si, prepared either by plasma anodization of aluminum (3) or thermal decomposition of Al-alkoxide (4) show better radiation resistance than SiO_2 grown in dry O_2, especially under conditions of positive bias. However, because of the widespread use of SiO_2 and the emergence of Al_2O_3 as a possible insulator in MIS devices, it seemed that exploration of Al-doped SiO_2 was warranted.

We have found that by doping the SiO_2 film with aluminum the radiation resistance of MIS capacitors can be modified such that as the Al content in the oxide increases the radiation-introduced oxide charge under positive bias decreases.

[1] Present address: Comsat Laboratories, Washington, D. C.

Experimental

P-type Si wafers of (100) orientation were cleaned in H_2 at 1200°C, then oxidized in dry O_2 at 900° or 1250°C, and subsequently annealed in He at 1100°C in an r.f. heated, gas-cooled silica tube (5). These three processing steps were performed *in situ*. The only deviation from this fabrication method was that during oxidation Al was introduced into the oxidizing ambient by bubbling He through Al-acetylacetonate dissolved in acetylacetone. At both oxidation temperatures high (1.0 l/min) and low (0.1 l/min) flow rates of He were investigated. The oxygen flow was kept constant at 0.15 l/min. Several specimens were prepared in each group. Specimens oxidized at 900°C with the lower flow rate of He were very conducting and were not investigated further. The thickness and refractive index of the SiO_2 film at 5460Å wavelength were determined by ellipsometry. The Al content of the SiO_2 films was determined by mass-spectrometry using an ultra pure gold counterelectrode for sparking. The Al content of the Si substrate has also been determined before oxidation and after dissolution of the oxide film. Some specimens were also analyzed for other impurities. The structure of the oxide films was investigated with reflection electron diffraction.

The electric charge distribution at the Si-SiO_2 interface was determined by the MOS capacitance method at a frequency of 1 MHz (6). For these tests the speci-

* The film thickness is about 1000Å except for the Al_2O_3 film which is 1400Å. In that case the values of V_{FB} corresponding to 1000Å oxide are given in parenthesis.
Legend: V_{FB} = voltage on the Al electrode at flat-band condition; Q_{FB} = charge in the oxide and/or at the interface at flat-band condition (includes charges originating from the work-function difference between Si and Al); Q_{ss} = charge in interface states within the Si forbidden band; e = absolute value of electronic charge.

mens were provided with 2000Å thick Al electrodes on the oxide and an Al back contact. This measurement, in combination with the thickness determination, also provided the dielectric constant of the oxide film. The specimens were irradiated with 1 MeV electrons while 0, −2, −5, −10, +2, +5, +8, and +10V bias was applied successively to the Al electrode. After each bombardment the MOS capacitance was determined. The fluence at each step was 10^{14} e/cm^2, amounting to a final fluence level of 1.4×10^{15} e/cm^2. Since the effect of irradiation under +2V bias is reasonably independent of an increase of fluence above 10^{14} e/cm^2, this sequence of irradiation and measurement is indicative mostly of the effect of applied bias rather than a combination of bias and fluence (1).

Results and Discussion

The mass-spectrometric analysis showed that aluminum was incorporated into the oxide film and that the concentration depended on the oxidizing conditions. In performing this analysis the oxide film and a portion of the silicon is removed. The major constituent in the vapor phase is silicon, but most of this comes from the substrate rather than the oxide film. The amount of Al is first determined in relation to the total amount of Si present in the vapor and expressed as an Al/Si ratio. This ratio varies from 40 to 2000 ppm (atomic). These values correspond to roughly 10^{19} to 10^{21} Al atoms/cm^3 in the oxide which are equivalent to 0.001 to 0.1 Al/Si ratio in the oxide.[2] The Al/Si ratio in the Si substrate, as determined before oxidation and after dissolution of the oxide, was 5 ppm. This clearly demonstrates that the measured Al is essentially in the oxide film. The impurity analysis (from B to Bi) before and after oxidation, as well as after dissolving the oxide, indicates that the oxide does not contain any impurity which is not present in the Si substrate, with the possible exception of chlorine.

Electron diffraction showed that the oxide films are noncrystalline. The thickness varies from 740 to 1000Å, the majority being about 1000Å. The refractive index (at 5460Å) varies from 1.49 to 1.53, with a modal value of 1.51. For thermally grown SiO_2 films the value is 1.48 (7), and for chemically deposited Al_2O_3 films about 1.60 (8). The relative dielectric constant at 1 MHz of the Al-doped SiO_2 films is 3.52. These observations demonstrate that despite their relatively high Al content the oxide films are essentially SiO_2.

The results of the MOS capacitance measurements are summarized in Fig. 1 and Table 1. Figure 1 shows that, as in the case of undoped SiO_2 (1), the effect of bias under irradiation is asymmetric and it saturates for both positive and negative voltages. The behavior of the specimen with the lowest Al content is essentially identical with that of an undoped SiO_2 film grown in dry oxygen. The shift of the flat-band voltage (determined from C-V measurements), ΔV_{FB}, as a result of irradiation under +10V bias, decreases with increasing Al content of the oxide film. Also, there is a tendency for saturation at lower voltage values under positive bias with increasing Al content.

The shift of the C-V curves alone is not the only indication of the irradiation effect, since these curves may deviate from the ideal C-V curve in their shape, indicating the presence of interface states. Furthermore, although the voltage shift is an important parameter from a device point of view, it is the charge at the interface and/or in the oxide which is relevant from the physical viewpoint.

The pertinent surface properties before and after irradiation under + 10V are given in Table I. We see that the amount of positive charge introduced by irradiation under +10V bias (measured at flat-band condition), ΔQ_{FB}, decreases with increasing Al content of the oxide. On the other hand, the density of interface states in the Si forbidden band, Q_{ss}, resulting from irradiation, increases with the Al content. This increase may be especially large in the accumulation regime. Thus, for the specimen with the highest doping level the average value of Q_{ss}, 3.3×10^{12} e/cm^2 (eV)$^{-2}$, can be divided into two components: 10^{13} e/cm^2 (eV) for $\psi < 0.05$V and 1.9×10^{12} e/cm^2 (eV) for $\psi > 0.05$V,[3] ψ being the surface potential and e the absolute value of the electronic charge.

A comparison of these results with undoped SiO_2 films and Si-Al_2O_3 structures reveals the following facts. The pre-irradiation values of the flat-band voltage, V_{FB}, for the Al-doped specimens are more negative than for dry O_2-grown and He-annealed SiO_2 (− 1 to − 2V) and deposited Al_2O_3 (+ 2 to + 4V) films of about 1000Å thickness. The effect of irradiation of V_{FB} for doped SiO_2 is much less than on dry

[3] These values were taken from a computer evaluation of C-V curves which supplied Q_{ss} as a function of ψ.

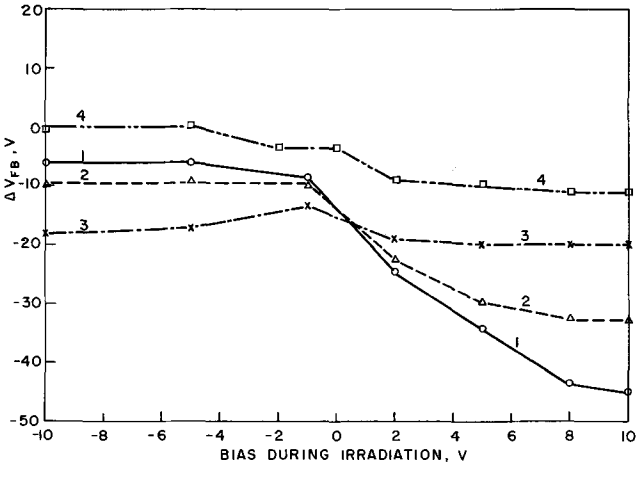

Fig. 1. Change in flat-band voltage, ΔV_{FB}, as a function of electrode bias during electron irradiation. For curves 1, 2, and 3 the values of the Al/Si ratio are ~0.001, ~0.01, and ~0.1, respectively. Curve 4 shows the behavior of a Si-Al_2O_3 structure.

[2] In the conversion of the measured Al/Si ratios to the Al content of the oxide the amount of Si removed from the substrate had to be taken into account. Because of uncertainties in the determination of this quantity, the Al-content of the oxide is given only as an order of magnitude. As a check the Al-content of a chemically deposited Al_2O_3 film was also determined. The value obtained was 6×10^{22} Al atoms/cm^3 oxide which is very close to the calculated one, 4.3×10^{22}, taking the density as 3.7 gcm^{-3}.

O_2-grown SiO_2 ($\Delta V_{FB} \cong 50V$) but is greater than on Al_2O_3 ($\Delta V_{FB} = 11.2V$ for one of the best specimens). (In the case of Al_2O_3 films even for the same value of ΔQ_{FB} and oxide thickness ΔV_{FB} is smaller because the dielectric constant of Al_2O_3 is about twice as large as that of SiO_2.) From the point of view of interface states introduced by irradiation, Al-doped SiO_2 is worse than either dry O_2-grown and annealed SiO_2 ($\Delta Q_{ss} \cong 0$) or properly prepared Al_2O_3 ($\Delta Q_{ss} \cong 7 \times 10^{11}$ e cm^{-2} $(eV)^{-1}$).

These observations can be tentatively explained by assuming that the defect structure of the aluminum oxide is significantly different from that of silicon dioxide. Recent investigations of Si-Al_2O_3 structures by MOS capacitance method showed indeed that, in contrast to SiO_2, substantial electron trapping occurs in Al_2O_3 (3, 4). This means that electrons and holes may be simultaneously trapped during electron bombardment, resulting in a build-up of two compensating space-charge layers. Another possibility is that the generated electrons and holes recombine before significant trapping took place. Thus, the insulator has essentially zero net charge after irradiation and no shifts in flat band voltage are observed. Apparently, introduction of Al into SiO_2 results in a similar behavior. Thermoluminescence glow curve studies also revealed a difference in the defect structures of Al_2O_3 and SiO_2 (9).

On the other hand, the presence of Al in SiO_2 apparently increases the radiation sensitivity of the interface. Thus, with increasing Al content the radiation induced disorder at the interface increases. In addition to interface states (as revealed by *C-V* measurements), a disordered interface generally shows slow trapping effects, *i.e.*, under negative gate bias electrons are injected into the silicon, shifting the flat-band voltage to more negative values (6). This is why V_{FB} shifts to more negative values under irradiation with negative bias.

Correction

In the Brief Communication "Luminescence of Gallates" by W. L. Wanmaker and J. W. ter Vrugt, June 1969, Vol. 116, pp. 871-872, the following corrections should be made in Table I:

$ZnGa_2O_4$ λ_{max}	460-470 instead of 465
$ZnGa_2O_4$ T_{50}	460 instead of 560
$(Mg \cdot Zn)_{0.5}$ Ga_2O_4 T_{50}	400 instead of 500

Behavior of Hydrophilic Porous Oxygen Electrodes with Silver Electrocatalyst

I. Lindholm[1] and I. Jonsson

Chemistry Laboratory, Allmanna Svenska Elektriska Aktiebolaget (ASEA), Västeras, Sweden

ABSTRACT

An experimental study of the behavior of porous hydrophilic oxygen electrodes shows the important influence of the electrochemical reaction on the shape of the i-E curves at low current densities. A correlation between mass transport properties of the electrolyte, $\sqrt{SD\chi}$, and the slope of the polarization curve is found at medium current densities. Convection appears to be important at high current densities. The depth of the effective reaction zone has been calculated under varying conditions.

The importance of mass transport of gas molecules through a liquid film on the behavior of partially submerged electrodes was first demonstrated by Weber *et al.* (1) and Will (2) in model experiments with plane electrodes. Will limited himself in his theoretical treatment (3) to the consideration of the hydrogen transport in the film, which process was found to be rate determining. Grens *et al.* (4), as well as Bennion and Tobias (5), refined the model and took into account the activation polarization and the transport parameters. Attempts to analyze the results from experiments with partially immersed solid electrodes with the aid of the liquid film theory have thus been relatively successful.

The film theory was extended to porous gas-diffusion electrodes by Lindström (6, 7).

Practical porous gas electrodes possess two essential differences: larger electrocatalyst surface area and larger surface for mass transport of gas molecules through a liquid film. These differences make an analysis more difficult. Katan *et al.* (8), however, have carried out an experimental study on a more realistic model of the gas-diffusion electrode. They studied an oxygen cathode comprising a bed of spherical silver grains with a diameter of about 55×10^{-4} cm. The data agreed with a theoretical treatment based on the film hypothesis, if the film thickness was assumed to be 5×10^{-6} cm. A study of porous hydrogen electrodes was carried out by Lindholm (9, 10). He applied Austin's mathematical treatment of the thin-film model (11) and found qualitative agreement. He observed that Austin's mathematical treatment should be modified so as to take into account the varying effective zone depth, the film thinning-out effect at higher differential pressures, and a decreasing electrolyte content in the film for increasing current density. Many mathematical treatments of the kinetics in porous electrodes have been made (11-20). A feature common to many of these treatments is a limited experimental background. In order to obtain more information on the reaction mechanism and kinetics, we have made an experimental study of the behavior of porous oxygen electrodes. The mass transport properties of the electrolyte were varied by changing KOH content and temperature. The effect of the depth of the reaction zone on electrode behavior was investigated with the use of three-layer electrodes.

Experimental

The experimental arrangement is shown in Fig. 1. All components in contact with electrolyte in the test cell were made of nickel, Teflon, or Penton.

I-p and i-v curves were measured stepwise with an interval of 3 min. The potential was set manually for each step and then controlled with an ASEA potentiostat. Steady state was attained in less than 2 min. The differential pressure between the O_2 and the electrolyte was measured with a pressure sensor from Ateliers de Construction de Bagneux. The current density was measured in a half cell with a 35-mm diameter porous disk as oxygen electrode in a Penton holder. Each solution was titrated to ±0.05 mole/liter. The half cell was heated in a water bath. Potentials were measured with a Radiometer PHM 22 by means of a Luggin capillary with the tip placed at the center of the electrode, 1 mm from the surface. The reference electrode was a porous hydrogen electrode with nickel boride electrocatalyst in 7M KOH at 50°C with an absolute pressure of 2.6 atm. This pressure gives about equal volumes of hydrogen and electrolyte in the pore structure. The potential is stable within ±0.1 mV. The absolute pressure on the electrolyte was 1 atm.

The high current densities obtained result in a considerable measuring problem. Current and potential were measured with two separate silver wires, welded to the gas side of the electrode. The outlets at these wires from the holder were placed above the electrolyte surface. These outlets were tightened with epoxy resin. One of the measuring problems is an unavoidable voltage drop between the tip of the reference capillary and the electrode surface. This IR drop was measured through rapid interruption of the current with a mercury relay at the same time as the voltage process was recorded on a storage oscilloscope. This purely ohmic voltage drop decays in less than 1μsec and can be easily distinguished from the other polarization components. All measured values have been corrected for the IR drop in this way.

Although the electrode potentials were always measured against the hydrogen reference at 50°C, these primary data are of little value in comparing performances. The reversible oxygen potential in the same solution is a more suitable reference potential. Our porous electrodes are not reversible oxygen electrodes, and the reversible oxygen potential must be known from other information. This problem was solved by

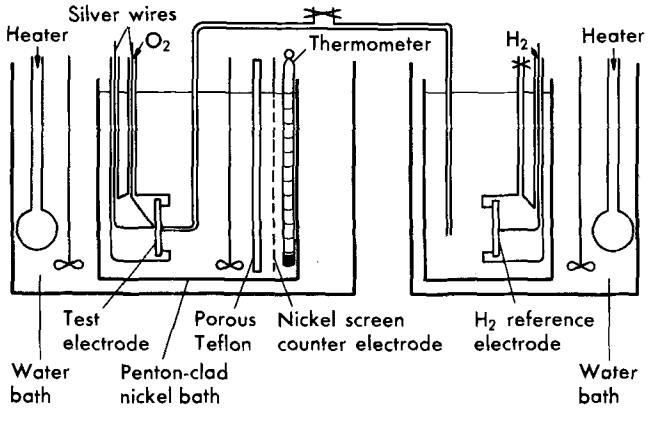

Fig. 1. Arrangement for electrode testing

[1] Present address: Swedish Delegation, OECD, 19, rue de Franqueville, Paris 8e, France.

first calculating the electromotive force for $H_2 - O_2$ in each combination of KOH concentration and temperature. This thermodynamic calculation includes the influence of temperature and KOH concentration using equations published by Salvi and de Bethune (21), Lee (22), and a correction for the gas pressures for equilibrium water pressure using data from Walker (23).

A nickel boride hydrogen electrode was then substituted for the O_2 test electrode in the arrangement of Fig. 1, and its potential against the hydrogen reference electrode of the same type in 7M KOH at 50°C was determined for each combination of temperature and KOH concentration used in the study. The reversible oxygen electrode potential was then calculated for the different electrolyte concentrations and temperatures.

An investigation of the potential distribution in three dimensions in the electrolyte, outside the electrode, showed a slightly uneven current distribution, with about 10% higher current density at the middle compared with the edge of the electrode disk. This test also showed that the distance of the capillary tip from the electrode is not important, since this is corrected for by measurement of the *IR* drop with the storage oscilloscope.

Hydrophilic oxygen electrodes were made with a diameter of 35 mm and a thickness of 1.8 mm. The electrodes for testing were provided with a fine porous layer on the electrolyte side. This layer did not contain any electrocatalyst. Three-layer electrodes were also manufactured. They consisted of an inactive coarse layer of nickel, an active layer of nickel with silver electrocatalyst, and a fine porous layer. The thicknesses of the layers were determined with an optical microscope. The silver content in the active layer was 5% by weight. The coarse, inactive layer had almost exactly the same pore structure as the coarse active layer. Figure 2 shows a model of a three-layer electrode with electrolyte films and gas phase.

The BET surface area of the active layer containing nickel and silver was 0.16 m^2/g and the surface area of the inactive coarse layer of nickel was 0.13 m^2/g.

The porosity of the active layer was 43.6% and that of the inactive layer 44.4%.

Results and Discussion

Effect of differential pressure.—The effect of the differential pressure between the oxygen and the electrolyte on the performance of electrodes with different active layer thicknesses is illustrated in Fig. 3, where current density at —350 mV from the reversible oxygen potential is plotted as a function of differential pressure. These curves were obtained in 7M KOH at 50°C. Curves with a similar shape are obtained in 1-10M KOH at 25°-85°C between —300 and —500 mV from the reversible oxygen potential. A change in these parameters will, of course, change maximum current density and the optimum differential pressure, but not the shape. In an electrode with a thick active layer, the current density increases with the differential pressure up to a maximum and then decreases. When the differential pressure is reduced, the maximum appears at a lower pressure. This hysteresis effect is consistent with a slow movement of the gas-electrolyte interface in smaller pores. It is possible to reduce the hysteresis effect somewhat by measuring with an interval of 60 min for each point.

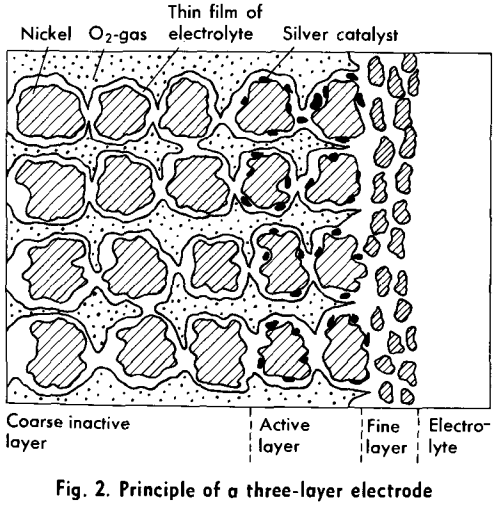

Fig. 2. Principle of a three-layer electrode

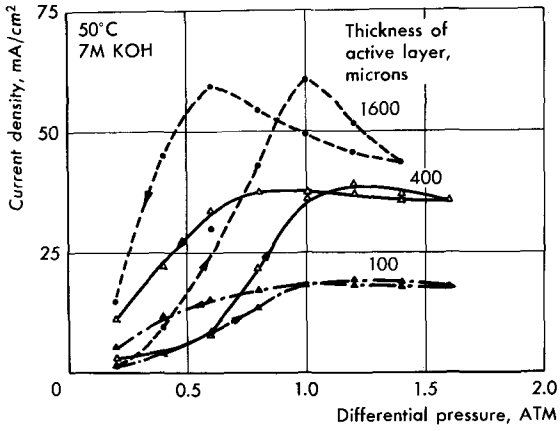

Fig. 3. Current density as a function of differential pressure at varying thickness of active layer.

There are three differences between a thick and a thin active layer:

(*A*) The maximum current density is higher for an electrode with a thick active layer.

(B) The optimum differential pressure is lower for an electrode with a thick active layer.

(*C*) Electrodes with a thick active layer show a considerable decrease in current density at a differential pressure above the optimum value, while electrodes with a thin active layer show an almost constant current at differential pressures above the optimum value.

The increase in the oxygen pressure leads to an increased solubility of O_2 in the electrolyte, which should increase the current density, if other conditions are equal. This occurs at first. The most probable physical explanation of the subsequent drop in the current density with increasing differential pressure for an electrode with thick active layer is that a thinning out of the electrolyte films in the pore system occurs (10), and this has two different effects. First, the speed of mass transport of gas through the liquid film is increased; second, the speed of mass transport of OH^- ions and water decreases. This decrease in mass transport of OH^- ions causes a lower current in electrodes with a thick active layer, *i.e.* long liquid films.

The current is generated in the active layer close to the fine layer. The results with three-layer electrodes show that the current is not proportional to the thickness of the active layer. An electrode with a thin active layer generates more current per micron thickness than an electrode with a thick active layer. It is thus possible to define a "reaction zone" in the active layer near the fine layer with a depth that gives 90% of the current compared to an electrode with a thick active layer operating under the same conditions. It is difficult to calculate the exact thickness of such a "reaction zone," but it is certainly possible to determine changes in "reaction zone" depth with changes in operating conditions.

Figure 3 indicates a decrease in the depth of the reaction zone with increasing differential pressure.

Effect of KOH *concentration.*—The dependence of electrolyte concentration has been studied at 50°C

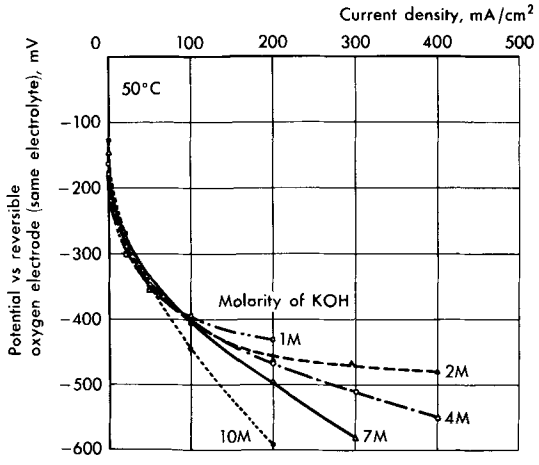

Fig. 4. Polarization curves for electrodes in varying KOH concentrations.

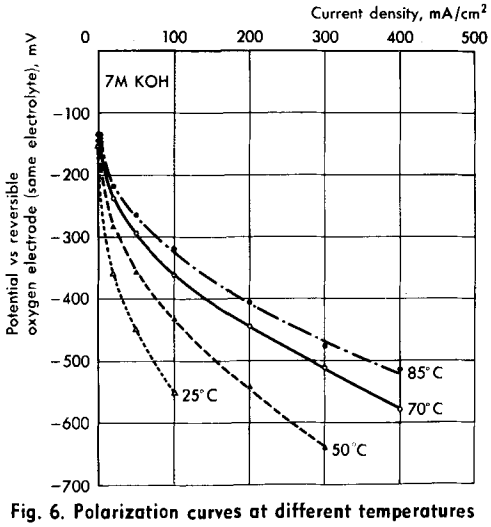

Fig. 6. Polarization curves at different temperatures

with potassium hydroxide varying from 1 to 10 moles/liter. Figure 4 shows polarization curves for an active layer depth of 1600μ. For a given low current density, the electrode shows the lowest polarization in 10M KOH. The rate-limiting step at low polarization is not associated with mass transport, but probably with the electrochemical reaction. At higher current densities, there is an increase in polarization for increasing KOH concentration and the highest polarization in 10M KOH. This behavior is in accord with rate-limiting mass transport at medium current density, as oxygen solubility and diffusivity are low in 10M KOH; compare Fig. 9.

Reaction zone depth at varying polarization.—In order to study the reaction zone depth, we have plotted in Fig. 5 the proportion of current density of an electrode with a thin active layer to the current density of an electrode with 1600μ active layer as a function of the electrode polarization in 2M KOH. The conclusion that can be drawn from Fig. 5 is that there is a relative increase in current density for thin active layer electrodes with increasing polarization, which implies that the depth of the reaction zone decreases with increasing polarization.

Effect of temperature.—Figure 6 shows polarization curves in 7M KOH for 25°, 50°, 70°, and 85°C at the optimum differential pressure for an electrode with an active layer of 1600μ. Electrodes with different active layer thickness give an approximately linear relationship between log current density at a given polarization and $1/T$, from which an activation energy can

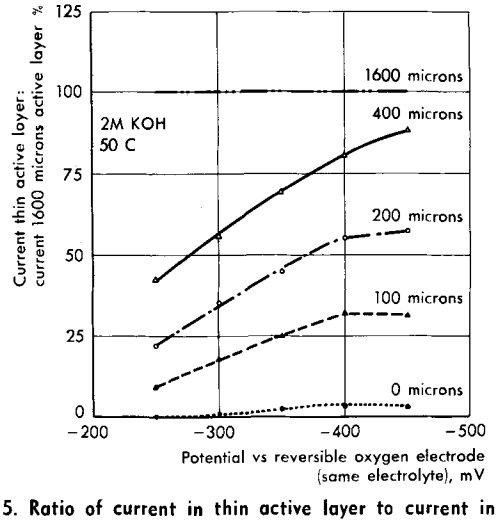

Fig. 5. Ratio of current in thin active layer to current in 1600μ active layer as a function of potential.

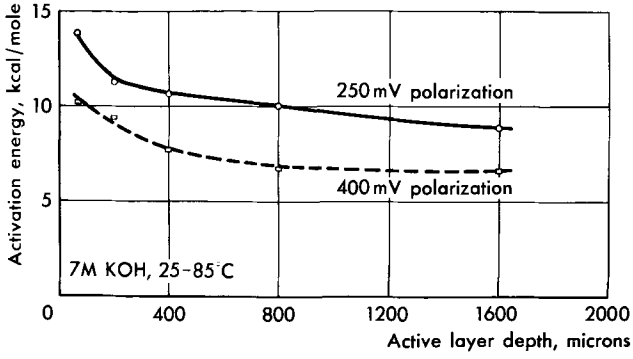

Fig. 7. Activation energies as a function of active layer thickness

be calculated which comprises the whole reaction cycle. Figure 7 shows activation energies for electrodes with varying active layer thickness at 250 and 400 mV polarization from reversible oxygen potential. The higher activation energy at −250 mV supports the conclusion that the electrochemical reaction is a rate-limiting factor at low current densities and that mass transport with a lower activation energy is the rate-limiting factor at medium current densities.

The activation energy is higher for electrodes with a thin active layer. This implies that the relation of current from a thin active layer to current from a thick active layer is increased with increased temperature, and indicates that the "reaction zone depth" decreases with increasing temperature.

Mass transport properties of the electrolyte.—The experimental results at medium polarization can be compared with data for mass transport of oxygen and hydroxyl ions in the liquid phase. Figure 8 shows oxygen solubility S, oxygen diffusivity D, and conductivity χ in 7M KOH as functions of temperature, and Fig. 9 the same variables as functions of KOH concentration at 50°C. These curves are calculated from literature data (24-26). D-values above 60°C are extrapolated.

Comparison with the thin-film theory.—The thin-film theory by Austin *et al.* (11) takes into account the diffusion of oxygen through a liquid film and the film resistivity. This theory predicts polarization curves of the form $i = k \cdot \eta^{1/2}$, if the activation polarization is small. Our experimentally measured curves do not obey this relationship, indicating an influence from the electrochemical reaction as well.

According to Austin's theory, the current-to-polarization ratio should be proportional to $\sqrt{SD\chi}$, when the film area and thickness are constant. This ratio should be valid at medium polarization, and we have

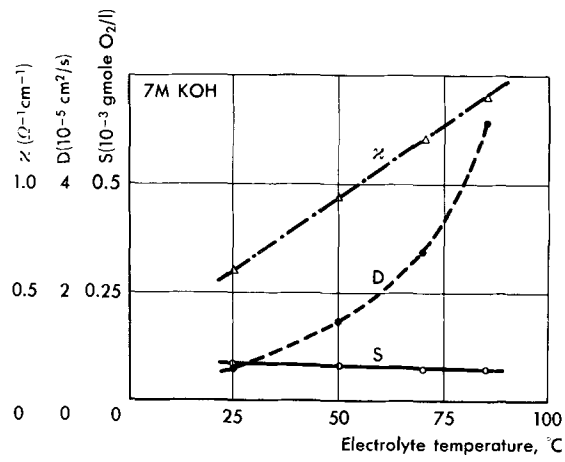

Fig. 8. Solubility and diffusivity of O_2 in KOH and conductivity of KOH as functions of temperature.

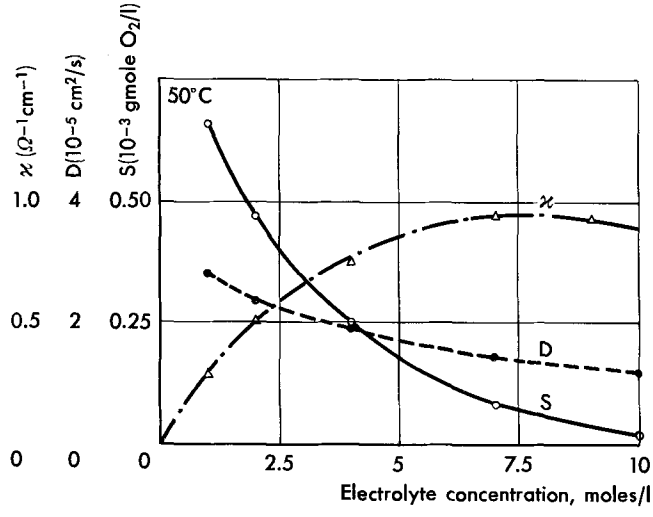

Fig. 9. Solubility and diffusivity of O_2 in KOH and conductivity of KOH as functions of KOH concentration.

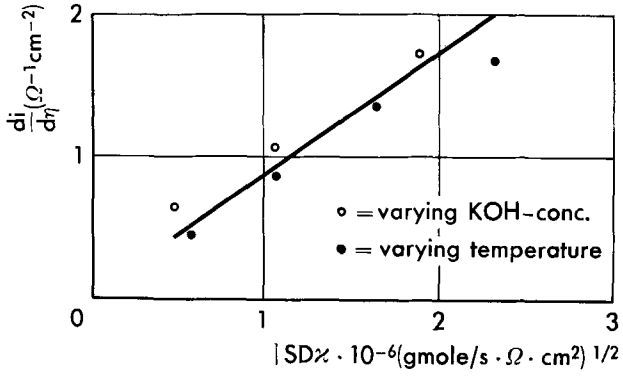

Fig. 10. Inverse slope of the polarization curve $di/d\eta$ at 450 mV polarization as a function of $\sqrt{SD\kappa}$.

tested it at —450 mV *vs.* reversible oxygen. Figure 10 shows experimentally measured $di/d\eta$-values at 450 mV polarization plotted as a function of $\sqrt{SD\kappa}$ for 4M KOH-10M KOH at 50°C and in 7M KOH at 25°-85°C for an electrode with 1600μ active layer. There is a linear relationship between $di/d\eta$ (—450 mV) and the mass transport parameter $\sqrt{SD\kappa}$. This relationship is not valid for lower concentrations than 4M KOH, because the half-cell reaction produces OH^- and gives a relatively large increase of OH^- in the films compared with bulk solution for low KOH concentration. The point with the highest temperature is below the line, which may be due to a thinner "reaction zone depth."

Austin's evaluation considers mass transport polarization through a liquid film and OH^- ion transport along the film, but not the polarization caused by the electrochemical reaction. A more detailed treatment has recently been carried out by Srinivasan and Hurwitz (27). Their treatment is also based on the thin-film model using cylindrical pores, but it considers mass transport of gas molecules through the liquid film, mass transport of ions along the film, and activation polarization on the inner electrode surface using i_o as reaction rate constant.

Figure 11 compares the numerical calculations according to Srinivasan and Hurwitz (27), with the rate constant for the electrochemical reaction $i_o = 10^{-9}$ A/cm² (28) and our experimental values for silver electrocatalyst in 4M KOH at 50°C.

This calculation requires a knowledge of the film geometry. This was obtained with an experimental technique using a gas porosimeter, which has recently been described in detail in a paper by Lindström (29). The relative amounts of gas and liquid in the pores are determined at varying differential pressure and the gas-electrolyte interface is calculated with a computer (GE 625).

The principal disadvantage of this method is that this physical measurement is carried out separately while there is no current flow. The mean thickness of the electrolyte film is 0.9μ and the gas-electrolyte interphase 360 cm²/cm² at optimum conditions.

The shape of the experimental curve is similar to the calculated curve. This indicates once more the strong influence of the electrochemical reaction on the polarization at low current densities. The agreement is good, considering the differences between the model and a real porous electrode, *i.e.* uneven liquid films introducing a tortuosity factor, and that the kinetics for the electrochemical reaction is probably more complex than indicated by one i_o-value.

Experiments up to high current densities.—Figure 12 shows a comparison of polarization curves up to high current densities for an electrode with an active layer thickness of only 100μ in 4M KOH, 7M KOH, and 10M KOH electrolyte. The optimum differential pressure oxygen-electrolyte was 1.4 atm at all KOH concentrations.

The local temperature at the electrode was measured during operation and is given in the figure at varying current densities. The increase of local temperature is about 20°C at 1500 mA/cm².

The polarization curves can be divided into three regions. In region I, low polarization (up to about —350 mV) *vs.* a reversible oxygen electrode, there is

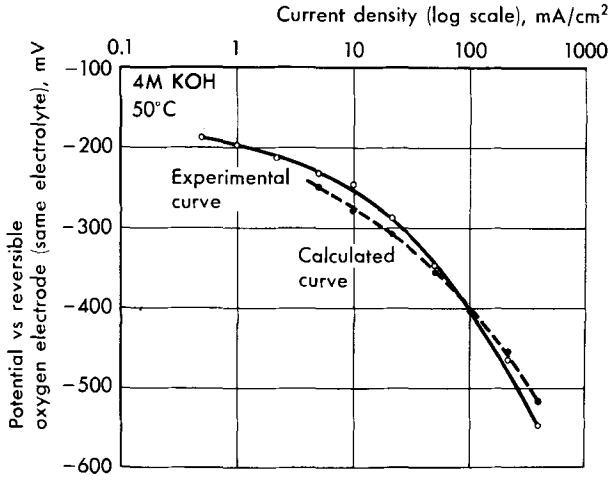

Fig. 11. Comparison of shapes of calculated and experimental polarization curves.

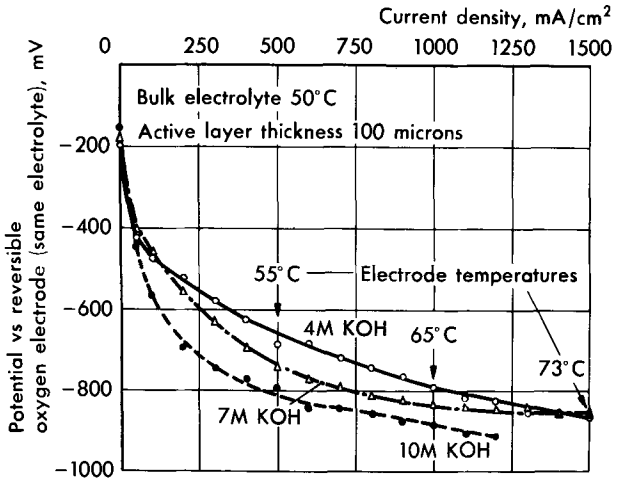

Fig. 12. Polarization curves up to 1500 mA/cm² with varying KOH concentration.

only a small difference among the curves. The polarization is slightly higher with 4M KOH. In region II, medium polarization from —350 to about —600 mV, there are approximately linear polarization curves. The slope is steepest with 10M KOH giving the highest polarization in the strongest KOH electrolyte. In region III, high polarization, more than —600 mV, there is a difference in the shape of the curves. The curves for 7M KOH and 10M KOH become less steep and the slopes of the three curves are almost the same at high current densities. There is a tendency for almost the same polarization to be obtained in 4M KOH and 7M KOH, in spite of the large difference in oxygen solubility and diffusivity, which are considerably lower in 7M KOH. The OH^- concentration in the liquid films is increased during the reaction owing to the formation of OH^- ions. A slow OH^- transport along the films would cause a further decrease in oxygen solubility and diffusivity at high current densities, and a *steeper* polarization curve at high current densities, while the experimental curves are almost horizontal at high current. This suggests that a new mechanism for mass transfer is operating. The positions of the regions depend on the active layer thickness, an electrode with 1600μ active layer, *i.e.*, larger electrocatalyst surface area, shows a shift from electrochemical reaction rate control to mass transport control at a lower polarization than 350 mV.

The limiting current densities for gas diffusion through a liquid film can be calculated from the formula:

$$i_l = \frac{n \cdot \mathbf{F} \cdot S \cdot D \cdot A}{W}$$

S = oxygen solubility in liquid
D = oxygen diffusivity in liquid
A = film surface area
W = film thickness.

The film thickness W was determined by the method previously described (29) to be 0.37μ and the film surface A was determined to be 35 cm²/cm² geometric by gas porosimeter experiments for an electrode with 100μ active layer at optimum differential pressure 1.4 atm. This electrode has a thin active layer. This means a high optimum differential pressure and a thinner film than the film in Fig. 11. The calculated value for limiting gas diffusion through an electrolyte film at a local temperature of 70°C is 410 mA/cm² in 10M KOH. The highest measured current density in 10M KOH is 1200 mA/cm², which is about three times higher than the calculated value and the limiting current is still higher.

The absence of limiting currents may reflect a new mass transport mechanism at high current densities.

The difference in mechanism at very high current densities is probably that convection occurs in the liquid film causing rapid transport of O_2 molecules through the film and OH^- and H_2O along the film. This can either be caused by the large amount of heat evolved in the solid-liquid interface or by a gradient in liquid tension, the Marangoni effect, as suggested by Will (30) and Ksenshek (31) for model electrodes.

Conclusions

A kinetic treatment of porous hydrophilic oxygen electrodes with three-layer electrodes indicates that the reaction zone decreases at higher differential pressure owing to a "thinning-out" effect of the liquid films. The reaction zone depth also decreases with increasing polarization.

The polarization curve can be divided into three regions. The reaction rate in region I (low polarization) is probably determined by the surface reaction with a low i_o-value.

In region II with medium polarization, the reaction rate is determined by a combination of mass transport of O_2 molecules by diffusion through a liquid film and mass transport of OH^- along the film. Region III with high polarization appears to have a convective mass transport of O_2 through the liquid film and the reaction rate is probably limited by transport of OH^- along the film.

Cathodic Oxygen Reduction in the Sealed Lead-Acid Cell

S. Hills[1,*] and D. L. K. Chu[2]

Exide Power Systems Division, ESB, Incorporated, Philadelphia, Pennsylvania

ABSTRACT

The steady-state current observed during the cathodic reduction of O_2 at a partially exposed, electrochemically active electrode does not always represent its true recombination capability. This is usually the case when ohmic dissipation of the applied potential, resulting from inclusion of a highly resistive, thin electrolyte film in the current path, limits the passage of an externally supplied current to only a small distance above the free electrolyte level. Chemical reduction of O_2 can then occur over the area of substrate in contact with the thin film which is above the level of current penetration. O_2 reduction was studied at such electrodes in order to delineate the conditions under which both current penetration and O_2 access could be maximized, allowing a closer approximation of the true recombination capabilities of maintenance-free storage batteries. The magnitude of the difference between the rate of O_2 reduction and the steady-state current was determined by monitoring the current obtained after reimmersing the exposed electrode. The effect on this difference of variables, such as electrolyte concentration, O_2 partial pressure, applied potential, separator position, and degree of electrode exposure, are presented for the Pb-acid system.

Sealed and/or maintenance-free cells, which do not employ auxiliary electrodes, are at present designed to operate on an O_2 cycle during overcharge. Overcharge capability is obtained from the presence of a discharge reserve on the negative electrode so that H_2 evolution does not accompany the liberation of O_2 after charging of the active material on the positive is completed. The O_2 migrates *via* the gas space and is reduced at the negative electrode, maintaining the discharge reserve of the latter. A similar process occurs in fuel cells utilizing O_2 as one of the fuels, and therefore cathodic reduction of O_2 has been extensively studied in various systems. Most of the fundamental investigations employed smooth inert electrode substrates in order to circumvent the experimental and theoretical problems peculiar to the use of active porous electrodes. Both these and developmental studies of this phenomenon at porous battery electrodes generally involved determination of the relations between cathodic current at constant potential and either O_2 partial pressure (at constant degree of electrode exposure) or degree of electrode exposure (at constant O_2 pressure), and use of these relations as a measure of the effects of various cell parameters upon establishment of the steady state.

The majority of such studies concentrated on the area of the electrode in contact with the electrolyte meniscus, as the reaction rate beyond the limits of the meniscus was believed to be negligible. On one side, it was limited by extremely slow diffusion through the bulk electrolyte. Beyond the opposite limit, reaction between the dry electrode and the gas phase, at low temperatures, was insignificant if not nonexistent. O_2 reduction thus became meaningful only in the vicinity of the meniscus where, although the rate was still diffusion controlled, the electrolyte layer became sufficiently thin to allow appreciable transport of the electroactive species. The observed steady-state cathodic current was believed to be equivalent to the maximum rate of O_2 reduction under the given conditions.

Recent studies (1-10) have shown that a film of electrolyte exists beyond the intrinsic meniscus. Although O_2 transport should be even more rapid through such a thin barrier, the area of substrate in contact with the film usually did not contribute appreciably to the total O_2 reduction capability of the partially exposed electrode. Ohmic dissipation of the applied potential, resulting from inclusion of this highly resistive thin electrolyte film in the current path, can limit passage of an externally supplied current to only a small distance above the free electrolyte level. With an inert substrate, this merely limits the reaction zone. However, the supply of electrons on an electrochemically active substrate is not subject to this restriction, and chemical reduction of O_2 can occur on the portion of such an electrode in contact with the thin film. This has been found to be the case in both acid and alkaline systems, resulting, in all cases, in the formation of a layer of solid oxidation product.

The steady-state current observed, under potentiostatic conditions on a partially exposed active electrode, thus represents reduction of O_2 only over the area which can be reached by the externally supplied current. It is not equivalent to the total recombination capability of such an electrode. Further study of O_2 reduction on electrochemically active substrates was therefore initiated in order to delineate the conditions under which both current penetration and O_2 access could be maximized, and thereby obtain a closer approximation of the true recombination capabilities of maintenance-free storage batteries. ported at this time details the investigation of O_2 reduction in the lead-acid system.

Experimental

Test electrodes (7.62 cm high x 3.81 cm wide x 0.25 cm thick) were prepared by halving dry-charged $Pb/PbSO_4$ electrodes selected from production stock.

Separators, where used, were cut to appropriate size from 1.3-mm thick, flat sheets of a commercially available grade of microporous rubber.

Various concentrations of electrolyte were prepared from reagent-grade H_2SO_4 to within ± 0.001 g/cm^3 of that desired.

A Plexiglas test cell, fabricated with replaceable inserts which divided the cell into three compartments, accommodated the test electrodes both in the presence and absence of separators. The configuration of the various components, for the three possible modes of electrode exposure, can be seen in Fig. 1. Both inserts were perforated to provide free electrolyte passage between the compartments. A screw-driven piston and appropriate shimming were employed to adjust the contact pressure between cell components whenever separators were present.

A controlled atmosphere was obtained by means of a Plexiglas pressure chamber capable of withstanding 50 psig. Provisions for evacuating the chamber and filling it with O_2, measuring the ambient pressure, thermostating the test cell, electrical connections, and variation of the degree of electrode exposure were made through the chamber walls. Electrolyte height was determined by visual sighting against a series of accurately ruled lines scribed on the optically clear test cell wall, and could be reproduced to within ± 0.4 mm.

Variation of electrolyte composition during a run was minimized by daily replacement of the relatively large volume held in the test cell and leveling bulb ($\sim$300 ml) and limiting electrochemical reactions to water decomposition by the use of charged test electrodes and sheet Pb counterelectrodes. Similarly, the large volume of the pressure chamber (1 ft^3) minimized variations in composition and total pressure of the ambient atmosphere resulting from the small amounts of gas evolved during the exposure studies. Except when it was the variable being investigated, O_2 pressure was maintained at 1 psig in order to prevent any leakage through faulty seals.

Electrode potential, cathodic current, and electrode temperature were continuously monitored with an L&N multipoint recorder-Keithley electrometer combination, capable after calibration of ± 5 mV accuracy over the 0-1V range. Signal currents were virtually eliminated by the 10^{14} ohm input impedance of the electrometer. A glass probe thermistor, encapsulated in epoxy to protect it from H_2SO_4, was fastened to the test electrode with its tip directly contacting the top grid member. Temperature could be determined to better than ± 0.5°C and was maintained at 25° $\pm$ 3°C without recourse to thermostatic control.

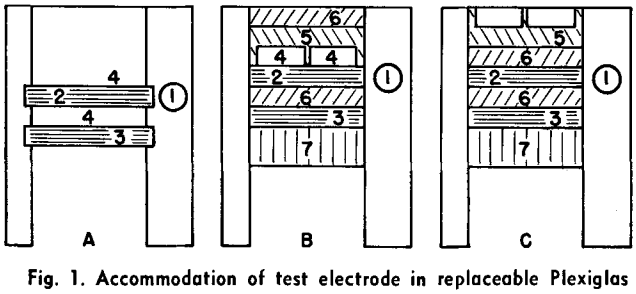

Fig. 1. Accommodation of test electrode in replaceable Plexiglas inserts: A—absence of separators, B—presence of separators on one side, C—presence of separators on both sides. 1—Reference electrode well (connected to test electrode chamber by salt bridge at bottom), 2—$Pb/PbSO_4$ test electrode, 3—sheet Pb counterelectrode, 4—gas space for test electrode, 5—Plexiglas spacer, 6—separators, 7—adjustable piston.

Potentiostatic conditions were obtained by means of an instrument designed and constructed by E.S.B. Incorporated. Before exposing an electrode to an O_2 atmosphere, it was charged overnight to assure that no utilizeable $PbSO_4$ remained.

O_2 reduction was first investigated in the absence of separators. The effect of each variable was studied on two electrodes to establish reproducibility of trends. Holding the cathodic overvoltage (η) constant at -50 mV, O_2 pressure at 1 psig, and H_2SO_4 s. g. at 1.300, the degree of exposure was varied from 1/16 to 7/8 of the full electrode height and I_{ss} determined for each exposure. After steady state was obtained, the electrode was reimmersed and the cathodic current monitored until it decreased to the value obtained prior to exposure. Graphical integration of the reimmersion current-time profile, taking the pre-exposure current into account, yielded the reimmersion capacity (Q_{im}). This represented the extent to which $PbSO_4$ was formed by chemical reduction of O_2. Division of Q_{im} by the time of exposure yielded an average current (I_{lag}), which represented the difference between I_{ss} and the current equivalent to the total rate of O_2 reduction. This was equivalent to the rate of formation of $PbSO_4$.

The effects of exposure time (10-60 min) and applied potential (-50 to -200 mV) were also investigated using the same technique. Cathodic η's larger than -200 mV were not investigated since in this region it was no longer possible to restrict the cathodic reaction to the reduction of O_2. Anodic overvoltage, equal to the difference in open-circuit voltage between the exposed and fully immersed electrode, was determined over the same exposure range mentioned previously.

Similar diagnostic experiments were run with varying thicknesses of microporous rubber separators on both sides of the test electrode. Under this condition, current penetrated the entire length of exposed electrode, removing this as a complicating variable, and enabling the effects of O_2 partial pressure and electrolyte concentration on diffusion control to be studied. A significant variation in open-circuit potential was observed over the range of concentrations investigated, 1.1 s.g. (1.68M) to 1.5 s.g. (9.15M). This was in agreement with data reported in the literature (11-13). The effect of the presence of other gases was spot-checked by determining I_{ss} in an air atmosphere.

Finally, O_2 reduction was studied with separator barriers of varying thicknesses sandwiched between the test electrode and the counterelectrode (inside face). Thus, when the free electrolyte level was dropped, the side of the test electrode facing away from the counterelectrode (back side) was exposed to the gas space by means of a spacer. This is a combination of the two cases discussed previously, and was studied more extensively since it proved to be the optimum combination of electrode and separator with regard to recombination.

Results and Discussion

In the absence of separators, establishment of the steady state always required times in excess of 10 min. Transient currents obtained prior to this always passed through a maximum. I_{ss} increased rapidly both with degree of exposure (Fig. 2) and η (Fig. 3), yielding reproducible limiting currents with regard to the former parameter. Reimmersion of the electrode after each exposure resulted in a rapid increase in cathodic current, sometimes as much as an order of magnitude over that obtained at steady state, followed by a slow decrease which often took hours to reach the value observed prior to exposure. I_{lag} and Q_{im} increased both with degree of exposure at a fixed time of exposure (Fig. 2) and with time at a fixed degree of exposure (Fig. 4). I_{lag} increased at a faster rate

Fig. 2. Fig. 3. Steady-state current *vs.* square root of electrode polarization: 1 psig O_2, 1.3 sp gr H_2SO_4. ○, No separators, 12.5% exposure; ●, 3 separators on one side of test electrode, 25% exposure; ◐, 3 separators on both sides of test electrode, 75% exposure.

than did the exposed area as can be seen in Fig. 2, indicating that the problem grew more severe with increased exposure. The existence of Q_{im} eliminated any possibility of the I_{ss} obtained at a given exposure being equivalent to the total recombination capacity of the electrode.

Similar behavior was reported in studies of various acidic and alkaline systems (1, 2, 4, 8, 9) in which it was concluded that, at a given applied potential, gas diffusion through the electrolyte was limiting. Most of the current was derived at a narrow zone in the vicinity of the upper boundary of the intrinsic meniscus, where the electrolyte layer was extremely thin and gas diffusion therefore extremely rapid. It was agreed that an even thinner film of electrolyte existed above the meniscus [except by Weber, Meissner, and Sama (1), who did not take this possibility into account] which could not contribute significantly to the electrochemical process, despite the fact that gas diffusion in this region should have been even more rapid, because of the inability of the current to penetrate the film. In agreement with the present study, Will (2) obtained transient currents on reimmersion of the electrode. However, in his case steady state was achieved within a few seconds after raising the electrode to a new position with I_{ss} always approached from below.

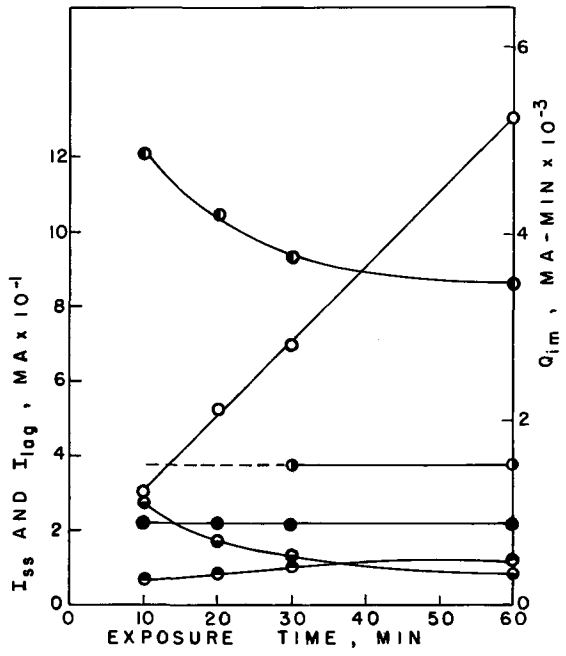

Fig. 4. Effect of exposure time on steady-state current, lag current, and reimmersion capacity in the absence of separators and with separators on one side of test electrode: 1.3 sp gr H_2SO_4, 1 psig O_2, 50% exposure, —50 mV η. ●, Steady-state current; ◐, lag current; ○, reimmersion capacity in the absence of separators; ◑, steady-state current; ◒, lag current; ◓, reimmersion capacity with separators on one side of test electrode.

These variations can be ascribed to a difference in the nature of the electrode substrates. Pt is essentially inert and H_2 oxidation can occur only by an electrochemical mechanism (no oxidized metal intermediates) at those sites at which electrons can be removed by an external source. The reaction product, H_3O^+, is soluble, eliminating the possibility of formation of a solid surface film. On the other hand, Pb was not inert under the experimental conditions employed. (This would also be the case for other metallic battery active materials.) Increased resistance in the electrolyte film, resulting from drainage, limited penetration of the externally supplied cathodic current to only a small distance above the intrinsic meniscus, and a film of $PbSO_4$ was formed (14). This provided an additional barrier to O_2 diffusion and possibly increased resistivity of the electrolyte film even further by removal of free acid. The net result was that the cathodic current passed through a maximum and I_{ss} was approached from above. I_{ss} was dependent on $\eta^{1/2}$ (Fig. 3) as predicted by Will (3) for a one-dimensional diffusional process which is further complicated by ohmic dissipation of the applied potential.

Upon reimmersion, the dissipation of the applied potential was eliminated and the $PbSO_4$ film became immediately available for reduction. Q_{im} was dependent on the amount of $PbSO_4$ formed, which in turn was a function of both the degree and time of electrode exposure, and thus the large reimmersion currents observed were not necessarily short lived. As the $PbSO_4$ film thickened, the access of O_2 was impeded further and the difference between the rate of O_2 reduction and I_{ss} decreased. However, this was a slow

process. I_{lag} for 50% exposure was still quadruple I_{ss} after 60 min exposure (Fig. 4), accounting for the relatively long time required for establishment of the steady state.

A penetration height of approximately 1.0 cm was observed with the 0.25-cm thick test electrodes which was similar to that obtained by Maget and Roethlein (10) for 100μ thick layers of sponge Pt and Teflon.

Anodic polarization of electrodes exposed to 1 psig O_2 in the absence of separators was slight because of the high exchange current for the conversion of Pb to $PbSO_4$ (15). It did not exceed 1 mV until the electrode was 50% exposed and reached a maximum of only 3 mV at 87.5% exposure. Smaller polarizations could be expected when one or both sides of the exposed electrode were shielded from the O_2 atmosphere by separator barriers wetted by H_2SO_4. Thus, it was likely that the externally supplied current was not significantly increased by the additional driving potential obtained from this source.

When both sides of the test electrode were masked from the gas space, Q_{im} was negligible for all exposures and applied potentials investigated and therefore I_{ss} was equivalent to the total rate of O_2 reduction. A true limiting current was obtained at each exposure as could be ascertained from the effect of applied potential upon I_{ss} at 75% exposure (Fig. 3). The slight decrease observed with increasing η was not unexpected, as eventually adsorbed, evolved H_2 occupied active sites and made them unavailable for O_2 reduction. The above resulted from a combination of hindered O_2 diffusion through and virtual elimination of ohmic dissipation of the applied potential in the highly conductive, thick electrolyte film retained in the separator barrier. Weber, Meissner, and Sama (1) found that even much thinner films would significantly reduce O_2 transport. In agreement with this, the magnitude and rate of increase of I_{ss} with degree of electrode exposure were greatly reduced below that obtained in the absence of separators (Fig. 2). Microporous rubber retains sufficient electrolyte that the *IR* drop through the separators for an 87.5% exposed electrode (as determined oscilloscopically by interruption of a known current) is the same as for a fully immersed electrode. This condition persisted for over an hour and there was no reason to suspect that it would change as long as the bottom of the separator was immersed in free electrolyte.

A linear relation was obtained between I_{ss} and O_2 pressure over the entire range investigated (Fig. 5), verifying that the limiting step under these conditions was the first-order diffusion of O_2 through the electrolyte retained in the separator barriers. Good agreement between the I_{ss}'s obtained at 0.2 atm of pure O_2 and those in an air atmosphere indicated that the rate of O_2 reduction, at a Pb electrode, was dependent on the partial pressure of O_2 regardless of the presence of other gases. However, other gases are to be avoided, if possible, since their presence will increase the total pressure in a sealed system.

Poor reproducibility could be ascribed to varying electrolyte retention in the test electrode separator combination (TESC) which depend on: (*a*) porosity of the test electrode, (*b*) porosity of the separator, (*c*) cell pack pressure, and (*d*) availability of free electrolyte. It was not believed feasible to control the first two factors in actual cell fabrication and so no attempt to do so had been made in this investigation. Cell pack pressure was adjusted by means of a movable piston and did not appear to be critical as long as reasonable contact with the test and counterelectrodes was maintained. The last factor is discussed later.

Maximum I_{ss} for a well-exposed electrode, at —50 mV η and 1 psig O_2 was obtained in the specific gravity range of 1.2-1.3. At the low η applied in the present study, electrolyte resistance was the most important factor controlling I_{ss}, outweighing both the solubility and diffusivity of O_2 in H_2SO_4. I_{ss} peaked strongly in

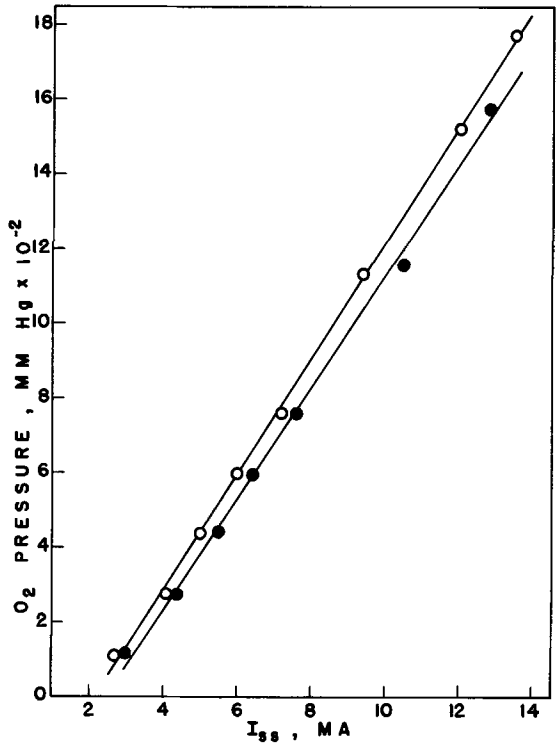

Fig. 5. Steady-state current with three separators on both sides of test electrodes as a function of O_2 pressure: —50 mV η, 1.3 sp gr H_2SO_4, 50% exposure. Data presented are for two similar electrodes.

the range of maximum electrolyte conductivity (16) at exposures of 50% and above. Below 1.2 sp gr, I_{ss} became controlled by ohmic dissipation of the applied potential, despite the presence of separators on both sides of the test electrode. This was manifested by the appearance of a significant Q_{im} at 1.1 sp gr. An increase in I_{ss} above 1.4 sp gr can probably be attributed to increased corrosion of Pb by H_2SO_4.

With only the back side of the test electrode exposed to the gas phase, the initial increase in I_{ss} with degree of exposure was not as rapid as in the absence of separators (Fig. 2). However, instead of becoming limited above 12.5% exposure, I_{ss} continued to increase. Above 50% exposure, the rate accelerated to the point where I_{ss} was increasing faster than was the area exposed. Despite a significant variation in I_{ss}'s between the TESC's the lowest values were much larger than the maximum current obtained in the absence of separators.

Use of separators on only the inside face of the test electrode decreased the severe O_2 diffusion limitation presented by separators on both sides, and increased the length of exposed electrode available for penetration of externally supplied cathodic current over that provided in the absence of separators. This physical setup allowed O_2 transport to take place relatively unhindered on the exposed back side of the $Pb/PbSO_4$ electrode, and at the same time provided a low resistance path for the externally supplied cathodic current through the well-wetted separators on the inside face of the test electrode.

The wide divergence of I_{ss} values observed with separators on only the inside face of the test electrode resulted from a change in the severity of diffusion limitation and extent of current penetration between electrodes. The lowest I_{ss}'s were found to be independent of potential and, in these instances, Q_{im} was negligible for all exposures and η's investigated. Apparently, sufficient electrolyte could be retained under certain conditions, as yet not completely understood, to provide a thick enough film of electrolyte on the exposed back side of the test electrode to greatly

inhibit O_2 diffusion. Under this condition, I_{ss}, for a given exposure, decreased with increasing thickness of separator barrier. This can be ascribed to the increased quantity of electrolyte retained and, consequently, the greater ability to "flood" the test electrode.

The highest cathodic currents were observed in those TESC's in which current penetration was incomplete even at very low exposures. Q_{im} and I_{lag} were significantly lower than in the absence of separators (Fig. 2 and 4) indicating that the improvement resulted from increasing penetration above the free electrolyte level. Apparently, ohmic dissipation of the applied potential was greatly decreased below that experienced in the absence of separators by the substantial amount of electrolyte retained in the separator barrier on the inside face of the test electrode. However, in these instances, the amount of electrolyte retained in the TESC was apparently reduced sufficiently to permit a significantly higher O_2 diffusion rate on the back side of the test electrode. A change from the "flooded" electrode condition to less-hindered O_2 access with increasing electrode exposure resulted in intermediate I_{ss} values. This accounted for the significant accelerations in the rate at which I_{ss} increased with degree of exposure usually observed above 50% exposure.

The relation between I_{ss} and O_2 pressure, when only the inside face of the test electrode was masked from the gas space, also varied depending on the extent of current penetration. A linear relation was obtained if ohmic dissipation of the applied potential was imposed over diffusion control over the whole range of pressures investigated. On the other hand, a relation which appeared to be parabolic but which in reality was probably two intersecting straight lines (Fig. 6) was obtained when inability to provide current equivalent to the total rate of O_2 reduction developed only at higher pressures. In the present case, this change occurred above 595 mm Hg. Good agreement between the I_{ss} obtained in air atmosphere and that at 0.2 atm of pure O_2 was again observed.

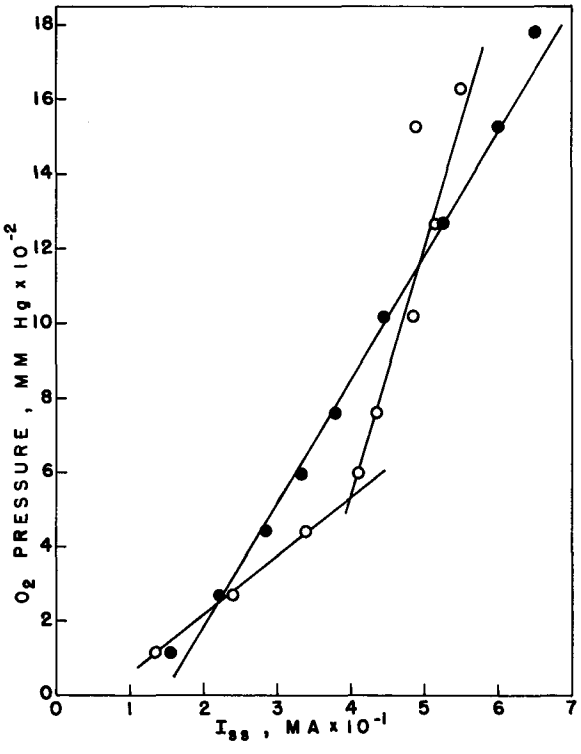

Fig. 6. Steady-state current with three separators on one side of the test electrode as a function of O_2 pressure: —50 mV η, 1.3 sp gr H_2SO_4, 50% exposure. ●, Ohmic dissipation imposed over diffusion control over entire pressure range; ○, pure diffusion control at low O_2 pressures with ohmic dissipation initiated at about 600 mm Hg.

Similar parabolic data were reported by Dehmelt and von Dohren (17) for the alkaline Cd electrode, and Maget and Roethlein (8) for the Pt electrode in H_2SO_4. The former believed that the relation between I_{ss} and O_2 pressure could best be described as parabolic below 1 kg/cm^2 (0.97 atm) but that it was linear from 1 to 6 kg/cm^2. The latter did not investigate O_2 pressures above 1 atm and concluded that a parabolic relation existed. It is likely that a gradual increase in the difference between I_{ss} and total recombination rate was responsible for the pseudoparabolic relation observed below 1 atm pressure in both cases. I_{ss}, in both studies, was dependent on applied potential, indicating the possibility of ohmic dissipation of the driving force as an additional complicating factor.

Maximum I_{ss} with separators on only one side of the test electrode was obtained at 1.3 sp gr (Fig. 7). The data are qualitatively similar to that obtained with separators on both sides of the test electrode. Q_{im} and I_{lag} data indicated that below 1.2 sp gr current penetration became severely limited by decreased electrolyte conductivity, while above 1.3 sp gr I_{ss} was essentially equivalent to the total rate of O_2 reduction. Several other studies (2, 4, 6-10) also indicated that the ability of cathodic current to penetrate the exposed section of the electrode was heavily dependent on the conductivity of the electrolyte film.

Conclusions

Optimum design for establishment of an O_2 cycle in a practical, maintenance-free Pb-acid cell has been demonstrated to require provisions for maximum access of O_2 gas to the negative electrode and a sufficiently conductive electrolyte path between the working electrodes. These requirements are necessary to prevent the imposition of severe limitations on I_{ss} by either diffusion control or ohmic dissipation of the applied potential. In general, both criteria can be satisfied by the use of negative electrodes with backs open to the gas space and well-wetted separators between the working electrodes.

It was also shown that, not only did limiting conditions vary between different TESC's, even when the type of separator was not changed, but that they could change on the same TESC because of varying electrolyte retention with increased electrode exposure.

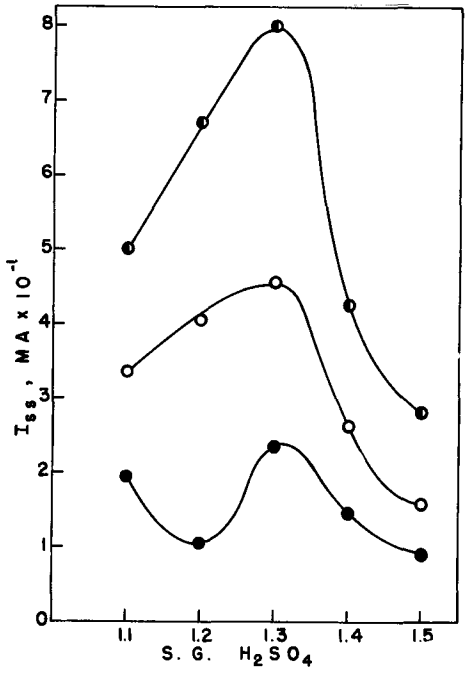

Fig. 7. Steady-state current with three separators on one side of the test electrode vs. specific gravity of H_2SO_4: 1 psig O_2, —50 mV η. Electrode exposure: ●, 25%; ○, 50%; ◐, 75%.

Apparently, electrolyte retention in the TESC was the most critical variable for reproducibility obtaining O_2 reduction at a rate sufficient to establish an O_2 cycle in a practical Pb-acid cell, without resorting to an auxiliary electrode. It is a complex function of the four variables mentioned previously. Since it was not feasible to optimize electrolyte retention through control of electrode and/or separator porosity or cell pack pressure, only elimination of the free electrolyte reservoir remained as a possible technique to achieve such control. This method was evaluated by raising the cell pack 0.5 in. above the bottom of the test cell. The electrolyte level could then be dropped below the bottom of the cell pack, eliminating all contact between them. Ionic contact to the reference electrode was maintained through a thin piece of separator on the back side of the test electrode which dipped into the electrolyte reservoir. Five such fully exposed electrodes, with three layers of microporous rubber on their inside faces, yielded I_{ss}'s of —110, —78, —114, —118, and —93 mA at —50 mV η and 1 psig O_2 in 1.3 sp gr H_2SO_4. These I_{ss}'s lie in a significantly narrower range toward the upper end of the values obtained previously.

Since both O_2 diffusion and the ability to send current through the system are heavily dependent on the amount of electrolyte retained in the TESC, over which there was no effective control, this data should not be considered to represent exactly the O_2 reduction capability of the $Pb/PbSO_4$ electrode. Satisfactory operation of maintenance-free Pb-acid cells will require close control of electrolyte metering. The optimum amount of electrolyte will have to be determined through a study of the initial distribution of electrolyte between electrodes and separators and its variation with cycling.

Manuscript submitted Jan. 16, 1969; revised manuscript received April 14, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Gas Depolarized Graphite Anodes for Aluminum Electrowinning

M. L. Kronenberg

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio

ABSTRACT

Anode potential sweep studies on electronic conducting refractories and several metals in a cryolite-alumina melt have shown copper, nickel, and graphite to be the most stable anode materials. However, even these materials were attacked in this electrolyte at anodic potentials normally attained in aluminum electrowinning. Uncatalyzed graphite electrodes could be depolarized by methane, but carbon monoxide would depolarize only catalyzed electrodes. There are significant fluoride losses from the electrolyte when hydrogen-containing fuel gases are used to depolarize the anode.

Carbon is an especially good anode choice for aluminum production for several reasons:

1. The products of anodic oxidation ($CO + CO_2$) are expelled from the electrolyte and do not contaminate the cathode product.
2. It is a good electronic conductor.
3. It is virtually insoluble in aluminum.
4. It is able to withstand the high operating temperature of Hall-Heroult cell (980°C).
5. It is a relatively inexpensive material.

Nevertheless, the use of 0.57 lb of carbon/lb of aluminum produced contributes about 8% to the cost of producing aluminum (1). This is not much less than the cost of the bauxite raw material.

Some work was initiated at Union Carbide to determine whether a gas depolarized anode using an inert, porous-refractory material might provide a reduction in anode costs if an inexpensive gas such as methane were used. This principle has been discussed elsewhere at various times, but to the author's knowledge no experimental data have been presented in support of it (2-5).

The plan of investigation was as follows:

1. Determine which anode materials exhibit the greatest resistance to attack by means of polarization and potential sweep studies of carbon, graphite, and other conductive materials (borides, carbides, and metals).
2. Conduct anode corrosion studies in the presence of depolarizing gases using the most stable materials as "inert" electrodes.
3. Improve anodic activity toward depolarizing gases by application of catalysts.

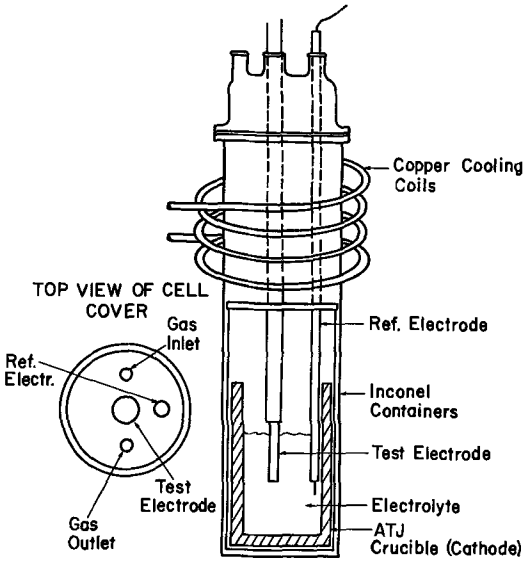

Fig. 1. Cell assembly used for Al electrowinning experiments

Experimental

A sketch of the cell evolved for polarization and sweep studies is shown in Fig. 1. The electrolyte commonly used was a melt containing 15 w/o (weight per cent) alumina, 78% cryolite, and 7% CaF_2 contained in the ATJ graphite crucible shown. The graphite crucible is contained in an Inconel crucible which in turn is contained in an Inconel sagger. A BN or alumina heat shield (not shown) was normally held just above the Inconel crucible. One final Inconel can (not shown) is used as an extra protection for the furnace walls and furnace thermocouple.

The cell cover had a ground glass flange which was held to the ground flange of the metal sagger by spring clips. A positive pressure flow of argon (Linde, 99.996%) was passed above the electrolyte except where noted.

A Lindberg model 59622 crucible furnace and 59344 controller were used to heat and control the cell temperature. An auxiliary thermocouple was not normally used, but the furnace controller was periodically rechecked against a shielded thermocouple in the melt.

A Pt-Al alloy reference electrode was chosen since it is solid at both operating temperatures, and the Pt component is inert. This alloy was prepared by cathodically diffusing aluminum from a saturated alumina, cryolite melt at 1000°C and 100 mA/cm² for 33 min. The reaction zone was 0.010 in. thick. Hardness tests gave a result of 100 kg/cm² for the Pt zone; 200 kg/cm² for the interface; and 320 kg/cm² for the reaction zone, suggesting that a Pt-Al alloy was formed. This reference electrode was checked against another Pt-Al electrode prepared in the same way. After an initial "settling down" period of about 30 min, the electrode potentials did not differ more than 20 mV over a period of several hours. A typical polarization or potential sweep run took about 20 min. While the reversible potential of this reference electrode is not known, it served our need for a simple, relatively stable electrode that would not contaminate our melt. The reference electrode was kept in an alumina sheath to prevent shorting to the anode or cathode.

The electrode construction used for testing nonporous anode materials is shown in Fig. 2. Only the test material was intentionally immersed in the electrolyte. The graphite crucible containing the electrolyte (Fig. 1) served as the cathode.

The potential correction for the position of the reference electrode was applied according to the following equation derived by Casper (6) for concentric cylinder electrodes:

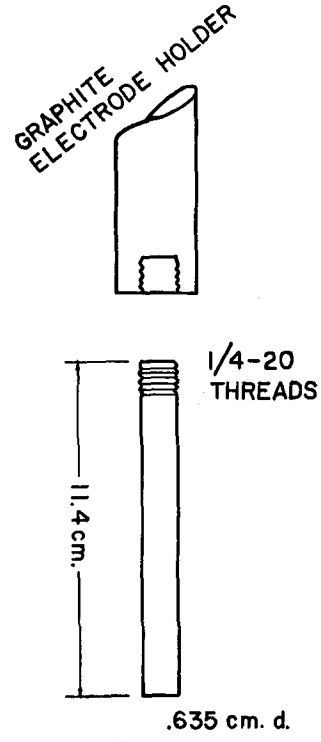

Fig. 2. Test electrode

$$R = \frac{2.3}{2\pi K} \log \frac{r_2}{r_1} \qquad [1]$$

where R is the total resistance per unit length, r_1 is the radius of the working electrode; r_2 the reference electrode distance from the center, and K the conductivity of the melt. The conductivity of the melt was taken as 2.09 ohm^{-1} cm^{-1}, averaging the values reported by Mashovets (7) and by Matrasovsky (8). The value r_1 was 0.634 cm and r_2 was 2.5 cm. The voltage correction as a function of current is $V = 0.107\,I$.

Polarization data were obtained with a Kordesch-Marko interrupter (9) which eliminated *IR* drop and activation polarization from the measurement. Calculations based on Eq. [1], direct resistance readings with an a-c bridge, and interrupter readings were used to help distinguish among solution resistance, interfacial resistance, and activation polarization.

An Anatrol 4100 potential controller, which was modified to provide slow linear sweeps, was used for potential sweep studies.

Experimental Results

Cell polarization data on nonporous materials.—Cell polarization data were obtained at 1000°C using the Kordesch-Marko interrupter. The electrolyte used for obtaining polarization data contained 87 w/o cryolite, 8% CaF_2 + 5% alumina. The cell resistance at 1000 cycles was 0.2-0.3 ohm for the cells discussed in this section of the report. The resistance-free polarization curves for AGKSP, pyrolytic graphite; L113 SP carbon; 50% TiB_2-50% BN; copper; and nickel are summarized in Fig. 3.

The data in Fig. 3 suggest that Cu and Ni have greater stability (less anodic current at corresponding potentials) than carbon and graphites.

Three copper-nickel alloy compositions ranging from 25 to 75% Cu were also tested. These had stabilities which were in between Cu (greatest stability) and nickel. Cu and Ni form solid solutions which range in melting temperatures from 1083° (pure Cu) to 1456°C (pure nickel). Carbon and graphite on the other hand were much more stable than pure TiB_2 or TiB_2-BN composites.

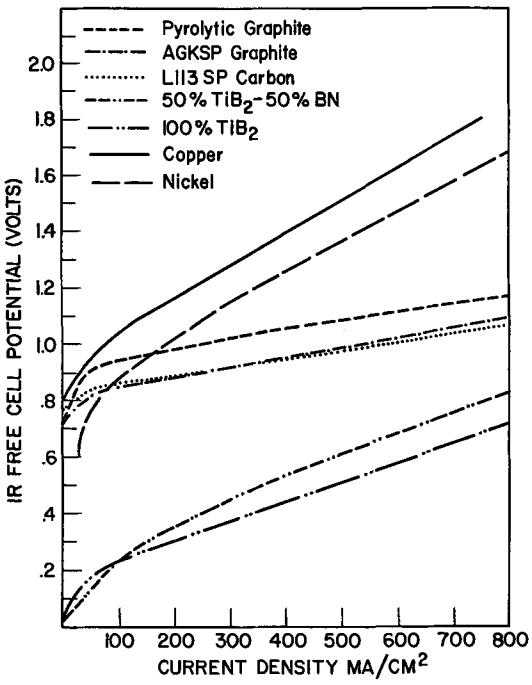

Fig. 3. Anodic polarization data for solid electrode materials

Tables I and II illustrate how polarization data were tabulated and results are given for AGKSP graphite and 50% TiB_2-50% BN, respectively. As seen in the tables, the difference between *IR*-free and *IR*-included cell voltage readings is used to determine the apparent cell resistance. This resistance always decreased with increasing currents until a steady value of about 0.2 ohm was obtained when carbon and graphite anodes were used.

The decrease in cell resistance with increasing cell voltage was not noted with materials other than carbon. This suggests that a resistive film is formed with carbon which tends to break up at high currents where significant gas evolution occurs. With materials other than carbon, either this film does not form or gas evolution occurs sooner (lower overvoltage).

Table I. Cell polarization data in ¼-in. AGKSP rod obtained with 60-cycle interrupter. Electrolyte temperature 1000°C. Electrode area 9.5 cm²

Current mA	Current potential (volts) *IR* free	*IR* incl.	ΔV *IR* incl.-*IR* free mV	Apparent resistance (ohms)
100	0.708	0.828	120	1.20
200	0.782	0.896	114	0.57
400	0.808	1.008	200	0.50
500	0.812	1.028	216	0.43
1000	0.834	1.161	327	0.33
2000	0.876	1.354	478	0 24
4000	0.928	1.820	992	0 25
6000	1.028	2.340	1212	0.20
10000	1.121	3.230	2109	0.21

Table II. Cell polarization data on ¼-in. rod of 50% TiB_2-50% BN. Electrode area = 9.5 cm²

Current mA	Current potential (volts) *IR* free	*IR* incl.	ΔV *IR* incl.-*IR* free mV	Apparent resistance (ohms)
100	0.045	0.066	21	0.21
200	0.073	0.112	39	0.20
300	0.096	0.156	60	0.20
500	0.152	0.251	99	0.20
750	0.188	0.350	162	0.22
1000	0.232	0.451	219	0.22
1500	0.278	0.566	288	0.19
2000	0.356	0.724	368	0.18
3000	0.460	1.040	580	0.19
5000	0.600	1.595	995	0.19
7000	0.760	2.20	1440	0.20
10000	0.890	2.98	2090	0.21

Cell resistance measured with an a-c bridge at 1000 cycles was 0.2 ohm which was about the same as the cell resistance calculated using the interrupter.

Sweep studies on nonporous materials.—All sweep experiments were run at potentials positive to the Pt-Al reference electrode already described. The potential of this reference was approximately 50 mV positive to the rest potential of the ATJ graphite cathode in an electrolyte containing 78 w/o cryolite, 7% CaF_2, and 15% alumina (saturated) (8). Reproductions of the sweep traces for Cu, Ni, AGKSP and pyrolytic graphite, L113-SP carbon, 50% TiB_2-50% BN, and silicon are summarized in Fig. 4. Except for a short range at low currents, the current-potential relationship was linear. It is this linear portion that is shown here extended to zero current. Only forward scans are shown, but in every case reverse scans were also run. These were virtually mirror images of the forward scans. The potentials were not corrected for resistance in Fig. 4, but the same geometric arrangement already described was used for each test. The scan rate was always 20 min for both the 0-1.0 and 0-2.0v scans. To verify that the system and refractory electrode were operating properly, a sweep on a new material was followed by a sweep on AGKSP graphite. The anode area immersed in electrolyte was close to 8 cm² for all the sweeps summarized in Fig. 4.

The potential sweep data show Cu as the most stable material, which is in agreement with the polarization studies. Intermediate in stability are Ni and graphite. Titanium diboride-BN and silicon were the least stable of the materials tested.

Data from potential sweep traces of six refractory borides and carbides are shown in Fig. 5. A potential sweep on AGKSP graphite was included for comparison. The anode area immersed in the electrolyte was

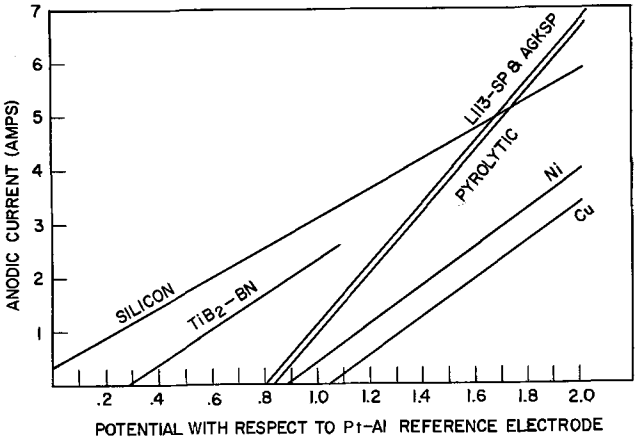

Fig. 4. Potential sweep data on various anode materials

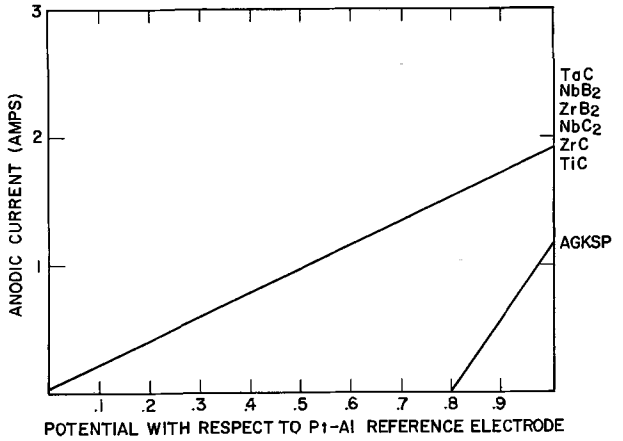

Fig. 5. Potential sweep data on refractory borides, carbides, and AGKSP graphite.

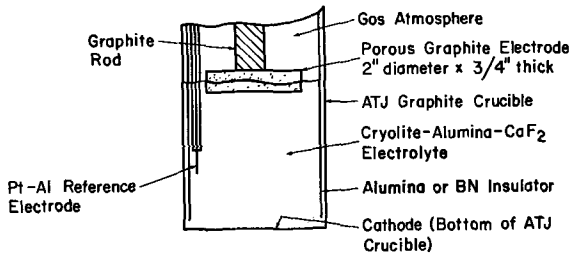

Fig. 6. Horizontal, porous gas depolarized anode

12-15 cm^2 for all six refractory materials tested. The refractory borides and carbides all had about the same resistance to anodic oxidation and this was far less than that of carbon and graphite.

Thus, the materials investigation to find something more stable than carbon as an anode material was only partially successful. While nickel and especially copper appear somewhat more stable, they are not immune from attack at the high current densities required. Porous electrodes for gas depolarization were, therefore, limited to carbon in this investigation to avoid possible contamination of aluminum product.

Results using porous, gas depolarized electrodes.— Two types of "flow-through" porous carbon electrodes were tried as gas depolarized electrodes. These were porous cylindrical electrodes and porous plug electrodes. No significant evidence of gas depolarization was observed for the four anodes run. The only porous electrodes that showed significant evidence of gas depolarization were the nonflow-through, horizontal ones.

These latter electrodes were operated as gas depolarized anodes in cryolite-CaF_2-alumina melts at 1000°C. The porous anode base materials used were PG-60 and PG-25 graphites which were impregnated with various salt solutions or run uncatalyzed. A sketch of the main cell components is shown in Fig. 6.

Table III summarizes the polarization data obtained when the gas atmosphere above the cell was changed as indicated. The electrode used was a PG-60 electrode catalyzed with 0.1% by weight of salts of platinum group metals. The reference electrode used was Pt-Al alloy, previously described.

Gases were alternated as shown in Table III and results were obtained on successive gasses within about 10 min. The higher currents at comparable polarizations in the presence of hydrogen and natural gas as compared with argon strongly suggest that the former gases depolarize the electrode. Similar depolarization experiments were conducted several times and verified both the gas depolarization of hydrogen and natural gas and the relative inactivity of the argon. Under the argon atmosphere, virtually all the anodic current is assumed to come from carbon utilization. A 254 A-hr experiment carried out under argon yielded an anode efficiency for carbon utilization of 98.4%.

To determine whether gas depolarization was possible without catalyst and to avoid possible catalysis by metal present as impurities, an anode was made of powders from AGKSP spectrographic graphite. The total metal content of the spectrographic rod was approximately 1 ppm. The *IR*-free cell voltage *vs.* time at a constant current of 2A while alternating the gas atmosphere between argon and natural gas is given in Table IV. The results suggest that gas depolarization has occurred, although the differences in cell voltage between argon and natural gas atmospheres settled down to only 20 mV.

Table III. Polarization data under various gas atmospheres using a catalyzed anode

Gas atmosphere above cell	Anode-reference potential (volts)	Current (mA)
Hydrogen	0.15	4000
Argon	0.17	500
Hydrogen	0.163	4000
Natural gas (92.7% methane)	0.19	2000
Hydrogen	0.15	2000
Argon	0.185	500

Table IV. Gas depolarization on an uncatalyzed electrode made of AGKSP graphite

Gas atmosphere	Cell potential (volts, *IR* free)	Time (minutes)
Argon	0.94	0
Natural gas	0.82	14
Natural gas	0.82	22
Argon	0.92	46
Argon	0.92	61
Natural gas	0.90	73
Natural gas	0.90	83
Argon	0.92	93

Table V. Gas depolarization on heavily catalyzed anode

Gas atmosphere	Cell potential (volts, *IR* free)	Time (minutes)
Argon	0.80	0
Carbon monoxide	0.74	10
Argon	0.80	20
Carbon monoxide	0.75	30
Argon	0.80	40

On heavily catalyzed electrodes with a highly developed gas-electrolyte interface, it is possible to observe gas depolarization by carbon monoxide. Table V summarizes the results obtained by alternating the gas atmosphere and comparing the cell potential at a constant current of 4A. The level of catalysis was 1% of salts from the platinum group metals. Carbon monoxide initially shows a very marked gas depolarization. However, the catalyst was not stable and was lost from the anode, even though the cell was left on open circuit in between measurements to slow down catalyst losses. After this happened carbon monoxide and argon gave the same polarization data.

Analytical results were obtained in two experiments which were run under a natural gas atmosphere using uncatalyzed graphite anodes for 167 and 533 A-hr, respectively. In these, and all other experiments under natural gas, a considerable quantity of a voluminous, white substance was condensed on the cell cover and cooler parts of the cell. The electrolyte analysis before and after a run and the condensate analysis for the 167 and 533 A-hr runs are given in Tables VI and VII.

It seems that the condensate has a high percentage of fluoride and contains a relatively low percentage of the principal metallic cations. It is probably a complex mixture of carbon-fluorine compounds, although this has not been verified by analytical results. The aluminum content of the electrolyte at the end of the

Table VI. Analytical results—167 A-hr run

	Weight per cent				
	Na	Al	Ca	F	O
Initial composition of electrolyte	26.9	14.7	6.49	50.0	3.68
Composition of condensed vapor	1.6	0.2	0.97	51.6	7.53
Final composition of electrolyte	15.7	20.85	5.50	37.6	9.41

Table VII. Analytical results—533 A-hr run

	Weight per cent				
	Na	Al	Ca	F	O
Initial composition of electrolyte	25.3	15.2	4.3	50.0	3.02
Composition of condensed vapors	4.0	5.8	0.4	58.6	1.12
Final composition of electrolyte	18.4	23.9	2.4	39.2	12.80

experiment is high because of Al_2O_3 additions and dispersions of Al product in the electrolyte.

Conclusion

The materials investigation did not result in a material that was significantly more resistant to attack than graphite at anodic potentials normally attained in aluminum electrowinning. Two metals, copper and nickel, however, exhibited stability comparable to graphite.

Through the use of porous graphite electrodes, this investigation has demonstrated that gas depolarization for aluminum electrowinning is possible with hydrogen or natural gas (~93% methane). Natural gas may be electrochemically equivalent to hydrogen since considerable thermal decomposition occurs at these temperatures. Carbon monoxide was far less reactive than hydrogen. While depolarization by hydrogen and methane occurred without added catalyst, carbon monoxide depolarization was accomplished only in the presence of active catalysts. Unfortunately, these catalysts were stripped from the anode even at moderate current densities.

There are serious fluoride losses from the electrolyte when hydrogen-containing fuels are used, due to reactions of the water product with the fluoride electrolyte. A quantitative determination of the rate of this deleterious reaction has not been made.

Technical Notes

Effects of Gamma Radiation on the Behavior of Nickel and Cadmium Electrodes[1]

G. R. Argue[2,*] and H. L. Recht*

Atomics International, A Division of North American Aviation, Incorporated, Canoga Park, California

and G. M. Arcand[3]

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

A number of workers have reported studies in which alkaline batteries were exposed to gamma radiation (1-3) and have stated that doses as high as 10^8 rads produced no discernable effects. However, Ho's data (3) showed that nickel-cadmium batteries lost about 10% of their capacity when irradiated in a nuclear reactor. This loss fell within the requirements for his particular work. In no instance previous to the present work have alkaline battery electrodes been studied as entities in experimental cells. Many of the materials (separators, cases, *etc.*) in a complete battery are known to be degraded by nuclear radiation. The present work was undertaken to study the effects of radiation on the electrodes in alkaline solutions without the possible interferences of these other materials.

Experimental

Materials.—All electrodes were obtained from Gulton Industries, Incorporated, nickel-cadmium type VO-0.8 cells. Each cell contained three cadmium electrodes and two nickel electrodes. The electrodes were 4.2 x 3.8 cm with capacities of 0.4 amp-hr for nickel and 0.5 amp-hr for cadmium. Each electrode weighed about 5g. Before disassembly, the cells were fully charged according to the manufacturer's specifications.

Thirty weight per cent KOH solutions, used in all experiments reported here, were freshly prepared from reagent-grade pellets as required.

Equipment.—High-rate irradiation (1.4 x 10^6 rad/hr)[4] was provided by an Atomic Energy of Canada Gammacell Model GC 200 Co^{60} source, low rate irradiation (8 x 10^4 rad/hr) by a 3300-curie unit built by Atomic International (4). Harrison Lab Model 855 power supplies provided constant currents. Data were recorded on Minneapolis-Honeywell Universal 5 mV instruments. Timers were Kelelet Model K213 and Industrial Time Kit MCK. Self Organizing Systems Model SV100 solions indicated state of charge. Pressures were measured with CEC Model 316 transducers having ranges of ±12.5 psig or 0-15 psig. All other control and measuring equipment was constructed by Atomics International.

Cell design.—The cell consisted of a quartz cup mounted in a sealable, stainless-steel container. The

* Electrochemical Society Active Member.

[4] Radiation dosage is based on the absorption of gamma radiation by water.

cup was divided into two compartments by a partition containing a sintered-quartz disk to maintain electrolytic contact between electrodes. Tabs fused to the cup walls held the electrodes firmly against the disk. The cell was filled with 50 ml of electrolyte solution. Each pair of experimental cells was made with electrodes taken from a single commercial cell. A Hg/HgO reference electrode was installed inside the stainless-steel container.

Procedure.—A current of 0.2A permitted operation of experimental cells through many cycles within a reasonable time without damaging the electrodes. After assembly with formed electrodes, each cell was discharged until the voltage began an abrupt and rapid decrease. This point will be called the "knee" of the voltage-time curve. The cell was then charged to the equivalent of 25% overcharge, discharged to some arbitrary state of charge (*e.g.*, 75% of full charge), and cycled for 24 hr. Each cycle consisted of 6 min of discharge, 4 min of open circuit, 6 min of charge and 4 min of open circuit. Current was controlled at 0.2A. All cells were so treated before being placed in the radiation source or controlled-temperature bath.

Operation of a pair of matched cells constituted one experiment. The equilibrium temperature within the high-rate Co^{60} source was measured to be 45°C; therefore, the water-bath temperature was set at that value. In every experiment, the behavior of the irradiated cell was compared with that of the matching cell in the water bath. Irradiation was continued until the desired dose was obtained. Doses ranged from 10^5 to 2×10^8 rads at rates depending on the Co^{60} source used.

Changes in cadmium electrode capacity were determined in cells that were cadmium limited; *i.e.*, the capacity of the cadmium electrode was less than that of the nickel electrode. About one third of the commercial cadmium plate was cut off for this purpose. Each cell was fully charged and discharged to the knee of the voltage-time curve several times at room temperature before the experiment; the average discharge times were used to determine the initial capacity. This was repeated after the experiment. The difference was taken as the change in capacity.

Results and Discussion

Electrode material loss.—Electrodes lost weighable amounts of material (>0.2 mg) whenever the total radiation dose was 5.8×10^6 rads or more. Visual indication of disintegration, appearing as a turbidity in the electrolyte solution, began at 1.4×10^6 rads. Losses in comparison cells in the water bath were negligible.

Figure 1 shows the relationship between material loss and total irradiation dose when the cells were cycled around 75% of full charge. The weights shown are total amounts lost from both electrodes. Although the data are scattered, the increased loss with increased dose is evident. Data for both low- and high-dose rates are included; there was no indication of a rate effect. The results in Table I show that most of the loss occurs at the cadmium electrode. Both electrodes, particularly the nickel, lose considerably more material when cycled at 100% of full charge than at any other state.

It is not surprising that material is physically removed from the electrodes, although one might expect both the nickel and the cadmium electrodes to behave similarly. Gas is evolved during irradiation, much of which may be catalytically formed at the solid-solution interfaces of the electrodes. Bubbles may be produced within the pores of the electrodes loosening or dislodging material. The shedding process would be accelerated when the cell is cycled because the $Cd(OH)_2$ formed would adhere to the plate less strongly than the metal. The effect of the presence of the electrodes on the rate of gas formation is shown in Table II.

The losses would be aggravated when the cell is cycled around 100% of full charge because electrochemical formation of gas would occur during the short periods of overcharge. At lower states of charge, the major electrochemical reaction probably occurs within the body of the plate so that much of the dislodged material is retained.

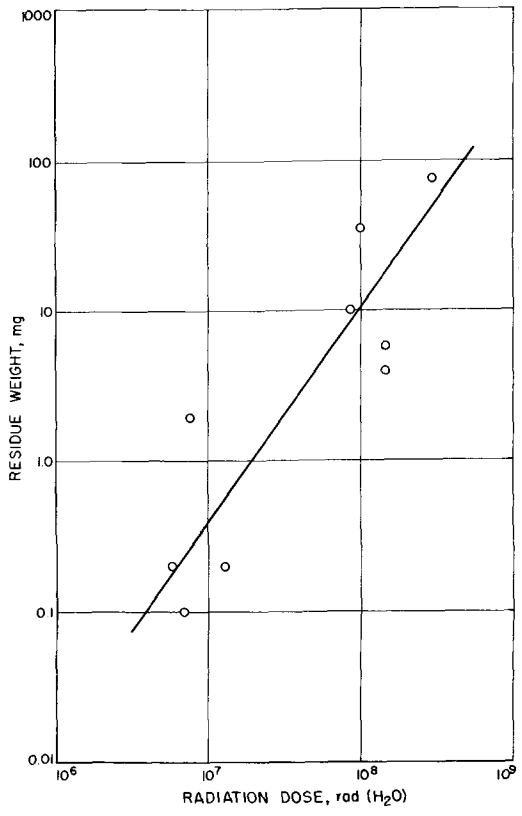

Fig. 1. Effect of radiation dose on electrode material loss

Capacity change.—Cadmium electrodes lost capacity when cycled during irradiations of 8×10^7 rads or more. Figure 2 represents the effects observed when the cells were cycled in the vicinity of preselected, initial state of charge. The solid line shows the difference in capacity between the irradiated and comparison cells and is considered the significant curve. The difference is quite constant except at 75% of full charge where the loss is greater. While data scatter is considerable, results of repeated experiments show the effects to be real.

Table I. Material loss from individual cycled electrodes during irradiation

No. of experiments	State of charge (%)	Cd electrode Weight loss (mg)	Cd electrode Standard deviation	Ni electrode Weight loss (mg)	Ni electrode Standard deviation
3	100	28.9	9.0	8.0	6.2
2	75	21.5	13.6	2.2	0.3
3	50	11.1	1.3	1.5	1.7
2	25	10.7	2.0	2.2	1.1

Total dose = 8×10^7 rads.

Table II. Gas formation in KOH solutions in presence of electrodes

Electrode	$G_{(H_2)}$	$G_{(O_2)}$
Ni	0.009	0.052
Cd	0.025	0

G = number of molecules of gas produced per 100 eV of gamma energy deposited in the sample.
Dose = 6.6×10^7 rads.
Cover gas is He.

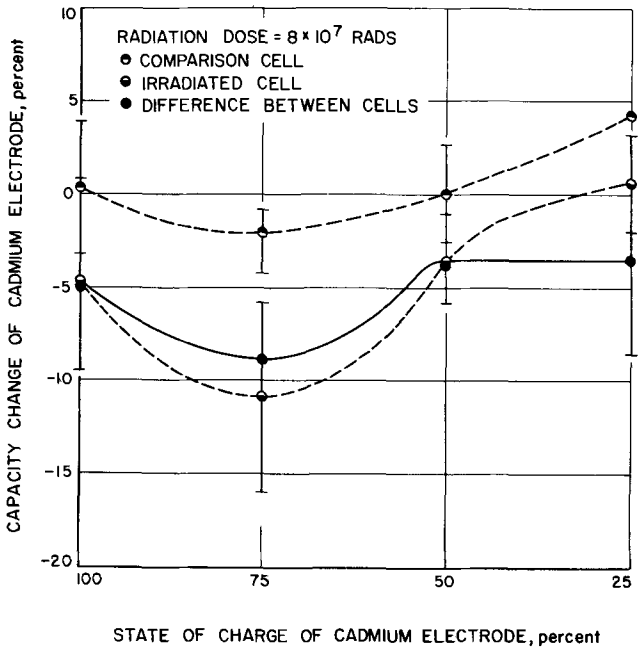

Fig. 2. Effect of radiation on capacity of cycled cadmium electrodes

Capacity losses were observed only when the cells were cycled; a few open-circuit experiments were performed at 75% of full charge with no loss observed. It is assumed that no open-circuit loss would be observed at other states of charge at the radiation doses used.

The effects of gas evolution may partly explain the permanent loss of cadmium electrode capacity. If the combination of gas formation and cycling causes a decrease in adhesion of active material, it may also result in poor electronic contact with the metallic collector so that some of the material is no longer available for electrochemical use. Certainly, the material loss cannot account for the capacity change. Whatever the mechanisms involved, they seem to occur whether or not the system is exposed to radiation; the radiation merely accentuates the effect.

Correction Factors for a Two-Point Probe Resistivity Measurement of Cylindrical Crystals

Helen H. Gegenwarth

International Business Machines Corporation, Components Division, East Fishkill Facility, Hopewell Junction, New York

Consider a conducting cylinder of radius C and length $2a$ with electrodes placed at each end, through which a current, I, flows (*see* Fig. 1). Two probes may be placed on the cylindrical surface and the potential difference between them measured.

Measurement

The potential at any point in the cylinder ($r \neq 0$) is (1)

$$V(r,z) = \frac{I\rho}{\pi a}\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2} \sin\frac{n\pi z}{2} \frac{K_1\left(\frac{n\pi C}{2a}\right)I_0\left(\frac{n\pi r}{2a}\right) + I_1\left(\frac{n\pi C}{2a}\right)K_0\left(\frac{n\pi r}{2a}\right)}{I_1\left(\frac{n\pi C}{2a}\right)}$$

where

I = current through cylinder
ρ = resistivity of cylinder
$2a$ = length of cylinder
C = radius of cylinder
I_n = modified Bessel function of the first kind
K_n = modified Bessel function of the second kind

The potential difference between the probes is then

$$\Delta V = V(C,D) - V(C,E)$$

Using the relation

$$K_{n+1}(x)I_n + K_n(x)I_{n+1}(x) = \frac{1}{x}$$

ΔV then simplifies to

$$\Delta V = \frac{I\rho}{\pi a}\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2}\left(\sin\frac{n\pi D}{2a} - \sin\frac{n\pi E}{2a}\right)\left(\frac{2a}{n\pi C}\right)\left(\frac{1}{I_1\left(\frac{n\pi C}{2a}\right)}\right)$$

or

$$\Delta V = \frac{4I\rho}{\pi^2 C}\left[\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2}\cos\frac{n\pi(D+E)}{4a} \sin\frac{n\pi(D-E)}{4a}\frac{1}{nI_1\left(\frac{n\pi C}{2a}\right)}\right]$$

Calling the expression in brackets F,

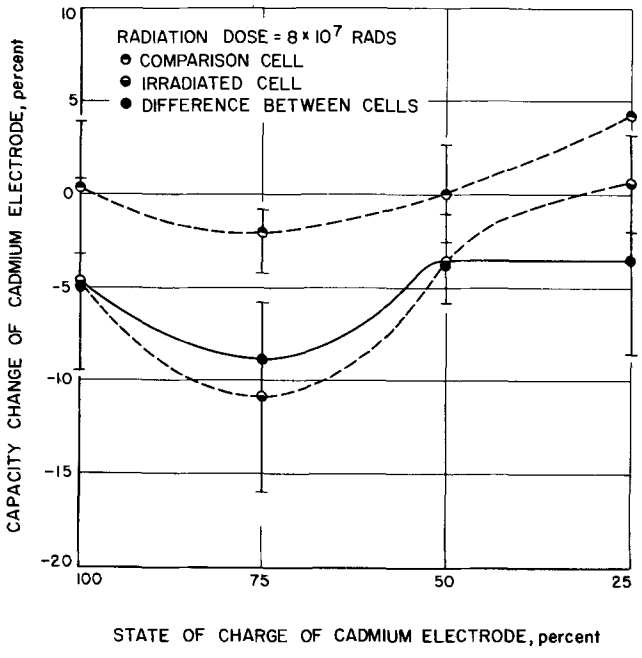

Fig. 2. Effect of radiation on capacity of cycled cadmium electrodes

Capacity losses were observed only when the cells were cycled; a few open-circuit experiments were performed at 75% of full charge with no loss observed. It is assumed that no open-circuit loss would be observed at other states of charge at the radiation doses used.

The effects of gas evolution may partly explain the permanent loss of cadmium electrode capacity. If the combination of gas formation and cycling causes a decrease in adhesion of active material, it may also result in poor electronic contact with the metallic collector so that some of the material is no longer available for electrochemical use. Certainly, the material loss cannot account for the capacity change. Whatever the mechanisms involved, they seem to occur whether or not the system is exposed to radiation; the radiation merely accentuates the effect.

Correction Factors for a Two-Point Probe Resistivity Measurement of Cylindrical Crystals

Helen H. Gegenwarth

International Business Machines Corporation, Components Division, East Fishkill Facility, Hopewell Junction, New York

Consider a conducting cylinder of radius C and length $2a$ with electrodes placed at each end, through which a current, I, flows (*see* Fig. 1). Two probes may be placed on the cylindrical surface and the potential difference between them measured.

Measurement

The potential at any point in the cylinder ($r \neq 0$) is (1)

$$V(r,z) = \frac{I\rho}{\pi a}\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2} \sin\frac{n\pi z}{2} \frac{K_1\left(\frac{n\pi C}{2a}\right)I_0\left(\frac{n\pi r}{2a}\right) + I_1\left(\frac{n\pi C}{2a}\right)K_0\left(\frac{n\pi r}{2a}\right)}{I_1\left(\frac{n\pi C}{2a}\right)}$$

where

I = current through cylinder
ρ = resistivity of cylinder
$2a$ = length of cylinder
C = radius of cylinder
I_n = modified Bessel function of the first kind
K_n = modified Bessel function of the second kind

The potential difference between the probes is then

$$\Delta V = V(C,D) - V(C,E)$$

Using the relation

$$K_{n+1}(x)I_n + K_n(x)I_{n+1}(x) = \frac{1}{x}$$

ΔV then simplifies to

$$\Delta V = \frac{I\rho}{\pi a}\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2}\left(\sin\frac{n\pi D}{2a} - \sin\frac{n\pi E}{2a}\right)\left(\frac{2a}{n\pi C}\right)\left(\frac{1}{I_1\left(\frac{n\pi C}{2a}\right)}\right)$$

or

$$\Delta V = \frac{4I\rho}{\pi^2 C}\left[\sum_{1}^{\infty}{}' \sin\frac{n\pi}{2}\cos\frac{n\pi(D+E)}{4a} \sin\frac{n\pi(D-E)}{4a}\frac{1}{nI_1\left(\frac{n\pi C}{2a}\right)}\right]$$

Calling the expression in brackets F,

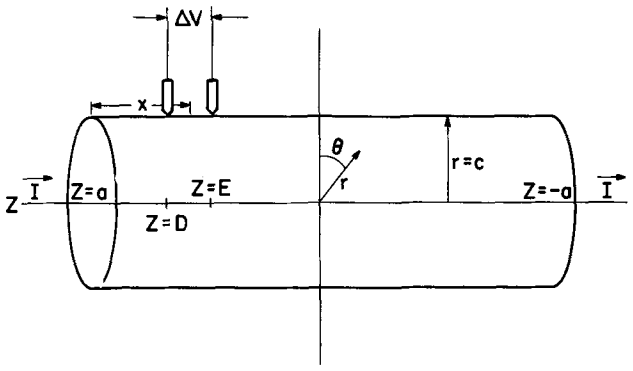

Fig. 1. Conducting cylinder through which a current flows

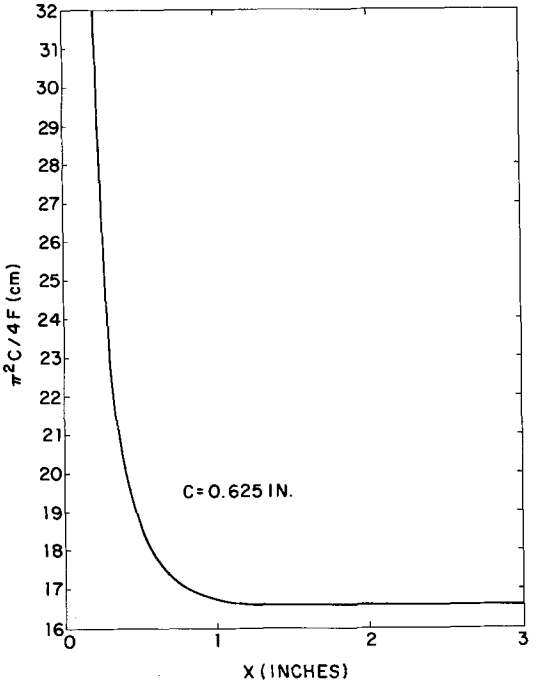

Fig. 2. Correction factor calculated for C = 0.625 in.

$$\Delta V = \frac{4I\rho F}{\pi^2 C}$$

or

$$\rho = \frac{\pi^2 C}{4F} \cdot \frac{\Delta V}{I}$$

Limiting Case

If the probes are placed symmetrically about the plane Z = 0,

$$\rho = \frac{\pi^2 C}{4F} \frac{\Delta V}{I}$$

should yield the same result as the case where the electrodes supplying the current I are disk contacts of the same diameter as the cylinder. In that case,

$$\rho = \frac{\pi C^2}{(D-E)} \frac{\Delta V}{I}$$

That is,

$$\lim_{(D+E)\to 0} \frac{\pi(D-E)}{4C} = F$$

Computer calculations of F verify that this is exactly true.

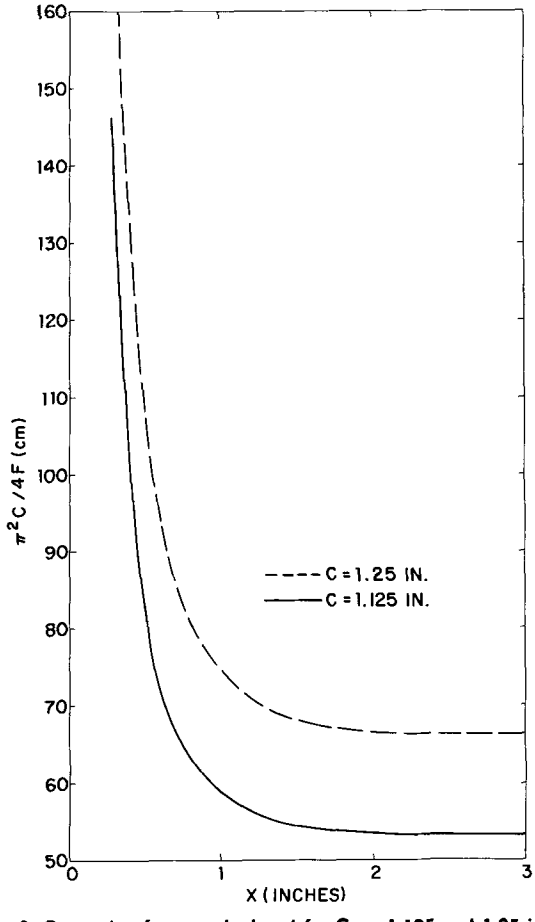

Fig. 3. Correction factor calculated for C = 1.125 and 1.25 in.

The correction factor, $\pi^2 C/4F$, has been calculated for several cases of particular interest. The results are given in Fig. 2 and 3. In each case, the quantity $(D-E)$, which is the probe spacing, is taken as 0.1878 in., and the correction factor is plotted against x, the average distance of the probes from the end of the cylinder (see Fig. 1).

Conclusions

The procedure for determining the resistivity along the length of a cylinder would be to place current probes at each end of the cylinder and measure ΔV between two travelling probes spaced a distance $(D-E)$ from each other. The resistivity at any given position is then calculated from

$$\rho = \frac{\pi^2 C}{4F} \cdot \frac{\Delta V}{I}$$

where the appropriate F is determined by X, the average distance of the probes from the end of the cylinder.

A Review of the Application of Stainless Steels in Desalination Equipment

E. H. Phelps,* R. T. Jones, and H. P. Leckie

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

The corrosion performance of various types of stainless steels is discussed for the variety of environments associated with distillation-type sea-water desalination plants. Several factors related to the design and operation of desalination equipment can have important bearing on the corrosion performance of the stainless steels. The most important of these are flow rate, presence of crevices, deposit formation, temperature, and oxygen content. The performance of present-day steels has been evaluated by full-scale plant tests and also by specimen-exposure tests. For the future, electrochemical procedures will help to explain the corrosion behavior of stainless steels in high-temperature water and offer a means for evaluating new steel compositions with improved corrosion resistance.

It is the purpose of this paper to present a review of the performance of stainless steels in desalination plants, with particular emphasis on distillation-type equipment. Over the years, a large amount of data has been collected on the corrosion performance of the stainless steels in salt water and brackish water (1). These data show that stainless steels have good resistance to corrosion in these waters at temperatures near ambient, provided that crevices and deposits which might lead to oxygen concentration cells can be avoided. Experience has shown that good performance can be obtained in sea water by maintaining flow rates above about 5 fps (this minimizes build-up of marine organisms and other deposits) and by eliminating crevices in equipment design. Thus, on the basis of past experiences, the stainless steels should be considered as promising candidate materials for desalination equipment that operates at temperatures near ambient and in which moderate flow rates are maintained.

At elevated temperatures, however, such as those characteristic of distillation-type desalination plants, the availability of specific service data is much more limited and was practically nonexistent prior to the construction of the demonstration plants by the Office of Saline Water at Freeport, Texas, and San Diego, California. The environmental conditions in such plants, consisting of hot water with relatively high concentrations of chloride, would generally be considered detrimental to the stainless steels, particularly with reference to localized forms of attack such as pitting and stress-corrosion cracking. Contrary to these expectations, however, corrosion tests in the plants themselves have shown that certain stainless steels are capable of resisting attack if the oxygen content in the water is sufficiently low. This paper reviews the types of stainless steels that might be considered for desalination plants and the service data that have been obtained with some of the steels in the demonstration distillation plants. The electrochemical principles involved in hot sea-water corrosion are also discussed.

* Electrochemical Society Active Member Representative of a Sustaining Member Company.

Types of Stainless Steel

There are many specific types of stainless steel currently produced in this country. The American Iron and Steel Institute (AISI) lists 39 standard types, some of which are listed in Table I. In addition to these, there are many "nonstandard" grades. However, the standard grades and most of the nonstandard grades can be grouped into the following three main categories, on the basis of alloy content and crystallographic differences:

1. Martensitic, typified by AISI Type 410 (12% Cr). These steels are hardenable by heat treatment, and in the heat-treated condition have a body-centered tetragonal crystal structure (martensite).
2. Ferritic, typified by AISI Type 430 (17% Cr). These steels are not hardenable by heat treatment. The crystal structure is body-centered cubic (ferrite).
3. Austenitic, typified by AISI Type 304 (18% Cr, 8% Ni). These steels are also not hardenable by heat

Table I. Compositions of several standard grades of stainless steel

AISI Type	Nominal composition, per cent C	Mn, max	Si, max	Cr	Ni	Other
			Martensitic steels			
502	0.10 max	1.00	1.00	4.0-6.0	—	0.40-0.65 Mo

316L	0.03 max	2.00	1.00	16.0-18.0	10.0-14.0	2.0-3.0 Mo
317	0.08 max	2.00	1.00	18.0-20.0	11.0-15.0	3.0-4.0 Mo
321	0.08 max	2.00	1.00	17.0-19.0	9.0-12.0	5xC min Ti
347	0.08 max	2.00	1.00	17.0-19.0	9.0-13.0	10xC min Cb-Ta

treatment. The crystal structure is face-centered cubic (austenite).

As a general rule, the inherent corrosion resistance of the stainless steels increases with increasing chromium content. Thus the steels with higher chromium content (18% and above) are generally of more interest for use in desalination equipment than steels with lower chromium content. The addition of 8% or more nickel to stainless results in the austenitic steels, which have very desirable fabricating characteristics. The addition of molybdenum in the Type 316 steels brings about a substantial improvement in resistance to pitting corrosion. The addition of titanium and columbium in the stabilized grades, Types 321 and 347, respectively, is intended to prevent grain boundary carbide precipitation and intergranular attack in environments causing this form of corrosion. Resistance to intergranular corrosion may also be obtained by restricting the carbon content of the steel to 0.03% maximum, as in Types 304L and 316L.

Field Corrosion Tests

Most of the field tests at the Freeport, Texas, and San Diego, California, demonstration plants have consisted of the installation of racks containing corrosion coupons in various process equipment of the two plants (2-4). Types 304 and 316 stainless steel tubes have also been tested in the first evaporator effect of the Freeport plant (4) to obtain corrosion data under actual service conditions. Although it is recognized that all of these tests were conducted under the inherently changeable process conditions associated with a production plant, the results obtained have aided in identifying the most important environmental factors governing the corrosion resistance of stainless steels in hot sea water. These are (a) dissolved oxygen concentration, (b) temperature, and (c) velocity of the sea water. The latter two factors are largely responsible for the extent to which solids are deposited from the sea water and, consequently, these factors govern the extent to which crevices are formed on the surface of stainless steels.

Dissolved oxygen concentration.—Data compiled from coupon tests conducted at the Freeport and San Diego desalination plants are presented in Tables II, III, and IV. These data indicate that localized penetration in stainless steels is substantially inhibited when the dissolved oxygen content is kept at a very low level. At Freeport, mechanical deaeration, which reduced the dissolved oxygen to 40-600 ppb (parts per billion), was not sufficiently complete to prevent pitting and/or crevice corrosion in the stainless steels tested (Table II). However, with essentially complete removal of the dissolved oxygen by evaporation (Table III), the depth of pitting and crevice corrosion was definitely less than that observed in the mechanically deaerated water (bottom portion of Table II). In this respect, it also is noteworthy that the amount of pitting and crevice corrosion was very low (or nonexistent) in deaerated brine at San Diego (Table IV), where efficient mechanical deaeration reduced the oxygen content to a low level of 5 ppb. The inhibiting effect of complete deaeration on pitting of stainless steels has also been obtained in pilot plant tests, Table V (3). It is apparent that localized corrosion of stainless steels was substantially prevented by complete removal of the dissolved oxygen in the sea water.

Temperature.—Increasing the temperature of sea water appears to increase somewhat the severity of pitting in stainless steels, as is shown from data in

Table II. Summary of corrosion coupon tests in raw and deaerated sea water—Freeport desalination plant

Average temperature, °F	Exposure period, days	Maximum penetration, mils: Surface Type 304	Surface Type 316	Crevice[a] Type 304	Crevice[a] Type 316

[c] Test pressure, 100 psi.
* Severe crevice attack beneath insulation washers.

Tables II, III, and IV. The effect of temperature, however, appears to be diminished if the sea water is raw or completely deaerated. This effect may, in the case of the plant coupon tests, be influenced by the amount of dissolved solids deposited from the sea water onto the coupon surfaces. An apparent interrelationship between dissolved oxygen, sea-water temperature, and dissolved solids deposited from the sea water is further indicated by the tests conducted with Type 304 stainless steel evaporator tubes at the Freeport plant (4). Data shown graphically in Fig. 1 represent the maximum pit depths measured on representative sections of the stainless-steel tubes after the tubes had been in service for various periods of time. The first effect of the long-tube-vertical evaporator system at Freeport receives hot sea water that has been deaerated to less than 100 ppb of dissolved oxygen. The sea water flows in a thin film down the tubes and heat passed through the tubes evaporates water from the film. As indicated in Fig. 1, during the first 12-15 months of service, the tubes were exposed to sea water at an average of 230°-235°F. However, the temperature was subsequently elevated to as high as 270°F during periods through the 25th month of service. As the graph shows, the depth of pitting in the top and middle tube sections increased when the evaporating temperature increased. However, the depth of pitting near the tube bottom appeared to be nearly independent of the temperature increase. It was noted during inspection that the inside surface of the top and middle sections of the tubes was consistently covered with scale deposit from the sea water, whereas the sections near the bottom of the tube remained nearly deposit-free. Furthermore, dissolved oxygen remaining in the deaerated sea water entering the first effect was being stripped from the sea water during initiation of boiling (evaporation) near the top of the tubes. Consequently, the sea water near the bottom of the tube was free of dissolved oxygen. It was postulated that the low rate of pitting and the independence of pitting rate with temperature change observed near the tube bottom were due to the deposit-free surface and low dissolved oxygen in the brine. The same type of pit inhibition has been observed by Russian investigators (5) in their studies utilizing experimental- and industrial-size long-tube-vertical evaporators.

Sea water velocity.—As mentioned previously, it is known that stainless steels are suitable for process equipment handling sea water at temperatures near ambient if the velocity is maintained above about 5 fps (6). At higher velocities, the deposition of solids onto stainless-steel surfaces is minimized, thereby reducing the number of crevice sites. The literature

* Coupon perforated, original thickness—0.039 in.
[a] Environmental conditions—raw sea water saturated with oxygen; brine concentration factor, 0.8-1.1; pH, 7.5-7.8.

indicates that stainless steels, particularly Type 316, are being successfully used for pump components (7,8) and for heat transfer tubes of steam condensers (9) in which sea water is the coolant. The results of tests on the effect of velocity in a desalination plant are shown in Table VI. Pitting and crevice attack were considerably less severe on stainless-steel coupons exposed at locations where turbulence was moderate to high (sea water impinged on the test coupons) than the attack on coupons exposed to low-velocity conditions.

Other environmental factors.—Other environmental factors of concern when stainless steel is used in hot sea water are sea water concentration (salinity or concentration factor) and hydrogen ion concentration (*p*H). With respect to salinity, the nature of the desalting processes at plants in which field tests have been conducted thus far has made it difficult to determine the single effect of salinity on the corrosion of stainless steels. Generally, other environmental factors, such as dissolved oxygen and/or temperature, have overshadowed the relatively small effects that might be expected with a change in salinity.

In regard to the effect of sea water *p*H, there are essentially no data available from the field tests in the demonstration desalination plants because the sea water in these plants is maintained nearly neutral except during the acidification operation which is utilized to remove carbonate-forming constituents. Plant operating experience has shown, however, that Type 316 stainless performs satisfactorily in deaeration equipment handling acidulated sea water at *p*H values as low as four.

Effect of steel composition on pit resistance in sea water.—Data from coupon tests at the Freeport Plant have shown that, regardless of the environmental conditions, the chromium stainless steels (Type 410 and 430) exhibit substantially less resistance to corrosion than the austenitic stainless steels (4). Corrosion of the chromium stainless steels was primarily the result of severe crevice corrosion initiated by solids that deposited from the sea water. The sensitivity of chromium stainless steels to crevice corrosion would probably eliminate them from consideration unless strict control of solids deposition could be assured.

A comparison of the effect of molybdenum on the pit resistance of austenitic stainless steels, Tables II through VI, shows that Type 316 is in general more pit-resistant than Type 304 in desalination environments. Type 316 stainless steel tubes exposed in the first evaporator effect at the Freeport plant have experienced, thus far, only slight pitting attack after about 20 months of service.

Effect of stress.—Erichsen-cup type, stress-corrosion specimens of Types 304 and 316 stainless steels were included in the field tests conducted at the Freeport plant. Examination of these specimens after exposure periods of several months' duration has not revealed any evidence of stress-corrosion cracking. Furthermore, stress-corrosion cracking has not been found to be a problem in the Type 304 and Type 316 stainless-steel test tubes exposed in the first evaporator effect at Freeport.

Electrochemical Principles Involved in Hot Sea Water Corrosion

Pitting of stainless steels is primarily associated with chloride environments, although a similar form of attack is also found in bromide solutions. This localized attack results from the breakdown of the passive film such that the local area of film breakdown becomes active, while the surrounding passive film serves to support the local cathodic reaction. Consequently, we find a condition of a very small anode supported by a large cathode, resulting in a very localized and rapid attack. The mechanism of breakdown of the passive film remains the subject of some controversy, but has been variously associated with the adsorption (10, 11) of chlorides or the inclusion (12) of chlorides at local sites in the passive film. After the initial breakdown, the process is autocatalytic in that the solution within the pit becomes increasingly acidic and corrosive because of the hydrolysis of ferrous ions resulting in an increased concentration of hydrogen ions. Pit geometry partially precludes the outward diffusion of these hydrogen ions into the bulk solution.

The pitting susceptibility of a passive steel is dependent on its alloy content and for a given steel also depends on such environmental variables as temperature, chloride concentration, pH, oxygen concentration, and the presence of inhibitors. The effect of many of these metallurgical and environmental variations has been described in the literature (10, 11, 13, 14).

The pitting susceptibility of a stainless steel in a given environment is characterized by a critical potential below which (more active) pitting does not occur. At potentials more noble than this value, pitting will occur at a rate primarily dependent on alloy composition.

The most noble corrosion potential that could be reached by a steel under natural corrosion conditions is governed by the equilibrium potential for the cathodic reduction reaction; under most conditions, this would correspond to the equilibrium oxygen reduction potential, which for the reaction:

$$O_2 + 4H^+ + 4\epsilon \rightarrow 2H_2O \qquad (E^\circ = 1.23v)$$

is given by the Nernst expression:

$$E = 1.23 + \frac{0.059}{4} \log [H^+]^4 pO_2$$

(at 1 atm) $E = 1.23 - 0.059$ pH (*vs.* hydrogen electrode).

Therefore, if no critical potential is observed during anodic polarization to the equilibrium potential for oxygen reduction, the alloy is immune to pitting because the natural corrosion potential could never be more noble than the critical pitting potential. This reasoning explains the immunity to pitting of titanium, which has an extremely noble critical potential in neutral chlorides (12-14v).

Most available data on electrochemical measurements of pitting susceptibility have been obtained in electrolytes at temperatures close to room temperature. The increased temperature used in desalination plants results in two opposing effects regarding localized corrosion of stainless steels. These are:

1. Increased propensity for pitting with an increase in temperature.

2. Reduction in oxygen concentration results in a more active corrosion potential. For a given set of environmental conditions, this decreases the tendency toward pitting.

Above approximately 100°F, there is only a very slight shifting of the critical pitting potential in the active direction with a further increase in temperature. Thus, for AISI Type 304 (see Fig. 2) in 0.1*N* sodium chloride solution, the critical potential shifts in the active direction by only approximately 0.1v as the temperature increases from 100° to 200°F. Increasing the temperature over this range only slightly

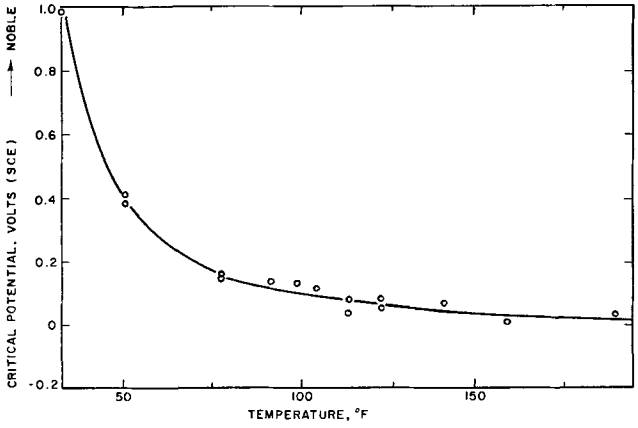

Fig. 2. Effect of temperature on critical potential for pitting of Type 304 stainless steel in 0.1*N* NaCl solution.

increases the aggressiveness of the environment for localized corrosion.

The removal of oxygen results in an increase in cathodic control in the system, with a corresponding shift of the corrosion potential in the active direction. This effect is demonstrated by Fig. 3, which shows potential-*vs*-time curves for AISI Type 304 stainless steel in air-saturated and deaerated 1M sodium chloride solution. In each case, the specimens were activated by holding at 1.2v for 5 min. The air saturated solution induced the formation of passivity in a relatively short time, as indicated by the noble potential attained after only 10 min. In deaerated solutions, however, the specimen potential remained approximately 0.5v more active than the air-saturated solutions. The decrease in oxygen content that occurs when water is heated and the resultant shift in corrosion potential in the active direction are more than sufficient to offset the slight active shift in critical potential, and result in the reduction in corrosion rate for stainless steels in chloride solutions that has been observed in open systems as the temperature approaches that for boiling (15). As mentioned, this pronounced effect of oxygen was observed in the plant tests at the Freeport plant.

Localized attack of stainless steels may be eliminated by the use of inhibitors. It has been shown that the mechanism of inhibition of pitting is one of competitive adsorption on the metal surface between the aggressive ions (chloride) and inhibitor (10). The concentration of inhibitor required depends primarily on the nature of the inhibitor and the concentration of chloride and follows an equation of the form:

$$\log [Cl] = A + B \log [\text{inhibitor}]$$

where chloride and inhibitor are expressed as activities.

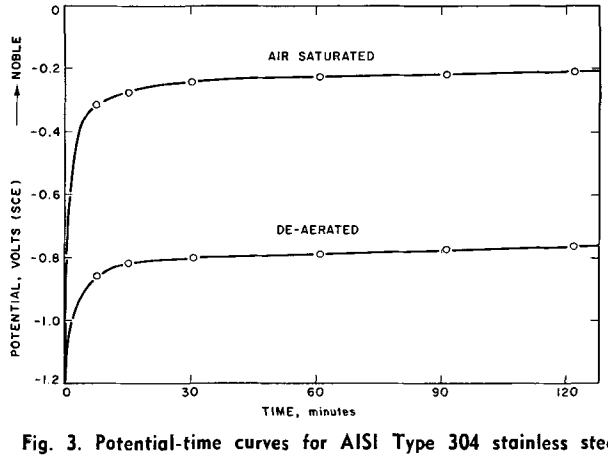

Fig. 3. Potential-time curves for AISI Type 304 stainless steel in aerated and deaerated 1M sodium chloride solution.

Electrochemical measurements have shown hydroxyl ions to be a very efficient inhibitor in preventing attack of stainless steels by chlorides. The amount of hydroxyl ion that may be added to sea water, however, is limited by scale formation which deposits under alkaline conditions and would hinder efficient heat transfer. Other anions (such as nitrates) are known to inhibit the pitting of stainless steels by chlorides and thus future studies might well include an evaluation of the effect of nitrate additions on stainless performance.

In addition to the reduction in efficiency of heat transfer produced by scale deposition, it may also be conducive to the occurrence of crevice corrosion. Crevice corrosion is normally initiated by a differential aeration cell having an anode located at a small area shielded from easy access of oxygen, and surrounded by a large cathode area where reduction of oxygen occurs. Once corrosion starts at anodic sites within the crevice, the outward diffusion of the corrosion product (predominantly hydrolyzed ferrous ions) is partially prevented by crevice geometry, resulting in a build-up in hydrogen ion concentration. The process is autocatalytic because the acid environment causes more rapid attack within the crevice. In this respect, pitting and crevice corrosion are very similar.

For the future, it is believed that electrochemical measurements should serve as the basis for the development of new stainless steels that are resistant to pitting attack and crevice corrosion in desalination environments. Elements should be added to the steel that will shift the critical potential as far as possible in the noble direction. It is believed to be particularly important that the critical potential measurements be made at temperatures encountered in desalination plants.

Summary

The field-test results reported herein indicate that under certain conditions the stainless steels exhibit excellent corrosion resistance in environments encountered in distillation-type desalination plants. The most important environmental factors are that the water or brine be substantially free of oxygen and that the operating conditions be adjusted so that deposits are not formed. Type 316 stainless offers the best resistance to attack; however, the test results indicate that Type 304 stainless may also have sufficient resistance to be a useful material of construction. Electrochemical measurements help to explain the effect of increased temperature on the corrosion of stainless steels and also offer a method for evaluating the performance of new steels.

Electronic Conduction in Dielectric Films

A. K. Jonscher

University of London, Chelsea College of Science and Technology, London, England

ABSTRACT

This review starts with a brief discussion of the structure of technically important dielectric films and proceeds to outline the relevant theoretical and experimental aspects of amorphous semiconductors and dielectrics. This is followed by a discussion of d-c conductivity in dielectric films at low and high fields, including dependence on temperature. Alternating-current techniques represent one of the most important tools in the study of dielectrics, and an account is given of the experimental results over a wide range of frequencies. This is followed by a description of the application of the method of thermally stimulated currents to the study of dielectric films—a relatively little used technique capable of supplementing the more conventional d-c and a-c measurements. The review concludes with brief accounts of impurity-induced conduction, photoelectric phenomena, and the so-called switching in dielectric films.

Among the many studies of the properties of dielectric films, the subject of electronic conduction has attracted perhaps rather less interest than it may deserve. One reason for this may be found in the fact that most people wish their dielectric films to be insulating and accordingly consider conduction phenomena simply as an accidental nuisance to be eliminated. Another reason may be that conduction in these films has been frequently associated with the movement of ions and only relatively recently was attention seriously diverted to the study of specifically electronic processes. Nevertheless, it is possible to state that our

knowledge of film properties would be very incomplete without a good understanding of the electronic phenomena and that valuable insight into general film properties is obtained from this study. The present paper is intended as a review of some of the relevant experimental and theoretical topics and attempts to provide a unified picture of the present stage of the subject.

The approach adopted is based to a large extent on the familiar concepts of conduction mechanisms in electronic semiconductors, with the necessary allowance for the primarily amorphous and glassy nature of many of the dielectric films in use at present. In this respect, we are in the fortunate position that the science of heavily disordered and amorphous semiconductors has made great progress in recent years and it is possible at least to speculate on the probable extension of these concepts to dielectric films. For this reason, the present review goes beyond the strict limits of dielectric materials in one or two instances which are considered to be illustrative of the general principles involved.

A word of caution is indicated: the science of dielectric films is not an exact discipline, as many of its practitioners no doubt realize. Reproducibility leaves a great deal to be desired, mainly on account of the imperfect understanding of the technological factors involved in the preparation of films. All numerical data should therefore be treated with caution, especially where structure-sensitive parameters are concerned.

Electronic tunneling phenomena in very thin films are specifically excluded from the present treatment since they are adequately covered elsewhere (1, 2). Ionic transport processes are also mentioned only incidentally as they represent a specialist subject in their own right (3).

The following account is intended to some extent as a review of progress in the last two years and should be read as a follow-up to an earlier paper by the author (4) in which many of the basic concepts are discussed in detail and to which references are made in the text in order to avoid unnecessary repetition.

Influence of Structure on Film Conduction

The structure of thin films represents a large topic in its own right and is dealt with here only insofar as it is known to affect their electrical properties (5). Single-crystal films may be obtained by thermal oxidation of single-crystal substrates at elevated temperatures (6) or by the well-known processes of epitaxial growth from the vapor phase which are widely applied in the technology of semiconductor devices involving both elemental and compound semiconductors. A majority of dielectric films of technical significance, however, are deposited from the vapor phase on relatively cool substrates or are anodized in aqueous solutions and their structure is substantially amorphous in the sense that there is an absence of any long-range order in the atomic or ionic configuration. Between the extremes of amorphous and single-crystalline structures there is a whole range of micro- and polycrystalline materials which may be obtained from the former by the process of thermal annealing, sometimes under the influence of electron beam bombardment (7). The latter feature makes it rather difficult to carry out structural determinations using electron diffraction and electron microscopy, since the measuring technique itself may influence the properties being investigated.

The electrical behavior of crystalline dielectric films may be understood in terms of conventional semiconductor concepts (8, 9): they represent materials with relatively large forbidden energy gaps and relatively high carrier mobilities, say between 10 and 10^3 cm^2/vsec, but with very low thermal carrier densities. They normally contain high densities of localized trapping levels, usually distributed over a considerable part of the forbidden gap energy. The most prominent feature of their behavior is bulk space charge limited flow in the presence of injecting contacts (10) or Schottky thermionic emission over a field-lowered potential barrier in the case of blocking contacts (6, 4).

The electrical properties of amorphous and glassy materials are much less clearly understood, although considerable progress has been achieved in recent years (4, 11-13). Here the concepts of conduction, valence and forbidden bands, free electrons and holes, mobility of carriers, donor and acceptor levels, *etc.*, require considerable modifications.

With regard to the energy band structure, there is general agreement that this depends mainly on nearest-neighbor dispositions and, to the extent to which these are similar in amorphous and crystalline structures of the same chemical composition, it may be expected that the main features of the band structure remain similar. However, the sharp band edges of crystalline lattices become diffuse in amorphous materials and give rise to a gradual transition from conducting states in which carriers are free to move to deep trapping levels in which carriers are strictly localized, as shown in Fig. 1. Electronic conduction in such structures does not normally occur by free electrons or holes but rather by more or less localized carriers "hopping" between sites by tunneling with or without slight thermal activation. In the presence of thermal activation, which is the normal process at all but the lowest temperatures, there is frequently no clearly defined activation energy but, instead, the graph of resistance *vs.* reciprocal temperature shows a continuous curvature (14, 15). This is due to the fact that the hopping sites are randomly distributed both in space and in energy and the activation energy increases with increasing temperature as more and more carriers become excited into the conduction process. Figure 2 gives an example of this behavior in the case of amorphous films of silicon and germanium. Another significant feature is that the resistivity is apparently insensitive to the nature of the material, in this instance silicon or germanium, and is determined mainly by the type of disorder present. This is an example of structure sensitivity which may be representative of the behavior of other dielectric films.

The optical properties of amorphous films generally show reasonable correspondence with the crystalline forms since they also depend primarily on nearest-neighbor interactions which are similar in both. The detailed picture of the structure of amorphous layers such as silicon dioxide, the so-called "silicon monoxide," and silicon nitride is not at all clear and there is very little concrete evidence on it. Silicon dioxide is more covalent in nature than silicon oxide which

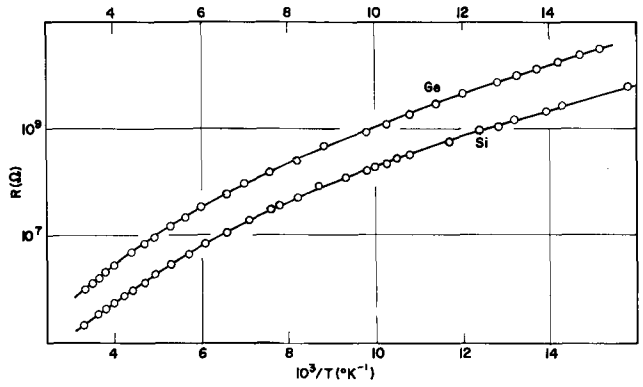

Fig. 2. Logarithm of resistance vs. reciprocal temperature for evaporated films of amorphous germanium and silicon [from Ref. (15)].

contains an appreciable ionic character in the bonding.

It may be said in general that the amorphous forms are less dense than the crystalline modification and they have a lower dielectric constant, at least in the absence of "doping" impurities (16-20).

Direct Current Conduction

In principle, any dielectric film should show an ohmic region of current-voltage characteristic at sufficiently low electric fields. In practice, most films other than those which are heavily "doped" or contaminated (*see* below) do not show this region because of very slow polarization phenomena at the contacts or in the bulk (29). Moreover, with the exception mentioned above, the ohmic region is normally characterized by high activation energies of the order of 1 ev (21) associated with ionic conduction and it is not discussed further in the present review.

At higher fields, the behavior depends to a large extent on temperature, and an example referring to evaporated silicon oxide is shown in Fig. 3, quoted from Servini and Jonscher (21). The dotted lines in the graph describe four regions. Region I is the ohmic region already mentioned. Region II gives linear graphs of log I *vs.* $V^{1/2}$, Fig. 3(b) corresponding to either Schottky or Poole-Frenkel emission (4) in which the current is given by

$$I = I_0 \exp\left[\frac{e}{kT}(\beta E^{1/2} - V_G)\right]$$

where E is the electric field, V_G is the ionization energy of the localized center (in P-F conduction) or the contact barrier height (in Schottky emission). The coefficient β is given by

$$\beta = (e/a\pi\epsilon_{0\epsilon})^{1/2}$$

where $\epsilon_{0\epsilon}$ is the high-frequency value of the dielectric permittivity and the coefficient $a = 1$ for Poole-Frenkel and $a = 4$ for Schottky mechanism.

Characteristics of this form have been obtained for a wide range of amorphous materials, frequently giving values of a between 1 and 4, and an extensive discussion of these mechanisms was given in Ref. (4). Some more recent results were reported for BN (22) and Si_3N_4 (19). It may be stated that, in the majority of known cases of amorphous materials, as distinct from thin crystalline films, the dominant mechanism in this range is some modification of bulk Poole-Frenkel electronic transport. It should be remembered that, in order to invoke the Schottky barrier emission mechanism, it is necessary to postulate that the bulk of the material offers negligible resistance so that the characteristic is barrier dominated up to the highest currents. This is seldom a plausible assumption in noncrystalline films of appreciable thickness, say in excess of 1000Å. The implication is, further, that the entire characteristic is electrode determined, down

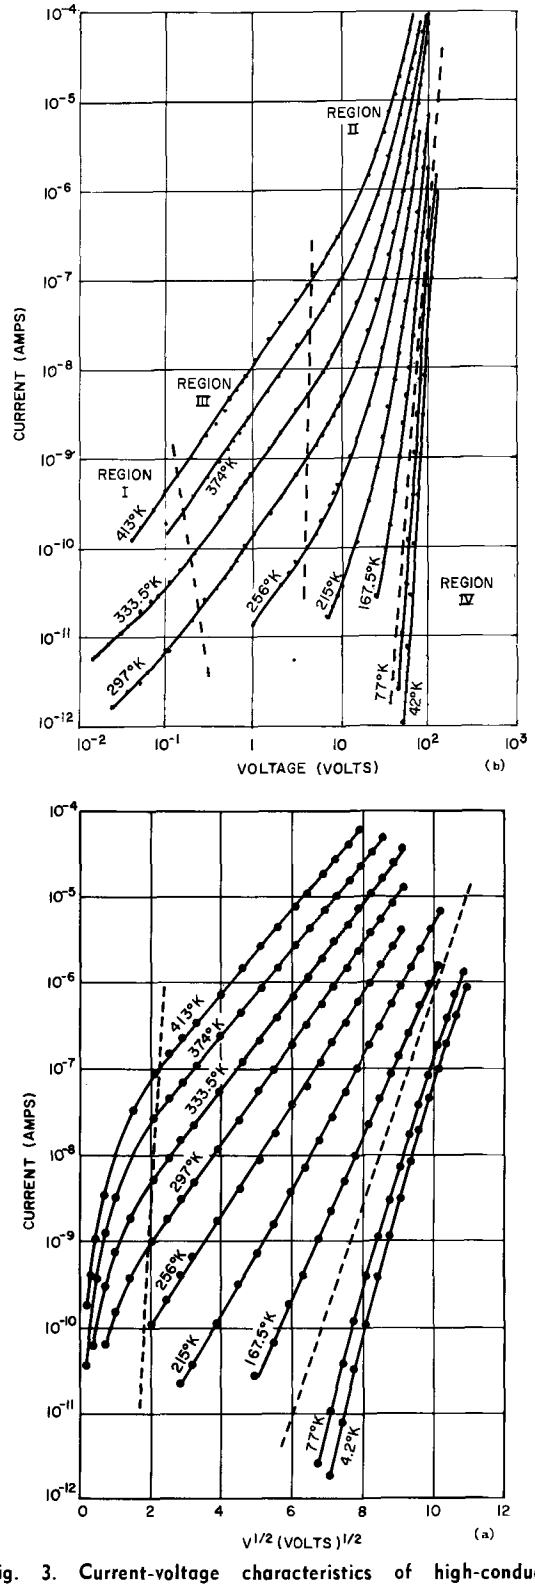

Fig. 3. Current-voltage characteristics of high-conductivity evaporated silicon "monoxide" at various temperatures, showing four regions of behavior. to the lowest currents. In this case, a useful check may be to try different metal electrodes with significantly different work functions.

The question of contacts to specimens showing bulk-limited Poole-Frenkel emission has been discussed in Ref. (4) and the point is merely repeated here that the available evidence suggests that no serious barrier limitation arises because electrons tunnel directly from the Fermi level of the metal into the localized

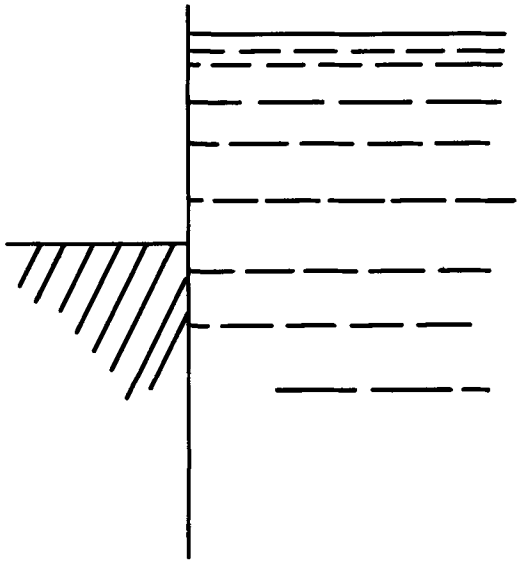

Fig. 4. Schematic diagram of a nonblocking contact between a metal and dielectric possessing a distribution of deep electronic levels [from Ref. (4)]. (Reprinted from *Thin Solid Films;* with the permission of Elsevier-Sequoia S.A., Lausanne, Switzerland.)

levels in the forbidden gap of the insulator and no activation over the contact barrier is involved, as shown in Fig. 4.

Region III of the characteristics shown in Fig. 3(a) is intermediate between regions I and II and is characterized by nonlinear V-I dependence, usually a power law $I \propto V^n$, with the exponent n in the range $1 < n < 2$. This region is strongly temperature dependent and may be due to some form of space charge limited flow. It should be pointed out, however, that it may be incorrect to apply directly to amorphous materials the concepts developed by Lampert (10) and others for crystalline insulators with traps.

An important aspect of d-c conduction which is not at present well understood is the mechanism dominating at low temperatures which has negligible temperature dependence and which is characterized by power-law dependence $I \propto V^n$, with large exponents n in excess of 5 and sometimes as high as 15. This power law corresponds to region IV in Fig. 3 and has already been discussed in Ref. (4). There are many examples of such characteristics in diverse amorphous films, for example SiO_x (21), Ge (23), TiO_2 (24). It may be stated that no other simple relation, exponential or otherwise, seems to fit the results quite so well as a high exponent power law. Figure 5 shows curves of current at constant voltage as a function of temperature for evaporated silicon oxide. It is seen that the current is independent of temperature up to approximately 20°K at lower voltages and up to 50°K at higher voltages. This mechanism, which is capable of passing currents as high as the Poole-Frenkel mechanism at much higher temperatures, is clearly related to some form of tunneling mechanism, and yet it differs from the familiar hopping mechanisms (4, 12, 25) which are thermally activated tunneling. It is suggested that the explanation may lie in tunneling between very closely spaced sites, for example nearest or next-nearest neighbor sites in the amorphous matrix. With their small separation, the energy difference due to either external or internal coulomb fields is sufficiently small to be accommodated by the inevitable "fuzziness" of the energy levels themselves so that no phonon collaboration need be involved, resulting in temperature-independent characteristics.

Mention may be made here of other power-law relations which are not necessarily temperature independent and may predominate at higher temperatures. Examples may be quoted of SiC (26), BN (22), and

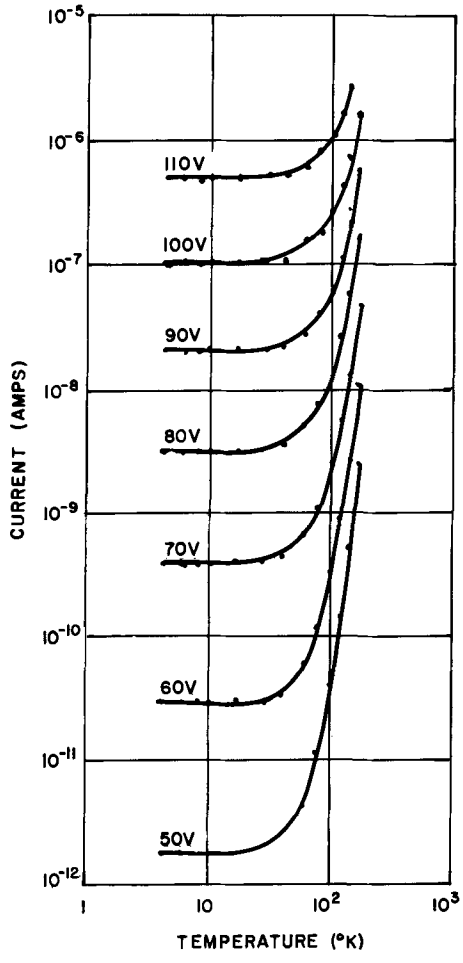

Fig. 5. The low-temperature part of the characteristics of Fig. 3, plotted as a function of temperature with voltage as a parameter and showing the constancy of current at low temperature [from Ref. (21)].

others, but it is not clear at this stage whether similar mechanisms apply there.

An interesting study of conduction in Nb-Nb_2O_5-Au structures produced by anodization of evaporated niobium was reported by Hickmott (27) who observed strong rectification and electroluminescence in the "forward" direction of current flow. His interpretation of the results is in terms of double injection into the insulator with space charge limited flow, with some conduction in impurity states. This is an example where concepts normally applicable to crystalline materials seem to fit the behavior of an amorphous film, although further results may be necessary before a firm judgment can be made of their validity.

The question may be asked to what extent is polaron transport responsible for conduction phenomena in dielectric films. Some speculation concerning the possibility of applying small polaron theory to conduction in glasses containing transition metal oxides was recently published by Schmid (28). Schmid points out the inadequacy of the present theory which deals mainly with ordered one-dimensional chains, while real glasses represent extremely disordered three-dimensional arrays. It is not proposed here to enter into detailed theoretical arguments, but it may be observed that the broad similarity of experimental results between amorphous polar and nonpolar (Ge,Si) materials suggests that polaron effects cannot dominate their behavior. The evidence in question relates in particular to voltage-current and conductivity-frequency dependence throughout the range of temperatures covered in the present paper.

In discussing the d-c conduction in dielectric films, it must be stressed that the essential criteria for the

predominance of electronic over ionic conduction must be the absence of long-term polarization and of mass transport effects.

Alternating-Current Conduction

Alternating-current measurements represent an important tool for probing the dynamic properties of a complex dielectric system with its relaxation times characteristic of the various processes of charge movement and dipole orientations. Available techniques cover a very wide frequency range, extending from below 10^{-3} Hz with the use of voltage step-function response methods, through a variety of a-c bridges, slotted line and microwave measurements up to 10^{11} Hz, with far infrared measurements becoming possible beyond that. The low frequency end of the spectrum gives information about slow, mainly ionic phenomena of both the bulk and interfacial type; they may also correspond to molecular rotations. Examples of such measurements on evaporated silicon oxide and anodized aluminum oxide were published recently by Argall and Jonscher (29) and they are discussed further here since they do not correspond to electronic phenomena. Characteristic features of this frequency region are the presence of pronounced peaks of loss tangent, a large dispersion of capacitance, and activation energies of the order of 1 ev typical of ionic phenomena.

A different behavior is found in evaporated silicon oxide and anodized aluminum oxide in the frequency range 10^2-10^6 Hz. Figure 6 shows the dependence of conductivity on frequency for a range of temperatures, while Fig. 7 shows the a-c conductivity plotted against reciprocal temperature for constant frequencies. The low-temperature activation energy is approximately 0.01 ev and is certainly of electronic origin. The high-frequency end shows a tendency to quadratic dependence of conductivity on frequency, a characteristic phenomenon observed in many other systems comprising highly disordered, amorphous, or glassy structures. Figure 8 gives the example of bulk polymeric CS_2 which is an "amorphous" substance lacking any long-range order (30). Resistivity and permittivity are plotted in the frequency range 10^2-5×10^{10} Hz. Conductivity shows three distinct regions: at frequencies below 10^6 Hz, conductivity increases rather less rapidly than proportionally to frequency and there is an activation energy of 0.15 ev. Beyond this frequency, there is a region of exact square-law dependence which appears to have a very small activation energy. The conductivity finally shows saturation at 10^9 Hz, which may be associated with a natural hopping frequency of the charge carriers. Somewhat similar frequency dependence has been found in some glasses (31) and also in transition metal oxides (32).

A common feature of all these mechanisms, showing a monotonic increase of conductivity with frequency with possible saturation at high frequencies, is their relatively weak temperature dependence. They have been interpreted (4, 29) in terms of electronic hopping motion, which corresponds to thermally assisted tunneling between discrete sites, as distinct from transport of effectively free carriers in the valence and conduction bands of conventional crystalline conductors, which shows a conductivity decreasing with frequency at sufficiently high frequencies.

It may be noted in this connection that the strong dependence of conductivity on frequency would normally be associated with electronic rather than ionic processes. This is so because the latter correspond to much lower natural hopping frequencies—of the order of 1 Hz or much less— and would therefore be saturated at radio and even audio-frequencies.

Thermally Stimulated Currents

The familiar voltage-current dependence at constant temperature, the $(I,V)_T$ characteristic, represents one means of characterizing the properties of a

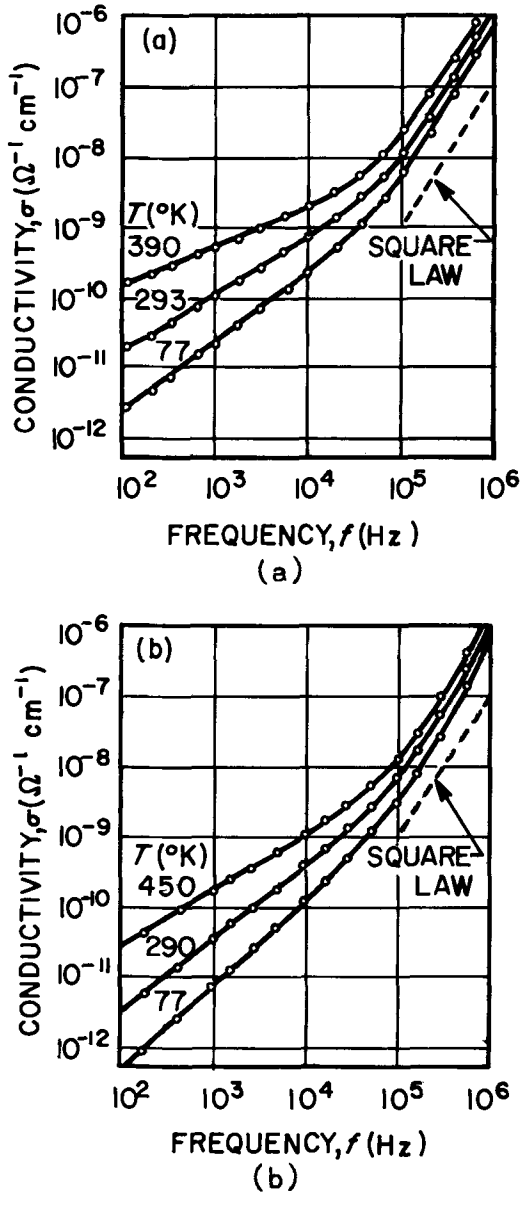

Fig. 6. Variation of a-c conductivity with frequency for (a) evaporated silicon oxide and (b) anodized aluminum oxide [from Ref. (29)]. (Reprinted from *Thin Solid Films;* with the permission of Elsevier-Sequoia S.A., Lausanne, Switzerland.)

conductor. A complementary characteristic which is particularly useful for dielectric and poorly conducting systems is the current-temperature characteristic at constant voltage, denoted as the $(I,T)_V$ characteristic. In nonconducting materials which have previously been excited from their thermal equilibrium condition by some external agency, this characteristic determines the thermal release of stored charge or polarization and is known as the method of thermally stimulated currents, in the case of photoconductors, and thermal glow curves in the case of phosphors (33-35). Prior excitation is an essential condition for obtaining thermally stimulated peaks, since without it one obtains the ordinary current-temperature characteristics at constant voltage, as for example in Fig. 5.

The application of this method to the thermally stimulated discharge of a capacitor previously charged by the application of a biasing voltage is not so well known, one account having come to our notice relating to thin layers of cadmium sulfide (36). One of the first experiments with silicon oxide and aluminum oxide films has been performed by Servini and Jonscher (21) and is described briefly here.

The method consists in applying a bias voltage V_b at some biasing temperature T_b and subsequently low-

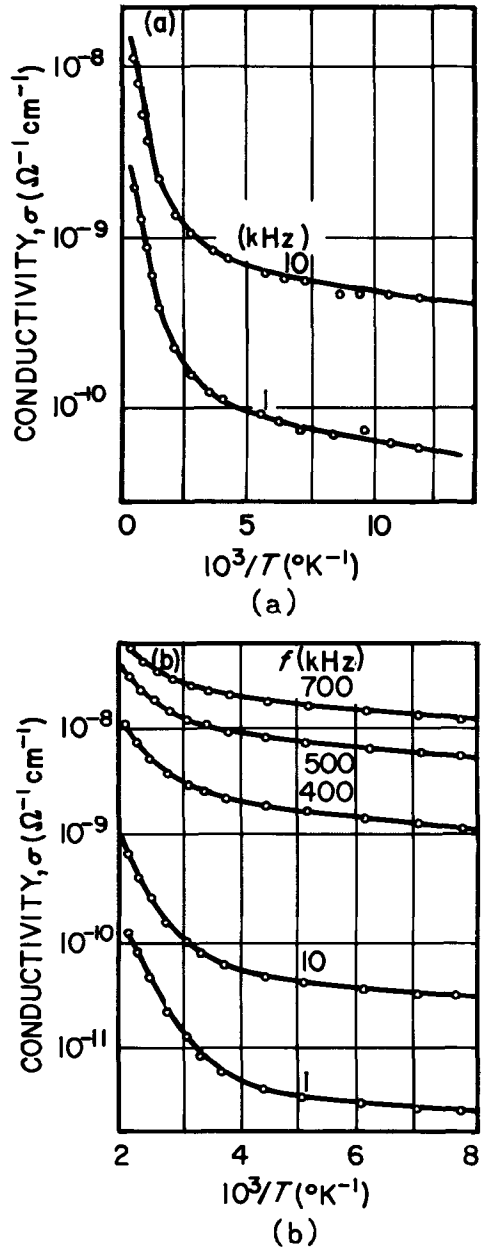

Fig. 7. Variation of a-c conductivity with reciprocal temperature for (a) silicon oxide and (b) aluminum oxide [from Ref. (29)]. (Reprinted from *Thin Solid Films;* with the permission of Elsevier-Sequoia S.A., Lausanne, Switzerland.)

ering the temperature, with the bias applied, to some suitable low temperature at which the current becomes negligibly small. A collecting voltage V_c, different from V_b, is then applied and the temperature is raised at a uniform rate $dT/dt = R$ and the current is recorded as a function of temperature. The response shows one or more peaks which correspond to the release of trapped charge or polarization. The relevant activation energies are related to the temperatures of the peak maxima and to the peak half-width. An example of the response with several peaks is shown in Fig. 9. Where two peaks are closely spaced on the temperature scale, the method of thermal quenching may be employed, as shown in Fig. 10, for peaks labeled H1 and H2. One of the characteristic features of thermally stimulated currents is the constant ratio of peak area A to heating rate R. The peaks reported here show a very good constancy of this ratio, confirming the correctness of the interpretation of their origin.

Altogether, five peaks have been identified in evaporated silicon oxide films. The one most easily ob-

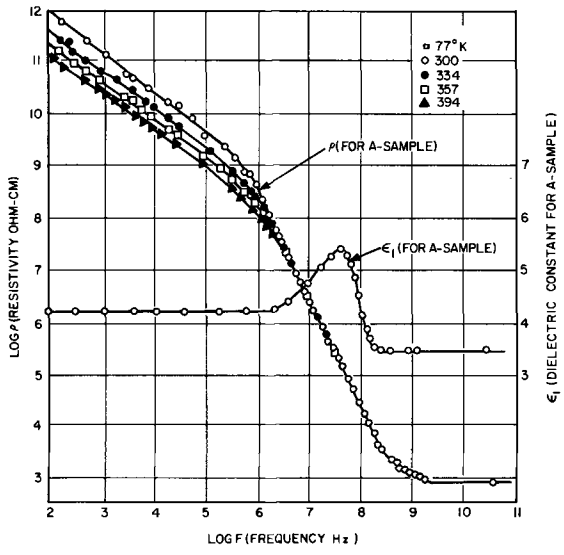

Fig. 8. Dielectric properties as a function of frequency of non-crystalline polymeric CS_2 showing resistivity and dielectric constant [from Ref. (30)].

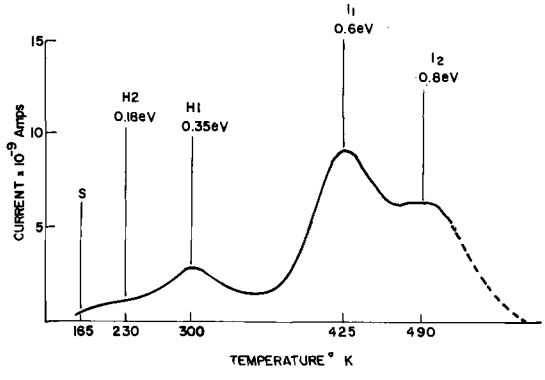

Fig. 9. Five thermally stimulated peaks observed in silicon oxide, showing their approximate positions in energy [from Ref. (21)].

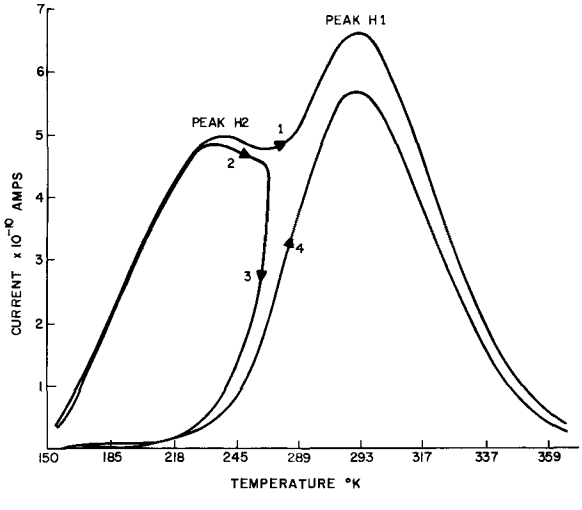

Fig. 10. Thermal quenching of two closely spaced peaks H1 and H2. Curve 1 gives a normal heating run. Curve 2 shows heating only up to the trough between the peaks, followed by cooling to low temperature (curve 3), and immediately reheating (curve 4) which produces peak H1 unencumbered by the tail of peak H2 [from Ref. (21)].

servable is labeled H1 and is obtained when films are cooled from room temperature or slightly lower with a moderate bias. Its area increases linearly with bias voltage and the charge involved is always much higher

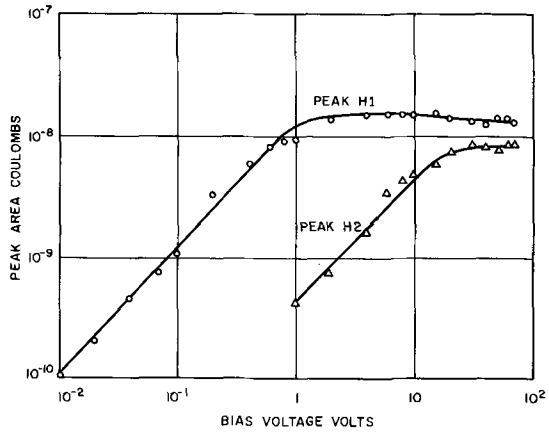

Fig. 11. The dependence of bias voltage of the area of peaks H1 and H2, expressed in coulombs, showing delayed onset of the lower energy peak H2 and eventual saturation of both peaks at high bias voltages [from Ref. (21)].

than that corresponding to the geometrical capacitance of the film. At sufficiently high bias voltages, corresponding to the onset of the Poole-Frenkel regime (region II), peak H1 saturates and a smaller peak H_2 appears. This peak has a lower activation energy than peak H1. The dependence of the areas of the two peaks on the biasing voltage is shown in Fig. 11.

At low biasing temperatures, of the order of 130°K, and high biasing voltages, a low-temperature, low-energy peak is observed, labeled S1. At high biasing temperatures, in excess of 330°K, two more peaks have been observed, labeled I1 and I2.

The interpretation of these results given by Servini and Jonscher is briefly as follows. Peak H1, the energy of which is 0.35 ev, corresponds to charge transfer between relatively widely spaced pairs of centers, *i.e.* a form of thermally assisted hopping. It is suggested that these are the same centers which are responsible for the d-c Poole-Frenkel process which shows an activation energy of 0.45-0.6 ev, when extrapolated to zero field. The lower value of the energy of peak H1 may be understood if one assumes that the peak arises from transitions between relatively closely spaced pairs of centers in which the barrier is lowered by Coulomb interaction, while the Poole-Frenkel emission occurs into relatively more distant centers against the full height of the barrier. Peak H2 is found to correspond to a spread of energies from 0.2 ev downward and is considered to be due to much more closely spaced centers than peak H1. It may be identified with the mechanism responsible for a-c conductivity reported by Argall and Jonscher (29).

Peak S1 is shown to be due to some form of injected space charge, its activation energy being distributed from probably 0.1 ev downward. All these peaks appear, thus, to be of electronic origin.

Peaks I1 and I2 have activation energies of 0.6 and 0.8 ev, respectively, and are clearly identified with bulk and interfacial ionic polarization mechanisms reported by Argall and Jonscher (29).

It is clear that further work on thermally stimulated peaks in a wider variety of dielectric films may lead to better elucidation of the mechanisms involved in the conduction processes.

Impurity-Induced Conductivity

In the case of crystalline semiconductors and insulators, impurity atoms and lattice defects of density N may act as relatively shallow donor and acceptor levels which at sufficiently low temperatures produce free electrons or holes in numbers n proportional to the square root of N

$$n \propto N^{1/2} \exp(-\epsilon_d/2kT)$$

where ϵ_d is the activation energy of the centers. At higher temperatures, such that $\epsilon_d < kT$, saturation may be reached with

$$n \approx N$$

A crystal lattice, however, has an upper limit to the solubility of defects, which is of the order of 10^{20} cm^{-3}, or 0.1 atomic per cent. Beyond this limit, the centers cease to be electrically active by forming a separate phase precipitating in the lattice.

The situation is rather different in an amorphous solid for two main reasons. First, the generally more loose structure of an amorphous material implies greater ability to accommodate impurities to the extent of several atomic per cent without necessarily losing the basic features of the host solid, for example the optical absorption spectrum. Second, however, the electrical effectiveness of defects is much reduced since, even if they did tend to produce free carriers, these are likely to be trapped in the deep levels present in the forbidden gap due to the disorder, Fig. 1. This point was made by Gubanov (11), among others, and is borne out by experimental evidence.

Given a sufficiently high density of impurities, however, the conductivity is found to increase, although as yet there is little quantitative information about this effect. Hu and Gregor (20) report an increase of the conductivity of amorphous silicon nitride films reactively sputtered in argon-nitrogen mixtures, with decreasing percentage of nitrogen in the gas. They attribute this to a dispersed silicon phase in the films. Walley (15) reported results with silicon and germanium films which may be interpreted in somewhat similar terms. Figure 12 shows his graph of the resistivity of silicon and germanium films *vs.* evaporation rate. At relatively fast deposition rates, the resistivity is independent of rate and hence, presumably, of the amount of oxygen included in the film. At sufficiently low rates, however, the resistivity increases rapidly until it reaches a value typical of silicon oxide. This end of the graph may be interpreted, therefore, as a contamination or "doping" of silicon oxide by silicon, with the resulting increase of conductivity. Germanium is less sensitive because of its lower oxygen affinity but the effect is qualitatively similar.

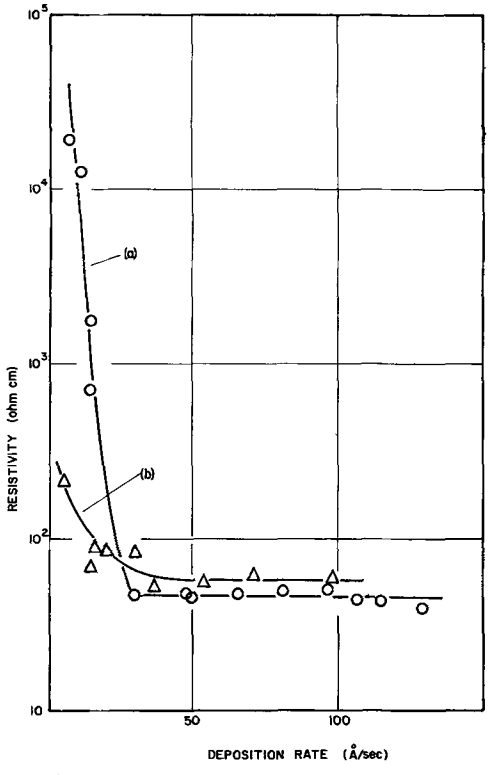

Fig. 12. The resistivity of evaporated amorphous films of silicon (a) and germanium (b) as a function of the deposition rate [from Ref. (15)].

The extreme case of highly impure dielectrics obtained by coevaporation of a metal such as chromium or gold and a dielectric such as silicon oxide are the so-called cermets which usually consist mostly of metal with up to, say, 40% of the dielectric. Relatively little quantitative information is available about the physical properties and mechanisms determining the conductivity in cermets (37), which is perhaps understandable in view of the very complex nature of these materials and also in view of the highly empirical and objective approach to their production (38-40).

Detailed work on the properties of silicon oxide coevaporated with copper and containing between 0 and 60% Cu shows not only an increase of conductivity by several orders of magnitude, but also the onset of ohmic electronic conduction at room temperature and a distinct lowering of the activation energy for Poole-Frenkel conduction (41).

Photoelectric Phenomena

In the case of crystalline conductors, especially those possessing relatively high resistivity, photoelectric phenomena offer valuable insight into the physical properties of the material, such as the mechanism of interaction with radiation and the kinetics of recombination processes. In addition, photoelectric effects at interfaces provide useful information about the barrier heights at contacts. Similar considerations apply to amorphous dielectric materials in the form of thin films, provided that due allowance is made for their structure. In particular, it is very unlikely that free electron-hole pairs should survive for anything like a sufficient length of time to give rise to ambipolar effects. Furthermore, transient measurements of rise and decay of photocurrent with rectangular light pulse excitation, which represent a most useful means of measuring the characteristic lifetimes in crystalline materials, may have limited application in view of the often long dielectric relaxation times.

The response of a dielectric film to illumination through a semitransparent top electrode may be due to one of three principal causes: photoinjection of carriers from one or both electrodes, photoconductivity due to excitation of carriers within the film itself, and spurious thermal effects due to heating by radiation. The last one represents a nontrivial problem and special experimental precautions are necessary to insure that it is negligible or properly allowed for.

Photoinjection from the electrodes was studied mainly in very thin films, of the order of 100Å, by Nelson and Anderson (42), Shepard (43), Schuermeyer (44), and Mead, Snow, and Deal (45), and in thicker SiO films by Hartman, Blair, and Bauer (46). These measurements give information about the height and shape of the potential barrier between the metal electrodes and the film. Photoconduction measurements by Ullman (47) on sputtered tantalum oxide films in the thickness range 700-7600Å were interpreted in terms of a single trap level of depth 0.25 ev. The presence in an amorphous film of such a clearly defined trapping level may be surprising, but it is confirmed in the case of silicon oxide by the results of Servini and Jonscher (21) already described above.

Switching in Dielectric Films

Many examples of so-called "switching" phenomena have been reported in the literature and many more are known by private contacts between individuals engaged in the study of this rather complex subject. Switching in this context is defined as a more or less controlled and reversible transition between two or more conducting states differing appreciably in resistance, with the proviso that one or both states may exhibit nonlinear voltage-current characteristics.

The whole subject has hardly yet reached a stage where detailed models may be put forward with any confidence and reproducibility leaves a good deal to be desired. The present discussion is therefore necessarily restricted to generalities and in the first place an attempt will be made to classify the rather diverse phenomena that are being referred to as switching.

It is felt that it may be helpful to distinguish between switching in definitely crystalline materials, on the one hand, and in amorphous and glassy materials, on the other. A variety of mechanisms have been proposed for the explanation of switching in the former (48), in particular double injection from end electrodes (10), avalanche injection (49), avalanche multiplication leading to a change in the scattering mechanism (50), more recently acousto-electric interaction in piezoelectric materials (51), and avalanche multiplication involving transit time effects (52). Some of these mechanisms are likewise being invoked in the case of glassy and amorphous materials, but the situation there is considerably more complex.

In general, in switching literature one distinguishes between current-controlled and voltage-controlled negative resistance, Fig. 13. This distinction is certainly helpful in those cases where the negative resistance itself is accessible and where no "memory" effects are involved. If memory is present, Fig. 14, then the distinction loses its significance since either branch may be traversed from the origin and it is not obvious which mechanism applies.

The presence of memory implies that some permanent changes take place in the material so that the last state of the device is preserved after the removal

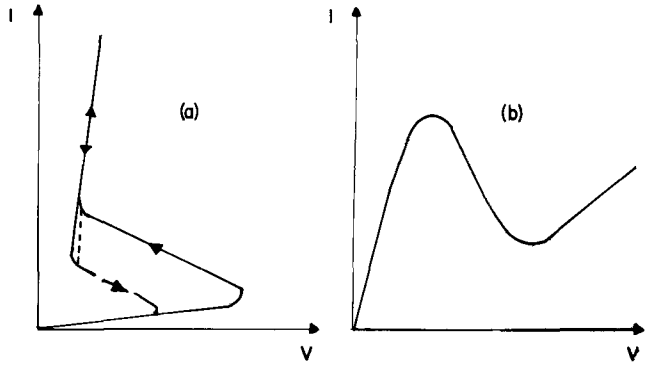

Fig. 13. Current-controlled negative resistance (a) and voltage-controlled negative resistance (b). A possible form of hysteresis is shown.

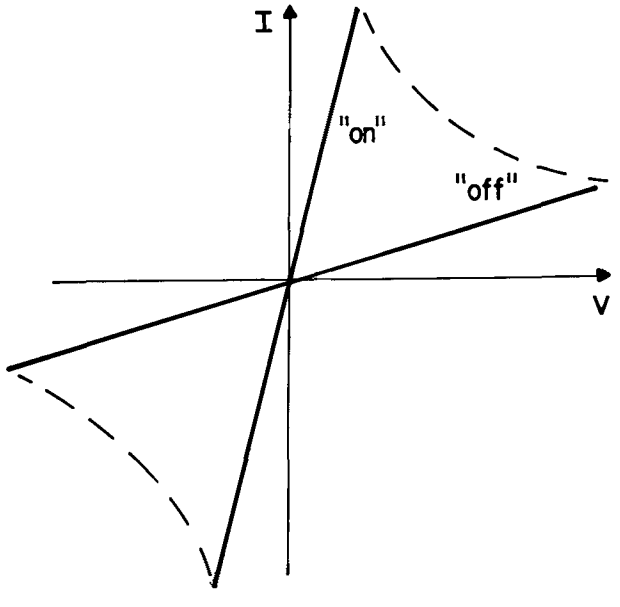

Fig. 14. Bistable switch with "memory"—the switch remains in either state when the current is reduced to zero and is subsequently increased again with the same or opposite polarity.

of bias. This normally means structural changes, although long-term trapping phenomena are sometimes mentioned as possible. Structural changes may mean, for example, localized crystallization in a noncrystalline matrix, transformation from one crystalline phase to another, or solid-state diffusion of atoms or ions. In the extreme case, it could mean localized melting of the material. The metal-insulator transition proposed by Mott (12) could fall in this category.

Switching was reported in semiconducting glasses by Pearson *et al.* (53) and Dewald *et al.* (54). In addition to fast reversible switching, these authors also describe the memory function which these devices could perform and which requires no holding voltage in either the "off" or "on" states. It was proposed that the effects could be explained in terms of a transformation of the glass to filaments of crystalline phases having high conductivity. This view was also expressed by Eaton (55). More recently, switching was also observed by Ovshinsky and led to the development of two devices, the Ovonic Threshold Switch and the Ovonic Memory Switch (56). The former is explained in terms of an increase of mobility, the latter by a transition to crystalline state in localized filaments.

Detailed studies of reversible memory switching in $CuO:P_2O_5$ glasses by Drake, Scanlan, and Engel (57) led to a model involving two valence states of the Cu ions which occupy differently coordinated sites in the glass. The high-resistance state is due to hopping between these sites, while the low-resistance state is the result of a structural transformation along a continuous path in the glass.

Argall (61) reported fast bistable switching in films of SiO_x and Al_2O_3. Chopra (62) postulated avalanche multiplication with space charge injection to explain current-controlled negative resistance which he found in films of anodized oxides of Nb, Ta, and Ti. A detailed account of switching in anodized TiO, showing three reproducible characteristics, is given by Argall (63), Fig. 15.

There is some discussion, mainly unpublished as yet, as to whether these and other switching phenomena observed in thin films are of a filamentary rather than distributed nature (64). It is suggested that crystalline filaments may grow in the glassy matrix under the influence of the intense electric field, particularly in the presence of some "nucleating" impurities. When once the filaments have bridged the film between the electrodes, enhanced current may flow, and memory persists, until a sufficiently high current causes thermal destruction of the filaments. It is rather early yet to pronounce definitely on the merits of this type of mechanism, although it is likely to account at least partially for some of the observed phenomena.

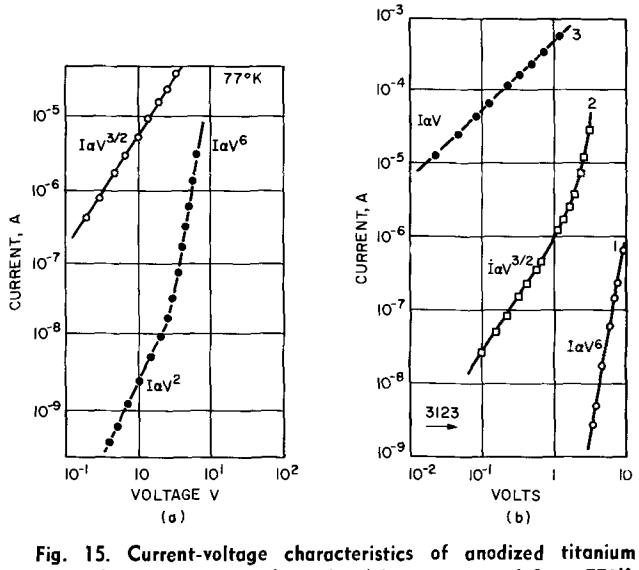

Fig. 15. Current-voltage characteristics of anodized titanium oxide with aluminum top electrode: (a) states 1 and 2 at 77°K, (b) states 1, 2, and 3 of a different sample at 300°K [from Ref. (61)]. (Reprinted from *Solid-State Electronics;* with the permission of Elsevier-Sequoia S.A., Lausanne, Switzerland.)

The principal shortcoming of all dielectric switches is their two-terminal nature which means the absence of a control or gate electrode. It may be that some mechanisms may be found possessing sufficient light sensitivity to be capable of being turned "on" by means of light. Purely two-terminal switches, especially those possessing memory, would be very useful if they could be made reliably in large numbers per unit area.

Conclusions

The experimental evidence and the theoretical considerations presented above lead to the conclusion that electronic conduction in dielectric films is responsible for a wide range of phenomena, even in materials which are traditionally considered to be ionic in nature. In particular, electronic conduction is likely to dominate the behavior at high electric fields, whether through Schottky or Poole-Frenkel mechanisms, at very low temperatures where the ionic motion is virtually "frozen out," and at frequencies in excess of the audio range, where the ions cannot move sufficiently rapidly. By contrast, low-frequency, low-field, and high-temperature transport is likely to be dominated by ionic motion with its higher activation energies and lower characteristic frequencies. Exceptions to this might be found in sufficiently heavily "doped" materials, so that electronic motion predominates even under these conditions. Combinations of ionic motion and electronic transport are possible, especially in phenomena such as switching, where the movement of ions may serve the purpose of modifying the electronic transport.

Our present-day knowledge of the detailed mechanisms of electronic conduction in dielectric films is rather scant. Experimental study of specific mechanisms, such as Poole-Frenkel transport, a-c conductivity, and thermally stimulated currents, may give information about the activation energies but not necessarily about the detailed nature of the centers which are responsible for conduction. More systematic study will be required of well-chosen specimens of dielectric films by a variety of complementary methods before a complete picture can be built up.

It is possible to state that d-c conduction is strongly structure sensitive and it may differ as much between samples of nominally the same material prepared by different methods, as between samples of different materials. Relatively large additions of foreign impurities or large departures from nominal composition are required to change significantly the level of d-c conduction. A-C conductivity may become high at sufficiently high frequencies. The dominant mechanism of a-c conduction is usually different from that responsible for d-c transport, as may be seen from different activation energies. Although both may well be interpreted as due to some form of hopping, little can be said at this stage about the nature of the hopping centers, and, in particular, about their correlation with structure.

Photoelectric studies appear to offer a rewarding field for further work and so does the effect of impurities. Switching is likely to remain a "happy hunting ground" for people with a strong device motivation and with confidence in their ability to conquer the forces of molecular chaos.

REVIEWS AND NEWS

JULY 1969

The Role of the Scientific Community in the Scientific Age[1]

Ivor E. Campbell*

The present age has within recent years been called in succession, the Scientific Age, the Atomic Age, and the Space Age. It might well be called the Age of Unrest.

Within the past twelve months we have seen increasing demands in the ranks of our sister societies for society involvement in matters of social concern. A concerted effort has taken place and is continuing in one major scientific society to develop a division that would, in effect, become a political action division.

A major engineering school was the focal point for a "Research Strike" called in support of protest against involvement of universities in certain government programs.

A major chemical company—one of the patron members of this Society—was the victim of vandalism by a group protesting the company's involvement in preparation of materials for the Department of Defense.

Unfortunately these are but a few of many examples that could be cited as signs of the times.

Dissent and unrest are widespread. Institutions and what is commonly referred to as "The Establishment" are being challenged on all fronts. It may be an oversimplification but I submit that this is in large measure due to man's failure to learn to live with himself.

Mutual respect and understanding have always been moral and spiritual goals. Today, they become a necessity for continuation of society itself. The unrest of today is grounded largely in the realization that man may not be able to cope with his own knowledge.

In a recent article, Dean Marlow of Catholic University cautioned that technology is a two-edged sword and said "our society cannot exist without it", pointing out that the North American continent, "which now supports a sophisticated life for a quarter of a billion inhabitants, scarcely supported a million people at a subsistence level before the advent of Western technology." He went on to say, "Yet we do not yet know whether or not we can continue to exist with it."

Is it not paradoxical that science and technology which have made the "Good Life" possible must now face the challenge of those who would blame science and technology both for man's failure to distribute more broadly the fruits of science and technology and for man's tendency to exploit more fully the destructive potential in scientific discoveries than the constructive?

Science, like "The Establishment", is now being challenged from diverse directions with increasing vigor. Some would even equate knowledge and evil.

However, as Glenn Seaborg has pointed out, "Knowledge is born without moral properties. It is man who applies it according to his acquired patterns of behavior. Man, not knowledge, is the cause of violence."

Further, as Professor William Kiefer stated, "Another myth that needs exploding is that some kinds of knowledge are bad, and others are good. Even worse is the idea that the search for knowledge can be good or bad depending on the use to which knowledge is put."

James Bryant Conant provided a thought-provoking and positive approach to challenges of the ultimate value of the quest for knowledge when he said, "There never has been a discovery of physical science that has not strengthened the hand of the Good Samaritan."

Those of us concerned with science and technology might be inclined to regard the challenge as preposterous. But the fact that such eminent scientists and educators as Conant and Seaborg have felt constrained to address themselves to it is evidence of its seriousness.

It is well to recognize that a major share of our total scientific effort today is based on government support. James Shannon puts the matter in focus when he asserts, "The ultimate patron of science is the public" . . . and . . . "they have not been given an understanding of science that can serve as a base for its continued support and evolution."

He calls upon the scientific community to devise means of fostering a broader understanding of the revolutionary technological forces that can be unleashed by a vigorous science for the betterment of society.

Science has, in the past, been to a large degree isolated, or at least insulated from the real world. Public attitudes reflected an unquestioning faith in the ultimate good of science. This has now changed—"The Establishment" of science is being challenged by its patrons—The Public.

In analyzing this matter, Dr. Kenneth Pitzer focused attention on certain facts of life for those interested in factors surrounding support of research. The following excerpts are germane to our consideration here. "The period of increasing, and largely unquestioning, support has ended." "In leveling off appropriations for research, business leaders and congressmen are now evaluating science more critically than previously by the same criteria they use in making decisions about

* Electrochemical Society Active Member.

[1] The Electrochemical Society Presidential Address, delivered at the New York Meeting of the Society, May 6, 1969.

other matters." "Now we are faced with the collapse of the assumption that more science is unquestionably desirable."

He concluded "We must be more explicit about the contributions of scientific research to particular national goals. We must discuss recent research which has been valuable as well as the degree of relevance of various basic fields to practical problems."

He went on to caution that esoteric subjects should not be avoided but asserted that the desire of more and more people to work in a given field is no longer an adequate reason for indefinite expansion of Federal support and concluded that more convincing criteria must be developed to justify the magnitude of effort in each discipline.

Aside from the number of respected scientists and engineers who have expressed their concern as to the role of the scientific community in the scientific age—more concrete evidence that the hour is here for concern has developed. A bill was recently introduced in the United States Senate by Senator Muskie—to establish a Senate Select Committee on Technology and The Human Environment.

Those testifying at the preliminary hearings were uniformly in favor of the bill. And it is undoubtedly a step in the right direction. However, a comment by the Senator is interesting, to say the least. He said, "We don't know what our policies of controlling science and technology should be."

The Senator may not have meant quite what a literal interpretation would imply—but there are increasing numbers who would. This may well be a forecast of things to come, with science and technology being subject to more criticism and control from without.

This is not to deny that criticism and control are not only justifiable but even essential in certain areas.

Referring again to Dr. Pitzer's review, it was pointed out that most major new technologies are already influenced or regulated by the government in some way. Notable examples are drugs, pesticides, nuclear energy, television, air transportation, pollution control, and oil drilling. Quoting Dr. Pitzer, "Thus it would not necessarily extend the range of government control to ask that this influence on, or regulation of new technologies be more sensitive to humanistic factors."

However, the pendulum never stops at the happy medium in human affairs, and the probability of controls and directions that are other than optimum is very real.

It is the responsibility of the scientific community to see that control is from an enlightened base and to become involved as individuals in the political and social implications of science and technology.

Harvard's Harvey Brooks stated at the Senate hearings, "Our problem is to discipline our mastery of nature and society so that man can live in harmony both with nature and his own human nature." He went on to say, "This means not less, but more and more sophisticated, science and technology."

However, the matter of support for science and technology is not unilateral. Since even the federal government does not have unlimited resources, it becomes a matter of choice.

The demands of society clearly exceed its presently available resources. In the establishment of priorities it is to be hoped that the selection will be based on enlightened self interest of the public. Former President Kennedy pointed out, "Scientists alone can establish the objectives of their research, but society, in extending support to science, must take account of its own needs."

The basic question is as Frederick Lindvall put it, "How should resources be allocated between science and other activities and needs of society? And within science, pure and applied, how should resources be allocated?"

I do not propose to speak to this subject, let alone to offer answers. My purpose here is to point out some of the searching questions that are being asked by the public, by public officials, and by their advisers and to discuss the importance of establishing better communication between the scientific community of which we are a part and other elements of our society for our mutual benefit and, what is more to the point, for the benefit of society as a whole.

Technology today has "Bad Press" in certain areas. Former President Johnson cautioned, "An aggrieved public does not draw the fine line between good science and bad technology. In a democratic society, the public attitude toward science must always be a real concern of the scientific community. If that attitude is to be favorable, science must be prepared to play its part in correcting the flaw in our environment."

A famous scientist once said, "Just as middle ages man could not ignore the church, nor renaissance man the arts, nor eighteenth century man political thought, so modern man cannot ignore science." Today, modern man is not ignoring science, and now science cannot ignore modern man.

The majority of our college students today are non-science majors, and they as voters, business men, administrators, and legislators will have much to say as to the direction of science and technology. If they are to have an understanding and appreciation of the role science has in the modern culture, the scientific community must abandon its stand-off posture.

The scientific community, being best prepared to sense the impact of its advances, should become more deeply involved as individuals in community, national and international affairs, which are so dramatically affected by scientific advance.

Please note, I said as individuals. There are those who disagree, but I am personally convinced that there are valid and sufficient reasons for the scientific societies to address themselves to their stated objectives and to stay out political affairs.

As individuals, the contrary is true, and there are compelling reasons for involvement.

Having presented the case before the argument, let us go back and consider a few of those areas of scientific advance which have a profound and serious impact on our society.

The weapons area is well publicized and perhaps more widely understood, or at least of more general concern than other areas, and will be noted only in passing—nuclear weapons, guided missiles, and homing devices, particularly in combination, present awesome capabilities of self-destruction and have had a profound impact on our thinking and action in international areas.

The weapons arsenal makes massive research efforts geared to defense mandatory—thereby affecting in theory, at least, our efforts in other areas. I say in theory, because I am not personally convinced that we would be willing to divert equivalent efforts to domestic problems. We have not so far addressed ourselves to such problems as medical research, hospitals, schools, slum clearance, pollution control, highways, etc. with the same intensity and with the same high level of funding that we have granted, however reluctantly, to defense needs.

Let us pass on, nevertheless, to other areas perhaps less commonly recognized by the man on the street.

Medical science has not in reality succeeded, as yet, in affecting the life expectancy significantly of those who escape accident or major illnesses, i.e., the Biblical three score and ten is still not too far off. It has, however, sharply curtailed the death rate at birth and in infancy, particularly in underdeveloped lands, and thereby played a major role in the population explosion with its attendant problems. One expert in the area of population growth pointed out in 1957 that in 20 years the population of India alone could equal that of the entire world at that time if the death rate were reduced to that in the United States and the birth rate remained at its current level. Conceding that the birth rate has in the past declined as countries have become more prosperous, most recent projections of the world-wide population trend indicate that inherent compensation factors will not solve the problems resulting from the mushrooming population.

The population explosion presents major areas for scientific and engineering development—improved sources of food, both natural and synthetic, will be required, areas not currently suitable for habitation must be reclaimed, water supplies must be improved, improved means of waste disposal must be developed, and pollution problems must be attacked more

vigorously. It seems incredible to consider the necessity of going to great lengths to reclaim waste land, while continuing to render available areas less and less habitable.

In the past, man has abandoned areas which he has rendered desolate and moved on to more fertile fields. In the future, the point will be reached where this is no longer possible. Society will have to live with the environment it creates, it will no longer be able to abandon it.

Our water resources will be a major problem. In fact, in certain areas it is already the number one problem. Usable water is confined to a relatively small are of the globe, and human and industrial wastes area contaminating this limited supply at a steadily increasing rate. Further, industrial development in remote areas is frequently contingent upon development of economic sources of water.

Climate control, or at least climate modification, may well be on the horizon. This may present major international problems. We are all aware of the legal concepts of the right to receive and discharge surface waters. Consider how infinitely more complex are the legal ramifications inherent in climate control. We see a forerunner of these in controversies over cloud seeding experiments.

To develop resources for servicing the expanding population, it is not sufficient to provide a water supply. All of the requirements of a concentrated population must be met. These include availability of other material resources, availability of energy transportation, etc.

As raw materials become less abundant, or of lower quality, new materials, new sources, and new process technology must be developed.

Jet air travel affects not only the speed with which we arrive at our destination, but our mobility as well. Isolationism, which was never justifiable in many of our minds, becomes impossible.

Further, with world wide television, underprivileged nations will become increasingly aware of their lower standards of living and will no longer be satisfied with a disproportionate share of the "Good Life."

Our own consumption of internally available raw materials and increasing awareness of other nations of the leverage they possess in raw materials supplies will present domestic as well as international problems. We may find economic balances arbitrarily changed by political decree in more pedestrian areas than gold and diamonds.

We have all heard impressive statistics relative to today's scientific effort—it being said that 90% of the scientists and engineers who have ever lived are alive today. What is germane to our consideration is that the rate of technological change has accelerated, so that job obsolescence and its related problems are of major concern at both professional and non-professional levels. This creates needs for better programs of continuing education and of re-education. Changes in our thinking as a nation with respect to responsibility for such programs is in a state of transition and may well be reflected to an increasing degree in legislation as well as in contract negotiations. One attendant problem that has attracted the attention of some professional societies is that of securing industry-wide benefit programs, with pension plans the major concern.

Increased leisure time and increased percentages of people of retirement age will present both problems and opportunities to science and technology.

Quite aside from the impact of world-wide television, other advances may well convert the world to a giant goldfish bowl, with all of us living in glass houses. Privacy will become more and more difficult to attain, as miniature wireless electronic devices become more commercial.

Computerized banking, health records, etc. will have their impact and present peripheral problems to us as individuals and to legislative bodies at all levels.

Computerization, in general, presents challenges in such diverse fields as education, medicine, labor law, and banking.

Space exploration creates questions of air rights, satellite use, and espionage as well as medical and insurance problems.

Refuse generation problems are not confined to air and stream pollution but involve the less sensational but none the less critical problem of disposal space for solid refuse.

Jet aircraft are creating an air pollution problem in heavy traffic areas. This is to say nothing of the sound pollution problem.

We have all read of the controversies surrounding the use of pesticides. It is regrettable that here as in many other instances public attention has been focused almost entirely on the price we pay for the benefit—with little or nothing being said about the benefits derived from their use.

Without discussing at all the merits of this or any of the other areas of controversy spawned by scientific progress, can we not all at least agree that the public could be better alerted to and informed of the impact of technological advances, both with respect to their advantages and their disadvantages?

Now each of you could develop your own list of scientific and technological advances that will present both challenges and opportunities to society. I make no brief for those presented here, they are only illustrative, and I have drawn, where possible, on examples that have involved advances in areas of particular interest to one or more of our Divisions.

The matter that should concern us is that increasing awareness is required of the impact of present and potential advances on our society. While it may be true that scientists and engineers are not a priori best qualified to assess the total social impact of their own findings—they should, on balance, contribute significantly to any analysis of such impact.

Dr. Pitzer summarized our responsibility well when he said, "It will not be easy to foresee all of the possibly damaging effects of a new product or machine, but we should try to do so. Since scientists are peculiarly able to visualize possible applications of new scientific knowledge and their efforts, scientists must play a major role in this judgment process. But other citizens who are sensitive to individual and community attitudes should also participate and help apply the humanistic value tests.

Our federal government is apparently becoming increasingly aware of the complexity of these matters and scientific advisors are being used more extensively and utilized in more responsible positions.

This is all to the good. However, we should consider carefully a warning issued by Dr. Cairns in his recent Perkin Medal Award Address when he warned that industrial scientists were not bearing their proportionate share of this responsibility but leaving it for the most part to their academic counterparts.

Of perhaps greater importance, however, is the lack of concern of the individuals who comprise the scientific community. We should, as individuals, take increasing interest in both domestic and international affairs. We should become involved in the determinations of our political system at all levels—local, state and national.

Very recently, during a television interview, a legislator was expounding on the merits of a technological advance. He was clearly, to those aware of the technology, at least, out of his field. Yet his views were taken by his audience as authoritative because of the committee responsibility he held.

In areas of complex technology, with even more complex social ramifications, the need for significant representation by trained technical people in all bodies of government, the legislative as well as the administrative, is apparent.

The fault lies not with "The Establishment" but with us as individuals. Many of us have erred in not wanting to get involved, claiming that politics was, at best, a messy business. We should encourage those with scientific and engineering training and ability to concern themselves in increasing numbers and in greater depth with domestic and international politics which most assuredly are being, and will continue to be, in increasing degree affected by scientific progress.

Even as more and more businesses are looking for executive talent in the scientific and engineering ranks, even so government by virtue of the increasing impact of science and technology will benefit from greater utilization of technically trained talent. Please note, I do not make a case for a scientific or an engineering

degree as a requirement for political office. I am only making a case for the benefits to be derived from increasing first-hand involvement and suggest that participation in the political system in all branches and at all levels in increasing numbers will have a synergistic effect on both the scientific community and our political bodies.

This should be coupled with a concerted effort by scientists and engineers from all vantage points, academic and industrial, to see that the public is well informed on all matters of scientific concern. A high order of statesmanship is required to insure that the effort is not self-serving and promotional, but that it is instructive. It will then be constructive—not destructive.

In summary then, a major challenge to the scientific community lies in the direction of (1) fostering a broader, more realistic understanding of the role of science and technology and (2) personal involvement in the political and social consequences of technological progress. For this to be effective we must (1) develop greater concern for the broader ramifications of technological progress; (2) become better informed in this area; and (3) open better lines of communication with those responsible for legislation affecting subsidization, implementation, and control of our technological effort.

The scientific societies per se should, however, as corporate bodies maintain their dedication to their presently stated objectives. To do otherwise would seriously hamper their progress toward their stated objectives.

The need for a forum combining scientific, technological, and humanistic interests cannot and should not be denied. In all such deliberations primary emphasis must be placed on the public interest and the human dimension. I submit, however, that this will be more effective if established outside the framework of the scientific and technical societies.

The Luminescence Efficiency of YVO_4 and $Y(V, P)O_4$

Henry F. Ivey and T. J. Isaacs, Westinghouse Research Laboratories, Pittsburgh, Pa.

It has been reported in the literature that the quantum efficiency for the blue emission of unactivated YVO_4 at room temperature is very low (5%) and can be greatly improved by forming solid solutions with YPO_4. We find that with sufficient care to eliminate accidental impurities, the efficiency at room temperature can be at least as high as 42% and that at liquid nitrogen temperature the same as for $CaWO_4$. With reduced impurity level, and reduced room-temperature quenching, the improvement upon introduction of YPO_4 is small.

329RNP

Luminescence of Pr^{+3} in (Y, Gd, or La)$_2O_2S$

Lyuji Ozawa, Zenith Radio Corp., Chicago, Ill.

It has been found that the emission lines, in eV, of Pr^{+3} in (Y, Gd, or La)$_2O_2S$ linearly shifted to higher energy (shorter wavelengths) when the ionic radius of the rare earth cation increases. The hexagonal lattice constants, a and c, also increase with an increase in cation radius. The change of the emission lines can be correlated with the distortion of the Pr^{+3} center. It has also been found that there is energy transfer from host to Pr^{+3} and from gadolinium to Pr^{+3}.

330RNP

The Degradation of Aperture Lamps

George T. Bauer, Research Laboratories, Xerox Corp., Rochester, N. Y.

A relatively fast degradation of zinc silicate coated aperture lamps has been observed when compared with conventional fluorescent lamps. Measurements and calculations indicate that the main cause of the degradation is the effect of ultraviolet irradiation on the luminous efficiency and the reflectance of the lamps' coating. The time dependence of the formation of absorbing centers of x-rayed zinc silicate phosphor has been studied and related to the degradation process in the lamps.

331RNP

Scanning Electron Microscopy of Sulfide Phosphors

P. Lubin, R. Simon, and J. Varon, The Bayside Laboratory, Research Center of General Telephone and Electronics Laboratories, Inc., Bayside, N. Y.

The scanning electron microscope is an ideal instrument for the study of phosphor materials on a point by point basis. Besides topographical displays, information relating to cathodoluminescence can also be obtained. A cathodoluminescent attachment has been constructed for the JSM-1 scanning microscope. Scanning micrographs have been obtained in both the secondary electron mode and the cathodoluminescent mode. Resolution in the cathodoluminescent mode is a function of beam size, penetration distance, nonradiative surface layers, and the absorption distance. Illustrations of the effect of voltage are shown.

332RNP

X-Ray Excited Fluorescence in Rare Earth Fluorides for Trace Analysis

R. J. Jaworowski, J. R. Cosgrove, and D. J. Bracco, The Bayside Laboratory, Research Center of General Telephone and Electronics Laboratories, Inc., Bayside, N. Y.

The use of x-ray excited fluorescence to detect trace rare earth impurities in oxide matrices has been described[1,2,3]. This paper describes the extension of the method to metal fluoride matrices, particularly YF_3 and GdF_3. Relative to oxide matrices, these compounds exhibit lower intensity and more nonradiative resonance transfer among rare-earth ions to the extent that detection limits are two orders of magnitude higher than in Y_2O_3 and identification of individual species in mixtures is difficult.

Measurement of Oxygen and Carbon Content of Semiconductor Grade Silicon

C. Cross,* G. Gaetano,* T. N. Tucker,† and J. A. Baker,† *Langley Research Center, Hampton, Va.; †Dow Corning Corp., Hemlock, Mich.

The oxygen and carbon content of several silicon single crystals have been measured using ^3He (15.4 MeV) activation techniques and are compared with values determined from infrared absorption measurements. The oxygen and carbon content of these crystals as determined from the activation analysis ranged from <0.05 to ~30 ppm and <0.05 to ~7 ppm, respectively. The infrared absorption measurements gave results that agreed favorably with these values.

High-Field Effects and Ohm's Law in N-Type Silicon

R. Jaggi, IBM Zurich Research Laboratory, 8803 Rüschlikon, Switzerland

The nonohmic behavior of elemental semiconductors is well described by an effective conductivity

$$\sigma = \frac{J}{E} = \sigma_0 \cdot \left(1 - \frac{J^2}{J_c^2}\right)$$

where J = current density and E = electric field. σ_0 is the ohmic conductivity in the limit $J \to 0$, $E \to 0$ where Ohm's law is valid. J_c is the saturation value of the current density in the limit $E \to \infty$. It is of special importance for materials analysis that J_c depend not only on the carrier concentration, but also on the geometry of the specimen. This is shown by evaluation of literature data and by recent experiments.

The Growth of Submicron Epitaxial Silicon Layers by Silane Pyrolysis

A. C. Adams and J. Simpson, Bell Telephone Laboratories, Murray Hill, N. J.

Epitaxial silicon layers, 0.3-1.0μ thick, have been grown on silicon substrates by the pyrolysis of silane between 950°-1150°C with

Cathode Materials and Performance in High-Temperature Zirconia Electrolyte Fuel Cells

C. S. Tedmon, Jr.,* H. S. Spacil,* and S. P. Mitoff

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

The high-temperature zirconia electrolyte fuel cell is materials-limited in both its performance and its range of potential application. The most significant materials limitations and problems occur with the cathode. Cathode materials must satisfy four general criteria: (*i*) chemical, (*ii*) electrochemical, (*iii*) mechanical, and (*iv*) economical. In this paper, the interaction between cathode materials and cell performance is considered quantitatively for three general classes of cathodes, *viz.*, metals, oxides with embedded current collectors, and electronically conducting oxides.

Successful and economical operation of high-temperature, zirconia electrolyte fuel cells requires that the electric current generated by the electrochemical combustion of the fuel be conveniently and inexpensively extracted from the cell. The design and selection of materials for this purpose, *i.e.*, electrodes and electrode leads, is a challenging problem in view of the operational requirements and working environment of the cell. In terms of both its range of application as well as its performance capability, the high-temperature zirconia electrolyte fuel cell is a materials-limited device. The most significant materials limitations at this time are imposed by the cathode and the cathode leads. In this paper, operational criteria are identified and applied to the problem of selecting materials for the cathodes; in addition, the interactions between cathode materials and cell performance are considered quantitatively.

Criteria for Cathode Materials

A perspective of the materials problems associated with the cathode of a high-temperature zirconia fuel cell may be obtained from a brief consideration of the over-all device, including test leads and auxiliary electrodes, in a typical operating environment, such as shown schematically in Fig. 1. The environmental characteristic to be noted in particular is the exposure of the cathode to a highly oxidizing atmosphere (usually air) at very high temperatures, *ca.* 800°-1200°C. It is this combination of high temperature and oxidizing atmosphere that leads to severe materials limitations for the cathode.

There are four general types of criteria to be satisfied: chemical, electrochemical, mechanical, and economical. The first three define the degree of technical performance of the device, and the last establishes its range of application. These various requirements are considered separately.

Chemical requirements.—These requirements arise as a consequence of the physical environment in which the cathode operates, and may be summarized as follows:

1. Chemical stability in air (stable with respect to oxidation or nitrification reactions).
2. Phase stability over the temperature range of operation, *i.e.*, no allotropic transformations.
3. Low vapor pressure (minimize volatilization losses).
4. Inert with respect to chemical reactivity with the electrolyte and lead wires. It will be seen subsequently that most potential cathode materials fail to satisfy one or more of these criteria.

The reasons for these criteria are generally obvious. A practical fuel cell will almost certainly use air as the oxidant, hence nitrification as well as oxidation reactions must be considered. Furthermore, in the temperature range of cell operation, chemical inertness *per se* does not exist but rather must be considered in a kinetic context. For long term (several years) operation of fuel cells, the kinetics of the reaction "ZrO_2(Stab.) + cathode materials → reaction products" must be considered. Examples of this problem will be described.

Electrochemical requirements.—The most fundamental electrochemical requirement for the cathode is that it be a satisfactory oxygen electrode. Since a definitive model of a high-temperature solid-state oxygen electrode is lacking, this criterion is not especially informative from a materials viewpoint. The over-all cathode reaction is

$$O_2\ (\text{gas}) + 4e^- = 2\,\underline{O}^=$$

where $\underline{O}^=$ denotes an oxide ion, *i.e.*, an oxygen ion incorporated in the zirconia anion sublattice. Details of the various stepwise reactions comprising the net reaction, such as adsorption, dissociation, surface migration, and ionization, are not known. However, since fuel cells with good cathodes can be operated reversibly (1), these steps must be fast, which is not unexpected in view of the high temperatures involved.

In addition, there are mass transport effects which can arise leading to electrode polarization. Assuming the cathode reaction takes place at or near the cathode/electrolyte interface, it will be necessary to bring the species participating in the reaction, oxygen molecules, oxide ions, and electrons, to that site. Of particular interest is the transport of molecular oxygen to the reaction site. If the cathode is porous, then

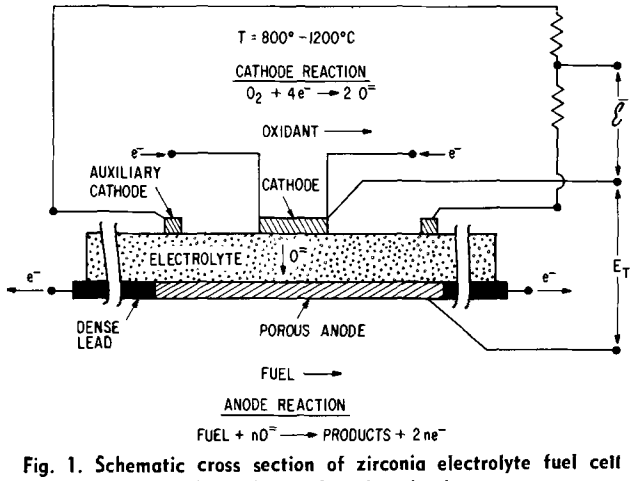

Fig. 1. Schematic cross section of zirconia electrolyte fuel cell with auxiliary electrodes and typical testing circuit.

* Electrochemical Society Active Member.

gas transport is involved, and a limiting current density may be defined based on the diffusion rate of oxygen gas from the air through the pores to the reaction site. As a consequence of nitrogen concentration (from oxygen depleted air) in the pores of the cathode, the amount of oxygen at the reaction sites is decreased. This phenomenon has been investigated using the experimental apparatus shown schematically in Fig. 1. The voltage E_T is the terminal voltage during cell operation and reflects changes in the oxygen partial pressure at each electrode as well as voltage drops across the electrolyte and at the electrodes. The voltage $\bar{\mathcal{E}}$ measures the difference between an average open-circuit voltage (obtained from two auxiliary electrodes which carry no current on the cathode side of the cell) and the terminal voltage. It then is a direct measurement of the total cell overvoltage including both ohmic and nonohmic voltage drops across the cell. Thus changes with different fuel and oxidant compositions in $\bar{\mathcal{E}}$ reflect changes in electrode characteristics. Results from a fuel cell tested using this apparatus are presented in Fig. 2. The cell employed in these experiments had a porous Ni anode, an yttria (10 m/o)-stabilized zirconia electrolyte, and a porous $PrCoO_3$ cathode about 0.13 mm thick. This particular cathode material is discussed in greater detail in a later section. The fuel was hydrogen containing initially 3% water vapor, and the oxidant was oxygen diluted with nitrogen to produce the compositions indicated. The effect of decreasing the initial oxygen content of the cathode gas from 50 to 5% is dramatic, leading to a large nonohmic overvoltage and a limiting current density of about 0.9 A/cm^2 for this cell. Although a practical fuel cell would not use an oxidant initially containing only 5% oxygen, it should be recognized that, if air is the oxidant, in cells operating with reasonably large fuel and oxidant conversion efficiencies, the oxidant composition at the downstream end of the cathode could very easily be reduced to 5% or less, resulting in significant gas phase polarizations. Since mass transport effects will be small at low current density, the fact that the slopes of the $\bar{\mathcal{E}}$ *vs.* current density curves are initially about the same indicates that any activation polarizations depending on oxygen pressure at the cathode are small compared to the resistive voltage drop.

A porous cathode operating on pure O_2 could show a mass transport polarization if pore sizes were sufficiently small, due to the viscous drag of the oxidant flowing through these pores. High-temperature fuel cell cathodes have pores exceeding the submicron size that would give rise to this effect, and the mass transport polarization of porous cathodes then results entirely from the interdiffusion of O_2 and N_2 in the pores. Under these conditions, since there is no net flow of N_2, the mass transport limiting current density can be obtained as

$$j_L = \frac{4\mathbf{F}cD_{O/N}p}{st} \ln \frac{1}{1 - x_{O_2}} \qquad [1]$$

where **F** is the Faraday constant, c is the molar density of the oxidant, $D_{O/N}$ is the interdiffusion coefficient for O_2 and N_2 mixtures. p, s, and t are the fractional porosity, tortuosity, and thickness, respectively, for the cathode, and x_{O_2} is the mole fractional O_2 content of the oxidant in the gas phase adjacent to the cathode. Taking $D_{O/N}$ at 900°C as 2.5 cm^2/sec, and assuming p and s have values of 0.25 and 1.5 for a cathode with a thickness of 0.15 mm (150μ), the value of j_L for air with 21% O_2 is 26.5 A/cm^2. This is not likely to be a problem as such, but Eq. [1] confirms that the value of j_L does depend on O_2 content, leading to the possibility of significant polarization at the cathode under some operating conditions as noted previously. Thus for 5% O_2, the same cathode parameters yield a value for j_L of 5.9 A/cm^2. The preceding analysis applies equally well to metallic or nonmetallic cathodes.

In addition to these features of a porous electrode, there is another factor that can introduce electrical losses, which arises from the fact that the cathode is generally not in continuous contact with the electrolyte, but rather is in contact in discrete areas separate from one another. Tannenberger and Siegert (2) have discussed this problem with zirconia cells having solid silver cathodes, and Gorin and Recht (3) have observed this effect in molten salt fuel cells. The result of this discrete contact is that ions and electrons will be restricted in their flow to points of cathode/ electrolyte/ oxidant contact, giving rise to regions of locally high current density. This introduces a resistive loss which is termed a "constriction" resistance and is added to the cell resistance that would be expected on the basis of bulk resistivities and geometry. Thus with porous cathodes, cathode voltage drop can arise from at least two sources: gas-phase polarization, and constriction resistances. The former can also show a mass transport limiting current density.

Nonporous cathodes have been tested. Because of its relatively high solubility for oxygen and its stability in an oxidizing environment, silver, both solid and molten, has been used in cells (4), but cell lifetimes are very short because of volatilization losses. Mixed conducting oxides, *i.e.*, oxides which conduct both oxygen ions and electrons, have also been tested. With a dense, nonporous cathode, constriction resistance is eliminated, but a limiting current density can again arise because of mass transport limitations in the electrode. For the case of a material, such as silver, which can dissolve oxygen and transport it to the electrolyte while simultaneously acting as an electronic conductor, the mass transport limiting current density is

$$j_L = \frac{2\mathbf{F}c_O D_O}{t} \qquad [2]$$

where c_O is the maximum solubility of oxygen in the material (expressed as a molar concentration) in equilibrium with the oxidant adjacent to the cathode, D_O is the diffusion coefficient for oxygen through the material, and t is the cathode thickness. For silver at 900°C, D_O is 3.5 x 10^{-5} while c_O is 1.8 x 10^{-5} when equilibrated with air. For a cathode with a thickness of 0.01 mm (10μ), the value of j_L is 0.125 A/cm^2. This is not high enough to allow satisfactory power densities. In addition, the value of j_L depends on c_O, which will decrease as the O_2 content of the oxidant decreases. Thus nonporous solid silver cathodes would have to be less than 10μ thick to allow sufficient oxygen transfer in operation.

Either the ionic or electronic conductivity in a mixed conduction oxide will be limiting, depending on which

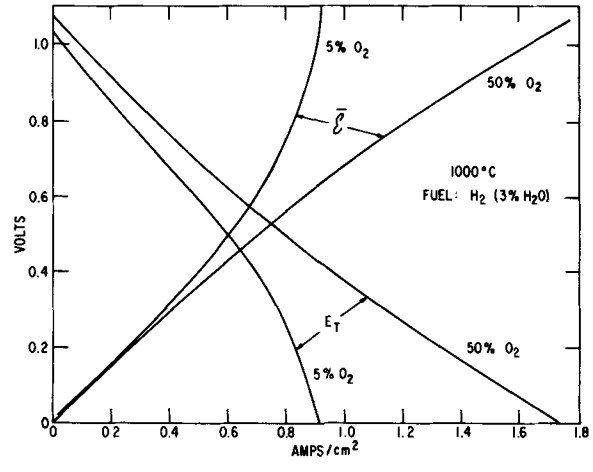

Fig. 2. Voltage-current characteristics for fuel cells operated with 50% O_2 and 5% O_2 initially in the oxidant, showing effect of oxidant composition on the terminal voltage (E_T) and the total cathode overvoltage ($\bar{\epsilon}$).

is smaller. In either case, the mass transport limiting current density in such a cathode is given approximately by the expression

$$j_L = \frac{\sigma_{i,e}\,\Delta E_c}{t} \quad [3]$$

where $\sigma_{i,e}$ is the conductivity of either ions or electrons, whichever is smaller, ΔEc is the maximum voltage drop across the cathode, and t is the cathode thickness. Equation [3] is employed by setting ΔE_c equal to 1V, the approximate value of the open-circuit voltage of most high-temperature cells. The relationship between Eq. [3] and the two preceding equations, both of which involved the product of a concentration and a diffusion coefficient, can be seen by substituting into Eq. [3] the value of $\sigma_{i,e}$ given by the Nernst-Einstein relation, namely

$$\sigma_{i,e} = \frac{z^2F^2c_{i,e}D_{i,e}}{RT} \quad [4]$$

where z is the number of electronic charges per charge carrier particle, $c_{i,e}$ is the molar concentration of ions or electrons, $D_{i,e}$ is the diffusion coefficient for ions or electrons through the oxide, R is the gas constant, and T is the absolute temperature. This relationship is actually used to determine the product $c_{i,e}D_{i,e}$ since neither of these quantities is normally experimentally accessible in conducting solids.

At 900°C, the value of $\sigma_{i,e}$ for either ions or electrons can be taken as 0.05 ohm-cm^{-1} for zirconia-based oxides that might be employed for cathodes. Then Eq. [3] gives the value of j_L of 3.3 A/cm^2 for a cathode 0.15 mm thick. From a mass transport standpoint only, this type of cathode should offer no problem.

In addition to these electrochemical criteria, there is an electrical resistance requirement, namely, that the cathode specific resistance, r_c (ohms-cm^2), cannot exceed a certain arbitrary upper limit, the magnitude of which will be dependent on the system configuration. For fuel cells which are electrolyte limited, that is, cells in which the electrolyte resistance dominates the total resistance of the cell, the specific resistance of the cell as viewed from the terminals is given by the relation

$$r_T = r_e + f(r_a + r_c) \quad [5]$$

where r_e, r_a, and r_c are the specific resistances of the electrolyte (including constriction resistances, if any), anode, and cathode, respectively, and f is a constant which takes into account the fact that the current distribution varies along the length of the electrodes ($f = 0.08 - 0.3$). This specific resistance, r_T, with dimensions of ohm-cm^2, is the resistance of a hypothetical cell 1 cm^2 in area which has the electrical properties of the actual cell under consideration. Equation [5] can be derived by a straightforward, although tedious, analysis of a one-dimensional distributed current network (5). The value of r_T must be 1 or less to achieve power densities above 0.25 w/cm^2, a realistic lower limit for feasible systems.

If r_a is small compared to r_e and r_c, as will generally be the case if metal anodes such as porous Ni are used, the following approximation results

$$r_T = r_e + f \cdot r_c \quad [6]$$

If L is the fractional voltage loss to be permitted at the cathode, then it follows directly that

$$r_c = \frac{r_e}{f}\,[L/(1-L)] \quad [7]$$

The application of this equation to specific systems will be demonstrated in a subsequent section.

The specific resistance of a cathode in the form of a thin layer is given by an expression of the form

$$r_c = \frac{\rho}{t}\,l^2 \approx \frac{1}{1-p}\,\frac{1}{\sigma t}\,l^2 \quad [8]$$

Table I. Summary of limiting current density and resistivity-thickness ratio data for thin cathodes

Cathode	t mm	σ ohm-cm^{-1}	j_L A/cm^2	ρ/t ohm/square	$j_L/(\rho/t)$
Porous oxide	0.15	5×10^2	26.5	0.178	149.0
Dense Ag	0.01	1.34×10^6	0.125	0.0075	16.7
Mixed σ oxide	0.15	5×10^{-2}	3.3	1340	0.0025

where ρ is the resistivity of the cathode material, σ the bulk conductivity, p the fractional porosity (if any), t the thickness, and l is the active length of the cell. Since a cathode should have a high value of j_L and a low value of ρ/t, a figure of merit for use without an embedded current collector grid is the ratio of these two quantities. This ratio, $j_L/(\rho/t)$, will be independent of thickness as can be seen by reference to Eq. [1]-[4] and [8], and is thus a measure of the ability of a cathode material to simultaneously deliver oxygen and electrons to the cathode/electrolyte interface. Table I summarizes the values of j_L, ρ/t, and their ratio for the three examples that have been considered so far. The conclusion is that porous oxides (with sufficiently high conductivity) and Ag (which is the most eligible material for a nonporous metallic cathode) have high figures of merit, but that a silver cathode would have to be very thin to be useful. Mixed conductivity oxides could not be used without embedded current collectors without a drastic increase in conductivity over that obtainable in zirconia-base oxides.

Mechanical requirements.—The mechanical criteria for the cathode are simply that the electrode must maintain any porosity required for O_2 transport and maintain physical and electrical contact with the electrolyte and lead wires throughout all phases of cell operation. This latter requirement applies especially to athermal conditions where differential thermal expansion can cause large interfacial stresses. If the cathode is largely metallic, stress-relief by plastic flow can occur without deleterious effects to the cell. However, if oxide electrodes are used, plastic deformation is unlikely and stress-relief may occur by means of cracking, spalling, or other mechanisms leading to loss of adherence at the interface. The mechanical integrity of an oxide cathode will depend on particular materials used. The strength of its bond to the electrolyte (which will probably depend in turn on the method of application) will also be a function of the thickness of the electrode, and the maximum temperature range traversed in a thermal cycle.

Economic requirements.—Technical and commercial success in high-temperature fuel cell technology essentially overlap in meaning since a fuel cell, as a power producing device, must compete economically with existent power producing systems. The use of noble metals in electrodes or leads, for example, may be acceptable from the viewpoint of their technical performance, but will generally place a significant, if not prohibitive, economic penalty on the system.

Electrode Materials

A wide variety of materials have been proposed for cathodes in high-temperature, zirconia electrolyte fuel cells. These materials may be categorized into three classes: (*a*) metals, (*b*) oxides with current collector grids, and (c) electronically conducting oxides without current collector grids. Each of these classes will be considered in turn.

Metals.—Because of the highly oxidizing environment at the cathode, only the noble metals, Pt, Pd, Au, and Ag, merit serious consideration. Since the oxygen solubility in the first three is relatively small, cathodes made from these metals will have to be porous in order to avoid a very low limiting current density arising from oxygen transport in the metal. The use of Au

as a cathode metal is limited by its melting point which would fix the maximum cell operating temperature. Furthermore, since typical cell operating temperatures are generally at least 90% of the absolute melting point of Au, excessive sintering of the porous electrode would occur. The same problem exists to an even greater degree with porous Ag cathodes. Because of their higher melting points, sintering of porous Pt or Pd electrodes is much less of a problem. Porous Pt electrodes are effective air electrodes and have been used by several investigators in zirconia fuel cells (6). Zirconia and Pt have very similar thermal expansion coefficients, and Pt electrodes can easily be applied from a resinate or paste, or by sputtering. Being a metal, Pt satisfies the electrical conductivity criterion. Porous Pd cathodes have also been tested and show satisfactory short-term performance. There are two disadvantages to using either Pt or Pd electrodes, however. The first is cost; their use imposes an economic penalty that is essentially intolerable for any practical application. The second disadvantage arises from the necessity of having a porous electrode, which means having a large surface to volume ratio in the metal. While this is desirable from the electrochemical viewpoint as previously discussed, it is deleterious with respect to surface reactions such as volatilization. Metal recession data are shown in Table II; these data were calculated from equilibrium vapor pressure data (7) assuming a vaporization coefficient of unity. Pd is obviously unacceptable because of volatilization.

Silver is an interesting material for fuel cell cathodes because of its high solubility and diffusivity of oxygen, particularly when it is molten, and because it is relatively oxidation resistant. It has been demonstrated (4) that molten silver is a satisfactory oxygen cathode in short term applications, and of course it has a high electronic conductivity. Unfortunately any long term use as a cathode is severely limited above its melting point (Table II). Below the melting point of Ag, its solubility for oxygen is greatly reduced, hence very thin electrodes must be employed to avoid significant limiting current densities (Table I). Even at temperatures as low as 800°C, volatilization rates are large, and the lifetimes of Ag electrodes at this temperature would be too short for practical consideration. It should be pointed out that the data shown in Table II were calculated assuming free evaporation into a vacuum with an evaporation coefficient of unit. In a fuel cell, the presence of the oxidant gas will substantially slow down volatilization. However, even if the evaporation coefficient for Ag, for example, were as small as 10^{-3}, substantial metal losses would still occur.

In summary, electrochemically effective oxygen cathodes can be made from Pt, Pd, or Ag, but their application in a practical fuel cell system is essentially nil because of economics in the cases of Pt and Pd, and volatilization in the cases of Pd and Ag.

Oxide-current collector cathodes.—Another type of oxygen electrode that has received attention is a composite system consisting of a matrix of an oxide which provides for oxygen transport either by being porous, or by being an anionic conductor, or both, and in which is embedded a grid of current collector wires which provide electronic conductivity. Porous stabilized zirconia, applied from a slip over a Pt grid, is an example of this type of electrode. Porous zirconia is a good cathode material, and obviously is compatible with the electrolyte. Its only shortcoming is its lack of electronic conductivity. This can be increased by doping with multivalent cations, but a current collector grid is still required as indicated by Table I. The use of nonnoble metals as current collectors is limited by their oxidation resistance and also by the fact that many of the oxidation resistant alloys commercially available form protective scales which are not electronic conductors and would thus insulate the current collector grid from the rest of the electrode. An approximate expression for the over-all specific resistance of this type of electrode is given by the relation

$$r_c = \frac{\rho}{12\,N\,t} \qquad [9]$$

where ρ is the resistivity of the oxide matrix (for electronic conduction), N is the number of square grids per unit area of cathode, and t is the cathode thickness. This expression is derived simply by considering the average distance that an electron must travel in a square grid to reach a current collector wire.

Fuel cells with this type of electrode have been built and tested, and satisfactory performance was obtained. However, cathodes of this type, using either Pt or Pd current collector grids, fail to satisfy economic criteria, as can be seen from the following discussion. In order to evaluate Eq. [9] for a typical case, consider an electrode with a porous zirconia matrix and Pt current collectors in a square grid. Assume the electrode is 0.25 mm thick, which is a typical value. Greater thicknesses will reduce the electrode resistance but increase the amount of gas-phase polarization. Further assume the oxide matrix of the cathode is yttria-doped zirconia, 50% dense, and heavily doped with iron to increase the electronic conductivity. At 1000°C, the resistivity for ionic conduction of zirconia, corrected for porosity, is about 20 ohm-cm (8). The electronic resistivity, due to the iron doping, is of the order of ten times the ionic resistivity, *i.e.*, about 200 ohm-cm. Let the maximum voltage loss to be tolerated be 10%, *i.e.*, $L = 0.1$. The specific resistance of the electrolyte, r_e, is the resistivity-thickness product, and for a fuel cell with an electrolyte of yttria-stabilized zirconia 0.50 mm thick, at 1000°C will be about 0.5 ohm-cm^2. Therefore, from Eq. [7] through [9], it is seen that $N = 950$, which means that the spacing of the wires is about 0.3 mm. Even using wire as small as 0.1 mm in diameter, the cost would be prohibitive for most applications. Substitution of Pd for Pt would not reduce the cost to an acceptable level for most applications. Consequently it is concluded that this type of cathode is not practical.

Electronically conducting oxide cathodes.—The third and most interesting class of cathodes is that in which the electrode is made from a porous oxide that has sufficiently high electronic conductivity that current collector grids are not required. The electrode must be porous because those oxides which possess high electronic conductivity do not exhibit high anionic conductivity. Therefore porosity is required to minimize gas-phase polarization.

Oxides of interest include Li-doped NiO, Sr-doped $LaCoO_3$, Sn-doped In_2O_3, doped ZnO, doped SnO_2, and $PrCoO_3$. Figure 3 presents electronic conductivity data as a function of temperature for these materials. The mechanisms by which these oxides obtain their high values of conductivity are not completely understood. Li-doped NiO has been most thoroughly investigated (9-11), and it is believed that when NiO, a p-type semiconductor is doped with Li_2O (up to 10 m/o), the Li^{+1} ions enter the Ni^{+2} cation sublattice, decreasing the cation vacancy concentration and increasing the number of electron holes, the latter being a consequence of the transition of Ni^{+2} to Ni^{+3} (10). Similarly in the case of the perovskite $Sr_{1-x}La_xCoO_3$ ($x \approx 0.9$), the replacement of the La^{+3} ions by Sr^{+2}

Table II. Metal recession due to volatilization in 10^4 hr

ions forces the transition of an equivalent number of Co^{+2} ions to Co^{+3} ions (12). It is presumed that the interaction of Sn^{+4} ions with In^{+3} ions produces an analogous effect in the case of SnO_2-doped In_2O_3. The conduction mechanism for ZnO doped with small amounts of Zr or Al ions is believed to be due to substitution of the doping ion into the Zn^{+2} sublattice with the generation of electrons in the conduction band (13). The conduction mechanism for $PrCoO_3$ and undoped $LaCoO_3$ is not understood, although several models have been described for the latter (14, 15).

From the data shown in Fig. 3, it is apparent that several compositions possess adequate electronic conductivity to satisfy the resistivity criterion previously discussed. None of these materials is without its limitations, however. Li-doped NiO, which has only a marginal value of conductivity, is unsatisfactory because of rapid loss of Li due to the high vapor pressure of LiOH in moist air at typical cell operating temperatures. The effect of Li volatilization on the conductivity of Li-doped NiO as a function of time is shown in Fig. 4. These data were obtained from a cathode sample which consisted of two Pt current collector loops tied around a 1 cm diameter zirconia tube, over which a porous cathode of $Li_{0.1}Ni_{0.9}O$ was applied to a thickness of about 1 mm. Four-point resistance data were obtained as indicated. In this type

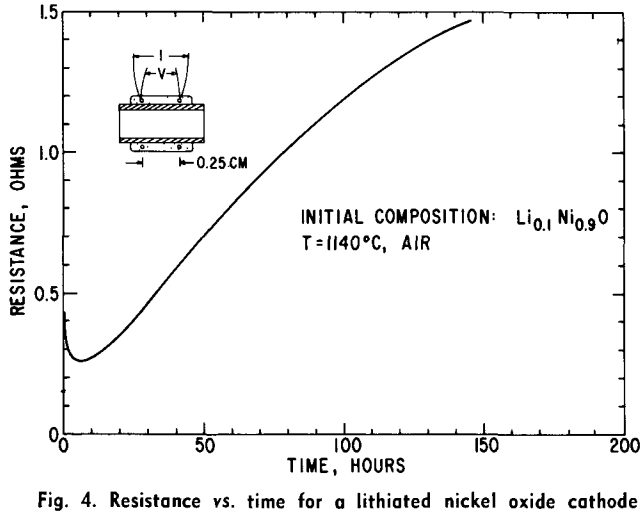

Fig. 4. Resistance vs. time for a lithiated nickel oxide cathode sample showing effect of Li loss on cathode resistance.

of test, the contact resistance between the current collectors and cathode is included in the total measurement. Also, the electrolyte substrate is in parallel electrically with the cathode; however, the resistance of the electrolyte is much larger than that of the cathode, at least initially. Many such tests of this type were conducted, and the results presented in Fig. 4 are typical. There is an initial decrease in resistance, probably due to sintering of the cathode. After several hours, the resistance begins to increase, and after several hundred hours, depending on the test temperature, will start to level out. Over a substantial interval the rate of increase is essentially linear with time, suggesting that Li volatilization is not diffusion limited. The slope dR/dt, for example, after 75 hr, is about 10^{-2} ohms/hr. The Li content for the sample shown in Fig. 4 after 150 hr was less than 10% of the original level, *i.e.*, the composition was less than $Li_{0.01}Ni_{0.99}O$.

Button and Archer (12) have examined in detail the performance of Sr-doped $LaCoO_3$ air electrodes and found a number of problems with them. Obtaining satisfactory adherence of the perovskite to the electrolyte was difficult. When the perovskite was applied to the electrolyte as a powder (in a slurry), and heated to a temperature high enough to produce a liquid phase, adherent coatings were produced, but subsequent electrical and structural studies indicated chemical interaction between the electrode and electrolyte. Vapor deposition from chlorides appeared to yield best results, but it is a rather complicated technique requiring close control.

During cell testing, other problems were reported, such as cracking of the cathodes due to thermal expansion mismatch with the electrolyte, and phase separation in the perovskite which had been melted. Also, overvoltages were frequently large, although this depended considerably on the fabrication technique for the cathode.

Fuel cells with $LaCoO_3$ air electrodes, with and without Sr-doping, were built and tested in this Laboratory. Like most of the cells tested, these cells were built with porous Ni anodes to which about 20 w/o zirconia had been added (to prevent grain growth and sintering), and yttria-stabilized zirconia electrolyte. The thicknesses of the anode and electrolyte were about 0.12 and 0.5 mm, respectively. The $LaCoO_3$ was applied from a slurry, forming a porous electrode about 0.3-0.4 mm thick. Initially, cell performance was quite good, with power densities in excess of 500 mw/cm^2 at 1100°C being obtained. However, this performance declined rapidly with time, and after 500 hr of operation, the power density was about one-half its initial value. Examination of the cells after operation disclosed that the $LaCoO_3$ electrode was chemically reacting with the electrolyte resulting in reaction products which were not electronically conducting. The reaction was complex and the reaction products were not completely identified. It was evident, however, that the electrolyte near the electrode was locally destabilized.

The adherence problem with $LaCoO_3$ electrodes arises from its large coefficient of thermal expansion. At 1000°C, the thermal expansion coefficient of $LaCoO_3$ is about 28 x 10^{-6} °C^{-1}, compared to a value for stabilized zirconia of about 10 x 10^{-6} °C^{-1}. Consequently, differential thermal expansion during athermal condition, particularly cooling cycles, leads to cracking and spalling of the electrodes.

Takahashi *et al.* (13) have reported on the use of ZnO cathodes doped with small amounts of Zr or Al. Conductivity data for these materials are presented in Fig. 3. They found that optimal conductivity was obtained with about 3% doping. Satisfactory results were obtained from fuel cells operated in the range of 800°-1000°C. Similar cells were tested in this Laboratory, and it was found that at temperatures above about 1000°C the ZnO attacked the zirconia electrolyte, leading to rapid failure of the cell. Below 1000°C, sat-

isfactory performance was obtained for tests of short duration.

Sverdrup *et al.* (16) have investigated the use of doped In_2O_3 and doped SnO_2 oxide films as air electrodes. Of these, Sn-doped In_2O_3 appeared the most promising as an air electrode for cells operating up to 1000°C. The electrodes were applied to the zirconia electrolyte by a vapor deposition process. Films of SnO_2 were applied in thicknesses between 10^{-3} and 10^{-2} mm; films of greater thickness than 3×10^{-2} mm led to cracking of the electrolyte during cooling of the cells. They concluded that satisfactory air electrodes could be built from doped SnO_2. In their tests with doped In_2O_3, they reported cracking of the electrode when its thickness exceeded 9×10^{-2} mm. Overvoltage measurements indicated that there was negligible electrode-electrolyte contact resistance. As-deposited electrodes exhibited high levels of gas-phase polarization, apparently due to the electrode being impervious to oxygen transport. However, a "reverse-current" treatment of the electrode, consisting of applying a voltage across the electrode/electrolyte interface with the electrode made positive compared to the electrolyte, resulted in a marked decrease in polarization. They postulated that this was due to oxygen paths opening up in the electrode during the reverse current cycle. This treatment did increase the contact resistance, however.

Another material of interest is the perovskite $PrCoO_3$. It is a good electronic conductor without doping; addition of Sr does not significantly change the over-all level of conductivity, but does result in a shift of the conductivity maximum from about 700° to 500°C (17). Like $LaCoO_3$, $PrCoO_3$ also reacts with zirconia in a complex manner. The result of this reaction in a fuel cell is an increase in resistance near the cathode/electrolyte interface, where the reaction is proceeding. However, the reaction kinetics of the $PrCoO_3$ are much slower than $LaCoO_3$ (18), and extrapolation from endurance tests on fuel cells with $PrCoO_3$ electrodes indicates that satisfactory performance should be possible for several years at cell operating temperatures of 1000°-1100°C.

Many tests have been carried out on cells with porous $PrCoO_3$ cathodes. The electrodes are applied by hand from a slurry, and are sintered *in situ* when the cell is heated to operating temperatures. Current-voltage characteristics have been obtained similar to those shown in Fig. 2. When air is used as the oxidant, the terminal voltage, and overvoltage curves fall between those shown for the 5 and 50% mixtures, as expected. Cathodes of this type typically have resistivity/thickness ratios of about 0.15 ohms/square. Using Eq. [7] this means that electrodes of 1-2 cm in length can be used without introducing significant losses. With hydrogen as the fuel and air as the oxidant, fuel cells of this construction have generated power densities of about 300 mw/cm² at 1000°C and 600 mw/cm² at 1100°C, for periods in excess of 5000 hr. Such cells, however, do not survive thermal cycling; the thermal expansion coefficient of $PrCoO_3$ is about 2.5-3 times larger than that of zirconia, which leads to interfacial stresses and spalling of the cathode during cooling. This problem does not arise on heating up a new cell, since the electrode is sintered *in situ*.

Table III. Summary of performance data on fuel cell cathodes made from electronically conducting oxides

Oxide	Investigator	Results
$Li_{0.1}Ni_{0.9}O$	GE	Li volatilizes leading to loss of conductivity.
Doped ZnO	Takahashi *et al.* (13)	Reported satisfactory at relatively low cell operating temperatures (800°C); marginal value of conductivity.
ZnO	GE	Reacted with zirconia.
Doped In_2O_3	Sverdrup *et al.* (16)	Satisfactory if applied in thin layers; some difficulty with cracking.
Doped SnO_2	Sverdrup *et al.* (16)	Satisfactory if applied in thin coatings.
$Sr_{0.1}La_{0.9}CoO_3$	Button and Archer (12)	Reacts with electrolyte; spalling and cracking during cooling cycles.
$LaCoO_3$	GE	Chemical reaction with zirconia prohibits long-term stable performance; thermal expansion mismatch.
$PrCoO_3$	GE	Satisfactory performance; capable of long-term performance; thermal expansion mismatch.

Summary

Of the three types of fuel cell cathodes considered, porous metals, oxides with current collectors, and electronically conducting oxides, the first two fail to satisfy economic criteria since they require the use of noble metals. Various types of electronically conducting oxides have been tested in fuel cells in this Laboratory and elsewhere. A summary of the results obtained with this type of electrode is presented in Table III.

It is apparent that a fully satisfactory air electrode for high temperature zirconia electrolyte fuel cells is still lacking.

The Intrinsic Charging Rate Capability of the Cadmium Anode

P. Bro* and N. Marincic*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Burlington, Massachusetts

ABSTRACT

The intrinsic charging rate limitations of the cadmium anode used in a new series of Cd/AgCl cells were determined by depositing cadmium from cadmium chloride solutions on plane electrodes in half-cells under constant current conditions at current densities between 30 mA/cm^2 and 3.48 A/cm^2. The charging was terminated at the onset of hydrogen evolution. Very fast charging rates were obtained, but at the expense of the specific capacity of the electrodes. The maximum specific capacities were 0.54 mAhr/cm^2 at the 1000*C* rate, 1.6 mAhr/cm^2 at the 100*C* rate, and 5.4 mAhr/cm^2 at the 10*C* rate.

The search for battery electrodes capable of accepting very high charging rates with impunity led us to an examination of a variety of conventional and novel electrode systems. The cadmium electrode was of particular interest because of its favorable characteristics in regard to hydrogen evolution. It is used extensively in alkaline cells, but the alkaline electrolytes do not provide the conditions most favorable for the high rate charging of cadmium anodes, and conventional cells are capable of only low or moderate charging rates.

We have examined the rate capability of the cadmium electrode in solutions more likely to accept high charging rates than alkaline solutions, and we have developed a new series of rechargeable Cd/AgCl cells capable of very fast charging operations. Since the rate of charging of an anode would be limited by any concomitant evolution of hydrogen, we adopted the criterion that the maximum charging rate be defined by the onset of hydrogen evolution. Normally, hydrogen evolution occurs when the electrolyte or the discharged material adjacent to the electrode becomes depleted in reducible ions, cadmium ions in this case.

Two types of processes may be distinguished in the charging of electrodes, *viz.*, solid-solid and solid-solution reactions. Although an electrode may function in either mode, depending on the current density and the chemical properties of the system, one of these mechanisms generally dominates. We have found that the solid-solution type of operation has the higher intrinsic rate capability of the two, and we selected it for a more detailed analysis. Because of the hydrolysis of cadmium salts in neutral and alkaline solutions we chose to work with acid electrolytes in which appreciable concentrations of dissolved cadmium salts can be obtained. The rate capability of the cadmium anode would be given, therefore, by the rate of supply of cadmium ions to the electrode via a solution diffusion process.

If no other limiting factors intervene the useful charging of a battery will be terminated by the shorting of the cells due to the formation of dendrites. Although dendrites may appear before the depletion point is reached, they are most likely to appear when the depletion point is reached. Therefore, the depletion of cadmium ions at the electrode represents a reasonable definition for the end of efficient charging.

The depletion point can be determined by chronopotentiometric measurements (1). The electrode is charged at a constant rate, and the time is noted when the electrode potential shifts from that of the deposition of the active material to that of hydrogen evolution. This transition time signals the end of efficient charging, and it is a function of the current density, the compositon of the solution, and the geometry of the electrode.

* Electrochemical Society Active Member.

Experimental Techniques

The charging experiments were conducted at 25° ± 1°C in the cell shown in Fig. 1. The cell was designed to give a uniform current density at the electrode, and the cadmium was deposited on a platinum substrate with a 0.81 cm diameter. The diameter of the platinum disk was made equal to the inner diameter of the solution cavity to eliminate edge effects.

Conventional circuitry was used for the chronopotentiometric measurements with current pulses derived from a 240V stack of lead-acid batteries. An Ebert Electronics, Model HD-4, mercury switch gave fast and clean switching at all the currents used. The maximum change in the current during any one pulse was 2.3%, attributable to the changing resistance of the cell during the pulse. The currents were measured with an accuracy of ±0.5% with a Greibach Model 700 ammeter. A battery derived bias voltage was used with the cadmium reference electrode to position the pulse suitably on the Tektronix Model 550 CRO screen, and the traces were recorded photographically. The time scale of the CRO was calibrated with a Servomex waveform generator, Model LF141, and the transition times were taken at the point of inflection of the voltage-time curves.

The cadmium chloride solutions were prepared from analytical grade reagents and the cadmium concentration of the stock solutions was determined polarographically. The precipitates formed as a result of the hydrolysis of cadmium chloride were dissolved by the addition of just sufficient perchloric acid to clear the solutions. The resulting *p*H values are given in Table I.

The solutions were deaerated with nitrogen, and a nitrogen blanket was maintained over the solutions. The platinum electrode was restored after every pulse by the anodic dissolution of the cadmium to the point

of incipient oxygen or chlorine evolution when the solution was again degassed with nitrogen.

Experimental Results

The chronopotentiometric transition time for a simple reduction process is given by (2)

$$(it^{1/2}/C) = \tfrac{1}{2}\, n\mathbf{F}(\pi D)^{1/2} = \text{a constant for a fully supported electrolyte solution.}$$

It was found that $(it^{1/2}/C)$ increased with the current density, Fig. 2, but its rate of change with the current density, $\partial/\partial i(it^{1/2}/C)$, decreased as the concentration of the supporting electrolyte increased. The current dependency of $(it^{1/2}/C)$ was expected for neither a fully supported nor a partially supported solution, as may be seen from the equations of Morris and Lingane (3). The most probable cause was the increasingly significant resistive component of the overvoltage associated with a decreasing concentration of the supporting electrolyte. The greater the resistive component, the more the initial portion of the transition region would be occluded, and the transition time would appear to increase with the current density. The displacement of the transition time would be expected to decrease as the concentration of the supporting electrolyte increased, as observed, and it would be expected to vanish as the current density approached zero, as was found to be the case. All the data for each of the solution compositions were therefore extrapolated to a zero current density to obtain the $(it^{1/2}/C)$ values given in Table I. The anodic oxidation of the cadmium deposits showed that the deposition process occurred without any side reactions.

The transition time group, $(it^{1/2}/C)$, had an average value of 516 A · sec$^{1/2}$ · cm/mole in the 2M $CdCl_2$ solution, and it extrapolated to 730 Asec$^{1/2}$ cm/mole for a vanishing $CdCl_2$ concentration. At any one $CdCl_2$ concentration the value of the transition time group increased slightly as the concentration of the supporting electrolyte decreased, the change being appreciable only for supporting electrolyte concentrations below 0.1M $NaClO_4$.

The *p*H of the solutions did not affect $(it^{1/2}/C)$ above *p*H 3.0. In the unsupported solutions the acid acted as a supporting electrolyte below *p*H 3.0 and $(it^{1/2}/C)$ changed in the expected manner.

The charging rate capabilities of the cadmium anode calculated from the transition time data are presented in parametric form in Fig. 3. The data show that the rate capability and the attainable specific capacity increased markedly with the cadmium concentration of the solutions, the relative increase being more marked at the lower cadmium concentrations. A charging rate of *e.g.* 200C would appear to be feasible, but it would give a low specific capacity of about 1 mAhr/cm². High specific capacities could not be obtained at the high charging rates, a capacity of 5 mAhr/cm² being the maximum obtainable at the 10*C* rate.

Discussion of the Results

The most significant result of the investigation was the observation that the cadmium electrode could be charged at very high rates in the cadmium chloride solutions, but that low specific capacities resulted for the fast charging regime. The chronopotentiometric equations provided a convenient formalism for correlating the charging rate and the electrode capacity, and their applicability suggested that the charging process was diffusion controlled. In principle, the behavior of the electrode can therefore be described by the diffusion coefficient of Cd^{+2} or of $CdCl_2$ depending on whether or not a supporting electrolyte is used. However, no data are available in the literature for cadmium salt solutions more concentrated than 0.0127M Cd^{+2} (4), and extrapolations to the concentrations used in our studies cannot be made with a high degree of confidence. The results for the 2.0M $NaClO_4$ solutions could be correlated with a diffusion coefficient of the Cd^{+2} ion of 11.8 x 10^{-6} cm²/sec which may be compared with the most recent literature value of 7.2 x 10^{-6} cm² sec (5) for dilute solutions containing $Cd(NO_3)_2$ and KNO_3. The diffusion coefficient of the salt cannot be obtained from our data. It appears that whether the use of the diffusion equations can be justified on theoretical grounds or

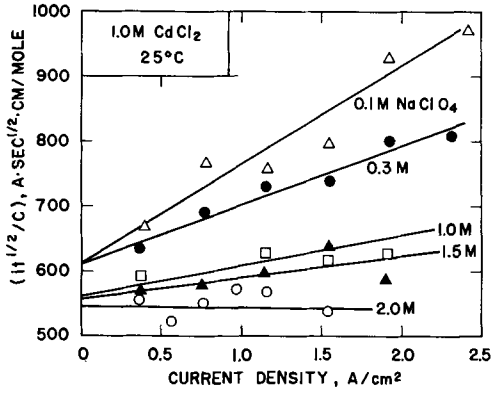

Fig. 2. Influence of the current density on the chronopotentiometric behavior.

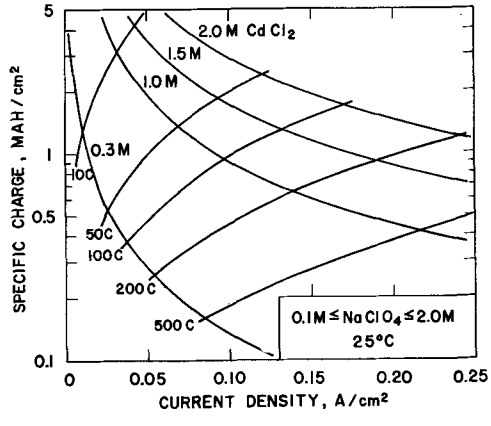

Fig. 3. Intrinsic performance curves for the charging of flat cadmium electrodes in acid solutions.

not they give a good estimate of the rate-capacity relationship of the electrode.

The changes of $(it^{1/2}/C)$ caused by the variations in the composition of the electrolyte are associated with the solution equilibria and the transference properties of the ions in a manner analogous to that discussed for zinc chloride solutions (6). However, they will not be discussed here since we are interested primarily in the charging rate of the electrode.

The experimental results indicated that highly concentrated cadmium chloride solutions were needed to achieve the ultra-fast charging rates. There was a practical upper limit to the attainable cadmium ion concentration because of the hydrolysis of the cadmium salts which led to the precipitation of $Cd(OH)_2$. The higher the concentration of the cadmium salt the lower must be the *p*H, and the more readily was hydrogen evolved during charging. A *p*H of about 6.6 could be maintained in the 0.1M $CdCl_2$ solutions without causing any $Cd(OH)_2$ precipitation, whereas the *p*H had to be maintained at about 4.2 in the 2.0M $CdCl_2$ solutions. The $(it^{1/2}/C)$ parameter decreased noticeably below about *p*H 3, *i.e.*, the specific capacity decreased.

Whereas the use of a completely unsupported cadmium salt solution would give a slightly higher rate capability than a supported solution, its use in a porous electrode would not be tolerable because of depletion polarization. In pure $CdCl_2$ solutions the deposition of Cd would deplete the reaction layer of charge carriers with a consequent resistive choking of the electrode. In porous electrodes, current penetration into the interior would be completely blocked in the absence of a supporting electrolyte. Furthermore, we observed that highly dendritic cadmium deposits were formed in the absence of a supporting electrolyte.

There was an upper limit to the amount of supporting electrolyte that could be used. The approximate rule appeared to hold that if the total salt concentration exceeded about 5 mols/liter, a solid phase would precipitate. Some of the solution conductivities are given in Table II. A high cadmium ion concentration was needed to achieve a high charging rate, yet a high supporting electrolyte concentration was also needed to achieve the same result. A 2M $CdCl_2$ concentration represented a reasonable compromise between the two conflicting requirements.

The experimental data are directly applicable to nonporous, flat cadmium electrodes, and the permissible operating regimes of such electrodes may be read directly from Fig. 3. More information would be needed for the application of the experimental data to porous electrodes, *e.g.*, the current distribution and the electrolyte thickness distribution in the electrode. Although the necessary calculations are possible in principle, adequate models remain to be developed to render the calculation practically meaningful. The more serious problem is the electrolyte thickness distribution in the electrode. In a porous electrode the local electrolyte layers are thinner and more complex in shape than the plane diffusion layer obtained in the chronopotentiometric experiments, and a lower rate capability would prevail in the interior of a porous electrode than at its front surface. It follows that for systems operating via a solution-solid charging process there is an optimum electrode thickness

Table II. Solution conductivities

$CdCl_2$ concentration, mols/l	Solution conductivity, ohm^{-1} cm^{-1} 10^3 $NaClO_4$ concentration, mols/l				
	0	0.5	1.0	1.5	2.0
1.0	26	52	70	84	101
1.5	26	48	64	75	91
2.0	25	44	57	68	80
2.5	22	38	50	63	72
3.0	19	34	43	55	61

for ultra-fast charging which is very small. The less soluble the salt from which the active material is obtained, the greater should be the effective participation of the interior of a porous electrode until the extreme case is reached of solid-solid transformation systems where very large interior surface areas are a pre-requisite for efficient charging. However, the intrinsic rate capability of solid-solid transformation systems is considerably less than that of solution-solid transformation systems.

Data on porous cadmium electrodes in alkaline electrolytes (7) indicate that they may possibly be charged at current densities of 200 mA/cm^2, based on the superficial electrode areas, to give a specific capacity of 5.1 $mAhr/cm^2$. This means that the porous cadmium electrode in an alkaline cell would have a higher capacity than a flat nonporous cadmium electrode in an acid cell at rates below about 150C. If the comparison is made on the basis of the actual surface areas rather than the superficial areas, the alkaline cadmium electrode can be operated at rates up to 0.005 mA/cm^2 to give a specific capacity of $1.3 \cdot 10^{-4}$ $mAhr/cm^2$, and the cadmium electrode operating in a cadmium chloride electrolyte would have the higher specific capacity at all rates of interest. The preceding remarks notwithstanding, it is believed that a realistic comparison must await data on comparable structures.

It is implicit in our studies that the conclusions are limited to constant current charging operations. No consideration was given to the optimization of the time profile of the charging current and the question remains open whether suitably shaped current profiles or pulse sequences may give greater net charging rates than those reported here.

The application of the cadmium charging rate data to rechargeable Cd/AgCl cells will be considered in a subsequent publication.

The Dissolution of MgO and $Mg(OH)_2$ in Aqueous Solutions

David A. Vermilyea*

Research and Development Center, General Electric Company, Schenectady, New York

ABSTRACT

This paper reports studies of the rates of dissolution of natural Brucite, optical grade MgO, and commercial $Mg(OH)_2$ in aqueous solutions. Natural Brucite dissolves by means of a surface reaction requiring protons, and while some protonated ions accelerate the dissolution no inhibitors were found. Dissolution of less perfect $Mg(OH)_2$ is normally diffusion limited; several substances which reduced the rate of dissolution of such $Mg(OH)_2$ were found. MgO first reacts with water to form an $Mg(OH)_2$ layer and the rate is controlled by dissolution of the $Mg(OH)_2$.

This paper is part of an effort aimed at relating the corrosion of metals with the dissolution rates of corrosion products formed on the metal surfaces. A recent study of aluminum corosion (1, 2) and inhibition has demonstrated that new understanding of corrosion phenomena as well as new ways of combating corrosion can be discovered by this approach.

In this report the dissolution behavior of MgO and $Mg(OH)_2$ in a variety of aqueous solutions is discussed. Perhaps the most interesting features of the dissolution are the following. Crystals of $Mg(OH)_2$ (natural Brucite) dissolve at rates limited either by a surface reaction or by proton arrival; the direct removal of Mg^{+2} and OH^- from the lattice into the solution seems to be slow. This behavior has the consequence that most proton donors such as carboxylic acids or inorganic oxyanions accelerate rather than inhibit the dissolution. Finely crystalline $Mg(OH)_2$ seems always to dissolve at a rate limited either by diffusion of protons to the surface or of dissolved species away. MgO behaves like Brucite at low *p*H and like finely crystalline $Mg(OH)_2$ at higher *p*H. It is probably always covered with a thin $Mg(OH)_2$ layer, and its rate of dissolution is controlled by dissolution of the $Mg(OH)_2$. The implications of these findings for corrosion of magnesium are discussed.

Experimental

The dissolution rates were determined by suspending 10-30μ diameter powders in the slowly stirred solution and computing the rate from the rate of change of *p*H. The *p*H was measured with a Corning model 12 *p*H meter and recorded on a Varian Model 14A-1 strip chart recorder. The initial *p*H of the 10^{-1}M KCl solution used in all experiments was about 3 and rose as the powder dissolved, so that a single experiment provided data for a wide *p*H range. Identical results were obtained using $KClO_4$ solutions. Most experiments were conducted at 25°C. Compared to methods based on titration, this method offers the advantages of speed and generation of data over a wide *p*H range from a single experiment.

Two major problems were encountered with this technique. The first was that the response of the glass electrode is very sluggish in unbuffered solutions between *p*H 6 and 8, so that only very low dissolution rates could be determined in that *p*H range. At *p*H 7 the time required to reach a stable reading following the addition of a small amount of acid or base to a 1M KCl solution was about 100 sec. A platinum-hydrogen electrode was somewhat faster but could not be used in all solutions and was subject to poisoning.

The second major problem was that the measured *p*H change following addition of acid or base to a solution containing no MgO or $Mg(OH)_2$ and having a *p*H in the range 5-9 was substantially less than that calculated from the known amounts added; Fig. 1 shows a typical result. It is believed that this effect results from traces of proton donors and acceptors in the solution, for in very carefully purified solutions made with water having a resistivity of 2×10^7 ohm-cm and dissolved spectroscopic KCl crystals for solute the effect was nearly absent. The use of such highly purified solutions did not change the results of dissolution rate studies, however, and as a practical expedient ordinary laboratory distilled water and reagent grade chemicals were used, and the calculated rates were corrected using data like that in Fig. 1. The same procedure was used for experiments in which a proton acceptor or donor was deliberately added, in which case the curve corresponding to Fig. 1 had a much more pronounced minimum.

The dissolution was conducted in a 1-l Pyrex vessel containing a Teflon covered magnetic stirrer, thermometer, and ports for inert gas inlet and outlet and for powder addition. Most of the results were obtained using an atmosphere of nitrogen purified by passing it over Ascarite to remove CO_2. Air or hydrogen gave indistinguishable results.

Powders of 10-30μ diameter were obtained by sieving and sedimentation in alcohol, followed by drying $Mg(OH)_2$ at 150°C and MgO at 400°C, and storage in a desiccator containing ascarite and anhydrous $CaSO_4$. Natural Brucite crystals were obtained from Ward's and ground in alumina mortars and ball mills. The natural Brucite contained 0.3% Ca, 0.05% Fe, 0.05% Mn, 0.02% Si, 0.02% Ba, 0.01% Al, and 0.001% Cu. The dissolution of 10^{-4} m/l (moles per liter) (a typical amount) of this material would introduce a maximum concentration of impurities of $5 \cdot 10^{-7}$ m/l, which is negligible. The MgO was ground from fused optical

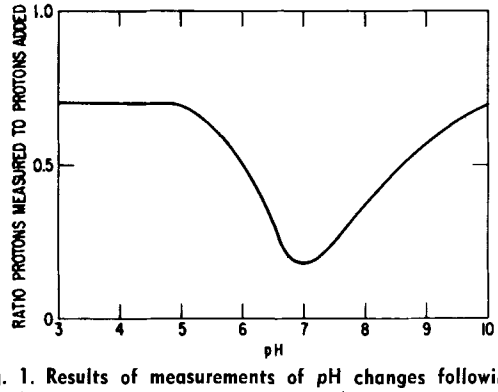

Fig. 1. Results of measurements of *p*H changes following additions of known amounts of HCl to a 10^{-1}M KCl solution.

* Electrochemical Society Active Member.

grade crystals obtained from Norton and from General Electric. Other $Mg(OH)_2$ powders were obtained by sedimentation fractionation of reagent chemicals and the "particles" were actually clumps of finely crystalline material. Examination of the various powders with a microscope confirmed that the particles were of reasonably uniform size and that the size was about that expected from a calculation based on Stoke's law.

The following method was used to calculate the dissolution rate from the pH change. Hydroxyl ions added from the dissolving crystals are utilized in two ways: to combine with protons and to increase the OH^- concentration of the solution. A mathematical description of this situation is

$$dN_{OH^-} = dC_{OH^-} - dC_{H^+} \quad [1]$$

in which N_{OH^-} is the number of hydroxyl ions (expressed as a concentration) dissolved from the crystal. Now using the following relationships

$$C_{H^+} = \exp(-2.3\,pH) \quad [2]$$

$$dC_{H^+} = -2.3 \exp(-2.3\,pH)\,d(pH)$$

$$= -2.3\,C_{H^+}\,d(pH) \quad [3]$$

$$C_{OH^-} = \frac{K_w}{C_{H^+}} \quad [4]$$

$$dC_{OH^-} = -\frac{K_w}{C_{H^+}^2}\,dC_{H^+} \quad [5]$$

$$= \frac{K_w}{C_{H^+}}\,2.3\,d(pH) \quad [6]$$

in which K_w is the dissociation constant of water, Eq. [1] reduces to

$$dN_{OH^-} = 2.3\,d(pH)\,(C_{OH^-} + C_{H^+}) \quad [7]$$

Using Eq. [7] the rate of addition of hydroxyl ions by dissolution is computed from the rate of change of pH and corrected by dividing by the ratio obtained at the appropriate pH from a curve like Fig. 1 for the solution used. The rates of dissolution were expressed as moles cm^{-2} sec^{-1}, the area being calculated from the particle size assuming the particle surfaces were smooth. The surface area was corrected for the amount of material dissolved.

Curves of rate *vs.* pH obtained for a particular sample of powder were reproducible to about 50%, and hence it is considered that the form of the curves is accurate, but because of uncertainties in the absolute area of the powders and because of effects of powder history the magnitudes of the rates should only be considered correct as to order of magnitude.

Results and Discussion

MCB $Mg(OH)_2$.—Figure 2 shows data for the dissolution of $Mg(OH)_2$ obtained from Matheson. Coleman, and Bell, and designated "MCB." The particles of this material are clumps of finer particles, and it is very reactive, probably because of a very high true surface area. When less than about 25% of the added powder has been consumed, the rate is quite simply diffusion limited as shown by the agreement between the calculated curve of Fig. 2 and the experimental points. The calculated curve was based on the assumption of spherical particles 2×10^{-3} cm in diameter. When about 50% of the powder has been dissolved away and then the solution acidified with HCl to make another run, the rate is considerably slower at pH > 4. At pH < 6 the rate is then controlled by arrival of protons at the surface, and from pH 6 to 9 the rate is approximately constant. Evidently there are two modes of dissolution for MCB material, one for highly active surfaces and one for surfaces produced by a considerable amount of dissolution. Probably the material which gave the lower curve of Fig. 2 still had some

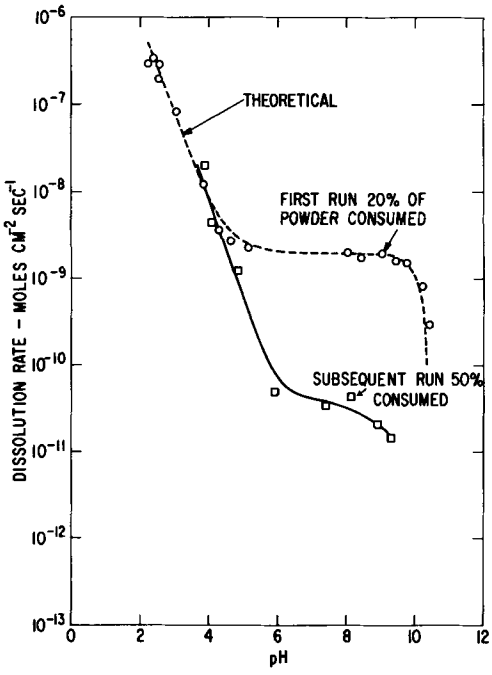

Fig. 2. Dissolution of MCB $Mg(OH)_2$ in 10^{-1}M KCl at 25°C. The dashed curve is calculated assuming control by diffusion of protons to the surface and of dissolved Mg^{+2} and OH^- away.

"active" surfaces and these were responsible for the approximately constant rate at pH 6-9.

Natural Brucite.—Natural Brucite behaves initially like MCB at pH > 5, except that the rates are lower than for MCB material. The first run (Fig. 3) already shows a rate which is nowhere diffusion limited, and after about 25% of the material has been dissolved, the rate finally reaches values which fall close to the theoretical line for control by proton arrival. Subsequent runs on the same sample give results indistinguishable from those for the third run. Such a low-rate sample will be referred to as "aged." It seems plausible that the initial, unaged surfaces contain

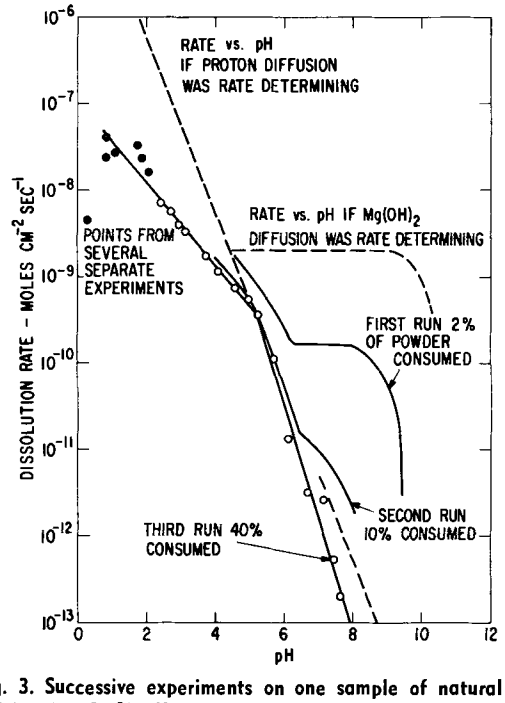

Fig. 3. Successive experiments on one sample of natural Brucite dissolving in 10^{-1}M KCl at 25°C. The open circles are from the third run only. Closed circles are from separate experiments, and indicate the greater uncertainty of the measurements at low pH.

"active" regions like those on the MCB material, and that these account for the higher rates of the first run.

The possibility that some impurity was dissolving into the solution from the natural Brucite and inhibiting the dissolution was investigated in two ways. First, some natural Brucite was dissolved completely to give a concentration more than ten times that normally reached, and then a fresh sample was introduced. No effect of the dissolved material could be detected. Second, a sample of natural Brucite was placed in the vessel at pH 10.55 with $2 \cdot 10^{-4}$ m/l $MgCl_2$ in the solution and left 50 hr. The initial run on that sample was very close to the second run in Fig. 3, although only 0.4% was consumed. Thus simply equilibrating the powder with the solution suffices to remove the highly active regions and the behavior is then like that of an aged sample.

At pH < 5 the curve deviates markedly from the proton diffusion line, and the dependence on proton concentration can be represented by the equation

$$\text{Rate} = \text{Const.}\ C_{H^+}{}^{0.47} \qquad [8]$$

Evidently the dissolution is controlled by a surface reaction in this pH range. A simple theory (3) of dissolution of oxides and hydroxides based on removal of hydroxyl ions by reaction with protons predicted that the dissolution rate of the hydroxide of a divalent metal would vary as $C_{H^+}{}^{2/3}$. According to the theory a dependence as in Fig. 3 could arise because of a low value of the transfer coefficient for cations. If, for example, the cation transfer coefficient was 0.35 and the anion transfer coefficient 0.7 the predicted exponent would be ½.

The fact that the curve for the third run at pH > 5 does not exactly follow the proton diffusion curve is probably the result of surface structure changes accompanying dissolution. Figure 4 shows some effects of such sample history. The sample was first dissolved between pH 4 and 8, then HCl was added to bring the pH to 5.2. There was a transient during which the rate increased with pH for a short time, followed by the usual decrease. Because of such history effects the absolute values of rates in this pH range are subject to a considerable uncertainty. The effect of adding Na_3PO_4 will be discussed in the section on accelerators and inhibitors.

Mechanism of $Mg(OH)_2$ *dissolution.*—The results for $Mg(OH)_2$ indicate the following. For single crystal particles (natural Brucite) the dissolution mechanism involves a surface reaction between hydroxyl ions and protons. At pH < 5 this surface reaction is rate determining and the rate increases roughly as the square root of the proton concentration. Above pH 5 proton arrival is the slow step, and there are some minor variations due to changes in surface activity. These surface activity changes may involve poisoning of portions of the surface or possibly changes in the number of surface steps and kinks.

A possible alternative mechanism, namely, direct removal of Mg^{+2} and OH^- ions at active sites and control by diffusion of such ions away from the crystal predicts a constant rate between pH 5 and 9 in conflict with experiment; the reasoning is as follows. The rate of removal of Mg^{+2} and OH^- together from such regions would be proportional to the product of the diffusion coefficient and concentration, $D_{Mg(OH)_2}\ C_{Mg(OH)_2}$. The rate of arrival of protons at such sites would be proportional to $D_{H^+}\ C_{H^+}$. In order for protons to influence the rate significantly it is necessary that

$$D_{H^+}\ C_{H^+} \gtrsim D_{Mg(OH)_2}\ C_{Mg(HO)_2} \qquad [9]$$

Using $D_{H^+} = 10^{-4}$, $D_{Mg(OH)_2} = 10^{-5}$, $C_{Mg(HO)_2} = 10^{-4}$ we obtain $C_{H^+} \gtrsim 10^{-5}$. Thus above pH 5 the proton concentration should not influence the rate, but at pH > 9 ($C_{OH^-} > 10^{-5}$) the rate would fall because of the common ion effect.

$Mg(OH)_2$ crystals normally have some (natural Brucite) or many (MCB) highly active regions from which direct removal of Mg^{+2} and OH^- is possible, and for such regions the rate is limited by arrival of protons or by diffusion away of dissolved $Mg(OH)_2$. These active regions give rise to a roughly constant rate from pH 5-9.

MgO.—The MgO powder comprised single crystal particles, and x-ray diffraction did not detect the presence of any $Mg(OH)_2$, although infrared absorption showed a small $Mg(OH)_2$ peak. Figure 5 shows that below pH 6 the dissolution behavior is similar to that for natural Brucite, while at pH 6-8 there is a nearly constant rate followed by a decreasing rate at pH 8-10.

It is proposed that the MgO first reacts to form $Mg(OH)_2$ and that dissolution of the latter is rate

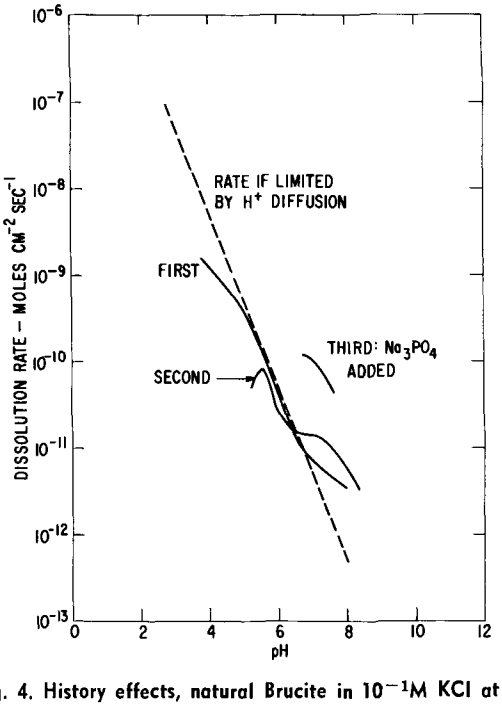

Fig. 4. History effects, natural Brucite in 10^{-1}M KCl at 25°C

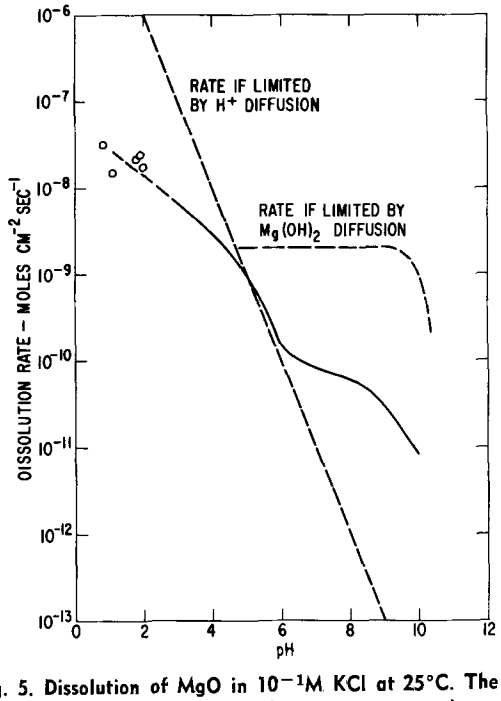

Fig. 5. Dissolution of MgO in 10^{-1}M KCl at 25°C. The individual points at low pH indicate the greater uncertainty of these measurements.

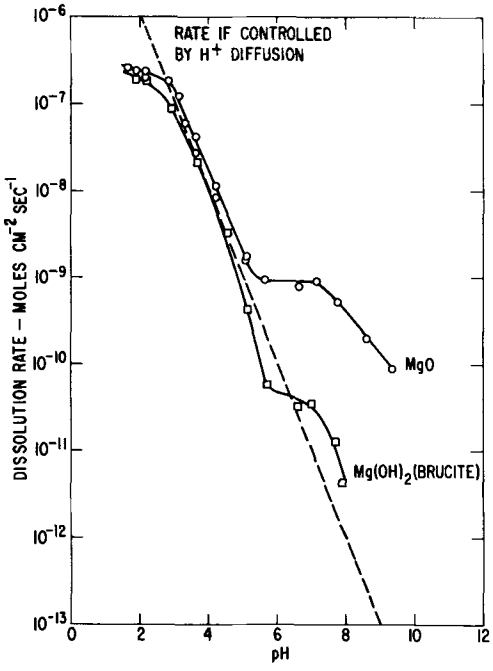

Fig. 6. Dissolution of MgO and natural Brucite in 10^{-1}M KCl at 75°C.

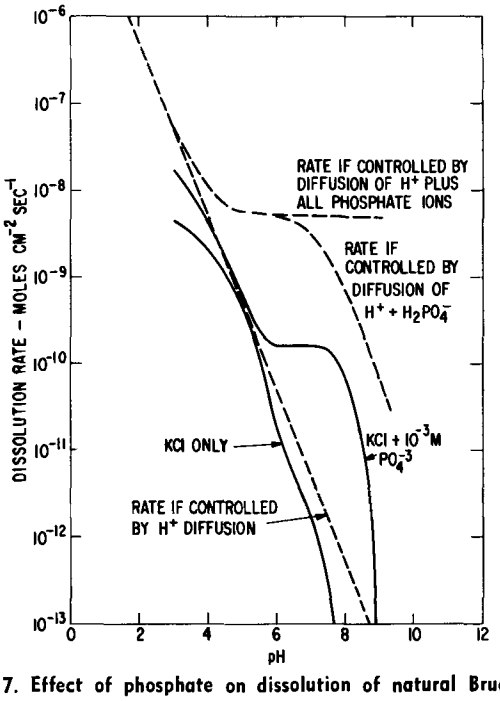

Fig. 7. Effect of phosphate on dissolution of natural Brucite at 25°C.

determining. The solubility of MgO is calculated to be about sixty times that of $Mg(OH)_2$, so it is reasonable that it should dissolve rapidly on initial exposure and become covered with a layer of $Mg(OH)_2$. The $Mg(OH)_2$ layer would probably in part be of the active type, hence the high rate (compared to Brucite) at pH > 6. Electron microscopic examination did not detect the proposed $Mg(OH)_2$ coating, which is probably very thin.

Effect of temperature.—Figure 6 shows results at 75°C for MgO and natural Brucite. At pH < 3 the rate appears to be limited by the surface reaction, which proceeds about ten times as fast as at 25°C. Such a change is consistent with an activation energy of about 10 kcal/mole. The dissolution of natural Brucite at pH > 3 is again controlled by proton arrival and the rate is only slightly higher than at 25°C. MgO dissolution is controlled by proton arrival at pH 3-5, while at higher pH direct dissolution of Mg^{+2} and OH^- plays a dominant role. At pH 5-7 the rate for MgO is nearly that expected if the surface were entirely covered with $Mg(OH)_2$ and if diffusion away of the latter controlled the rate.

Effects of solution composition.—Natural Brucite.—Many substances added to the solution were without effect on dissolution of natural Brucite. These included I^-, ClO_4^-, Na^+, Pb^{+2}, Ni^{+2}, Al^{+3}, Ca^{+2}, $Fe(CN)_6^{-4}$, and $(C_4H_9)_4N^+$. Several substances accelerated the dissolution in a limited pH range; the effect of phosphate is shown in Fig. 7. The accelerators, which include acetate, chromate, periodate, germanate, and tellurate are all substances which form protonated ions. However, not all protonated ions are accelerators. For instance, borate has no effect on the dissolution rate, and phosphate is not effective at higher pH. In fact, it seems that pK_a should be in the range of about 5 to 8 for a proton containing ion present at 10^{-3} m/l to accelerate dissolution of natural Brucite.

It seems likely that accelerators exert their influence by reacting directly with surface hydroxyl ions just as do protons. If pK_a is too small, then few protonated ions will be present except at low pH, where the more reactive protons are present in greater numbers. If pK_a is too large the proton is bound so tightly that it does not react readily with hydroxyl ions in the crystal.

One other possible effect of accelerators is that they might change the surface to one containing more highly active material. The third run of Fig. 4 shows that the addition of phosphate to an aged surface immediately increases the rate about an order of magnitude, and it therefore seems probable that a different type of surface is not the only factor involved in the acceleration.

No substances were found to inhibit the dissolution of natural Brucite.

MgO *and MCB* $Mg(OH)_2$.—A few moderately effective inhibitors of dissolution of these compounds were found, along with a large number of ineffective substances. Figure 8 shows the effects of periodate, one

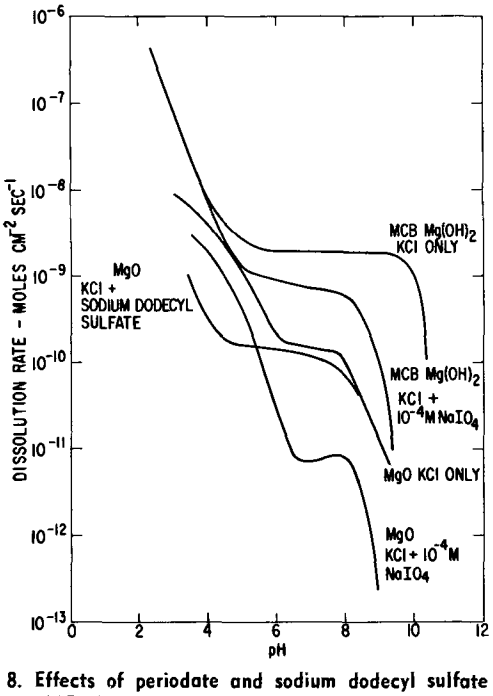

Fig. 8. Effects of periodate and sodium dodecyl sulfate on dissolution of MCB $Mg(OH)_2$ and MgO at 25°C.

of the strongest inhibitors, and sodium dodecyl sulfate. The greatest effect for periodate is found at pH > 8, while sodium dodecyl sulfate is only effective at pH < 6. The dodecyl sulfate ion is probably attached to the surface by the high positive charge of the particles at low pH, as well as by the repulsion between water and the aliphatic hydrocarbon portion of the ion.

Periodate, germanate, tellurate, vanadate, and tellurite are about equally strong inhibitors; arsenite, arsenate, and permanganate are very weakly effective. It is believed that these ions are effective because they are able to fit the structure of the $Mg(OH)_2$ and to make strong bonds with its surface. As with Al_2O_3 (2), the effective ions all fall in a small region of a plot of radius ratio against proton level (Fig. 9); the corresponding quantities for $Mg(OH)_2$ are also in the same region at pH 10. The radius ratio is believed to determine the structural fit of the ion and the surface, while the proper proton level is probably necessary in order that strong hydrogen bonds can be formed.

Some ineffective substances not shown in Fig. 9 are NH_4^+, dimethyl formamide, palmitic acid, and $Fe(CN)_6^{-4}$. The absence of an effect for $Fe(CN)_6^{-4}$, which should be strongly attracted to the positively charged particles, shows that electrostatic effects alone will not suffice to produce inhibition.

Implications for corrosion of magnesium.—The corrosion product formed on magnesium in aqueous solutions is usually $Mg(OH)_2$, and some protection is provided by this product. To the extent that the corrosion product resembles aged natural Brucite these results do not offer much hope that good inhibitors can be found. If the product resembles MCB $Mg(OH)_2$, however. then there are some possibilities for inhibition. It seems unlikely that the corrosion product would comprise $Mg(OH)_2$ crystals as perfect as those of natural Brucite, and more probable that some highly active surfaces would be present. It therefore seems likely that some of the inhibitors of MCB $Mg(OH)_2$ may also be effective for the metal. Studies to test this prediction are in progress.

Comparison with previous studies.—A reviewer has pointed out that Brunner (5) studied dissolution of $Mg(OH)_2$ in various organic acids and in HCl. Those studies were conducted for the purpose of verifying the Nernst diffusion layer theory of heterogeneous reactions. Rather concentrated solutions (compared to the present studies) were used (acid concentrations 0.02 to 0.05 equivalents/liter), and the rate of dissolution was shown to be always diffusion limited. There are no data showing surface reaction limited rates of dissolution with which the present experiments can be compared.

Conclusions

1. The mechanism of dissolution of natural Brucite involves a surface reaction between protons and hydroxyl ions. The activation energy for this process is about 10 kcal/mole.

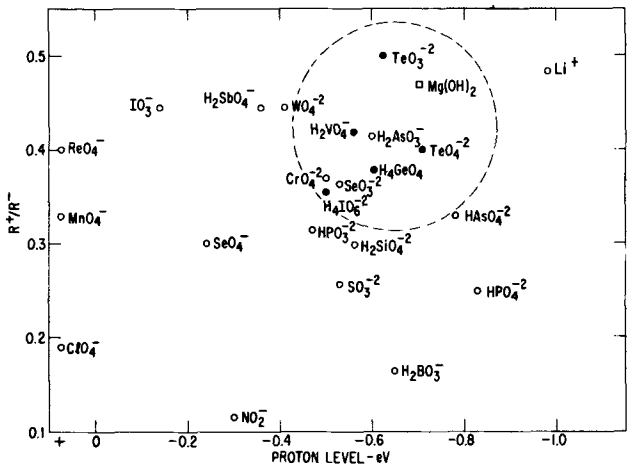

Fig. 9. Inhibitors of MCB $Mg(OH)_2$ dissolution. R^+ and R^- are the radii of the cation and oxygen ions in the oxyanion. The proton level is the free energy difference between the proton on the ion and a proton on a water molecule (H_3O^+) (4). The closed circles designate moderately effective substances, while ineffective substances are indicated by open circles.

2. Less well aged $Mg(OH)_2$ contains highly active surface regions from which dissolution is controlled either by proton arrival or by diffusion away of dissolved Mg^{+2} and OH^-.

3. MgO first reacts with water to form a $Mg(OH)_2$ layer on the surface and the rate is controlled by dissolution of the $Mg(OH)_2$.

4. No inhibitors were found for dissolution of natural Brucite. Protonated species with pK_a between 3 and 8 accelerate Brucite dissolution.

5. Inhibitors for dissolution of MCB $Mg(OH)_2$ and MgO are periodate, tellurate, tellurite, germanate, and vanadate.

Acknowledgment

Preparation of the powders from natural Brucite and MgO was accomplished by J. W. Szymaszek whose help is gratefully acknowledged. Very high purity water was kindly supplied by R. W. Powers. I am indebted to W. Vedder for many stimulating discussions of the experimental results.

Manuscript submitted Feb. 28, 1969; revised manuscript received *ca.* May 2, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

A Study of the Anodic Oxidation of Bismuth

D. J. De Smet* and M. A. Hopper*

Department of Physics, University of Alabama, University, Alabama

ABSTRACT

The galvanostatic oxidation of bismuth in sodium borate-boric acid and sodium carbonate solutions has been studied over a potential range of 90V by analysis of open-circuit transients. An anodic layer which shows bright interference colors is found to grow on the metal surface. Experimental results indicate that the dependence of the oxidation current density, i, on the overpotential, V, is expressable in the form $i = i_o \exp(V/V_o)$, where i_o and V_o are parameters determined from the data analysis. The parameter V_o is found to vary linearly with the overpotential during galvanostatic oxidation, while the parameter i_o depends on the applied current density. These results are related to a high field conduction model.

The anodic oxidation of the so-called "valve" metals has been the subject of many investigations (1). Nevertheless bismuth, although classified as a typical "valve" metal, has received little attention. Since the study of the anodic oxidation of bismuth by Guntherschulze and Betz in 1931 (2), there has been no published work on the anodic oxidation of bismuth in neutral or slightly alkaline solution, and little work in other electrolytes. This deficiency arises partly because bismuth does not find the application to capacitor manufacture that tantalum and some of the other "valve" metals do; and also because bismuth appears to have a somewhat more complex electrical behavior than, for example, tantalum does.

The open-circuit transient analysis technique has been used in the study of the anodic oxidation of several metals (3-8). Although bismuth and tantalum have been reported to show similar behavior, an examination of the literature shows that there are differences in the reported values of the electrical parameters of the oxide films formed on the two metals. The aims of this investigation were to determine whether the analysis of open-circuit transients would yield results when applied to the anodic oxidation of bismuth, and whether this technique would show the reported differences in the electrical behavior of the oxide films formed on bismuth and tantalum. In addition, a study of the anodic oxidation of bismuth and a comparison of these results with similar results found for other metals will aid in determining which properties of anodic oxidation are dependent on the particular system being investigated and which are more general properties of the process itself.

A study of the literature also reveals that there are differences in the reported values of certain electrical parameters of the anodic oxide film on bismuth, as determined by different methods. The present work thus helps to determine whether the differences were real or merely the result of some aspect of the experimental techniques used.

Experimental

The anodes used in this investigation were prepared from single crystals of bismuth (better than 99.99% pure) obtained from various sources. Hollow cylindrical samples 0.2 in. in diameter and 0.3 in. in length were machined from this material. The samples were then electropolished in a 2% hydrochloric acid, 98% saturated potassium iodide solution (9). After rinsing in distilled water and drying, the samples were mounted between Teflon washers in an electrode holder similar to that described by Feller and Osterwald (10). Each sample was then anodically oxidized to a potential of 100V using a constant current, and the oxide film thus formed was removed from the sample by dissolution in 0.1M sulfuric acid. This last procedure was repeated several times (usually 8 to 10) until the electrical behavior of the electrode became reproducible, thus ensuring that all experimental results reported here were obtained from identical surfaces.

The cell used was a jacketed four-necked flask fitted with standard taper joints through which the electrode assembly, a platinum wire cathode, a mercury-mercurous sulfate reference electrode, and a gas dispersion tube were fitted. All experiments reported here were carried out at room temperature.

Two electrolyte solutions were used in this study: a solution 0.0375M in sodium borate and 0.025M in boric acid (referred to as the borate buffer solution), and a 0.075M solution of sodium carbonate. Solutions were bubbled with argon for at least 12 hr prior to an experiment, the bubbling being continued throughout the course of the experiment.

A schematic diagram of the electrical circuitry used is shown in Fig. 1. High input impedance differential operational amplifiers (Philbrick SP102) were used for the galvanostat and follower. These amplifiers operate over a range of ± 100V. Potentials and open-circuit transients were recorded on a fast strip chart recorder (Sanborn 7700). All potentials were recorded relative to the mercury-mercurous sulfate reference electrode, and overpotentials were calculated from observed potentials by subtracting the value of the open-circuit potential. Current densities were calculated by dividing the applied current by the macroscopic surface area of the anode.

We have observed that the anodic layer on bismuth exhibits a fairly large optical effect when illuminated with visible light, therefore all results reported here were obtained in a darkened room unless otherwise noted. This eliminated the possibility that light falling on the electrode influenced the experimental results.

Results

If an oxide film on the surface of an electrode is considered to be equivalent to a capacitor with a dielectric medium between the capacitor plates which

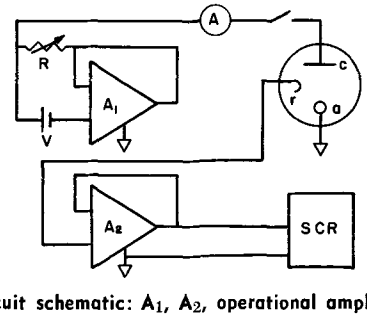

Fig. 1. Circuit schematic: A_1, A_2, operational amplifiers; R, variable resistor; V, battery; A, ammeter; SCR, strip chart recorder; a, anode; r, reference electrode; c, cathode.

* Electrochemical Society Active Member.

carries current in some manner, then the differential equation which relates the current density through the film, i, the overpotential, V, and the externally applied current density, i_e, is given by

$$C\ dV/dt + i = i_e \quad [1]$$

During an open-circuit transient $i_e = 0$, and the differential equation of the circuit becomes

$$i = -C\ dV/dt \quad [2]$$

so that if the rate of change of the potential is known, the current density through the layer may be determined (assuming that the behavior of the capacitance is known). If, for example, the voltage decay during such a transient were found to be an exponential function of time, then it could be deduced that the dielectric layer behaved as an ohmic resistance.

The experimental open-circuit transients found for bismuth fit an expression of the form

$$V = k - V_o \log(t + \theta) \quad [3]$$

extremely well. Here V_o, θ, and k are parameters which are determined by the particular transient and its initial conditions. Such transients may, for example, be analyzed by plotting the overpotential during the open-circuit decay against $(t + \theta)$ on semilogarithmic graph paper. For each transient θ is varied until a straight line is obtained for V against $\log(t + \theta)$ for the transient or some initial portion of the transient.

Differentiation of Eq. [3] with respect to time gives

$$dV/dt = -V_o/(t + \theta) \quad [4]$$

which may be written in the form

$$dV/dt = -V_o \exp(-k/V_o) \exp(V/V_o) \quad [5]$$

Comparison of Eq. [2] and [5] gives the current density in the layer as

$$i = CV_o \exp(-k/V_o) \exp(V/V_o)$$

which may be written as

$$i = i_o \exp(V/V_o) \quad [6]$$

where i_o and V_o are parameters which have the same dimensions as i and V, respectively, and whose values may be determined experimentally.

Certain assumptions have been made in the above derivation. First, it was assumed that the layer capacitance, C, does not change appreciably during the analyzed portion of the open-circuit transient. Because very little charge transfer occurs during an open-circuit transient no appreciable thickness changes take place, thus partially justifying this assumption. Second, open-circuit transients did not fit a relation of the form of Eq. [3] during the entire transient, but only over an initial portion of the transient. In terms of the results presented here, Eq. [6] may be considered to represent a high field conduction process. Since the electric field in the layer decays to zero as the overpotential decays to zero, this equation would not be expected to describe the relation between the overpotential and the current density after the circuit has been open a long time. Nevertheless, each transient analyzed was found to fit an expression of the form of Eq. [3] for at least 1½ decades of time, or a change in dV/dt of at least a factor of 30. An analysis of this type of transient was described by Grahame (11), and such transients have been employed in studies of the anodic films formed on passive iron (3-6) and of the anodic oxidation of tantalum (8).

A series of open-circuit transients were recorded during galvanostatic oxidation. In order to avoid confusion in the following discussion, we will use the term formation current density to designate the applied current density during galvanostatic oxidation and the term formation potential to designate the overpotential at which the circuit was opened. Figures 2 and 3 show the values of V_o, as determined from the open-circuit transient, as a function of the formation potential for bismuth in borate buffer (Fig. 2) and sodium carbonate (Fig. 3) at various formation current densities. For both electrolytes the plots of V_o against formation potential are linear for any particular formation current density, and all lines pass through the zero of overpotential. There is a noticeable difference in the slopes of the lines for different formation current densities.

A value for the parameter i_o can be determined from each open-circuit transient; but because the values of V_o are proportional to the formation potential (for any particular formation current density), i_o will have the same value for every open-circuit transient from the same formation current density. Thus i_o can be determined by using Eq. [6] and the slope of the graph of V_o *vs.* formation potential for each value of the formation current density. Figure 4 shows a plot of the logarithm of i_o (determined as above) against the logarithm of the formation current density, i_f, for formation current densities ranging from 5 to 175 μA/cm^2. From this figure, at least for formation current densities ranging from 5 to 50 μA/cm^2, the relation between i_f and i_o may be written in the form

$$i_o = \kappa(i_f)^\alpha \quad [7]$$

for both the borate buffer and the sodium carbonate solutions.

Assuming that all the charge passed during galvanostatic oxidation goes into the formation of a uniform layer, the change in overpotential with respect to charge passed (dV/dQ) can be used as a measure of the electric field in the layer. With this assumption it is possible to determine the dependence of the electric

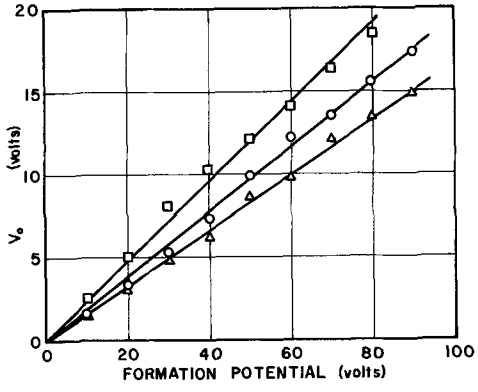

Fig. 2. Dependence of V_o on formation potential for bismuth in borate buffer. The formation current density was 5 μA/cm^2 for the data represented by the squares, 50 μA/cm^2 for the data represented by the circles, and 117 μA/cm^2 for the data represented by the triangles.

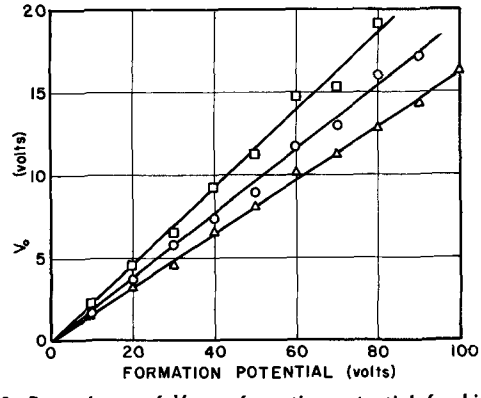

Fig. 3. Dependence of V_o on formation potential for bismuth in sodium carbonate. The formation current density was 10 μA/cm^2 for the data represented by the squares, 50 μA/cm^2 for the data represented by the circles, and 100 μA/cm^2 for the data represented by the triangles.

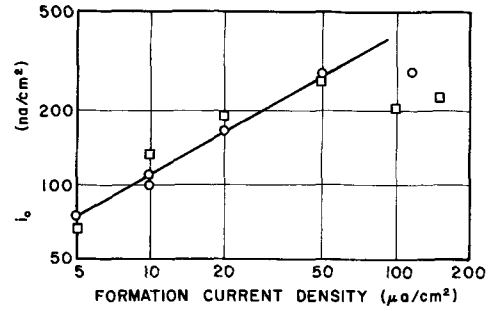

Fig. 4. Dependence of i_0 on the formation current density. The data represented by the squares are for the sodium carbonate electrolyte and the data represented by the circles are for the borate buffer electrolyte.

field in the layer on the formation current density by measuring dV/dQ as a function of the formation current density. Figure 5 shows dV/dQ as a function of the logarithm of the formation current density for bismuth in sodium carbonate solution.

Figure 6 shows a transient in which the formation current density was switched from 200 to 40 μA/cm^2 and then back to 200 μA/cm^2. In producing this figure the speed of the strip chart recorder was changed by a factor of five when the current density was switched from 200 to 40 μA/cm^2, and back to its original speed when the current density was returned to 200 μA/cm^2, producing a plot of potential against charge. This figure will be discussed further in the next section.

The effect of visible light on the overpotential of the electrode while undergoing galvanostatic oxidation is vividly shown in Fig. 7 for a bismuth anode in the borate buffer solution. The light was shone on the electrode when the formation potential reached a value of 43V, a formation current density of 10 μA/cm^2 being maintained. The light caused the overpotential to decrease suddenly, the electrode returning to its original overpotential when the light was removed.

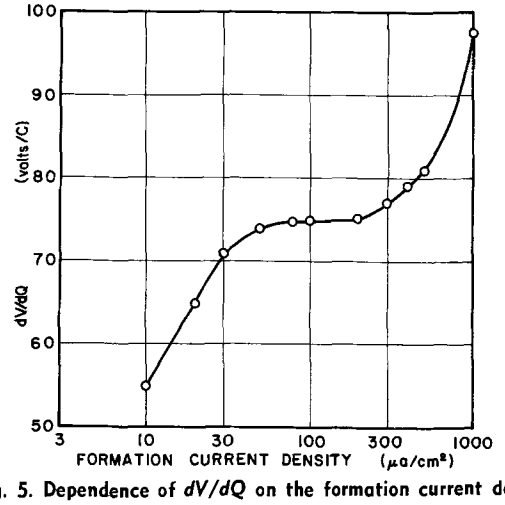

Fig. 5. Dependence of dV/dQ on the formation current density

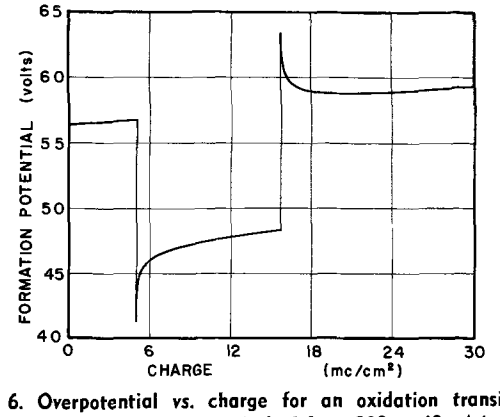

Fig. 6. Overpotential vs. charge for an oxidation transient in which the current density was switched from 200 to 40 μA/cm^2 and then back to 200 μA/cm^2. The electrolyte was borate buffer.

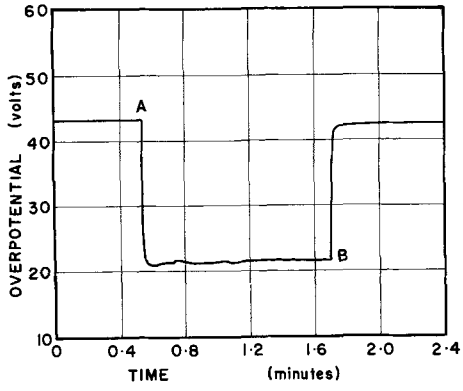

Fig. 7. Overpotential vs. time for a bismuth electrode in borate buffer under galvanostatic conditions with an applied current density of 10 μA/cm^2. At point A the electrode was illuminated with visible light and at point B the light was removed.

Preliminary experiments indicate that the magnitude of the photo effect (*i.e.*, the change in overpotential when light is allowed to reach the surface of the electrode) increases with increasing overpotential under galvanostatic conditions. The photo effect is thus related to the thickness of the oxide layer and perhaps to the electric field in the layer. The photo effect was found to decrease with increasing applied current density and could not be detected at all for applied current densities much above 100 μA/cm^2. It has also been determined that if only red light is used the effect diminishes considerably.

The above must be considered as only a qualitative discussion of the photo effect on bismuth; a more complete study is at present underway in this laboratory. Some of the preliminary results of this study are worthy of note here. One is that the oxide layer formed while under constant exposure to light proves far more difficult to remove than the layer formed in the dark. Another is that the film formed under strong illumination does not show uniform interference colors (certain crystal orientations showing distinctly different colors) which were always found on films grown in darkened conditions. These observations are true even when the formation current density is large enough to make the photo effect otherwise undetectable. These results suggest differences in the properties of the oxide formed in the two cases which may account for certain of the discrepancies in previously published results.

Discussion

An exponential dependence of the current density through the layer on the overpotential may be interpreted in terms of an activation energy controlled process (1) using a simple Mott-Cabrera model (12). The theoretical relation for such a process, in the high field case, is given in its simplest form by

$$i = 2a\nu n \exp(-U/kT) \exp(\lambda eaE/kT) \quad [8]$$

where a is the half-jump distance of the activation barrier, ν the frequency of oscillation of ions, n the density of charge carriers, U the activation energy for the process, λ the valence of the charge carriers, and E the electric field at the activation barrier. The other symbols have their usual meanings.

If the local electric field at the activation barrier may be presumed equal to the average electric field in the layer (*i.e.*, the overpotential across the layer divided by its thickness) then a comparison of Eq. [6] and [8] yields the relation

$$V_o = (kT/\lambda ea)\, D \quad [9]$$

Thus V_o is proportional to the thickness of the oxide layer, D.

The experimental data presented here strongly support a model of this type. Figures 2 and 3 show that the values of V_o are linearly proportional to the formation potential for a fixed formation current density over a wide range of values. This result indicates that a high field conduction process limits the current through the layer. Data taken for different formation current densities fall on lines of different slopes, indicating that the field in the layer depends on the formation current density, and also that i_o depends on the formation current density.

The dependence of i_o on the formation current density cannot be interpreted in terms of the model used, since the model assumes that all of the factors in Eq. [8] other than the exponential factor containing the electric field are constants. The variation of i_o could be made consistent with Eq. [8] by allowing at least one of the "field independent" factors in Eq. [8] to vary. We feel that we cannot deduce a meaningful model to account for the variation of i_o based solely on the present experimental data. It should be noted that i_o was plotted as a function of the formation current density in Fig. 4, but it could equally well be considered to be a function of the formation field.

The change in overpotential when the current density is suddenly switched from one constant value to another is shown in Fig. 6. This figure also shows the potential overshoot that occurs when the current density is changed in this manner. Such behavior has been reported for several other metals (1, 5). We have found that i_o depends on the formation current density; therefore, when the formation current density is changed i_o will change, at a rate less than the rate of change of the formation current density (or the rate of change of the electric field), until its value is correct for the new formation current density. Ord (5), in a study of the anodic oxidation of passive iron, suggested that it may be possible to account for the potential overshoot by consideration of the manner in which i_o changes. Similar arguments may be advanced here, since our experimental results clearly indicate that i_o is a function of the formation current density and changes when the formation current density is changed.

The results obtained for $d\nu/dQ$ (which may be considered to be directly proportional to the electric field in the layer) as a function of the formation current density (Fig. 5) suggest that the usual relation between the current density through the layer and the electric field, $i = A \exp(BE)$, is not valid for this system, at least over the range of applied current densities studied here. Even the modified form of this expression given by Young (13), $i = A \exp(BE + CE^2)$, cannot fit the experimental results of Fig. 5. The curvature of this plot at low applied current densities may be due to leakage; nevertheless, it proved possible to obtain a linear increase in overpotential with time for applied current densities as low as 0.1 μA/cm^2. Thus any leakage current present must be non-ohmic; that is, it must be a function of the applied current density but not an explicit function of the overpotential.

A comparison of the present work with earlier studies of the anodic oxidation of bismuth is difficult because dV/dQ was not found to be a linear function of the logarithm of the applied current density. In contrast, the relation $i = i_o \exp(V/V_o)$ has been shown to be applicable to this system. A high field conduction mechanism can be deduced from this relation without requiring dV/dQ to vary linearly with log i.

Guntherschulze and Betz (2) reported that the electric field strength in tantalum oxide was a factor of five greater than that in bismuth oxide. Young (1) found that at an applied current density of 100 μA/cm^2 and 25°C the electric field strength in tantalum oxide is about $7 \cdot 10^6$ V/cm, while Masing and Young (14) have determined that the electric field strength in bismuth oxide (formed in sodium hydroxide solution) was $8.5 \cdot 10^5$ V/cm. These latter results indicate that the electric field strength in tantalum oxide is about eight times that in bismuth oxide. To compare these determinations of the field strength with our results, Eq. [9] must be used to obtain the relation between V_o and thickness, *viz.*

$$V_o = D/(\lambda a A) \qquad [10]$$

where A is given by (e/kT). Dividing both sides of this equation into the formation potential, V, gives

$$V/V_o = \lambda a A E \qquad [11]$$

where E, the average electric field strength within the layer, is given by V/D. At an applied current density of 100 μA/cm^2 the value of V/V_o for tantalum oxide is approximately 12.0 (8), while for bismuth oxide it is approximately 6.0 (see Fig. 3). Thus, if the field strength in tantalum oxide is eight times that in bismuth oxide, the valence-jump distance product for bismuth oxide should be four times that for tantalum oxide. Masing and Young determined that the jump distance in bismuth oxide is four times as great as it is in tantalum oxide. The values of the electric field strength determined by Guntherschulze and Betz and by Masing and Young for bismuth oxide may be slightly low since they were apparently not aware of the photo effect of visible light. This effect, which we have found to cause large changes in the overpotential at low current densities, may produce a reduced field strength at higher current densities.

A comparison of the results presented here for bismuth with those found for iron (5) and tantalum (8), using the same experimental techniques and methods of data analysis, yields several striking similarities. The decay of the overpotential during an open-circuit transient has the same form for all three materials. The systems all show a linear dependence of V_o on the formation potential at fixed formation current density. The values of the slopes of these plots are comparable (0.09 for tantalum, 0.2 for iron, and 0.16 for bismuth). The slope of V_o against formation potential is dependent on the formation current density for all three systems, in all cases increasing with decreasing formation current density. The parameter i_o will therefore depend on the formation current density in much the same manner for each of these systems. (An equation of the form of Eq. [7] has been found for this dependence in tantalum, the exact form of the relation for iron is not presently known.) The values of i_o for these three systems at comparable formation current densities are $7 \cdot 10^{-5}$ μA/cm^2 for tantalum, $5 \cdot 10^{-3}$ μA/cm^2 for iron, and $3 \cdot 10^{-1}$ μA/cm^2 for bismuth. Finally, all three systems show a potential overshoot whenever the applied current density is changed abruptly from one value to another.

It is for these reasons that we feel that some of the features which these systems exhibit, as exemplified by this work, are general features of the anodic oxidation process which will be independent of the particular system under investigation. Further, it is our opinion that the analysis of open-circuit transients is a useful technique which yields valuable information as to the behavior of metals undergoing anodic oxidation.

Cathode Overpotential and Electrosorption Effects of Straight-Chain Carboxylic Acids during Electrodeposition of Copper

Alan K. P. Chu[1] and A. J. Sukava*

Department of Chemistry, University of Western Ontario, London, Ontario, Canada

ABSTRACT

The effects of straight-chain carboxylic acids on cathode overpotential during electrodeposition of copper were studied by galvanostatic methods at current densities up to 0.020 A-cm^{-2}. No modification of the charge-transfer mechanism of copper deposition occurred. Overpotential increments caused by lengthening of the carbon chain can be correlated with the reduced concentrations of the carboxylic acids in accordance with Traube's rule. This can be rationalized in terms of the general relation between adsorbability and solubility of the additive. The general behavior is consistent with the blocking theory of additive function according to which overpotential increments are directly dependent on additive adsorbability. The fractional surface coverage calculated from overpotential increments appears to fit a Langmuir-type isotherm from which the free energies of adsorption of the carboxylic acids can be determined. The magnitudes of these free energies are consistent with physical adsorption forces. A relation was derived between the free energy of adsorption and the free energy contributions from the carboxyl group and the carbon chain. This shows that the longer the chain, the higher the adsorbability.

Overpotential and adsorbed additives.—The rate-determining step in electrodeposition varies with the overpotential region (1). The charge-transfer process is believed to be rate-determining at high overpotentials (2) and the accepted mechanism in the case of copper deposition is the two step charge transfer

$$Cu^{2+} + \epsilon \rightarrow Cu^{+} \qquad \text{slow}$$
$$Cu^{+} + \epsilon \rightarrow Cu \qquad \text{fast}$$

The charge-transfer overpotential η is related to the current density i by the Tafel equation (3)

$$\eta = a + b \ln i \qquad [1]$$

Under high overpotential conditions, the measured overpotential will represent the magnitude of η if other sources of overpotential can be eliminated or sufficiently minimized.

The presence in the solution of surface-active additives results in a considerable increase in cathode overpotential in many instances (4-7), due primarily to adsorption of the additive on the cathode surface (4-6, 8, 9). Since this adsorption undoubtedly modifies the surface conditions for electrodeposition, it is essential to try to correlate the resulting overpotential increment and the additive adsorbability.

In metal deposition, overpotential increments caused by additives are generally believed to arise from an increased true current density because of partial blocking of the electrode by adsorbed additive. If a fraction θ of the cathode surface is covered by additive molecules, and if electrodeposition occurs only on the uncovered fraction $1 - \theta$, then the true current density will be increased from i in the absence of aditive to i', in the presence of additive, such that

$$i' = \frac{i}{1 - \theta} \qquad [2]$$

If the charge-transfer process remains rate-determining, the increased charge-transfer overpotential η' in the presence of additive will be given by

$$\eta' = a + b \ln i'$$
$$= a + b \ln\left(\frac{i}{1 - \theta}\right) \qquad [3]$$

An expression relating the overpotential increment and the fractional surface coverage can then be obtained by subtracting Eq. [1] and [3] to give

$$\theta = 1 - \exp(-\Delta\eta/b) \qquad [4]$$

Equation [4], based on the simple blocking theory, has been used in the study of hydrogen overvoltage at solid electrodes (8, 10) and values of θ calculated in this way from overvoltage data have been found to agree satisfactorily with values obtained from double-layer capacity measurements (10). If it can be as-

sumed that this equation applies equally well to metal deposition, then the fractional surface coverage for additives which adsorb randomly on the electrolytically active sites is readily calculable from experimental measurements of $\Delta\eta$.

It should be pointed out that overpotential is not always increased by the presence of additive. Certain alkaloids have been found to lower the hydrogen overvoltage of mercury and lead, but presumably because the specifically adsorbed alkaloid acts as a low-stability source of electroactive hydrogen (11).

Electrosorption of additives.—Various aspects of electrosorption have been reviewed by Frumkin (12). Mercury electrodes have been used for much of this work because they allow the extent of adsorption to be determined from electrocapillary data. In the case of solid electrodes, radiotracer methods have been used with some success (13, 14), but useful information can also be derived from studies of ordinary adsorption (15, 16), particularly concerning the adsorbability of additive and the type of bonding with the electrode surface. It is known that adsorbability in ordinary adsorption depends on the solubility of the adsorbate (15). In general, the lower the solubility, the higher the adsorbability.

In electrosorption, as in ordinary adsorption, solvent adsorption occurs at the electrode, and adsorption of additive involves a displacement of solvent molecules (17-19). Competition between solvent and additives for the electrode surface therefore occurs. Generally, if the adsorbed molecules are polar, their orientation might be expected to depend on the sign of the electrode charge, and the competition for adsorption sites between water and an organic additive might be expected to be potential dependent (20, 21). Accordingly, water molecules should be least strongly attached to the electrode at the point of zero charge, with maximum adsorption of the organic additive the expected result, but this is not always the case (17, 20, 22). In chemisorption particularly, the orientation of an adsorbed molecule will depend on the functional group that determines the point of attachment (15), and so the potential dependence of such adsorption would be relatively unimportant.

The equilibrium between adsorbed additive on an electrode surface and additive in the solution phase can be described in the customary way by an adsorption isotherm. In general, since the major difference between gas-phase and liquid-phase adsorption is merely that the substrate surface is bare in the former and solvated in the latter, it follows that isotherms originally derived for gas-phase adsorption also find application in electrosorption studies. In these studies, the Langmuir isotherm has been found useful.

Langmuir adsorption isotherm.—The Langmuir isotherm, derivable from either a kinetic or statistical treatment (23, 24), can be written in the form

$$\frac{\theta}{1-\theta} = CK = C \cdot \exp\left(-\frac{\Delta G^\circ_a}{RT}\right) \qquad [5]$$

where θ and C are the fractional surface coverage and concentration of additive, respectively, K is the equilibrium constant (the adsorbability), and ΔG°_a is the standard free energy of adsorption. From the model and assumptions made in the derivation, this isotherm can be expected to apply to localized monolayer adsorption with no lateral interference (*i.e.*, free energy of adsorption is not coverage dependent) and to the condition where each adsorbed molecule occupies a single site on the surface. At low coverage, Eq. [5] describes many electrosorption systems to a good approximation (13, 25, 26).

Langmuir adsorption from solution.—Adsorption of an additive A on a solvated electrode surface can be written as a displacement reaction

$$A_{(soln.)} + nH_2O_{(ads.)} \rightleftarrows A_{(ads.)} + nH_2O_{(soln.)}$$

where n is the number of water molecules displaced by a molecule of additive. A Langmuir-type isotherm for this kind of displacement adsorption has been formulated as (17)

$$\frac{\theta}{(1-\theta)^n}\,\frac{\{\theta + n(1-\theta)\}^{n-1}}{n^n} = CK = \frac{C}{55.5}\exp\left(\frac{-\Delta G^\circ_a}{RT}\right) \qquad [6]$$

When n is unity, Eq. [6] reduces to the ordinary Langmuir isotherm

$$\frac{\theta}{1-\theta} = \frac{C}{55.5}\exp\left(\frac{-\Delta G^\circ_a}{RT}\right) \qquad [7]$$

This is essentially the same form as Eq. [5] except that it contains the factor 1/55.5 which arises from taking unit mole fraction of adsorbed species as standard state.

Experimental

Some of the overpotential measurements in this work were made with a Haring cell (5), while others were made with a Luggin probe in contact with the bottom end of a copper-wire cathode (about 2.0 mm diameter) in a specially constructed H-cell similar to one described by Turner and Johnson (7). The Haring cell was designed to contain 150 ml of solution with 10 cm^2 of electrode area immersed. The cathode compartment of the H-cell contained about 65 ml of solution with 1 cm^2 of cathode surface immersed. Cathode overpotentials were measured with a Sargent SR recorder in some cases and with a Leeds and Northrup Type K potentiometer in others. Overpotential increments were determined for several straight-chain carboxylic acids added to the standard reference solution of copper sulfate and sulfuric acid (4, 5). Effects of additive concentration and current density were determined.

Electrolyte containing 0.5M $CuSO_4$ and 1.0M H_2SO_4, both reagent grade, was used as the standard solution. The water was triply distilled in all-glass apparatus. Precautions were taken to remove possible organic contaminants from the copper sulfate pentahydrate solid before preparing the solutions. This was done by heating at 750°C for several days to cause complete decomposition to copper oxide, which was then dissolved in the required amount of sulfuric acid. All copper electrodes were heated to redness before use to remove any organic substances. Solutions containing the additives were always freshly prepared and only high-purity compounds were used.

Results

All overpotentials reported in this paper are steady-state total values reproducible to within ±5%. Minor variations in electrode surfaces appeared to be the main factor affecting the reproducibility. In the electrolysis of the standard solution at 25° ±0.1°C and 20 $mA\text{-}cm^{-2}$, the total cathode overpotential was 100 ±5 mV (4, 5). Some overpotential decay measurements indicate that under these conditions with natural free convection, the concentration overpotential, which is less than 5 mV, is not significantly affected by the additives employed in this work (27). It may therefore be assumed that the main effect of the additives is to increase the charge-transfer overpotential only. The overpotential increment in each case was obtained by subtracting 100 mV from the measured total value.

Steady-state overpotential.—The total steady-state cathode overpotential is shown in Fig. 1 as a function of additive concentration for several straight-chain carboxylic acids, methanoic, propanoic, pentanoic, heptanoic, and hexanedioic acids. These compounds were chosen to show the effect of carbon chain length on overpotential, the only variation in functional

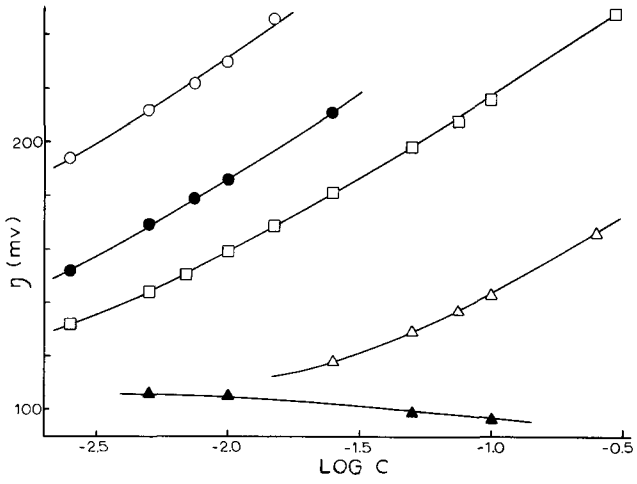

Fig. 1. Steady-state cathode overpotential and additive concentration. Temperature, 25° ± 0.1°C; current density, 20 mA-cm^{-2}. ○, Heptanoic acid; ●, hexanedioic acid; □, pentanoic acid; △, propanoic acid; ▲, methanoic acid.

group being in the dicarboxylic hexanedoic acid. Additives differing by two methylene groups were chosen to cover a wide range of chain length with a minimum of experimental data. The curves in Fig. 1 show that cathode overpotential generally increases with increasing concentration and with increasing chain length of these additives. No effect on overpotential was found with methanoic acid up to about 0.1M, apart from a tendency to decrease the overpotential slightly though not significantly.

In the measurement of cathode overpotential at constant current density and with different concentrations of additive, it was found that, apart from the overpotential increase, the carboxylic acids had no effect on the time variation of overpotential. Good steady states were obtained in most cases in about 1 hr, after which prolonged electrolysis for several hours produced no further change. An exception was observed with heptanoic acid at a concentration close to saturation (0.015M). In this case the time required for steady state was about 8 hr.

Overpotential-current density effects.—Overpotential measurements at different apparent current densities were made by reducing the current density in 2-mA steps from 20 mA-cm^{-2} down to 2 mA-cm^{-2} with no current interruption during the step. The time required for steady state at each new current density varied from about 5 to 10 min. Typical overpotential-current density data are shown as Tafel plots in Fig. 2. These show a linear behavior extending from about 8 mA-cm^{-2} to about 20 mA-cm^{-2}, with the additives having no marked effect on the Tafel slope. In accordance with Eq. [3] and the natural logarithm of current density, this slope was found to be 50 ± 1 mV, in agreement with the theoretical value calculated from the relation

$$b = RT/\alpha zF$$

with the transfer coefficient α taken as 0.5 and z taken as unity (2). Therefore, under conditions where charge transfer is rate-determining, carboxylic acids have no significant effect on the kinetics of copper deposition. Their primary effect is merely to increase the charge-transfer overpotential by increasing the true current density.

Discussion

Adsorption isotherm and surface coverage.—The fractional surface coverage θ due to additive adsorbed on the cathode was calculated from the overpotential increment $\Delta\eta$ by applying Eq. [4] to the data for propanoic, pentanoic, heptanoic, and hexanedioic acids. For these calculations, the Tafel slope b was taken as

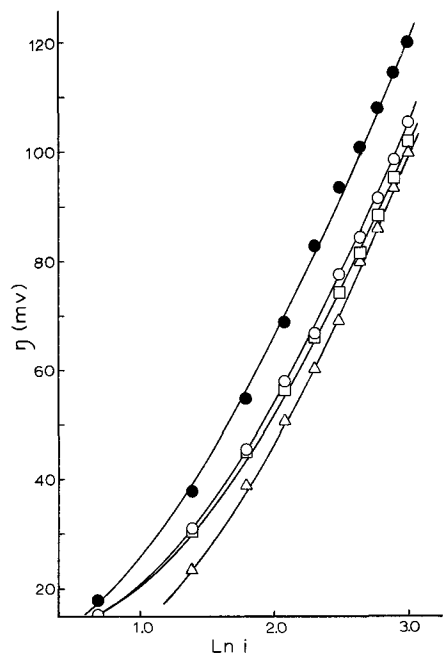

Fig. 2. Overpotential-current density relations. Temperature, 25° ± 0.1°C. △, Standard solution, □, 1.0 × 10^{-3} M methanoic acid; ○, 1.0 × 10^{-2} M methanoic acid; ●, 3.0 × 10^{-2} M propanoic acid.

the experimental 50 mV, with results as shown in Table I. A test was made for Langmuir adsorption by plotting the left hand side of Eq. [6] against additive concentration, and it was found that if n, the number of water molecules replaced by a molecule of adsorbed additive, is taken as 2, a straight line passing through the origin is obtained for each of the four additives. Typical results are shown in Fig .3.

Free energy of adsorption.—Since the behavior of carboxylic acids shown in Table I and Fig. 3 appears to be consistent with Langmuir adsorption, Eq. [6] may be used to evaluate the standard free energy of adsorption of these additives. The values of the adsorbability K and standard free energy $\Delta G°_a$, calculated from the slopes of the lines as illustrated in Fig. 3, are listed in Table II. The results show that, with other things being equal, the free energy of adsorption and the adsorbability increase with the length of the carbon chain. From the magnitude of the net standard free energy, it would appear that physical forces are primarily involved in the adsorption process.

Table I. Adsorption data

Temperature = 25° ± 0.1°C
Current density = 20 mA-cm^{-2}

$$f(\theta) = \frac{\theta}{(1-\theta)^2}\left[\frac{\theta + 2(1-\theta)}{4}\right]$$

(See Eq. [6])

Additive	C (moles l^{-1})	$\Delta\eta$ (mV)	θ	$f(\theta)$
Propanoic acid	2.5 × 10^{-2}	18.0	0.302	0.263
	5.0 × 10^{-2}	29.4	0.445	0.562
	7.5 × 10^{-2}	37.2	0.525	0.851
	1.0 × 10^{-1}	43.0	0.577	1.145

	7.5 × 10^{-3}	79.0	0.794	5.65
	1.0 × 10^{-2}	86.0	0.821	7.56

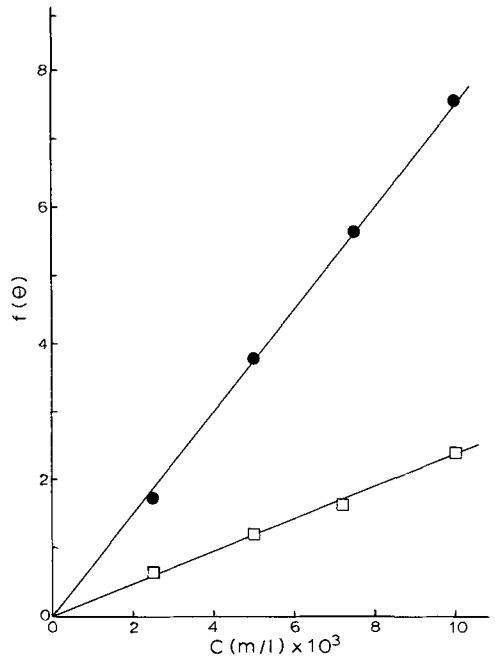

Fig. 3. Langmuir isotherm plots. ●, Hexanedioic acid; □, pentanoic acid.

Since the net free energy of adsorption shown in Table II is in every case significantly greater than the molal thermal energy *RT*, it may be argued that adsorption of carboxylic acids on a copper cathode is localized to a degree such that the effective blocking is the primary factor responsible for the overpotential increment. Delocalized (*i.e.*, mobile) adsorption of additive would presumably not contribute greatly to this increment.

With carboxylic acids as additives, the affinity of the carboxyl group for the copper surface is presumably sufficient to assure localized adsorption provided that the carbon chain is of sufficient size to have the necessary effect on the free energy of the process. Considerable surface coverages can be expected, as shown by the experimental results (Table I). The small or nearly zero overpotential effect of methanoic acid presumably arises from the hydrophilic nature of this compound, resulting in relatively ineffective competition with the solvent in the adsorption process, with a consequent low adsorbability. This view is supported by some studies of hydrogen evolution on a copper cathode with ethanoic acid as additive (10) which indicate that little or no adsorption occurs up to a concentration of 2.5M.

Components of adsorption free energy.—In the adsorption of carboxylic acids at the electrode surface, the polar functional group probably determines the energy required for appropriate bonding or physical attraction with the surface, while the hydrophobic carbon chain contributes part of the free energy to assist the adsorption process. The adsorption energy of the functional group presumably depends in part on the nature of the adsorbent (the electrode surface), while the adsorption energy of the carbon chain depends primarily on the solution. For the additives studied, the increase in adsorption free energy is found to be the same for each increase in chain length by two methylene groups, within experimental error. If the free energy of adsorption of the functional group, ΔG°_p, remains unchanged as the carbon chain is varied, the free energy due to each added methylene group, $\Delta G^\circ_{CH_2}$, may be calculated from the data for the monocarboxylic acids in Table II by applying the equation

$$\Delta G^\circ_a = \Delta G^\circ_P + n_{CH_2} \cdot \Delta G^\circ_{CH_2} \quad [8]$$

where n_{CH_2} is the number of methylene groups in the molecule (including the terminal methyl). The mean values of ΔG°_p and $\Delta G^\circ_{CH_2}$ were found to be 2047 and 885 cal-mole^{-1}, respectively. However, if these values are used for hexanedioic acid, taking into account the two carboxyl groups, the calculated ΔG°_a is found to be 7634 cal-mole^{-1}, significantly higher than the experimental 6309 cal-mole^{-1}. Steric effects and possible cyclization are probable factors in preventing adsorption of this compound to the extent predicted from the monocarboxylic behavior.

Calculation of ΔG°_a.—Since adsorption of additive from solution is a water-replacement process as stated previously, the net standard free energy of adsorption will be the difference between the free energies of adsorption of additive and water from solution

$$\Delta G^\circ_a = \Delta G^\circ_{A(soln)} - n\Delta G^\circ_{W(soln)} \quad [9]$$

But adsorption of additive at an electrode-solution interface can be regarded as the sum of two processes: (*i*) the transfer of additive from the solution bulk to the pre-electrode layer, and (*ii*) the attachment of additive, physically or chemically, to the electrode surface from the pre-electrode layer.

The first of these processes appears to be analogous to the adsorption of additive at a liquid-water interface (28, 29). In the adsorption of carboxylic acids on an electrode surface, the carboxyl group probably has a higher affinity for the metal than it does for the solvent, while the hydrophobic carbon chain is effectively rejected by the solvent. Due to this solvent rejection, the additive will transfer spontaneously to the pre-electrode layer and thus make further interaction with the electrode surface possible. The first term on the right in Eq. [9] is then given by

$$\Delta G^\circ_{A(soln.)} = \lambda + \Delta G^\circ_{A,M} \quad [10]$$

where λ is the free energy due to solvent rejection and $\Delta G^\circ_{A,M}$ is the free energy due to additive-metal interaction. The quantity λ may in turn be regarded as the sum of the energies required to bring both the polar and nonpolar portions of the additive molecule from the bulk to the pre-electrode layer

$$\lambda = \lambda_P + n_{CH_2}\lambda_{CH_2} \quad [11]$$

This equation, which has been generally accepted as valid for adsorption at the air-water and liquid-water interfaces (29, 30), can be used with adsorption data from such studies to provide useful information in the interpretation of additive adsorption on electrodes.

Combination of Eq. [9], [10], and [11] gives

$$\Delta G^\circ_a = \Delta G^\circ_{A,M} + \lambda_P - n\Delta G^\circ_{W(soln.)} + n_{CH_2}\lambda_{CH_2} \quad [12]$$

Accordingly, for a given functional group, the net standard free energy of adsorption ΔG°_a increases as the number of methylene groups increases, provided of course that the signs of ΔG°_a and λ_{CH_2} are the same. The magnitude of $\Delta G^\circ_{A,M}$ may be considered to depend primarily on the nature of the functional group as suggested earlier. Generally, the magnitude of λ_P is small relative to that of $n_{CH_2}\lambda_{CH_2}$. For an organic polar molecule with a long carbon chain, it may be expected that the greatest contribution to the free energy of adsorption from solution to the pre-electrode layer comes from the carbon chain. Thus, with other factors equal, the longer the carbon chain, the greater the adsorbability.

Table II. Net free energy of adsorption

Additive	Temperature = 25° ± 0.1°C *K* (l mole^{-1})	ΔG°_a (cal mole^{-1})
Propanoic acid	11.2	−3812
Pentanoic acid	243	−5597
Heptanoic acid	4400	−7351
Hexanedioic acid	758	−6309

To compare the quantities in Eq. [12] with the values calculated for $\Delta G°_{CH_2}$ and $\Delta G°_P$ (885 and 2047 cal-mole^{-1}), we may write, in view of Eq. [8]

$$\Delta G°_P = \Delta G°_{A,M} + \lambda_P - n\Delta G°_{W(soln.)} \quad [13]$$

and

$$\Delta G°_{CH_2} = \lambda_{CH_2} \quad [14]$$

The experimental value of $\Delta G°_{CH_2}$ for the carboxylic acids studied, 885 cal-mole^{-1}, may be compared with the value 820 cal-mole^{-1} for the oil-water interface (29) and 625 cal-mole^{-1} for the air-water interface (30). Hence, the value of $\Delta G°_{CH_2}$ for an electrode-solution interface may be approximately predicted from data for the liquid-water interface, which are readily available and known for many systems (15).

As a special case of Eq. [13], if the magnitude of $\Delta G°_{A,M}$ is comparable to that of $n\Delta G°_{W(soln.)}$, $\Delta G°_P$ is approximately equal to λ_P. For the carboxyl group, the values of λ_P for the oil-water interface, 1630 cal-mole^{-1} (29), and for the air-water interface, 437 cal-mole^{-1} (30), are relatively small compared to the value of $\Delta G°_{W(soln.)}$, 4800 cal-mole^{-1} (26, 31) calculated from data for adsorption of water vapor on mercury. Obviously, the magnitude of $\Delta G°_P$ depends largely on the number of water molecules replaced, *i.e.*, n. If other factors are equal, additives will tend to adsorb on an electrode surface in such a way that the least number of water molecules will be replaced.

For the carboxylic acids employed in this study, the number of water molecules replaced is taken as 2 (see Fig. 3). If the value of λ_P for the oil-water interface, 1630 cal-mole^{-1} (29), is applicable to the electrode-solution interface, and if the value of $\Delta G°_{W(soln.)}$ quoted above, 4800 cal-mol^{-1} (26, 31), is also applicable, the value of $\Delta G°_{A,M}$ may be found from Eq. [13], using the experimental value, 2047 cal-mole^{-1}, for $\Delta G°_P$. The value obtained is 10,020 cal-mole^{-1}.

Since $\Delta G°_{A,M}$ and $2\Delta G°_{W(soln.)}$ differ by only 420 cal-mole^{-1}, an approximate prediction may be made of the net standard free energy of adsorption of an additive on an electrode surface, using adsorption data from liquid-water interfacial studies. This is seen by writing Eq. [12] in the approximate form

$$\Delta G°_a \approx \lambda_P + n_{CH_2}\lambda_{CH_2} \quad [15]$$

Accordingly, with additives having a long carbon chain, the greatest contribution to the net free energy of adsorption comes from this chain.

Correlation between overpotential increment and additive solubility.—Since the adsorbability of a carboxylic acid depends to a considerable extent on the carbon chain length, for a given functional group, and since it is known that the solubility of a hydrocarbon compound is also carbon chain dependent, then it may be expected that a direct correlation can be derived between overpotential increment and additive solubility. If the simple blocking action arising from adsorption of additive is the primary cause of overpotential increase, then such a correlation should be possible between overpotential increment, a function of additive concentration, and the reduced concentration of additive, which accounts for the effect of solubility. The reduced concentration has been defined as (32, 33)

$$C_r = \frac{C}{C_s} \quad [16]$$

where C and C_s are the concentrations of bulk and saturated solution, respectively.

If overpotential increments are plotted against reduced concentration calculated from known solubilities (34, 35) of the additives used in this study, a generalized behavior results as shown in Fig. 4. It is seen that the overpotential increment for a given reduced concentration is approximately the same for all the carboxylic acids employed. These results may be compared with those obtained for the adsorption of carboxylic acids on graphite (33). The relation between overpotential increment and the chain length of the carboxylic acids can therefore be generalized if the solubilities are taken into account.

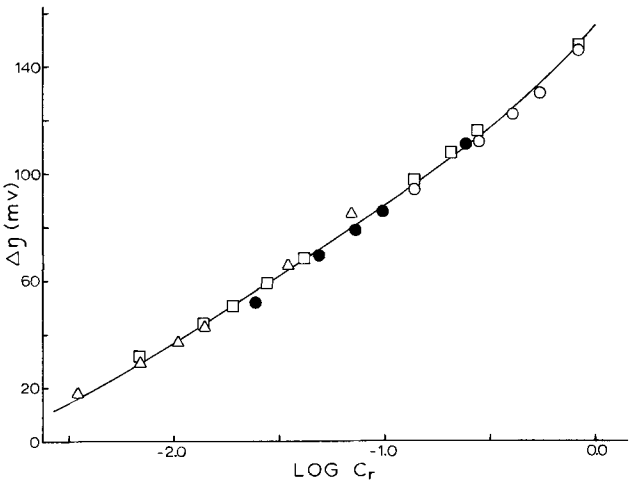

Fig. 4. Overpotential increment as a function of reduced concentration. Temperature, 25° ± 0.1°C. ○, Heptanoic acid; ●, hexanedioic acid; □, pentanoic acid; △, propanoic acid.

Since the effect of the carbon chain on the overpotential increment can be related to additive solubility, then Traube's rule which relates the effect of carbon chain on surface tension (36) might be applicable to overpotential data. This was verified for the monocarboxylic acids used in this study, and it was found that by adding one methylene group to the carbon chain, the additive concentration required to cause the same overpotential increment reduces to approximately 1/4.3. The value 4.3 can therefore be regarded as the approximate Traube coefficient in this instance. The relation can be generalized as

$$\Delta\eta_{(n_{CH_2},C)} = \Delta\eta_{(n_{CH_2}-s,(\omega)^sC)} \quad [17]$$

where $\Delta\eta_{(n_{CH_2},C)}$ is the overpotential increment due to additive containing n_{CH_2} methylene groups at concentration C, and $\Delta\eta_{(n_{CH_2}-s,(\omega)^sC)}$ is the overpotential increment due to additive containing $n_{CH_2}-s$ methylene groups at concentration $(\omega)^sC$, ω being the Traube coefficient 4.3. As an example, the overpotential increment caused by pentanoic acid can be predicted from data for propanoic acid by writing

$$\Delta\eta_{C(\text{pentanoic})} = \Delta\eta_{(4.3)^2C(\text{propanoic})}$$

since $s = 2$. This prediction can be generalized further in the form

$$C_1 = (4.3)^sC_2 \quad [18]$$

for straight-chain monocarboxylic acids 1 and 2 such that the chain length of 2 is longer than that of 1 by s methylene groups, and where C_1 and C_2 are concentrations that give the same overpotential increment. It is immediately apparent that Eq. [18] is consistent with the obvious parallelism of the overpotential *vs.* log C curves in Fig. 1. Since the difference between log C-values remains constant for any two of the monocarboxylic additives, then the ratio of the concentrations will also be constant.

Overpotential increments predicted in accordance with Eq. [17] and [18] are compared with experimentally measured values in Fig. 5. Satisfactory agreement is found. In a similar manner, a theoretical prediction can be made concerning the concentration of methanoic acid that would be required to cause a given overpotential increment. As an example, for an increment of 50 mV (total overpotential 150 mV), the methanoic acid concentration would have to be about 2.5M, high enough to have a significant effect on the solvent activity.

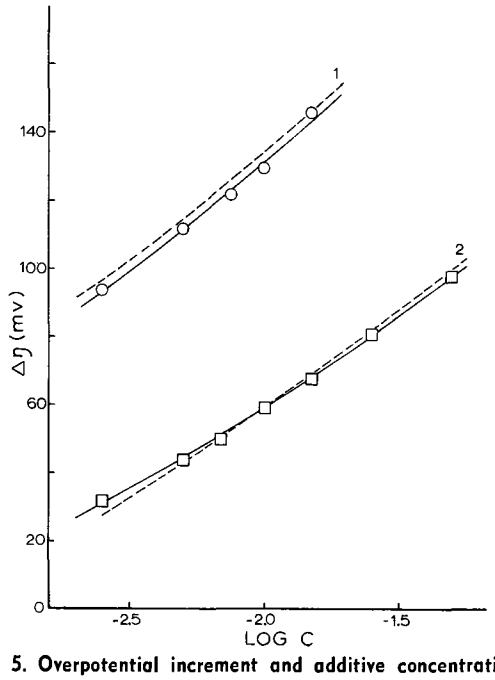

Fig. 5. Overpotential increment and additive concentration. ○, Heptanoic acid. Curve 1, calculated for heptanoic acid from pentanoic data. □, Pentanoic acid. Curve 2, calculated for pentanoic acid from propanoic data.

Another observation concerns the overpotential effects of hexanedioic acid shown in Fig. 1. According to Eq. [17] and [18], the η *vs.* log C curve for hexanoic acid should lie halfway between the curves for heptanoic and pentanoic acids, meaning that the overpotential effect of hexanedioic acid is less than that expected for hexanoic acid. This difference might be rationalized on the basis of partial cyclization of the hexanedioic acid in the aqueous solution. Studies are in progress to compare overpotential effects of a series of straight-chain dicarboxylic acids with their monocarboxylic counterparts.

Epitaxial Chromium Deposition

David W. Hardesty*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan

ABSTRACT

On nickel, copper, iron, and steel substrates, chromium has been deposited epitaxially from a fluoride catalyzed chromic acid electrolyte at temperatures above 80°C. Prominent planar facets on the deposit surfaces are parallel to chromium {110} crystallographic planes and have structural details indicative of growth by "bunching." Reflections from these facets differ in intensity, according to orientations of substrate grains, and suggest applications in metallography for study of preferred orientations and contrast improvement of "flat etching" metals.

In the course of work reported previously (1), it was observed that appearance and porosity of 0.5 μm (micrometer) thick chromium deposits depended on the crystallographic orientation of electropolished nickel substrates. It was inferred that the topography and deposit structure of the chromium were significantly affected by interfacial epitaxy. Epitaxy of chromium has previously been observed only in thin (<0.1 μm) deposits on nickel (2-4) and on copper (5). Anticipating discernible effects on deposit structure, 15-30 μm deposits from sulfate and sulfate plus silicofluoride catalyzed baths were examined microscopically and by x-ray diffraction. Only the structures and preferred orientations described by Kaiser and Wiegand (6) were found (7). Together with information previously available (8, 9), these results indicate that the characteristic structural elements of chromium deposits are submicroscopic crystallites (10^{-7} to 10^{-4} cm), and further investigation of the influence of epitaxy would require that electron microscopy and diffraction be used. No further work was done as it was obvious that epitaxial effects on deposit structure were limited to a very thin zone at the interface.

The work was resumed when it was noted that surfaces of chromium deposited from a fluoride catalyzed bath at 85°C consisted of well-formed, apparently crystalline, facets. Strongly epitaxed deposits, it was found, can be plated on a number of different metals. This report describes the procedures employed in an exploration of the characteristics of such epitaxial chromium deposits, using metallographic and x-ray diffraction methods. The results obtained are discussed with reference to the deposition process.

Experimental

The chromium plating bath, prepared from reagent grade materials and distilled water, contained 250 g/l (2.5M) chromium trioxide and 5 g/l (0.25M) fluoride ion (from hydrofluoric acid or sodium fluoride). The bath, in a Teflon beaker, was maintained at temperatures of 75°-95°C by immersion in a controlled temperature water bath. Anodes were cut from sheet lead and had areas of 120 cm^2. A polyethylene propeller-type stirrer was used to provide mild agitation to minimize temperature and concentration gradients. Cathodic current density was varied from 300 to 1500 mA/cm^2, but was usually 500-700 mA/cm^2. Power was obtained from a laboratory rectifier (filtered, single-phase full wave) or an electronically regulated constant voltage/current power supply.

The cathodes used were nickel (single crystal disks and annealed polycrystalline sheet), copper (blocks cut from large-grained castings), high purity iron, stainless steel (Type 434), and low carbon sheet steels. Grain sizes ranged from 0.01 mm (steels) to 15 mm (nickel single crystals). Cathodes (1.2-1.5 cm wide by 2.5-3.0 cm long) cut from sheet materials were plated in half-boxes (10) to assure uniform current density. Cathodes cut from bar stock or castings were mounted in cold setting epoxy resin and prepared by metallographic polishing. To ensure that surfaces were free of distortion, all specimens were subjected to suitable chemical or electrolytic polishing treatment.

Nickel was electropolished in the phosphoric-sulfuric-chromic acid mixture used before (1), or chemically polished in a mixture of 70 parts (by volume) glacial acetic acid, 30 parts concentrated nitric acid, and 0.5 parts concentrated hydrochloric acid (11). Although the steels could be electrolytically polished to a smooth, dull surface in the same electrolyte used for nickel, a fully bright polish was obtained in a modification of a solution used by Takeiuchi (12) containing 5 parts concentrated hydrofluoric acid, 40 parts 30% hydrogen peroxide, and 55 parts water. Copper was electropolished in conventional orthophosphoric acid solution (11). After chemical or electrolytic polishing, the specimens were rinsed thoroughly with running water to remove viscous polishing solution. To permit the cathode to come to bath temperature before beginning deposition, electrical connections were made after immersion in the chromium bath.

It was shown, by dissolving representative samples of substrates in 25-50% (by volume) nitric acid and examining the substrate side of the chromium deposit, that there was no appreciable etching of the polished surface. Cross-sections and surfaces of deposits were examined metallographically. Cross-section structure of chromium was revealed by etching at room temperature with Fry's alkaline ferricyanide reagent (13). It was found necessary to etch the substrate prior to the chromium deposit. For nickel, electrolytic etching in acidulated potassium bromide (1) was employed. Copper was etched to high contrast in ammonia-peroxide reagent (14) and the steels in 2-4% nital. All etching times were determined by inspection and were, typically, 30 min for chromium, 1 to 2 min for nickel, and approximately 5 sec for copper or steel.

The angles of facets, with respect to the substrate surface, were determined with a microgoniometer. Back-reflection Laué photographs of large (at least 2 mm) substrate grains and of deposits on these grains were made in a 3-cm camera using unfiltered copper x-rays Intensity of "white" radiation from copper is low and intensities of diffraction spots, except for those from sets of lattice planes so oriented as to satisfy diffraction conditions for the higher intensity K_α emissions, were also low. Contrast between diffraction spots and background darkening therefore tended to be poor. Attempts to improve contrast, so that diffraction patterns could be completely indexed and to provide illustrative examples, were unsuccessful. However, symmetry of patterns from favorably oriented grains (those with surfaces near low index planes) was qualitatively obvious, and identification of orientation could be made.

Results and Discussion

At bath temperatures below 80°C, structures are not substantially different from the usual deposits, while

* Electrochemical Society Active Member.

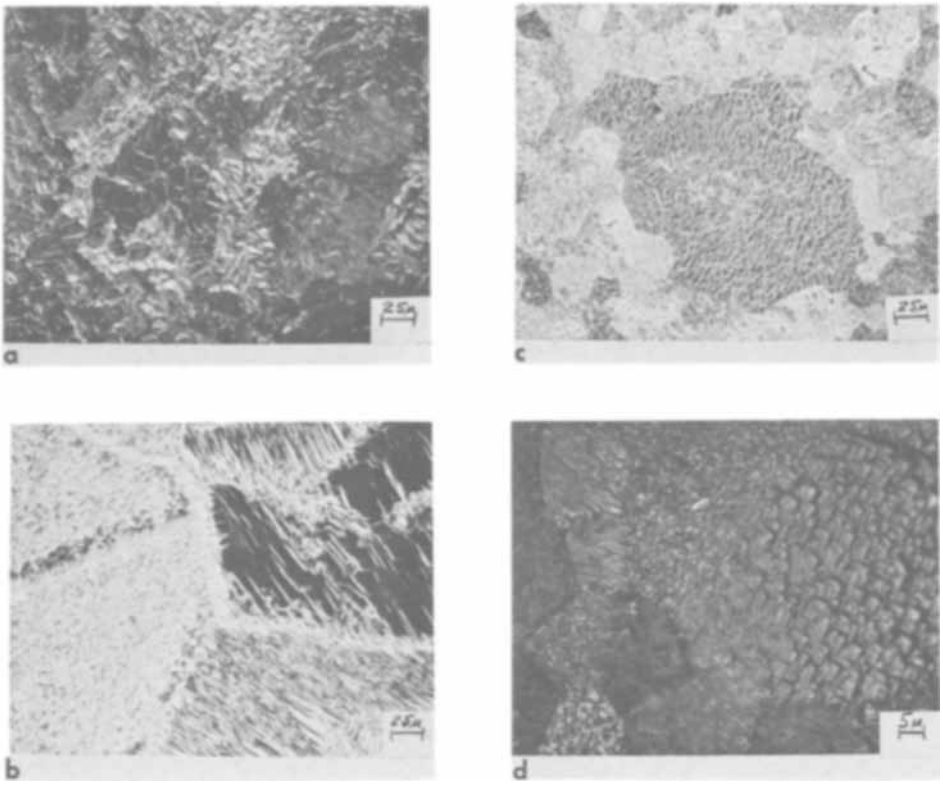

Fig. 1. Typical faceted surfaces of chromium deposited from fluoride catalyzed bath at high temperatures on polycrystalline substrates. Current density: 500 mA/cm^2. (a) On electropolished copper, 10 μm thick, (dark field, 300X); (b) on electropolished nickel, 10 μm thick, (dark field, 300X); (c) on chemically polished low-carbon steel, 2 μm thick, (dark field, 300X); and (d) detail of deposit "c", (bright field, 1000X).

faceted deposits are obtained, at all current densities, at temperatures above 80°C. Typical examples are illustrated in Fig. 1. On these polycrystalline substrates, it was found that size and distinctness of facets depend complexly on the substrate material, grain size, and grain surface orientation. The facets tend to become smaller, more uniform, and less differentiated as deposit thickness is increased. The effect of substrate structure on deposit structure is indicated by the cross-section shown in Fig. 2. Most clearly shown here is the continuation of substrate grain boundaries through the deposit. Differences in the fine structure of deposit above substrate grains can be observed visually, but are not so readily apparent in the photograph.

Relationships between substrate and deposit orientations were demonstrated using large-grained substrates, an example of which is illustrated in Fig. 3. This sample of high-purity iron was etched before plating, and the crystallographic orientation of three large grains was determined by x-ray diffraction. In these grains (indicated by the markings), the iron {110} planes were tilted 2°, 8°, and 15° (± ½°) with respect to the surface. After plating with 20 μm of chromium, orientations of the deposits on these grains was again determined and found to be identical to that of the iron substrates. Clearly, the chromium deposit continued, or copied, the structure of the iron substrate as expected, since the lattice parameters of these isomorphic (body-centered cubic) metals differ by less than 1%. On face-centered cubic (nickel, copper) substrates, the orientations of the deposit were as found by Reddy and Wilman (5) in very thin deposits on copper.

The angles of facets to the surface were found to be those of deposit {110} planes. Where these planes were near to being parallel to the surface (angle <20°), only one distinct reflection, the direction of which could be determined to within ± 1°, could be detected with the microgoniometer. Where the facet angles were greater, the reflecting direction could be determined with less precision (± 2°-3°), but several reflections at approximately 90° angles were observed. Interference microscopy of low-angle facets showed them to be non-planar surfaces with curvatures similar to those on the surfaces of facets on copper deposits noted by Howes (15) who, in his detailed discussion, attributed the apparent curvature to submicroscopic morphology engendered by lateral advance of layers as the deposit

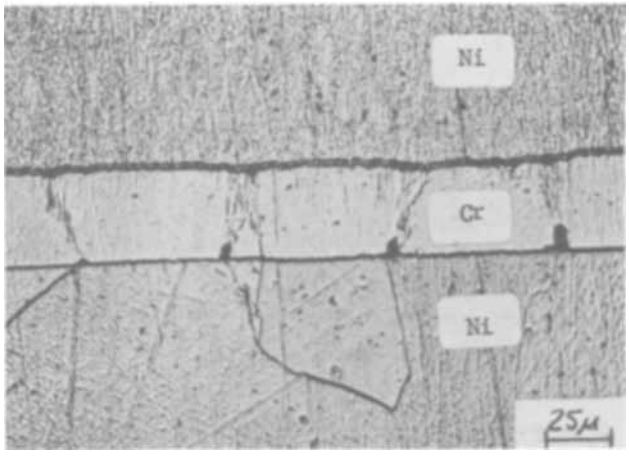

Fig. 2. Cross-section of thick chromium deposit from fluoride catalyzed bath on electropolished nickel (400X).

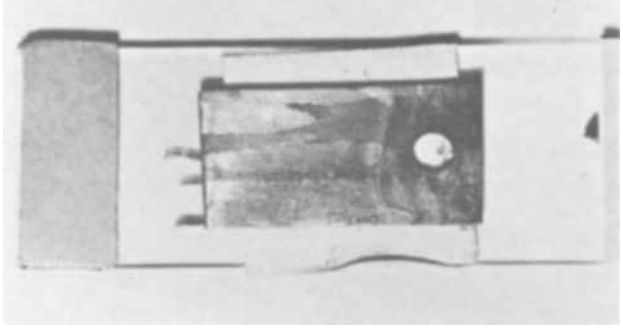

Fig. 3. Macrograph of chromium deposit on large-grained iron cathode used in determination of orientations. Plated area: 1.5 × 2 cm (coupon size 1.5 × 3 cm); chromium thickness, 25 μm.

grew. By a "bunching" process, these layers cease to grow, and the microscopic (and even macroscopic) morphology is developed.

Further evidence that the topography of these epitaxed chromium deposits is a manifestation of the crystallinity of the deposits is provided by the effect of using polarized light. When deposit surfaces are examined, each grain appears to reflect in a shade of gray as shown in Fig. 4a. When the plated sample is rotated through 360°, the gray shade from each grain will change, passing through four diffuse maxima and four distinct minima of reflected light intensity. If the "sensitive tint" technique is employed, each grain has a distinctive color which varies systematically, as the sample is rotated, from magenta through blue to green to gold. The effects are striking in color and photograph in black-and-white as finely graded shades of gray as shown in Fig. 4b. Such responsiveness to illumination by polarized light depends, as shown by Jones (16) and confirmed by electron microscopy (17), on the surface being composed of parallel, right-angle grooves. In the present instance, these grooves are formed by {110} plane facets on the chromium deposit surface.

A somewhat similar, but less distinct, effect is observed if dark-field illumination is used, as shown in Fig. 5. Here, the shading variations depend solely on the angular inclinations of facets of the deposit on each substrate grain. This was the first nonstandard

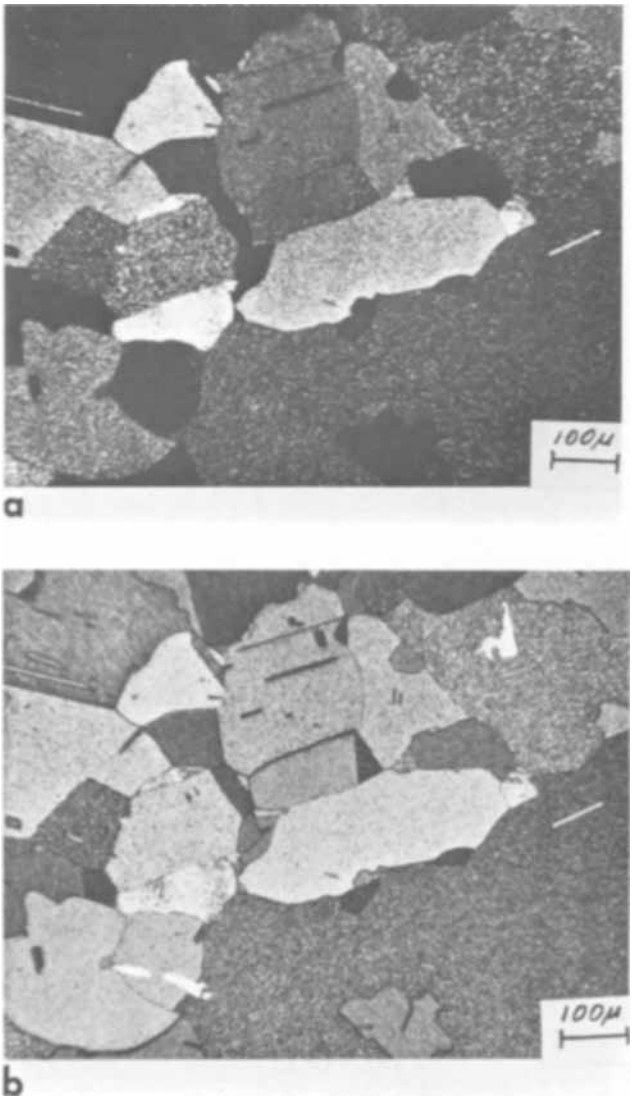

Fig. 4. Orientation-sensitive effects of chromium deposit revealed by using polarized light: (a) crossed polarizers only and (b) "sensitive tint" plate added. Chromium thickness, 5 μm (100X).

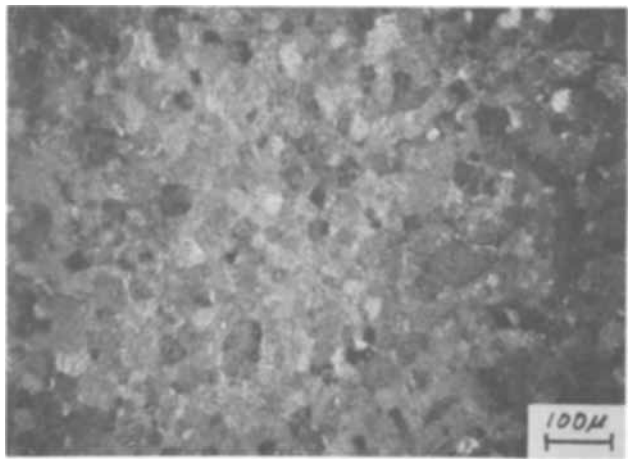

Fig. 5. Epitaxial chromium deposit surface. Substrate: low carbon steel (fully annealed) (dark field, 100X).

illumination technique employed, and it was found that bands of similarly reflecting grains were readily detected visually in deposits on Type 434 stainless steel which displayed "roping" when drawn. An example is illustrated in Fig. 6, which shows one such band. Steel with satisfactory drawing properties contained no such bands. It was concluded that the banding was evidence of preferred orientation or rolling texture made visible by nearly uniform intensity of light reflected from {110} facets on bands of similarly oriented grain surfaces resulting from rolling and annealing treatments of the steel. With dark-field illumination, such texture can easily be detected visually and could perhaps be used as an inspection method. Such a method would, unfortunately, be only qualitative in nature. The polarized light effects probably can be used quantitatively since such use has been reported (18) for etched metals.

It seems clearly established that chromium can be deposited epitaxially on a variety of isomorphous (iron, steel, ferritic Type 434 stainless steel) and nonisomorphous (copper, nickel) substrate metals. From the similarities of morphologies of the deposits, it appears that chromium is deposited from this fluoride catalyzed bath at high temperatures (above 80°C) under conditions whereby growth occurs by a "bunching" mechanism. Keen and Farr suggest that this may be a widely applicable concept, and evidence is available which so indicates (15, 19, 20) for copper, zinc, and other metals. Such growth was demonstrable in nickel and

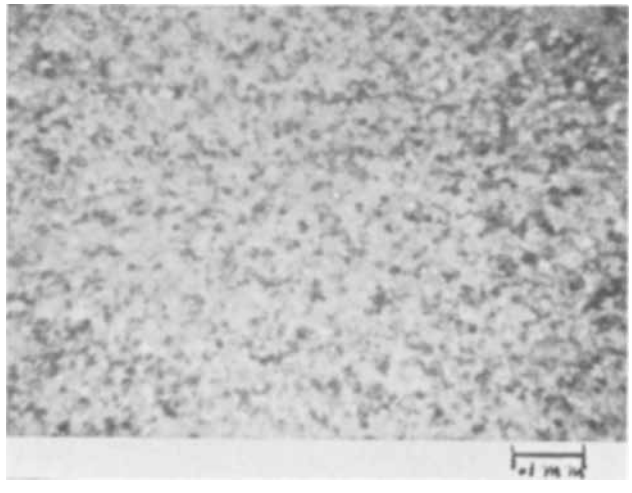

Fig. 6. Possible zone of differential orientation in Type 434 stainless steel from lot which displays "roping" when drawn. Chromium thickness, 1.2 μm (dark field, 100X).

cobalt deposits (20) only at high electrolyte temperatures, confirming Keen and Farr's caution that the applicability of the bunching hypothesis is probably limited to specific conditions of deposition (19). In the present instance, it is obviously the combination of high bath temperature and the fluoride catalyst which permits deposition of clearly crystalline, epitaxed chromium with morphology indicating that the deposit grew by "bunching."

It may be postulated that the deposition of chromium under the conditions employed in this work is not actually different from those more usually employed. With conventional conditions (sulfate catalyst and lower bath temperatures), the deposits tend to develop preferred orientations and consist of extremely small crystallites (8). This may be due to the disruptive influence of chromium depleted complexes at the cathode surface (21). When the chromium cation is removed from such a complex and added to the deposit, the residuum may, by adsorption on the cathode or merely by being slow to diffuse away, effectively insulate the cathode and inhibit further deposition so that crystallites reach only a limited size as the available supply of chromium ion is exhausted. When a new supply of ions becomes available, growth evidently resumes on the previously deposited crystallite, but under such conditions that appreciable enlargement of the crystallite does not occur. Such a process could account for the periodic activity observed at chromium cathodes (22, 23) and the small, rodlike bodies discernible in cross-sections at high magnifications (24). When the temperature of a sulfate catalyzed bath is raised, the deposit structure gradually changes from apparently laminar to markedly columnar (6, 7), possibly due to enhanced mobility or more rapid desorption of the depleted complex. In the case of the fluoride catalyst, the change in deposit structure is more radical in that epitaxy occurs and the deposit grain size duplicates that of the substrate. This indicates either that growth is continuous or, if interrupted, the "new" growth adopts the "old" orientation. If as theorized, deposition of chromium does involve complexes, the complex formed in the fluoride bath has properties vastly different from the complexes formed in a sulfate or sulfate-silicofluoride bath. The parallelism of effect of temperature on chromium deposit structure and the structure of nickel plated from a bath containing organic additives (25) suggests that the adsorption hypothesis is the more tenable.

Conclusions

1. It has been found that substantial thicknesses of chromium can be deposited epitaxially on a number of metals.

2. Structural details of surface facets on these deposits indicate that growth takes place by a "bunching" mechanism similar to that governing the growth of other metals deposited from simpler electrolytes.

3. The specific effects of catalysts and bath temperature on deposit structure indicate that adsorption of some species, possibly a chromium depleted complex, is the cause of the small crystallite size of the ordinary chromium deposit.

4. The differences of reflected light intensity from {110} facets of these epitaxial deposits, due to varying orientation of each substrate grain, may prove useful in metallography of "flat etching" meals by improving contrast.

Film Formation at Anodes in Nominally Anhydrous Acetic Acid Solutions

H. W. Salzberg,* Allan Barnett, and Stephen Kandler

City College, City University of New York, New York, New York

ABSTRACT

Steady-state measurements over prolonged time periods were made on platinum, gold, and palladium anodes in unstirred, nominally anhydrous potassium acetate-acetic acid solutions, at current densities as low as 10^{-8} A/cm^2. Between 10^{-8} and 10^{-4}-10^{-5} A/cm^2, the results were reproducible and the Tafel lines had a slope of 0.06-0.07. Within experimental error, the points for platinum and gold both fell on the same straight line. The results are interpreted to mean that below about 10^{-4} A/cm^2, acetate ions were oxidized in a reversible 1-electron reaction. At about 10^{-4}-10^{-5} A/cm^2, a film of adsorbed acetic acid molecules was formed and molecular acetic acid became the source of anodic electrons.

In previous work (1) steady-state current-potential measurements were made at platinum anodes in "nominally anhydrous" (2) potassium acetate-acetic acid systems. The curves were roughly sigmoid with a large hysteresis loop, as shown in Fig. 1. We suggested that the lower plateau corresponded to the oxidation of acetate ion

$$CH_3COO^- - e \rightleftharpoons CH_3COO \qquad [1]$$

and that the upper plateau corresponded to the oxidation of molecular acetic acid. The rise from the potentials of the lower plateau to those of the upper plateau we felt, at the time, was due to the depletion of acetate ion from the surface when the current exceeded the limiting diffusion current of acetate ions in the unstirred solution. The oxidation of the molecular acetic acid could take place by either of the following reaction mechanisms. The first is an electron transfer followed by a proton transfer, Eq. [2], and the second is a simultaneous electron and proton transfer, Eq. [3].

$$(a)\quad CH_3COOH - e \rightleftharpoons CH_3COOH^+$$

$$(b)\quad CH_3COOH^+ + CH_3COO^- \rightarrow CH_3COOH + CH_3COO\cdot \qquad [2]$$

$$CH_3COOH - e \xrightarrow{CH_3COO^-} CH_3COOH + CH_3COO\cdot \qquad [3]$$

In the present work we have extended the investigation of this system to gold and palladium anodes and to current densities as low as 10^{-8} A/cm^2.

Experimental

The solutions were not rigorously anhydrous. The solvent was glacial acetic acid. For some runs the solvent was purified by freezing and discarding any unfrozen liquid. For most runs, a sample of solvent was boiled down to about half of its volume. The solution was saturated with potassium acetate, concentration being 7 moles/kg of solvent. The potassium acetate was dried by melting and heating at temperatures in excess of 300°C. The cell was kept in a dessicator during runs and the only contact between solution and laboratory air was during the short periods when the heated reagents were transferred to the dessicator and when the cell was filled. Undoubtedly, some moisture entered the system during those time periods but we estimate the quantity to be rather small, based on a rough calculation of the moisture present in the air in the empty cell.

The cell was a Teflon cylinder with a fitted Teflon top and Teflon tubes extending through the top into the cell. The electrode wires were passed through these tubes into the cell. The cell volume was about 24 ml. Some runs were made with one anode in the solution, others were made with two or three anodes, so that comparisons could be made using several different electrodes in the same batch of solution. There was no detectable difference in results due to the number of electrodes present.

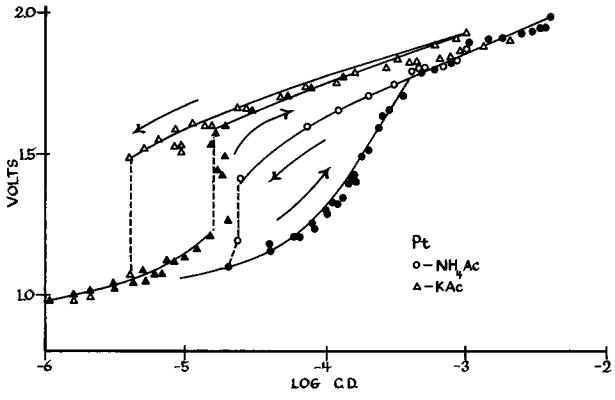

Fig. 1. Voltage-current density measurement on platinum anodes in anhydrous acetic acid. Ordinate is potential *vs.* a silver-silver chloride reference.

Measurement techniques were varied. In runs at high current densities, the interrupter method was used. Both working potential and ohmic drop were measured at each point in the curve. In other runs we obtained a complete curve of working potential *vs.* current density, by direct measurement, and then used the interrupter method to determine the ohmic drop. The electrode potential was then obtained by difference. The results of this procedure showed that at current densities below 10^{-5} A/cm^2, the ohmic drop was within the experimental error of the potential measurement. In further work, therefore, no correction was made for ohmic drop below 10^{-5} A/cm^2 and potentials were obtained by direct measurements.

Constant potential runs were made with a Heath operational amplifier system, equipped with a polarography module and with a Beckman Electroscan 30. Constant current runs were made with the Electroscan. The results did not depend, perceptibly, on the choice of apparatus. When the steady state was reached, results were the same for both constant current and constant voltage runs. Differences between constant current and constant voltage runs occurred only during the approach to the steady state.

The cathode was a silver-silver chloride electrode about 4 cm^2 on a face. The reference electrode was a silver-silver chloride wire. The platinum and palladium anodes and one of the gold anodes were of the flag type, about 1 cm^2 on a face. Both faces of the flag electrodes were exposed and no attempt was made to

* Electrochemical Society Active Member.

determine the potentials of each face separately. The gold flag was 24 karat, the other gold electrode was an 18 karat wire whose tip was melted to a hemisphere of 0.2 cm^2 surface area. The gold wire was inserted in a Teflon tube so that only the hemispherical surface was exposed to the solution. The platinum and palladium electrodes were repeatedly flamed and dipped into nitric acid and then soaked in acetic acid. The gold electrodes were soaked in nitric acid for prolonged periods and then in acetic acid. The solution was saturated with KCl to supply the Ag/AgCl electrodes. The solution contained about 3×10^{-2} moles of KCl/kg of solvent. The temperature range of the experiment was 25° ± 2°C, *i.e.*, room temperature.

Some runs were galvanostatic, others potentiostatic. At the start of a run it took many hours for the first few points. Sometimes overnight runs were made. However, after the first few points had been obtained, steady-state values could be determined within an hour or so, for each point. Our arbitrary criterion of steady state was a voltage change of less than 5 mv (about 1%) in a half hour.

Other authors (2, 3) have made measurements at fixed time intervals, for example, 60-sec intervals, 1-hr intervals, etc., to avoid "long-time variations in the potential which commonly occur in anodic processes" (4). Almost certainly, most data obtained in time intervals of less than one hour per point are not steady-state data. To check our experimental method, we took trial points at fixed time intervals and found the data relatively irreproducible, while our steady-state measurements, as defined above, were quite reproducible, as shown below.

Results and Discussion

Figure 2 shows a typical current-voltage curve at a gold anode. Note that the hysteresis loop is much wider than in the case of platinum and extends down to current densities at least as low as 5×10^{-5} A/cm^2. At points 1 and 2 both current and potential are stable for 18 hr or more. If the difference in potential between the upper and lower plateaus resulted from depletion of ions from the surface at 10^{-4} A/cm^2 (the rising portion of the curve) then, after 18 hr at point 1, enough acetate ions should have diffused in to lower the potential to that of the lower plateau. No such change takes place. If, however, the current is interrupted for a few seconds, the potential drops immediately down to that corresponding to the lower plateau. Obviously, the potential at point 1 is not maintained by slowness of ion transport to the surface. If diffusion to the surface were slow enough so that at 10^{-5} A/cm^2 the surface should be depleted of acetate ions, then after 18 hr the potential should rise from that at point 2 to the values of the upper plateau. This rise also does not occur. The wide hysteresis loop

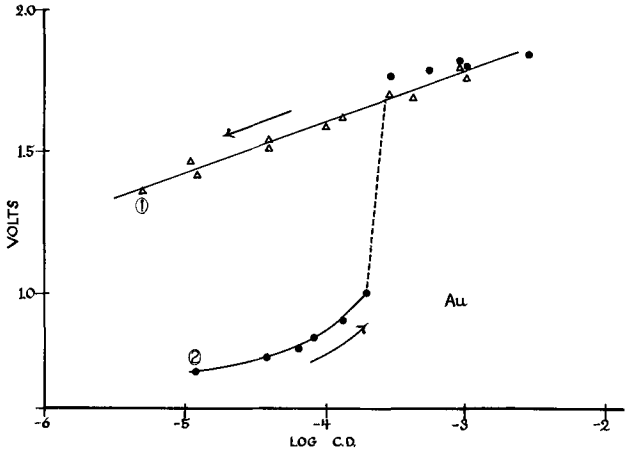

Fig. 2. Voltage-current density measurements on a gold anode in KAc-HAc.

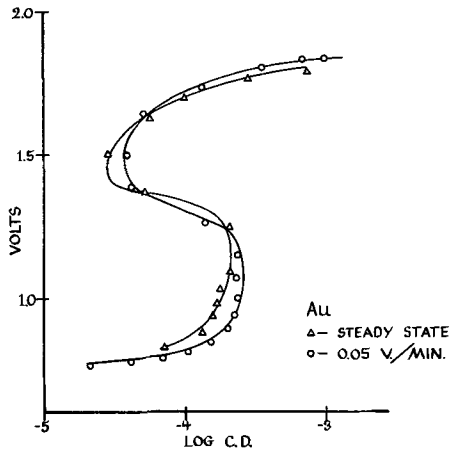

Fig. 3. Potentiostatic voltage-current density measurements on a gold anode in KAc-HAc.

at 10^{-5} A/cm^2 and below is therefore not due simply to a mass-transport phenomenon.

Some potential-step measurements were made on platinum. At currents below 10^{-4}-10^{-5} A/cm^2, when the potential was stepped up, there was the expected initial sharp increase in current followed by a slow decrease. At current densities above 10^{-4}, there was no decay in the current after the initial sharp rise. We interpret this as indicating that at these higher current densities, the solvent (molecular acetic acid) is oxidized, and that at lower currents acetate ions are being oxidized.

Figure 3 shows potentiostatic voltamograms on gold anodes. Qualitatively similar results were observed on platinum. The circular points were obtained with a linear sweep, the triangular points were the result of steady-state measurements. Both curves show a decrease in current at constant potential at currents corresponding to the rise in potential from the low plateau to the high values. Curves such as these are characteristic of film formation and are often associated with passivation (5).

Figure 4 shows the results of measurements of the lower plateaus over prolonged periods (up to two weeks per solution) with several different anodes in several different batches of solution. The currents were kept (for the most part) below values at which the potential rise commenced. In some cases, the potentials rose to the upper plateau. However, opening the circuit for a few seconds was sufficient for the potential values to drop back down to those shown on the graph. Some runs were deliberately continued to the upper plateau, where the observed values were in agreement with previously published data (1, 6). The results at the low currents were sufficiently reproducible for one straight line to be drawn through several sets of

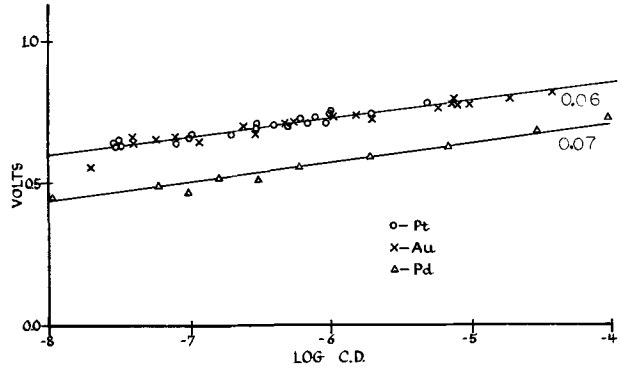

Fig. 4. Steady-state measurements at low current densities in KAc-HAc.

measurements with each of two gold and two platinum electrodes in several batches of solution. This is in marked contrast to the previously published data, at high current densities, on the upper portion of the curve, where at the same electrode in the same solution results differed by as much as 60 mV from day to day (6).

Figures 2 and 3 taken together indicate that the hysteresis loop shown in Fig. 1 is the result of formation of a film. Figure 4 shows that at current densities below that necessary for film formation, *i.e.*, below 10^{-4} A/cm^2, the slope of the voltage-log current density curve is 0.06, which is consistent with a reversible 1-electron transfer, such as that in Eq. [1]. The voltage-log current curves in the region of the upper plateau, *i.e.*, at 10^{-3} A/cm^2 and above, have slopes of 0.10-0.15 (1) which correspond to irreversible 1-electron oxidations, such as in Eq. [2] and [3].

The Tafel slopes and the close agreement between results on platinum, gold, and palladium electrodes indicate that the process taking place is probably thermodynamically controlled and reversible, rather than irreversible and kinetically controlled. The small difference (0.1V) between the values on Pd and those on the other two electrodes could be explained either on the basis of a roughness factor or on the basis of a small heat of adsorption. If the radical formed in Eq. [1] were adsorbed on the electrode surface, a difference in heats of adsorption of only 2-3 kcal/equivalent would be enough to account for the potential difference.

At this point it is necessary to discuss the effects of the undoubted presence of trace amounts of water in our solutions. This water could: (*a*) be the substance oxidized at low currents and potentials (*i.e.*, at current densities below 10^{-4} A/cm^2); (*b*) be the substance which is oxidized to produce a film.

Any water present would be in the form of either hydronium ions, which would not diffuse to the anode, or water molecules. (Since the ionization constant of acetic acid is 10^9 that of water, the OH^- resulting from the self-ionization of water in acetic acid solution should be negligible.) The water molecules oxidizing at the anode would form either molecular oxygen with a Tafel slope of 0.12 (7, 8) or a metallic oxide.

In the low-potential low-current density region, the Tafel slopes are 0.06 and there is no evidence of either film formation or of any change in either mechanism or identity of reacting substance until the current density has reached the 10^{-4} A/cm^2 region. In addition, since the potential current density curves on gold and platinum are identical, any oxides forming would have to form at the same potential, which would be within 0.1V of the potential at which the palladium oxide would form. This would be unlikely. Finally, for the lower slope to be due to the oxidation of water up to 10^{-4} A/cm^2, the water concentration would have to be about 10^{-3} moles/liter. While our solutions were not rigorously anhydrous, this figure is probably several orders of magnitude above our water concentration. By the same argument, for water to be the source of the current at 10^{-4} A/cm^2 and above, the water concentration would have to be hundredth or even tenth molar, which is out of the question. To arrive at the figure of 10^{-3} moles/liter as being necessary to support a current density of 10^{-4} A/cm^2, we assume only that the diffusion constant for water molecules in acetic acid is 10^{-5}, which is the same order of magnitude as that of most salts in aqueous or methanolic solution. To support a current of 10^{-4} A/cm^2 = 10^{-9} moles/sec-cm^2, if the diffusion constant is 10^{-5} cm^2/sec, the concentration gradient, $dC/dx = 10^{-4}$ mole/cm^4. In a stirred solution, the diffusion zone is 10^{-2}-10^{-3} cm (9), so taking the larger figure for our work in unstirred solutions, the difference in concentration across the Nernst diffusion layer is 10^{-6} moles/cm^3 or 10^{-3} moles/liter. Even if the surface concentration were zero, the bulk water concentration to support a 10^{-4} A/cm^2 current density would have to be millimolar.

We therefore conclude that under our steady-state conditions, the effect of water is not significant. Under conditions where rapid potential measurements were made, the presence of water would most probably have significant effects.

Conclusions

We consider that these results can best be explained in terms of the reversible 1-electron oxidation of acetate ions at current densities up to about 10^{-4} A/cm^2, in unstirred solution, and the irreversible oxidation of molecular acetic acid at current densities above 10^{-4} A/cm^2. At about 10^{-4} A/cm^2, the diffusion layer is depleted of acetate ions and the potential rises, by about 0.8V, to the level at which acetic acid molecules are oxidized. At these high potentials, the field across the adsorbed double layer is strong enough to both polarize and adsorb the un-ionized acetic acid molecules, forming a film. Once the film has formed, the potential across the double layer maintains it, even when the current is lowered. The persistence of the film would explain the hysteresis loop, and the stability of point 1 on Fig. 2. At current densities below 10^{-4} A/cm^2 when the circuit is interrupted, the field relaxes and the film desorbs. The potential then drops immediately down to the level at which acetate ions are oxidized.

The film most probably consists of a monolayer of acetic acid molecules oriented with the carboxy groups at the surface of the metal and the hydrocarbon tails in the diffuse double layer. [This is essentially the type of barrier film proposed by Conway *et al.* (10-12).] Since most preparative runs utilizing the Kolbe reaction take place at current densities in the 0.1-1 A/cm^2 region, probably most of the reactions reported in the organic chemistry literature have taken place at a surface of adsorbed acid molecules.

Polarographic Reduction of Alkyl Halides at a Stationary Lead Electrode

Harris E. Ulery

Jackson Laboratory, Organic Chemicals Department,
E. I. du Pont de Nemours and Company, Wilmington, Delaware

ABSTRACT

The polarographic reduction of some simple alkyl halides at a stationary lead electrode was investigated. Both the iodides and bromides undergo an irreversible one electron reduction with sacrifice of the electrode metal in acetonitrile. The bromide results are compatible with a "backside attack" by the electrode, while the iodides, in keeping with the reverse polarization of the C-I bond, have a substantially different orientation. In both series the reductions were strongly dependent on the nature of the supporting electrolyte cation. The process of metal alkylation and removal are discussed in light of supplementary data from large scale electrosyntheses of organoleads.

The electroreduction of organic halides has drawn much attention in recent years (1), but principally in the context of the dropping mercury electrode (dme), and generally under conditions which give hydrocarbon as the major product (Eq. [1])

$$RX + H^+ + 2e^- \rightarrow RH + X^- \qquad [1]$$

In solvents of low proton activity such as anhydrous DMF and acetonitrile, however, many soft metal electrodes (2, 3) are consumed on reduction of the organic halide. The sacrificial cathode reaction can conform to Eq. [2] (M = cathode metal)

$$nRX + M + ne^- \rightarrow R_nM + nX^- \qquad [2]$$

In view of the economic importance of lead alkyls, a study was undertaken of the polarographic behavior of some simple alkyl halides at a stationary lead electrode.

Experimental

Materials.—The tetralkylammonium halides were Eastman white label grade. These will be referred to by their acronyms (*e.g.*, TEAB for tetraethylammonium bromide). Commercial acetonitrile was dried by the usual P_2O_5 method (4), although improved procedures have appeared since this work (5). Excepting the t-butyl halides which were distilled and stored under argon prior to use, the alkyl halides (also white label or equivalent grade) were used without additional purification. Lead metal obtained as shot analyzed as 99.97%.

Equipment.—The three electrode system used has been described previously (6). The reference electrode was aqueous saturated calomel (SCE). Transfer of water across the bridge during the course of a run was found to be negligible by Karl-Fischer titration.

The stationary working electrode was the 4 mm disk end of a melt-cast lead rod with a heat shrunk outer sheath of polyethylene. The assembly was thermostated at 25.0° ± 0.5°C.

Method.—The use of relatively high alkyl halide (RX) concentrations (1-20 mM) was dictated by two considerations: (*i*) the interference by background electrolyte activity which was appreciably greater than observed with a quiet mercury electrode, and (*ii*) the sloughing of metallic lead which occurs, depending on the supporting electrolyte, when the RX concentration is too low. Convection, pronounced at the sacrificial electrode due to the high densities of the organometallic products, was further aggravated by the passage of high currents. A 3-10% increase in the $it^{1/2}$ values over a 30 sec interval was common.

Key words: alkyl halides, lead cathode, polarography, reduction, sacrificial electrode, tetraalkyllead.

To avoid volatilization of RX (7), these and the solvent were thoroughly deoxygenated by sparging with argon prior to volumetric preparation of the test solutions.

Typically, the electrode was lightly polished on filter paper and the blank electrolyte was scanned from −1.0V one or more times to provide a suitable reference and to insure the reduction of all surface halide. The calculated amount of a 1.0M RX solution was added and the mixture scanned cathodically several times. Half-wave potentials and not peak potentials are reported in view of the greater uncertainty associated with the latter. Values given are the averages of four or more runs. Unless otherwise specified the scan rate was 0.22 V/min.

Results and Discussion

Limiting potentials.—The potential ranges accessible to the lead electrode with tetraalkylammonium bromide are illustrated by the limiting cathodic values given in Table I. In anhydrous acetonitrile, the organic cation is reduced to the trialkyl amine, which was identified for R = Et, n-Pr, and n-Bu; some soluble lead product is also formed. In aqueous media reduction of hydrogen ion may be the limiting reaction, although this does not seem to be the case on mercury (8) which has the greater hydrogen overvoltage. For aqueous acetonitrile mixtures the limiting potentials varied linearly between these extremes with log $[H_2O]$.

Reaction products for bromide system.—The reduction of MeBr at a lead electrode in TEAB/MeCN/H_2O mixtures gives TML in yields approaching 100% based on metal consumption and current use (9, 10). The observed stoichiometry is (RX=MeBr)

$$Pb + 4RX + 4e^- \rightarrow PbR_4 + 4X^- \qquad [3]$$

The reduction of EtBr produces both TEL and hexaethylbilead. Schuler (9) has estimated that only about 40% of the current is consumed by way of Eq. [3], while the remainder is used according to Eq. [4] (RX = EtBr).

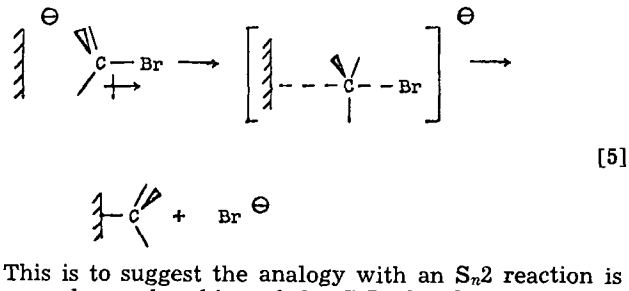
$$2Pb + 6RX + 6e^- \rightarrow Pb_2R_6 + 6X^- \qquad [4]$$

With i-PrBr less than 30% of the current is utilized in the formation of organolead products, and only traces of organoleads are found among the reduction products of t-BuBr. Respectively, isopropylene and isobutylene are also produced. The formation of metal fines is greatest for the reduction of i-PrBr.

Peak currents (bromide system).—The polarograms of the alkyl bromides are strongly influenced by the nature and concentration of the supporting electrolyte, as well as the concentration of RBr itself. MeBr and EtBr produced principal peaks whose heights were proportional to concentration up to 5-6 mM, after which low but increasing values were observed to 15 mM. A second, more cathodic peak, ¼ to ½ the height of the primary was evident for RBr concentrations > 3-4 mM. The total current was proportional to concentration in all cases. In TEAB especially, a decrease in the residual current occurred on addition of RBr, and a small capacity wave near −1.5V preceded their reductions.

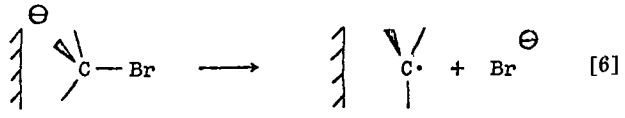
The relative, viscosity corrected currents (Table II) decrease with the increasing size (lower mobility) of RBr and with increasing supporting cation size. The latter may reflect cation adsorption leading to a decrease in the active electrode area (11).

Half-wave potentials (bromide system).—The ease of reduction as evidenced by the half-wave potentials of the principal peaks (Table II) decreases in the order Me>t-Bu>Et>i-Pr. Also listed are the pseudo first-order rate constants for the decomposition of the alkyl bromides in aqueous ethanol (12). The nearly linear relationship between $E_{P/2}$ and log (K_1) suggests a possible mechanistic similarity between the two reactions; *i.e.*, the factors which dominate in controlling the rate of RBr reduction at the lead electrode and the rate of RBr solvolysis may be the same. This result is accommodated by Elving's postulate (1) of a general nucleophilic substitution process in which the electrode, functioning as the nucleophile, performs a backside displacement on the halogen bearing carbon. The transfer step may be written as follows:



[5]

This is to suggest the analogy with an S_n2 reaction is a good one: breaking of the C-Br bond is concurrent with and to some extent compensated by the formation of the new C-M bond. An alternative would be bond rupture without new bond formation [6]:



[6]

Such a scheme would be expected when C-M bond formation is opposed by the nature of the metal, high R· stability, steric hindrance, or possibly precluded by the interposition of sorbed species. In such cases, a separate chemical step is required to produce the C-M bond, one perhaps analogous to Paneth's classic metal scavenging reaction (14).

Although several examples of cathodic dimerization are known (15) which establish the intermediacy of radicals (Eq. [6]), the efficiency of the electrosynthesis of Me_4Pb and Et_4Pb argues for direct formation of the Pb-C bond. Only at high current densities does dimerization become significant. We believe the principal polarographic wave for MeBr and EtBr is due to the reduction mode of Eq. [5], while the more energetic process of Eq. [6] could account for the smaller, more cathodic secondary wave (bond breaking only).

An increase from 5 to 10 mM in the MeBr or EtBr concentration results in an anodic E_p shift of 20-30 mV. This behavior is consistent with (*i*) deposition of the reduction product (29), *e.g.*, Eq. [5], or (*ii*) a rate determining step greater than 1st-order in depolarizer concentration (25) such as the metal removal step (*vide infra*).

The similarity of the reduction potentials of the alkyl bromides on lead and mercury invites further consideration in view of the *ca.* 0.35V difference in the zero-charge potentials (ψ_o) of these metals (16). For comparison, the reductions of the alkyl bromides at a stationary cast tin electrode were examined briefly. Only methyl bromide gives a distinct wave in 0.2 F TBAB. The product is Me_4Sn. The reduction data for MeBr on these three metals and estimates of the corresponding rational half-wave potentials ($E_{p/2} - \psi_o$) are included in Table III. The importance of rational potentials for comparing reductions on different metals has been stressed (17).

Both measures of the reaction potential point to metal participation in determining the over-all reaction rate. Some pertinent characteristics of these metals are also collected in Table III. The only obvious correlations are with the atomic numbers and the related average electron densities. As in a familiar chemical S_n2 reaction, the rate should be enhanced as the nucleophilicity of the electrode is improved, *i.e.*, as the availability of electrons is improved by increased density and/or polarizability. Accordingly we might expect the larger directed 6p orbitals on lead[1] to be much more available to participate in the transition state of Eq. [5] than would the 5p orbitals on tin and slightly more so than the smaller symmetric 6s orbitals on mercury.

[1] Strictly speaking one must consider the orbitals of the metal crystal and not atomic orbitals.

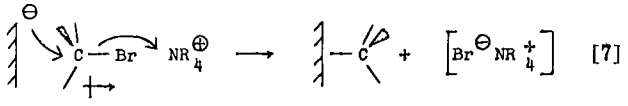
Sn (s)	−2.45	−1.93	50	3.5	46	7.30	31	4.09

[a] 0.2 F TBAB/MeCN at 25°C.
[b] ψ_o measured in the absence of specific adsorption.
[c] Metal-metal bond dissociation energy in kcal/mole.
[d] First atomic ionization potential in eV.
[e] Fermi energy in ergs $\times 10^{14}$.
[f] Work function from contact potential method in eV. Recent work has shown that this function cannot affect the electrode kinetics (28).

The negative shift in $E_{P/2}$ with increasing cation size is consistent with cation adsorption (18). Alternatively, extensive ion pairing in acetonitrile (19) could facilitate the transfer step as indicated below



[7]

The rate enhancement would be greatest for the smallest member of the cation series and be revealed as the largest positive shift. A very similar rationalization has been proposed to account for some observed salt effects in the reduction of quinones in DMF (20) and nitroaromatics in DMF and MeCN (19b).

Reduction products (iodide system).—Both MeI and EtI are reduced to the corresponding lead alkyls. Although the iodide reaction has not been explored in as great detail as in the case of the bromides, it is clear that very high current efficiencies are obtainable. It appears that more hexaethyl dilead is produced from ethyl iodide than from the bromide, and that the amount of this product depends on the supporting electrolyte.

Peak currents (iodide system).—The polarograms of RI in tetraalkylammonium iodide media were more sharply spiked than those of the analogous bromide system. MeI and EtI displayed the smaller more cathodic peak in the concentration range 8-10 mM. The polarograms of i-PrI and t-BuI were more complicated displaying a small prewave which was most prominent with the latter halide. These might be associated with alkyl iodide desorption (7) or the reduction of HI derived through elimination (21). In all cases the sums of the wave heights were proportional to concentration. Erratic results were obtained with TPAI.

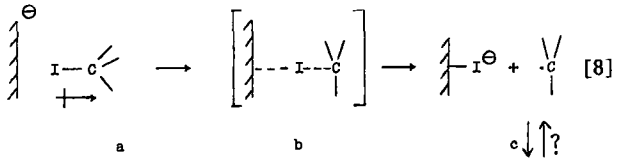
The relative over-all currents are shown in Table IV. The order with respect to alkyl group is the same as for the bromides. In the presence of the corresponding tetrabutylammonium halide (0.2 F) the ratios of the viscosity corrected currents, *i.e.*, $(i_p\eta^{1/2})_{RBr}/(i_p\eta^{1/2})_{RI}$, were 1.28 (Me), 1.31 (Et), 1.10 (i-Pr), and 1.02 (t-Bu). The bromides would be expected to have larger diffusion coefficients, differences being least for the largest alkyl group.

Reduction potentials (iodide system).—The pattern of RI reduction potentials contrasts significantly with that of the bromides. In TPAI and TBAI the half-wave potential of the principal wave becomes more negative as the alkyl size increases. In TEAI, the reductions are nearly reversible and virtually independent of R. Since the slopes differ widely within a series, a potential near the foot of the wave, *e.g.*, $E_{1/4}$, better reflects the relative ease of reduction. The indicated order is

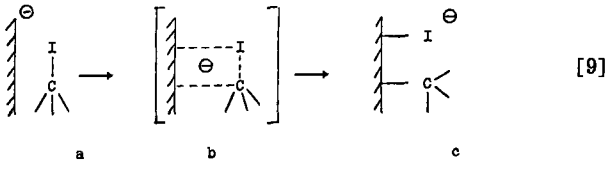
$$Et > Me \gtrsim i-Pr > t-Bu$$

The range of potentials is only 20-200 mV depending on the supporting electrolyte *vs. ca.* 550 mV for RBr.

The general positive shift and narrower spread in the RI potentials is consonant with C-I bond rupture during the potential determining step. The observed order, however, cannot be understood in terms of an S_n2 process analogous to that of Eq. [5]. A consideration of the polarization properties of C-I and C-Br bonds suggests a plausible basis for a difference in reduction mechanism. Although some discrepancies exist in the literature, it is likely that the C-I bond differs from the other carbon-halogen bonds in the direction of polarization. The recent Allred-Rochow (22) electronegativities which most strongly bear out this conclusion are considered the most reliable since the values are strictly empirical (23). Accordingly, under the influence of the electrode field, the RI orientation would favor a proximal location of the iodine atom; two reasonable orientations are shown in [8a] and [9a].



[8]



[9]

If iodine is presented directly to the surface, a displacement process, *e.g.*, Eq. [8], should be relatively insensitive to the bulk attached to carbon and the potential should be controlled essentially by the R-I bond strength. If C-M bond formation is concurrent with electron transfer, a compromised orientation such as [9a] may be required; a greater potential dependence on the alkyl identity follows. The transition state could resemble that for S_ni type displacements as has been suggested for the reduction of certain bridgehead bromides (24) or the 4-centered configuration, [9b].[2] The greater chemisorption of iodide at relatively negative potentials could also favor its proximal orientation. Molecular models show [9a] to be plausible for MeI and EtI. Additional α-alkyl substitution, however, forces the orientation in the direction of [8a].

The potentials for MeI and EtI in the various electrolytes parallel the expected shifts in the E.C.M. Just

[2] Note that the transfer [9a] → [9b] is very similar to the model proposed by Lambert (1f). The principal distinction is that the product [9b] is chemisorbed, *i.e.*, some carbon-metal bond formation occurs. In other words, the radical anion RX· exists not as a diffusible species but only as a component in the resonating transition state structure, so long as alkylation is strongly favored.

Table IV. Polarographic properties of alkyl iodides at a Pb electrode[a]

the opposite was observed for the bromide system; apparently another reflection of a change to a mechanism in which steric factors are less important. Compared to bromide, displacement of the larger iodide ion should not be much facilitated by ion-pairing, nor is there any evidence that it is.

Metal removal.—The very high current efficiencies with respect to organometallics formation noted for the methyl and ethyl halides suggests that the alkyl group resulting from the reduction is either unable to diffuse into solution and react in the manner of a simple free radical, or that alkylation is faster than diffusion. The first step in the metal removal sequence will be alkylation of the surface; for convenience the unit species may be written as $(Pb)_xPbR$. There is no evidence that the monomer Pb-R is formed. Such a species is known at the present time only among the mass spectral products of organoleads. The dialkyl metal, PbR_2 may be free to quit the electrode surface depending on the nature of R. Thus some organolead halide is formed when R = i-propyl or phenyl and the solutions are darkly colored. These observations correlate directly with known properties of isolable PbR_2 compounds (26).

With MeBr and EtBr alkylation probably proceeds at the interface at least until a trialkyllead species is formed. The trialkyllead radical is believed to have an appreciable lifetime in solution and has been implicated as an intermediate in numerous conversions of organolead compounds (26). Hexaethylbilead could result either from the trialkylation of adjacent lead atoms or the combination of two diffusing trialkyllead radicals. About 40% of the triethyl lead, however, is further ethylated before the above "hexa" reaction can occur. With MeBr tetralkylation is sufficiently favored to preclude "hexa" formation altogether.

To summarize the processes leading to metal removal, we write the following equations

$$(Pb)_xPb + RX + e^- \rightarrow (Pb)_xPbR + X^- \quad [10i]$$

$$(Pb)_xPbR + RX + e^- \rightarrow (Pb)_xPbR_2 + X^- \quad [10ii]$$

$$(Pb)_xPbR_2 + RX + e^- \rightarrow (Pb)_xPbR_3 + X^- \quad [10iii]$$

$$(Pb)_xPbR_3 + RX + e^- \rightarrow (Pb)_x + PbR_4 + X^- \quad [10iv]$$

$$2(Pb)_xPbR_3 \rightleftarrows 2(Pb)_x + 2 \cdot PbR_3 \quad [10v]$$

$$\downarrow\uparrow$$

$$2(Pb)_xPbR_3 \leftrightarrows 2(Pb)_x + Pb_2R_6 \quad [10vi]$$

When R = Me alkylation proceeds rapidly through [10iv]. For R = Et, however, reaction [10iv] is slowed appreciably by the increased steric requirements of this larger alkyl. At the same time, increased crowding at the trialkylated surface would facilitate expulsion of either $R_3Pb\cdot$ [10v] or Pb_2R_6 [10vi]. For larger R groups the degree of alkylation which the surface can sustain diminishes accordingly.

Preparation of Thick Crystalline Films of Tin Oxide and Porous Glass Partially Filled with Tin Oxide

R. F. Bartholomew and H. M. Garfinkel

Research and Development Laboratories, Corning Glass Works, Corning, New York

ABSTRACT

A method is described for producing films of SnO_2 on a 96% silica glass substrate by oxidation of stannous chloride. Surface x-ray patterns of such films showed the preferred orientation of the films depended on temperature and time of growth. The pores of porous glass were partially filled with SnO_2 by the same technique used for the growth of the films. The measured resistivities of the porous glass-tin oxide material are discussed in terms of a model of cylindrical noninterconnecting pores going from one side of the sample to the other.

In recent years considerable effort has been made in the area of producing metal oxide films. Tin oxide, in particular, has been studied in detail. Methods of preparing tin oxide films include hydrolyzing a volatile tin compound on a hot surface (1, 2) and reactive sputtering (3-5). Films of this oxide exhibit a small temperature coefficient of resistance and are chemically stable, making them ideal resistor materials. New methods for the growth of such oxides, in films and other forms, are of interest, therefore, for possible applications in the electronics field.

This paper will describe a new method for growing films of SnO_2 and for partially filling porous glass with SnO_2. The characterization of the products was carried out by x-ray diffraction methods. Some of the electrical properties of the materials obtained are reported.

Experimental

Materials.—Anhydrous $SnCl_2$ (Technical Grade) was supplied by Fisher Scientific. No attempt was made to purify this material.

Corning Code 7900 96% silica glass was used as a substrate for growth of the films. The porous glass was Corning Code 7930 with a nominal pore diameter of 60Å.

Procedure for preparing films of SnO_2.—The anhydrous $SnCl_2$ (mp 246°C) was fused in a 100-ml VYCOR® brand glass crucible contained in a 500-ml VYCOR® brand glass beaker placed in a furnace. The initial experiments were carried out open to the atmosphere, except for flushing continuously with predried argon. The tin chloride is oxidized to SnO_2 by reaction with oxygen in the air. This is discussed further in the Results and Discussion section. To verify the required conditions for growth, a completely closed system was used in later experiments in which a Corning Code 7900 96% silica glass tube was used instead of the beaker. The tube was sealed at one end and had a silicone oil trap at the other end. Dry argon was flushed continuously through the system. Plates of the 96% silica glass (approximately 5 x 1.8 x 0.65 cm) were placed in the melt, such that part of the glass was in the melt and part in the vapor above the melt. Treatment temperatures varied from 400° to 525°C, with times ranging from 1 to 72 hr.

Impregnation of the porous glass.—Samples of porous glass of dimensions 5 x 1.8 x 0.5 cm (approximately) were cut from sheets of the material. These plates were pretreated by evacuating at temperature (>400°C) in order to remove moisture; in some cases the plates were reacted further with O_2, then reevacuated in order to remove organic materials absorbed in the glass. The pores were filled either by direct immersion in a melt, or by suspension in the vapor above the melt. A closed system was used throughout the filling of the glass by the halide. The resulting material was then transferred to a closed container in a furnace and treated by heating in an oxygen atmosphere to convert the halide to the oxide. For treatment times and temperatures see Table IV.

After converting the tin chloride to the oxide, the samples were ground and polished. The initial polishing was done with diamond paste; the final polishing was performed by using 0.05μ Al_2O_3 paste, until no scratch marks could be detected with a low power magnifying glass. The sample was then washed in water several times to remove the polishing paste. Some of the samples cracked during the oxidation reactions. However, if the pretreatment was carried out at about 500°C, this did not occur.

Electrical measurements.—The d-c electrical resistance of the tin oxide films was measured at room temperature with a Model 260 Simpson meter. Point

Table I. Summary of experimental data on the growth of SnO_2 film from stannous chloride

Sample	Substrate	Temp, °C	Atmosphere	Time of treatment, hr	Comments
1	Code 7900 Plate	525	Argon, system open to air	1	Black coating, SnO_2
2	Code 7900 Plate	525	Argon, system open to air	4	Black coating, of SnO_2. Thick at melt-atmosphere interface becoming thinner as distance from interface decreases
3	Code 7900 Plate	400	Argon, system open to air	16	Thin black coating, SnO_2
4	Code 7900 beaker	Used in previous three runs	Argon, system open to atmosphere	48	Thick black coating, SnO_2
5	Code 7900 crucible	Used in previous three runs		48	Black coating above level of melt
6	Code 7900 Plate	525	Completely sealed system, Argon blanket	72	No SnO_2
7	Alumina plate	525	Completely sealed system, Argon blanket	72	No SnO_2

contact probes were used to connect the sample to the meter. The resistivity of the films quoted in this paper are only meant to be estimates.

Silver electrodes with a guard ring were applied to ground and polished plates of the porous glass-tin oxide material as du Pont Silver Preparation 4817-Electrical Grade and air dried. A Model 311 Simpson VTVM was used to measure resistance. Contact to the meter was made through heavy stainless steel gold plated electrodes placed on the silver electrodes. Dielectric properties of the porous glass-tin oxide material were investigated with a General Radio capacitance bridge.

X-ray measurements.—A General Electric XRD-5 diffractometer was used. The radiation was nickel-filtered Cu K_α.

Results and Discussion

Films of tin oxide.—Table I summarizes the effect of temperature and time on the growth of SnO_2 films on the 96% silica glass substrate. After a 1-hr treatment at 525°C, a black coating of SnO_2 was observed on the glass. The black color of the films indicates an oxygen deficient material. Longer treatment times led to a thicker coating; the thickness of this coating became less the further the distance from the melt-air interface. After this series of runs, the crucible containing the melt and the VYCOR® brand glass beaker holding the crucible were covered with a black coating. The thickness of these coatings was never determined precisely, but was of the order of 1 mm at the most.

A spectrographic technique was used to examine the coating on the beaker for impurities. These data are given in Table II. Silica, the major impurity, in all probability results from a reaction between the oxide and glass at their mutual interface. Bond formation of the type -Si-O-Sn- has been postulated by Kuznetsov to occur at SnO_2-silica surfaces (1). The spectrographic analysis of the melt is given in Table II for comparison.

The experiment in which a closed system was used showed that after 72 hr 96% silica glass plates as well as alumina plates gave no evidence of film formation. This result rules out the possibility of a reaction taking place at the halide-glass interface.

Surface x-ray diffraction patterns were determined on some of the samples listed in Table I. The pattern given by sample 4 is shown in Fig. 1. As indicated in Table III, the side of the film that was in contact with the vapor phase has a slightly different x-ray diffraction pattern from that side in contact with the glass.

Table II. Spectrographic analysis of SnO_2 film and quenched sample of $SnCl_2$ melt

Melt	Film	% Range
SnO_2	SnO_2	>10
	SiO_2	0.05-0.5
	Al_2O_3	0.01-0.1
Fe_2O_3, CaO	CdO	0.005-0.05
SiO_2, NiO	B_2O_3, MgO, Fe_2O_3, PbO	0.001-0.01
PbO, Al_2O_3	TiO_2	0.0005-0.005
MgO, MnO_2, CuO	CuO	0.0001-0.001

Table III. Preferred orientation of SnO_2 film on 96% silica glass substrate as determined by surface x-ray (nickel-filtered Cu K_α radiation)

Sample No. (Table I)	Temp, °C	Time, hr	Preferred orientation
2	525	4	Random (211)
3	400	18	002 (101)
4	525	48	Film-vapor interface: 301* Glass-film interface: 301 (211)

Values in parenthesis indicate minor orientation.
* See Fig. 1.

Presumably, the film was grown initially by nucleation on the glass surface followed by growth on the oxide film. However, it appears that temperature as well as time has an effect on the orientation of the SnO_2 film. By going to a lower temperature, the film is no longer oriented in the 301 plane, but rather in the 002 plane with some growth along the 101 plane. With Corning Code 7740 borosilicate glass substrates, the deposited film was determined by x-ray techniques to be polycrystalline. There was no x-ray evidence to indicate the presence of metallic tin within the limits of detection of this technique. Previous work in these laboratories has shown that it is not possible to predict beforehand the orientation of a film of SnO_2 (6).

The room-temperature value for the surface resistivity of the film was of the order of 1 ohm/square. Several identical heat treatments on the same samples gave similar results. In some instances the measurements were made on films bonded to the glass substrate. With some samples, the film remained strongly

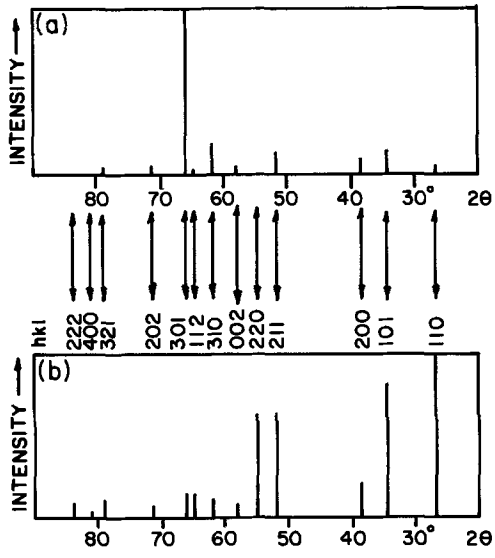

Fig. 1. Comparative x-ray scattering of oriented and nonoriented tin oxide (nickel-filtered Cu K_α radiation). (a) Surface x-ray of film; (b) powder x-ray of polycrystalline material.

Table IV. Summary of experimental data on the methods used for filling porous glass with SnO_2

Sample No.	Pretreatment	Method of filling with $SnCl_2$	Treatment in O_2 Temp, °C	Time, hr	Comments
8	Filled with water	Vapor	540	48	Black coating on outside, gray inside
9	Evacuated at 500°C, then cooled in O_2	Vapor	540	48	Black coating outside, white center
10	Evacuated at 200°C for 3 days	Vapor	540	4	2 hr in O_2 at 550°C. Sample black clear through
11	Evacuated at 200°C for 3 days	Vapor	540	4	550°C in O_2 for 3 days. Sample brown throughout
12	Evacuated at 500°C for 3 days, then exposed to O_2 at 500°C, and evacuated	Vapor	525	24	16 hr at 500°C in oxygen. Black outside, white inside
13	Evacuated at 500°C for 2 days, oxygen at 500°C for 1 day. Evacuated	Dipped in melt	500	16	24 hr in oxygen. Black clear through
14	Evacuated 125°C for 2 days	Melt (+4 wt % $SbCl_3$)	390	16	24 hr at 500°C in oxygen. Only surface was black
15	Same as 13	Same as 14	390	16	24 hr at 500°C in oxygen. Gray outside and black inside

bonded to the glass surface, while spalling resulted after two or more cycles with other samples.

Tin oxide in porous glass.—The results of different schedules for the growth of SnO_2 in porous glass are given in Table IV. It appears from these data that the optimum treatment requires evacuation of the porous glass sample at 200°-500°C for several days, followed by treatment in an oxygen atmosphere to remove any absorbed organic compounds. The sample is treated in the melt at 500°C for nearly a day. The resulting sample is oxidized then in an oxygen atmosphere at 500°-550°C for a day. Sample 3 had the shortest treatment schedule that resulted in a sample of uniform black color. Powder x-ray diffraction patterns indicated the presence of SnO_2 in all samples. No attempt was made to determine accurately the percentage of free volume in the pores occupied by the SnO_2 as a function of experimental conditions. However, one weight change measurement showed that the SnO_2 occupied approximately 20% of the pore volume.

The fact that SnO_2 was produced in porous glass by reaction between $SnCl_2$ and oxygen to the exclusion of everything else, means that the over-all reaction can be written as

$$SnCl_2 + O_2 \rightarrow SnO_2 + Cl_2 \qquad [1]$$

This reaction would also explain the formation of the films on the 96% silica glass substrate.

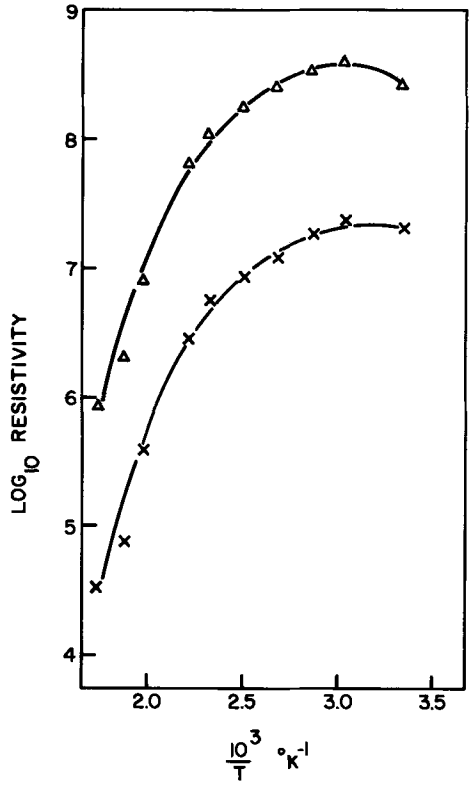

Fig. 2. Resistivity of porous glass partially filled with tin oxide. x, Volume resistivity (ohm-cm); Δ, surface resistivity (ohm/square).

Thermodynamic calculations were carried out to determine the feasibility of reaction [1] occurring at 700°K. The value of ΔG_{700} for $SnCl_2$ was obtained from emf data (7), while data for the other compounds involved in the reactions were obtained from thermodynamic tabulations (8). The free-energy change for reaction [1] was calculated to be −88 kcal mole^{-1}. This calculation predicts that the reaction lies far to the right-hand side, as the case was found to be experimentally.

The electrical resistivity is given in Fig. 2 for sample 13 (Table IV) as a function of temperature. X-ray diffraction patterns of this sample showed only SnO_2 present. There was no evidence for unreacted $SnCl_2$. The surface and volume resistivities were obtained by measuring the surface and volume resistances from 25° to 200°C, then cooling to 25°C and measuring the resistances again to 200°C. The surface and volume resistances shifted to slightly higher values with reheating; the results shown in Fig. 2 were obtained after one heating cycle. Unfortunately, these data are not reproducible from sample to sample, but the same dependence on temperature was evident with different samples. Moreover, several things should be noted. First, "volume" represented the total volume of the sample, not just the pores filled with oxide. Second, the surface and volume resistivities roughly parallel each other, with the value for the former being approximately an order of magnitude higher than the latter. Finally, the temperature coefficients of the surface and volume resistivities of the sample are approximately zero from around room temperature to 100°C, then increase with increasing temperature above 125°C. A value of approximately 1 eV was obtained for the temperature coefficient as the plots in Fig. 2 approached linearity at temperatures above 150°C for the d-c-resistivity data. Attempts were made to increase the electrical conductivity by doping the melt with $SbCl_3$ (Table IV, samples 14, 15). The volume resistivity of sample 15, ground and polished to remove the gray coating, was about 1.5 x 10^7 ohm-cm at 25°C. This is about the same as that given in Fig. 2 for sample 13 with no antimony (III) chloride. No attempt was made to determine whether any antimony had actually been incorporated in the tin oxide.

The values of the specific resistivity obtained for the SnO_2-porous glass sample are surprisingly high. Calculations based on a model of cylindrical noninterconnecting pores going from one side of the sample to the other suggest that the specific resistivity should be approximately 10^{-3} ohm-cm. This value was determined using a radius of 30Å for each pore, and 10^{12} pores per unit cross sectional area. Several explanations for this high resistivity can be given. First, the pores are incompletely filled and not interconnecting from one side to the other. Second, using the bulk resistivity of SnO_2 may be incorrect when considering bundles of SnO_2 of radius 30Å. Electrical conductivity measurements on SnO_2 films as a function of thickness showed that above several hundred angstroms thickness the specific resistivity was independent of thickness. However, below this thickness the specific resistivity increased as the film thickness decreased (1).

Unfortunately, it is not possible to use the data to extrapolate back to the thickness of "films" present in porous glass. Another factor which might influence the reproducibility of data is the problem of contact resistance between the porous glass and the measuring device.

The dielectric constant of sample 13 was found to be 15.1 at room temperature and 21.7 at 75°C. Above this temperature the dielectric constant increased rapidly to a value of 132 at 176°C. A plot of log of the loss tangent against room temperature was linear between room temperature and 176°C. The room-temperature value of the loss tangent was 0.38, rising to 1.5 at 176°C.

Acknowledgments

The authors wish to thank S. S. Lewek for preparation of the samples, Dr. H. J. Holland for the x-ray data, Mrs. M. T. Mizzoni and Dr. M. P. Teter for the electrical measurements, and Dr. J. A. Murphy and Dr. M. E. Nordberg for helpful discussions.

Manuscript submitted Feb. 6, 1969; revised manuscript received May 20, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Adsorption of Cadmium(II) and Zinc(II) on Mercury Induced by Azide Anions

Zygmunt Kowalski[1] and Fred C. Anson*

Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, California

ABSTRACT

The adsorption of cadmium(II) and zinc(II) on mercury electrodes from solutions containing azide ion has been measured. The effects of electrode potential, electrode charge, and azide concentration were determined. The data support the conclusion that the neutral complexes, $Cd(N_3)_2$ and $Zn(N_3)_2$, are the species that are preferentially adsorbed.

The ability of anions which are specifically adsorbed on mercury electrodes to induce the adsorption of white metal cations which can form complexes with the anion has been studied recently in some detail (1-3). The data for the induced adsorption of cadmium(II) in iodide, bromide, and thiosulfate solutions have led to the conclusion that the primary adsorbing species is the neutral complex, *i.e.*, CdI_2 or CdS_2O_3, which becomes attached to the electrode by means of the specifically adsorbed anions (2, 3). It has been suggested that this adsorption scheme is general and will account for the anion induced adsorption of many of the white metallic cations such as lead(II), zinc(II), cadmium (II), and indium(III). In this paper we report studies in which the azide anion is examined as an adsorption inducer. Azide, like thiocyanate but in contrast with the halides, forms strong complexes with zinc(II) as well as cadmium(II) so that a comparison could be made of the relative effectiveness of azide to induce the adsorption of both metals.

Experimental

The experimental technique employed was double potential-step chronocoulometry. The procedure and apparatus were identical to that used in previous studies (2, 3) and made use of the computer-based data acquisition and analysis system which has been described in detail (4).

Sodium azide solutions were prepared freshly each day from twice recrystallized salt. The zinc, cadmium, and sodium nitrate employed were reagent grade salts. Solutions were prepared from triply distilled water and were deoxygenated with prepurified nitrogen. The ionic strength of all solutions was maintained at 1.0 with sodium nitrate. The temperature was 25° ± 2°C. All potentials are referred to the saturated calomel electrode.

Results

Adsorption of cadmium (II).—The dependence of cadmium(II) adsorption on potential, azide concentration, and Cd(II) concentration was measured. The reproducibility of the individual values of $2F\Gamma_{Cd}$ was about ± 0.5 $\mu C/cm^2$. Figures 1, 2, and 3 summarize the data. Because the charge on the electrode or, better, the amount of adsorbed anion appear to be more characteristic independent parameters for anion induced adsorption (2) the values of $2F\Gamma_{Cd}$ were also plotted against q_m and $\Gamma_{N_3^-}$, Fig. 4 and 5. In the chronocoulometric experiments the electrode potential was stepped from the initial potential, E_i, to —1.0V in every case. The charge on the electrode at —1.0V was assumed equal to the value given by Russell (5) for 1M NaF because the data of Parsons (6) shows that N_3^- adsorption at —1.0V is negligibly small. The values of q_m at the initial potentials, E_i, needed to prepare Fig. 4, were obtained in the presence of adsorbed cadmium by subtraction of the charge at —1.0V (—10 $\mu C/cm^2$) from $\Delta Q_{d.l.}$ (the difference in q_m between E_i and —1.0V), a parameter that results from the analysis of the double potential step charge time data (1, 7).

The values of $\Gamma_{N_3^-}$ needed for Fig. 5 were taken directly from the data of Parsons (6) or by linear extrapolation of plots of $\Gamma_{N_3^-}$ *vs.* q_m to values of q_m outside the range covered by Parsons' data.

Adsorption of zinc.—Data for zinc adsorption were obtained by the same procedure that was employed

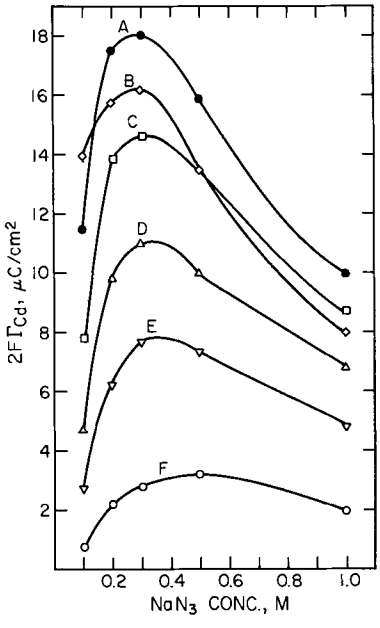

Fig. 2. Dependence of Cd(II) adsorption on the concentration of azide. All solutions were 0.5 mM in $Cd(NO_3)_2$. A, E_i = —100 mV; B, E_i = —50 mV; C, E_i = —150 mV; D, E_i = —200 mV; E, E_i = —250 mV; F, E_i = —350 mV.

with cadmium except that the potential was stepped to —1.4V to attain diffusion limited zinc reduction. The value of q_m at —1.4V was taken to be —17.8 μC/cm² (5). The data are summarized in Fig. 6-9. In contrast with solutions of cadmium(II), the pH of the zinc azide solutions appeared to be a critical parameter. Unless the pH was carefully controlled to lie between *ca.* pH 7-8 anomalous results were often obtained in the form of larger and irreproducible slopes in the chronocoulometric charge—(time)½ plots and erratic values of 2 $F\Gamma$. This difficulty is apparently associated with hydrazoic acid catalyzed hydrogen evolution at —1.4 V if the initial pH is too low or incipient formation of zinc hydroxide if the pH is too high.

Discussion

The general features of the azide induced adsorption of both cadmium(II) and zinc(II) are similar to those for halide induced adsorption of cadmium(II) (2). It seems reasonable therefore to interpret the adsorption

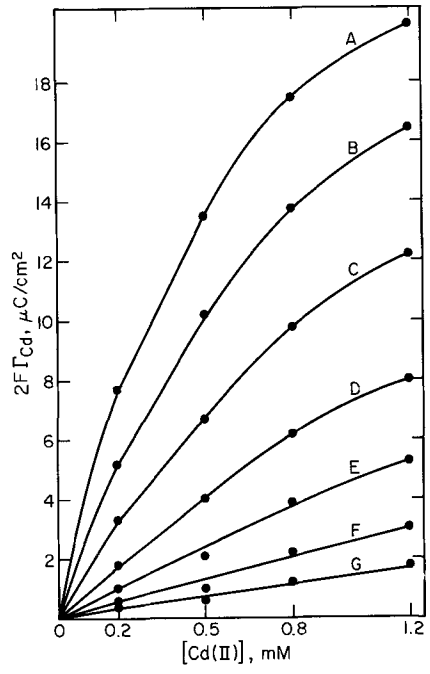

Fig. 3. Dependence of Cd(II) adsorption on the concentration of Cd(II). Electrolyte was 0.2M NaN_3-0.8M $NaNO_3$. A, E_i = —100 mV; B, E_i = —150 mV; C, E_i = —200 mV; D, E_i = —250 mV; E, E_i = —300 mV; F, E_i = —350 mV; G, E_i = —400 mV.

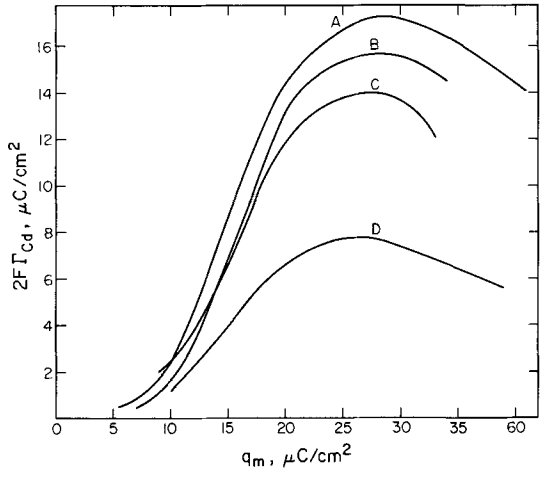

Fig. 4. Adsorption of Cd(II) plotted *vs.* the charge on the electrode. All solutions were 0.5 mM in $Cd(NO_3)_2$. A, 0.2M NaN_3-0.8M $NaNO_3$; B, 0.1M NaN_3-0.9M $NaNO_3$; C, 0.5M NaN_3-0.5M $NaNO_3$; D, 1.0M NaN_3.

patterns with the same kind of rationale as was previously employed (2): (*i*) The adsorbed species is the neutral, bisazido complex. Evidence in support of this is the correspondence of the maximum cadmium(II) adsorption with the solution composition corresponding to the maximum concentration of $Cd(N_3)_2$ when 2 $F\Gamma_{Cd}$ is evaluated at constant values of $\Gamma_{N_3^-}$, Fig. 10. The reason for preferring to construct figures such as Fig. 10 at constant values of specifically adsorbed anions has been given. It represents an attempt to hold constant one factor involved in the adsorption while systematically varying the other. Comparison of Fig. 10 with Fig. 2 shows that if 2 $F\Gamma_{Cd}$ is not evaluated at a constant value of $\Gamma_{N_3^-}$ the maximum in the adsorption occurs at a somewhat higher concentration of azide than corresponds to the maximum concentration of $Cd(N_3)_2$. (Insufficient complex formation constants are available for the zinc-azide system to permit a similar comparison.) (*ii*) The charge on the electrode changes very little when Cd(II) or Zn(II) are adsorbed, Table I.

Points (*i*) and (*ii*) taken together imply that only very small changes in the potential at the outer Helmholtz plane, ϕ_2, should result from the adsorption of

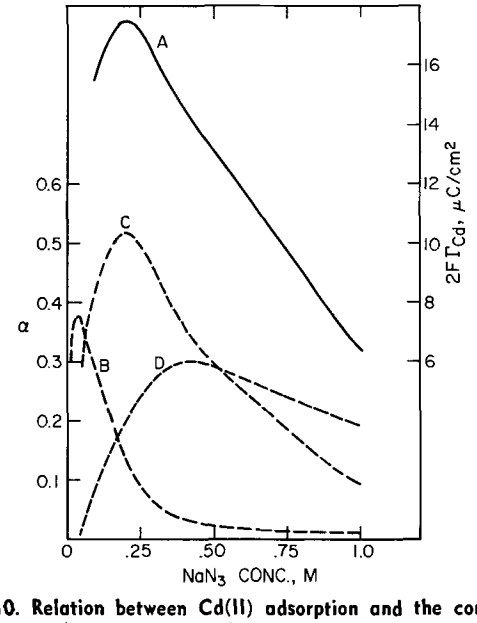

Fig. 10. Relation between Cd(II) adsorption and the concentrations of CdN_3^+, $Cd(N_3)_2$, and $Cd(N_3)_3^-$. A, 2 $F\Gamma_{Cd}$ evaluated at $F\Gamma_{N3-}$ = —40 $\mu C/cm^2$, which corresponds to near the maximum adsorption of Cd(II) at all azide concentrations; B, $\alpha_1 \equiv [CdN_3^+]/[Cd(II)]$; C, $\alpha_2 \equiv [Cd(N_3)_2]/[Cd(II)]$; D, $\alpha_3 \equiv [Cd(N_3)_3^-]/[Cd(II)]$. The α-values were calculated from the complex formation constants given in ref. (8).

Table I. Changes in q_m resulting from adsorption of Cd(II) and Zn(II) in 0.2M NaN_3-0.8M $NaNO_3$. Cd(II) or Zn(II) = 0.5 mM

$-E_i$, mV	50	100	200	300	400
$2F\Gamma_{Cd}$ $\mu C/cm^2$	15.9	13.5	6.7	2.1	0.6
Δq_m(Cd) $\mu C/cm^2$	2	1	0.5	0.5	−0.3
$2F\Gamma_{Zn}$ $\mu C/cm^2$	4.9	4.9	4.5	3.6	2.5
Δq_m(Zn) $\mu C/cm^2$	0	0	0.2	0	0.2

Cd(II) or Zn(II), because the adsorbing species is neutral and the electronic charge on the electrode is little affected by its adsorption. Hence, the rate of a suitable irreversible electrode reaction should remain relatively unchanged when Cd(II) or Zn(II) is added to an azide supporting electrolyte. [This line of reasoning has been expounded in detail in a previous study (2).] The reduction of $Co(NH_3)_6^{+3}$ in 0.2M NaN_3 at *p*H 6 proved to be a suitable irreversible reaction. At −0.05V, the rate of this reaction was increased by factors of 1.5 and 2.3 on addition of 1.2 mM/l of Zn(II) and Cd(II), respectively. Under these conditions, $2F\Gamma_{Zn}$ is 7.9 $\mu C/cm^2$ and $2F\Gamma_{Cd}$ is 24 $\mu C/cm^2$ and both of these adsorptions change q_m by less than 1 $\mu C/cm^2$. If the adsorbing species bore a positive charge the reduction of $Co(NH_3)_6^{+3}$ should have decreased sharply. If a singly charged anion were the adsorbing species, the rate of reduction of $Co(NH_3)_6^{+3}$ can be calculated[2] to increase by a factor of 3.2 in the case of Zn(II) and 74 in the case of Cd(II) adsorption. The observed rate enhancements are smaller than the calculated values which supports the contention that the adsorbing species is uncharged. The small rate enhancements that are observed could arise in a number of ways [partial anionic complex adsorption, changes in the electric field in the compact layer resulting from the adsorption, specific chemical interactions between $Co(NH_3)_6^{+3}$ and the adsorbing complexes which lead to catalysis of the reduction, etc.] which were not further examined.

(*iii*) The adsorbed metal-azide complex is bound to the electrode by means of one or two additional, specifically adsorbed azide anions. Evidence for this assertion is the shape of the plots of the amount of adsorbed metal *vs.* potential, electrode charge, and specifically adsorbed azide (Fig. 1, 4, 5, 6, 8, and 9). At every azide concentration, the metal adsorption increases in parallel with increasing azide anion adsorption as the electrode is made more positive. This reflects strong participation of adsorbed azide in the metal adsorption. The decrease in adsorption at the highest azide coverages may reflect a steric limitation that arises when the adsorbed azide anions are packed too closely to accommodate their bonding to the adsorbing metal azide complex. Thus, when the coverage of the electrode with adsorbed azide ions is very large, the distance between adjacent azide ions can become smaller than their equilibrium distance of separation in the metal-azide complex. Similar behavior is observed with the cadmium(II)-halide systems (2). In the case of Cd(II) in azide, the decrease in adsorption at the most positive charges comes quite close to the anodic limit of accessible potentials and may arise, in part, from the incipient oxidation of the electrode to form a precipitate of mercurous azide on the electrode surface.

The fact that the Cd(II) adsorption increases rapidly only after the adsorbed azide exceeds *ca.* 10 $\mu C/cm^2$ suggests that more than one adsorbed azide ion participates in the attachment of each $Cd(N_3)_2$ complex to the electrode. On the other hand, the slope of the rising portion of the Γ_{Cd} *vs.* $\Gamma_{N_3^-}$ plots varies from 0.35 mole Cd(II)/mole N_3^- with 0.2 mM Cd(II) up to 0.82 mole Cd(II)/mole N_3^- with 1.2 mM Cd(II), so that at high Cd(II) concentrations a single additional adsorbed azide anion may be sufficient to induce the adsorption of a $Cd(N_3)_2$ molecule.

The importance of specifically adsorbed azide in inducing the adsorption of Zn(II) can be demonstrated in another way: zinc(II), unlike cadmium(II), forms only very weak complexes with iodide ion and is not adsorbed to a measurable extent in sodium iodide supporting electrolytes. Iodide anion is adsorbed more strongly on mercury than azide so that addition of iodide to an azide solution would be expected to lead to a gradual replacement of the specifically adsorbed azide ions by iodide ions as the iodide concentration is increased. Figure 11 shows how the adsorption of Zn(II) is diminished as the iodide concentration is increased in a 0.5M NaN_3 – 0.5M $NaNO_3$ solution. The added iodide should have no effect on the zinc-azide complex species present in the bulk of the solution because there is so little tendency for Zn(II) to form iodide complexes (10). The lowering of Γ_{Zn} by iodide addition must therefore result from the competitive desorption of the N_3^- anions from which it follows that adsorbed anions which also form complexes with Zn(II) are essential for the induced adsorption to occur.

The adsorption of zinc(II) is not as great as that of cadmium(II) and it increases much less rapidly as more azide anions are adsorbed on the electrode (Fig. 9). Both of these features reflect the fact that zinc(II) forms weaker complexes with azide than does cadmium(II). The lower dependence of Γ_{Zn} on the amount of adsorbed azide results, under some conditions, in a crossing of the Γ_{Cd} and Γ_{Zn} *vs.* $\Gamma_{N_3^-}$ curves at low values of $\Gamma_{N_3^-}$ so that the adsorption of Zn(II) exceeds the Cd(II) adsorption. Thus, with 0.5 mM Cd(II) or Zn(II) in 0.3M azide at −450 mv, $2F\Gamma_{Cd} = 0.6$ $\mu C/cm^2$ while $2F\Gamma_{Zn} = 2.9$ $\mu C/cm^2$.

A puzzling feature of the data is the fact that the maxima in the plots of Γ_{Cd} *vs.* $\Gamma_{N_3^-}$ occur at higher values of $\Gamma_{N_3^-}$ for Cd(II) than for Zn(II) (Fig. 5, 9). On the basis of crystal radii, $Cd(N_3)_2$ is expected to be slightly more voluminous than $Zn(N_3)_2$ so that one might have expected the maxima for Zn(II) to come at even higher values of $\Gamma_{N_3^-}$ than that for Cd(II). A possible explanation for the observed behavior is the fact that zinc-halide complexes tend to retain coordinated water more strongly than the corresponding cadmium complexes (11). If the adsorbing zinc species carried one or two water molecules with it, the steric interactions of the adsorbed zinc-azide complexes with each other and with adsorbed azide anions could become large enough to result in a decrease in Γ_{Zn} at smaller values of $\Gamma_{N_3^-}$ for Zn(II) than for Cd(II).

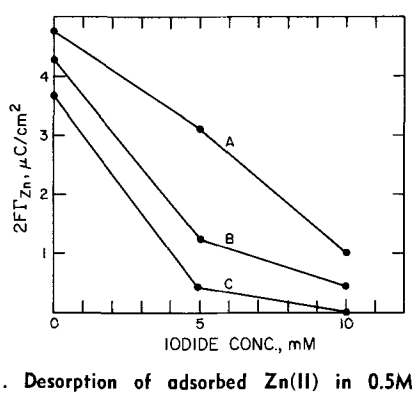

Fig. 11. Desorption of adsorbed Zn(II) in 0.5M NaN_3-0.5M $NaNO_3$ electrolyte by addition of sodium iodide. A, $E_i = -200$ mV; B, $E_i = -300$ mV; C, $E_i = -350$ mV.

[2] The relative rate (with and without added metal ion) is equal to $\exp\left[\frac{\Delta\phi_2 F}{RT}(\alpha n - Z)\right]$, where $\Delta\phi_2$ is the change in the potential at the outer Helmholtz plane produced by the addition of Zn(II) or Cd(II), $\alpha n = 0.5$, and Z is the average charge of the reactant in the bulk of the solution. Ion-pairing occurs between N_3^- and $Co(NH_3)_6^{+3}$ (9) to the extent that $Z = 2.2$ in 0.2M NaN_3. The expression for the relative rate therefore reduces to: $10^{-1.7(\Delta\phi_2/59.6)}$, where $\Delta\phi_2$ is in millivolts.

Conclusions

This study permits azide ion to be added to the list of specifically adsorbed anions that induce the adsorption on mercury of white metal cations with which they form complexes. The consistency in behavior from system to system suggests that the same chemical factors are involved in all the systems studied. Recent faradaic impedance measurements with Pb(II) in chloride solutions by Timmer *et al.* (12) lead them to conclude that chloride-induced adsorption of Pb(II) occurs. The precision of the adsorption data available from these experiments is not as high as that obtained from chronocoulometric measurements but Timmer *et al.* found that their data could be interpreted best if the uncharged complex, $PbCl_2$, were the adsorbed species. Unpublished data obtained in this laboratory (13) support the same conclusion in the case of thiocyanate induced adsorption of Pb(II). It was suggested earlier (2) that an explanation for the preferential adsorption of the uncharged complexes in every case is the importance of solvation energy and entropy in determining the resistance toward adsorption of individual species. This explanation continues to be attractive. For example, the entropy of reaction in aqueous solution for the reaction $MCl_2 + Cl^- \rightarrow MCl_3^-$ is over 30 eu greater for M = Zn(II) than for M = Cd(II) (10). This presumably reflects a considerably stronger hydration of $ZnCl_2$ than of $CdCl_2$ and the same trend would be expected with the azide complexes. A recent report that the uncharged complex, $PbBr_2$, appears to be preferentially adsorbed from molten nitrate electrolytes (14) suggests that similar factors may also be important in molten salt solvents.

Oxygen Dissolution and Evolution on Platinum in 85% Orthophosphoric Acid at Elevated Temperatures

A. J. Appleby* and Alina Borucka*

Institute of Gas Technology, Chicago, Illinois

ABSTRACT

Kinetics and mechanisms of oxygen electrode reactions on bright platinum have been studied in 85% orthophosphoric acid at elevated temperatures. Oxidized, oxide-free, and active platinum surfaces are kinetically different. Results obtained on oxidized and oxide-free platinum show that two different reaction mechanisms are followed. We consider that these mechanisms are common to all stable acid electrolytes in which platinum and its oxides remain unattacked, irrespective of concentration and temperature. For the oxidized surface we suggest that the mechanism may be more complex than has hitherto been supposed, although the predominant rate-determining step is water discharge. For oxide-free and active platinum the rate-determining step is the primary charge transfer involving activated oxygen adsorption, which takes place under Temkin and Langmuir conditions, respectively. The nature of the three platinum surfaces is discussed and explanations for their kinetic, adsorption, and mechanistic differences are offered. Fuel cell implications are also briefly discussed.

The kinetics and mechanism of the oxygen electrode reaction on platinum have been extensively studied in dilute acid electrolytes at room temperature (1-5) and have been recently reviewed by Hoare (6).

However, in concentrated orthophosphoric acid the studies published so far deal only with diffusion-controlled phenomena (7, 8) and rest potentials (9). This acid is of special importance as a fuel cell electrolyte. It has a particularly wide range of thermal stability and is neither reduced nor oxidized at the potentials of fuel cell electrodes. On the other hand, it is sufficiently different in physical and chemical character from the dilute strong acids previously studied (2-4)

* Electrochemical Society Active Member.

to discourage any *a priori* conclusions concerning its effect on the oxygen electrode mechanism or kinetics.

The present paper is intended as a general summary of the kinetic and mechanistic features of the oxygen electrode in 85% orthophosphoric acid, with some emphasis on aspects which are of interest in fuel cell development. The conclusions presented concerning oxygen reaction mechanisms and kinetics are based on results covering the temperature range 25°-136°C, but the typical kinetic data presented here are predominantly those obtained at 95.9°C.

Experimental

The apparatus for this work was constructed so that only fused silica was in direct contact with the electrolyte. To eliminate oxidizable impurities, the 85% orthophosphoric acid was refluxed with 20% of its volume of 30% hydrogen peroxide for 40 min before use. The remaining water was then distilled out until the acid returned to its original concentration with no detectable hydrogen peroxide content. Specially purified oxygen and nitrogen were mixed accurately using capillary flowmeters and a mixing chamber.

Platinum foil or disk electrodes of 99.999% purity were washed with HCl, conductivity water, and the electrolyte itself before use. The rotating disk-ring electrode used in this work will be described elsewhere. Steady-state measurements were obtained galvanostatically, although for the disk-ring electrode a potentiostat was used. Potential-scan techniques were used in the study of platinum oxidation kinetics. All potentials were measured directly against the hydrogen reference electrode (HRE) in the same solution at the working temperature. Cathodic currents are treated as negative.

Oxidized, oxide-free, and "active" platinum surfaces. —It is now well established that the kinetics and mechanism of the oxygen electrode on platinum differ according to the nature of the metal surface, which depends on electrode pretreatment (3). For this reason, the present study was conducted on three types of carefully prepared electrode surfaces:

1. A fully oxidized surface, covered by a separate oxide phase produced by anodizing at high potential
2. An oxide-free surface, considered to have oxygen atoms or —OH radicals adsorbed is less than monolayer quantity (3, 10). This surface is produced by reduction of an oxidized surface at about +300 mV HRE for 10-12 hr or, alternatively, it is a surface which has had no history of oxidation.
3. A surface in an "active" state, consisting of a partially reduced oxide film, considered by Schuldiner and Warner (11) to contain oxygen atoms absorbed in the first few layers of the lattice and by Feldberg *et al.* (12) as an oxide layer half-reduced to PtOH.

As illustrated by the results of Fig. 1, the three surfaces studied display very different kinetics; for this reason, they are discussed separately.

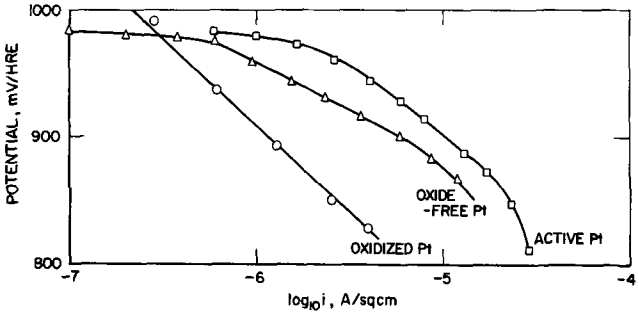

Fig. 1. Comparison of Tafel plots for reduction of oxygen on platinum in 85% orthophosphoric acid at 95.9°C.

Oxidized Electrodes

Above about 1000 mV/HRE platinum is covered by a phase oxide (13). For accurate kinetic study the thickness of the oxide film must be made reproducible by anodizing the platinum surface, as was first noted by Hoar (1).

In the work reported here, anodic treatment of platinum electrodes at 2000 mV/HRE for 15 min led to very reproducible anodic galvanostatic Tafel plots which could be traced backwards and forwards with very little hysteresis. For these experiments the electrolyte was saturated with oxygen at atmospheric pressure. At current densities below about 10^{-7} A/cm^2, a depolarizing effect was noted where the potential of the electrode fell rapidly with decreasing current density. In all probability, this current density represents the diffusion current for the oxidation of traces of impurities present in the solution (10), probably mainly hydrogen peroxide produced at the counter-electrode during anodizing.

Cathodic Tafel lines on the oxidized surface were obtained by reversing an anodic current until the potential of the electrode fell to 1100-1050 mV/HRE on a preanodized electrode, and then the current was adjusted to the appropriate value. An initial plateau was observed for each applied current density, after which a decay occurred due to gradual reduction of the oxide. To overcome this difficulty, a reproducible oxidized surface was obtained by anodizing the electrode at 2000 mV for 2 min before each reading was taken.

Typical examples of anodic and cathodic Tafel slopes obtained on oxidized platinum are shown in Fig. 2. The intersection of these slopes occurs at about 1200 mV/HRE.

For the over-all reaction

$$O_2 + 4H^+ + 4e^- = 2H_2O$$

at 95.9°C, E° (calculated from data for the free energy of formation of liquid water) (14) is 1169 mV. However, corrected for the presence of water vapor above 85% orthophosphoric acid at 95.9°C (15), the theoretical emf of the cell

$$Pt/H_2, \quad 85\% \text{ orthophosphoric acid}, \quad O_2/Pt$$

is 1199 mV/HRE, which agrees very closely with the intersection point in Fig. 2.

A typical exchange current is about 5 x 10^{-9} A/cm^2, but this value was observed to depend to a small ex-

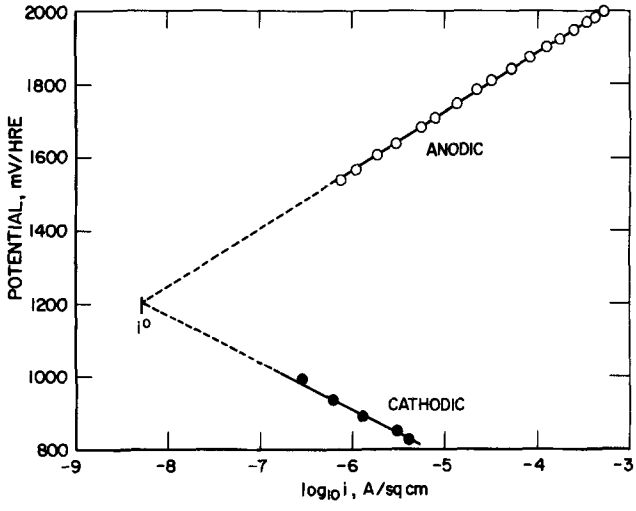

Fig. 2. Oxygen electrode on oxidized platinum in 85% orthophosphoric acid at 95.9°C.

Table I. Reaction paths on oxidized platinum electrodes

		ν	$\left(\frac{\partial \log i}{\partial \log p_{O_2}}\right)_V$
A. Oxide path			
1. Rate-determining	$S + H_2O \rightarrow SOH + H^+ + e^-$	4	0.25
2.	$2SOH \rightarrow SO + SH_2O$		
3.	$2SO \rightarrow O_2 + 2S$		
B. Hydrogen peroxide path			
4. Rate-determining	$S + H_2O \rightarrow SOH + H^+ + e^-$	4	0.25
5.	$2SOH \rightarrow SH_2O_2 + S$		
6.	$SH_2O_2 + SOH \rightarrow SOH_2 + SO_2H$		
7.	$SO_2H + SOH \rightarrow SH_2O + S + O_2$		
C. Metal peroxide path			
8. Rate-determining	$S + H_2O \rightarrow SOH + H^+ + e^-$	4	0.25
9.	$2SOH \rightarrow SO + SH_2O$		
10.	$SO + SOH \rightarrow S + SHO_2$		
11.	$SHO_2 + SOH \rightarrow O_2 + S + SH_2O$		
D. Electrochemical oxide path			
12.	$S + H_2O \rightarrow SOH + H^+ + e^-$	2	0.5
13.	$SOH \rightarrow SO + H^+ + e^-$	2	0.5
14.	$2SO \rightarrow 2S + O_2$		

Note: "S" represents an undefined surface site on platinum oxide, which must remain unaffected during the reaction sequence.

tent on the time allowed for the anodic treatment of the electrode surface. Anodic Tafel slopes were 159 mV/decade (or 2.17 x 2.3 $RT/\mathbf{F}$), and cathodic slopes were —131 mV/decade (or —1.78 x 2.3 $RT/\mathbf{F}$).

The order of reaction for oxygen was measured at 25.1°C because at this temperature oxide films were observed to be more stable and results were therefore more reproducible.

The oxygen concentration in dilute oxygen-nitrogen mixtures was determined by the magnitude of the diffusion-limiting current, compared with that for 1 atm oxygen. The difficulty of obtaining reproducible Tafel slopes made the determination of the reaction order somewhat unreliable, but a value of 0.29 was obtained at constant potential. For the same temperature but at constant overpotential in N $HClO_4$, Damjanovic *et al.* (4) obtained the value of 0.30, which is equivalent to 0.34 at constant potential, as $(\partial E/\partial \log i)_{P_{O_2}} = 2 \times 2.3\ RT/\mathbf{F}$ and $(\partial E/\partial \log p_{O_2})_i = 2.3\ RT/4\mathbf{F}$. Considering the general difficulty of obtaining good cathodic Tafel slopes, this agreement is reasonably good.

To clarify the mechanism further, H^+ reaction order data would be desirable. Unfortunately, it is not possible to vary H^+ at constant ionic strength in concentrated acids.

Since the anodic Tafel line extends over a very wide range of potentials, we may assume that we are dealing with Langmuir, rather than Temkin, adsorption of reaction intermediates. Furthermore, the intersection of the anodic and cathodic Tafel slopes at the reversible potential (1200 mV/HRE) suggests that the rate-determining steps for the cathodic and for the anodic reactions are the same and that their rates at the reversible potential must be approximately equal.

If these assumptions are valid and if we express the experimental Tafel slope as $b = 2.3\ RT/\alpha\mathbf{F}$, then we may use the equation of Parsons (16) for the determination of the stoichiometric number ν

$$\frac{n}{\nu} = (\alpha_a - \alpha_c) \qquad [1]$$

where n is the number of electrons involved in the over-all process, ν is the stoichiometric number of the rate-determining step, and α_a, α_c refer to the anodic and cathodic processes, respectively.

Using the observed values of $1/\alpha_a = 2.17$ $1/\alpha_c = -1.78$, we have $\nu = 3.9$ (effectively 4) for $n = 4$. At room temperature Hoar (17) obtained the value of 3.1 in $N/10$ H_2SO_4 on bright platinum, Bockris and Huq (2) obtained 3.5 in N H_2SO_4, and Damjanovic, Dey, and Bockris (4) also obtained the value of 3.5 in N $HClO_4$.

Assuming the simplest case of a sequence of simple consecutive steps and Langmuir adsorption, we may apply the equations[1]

$$\alpha_a = \beta n_k + \frac{n_a}{\nu} \qquad [2]$$

and

$$\alpha_c = (1-\beta) n_k + \frac{n_c}{\nu} \qquad [3]$$

where β is the anodic symmetry factor, n_k is the number of electrons involved in the (unique) rate-determining step, and n_a, n_c are the total number of electrons transferred before the rate-determining step in the anodic and cathodic directions, respectively.

According to Eq. [2] and [3] we see that: for $\nu = 4$, assuming $\beta \sim \frac{1}{2}$, and $\alpha_a \sim -\alpha_c \sim \frac{1}{2}$

$$n_k + \tfrac{1}{2} n_c = 1 = n_k + \tfrac{1}{2} n_a$$

The only consistent solutions for this equation are either $n_k = 1$, with $n_c = n_a = 0$; or $n_k = 0$, with $n_c = n_a = 2$. Assuming, therefore, that the rate-determining step is a charge transfer, $n_k = 1$ and $n_c = n_a = 0$ for $\nu = 4$.

This requires that no electrons are transferred before the rate-determining step in either the anodic or cathodic directions. The rate-determining step itself occurs four times in the over-all sequence and results in the total transfer of four electrons.

The only reactions schemes proposed so far (20) which satisfy these conditions are A, B, and C in Table I. Another interesting proposition for the mechanism of this reaction was offered by Riddiford (18). He supposes that steps 12 and 13 in path D (Table I) have similar exchange currents and suggests that step 12 will control anodically and step 13 cathodically; in each case the reaction with the higher slope controls the over-all process. The simple stoichiometric number equation (Eq. [1]) is, of course, not applicable to such reactions.

It is interesting to note that in another connection, Böld and Breiter (21) have postulated that the reactions

$$Pt + H_2O \rightarrow PtOH + H^+ + e^-$$

and

$$PtOH \rightarrow PtO + H^+ + e^-$$

which resemble steps 12 and 13, have about the same rate constants.

The oxygen reaction order data in the current work (about 0.3) suggest that Riddiford's proposition cannot

[1] These equations have been quoted without derivation in ref. (17) and derived in ref. (18) and (4) from the equations of Mauser (19).

fully explain either our experimental results or those obtained by Damjanovic *et al.* (4). It is possible, however, that, apart from the dual rate-determining steps that Riddiford (18) suggests, more than one reaction path may occur simultaneously on the electrode. In particular,[2] of the paths quoted in Table I, D and A may occur in parallel on different parts of the electrode surface. Both of these paths involve initial dissociative adsorption of oxygen. The occurrence of steps 2 or 13 followed by the controlling steps 1 or 12 could depend on local variations in oxide structure. This would explain the inexact values of the stoichiometric numbers and oxygen reaction orders observed here and by other workers (2, 3).

The anodic Tafel slopes in the present work are higher than those observed at room temperature in dilute acids (1, 2, 4). However, increase of these slopes with acid strength as observed by Kaganovich *et al.* (22) may be due to changes in the symmetry factor caused by alteration of the double-layer structure in highly concentrated acid electrolytes.

In conclusion, our results suggest that oxygen reduction and evolution mechanisms on anodized platinum in 14.6M (85%) orthophosphoric acid at a relatively high temperature are essentially similar to those in dilute acids such as sulfuric (1, 2) and perchloric (4) at room temperature and involve the same rate-determining step, namely, the water-discharge mechanism proposed by Bockris and Huq (2) for dilute sulfuric acid at room temperature. However, this step may not necessarily be rate-controlling cathodically, and more than one mechanism may operate simultaneously. The data obtained suggest that the water-discharge rate-determining step for oxygen evolution may generally apply in all acid electrolytes in which platinum oxides are stable, irrespective of the anion, concentration, and temperature. The nature of the anion appears to influence only the rate constant of the reaction and, to some extent, the symmetry factor.

Oxide-Free Electrodes

The surface of these electrodes was prepared as already described. Particular experimental precautions are necessary for these surfaces to ensure reproducibility because of their sensitivity to capillary-active impurities which always persist in the electrolyte.

After being subjected to a procedure for desorbing capillary-active impurities (23) (consisting of an anodic pulse to 1.2 V/HRE for 1 sec followed by a number of cathodic pulses to +0.50 V/HRE, for a few seconds each), they reached steady rest potentials of 985-999 mV in a few minutes. The initial rest potential usually rose to over 1000 mv after a few hours, reaching potentials of about 1010 mV. A slow decay followed; a final potential of about 990-1000 mV was generally noted after 24 hr, which then remained steady for some days. A typical galvanostatic Tafel plot for this surface is shown in Fig. 1. To ensure a reproducible surface, a cathodic pulse was used between each point, as it was noted that a slow decay of potential at constant current took place after initial stability. This is caused by the deactivation of the electrode by nonoxidizable impurities and is more apparent at lower potentials, leading to steeper Tafel slopes than those initially observed. The adsorption of capillary-active impurities is evidently potential-dependent, as has been noted by other workers (24, 25). Such nonoxidizable impurities, which may be of organic origin (or, in this case, possibly polyphosphates), are eliminated from the electrolytic solution only by extreme purification procedures (25).

With the precautions described above, very reproducible Tafel plots with slopes close to 2.3 RT/F were obtained. The i° value (corrected to 1 atm oxygen) was 4×10^{-10} A/cm^2 (Fig. 1).

The reaction order for oxygen was measured at 52.1°C. Galvanostatic results for four different oxygen partial pressures are shown in Fig. 3. In contrast to the oxidized platinum results in this case oxygen reduction at constant potential is approximately first order.

Ring-disk electrode studies.—Studies with a rotating ring-disk electrode, were carried out at 76.1°C to examine the possibility of hydrogen peroxide formation. Figure 4 shows a plot of the ring (maintained at 1.3V) and disk currents at 3140 rpm. The apparent double-wave effect is due to impurity adsorption. In the region of the plot between +700 to +400 mV/HRE, the disk was reactivated (pulsed to +50 mV/HRE) before each point. Points shown in Fig. 4 are the highest stable values of current that could be attained. The limiting current for oxygen (not reached in Fig. 4) can be calculated from Levich's equation (26) using published data for the oxygen solubility (27), its diffusion coefficient (27), and the kinematic viscosity of the acid (15). The expected value lies between 50 and 100 mV/HRE. As observed by other workers (24, 25), currents shown in Fig. 4 in the potential range of 600-400 mV/HRE slowly decayed to lower values with time.

No hydrogen peroxide was detected in the Tafel region, but, in the region where impurities are adsorbed, small amounts of hydrogen peroxide were present (25), as may be seen in Fig. 4. The maximum detected at the ring amounted to 16% of the total oxygen consumed at the disk, as the ring collects about 35% of the hydrogen peroxide produced. If impurity adsorption causes a reduction in bond energy of adsorbed peroxy-radical reaction interme-

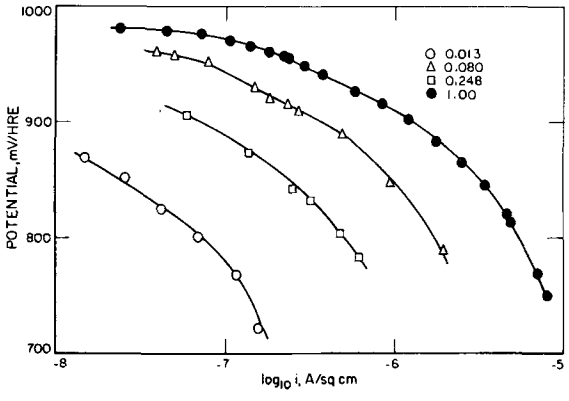

Fig. 3. Effect of oxygen partial pressure reduction of oxygen on oxide-free platinum in 85% orthophosphoric acid at 52.1°C.

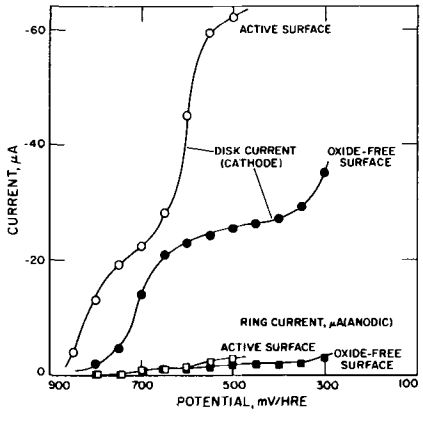

Fig. 4. Oxygen reduction on platinum ring-disk electrode at 3140 rpm and 76.1°C.

[2] The rotating ring-disk electrode detected less than 2.10^{-7} A/cm^2 at the ring at 76.1°C and 3140 rpm when the disk was anodized and held at a potential of 850 mV/HRE in oxygen-saturated solution. We may therefore conclude that hydrogen peroxide is not appreciably involved in the mechanism.

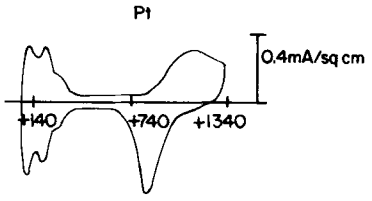

Fig. 5. Cyclic voltammetric scan on platinum at 260 mV/sec at 95.9°C (horizontal scale = mV/HRE).

diates,[3] the latter may tend to desorb rather than undergo O-O bond dissociation on the platinum surface.

Nature of the oxide-free surface.—Before considering the reaction mechanism for this surface, it is necessary to decide which adsorption isotherm is likely to apply on this surface. Böld and Breiter (21) have shown that a platinum electrode which is oxidized and reduced by a continuously cycling potential in *N* $HClO_4$ and other dilute acid solutions has a coverage of adsorbed oxygen radicals which reaches one monolayer at a potential of about 1.5 V/HRE. In the range of 900-1500 mV, an approximately linear variation of coverage with potential exists, which they interpreted in terms of the Temkin adsorption isotherm.

An integrated curve, showing the variation of coverage with potential, based on this work, is quoted by Damjanovic and Brusic (3). It must be emphasized that results obtained by this rapid-scanning technique do not allow equilibrium to be attained, especially at lower potentials. The steady-state coverage-potential plot given by Damjanovic and Brusic (3) shows that, in fact, the linear variation of coverage extends to potentials about 130 mV lower than those shown in cyclic voltammetric plots taken at a scan rate of 1 V/sec.

A cyclic scan plot on 85% orthophosphoric acid at 260 mV/sec at 95.9°C is shown in Fig. 5. Compared with results in 0.1*N* perchloric acid at room temperature (21), Fig. 5 shows a considerable anodic displacement of the oxygen region. This may be attributed to adsorption of phosphate ion in the double layer, which would tend to reduce the bond strength of adsorbed oxygen radicals on the platinum surface, leading to less favorable kinetics. It seems reasonable that Temkin conditions will also apply for 85% orthophosphoric acid, but will exist in a somewhat higher range of potential than that noted by Damjanovic and Brusic (3) in *N* perchloric acid at room temperature.

Mechanism.—Damjanovic and Brusic (3) showed that their results were accounted for by the rate-determining step

$$S + O_2 + H^+ + e^- \rightarrow S\text{-}O_2H$$

where the adsorption of the O_2H radical (the reaction product of the rate-determining step) is presumed to follow the same Temkin isotherm as that experimentally obtained for the O radical adsorbed on the electrode above 700 mV (21). The equation then accounts for the observed first-order dependence of current on oxygen partial pressure, Damjanovic and Brusic's experimental order of reaction for $[H^+]$ (3), and has a Tafel slope of 2.3 $RT/\mathbf{F}$ in the case where the heat of adsorption of O_2H is potential dependent. Under Langmuir conditions without previous charge transfer the same reaction would be expected to have a Tafel slope of $1/\beta \times 2.3\ RT/\mathbf{F}$, where β is the symmetry factor ($2 \times 2.3\ RT/\mathbf{F}$ if $\beta = \frac{1}{2}$).

It is concluded that the same rate-determining step is applicable in 85% orthophosphoric acid. It is also interesting to note that the i° in the present electrolyte at 95.9°C (4×10^{-10} A/cm²) is of the same order of magnitude as that noted by Damjanovic and Brusic (3) in *N* perchloric acid at 25°C. It seems therefore that, as in the case of the oxidized surface, the rate-determining step on the oxide-free platinum is common to all acid electrolytes, independently of the nature of the anion, the temperature, and the concentration. Normally it takes place under Temkin conditions of adsorption; however, in the presence of a strongly adsorbing anion (*e.g.*, Cl^-), it apears that low rate constants (weakening of the $S\text{-}O_2H$ bond) and higher slopes do occur. This effect is probably indicative of Langmuir adsorption (high coverages of strongly adsorbed material, in this case Cl^-) and of the progressive deactivation of the electrode with increasing overpotential. This is apparent from results obtained by Bianchi and Mussini in dilute halo-acids at room temperature where Tafel slopes greater than 2 x 2.3 $RT/\mathbf{F}$ were observed (5). Apart from this case, Tafel slopes of 2.3 $RT/\mathbf{F}$ appear to be typical if capillary-active material is absent.

[3] This may be equivalent to saying that impurity adsorption blocks the high energy sites where O-O bond dissociation can take place.

Active Platinum

Active platinum electrodes were prepared by anodizing at 2000 mV/HRE for a period of about 5 min. They were then reduced galvanostatically, but were not allowed to reach potentials below +500 mV/HRE. On switching off the galvanostatic cathodic current, these electrodes immediately took up an open-circuit potential of about 1000 mV/HRE.

Very reproducible galvanostatic Tafel plots, which could be retraced forwards and backwards several times, were obtained. They had a slope of about 1.69 x 2.3 $RT/\mathbf{F}$ (124 mV/decade), with an i° of about 4×10^{-8} A/cm². A typical Tafel plot for this surface is shown in Fig. 1 for 95.9°C.

The active surface is clearly a better electrocatalyst than oxidized or oxide-free surfaces. The reaction order for oxygen on active platinum was determined at 52.1°C. The Tafel plots shown in Fig. 6 were obtained after preparing a fresh surface for each partial pressure. Because of oxygen evolution during anodizing, a short time elapsed before steady readings were obtained in each case. Again, an approximately first-order dependence of current on oxygen partial pressure is observed.

Hydrogen peroxide formation was studied using the rotating ring-disk electrode. Potential current plots of ring and disk currents at 76.1°C are shown in Fig. 4. It can be seen that the active surface suffers less than the oxide-free surface from the effect of impurities in the range of potential below 700 mV; in proportion, much smaller amounts of hydrogen peroxide were detected.

Nature of the active surface and discussion of reaction.—Feldberg *et al.* (12) have explained the well-known observation, [reviewed by Vetter (28) and Hoare (6)] that about twice as many coulombs are required to produce a platinum-phase oxide than to reduce it by supposing that the reactions

$$Pt + H_2O \rightarrow PtOH + H^+ + e^-$$

$$PtOH \rightarrow PtO + H^+ + e^-$$

are, respectively, slow and very fast. These authors have noted that a platinum electrode which has been strongly oxidized and then reduced is in an "active" form which remains stable for some hours. They consider this electrode to be covered by a layer of PtOH. This would imply that the surface of a platinum electrode undergoing cyclic potential scanning as described by Böld and Breiter (21) is covered by a layer of PtOH during the reduced part of the cycle.

On the other hand, Schuldiner and Warner (11) have suggested that, after anodizing and reduction, a disordered lattice of metal atoms is formed which contains dissolved atoms. This they termed "dermasorbed" oxygen.

In the discussion of the oxide-free electrode above, we have assumed that the coverage data, obtained by

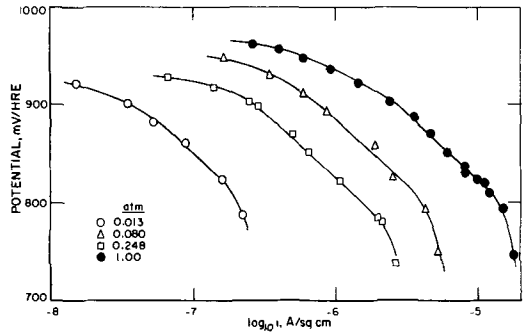

Fig. 6. Effect of oxygen partial pressure on reduction of oxygen on active platinum in 85% orthophosphoric acid at 52.1°C.

Damjanovic and Brusic (3), included all strongly bound oxygen-containing species, including —OH. Breiter (29) and Lukyanycheva *et al.* (30) have shown that the first cycle of a cyclic voltammetric scan behaves differently from subsequent cycles. There is evidence that the first anodic cycle is of a considerably larger area than subsequent cycles, so that the number of coulombs involved is greater than in the reduction part of the cycle, as in charging curves. This could be explained equally well either in terms of the proposition of Feldberg *et al.* (12) or in terms of oxygen radicals being "dermasorbed" during the first cycle (11).

However, from the present results and from those of Damjanovic and Brusic (3), it appears that an electrode which has been taken momentarily to 1.2-1.5V followed by reduction is not "active," but behaves as a normal oxide-free surface. According to Feldberg *et al.* (12), such an electrode should have an adsorbed monolayer of PtOH. If such were the case, adsorption of OH and other oxy-intermediates would not obey the Temkin isotherm, which only applies in the region $0.1 < \theta < 0.9$. Hence, we consider that the coulombs unaccounted for in the reduction of platinum oxide correspond to "dermasorbed" oxygen rather than to a layer of PtOH.

Undoubtedly, the surface produced by momentarily oxidizing at 1.5V, followed by reduction, must involve some "dermasorbed" oxygen. It is, however, important to note that the true active surfaces are only produced by prolonged anodizing or treatment with powerful oxidizing agents (31). It seems reasonable to suppose that the reduced oxide lattice contains a good deal of trapped oxygen (oxide ions or oxygen radicals), and perhaps also OH radicals, as proton diffusion through the lattice is likely to be easy. The outermost layers of the platinum surface must therefore be disordered and contain numerous vacancies. The surface is not particularly stable, but is more stable than would be expected if it were only lightly platinized as was suggested by Anson (32).

The high lattice energy created by the presence of oxygen radicals prevents easy diffusion and restoration of a regular crystalline array. With increased metal lattice energy, it is reasonable to suppose that the bond strength of adsorbed reaction intermediates in the oxygen reduction reaction will increase substantially, hence accounting for the higher reaction rates observed on this surface.

Because of the permanent presence of relatively large amounts of dissolved oxygen radicals in the few monolayers of the lattice, we may expect that oxygen radicals additionally adsorbed on the outer surface as potential increases will have a much smaller effect on the heat of adsorption of reaction intermediates than is the case on oxide-free platinum. In this situation adsorption should more nearly approach Langmuir rather than Temkin conditions.

We therefore suggest that the same rate-determining step applies as on bare platinum, that is

$$S + O_2 + H^+ + e^- \rightarrow SO_2H$$

but under more nearly Langmuir conditions. This explanation agrees with our Tafel slopes and the results of oxygen partial-pressure dependence.

Another interesting implication of the above concept concerns the reaction

$$S - OH + H^+ + e^- \rightarrow S + H_2O$$

which is rate-determining on oxidized platinum but apparently much faster on the oxide and active surfaces. In all cases it is likely to be the last step in the over-all cathodic process (3). The slow rate of this reaction on oxidized platinum can be explained by considering that oxidized surfaces are highly negative in character, as shown by their ability to absorb cations, even at high anodic potentials (33). We may conclude therefore, that, on such a substrate, adsorption of —OH would be weak, making the free energy of activation for this step correspondingly high.

Fuel Cell Implications

Neither oxidized nor active surfaces are stable with time at about 800 mV/HRE on massive platinum substrates; both ultimately degrade to bare platinum.

At fuel cell operating temperatures oxide-free platinum has a relatively poor i° value compared with the oxidized surface, but its more favorable Tafel slope makes it a more effective reducing surface in the relevant range of potential. Active surfaces, in spite of their high Tafel slopes, are still more effective.

It is possible that, owing to the highly fragmented nature of platinum black, kinetics on such electrodes may resemble those on active massive platinum, although the two differ drastically in their stability characteristics.

Specific Conductance of Molten Potassium Nitrate

G. D. Robbins* and J. Braunstein

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

A careful determination of specific conductance of molten potassium nitrate over the temperature range 345°-541°C has demonstrated its suitability as a molten salt standard in electrical conductance work. The data are well represented ($\sigma = 0.0008$) by the computer-fitted, least squares equation

$$\kappa = -0.7098 + 4.6203 \times 10^{-3}\, t(°C) - 2.0221 \times 10^{-6}\, t^2$$

The estimated accuracy is better than ±0.5%. Of the previous investigations on this system, the limited temperature equation of Smith and Van Artsdalen agrees best with the results reported here.

Investigations of electrical conductivity in molten salts are essential to the understanding of transport processes in these materials. In particular, the testing of theories, such as the zero mobility concept of Angell (1, 2) requires accurate and precise determination of the temperature variation of specific conductance. In addition, the advent of molten salt nuclear reactors employing fused salts as fuel salt solvent and coolant salts (3) necessitates accurate measurement and better understanding of electrical transport.

As is well known, specific conductances, κ, are obtained from measured resistances, R, by employing the relation

$$\kappa = \frac{1}{R}\,(l/a) \qquad [1]$$

where (l/a) is the cell constant. The value of (l/a) usually is obtained by measuring the resistance of a material of known specific conductance, preferably one having similar properties to the system to be investigated. There are, at present, no accepted molten salt secondary standards for the determination of cell constants for conductivity measurements. Based on ease of handling, availability, stability to atmospheric conditions, and compatibility with container materials (especially silica), molten potassium nitrate would seem the most reasonable choice among molten salts for such a reference material. However, as Fig. 1 demonstrates, the results of several reported investigations in this system at temperatures up to 100°C above the melting point differ by amounts considerably larger than the claimed experimental uncertainty. In the work of Bloom and co-workers (4) and Smith and Van Artsdalen (5) specific conductance data are not given, only an equation. Although in the early work of Jaeger and Kapma (6) considerable attention was devoted to experimental detail, the scatter in the data is large. The recent results of De Nooijer (7) appear uncommonly low in the low temperature region, where one would expect nitrite formation to be least and results to agree best.

In a recent review of electrical conductance measurements in molten fluorides (8) errors arising from the indiscriminate use of a Wheatstone type (or Jones) conductance bridge were discussed. Some possible origins of frequency variation of the measured resistance were also presented. Two subsequent discussions (9, 10) of the relation of measured resistance to measuring frequency have also appeared. Kröger and Weisgerber (11) have addressed themselves to these questions, and as Fig. 1 demonstrates, their data show some divergence from those of the others, although they do not result in a smooth curve. In addition, resistance measurements were performed only over the frequency range 1-4 kHz, and the resultant extrapolation to infinite frequency was 2-3%.

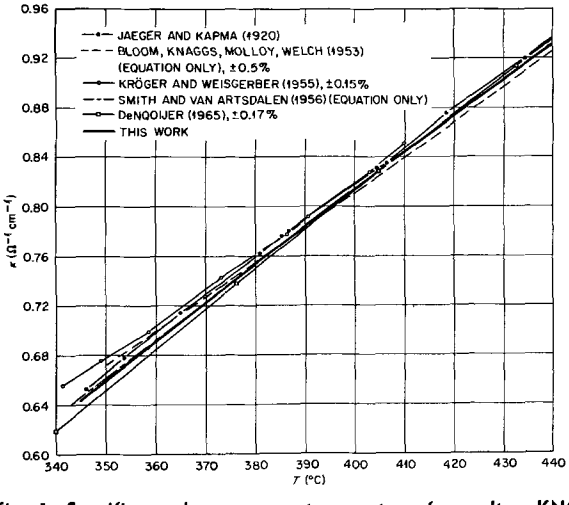

Fig. 1. Specific conductance *vs.* temperature for molten KNO_3. Comparison of this and previous work.

* Electrochemical Society Active Member.

No attempt has been made in Fig. 1 to include all references to work on molten potassium nitrate due to the limited number of curves which can be distinctly represented. Investigations in this system date back to 1874 (12), and no work previous to 1920 is cited. Several investigations not referenced in Fig. 1 should be mentioned: Direct current measurements at four temperatures have been reported by King and Duke (13). Over the larger part of their temperature range the data lie above those of Kröger and Weisgerber. Angell (14) has measured specific conductances employing an a-c technique over a 75° temperature interval. Agreement of ±0.1% with the data of King and Duke is claimed, although one of the seven data reported differs by 2.8% probably the result of a typographical error. For additional references, the recent compilation by Janz *et al.* (15) is useful.

In this paper we present new measurements on the conductance of KNO_3 over an extended range of temperature with a bridge designed for use with molten salts. We consider the possible effects of impurities and demonstrate the suitability of KNO_3 as a secondary standard for molten salt conductance measurements.

Because of the frequent use of potassium nitrate as a reference point in studies of transport properties of molten salts (1, 2, 7, 16), accurate values of its specific conductance and temperature dependence are important quantities in their own right to the physical chemistry of molten salts.

Experimental and Results

Since the importance of this work lies in the credibility of the data, careful attention will be given to the experimental details of the measurements.

Figure 2 shows the type of silica conductance cell employed in these determinations. The interior dip cell consists of two silica tubes, the lower portions of which are 3 mm ID tubing, attached to a silica rod. Platinized platinum electrodes (20 gauge) are held immobile relative to the dip cell assembly by silica hooks and glass tape. The 12-cm conducting path resulted in measured resistances of 120-225 ohms, and the L-shaped electrode design rendered measured resistance independent of depth of immersion (3-7 mm below salt surface). The electrolyte is contained in a 3.3-cm ID silica cell which stands on a silica foot. A Teflon cap (not shown) holds the dip cell in place and admits the electrodes and a thermocouple through close fitting holes. The entire cell assembly is immersed in a stirred, temperature controlled, molten potassium nitrate bath contained in a silica and lavite furnace (17) which permits visual observation of the melt (9). A calibrated chromel-alumel thermocouple contained in the silica thermocouple well and a type K-4 potentiometer measured temperature with an estimated uncertainty of ±0.5°C.

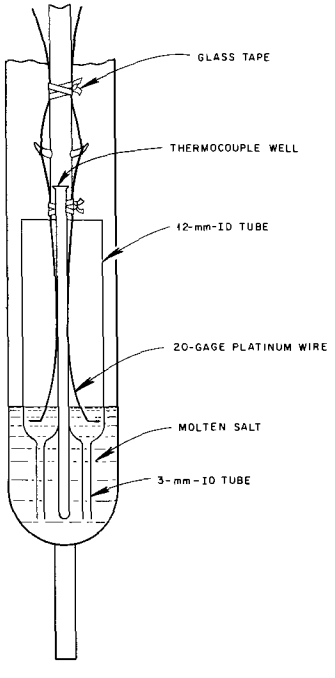

Fig. 2. Silica conductance cell

As discussed previously (8, 9), errors can arise in determining molten salt conductivities from the use of measuring bridges with a balancing arm having a parallel resistance and capacitance. Accordingly, a specially constructed bridge (9) with series components in the balancing arm was employed in measuring resistances in the molten nitrate. A test of the bridge employing a dummy cell consisting of a standardized resistance and capacitance connected in series revealed that the accuracy was better than ±0.2% for resistance of the order of 100 ohms (with a capacitance of 21 μf) in the frequency range 1-50 kHz. Measurements with the dummy cell included leads employed with the real cell, thus insuring no error from lead resistance. The accuracy in determining capacitance was much less and depended on the magnitude of the resistance and on the frequency (for 100 ohms ±1% at 2.5 kHz and ±10% at 7.5 kHz). However, even though the value of capacitance required for bridge balance was not an accurate measure of the dummy capacitance at higher frequencies, at balance the accuracy of the resistance measurement was maintained.

Similar tests on a Jones bridge available in our laboratory (Leeds and Northrup) (18), which has a parallel-component balancing arm, revealed that while this bridge is extremely accurate for measuring high resistance, the accuracy at 100 ohms was only ±1% in the frequency range 1-50 kHz. Consequently, the Jones bridge was employed in determining cell constants in dilute aqueous solution where the resistances were large and the bridge accuracy high, while the much lower resistances of the molten salt were determined with our specially constructed bridge, its accuracy being high in this resistance range.

For the determination of the cell constant a 0.1 demal aqueous potassium chloride solution (prepared from single crystal KCl) was used for which the specific conductance is well established (19, 20). The resistance of the aqueous electrolyte was determined in a controlled temperature bath at 25°C employing the Jones bridge because of the large resistances involved. A test of the bridge with dummy components of magnitude comparable to this solution showed an accuracy of ±0.05% in the frequency range 0.5-5 kHz. The cell constant (145.9 cm^{-1}), determined on two consecutive days and at three depths of immersion, was independent of frequency in this range and of the depth of immersion (3-7 mm) to ±0.3 cm^{-1}.

"Baker Analyzed," reagent grade, potassium nitrate was dried at 100°C for several days, and a molten portion showed no clouding on addition of silver nitrate crystals. The maximum peak-to-peak voltage applied to the series-component bridge was 30-110 mV, and the measured resistance did not vary with frequency (±0.2 ohm < 0.2%, random) from 1-20 kHz. Table I shows specific conductance *vs.* temperature data for molten potassium nitrate as determined with the series-component bridge.

To check for errors in conductance due to nitrite formation, the following procedure was adopted. Between each resistance determination at successively higher temperatures, the resistance was remeasured near the melting point (see Fig. 3). It was planned to discard the last datum at the elevated temperature when a value failed to duplicate the previously determined values. However, no discrepancy appeared up to 541°C, the temperature limit of the furnace. From this one might conclude either that sufficiently little nitrite had formed to be detected, or that the specific conductances of KNO_3 and KNO_2 were identical

541.3	1.198_8

within the limits of measurement, in which case the results remained valid. However, the possibility exists for identical conductivities near 350°C with divergent values appearing at increased temperatures. Accordingly, an addition of 5 m/o (mole per cent) KNO_2 resulted in the triangular datum (see Fig. 3) at 359°C, a change of 1.8%, well outside the data scatter. This is consistent with the data of Bartholomew (21), who studied the equilibrium $KNO_3 \rightleftharpoons KNO_2 + \frac{1}{2}O_2$ from 550° to 750°C and found an equilibrium nitrite concentration of only 0.009 mole fraction at 550°C. The effect of 1 m/o nitrite on the specific conductance of KNO_3 may be estimated from specific conductance data for $NaNO_3$ and $NaNO_2$ (22). Assuming additivity of conductances, the increase in specific conductance due to 1 m/o nitrite would be 0.3% at 550°C.

The curve shown in Fig. 3 represents the computer-fitted, least squares equation ($\sigma = 0.0008$)

$$\kappa = -0.7098 + 4.6203 \times 10^{-3}\, t(°C) - 2.0221 \times 10^{-6}\, t^2 \quad [2]$$

based on the 24 data of Table I.

To recheck the KNO_3 specific conductance results, a completely new dip cell was constructed and its cell constant (141.4 cm^{-1}) determined in 0.1 demal KCl as before. A newly calibrated Pt vs. Pt-Rh (10%) thermocouple measured temperature. The open circle data points at 370° and 422°C show these results, which agreed with the previous results within 0.2% A comparison of these data with previous investigations is shown in Fig. 1, where it is evident that only the limited temperature range equation of Smith and Van Artsdalen (5) agrees well with the results reported here (maximum deviation = 0.4%). If all errors are assumed to be random and independent with uncertainties assigned to κ of 0.2% from cell constant determination, 0.1% from resistance measurement, 0.2% from possible nitrite impurity, and 0.2% from temperature measurement, the probable error is 0.3%. We consider these results to have an accuracy of better than ±0.5%.

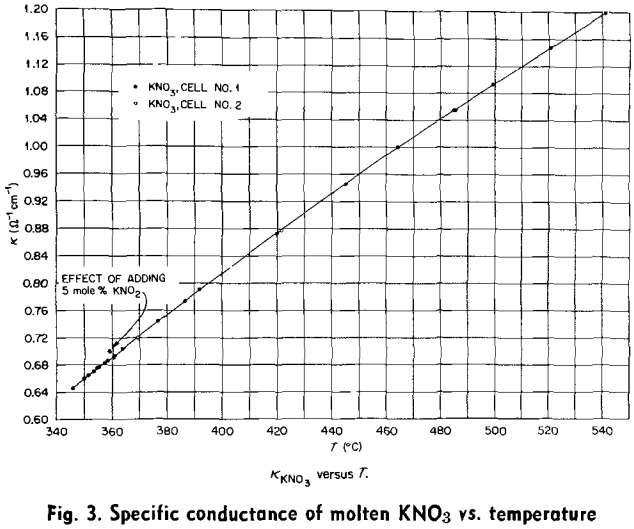

Fig. 3. Specific conductance of molten KNO_3 vs. temperature

Discussion

The density-temperature equation of Smith and Petersen (23) was employed in calculating equivalent conductances, Λ, the natural logarithms of which were examined for curvature when plotted vs. $1/T$(°K). These density data were employed because of the wide temperature range which they encompass. Still, the two conductance points of highest temperature are beyond their range of measurement, and densities at these two temperatures were estimated from the same equation. Similar calculations with the density data of Smith and Van Artsdalen (5) in the limited temperature range 344°-398°C resulted in slightly lower values of ln Λ, which paralleled the previous plot.

The slight curvature observed in the graph of specific conductance vs. temperature (Fig. 3) persisted in the ln Λ vs. $1/T$(°K) plot. Thus, the three parameter, Vogel-Tammann-Fulcher (VTF) equation successfully employed by Angell (1, 2, 24, 25) for glass-forming melts in the KNO_3-$Ca(NO_3)_2$ system has been fitted to the data with the aid of a computer. The least squares representation of the data ($\sigma = 0.0012$) is

$$\ln \Lambda = 9.590\ (\pm 0.029) - \tfrac{1}{2} \ln T - \frac{1308.9\ (\pm 31.4)}{T - 153.93\ (\pm 6.43)} \quad [3]$$

where T is in degrees Kelvin and the values in parentheses are standard errors of the parameters. It is not surprising that Angell's values for k and T_0 (the zero mobility temperature) in the VTF equation

$$\ln \Lambda = A - \tfrac{1}{2} \ln T - \frac{k}{T - T_0} \quad [4]$$

of 690°K (±5%) and 237°K (extrapolated from a plot of T_0 vs. composition from the glass-forming region) do not agree with the constants in Eq. [3]. Equation [4] was strictly applicable only for temperatures $\leq 1.7\ T_0$, while the data presented here are in the range $2.6\ T_0 \leq T \leq 3.4\ T_0$ based on Angell's suggested value of $T_0 = 237$°K. In addition, Angell's data for pure KNO_3 do not lie exactly on his linear plot [see ref. (24), Fig. 2], but on a line corresponding to a k of 580°K. Constraining a two-parameter least squares fit of our data to the equations

$$\ln \Lambda = A - \tfrac{1}{2} \ln T - \frac{690}{T - T_0} \quad [5]$$

or

$$\ln \Lambda = A - \tfrac{1}{2} \ln T - \frac{k}{T - 237} \quad [6]$$

resulted in fitted values of $T_0 = 300$°K (±1) ($\sigma = 0.0078$) or $k = 935$°K (±3) ($\sigma = 0.0039$). [The corresponding values of A were 8.932 (±0.006) and 9.220 (±0.007), respectively.] Thus, we must conclude that the temperature range of our data is sufficiently outside the "low temperature" region ($\leq 2\ T_0$) as not to warrant a precise evaluation of T_0 based on data in this range.

From the derivative of the analytic representation of our data (Eq. [3]) the Arrhenius coefficient for equivalent conductance, E_Λ can be evaluated

$$E_\Lambda = -R \frac{\partial \ln \Lambda}{\partial\,(1/T)} = -\tfrac{1}{2} RT + 1308.9R \left(\frac{T}{T - 153.93}\right)^2 \quad [7]$$

The variation of E_Λ with temperature is shown in Fig. 4, together with that obtained from data by other in-

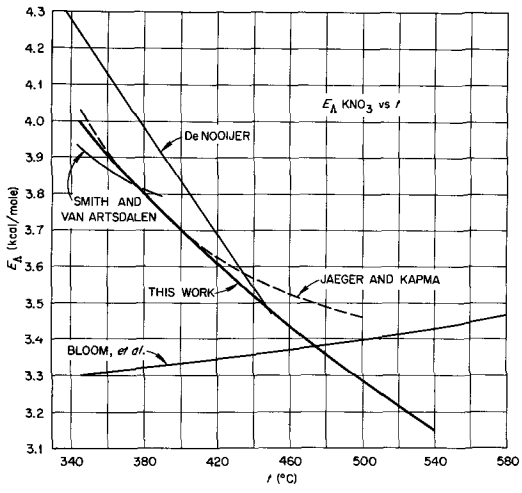

Fig. 4. Arrhenius coefficient for equivalent conductance vs. temperature for molten KNO_3.

vestigators. While agreement among our work, that of Smith and Van Artsdalen (5), and that of Jaeger and Kapma (6) (at lower temperatures) is good, the sign of the variation of E_A with t from the data of Bloom and co-workers (4) is opposite to that of all others.

Conclusion

While no set of specific conductance data should be considered as an unequivocal standard until such measurements are directly compared with an absolute standard, the authors feel the results reported herein demonstrate the suitability of molten potassium nitrate for use as a reference standard in molten salt conductivity work. Of the previous investigations of electrical conductivity in this system the limited temperature range equation of Smith and Van Artsdalen (5) agrees best with these data.

The temperature dependence of the energy of activation for equivalent conductance, while significant over the temperature range investigated, does not result in a value of the zero mobility temperature in agreement with that predicted by extrapolation from the glass-forming region of a binary system.

Polarization of Partly Wetted Porous Electrodes

P. Ruetschi*[1] and J. B. Ockerman[2]

ESB Incorporated, C. F. Norberg Research Center, Yardley, Pennsylvania

ABSTRACT

The polarization behavior of partly wetted electrodes, on which the electrode reaction proceeds beneath thin electrolyte films in the large, nonflooded pores, is described for the two cases where either diffusion through the liquid films, or the charge transfer process at the solid-liquid interface beneath the film, are rate limiting, and whereby consideration is given to the ohmic drop in the electrolyte films and the flooding of the small pores. The treatment is verified experimentally with waterproofed porous graphite electrodes.

During the past decade, porous electrodes which are only partly wetted by electrolyte have been the subject of many studies. Such electrodes are generally used when the reactant is a gas with relatively small solubility in the electrolyte, as for instance in continuous-feed galvanic cells (1), air-depolarized cells (2), and hermetically sealed cells (3). As realized some time ago for the case of electrodes in which pores are completely filled or flooded, electrolyte resistance effects in the pores and wetting films are of major importance in determining polarization characteristics (4-17). Progress in the understanding of partly wetted electrodes has been achieved in studies on partly immersed, nonporous electrodes. Oxygen reduction was investigated in this manner by Hersch (18), Weber, Meissner, and Sama (19), and more recently by Maget and Roethlein (20), Fedotov *et al.* (21), and Bennion and Tobias (22). Hersch was the first to point out that gases could diffuse rapidly through thin electrolyte films existing above the wetting meniscus, thus allowing fast transport rates.

Experiments relating to the electrochemical oxidation of hydrogen on partly immersed solid electrodes were first carried out by Will (23), who also has given the first thepretical treatment for the polarization behavior of such electrodes. His treatment was restricted to the particular case when diffusion of the gas through the electrolyte meniscus or film was current-limiting. However, under certain conditions the wetting films may be extremely thin, and diffusion therefore very fast, such that the ionization rate could become limiting.

Theoretical and experimental studies with partly wetted porous electrodes were carried out by Winsel (24), Iczkowski (25), Grens *et al.* (26), Austin *et al.* (27), Rockett and Brown (28), Lightfoot (29), and Grens (30), as well as by others.

Recent work in the USSR (31-36) stresses the importance of electrocapillary equilibrium and relative distribution of gas and electrolyte in the pores. Small pores are completely flooded with electrolyte, while large pores remain gas-filled. Assuming certain pore-size distributions, the relative gas to electrolyte volume ratio in porous electrodes may be calculated. The small electrolyte-filled pores are thought to intersect randomly with large gas-filled pores, and with this model certain characteristic features, in particular relating to the effect of applied pressure differential across the electrode, may be derived. However, one is not allowed to neglect the consequences originating from the extremely small wetting angles of strong electrolytes with most solid surfaces. Thus, even the walls of the large, nonflooded pores are therefore covered with very thin electrolyte films, resulting from electrolyte "creep" along the metallic surface.

The model used here is that of the Russian workers, with special emphasis on the influence of wetting films in the nonflooded pores. As illustrated in Fig. 1, the electrolyte is depicted to wet the solid internal surface of the nonflooded pores, forming long and thin films. Hydrophobic particles, *e.g.*, of Teflon, prevent flooding of the large pores, but do not restrict the spreading of thin films. In the flooded portion, at $x < 0$, gas diffusion is slow, and the current generated there thus is negligible.

A high concentration of H^+ or OH^- ions is provided to minimize concentration effects. Although such effects may in certain cases be important, they are neglected in the present treatment. The conductivity of the solid electrode is presumed high, such that no noticeable ohmic voltage drops occur within the solid parts of the electrode. Diffusion limitations in the gas phase, that is in the gas-filled portions of the porous electrode, are not considered here.

The present analysis lies largely with the mathematical framework of the listed references but relates specially to a comparison of the behavior for limiting diffusion of the reacting gas through the electrolyte films on one hand, and limiting ionization beneath the films on the other hand, whereby proper consideration is given in both cases to the ohmic drop in the electrolyte films.

According to the model of Fig. 1, the electrode is characterized by the presence of a specific volume of electrolyte per cubic centimeter contained in the films of the nonflooded pores, v_f. The electrode is further characterized by the total specific electrolyte volume v_e/cm^3. The surface area of the pores whose walls are covered with thin electrolyte films (that is the electrochemically active surface) is designated s_f (cm^2/cm^3). The average effective film thickness of the nonflooded pores is thus v_f/s_f.

Theoretical Framework

A thin sectional layer, positioned across the electrode at depth x, and normal to the x axis, contributes

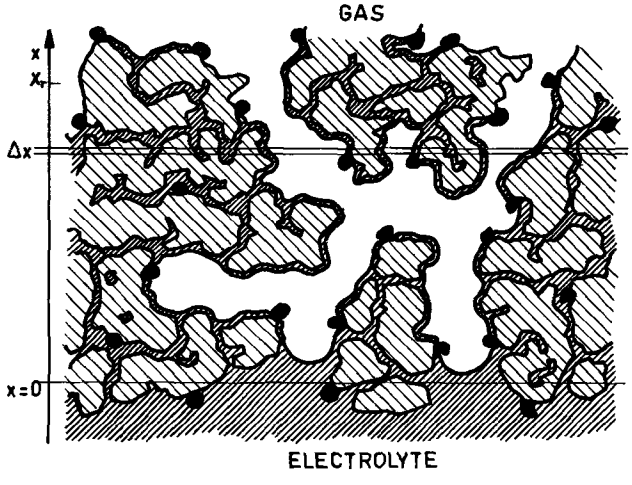

Fig. 1. Model of partly wetted electrode. Dark hatched area, electrolyte; light hatched area, solid particles with catalyzed surface; white area, gas filled pores; black dots, Teflon waterproofing particles.

[2] Present address: Gould National Batteries Inc., Research and Development Laboratories, Minneapolis, Minnesota.

to the total electrode current density in the direction of x, the infinitesimal fraction

$$dI(x) = -s_f\ i(x)\ dx \qquad [1]$$

where $i(x)$ is the true average local current density across the solid-liquid interface at depth x.

The decrease in local polarization $\eta(x)$ due to the ohmic drop caused by the current flowing in the electrolyte in the direction of x is given by[3]

$$\mp d\eta(x) = I(x)\ d\ R_e \qquad [2]$$

where $d\ R_e$ is the electrolyte resistance of a thin cross-sectional layer, parallel to the geometric electrode surface, and normal to the direction x, placed at a given depth x

$$d\ R_e = (\rho/v_e)\ dx \qquad [3]$$

Diffusion is rate limiting.—If the local current density i is determined by the diffusion rate at which dissolved gas can be transported across the electrolyte film, one obtains from Ficks law for the one-dimensional case (valid for v_f very much smaller than the porosity, that is, for very thin films) and the Nernst equation

$$i(x) = (s_f/v_f)\ C_o n_m\ \mathbf{F} D\ \{1 - \exp\ [\mp\ \eta(x)\ n\mathbf{F}/RT]\} \qquad [4]$$

where C_o is the solubility of the gas in the electrolyte (moles/cm^3) at the partial pressure and temperature in question, n_m the number of electrons required to ionize one gas molecule ($n_m = 2$ for H_2, and $n_m = 4$ for O_2), n the number of electrons in the potential determining Nernst equation, $\mathbf{F}$ the Faraday number, D the diffusion coefficient (cm^2/sec), and $\eta(x) = E(x) - E_r$ the local polarization. E_r is the reversible open circuit potential of the electrode approached at x_r; η is positive for hydrogen oxidation, negative for oxygen reduction.

The current $I(x)$ flowing through the cross section at any particular depth x must be a continuous, single valued function of the independent variable x. The same must be true for $\eta(x)$. One can therefore eliminate the differential dx between Eq. [1], [2], and [3], and substituting [4] for $i(x)$ one derives a differential equation which is readily integrated to give with the boundary conditions

$$x = 0; \quad \eta = \eta_a; \quad I = I_a$$

$$x = x_r; \quad |\eta|\ (x_r) << |\eta_a|; \quad I\ (x_r) << I_a$$

the following result

$$I_a^2 = 2n_m \mathbf{F} D C_o\ s_f^2\ v_e/v_f\rho\ \{\pm\ \eta_a - (RT/n\mathbf{F}) + (RT/n\mathbf{F})\ \exp\ [\mp\ n\mathbf{F}\eta_a/RT]\} \qquad [5]$$

where I_a is the projected current density relating to the geometric electrode surface in contact with the electrolyte, and where $\eta_a = E_a - E_r$, with E_a being the external potential applied to the porous electrode. According to [5] the current depends at constant η_a on the square root of the pressure of the reacting gas, since, in accordince with Henri's law

$$C_o = k_h\ p \qquad [6]$$

where k_h is the solubility constant. It must be pointed out that pressure here means the absolute partial pressure of the reacting gas in the gas-filled pores of the system, but not some sort of pressure differential across the porous electrode.

If the potential E_a of the porous electrode is expressed *vs.* the potential E_{r0} of a reference gas electrode in the same electrolyte held at $p_0 = 760$ mm, then

$$\eta_a = E_a - E_{r0} \pm (RT/n\mathbf{F})\ \ln\ (p/p_0) \qquad [7]$$

[3] Here, and in the following, the upper sign for η is valid for H_2 oxidation, the lower sign for O_2 reduction.

With [5], [6], and [7] one derives the pressure-dependence of the current under conditions where the potential is held constant with respect to a reference electrode which is independent of the partial pressure of the reacting gas. For absolute values of η_a larger than about 0.05V one obtains from [5] the relation

$$\log\ I_a = \text{const} + (1/2)\ \log\ p + (1/2)\ \log\ (\pm\ \eta_a - RT/n\mathbf{F}) \qquad [8]$$

The result [5] is equivalent to an equation already derived by Will (31) in a less general and more complicated manner for the case of limiting hydrogen diffusion to a partly wetted platinum electrode. The present derivation brings out the importance of the ratio v_e/v_f, a fact neglected in previous treatments, and is extended to show for the first time the proper pressure-dependence of current at fixed potentials.

Ionization is rate-limiting.—If the electrode process is rate-limiting then the local true current density $i(x)$ across the solid-liquid interface may, in the absence of H^+ and OH^- concentration effects, be described by the equation

$$i(x) = i_0\ \{\exp\ [\pm\ \alpha n_i \mathbf{F}\eta(x)/RT] - \exp\ [\mp\ (1-\alpha)\ n_i\mathbf{F}\eta(x)/RT]\} \qquad [9]$$

with i_0 being the exchange current, α the transfer coefficient and n_i the valence change in the ionization step.

Again eliminating dx between Eq. [1], [2], and [3], and inserting [9] for $i(x)$, one derives a differential equation between $I(x)$ and $\eta(x)$, which is easily solved in closed form for the case where v_f and v_e are constant throughout the limits involved.

With the boundary conditions stated earlier,[4] one obtains the following result

$$I_a^2 = (2i_0\ RT\ s_f\ v_e/\rho\alpha n_i\mathbf{F})\ \{\exp\ [\pm\ \alpha n_i\mathbf{F}\eta_a/RT] - 1\} - (2i_0\ RT\ s_f\ v_e/\rho(1-\alpha)\ n_i\mathbf{F})\ \{1 - \exp\ [\mp\ (1-\alpha)\ n_i\mathbf{F}\eta_a/RT]\} \qquad [10]$$

which reduces for absolute values of η_a larger than 0.1V to

$$I_a = (2i_0\ RT\ s_f\ v_e/\rho\alpha n_i\mathbf{F})^{1/2}\ \exp\ [\pm\ \alpha n_i\mathbf{F}\eta_a/2\ RT] \qquad [11]$$

If one writes for the hydrogen oxidation process

$$H_2(g) \rightarrow 2\ H^+\ (aq) + 2e^-$$

one derives from [11] with $\alpha = 1/2$ and $n_i = 2$ a theoretical Tafel slope of $b = 0.118$V.

For oxygen reduction, written in the form

$$2e^- + 2\ H^+\ (aq) + O_2 \rightarrow H_2O_2\ (aq)$$

one would calculate with $\alpha = 1/2$ and $n_i = 2$ the same value, namely, $b = 0.118$V.

However, these calculated Tafel slopes are not to be used as "diagnostic criteria" because of the uncertainty relating to values of α and n_i for these ionization processes involving uncharged reacting molecules. Nevertheless, the logarithmic dependence of potential on current remains a valid criterion for indicating limiting ionization rate.

Although equations similar to [10] and [11] have been derived previously (6, 7, 24) the influence of gas pressure on the current I_a for limiting ionization has not yet been discussed. The exchange currents for hydrogen oxidation and oxygen reduction, as written above, depend on concentration of the reacting species as follows

$$i_0\ (H_2) = k_f \cdot 2\mathbf{F} \cdot p_{H_2}{}^{(1-\alpha)} \cdot a_{H^+}{}^{2\alpha}$$

$$i_0\ (O_2) = k_f \cdot 2\mathbf{F} \cdot p_{O_2}{}^{(1-\alpha)} \cdot a_{H^+}{}^{2(1-\alpha)} \cdot a_{H_2O_2}{}^{\alpha} \qquad [12]$$

[4] (x) approaches zero in fact only for infinite values of x_r, that is, for infinite film length.

where the k_f's are the formal rate constants at $E = E_r$. With [7], [11], and [12] one deduces for values of $|\eta_a|$ larger than 0.1V the following dependence of current on pressure at constant applied potential E_a

$$\log I_a = \text{const} + (1/2) \log p \qquad [13]$$

A comparison of [8] and [13] shows that under the stated conditions and for constant E_a the response of current on pressure is nearly identical for rate-limiting diffusion and rate-limiting ionization.

Electrochemical Reduction of O_2

The cell used for the experimental tests is shown in Fig. 2. The electric arrangement schematically is indicated in Fig. 2a. The partly wetted electrode F consisted of a porous graphite rod (National Carbon, grade 60), 25 mm long and 12 mm in diameter. This electrode was mounted vertically into the cell, such that it was half-way immersed in the electrolyte. In order to impose a fixed potential to this porous graphite electrode it was short-circuited to a large $Pb/PbSO_4$ electrode, immersed below the porous graphite rod. The $Pb/PbSO_4$ electrode consisted of a section of a lead-acid storage battery plate, measuring 17 x 30 x 1.5 mm and containing an antimony-free grid alloy (99.95% Pb + 0.05% Ca).

The porous graphite was pretreated in the following manner (37). It was first repeatedly heated to a bright red heat with an oxygen-gas torch. After cooling, the graphite cylinder was dipped for 30 sec into a solution of 2g of $AgNO_3$ in 100 cm^3 H_2O to which was added 0.1 cm^3 of the non-ionic wetting agent Triton X-100. The $AgNO_3$ absorbed in the graphite was then decomposed to metallic silver by heating over a Bunsen flame until a faint red glow appeared. The porous graphite cylinder was then rendered water repellent by saturating it with a dilute aqueous emulsion of Teflon particles, and subsequently baking it in an oven at 360°C for 30 min. At this temperature, the individual Teflon particles are sintered firmly to the silver-impregnated porous graphite matrix. The dilute Teflon emulsion was prepared by stirring 5 cm^3 of 60% commercial du Pont Teflon emulsion into 100 cm^3 of distilled water. The Teflon particles do not prevent the spreading of electrolyte films, but do avoid complete flooding of the pores (Fig. 1). Reference (37) appears to be the first disclosure concerning the use of Teflon for waterproofing electrodes.

With this treatment, the porous graphite electrode was able to reduce oxygen at a rate of up to 70 mA/cm^2 of submerged geometric electrode surface at 760 mm pressure and at 25°C. Molten lead was poured into a central hole of the graphite electrode to establish a soldered joint to the lead-acid storage battery plate below.

The positive electrode was a pure lead wire. Oxygen gas or oxygen-containing gas mixtures could be introduced at the stopcock C. Gases leaving the exit trap were passed through a mercury manostat and collected in a gas burette. The cell pressure could be varied between 25 and 1150 mm Hg by means of the manostat. The electrolyte, 1.225 sp. gr. sulfuric acid, was prepared from cp H_2SO_4 and triple distilled water. All experiments described here were performed at 25°C.

A first series of experiments was carried out by evacuating the cell to 25 mm Hg and filling it with pure O_2 at a given pressure. Then stopcock C was rapidly closed and a constant current applied between the two cell terminals. The current was adjusted to a value that no O_2 was leaving the exit trap, the pressure remaining constant. In this manner, oxygen gas was anodically generated at the positive electrode and cathodically reduced at the graphite electrode at equal rates, thus simulating the steady state condition during overcharge of a sealed lead-acid cell (3). The steady-state current was investigated as a function of partial oxygen pressure. Also studied was the influence of inert foreign gases, N_2 and He, on the steady state current.

In the current range between 1 and 500 mA, the potential of the combined graphite-lead electrode remained at the reversible $Pb/PbSO_4$ potential, that is at — 0.368V *vs.* H_2, corresponding to a polarization of the O_2/H_2O_2 couple in the order of one volt. At steady state currents below 300 mA, the logarithm of the current was found to depend linearly on the logarithm of O_2 pressure (Fig. 3), the slope being close to that predicted by [13]. At higher currents, there is a pronounced deviation from the predicted behavior, due probably at least in part to lagging gas flow in the pores of the electrode. Local heating might create relatively high water vapor pressures in the interior of the electrode, hindering the diffusion of O_2. Local heating might also be the reason for the somewhat higher than theoretical slope.

In the presence of foreign gases, the steady-state currents were strongly decreased. For instance at a constant partial O_2 pressure of 100 mm Hg, the current decreased from 170 mA in pure O_2 to 105 mA in 80% He/20% O_2 and even to 45 mA in 80% N_2/20% O_2.

This drastic reduction of the steady state current in the presence of foreign gas is due to the accumulation of inert gas in the pores and a concurrent depletion of oxygen therein. As oxygen is being electrochemically removed, the inert gases are left behind, effectively decreasing the partial oxygen pressure in the pores. This depletion effect has been treated theoretically by Winsel (38).

In order to study the influence of electrode potential on the rate of O_2 reduction, the lead electrode was disconnected from the porous graphite electrode, and various constant currents applied between the positive lead wire and the porous graphite electrode. The potential of the latter now became a function of the applied current, and was followed with a Hg/Hg_2SO_4

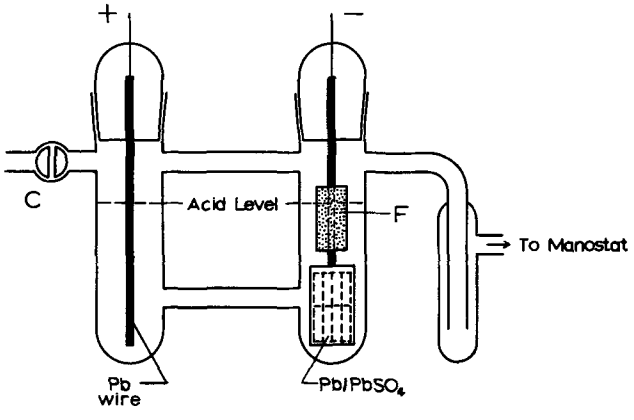

Fig. 2. Experimental cell for the study of electrochemical reduction of oxygen on partly immersed electrodes.

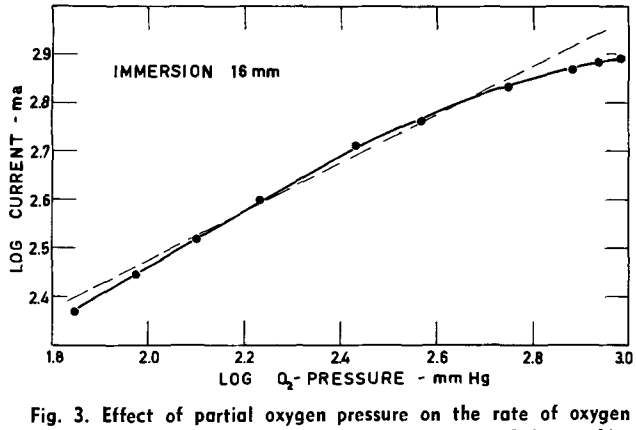

Fig. 3. Effect of partial oxygen pressure on the rate of oxygen reduction on a silver-activated, porous waterproofed graphite electrode in sulfuric acid at —0.368V vs. H_2.

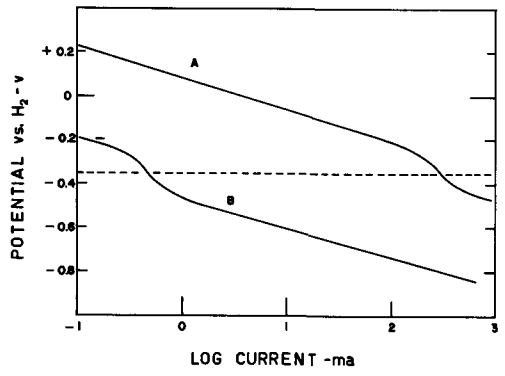

Fig. 4. Rate of oxygen reduction as a function of electrode potential at 760 mm Hg oxygen pressure. Curve A, oxygen reduction; curve B, hydrogen evolution.

reference electrode, not shown in Fig. 2. The results of these experiments are shown in Fig. 4. Curve A represents measurements in pure oxygen at 760 mm Hg, maintained by steady external gas flow through the manostat. The semilogarithmic plot is linear up to currents of 200 mA, with a Tafel slope of 0.130. At higher currents, the curve shows a deviation toward negative potentials, indicating a less rapid increase of the O_2 ionization in the potential range between —0.2 and —0.4V. It is possible that increased water vapor pressure due to local heating, as indicated earlier, as well as concentration effects in the film might enter into the picture. At the most negative potentials H_2 evolution sets in, while simultaneously O_2 reduction proceeds at a high rate.

The linear relation between potential and logarithm of current over three decades, between 0.2 and 200 mA, suggests, in accordance with Eq. [11], that the process is limited by the ionization rate.

Curve B of Fig. 4 was obtained with the graphite electrode completely submerged in the electrolyte. Under these conditions, hydrogen begins to evolve at the graphite electrode even at small currents, since hardly any oxygen reaches the electrode. The Tafel slope for hydrogen evolution was found to be 0.13 which is a conventional value. Of interest is the relatively high absolute value for the hydrogen overvoltage on the silver-Teflon-treated porous graphite electrodes used here. At the potential of the $Pb/PbSO_4$ electrode, indicated in Fig. 4 by a dotted line, extrapolation of the Tafel line yields a current of 10^{-4}A.

The deviation of the curve B toward more positive potentials at low currents is probably due to the effect of dissolved oxygen, diffusing toward the submerged graphite electrode, and causing a depolarizing effect on hydrogen overvoltage.

In sulfuric acid, the silver-activated porous graphite electrodes cannot be held at potentials higher than about + 0.4V *vs.* H_2, otherwise Ag starts to dissolve anodically. The Ag/Ag_2SO_4 electrode has a potential of about + 0.6V, and Ag_2SO_4 is appreciably soluble in H_2SO_4. For practical O_2-consuming electrodes in sealed lead-acid cells, where a long life is required, the potential should be kept below about 0.1V since the partly wetted structure encounters locally much higher potentials than those applied externally. Oxygen consuming electrodes catalyzed with platinum may be held at potentials much more positive, *e.g.*, up to +0.9V *vs.* H_2.

Experiments on Electrochemical Oxidation of H_2

The experimental set-up used for hydrogen oxidation is schematically shown in Fig. 5. The cell again contained three electrodes: (*i*) A positive electrode consisting of a section of a lead-acid battery positive plate, 7 x 2 x 0.6 cm, with calcium alloy grid; (*ii*) a negative electrode of a pure lead wire (99.99% Pb), and (*iii*) a partly wetted porous graphite electrode. This simulates conditions for sealed lead-acid cell operation on the H_2

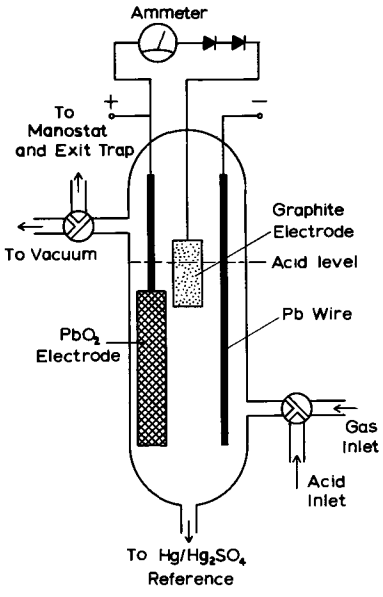

Fig. 5. Experimental cell for the study of hydrogen oxidation on partly immersed electrodes.

cycle (3). The graphite electrode was a cylinder machined from National Carbon grade 60 porous graphite, 25 mm long and 12 mm in diameter. After repeated heating of the graphite cylinder to a bright red glow at about 800°C with an oxygen-gas torch, it was cooled and impregnated with a solution of 2g, of $PdCl_2$ in 100 cc of 10% HCl. After drying under infrared light, the graphite cylinder was heated over a Bunsen flame to dull red heat or about 550°C to decompose the palladium salt. The graphite was then waterproofed by immersion in a dilute Teflon emulsion, prepared by mixing 10 cm^3 of du Pont Teflon 30 emulsion with 100 cm^3 of water, containing 0.1 cm^3 of a non-ionic wetting agent (Triton X-100). After drying by infrared light at 100°C, the graphite cylinder was then baked at 400°C for 30 min, a procedure which destroyed the wetting agent and firmly sintered the Teflon particles to the palladium-impregnated graphite matrix (39). The graphite cylinder was tapped centrically to a depth of 12 mm at the upper end to receive a threaded nonporous graphite rod to which electrical contact was made by a platinum wire.

To start the experiment, the cell was filled with H_2, and the PbO_2 electrode connected to the graphite electrode through a low-resistance ampere-meter and voltage regulating means, *e.g.*, diodes or a variable voltage supply. The purpose of these means was to keep the potential of the graphite electrode at a less positive potential than that of the PbO_2 electrode (39). As constant currents were applied between the terminals, hydrogen generated at the negative lead electrode was electrochemically oxidized at the positive graphite electrode.

Steady state currents were determined for various H_2 pressures in the cell. At 760 mm Hg hydrogen pressure, electrodes activated in the described manner were able to oxidize hydrogen at rates up to 100 mA/cm^2 of geometric submerged electrode area. For a submerged area of 4.6 cm^2, currents up to 460 mA were therefore obtained. At the highest currents, the voltage drop across the two silicon diodes in series shown in Fig. 5 was about 1.32V. Since the open circuit potential of the PbO_2 electrode in sulfuric acid of 1.225 sp. gr. is 1.72V, the graphite electrode was forced to a potential of about 0.40V *vs.* H_2 at this current, and slightly more positive at smaller currents.

The influence of H_2 partial pressure on the steady state current at constant polarization of about 0.4V is illustrated in Fig. 6. It is clearly apparent that the current is approximately proportional to the square root of pressure, in agreement with Eq. [8]. The somewhat

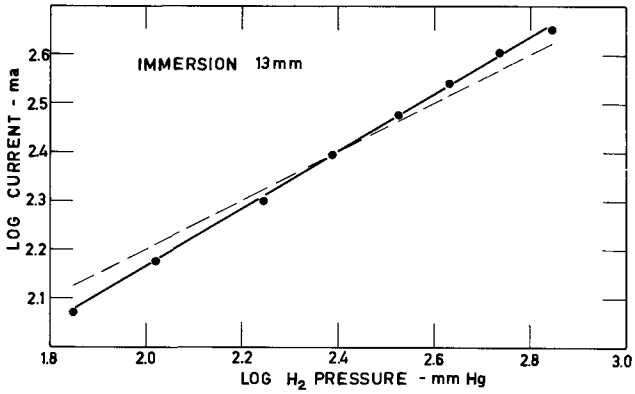

Fig. 6. Dependence of hydrogen oxidation current on hydrogen pressure at 0.4V polarization.

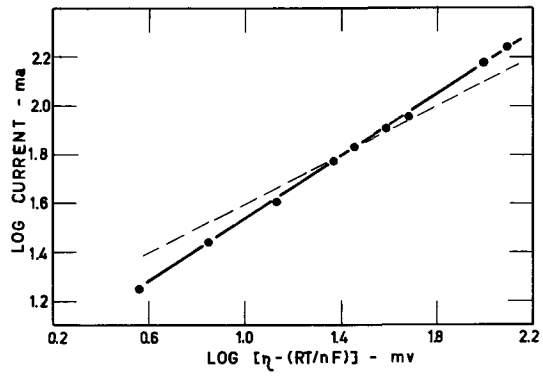

Fig. 8. Logarithm of current as a function of log $[\eta - (RT/nF)]$

higher than theoretical slope is probably due to heating effects in the wetting films.

The presence of foreign gases decreased the current. At 650 mm Hg of partial nitrogen pressure, *e.g.*, a partial hydrogen pressure of 130 mm Hg was required to produce 100 mA. In the presence of 430 mm Hg of carbon dioxide, the partial hydrogen pressure had to be 150 mm Hg to achieve the same steady state current of 100 mA. In the absence of foreign gases, the same current was obtained already at 65 mm Hg hydrogen pressure. Hydrogen diffuses considerably faster than oxygen. The accumulation of foreign gas in the pores produced therefore a smaller effect in the case of H_2 oxidation than of O_2 reduction.

Steady state currents were also investigated as a function of electrode potential at constant H_2 pressure of 760 mm Hg. A typical result is shown in Fig. 7. The electrode potential is here given with respect to a reversible H_2 electrode in the same solution. With the particular electrode immersion depth used in this experiment, the current reached a maximum of 190 mA when the hydrogen electrode potential was +1.5 to +1.7V, then passed through a minimum at +1.9V, and increased rapidly at more positive potentials. At the point of minimum current, visible oxygen evolution began on the graphite electrode. Above 1.9V, the relation between potential and logarithm of current became linear, representing a Tafel line for oxygen evolution. The result of Fig. 7 is very similar to a curve obtained by Will (23) for the oxidation of hydrogen on a partly immersed Pt rod. In Fig. 8, the logarithm of current has been plotted against

$$\log\left[\eta_a - \frac{RT}{n\mathbf{F}}\right]$$

The straight line up to potentials where adsorption inhibition sets in [3], that is at 1.5V, indicates, in accordance with Eq. [8], that H_2 diffusion through the wetting film is rate limiting. Solubility and diffusion coefficient of H_2 in sulfuric acid (40, 41) are smaller than the corresponding values for O_2. Again, the higher than theoretical slope is probably caused by local heating in the electrolyte films.

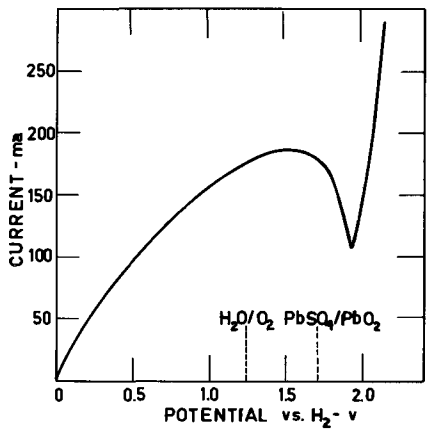

Fig. 7. Hydrogen oxidation rate as a function of electrode potential.

Conclusions

From the result of the present study, it may be concluded that for oxygen reduction on silver-activated, waterproofed porous graphite electrodes in sulfuric acid, the rate of ionization is the current limiting factor, except at the very highest currents investigated, where concentration effects started to interfere. For hydrogen oxidation on palladium-activated, waterproofed porous graphite electrodes in sulfuric acid, the rate of H_2 diffusion through the wetting films was limiting, except at the highest anodic potentials, where the rate of ionization became inhibited by adsorbed oxygen.

The technically important result is, that both hydrogen and oxygen may be consumed at high rates in sealed lead-acid cells on partly immersed porous, waterproofed electrodes, held at suitable potentials for the corresponding reactions.

Brief Communications

Electrodeposition of Titanium Diboride Coatings

David Schlain,* Frank X. McCawley,* and Charlie Wyche

College Park Metallurgy Research Center, Bureau of Mines, U. S. Department of the Interior, College Park, Maryland

Adherent, smooth coatings of titanium diboride, metallic in appearance and 3 to 6 mils in thickness, were electrodeposited on Inconel[1] from a molten salt electrolyte at 900°C (Fig. 1). The electrolyte consisted chiefly of $NaBO_2$ and $LiBO_2$ with smaller amounts of Na_2TiO_3, Li_2TiO_3, and TiO_2. The electrolytic cell was operated under an argon atmosphere at cathode and anode current densities of approximately 0.4 A/in.^{2} (6.2 A/dm^2). The coating was formed at the rate of about 1 mil/hr. The soluble titanium anode was stationary and the cathode was rotated at 250 rpm. The cell voltage was approximately 0.3V.

The deposits were identified as TiB_2 by x-ray diffraction. Titanium and boron were the only elements detected in the deposits by optical spectrographic analyses. However, it should be noted that both of the sampling techniques used, the laser microprobe and electrode transfer, may reduce the sensitivity of detection to the point where many trace elements would not be detected. Hardness measurements were made on surfaces and cross sections of the titanium diboride deposits using a Tukon Microhardness Tester with a Knoop indentor, a X50 objective, and a 100g load. Variations in hardness on the cross sections were random with respect to distance from the substrate; there was no indication of diffusion. The data in Table I show that the cross-section hardness of the electrodeposits is approximately the same as the hardness value Lynch and his co-workers obtained for annealed single crystals of TiB_2 (1), but that it is higher than those for unannealed single crystals of TiB_2 (1) or for hot-pressed material (2). However, the surface hardness of the electrodeposits was higher than any known value for TiB_2. Figure 2 is a cross section of a 2.3 mil thick deposit showing columnar structure and good bonding to the substrate.

Table I. Average Knoop hardness numbers

	KHN_{100}	Average deviation
Surfaces of TiB_2 electrodeposits	5000	300
Cross sections of TiB_2 electrodeposits	3200	200
Cross section Inconel substrate	232	5
Tungsten carbide[a]	1760	90
Hot-pressed TiB_2[b]	2710	
Single crystals TiB_2,[c] as grown	2800 ± 250	
Single crystals TiB_2,[c] annealed	3370 ± 375	

[a] Hardness measured in order to evaluate technique. Literature value for tungsten carbide is 1880 (3).
[b] Value given by Powell, p. 367 (2).
[c] Values given by Lynch and co-workers (1).

Initially, the electrolyte contained 39.08% $NaBO_2$ (33.08 m/o), 58.62% $LiBO_2$ (65.79 m/o), 0.99% Na_2TiO_3 (0.39 m/o), 0.76% Li_2TiO_3 (0.39 m/o), and 0.55% TiO_2 (0.38 m/o). Residual moisture was carefully removed from each component before preparing the mixture. Prior to the preparation of the coatings the electrolyte was conditioned by 12 hr of electrolysis with a titanium anode and a cathode of molybdenum or Inconel. During the conditioning step, the titanium content of the bath increased from 1 to 2.3%. Deposits made during this period consisted of dark, fine, nonadherent powder over a bright, consolidated, adherent coating. The quantity of material which was in the form of powder became progressively less with successive deposits. The powder was identified by x-ray diffraction as chiefly TiB_2 with a minor amount of TiO. At the end of the series of experiments the platinum crucible was found to have been attacked; the corrosion product contained platinum and titanium.

Andrieux (4) and Powell (2) have described the electrodeposition of TiB_2 from molten baths such as MgO, MgF_2, $2B_2O_3$ and ½ TiO_2 or 2CaO, CaF_2, $2B_2O_3$, and ¼ TiO_2, but the material was deposited only in the form of fine crystals or powders. The use of powder metallurgy techniques is required to form such powders into massive articles. Mellors and Senderoff described the electroforming and the electrodeposition of coherent coatings of ZrB_2 from a molten bath of LiF-KF-K_2ZrF_6 containing 12 w/o KBF_4 at 800°C (5, 6).

Fig. 2. Cross section of titanium diboride coating on molybdenum. Deposit is 2.3 mils thick and has columnar structure. Magnification approx. 430X.

Satisfactory coatings of TiB_2 will find many applications. The material is extremely hard and has high electrical conductivity, low volatility, and a high melting point (*ca.* 2600°C). It is stable up to the melting point. Titanium diboride is resistant to oxidation up to 1400° to 1500°C, superior in this respect to most other borides.

Manuscript received May 5, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electrochemical Reduction of the Benzene Ring by Electrogenerative Hydrogenation

Stanley H. Langer and Sergei Yurchak

Chemical Engineering Department, University of Wisconsin, Madison, Wisconsin

Benzene is notoriously difficult to hydrogenate by conventional cathodic electrochemical means, often requiring complex solvent mixtures and high potentials while reaction does not proceed stoichiometrically (1-5). This prompted us to attempt the electrochemical reduction of benzene with the electrogenerative hydrogenation technique (6) whereby the favorable thermodynamic driving force of the reduction is brought to bear on the reaction; a positive potential is generated and no external power source is necessary. Hydrogen (at the anode) and benzene (at the cathode) were reacted at catalytic porous electrodes separated by strong acidic electrolyte for hydrogen ion transport with generated current being conducted through an external circuit. Benzene reacted to give cyclohexane at a porous platinum black electrode (7, 8) in a conventional filter paper matrix cell (6-8) as well as in a horizontal liquid cell in which a platinized platinum screen electrode was placed at the liquid aromatic-liquid electrolyte interface.

Over-all reaction may be represented as

$$\text{Anode:}\quad 3H_2 \rightarrow 6H^+ + 6e \qquad [1]$$

$$H^+ \text{ transported through electrolyte} \qquad [2]$$

$$\text{Cathode:}\quad 6H^+ + 6e + C_6H_6 \rightarrow C_6H_{12} \qquad [3]$$

Some data from our ensuing study of electrogenerative hydrogenation of benzene, toluene, and fluorobenzene vapors on several American Cyanamid porous noble metal-Teflon electrodes (7, 8) are reported in Table I.

Nitrogen saturated with the aromatic compound at room temperature was passed through the cathode compartment at an excess rate so as not to affect current. The platinum black hydrogen anodes exhibit

negligible polarization at the current densities of this study (7, 8). The electrolyte matrix consisted of 4 sheets of filter paper saturated with 3*N* perchloric acid. All experiments were performed at room temperature. The system was designed so that coulometric data could be obtained (6). The current generated by the hydrogenation cell was equivalent to hydrogen consumed as measured by gas volume changes. The effluent cathodic product gas mixture was collected in gas bulbs and analyzed by gas-liquid chromatography.

Under favorable reaction conditions, the open-circuit potentials of Table I were surprisingly close to the calculated ones as had been observed for olefins (6). Hexafluorobenzene also gives an open-circuit potential (~ 0.19V); this and consideration of our earlier results for olefin-hydrogen cells (6) would indicate that the characteristic open-circuit potentials of these cells does not result from dissociative carbon-hydrogen adsorption (9, 10) although this process probably takes place under some conditions on the electrode surface. However, with cyclohexene on platinum, the open-circuit potential could be a consequence of disproportionation and bezene (11, 12) formation at the cathode. Indeed benzene was found in the effluent stream at all current densities studied.

On platinum, while benzene was hydrogenated quantitatively to cyclohexane (cyclohexene was less than 0.1% if present at all), electrochemical hydrogenation of toluene to methylcyclohexane accounted for only about 80% of the observed current; the remainder was due to simple electrochemical hydrogen transport (13, 14) to the reducing electrode gas stream from whence it was analyzed in the exit stream. The electrochemical reduction of fluorobenzene gave an approximately equal mixture of cyclohexane and benzene, probably a result of relatively strongly adsorbed fluorobenzene displacing benzene. The hydrogenolysis of the carbon-fluorine bond to give benzene is of interest since a similar hydrogen treatment in a chemical system gave only cyclohexane (15). With the other metals and substrates of Table I, electrochemical hydrogen transfer accounted for at least 75% of the generated current. It would appear that electrochemical discharge of hydrogen ions to form atoms and a subsequent addition to the substrate (16), where kinetically favored, is the initiating sequence of events in aromatic electrogenerative hydrogenation.

The currents of Table I at given voltages are an approximate measure of over-all reaction rates especially when product analyses are taken into account. On this basis, the order for electrochemical hydrogenation of aromatics is Pt >> Pd ~ Ru—approximately the same as that observed for chemical hydrogenation (17). However, the low electrochemical activity of palladium relative to platinum is in contrast to the earlier results of Langer and Landi (6) for electrogenerative ethylene hydrogenation where the metal activities were quite comparable. A similar diminution in activity has been observed for chemical hydrogenation of benzene (18,19). In a nitrogen-hydrogen concentration cell (13, 14) the activity sequence was Pt ≈ Pd > Ru with platinum being more active than ruthenium by less than a factor of two. Thus differences in reduction rate would seem to be an indication of catalytic effectiveness for reaction of aromatic substrate with hydrogen atoms (under these conditions) rather than a measure of rate of hydrogen ion discharge. Improving catalytic activity through alloying of platinum as reported for ruthenium-platinum (20) catalysts would seem to be a strong possibility. Because of its advantages and the similarity between electrogenerative catalytic activity and conventional catalytic hydrogenation, we hope to continue our investigation of electrogenerative aromatic systems.

Mechanical Properties of Metal Oxide Films

J. C. Grosskreutz

Center for Applied Research on Materials, Midwest Research Institute, Kansas City, Missouri

ABSTRACT

A brief review is given of mechanical property measurements on oxide films. This review is followed by a detailed discussion of the mechanical and fracture properties of anodic aluminum oxide films as observed in the author's laboratory. Extensive measurement of Young's modulus, E_c, and fracture strain, ϵ_f, for separated films 3000Å thick is reported as a function of environmental water vapor pressure. The fracture of these unsupported films is shown to occur by a brittle mechanism. Mechanical properties of adhering aluminum oxide films are given as a function of their thickness. These oxides were observed to fracture either at slip steps, or at right angles to the tensile axis in a regularly spaced fashion. A theory of adhering oxide fracture is discussed which accounts well for the observations. An equation which describes the spacing d of regular oxide fracture cracks as a function of substrate strain ϵ is given in the form $\ln(\epsilon/\epsilon_o) = k\sqrt{t}(1/d - 1/d_o)$, where (ϵ_o, d_o) are the initial conditions for regular fracture, t is the oxide thickness, and k is a constant.

The effect of oxide coatings on the mechanical properties of the metal substrate was first observed nearly 35 years ago (1). In general the effect of the coating is to increase the critical resolved shear stress for plastic yielding in the substrate. The thickness of the oxide and the thickness of the substrate both have an important bearing on the magnitude of the effect. Not only oxide layers, but other surface films as well can significantly affect the macroscopic stress-strain behavior (2). More importantly, surface oxide layers can often have a direct effect on the fracture of the substrate, particularly in the cases of fatigue and stress corrosion cracking.

The above macroscopic effects are the result of certain microscopic, surface events which depend sensitively on both the presence and the properties of the oxide film. For example, dislocations can either be attracted or repelled by the surface, depending on whether the elastic modulus of the oxide, E_c, is less than, or greater than, the modulus of the substrate E_s (3). For a certain range of the ratio E_c/E_s, dislocations become trapped at the oxide-metal interface (4). The way slip steps develop at a surface will be quite different depending on whether or not the oxide fractures. For example, the formation of slip band intrusions and extrusions, which act as fatigue crack nuclei, can occur only after rupture of the original oxide film. Finally, microfractures in the protective oxide coating on metals like stainless steel and titanium may provide the initiation site for stress corrosion cracking.

Any quantitative treatment of these microscopic events requires a knowledge of the mechanical and fracture properties of the oxide film as well as the substrate metal. For this reason, there has recently developed an intense interest in the measurement of these oxide properties. It is not enough to assume that the properties of bulk alumina, for example, can be used to describe a natural aluminum oxide layer which is amorphous and only 50Å thick. Rather, it is necessary that measurements be performed on very thin oxide films which have been separated from their substrate, or that measurements on the oxide-metal system be made in such a way that the mechanical and fracture properties of the oxide can be inferred.

Except for some early measurements of the tensile strength of completely oxdized wire ($\sim$ 0.010 in. — 0.030 in. diameter) (5), the first comprehensive study of thin oxide films was made by Bradhurst and Leach on adhering and separated Al_2O_3 films (6). The fracture strain of adhering films was measured by a variety of techniques, and stress-strain curves of separated films 1500Å thick were obtained from which Young's modulus and the fracture stress and strain could be obtained. The thin films were about five times stronger than bulk alumina and could be strained about ten times more prior to fracture. In the five years since these results were published, several other workers have attacked the problem with various modifications in technique (4, 7-9).

Reliable measurement of the mechanical properties of thin oxide films, whether adhering or separated, is difficult. Nearly always the natural oxide must be enhanced in thickness by anodization or thermal treatment in order to make any measurement at all. Thus, the question remains open as to whether the results are indeed representative of the natural oxide layer. There is also a large scatter in the measured values of moduli and fracture stresses which is most likely due to variations in the films or to problems in experimental technique. These difficulties notwithstanding, the results thus far reported have been quite useful.

In the paper which follows, the mechanical and fracture properties of both separated and adhering aluminum oxide films are reported. Part of the paper is an extension of earlier work which demonstrated the effects of water vapor on the properties of separated films (4). In addition, some new measurements are given for the fracture strain of adhering films as a function of their thickness. Finally, an extensive analysis of the fracture of adhering coatings is given, and the results are compared with both existing and new data. An important feature of this work is the ability to deal quantitatively with the fracture of adhering films.

Mechanical Properties of Separated Al_2O_3 Films

The oxide films used in these measurements were grown to 3000Å thick on 99.99% Al in tartaric acid electrolyte.[1] These anodic films are coherent and amorphous and resemble closely the natural oxide film (10). Thin film specimens 2 x 6 mm were prepared by (*a*) coating the anodized sheets of aluminum with Kodak KMER photoetch resist; (*b*) placing a mask over the sheet so as to expose a large number of rectangular areas 2 x 6 mm to ultraviolet light; (*c*) removing the unexposed photoresist and dissolving the unprotected anodic film in 2% hydrofluoric acid solution; and (*d*) removal of the exposed photoresist which still covered the "islands" of aluminum oxide. The sheet of anodized aluminum was then cut into individual rectangles, each containing an Al_3O_2 sample. The thin films were removed from these substrates by amalgamation in mercuric chloride.

[1] Thickness was measured by (*i*) using the growth relation of 13.5 Å/V in this electrolyte, and (*ii*) by direct measurement in the electron microscope. The figure 3000Å is accurate to ±5%.

Stress-strain curves for these separated anodic films were obtained by means of a specially constructed microtensile tester. The ends of the separated film were carefully glued with Eastman 910 cement to a fixed and to a movable grip. The driving force for the movable grip was supplied by thermal expansion of a silicone oil which is contained in the space between concentric fixed and movable cylinders. Expansion of the oil drives the movable cylinder to which the movable grip is attached. Displacement of the movable grip was measured by a photopotentiometer, and the load applied to the specimen was measured by semiconductor strain gauges mounted on a proof ring. The electrical output of the photo pot and the strain gauge bridge was fed to an XY recorder so that load-displacement curves were plotted directly. The displacement sensitivity of the apparatus is 0.2 μ/cm of chart and the load sensitivity is 0.7 g/cm of chart. The apparatus is mounted in an enclosed chamber which allows control of the surrounding atmosphere.

These films behave elastically to the point of fracture. Values of Young's modulus, E_c, the fracture stress σ_f, and the fracture strain, ϵ_f, were obtained from each stress-strain curve. Results are shown in Fig. 1, where E_c is plotted as a function of the absolute humidity. The remarkable increase of E_c with decreasing water vapor content, which was previously reported (4), is seen to occur monotonically with decreasing water vapor content. The decade between 10^{-4}-10^{-5} g/m^3 of water vapor was not explored. It represents the gap between the driest air we could obtain and a vacuum of 1 x 10^{-5} Torr. As the oxide films were exposed to lower vacua, the modulus increased toward the value for bulk, crystalline γ-Al_2O_3 (marked on the ordinate of Fig. 1). Values for ϵ_f (and hence σ_f) were subject to considerable scatter, due principally to defects in the films and occasional fracture at the grips. Nevertheless, a trend was clearly observable as water vapor concentration decreased. In the range 10^{-2}-20 g/m^3, ϵ_f was fairly constant and $\approx$ 3 x 10^{-3}. At lower values of the humidity, ϵ_f decreased, reaching a value $\approx$ 1.5 x 10^{-3} in the range 10^{-5}-10^{-6} g/m^3.

While it is intriguing to speculate on the mechanism by which the removal of water vapor increases the modulus of these films, it is more useful at this point to analyze the data in terms of fracture mechanisms. Examination of the fracture of adhering oxide films (see section on Fracture of Elastic Oxide Coating on Aluminum) has shown that all fractures begin at defects in the oxide. This observation, coupled with the purely elastic behavior of these films, suggests that fracture may be occurring by a brittle (Griffith) mechanism. If such be the case, the nominal fracture stress will be given by

$$\sigma_f = (\gamma E_c/2c)^{1/2}$$

where γ is the average surface energy, and c is the size of the flaw at which the crack begins.

The ratio of the fracture stress in vacuum to that at nominal air pressures is then given by (assuming crack growth is too rapid for γ to be affected by environment)

$$\frac{\sigma_f(\text{vacuum})}{\sigma_f(\text{air})} = \left(\frac{E_c(V)}{E_c(A)}\right)^{1/2} = \frac{\epsilon_f(A)}{\epsilon_f(V)}$$

This equality can be checked by substituting our experimental values for ϵ_f and E_c measured in vacuum and in moist air. For the ratio of fracture strains, we find the value 1.96; for the square root of the ratios of Young's moduli, we find 2.0. This rather good agreemen is consistent with the hypothesis that the fracture proceeds by a brittle mechanism.

If one assumes that the average surface energy for Al_2O_3 is approximately 10^3 ergs/cm^2, then the average length c of the microcracks which cause failure is c $\cong$ 300Å.

The advantage of measuring the mechanical properties of separated oxide films is that it is direct and unambiguous. On the other hand, experimental techniques are extremely tedious and time-consuming, and only about one-fifth of the test attempts are successful. Thus, the greater amount of effort and time required to obtain statistically significant measurements is only justified if there are not other means for obtaining the same, or related data. Although ϵ_f can be obtained by simpler methods (see next section), E_c has not yet been measured by methods other than the one described in this section.

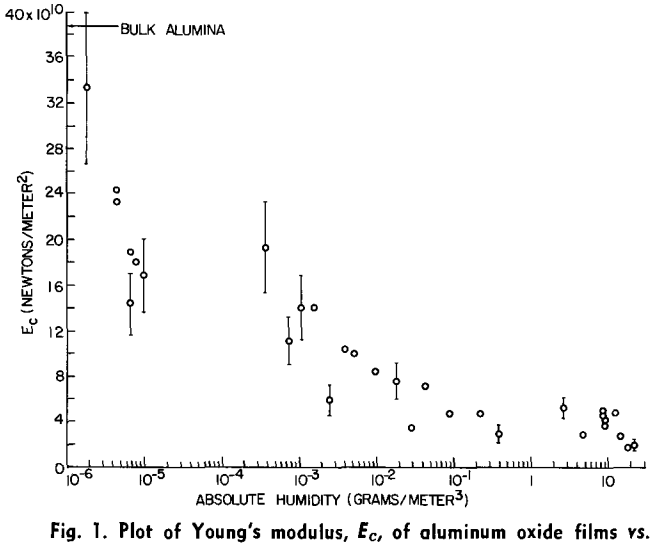

Fig. 1. Plot of Young's modulus, E_c, of aluminum oxide films vs. water vapor concentration. Each point represents one test. Error of $\sim$ 20% is shown for selected points.

Mechanical Properties of Adhering Al_2O_3 Films

Although Young's modulus for an adhering oxide film has not yet been measured, the environmental effect which was reported in the previous section does indeed hold for adhering, natural oxide films on aluminum. This conclusion was reached in an earlier paper (4) in which the behavior of dislocations near the surface was observed by means of transmission electron microscopy. The fact that dislocations were trapped near the oxide metal interface under vacuum, but did not accumulate there under normal atmospheric conditions could only be interpreted in terms of a change in the elastic modulus of the oxide under these two different conditions.

Direct measurement of fracture strains for adhering oxides are, however, easily obtained. The technique we have used involves pulling an anodized aluminum sample in an Instron testing machine until the oxide fractures. A water-tight cell of molded silicon rubber was built to surround a portion of the gauge length. The cell was filled with the anodizing solution and a 5V potential applied between the sample and a platinum electrode. Any microcrack which occurs in the oxide film will then produce a current flow in the cell. The fracture strain ϵ_f is then taken as the macroscopic strain at which measurable current begins to flow.

Values of ϵ_f for various thicknesses of anodic films on 1100-0 aluminum are given in Table I. A few results are also included for films on some of the more common alloys of aluminum.

The lower fracture strains recorded for the thinner oxide films on high-purity and commercially pure aluminum can be accounted for in terms of the observed fracture modes. The thinner films are observed to crack along slip bands whereas the thicker films fracture at right angles to the applied tensile load without regard for crystallographic orientation. (A detailed analysis of these two fracture modes is given in the next section.) Inasmuch as the measured frac-

Table I. Fracture strain, ϵ_f, of anodic layers on various aluminum substrates

	1500	$(5.5 \pm 0.7) \times 10^{-3}$
2024-T4	1500	$(3.1 \pm 0.4) \times 10^{-3}$
7075-T6	500	$(1.7 \pm 0.4) \times 10^{-3}$
	1000	$(2.5 \pm 0.3) \times 10^{-3}$
	1500	$(2.0 \pm 0.2) \times 10^{-3}$

ture strain, ϵ_f, is actually the macroscopic strain in the substrate-oxide system at which oxide failure begins, we conclude that (*i*) the values quoted for the thicker coatings are characteristic of the strains in the oxide at fracture, and (*ii*) that strain concentrations of the order of 3 occur at the slip steps where fracture occurs for the thinner coatings.

The correlation of these fracture strains with those observed for separated anodic films must be made with caution. Values quoted in Table I are strictly applicable only for films fractured in a tartaric acid electrolyte. These differences in environment notwithstanding, the agreement between the fracture strain of adhering films on high-purity aluminum and separated films fractured in a high-humidity atmosphere is quite good.

Fracture of Elastic Oxide Coatings on Aluminum

Mechanisms of fracture.—In the previous section, the observation was introduced that the mode of oxide fracture depended on the thickness of the coating. In general, films 500Å thick or less on high-purity aluminum will fracture at slip steps when the substrate is strained. The frequency and spacing of these cracks appears to be determined entirely by the plastic deformation of the substrate. On commercially pure aluminum (1100-0) somewhat thinner films are necessary for the slip step cracking mode to occur (Table I). For thicker films on these substrates and for all of the films we have observed on high-strength aluminum alloys, regularly spaced cracks occur at right angles to the tensile axis, *e.g.*, Fig. 2.

The development of these regularly spaced cracks is interesting. Cracks initially appear at the defects in the oxide (Fig. 2) and are randomly spaced at rather wide intervals. Although the fracture strains recorded by the potentiometric method (Table I) are

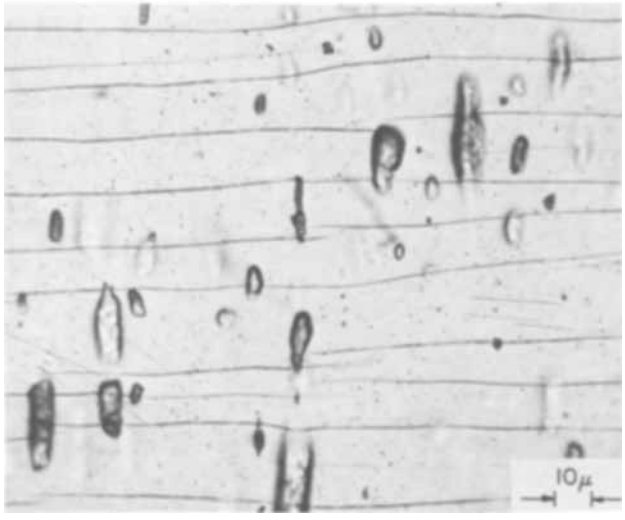

Fig. 2. Regular fracture of 1500Å anodic film on 1100-0 Al. Tensile axis at right angles to cracks (optical micrograph).

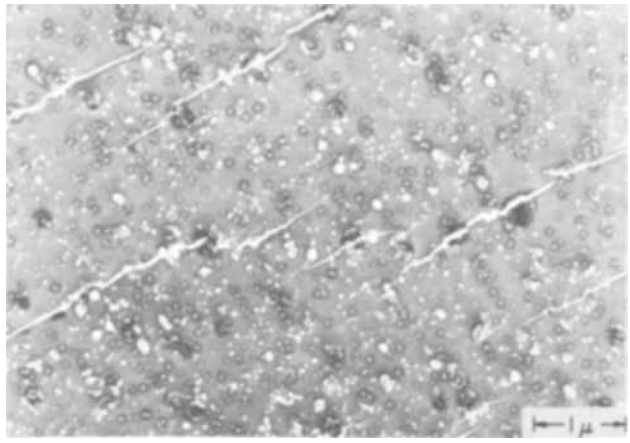

Fig. 3. Regular fracture cracks in 1500Å anodic film grown on 7075-T6 Al showing initiation at defects (electron micrograph).

of the order of 3×10^{-3}, cracks are not observed at optical magnification (1000X) until strains of about 0.01 are reached. As the substrate is further strained, additional random cracks appear and existing cracks continue to grow in length. A point is reached where interaction between adjacent cracks apparently reduces the probability of further crack formation between them. Eventually this "minimum random crack spacing" exists between all cracks and the sample is rather uniformly filled with cracks. Additional straining now begins to produce cracks at the midpoints between existing cracks, and this mechanism continues (with the crack spacing being approximately halved with the formation of each new generation of cracks) until the crack density reaches some saturation value. Further straining of the substrate then produces only a widening of the existing cracks. Similar observations were reported by Edeleanu and Law (11).

Regular fracture cracks initiate almost entirely at defects in the oxide film. (And for this reason the crack spacings are statistically scattered about mean values.) Unusually good micrographs have been obtained by transmission electron microscopy of anodic films strained to fracture on a 7075-T6 substrate. Portions of the substrate were electropolished away leaving the oxide film intact across the perforation. Figure 3 illustrates some of these cracks.

Two experiments were performed to determine whether plastic deformation in the substrate had any significant effect on the mechanism of regular fracture of the oxide coating. In the first experiment three aluminum alloys with different yield stresses were anodized to 1500Å thickness and pulled well into the plastic region ($\epsilon = 0.045$). The average spacing of the cracks in the oxide was then measured. Results are shown in Table II. The obvious conclusion is that the density of cracks is not influenced by differences in the plasticity of the substrate.

The second experiment was designed to look directly for evidences of plastic deformation in the regions just below cracks in the oxide layer. Specimens of 7075-T6 which had been anodized to 1500Å and pulled to a strain of 0.045 were thinned to electron transmission thickness by electropolishing from

Table II. Regular fracture spacings on substrates having different yield stresses

Substrate	(Spacings measured at $\epsilon = 0.045$) Yield stress (psi)	Average fracture spacing (microns)
7075-T6	61,950	3.3
7075-W	36,500	3.3
2024-T4	47,000	3.1

the side opposite the oxide coating. Dislocation structures which were characteristic of the alloy were observed, and there were no variations in dislocation density in the vicinity of oxide cracks. From this and the preceding experiment, it was concluded that the mechanism of regular fracture depends only on the total strain in the substrate.

Theory of oxide fracture.—In a recent paper (12) Grosskreutz and McNeil considered the theory of oxide fracture on a strained substrate. For those substrates which deform by slip we showed that fracture at a slip step occurs only if the oxide coatings are unable to sustain the tensile stresses necessary to separate and peel the oxide from the substrate in the vicinity of the slip step, Fig. 4(a). Fracture is more likely to occur for thinner films and lower fracture strains. Because the adhesion stresses between oxide and substrate are not known with any degree of certainty, it was impossible to predict accurately the conditions under which fracture at slip steps occurs. However, assuming the shear adhesion stress to be the maximum shear strength exhibited by whiskers, and inserting the fracture strain of adhering oxides into the formulas, we found that an oxide thickness of approximately 500Å forms the dividing line between the fracture and nonfracture at a slip step, in agreement with the results of the section on Mechanical Properties of Adhering Al_2O_3 Films.

In the case of thick (> 500Å) anodic coatings, or if substrate slip does not occur before the oxide fracture strain is reached, regular fracture will occur in the manner described in the preceding section. Quantitative treatment of the development of these fractures is possible in the following way. Suppose that a crack has occurred at a randomly located defect in the oxide. In the immediate vicinity of this crack the stress in the oxide layer will be relaxed and will not build back up to the fracture stress until some distance removed from the initial crack. This situation is shown schematically in Fig. 5(a). We represent the stress in the coating, σ_c, as

$$\sigma_c(x) = \sigma_f - \Delta\sigma; \quad x > w/2$$

where $\Delta\sigma$ is the stress relaxation. In ref. (12) we took $\Delta\sigma$ to be equal to $g\sigma/x$ where σ is the nominal stress level in the coating and g is a parameter with dimensions of length. Under these conditions the stress in the coating builds asymptotically back toward σ_f as x approaches infinity. Theoretically, the next crack will occur at $x = \infty$ where $\sigma_c = \sigma_f$. Actually, because the fracture stresses in the oxide will be distributed around a mean value, the next fracture will occur wherever σ_c exceeds the local fracture stress at some given defect.

Random cracking will continue until two cracks appear closely enough together that their stress fields interact to give a significant reduction in the coating stress at all points between the two cracks. This situation is illustrated in Fig. 5(b). The stress in the coating between the two cracks can now be represented as

$$\sigma_c(x) = \sigma_f \left[1 - g\left(\frac{1}{x} + \frac{1}{d_o - x}\right)\right]; \quad w/2 < x < (d_o - w/2) \quad [1]$$

At the midpoint, $x = d_o/2$

$$\sigma_c(d_o/2) = \sigma_f\,[1 - 4g/d_o] \quad [2]$$

As a boundary condition on Eq. [1] we have that at $x = w/2$ and $d_o - w/2$, $\sigma_c = 0$. For this condition to hold

$$g = w/2 - w^2/4d_o$$

In general, $w << 4d_o$ and we can write $g = w/2$.

In this treatment w is the crack width, illustrated in Fig. 5. Actually, the crack will look more nearly like the schematic drawing shown in Fig. 6 because of the relaxation of the shear stress in the film as the free surface is approached. If the appropriate value of w is taken to be the crack width at the top surface of the oxide film, then w can be expressed in terms of the thickness, t. The free surface of the cracked film can be approximated either as linear (dashed line, Fig. 6) or as parabolic. In these two approximations, g would be given as

$$g = w/2 = k't \text{ --- (linear approximation)} \quad [3a]$$

or

$$g = w/2 = k\sqrt{t} \text{ --- (parabolic approximation)} \quad [3b]$$

Once the configuration shown in Fig. 5(b) obtains over the entire surface of the strained oxide, regular cracking can proceed if the stress in the oxide film is raised until the stress at $x = d_o/2$ reaches σ_f. Additional cracks will occur at $x = d_o/4$, $d_o/8$, etc., as the stress is increased continuously.

Given this model for the multiplication of cracks, it can be shown that (12)

$$\ln \epsilon/\epsilon_o = (4g/d)\,[1 - d/d_o] \quad [4]$$

where ϵ_o and d_o are the substrate strain and oxide fracture spacing for which the coating begins the process of regular fracture. Given the initial conditions (ϵ_o, d_o),

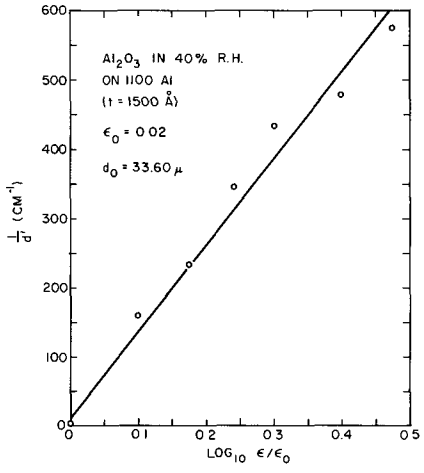

Fig. 7. Plot of crack density $1/d' = \left(\frac{1}{d} - \frac{1}{d_o}\right)$ vs. $\log_{10} \epsilon/\epsilon_o$ for anodic film on 1100-0 Al pulled in laboratory air.

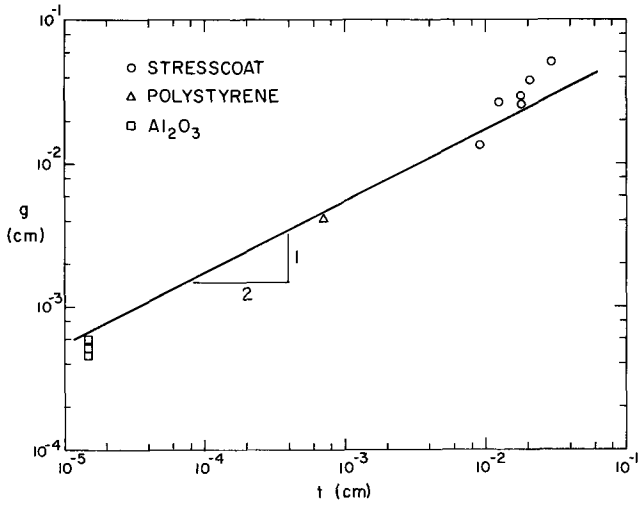

Fig. 8. Plot of g (Eq. [4]) vs. film thickness, t. Solid line has slope of 1/2.

Eq. [4] allows us to predict the spacing, d, at any subsequent strain, ϵ. The constant, g, depends on the thickness of the film (Eq. [3]) with a constant of proportionality, k, to be determined by experiment.

An interesting consequence of our model of regular fracture is that when d is of the order of $2g = w$, further cracking should not occur. Thus, the saturation crack spacing, d_s, should be larger, the thicker the oxide film.

Experiments on regular fracture.—Equation [4] has already been checked (12) against published crack density *vs.* strain data for both Al_2O_3 and "stresscoat," a brittle surface coating used to determine surface stress distributions. In both cases, the fit of the data with the theoretical equation was excellent. Further verification is shown in Fig. 7 where recent measurements of crack density in an adhering, anodic coating are fitted to Eq. [4]. Data on regular fracture of anodic layers strained under distilled water and in dry air have also been compared with Eq. [4] with equally good agreement. The fracture spacings in a thin polystyrene film on a cellulose acetate substrate have correlated well. There is a wealth of experimental data on "stresscoat" of various thicknesses and fracture strains with which Eq. [4] can be compared (13). All of these different data have been analyzed to yield values of the parameter, g. Table III lists the important results.

The first item of interest is the dependence of g on the thickness of the oxide coating. A log g *vs.* log t plot is shown in Fig. 8, and it is evident that the parabolic dependence assumed in Eq. [3b] most nearly fits the experimental results. The parameter k in the expression $g = k\sqrt{t}$ has the dimensions of (length)$^{1/2}$ and varies between 0.1 and 0.25 for the data recorded in Table III.

A second item of interest in Table III is that the parameter, g, is independent of ϵ_o for a given thickness of coating. Finally, we note that the saturation crack spacing, d_s, is very nearly equal to $2g$, as predicted, for the majority of cases cited.

The predictive value of Eq. [4] remains limited because the initial conditions (ϵ_o, d_o) cannot be expressed in terms of measurable, mechanical properties of the oxide film. ϵ_o is certainly related to ϵ_f, the fracture strain, but is, in fact, somewhat larger by an indeterminant amount depending on the distribution of fracture strengths about the mean. The parameter d_o is surely a function of the physical properties of the film, but as yet no quantitative relationship has been derived without introducing yet another parameter, equally difficult to estimate.

Table III. Analysis of fracture spacing data in terms of the parameters in Eq. [4]

Coating	Thickness, t (cm.)	ϵ_o	d_o (cm.)	g (cm.)	$d_{sat}/2g$
Al_2O_3[a]	1.5×10^{-5}	0.02	3.4×10^{-3}	4.6×10^{-4}	1.24

Effects of Environment on Fracture of Adhering Films

Because water vapor was observed to have such a marked effect on the mechanical behavior of separated oxide films of aluminum (Fig. 1), an experiment was performed to determine whether similar effects could be observed for adhering films. Two sets of anodized, 1100-aluminum samples were pulled in tension, the one immersed in distilled water and the other contained in an atmosphere of dry air whose dew point was −60°C. Results are plotted in terms of d *vs.* ϵ in Fig. 9. That an effect exists is clear from the data. It was not

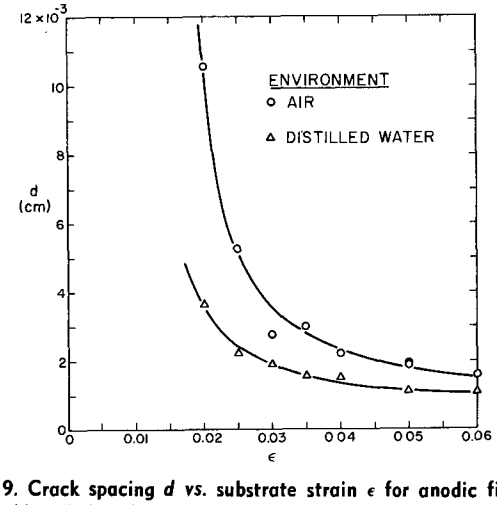

Fig. 9. Crack spacing d vs. substrate strain ϵ for anodic films on 1100-0 Al pulled under distilled water and in a dry air (dew point −60°C) environment.

possible to measure the onset of fracture of these films in a manner consistent with that reported in the section on Mechanical Properties of Separated Al_2O_3 Films. However, optical examination of the films showed that detectable cracks occurred at a lower strain for the sample immersed in distilled water than for the dry oxide. This observation is contrary to the results obtained on separated films where the fracture strain was higher for films in an atmosphere of saturated water vapor.

Analysis of the curves in Fig. 9 in terms of Eq. [4] reveals that both sets of data give the same value of g. Hence, we can conclude that g is independent of E_c. On the other hand, we must account somehow for the fact that smaller crack spacings occur in the wet film for a given total strain. The best explanation for this behavior is in terms of the relative magnitude of ϵ_o for the two cases. The fact that the wet film started to crack earlier allowed uniform coverage with cracks at a lower strain than for the dry sample. Hence, the progress of regular fracture is more advanced at a given strain in the case of the wet film.

The difference in the influence of moisture on the strain at which cracks grow in adhering and separated films must be attributed to the effect of the substrate. The details of this interaction are not yet clear and will require further experimentation.

Conclusions

From this survey of the mechanical properties and fracture behavior of separated and adhering aluminum oxide films several important conclusions can be drawn.

1. Separated aluminum oxide films fail by a brittle mechanism. Increasing water vapor concentration decreases both E_c and σ_f and raises ϵ_f, consistent with such a mechanism.

2. The fracture strains measured on separated and adhering Al_2O_3 films are of the same order of magnitude, *i.e.*, 1-3 x 10^{-3}; however, the effect of environment on the strain at which cracks grow appears to be different for separated and adhering films.

3. Fracture of adhering oxide films may occur at slip steps or regularly spaced at right angles to the tensile axis. The choice of mode depends on the oxide thickness, on ϵ_f, and on the adhesion stresses between the oxide and substrate.

4. Initiation of regular fracture is dominated by defects in the oxide.

5. The mechanism of regular fracture is mainly elastic; plasticity in the substrate does not play a major role.

6. The dependence of regular fracture spacing on ϵ is well accounted for by the expression $\ln \epsilon/\epsilon_o = [kt^{1/2}](1/d - 1/d_o)$. The saturation (minimum) spacing $d_s \cong 2kt^{1/2}$.

Acknowledgments

The author would like to acknowledge the Metallurgy Branch of the Office of Naval Research for their continued support, and to thank Dr. W. G. Rauch and Dr. R. C. Carlston for their encouragement. Mr. C. Q. Bowles performed the difficult experiments on separated oxide films, and Dr. Michael McNeil and Mr. David K. Benson provided stimulating discussion concerning the interpretation of regular fracture mechanisms. This work was supported by the Office of Naval Research, Contract No. Nonr-3908(00).

An Imaging Technique for Studying Localized Electronic Conduction in Valve Metal-Oxide Systems

N. Ramasubramanian

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

The light sensitive and semiconducting properties of cuprous iodide are used in a new technique for studying the electronic conduction behavior of oxide films on valve metals. Information about the distribution and nature of the conduction sites can be obtained. The chief advantage of this method over existing methods is that specimens biased to positive or negative potentials can be tested. The resolution (size of the copper deposits in the image) is better than or equal to that of the other methods. Specimens can also be studied directly by optical and/or electron optical means at different stages during the testing, because the process is a solid-state one. Oxide films on zirconium and its alloys were studied.

The color change associated with redox indicators in going from one state to another has been used to detect easy paths of electronic conduction in valve metal-oxide systems (1, 2).

In our research program on the corrosion behavior of zirconium and its alloys, electron transport through zirconia films is one of the important factors (3). The presence of localized conduction sites was indicated by

preferential reduction of Ag^+, Cu^{++}, Au^{+++}, or MnO_4^- from suitable electrolytic baths at these areas and by the iodide printing technique (1). We were interested in developing a technique that was nondestructive and could be used to study these conduction sites during both anodic and cathodic polarization of the metal or alloy. In the imaging technique described here, use is made of the photosensitive properties of cuprous iodide. The iodide is reduced to the metal at sites of electronic current flow and the deposits may be examined by optical and/or electron optical means. Current-voltage measurements, which were complementary to the observations by the imaging process, were obtained using aqueous electrolyte or evaporated metal counterelectrodes.

Experimental

Materials.—Oxide films on zirconium and Zircaloy-2 grown by anodic and thermal means were tested. Paddle shaped samples (the blade portion measuring 2x2x 0.1 cm) were cut from material supplied by Wah Chang Corporation and Foote Mineral Company. The surface preparation employed was the standard procedure of abrasion followed by pickling in a hydrofluoric-nitric acid bath. Anodic films were grown in a variety of electrolytes and thermal films in flowing oxygen at 300°C.

Imaging technique.—The method consisted of two parts, *viz.*, evaporation onto the oxide surface of a thin film of cuprous iodide followed by either the image recording step or current-voltage measurements with a suitable counterelectrode.

The system was pumped to 10^{-6} Torr and cuprous iodide was evaporated onto the oxide surface from a platinum boat at a rate of ~25 Å/sec. The specimen to source distance could be varied and was maintained at ~5 cm. Cuprous iodide showed a sequence of color changes with increasing temperature and the heater current was adjusted to maintain the orange-red color during evaporation.

A control strip of pickled zirconium foil of known area was attached to the specimen during the iodide evaporation and covered part of the specimen surface. The iodide from the control strip was dissolved and the copper determined by the dithiozone complexing method (4). The thicknesses of the evaporated films were calculated assuming a density of 5.62 for the cuprous iodide.

The images were produced by polarizing a small area of the specimen with its evaporated cuprous iodide film to a cathodic or anodic potential in a 1M NH_4NO_3 solution 0.0005M in $Na_2S_2O_3$ under irradiation from a u.v. lamp (100w, Type H-4 mercury vapor with peak emission at ~3660Å) for about a minute. A silicone rubber gasket carrying a platinum wire electrode was pressed down firmly onto the surface and contact made by a few drops of the solution. The area of contact was only 0.16 cm^2 and therefore different areas of the specimen could be tested with a positive or negative potential applied. The applied potentials ranged from 1% of the formation voltage to 0.4 V/1000Å for the anodic and thermal films, respectively.

The iodide film with the copper deposits was then washed, dried, and stripped off the oxide surface. The initial method was to dip the specimen in a collodion solution and allow to drain and dry, when a slight pressure along the edges would release the iodide film with the collodion backing. A procedure similar to the replica technique used in electron microscopy was found to be better, however. A thin coating of Formvar overlaid by one of polyvinyl acetate was applied to the specimen and this combination with iodide film was peeled off using an adhesive tape. Then the routine of coating with platinum-carbon and dissolving the PVA and Formvar was followed. The platinum-carbon film was collected on copper grids. The stripped films were examined on the optical and electron microscopes. The specimen was subsequently rinsed with dilute ammonia, washed and dried, when it was ready for another experiment.

Current-voltage measurements were made using gold or 1M NH_4NO_3 solution contacts.

Results

The evaporated film showed bright interference colors and the control strip was used to monitor the thickness during evaporation. The thickness of the evaporated iodide film was usually in the range 900-1100Å. Electron optical examination showed that the iodide film was for the most part a continuous sheet of crystals, oriented randomly and varying in size and thickness.

Imaging.—Anodic oxide films to ~4000Å and thermal films up to 1 μm thick were studied. To illustrate the usefulness of the technique a few typical sets of data on anodic films are presented here.

The current flow during imaging was usually in the μA/cm^2 range. An increase in the voltage or the time of recording led to a slight increase in the size of the copper deposits; the use of dilute thiosulphate solution for dissolving the unreacted iodide had no effect. In the absence of either the u.v. irradiation or the bias during the imaging the area tested showed only a few large deposits, similar to the untested parts of the surface.

The use of the collodion for stripping the iodide film with the image had the advantage of retaining the replicated grain structure of the specimen. In Fig. 1a are shown transmission micrographs of a collodion film carying the recorded image of copper deposits. It was stripped from a 500Å anodic film on zirconium following the imaging step and was washed in dilute thiosulfate solution. The light beam was incident obliquely and the copper particles scattering the light appear bright on a dark background. The collodion film had a wavy topography which led to difficulty in focusing the whole field of view. Nevertheless, this stripping procedure was helpful in identifying the locations of the copper deposits.

Using the two stage replica method of stripping the iodide film, a larger portion of the area under study could be brought into focus on the optical microscope. An added advantage was that the iodide film could be examined in the electron microscope also. A set of transmission micrographs of the same area of an iodide film stripped off a 1800Å anodic film on zirconium with varying incident light is shown in Fig. 1b. It is seen that a number of deposits remain un-

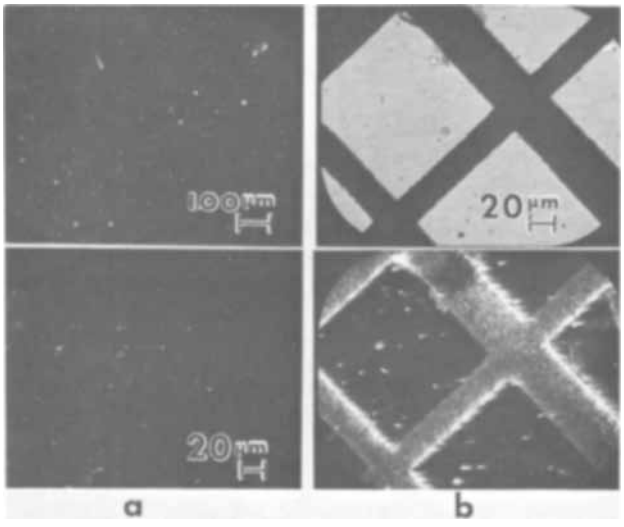

Fig. 1. Transmission optical micrographs of (a) collodion film carrying copper deposits and (b) cuprous iodide film supported on platinum-carbon with the incident light normal and oblique to the film.

focused and appear as circular interference fringes in this technique of supporting the iodide film also. However, a comparison with Fig. 1a shows a definite improvement in focusing conditions and therefore a higher visible density of deposits.

There was good reproducibility of the position of the deposits but not their size when a cathodic or anodic test was repeated on the same area. The irreproducibility of the deposit size may be due to variations of crystal size and thickness in the evaporated films. In successive anodic or cathodic testings on the same area nearly half the number of deposits matched precisely as to their location. It is believed that the difficulty in focusing is partly responsible for the lack of a complete one to one correlation.

In Fig. 2 transmission electron micrographs and diffraction patterns of the film referred to in Fig. 1b are shown. The copper deposits (a) are several times the size of the cuprous iodide crystallites (b), and range in size from ~0.5 to 2 μm. Electron diffraction patterns of the deposits show additional reflections arising from copper and cuprous oxide.

Current-voltage relationships.—The curves obtained in testing a specimen carrying gold contacts of different areas (varying from 0.1 to 0.6 cm^2) were identical in shape and the current density was constant to within ±5%. The results of these measurements and of other experiments in which an evaporated guard ring of gold was used and the area of the iodide film was varied confirmed the fact that no surface conduction was involved.

The current density was found to decrease with increasing iodide film thickness. Therefore, variations in the conductivity of the oxide with thickness were inferred from results on individual specimens carrying anodic films of several thicknesses. By such a procedure the only variations in iodide film thickness were those inherently present and were the same on the different anodized areas of the specimen. Any effects due to variations in the properties of the cuprous iodide and in the conductivity of different specimens from the same batch were also avoided. In the case of thermal films comparison was made among specimens oxidized to different extents with the iodide evaporated onto them simultaneously.

In Fig. 3a and b curves obtained with anodic oxide films of two different thicknesses grown on the same specimen are compared. It should be noted that the current density at a given voltage decreases with but not proportionately to the increase in oxide thickness. The curves shown in Fig. 3c and d were obtained with 1M NH_4NO_3 contacts. Cuprous iodide was evaporated onto part of the oxide surface. The anodic blocking behavior of such oxide films is readily seen from curve d obtained with direct contact to the oxide. With cuprous iodide present, curve c, an anodic current flow was observed. This current was time dependent and the current density at a fixed anodic voltage decreased only slightly with increase in oxide thickness and was not proportional to the oxide thickness. The anodic current at zero volt is due to the emf developed by the metal when the iodide is contacted by the electrolyte.

Observations using the SEM.—Because the imaging technique involves a solid-state process, an added advantage is that specimens can be examined by optical and/or electron optical means immediately following one or other of the various steps, *viz.*, evaporation of the iodide, the gold counterelectrode, and polarization. For such studies the scanning electron microscope (SEM) offers a wide range of possibilities. Specimens were examined in the JSM-2 before and after evaporation of cuprous iodide, with and without gold counterelectrodes and in the biased and unbiased conditions. In Fig. 4 the images of the specimen surface obtained in the secondary electron mode of operation of the SEM are shown. The presence of the iodide layer did not produce detectable changes in the image characteristics but gold did. At a few selected spots (Fig. 4a and b) deposits, varying in size from 1 to 10 μm, were thicker. When polarized, circular regions several mi-

(a and b) anodic oxide films (1) 400 and (2) 2500Å thick, respectively with 0.27 cm^2 gold contacts and (c and d) anodic oxide film 2000Å thick with 0.16 cm^2 NH_4NO_3 (1M) contacts on oxide with and without an iodide film, respectively.

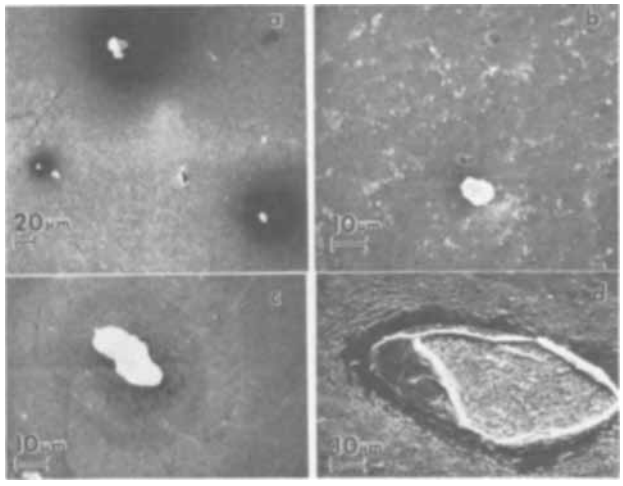

Fig. 4. SEM micrographs of anodic-oxide films on zirconium and Zircaloy-2 following cuprous iodide evaporation and one of the various steps; (a) 1000Å anodic oxide film on zirconium; the gold contact on cuprous iodide is biased to +0.2V wrt specimen; (b) 500Å anodic oxide film on Zircaloy-2 after evaporation of gold contacts; (c and d) breakdown areas; 1500 and 1000Å anodic oxide films on zirconium and Zircaloy-2 with gold and 1M NH_4NO_3 contacts, respectively, taken to breakdown voltages.

crons in diameter around these deposits showed different image characteristics from the rest of the surface (dark areas in Fig. 4a). A negative bias on the specimen was associated with large sporadic current increases (0.5 to 10 $\mu A/cm^2$ at $\sim$0.2V) as the electron beam scanned the surface and the subsequent observation of breakdown regions similar to that in Fig. 4c. Specimens were examined after polarization studies using 1M NH_4NO_3 solution contacts. A few sites of the type shown in Fig. 4d were observed.

Discussion

A number of semiconducting halides, sulfides, etc. have been shown to possess image forming characteristics (5, 6). Cuprous iodide was chosen because of its low solubility in water, a high vapor pressure at moderate temperatures, and its usefulness as a solid ohmic contact (7).

The conducting sites in the metal-insulating oxide system might form an ohmic or blocking contact with the evaporated cuprous iodide film. In the present study imaging was carried out on dielectric substrates at room temperature with low applied fields and therefore the mechanism proposed by Tubbs *et al.* is to be preferred (5). The various processes that lead ultimately to the formation of copper deposits during the imaging step are the production of excitons on u.v. absorption (8), reaction between a pair of excitons at a suitable site, and formation of copper nuclei. The centers for the initiation of reaction between a pair of excitons are likely to be Cu^{++} sites and are provided by the forward hole current. Growth of the nuclei would then follow by pairs of excitons reacting at a site adjacent to a copper nucleus.

Both n and p-type (homogeneous) conductivity have been reported for zirconia films on zirconium and Zircaloy-2 (9, 10). The alloy has intermetallic precipitates (major constituents are Zr, Fe, Cr, and Ni) distributed fairly uniformly through the material, and the metal a number of impurity centers. When imaging the metal or alloy-oxide structures the copper deposits are located at these sites of intermetallic and impurity precipitates. The purity of the materials used in the present study compares favorably with those used by the other workers and the reported homogeneous conductivity might very well be that of similar localized conduction sites.

The complex nature of these sites is revealed by the results obtained in the imaging step and the current-voltage characteristics. From the data reported here it is seen that cuprous iodide forms an ohmic contact with some of these sites. More than half the number of sites were imaged by both anodic and cathodic polarization. The inference would then be that a doped oxide film is formed on these conduction sites during the oxidation. A small fraction behaves as either an n or p-type semiconductor and is imaged during cathodic or anodic bias on the specimen; whereas the majority is of the compensated intrinsic type and under the testing conditions allows current to flow in either direction. The results obtained in experiments using the SEM and imaging in the absence of u.v. irradiation or bias indicate a wide range of conductivity among these sites; a large percentage of current flowing at a few excessively active sites.

Conclusions

The imaging technique reported here has several advantages for studying the sites of easy electronic conduction in valve metal-oxide systems. The photosensitivity and carrier injection capacity of cuprous iodide permit the use of low testing voltages, a favorable requirement in studying low dielectric strength materials. The technique is nondestructive and provides information about the distribution and electrical properties of the conducting sites. The resolution is good and sites active during both anodic and cathodic polarization can be studied. Because the process is a solid state one samples can also be studied directly by electron optical means.

In zirconia films on zirconium and its alloys, localized conduction sites are present and assigning a homogeneous conductivity for oxide films up to $\sim$1 μm thick is questionable. The electrical characteristics of these sites are of a complex nature.

Acknowledgments

The author wishes to thank Mr. T. Trottier for his assistance in the experimental part of this work and Dr. B. Cox for his encouragement and helpful discussions.

Exposure of Photoresists: Electron Beam Exposure of Negative Photoresists

Barret Broyde

Engineering Research Center, Western Electric Company, Inc., Princeton, New Jersey

ABSTRACT

A threshold flux is required to form an image in negative photoresists when they are exposed to kilovolt electron beams. This threshold is related to the gel point of the photoresist. Using the known number of crosslinks per molecule at the gel point, the G values for the crosslinking of KPR and KTFR, were calculated from the absorbed energy of 2.5 ± 0.2 x 10^{20} ev/cm^3 at the threshold, to be 0.65 and 1.20, respectively. An energy transfer model based on Bethe's penetration range for an electron and on the distribution of energy with depth of penetration found by Charlesby describes the change in threshold flux with changes in accelerating potential. Electron fluxes above the threshold value fully insolubilize the resist. The efficiency of absorbed energy for total insolubilization is a function of the energy of the incident electrons. 5 keV electrons are 3.3 times more efficient than uv light, but 15 keV electrons are only as efficient as photons.

During the manufacture of semiconductor devices, parts of the semiconductor substrate have to be protected against etchants. This is accomplished by exposing photosensitive etch-resistant polymers called photoresists to light through a mask. The desired pattern of etch resistant polymeric material is obtained after a development process, which removes the unexposed portions of negative resists and removes the exposed portions of positive resists (1). The use of light in patterning the photoresist through a mask, limits the narrowest line and the edge resolution that can be routinely made in the photoresist to be wider than 2 μm and 0.3 μm, respectively.

On the other hand, lines only 0.25 μm wide (2) with edge resolutions of 0.05 μm (3) have been prepared by using an electron beam to expose photoresist. Thornley and Sun (4) showed that both 14 and 20 keV electron beams could expose negative resists so that the resists were able to protect SiO_2 against etchants. They found that a threshold existed in the exposing electron flux, below which no protection was provided. Above the threshold the amount of protection increased with increasing flux until full protection resulted. Kanaya, Yamazaki, and Tanaka (3) also found a threshold when they studied the thickness of a developed negative resist as a function of electron flux, for electrons accelerated between 20 and 100 keV. Matta (5) showed that the flux required for optimum exposure depends on the energy of the electrons. He feels that backscattered electrons play a part in the exposure process, but Kanya *et al.* (3) indicate that backscattering should be negligibly small for energies below 20 keV.

The electron beam exposure of two negative photoresists has been investigated here. The first resist, Kodak Photosensitive Resist (KPR), contains a polyvinyl cinnamate polymer, while the second Kodak Thin Film Resist (KTFR), contains a polymerized isoprene dimer.

This work assumes that the threshold flux found in the exposure of these resists is related to the gel point of the resist. If this is the case, then the threshold flux should change when the accelerating potential of the electron beam is varied, but the amount of energy absorbed at the threshold should be constant. It is shown here, using Bethe's model for penetration range and Charleby's data on energy transfer, that the calculated threshold energies are constant, although the experimentally determined values of the threshold flux are a function of the energy of the electron beam. The shape of the exposure curve and the efficiency of energy usage in totally exposing the photoresist is also discussed.

Experimental

The exposure characteristics of photoresists were determined by irradiating thin films of the resists with varying electron fluxes. Typically, resist solution was spun onto a flat glass plate covered by 700Å of chromium to the required thickness. The resist-covered-plate was then baked at 150°C for 10 min to remove solvents, put into a specially designed vacuum system and pumped down to 2 x 10^{-5} Torr. At this point, the electron gun was turned on, allowed to stabilize at the desired accelerating potential, focused to give a spot about 2.5 cm^2, and the beam current measured using a Faraday cup. The resist-coated plate was then moved into the beam and left there until the desired electron flux was reached. After exposure, the plate was moved out of the beam, and the beam current was measured again to make sure that it did not change during the irradiation of the resist. Typical exposure times were 100 sec. Fluxes measured in this way were accurate to ± 5%. The resist-coated-plate was spray developed and baked at 150°C before its thickness was measured with either a Model 3 Taylor-Hobson Talysurf Profilimeter or with an interferometer. The thickness measurements on the Talysurf were reproducible to ± 300Å.

Identical results were obtained when either a glass plate or an oxidized silicon wafer was used instead of a chromium coated plate. Applying the resist by spray methods and dip developing after exposure also yielded the same data, as long as the application and development were carefully done.

Results

The thickness of exposed and developed resist layers was determined as a function of electron flux for different accelerating potentials and for different initial thicknesses of resist. Results for the exposure of KTFR are shown in Fig. 1 and 2, while Fig. 3 contains the data on KPR.

Both KPR and KTFR always show a threshold in exposure; that is, below a specific flux no insolubilized resist is formed. Above the threshold, an increase in flux gives an increase in resist thickness until the maximum resist thickness is reached. Both Thornley and Sun (4) and Kanaya *et al.* (3) have shown that resists must be exposed to their full thickness in order to afford full protection to SiO_2 layers. For this reason the lowest flux required to achieve maximum thickness will be designated as the lowest usable flux.

The lowest usable flux is a function of both the incident electron energy and the initial thickness of the resist, but the threshold flux principally depends

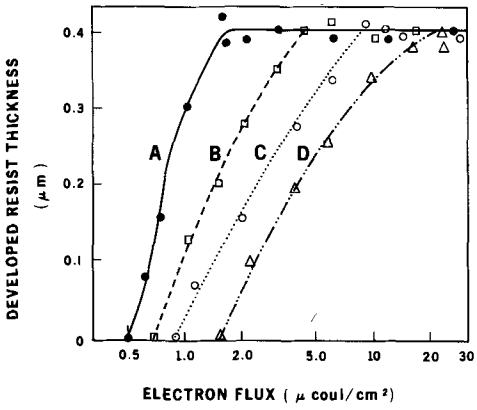

Fig. 1. Exposure of KTFR films (initial thickness 6000Å) to kilovolt electrons. Curve A, exposure to 5 keV electrons; curve B, to 10 keV electrons; curve C to 15 keV electrons; curve D to 20 keV electrons.

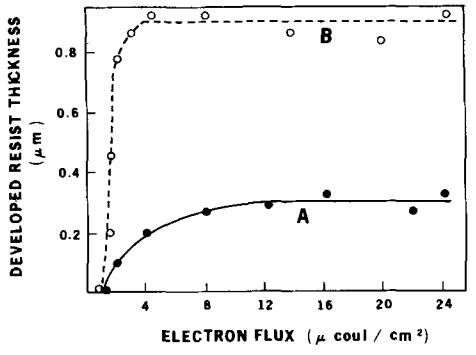

Fig. 2. Exposure of KTFR films to 15 keV electrons. Initial film thickness curve A, 12000Å, curve B, 3600Å.

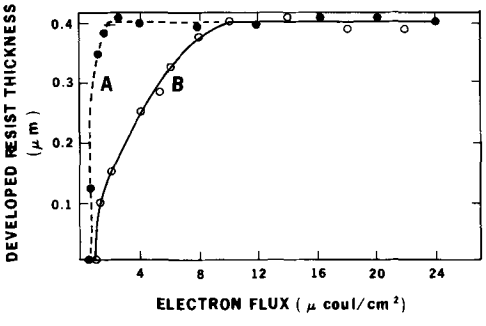

Fig. 3. Exposure of KPR films (initial thickness 6000Å) to kilovolt electrons. Curve A, exposure to 5 keV electrons, curve B to 15 keV electrons.

on the incident energy of the beam and is only somewhat dependent on the initial resist thickness (Fig. 1-3). The data that have been obtained are summarized in Table I. Also included in this table is the value of the contrast function of the resist, Γ, which is defined here as

$$\Gamma = \frac{\text{threshold flux}}{\text{lowest usable flux}}$$

Γ is a function of both the beam energy and resist thickness. It increases with the initial thickness of the resist, but decreases as the potential energy of the beam is increased, in the regions examined here.

It will be shown in the next section that one of the factors that determine the threshold flux is the range that the electron can penetrate into the photoresist. This range has been taken to be the maximum thickness of resist that can be exposed by a given incident electron energy. The range for 5 keV electrons has been determined to be 6500 ± 200Å, while 10 Kev electrons can penetrate between 2.0 and 2.5 μm. If

Table I. Exposure and contrast values for KTFR and KPR

Incident electron energy, keV	Resist	Initial thickness of resist, Å	Threshold flux, μcoul/cm²	Minimum useful flux, μcoul/cm²	Contrast function, Γ
5	KTFR	6000	0.5	1.5	0.33
10	KTFR	6000	0.7	3.5	0.20
15	KTFR	3600	1.1	12.0	0.09
		6000	0.9	8.0	0.11
		12000	0.9	4.0	0.22
20	KTFR	6000	1.6	16.0	0.10
5	KPR	6000	0.5	1.8	0.28
15	KPR	6000	0.9	10.0	0.09

layers thicker than these are exposed and developed, the exposed spot floats off the substrate. The maximum thickness of resist that can be exposed by 15 and 20 keV electrons was too great (> 3 μm) to be determined accurately by the Talysurf.

Discussion

Solubility of crosslinking systems.—Polymer molecules may react together forming intermolecular bonds, which eventually result in an "infinite" three-dimensional network of molecules. If the molecules are initially in solution, then a gelled or insoluble product is obtained when this occurs, and the reaction is said to have reached the gel point (6). This terminology has been carried over to describe the point at which solid crosslinking polymers, such as negative photoresists, become insoluble.

The solubility of irradiated crosslinking systems after radiation has been described by Charlesby (7, 8). He showed that polymers in which an initiated reaction does not propagate and therefore can lead to no more than one set of crosslinked units, will become insoluble, when the number of crosslinked units per weight average molecular weight molecule, designated δ, equals one. At this point, the weight average molecular weight of the polymer approaches infinity (7). This model should predict the behavior shown by KPR, since it becomes insoluble after being exposed to light, as the result of the formation of 4-membered rings having a substituted truxillic acid structure (9). The formation of 4-membered rings (10), indicates that in the insolubilization of KPR, the initiated reaction does not propagate. The lack of dependence of the photosensitivity of KPR on the presence of oxygen indicates that free radical reactions are improbable (10, 11).

On the other hand the exposure of KTFR is oxygen dependent, and its polymerized isoprene dimers (12) probably crosslink via a chain propagating free radical reaction. Its solubility characteristics would therefore be different from those of KPR. Charlesby has determined that, when a single crosslink can propagate and if the initiation sites are far enough apart so that chain termination arises from an inherent property of the polymer such as resonance stabilization, then the weight average molecular weight of the polymer approaches infinity when $\delta = [V/(V-1)][i/2(1-i)]$ (8). V is number of sites on the entire polymer molecule that are available for crosslinking and $(1-i)/i$ is the number of links in the crosslinking chain. Chain termination by disproportionation or by the combination of two chains is excluded in this discussion. $[V/(V-1)]$ is unity for photoresists since KTFR has a number average molecular weight of 6.5×10^4 and a weight average molecular weight of about 100,000 (13) and each isoprene dimer (molecular weight = 130) in the molecule has a site available for crosslinking, so that $V > 700$.

Gel point requires a threshold flux.—As long as the weight average molecular weight does not approach infinity, *i.e.*, $\delta < 1$ for KPR and $\delta < i/2(1-i)$ for KTFR, then the photoresists can be dissolved. The value of δ which is initially zero is determined by the amount of energy absorbed per molecule and the number of crosslinks formed by a molecule per unit of

absorbed energy. When crosslinking systems such as negative photoresists are exposed to an electron beam, then the average number of crosslinks per molecule is related to the dose by

$$\delta = 1.04 \times 10^{-6} rGW \qquad [1]$$

where r is the absorbed dose in megarads (10^8 ergs absorbed/g), G is the number of crosslinks formed per 100 eV absorbed, and W is the weight average molecular weight of the polymer being irradiated.

A value for W of about 3.2×10^5 has been reported for KPR (13) so that unless $r \geq 3/G$ megarads for this resist or $r \geq 4.8\, i/(1 - i)G$ megarads when KTFR is irradiated, none of the resist will be insolubilized. The value of r required to reach the gel point is called the gel dose and is designated as r_{gel}. The exposure threshold is the flux of electrons needed to transfer the amount of energy equivalent to r_{gel} from the beam to the resist. The thresholds that are reported with light exposures (10, 11, 14) are also brought about by the existence of a gel point and gel dose in crosslinking systems.

A method for calculating r_{gel} is presented in the next sections.

Energy transfer to photoresists.—It is expected that the amount of ionization and excitation produced by electrons changes as the electrons penetrate the absorber, since the probability of inelastic collisions increases as the energy of the electron decreases, but the amount of energy transferred at each collision decreases. Studies of energy loss as a function of penetration in polymers (15), water (16), and luminescent materials (17) show that the amount of energy transfer varies in essentially the same way in all media.

Charlesby determined (15) the density of ionization in polymers as a function of

$$\frac{\text{penetration into the polymer}}{\text{penetration range in the polymer}}$$

The density of ionization is related to the fraction of energy transferred, and his data are replotted in Fig. 4. Hatzakis (18) has reported that electron radiation of a positive resist yielded a pear shaped hole. His observation is consistent with Charlesby's measurements.

If it is assumed that the fraction of energy transferred from the beam to the photoresist layer also follows Charlesby's function and is related to

$$\frac{\text{thickness of the photoresist layer}}{\text{penetration range in the photoresist}}$$

then the amount of energy transferred from the beam to the resist can be calculated if the penetration range of electrons into photoresist is known. This calculation assumes negligible backscatter from the substrate and is valid since changing the substrate from chromium to oxided silicon did not affect the results.

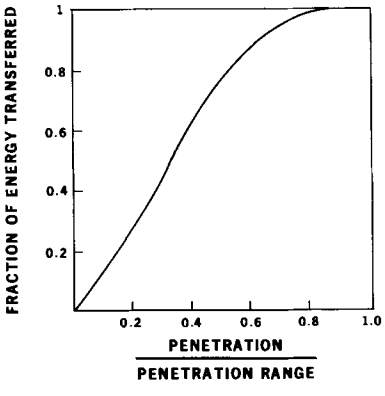

Fig. 4. Charlesby's relation of energy transfer as a function of (penetration/penetration range).

Since the penetration range of electrons into resists could not be precisely measured over the full range of exposure energies used here, a theoretical model for penetration range was chosen.

Penetration range of electrons.—Bethe has advanced a model for the transfer of energy from nonrelativistic electrons by inelastic collisions, in which the electrons follow a straight path into the absorbing medium up to a point, after which they randomly diffuse (19). The energy loss per cm is

$$\frac{dE}{dx} = \frac{2\pi e^4 NZ}{E} \ln \frac{2E}{J} \qquad [2]$$

which, when integrated using the limits proposed by Worthington and Tomlin (20), gives the range

$$R = \frac{J^2}{8\pi e^4 NZ}\left[Ei\left(2 \ln \frac{2E}{J} \right)\right] \qquad [3]$$

In these equations R is the range of the electron, and E, e, and x are its energy, charge and its distance into the absorber, respectively. NZ is the number of electrons/cc in the absorber and is equal to 3×10^{23} for both KPR and KTFR. $J = \frac{8}{\epsilon} I$ is the energy needed to form an ion pair in the absorber (ionization potential) and ϵ is the base of natural logarithms. I has been measured to be 26.4 eV when gaseous ethylene is irradiated with electrons (21). Since photoresists contain ethylenic groups, and since it is usually presumed that I is the same in solids and liquids (22), I has been taken to be 26.4 eV for photoresists. Any error arising from the use of this value should be small since other hydrocarbon vapors have values between 24.8 and 27.1 eV (21). $[Ei\ 2 \ln(2E/J)]$ is the exponential integral (23) which can be evaluated as

$$\left[\frac{\epsilon^{2 \ln(2E/J)}}{2 \ln(2E/J)}\right]\left(1 + \frac{1}{2 \ln(2E/J)} + \frac{2}{[2 \ln(2E/J]^2} \right)$$

to give the ranges shown in Table II.

The range of 5 and 10 keV electrons predicted by this model is in good agreement with the maximum thickness of photoresist that can be exposed at these accelerating potentials. On the other hand, the Thomson-Whiddington law (24) predicts ranges that are 5 times lower than the thickness of photoresist that can be exposed.

The ranges from Eq. [3] can now be used to calculate the total amount of energy transferred to the photoresists by the threshold fluxes at various incident electron energies. The gel doses obtained for the energies used here (Table III) show that layers of KPR and KTFR require the threshold flux to transfer $2.5 \pm 0.2 \times 10^{20}$ eV/cm^3 just to make an image visible in the photoresist. The uncertainty is within experimental error. Charlesby's experimentally obtained function was used for these calculations since Eq. [2] does not predict correctly energy transfer as a function of penetration in materials (15-17). The constant value of the threshold dose supports the assumption of a gel point.

G value.—The G value for KPR can be calculated from Eq. [1] since the threshold flux is 0.5 μcoul/cm^2

Table II. Penetration range in KPR and KTFR

Incident electron energy, keV	Range, μm Experimental	Calc.
5	0.65	0.66
10	2-2.5	2.3
15	—	4.8
20	—	8.3

5	6000	0.90	1.0	5.0	0.5	1.6	2.7
10	6000	0.26	0.36	3.6	0.7	1.6	2.7
15	3600	0.075	0.082	1.2	1.1	0.83	2.3
	6000	0.125	0.16	2.4	0.9	1.4	2.3
	12000	0.245	0.34	5.1	0.9	2.9	2.4
20	6000	0.072	0.078	1.6	1.6	1.6	2.7

at 5 keV, and it was established in the last section that the energy of the beam is totally transferred to the resist layer so that r_{gel} is 4.65 megarads and $G = 0.65$. The G value of KTFR cannot be as readily calculated since the number of links in the free radical chain is not known.

If it is presumed, however, that the number of intermolecular reactions initiated per hundred eV absorbed is the same for KPR and KTFR, i can be estimated. With this assumption, the G value for intermolecular reactions initiated in KTFR is equal to G_{KPR} since there are 2 bonds between each pair of KPR molecules and

$$G_{KTFR} = G_{initiated}\left(1 + \frac{1-i}{i}\right) = \frac{G_{KPR}}{i}$$

$$\text{At the gel point } G_{KTFR} = \frac{i}{2(1-i)} \quad (0.48)$$

so that $i = 0.54$ and $G_{KTFR} = 1.20$

This value of i implies that there is about 1 link in a crosslinking KTFR chain. A G value of 1.05 has been reported for smoked-oriented isoprene rubber (25) indicating that the result obtained here is reasonable.

These calculations presume that chain scission does not occur to an appreciable extent at low fluxes. Thornley and Sun (4) showed that scission is a minor process in the radiation of negative resists, since they were able to irradiate resists with up to 6 x 10^{-4} coul/cm² without increasing the solubility of the resists. Fluxes greater than 10^{-3} coul/cm² caused changes in solubility which may arise from scission.

Characteristic curves.—The curves in Fig. 1-3 can be considered to be the characteristic curves of the photoresists. They are analogous to the curves reported for silver halide emulsions except that thickness rather than optical density is measured as a function of exposure. Contract functions can be used to describe the properties of a photoresist and to predict the relative edge accuities expected in photoresist systems. Consider the contrast function, Γ, defined in the Results Section. Γ has been related to the end points of the thickness *vs.* exposure curve, rather than the slope of the curve, since each of the end points has special significance. As defined, $0 < \Gamma \leq 1$.

Γ appears to depend on the properties of the resist, its thickness, and the incident energy of the beam, but in a manner different from the threshold flux. The different functional dependence probably arises because the lowest usable flux is not reached when a certain number of crosslinks is achieved (as is the threshold flux) but rather is reached when all the photoresist molecules have reacted. Thus, the distribution of energy to uncrosslinked molecules becomes important and determines the efficiency of energy usage for total insolubilization.

The efficiency of energy usage for total insolubilization can be measured by comparing the minimum number of crosslinking reactions theoretically required for total insolubilization to the number of crosslinking reactions that actually occur during irradiation. The minimum number of crosslinks required is equal to the number of molecules, for if each molecule reacts with its neighbor then all the molecules could be linked together. The number of crosslinks that actually occur is equal to the number of electrons multiplied by the number of reactions that each electron can cause. This latter quantity is the product of the G value and the energy each electron transfers to the photoresist divided by 100. The number of molecules in a photoresist layer can be calculated from the molecular weight and the density of 0.9. Table IV contains the information required to calculate efficiency. It can be seen by comparing Tables I and IV that KTFR has an efficiency of about 1.7Γ, while for KPR it is 1.1Γ, but this quantitative relation has not yet been explained.

While no quantitative relation has been established between Γ and the most probable amount of energy transferred during an inelastic collision, they both vary in the same way when the energy of the beam is decreased or when the thickness of the resist is increased. The most probable amount of energy transferred in a collision is (26)

$$\Delta E_p = \frac{2\pi e^4 NZT}{2E}\left(\ln\frac{2\pi e^4 NZT}{I^2(1-\beta^2)} - \beta^2 - 0.34\right) \quad [4]$$

where the symbols are the same as in Eq. [2] while T is the thickness of the resist layer and β is the velocity of the incident electron divided by the velocity of light. Values of ΔE_p are given in the last column of Table IV.

Exposure energy: light vs. electrons.—Htoo has reported that 6000Å layers of KTFR can be fully exposed by 2.75 x 10^5 erg/cm² of 3650Å light (11). It

Table IV. Efficiency and probable energy transfer

Incident electron energy, keV	Resist	Initial thickness of resist, Å	Number of molecules in resist layer/cm², × 10⁻¹⁴	Number of electrons required for total exposures/cm², × 10⁻¹²	Number of molecules an electron can react with	Total number of reactions that actually occur/cm² (× 10⁻¹⁴)	Efficiency	Most probable amount of energy transferred ΔE_p (eV)
5	KTFR	6000	3.24	9.38	60	5.62	0.58	1780
10	KTFR	6000	3.24	21.9	43.2	9.46	0.34	887
15	KTFR	3600	1.94	75.0	14.4	10.8	0.18	344
		6000	3.24	50.0	28.8	14.4	0.23	582
		12000	6.48	25.0	61.2	15.3	0.42	1330
20	KTFR	6000	3.24	100	19.2	19.2	0.17	467
5	KPR	6000	1.08	11.3	32.6	3.68	0.30	1780
15	KPR	6000	1.08	62.5	15.6	9.75	0.11	582

was found here that when 5 keV electrons are used to expose this thickness of KTFR, 1.5 μcoul/cm^2 are required for full exposure. Since complete energy transfer occurs under these conditions, this flux is equivalent to 7.4 x 10^4 erg/cm^2 and 5 keV electron energy is 3.3 times more efficient than light energy in exposing KTFR. As the energy of the incident beam is increased, its efficiency in exposing the resist is decreased (lower Γ) and 15 keV electrons are only about as efficient in exposing KTFR as 3650Å light.

Conclusions

It has been shown here that:

1. The range of electrons in photoresist can be predicted from Bethe's integrated energy loss equation.
2. The amount of energy transferred at the threshold can be calculated from Charlesby's energy transfer relation and the range.
3. The amount of energy transferred/cm^3 at the threshold is constant for a given photoresist and is equal to 2.5 $\pm$ 0.2 x 10^{20} eV/cm^3 for KPR and KTFR. This is strong evidence that supports the assumption that the threshold is due to the gel point of the photoresist.
4. G values for KPR and KTFR were calculated to be 0.65 and 1.20, respectively. On the average, an excited KTFR molecule reacts only with one nearest neighbor.
5. The efficiency of insolubilization changes with both the thickness of the photoresist layer and the energy of the incident electrons. The efficiency may be related to the contrast function of the resist and to the most probable amount of energy transferred by an electron during an inelastic collision.

Electronic Structure of the Vanadate and Tungstate Complexes

Wolfgang Walter and Keith H. Butler*

Sylvania Electric Products Incorporated, Danvers, Massachusetts

ABSTRACT

The excitation and emission spectra of unactivated yttrium vanadate and calcium tungstate have been measured. Relative absorption spectra were derived from the excitation spectra. In order to aid in the interpretation of the absorption and emission, a series of semiempirical LCAO-MO calculations were carried out on the vanadate and tungstate complexes. These calculations indicate that the transitions primarily responsible for absorption are the charge transfer transitions $t_1 \rightarrow 2e$ and $t_1 \rightarrow 4t_2$. The vanadate emission peak is accounted for by an increase of 0.15Å in the vanadium-oxygen distance for the excited state. Electrostatic splitting and the effects of lowering of symmetry from T_d to D_{2d} are discussed.

Calcium and magnesium tungstates (1) are important phosphors, frequently used for color correction in fluorescent lamps. Yttrium vanadate is an important host material in the red emitting phosphor obtained by activating it with trivalent europium. Various unactivated vanadates (2) are also known to fluoresce with moderate efficiency when excited by a low pressure mercury discharge. It has also been shown that the anions WO_4^{-2} and VO_4^{-3} can serve as activators in sulfates and silicates (3).

* Electrochemical Society Active Member.

In general, the excitation and emission spectra of phosphors activated by cations, such as Sb^{+3}, Sn^{+2}, Pb^{+2}, can be explained as being due to the promotion of an electron of the activator to an excited state, followed by lattice relaxation to a new equilibrium position and then by a transition to the ground state with emission of radiation. The energy levels of the ion are modified by the influence of the surrounding ions so that the energy required to excite the ion in the crystal is approximately half that needed to excite the free ion.

If the ion responsible for fluorescence is considered to be W^{+6} or V^{+5}, it is found that the energy needed for excitation would fall deep in the vacuum ultraviolet, if the crystal field effect were the same as that on a cation activator. Hence it was recognized very early (4) that the luminescence must be ascribed to the whole complex rather than to the central ion and that the energy levels of the complex must be quite different from those of the central ion.

In spite of this recognition of the unique nature of the activation, no attempt has been made to apply modern molecular orbital calculations to the problem of interpreting the excitation and emission spectra of crystals containing these complex ions.

For these reasons we have made a study of the electronic structure of the VO_4^{-3} and WO_4^{-2} complexes in YVO_4 and $CaWO_4$, respectively. These two complexes can be studied together because of their identical symmetry and coordination and because they are isoelectronic in their valence electrons.

Phosphors were made with high-purity components using methods described in the section on Preparation of Materials. The excitation and emission spectra of YVO_4 and $CaWO_4$ were measured and the excitation spectra were converted into relative absorption spectra, as described in the section on Excitation and Derived Absorption Spectra. Semiempirical LCAO-MO (linear combination of atomic orbitals-molecular orbital) calculations were carried out on the complexes assuming them to have tetrahedral symmetry. The methods of calculation are described and the results are given. The effects of electrostatic splitting and the reduction to D_{2d} symmetry are discussed and an interpretation of the derived absorption spectra is given.

Preparation of Materials

The yttrium vanadate sample was prepared from a mixture of American Potash and Chemical Company Y_2O_3 of 99.9999% purity and Baker V_2O_5, 99.8% pure. The mixture was fired for 1 hr at 1300°C.

The calcium tungstate sample was prepared by mixing hot solutions of highly purified Na_2WO_4 and $CaCl_2$, followed by washing until free of sodium chloride and firing for 16 hr at 1040°C.

Excitation and Derived Absorption Spectra

The excitation spectra of unactivated YVO_4 and $CaWO_4$ were measured with a vacuum spectroradiometer that automatically corrects for the spectral variation of the lamp output. These are shown in Fig. 1 and 2. In order to get a more appropriate experimental basis for our theoretical studies, we converted the excitation curves into relative absorption spectra. This was done by applying some results of the theory of the optical properties of powder layers (5). For powder layers thick enough for no transmission of exciting radiation, the absorption coefficient μ is related to the reflectance R by

$$\mu/\beta = (1-R)^2/2R \qquad [1]$$

where β is the scattering coefficient. If the reflectance spectrum is known, Eq. [1] can be used to derive a relative absorption curve since β remains nearly constant with wavelength. Reflectance spectra of YVO_4 and $CaWO_4$ were measured with a Beckman DK spectrophotometer. However, the resolution was not great enough to show any appreciable structure. In the excitation spectrum the emitted light intensity I of the phosphor layer is proportional to the absorbance A or, for a thick layer, proportional to $1 - R$

$$I = KA = K(1-R) \qquad [2]$$

The constant K was determined by estimating the value of R at the wavelength of the highest excitation peak. The relative absorption spectrum was calculated from the excitation data by application of Eq. [1] and [2]. The derived relative absorption spectra, which are shown in Fig. 1 and 2, were resolved into Gaussian functions by a computerized trial and error method. The resolutions are shown in Fig. 3 and 4, and Table I

Table I. Gaussian function parameters used in fitting absorption curves and transition assignments. The functions have the form: A exp- $(\nu - \nu_0)^2/\sigma^2$. The transitions are all from the ground state, $^1A_1$.

	ν_0 (kK)	A	σ (kK)	Assignment
		YVO_4		
a	32.6	100	1.05	$^1T_1$ ($t_1 \rightarrow 2e$)
b	35.1	14	0.80	$^3T_2$ ($t_1 \rightarrow 2e$)
c	36.6	5	0.60	$^1T_1$ ($3t_2 \rightarrow 2e$)
d	40.4	52	1.80	$^1T_2$ ($t_1 \rightarrow 2e$)
e	45.0	14	2.00	$^1T_1$ ($t_1 \rightarrow 4t_2$)
f	49.5	12	2.00	$^1T_2$ ($t_1 \rightarrow 4t_2$)
		$CaWO_4$		
a	40.0	47	1.00	$^3T_1$ ($t_1 \rightarrow 2e$)
b	42.4	94	1.40	$^1T_1$ ($t_1 \rightarrow 2e$)
c	44.8	54	1.00	$^3T_2$ ($t_1 \rightarrow 2e$)
d	46.5	24	0.80	$^1T_1$ ($3t_2 \rightarrow 2e$)
e	48.4	53	1.70	$^1T_2$ ($t_1 \rightarrow 2e$)
f	52.3	49	1.75	$^1T_1$ ($t_1 \rightarrow 4t_2$)
g	55.8	77	1.24	$^1T_2$ ($t_1 \rightarrow 4t_2$)
h	58.0	37	0.70	$^1T_1$ ($3t_2 \rightarrow 4t_2$)

lists the Gaussian parameters. We have used the minimum number of Gaussians that result in a good fit to the absorption curves. The emission spectra of YVO_4 and $CaWO_4$ are shown in Fig. 5. Each curve consists of a single almost perfect Gaussian with maxima at 22.5 kK and 24.0 kK, respectively (kK = kilokayser, 1 kK = 10^3 cm^{-1}).

Semiempirical Molecular Orbital Calculations

In order to facilitate the interpretation of the absorption spectra, semiempirical molecular orbital calculations were carried out on the VO_4^{-3} and WO_4^{-2} complexes. The method is described below.

LCAO-MO theory.—As usual in molecular orbital theory (6), the molecular orbitals ϕ_i are assumed to be linear combinations of the atomic orbitals u_j

$$\phi_i = \Sigma_j C_{ij} u_j \quad [3]$$

The atomic orbitals considered in the calculations were the 3d, 4s, and 4p orbitals of the vanadium or the 5d, 6s, and 6p of tungsten, together with 2s and 2p orbitals of the four oxygen ligands. The inner orbitals were regarded as part of the core. By application of the variational principle, the assumption of Eq. [3] leads to a set of linear homogeneous equations for the coefficients C_{ij}

$$\Sigma_k C_{ki} (H_{jk} - E_i S_{jk}) = 0 \quad [4]$$

H_{jk} is the matrix element of the one-electron Hamiltonian between orbitals u_j and u_k, S_{jk} is the overlap integral between the two orbitals, and E_i is the energy. The set of Eq. [4] can only have nontrivial solutions for the C_{ki} if the determinant of their coefficients is zero. This leads to the secular equation

$$|H_{jk} - ES_{jk}| = 0 \quad [5]$$

Equations [3] to [5] can be solved for the molecular energies and orbitals.

Considerable simplification in the calculation results from the application of group theory. Instead of using the ligand orbitals directly in the expansion of Eq. [3], one first finds linear combinations of them that are basis functions for the irreducible representations of the tetrahedral group T_d, and then combines these with the central atom orbitals (7). The orbital combinations used are the same as those given by Viste and Gray (8). The simplification comes about because the matrix elements between orbitals belonging to different irreducible representations and to different rows of the same representation are zero. This reduces the determinant of Eq. [3] to a product of smaller determinants. In our case, there are twenty-five atomic orbitals, so that Eq. [5] contains a 25 x 25 determinant. This determinant reduces to a 3 x 3 determinant of A_1 symmetry, two identical 2 x 2 determinants of E symmetry, three identical 5 x 5 T_2 determinants, and three identical 1 x 1 T_1 determinants.

Matrix elements.—The overlap integrals were calculated by means of a computer program from published analytic atomic orbitals of neutral vanadium (9) and oxygen (10) atoms. The tungsten orbitals were computed by the Herman-Skillman (11) program and then converted to analytic form.

The metal-oxygen internuclear distances were taken to be 1.706Å for vanadate (12) and 1.79Å for tungstate (13). Ligand-ligand overlaps were neglected.

The diagonal elements of the Hamiltonian matrix were approximated in different ways in two separate calculations. In the first method, we followed the procedure of Basch, Viste, and Gray (14). Namely, the diagonal elements were set equal to their respective VOIP's (valence orbital ionization potentials). That is, H_{ii} was set equal to the energy the i'th electron would have if its ion were free. This, of course, is a function of the charge on the ion. Following Basch *et al.*, we varied the vanadium VOIP's as a function of effective charge and fixed the oxygen VOIP's to the values given in their paper. We did not, however, consider the variation of VOIP with configuration, but only used the VOIP's for the lowest configuration. We felt that the change of VOIP with configuration was relatively small and the roughness of the approximation involved in this type of calculation did not warrant the additional refinement.

The second method of approximation of the diagonal Hamiltonian elements consists essentially, of adding a term to each VOIP. The VOIP only takes into account the effect on the electron of its own ion and neglects the effects of the other ions. To compensate for this, we have added the Madelung potential; that is the electrostatic energy due to the other ions in the complex and in the rest of the solid, assuming them to be point

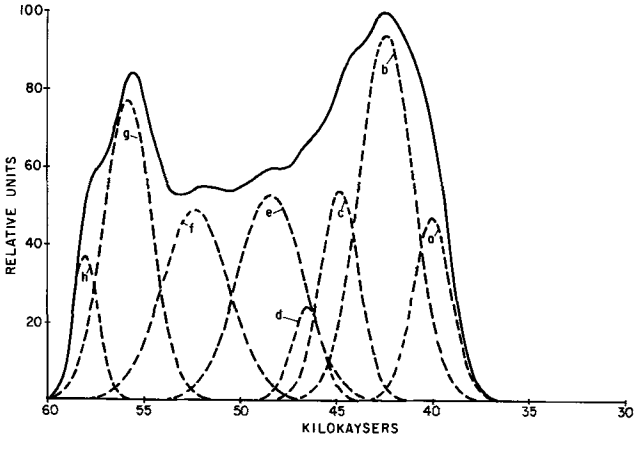

Fig. 4. Derived absorption spectrum of $CaWO_4$ resolved into Gaussian functions. The solid curve shown is the sum of the Gaussians. Compare this to the actual absorption curve in Fig. 2. States are assigned to the peaks; see text for details.

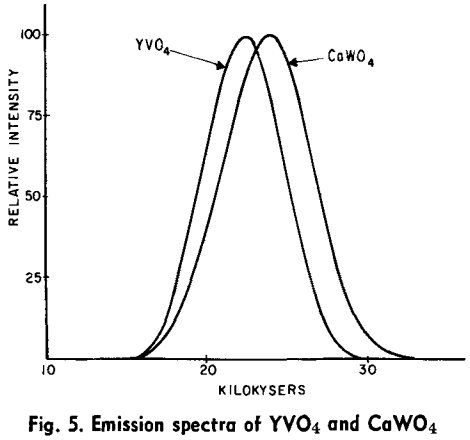

Fig. 5. Emission spectra of YVO_4 and $CaWO_4$

charges (15). With this method, we did not fix the oxygen VOIP's but allowed them to vary with charge as with the vanadium VOIP's. Basch *et al.* (14) fixed the oxygen VOIP's to correspond to the experimental values found in oxygen containing molecules. This partially compensated for the neglect of the effect of the other ions. In our method, there is no need to fix the VOIP's. The addition of a point charge energy was also suggested by Fenske *et al.* (16), and more recently by Brown *et al.* (17).

The off-diagonal matrix elements of the Hamiltonian were approximated by using the Wolfsberg-Helmholtz approximation (18)

$$H_{ij} = \frac{1}{2} F(H_{ii} + H_{jj}) G_{ij} \qquad [6]$$

where G_{ij} is the group overlap integral and F is an adjustable parameter. This relationship was used for both methods of approximating the diagonal elements. In order to minimize the number of parameters, the same value of F was used for both σ and π overlaps.

The calculations were performed on an I.B.M. 1130 computer. The input effective charge was varied to make it self-consistent with the charge calculated from the resulting wave functions by a Mulliken populations analysis (19).

Results of Calculations

Figure 6 shows the energy level diagrams for the vanadate and tungstate complexes obtained from these calculations using the first method of approximation. A value of F, the Wolfsberg-Helmholtz parameter, of 1.87 was used for both complexes. The self-consistent effective charge on the vanadium was 0.98 and therefore —0.995 on each of the oxygens. The tungsten effective charge was 0.63 with —0.66 on its ligands. Vanadate and tungstate are isoelectronic in their valence electrons. In their ground states the t_1 level is the highest occupied level and is completely filled. We believe that the transitions primarily involved in absorption are transitions from the filled t_1 level to the first two unoccupied levels: $2e$ and $4t_2$ (see next section). The orbital of the t_1 level is based solely on the ligands. On the other hand, the $2e$ and $4t_2$ levels have orbitals that are shared between the metal and its ligands. The calculated molecular orbitals in vanadate indicate that an electron on the $2e$ level spends 65% of its time in a vanadium orbital and the rest in ligand orbitals, while if it is on the $4t_2$ level the percentage increases to 75%. The corresponding figures for tungstate are 52% and 53%. This shows that the tungsten bonds are more covalent than those of vanadate.

The order of the levels resulting from the second method of calculation, in which the Madelung potential is added to H_{ii}, is substantially the same. However, there are notable differences in some of the results. Smaller values of F are required to give reasonable results. The dependence of the position of the $2e$ and $4t_2$ levels on F for both methods are shown in Fig. 7. F values of 1.65 for vanadate and 1.54 for tungstate leave the positions of the two levels at about the same positions as in the previous calculations. The self-consistent effective charges were quite different than previously. In vanadate, they were 3.0 and —1.5 for vanadium and oxygen, respectively, and in tungstate 3.9 and —1.5. These values are closer to the ones expected in a purely ionic model, indicating the approximation has been improved.

The emission peak can be accounted for by a $2e \rightarrow t_1$ transition after the excited state has come to equilibrium with a larger metal-ligand distance. A series of calculations on vanadate were made to study the effect of the metal-ligand distance R on the energy levels. The results are summarized in Fig. 8 for the $2e$ and $4t_2$ levels. It can be seen that in order to get the observed emission at 22.5 kK, the value of R for the excited state must be 1.85Å. This requires an increase in R of 0.15Å, which is quite reasonable.

Additional Splitting of Energy Levels

The calculations described in the previous section neglected to take into account the complete effects of the electrostatic repulsion of electrons. These interactions will further split the energy levels. The ground state configuration of both complexes is $(t_1)^6$, which results in a singlet term, $^1A_1$. The configuration of the first excited state is $(t_1)^5$ $(2e)$. This configuration splits up into the multiplets $^1T_1$, $^1T_2$, $^3T_1$, and $^3T_2$. Ballhausen (20) gives the order of the levels as $^1T_1 > {}^1T_2 > {}^3T_2 \approx {}^3T_1$. The other excited state of interest has the configuration $(t_1)^5$ $(4t_2)$ and splits into singlets and triplets of T_2, T_1, E, and A_1 in that order of decreasing energy, according to Wolfsberg and Helmholtz (18).

The order of the levels taken from the above two

references were based on simplified calculations that neglected overlap integrals. Since some of the overlaps are large, the order given need not necessarily be the actual order. From symmetry considerations, the only allowed electric dipole transitions from the $^1A_1$ ground state are to T_2 states. Each of the two excited configurations has one triplet $^3T_2$ and one singlet $^1T_2$. Since the ground state is a singlet, transitions to triplet states are allowed only to the extent that there is spin-orbit coupling. The magnitude of spin-orbit coupling is greater in tungsten than in vanadium so that the transition intensities to the triplet states should be relatively larger.

The analysis thus far does not account for all the peaks in the absorption spectrum. The magnitude of the spin-orbit splitting is too small to be observed in such a curve. This indicates that "forbidden" transitions are present. These can become allowed because of vibronic interactions or a reduction of symmetry. The vanadate and tungstate complexes in YVO_4 and $CaWO_4$ are actually slightly distorted tetrahedra having D_{2d} symmetry. The vanadate is elongated along the z axis, while the tungstate is contracted. The lowering in symmetry splits each of the tetrahedral levels, except the A_1 levels, into two separate levels. Because of the smallness of this perturbation, it is not expected that this splitting is observed in our derived absorption curves. However, the new selection rules now allow a greater number of transitions. The T_1 states split into E and A_2 states in D_{2d} symmetry. With tetrahedral symmetry transitions to T_1 states were forbidden. However, in D_{2d} symmetry transitions to E states are allowed.

Assignment of the various Gaussian components of the calculated absorption spectra to specific transitions is necessarily highly speculative. Using Ballhausen's ordering, it is probable that the two major absorptions in the vanadate at 32.6 kK and 40.4 kK are the $^1T_1$ and $^1T_2$ levels of the transition $t_1 \rightarrow 2e$. The two absorptions at 45.0 kK and 49.5 kK are then assigned to $^1T_1$ and $^1T_2$ of $t_1 \rightarrow 4t_2$.

The weaker absorption at 35.0 kK may be $^3T_2$ of $t_1 \rightarrow 2e$ with the $^3T_1$ being buried in the major absorption peak. The weak peak at 36.4 kK may be a $^1T_1$ level for the transition $3t_2$ to 2e. The assignments give an experimental gap of 11 kK between 2e and $4t_2$ and 4.0 kK between $3t_2$ and t_1. The triplet level is 5.5 kK below the singlet.

In the more complex tungstate spectrum, the 42.4 kK and 48.4 kK peaks are assigned to $^1T_1$ and $^1T_2$ of $t_1 \rightarrow 2e$ with the triplets $^3T_1$ and $^3T_2$ giving 40.0 kK and 44.8 kK peaks. The greater intensities of the triplets is in agreement with the greatly increased spin-orbit coupling in tungsten which will mix singlet and triplet states.

The singlets $^1T_1$ and $^1T_2$ for the $t_1 \rightarrow 4t_2$ transitions are placed at 52.2 kK and 55.8 kK. The remaining absorptions at 46.0 kK and 58.0 kK can be tentatively ascribed to $^1T_1$ for $3t_2 \rightarrow 2e$ and $3t_2 \rightarrow 4t_2$.

These assignments give an experimental gap of 9.0 kK between 2e and $4t_2$ with an average value of 4.6 kK between $3t_2$ and t_1. The triplet levels are about 3.0 kK below the singlets. These assignments are summarized in Table I.

Conclusions

This paper is a first attempt to apply semiempirical molecular orbital theory to problems of oxygen-dominated phosphors. The excitation spectra, assumed to be due to absorption by a complex ion with appreciable covalent bonding, allows derivation of an absorption spectrum with much more detail than can be obtained by a reflectance measurement. Analysis into Gaussian components reveals that a rather complex array of separate energy levels must be present in the ions.

The approximations made in the molecular orbital calculations were introduced in order to simplify the rather formidable mathematical problem involved in computing the electronic structure of such complex systems. These approximations limit us to determining the average energies of configurations only.

Recently, molecular orbital calculations were performed by Dahl and Johansen (21) on a series of tetrahedral complexes, including VO_4^{3-} but not WO_4^{2-}. Their calculations involved the actual computation of diatomic coulomb and exchange integrals and thus contained less severe approximations than in our work. However, their extensive computations on the permanganate complex have shown that the results are quite sensitive to the choice of atomic orbitals. It therefore might be questionable as to whether more exact calculations are warranted until more is known on how the atomic functions change when the ion is brought into the complex. The order of the levels obtained by Dahl and Johansen for vanadate is different from ours. Their results show the $4t_2$ level to be lower in energy than 2e. From a simple crystal field theory point of view, it is more plausible for the 2e state to be lower in tetrahedral symmetry (22). Furthermore, this would make the results consistent with the level ordering in permanganate.

Even with these limitations, the present calculation gives useful results. Selection of a value of the parameter *F* to fit the lowest major peak by a t_1 to 2e transition places the t_1 to $4t_2$ transition at energy very close to the second major peak of the absorption spectrum.

The existence of other energy levels is predicted by group theory for the distorted tetrahedral shape of the complex ion in its crystal site. For the vanadate ion, tentative assignments can be made and the observed splitting of the average energy of the configuration into singlet A, E, T_1, and T_2 terms is of the anticipated order of magnitude.

The more complex spectrum of the tungstate can be ascribed to transitions to triplet terms. The probability of such transitions would be low for vanadate and considerably higher for tungstate.

Assuming a relaxation of the lattice after excitation is responsible for the Stokes shift giving visible blue emission from the ultraviolet absorption, the change in interionic spacing was found to be 0.15Å, which appears reasonable.

Further refinement of the calculation to fix more definitely the order and position of the separate terms of the various configurations would add to its value. Work on such a refinement is in progress.

Acknowledgments

We wish to thank Costas Lagos for synthesizing the YVO_4 sample and Robert F. Craig, Stanley Reczek, and Robert Maleszyk for taking measurements of the spectra.

Luminescence Properties of Rare Earth Tellurates

S. Natansohn

The Bayside Research Center of General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

The fluorescent properties of a new class of inorganic phosphor materials based on rare-earth tellurates R_2TeO_6 as host materials are discussed. Yttrium, lanthanum, gadolinium, and lutetium tellurates, activated by trivalent rare-earth or by uranyl ions, show significant luminescence under ultraviolet or cathode ray excitation. The cathodoluminescent response of the uranyl-activated rare-earth tellurates is comparable to that of the most efficient uranyl phosphors known. The effect of structural variations on the spectral energy distribution of the UO_2^{2+} and Eu^{3+} emission is considered.

The chemical literature contains few references to the rare-earth tellurates. Mellor (1) reports the synthesis of yttrium tellurate by Berzelius but gives no formula for the compound. Kent and Eick (2) mention parenthetically the formation of compounds of the form R_2TeO_6 under certain conditions in their synthesis of rare-earth (III) monoxotellurides without providing identifying information about these materials. Furthermore, available literature sources contain no reference to fluorescent materials based on metal tellurates as the host matrix. This paper describes the luminescence phenomena observed on activation of the optically inert Y, La, Gd, and Lu tellurates. The green-emitting uranyl ion, UO_2^{2+}, and the red-emitting trivalent Eu ion were the principal activators used in this study, although other activators were also examined.

Experimental

The compounds were prepared by mixing equimolar amounts of the appropriate reagent-grade rare-earth sesquioxides and orthotelluric acid, $Te(OH)_6$, and then heating the mixture in silica crucibles in a series of steps up to a temperature of 1200°C. For best luminescent results, the heat treatment was done in an oxygen atmosphere, although the compounds can be readily formed in air. Typically, the samples were fired at 800°, 1000°, and 1100°C for 4 hr each, and the charge was mortared between the heating steps. The rare-earth activators were added substitutionally in the form of oxides, while the uranyl activator was conveniently added as the nitrate or acetate. The activator concentration was generally between 0.005 and 0.10 mole/mole of R_2TeO_6.

The procedure for establishing the composition of the rare earth tellurates was given elsewhere (3) and the presence of the desired phases was checked after each firing step by x-ray diffractometry. Unless otherwise indicated, the excitation and emission spectra are given in terms of relative energy *vs.* wavelength and were obtained by the procedure described by Amster and Wiggins (4). Diffuse reflectance spectra were obtained on the Cary 14 spectrophotometer.

Results and Discussion

The Y, La, Gd, and Lu tellurates are white crystalline substances whose x-ray powder diffraction patterns were indexed on the basis of a hexagonal unit cell (3) (Table I). They are structurally different from the rare-earth tungstates and molybdates with analogous formulas which have been the subject of extensive investigations as phosphor materials (5-7). The nature of the diffractograms and analysis of the observed systematic extinctions indicate that Y, La, and Gd tellurates are isomorphous, but Lu_2TeO_6, although hexagonal, is of a different crystalline system. The x-ray powder diffraction data are insufficient to determine the space

group of these compounds; however in the case of Y, La, and Gd tellurates it is possible to narrow down the choice to three space groups $P6_3$, $P6_{3/m}$, and $P6_322$.

Spectroscopic Properties of Eu^{3+}*-Activated* R_2TeO_6

Activation of the rare-earth tellurates by lanthanide luminogens results in phosphors with emission characteristics typical of the particular activator. The photoluminescent spectra of Eu^{3+}-activated lutetium and yttrium tellurates are depicted in Fig. 1. The dominant emissions in the fluorescence spectra of the rare-earth tellurates are observed in the 600-620 nm spectral region corresponding to the $^5D_0$-$^7F_2$ transition. Significant emission is also observed around 700 nm, corresponding to the $^5D_0$-$^7F_4$ transitions. The intensity of these electric dipole transitions implies that the Eu^{3+} site is not a center of symmetry. Emissions corresponding to transitions from the $^5D_0$ to the other levels of the ^7F multiplet, namely $^7F_0$, $^7F_1$, and $^7F_3$, are also present. Blasse and Bril (8) postulate the occurrence of the $^5D_0$-$^7F_0$ transition only for point symmetries of C_s, C_n, and C_{nv}. These site symmetries are found in each of the three possible space groups formulated for the Y, La, and Gd tellurates on the basis of x-ray powder diffraction data.

The luminescence spectrum of Eu^{3+}-activated yttrium tellurate is quite complex, and the multiplicity of emission lines suggests strongly that the Eu is located in more than one site. This is supported by the fact that there are two distinct emission lines present in the spectral region of 575 to 578 nm, where the $^5D_0$-$^7F_0$ transition is generally found. Since this $J = 0 \rightarrow J = 0$ transition is not split by the crystal field, the occurrence of two components of this assignment would indicate that the Eu in Y_2TeO_6 occupies sites of different symmetry. This is not the case for the structurally different lutetium tellurate, where only one emission line is observed for the $^5D_0$-$^7F_0$ transition at 576 nm and where the total number of spectral lines is significantly lower. These facts imply a single Eu site in this compound. The emission spectra of Eu-activated lanthanum and gadolinium tellurates (Fig. 2) are similar in their gross features to the spectrum of Y_2TeO_6 with which they are isostructural but are different in detail. The two components of the $^5D_0$-$^7F_0$ transition can be distinguished in both phosphors. The relative intensity of the various emission lines of the $^5D_0$-$^7F_2$ transition, however, varies in the isostructural rare-earth tellurate phosphors. It is possible to distinguish two groupings

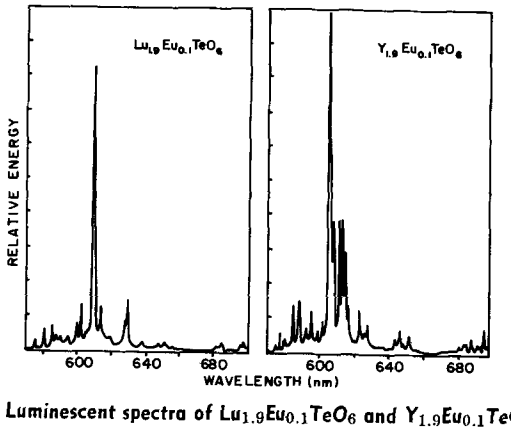

Fig. 1. Luminescent spectra of $Lu_{1.9}Eu_{0.1}TeO_6$ and $Y_{1.9}Eu_{0.1}TeO_6$

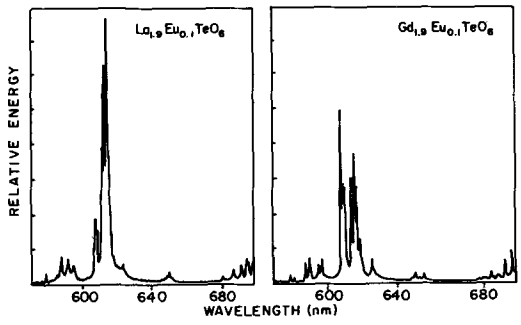

Fig. 2. Luminescent spectra of $La_{1.9}Eu_{0.1}TeO_6$ and $Gd_{1.9}Eu_{0.1}TeO_6$

in the emission lines of the $^5D_0$-$^7F_2$ transition. The relative fluorescence intensity of the group at longer wavelength increases with increasing ionic radius of the host cation, *i.e.*, from Y → Gd → La. A detailed analysis of the luminescence spectrum of Eu^{3+} in rare-earth tellurates is in progress.

The excitation spectra for the Eu^{3+} emission in these four phosphors are given in Fig. 3. They all have broad excitation bands in the short ultraviolet range which have been ascribed by Blasse and Bril (9) to a europium-oxygen charge-transfer band. The positions of the band maxima are 240 nm for Lu_2TeO_6, 255 nm for Y_2TeO_6, 260 nm for Gd_2TeO_6, and 272 nm for La_2TeO_6. The excitation spectra also contain narrow bands of varying intensity in the near ultraviolet corresponding to the f-f absorptions of the Eu^{3+} ion. The diffuse reflectance spectra (Fig. 4) show an absorption band at 300 nm which does not appear in the excitation spectrum of the phosphors. This absorption is most clearly defined in the Lu_2TeO_6 phosphor but is present in all the investigated compounds, and apparently results in a nonradiative dissipation of the absorbed energy.

The Eu-activated rare-earth tellurates are moderately efficient phosphors. They respond to ultraviolet or cathode ray excitation with a luminous efficiency up to 40% that of the YVO_4:Eu^{3+} (10). The energy trans-

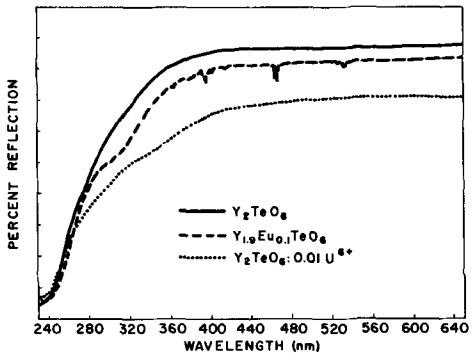

Fig. 4b. Diffuse reflectance spectra of $Y_{1.9}Eu_{0.1}TeO_6$

fer from the tellurate lattice to the rare-earth activators appears to be inefficient. This is indicated by the uncorrected fluorescence spectra of the Dy, Ho, and Er-activated lanthanum tellurates (Fig. 5) which show the dominant excitations occurring directly into the 4f levels of the particular trivalent lanthanide ion and no apparent excitation of the host matrix.

Spectroscopic Properties of U^{6+}*-Activated* R_2TeO_6

The fluorescence spectra of the uranium-activated Y, La, and Gd tellurates are virtually identical. A typical example is given in Fig. 6 which depicts the cathodoluminescence spectrum of La_2TeO_6:$0.01U^{6+}$. The peak emission is at 515 nm and the halfwidth is 35 nm. The emission curve is asymmetrical and skewed toward the longer wavelength. The position of the emission band is at a shorter wavelength than that observed in other uranium-activated phosphors such as $Mg_5Li_6Sb_2O_{13}$:U^{6+} (10) and Li_4WO_5:U^{6+} (12). The cathodoluminescence spectrum of uranium-activated lutetium tellurate is shown in Fig. 7. The different crystalline structure of this compound results in a significant change in the spectral energy distribution. The emission is characterized by two distinct peaks, a

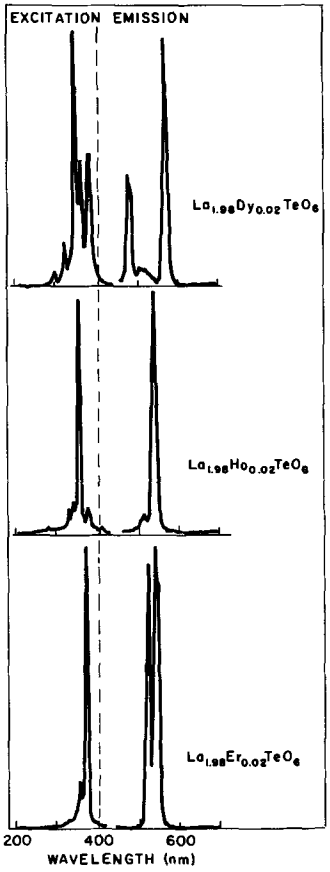

Fig. 5. Emission spectra of $La_{1.98}R_{0.02}TeO_6$ (R = Dy, Ho, Er)

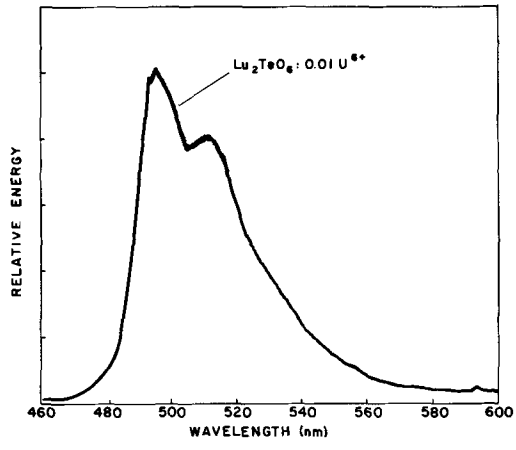

Fig. 7. Cathodoluminescent spectrum of Lu_2TeO_6:$0.01U^{6+}$

principal one at 495 nm and a secondary band with a maximum at 510 nm. These results demonstrate that the spectrum of the hexavalent uranium center is strongly affected by the nature of the crystalline host matrix.

The exact nature of the emission center in uranium-activated phosphors is not known. The emission is generally ascribed to the molecular uranyl ion, UO_2^{2+}, which when solvated or in loosely coordinated compounds such as uranyl salts or glass, exhibits a series of equispaced narrow fluorescence bands in the blue and green regions of the visible spectrum. In Fig. 8, which depicts the spectrum of uranyl nitrate, it is possible to

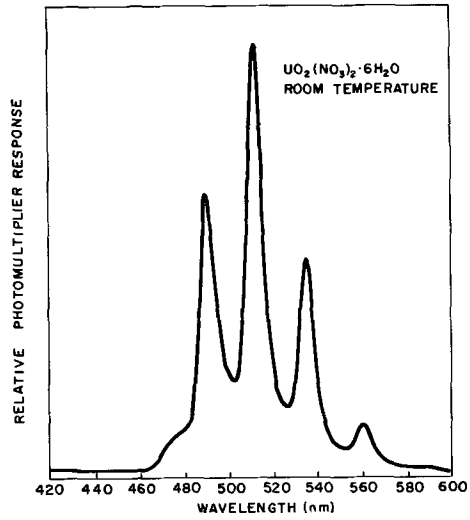

Fig. 8. Emission spectrum of $UO_2(NO_3)_2 \cdot 6H_2O$

distinguish six of these bands which are ascribed (13) to electronic transitions from the lowest excited level to the vibrational levels of the ground state. Recently, Bell and Biggers (14), in a study of aqueous uranyl ion in perchlorate medium, reported the existence of two radiation-emitting levels. They found that five emission bands separated by the ground state vibrational frequency came from the lowest absorption level of the uranyl ion, while the emission band at the shortest wavelength (whose separation is smaller than that of the others) came from the next higher absorption level; the higher level is not noticeably affected by the ground state vibrations and accounts for only a small fraction (some 4-5%) of the emitted energy.

In the case of solids such as uranyl-activated phosphor materials, it is assumed that the molecular UO_2^{2+} species is preserved in the oxygen-dominated crystalline matrix by having the uranium coordinated by two oxygen ions at a distance which is of the order of that found in the uranyl linkages (the length of the U-O bond in solids varies considerably and is given as 1.6-2.3Å), while the additional oxygen ligands required by the crystal symmetry are located at distinctly greater distances (15). In such systems the interaction of the host lattice with the uranyl ion is sufficiently strong to alter significantly the nature of the radiative transition so that the uranyl emission in such compounds is characterized by a relatively broad fluorescence band which may have some additional structure. The fact that the identity of the uranyl ion is preserved to some extent in the rare-earth tellurates is demonstrated by Fig. 9 which depicts the photoluminescent spectrum of uranyl-activated Gd_2TeO_6 taken at room and liquid N_2 temperatures. In the low-temperature spectra it is possible to discern the presence of at least three emission peaks which were undistinguishable at room temperature. There seems to be no radiation at liquid N_2 temperatures in the blue-green region where Bell and Biggers (14) observed the transition from the second, higher absorption level, although it is present at room temperature. Similar resolution at liquid nitrogen temperature of the SED curve into more distinct bands is observed in Y, La, and Lu tellurates.

The positions of the clearly discernible uranyl emission peaks in the rare-earth tellurates at liquid N_2 temperatures and the separation between them is given in Table II. Data for uranyl nitrate at room temperature measured here are included for comparison; these agree quite well with the values cited in the literature (16). The vibrational spacings obtained in the rare-earth tellurates are significantly smaller than those of the uranyl nitrate. This fact implies the crowding of the vibrational levels which is indicative of the weakening of the internal bonding of the uranyl ion. There is a significant difference between the spacing observed in lanthanum tellurate and the other three compounds. It may be due to an increase in length of the uranyl axial bond in the larger La-compound which could lead to a decrease in vibrational frequency (17).

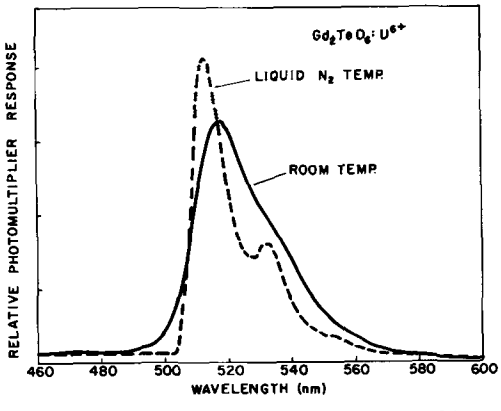

Fig. 9. Emission spectrum of $Gd_2TeO_6:0.01U^{6+}$

Table II. Vibrational spacing of uranyl emission peaks

Compounds	Emission peaks λ (nm)	ν (cm⁻¹)	Δν (cm⁻¹)
$UO_2(NO_3)_2 \cdot 6H_2O$	489	20,450	880
	512	19,570	840
	534	18,730	870
	560	17,860	
$La_2TeO_6:0.01U^{6+}$	508	19,680	600
	524	19,080	630
	542	18,450	
$Gd_2TeO_6:0.01U^{6+}$	513	19,490	690
	532	18,800	680
	552	18,120	
$Y_2TeO_6:0.01U^{6+}$	513	19,490	690
	532	18,800	680
	552	18,120	
$Lu_2TeO_6:0.01U^{6+}$	491	20,370	690
	508	19,680	700
	527	18,980	

The band spacing and the relative intensity of the discernible bands is the same in the Y, Gd, and Lu tellurates regardless of the position of the principal emission peak (in liquid N_2, 491 nm for Lu_2TeO_6 or 513 nm for Y_2TeO_6 and Gd_2TeO_6). This implies that the transitions involved are the same in all compounds but that the energy gap between the ground state and first excited level is different.

Bell and Biggers (14) distinguish seven major absorption bands in the spectrum of solvated uranyl ion. The oscillator strength of these bands increases with increasing band energy. A somewhat analogous situation exists in the uranium-activated rare-earth tellurates. In the excitation spectra of these materials, shown in Fig. 10, several bands can be distinguished whose intensity increases with increasing band energy. The location of the bands corresponds approximately to the positions resolved by Bell and Biggers (14). This analogy leads to the assumption that the excitation occurs directly into the uranium center which in this case, where the uranium most likely occupies a tellurium site in the lattice, is coordinated by oxygen in such a manner so as to preserve the identity of the uranyl species. This hypothesis is supported by the fact that the diffuse reflectance spectra of these compounds (Fig. 4) do not show corresponding host absorption bands which would indicate an absorption of the energy into the lattice and subsequent transfer to the activator.

As indicated by their excitation spectra, the uranium-activated rare-earth tellurates respond to both short- and long-wave u.v. radiation. They are comparable in luminous efficiency to $Zn_2SiO_4:Mn^{2+}$ under excitation by a low-pressure mercury vapor lamp (dominant λ:2537Å) and to ZnS:Cu under medium-pressure Hg lamp (dominant λ:3650Å). The luminosity under cathode-ray excitation compares favorably with that of the best cathodoluminescent uranium-activated phosphors known, but it is only 20-25% that of Zn_2SiO_4:Mn.

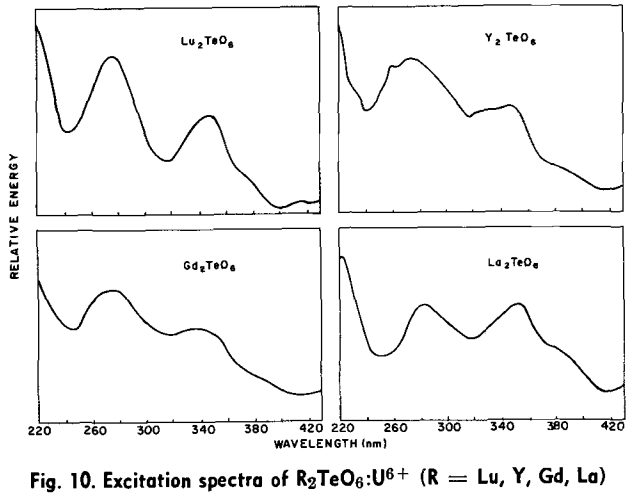

Fig. 10. Excitation spectra of $R_2TeO_6:U^{6+}$ (R = Lu, Y, Gd, La)

The rare-earth tellurates are a new class of inorganic phosphors with interesting luminescent properties. When activated by trivalent europium, they exhibit characteristics which are consistent with the observations made by numerous researchers in the field. The exact assignment of transitions is not possible pending the clarification and resolution of the crystal structure. The significant conclusion of the research with uranium activated tellurates is the indication that the identity of the molecular ion uranyl species is preserved in a solid crystalline matrix as demonstrated by its fluorescent properties. Further analysis is required to define more closely the luminescence mechanisms in uranium activated compounds.

Acknowledgment

The author gratefully appreciates the assistance of R. Francis in much of the experimental work, the spectroscopic measurements of C. Wiggins, and the helpful discussions with F. Avella, G. Gashurov, F. Palilla, and O. Sovers. The diffuse reflectance spectra were kindly provided by E. Lanning.

Manuscript submitted March 20, 1969; revised manuscript received May 21, 1969. This was Paper 36 presented at the Boston Meeting, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Glow Curves with General Order Kinetics

Reuven Chen

Physics Department, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Thermoluminescence and thermally stimulated current curves obeying general order kinetics laws are being investigated. For these cases, whose order is not necessarily first or second but rather may have some noninteger value, an effective method of calculating the activation energy is given. This method is based on measuring the temperature at the maximum of the glow peak and the half intensity temperatures. Numerical calculations for orders between 0.7 and 2.5, activation energies between 0.1 and 1.6 eV and frequency factors between 10^5 and 10^{13} sec^{-1} have been done using an I.B.M. 360 computer. The results reveal the general characteristics of these peaks and their dependence on the parameters. The new method for calculating the activation energy is also checked numerically.

The measuring of glow curves was found to be one of the most convenient ways to determine the activation energies of trapping levels in crystals. This includes the phenomena of thermoluminescence (TL) (1), thermally stimulated current (TSC) (2), thermally stimulated electron emission (TSEE) (3), and thermally stimulated capacitor discharge (TSCD) (4). The glow curves were analyzed usually by assuming first or second order kinetics. The first order case was investigated first by Randall and Wilkins (5) who assumed that the glow intensity I may be given by

$$I = -dn/dt = sn \exp(-E/kT) \quad [1]$$

where n is the concentration of trapped carriers (cm^{-3}), t the time, s the frequency factor (sec^{-1}), sometimes referred to as "the preexponential factor," E is the activation energy (ev), k is Boltzmann's constant, and T the absolute temperature. By solving this differential equation and assuming a linear heating rate of β °K/sec, one has for the intensity

$$I = sn_o \exp(-E/kT) \exp\left[-(s/\beta)\int_{T_o}^{T} \exp(-E/kT')\,dT'\right] \quad [2]$$

Key words: glow curves, thermoluminescence, thermally stimulated current, activation energy, kinetics order, frequency factor.

where n_o is the initial concentration of carriers and T_o the initial temperature. The condition for the maximum of the peak is found by differentiating Eq. [2] and equating the derivative to zero. Thus

$$\beta E/(kT_m^2) = s \exp(-E/kT_m) \quad [3]$$

where T_m is the temperature at the maximum. Garlick and Gibson (6) introduced the possibility of second order glow peaks, obeying the equation

$$I = -dn/dt = s'n^2 \exp(-E/kT) \quad [4]$$

where s' is a "preexponential constant" (cm^3 sec^{-1}). The solution of the equation gives

$$I = s'n_o^2 \exp(-E/kT) \left[1 + (s'n_o/\beta)\int_{T_o}^{T} \exp(-E/kT')\,dT'\right]^{-2} \quad [5]$$

and the condition for the maximum is

$$1 + (s'n_o/\beta)\int_{T_o}^{T_m} \exp(-E/kT)\,dT = \frac{2kT_m^2\, s'n_o}{\beta E} \exp(-E/kT_m) \quad [6]$$

Many methods for calculating the activation energies of glow curves have been given (2). Only one of these, the "initial rise" method (6) is expected to be useful for all the possible orders of the process. However, in many cases, the use of this method is limited because of experimental (7) and theoretical (8, 9) reasons.

A useful method of calculating the activation energy by using the temperature maximum T_m and the falloff half of the peak $\delta = T_2 - T_m$ where T_2 is the higher of the two half intensity temperatures, was given by Lushchik (10) for first and second order kinetics. Another method using the low temperature half width $\tau = T_m - T_1$ was developed by Halperin and Braner (11). These two methods were slightly modified by Chen (12) and are now more accurate and more easily usable. Chen also gave another method in which the total width $w = T_2 - T_1$ is used, and showed that in certain cases this method is preferable. The three methods were summed up (12) as

$$E_\alpha = c_\alpha (kT_m^2/\alpha) - b_\alpha (2kT_m) \qquad [7]$$

where α is δ, τ, or w. The values of c_α and b_α for the three methods and for first and second order processes are given in Table I. The equations [7] are slightly changed in cases where the preexponential factor depends on temperature as a power function $s = s''\ T^a$ where usually $-2 \leq a \leq 2$ (11-13) (see below).

Halperin and Braner (11) showed that an easy way to determine the order of a peak is by checking the values of $\mu_g = n_m/n_o$ where n_m is the concentration of carriers at the maximum. Values of μ_g of about $(1 + \Delta)/e$ where $\Delta = 2kT_m/E$, should indicate first order kinetics, whereas values around $(1 + \Delta)/2$ indicate second order. As an aproximation to μ_g the value of $\mu_g' = \delta/w$ was taken. Chen (12) found that a characteristic value of μ_g' for first order peaks is 0.42 and for second order 0.52.

Although the conventional way for analyzing glow curves is assuming either first or second order kinetics, this by no means covers the general case even if only a single activation energy is involved. Halperin and Braner (11) wrote three simultaneous differential equations relating the variables n = the concentration of trapped electrons, m = the concentration of holes in centers, and n_c = the concentration of free electrons. However, Halperin and Braner solved the problem only for those conditions leading to reduction of the three equations to the first or second order cases.

A better approximation for the general case may be given by the equation given by May and Partridge (14)

$$I = -dn/dt = s'n^l \exp(-E/kT) \qquad [8]$$

where l is not necessarily 1 or 2. The general case of $l \neq 1$ is essentially limited to samples in which the concentration of trapped carriers involved in the glow peak is equal to that of the empty centers. May and Partridge (14) proved that for simultaneous activation of two electrons, the value of l should be 1.5. This same value was found by them experimentally for TL peaks in KCL samples. Partridge and May (15) report the same order of 1.5 for NaCl samples after a certain heat treatment, whereas other peaks in NaCl yield values of 0.7 ± 0.1.

In the present paper, this problem of general order kinetics is further investigated. Some of the properties of the peaks are found by numerical calculations of the peaks' parameters by the use of an I.B.M. 360 computer. Several interpolation methods for calculating the activation energies based on the methods of Lushchik, Halperin and Braner, and Chen for first and second order are introduced and checked. The method based on the measurement of τ is found to be the most accurate.

Table I. Coefficients appearing in Eq. [7] for the various methods of calculating activation energies

	First order			Second order		
	τ	δ	w	τ	δ	w
c_α	1.51	0.976	2.52	1.81	1.71	3.54
b_α	1.58	0	1	2	0	1

Theoretical Approach and Numerical Calculation

The solution of Eq. [8] gives for $l \neq 1$

$$I = s'n_o^l \exp(-E/kT) \left[\frac{(l-1)s'n_o^{(l-1)}}{\beta} \int_{T_o}^{T} \exp(-E/kT')\,dT' + 1 \right]^{-l/(l-1)} \qquad [9]$$

A special case of this equation for $l = 2$ is Eq. [5]. $s'n_o^{l-1}$ has the units of sec^{-1} and in this sense it is similar to s in the first order case. If one writes s instead of $s'n_o^{l-1}$, one has

$$I = sn_o \exp(-E/kT) \left[\frac{(l-1)s}{\beta} \int_{T_o}^{T} \exp(-E/kT')\,dT' + 1 \right]^{-l/(l-1)} \qquad [10]$$

Although Eq. [10] is not valid for the case $l = 1$, it can easily be shown that it reduces to Eq. [2] in the limit when $l \to 1$. It is in this sense that Eq. [10] is a general formula applicable for all possible values of l.

The condition for maximum is found by equating the derivative of [10] to zero

$$[(l-1)\ s/\beta] \int_{T_o}^{T_m} \exp(-E/kT)\,dT + 1 = \frac{slkT_m^2}{\beta E} \exp(-E/kT_m) \qquad [11]$$

Again, a special case for $l = 2$ would be Eq. [6]. It should also be noted that Eq. [11] reduces to Eq. [3] for $l = 1$ which might be expected from the fact that Eq. [9] and [10] are valid for the first order case in the sense of the limit for $l \to 1$.

In a way similar to what has been done previously (12) for first and second order peaks, Eq. [11] can be solved numerically for given values of l, s, E, and β (and assuming that T_m is sufficiently larger than T_o) to give the value of T_m. This is done by approximating the integral of the left hand side of Eq. [11] by a certain number of terms of the asymptotic series (7)

$$\int_{T_o}^{T} \exp(-E/kT')\,dT' \cong T \exp(-E/kT) \sum_{n=1} \left(\frac{kT}{E}\right)^n (-1)^{n-1}\, n! \qquad [12]$$

and solving the equation by the iterative Newton-Raphson method (12).

This has been done for values of l between 0.7 and 2.5, values of s between 10^5 sec^{-1} and 10^{13} sec^{-1} and values of E between 0.1 and 1.6 eV. These ranges seem to cover practically all the parameters' values found experimentally. β was taken to be 0.5°K/sec and this parameter has not been varied since we can consider s/β as one parameter in Eq. [11] and s was varied by several orders of magnitude. As a first approximation for the iterative process, it was found useful to take $T_m = 500 \times E$. These calculated values of T_m are seen in column 4 of Table I for given values of E, s, and l shown in columns 1, 2, and 3, respectively. Only the cases with $1 < l < 2$ are given in some detail, whereas only examples for $l = 2.5$ and $l = 0.7$ are shown. The calculations were done, however, for the whole mentioned range and the conclusions are based on all of these results. It is to be noted that the computed values of T_m for fixed values of E and s depend

very slightly on the value of l. This can be understood by examining Eq. [11]. By taking only the first two terms in the series [12] which is a good approximation for most of the cases (11), Eq. [11] yields

$$\beta E/(kT_m^2) = s\exp(-E/kT_m)[1 + (l-1)\Delta] \quad [13]$$

where $\Delta = 2kT_m/E$. This again, reduces to the simple equation [3] for the first order case ($l = 1$). Since Δ is usually of the order of magnitude of 0.1, the term in brackets changes by 20% at most for extreme l values, which may cause changes of only around 1% in T_m because of the appearance of T_m in the exponential. Thus we may expect T_m to depend only very slightly on l for the same values of E and s, which is clearly seen in column 4.

Once the value of T_m is found, the intensity at the maximum I_m can be found by inserting T_m into Eq. [9] and using again the asymptotic series as a good approximation for the integral.

Now the values of T_1 and T_2, the low and high temperatures of half intensity, can be calculated by solving numerically the equation $I(T) = I_m/2$, when $I(T)$ is given by Eq. [9]. Again, the series approximating the integral is used throughout the iteration process. As a convenient first approximation we take 0.95 T_m for T_1 and 1.05 T_m for T_2. A similar process with somewhat more details was given previously by Chen (12) for the case of $l = 1$ and $l = 2$. By using the T_1, T_m, and T_2 values, the parameters $\delta = T_2 - T_m$ (the high temperature half width), $\tau = T_m - T_1$ (the low temperature half width and $w = T_2 - T_1$ (the total half width) are easily found, and shown in columns 5, 6, and 7 of Table I, respectively. The geometrical factor $\mu_g' = \delta/w$ is found and shown in column 8. Figure 1 gives calculated values of μ_g' as a function of the given l values. The upper and lower curves give the limits of variations of μ_g' values when E and s are varied, whereas the center curve shows the average values. This curve may be used for estimating the value of l by the measured μ_g's. The possible error is seen not to exceed ±7%. The curve gives more information than column 8 in Table II since the given average values and possible deviations (for various E and s values) are based on many sets of calculations not included in the table. Another factor characterizing the geometrical shape of a peak, namely, $\gamma = \delta/\tau$ (13) can be directly found, this is shown in column 12.

Methods for Calculating E and s

In order to find the activation energies by one of the half width methods, it is suggested to interpolate (and to some extent extrapolate) the constants appearing in the first and second order equations [7]. The interpolation could be done according to the values of l. However, this magnitude is not found directly by the experimental results. A much more convenient interpolation parameter seems to be μ_g' which is found directly and easily from the geometrical shape of the peak. μ_g' depends almost only on l, with only minor dependence on E and s (Fig. 1). Thus, interpolation with respect to the argument μ_g' is in a way interpolation with respect to l. We tried first, naturally, the simplest way of interpolation, namely, the linear interpolation. We have to write the general equations so that they would give the first order case for $\mu_g' = 0.42$ and the second order one for $\mu_g' = 0.52$ (12). With the coefficients given in Table I, the factors in Eq. [7] for the interpolated-extrapolated τ method would be

$$c_\tau = 1.51 + 3.0\,(\mu_g' - 0.42);\quad b_\tau = 1.58 + 4.2\,(\mu_g' - 0.42) \quad [14]$$

For the equation using the δ value one has

$$c_\delta = 0.976 + 7.3\,(\mu_g' - 0.42);\quad b_\delta = 0 \quad [15]$$

and for the w method we find

$$c_w = 2.52 + 10.2\,(\mu_g' - 0.42);\quad b_w = 1 \quad [16]$$

The results found by [14], [15], and [16] calculated by the computed μ_g' values are given in columns 9, 10, and 11 of Table II, respectively. These results may be compared to the known energies in order to evaluate the accuracy of each method separately. It is seen very clearly that the methods using the values of δ or w give poor evaluations for the activation energy, whereas Eq. [14] gives results which are always within 2% or better of the correct E value. This is true not only for the examples given in Table II but also for all the checked possibilities (see the ranges of the parameters above). Thus we cover most of the experimentally possible cases.

Once the activation energy is known, an estimate on the frequency factors can be found by the use of Eq. [13]. A reasonable value of s is found even when the factor $(l - 1)\Delta$ is neglected. A better evaluation can be calculated by estimating the value of l according to the measured μ_g' and using Fig. 1. It is self evident

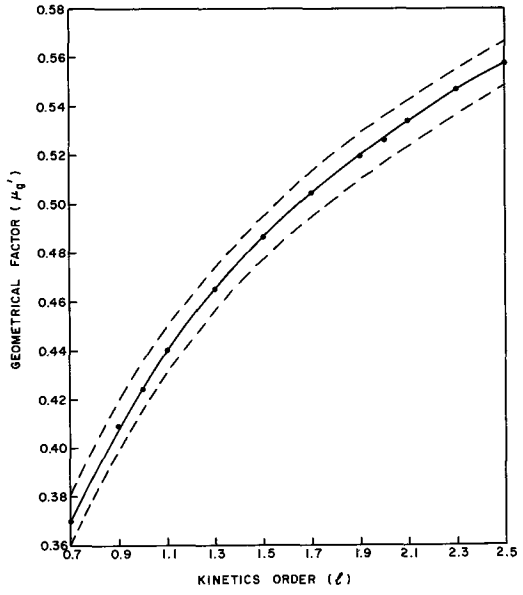

Fig 1. Calculated geometrical factor (μ_g') as a function of the given kinetics order (l). Central line gives the average values, upper and lower lines give the largest possible variations (for various E's and s's) for the given l's.

that the better the approximation in finding E, the better the corresponding calculated factor s. In order to find the constant $s'(s = s'n_o^{l-1})$, we have to have some additional information about n_o.

Discussion

Glow curves obeying a general kinetic law of the form given by Eq. [8] have been investigated. A method for calculating activation energies by the use of the maximum temperature and the low temperature half width was found by linear interpolation between the known formulas of first and second order kinetics. Similar methods using the high temperature half width and the total half width have failed. It is possible that by the use of nonlinear interpolation, better formulas could be found for the energy. However, this would make the equations more complicated. The results found by Eq. [14] are accurate to about 2%, which is comparable to the precision of the original first and second order formulas. This seems to be satisfactory for practically all the cases, especially since the possible experimental errors may contribute higher inaccuracies. Moreover, it has been shown (11, 12) that methods using the low temperatures half width are better in the sense that this portion of the peak can be "cleaned" by thermal bleaching in order to get rid of possible satellites, which would result in better calculated energy values.

It should be mentioned that the success of interpolating the equations using the low temperatures half width seems to be due to the fact that the value of τ does not depend strongly on l. The error done by using the first order τ equation for a second order peak, for example, would not exceed usually 20%. The reduction of the possible error to less than 2% by interpolation seems, however, to be essential.

Interpolation with respect to the other geometrical factor γ (7) in the same way yielded results about as good as the mentioned ones when the τ method was used, and about as bad for the δ and w methods. Another method employing the value of τ for finding the activation energy was given by Grosswiener (16) as follows

$$E_G = a_\tau kT_1T_m/\tau \qquad [17]$$

where $a_\tau = 1.41$ for first order and $a_\tau = 1.68$ for second order (12). By interpolation between these two coefficients according to the μ_g' values, results good to about 2% were found again.

The present method for estimating the value of l by the use of Fig. 1 seems to be quite reliable and appreciably simpler than the method mentioned by May and Partridge (14). An important point to be emphasized is that the present investigation gives a better insight to the relation between the various order kinetics. Equations [8], [9], [10], [11], and [13] are applicable for all values of l including 1 and 2 (Eq. [9] and [10] in the sense of the limit for $l \to 1$). Although the present treatment does not cover the problem of general glow peak associated with one activation energy, this approach seems to give much more reliable results for the calculated parameters than just using first or second order assumptions, which is the conventional approach.

Finally, it has to be noted that we dealt here only with the case of frequency factors independent of temperature. It has been mentioned above that in some cases s depends on temperature as some power function, $s = s'' T^a$ where s'' is a constant and $-2 \leq a \leq 2$. For this case, it has been shown (12) for first and second order kinetics that a better approximation can be found by subtracting akT_m from the value calculated by any of the usable methods. It can be shown that this correction is applicable for the presently discussed more general case, and thus, when "a" is known by some other measurements, it may be used. This correction seems to be significant, since in some cases it may change the calculated energy value by up to 10%.

Symbols

E	activation energy, eV
s	frequency factor, sec^{-1}
s'	preexponential factor, sec^{-1} $cm^{3(l-1)}$
l	kinetics order
T, T'	temperatures, °K
T_o	initial temperatures, °K
T_m	temperature at the maximum, °K
T_1, T_2	half intensity temperatures, °K
β	heating rate, °K/sec
t	time, sec
k	Boltzmann constant, eV/°K
I	glow intensity
I_m	maximal glow intensity
n	concentration of trapped electrons, cm^{-3}
n_o	initial concentration of trapped electrons, cm^{-3}
n_m	concentration of trapped electrons at the maximum, cm^{-3}
m	concentration of holes in centers, cm^{-3}
n_c	concentration of free electrons, cm^{-3}
τ	low temperature half width, ° K
δ	high temperature half width, ° K
w	total half width, °K
$E_\alpha, E_\tau, E_\delta, E_w$	activation energies calculated by various methods, eV
$c_\alpha, b_\alpha, c_\tau, b_\tau, c_\delta, b_\delta, c_w, b_w, a_\tau$	constants appearing in various equations for finding activation energies
Δ	correction factor $(=2kT_m/E)$
μ_g	characteristic factor $(=n_m/n_o)$
μ_g'	geometrical factor $(=\delta/w)$
λ	geometrical factor $(=\delta/\tau)$

Growth of Calcite Crystals in Gels

H. J. Nickl and H. K. Henisch[1]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

Procedures for the growth and doping of calcite crystals in gel systems are described. Crystals surrounded by gel tend to incorporate the silica network with its structure intact. Hybrid methods avoid this contamination. Crystals then grow in small volumes of solution, the solution being replenished by diffusion through gel filtering media. The solution cavities can be seeded with calcite crystals which then serve as substrates for epitaxial growth. Weight increases by factors up to 10 are easily achieved.

Calcite crystals have well-known applications in optical instrumentation and laser technology (1), and since the sources of natural specimens appear to be diminishing, a special interest attaches to all methods of growing the material artificially. Control over the nature and concentration of dopants should be achieved at the same time. Previous growth attempts of calcium carbonate by a hydrothermal method have been described by Ikornikova and co-workers (2), experiments on growth in solution by Gruzensky (3) and by Kaspar (4), and in electrochemical systems by Barta and Zemlicka (5). Morse and Donnay (6) and McCauley (7) have dealt with growth in gels, the last with emphasis on reaction mechanism and phase aspects. In the present paper some new procedures for gel growth are described and the factors which control crystal perfection are discussed, with special reference to the inclusion of silica. Experiments with rare earth and transition metal dopants are also reported.

Growth Methods

The formation of calcite is accomplished by the reaction between carbonates and calcium salts in sodium metasilicate gels. Two methods have been developed for this purpose. In the first the gel itself contains the carbonate. An aqueous mixture of sodium metasilicate and a carbonate is prepared and the *p*H adjusted to between 7 and 8, usually by means of acetic acid. After the gel has set, calcium salt solution is put on top and allowed to diffuse. Test tubes (25 x 200 mm) are used in the ordinary way (Fig. 1), but bottles up to ½ gallon volume were employed for some of the large scale experiments. Attempts to mix the calcium salt with the gel in the same way fail because calcium silicate precipitates at and above a *p*H of 7. At lower *p*H values this precipitation is avoided, but any subsequent diffusion of carbonate leads to CO_2 production which destroys the gel.

In the second method the neutral gel is initially free of calcium and carbonate ions. The reagents diffuse into it from two sides and form calcite where they meet. This is conveniently done in U-tubes (25 x 200 mm) or in tubes (45 x 130 mm) with fritted inserts (Fig. 2).

There appears to be no significant difference between the merits of the two methods; both produce well-shaped calcite rhombohedra of up to 6 mm size, within 6 to 10 weeks. A few spherulites of aragonite and vaterite also appear. The three modifications have been verified by comparison of the d-values derived from x-ray diffraction measurements with those compiled by Swanson and Fuyat (8, 9) and by McConnel (10). Room temperature (25°C) proved to be optimum for growth. High temperatures, *e.g.*, 70°C or so, favor the formation of aragonite (11-13) and cause bubbles to appear which disrupt the medium.

In all cases the gels were made from analytic grade $Na_2SiO_3 \cdot 9H_2O$, with final densities between 1.02 and 1.03, corresponding to between 0.17 and 0.23M Na_2SiO_3 in the gelling solutions. As a source of carbonate ions, solutions of Na_2CO_3 (*p*H 11.6), $(NH_4)_2CO_3$ (*p*H 9), $NaHCO_3$ (*p*H 8.6), and NH_4HCO_3 (*p*H 8.4) were used, and the calcium was derived from $CaCl_2$ or $CaAc_2$. The combination which yielded the best results was found to be $(NH_4)_2CO_3$ + $CaCl_2$ in equal concentrations (0.16M). Na_2CO_3 is less suitable on account of its high *p*H which, on neutralization, leads to high sodium acetate concentrations. These have been found to affect the quality of the resulting crystals adversely whereas ammonium acetate appears to have no such effect.

Growth Products

Crystals grown in the normal way as described, although well-formed rhombohedra (Fig. 3), are almost invariably turbid, obviously due to inclusions. As far as metals are concerned, the crystals contain

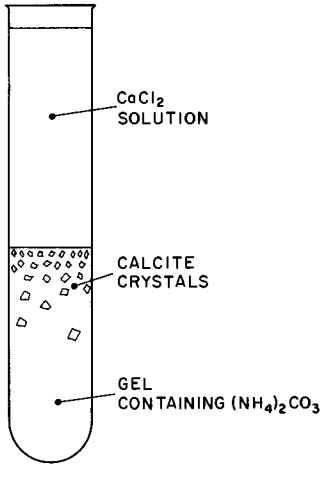

Fig. 1. Test-tube method for growing calcite crystals in gel

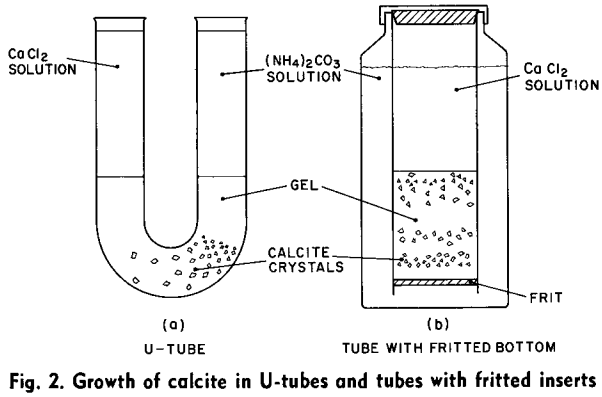

Fig. 2. Growth of calcite in U-tubes and tubes with fritted inserts

[1] Also Department of Physics.

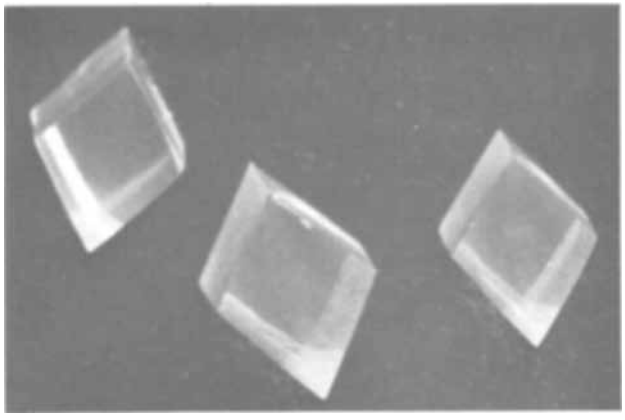

Fig. 3. Rhombohedra of gel-grown calcite. Edge lengths: 2.5 mm

about 80 ppm of Sr and smaller amounts of Ba, Mg, and Cu, as determined by emission spectroscopy. However, they also contain relatively large amounts of Na and Si (as SiO_2), both nonuniformly distributed, but not in coinciding patterns, as shown by electron microprobe tests. Quantitative analysis showed that the amount of SiO_2 varies between 0.47 and 1.7% when prepared in gels of varying density between 1.02 and 1.03 g/cc. Despite this gross contamination, the specimens have well-developed and smooth crystal faces. Dissolution of a turbid crystal in acid leaves a residue which maintains the shape of the original specimen. Figure 4 shows this after partial solution; the dense inner core is part of the original calcite crystal. The surrounding residue turns out to be silica gel which can be examined by the freeze-drying technique already described (14) and shown to have the same structure as the original growth medium (Fig. 5). It is clear from the results that the silica network which constitutes the gel is incorporated into the growing crystals more or less intact. In this way, calcite differs greatly from other gel-grown crystals, *e.g.*, calcium tartrate, which are surprisingly free from silica contamination. In these cases, the gel is bodily displaced by the advancing growth surface, whereas calcite permeates the silica network while maintaining a high level of short-range order. In this respect, the gel-grown specimens resemble certain natural calcite structures, *e.g.*, the spikes of sea urchins.

A few of the crystals are found to grow in fissures, and thus at the boundaries between gel and solution. These are turbid to the extent to which they overlap the gel and clear to the extent to which they grow in solution. The two regions can be clearly seen in Fig. 6. The same observations were made on crystals

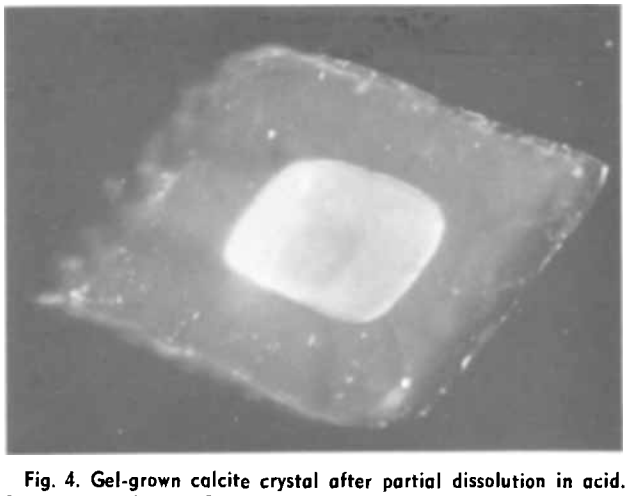

Fig. 4. Gel-grown calcite crystal after partial dissolution in acid. Original edge length: 2.5 mm.

of aragonite and vaterite grown by the same procedures.

Doping

The methods described above can also be used for the preparation of doped crystals. Dopants in the form of chlorides or nitrates can be incorporated in the sodium metasilicate solution before gelling or else in the supernatant solution. Small amounts did not affect the growth habit of the calcite crystals, but high dopant concentrations were found to prevent the growth of regular rhombohedra. The maximum permissible concentrations for regular growth differed for the various metal ions examined. For Co^{+2}, Ni^{+2}, Cu^{+2}, Mn^{+2}, Mg^{+2}, and Zn^{+2}, they were of the order of 10^{-3}M in the gel and 5 to 20 times higher in the supernatant solution. For Cr^{+3} the maximum is about 0.1M (in the gel). All these metals form hydroxides which are insoluble in pure water but somewhat soluble in the presence of NH_4OH and ammonium salts. For Nd^{+3}, Ho^{+3}, Er^{+3} and Fe^{+3}, the maximum permissible concentrations in the gel were of the order

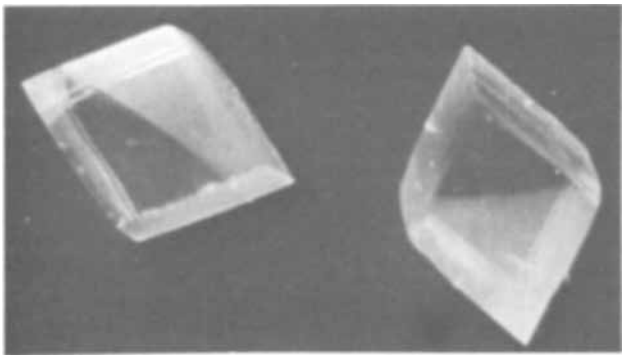

Fig. 6. Boundaries between calcite regions grown in gel and those grown in solution. Edge lengths: 2.5 mm.

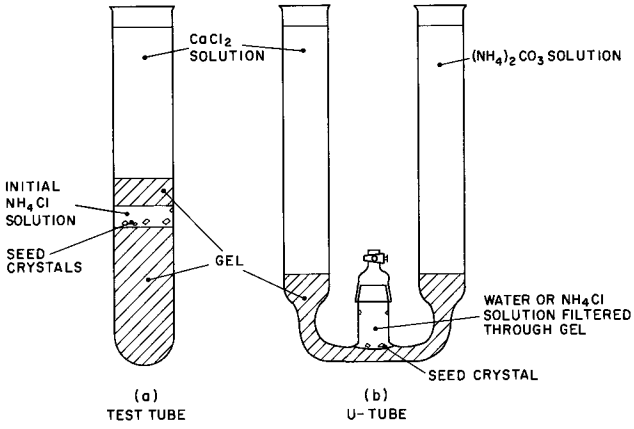

Fig. 7. Systems for calcite growth by hybrid gel method

of 10^{-4}M or, as in the last case, too small to be readily determined. These metals form hydroxides and carbonates which are even more insoluble than those listed above under the growth conditions employed. It is therefore reasonable to assume that they precipitate earlier in microcrystalline form. Subsequent calcium carbonate growth would then occur by epitaxy, as suggested by Johnston and co-workers (12, 15), and discussed by McCauley (7) who list many other references. Epitaxy would lead to growth without any particular relation to the rhombohedra found at lower concentrations. For the metals which form more soluble hydroxides and carbonates, the same effect would occur at higher concentrations. This interpretation is in harmony with the fact that dopant concentrations which are high enough to destroy regular growth also lead to greatly increased nucleation. Valency consideration must, of course, enter into this picture, but the high permissible concentrations of Cr^{+3} discount their dominating importance. For reasons which are not yet clear, there is an enrichment of dopants in the crystals by a factor of about 100, as compared with the average dopant concentrations in the gel.

It was shown by means of the electron-microprobe that the dopants are uniformly distributed within the crystals, whether clouded by silica networks or not. Of the crystals doped with the above elements, only those containing Mn were found to be (slightly) photoluminescent in the orange region of the spectrum, and also cathodoluminescent in the red.

Hybrid Procedures

The success of the gel method is believed to depend, in the ordinary way, on two principal features: (*a*) crystals are grown by diffusion, which means that the solute concentration at the growth boundary is self-regulating in accordance with the needs of the growth process itself, and (*b*) nucleation is suppressed by the gel, partly because it acts as an efficient filtering medium and serves also to isolate a good deal of solute in cavities which are too small to permit homogeneous nucleation to be effective. As shown above, the method has, at any rate for calcite, the disadvantage of leading to substantial inclusions of silicate gel network into the growing crystals. This suggested that hybrid methods should be more successful. In these, crystals are grown in solution without, in principle, losing the general benefits of the gel method. To achieve this, the volume of the solution should always be comparable with that of the growing crystals, a condition not easily achieved, and especially not during the initial stages of growth. In practice, a compromise must therefore be made, the solution volume being kept as small as is technically feasible. The solute must be replenished by diffusion in order to approach the self-regulating boundary concentration mentioned above, and the diffusion medium must be a gel. These requirements distinguish the optimum arrangement from the systems, otherwise similar, proposed by Torgesen and Peiser (16). Figure 7 gives two examples. In the test-tube system on the left, sodium metasilicate solution is floated on a concentrated solution of NH_4Cl and allowed to gel before adding the supernatant $CaCl_2$ solution. Crystals then grow primarily in the solution belt. Unwanted nucleation on the wall of the tube can be diminished by giving it an initial gel coating. The system on the right involves diffusion of the reagents through separate gel columns, and the entire growth medium is filtered in this way. The solution can be seeded with a small calcite crystallite derived from a pure gel system or from other sources. Epitaxial growth occurs, and the new layers are clear, no matter whether the seed contains a silica network or not. When clear seeds are used, no boundary between substrate and new growth can be optically detected. Weight increases by factors up to 10 are easily achieved.

The Etching of Germanium with Water Vapor and Hydrogen Sulfide

T. L. Chu* and R. W. Kelm

Electronic Sciences Center, Southern Methodist University, Dallas, Texas

ABSTRACT

The reaction of single crystal germanium with water vapor and hydrogen sulfide at low partial pressures in hydrogen was studied in a gas flow system in the temperature range 650°-900°C. At linear gas velocities of 30 cm/sec or higher and water partial pressures of 26 Torr or lower, the reaction of germanium with water vapor is surface limited with an activation energy of 46 ± 2 kcal/mole. Clean and structureless surfaces were produced, independent of the dislocation density in germanium, at 900°C and a water partial pressure of 26 Torr. At low partial pressures of hydrogen sulfide in hydrogen, the etching of germanium is diffusion limited at temperatures above 800°C and is surface limited at lower temperatures with an activation energy of 20 ± 1 kcal/mole. The hydrogen-hydrogen sulfide mixture is a less effective nonpreferential etchant than the hydrogen-water vapor mixture.

Chemical etching is the most common technique for the surface preparation of semiconductor crystals. Room temperature aqueous etchants, such as CP_4 (1) and iodine etch A (2), and high-temperature gaseous etchants, such as hydrogen chloride (3) and hydrogen iodide (4), are used for germanium. The behavior of germanium toward these etchants depends strongly on the mechanical preparation of its surface prior to etching. Smooth and damage-free surfaces are readily obtained from a mechanically polished specimen. The etching of mechanically lapped surfaces always induces preferential attack along dislocations in the bulk leading to the formation of pits. This is highly undesirable. For example, an epitaxial layer grown on a pitted substrate retains its surface appearance, and any junctions formed in the epitaxial layer would not be planar.

The etching of silicon by gaseous reagents has been studied more extensively. Water vapor and hydrogen sulfide at low partial pressures in a hydrogen atmosphere are superior to hydrogen halides in several respects (5, 6). The reaction between silicon and water vapor is chemically irreversible, thus facilitating the control of electrical resistivity of epitaxial layers. The use of hydrogen sulfide as an etchant provides clean and structureless surfaces at temperatures considerably below those required by hydrogen halides. However, water vapor and hydrogen sulfide have not been used as etchants for germanium.

Germanium reacts with water vapor or oxygen at high temperatures to produce volatile germanium monoxide (7, 8). The chemical reactions may be written as

$$Ge(s) + H_2O(g) = GeO(g) + H_2(g)$$

$$2Ge(s) + O_2(g) = 2\ GeO(g)$$

The vapor pressure of germanium monoxide over germanium and germanium dioxide corresponding to the reaction

$$Ge(s) + GeO_2(s) = 2GeO(g)$$

is at least 10^{-3} Torr at temperatures above 550°C (9). The equilibrium constant of the reaction between germanium and water vapor has been approximated as $\log K = 6.45 - 10{,}270/T$ (10). Since the equilibrium is shifted to the formation of germanium as the temperature is decreased, germanium monoxide produced in the high-temperature region will be reduced by hydrogen in the lower temperature region. This reversibility has been utilized in the chemical transport of germanium.

The reaction of germanium with hydrogen-hydrogen sulfide mixtures at 850°-870°C yields volatile germanium monosulfide (11). Germanium monosulfide is the most stable divalent germanium compound and may be melted and vaporized without decomposition.

* Electrochemical Society Active Member.

In the present work, the reaction of a germanium single crystal with hydrogen-water vapor and hydrogen-hydrogen sulfide mixtures was studied in the temperature range 650°-900°C. Clean and structureless surfaces have been obtained by using hydrogen-water vapor mixtures over a limited range of concentration and temperature conditions.

Experimental

The etching of germanium crystals with hydrogen-water vapor and hydrogen-hydrogen sulfide mixtures was carried out in a gas-flow system. Hydrogen was purified by diffusion through a palladium-silver alloy. Hydrogen-water vapor mixtures containing up to 26 Torr of water were obtained by saturating all or part of the hydrogen with distilled water at 26.5°C. To insure saturation, hydrogen was first bubbled through water at 45°C and excess water was condensed in a second reservoir maintained at 26.5°C. A hydrogen-hydrogen sulfide mixture containing 2.8% hydrogen sulfide, purchased from the Matheson Company, East Rutherford, New Jersey, was further diluted with hydrogen to the desired concentration.

Germanium crystals were in the form of wafers, 1.7 x 1.7 x 0.05 cm in size, with main faces of {111}, {110}, and {100} orientations. The {111}-oriented wafers, 3 ohm-cm p-type with an average dislocation density of 4×10^3 cm^{-2} and 0.03 ohm-cm p-type with an average dislocation density of 2×10^4 cm^{-2}, were used in most experiments. The {110} and {100}-oriented wafers were 1 ohm-cm p-type and 0.02 ohm-cm n-type, respectively. These wafers were mechanically lapped with 15μ alumina or polished with 0.3μ alumina followed by chemical etching with iodine etch A (2) for 1 to 2 min. The lapped and etched specimens always exhibited pitted surfaces with the degree of pitting related to the dislocation density.

Both resistance heating and rf heating of germanium wafers were used. In the former, the wafers were supported on a fused silica plate in a silica tube of 2.5 cm ID, heated by a tube furnace. In rf heating, the wafers were supported on a silicon carbide coated-graphite susceptor in a fused-silica tube of 5.5 cm ID, and the susceptor was heated externally by an rf generator. Results obtained by both heating techniques were qualitatively the same. Resistance heating was used in obtaining the data reported here because of the ease of temperature control. The specimen temperature usually fluctuated no more than ± 1°C during the etching experiments.

The etch rate of germanium was determined by the weight change of the sample, its surface area, and the reaction time. The reaction time, 30-120 min, was adjusted so that weight differences were more than 20 mg. The weights were measured to ± 0.1 mg. The etch rates were usually reproducible within 5% or better.

The surface conditions of germanium wafers were also examined before and after etching with an optical microscope.

Results and Discussion

The reaction of germanium with hydrogen-water vapor mixtures in a gas flow system involves five consecutive steps: (*a*) transport of water molecules to the germanium surface, (*b*) chemisorption of water molecules, (*c*) chemical reaction at the surface to yield hydrogen and germanium monoxide, (*d*) desorption of germanium monoxide, and (*e*) the transport of germanium monoxide away from surface. The rate-controlling step in this type of gas-solid reaction can be distinguished by measuring the etch rate as a function of etchant composition, etchant flux, and temperature. In transport-controlled processes, the etch rate depends strongly on etchant flux and is essentially independent of temperature. On the other hand, the surface processes have high activation energies, and, if these processes were rate controlling, the etch rate would depend appreciably on temperature.

The effect of etchant flux on the etch rate of germanium by hydrogen-water vapor mixtures was first determined under conditions of fixed temperature and etchant composition. The etchant flux over the germanium surface was varied by a large factor using hydrogen flow rates in the range of 1-12 l/min. The etching temperature and the partial pressure of water vapor in the etchant were 900°C and 26 Torr, respectively, the upper limits of experimental conditions used in this work. If the etching process is surface controlled under these conditions, it will remain surface controlled at lower temperatures and pressures. The etch rates of p-type germanium of {111} orientation and 3 ohm-cm resistivity are shown in Fig. 1. N-type germanium of 20 ohm-cm resistivity showed the same etch rates. At hydrogen flow rates lower than approximately 2 l/min, corresponding to a linear gas velocity of 30 cm/sec, the etch rate decreases rapidly with decreasing etchant flow rate. The etching process is thus limited by the transport processes. At higher flow rates, the etch rate is essentially independent of the etchant flow rate, and the etching process becomes surface limited. Under this condition, the observed rate represents the difference between the etching and its reverse reaction and is approximately 0.5 μ/min. The presence of large excess of hydrogen greatly impedes the etching process. The use of argon as a diluent under similar conditions increases the etch rate by more than a factor of five.

The etch rate of germanium in the surface-controlled region was determined as a function of temperature and etchant composition. The hydrogen flow rate was 4 l/min, the partial pressures of water vapor in the etchant were 26, 13, and 6.5 Torr, and the etching temperature was in the range of 800°-900°C. The etch rates become too low at lower temperatures. Results obtained from p-type germanium of {111} orientation and 0.03 ohm-cm resistivity are shown in Fig. 2. The 3 ohm-cm p-type germanium exhibited the same etch rates. In the concentration range under study, the etch rate at a given temperature is essentially a linear function of concentration. Furthermore, the logarithm of etch rate is linear with respect to reciprocal temperature, and the lines obtained at various etchant concentrations are parallel. The activation energy of the over-all reaction calculated from the slope of the lines is 46 ± 2 kcal/mole. At a water partial pressure of 26 Torr, the etch rates of {110} and {100}-oriented germanium were also determined in the same temperature range (Fig. 2). The etch rate was found to vary with the crystallographic orientation of germanium, increasing in the order {111}, {100} and {110}. However, the slope of the Arrhenius plots remains the same, indicating that the rate-controlling step is independent of the crystallographic orientation. The variation of etch rate with orientation may be attributed to the difference in atomic arrangements on the {111}, {110}, and {100} faces. On a {110} face, each surface atom is bonded to two neighboring surface atoms and one atom in the layer below, while each surface atom on the {111} and {100} faces is bonded to three and two atoms in the next layer, respectively. It is thus reasonable that reactivity of atoms increases with orientation in the order {111}, {100}, and {110}.

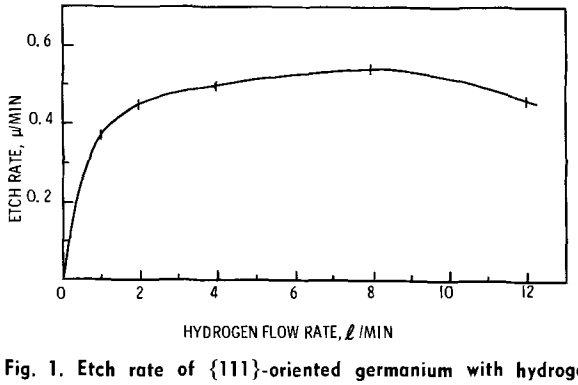

Fig. 1. Etch rate of {111}-oriented germanium with hydrogen-water vapor mixture as a function of hydrogen flow rate. Temperature, 900°C, partial pressure of water vapor, 26 Torr.

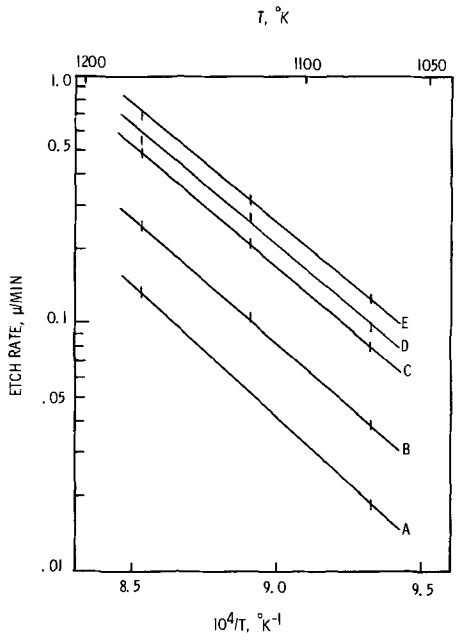

Fig. 2. Etch rate of germanium with hydrogen-water vapor mixture as a function of temperature. Hydrogen flow rate: 4 l/min. A, {111} orientation, partial pressure of water, 6.5 Torr; B, {111} orientation, partial pressure of water, 13 Torr; C, {111} orientation, partial pressure of water, 26 Torr; D, {100} orientation, partial pressure of water, 26 Torr; E, {110} orientation, partial pressure of water, 26 Torr.

The appearance of germanium surfaces after etching with hydrogen-water vapor mixtures varies with temperature and etchant composition. Clean and structureless surfaces were obtained at high temperatures and high water partial pressures. For example, the treatment of lapped and etched germanium surfaces at 900°C with a hydrogen-water vapor mixture containing 26 Torr water vapor at a flow rate of 4 l/min for 30 min is sufficient to yield pitless surfaces. The appearance of the germanium surface is essentially independent of the linear gas velocity in the surface-controlled region. However, as the etching temperature and water partial pressure gradually decreased, the pitted germanium surface from lapping and polishing showed correspondingly less improvement.

The reaction of germanium with hydrogen-hydrogen sulfide mixtures was also studied at a hydrogen flow

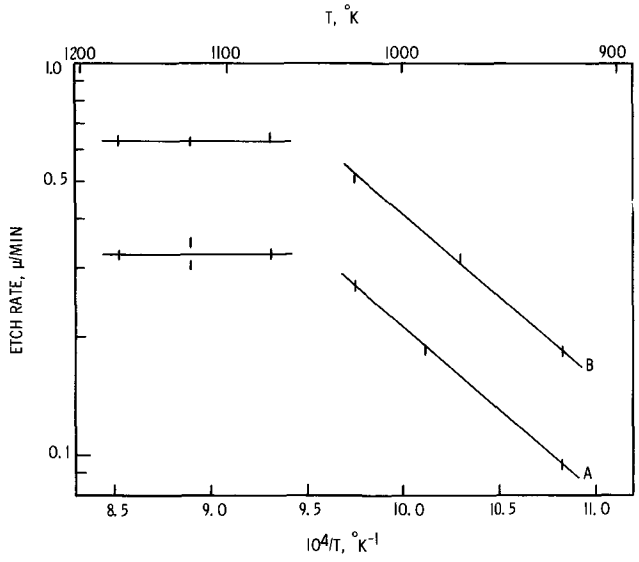

Fig. 3. Etch rate of {111}-oriented germanium with hydrogen-hydrogen sulfide mixture as a function of temperature. Hydrogen flow rate: 4 l/min. A, Partial pressure of hydrogen sulfide, 0.19 Torr; B, Partial pressure of hydrogen sulfide, 0.38 Torr.

rate of 4 l/min. Appreciable etch rates were obtained at relatively low partial pressures of hydrogen sulfide. Figure 3 shows the etch rates of {111}-oriented 0.03 ohm-cm p-type germanium using hydrogen sulfide partial pressures of 0.38 and 0.19 Torr in the temperature range 650°-900°C. In the higher temperature region, the etch rate is essentially independent of temperature, indicating that the etching process is limited by the transport processes. At temperatures below 800°C, the logarithm of etch rate becomes linear with respect to reciprocal temperature with an activation energy of 20 ± 1 kcal/mole. In this region, the etching of germanium is limited by the surface processes. A comparison of Fig. 2 and 3 indicates that, to achieve the same etch rate at a given temperature, the concentration of hydrogen sulfide required in the etchant is considerably lower than that of water vapor. This difference may be related to the difference in bond energies. The H-S bond energy is approximately 81 kcal/mole as compared with 110 kcal/mole for the H-O bond (12); the lower bond energy in hydrogen sulfide would facilitate its reaction with germanium. However, the etching of germanium by hydrogen-hydrogen sulfide mixtures is more selective than that by hydrogen-water vapor mixtures, particularly at high temperatures. At 800°-900°C, the germanium surface is usually quite pitted after etching. Marked improvements are observed at lower temperatures; lapped germanium surfaces etched with hydrogen-hydrogen sulfide mixtures at 650°C are less pitted than those etched with iodine etch A.

Summary and Conclusions

Germanium surfaces are readily etched with hydrogen-water vapor mixtures in the temperature range 800°-900°C. Using a water partial pressure of 26 Torr, a clear demarcation between surface-limited and transport-limited regions exists. The etching process is transport-limited at linear gas velocities lower than about 30 cm/sec and becomes surface limited at higher gas velocities. In the surface-limited region, the rate is approximately proportional to the partial pressure of water vapor, and the activation energy is 46 ± 2 kcal/mole. Clean and structureless germanium surfaces can be produced at 900°C by using hydrogen-water vapor mixture as an etchant.

Germanium surfaces can also be etched by using hydrogen-hydrogen sulfide mixtures in the temperature range 650°-900°C. Using a linear gas velocity of 60 cm/sec and hydrogen sulfide partial pressures of 0.38 and 0.19 Torr, the etching process is transport limited at 800°C and above, and is surface limited at lower temperatures with an activation energy of 20 ± 1 kcal/mole. Hydrogen-hydrogen sulfide mixtures are less effective polishing etchants than hydrogen-water vapor mixtures.

Calculation of the Minimum Pressure, *p*-T Diagrams, and Solidus of ZnTe

A. S. Jordan and R. R. Zupp[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The partial pressures of the components, p_{Zn} and p_{Te_2}, for the Zn-Te system were evaluated along the liquidus curve on the basis of previously derived activities for a regular associated solution. Results are in good agreement with available experimental data. The minimum pressure of ZnTe was calculated from ΔH°_{vap} (298°K) and the free energy function, $(G^\circ_T - H^\circ_{298°K})/T$, of ZnTe and the component gases. The thermodynamic data for ZnTe needed for these calculations have also been critically reassessed or evaluated. By a combination of the measurements of Thomas and Sadowski with the values of p_{Zn} along the liquidus, a retrograde solidus for ZnTe was calculated. The calculated maximum solid solubility of Te in ZnTe is approximately 4.6 x 10^{-3} a/o (atom per cent) at 1200°C.

ZnTe is a group II-VI semiconducting compound which has been investigated extensively in the last decade for its potentially promising electrical and optical properties. The physical properties of ZnTe are governed to a great extent by its defect chemistry which in turn depends on the thermodynamic properties of the Zn-Te system at the high temperatures prevailing during the growth or annealing of the crystalline compound. The equilibrium thermodynamic properties of the Zn-Te system can be best described in terms of its pressure-temperature-composition (p-T-x) diagram. The primary object of this communication is to calculate some sections of this diagram.

First, the thermodynamic properties of solid ZnTe required for further calculations are reassessed or evaluated. Then, by the third law method the heat of vaporization of ZnTe and the minimum pressure of congruently subliming ZnTe are calculated. In addition, the partial pressures of the components in the Zn-Te system are evaluated as a function of temperature along the liquidus curve (p-T diagrams) by the use of a theory of regular associated solutions (1). Finally, by a combination of the results of Thomas and Sadowski (2) for the concentration of Zn vacancies as a function of p_{Zn} with the values of p_{Zn} along the liquidus, the solidus for ZnTe is calculated.

Thermodynamic Properties of ZnTe

Specific heat.—Kelemen *et al.* (3) have measured the specific heat, C_p, of ZnTe between 273° and 773°K. From their graphically presented data one can derive the following equation for C_p

$$C_p = 11.03 + 3.84 \times 10^{-3}T \qquad [1]$$

where T is the temperature in °K and the unit of C_p is cal/g mole deg. At 298°K the experimental value of C_p is 12.17 cal/g mole deg, in excellent agreement with the value of 12.22 cal/g mole deg, calculated from standard tabulated values and the Neumann-Kopp rule.

Debye temperature.—One can calculate the Debye temperature, θ_D, of ZnTe from the room temperature elastic constants measured by Berlincourt *et al.* (4). θ_D is evaluated at 0°K by the semianalytic method of deLaunay (5). Unfortunately no measurements of the elastic constants have been made near absolute zero. However, Berlincourt *et al.* (4) have measured the elastic constants of ZnS at 298° and also at 77°K. Assuming that the temperature coefficients of the elastic constants of ZnS and ZnTe are not too different, one can adjust the elastic constants of ZnTe to 0°K and obtain $C_{11} = 7.35 \times 10^{11}$ dynes/cm^2, $C_{12} = 4.17 \times 10^{11}$ dynes/cm^2, and $C_{44} = 3.16 \times 10^{11}$ dynes/cm^2. Substituting these values into deLaunay's expression yields $\theta_D = 223$°K for ZnTe.

Standard entropy at 298°K.—Two methods have been used to evaluate the standard entropy of ZnTe at 298°K, $S^\circ_{298°K}$. Assuming that ZnTe behaves like a Debye solid, one can compute $S^\circ_{298°K}$ using standard tables (6) of Debye entropy functions. Using the calculated value of $\theta_D = 223$°K, one obtains $S^\circ_{298°K} = 9.80$ eu/g atom = 19.6 eu/g mole.

From the electrochemical cell data of McAteer and Seltz (7), one can derive $\Delta S^\circ_{660°K} = 2.85$ eu for the reaction

$$ZnTe(s) = Zn(s) + Te(s), \quad \Delta S^\circ_{660°K} \qquad [2]$$

Then, $S^\circ_{298°K}(ZnTe)$ is given by

$$S^\circ_{298°K}(ZnTe) = S^\circ_{298°K}(Zn) + S^\circ_{298°K}(Te) - \Delta S^\circ_{298°K} \qquad [3]$$

where

$$\Delta S^\circ_{298°K} = \Delta S^\circ_{660°K} - \int_{298°K}^{660°K} \frac{\Delta C_p}{T}\, dT$$

Values of $S^\circ_{298°K}$ for the pure solid elements were obtained from Stull and Sinke (8). The heat capacities of the pure solid elements in Eq. [5] were taken from the tables of Kelley (9) and that of ZnTe from Eq. [1]. Finally one gets $S^\circ_{298°K} = 19.5$ eu, in excellent agreement with the entropy derived from the Debye temperature. The estimated error in $S^\circ_{298°K}$ is ±0.3 eu.

Free energy function.—The function $(G^\circ_T - H^\circ_{298°K})/T$ is defined as the free-energy function (FEF) (6). For solids the FEF is calculated from a combination of related thermodynamic data, if the third law of thermodynamics is applicable ($S^\circ_{0°K} = 0$). The following identity is used to calculate the FEF of ZnTe

$$\text{FEF} = \frac{G^\circ_T - H^\circ_{298}}{T} = \frac{H^\circ_T - H^\circ_{298}}{T} - S^\circ_T \qquad [4]$$

where

$$\frac{H^\circ_T - H^\circ_{298}}{T} = \left(\int_{298}^{T} C_p\, dT\right) \Big/ T$$

and

$$-S^\circ_T = -\left[S^\circ_{298°K} + \int_{298}^{T} \frac{C_p\, dT}{T}\right]$$

Substituting C_p from Eq. [1] and $S^\circ_{298°K} = 19.5$ eu into Eq. [4], the FEF of ZnTe was evaluated. Numerical values are presented in 50°K intervals in Table I. The probable error in these values is approximately ±2%.

Heat of Vaporization and Minimum Pressure of ZnTe(s)

Sublimation of ZnTe(s).—In an exhaustive study of nine II-VI compounds, Goldfinger and Jeunehomme (10) have demonstrated by the use of mass spectrometry that ZnTe decomposes at high temperature into the component gases according to

$$ZnTe(s) = Zn(g) + \tfrac{1}{2}Te_2(g), \quad K = p_{Zn}\sqrt{p_{Te_2}} \quad [5]$$

where p_{Zn} and p_{Te_2} are the partial pressures of Zn and Te_2 and K is the equilibrium constant.

It can be shown that, if an evaporating solid compound is in equilibrium with its vapor phase and both have the same composition, at a constant temperature, then the total pressure is at a minimum (or maximum) (11) and one speaks of congruent sublimation (12). The vapor is stoichiometric if $p_{Te_2} = \tfrac{1}{2}p_{Zn}$. It can be readily demonstrated that, if the composition of the solid deviates only slightly from stoichiometry, then the composition of the congruently subliming vapor equals that of the stoichiometric vapor and the total pressure is at a minimum. Moreover, if the total pressure is at a minimum, mass transfer from solid to vapor of the same composition occurs without diffusional limitation at a maximum rate, as if molecules of ZnTe were transported.

The concept of minimum pressure is analogous to that of the azeotropic pressure in binary liquid-vapor systems. The composition of the congruent vapor corresponds to the azeotropic point (13).

In order to calculate the minimum pressure of ZnTe at high temperatures the ΔG° for reaction [5] is required. Unfortunately measurements of ΔG° have been restricted to temperatures below 1100°K, which is approximately 470°K below the melting point of the compound. However, a thermodynamically consistent extrapolation of the low-temperature data can be performed by the third law method.

Heat of vaporization of ZnTe(s).—Goldfinger and Jeunehomme (10) have measured the pressures over ZnTe(s) between 862° and 1100°K by Knudsen's method. They calculated K for Eq. [5] and derived ΔH° and ΔS°, the standard heat and entropy of reaction, by the use of the Gibbs-Helmholtz equation, assuming $\Delta H^\circ/T - \Delta S^\circ = \Delta G^\circ/T = -R \ln K$ is a linear function of temperature (the second law method).

Likewise, Reynolds *et al.* (14) have used a Knudsen cell to measure pressures over subliming ZnTe(s) between 923° and 1003°K. They have given K for Eq. [5] and also calculated ΔH° and ΔS° by the second law method.

Korneeva *et al.* (15) have utilized a modified Langmuir technique between 793° and 993°K and a Knudsen cell between 938° and 983°K. They presented the observed total pressure, p_{obs}, as a function of temperature, assuming, wrongly, that ZnTe(g) was the major volatile species. However, it is possible to reinterpret their tabular data of p_{obs} for the correct mode of vaporization in terms of p_{Zn} and p_{Te_2} and to calculate K for Eq. [5] based on an analysis given by Goldfinger and Jeunehomme (10). Accordingly, one has

$$p_{obs} = p_{Zn}\left(\frac{M_{ZnTe}}{M_{Zn}}\right)^{1/2} = (p_{Te} + \sqrt{2}p_{Te_2})\left(\frac{M_{ZnTe}}{M_{Te}}\right)^{1/2} \quad [6]$$

where p_{Te} is the pressure of monatomic Te_1 related to p_{Te_2} by the equilibrium constant $k = p_{Te}/\sqrt{p_{Te_2}}$ for the reaction $\tfrac{1}{2}Te_2(g) = Te(g)$, and M_i is the molecular weight of the designated species. Solving Eq. [6] for the partial pressures at selected temperatures, obtaining k from the tables of Stull and Sinke (8), one finds that in the temperature range of interest p_{Te} is negligible. Hence Eq. [6] and the condition of congruent vaporization yield the following simple proportionality between the minimum total pressure, p_{tot} (min), and p_{obs}

$$1.09\ p_{obs} = p_{tot}\ (min) = 1.5 \times 2^{1/3} K^{2/3} \quad [7]$$

Using the tabular data of Korneeva *et al.* (15) for p_{obs}, values of K for Eq. [5] were readily evaluated by solving Eq. [7].

In order to facilitate the comparison of all these experimental data obtained by different techniques at various temperatures in a thermodynamically consistent manner, the third law method was utilized (16), (17). The heat of vaporization at 298°K, ΔH°_v (298°K), was calculated, for every experimental determination reported above, according to the identity

$$\Delta H^\circ_v(298°K) = -T\Delta(FEF) - RT \ln K \quad [8]$$

where for Eq. [5]

$$\Delta(FEF) = FEF[Zn(g)] + \tfrac{1}{2}FEF[Te_2(g)] - FEF[ZnTe(s)]$$

The FEF of ZnTe(s) is given in Table I. The FEF's of Zn(g) and Te_2(g) were taken from the tables of Stull and Sinke (8) and values of K were obtained from the previously discussed experimental sources. The results of these calculations are summarized in Table II.

Two values of ΔH°_v(298°K) derived from low-temperature measurements for the reaction represented by Eq. [2] are also listed in Table II. Pool has used (18) a liquid tin solution calorimeter to measure the enthalpy change, ΔH°_1, associated with Eq. [2] at 273°K. Since the difference between ΔH°_1 at 273° and 298°K is very small, one can readily calculate ΔH°_v (298°K) by adding the enthalpy changes for the reactions Zn(s) = Zn(g), ΔH°_2(298°K), and Te(s) = $\tfrac{1}{2}Te_2$(g), ΔH°_3(298°K), as given by Stull and Sinke (8), to ΔH°_1 which yields

$$\Delta H^\circ_v(298°K) = \Delta H^\circ_1 + \Delta H^\circ_2 + \Delta H^\circ_3 \quad [9]$$

McAteer and Seltz (7) have utilized a reversible galvanic cell to measure the electromotive force, E, between 628° and 691°K for the reaction represented by Eq. [2]. Using the third law method for that reaction, one obtains ΔH°_1(298°K) according to

$$\Delta H^\circ_1(298°K) = -T\Delta(FEF) - RT \ln K_1 \quad [10]$$

Table II. Heat of vaporization of ZnTe

ΔH°_v (298°K) in kcal	Author	Exptl. technique
78.4 ± 0.6	Korneeva *et al.* (15)	Knudsen Modif. Langmuir
79.5 ± 0.5	Pool (18)	Calorimetry
79.0 ± 0.5	McAteer and Seltz (7)	Electrolytic cell
79.5 ± 0.6	Goldfinger and Jeunehomme (10)	Knudsen
82.8 ± 0.7	Reynolds *et al.* (14)	Knudsen

where $-RT \ln K_1 = -nFE$ and $\Delta(\text{FEF}) = \text{FEF}[\text{Zn(s)}] + \text{FEF}[\text{Te(s)}] - \text{FEF}[\text{ZnTe(s)}]$. Finally, $\Delta H^\circ_v(298^\circ\text{K})$ can be immediately calculated from Eq. [9].

The errors listed in Table II were obtained by a combination of the standard deviation in the measurements of any one of the authors with the estimated error in the free energy functions. It is apparent that the value of ΔH°_v derived from the results of Reynolds *et al.* (14) is outside the error limits of all the other measurements. The reason for this disagreement is not at all obvious. It is possible that the results are too low due to calibration error. However, the estimated calibration error (25%) (19) could not account for the observed difference among the listed values of ΔH°_v.

Since four of the calculated ΔH°_v values are in good agreement within their respective errors, we recommend their average of 79.1 ± 1.0 kcal/mol as the best value for the heat of vaporization of ZnTe(s) into Zn(g) and ½Te_2(g) at 298°K.

Minimum pressure over ZnTe(s).—p_{tot}(min) was extrapolated to higher temperatures by the third law method. Using Eq. [7], one can obtain ln p_{tot} (min) in terms of ln K in the form

$$\ln p_{tot}(\text{min}) = 2/3 \ln K + 0.637 \qquad [11]$$

ln K was readily evaluated by rewriting Eq. [8] to yield

$$\ln K = -\frac{\Delta H^\circ_v(298^\circ\text{K})}{RT} - \frac{\Delta(\text{FEF})}{R} \qquad [12]$$

Calculated values of p_{tot}(min) above 1000°K are given in Table I in 50°K intervals.

A plot of p_{tot}(min) as a function of $1/T$ above 1300°K is presented in Fig. 1. $p_{Zn}(\text{min}) = 2/3p_{tot}(\text{min})$ and $p_{Te_2}(\text{min}) = 1/3p_{tot}(\text{min})$ are also given. In Fig. 2 and 3, p_{Zn}(min) and p_{Te_2}(min) are extended to temperatures below 1300°K. The minimum pressure-temperature curves are terminated at their intersection with the partial pressure-temperature curves of the three phase solid-liquid-gas equilibria, constructed in the following section.

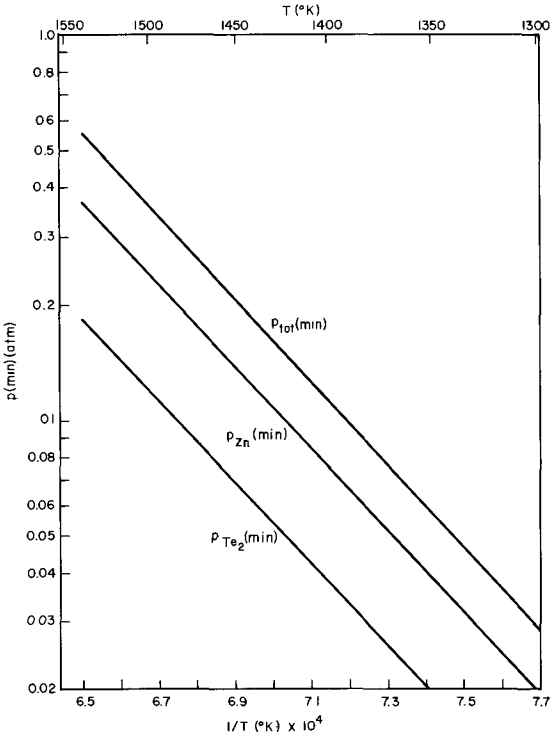

Fig. 1. Calculated dependence of minimum pressure on reciprocal temperature over congruently subliming ZnTe(s).

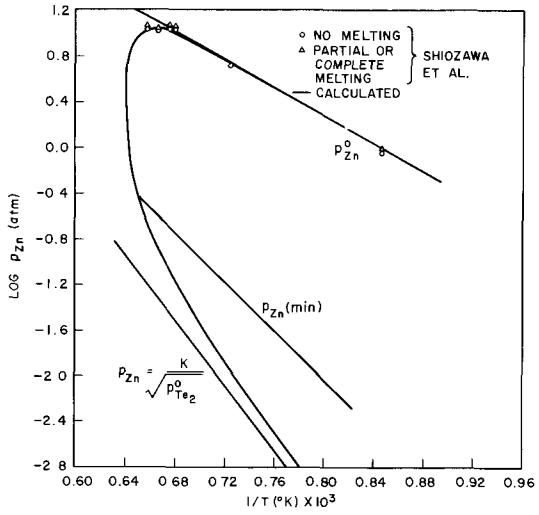

Fig. 2. Log Zn pressure vs. reciprocal temperature for the Zn-Te system.

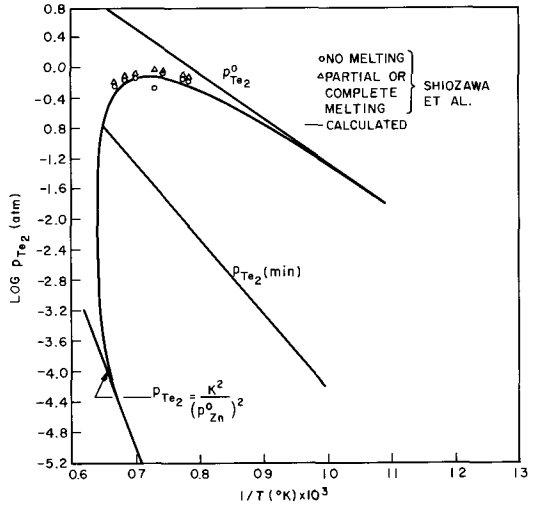

Fig. 3. Log Te_2 pressure vs. reciprocal temperature for the Zn-Te system.

Calculation of the p-T Diagrams

Theory.—It has already been pointed out that at the temperatures of interest ZnTe dissociates into the component gases according to Eq. [5]. In order to calculate the variation of the partial pressures of these gases with temperature in a binary system with three coexisting phases, *i.e.*, ZnTe in simultaneous equilibrium with a liquid and a gas phase, it is necessary to know the activities along the liquidus curve. By definition in the Zn-Te system

$$p_{Zn} = p^\circ_{Zn} a_{Zn} \qquad [13]$$

and

$$p_{Te_2} = p^\circ_{Te_2} a^2_{Te} \qquad [14]$$

where a_i and p°_i are the activity and pressure of pure liquid component i (Zn or Te), respectively, at the temperature of the solution.

The partial pressures of the group V components along the liquidus in some III-V compounds have been calculated assuming regular solution behavior in the liquid by Vieland (20). Kroger (21) and Reynolds *et al.* (14) have evaluated some segments of the p-T diagrams in the Zn-Te system assuming that the liquid was ideal. However, it has been demonstrated by one of us (1) that the Zn-Te and also the Cd-Te liquidus curves could not be described by assuming regular or ideal behavior in the liquid. In fact, the liquidus curves for the Cd-Te and Zn-Te systems, in which the observed shapes of the liquidus strongly

suggest association in the liquid, have been calculated in good agreement with experimental results by the use of activities derived from a regular associated solution model. Assuming the presence of ZnTe complexes as well as Zn and Te atoms in chemical equilibrium in the liquid and identifying the activity coefficients of these species with those of a regular ternary solution, the approximate gross activities for the components in a regular associated solution have been derived in the following form

$$\frac{p_{Zn}}{p^{o}_{Zn}} = a_{Zn} = \gamma_{Zn}x_{Zn} = \frac{x_{Zn} - x_{Te} + P}{1 + P} e^{\alpha x^2_{Te}/RT} \quad [15]$$

$$\sqrt{\frac{p_{Te_2}}{p^{o}_{Te_2}}} = a_{Te} = \gamma_{Te}x_{Te} = \frac{x_{Te} - x_{Zn} + P}{1 + P} e^{\alpha x^2_{Zn}/RT} \quad [16]$$

where

$$P = \sqrt{1 - 4x_{Zn}x_{Te}(1 - \beta^2)}$$

and x_i and γ_i are the atom fraction and activity coefficient for component i (Zn or Te). α and β are constants incorporating the equilibrium constant for association and the interaction coefficients among the species.

Using Eq. [15] and [16] the equation of the liquidus boundary for the Zn-Te and Cd-Te was derived and given by (1)

$$T = \frac{\alpha(x_{Te} - 0.5)^2 + \Delta H_f}{R/2 \ln s(x_{Te}) + \Delta H_f/T_f} \quad [17]$$

where

$$s(x_{Te}) = \frac{[1 + \sqrt{4(x_{Te} - 0.5)^2 + \beta^2[1 - 4(x_{Te} - 0.5)^2]}]^2}{(1 + \beta)^2[1 - 4(x_{Te} - 0.5)^2]}$$

ΔH_f and T_f are the heat of fusion/gram atom and melting point of the compound, respectively. Approximate values of ΔH_f and T_f for both systems can be obtained from the work of Kulwicki (22). Values of α and β were evaluated (1) for the Zn-ZnTe, Te-ZnTe, Cd-CdTe, and Te-CdTe subsystems by the application of an approximate form of Eq. [17], valid for small values of β and if $2(x_{Te} - 0.5) > \beta$, to the liquidus data of Kulwicki (22) which, as discussed in ref. (1), appears to be the most reliable source of data.

The p-T diagrams in the Zn-Te system can be readily calculated by the use of Eq. [13] through [17].

Computational procedure.—The calculation of p_{Zn} and p_{Te_2} as a function of temperature along the liquidus curve was performed on a computer. First, x_{Zn} was decreased from 1.0 to 0.0 in intervals of 0.02, and the liquidus temperature corresponding to each of these compositions was computed by the use of Eq. [17]. Then, pairs of values of x_{Zn} and T were substituted into Eq. [15] and [16] to obtain the pressures. Equation [15] was used to calculate p_{Zn} in the Zn-ZnTe subsystem and Eq. [16] to calculate p_{Te_2} in the Te-ZnTe subsystem. Having obtained p_{Zn}, p_{Te_2} in the Zn-ZnTe subsystem was evaluated from the equilibrium constant for Eq. [5] by $p_{Te_2} = K^2/p^2_{Zn}$.

Similarly, p_{Zn} in the Te-ZnTe subsystem was calculated from Eq. [5] as $p_{Zn} = K/\sqrt{p_{Te_2}}$.

K was evaluated by the third law method according to Eq. [12]. The pressures of the pure superheated liquids, p^{o}_{Zn} and $p^{o}_{Te_2}$, were obtained from the recent high-pressure measurements of Baker (23, 24). $p^{o}_{Te_2}$ was computed from the total pressure data of Baker by subtracting from it a small pressure ($\approx$1%) due to monatomic Te. The dissociation constant to perform this calculation was taken from Stull and Sinke (8).

Comparison with experiment.—Figures 2 and 3 illustrate the calculated dependence of log p_{Zn} and log p_{Te_2} on $1/T$, respectively, and the measurements of Shiozawa *et al.* (25) along the liquidus curve of the Zn-Te system. These p-T diagrams also show the limiting straight lines at $x_{Zn} = 1$ and 0. For example, in Fig. 2 the limiting lines log p^{o}_{Zn} and log p_{Zn} = log $K/\sqrt{p^{o}_{Te_2}}$ *vs.* $1/T$ were drawn. In addition, as mentioned earlier, values of log p_{Zn} and log p_{Te_2} *vs.* $1/T$ at p_{tot}(min) were also plotted.

The p-T diagrams in the Zn-Te system have been recently studied by Shiozawa *et al.* (25). An evacuated ampoule containing a ZnTe crystal and Zn or Te at opposite ends was placed in a two-zone furnace. At a constant temperature ZnTe was exposed to increasing Zn or Te_2 pressures by raising the reservoir temperature, in steps, until partial or complete melting of the crystal was achieved. At each step the ampoule was removed from the furnace for observation. Figures 2 and 3 illustrate the experimental maximum values p_{Zn} and p_{Te_2}, taken from the report of Shiozawa *et al.* (25), at which no melting took place and the minimum values of p_{Zn} and p_{Te_2}, at which partial or complete melting was observed. Noting that the actual experimental points must lie between the upper and lower pressure limits, the agreement with the theoretical p-T diagrams is excellent.

Solidus Curve of ZnTe

De Nobel (26) has calculated the deviation from stoichiometry of solid CdTe in equilibrium with the liquid from a knowledge of p_{Cd} and the defect structure. Similarly, Kroger (21) and Reynolds (27), utilizing the defect study of Thomas and Sadowski and assuming ideal solution behavior in the liquid, have estimated the solidus of ZnTe. In this section the solidus curve of ZnTe will be determined on the basis of the previously calculated p_{Zn}, plotted in Fig. 2.

Thomas and Sadowski (2) have measured the p-type conductivity of ZnTe crystals between 973° and 1223°K and for p_{Zn} between 10 and 400 Torr. By assuming the presence of doubly ionized Zn vacancies on the Zn sublattice, V''_{Zn}, in excess of any other acceptor, they could explain their experimental results. They showed that the concentration of the vacant Zn sites, $[V''_{Zn}]$, can be related to the hole concentration, $[h\cdot]$, and to p_{Zn} by the equilibrium constant for the reaction

$$Zn_{Zn} = V''_{Zn} + 2h\cdot + Zn(g)$$

Consequently, observing that $[V''_{Zn}] = [h\cdot]/2$, they fitted their data by the following equation

$$[h\cdot] = 3.73 \times 10^{23}\, p_{Zn}^{-1/3} \exp - \left(\frac{1.31 \text{ ev}}{kT}\right) \quad [18]$$

where p_{Zn} is given in Torrs, the unit of $[h\cdot]$ is holes/cc, and k is Boltzmann's constant. By simple conversion of units, one can readily rewrite Eq. [18] in terms of the site fraction of Zn vacancies on the Zn sublattice, v, as

$$v \equiv \frac{[V''_{Zn}]}{[Zn_{Zn}] + [V''_{Zn}]} = \frac{1.17}{p_{Zn}^{1/3}} \exp - \left(\frac{30.2 \text{ kcal}}{RT}\right) \quad [19]$$

where p_{Zn} is in atmospheres.

If one assumes that the major defect in the crystal is V''_{Zn}, then utilizing the relations $[Te_{Te}]/[Zn_{Zn}] + [V''_{Zn}] + [Te_{Te}] = 0.5$, $[Zn_{Zn}] + [V''_{Zn}]/[Zn_{Zn}] + [V''_{Zn}] + [Te_{Te}] = 0.5$ and Eq. [19], one can express the atom fractions of Zn and Te in the solid, x^{s}_{Zn} and x^{s}_{Te}, in the form

$$x^{s}_{Zn} = \frac{[Zn_{Zn}]}{[Zn_{Zn}] + [Te_{Te}]} = \frac{1 - v}{2 - v}$$

and

$$x^{s}_{Te} = \frac{[Te_{Te}]}{[Zn_{Zn}] + [Te_{Te}]} = \frac{1}{2 - v} \quad [20]$$

where $[Zn_{Zn}]$ and $[Te_{Te}]$ denote the concentrations of Zn atoms on the Zn sublattice and Te atom on the Te sublattice, respectively.

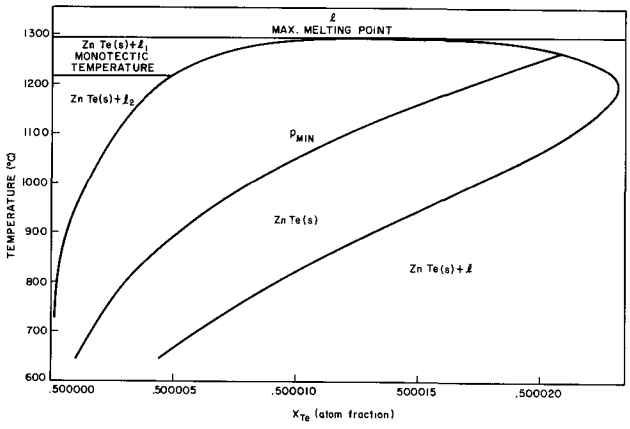

Fig. 4. Calculated solidus curve of ZnTe(s)

At any temperature along the p-T curve (Fig. 2) p_{Zn} over the liquid equals p_{Zn} over the coexisting solid. Therefore, if these values of p_{Zn} are substituted into Eq. [19], v as a function of temperature is obtained. Furthermore, a knowledge of v makes it possible by the use of Eq. [20] to evalaute x^s_{Te} and x^s_{Zn} as a function of temperature, thus giving the solidus curve.

The values of x^s_{Te} and x^s_{Zn} along the solidus curve were computed, and they are plotted in Fig. 4. If in the calculation p_{Zn} along the three phase equilibria is replaced by $p_{Zn} = 2/3p_{tot}(min)$ on the minimum pressure line, the composition of solid ZnTe corresponding to congruently subliming ZnTe is obtained. The curve labeled p_{min} in Fig. 4 shows the dependence of this specific solid composition on temperature. The monotectic temperature at 1213°C is a consequence of the theory of regular associated solutions and it is consistent with the flat experimental liquidus curve in the Zn-ZnTe subsystem (1).

Qualitatively, the shape of the calculated solidus agrees with the previously reported curves of Kroger (21) and Reynolds (27). This is a consequence of utilizing in all of these calculations the study of Thomas and Sadowsky (2) for the defect structure of ZnTe. At low temperatures the boundary in Fig. 4 essentially coincides with the previously estimated curves, but at high temperatures the curves differ. This is not surprising since at low temperatures ZnTe is in equilibrium with almost pure Zn (or Te) liquid and the p_{Zn} calculated from the theory of regular associated solutions reduces to that of an ideal solution. However, at high temperatures ZnTe is in equilibrium with concentrated solutions of Zn and Te in which departures from ideality become significant.

The solidus curve of ZnTe delineates a region with an excess of Te. This is consistent with the p-type behavior of ZnTe. It can also be seen in Fig. 4 that the solidus of ZnTe is retrograde with a maximum at 1200°C. At this temperature the solid solubility of Te in ZnTe is approximately 4.6×10^{-3} a/o or 8.1×10^{17} at./cc. The retrograde nature of the ZnTe solidus has already been suggested by Reynolds *et al.* (14). Moreover, according to de Nobel (26), the solidus of CdTe is also retrograde. It is interesting to note that below 600°C the ZnTe crystal becomes nearly stoichiometric.

Acknowledgments

The authors are grateful to Dr. C. D. Thurmond and Dr. F. A. Trumbore for helpful discussions, to Professor Goldfinger for providing some unpublished data, and to Mr. J. Jost, of Clevite Corporation, for bringing the work of Shiozawa *et al.* to our attention.

Vapor Phase Growth of Stannic Oxide Single Crystals

C. G. Fonstad, A. Linz, and R. H. Rediker

Department of Electrical Engineering and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Single crystals of stannic oxide, SnO_2, of higher purity and with higher Hall mobility than any previously reported have been grown from the vapor using the reaction

$$SnCl_4 + 2H_2 + O_2 \overset{\Delta}{\rightleftarrows} SnO_2 + 4HCl$$

at 1250°C and 10 Torr. The stannic chloride is obtained from the reaction

$$Sn + 2Cl_2 \rightleftarrows SnCl_4 + \Delta$$

which is performed in an external reactor and electrical doping is achieved by adding the desired dopant materials to tin charges in parallel doping reactors. The growth rate of the SnO_2 is controlled by adding additional Cl_2 to the $SnCl_4$ flow before it is introduced into the furnace; with sufficient Cl_2 the crystals can also be etched. Important to the furnace design is a gas injection nozzle which eliminates growth immediately where the gases enter the furnace. Undoped crystals of 6 x 10^5 ohm-cm resistivity at 300°K, and antimony-doped n-type crystals with resistivity, carrier concentration, and mobility of 0.1 ohm-cm, 4 x 10^{17} cm^{-3}, and 160 cm^2/V-sec at 300°K and of 0.1 ohm-cm, 6 x 10^{16} cm^{-3}, and 1200 cm^2/V-sec at 77°K have been grown, as have n-i junctions.

As part of a program to evaluate stannic oxide, SnO_2, as a material for semiconductor devices that will operate in excess of 400°C, single crystals of SnO_2 have been grown from the vapor phase. Single crystals of stannic oxide have previously been obtained from the reaction of tin vapor and oxygen at 1450°C (1), by growth from a Cu_2O flux at 1250°C (2), and by the high-temperature decomposition of SnO_2 to produce SnO vapor which in turn reoxidizes at lower temperatures to form SnO_2 crystals (3-5). Of the published SnO_2 growth methods ours is closest to that of Nagasawa *et al.* (6), who grew these crystals using the vapor reaction of $SnCl_4$ with H_2O at 1100°-1300°C. The growth technique reported in this paper, however, is more comparable to that used by Schaffer (7) to grow Al_2O_3 in that no carrier gases are used and all reactions and growth occur at low pressure. The process to be described has produced SnO_2 with higher Hall mobilities and of higher purity than previously reported and is compatible with introducing dopants during the growing process. High resistivity ($> 10^5$ ohm-cm) crystals as well as lower resistivity (0.1 ohm-cm) n-type crystals produced by Sb doping have been grown and crystals containing $n-i$ junctions have also been grown.

Preparation of Single Crystals

The growing system is based on reacting oxygen, hydrogen, and stannic chloride in a quartz tube at 1250°C at reduced pressure of 10 Torr to produce stannic oxide

$$SnCl_4 + 2H_2 + O_2 \overset{\Delta}{\rightleftarrows} SnO_2 + 4HCl \qquad [1]$$

The $SnCl_4$ is produced by flowing chlorine through 30-mesh tin metal at 100°C also at 10 Torr pressure

$$Sn + 2Cl_2 \rightleftarrows SnCl_4 + \Delta \qquad [2]$$

Figure 1 shows the furnace system. The starting materials for the growth of SnO_2 crystals are the gases Cl_2, O_2, and H_2 and metallic Sn; in the results reported here reagent grade Sn and Cl_2, and prepurified H_2 were used. The flows of the gases are controlled by a system of gas cylinder regulators, shut-off valves, and flowmeters (not shown in Fig. 1) before they enter the furnace system through needle valves as indicated in the lower left of the figure. The total gas flow is typically 100 cm^3/min as measured at 900 Torr and 300°K by the flowmeters which are on the upstream side of the needle valves; this total flow is made up of individual Cl_2, H_2, and O_2 flows in the proportions of 2:10:5, respectively. On the downstream side of the needle valves and in the entire system shown in the figure the pressure is maintained at 10 Torr through the use of a vacuum pump with a throttling valve.

As shown in Fig. 1, the reaction of Sn and Cl_2, Eq. [2], occurs in a Pyrex Buchner type funnel with a coarse fritted disk on which a 30 mesh tin charge rests. This "$SnCl_4$ reactor" is wrapped with heater tape and heated to 100°C which is sufficient at 10 Torr to give a uniform and complete reaction. Electrically active dopants are introduced into the crystals by using, in parallel with the "pure" $SnCl_4$ reactor, other $SnCl_4$ reactors in which the tin charges contain small proportions of the desired dopants (Sb for example).

The furnace tube is a 5-cm diameter mullite tube horizontally mounted in a Globar furnace and sealed with Inconel endcaps. As shown in Fig. 1, the O_2 inlet, and the H_2 and Cl_2-$SnCl_4$ injector tubes are on the input endcap; the output endcap provides a mount for a diaphragm pressure gauge, a quartz viewing window, and a connection to the cold traps and vacuum pump. A quartz tube closely fitting inside the mullite tube is used as the growing substrate. It is made long enough to cover the entire high-temperature region of the furnace to protect against contamination from the mul-

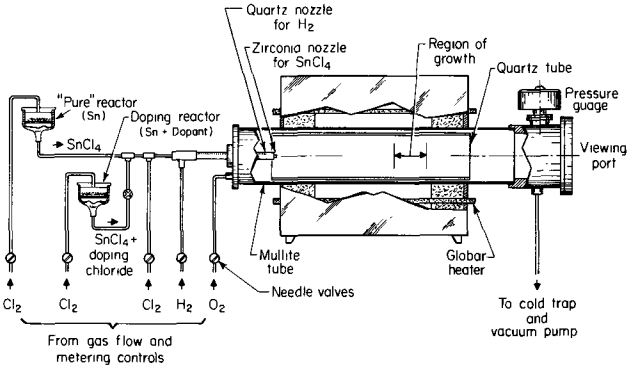

Fig. 1. Stannic oxide crystal growing system. The drawing is not to scale; the actual mullite tube is 90 cm long, 5 cm ID.

lite and to preserve the mullite tube. A spiral of 20-mil Pt wire wrapped around the quartz liner keeps it from touching and possibly sticking to the mullite.

In the SnO_2 growth, chlorine gas flows into the $SnCl_4$ reactor and reacts with the tin to form stannic chloride, $SnCl_4$, which at 10 Torr is also a gas. When doped material is desired, the chlorine flow to the doping reactor is turned on, and the appropriate dopant chloride is also formed and travels with the $SnCl_4$ gas. The total chlorine flow to all the reactors is kept constant and the desired doping concentration and/or doping profile is obtained by adjusting the fraction of this flow which goes to the doping reactor. As shown in Fig. 1, additional chlorine (< 1 cm^3/min) is added to the combined $SnCl_4$ gas from the reactors, and these gases are injected into the furnace tube through a 0.32-cm OD, 0.16-cm ID zirconia nozzle coaxial with the furnace tube. Hydrogen gas is introduced into the furnace through a 0.9-cm ID quartz tube concentric with the nozzle and acts as a sheath about the zirconia nozzle shielding it from the oxygen which enters the furnace near the periphery of the input endcap and is flowing in the region about the injection nozzles. Using this H_2 shield prevents the immediate occurrence of the reaction, Eq. [1], and eliminates the growth of SnO_2 on the injector tubes which has plagued several groups (3, 5). The concentric tubes must, of course, be properly constructed to minimize turbulence at their ends or the purpose of the H_2 shield is defeated. As the gases flow further into the furnace tube they mix and react producing tin oxide. The additional Cl_2 which was added to the $SnCl_4$ flow slows the reaction, Eq. [1], and is used to control the growth rate and can even be used to reverse the reaction if it is desired to back-etch seeds or remove unwanted nucleation. Nucleation occurs on the walls of the quartz liner and the largest, best-formed crystals grow in the region downstream from the center of the furnace where the temperature is decreasing at 10°C/cm from 1250° to 1175°C. The "exhaust" gases are passed through liquid nitrogen cold traps and are then pumped into the exhaust of a chemical hood. Helium gas is used to purge the lines before and after a growth run.

The procedure for a growth run is as follows. Initially, He gas is flowing in all of the system with the furnace hot and the pressure adjusted to approximately 10 Torr. To start the run the He flow is turned off and the other gas flows are started, H_2 and O_2 first,[1] then Cl_2. The progress of the growth is observed through the viewing window and the flow of additional Cl_2 is varied to give slow initial growth which has been found to be advantageous. This additional Cl_2 flow, approximately 1 cm^3/min initially, is slowly reduced to zero as the crystals grow larger and expose more surface area. If and when it is desired doping can be started. After growth has proceeded as far as desired the gas flows are stopped, He gas is again turned on, the pressure is increased to 760 Torr, and the crystals are removed, usually as soon as possible. Such a growth run typically results in over 10 large crystals, such as shown in Fig. 2, and many smaller ones.

Properties of Crystals Grown

The stannic oxide crystals grow as rods with diamond cross section, anchored at their base to the quartz liner and sticking out into the gas stream. Figure 2 illustrates the most common habit (note the twinning). Typical dimensions are $A = 2.5$ mm, $B = 5$ mm, and $C = 5$ mm for crystals grown 40 hr. Undoped crystals are clear and colorless showing no optical distortion in untwinned portions. Antimony-doped crystals are slightly bluish in color. No change in growth habit is observed when small concentrations of antimony are introduced, and we have successfully grown antimony-doped layers

[1] Because of the small gas flows (<100 cm^3/min at STP), the exothermic reaction of H_2 and O_2 produces approximately 10w of power and does not significantly affect the furnace temperature.

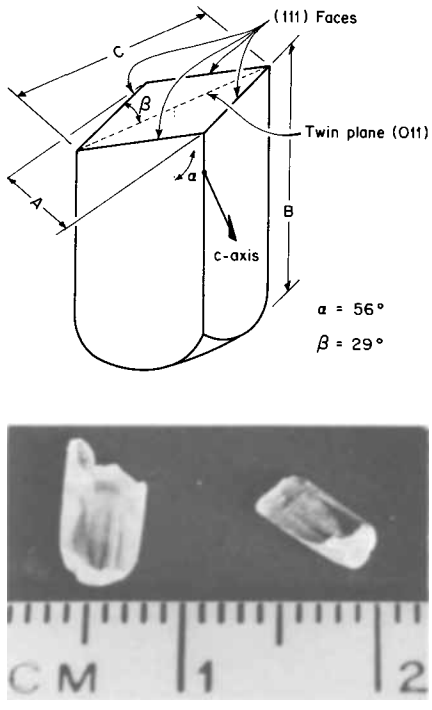

Fig. 2. Stannic oxide crystals: (top) artist's sketch of a crystal illustrating growth habit, and (bottom) photograph of two typical crystals.

on undoped crystals by turning on the chlorine flow to the doping reactor during the run as described above.

In order to characterize the crystals, x-ray and spectrochemical analyses and electrical measurements have been made. Laue x-ray photographs, taken mainly for purposes of orienting crystals, show a large number of sharp spots indicating good crystal quality. Spectrochemical analysis of crystals indicates less than 10 ppm Si (except at the base where the crystals anchor to the liner and where over 0.1% Si is found in the crystals) and less than 1 ppm of Ca, Cu, and Fe. No other elements were found except for the dopants in doped crystals, but the analysis technique used cannot detect the presence of chlorine so its existence cannot be discounted.

Hall effect and resistivity measurements of two antimony-doped crystals indicate n-type Hall mobilities, resistivities, and carrier concentrations of 160 cm^2/V-sec, 0.1 ohm-cm, and 4×10^{17} cm^{-3}, respectively, at 300°K, and of 1200 cm^2/V-sec, 0.1 ohm-cm, and 6×10^{16} cm^{-3} at 77°K. The resistivity of an undoped crystal has been measured as 6×10^5 ohm-cm at 300°K. In determining the carrier concentrations above, the Hall and drift mobilities have been assumed to be the same, which is not *a priori* obvious for this wide band-gap semiconductor.

Discussion

The spectrochemical analysis of the crystals grown indicates that they contain fewer impurities than those grown by other techniques (1-6). The fact that the Hall mobility at 77°K is 1200 cm^2/V-sec as compared to the highest previously reported value of 1000 cm^2/V-sec (8) is a further indication that the crystals are very pure. The high purity results from the method's inherent requirement that the elements in the crystals either be inside the furnace initially or be transported into the furnace in a gaseous form, most probably as a compound with chlorine. The dry chlorine used reacts slowly, if at all, with many elements below 100°C, and few of the compounds formed when it does react have sufficient vapor pressure at room temperature to readily enter the gas stream (9). This fact, of course, must also be taken into account when choosing dopants to insure that they will be transported into the furnace as

desired. Another interesting and very useful feature of the described method is the use of additional chlorine to control the reaction rate. Its main utility comes at the start of a run where it can be used to obtain slow initial growth and can be used by increasing the flow enough to reverse the reaction to back-etch seeds or to remove unwanted nucleation. Finally, the method of growing SnO_2 presented here, in addition to producing crystals having high mobility, is well suited for growing crystals for various electrical studies. Since dopants are introduced as the crystals grow and can be switched on and off without interrupting growth, the production of doped, conducting layers on higher resistance bases is straightforward as is the production of numerous other layered geometries.

Phosphorus and Arsenic Doping of Epitaxial Silicon Films in the 1000° to 1200°C Temperature Range

Terry B. Swanson*[1] and Ross N. Tucker*

Research and Development Laboratory, Fairchild Semiconductor, Palo Alto, California

ABSTRACT

The doping of silane grown epitaxial films has been studied in the 1000°-1200°C temperature range. Dopant sources were PH_3 and AsH_3. It is found that a gas phase equilibrium between the dimer (P_2 or As_2) and monomer (P or As) species occurs. The monomer is responsible for doping the silicon and does so in accordance with Henry's law. Reasonable agreement between the calculated and experimental doping concentration has been obtained.

Although a great deal of effort has been expended on studies concerning the doping of epitaxial silicon films, very little is known about the physicochemical processes involved. However, Shepherd (1) recently proposed a model to explain the doping of silicon epitaxial films grown in horizontal, gas flow reactors. Although Shepherd (1) tested his model for films deposited by the hydrogen reduction of $SiCl_4$ (temperature range 1100°-1350°C) and doped with n-type dopants introduced as the chloride species, many of the ideas are thought to be of general applicability. In the present work, we have studied the doping of SiH_4 grown epitaxial films using PH_3 and AsH_3 as the dopant gases. Several ideas are extracted from the Shepherd (1) model and are found to apply quite well to the temperature range suitable for epitaxial growth with SiH_4 ($\sim$ 1000°-1200°).

Theory

Both PH_3 and AsH_3 are thermodynamically unstable molecules at high temperatures. When introduced into a high temperature gas stream these molecules undergo almost complete decomposition and various other atomic and molecular species are formed. In the 1000°-1200° temperature range the two important gas phase species formed from the PH_3 molecule are the phosphorus monomer and the phosphorus dimer. This has been found from thermodynamic calculations (2). A similar situation exists in the case of AsH_3 in that the arsenic monomer and dimer are the predominant species between 1000° and 1200°C (3). In each case an equilibrium exists between the monomeric and the dimeric species in the gas phase. Only minute quantities of PH_3 or AsH_3 remain in the high temperature gas stream.

$$2PH_3(g) \xrightarrow{\Delta} P_2(g) \rightleftharpoons 2P(g) \quad [1]$$

$$2AsH_3(g) \xrightarrow{\Delta} As_2(g) \rightleftharpoons 2As(g) \quad [2]$$

Following the approach of Shepherd (1), we propose that the monomer in the gas phase is in equilibrium with the monomer in the solid phase. The solid phase in the present case is predominantly single crystal silicon formed by the thermal decomposition of SiH_4. The equilibrium can be expressed as

$$P(g) \rightleftharpoons P\ (ss) \rightarrow P^+\ (ss) + e^- \quad [3]$$

$$As(g) \rightleftharpoons As(ss) \rightarrow As^+\ (ss) + e^- \quad [4]$$

In Eq. [3] and [4], P (ss) and As (ss) refer to phosphorus and arsenic in solid solution at the silicon surface.

* Electrochemical Society Active Member.
[1] Present address: Applied Materials Technology, Santa Clara, California.

Both the phosphorus and arsenic monomers in the solid phase ionize to give an ionized donor (P^+ or As^+) and an electron. This nearly complete ionization of the donor species occurs at the actual doping temperature and persists at room temperature. In no case in the present work is the doping level sufficiently high such that both the ionized and un-ionized species need be considered.

We now assume that Henry's law may be applied to the above equilibria allowing us to write the following relationships. These relationships are correct as long as the intrinsic electron concentrations are large compared to the concentrations of ionized donors.

$$p_P = k_P [N_{P+}/N_{Si}]_s \quad [5]$$

$$p_{As} = k_{As} [N_{As+}/N_{Si}]_s \quad [6])$$

In the above equations p_P and p_{As} refer to the partial pressures of the phosphorus monomer and the arsenic monomer, respectively. The Henry's law constants are k_P and k_{As} for the two monomers while the bracketed terms refer to the ratio of the number of ionized donors to the number of silicon atoms in the solid phase, s. In order to calculate the expected doping level under various experimental conditions we need to know the partial pressures of the monomer species in the gas phase and the Henry's law constants. The partial pressure of the monomer can be obtained if one knows the partial pressure of the hydride originally introduced into the gas stream along with the appropriate equilibrium constant for either Eq. [1] or [2].

Using phosphorus as an example, the equilibrium constant for Eq. [1] is given by

$$K_p = [p_P]^2/[p_{P_2}] \quad [7]$$

and an analogous relationship exists for the arsenic equilibrium, Eq. [2]. Solving for the partial pressure of the phosphorus monomer we see that

$$p_P = [\{K_p(8p_{PH_3} + K_p)\}^{1/2} - K_p]/4 \quad [8]$$

Again, a similar relationship holds for the arsenic case. Combining Eq. [5] and [8] allows calculation of the expected doping level as a function of the equilibrium constant for the dimer-monomer equilibrium, the partial pressure of the dopant hydride introduced into the gas stream, the Henry's law constant for the monomer, and the density of silicon. For phosphorus

$$[N_{P+}]_s = [N_{Si}]_s [\{K_p(8p_{PH_3} + K_p)\}^{1/2} - K_p]/4k_P \quad [9]$$

It should be noted that Eq. [9] contains two strongly temperature dependent terms; namely, the equilibrium constant and the Henry's law constant. Both depend in an exponential manner on the temperature. The relative temperature variation of these terms will determine the nature of the calculated temperature dependence of the doping level. An expression analogous to Eq. [9] holds for arsenic doping.

Experimental Details

The experiments in the present investigation were carried out in a horizontal, RF heated, gas flow reactor operating at atmospheric pressure. A reaction chamber containing a silicon carbide coated-graphite susceptor and having a length of 29 in. and a rectangular cross section 2 in. x 4 in. was used. Highly doped substrates ($\sim$ 0.005 ohm-cm) of (111) orientation and approximately 1 in. diameter were placed along the length of the susceptor.

A typical run consisted of three substrates of opposite type to that of the grown epitaxial films. Prior to introduction of the substrates into the reactor, the susceptor was coated with high resistivity silicon ($\sim$ 60 ohm-cm). After introduction of the substrates into the reactor but prior to growth, the substrates were etched for about 5 min with HBr at 1250°C. This procedure removed surface damage from the substrates. The source of silicon in the present work was 5% SiH_4 in ultrahigh purity hydrogen obtained from The Matheson Company, Inc. The silane-hydrogen mixture was combined with additional hydrogen obtained from a liquid hydrogen source. In all experiments the total gas flow was maintained at 68 liters/min. The silane concentration was approximately 0.15 m/o (mole per cent). Doping sources for the present work were 10 ppm PH_3 in hydrogen and 46 ppm AsH_3 in hydrogen, both obtained from The Matheson Company, Inc. Gas flows were monitored through Fischer & Porter Tri-Flat Variable-Area Flowmeters.

Deposit thicknesses were normally about 15μ and were determined by the IR interference technique. In all cases in the present work, a growth rate of 0.5 μ/min was maintained. Four point probe V/I measurements and IR thicknesses were used to obtain the film resistivity. Dopant concentrations were then obtained from the relationship between dopant concentration and resistivity (4). All temperature measurements quoted in the present study are actual temperatures which were obtained by correcting optical pyrometer readings. Temperatures are believed accurate to $\pm$5°C. Concentrations are estimated to have a $\pm$10% uncertainty.

Results and Discussion

Phosphorus doping experiments were carried out at four temperatures between 1000° and 1200°C: 1010°, 1050°, 1100°, and 1175°C. Table I shows the equilibrium constants for the phosphorus dimer-monomer equilibrium and the Henry's law constant for the phosphorus monomer at the above four temperatures. The equilibrium constants were calculated from free energy functions and heats of formation taken from the literature (2). Henry's law constants were taken from the work of Shepherd (1) and Coupland (5). Since these workers performed their experiments at temperatures generally higher than those used in the present work, a simple linear extrapolation of the k *vs.* $1/T$ curves was necessary to obtain some of the k-values in Table I.

Arsenic doping experiments were carried out at 1000°, 1050°, 1100°, and 1150°C. Calculated equilibrium constants (3) for the arsenic dimer-monomer equilibrium and Henry's law constants (1) for the arsenic monomer are shown in Table II.

Figure 1 shows the calculated per cent monomer obtained at various temperatures for both phosphorus and arsenic. The two curves refer to one particular initial dopant hydride pressure, namely, the lowest pressure used in each set of doping experiments. At any chosen temperature the per cent monomer decreases as the initial hydride pressure increases. Note that the phosphorus composition ranges from $\sim$ 0.25% monomer at 1000°C to $\sim$ 5% monomer at 1175°C, whereas the arsenic composition ranges from $\sim$ 20%

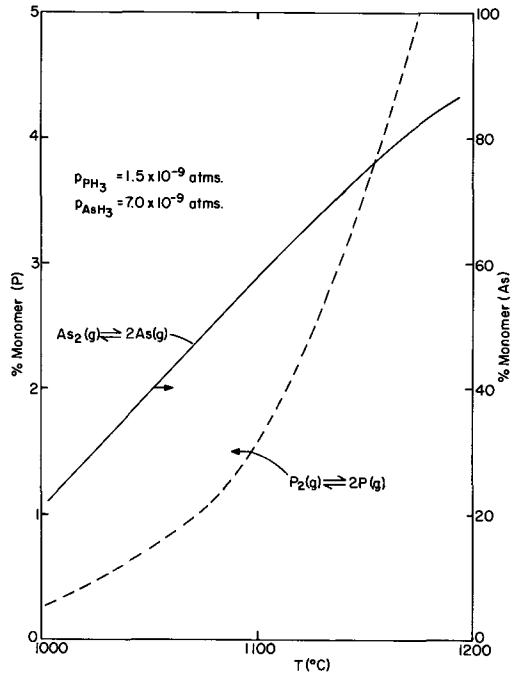

Fig. 1. Calculated per cent monomer as a function of temperature. Obtained from the equilibrium constants for the dimer-monomer equilibria of phosphorus and arsenic.

monomer to ~ 80% monomer over the same range of temperature.

Through the use of Eq. [9] and Table I, we are able to find the expected effect of increasing temperature on phosphorus doping level for a given phosphine partial pressure. As the temperature increases the dimer-monomer equilibrium constant increases; *i.e.*, the monomer partial pressure increases. In addition the Henry's law constant increases with increasing temperature. Since in Eq. [9] one term (K_p) occurs in the numerator and the other (k_p) occurs in the denominator, the effect of a temperature increase on the doping level ($[N_{P+}]_s$) will depend on which of the two terms is dominant. Calculations show that for phosphorus the doping level is expected to decrease with increasing temperature since the k_P term dominates. In the case of arsenic a similar situation occurs in that the calculated doping level decreases as the temperature increases.

Figure 2 shows a comparison between the calculated and observed doping level for phosphorus doping. The dotted lines represent the calculated doping level, as a function of phosphine pressure, obtained using Eq. [9] along with the data of Table I. A value of $[N_{Si}]_s = 5.00 \times 10^{22}$ atoms/cm³ taken from the literature (4) was used in the calculations. The phosphine partial pressure was that determined experimentally from the gas flow rates. For the calculated doping level note that doping decreases as the temperature increases for a given phosphine partial pressure. The agreement between calculated and experimental values of the dopant concentration, as shown in Fig. 2, is reasonably good in view of the complexity of the situation. Better agreement is obtained at the low end of the phosphine partial pressure range and although the dopant concentration increases with phosphine partial pressure for a given temperature the agreement becomes less satisfactory as the partial pressure increases. Probably the most significant point regarding Fig. 2 is the experimental observation that dopant concentration at constant pressure falls off as the temperature increases. This is what is predicted by the theory. In connection with Fig. 2 it should be pointed out that the background doping level (*i.e.*, the dopant concentration obtained in a nominally intrinsic deposition) is approximately 2 x 10¹⁴ atoms/cm³.

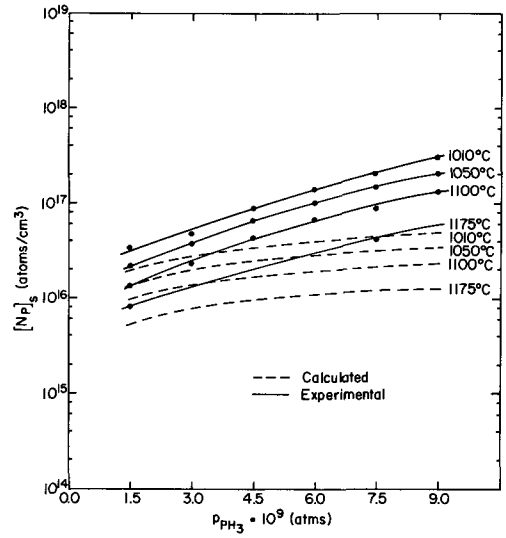

Fig. 2. Doping concentration vs. partial pressure of phosphine at various temperatures. Comparison of calculated and experimental values.

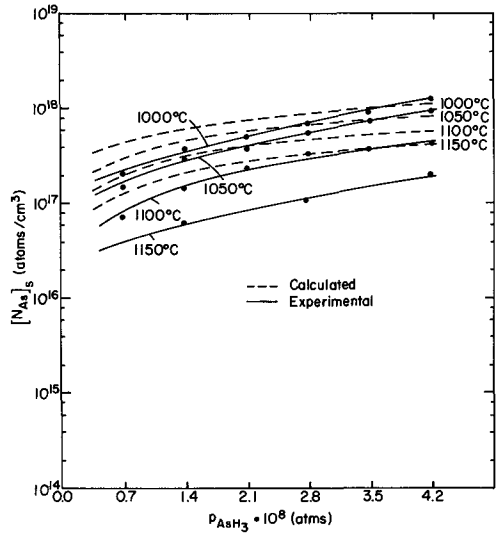

Fig. 3. Doping concentration vs. partial pressure of arsine at various temperatures. Comparison of calculated and experimental values.

Figure 3 shows a comparison between experimental and calculated doping concentrations for arsenic. The effects are qualitatively similar in all respects to those noted for phosphorus doping. We find, however, that the agreement between calculated and experimentally determined concentrations is better in the case of arsenic than it is in the case of phosphorus. We also note that for arsenic the agreement becomes less satisfactory at the higher end of the temperature range.

For the case of phosphorus doping and under the experimental conditions used in the present work, Eq. [9] can be simplified as follows. Rewriting this equation in a slightly different form gives

$$[N_{P+}] = [N_{Si}]_s K_p [(8p_{PH_3}/K_p + 1)^{1/2} - 1]/4k_P \quad [10]$$

Since $(8p_{PH_3}/K_p + 1) \approx 8p_{PH_3}/K_p$ for our experimental conditions and also since $[(8p_{PH_3}/K_p)^{1/2} - 1] \approx (8p_{PH_3}/K_p)^{1/2}$ we find that

$$[N_{P+}]_s = \frac{[N_{Si}]_s (2K_p)^{1/2}}{2k_p} (p_{PH_3})^{1/2} \quad [11]$$

Clearly the theory predicts a phosphorus doping level proportional to the square root of the phosphine partial

pressure. Experimentally we find that the doping level increases somewhat more rapidly with phosphine pressure than predicted by Eq. [11].

In the case of arsenic doping a simplification similar to Eq. [11] cannot be made since the relationship $(8p_{AsH_3}/K_p + 1) \approx 8p_{AsH_3}/K_p$ is not always valid and indeed the term $8p_{AsH_3}/K_p$ can be as small as approximately 4.7.

We can offer no explanation for the deviation of the experimental and calculated doping levels. It is possible that some refinement of the theory is needed. However, it is felt that the theory is essentially correct in that the trends in the experimental results closely approximate calculated values.

Partial Pressures of Zn and Te_2 over ZnTe up to 917°C

R. F. Brebrick

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The partial pressures of Zn, P_{Zn}, and of Te_2, P_2, for ZnTe(c) of different compositions have been determined up to 917°C by measuring the optical density of the coexisting vapor as a function of wavelength in the uv and visible. Over the whole temperature range the value of P_{Zn} over Zn-saturated ZnTe is the same as that over pure Zn to within the experimental error of ±2%. The values of P_2 for Te-saturated ZnTe indicate a solubility of Zn in Te(c) at 450°C of the order of 1 a/o (atomic per cent). For compositions within the homogeneity range both P_{Zn} and P_2 were measured. Evidence is presented for a slow reaction with silica near 900° by which Zn is lost from the ZnTe but which can be inhibited by a carbon coating on the silica tube. Between 688° and 917°C

$$\log P_{Zn}P_2^{1/2}\ (atm^{3/2}) = -(16{,}350 \pm 68)/T + (9.680 \pm 0.062)$$

with a standard deviation of 0.016 in the logarithm. The result is compared with published values, which spread over a factor of 10 in $P_{Zn}P_2^{1/2}$.

In this paper we report the determination of, (*a*) the partial pressures of Zn, P_{Zn}, over Zn-saturated ZnTe(c), (*b*) the partial pressure of Te_2, P_2, over Te-saturated ZnTe(c), and (c) both P_{Zn} and P_2 over ZnTe with compositions within the homogeneity range. Such data are useful in investigations of the correlation between the electrical and optical properties of ZnTe and the concentrations of native, atomic, point-defects present in the compound. The defect concentrations are determined by deviations from the stoichiometric composition, which are most readily controlled, when small, by fixing the temperature and either P_{Zn} or P_2. No previous detailed measurements have been reported for cases (*a*) and (*b*). Three investigations (1-3) have determined the product, $P_{Zn}P_2^{1/2}$, by using Knudsen-cell, weight-loss measurements. Lee and Munir (4) determined this product by using the angular displacement (but not weight-loss) of a torsion-effusion cell. Although all four determinations give nearly the same temperature dependence of $P_{Zn}P_2^{1/2}$, the magnitudes of the product at a given temperature vary by a factor of ten. The values reported here, which are about 40% below the highest values obtained by the dynamic methods, were obtained by a static method in which the optical density of the vapor coexisting with ZnTe(c) in a closed system was measured as a function of wavelength.

Experimental

In a number of synthesis steps it was necessary to heat samples. This was always done in a fused silica tube which had been rinsed in HF, followed by distilled water, dried, and outgassed 16 hr at 1060°C and pressures of 10^{-7} Torr or below. After the sample was loaded into the tube, it was outgassed again for 3-5 hr at 200° and 10^{-7} Torr and finally sealed off.

Samples containing Te-saturated or Zn-saturated ZnTe(c) were synthesized by weighing the individual high-purity elements to the nearest 0.1 mg to make a total of 15g. The over-all compositions were respectively 55.0 and 40.0 a/o (atomic per cent) Te. The elements were loaded into a silica tube which was evacuated and sealed off. A vigorous, exothermic reaction was initiated with a hand torch, and heating was continued until it appeared that all the Zn had been attacked. The tube was then heated for 16 hr at 560° for the 55.0% sample and for 168 hr at 596° for the 40.0% sample. The material was ground with an agate mortar and pestle to pass a 1 mm opening, stainless steel, standard sieve. For each composition about 2g of material was loaded into the sidearm of an optical cell which was then evacuated, outgassed, and sealed off.

Experiments with samples inside the homogeneity range used ZnTe crystals which were either vapor-grown by using ZnTe at 1080°C as a vapor source and He as a carrier gas (5) or were grown from a 70 a/o Te melt by a traveling-zone technique (6). In the latter case, the crystals to be used were annealed in liquid Zn for 24 hr at 1050°, then 24 hr at 700°, then furnace cooled. This served to significantly reduce, if not completely eliminate the amount of Te present as

an internal precipitate and visible as black occlusions under magnification with transmitted light. The crystals were ground to a maximum particle size of 1 mm and loaded into the sidearm of a silica optical-cell, which was then evacuated, outgassed, and sealed off. The weight of the samples used ranged from 0.5 to 300 mg. There were no significant differences in the values of $P_{Zn}P_2^{1/2}$ obtained that could be attributed to sample origin or size. In one case the sidearm of the optical cell was coated with carbon by the pyrolytic decomposition of acetone vapor before the cell was outgassed at 1060° in the cleaning step. A small, carbon-coated silica tube outgassed with the optical cell was used to transfer the 2.1 mg, 0.125 mm maximum particle size, sample into the sidearm of the optical cell.

The 22 mm OD, cylindrical, silica, optical cells were generally about 103 mm long. A 22 cm long sidearm bisected this length at right angles. The sample was spread over the last 2 cm of the sidearm. The optical cell proper was held at a fixed temperature of 1000°C by a 32 cm long, 3.8 cm ID, 3-zone split furnace. The opening through the wall of this furnace, through which the sidearm of the optical cell passed, also contained a 5 cm long, 1.3 cm ID auxiliary furnace. The auxiliary furnace extended about 1 cm into a 30 cm long, 3 cm ID sidearm furnace. The power through the auxiliary furnace could be set so that no minimum in temperature developed between the main furnaces. A 10 cm long, 6 mm wall thickness, Pt-coated, Ag liner surrounded the end 5 cm of the sidearm and served to reduce the temperature variation over the sample to less than 2° for all the measurements. Only a slight surface reaction could be observed between the liner and the surface of a silica tube after about 100 hr at 900°C. The sample temperature was taken as that measured by a calibrated Pt; Pt, 13% Rh thermocouple protected by a two hole alundum tube and located in the Ag liner at a position corresponding to the middle of the sample. Calibrations taken over a period of months showed no change in the thermocouple. The sample temperature was measured to the nearest 0.1°C and varied by less than 0.3° during the 5-10 min required to make the optical density measurements.

The procedure used to make optical density measurements with a Cary 14H double-beam spectrophotometer has been described in detail (7). To obtain the lowest values of P_{Zn} and P_2 the spectrum was scanned between 2200 and 1990Å at 5/8 Å/s using the hydrogen light source of the Cary, a chart speed giving a display of 3.4 Å/cm, and a recorder-pen period of 1s. For the highest values of P_2 the spectral measurements were made in the visible portion of the spectrum as previously described (8). According to the manufacturer's dispersion curves, the spectral band-pass was 1.12Å at 2138Å and 1.84Å at 1995Å. Special care was taken to reproduce the slitwidths in each scan, especially in the uv. Optical densities, $D = \log I_0/I$, were measured between about 0.01 and 2.0. The noise near zero optical density was ± 0.005. Using optical density measurements, we have determined the partial pressures for a number of tellurides and selenides as well as for Te and Se themselves. These references are given in ref. (7) and (8).

Results

Pure tellurium.—For a pure Te sample the spectrum is that of $Te_2(g)$. The dependence of the optical density on the temperature of the liquid Te sample has been described for a number of wavelengths in the visible and for a 1000°C optical cell (8). The behavior of a number of band maxima in the uv has been described for an optical cell temperature of 755°C (7). These uv band maxima behave similarly when a 1000° optical cell is used. The results for a 1000°C optical cell can be summarized by the equations

$$P_2(\text{atm}) = 0.0433\, D_{1995}/L(\text{mm}) \quad [1]$$

$$D_{1995}:D_{2025}:D_{2056}:D_{2138}:D_{4357}:D_{5000} = 100:43.5:37.3:4.70:11.2:2.57 \quad [2]$$

where D_λ is the optical density at a wavelength λ, and L is the optical path length. These equations are accurate to within ± 2% for path lengths between 22 and 100 mm and for values of D_λ between about 0.01 and 2 provided: (*i*) one corrects for instrumental stray-light errors at values of D_λ greater than about 1, and (*ii*) one uses D_λ/L values greater than 0.007 for λ = 4357 or 5000Å. Band maxima occur at the wavelengths cited above except at 2138 and 5000Å, where the spectrum is apparently continuous.

Pure zinc.—The strongest Zn(g) absorption line is centered at 2138Å. This line has a calculated Doppler half-width of about 0.03Å at 1000°C, some 40 times smaller than the narrowest spectral band-pass which we used. As a result D_{2138} is sensitive to slit-width. The slope of log D_{2138} *vs.* $10^3/T$ for a 1000° optical cell varies with temperature and is somewhat smaller than the slope of log P_{Zn} *vs.* $10^3/T$. Calibration runs with a pure Zn sample were made with 49.3 and 98.8 mm path-lengths and with slit-widths of 0.08 and 0.158 mm (1.12 and 2.2Å band-pass, respectively). Measurements were taken at about 5° intervals in the Zn-sample temperature and covered optical densities between 0.02 and 2.0. For a given path length the values of D_{2138} obtained with the two slit-widths fall on parallel lines, that for the smaller slit-width being higher by a factor of 1.60, somewhat less than the factor of 2 expected. At a given Zn-sample temperature and slit-width, the values of D_{2138} obtained with the 98.8 mm cell are 1.31 times as large as those obtained with a 49.3 mm cell. This is consistent with D_{2138} depending on the 0.39 power of the path-length rather than the first power. These anomalies in path length and slit width dependence can be attributed to the fact that the spectral band-pass used is so much larger than the half-width of the 2138Å adsorption line.

With increasing Zn-sample temperature the 2138Å line broadens extensively toward the visible (9), a subsidiary line develops at 2066Å, and the well-known line at 3070 develops. Between 2150 and 2800Å, in the long wavelength tail of the 2138 line, the slope of log D_λ *vs.* $10^3/T$ is twice that shown by log P_{Zn} for p_{Zn} between 0.01 and 1 atm. Thus the absorption grows as the square of the number of atoms in the light path, consistent with the statistical theory of pressure broadening (10) and similar to the behavior of the 2540 Hg (9, 11, 12) and 2287 Cd (9) absorption lines. For D_{2138} as high as 1.6 the optical density at 1995Å is below 0.01. Thus in those cases where we see absorption due to both Zn and Te_2, the absorption at 1995 is essentially all due to Te_2.

The vapor pressure of Zn was taken from the table in the critical compilation of Hultgren *et al.* (13). To within better than 1% in P_{Zn} the data can be represented by the equations

$$\log_{10}P_{Zn}(\text{atm}) = -6{,}714.7/T + 5.9839 \quad (600 < T°K < 692.7) \quad [3]$$

$$\log_{10}P_{Zn}(\text{atm}) = -6{,}281.3/T + 5.3586 \quad (692 < T°K < 900) \quad [4]$$

Zn-*saturated* ZnTe(*c*).—From 500° to 910°C, the maximum temperature measured, the value of P_{Zn} over Zn-saturated ZnTe(c) is the same as that over pure Zn(l) within the experimental error of ±2%. This is 1.17 atm at 1200°K and 0.114 atm at 1000°K (13). This is to be expected in view of the fact that the compositions along the Zn-rich liquidus fall below 0.1 a/o Te up to 910°C. The values of P_{Zn} were obtained from D_{2138} below 540° and from D_{2150} and D_{2200} at higher temperatures. The value of P_2 was below our

experimentally detectable limit of about 10^{-5} atm at all temperatures.

Te-saturated ZnTe(c).—The partial pressure of Te_2, P_2 over Te-saturated ZnTe(c) between 398° and 913°C was determined using two different optical cells at 1000°C. For sample temperatures above 520° the values of D_λ for the uv maxima were greater than 2.0 so that P_2 was obtained from D_λ at 4357 and 5000Å. Between 398° and 438°C the measurements were repeated with a 755° optical cell temperature to check on the magnitude of possible thermal effects arising because of the difference in temperature between the sample and the optical cell proper. No such effects were seen. The values of P_{Zn} were below the detection limit of 8×10^{-6} atm. The values of P_2 from the two optical cells and the two optical cell temperatures all fall within ±3% of a smooth curve. For this reason and because we have 63 experimental points, values interpolated from this curve are listed in Table I. (The proportionality constants between D_λ and P_2 for the 755° optical cell were taken from an earlier study (7).) Near 900°C the observed values of P_2 are close to those calculated from the liquidus (14) assuming the liquid is ideal. This is not true at the lower temperatures, however, the P_2 curve running parallel to that for pure Te (l) and about 15% lower between about 540° and 450°C. The P_2 curve shows a break at 450°, similar to that for pure Te, and continues to run parallel to the pure Te(c) curve down to the lowest temperature measured, 398°C. It would seem that this result is most likely, though not necessarily, inconsistent with the results of thermal analysis. The ZnTe-Te eutectic temperature has been reported (14) as 449° ± 2°C, agreeing with the melting point of pure Te. The eutectic composition appears to be not less than 98 a/o Te, indicating a solubility of Zn in Te(c) at 450° of less than 2 a/o. On the other hand, according to our results, the solubility of Zn in Te(c) must be large enough to depress the Te_2-partial pressure by 15%. One would think this requires a solubility of the order of 1 a/o.

ZnTe(c) *within the homogeneity range.*—The spectra obtained with ZnTe(c) samples within the homogeneity range were a superposition of those obtained with pure Zn and pure Te. Thus Zn(g) and Te_2(g) were the major vapor species, in agreement with mass spectrographic results (2). It is characteristic of the II-VI compounds that the gaseous MX molecule is a minor constituent of the vapor phase (2, 12, 15, 16).

The Te_2 contribution to the absorption at 2138Å, which is $0.047D_{1995}$ according to Eq. [2], was about 10% of the observed value of D_{2138} and was subtracted from the latter to get the Zn contribution. The value of $10^3/T$ of a pure Zn sample that would give the same value of D_{2138} for the same path length was then read from the calibration graphs. (The cells used had path lengths matching one of the two used in the measurements on pure Zn.) The corresponding value of P_{Zn} was calculated using Eq. [3] or [4]. For the various samples, P_{Zn} and P_2 could both be measured from about 688° to 917°C. At the lowest measurable pressures, P_{Zn} was as much as 5 times larger than P_2. The ratio $P_{Zn}/P_2 = R$ decreased to values between 1 and 2 as the ZnTe sample was heated, due to the preferential loss of Zn to the vapor phase and the dependence of the partial pressures on solid composition. Although the D_λ values apparently became steady simultaneously with the sample temperature, they changed slightly on standing 16 hr at temperature in the 850°-917°C range, in such a way as to yield a reduction in the ratio R. Values as low as 1.3 were observed. However, the product $P_{Zn}P_2^{1/2}$ obtained after such changes was within 3% of that obtained before.

Table I. Partial pressure of Te_2(g), P_2, over Te-saturated ZnTe(c)

$10^3/T$	$10^4 \times P_2$ (atm)	$10^3/T$	$10^4 \times P_2$ (atm)
0.85	3460	1.25	16.3
0.90	1880	1.30	8.15
0.95	1000	1.35	4.07
1.00	515	1.38	2.69
1.05	265	1.39	2.23
1.10	135	1.40	1.83
1.15	65.5	1.45	0.667
1.20	32.5	1.49	0.300

The measurements obtained with the carbon-coated cell gave values of $P_{Zn}P_2^{1/2}$ in good agreement with those obtained with the uncoated cells. However, there were no significant changes in either P_{Zn} or P_2 on standing 16 hr at 855°C. Presumably the carbon barrier inhibited a reaction between ZnTe(c) and silica which caused a relative loss of Zn from the ZnTe(c). The data from the carbon-coated cell are listed in Table II. It is seen that with increasing temperature the ratio R decreases from 4.58 and between 827° and 919°C holds at an average value of 1.8 ± 0.1. Now if the homogeneity range of ZnTe were between 49.5 and 50.5 a/o Te, congruent sublimation with Zn and Te_2 as the only vapor species would give a value of R between 2.05 and 1.95. The reason we obtain a value that appears to be significantly different is not clear. Perhaps the experimental conditions of sample weight and gas phase volume were not right to obtain congruent sublimation although comparable conditions gave (15) congruent sublimation with CdTe(c). Perhaps our values of P_{Zn} and P_2 suffer a systematic error when both pressures are comparable. Our estimated error of 3% in each pressure leads to a 4.2% error in R. However, an error of 10% in either pressure for any cause, including errors in the published vapor pressures, would account for an observed value of 1.8 for R when the true value is 2.0. Or least likely, we believe, perhaps the homogeneity for ZnTe(c) is more Te-rich than 50.5 a/o Te.

The behavior seen in the last four sets of measurements shown in Table II is consistent with the above hypothesis concerning the loss of Zn in an uncoated silica tube. The ZnTe(c) temperature was dropped from 919° to about 855°C and a measurement made. Over the next 40 hr three additional measurements were made with the temperature between 851° and 885°C. As can be seen, the ratio, R, decreases with time and is significantly below 2.0. The initial cooling resulted in the deposition of some ZnTe(c) at the extreme end of the sidearm, where there was no carbon coating. The subsequent slow loss of Zn from the ZnTe(c) led to a continuing decrease in R.

Table II. Partial pressure of Zn(g), P_{Zn}, and of Te_2(g), P_2, for compositions within the ZnTe(c) homogeneity range (carbon-coated cell)

$10^3/T$°K	$10^5 \times P_{Zn}$ (atm)	$10^5 \times P_2$ (atm)	$P_{Zn}/P_2 \equiv R$	$10^7 \times P_{Zn}P_2^{1/2}$ ($atm^{3/2}$)

* 16 hr at temperature before making measurements.

A least squares fit of all 26 points in Table II gives

$$\log P_{Zn}P_2^{1/2} = -(16{,}350 \pm 68)/T + (9.860 \pm 0.062) \quad (961°\text{-}1190°K) \quad [5]$$

where the pressures are in atmospheres and the quoted errors are the standard deviations in the slope and intercept. The standard deviation in the logarithm of the pressure product is 0.016. Equation [5] fits 17 of the points to within 3% in $P_{Zn}P_2^{1/2}$ and all 26 are fit to within 7.5%.

A least squares fit to the 107 points from 4 uncoated optical cells gives

$$\log P_{Zn}P_2^{1/2} = -(16{,}328 \pm 74)/T + (9.835 \pm 0.068) \quad (961°\text{-}1190°K) \quad [6]$$

The standard deviation in the logarithm of the pressure product is 0.038. Equation [6] fits 38 points to within 3% in $P_{Zn}P_2^{1/2}$, 67 to within 6%, 94 to within 20%, and all 107 to within 30%. It is seen that within the statistical error, Eq. [5] and [6] are the same. We emphasize for future reference, that Eq. [5] and [6] hold for values of R between 5 and 1.3 and therefore for $R = 2$.

Lattice parameters.—The Te-saturated and Zn-saturated ZnTe samples used in this study were further characterized by determining their lattice parameters at 25°C. The x-ray patterns were taken with 40 kV, 40 mA, CuKα radiation and a Philips diffractometer using a 1° divergence slit and a LiF monochromator in the diffracted beam. A scanning speed of ¼°/min in 2θ and a chart speed of 30 in./hr allowed the value of 2θ to be read with a precision of ±0.005°. Si(a_0 = 5.4301Å) and 99.99%W (a_0 = 3.1650Å) powders were used as external standards. Zn-lines were seen in the pattern for the 40 a/o Te samples and Te lines in the 55 a/o Te sample patterns. Since the 2θ-values for the various peaks of ZnTe between 25° and 151° were measured with about the same precision, the cubic parameter was obtained by using a computer technique (17) to minimize the residual function, $\sigma(\Delta 2\theta) = \{\sum_{i=1}^{M} (2\theta_{i,obs} - 2\theta_{i,calc})^2/M\}^{1/2}$. The results are shown in Table III for four samples. It is seen that the parameters are close to the literature value (18) and in three cases agree with it within the standard deviations shown. Assuming equilibrium had been attained in annealing the powders and that no large changes in the composition of the ZnTe phase occurred on quenching, the homogeneity range of ZnTe(c) must lie within the 40-55 a/o Te interval near 1000°C. In contrast, Godau and Ormont (19) find the lattice parameter of ZnTe decreases linearly with decreasing Te content, attaining a minimum value of 6.092Å at 40 a/o Te. The inference of course is that the ZnTe homogeneity range extends between 40 and 50 a/o Te at some high but ill-defined temperature. These authors synthesized samples near 1200°C, then lowered the temperature to 1000°C over 2 hr, then furnace-cooled the samples. It seems unlikely to the author that these results are correct.

Table III. Lattice parameters for ZnTe(c) at 25°C using λ = 1.5405Å for CuKα_1 radiation

Sample	$\sigma(\Delta 2\theta)$, °2θ	$a_0 \pm \sigma(a_0)$ Å
40 a/o Te Zn-Te, 20 hr 345°C[a]	0.012	6.1026 ± 0.0001
40 a/o Te Zn-Te, 2 hr 1000°C[b]	0.014	6.1028 ± 0.0002
55 a/o Te Zn-Te, 20 hr 345°C[c]	0.014	6.1024 ± 0.0001
55 a/o Te ZnTe, 120 hr 1050°C[d]	0.017	6.1023 ± 0.0002
ZnTe[e]	0.010	6.1026 ± 0.0001

[a] Synthesized as described in the text, ground to pass a 44μ standard sieve, heated in evacuated, sealed-off silica tube 20 hr 345°C, then quenched in water.
[b] As in (*a*) except that anneal at 345°C replaced by anneal at 1000°C.
[c] Similar to (*a*).
[d] After synthesis as described in text, sample heated 120 hr 1050°C, quenched in water, sintered sample then ground to pass 44μ standard sieve.
[e] Ref. (18). Data analyzed using our program. Parameter agrees with that given in ref. (18).

Discussion

The use of absorption measurements at a few wavelengths to determine partial pressures is subject to possible error due to the distortion of the absorption spectra of one vapor species by another. In a number of previous investigations [listed in ref (8)] we have found that this type of error is in fact negligible for molecular species, and for Te_2 in particular, for pressures as high as 10^{-2} atm. However, when as is done here for P_{Zn}, the peak value of a narrow absorption line is used to obtain a partial pressure, the possibility of error is greater. To an unknown extent the error is compensated by the use of a spectral bandpass much wider than the true half-width of the absorption line. The magnitude of this error was checked in one run on a ZnTe crystal. The values of P_{Zn} were determined between 800° and 900°C (where the values of P_2 observed for ZnTe crystals were the highest and the magnitude of the error should be the largest) from measurements using a 0.158 mm slit width at 2138Å as well as the 0.086 mm slit width used for the measurements given in the last section. (In both cases the same Te_2 contribution was subtracted from the total optical density at 2138Å.) It was found that the values of P_{Zn} obtained using the two slit widths agreed to within 5%. Since the spectral bandpass was varied by almost a factor of 2 in the alternate determination, we conclude our values of P_{Zn} are in error by 5% or less due to broadening of the Zn absorption line by Te_2.

For the measurements given in Table II, as well as for those obtained with the other four ZnTe crystals investigated, the value of P_{Zn} at any temperature is intermediate between that observed for the 40 a/o Te sample and that for the 55 a/o Te sample, which was below our experimental limit of 8 x 10^{-6} atm. Moreover, the value of P_2 is similarly between the value observed for the 55 a/o Te sample as given in Table I and that for the 40 a/o Te sample, which was below our experimental limit of 10^{-5} atm. Therefore, what we have called ZnTe crystals were indeed within the homogeneity range of the ZnTe(c) phase over the temperature range of the measurements. Second, the values of $P_{Zn}P_2^{1/2}$ obtained from these crystals all fall within a few per cent of the same straight line on a log-1/T plot for all values of R between about 5 and 1.3. By the Gibbs phase rule, all intensive variables of the ZnTe(c)-vapor system are fixed when any two are given. In particular they are fixed when T and R are given. Thus for a given T and for $R = 2$, the composition of ZnTe(c) is unambiguously defined in a thermodynamic sense regardless of the lack of any analytical data specifying this composition in terms of atomic per cent and independent of the width or the position of the ZnTe(c) homogeneity range. For brevity we shall call this particular composition, whose coexisting vapor is stoichiometric, the s-composition. It is recognized that if the homogeneity range is narrow, say within 0.5 a/o of 50.0 a/o, that the partial pressures must then depend very strongly on composition and the s-composition at any temperature will be very close to the congruently subliming composition for which R must be between 2.05 and 1.95.

At any temperature, the standard Gibbs free energy of formation of 2 g-atoms of the s-composition from pure Zn and Te is given in terms of the atomic fraction of Te for this composition, ½ + δ, by

$$\Delta G^\circ_f = (\tfrac{1}{2} + \delta)RT \ln (P_2/P^\circ_2) + 2(\tfrac{1}{2} - \delta)RT \ln (P_{Zn}/P^\circ_{Zn}) \quad [7]$$

Here P_2 and P_{Zn} are the partial pressures for the s-composition and P°_2 and P°_{Zn} are those for the pure elements. Using Eq. [5], $P_{Zn} = 2P_2$, and published data

for the vapor pressures of Te and Zn, Eq. [7] becomes

$$\Delta G^{\circ}_f = -(34{,}360 \pm 310) + (11.49 \pm 0.28)T + C;$$
(cal/2 g-atoms, 960°-1190°K) [8]

where C is a correction term that goes to zero if δ does and is given by

$$C = 3.974\,\delta\{T \ln (P^{\circ}_{Zn}/P^{\circ}_{2}{}^{1/2}) + 12{,}501 - 8.031T\}$$
(cal/2 g-atoms) [9]

Thus a free energy of formation cannot be obtained from our data unless δ is known. However, even for $|\delta| < 0.02$, corresponding to the composition falling between 48 and 52 a/o Te, the correction term given by Eq. [9] is only 300 cal/2 g-atoms or less between 900° and 1200°K and the error in ΔG°_f committed by neglecting C in Eq. [8] is only 1.2%.

For those measurements in which there appeared to be no loss of Zn to the silica, *e.g.*, all those in Table II except the last four, the change in composition of the sample due to preferential sublimation of one component can be obtained in terms of the unknown initial composition. For the 40 cm³ gas phase volume and the initial sample weight of 2.5 mg, the calculated change is about the same for all assumed values of the initial composition between 45 and 55 a/o Te. For each of the first eight measurements in Table II (through $10^3/T = 0.9251$), the Te content of the sample is greater than initially by an amount between 0.01 and 0.05 a/o. The estimated error in the calculated change is comparable to the change itself. For the measurements with $R < 2$, the Te-content of the sample is less than initially. The decrease is largest at $10^3/T = 0.8864$, where it is 0.2 a/o. However, for this particular measurement, as well as for the others with $R < 2$, an error of 3% in either partial pressure introduces an error in the calculated composition change comparable to the change itself. Thus over the range of the measurements the composition of the sample, known to be in the ZnTe homogeneity range from the values of the partial pressures, changes by no more than 0.2 ± 0.2 a/o. The measurements therefore are consistent with the assumption that the homogeneity range of ZnTe is less than 1 a/o wide, although they do not prove this assumption.

We have shown that our results are meaningful independent of any assumption concerning the homogeneity range of ZnTe(c). In the remaining discussion, in which we compare our results with other studies, we shall assume, as indeed the previous workers have implicitly or explicitly assumed, that the homogeneity range of ZnTe(c) is narrow and close enough to 50 a/o that $P_{Zn}P_2{}^{1/2}$ and ΔG°_f can be taken as independent of composition without incurring any significant errors in these quantities.

Our values of $P_{Zn}P_2{}^{1/2}$ as given by Eq. [5] are plotted on a log scale against $10^3/T$ in Fig. 1. Results from other measurements are summarized in Table IV and shown in Fig. 1 for comparison. Korneeva *et al.* (1) made Knudsen-cell, weight-loss measurements. Langmuir measurements gave identical results within

Table IV. Literature values for the constants A and B in the equation, $\log_{10}P_{Zn}P_2{}^{1/2}$ (atm$^{3/2}$) $= -A/T + B$

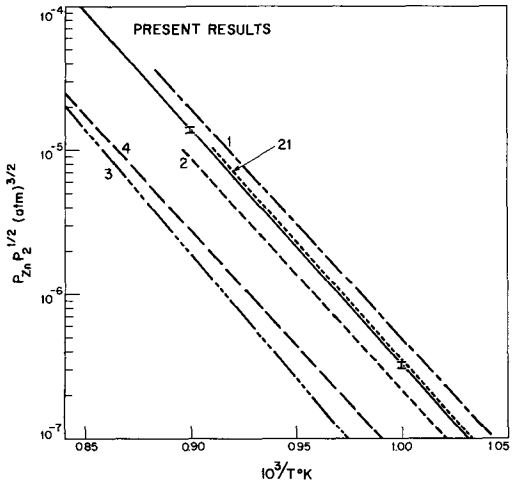

Fig. 1. Partial pressure of Zn times the square root of the partial pressure of Te_2, $P_{Zn}P_2{}^{1/2}$ (atm$^{3/2}$) $= K$, for ZnTe(c) plotted on a log scale against $10^3/T$. The solid line shows the present results as given by Eq. [5]. The total width of the brackets at $10^3/T = 1.00$ and 0.90 is twice the standard deviation in log K. The numbers on the other lines are the appropriate reference numbers.

experimental error. Their analysis erroneously assumed ZnTe(g) was the only vapor species. Assuming a steady state effusion with Zn(g) and Te_2(g) as the vapor species, we have converted their values for the apparent ZnTe pressure, P^*, to the corresponding partial pressures of Zn and Te_2 using the equations: $P_{Zn} = 0.582\,P^*$, $P^*_2 = 0.575\,P^*$, and calculated the product (*i.e.*, we have assumed a steady state in which the composition of the material emanating from the effusion cell and that in the cell are both 50.0 a/o Te). The values so obtained are shown as line 1 in Fig. 1, which is nearly parallel to ours but about 40% higher. Goldfinger and Jeunehomme (2) made Knudsen-cell, weight-loss measurements. Their results are represented by line 2, which is nearly parallel to ours but is about 55% lower. By using radioactive Zn, Reynolds *et al.* (3) confirmed that the composition of the effusion produce from their Knudsen-cell was ZnTe. Their results (line 3 in Fig. 1) are the lowest obtained, about eight times smaller than ours, but in fair agreement with those of Lee and Munir (4) shown as line 4. The latter authors used a torsion-cell but made only angular displacement measurements, assuming the same steady state we assumed above in the recalculation of the data of Korneeva *et al.*

The large discrepancies in Fig. 1 could be attributed to a lack of solid-vapor equilibrium in those studies yielding the lowest values of $P_{Zn}P_2{}^{1/2}$. However, the ratio of the cell orifice area to the sample area is apparently about the same for all the dynamic determinations. Moreover, as mentioned above, Korneeva *et al.* (1) obtained the same results in both Knudsen-cell and Langmuir measurements. Thus a low sticking coefficient and consequent difficulty in attaining solid-vapor equilibrium does not seem to be a plausible explanation. It has been observed (20) that between 1000° and 1200°C the vapor transport of ZnTe is effectively stopped when ZnO is formed and presumably coats the ZnTe. Perhaps the low results are due to such an accidental oxide coating.

McAteer and Seltz (21) measured the emf of a cell whose reaction was the formation of ZnTe(c) from the solid elements. They obtained $\epsilon = 0.5703$V at 387°C and $-d\epsilon/dT = 6.17(10^{-5})$V/°C between 355° and 418°C. From these results and tabulated (22) melting points and heats of fusion for Zn and Te, the Gibbs' energy of formation for the reaction

$$Zn(l) + Te(l) \rightarrow ZnTe(c)$$

is given by

$$\Delta G^{\circ}_f = -34{,}128 + 11.4302T \quad \text{cal/mol}, T > 723°K \quad [10]$$

assuming $\Delta C_p = 0$. Using Eq. [10] and published data (22) for Zn and Te, the product $P_{Zn}P_2^{1/2}$ was calculated. The results are shown as line 21 in Fig. 1, which is slightly higher than ours but just within the brackets set by our standard deviation in log $P_{Zn}P_2^{1/2}$. It is seen that Eq. [10] agrees with our result given by Eq. [8] if the correction term C in Eq. [8] is zero.

Acknowledgments

The author wishes to thank T. B. Reed, J. Steininger, and G. Iseler for several ZnTe crystals. He also wishes to acknowledge the capable experimental assistance of R. N. Capes. This work was sponsored by the U.S. Air Force.

The Purification of Cesium and Rubidium Metals by Chloride Reduction under High Vacuum Conditions

P. H. Schmidt

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

High-purity Cs and Rb metal has been obtained for the first time for electronic structure studies. High-purity results were obtained by the reduction of a purified chloride using Ca metal. Apparatus design, low operating temperature (<400°C), high-purity salts, improved collection practices, and high vacuum operation were essential for successful results. Electrical resistivity ratios of purified Cs and Rb metals are $R_{300°K}/R_{1.5°K}$ 4400 and 3500, respectively.

The purification of cesium and rubidium metals by chloride reduction has been discussed by Schmidt, Studer, and Sottysiak (1), Hackspill (2), Hampel (3), Ephraim (4), Perel'man (5), and Mellor (6). Electronic structure studies of cesium and rubidium require metal of very high purity that has not been obtained using the techniques described by the above. Investigations were therefore initiated to satisfy our requirements and obtain the highest possible purity cesium and rubidium metals. Salt reduction (7) was selected as the method for purification. Although purity improvements could be made by distillation of these metals, removal of cesium or rubidium impurities from the desired alkali was marginal as a result of their similar vapor pressures. Alkali metal purity was found to be affected by apparatus design, salt purity, reduction temperatures, and collection practices. For the first time, very high-purity cesium and rubidium metals were obtained that were useful for electronic structure studies (8-10). Modification of previous salt reduction techniques combined with distillation was determined to be most successful.

Highly purified chlorides of both Cs and Rb [1] Table I, and fractionally redistilled Ca [2] metal granules were used for the reduction process. The reduction typically proceeds according to the following reaction

$$2MCl + Ca \xrightarrow{\text{Heat}} CaCl_2 + 2M \qquad [1]$$

where M is the alkali Cs or Rb. High vapor pressure impurities in both the chloride and reducing metal change the above reaction to

$$2MCl + \text{excess Ca} + \text{metal impurities} \xrightarrow{\text{Heat}} CaCl_2 + 2M + (\text{Ca} + \text{metal impurities}) \qquad [2]$$

The primary objective was therefore separation of the alkali metal from its respective contaminants and prevention of any reaction of the purified alkali with its container material.

[1] RbCl and CsCl purchased from Johnson Matthey & Company, Limited, London (99.999+% purity).
[2] Ca metal purchased from NELCO Metals, Inc., Canaan, Connecticut (redistilled grade).

Ba	10		
Cu	5		
Mn	5		
Sr	8000		

Apparatus

Three purification and reaction devices were constructed for this purpose and they are shown in Fig. 1 A, B, and C.

Device A.—This is an all metal system previously described for the purification of Li (11) Na and K (12). The charge is contained in a 100 cc capacity molybdenum cup, 1*,[3] which rests on the bottom of a closed end 321 stainless steel tube 16½ in. long and 2½ in. diameter, 4*. A molybdenum sheet liner protects the inner stainless surfaces and extends from the top to the bottom of the column. Ten molybdenum sieve-type baffle plates, 2*, are placed directly above the cup. Each plate is separated with molybdenum tube spacers 0.292 in. long. The top of the column is water cooled. A closed end stainless steel tube projects downward from the top of the column and is terminated with a detachable inverted molybdenum cup collector, 3*. The column is heated externally with an electric resistance furnace 6*. A large temperature gradient is imposed across the baffle section. Purified metal is collected in the molybdenum cup collector after by-passing a gettering fraction to the top of the column by controlling the temperature of the collector. Removal of the alkali metal could be effected by either back-filling the column with degassed and prereacted mineral oil or unloading in an argon filled dry box.

Device B.—This unit is similar to system A, having a molybdenum reducing chamber or cup containing a mixture of the alkali metal chloride and Ca metal granules, 1*, and a set of three molybdenum sieve plates, 2*. The plates were completely enclosed with ring spacers. An inverted molybdenum cup 7 in. long covered the reducing chamber and plates for reverse take-off of the alkali metal vapor. This unit was enclosed within a fused silica tube, 8*, and attached to a vacuum system. The chloride was reduced by heating the inner molybdenum container with an electric heater, 6*, placed around the outside of the fused silica tubing. Alkali chloride was reduced, distilled, deflected downward through the plates below the reducing chamber and then collected in a fused silica ampoule. The ampoule could be torched off at any time for material measurement and storage.

Device C.—Fused silica and molybdenum construction made this system very much like B, Fig. 1. The molybdenum reducing chamber, 1*, and baffle section, 2*, however, were located separately from an all fused silica collecting area, 3*, and ampoule section, 8*. The two sections were connected with a silica tube, 5, 7*. The alkali chloride was reduced and distilled in the first section. The alkali metal was redistilled in the connecting tubing at a much lower temperature. The purified metal was then condensed as a solid on a water-cooled silica collector after bypassing a getter envelope on the walls surrounding the collector tube. The alkali metal on the collector was protected from reaction with residual gasses in the system by this getter envelope. Fractions could be collected for storage and measurement in silica ampoules located directly below the collector tip. Ampoules were filled by heating the collector tip with an electric cartridge heater and melting off the desired material into an ampoule. The getter envelope was always left in place to protect the condensed metal on the collector.

[3] The numbers with asterisks used in the following paragraphs refer to Fig. 1.

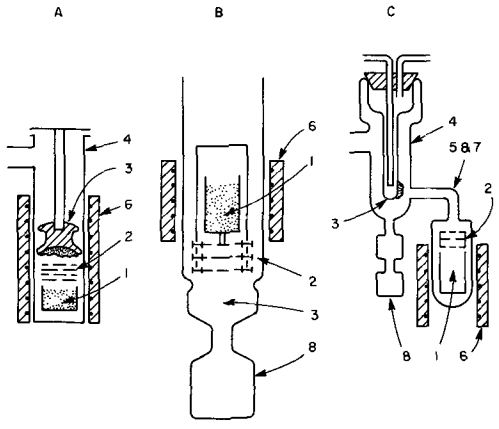

Fig. 1. Schematic drawing of three reduction and purification systems. System A is an all metal device. Systems B and C are constructed from fused silica and molybdenum. The reduction chamber 1; baffles 2; collector 3; getter shield 4; connecting tubing 5; heater 6; heater tapes 7; and ampoules 8 are indicated.

Each device was theoretically capable of producing ~ 40 cc of either Cs or Rb metal. Typical yields of high-purity metal, however, were ~ 35% of the theoretical value as predicted from reaction [1]. High vacuum conditions, with pressures of $< 1 \times 10^{-8}$ Torr, were maintained for all reduction operations using a 15 l/sec diode-type getter ion pumping system, stainless steel plumbing, and copper o-ring seals. A molecular sieve-type roughing pump was used to start the ion system and eliminated any possibility of oil contamination.

Each of the systems incorporated both reduction and distillation operations. Construction geometry however, drastically affected the purity of metal produced in both systems A and B. In system A it was difficult to prevent vapor channeling of impurities such as Ca, Mg, K, and Na through the baffle plates. It was also difficult to maintain a large enough temperature gradient between the reducing chamber and baffles necessary for optimum purification. Reduction of the chloride was carried out at the lowest possible temperature to minimize the vapor pressure of the reducing metal. This led to incomplete fill of the baffle plates in system A resulting in vapor channeling of impurities to the collector and incomplete distillation. Unloading the apparatus was awkward (oil backfill) and could be associated with possible contamination from the reduced chloride and calcium metal. Alkali metal that condensed in the collector cup deteriorated due to moisture and gas pick-up from the oil in which the alkali was stored. The primary disadvantage of system B was that the alkali metal vapor was forced to pass downward back through the high-temperature reducing zone where it could then impinge on the fused silica wall. High-purity results were never obtained from either of these systems.

System C was designed to overcome the difficulties and disadvantages associated with the above systems. Reduction and collection areas were separated, thereby permitting more precision in controlling the operating temperature of each section. The reduction chamber, baffles, and collector could therefore be set at any desirable temperature independently of each other. Alkali metal vapor was directed upward through the baffle plates. The fused silica connecting tube acted as another distillation stage. It was preset to a very low temperature so that only Cs or Rb could be transported to the collector. The getter envelope helped to reduce contamination of the condensed alkali metal

on the collector with any residual gasses in the vacuum system.

Experimental Procedure

Assembly and operation of system C is outlined below. Prior to any run all components of the system were thoroughly cleaned. Molybdenum cups and baffle plates were cleaned in an acid mixture of 80p HNO_3, 20p H_2SO_4, and 1p HCl followed by several rinses in water and a final rinse in methanol. Just prior to loading of the reactants, the molybdenum cup was induction heated to ~1100°C in dry hydrogen. The fused silica tubing was cleaned for 30 sec in 1p HF and 1p H_2O followed by several rinses in water and a final methanol rinse. The inside of all stainless steel vacuum fittings were electropolished and given a final rinse in methanol. The ion pump was also acid cleaned and given several rinses in methanol. The fused silica components, stainless steel vacuum fittings and ion pump were subsequently heated to 200°C for 2 hr following acid cleaning. The apparatus was now completely assembled and the system baked for several days at 250°C. The system was then cooled and back-filled with dry nitrogen gas.

The crucible was loaded with a mixture of the purified chloride and Ca metal granules. Weighing and mixing of the reactants was carried out in a polyethylene bag in air. Four to five times the theoretical weight of Ca metal required was added to the charge. The system was resealed and then baked as above.

The system was now slowly brought to operating temperature (~4 days). The vacuum system, collector, and all fused silica components were maintained at 160°C and continuously monitored at several points with thermocouples. At the first sign of alkali metal, usually a bluish film, the vacuum system and silica tubing were cooled to room temperature. The getter envelope was deposited on the walls of the silica tubing surrounding the collector. The collector was then cooled to ~10°C with cold water. A desired fraction was then deposited on the collector and later melted into an ampoule. The collection rate was ~1 cc/day of either Cs or Rb. The getter envelope always remained in place. Ampoules were removed by sealing the silica tubing with a hand torch. The alkali metal was maintained as a solid during the seal-off procedure.

Critical details of operation for obtaining high-purity metal were as follows:

1. Highest purities were obtained with reduction temperatures of 395°-405°C for Rb and 382°-400°C for Cs. Higher reduction temperatures resulted in less pure alkali metal.
2. The fused silica connecting tubing should not be heated above 160°-170°C. Contamination was observed to occur at 200°C.
3. The getter envelope should always remain in place to protect the alkali on the collector.
4. High vacuum operation ($<1\times10^{-8}$ Torr) and system cleanliness are essential for high-purity results.
5. The alkali metal was maintained as a solid during the removal of an ampoule from the system. This procedure prevented contamination of the bulk alkali from any contaminants subliming from the hot fused silica.

Discussion

Analysis for residual metallic impurities was attempted by both atomic absorption and emission spectroscopy. Principal contaminants of commercial purity Cs and Rb are other alkalies (with the exception of Li), Al and Ca. No detectable impurities were observed in either purified Cs or Rb samples. Primary purity evaluation was therefore based on electrical resistivity ratio measurements. The eddy current decay method (13) for measuring resistivity ratios was used since electrical connections to the samples were not required. Bulk alkali metal was used for these measurements and was typically contained in fused silica collecting ampoules. A summary of these measurements is shown below.

		Cs	Rb
Highest purity (this study)	$R_{295°K}/R_{4.2°K}$	680	1230
	$R_{295°K}/R_{1.5°K}$	4.4×10^3	3.5×10^3
	$R_{295°K}/R_{1.0°K}$	4.7×10^3	$3.5\text{-}3.6\times10^3$
Highest purity of commercially available alkalies Cs and Rb[4]	$R_{295°K}/R_{4.2°K}$	460	400
	$R_{295°K}/R_{1.5°K}$	1375	600
Highest purity obtained by distillation	$R_{295°K}/R_{4.2°K}$	475	550

A detailed study of annealing effects has not been made; however, improvement of resistivity ratios were observed to occur after annealing Cs and Rb at 77°K for 24 hr. Ratio improvement may be due to stain relief, solid-state precipitation of impurity elements, or vacancy migration. Crystallite size was not believed to affect ratio measurements since ampoules typically contained from 2 to 4 large grains.

Electron spin resonance line width measurements made on bulk Cs and Rb samples taken at 12 GHz frequency at 1.5°K yielded line widths of 30 gauss and and 0.4 gauss, respectively. This is the narrowest line width ever reported for bulk Rb. Line width measurements on Cs metal were believed to be broadened by strain.

Since resistivity ratio measurements are not specific for any one impurity a residual gas partial pressure analyzer was used to determine the predominant gas species in both systems A and C, as shown in Fig. 2. Both traces were taken under similar source temperatures and pressures during collection of Rb metal. Higher residual gas levels of H_2, OH, O_2, N_2, and H_2O are seen to occur in system A. No chlorine was detectable in either system A or system C. Since Rb and Cs oxidize and nitride very easily, contamination was therefore thought more likely to occur in system A. System C was therefore believed to be constructed of superior materials.

Pure Cs is golden in color and Rb a silver color. The first Cs or Rb deposited as the getter envelope however is a blue color. A blue colored film was also observed after melting of either alkali off the collector. Pink or purple colorations were always observed when using impure starting salts. The blue color of the getter envelope was therefore always thought to be associated with high-purity metal.

Growth of single crystals was markedly affected by purity. Commercial purity Cs or Rb always displayed a characteristic "burlap-like" surface appearance. It was very difficult to grow single crystals of impure Cs or Rb. Pure Cs or Rb however could be easily grown into large single crystals having near "mirror-like" surfaces.

High-purity results were never obtained from those runs using impure salts, high reduction temperatures, or where alkali metal was allowed to react with fused silica at temperatures >200°C. The effect of reduction temperatures on resistivity ratios of Rb is shown below.

Reduction temp, °C	$R_{295°K}/R_{1.5°K}$
500	710
420	2.8×10^3
395-400	3.5×10^3

Similar results were obtained for cesium. The lowest reduction temperatures were always associated with the highest purity results. Reduction temperatures of 382°-400°C for Cs and 395°-405°C for Rb are the

[4] Special high-purity Cs and Rb samples from the Kawecki Chemical Company, Royertown, Pennsylvania, and MSA Research Corporation, Callery, Pennsylvania.

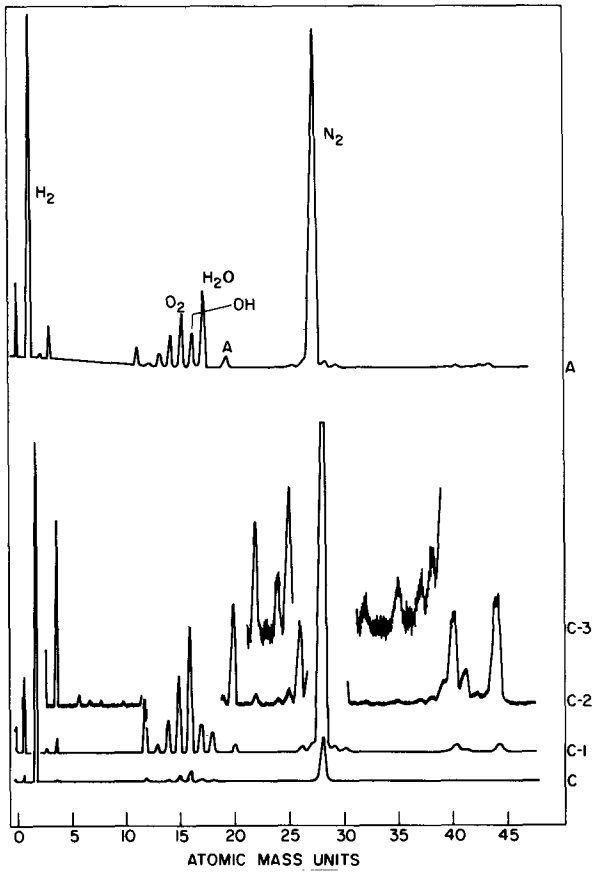

Fig. 2. Partial pressure analyzer traces from 0 to 50 atomic mass units taken of system A (top) and C (bottom) during collection of rubidium at 400°C. The y sensitivity has been increased 10X, 100X, and 1000X, respectively, in traces c-1 to c-3. Only a very slight trace of Cl_2 is observable with maximum sensitivity (c-3).

lowest reduction temperatures yet observed for salt reduction systems.

Conclusion

For the first time high-purity Cs and Rb has been obtained that is useful for electronic structure studies. High-purity results are critically dependent on low operating temperature (<400°C), high vacuum operation, and use of a high-purity salt and reducing metal. A getter envelope was used to protect the collected alkali from contamination by residual gases. Maximum electrical resistivity ratios obtained between 295° and 1.5°K for Cs and Rb are 4.4×10^3 and 3.5×10^3, respectively. The eddy current decay method of measuring resistivity ratios was found to be a simple and rapid means for material evaluation.

Acknowledgments

The author would like to thank W. M. Walsh, Jr., and C. C. Grimes for their encouragement and many helpful discussions. He would also like to acknowledge G. Adams for many resistivity ratio measurements and L. W. Rupp, Jr. for ESPR line width measurements. Special thanks should also be given to Mrs. L. M. Steuber for her capable assistance.

Technical Note

A Method for Reducing the Mobile Electric Charge in MNOS Structures

C. T. Naber*

The National Cash Register Company, Dayton, Ohio

The adverse effect of alkali ions, particularly sodium, on the electrical charge stability of metal-oxide-semiconductor (MOS) structures is well known (1-3). Silicon dioxide, which is the most widely used passivating layer over semiconductor devices has a distinct deficiency in that it offers a low resistance to the electric field migration of sodium ions (1). Yarash and Deal have recently shown that sodium ions can readily be incorporated in device structures during fabrication (4). Silicon nitride is impervious to sodium ions (5, 6); however, the charge distribution of metal-nitride-silicon (MNS) structures is unstable under

* Electrochemical Society Active Member.

large voltage bias at room temperature (7, 8). The charge instability is suppressed if a layer of silicon dioxide is imposed between the silicon nitride and silicon. In order to realize the advantages of silicon nitride in metal-silicon nitride-silicon dioxide-silicon (MNOS) structures, it is essential that sodium ions be absent from the silicon dioxide portion of the structure.

In this work, the mobile charge of MNOS structures is determined by analyzing the capacitance-voltage (C-V) characteristics before and after bias-temperature treatments. A method for reducing the mobile charge in silicon dioxide prior to silicon nitride deposition is described.

Structure Fabrication

N-type silicon wafers of (100) orientation with resistivities between 10 and 14 ohm-cm were used. Thermal oxides were grown in a resistance-heated tube furnace by two standard techniques (9): (*i*) in dry oxygen at 1100°C, and (*ii*) in steam at 1100°C. No special precautions were taken to eliminate the sodium content in the furnace or in the laboratory glassware used in growing the silicon dioxide layers. The thermal oxide coated wafers were then placed in a vertical epitaxial reactor with a silicon-coated graphite susceptor and silicon nitride was deposited by the nitration of silane with ammonia in an excess of hydrogen (10, 11). The silicon nitride films were deposited at 900°C with a hydrogen flow of 30 l/min, a silane flow of 30 ml/min, and an ammonia flow of 380 ml/min. The thicknesses of the silicon nitride films were between 1000 and 1500Å. Aluminum electrodes of 1 mm diameter were deposited by vacuum evaporation from a tungsten filament and the thermal oxides were etched off the reverse sides of the wafers. C-V measurements were then made on the MNOS structures at a frequency of 130 kHz.

Sodium in Thermal Silicon Dioxide

Figure 1 shows C-V plots, before and after bias-temperature treatments of (*a*) 20 min at 200°C and +18V and (*b*) 20 min at 200°C and −18V, of a MNOS structure which has approximately 1000Å of silicon nitride on top of approximately 1200Å of silicon dioxide grown in steam at 1100°C. As can be seen, the flat-band voltage shifts approximately 12V after the positive and negative bias-temperature treatments. Figure 2 shows C-V plots before and after bias-temperature treatments of a MNOS structure which has approximately 1000Å of silicon nitride on top of approximately 1200Å of silicon dioxide grown in dry oxygen at 1100°C. As can be seen, a flatband voltage drift of only 0.2V occurs due to the bias-temperature treatment. This indicates, in agreement with Yurash and Deal, that silicon dioxide layers grown in dry oxygen have less sodium ions than silicon dioxide layers grown in steam (4).

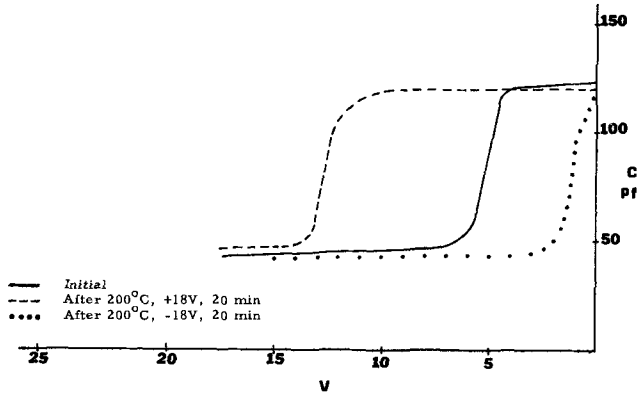

Fig. 1. C-V plots for MNOS structure with 1200Å of oxide grown in steam at 1100°C.

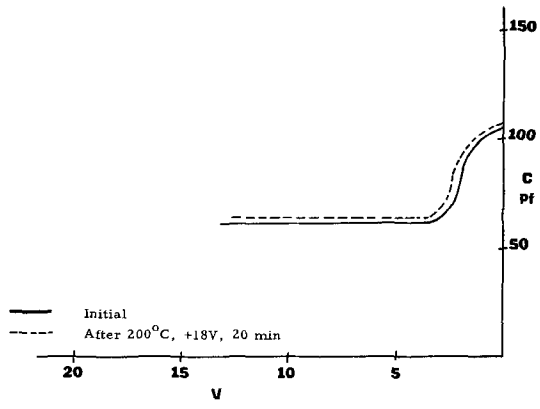

Fig. 2. C-V plots for MNOS structure with 1200Å of oxide grown in dry oxygen at 1100°C.

Reduction of Mobile Charge in Silicon Dioxide

Figure 3(a) shows C-V plots, before and after a bias-temperature treatment of 20 min at 200°C and +18V, of a MNOS structure which has approximately 1200Å of silicon nitride on top of approximately 5500Å of silicon dioxide grown in steam at 1100°C. Figure 3(b) shows similar C-V plots for a similar structure, but in this case the silicon dioxide-coated silicon wafer was heated *in situ* in the epitaxial reactor at 1200°C for 2 min with hydrogen flowing at a rate of 30 l/min prior to the nitride deposition at 900°C. As can be seen, a flatband voltage drift of approximately 90V occurs in the MNOS structure that was not heated in hydrogen, while a drift of only 2V occurs in the structure that was heated in hydrogen prior to nitride deposition. This indicates the high-temperature hyrogen treatment reduces the effects of mobile charge in the silicon dioxide layer.

It has previously been shown that the surface-state density of MOS structures can be reduced by either a low-temperature (400°-700°C) or a high-temperature (1000°-1200°C) hydrogen heat-treatment (12-14). In order to determine the effect of temperature and time

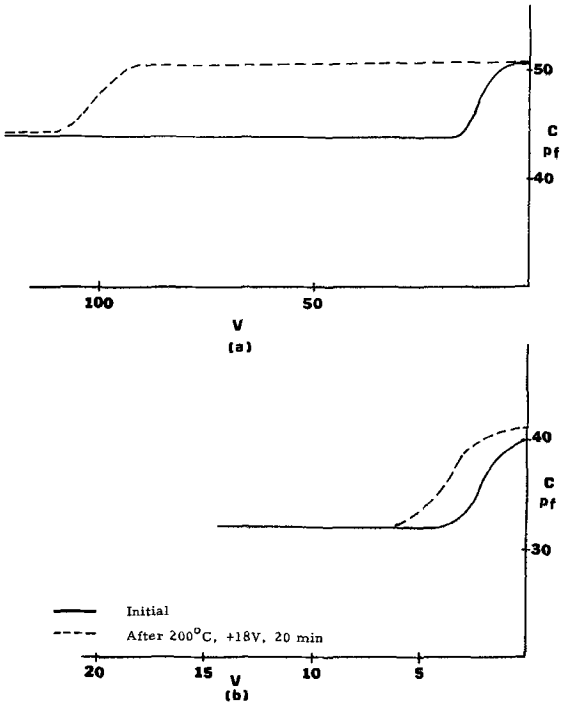

Fig. 3. C-V plots for MNOS structures with 5500Å of oxide grown in steam: (a) oxide not heated in hydrogen prior to nitride deposition; (b) oxide heated in hydrogen at 1200°C for 2 min prior to nitride deposition.

on the reduction of the mobile charge in silicon dioxide by the high-temperature hydrogen treatment described here, a number of samples which had 5000Å of oxide grown in steam were heated in hydrogen at temperatures between 1000° and 1200°C for durations between 1 and 4 min prior to nitride deposition. The flat-band voltage shifts were measured after bias-temperature treatments of 20 min at 200°C and +18V. The results of this investigation are listed in Table I. It should be pointed out that no attempt was made to reproducibly control the amount of sodium incorporated in the silicon dioxide during growth. It can be seen from Table I that a high-temperature (1100°-1200°C) hydrogen treatment is required to reduce the mobile-charge content in silicon dioxide effectively. The mechanism by which the quantity of mobile charges is reduced by the high-temperature hydrogen treatment is not fully understood.

Brief Communications

Solubility of Gold in p-Type Silicon

R. C. Dorward[1] and J. S. Kirkaldy

Department of Metallurgy & Materials Science, McMaster University, Hamilton, Ontario, Canada

In recent years considerable attention has been given to the properties of gold in silicon because of its use in controlling minority carrier lifetime. At room temperature this element introduces a donor level 0.35 eV above the valence band and an acceptor level 0.54 eV below the conduction band (1). Both of these levels are believed to be due to substitutional gold. Wilcox and LaChapelle (2), for example, have shown by diffusion measurements that the ratio of substitutional to interstitial gold is about 10 at 1000°C and increases with decreasing temperature.

Numerous investigations have dealt with the enhanced solubility of gold in n-type silicon (3-6). This was originally attributed to an electronic effect arising from a change in the Fermi energy. Assuming that the acceptor level population is predominant at elevated temperatures, an increase in the Fermi energy should cause an increase in solubility (7). The most recent study (6), however, has shown that ion pairing also plays an important (and perhaps dominant) role, at least when phosphorus and arsenic are used as the n-type dopants. These ionic and electronic effects often interfere in experiments of this kind and make data analysis difficult and uncertain.

If the electronic interaction contributes to the increased solubility of gold in n-type silicon, there should also be a solubility decrease in p-type material, provided of course that the acceptor concentration used is not large enough to increase greatly the number of gold donor states. In this case ion pairing should not influence the results since both dopants have the same charge state, *i.e.*, a repulsive interaction.

Recent exploratory work on the solubility of gold in boron-doped silicon helps to clarify this question. Wafers of intrinsic (2000 ohm-cm) and boron-doped (1×10^{19} at./cm^3)[2] silicon were displacement plated from a radioactive gold chloride solution containing a small amount of hydrofluoric acid. They were then diffused to saturation at 1000°C, and the gold solubilities were determined by standard radiochemical techniques. The details of the equilibration and analysis procedures are given elsewhere (8). The solubility of gold in intrinsic silicon was found to be (11.1 ± 0.6)

[1] Permanent mailing address: Box 248, Viking, Alberta, Canada.

[2] Purposely chosen low to eliminate possible effects due to degeneracy and band gap shrinkage.

x 10^{15} at./cm^3 (8) compared to (7.0 ± 0.4) x 10^{15} at./cm^3 for the boron-doped material. We note a reduction in solubility of about 40%. As shown below, this is in good agreement with what may be expected on the basis of the electronic interaction.

According to the Shockley-Moll theory (7), the solubility, N, of gold in p-type silicon is given by

$$N = N_o \exp(-\Delta E_f/kT)$$

where N_o is the intrinsic solubility and ΔE_f is the absolute difference between the Fermi energy of intrinsic and extrinsic material. ΔE_f may be determined from the relation

$$p/n_i = \exp(\Delta E_f/kT)$$

where p, the hole concentration, is given by

$$p = \tfrac{1}{2}[N_B + (N_B^2 + 4n_i^2)^{\tfrac{1}{2}}]$$

n_i is the intrinsic carrier concentration, and N_B is the boron concentration. Setting n_i = 7 x 10^{18}/cm^3 at 1000°C (9) gives $N \simeq 0.5N_o$.

The gold solubilities found by Cagnina (6) in n-type silicon must therefore be due to joint contributions of an electronic effect as predicted by the Shockley-Moll theory and ion pairing. This result is also additional proof that the concentration of gold in the negatively charged state is predominant at elevated temperatures as well as at room temperature.

Calculation of the p-T Diagrams of CdTe

A. S. Jordan and R. R. Zupp[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

In this communication we present the calculated p-T diagrams for the Cd-Te system and compare them with the available experimental data. The partial pressures of components (p_{Cd} and p_{Te_2}) were evaluated along the liquidus curve of the Cd-Te system based on approximate activity functions in two semi-empirical parameters, α and β, derived for a regular associated solution (RAS) (1).

The theory of RAS has been discussed elsewhere (1). It is sufficient to note for the purposes of this comunication that the theory was necessitated by the inability of regular solution theory to describe the liquidus curves of the Zn-Te and Cd-Te systems. The appearance of the liquidus curves in these systems suggests association in the liquid phase. Therefore, Jordan (1) assumed the presence of ZnTe (or CdTe) complexes in addition to Zn (or Cd) and Te atoms in the liquid, all three species forming a regular ternary solution. The analysis of a RAS resulted in explicit expressions for the approximate activities of the components. These were substituted into the thermodynamic equation of the liquidus boundary to yield a liquidus equation in the constants α and β. Having evaluated α and β from the liquidus data of Kulwicki (2), Jordan (1) calculated the full liquidus curves in the Zn-Te and Cd-Te systems, in very good agreement with the available experimental determinations.

Recently, we reported (3) the calculated p-T diagrams for the Zn-Te system. The calculated partial pressures p_{Zn} and p_{Te_2} along the liquidus curve of this system, evaluated from the approximate activity functions for a RAS and the previously derived values of α and β (1), are in excellent agreement with the experimental results of Shiozawa *et al.* (4).

The calculation of p_{Cd} and p_{Te_2} along the liquidus curve of the Cd-Te system followed the procedure adopted in calculating the p-T diagrams in the Zn-Te system (3). Thermodynamic data required to perform the calculations were obtained from several sources. The constants α and β were previously derived (1) for the Cd-Te system from the liquidus data of Kulwicki (2). The equilibrium constant, K, for the dissociation reaction

$$CdTe(s) = Cd(g) + \tfrac{1}{2}Te_2(g) \qquad [1]$$

was evaluated from the free energy equation of Brebrick and Strauss (5) for Eq. [1]. The pressures of pure superheated liquid Cd and Te, p^o_{Cd} and $p^o_{Te_2}$, were taken from the recent high pressure measurements of Baker (6, 7). It should be noted that $p^o_{Te_2}$ was computed from the total pressure data of Baker by subtracting from it approximately 1%, due to the presence of monatomic Te (8).

The calculated dependence of log p_{Cd} and log p_{Te_2} on reciprocal temperature for the Cd-Te system is shown in Fig. 1 and 2, respectively. In addition, the experimental pressure data of Lorenz (9) and de Nobel (10) are presented. The p-T diagrams also illustrate the limiting straight lines at x_{Cd} = 1 and 0, where x_{Cd} is the atom fraction of Cd in the liquid. For example, in Fig. 1, log p^o_{Cd} and log p_{Cd} = log $K/\sqrt{p^o_{Te_2}}$ *vs.* $1/T$ were drawn. Finally, values of log p_{Cd} (min) and log p_{Te_2} (min) as a function of $1/T$ at the minimum total pressure, p_{tot} (min), were plotted. These pressures are interrelated by p_{Cd} (min) = 2/3 p_{tot} (min) and p_{Te_2} (min) = 1/3 p_{tot} (min). p_{tot} (min) was calculated from the equilibrium constant for Eq. [1] according to p_{tot} (min) = $3(K/2)^{2/3}$.

The calculated p-T diagrams for the Cd-Te system are generally in good agreement with the experimental data of Lorenz (9) and de Nobel (10). Both of these authors have directly observed the freezing points of solid CdTe, corresponding to various fixed Cd or Te_2 pressures. In particular, it can be seen in Fig. 1 that there is indeed a very good agreement

[1] Present address: University of Washington, Seattle, Washington.

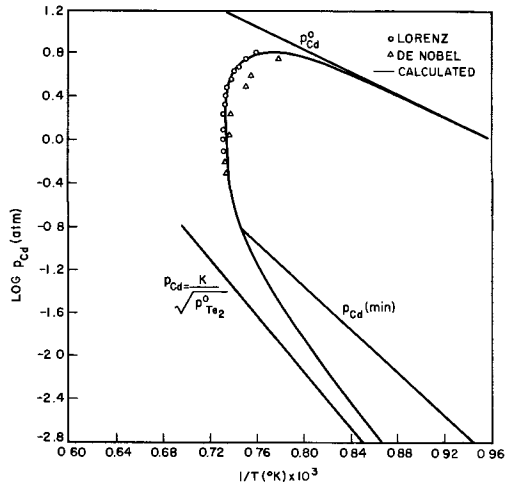

Fig. 1. Log Cd pressure vs. reciprocal temperature for the Cd-Te system.

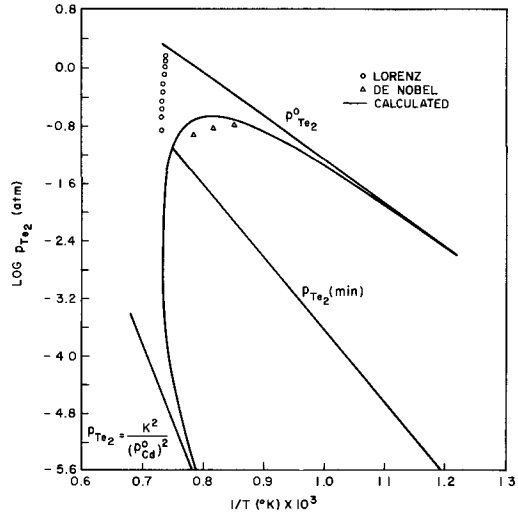

Fig. 2. Log Te_2 pressure vs. reciprocal temperature for the Cd-Te system.

between Lorenz's (9) experimental values of p_{Cd} and the theoretical curve. However, the calculated p_{Te_2} curve, shown in Fig. 2, lies between the somewhat discrepant experimental points of Lorenz and de Nobel.

In Fig. 2, one can observe that, according to the data of Lorenz, near the melting point of the compound the maximum p_{Te_2} along the liquidus is only slightly lower than $p^o_{Te_2}$. This pressure would correspond to $a_{Te} \approx 0.9$ for x_{Te} extending almost to 0.5, which would seem unlikely unless the liquidus were as flat as in the Zn-ZnTe subsystem (1, 2). However, the liquidus curve in the Te-CdTe subsystem (2) changes gradually without any flat regions. It is very difficult to explain the seemingly high results of Lorenz. In fact, in the Hg-Te system, a similar system where thorough measurements have been made, Brebrick and Strauss (11) found the maximum value of p_{Te_2} to be much lower than $p^o_{Te_2}$, corresponding to $a_{Te} \approx 0.4$. Similarly, in the Zn-Te system it is estimated from the work of Shiozawa *et al.* (4) that $a_{Te} \approx 0.5$ at the maximum pressure of Te_2.

Metal Transport in Voids at Metal-Oxide Interfaces

V. R. Howes[1]

Materials Division, Central Electricity Research Laboratories, Leatherhead, Surrey, England

It has been shown recently (1, 2) that, during high-temperature oxidation of an Fe-28% Cr alloy, the metal surface became extremely corrugated due to the formation of voids at the metal-oxide interface. The detection of a fine line structure on the smooth metal surfaces in the voids was associated with chromium transport within the voids.

Further observations have shown that for alloys of lower chromium content (16 and 19%) the fine structure takes the form of regular terracing or faceting as can be seen in the scanning electron micrograph in Fig. 1. The surface of the Fe-19% Cr alloy specimen has been revealed by the spalling away of the oxide during cooling after 6-hr oxidation at 950° in pure oxygen. The high peaks are where the metal and oxide were in contact, and the hollows are where voids had formed during oxidation.

[1] Present address: Wolfson Institute of Interfacial Technology, University of Nottingham, Nottingham, NGY 2 Rd., England.

Benard *et al.* (3, 4) have shown that specular surfaces of Fe-Cr alloys are obtained at extremely low oxygen pressures, but that at higher pressures (still lower than the dissociation pressure of chromium oxide) adsorbed oxygen produces surface energy anisotropies so that energy minimization leads to the formation of facets. Morris and Smeltzer (5) have measured the evaporation rates for Fe-Cr alloys and have pointed out that the low oxygen pressures necessary for the prevention of faceting may be obtained in the vicinity of the surface by the gettering action of evaporating metal. They obtained facets on Fe-5% Cr alloy surfaces, but specular surfaces were found on an Fe-25% Cr alloy after evaporation at 950°C in a nominal vacuum of 10^{-6} Torr. This difference was explained by the observed increased evaporation rate for the second alloy, which reduced the effective oxygen pressure at the surface so that adsorption became negligible.

Fig. 1. Metal surface, observed at a tilt of 30°, showing terracing, beneath an oxide layer where this has spalled away from a specimen of an Fe-19% Cr alloy during cooling after oxidation at 950°C for 6 hr in pure oxygen.

These results suggest that the terracing observed in the interfacial voids in the present 16 and 19% Cr alloys was a consequence of adsorbed oxygen on the metal and that the rate of metal evaporation into the voids was likely to have been less than 3.3×10^{-3} mg cm^{-2} hr^{-1} (the value for the Fe-25% Cr alloy at 950°C found by Morris and Smeltzer). In the presence of evaporation and an adsorbed oxygen layer that has led to faceting by surface energy minimization, long distance surface diffusion of metal around the voids seems unlikely. The oxygen that was adsorbed on the metal most probably came from the voids, supplied either by dissociation of the Cr_2O_3 on the other side or by an anion component of diffusion through the oxide during oxidation. The rate of Cr evaporation across the voids is certainly less than the metal consumption rate after 6-hr oxidation at 950°C ($\sim 9 \times 10^{-2}$ mg cm^{-2} hr^{-1}) calculated from the measurements of Mortimer and Sharp (6). The consequent reduction in the supply of chromium to the oxide is most probably a main reason for the slight but definite negative deviation from the initial parabolic oxidation rate that has been observed previously (6) and discussed in relation to interfacial void formation (7).

Voltage Oscillations of the H_2-CO System

Max C. Deibert*

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

and David L. Williams*,[1]

Monsanto Company, Everett, Massachusetts

ABSTRACT

A Pt catalyst in a porous fuel cell anode is poisoned by adsorption of CO from a H_2-CO fuel mixture. Under constant current conditions, this forces the electrode to high potentials. The electrode may reach potentials sufficiently high to oxidize the adsorbed CO and initiate a period of efficient electro-oxidation of the H_2 in the fuel mixture. Natural oscillations of potential are caused by repeated poisoning and reactivation of the electrode. More efficient activation of the electrode at high currents can result in a lower time-averaged anode potential at high current than at lower currents. The frequency of natural oscillations of the H_2-CO system is relatively independent of the current density, but is dependent on the partial pressure of CO. The oscillatory behavior is explained on the basis of poisoning of an electrode system having a passivation-type polarization curve. The maximum rate of potential increase is correlated with the charging of the double layer by the imposed constant current. The maximum rate of potential recovery is explained by the charging, or collapsing, of the double layer by the electrode reaction current.

Naturally occurring oscillations have been observed in many fuel cell systems, and in fundamental studies at smooth electrodes even for simple fuels such as H_2 (1, 2). Analyses of the interrelationships between the operating characteristics of auto-oscillating electrochemical systems and their surface chemical, electrical, and kinetic properties have been presented by Chizmadzhev (3) and Hunger (4). The first paper concludes that the slow reaction of oxygen-containing species on the electrode compared to hydrogen is the cause of oscillations. The second paper attributes the oscillations of a formaldehyde anode to a diffusion-adsorption step coupled to surface reaction steps in the reaction sequence. A discussion of fuel cell battery operating characteristics in cells containing naturally oscillating anodes has also been presented by Hunger (5). This paper indicates the operating conditions under which natural oscillations can be expected and the types of oscillations that can be obtained depending on cell operating constraints, *i.e.* constant cell current, potential, or load.

The importance of this area to fuel cell technology is that electrocatalysts are often susceptible to periodic activation processes which improve the performance of electrodes. The improvement of fuel cell power production by the imposition of electrical pulses under operating conditions in which natural oscillations do not occur has been extensively reported (6-9). Diller (10) describes a technique of decreasing the power requirements in cells for the Hall process for electrowinning aluminum by periodically imposing short, high-power electrical pulses to the cell, indicating the applicability of similar activation procedures to process electrochemistry.

This study demonstrates the cyclic operating characteristics of an anode consuming a simple fuel, H_2, in the presence of dilute CO. The dependency of the amplitude and frequency of the oscillations on the anode current and fuel composition were investigated in an attempt to determine conditions of electrode design and operation in which CO might be efficiently electro-oxidized, or otherwise removed, by the aid of the natural activation process at the anode. This type of fuel mixture is important in fuel cell technology, since it may result from incompletely purified hydrogen, produced from the reaction of steam with carbon or hydrocarbons. The system is also a model fuel-poison couple in which the poison concentration can be varied at will by changing the CO partial pressure.

Key words: fuel cell, oscillations.

Experimental

The electrochemical system utilized a platinized porous carbon anode with 1.3 cm^2 apparent area, a platinum foil auxiliary cathode, and a saturated calomel reference electrode. The electrolyte was 2M H_2SO_4 maintained at 95°C. Current was supplied by a Harrison Laboratory Model 6200A power supply. In initial tests, time average potentials were measured with a damped voltmeter. In later tests, voltage-time traces were measured with a Tektronix 545-A Oscilloscope with Polaroid camera attachment. The fuel gas was continuously passed behind the electrode, the excess being vented.

The electrode was prepared from Shawinigan acetylene black, Teflon powder, and a platinum mesh screen support, by the method described by Deibert (11). The carbon loading was about 8 mg/cm^2. The electrode was platinized by the method of Brown and Brown (12). The final microporous electrode contained about 10 w/o (weight per cent) platinum, based on the carbon content. The Shawinigan acetylene black had a BET surface area of about 65 m^2/g. This was probably not greatly affected by the addition of 10% platinum. The total surface area of conductive solid was therefore about 5000 cm^2/cm^2 of electrode. Since the Pt rendered the entire structure hydrophilic, nearly all this surface was wetted by the electrolyte.

Results

Three fuel streams were tested for their polarization behavior. These were pure H_2, 1% CO in H_2, and 5% CO in H_2. The recorded, time-averaged potentials relative to the open-circuit potential of the pure hydrogen electrode are shown in Fig. 1 as a function of apparent current density. The polarization curve for pure H_2 demonstrates that hydrogen is readily oxidized on the platinum electrode, sustaining a current density of 200 mA/cm^2 with a polarization of less than 0.05V. The reversible character of the H_2-Pt electrode makes this open-circuit potential a valid reference for this system. Addition of 5% CO to the H_2 severely poisons the electrode, increasing the open-circuit potential by 0.77V and polarizing the electrode to oxygen evolution potentials below a current density of 200 mA/cm^2.

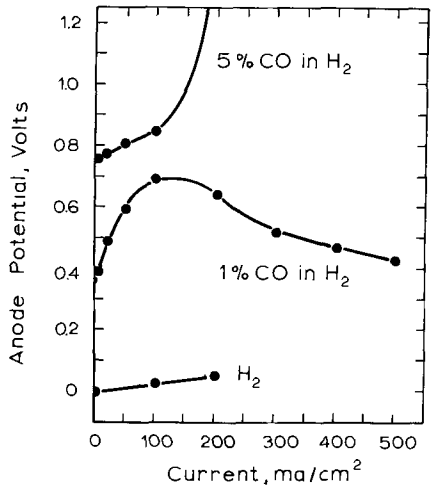

Fig. 1. Time-averaged polarization of H_2-CO system using current control.

The electro-oxidation of 1% CO in H_2 mixture poisons the electrode, but less than 5% CO in H_2. Above a current density of 100 mA/cm², the polarization of the electrode decreases with increasing currents up to 500 mA/cm². This is a demonstration of an unusual phenomenon of an increase in reaction rate being accompanied by a decreasing time-average thermodynamic driving force for the reaction. That this is most probably the result of a natural periodic activation of the platinum electrocatalyst is revealed by the time-dependent potential measurements.

The oscillatory behavior of the potential of the 1% CO in H_2 fuel electrode is shown by potential-time traces in Fig. 2 for six current densities between 50 and 500 mA/cm². The effect of CO content of the fuel on potential oscillation frequency is shown by replacing the flow of 1% CO in H_2 with pure H_2 while maintaining the current at 100 mA/cm². A potential-time trace taken a short time after this replacement is shown by the broken line in Fig. 2(c).

Low-amplitude (0.2V) potential oscillations are observed at 75 mA/cm² in Fig. 2. The amplitude of these oscillations increases with increasing current density, to about 1.3V at 500 mA/cm². The frequency decreases slightly with increasing current between 75 and 200 mA/cm², and then remains relatively constant at approximately 1.7 Hz at higher current densities up to 500 mA/cm². At 100 mA/cm², the frequency of the potential oscillations decreased gradually to zero after introducing pure hydrogen. However, the oscillation amplitude remained approximately constant as the CO content decreased.

Discussion

One possible explanation for the observed voltage oscillations can be based on the assumption that the electrode reaction has a passivation-type polarization curve. Figure 3 shows a schematic of such a curve. This curve could be obtained by voltage control of the electrode, as for example by use of a potential sweep. In a passivation-type curve on an anode, there is a region in which an increasing potential lowers the current. This effect may be caused by anion adsorption or oxide formation, which would commence at the potential near *D* in Fig. 3. These effects can poison a platinum electrode for hydrogen oxidation. Passivation-type curves have been reported by Schuldiner for H_2 oxidation which he attributes to anion adsorption on the Pt catalyst (13). At very high potentials, other anodic reactions will occur, *e.g.* water oxidation, which may not be passivated, section *E, F*, Fig. 3. A deactivation phenomenon which is relatively independent of potential can also occur on the anode. This can result from CO adsorption in the present case. In other instances, deactivation can be attributed to adsorption of impurities from solution (14), or to catalyst recrystallization as suggested by Sawyer and Seo (2) for H_2 anode deactivation. Thus, both deactivation and passivation may be expected even for H_2 oxidation under normal fuel cell conditions.

The importance of the passivation and deactivation effect is that together they can give rise to potential oscillations of the type observed in this investigation. If the current is adjusted to the level indicated by the straight line *ABC*, the voltage will initially be at point *A*. However, as deactivation occurs, the voltage shifts toward *B*. At this time, the voltage shifts quickly to *C*. It is possible that at *C* the poison is oxidized or electrodesorbed. It is known that CO oxidation occurs on this PtO surface at high potentials (15). When this occurs, the electrode is reactivated and the potential shifts to *A*. At this point, deactivation again occurs and the oscillations repeat.

These phenomena are demonstrated by the experimental data shown above. The high potential attained at 500 mA/cm² is believed to cause a more efficient cleaning of the electrode surface (*i.e.*, more complete oxidation of CO), than the potential achieved in the 100 mA/cm² oscillation. This effect is believed to be the cause of decreasing time average overpotential with increasing current at 1% CO (Fig. 1). That is, the oscillating effect with high current is more effective in oxidizing the CO poison, thus giving a longer period of efficient oxidation of H_2. In the data of Fig. 1, no

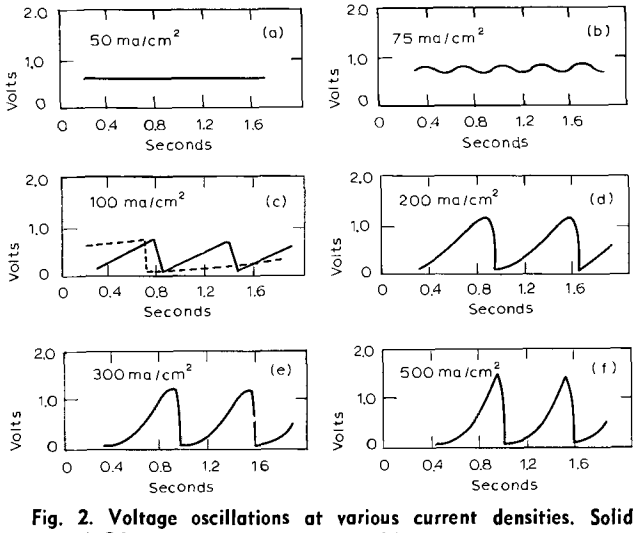

Fig. 2. Voltage oscillations at various current densities. Solid lines, 1% CO in H_2. Dashed line, <1% CO in H_2.

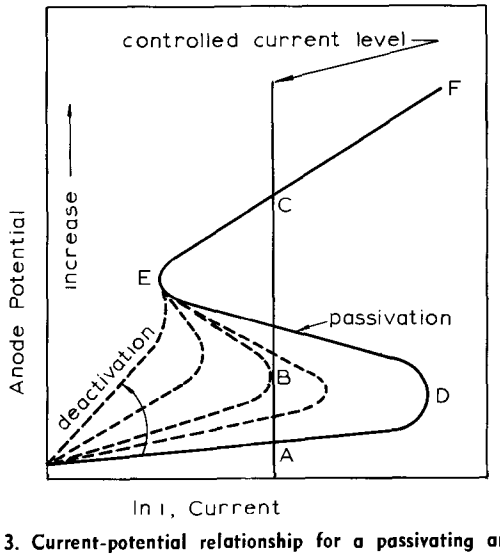

Fig. 3. Current-potential relationship for a passivating and deactivating anode.

attempt was made to read the damped meter needle to observe oscillations.

Figure 2(c) shows the effect of decreasing the partial pressure of CO. The curve shape is similar but the period of oscillation increases as less CO is available to cause deactivation. Thus, the rate of deactivation is slower. With 5% CO, there is no oscillation and the electrode is permanently poisoned. Thus, the oxidation of CO is not sufficiently rapid at the high potential to generate a clean surface for a period of H_2 oxidation at low overpotential.

An analysis of this oscillatory behavior will be made based on an equivalent circuit for the anode involving a resistor and capacitor in parallel. The capacitor C denotes the double layer capacitance of the electrode, and R is the resistance to current flow due to electrode polarization. The analysis assumes that the current passing through the electrode is held at a constant value i_c which goes either into the charge or discharge of the capacitor or into the electrode reaction process. Experimentally, the voltmeter reads the anode potential *vs.* a reference voltage (saturated calomel electrode). This potential is adjusted to the H_2/H^+ potential of the solution for further analysis.

The reaction current is denoted, for illustrative purposes, in terms of the exchange current, i_o, and the overvoltage. Such a behavior might be expected at low potentials even for the complex electrode system used in this study. The capacitance current is $C\ dV/dt$ giving a total current of:

$$i_c = C\frac{dV}{dt} + i_o \exp aV \qquad [1]$$

It was noted earlier that, when the electrode became deactivated to B of Fig. 3, due to decreased i_o values, the potential shifted to C. The rate of this voltage change will depend primarily on the double-layer capacitance. If the reaction current is assumed to be small compared to i_c during deactivation, then a limiting rate of voltage change is:

$$\frac{dV}{dt} = \frac{i_c}{C} \qquad [2]$$

Based on this model and assumption, the experimental data shown in Fig. 2 can be used to calculate an electrode capacitance. Taking the limiting, steepest slopes of the voltage increase lines as a measure of this limiting case, this method yields values of 0.08, 0.07, 0.07, and 0.10 farads/cm^2 for currents 100, 200, 300, and 500 mA/cm^2, respectively. This constancy of the calculated capacitances gives credence to the model and assumptions. The platinized carbon electrode used had an actual (BET) surface area of about 5000 (cm^2/cm^2). The capacitances calculated above indicate that the specific capacitance of this surface was about 15 to 20 μf/cm^2, which is the correct magnitude for a double-layer capacitance of this system.

The speed of potential recovery, from C to A, can also be explained in terms of the above equivalent circuit. In this case, the current applied is assumed to be much smaller than the "regenerated" reaction current. The limiting rate of reactivation is therefore denoted by:

$$\frac{dV}{dt} = \frac{i_o}{C} \exp aV \qquad [3]$$

Thus, the rate of potential decrease will be the rate of the reaction current charging or discharging the double-layer capacitance. This is shown as an exponential function of overvoltage, but is directly dependent on the reaction exchange current and inversely dependent on the double-layer capacitance. Although no calculations are presently warranted, based on this model, it should be noted that the voltage decrease is much faster than the voltage increase which was dependent on the applied current charging the double layer capacitance.

Conclusion

The oscillatory behavior of an electrode is explained on the basis of poisoning of an electrode having a passivation-type polarization curve. The maximum rate of potential increase has been correlated with the charging of the electrode double layer by the applied current, and the maximum rate of potential recovery is explained by the charging or discharging of the double layer by the reaction current, after electrode reactivation.

Many other observations of oscillatory behavior of anodes operating at constant current have revealed much more rapid potential recovery than potential decay (1, 2, 13). The observation by Schuldiner (13) of oscillations in the electro-oxidation of formaldehyde on platinized platinum shows breaks in the slope of the potential decay line. Using the average actual surface area of the electrode given in that paper, the specific capacitances of his electrode are 40-60 μf/cm^2 in the low potential region, and 10-22 μf/cm^2 in the high potential region. The latter values are probably closer to the real capacitance values, since more complete passivation, in this case by anion adsorption, would be expected at high potentials. In any case, both the present study and Schuldiner's data indicate that poisoning of an oscillating electrode is essentially complete at the initiation of potential decay, rather than progressively effecting the entire decay process.

The Electrochemical Behavior of Decorative Nickel-Chromium Coatings in 3% NaCl under Potentiostatic Conditions

S. R. Maloof*, [1]

Exploratory Development Laboratory, United-Carr, Incorporated, Watertown, Massachusetts

ABSTRACT

Electrochemical measurement of the corrosion currents of commercially prepared decorative nickel-chromium coatings indicates that the addition of a chromium topcoat to duplex nickel reduces the dissolution rate of nickel by only a factor of 2, while at the same time increasing the susceptibility of the coating system to pitting corrosion. Indications are that a "critical" potential for macro pitting may exist for these coating systems that could explain the frequent disagreement of results obtained on the pitting behavior of decorative nickel-chromium coatings at different tests sites. Preliminary results obtained with a silver undercoat indicate that the corrosion current may be reduced by a factor of 10 compared to that for duplex nickel with a similar topcoat of microcracked chromium. Moreover, there is little or no corrosion penetration of the silver layer. A possible explanation for these findings is advanced and a model developed to explain the corrosion behavior of decorative nickel-chromium coatings.

Introduction in the early 1950's of decorative duplex nickel-chromium coatings for protection against corrosion of car bumpers and exterior automotive trim was a major step forward, since the partial replacement of the semibright nickel by an outer layer of bright nickel served a dual purpose. It eliminated the need for buffing of the nickel prior to chromium plating and, more important, it caused the corrosion pits to spread sideways instead of directly downward to the basis metal. These facts are generally well known and well documented in static and mobile tests carried out by earlier investigators (1-5).

Wesley and Knapp (1) were probably the first to identify the mechanism of failure as due to pitting corrosion in the nickel undercoat. Pitting is initiated at flaws or cracks in the chromium topcoat serving as the cathode for the reduction of oxygen, while the dissolution of the nickel underneath occurs at the anode of the galvanic cell. Furthermore, Flint and Melbourne (3) showed that the process is under cathodic control and increasing the degree of cathodic polarization should lead to increased corrosion protection. This is undoubtedly the explanation for the apparent, improved corrosion resistance of coating systems with a topcoat of microcracked or microporous chromium instead of ordinary chromium. In more recent years, further improvements have resulted from the use of multilayered nickel coatings of different electrochemical properties (6, 7).

The purpose of this research was threefold: (*a*) to measure electrochemically the corrosion currents of nickel-chromium type protective systems, (*b*) to determine if pitting is initiated at a fairly well-defined potential as is known for stainless steel and aluminum anodically polarized in 3% NaCl (8); this point was not investigated in any great detail; and (c) to determine if another undercoat metal might provide improved corrosion resistance by virtue of its electrode potential being more nearly equal to that of chromium after atmospheric exposure or by its forming a protective reaction film *in situ* in the aqueous environment after anodic polarization. One metal investigated was silver, since a solid film of silver chloride is formed at small positive overpotentials (20-40 mV) in 3% NaCl.

Experimental

The decorative nickel-chromium coatings were furnished by the Harshaw Chemical Company on an annealed low-carbon steel substrate in the form of panels approximately 4 in. by 6 in. by 1/16 in. thick. They were cut with a jeweler's saw into specimens ½ in. wide by 2 in. long. One end of each specimen was carefuly bent to a ½-in. radius and a hole drilled and tapped at the apex of the bend to accommodate an 0-80 threaded rod for electrical connection. The method of attachment and the electrolytic cell used were similar to that described by Leckie and Uhlig (9).

The decorative coatings were of duplex nickel ¾ mil thick, duplex nickel 1 mil thick with a topcoat of 0.10 mil of ordinary chromium, and duplex nickel 1.25 mils thick with a topcoat of 0.050 mil of microcracked chromium. In all these coatings, the outer bright nickel was about 1/3 the thickness of the semibright nickel.

Two other coating systems were prepared: one consisted of 1.3 mils of silver electrodeposited directly onto a cold-rolled steel substrate, followed by a layer 0.060 mil thick of electroless nickel and an outer layer 0.120 mil thick of microcracked chromium; the other consisted of a layer of 0.050 mil of silver interleaved between duplex nickel and ordinary chromium.

Anodic and cathodic polarization curves were developed for each of the coating systems investigated. The electrolyte in all cases was 3% NaCl (pH = 5.5) deaerated with bubbling argon and stirred at 200 rpm. The exposed area to the electrolyte was 1 cm^2—the remainder of the surface was covered with a commercial stop-off lacquer. No special attempt was made to control the temperature but, in general, the temperature did not deviate more than ±1° from a temperature of 23°C. All potentials were measured relative to a SCE with a Luggin capillary located within 2-3 mm of the sample surface. The potentials were set with a potentiostat constructed from commercially available parts. The potential could be set to within 1 mV of the desired potential and the current read in the range of 0.05 μA to 1.5A.

The specimens were cathodically polarized first. Current readings were taken at each preset value of the potential after a period of 5 min. The solution was then changed and the anodic polarization curve developed in a similar manner.

Anodic polarization was not continued beyond a potential of +500 mV (*vs.* H_2), since in some cases the corrosion had already penetrated to the basis metal.

The corrosion currents were determined from the polarization data as described earlier (10). Current densities given on the abscissa are to be read as apparent current densities.

Results

Any study of pitting corrosion is usually concerned not only with the mechanism of pitting, but also with the location of the pitting sites. It is evident in Fig. 1 that pitting occurs mainly at the microcracked boundaries. The metallographic evidence shown in Fig. 2 shows that the pits formed in the bright nickel directly below the cracks in the chromium topcoat are hemispherical in shape. Since there is little or no apparent attack of the chromium, pitting is the apparent result of the anodic dissolution of the nickel below as postulated earlier (3, 5). It is also of interest to note that, as the pits grow in size and merge together, there is undermining of the chromium topcoat.

The potentiostatic anodic and cathodic polarization curves of duplex nickel over an annealed low-carbon steel substrate are shown in Fig. 3. The apparent corrosion rate as determined by extrapolation of the linear portions of the polarization curves to the open-circuit potential is 0.18 $\mu A/cm^2$. The anodic polarization curve which is of special interest shows a linear Tafel slope (40 mV per decade) between a potential of —0.10V and 0V on the hydrogen scale. In this potential range, the bright nickel surface turned black. At higher positive potentials, the initially formed black film began to disintegrate and, at a potential of +0.13V where a reversal in current occurs, it was completely free of the surface, revealing a matte surface below. Beyond a potential of +0.14V there is a further increase in the current, but at a slower rate, indicative of the dissolution of the more noble semibright nickel. Semibright nickel is known to be more noble than bright nickel (3, 11).

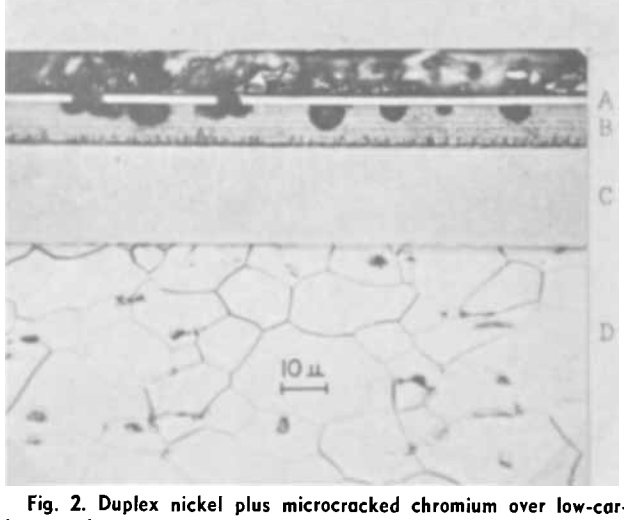

Fig. 2. Duplex nickel plus microcracked chromium over low-carbon steel corroded under static conditions for 30 days in 3% NaCl: A—chromium, B—bright nickel, C—semibright nickel, D—steel. Etched in 50:50 glacial acetic-nitric acid.

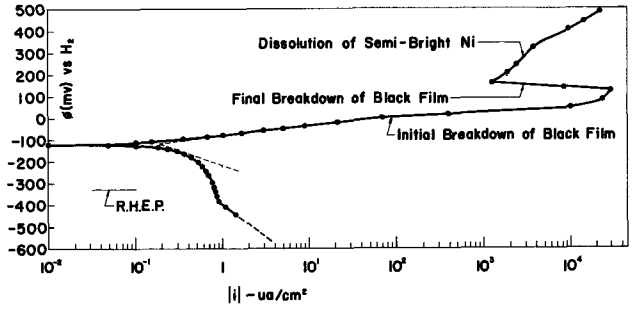

Fig. 3. Anodic and cathodic polarization curves of duplex nickel over low-carbon steel in 3% NaCl (pH = 5.5). Rotation @ 200 rpm and bubbling argon.

The anodic and cathodic polarization curves of duplex nickel and ordinary chromium over steel under the same test conditions are shown in Fig. 4. The open-circuit potential of this coating sytem is —0.30V on the hydrogen scale, and its apparent corrosion rate is 0.10 $\mu A/cm^2$. This particular sample was not anodically polarized beyond a potential of +0.060V. However, an identical sample gave a similar anodic polarization curve and the onset of pitting was observed at a potential of about +0.20V. This is indicated by the dotted portion of the curve. Anodic polarization to as high as +0.50V showed that the corrosion pits had penetrated to the steel basis metal (Fig. 8). Similar polarization curves obtained for duplex nickel and microcracked chromium over steel are shown in Fig. 5. This sample was initially polarized only to a potential of —0.10V and showed no evidence of macropitting. At a later date, it was anodically polarized further to a potential of +0.30V and the current flowing was 90 mA. Visible pitting, however, occurred at a potential of about +0.10V and at +0.30V the surface was heavily pitted. Attempts to polarize this coating system anodically to a potential of +0.50V on other identical samples resulted in a complete separation of the chromium topcoat.

The polarization curves shown in Fig. 6 are of special interest. In this coating system, a thick layer of electroplated silver (1.3 mils) was used in place of

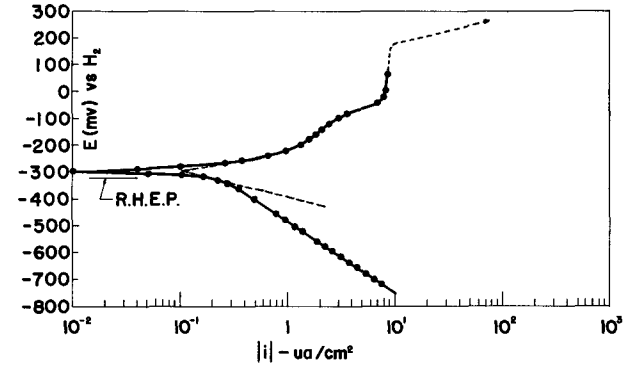

Fig. 4. Anodic and cathodic polarization curves of duplex nickel and ordinary chromium over low-carbon steel in 3% NaCl (pH = 5.5). Rotation @ 200 rpm and bubbling argon.

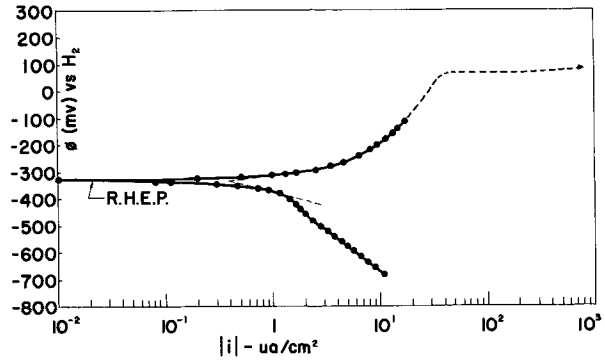

Fig. 5. Anodic and cathodic polarization curves of duplex nickel and microcracked chromium over low-carbon steel in 3% NaCl (pH = 5.5). Rotation @ 200 rpm and bubbling argon.

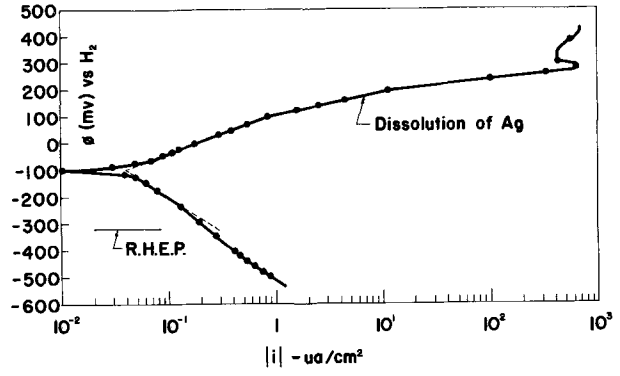

Fig. 6. Anodic and cathodic polarization curves of electroplated silver and electroless nickel and microcracked chromium over low-carbon steel in 3% NaCl (pH = 5.5). Rotation @ 200 rpm and bubbling argon.

duplex nickel. Although the open-circuit potential is comparable to that for duplex nickel (Fig. 3), the apparent corrosion rate is lower, namely 0.04 μA/cm^2 compared to 0.18 μA/cm^2. This is attributed to the greater degree of anodic and cathodic polarization. Above a potential of about +0.20V, there is a sudden increase in the anodic dissolution rate. This is due to the anodic dissolution of silver as was shown by anodic polarization of pure solid silver in the same electrolyte. The limiting current density occurring at about 1 mA/cm^2 is the result of the formation of silver chloride as was demonstrated by x-ray diffraction studies. As will be shown presently, this coating system appeared to be the most resistant to pitting corrosion.

The results of the metallographic studies conducted on these coating systems after anodic polarization to a maximum potential of +0.50V are shown in Fig. 7-10. Figure 7 shows the appearance of duplex nickel before and after anodic polarization. It is evident that complete anodic dissolution of the bright nickel has occurred with little dissolution of the semibright nickel. This result is in good agreement with that expected from the appearance of the anodic polarization curve for this coating system shown in Fig. 3. Furthermore, and more important, there is no evidence of pitting either in the semibright nickel layer or the steel basis metal. Evidently, the dissolution of bright nickel under the test conditions used occurs quite uniformly over the entire exposed surface.[2] On the other hand, the coating systems shown in Fig. 8 and 9 are apparently very susceptible to pitting corrosion. In the case of duplex nickel plus ordinary chromium anodically polarized to +0.50V (Fig. 8), corrosion due to the anodic dissolution of the duplex nickel has penetrated to the basis metal with the formation of a large hemispherical-shaped pit in the steel (far right) and a well-defined taper in the semibright nickel layer. Anodic polarization of several additional samples of this coating system to the same potential indicated that only a few (3-4) large pits are formed. Also, in the system duplex nickel plus microcracked chromium anodically polarized to the +0.30V pitting is quite evident down to the semibright nickel layer as shown in Fig. 9. As mentioned earlier, anodic polarization to +0.5V resulted in a complete separation of the chromium topcoat and corrosion penetrated to the basis metal. The pits developed electrochemically are quite similar in appearance to those developed under static conditons of corrosion (Fig. 2) and this is further confirmation of the fact that pitting corrosion in these systems is electrochemical in nature. Consequently, it appears that the addition of a chromium topcoat to duplex nickel increases the susceptibility of the coating system to pitting corrosion.

The result shown in Fig. 10 is quite striking. Corrosion appears to be restricted mainly to attack of the electroless nickel and there is some blistering or lifting of the chromium topcoat, but there is no evidence of pitting. Electroless nickel is known to be less noble than pure silver in 3% NaCl; in other words, it serves as a sacrificial coating. The anodic polarization curve for this coating system (Fig. 6) indicated that dissolution of silver also occurs, but at a small overpotential the dissolution rate is controlled by the dissolution rate of the protective film of silver chloride. Thus, the metallographic findings are in good general agreement with the electrochemical data. The results obtained with the thin layer of silver interleaved between duplex nickel and ordinary chromium were not encouraging. Nevertheless, the idea of obtaining corrosion protection through the formation of a reaction film *in situ* embodies a new principle and hitherto has received no attention in these coating systems. Additional work with an undercoat of silver is planned.

The measured corrosion currents expressed as ap-

[2] In static corrosion tests, however, indications are that duplex nickel is slightly susceptible to pitting corrosion.

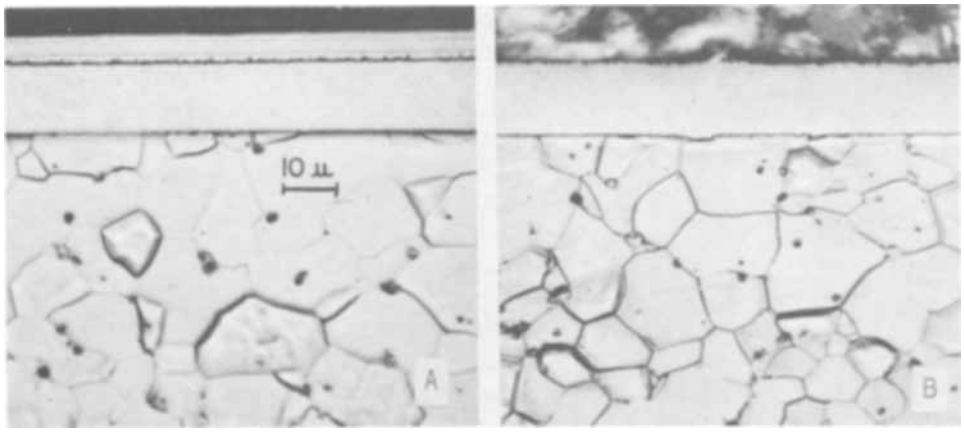

Fig. 7. Duplex nickel over low-carbon steel, (a) before, and (b) after, anodic polarization to +0.50V (vs. H_2) in 3% NaCl (pH = 5.5). Etched in 50:50 glacial acetic-nitric acid. Note the complete dissolution of the bright nickel layer and the absence of pitting.

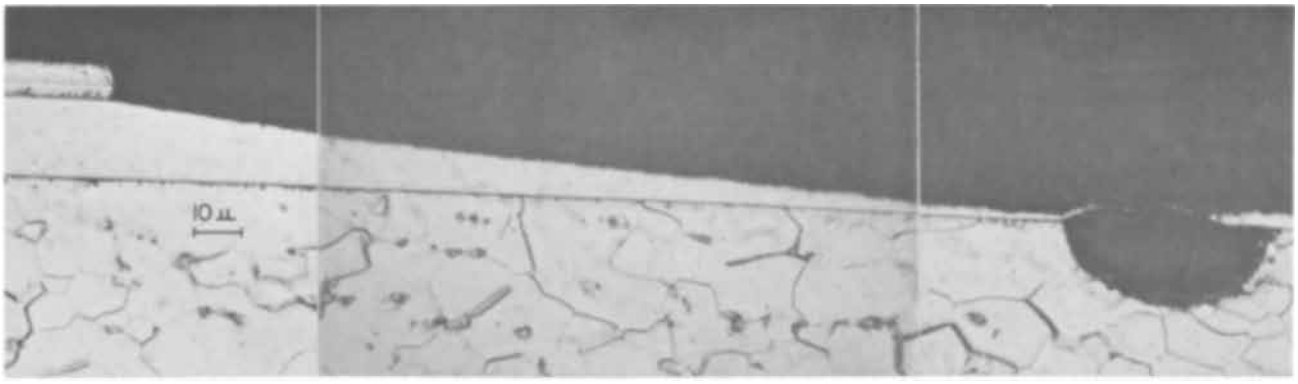

Fig. 8. Duplex nickel and ordinary chromium over low-carbon steel anodically polarized to +0.50V (vs. H_2) in 3% NaCl (pH = 5.5). Etched in 50:50 glacial acetic-nitric acid. Note the hemispherical-shaped pit at the right in the steel and the taper in the semibright nickel layer.

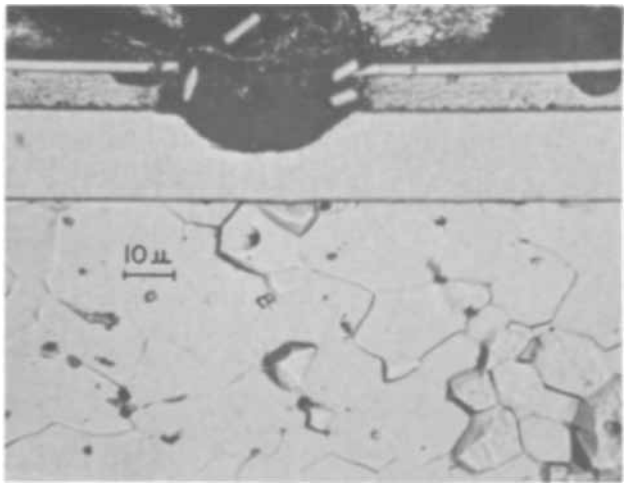

Fig. 9. Duplex nickel and microcracked chromium over low-carbon steel anodically polarized to +0.30V (vs. H_2) in 3% NaCl (pH = 5.5). Etched in 50:50 glacial acetic-nitric acid. Note the undermining of the chromium topcoat by the coalescence of pits in the bright nickel and the absence of corrosion in the chromium layer.

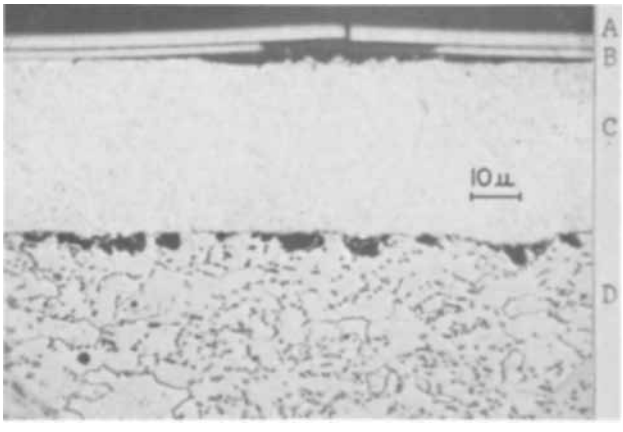

Fig. 10. Electroplated silver and electroless nickel and microcracked chromium over low-carbon steel anodically polarized to +0.50V (vs. H_2) in 3% NaCl (pH = 5.5). A—chromium, B—electroless nickel, C—silver, D—steel. Etched in 1% Nital. Note the very shallow corrosion penetration of the silver layer and the sideways attack of the electroless nickel.

parent corrosion rates in $\mu A/cm^2$ for the various coating systems investigated are summarized in Table I.

Discussion

For many years, it has been assumed that the only purpose of the chromium topcoat is to prevent tarnishing of the nickel. Chromium is known to possess good tarnish resistance as well as good resistance to "fogging" by H_2S. As shown in this study and in an earlier study (12), the addition of a topcoat of ordinary chromium reduces the dissolution rate of nickel by only a factor of about 2. The data of Saur (12) also show that, while the initial dissolution rate of nickel is linear with the area of exposed nickel, it becomes constant above an exposed nickel area of about 10%. This indicates that as the concentration of chromium defects is increased, exposing more underlying nickel, the time to basis metal corrosion should increase. Since no one has advanced an explanation as to why increasing the number of defects in the chromium layer leads to a saturation of the dissolution rate of nickel, we propose the following model to explain this behavior.

The chromium layer is considered to have a uniform surface density N of round pits of radius r, one of which is shown in Fig. 11. The dissolution of nickel occurs at the bottom of the circular hole as the result of a "local" current developed between the chromium, the nickel, and the electrolyte centered about the reentrant corner o. The electrical resistive path length (l) for both the nickel and chromium is taken to be of the same order of magnitude as the distance oo', although most of the potential drop will occur at the metal-solution interface. As corrosion proceeds as the result of nickel dissolution, the corrosion product formed (assumed to be nickelous hydroxide) is imagined to fill each circular well and even to spill over, covering a certain area a of the chromium top surface. Consequently, in order for the dissolution of nickel to continue at a steady rate, the reduced species (assumed to be oxygen) must be now supplied to the chromium cathodic surface in the vicinity of the bottom of the well by diffusion from the bulk electrolyte (surface SAS') through the "mushroom-shaped" cap. Since only mild agitation of the electrolyte is assumed, the rate-controlling step for nickel dissolution must therefore be considered to be the diffusion of oxygen.

Table I. Electrochemical corrosion currents of various protective coating systems over low-carbon steel in 3% NaCl (pH = 5.5). Rotation @ 200 rpm plus bubbling argon

Material	Apparent corrosion rate ($\mu A/cm^2$) *
Low-carbon steel	2.50
Duplex nickel over steel	0.18
Duplex nickel plus ordinary chromium over steel	0.11
Duplex nickel plus microcracked chromium over steel	0.40
Electroplated silver plus electroless nickel plus microcracked chromium over steel	0.04
Duplex nickel plus electroplated silver plus ordinary chromium over steel	0.10

* Geometrical area = 1 cm^2.

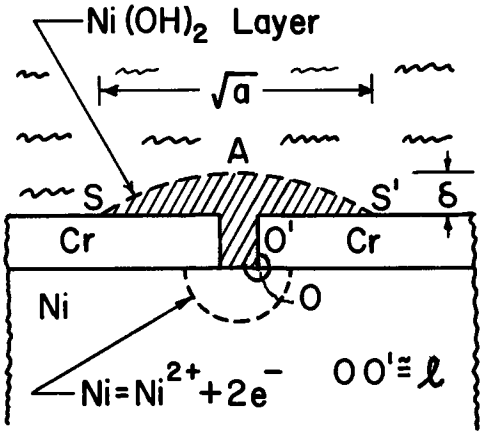

Fig. 11. Schematic representation of the corrosion of nickel in the vicinity of a circular pit in the chromium layer. As corrosion proceeds, a hemispherical pit is formed in the nickel undercoat as indicated by the dotted line.

The diffusion path length for oxygen is of the same order of magnitude as the distance δ shown in Fig. 11.

The mass rate of nickel dissolution per unit area may be written as

$$\frac{dm}{dt} = kI_p \cdot N \qquad [1]$$

where k is a constant relating the electrical current to the material current, I_p the equivalent electrical current passing through the well, and N the surface density of pits. If ρ_a, ρ_c, and ρ_e represent the resistivities of the nickel, chromium, and electrolyte, and assuming that Ohm's law is valid for small currents, the pit current, I_p, can be written as

$$I_p = \frac{E}{\frac{l}{2\pi rl} \cdot (\rho_a + \rho_c) + \rho_e \left(\frac{\delta}{a}\right)} \qquad [2]$$

where E is the potential difference between the nickel and chromium, and all other geometrical symbols are as defined in Fig. 11. The resistivity of the electrolyte ρ_e is considered here to be an equivalent electrical resistivity in our electrical analog model; in reality, it represents the diffusional resistivity of the mushroom-cap to oxygen.

When the surface area a of the mushroom-cap is less than the surface area $A = 1/N$ allocated to a pit, there is no interference between pits and the dissolution rate of nickel will increase linearly with increasing numbers of pits according to Eq. [1]. When the pit density increases to such an extent that the area a is equal to A, then the pits will begin to interfere and the resistance per pit will rise as a decreases with decreasing A. This is tantamount to saying that the current flowing from each pit (I_p) will decrease as the number of pits is increased. We represent this phenomenon by writing the area a as

$$a = \alpha\pi r^2 \qquad [3]$$

where α is a constant and equal to α_o in the noninterference region and decreases with the reciprocal of the fraction $c (c = \pi r^2/A)$ of the nickel area exposed in the interference region as shown in Fig. 12. Substitution of Eq. [2] and [3] in [1] leads to the final form for the dissolution rate equation, namely

$$\frac{dm}{dt} = \begin{cases} \dfrac{K\dfrac{c}{c_o}}{1+R} & \text{for } c/c_o \leq 1 \qquad [4a] \\ \dfrac{K\dfrac{c}{c_o}}{1+R\dfrac{c}{c_o}} & \text{for } c/c_o \geq 1 \qquad [4b] \end{cases}$$

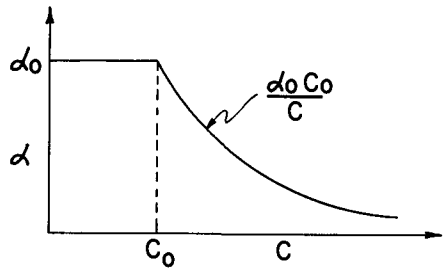

Fig. 12. Influence coefficient α as a function of fraction c of the area of nickel exposed.

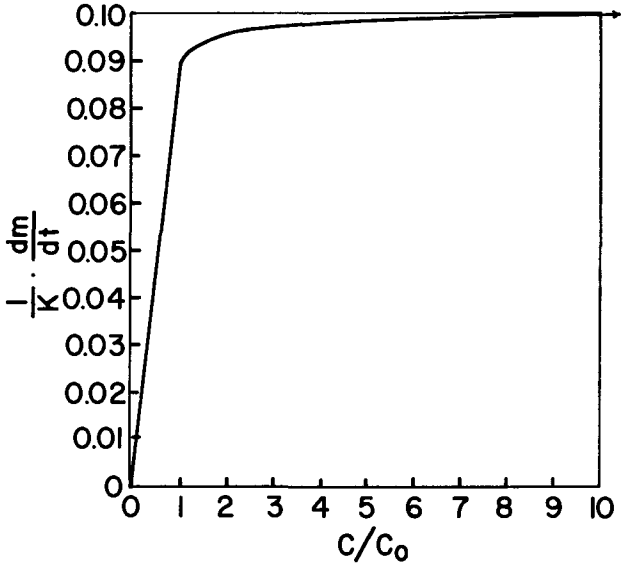

Fig. 13. Dissolution rate of nickel plotted as a function of the ratio c/c_o. Note that for c/c_o values > 1, the rate approaches the saturation value of 0.10.

where

$$K = \frac{2kEc_o}{r(\rho_a + \rho_c)}$$

$$R = \left(\frac{\rho_e}{\rho_a + \rho_c}\right) \cdot \frac{\beta}{\alpha_o}$$

and

$$\beta = \frac{\delta}{r}$$

It is assumed that the ratio $\rho_e/(\rho_a + \rho_c)$ is of order larger than 10^2, while β and α_o are of order unity and 10, respectively, making R of order larger than 10.

The dissolution rate $1/K \cdot dm/dt$ is shown plotted in Fig. 13 as a function of the ratio c/c_o[3] where R was taken equal to 10. It is seen that the rate is initially linear and rises very steeply in the range $c/c_o \leq 1$; thereafter, the rate increases much more slowly, tending to approach a steady-state value. The result appears to be in excellent agreement with the experimental data of Saur (12). Saturation of the dissolution rate is, therefore, a result of pit interference with increasing pit density N. For large N and dm/dt = constant, the product $kI_p \cdot N$ is also a constant as dictated by Eq. [1]. In other words, the pit current I_p decreases with increasing N so as to maintain essentially a constant value for their product.

An examination of Eq. [4a] and [4b] indicates the dissolution rate for a given value of the ratio c/c_o may be reduced further by minimizing the value of K and maximizing the value of R. For large c/c_o, it is easily shown that $dm/dt = K/R$. Since $K \sim 1/r$ and $R \sim 1/r$,

[3] This ratio is the ratio of the fraction of the area of nickel exposed to the fraction at the initial interference of the surface area a of each mushroom-cap shown in Fig. 11. At this instant, $c = c_o$, or $c/c_o = 1$.

the dissolution rate of nickel is independent of r and should not be affected by changes in pit size. Also, increased agitation should increase c_o because a is decreased with agitation, resulting in an increase in the value of K. This agrees with the general observation that increased agitation results in an increase in the dissolution rate of a corroding surface.

On the basis of the foregoing model, it now appears possible to explain the experimental observations. Where only a few corrosion sites are active, the "true" current density per pit (corrosion rate) is obviously much higher than in a uniformly corroding surface. Consequently, the rate of corrosion penetration of nickel should be most rapid in the former case, slowest in the latter case, and intermediate in cases where a greater number of defects exist in the chromium layer (microcracked or microporous chromium). These predictions are in reasonably good agreement with the results shown in Fig. 7 and 8, but the result obtained with the topcoat of microcracked chromium over duplex nickel (Fig. 9) was not very convincing. As mentioned earlier, anodic polarization of this coating system to +0.50V resulted in a complete separation of the chromium layer and corrosion did extend to the steel basis metal (not shown).

The addition of a topcoat of chromium to duplex nickel is also shown to increase the susceptibility of the coating system to pitting corrosion. Furthermore, the results, although limited, suggest that a "critical" potential for macro pitting may exist for these coating systems. Since the critical potential for pitting of stainless steel is known to be affected by temperature, chloride ion concentration, and the presence of other anions (9), it is no wonder that the results obtained at different test sites (Birmingham, Detroit, Kure Beach, *etc.*) are frequently in disagreement. Furthermore, the results obtained on the pitting behavior of these materials can be influenced also by the test conditions. As a case in point, no pitting was observed when duplex nickel was anodically polarized to +0.50V. Earlier investigators (11, 13), however, did observe pitting in both bright and semibright nickel. The former investigators carried out their pitting studies at a constant current density of only 2 $\mu A/cm^2$ and, as indicated in Fig. 3, the bright nickel is coated with a black film in this current density range. However, at higher current densities, the film is completely exfoliated and no pitting is observed in the semibright nickel layer (Fig. 7).

Finally, the result shown in Fig. 10 is considered remarkable in comparison to the results shown in Fig. 8 and 9 for the more conventional decorative nickel-chromium coatings. The corrosion as seen in Fig. 10 has been confined essentially to the electroless nickel layer and there has been little or no penetration of the silver layer. The low value for the corrosion current of this coating system (Table I) appears to result from the increased anodic polarization as suggested in Fig. 6. The remarkable resistance of the silver layer to penetration by corrosion may in part be attributed to the sacrificial nature of the electroless nickel layer. It is believed, however, that the main reason for the improved resistance to corrosion results from the slower dissolution rate of the protective film of silver chloride compared to that of duplex nickel. A further benefit to be accrued from the use of a silver undercoat is that the enhanced ductility of the silver would permit larger strains to be imposed on the coating system. One of the beneficial effects of the semibright nickel layer in duplex nickel is that cracks induced in the more brittle bright nickel layer by bending are arrested at the semibright/bright nickel interface (14).

Conclusions

1. The corrosion currents determined electrochemically for duplex nickel, duplex nickel plus ordinary chromium, and duplex nickel plus microcracked chromium do not differ by more than a factor of 2-4.
2. A coating system with a silver undercoat and a microcracked chromium topcoat possesses superior corrosion resistance to any of the commercial decorative nickel-chromium coatings tested under the same conditions.
3. The addition of a chromium topcoat to duplex nickel increases the susceptibility of the coating system to pitting corrosion.
4. A high density of pores of uniform size and distribution in the chromium layer should lead to increased corrosion protection of steel by nickel-chromium coatings due to a reduction in the current density per pit as the number of pores is increased.

Acknowledgments

The author would like to acknowledge the stimulating discussions with Professor A. S. Argon of the Materials Division in the Mechanical Engineering Department at Massachusetts Institute of Technology and Dr. M. S. Osman of the Exploratory Development Laboratory, United-Carr, Incorporated, concerning the formulation of a model for the pitting process. The support and kind permission of W. R. J. Brown, Director and Vice President of the Exploratory Development Laboratory, to publish this work, is greatly appreciated. The Harshaw Chemical Company kindly furnished the decorative nickel-chromium coated panels used in the present study.

Manuscript received Nov. 26, 1968. This was Paper 429 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Surface and Corrosion Characteristics of Tin-Free Steel—Chromium Type for Beverage Containers

G. G. Kamm,* A. R. Willey, and N. J. Linde

American Can Company, Research and Development, Barrington, Illinois

ABSTRACT

The new tin-free steel-chromium type (TFS-CT) materials are described which constitute a new generation of tin-free materials for can making. The steel is electroplated with a very thin film of metallic chromium approximately 0.3 x 10^{-6} in. thick which is covered by a thin layer of chromium oxide. Processes for producing TFS-CT are reviewed and the relative amounts of metallic chromium and chromium oxide are indicated for the products now available commercially. Performance requirements, bench tests for rapid evaluation of performance, and analytical techniques for measuring the amounts of chromium in the metallic and oxide layers are described. Results of electrochemical and corrosion tests are reported which indicate the relative importance of the metallic chromium and chromium oxide layers as they affect corrosion resistance.

TFS (tin-free steel) was first introduced in August 1965 for use in cemented side seam cans for beer and carbonated beverages. This required good rust resistance both before and after enameling, exceptional enamel adhesion, resistance to undercutting corrosion of enameled plate exposed to beverages, and a lustrous surface resistant to discoloration during enamel baking. These requirements, along with corrosion resistance of the base steel needed for use in cans for carbonated beverages, dictated that the TFS be a steel of the type normally used for tin plate but with a surface treatment applied instead of tin plating.

The first TFS available commercially in the United States was an electrolytic chromate-phosphate treated steel which showed promise initially for use in beer cans but was recognized as being inadequate for carbonated beverages which are more corrosive. This led to a search for improved materials.

Work in our own laboratories during 1957-1958 had shown that steel plated with a thin film of metallic chromium performed better than chromate chemically treated steel available at that time; it was also observed that chromium films 1 μin. or less in thickness were superior to heavier chromium deposits. That experience, augmented by evaluation and analyses of two commercial materials, one a chromium-plated steel with a chromate chemical post treatment (1) and another purported to be steel covered by an electrolytically deposited chromium oxide film (2), suggested that the desired performance could be obtained from steel covered by a duplex film consisting of less than 1 μin. of electroplated chromium with a thin layer of chromium oxide over the metallic chromium. This information was obtained through use of analytical and performance test techniques developed in our earlier work on chromium plating and in more recent studies of TFS materials.

The presently produced TFS-CT (tin-free steel—chromium type) is the result of those observations and subsequent cooperative work with steel producers which established that adequate performance can be obtained with metallic chromium in the range of 0.3-0.5 μin. and chromium oxide films containing 0.5-4.0 mg/ft^2 of chromium. The TFS-CT designation is applied to a number of chromium-chromium oxide treated steels, all of which meet the performance requirements outlined earlier.

Review of TFS-CT Processes and Products

Processes.—A number of papers and patents have been published (1-11) pertaining to processes for producing the chromium-chromium oxide films characteristic of TFS-CT. No attempt is made here to describe the various processes in detail; instead, they are divided into two categories, one-step and two-step, and the general differences between the two types are reviewed.

In the one-step processes (2, 5, 11), the chromium is plated from a relatively dilute solution containing less than 100g/liter of chromic acid. Plating takes place through a layer of chromium oxide which forms before chromium starts to plate (6). Reduction to metallic chromium takes place at the oxide-metal interface, forming a layer of chromium metal on the steel surface under the oxide layer. Final thickness of the oxide is controlled by regulation of solution concentration, bath temperature, and current density, particularly in the last tank of the treatment section. Plating efficiencies of around 20%, very close to those obtained with conventional chromium plating baths, are claimed for the two one-step processes being used commercially in Japan and by at least two companies in Europe.

Two-step processes are being operated by three companies in the United States (3, 4, 8). These processes differ markedly from the process originally patented (1) and used commercially in Japan as late as 1966. The early material was plated with approximately 2 μin. of metallic chromium from a conventional plating bath containing approximately 250g/liter of chromic acid. The chromium plating was followed by a dilute chromic acid rinse as a post treatment. The resultant chromium oxide layer over the relatively thick chromium deposit did not provide the same high degree of corrosion resistance achieved by the oxides on present TFS-CT materials with thinner metallic chromium films. A cathodic post treatment which produces a heavier, more corrosion resistant oxide has since been developed (9) and has been found satisfactory for TFS-CT production.

The two-step processes operated in the United States employ a chromium-plating step followed by one of several cathodic post treatments which add a stable and resistant chromium oxide over the chromium metal, in most cases considerably thicker than the natural oxide formed during plating (0.35 mg/ft^2 of Cr in the oxide). The chromium layer is only 0.3-0.5 μin. thick, but in combination with the oxide layer provides exceptional corrosion performance.

A fourth company in the United States is also producing a TFS-CT product, consisting of a 0.3-0.5 μin. layer of metallic chromium covered by a relatively thin layer of chromium oxide. The exact nature of the process, whether one-step or two-step, has not been disclosed.

Products.—The various TFS-CT materials being produced commercially are all considered equivalent on

Product U (4)	5.0	0.3	1.8
Product V (8)	5.0	0.3	1.5
Unclassified			
Product W	5.0	0.3	0.5

the basis of performance for beer and carbonated beverage cans, even though they differ somewhat with regard to metallic chromium and chromium oxide weights. Typical chromium and oxide weights for the various materials are shown in Table I.

Experience indicates that metallic chromium in the range of 0.3-0.5 μin. is desirable, with no areas less than 0.2 μin. Below 0.2 μin., the chromium layer is less continuous and results in reduced corrosion resistance. The one-step materials with 0.8 μin. show acceptable performance but, for the applications under consideration in the United States, have shown no increase in performance to justify the additional cost of the thicker chromium layer.

The chromium oxide layer is an essential part of the TFS-CT material, being equally as important as the layer of metallic chromium for providing corrosion resistance. The amount of oxide present varies from one material to another, as seen in Table I, but all seem to be equivalent in performance. Appearance may differ somewhat, with the heavier oxides giving blue or brown interference colors; however, when the plate is enameled the colors disappear, giving a lustrous gray appearance closely related to the surface finish of the steel base.

Performance Characteristics

The TFS-CT materials described in Table I were developed to meet the specific needs for use in cemented side seam beer and carbonated beverage cans. This usage required that they possess certain performance characteristics. Bench tests were established for screening of developmental materials, and some of the tests are now used for checking quality of commercial production.

Enamel adhesion.—Extremely good lap shear and peel adhesion is obtained with organic coatings applied to the TFS-CT materials. This is important in cemented side seam cans where the enamel-to-plate bond is a part of the adhesive bonding system. A peel adhesion test was devised whereby two ¾ in. wide strips of TFS-CT, enameled with epoxy-phenolic enamel and bonded in a heated press by means of a polyamide cement, are pulled in peel around a special fixture of the type shown in Fig. 1. Maximum load is recorded as the peel strength. The TFS-CT materials average over 60 lb/¾ in. width (after subtracting a 5 lb blank, *i.e.* the force required to pull unbonded 0.006 in. 2CR type L steel strips through the test fixture). In lap shear, a ¼ in. overlap bond is stronger than the 0.006 in. steel which has a tensile strength around 90,000 psi.

In addition to having excellent enamel adhesion initially, the chromium-chromium oxide surface resists undercutting attack at the enamel-plate interface when the edge of a bond is exposed to corrosive acid media. Untreated steels or steels treated with chromate, phosphate, or combinations of chromate and phosphate are attacked by media such as carbonated beverages; corrosion at the enamel-plate interface can ultimately result in complete failure of the adhesively bonded joint. The metallic chromium prevents this undercutting attack completely.

Corrosion resistance.—Rust resistance unenameled.—Resistance to rusting during shipment and storage is necessary to provide a rust-free surface for enameling.

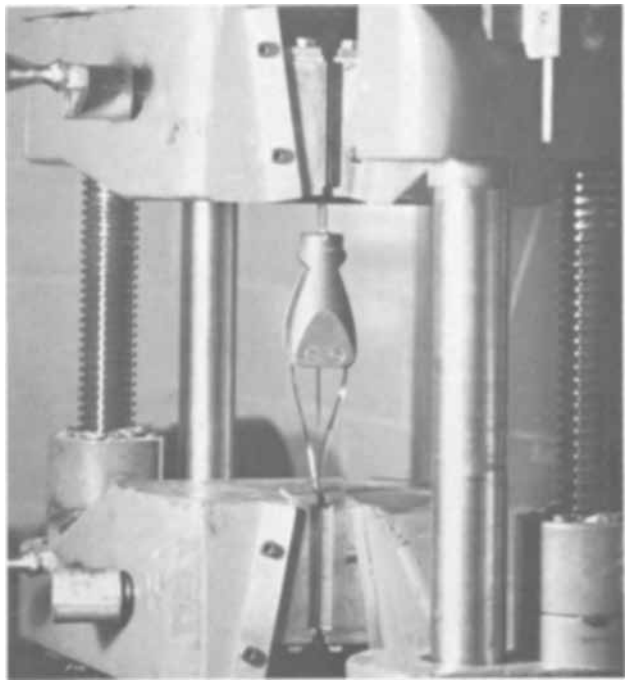

Fig. 1. Peel adhesion test fixture

A pack rust test is used to check this characteristic. It consists of stacking approximately 25 unenameled panels 6 in. x 6 in. between two pieces of ½ in. plywood and strapping the stack tightly before placing in storage at 85°F and 85% relative humidity. The pack of panels is shown in Fig. 2. One month without rusting is considered satisfactory; this is roughly equivalent to 12 months' storage in a warm, humid climate such as Houston or New Orleans. Most treated steels will meet this requirement. TFS-CT materials have passed the pack rust tests and have also undergone more than 1 yr of storage at Houston with good results.

Underfilm rusting.—Rusting after enameling is also a problem with untinned steel. Without a surface treatment on the steel, rusting may start from edges, scratches, or imperfections in the enamel, or even at areas which show no defects. This type of rust spreads under the enamel, resulting in unsightly appearance. This property can be checked by putting scribed enameled samples of the type shown in Fig. 3 in a cabinet at 85°F and 85% R.H. for 2 months. There should be no underfilm rusting at the end of 2 months under those conditions. The TFS-CT performs well in this respect, as indicated in Fig. 4. Chromate-phosphate TFS, which has no metallic chromium in the treatment layer, is far superior to the cleaned and oiled steel but is not as good as the TFS-CT. Both the

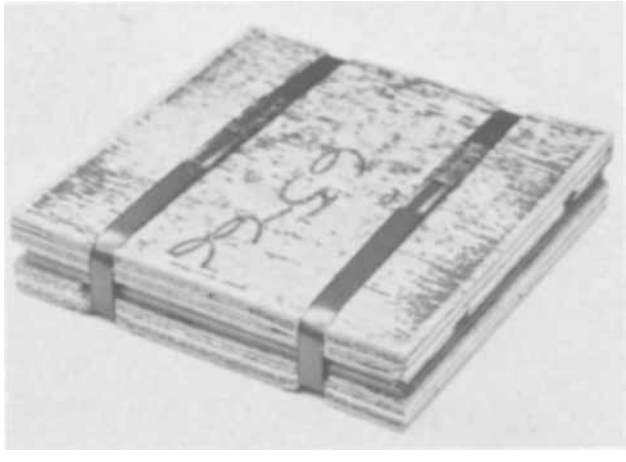

Fig. 2. Pack rust test—strapped panels

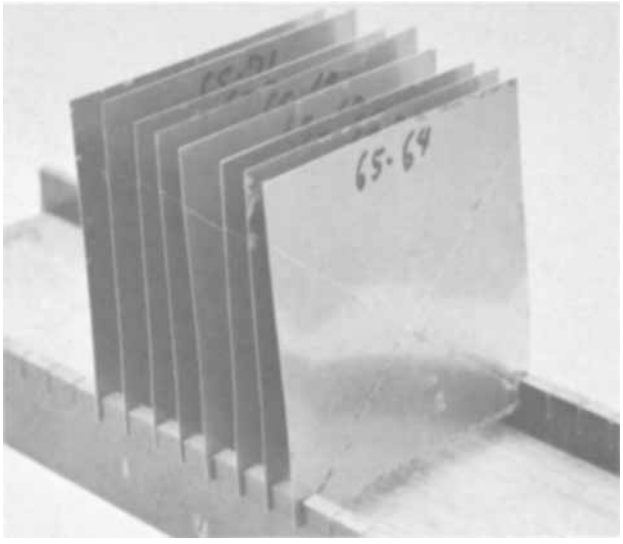

Fig. 3. Underfilm rust test panels

metallic chromium and chromium oxide of the TFS-CT are important to good performance.

Ability to resist underfilm rusting is important for the outside of can parts where possible scratches or fractures in enamel at end seams may be exposed to humid conditions during storage or chilling. A number of tests are employed for measuring rust resistance of can end seams, all of which are quite severe and not very reproducible. However, from many tests comparing TFS-CT, No. 25 electrolytic tin plate, and other TFS materials, the TFS-CT consistently ranks better than the other TFS materials and is equivalent to the No. 25 tin plate.

Undercutting resistance.—Resistance to undercutting corrosion at edges or imperfections in enameled plate is one of the most difficult requirements for a tin-free material. To test this property, scribed enameled samples are placed in a lemon-lime beverage under a CO_2 atmosphere for 2 weeks at 80°F; samples are then removed, rinsed, and dried, and then "Scotch taped" prior to examining for evidence of undercutting corrosion and enamel lifting adjacent to the scribe marks. Examples of materials after the undercutting test are seen in Fig. 5. It is apparent that the TFS-CT is far superior to cleaned and oiled steel and electrolytic chromate-phosphate treated steel, and is even slightly better than No. 25 electrolytic tin plate. Immersion for 4 days in a 1.5% sodium chloride-1.5% citric acid solution provides the same evaluation in a shorter time (3). Only TFS materials with metallic chromium on the steel surface show excellent resistance to this type of attack, a characteristic required for good performance in beer and carbonated beverage cans where undercutting could result in high iron pickup or, in some carbonated beverages, failure of cemented side seams as mentioned earlier. The chromium appears to be more important than the chromium oxide in this particular type of corrosion.

Sulfide stain resistance.—The TFS-CT materials offer exceptional resistance to staining by products containing high levels of sulfides. This is not a direct requirement for use in beer and carbonated beverage cans but results from the same combination of chromium and chromium oxide that provides good resistance to rusting before and after enameling. This stain resistance would be more important if TFS-CT were to be used in containers for meat, fish, and sulfide-containing vegetables. Figure 6 shows a comparison of No. 25 tin plate, electrolytic chromate-phosphate treated TFS, and TFS-CT, all of which were coated with the same enamel and processed as ends on cans packed with a synthetic medium known to cause severe sulfide staining. The TFS-CT is far superior to the chromate-phosphate material and is even substantially better than the electrolytic tin plate. The one completely blackened end is TFS-CT with the chromium oxide removed prior to enameling. Without the protective oxide film, a black chromium sulfide forms over the entire surface, emphasizing the need for a resistant chromium oxide layer.

Appearance.—The appearance of TFS is important to the external appearance of the finished containers. In many cases, the outside lithographed can labels utilize clear inks or varnishes to take advantage of the bright appearance of the metal underneath. Although TFS-CT is not as bright as tin plate, it does present a consistent lustrous gray appearance which has been used successfully with transparent labels. Other TFS materials present a less attractive appearance initially and some show variable tendency to turn brown during baking of enamels before can manufacture. The inconsistent and relatively unattractive surface is a problem, both under labels and in can ends, because of the effect on appearance under clear or tinted varnishes and even under solid colors unless extremely heavy coatings are applied. Some variations are seen in TFS-CT before enameling because of interference colors at certain oxide thicknesses; however, these disappear when a coating or varnish is applied to the surface.

Surface mobility.—Most TFS materials, and TFS-CT in particular, have a higher coefficient of friction than tin plate, thus requiring slightly greater surface lubrication for ease of handling before enameling. For TFS-CT, a DOS (dioctyl sebacate) level of approximately 0.27 g/BB[1] has been found adequate to allow shearing on coil lines and handling in enameling operations, without interfering with enamel wetting or integrity. This is higher than the 0.17 g/BB of DOS normally specified for tin plate but is in the range commonly found on aluminum stock for beer and carbonated beverage ends.

Even with the higher level of lubrication, the coefficient of friction of the TFS-CT surface is too high

[1] BB stands for base box, equivalent to 62,720 in.^{2} of plate surface (includes both top and bottom surfaces of 31,360 in.^{2} of plate).

to permit efficient fabrication of container parts from unenameled stock. Work to date indicates that both sides of the TFS-CT must be coated prior to fabrication for practical operation.

Chromium and Chromium Oxide Films

Analysis of the duplex treatment.—Considerable effort was expended in establishing suitable methods for determining chromium and oxide weights. The results are a coulometric method for determining metallic chromium and a chemical colorimetric procedure for measuring chromium in the oxide.

The oxide determination consists of stripping the entire oxide film from the plate surface by immersing for 3 min in 7.5*N* KOH at 195°F. This removes essentially all of the oxide without removing a significant amount of metallic chromium. The chromium in the stripping solution is then measured colorimetrically by the diphenylcarbazide method. The procedure is described in detail in Appendix A. Measurement of chromium in the stripping solution can also be achieved by atomic absorption techniques if desired.

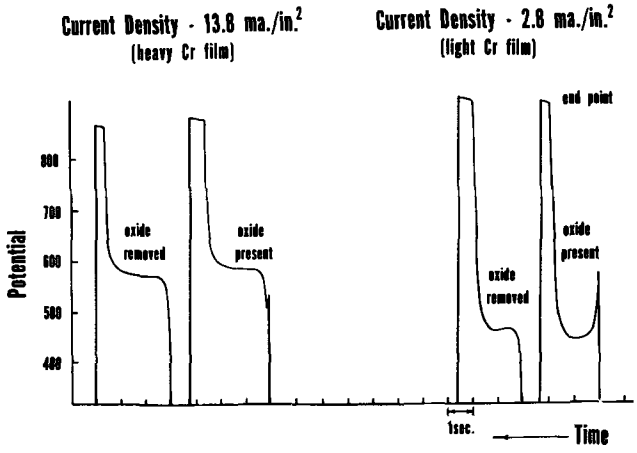

Fig. 7. Potential-time curves for coulometric determination of metallic chromium.

Metallic chromium is determined coulometrically by anodic stripping at constant current in 1*N* NaOH, using a platinum cathode and a stainless steel reference electrode. Current densities ranging from 2.8 to 13.8 ma/in.² have been used with equivalent results. The end point is determined by the potential break measured on a recording potentiometer.

For all practical purposes, the order in which chromium and oxide are measured is not important, since either can be measured first without affecting appreciably the subsequent measurement of the other. The shape of the time-potential curve in the metallic chromium determination will differ somewhat depending on whether the oxide has been removed or is still present. Typical curves are shown in Fig. 7. With the oxide present, there is a peak in the curve at the start which drops off rapidly to the dissolution potential of metallic chromium. If the oxide is removed first, there is no initial peak in the potential curve but the total coulombs measured are the same as when the oxide was not removed. Apparently the anodic treatment oxidizes only the metallic chromium and has no effect on the oxide film. The oxide remains on the steel surface and can then be removed by the hot KOH method; the amount of chromium in the oxide so determined is the same as when the oxide is removed for analysis before anodic stripping of the metallic chromium.

Peroxide should *not* be used in hot alkaline solutions for stripping the oxide film. The presence of peroxide causes attack of the metallic chromium layer which results in erroneously high values for chromium in the oxide and low values in subsequent coulometric measurement of metallic chromium.

The composition of the oxide layer appears to be somewhat variable, even for a given process. The data in Table II show the total oxide weight, weight of chromium in the oxide, and the ratio of the two. For the two-step material the ratio varied from 1.2 to 3.9, and for the one-step material from 2.9 to 6.8. Some of this variability is probably the result of inaccuracies in measuring the total weight of these very thin films by weight loss technique. However, a substantial part is believed to be real and may represent differences

Table II. Total oxide weight *vs.* weight of Cr in oxide

in degree of hydration of the oxide film. These variations over the range indicated have not been found to affect performance, either corrosion-wise or with regard to enamel adhesion.

The true nature of the chromium and chromium oxide films is not firmly established. Schneider *et al.* (8) have indicated that the layer of metallic chromium is relatively continuous but does require the oxide layer to provide essentially complete coverage. Carter and Lee (7) have shown optical photomicrographs of duplex chromium-chromium oxide films indicating relatively large voids in the chromium layer which are filled in by the chromium oxide layer to give continuous coverage. Our own experience with transmission electron microscopy supports the concept of a surprisingly continuous film of metallic chromium covered by a continuous layer of amorphous chromium oxide. Typical electron micrographs (transmission) are shown in Fig. 8. All transmission samples were obtained by evaporating carbon onto the surface prior to scribing in ⅛ in. squares and separation from the base steel in an alcoholic bromine solution. Figure 8a is the duplex chromium-chromium oxide film which appears to be continuous but variable in thickness or density. There is evidence of what appear to be grain boundaries suggesting epitaxial growth on the grains of the steel substrate. Figure 8b shows the metallic chromium layer with the oxide removed. Again, the layer appears continuous but with what appear to be small nodules of heavier chromium scattered over the surface. The square area and square loops have been related to etch pits in the steel base (8); the chromium appears more dense but this may only be an orientation effect. Evidence of grain boundaries of the base steel is less pronounced. Figure 8c shows the oxide film after the metallic chromium was stripped anodically from under the oxide in 1*N* NaOH. There appear to be definite differences in texture which follow the grain structure of the steel base, but the oxide appears quite continuous.

Electrochemical and corrosion studies.—Electrochemical measurements indicate that the metallic chromium layer is not completely continuous. Corrosion studies in two carbonated beverages and a fruit juice also support the idea that the chromium oxide layer plays an important role by providing protection to both the chromium layer and the areas of steel not covered by the chromium.

Potential measurements with steel, pure chromium, and steel plated with various thicknesses of metallic chromium (no post treatment) indicate that the chromium electroplate does not cover the steel base completely, leaving some active sites exposed through voids in the chromium layer. The data shown in Fig. 9 were obtained by immersing samples, masked with microcrystalline wax to expose the desired area, in cola and lemon-lime beverages (CO_2 atmosphere) and grapefruit juice (N_2 atmosphere) at 80°F and measuring potentials after 1 day against a saturated calomel electrode as a reference. The pure chromium samples included: (*a*) reagent grade electrolytic chromium, (*b*) a 100 μin. layer of electroplated chromium separated from the base steel by controlled anodic dissolution of the steel base in 1*N* H_2SO_4, and (*c*) a 10,000 μin. layer of chromium electroplated on a steel base. Although the chromium samples were activated in dilute HCl prior to immersion in the test media, they appeared to passivate after 1 day in test to give corrosion potentials considerably less negative than plain steel, the difference ranging from 100 mv in cola to 175 mv in grapefruit juice. Therefore, if the chromium layer on plated samples were continuous the potential would be that of pure chromium, and if not continuous the potential of plated samples would be expected to fall between the potentials measured for pure chromium and unplated steel. Instead, plated samples with more than 0.1 μin. of metallic chromium show potentials significantly more negative than either chromium or steel. The shape of the curves suggests that maximum coverage of the steel is attained with 0.2 μin. or more of chromium.

A possible explanation for the negative potentials of plated steel is that, during the chromium electroplating process, the chromium plates preferentially

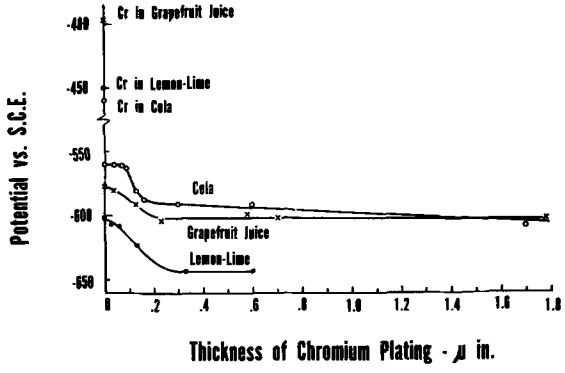

Fig. 9. Potentials of steel, chromium, and steel plated with various thicknesses of chromium, measured against a saturated calomel electrode in three acid media.

on the less negative (cathodic) areas of the steel surface, leaving the most negative (anodic) areas exposed through voids in the chromium layer. The corrosion potential of the plated steel then becomes the couple potential of the plated chromium and the steel anodes exposed through it. Because the chromium is a less efficient cathode than the original steel cathodes and polarizes more easily, the corrosion potential of the plated steel is more negative than the original steel corrosion potential as illustrated schematically in Fig. 10. This should result in either a reduction in steel corrosion rate (Fig. 10A) or essentially no change (Fig. 10B), depending on the polarization characteristics at the steel anode areas.

Corrosion studies were also conducted in cola and lemon-lime beverages to determine the effect of the chromium and oxide layers on rate of corrosion of the steel base. TFS-CT samples were tested as received, after removal of the chromium oxide layer in hot 7.5*N* KOH, and after removal of both the oxide in hot 7.5*N* KOH and the metallic chromium by anodic stripping in 1*N* NaOH. Samples masked with microcrystalline wax to cover all edges and expose an 8 cm^2 area of surface were corroded in the beverages (CO_2 atmosphere) for 96 hr at 80°F. Two samples, not in electrical contact, were immersed in each flask containing 500 ml of beverage. At the end of the test, the samples were removed, rinsed, and dried with acetone. Metallic chromium remaining on the test surfaces was measured electrolytically in 1*N* NaOH. Steel corrosion rate was determined after removal of the wax masking by comparing final weight to the weight of the samples before masking and testing. The extremely small weight loss from stripping of the metallic chromium did not affect the steel weight loss significantly. Typical data are shown in Table III.

The oxide layer contributes significantly to corrosion resistance in both cola and lemon-lime beverages by providing protection to both the metallic chromium and steel base. With the oxide present, the chromium showed no corrosion during the 96 hr test and the rate measured for the base steel was held to a low level.

With the oxide removed, the metallic chromium provides little, if any, protection to steel in cola, except in the case of the heavy 1.77 μin. plating. However, not all heavy chromium coatings showed this beneficial effect. The chromium layer also shows corrosion by the cola. On the other hand, in lemon-lime beverage the chromium is not attacked, even with the oxide removed, and the chromium alone provides appreciable protection to the base steel.

The significance of the potential and corrosion data from the unenameled samples has not been fully determined. Results indicate that the chromium is not completely continuous in the thickness applied to TFS-CT materials, but the coverage is approximately the same for thickness from 0.2 μin. on up to levels far heavier than are practical for these materials. Less than 0.2 μin. provides less coverage to the steel which should result in lower corrosion resistance. The oxide definitely adds to the corrosion resistance by reducing corrosion of both the metallic chromium and the base steel. This undoubtedly is important to good rust resistance before enameling and probably after enameling, also. It is clear that the TFS-CT would not be suitable for use in acid products without a protective coating of enamel, but the exact significance to corrosion of enameled TFS-CT in acid foods or beverages cannot be ascertained from the work reported.

The superiority of TFS-CT over other tin-free materials for beer cans was discussed by Kidder *et al.* (12). It has also been found satisfactory for use in carbonated beverage cans. Limited experience with test packs of other products indicates that, for moderate to highly corrosive acid foods, enameled TFS-CT ends combined with unenameled tin plate bodies perform very well; the tin surface apparently provides cathodic protection to any of the TFS-CT exposed. With the same products packed in fully enameled tin plate bodies, enameled TFS-CT ends are subject to rapid pitting corrosion at any enamel fractures.

Summary

TFS-CT materials are now produced by at least eight companies throughout the world. All are characterized by a layer of metallic chromium in the range of 0.2-0.8 μin. in thickness, covered by a layer of chromium oxide containing from 0.5 to 3.5 mg of Cr/ft^2. Some are produced by one-step processes and others by two-step processes, but corrosion resistance, enamel adhesion, and appearance of all are essentially equivalent.

Performance tests and analytical procedures are described which were used in cooperative work with the steel companies in establishing optimum levels of chromium and chromium oxide for performance in beer and carbonated beverage cans. The TFS-CT materials show performance superior to that of other tin-free materials in those applications and also show promise of providing excellent performance in certain food can applications where other chemically or electrochemically treated steels have been only borderline or unacceptable.

Electrochemical and corrosion studies are reported which indicate that the metallic chromium layer is not continuous, but suggest that a 0.2-0.5 μin. thickness is the most practical range for this material. It is also shown that the chromium oxide layer plays an important part in the over-all corrosion performance of TFS-CT materials.

Manuscript submitted Dec. 23, 1968; revised manuscript received May 2, 1969. This was Paper 433 presented at the Montreal Meeting, Oct. 6-11, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

APPENDIX A

Determination of Chromium Oxides on TFS-CT

Alkaline Stripping—Permanganate Oxidation

Reagents

A. 56g KOH dissolved in 90 ml H_2O (approx. 7.5*N*).
B. (1 + 5) H_2SO_4 (1 part conc H_2SO_4 + 5 parts H_2O).
C. Saturated $KMnO_4$.
D. Diphenylcarbazide reagent: add 0.2g diphenylcarbazide to 10 ml acetone. Next, add 10 ml 95% ethanol and 20 ml of dilute H_3PO_4 (85% H_3PO_4 diluted with an equal part of water). For the diphenylcarbazide reagent, we are currently using Eastman-Kodak No. 618 1,5-Diphenylcarbohydrazide.

Procedure

Place 20 ml of the KOH reagent in a 250 ml beaker. Immerse a 4 in.^{2} disk (dimpled) or, if only one side is to be determined, place the disk on a "vacuum-rubber stopper" and immerse in the solution. Heat near boiling for 3 min. Remove the sample and rinse, collecting the rinsings in the beaker. Dilute and add 50 ml of the H_2SO_4 reagent (B). Heat to boiling and add 2 drops of saturated $KMnO_4$. Boil for 2-3 min and add 5 drops conc HCl to decompose the permanganate. Boil for several minutes until the pink color has been replaced by a brown suspension. Cool, dilute, and transfer to a 100 ml volumetric flask. Add 3.0 ml of diphenylcarbazide reagent. Dilute to the mark and allow to stand for 15 min. Read at 540μ. The color is stable for 15 min after color is read.

Prepare standards by placing a solution of 0, 10, 20 μg, *etc.*, Cr as $K_2Cr_2O_7$ in beakers. Add the KOH, H_2SO_4, and $KMnO_4$, *etc.*, just as above. It is not necessary to include a precleaned steel disk inasmuch as the plot of absorbance *vs.* concentration will be the same whether or not the disk has been present, according to our findings.

Intergranular Corrosion of Ferritic Stainless Steels

A. P. Bond* and E. A. Lizlovs*

Research Laboratory, Climax Molybdenum Company of Michigan, Ann Arbor, Michigan

ABSTRACT

The susceptibility of both commercial and experimental ferritic stainless steels to intergranular corrosion was investigated. It was found that heating to 1700°F or higher and cooling rapidly sensitized a wide variety of ferritic steels to intergranular corrosion. The effects of Mo, Ni, Cb, and Ti additions to the steels were studied. It was found that Cb and Ti were effective in preventing intergranular corrosion in the Strauss test after high-temperature heat treatment. However, in highly oxidizing media such as boiling 65% nitric acid, titanium-containing steels could be sensitized to intergranular corrosion, while the columbium steels resisted intergranular attack even in boiling 65% nitric acid. Controlled potential polarization experiments gave results that agreed with the exposure results.

It is well known that some ferritic stainless steels are subject to intergranular corrosion after welding or improper heat treatment (1, 2). There is also evidence, although it is somewhat contradictory, that additions of titanium or columbium reduce or eliminate this problem in a manner analogous to that for austenitic stainless steels (1, 3, 4). The influence of other alloy additions on the susceptibility of ferritic stainless steels to intergranular corrosion has not been extensively investigated.

The influence of molybdenum on the intergranular corrosion of this class of steels is of particular interest since it has been shown that molybdenum has a very strong favorable effect on the resistance to general and pitting corrosion (5, 6). Nickel additions were also studied since it has been suggested that the presence of austenite at high temperature alleviates the sensitivity of nominally ferritic steels to intergranular corrosion (7); however, nickel additions to ferritic stainless steels can cause susceptibility to stress corrosion cracking in chlorides (8). Thus, nickel additions to steels of this type would probably be limited to special applications.

The present work was undertaken to investigate the effects on intergranular corrosion of additions of Mo, Ni, Ti, and Cb to ferritic stainless steels containing about 18% chromium. In addition, some information was obtained on the interaction of these alloying elements.

Experimental Procedures

Materials

This work was performed with commercially produced steels and with experimental alloys. The experi-

[a] NA = Not analyzed, but in the range of the series.

mental alloys were produced by induction melting in an argon atmosphere. Each series was prepared using the split heat technique. In this technique, the base composition is melted and part of the melt is poured off to produce an ingot. To the balance of the melt, the required titanium or nickel additions are made and the next ingot cast. This process is repeated until the desired compositions are cast. By this procedure, the impurity levels are held nearly constant within each series. The compositions of the steels produced are shown in Table I. The steel of the base composition contained 0.11% nickel as a residual element. This level of nickel is thought to be somewhat lower than would be encountered in similar steels produced commercially.

The resulting ingots were hot forged and hot rolled to 0.76-cm-thick strips, and then cold rolled to a 0.38-cm thickness. All strips were given a 1-hr anneal at 1500°F before test specimens were prepared.

Heat treatment.—The sensitizing heat treatments at 1700°, 1900°, and 2100°F were performed in air, followed by water quenching. The simulated welds were made on specimens annealed at 1500°F, except the specimens from the 1.27% titanium steel and the 2.08% nickel-1.75% titanium steel which were annealed at 1700°F, and those from the 1.86% titanium steel which were annealed at 1900°F. Welds in the corrosion specimens were simulated by forming a molten puddle across one surface of each specimen using the TIG welding technique.

Specimen preparation.—Specimens measuring 1 by 2 in. for the 65% nitric acid test and ⅜ by 3 in. for the modified Strauss test were wet-surface ground to remove surface irregularities and polished through 3/0 dry metallographic paper. Specimen thickness was about 0.14 in. Immediately prior to testing, the specimens were washed in acetone and then in a solution of detergent in hot water, rinsed in distilled water, dipped in methanol, dried, and weighed.

Nitric acid tests.—Tests in 65% nitric acid (HNO_3) were performed according to ASTM Designation A262-64. The corrosion cells consisted of 1-liter Erlenmeyer flasks fitted with cold-finger condensers. The test specimens were immersed in 700 ml of boiling 65% HNO_3 solution for 48 hr. They were then removed, washed in distilled water, rinsed in methanol, dried, and weighed. The specimens were then exposed in fresh solution for another 48-hr period. This procedure was repeated for a total of five 48-hr periods.

Modified Strauss tests.—Modified Strauss tests (9, 10) were performed in 1-liter Erlenmeyer flasks fitted with cold-finger condensers. The specimens were suspended in vented glass cradles made from 30-ml beakers. A total of 50g of heavy copper turnings was packed around the sample in the cradle. Care was taken to ensure good electrical contact between turnings and test piece. The baskets containing the copper and the specimen were immersed in 700 ml of solution containing 16% sulfuric acid and 6% copper sulfate by weight. The test was conducted in the boiling solution for 24 hr. After exposure, the specimens were bent through 180 deg or until failure. In the case of welded specimens, the weld was at the apex of the bend. If no cracks could be detected at a magnification of 20 diam, the steel was considered to have passed the test.

Some bend tests were supplemented by measuring the electrical resistance of the specimens before and after testing. This was done by passing a constant current of about 1A through the specimen and through a standard specimen of similar material and dimensions in series with it. A potentiometer was used to measure the *IR* drop across the test specimen and across the standard specimen. Since measurements on the standard and test specimens were completed in less than 1 min, the effects of variations in current or temperature were largely eliminated by normalizing the test specimen resistance against the standard specimens.

Polarization measurements.—The polarization measurements were made with the aid of a potentiostat. Standard procedures were followed. The electrolyte was 1*N* sulfuric acid saturated with argon. The temperature was 24° ± 1°C.

Results

Effects of molybdenum.—The results of applying the modified Strauss test to the alloys containing molybdenum alloying additions are shown in Table II. Annealing at 1500°F led to a satisfactory resistance. This was true regardless of the rate of cooling from the annealing temperature. Heat treatment at 1700°F sensitized all the alloys to intergranular corrosion in the test environment.

These same alloys and heat treatments were examined using the boiling nitric acid test, as shown in Fig. 1. This test also shows that heat treatment at 1700°F sensitized all the alloys to intergranular corrosion. However, these results do show that the behavior of the steels containing 1 or 2% molybdenum is sensitive to the rate of cooling after annealing, but the steel containing no molybdenum was only slightly affected by changes in cooling rate. To ascertain whether or not the higher corrosion rates of the molybdenum steels after a slow cool represented intergranular attack, the corroded specimens were examined metallographically. Figure 2 shows a definite intergranular attack by boiling nitric acid on the furnace-cooled specimen containing 1% molybdenum. There was less preferential grain boundary attack on the air-cooled specimens, but there was enough to be clearly evident. Although the water-quenched specimen showed some nonuniformity of attack, there was no evidence of intergranular corrosion.

Table II. Results obtained from the modified Strauss test on ferritic stainless steel containing 0-2% molybdenum

Final heat treatment	Strauss test results[a] on indicated alloy: Alloy 5 (0% Mo)	Alloy 6 (1% Mo)	Alloy 1a (2% Mo)
1 hr at 1550°F, furnace cooled at 50°F/hr to 1100°F, air cooled	P	P	P
1 hr at 1500°F, air cooled			P
1 hr at 1500°F, water quenched	P	P	P
1 hr at 1700°F, water quenched	F	F	F

[a] P = No cracks visible at a magnification of 20 diam on bending the specimen through 180 deg after 24 hr of Strauss testing; F = Cracks visible at a magnification of 20 diam on bending the specimen through 180 deg after 24 hr of Strauss testing.

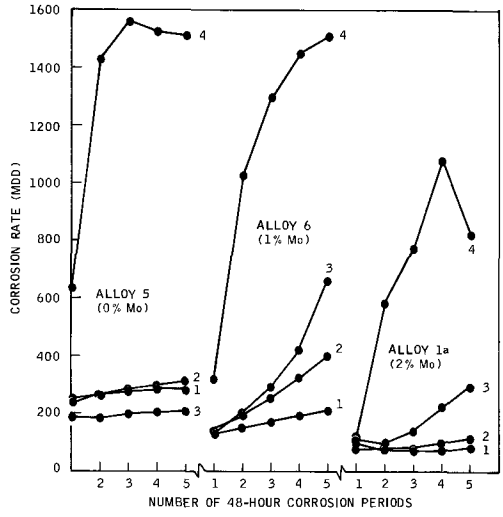

Fig. 1. Effect of heat treatment on the intergranular corrosion susceptibility in boiling 65% nitric acid 18% chromium steels containing 0-2% molybdenum: 1 = 1 hr at 1500°F, water quench; 2 = 1 hr at 1500°F, air cool; 3 = 1 hr at 1550°F, furnace cool at 50 F/hr to 1100°F, air cool; 4 = 1 hr at 1700°F, water quench.

These results suggest that the behavior of molybdenum-containing ferritic steels is analogous to that of austenitic stainless steels containing molybdenum. Under some conditions, the steels may be susceptible to intergranular corrosion only in highly oxidizing media such as boiling nitric acid, but not in less oxidizing media.

Effects of nickel.—The effect of nickel additions on the behavior of these steels in the Strauss test is shown in Table III. Nickel additions did raise the heat treatment temperature that could be tolerated without producing susceptibility to intergranular attack. However, the 2% nickel addition was insufficient to avoid sensitization by welding.

Metallographic examination of these alloys revealed that the 2% nickel alloy contained a large amount of martensite after quenching from 1900°F. The 1% nickel alloy contained only a small amount of martensite. Thus, increased resistance to intergranular corrosion was associated with the presence of austenite in the alloy at the sensitizing temperature.

Tests on a few of these combinations of alloys and heat treatments were also run in boiling nitric acid (Table IV). These results are in complete agreement with the results of the Strauss tests.

To learn how the effects of a prior sensitization could be removed, heat treatment of sensitized specimens was studied. Welding was chosen as the sensitizing treatment because it is believed to lead to the most severe susceptibility to intergranular corrosion. The results of postweld heat treatment of the nickel-containing steels are shown in Table V. In the presence of 1 or 2% nickel, a 1-hr postweld treatment at 1500°F is sufficient to alleviate the susceptibility to intergranular corrosion. The lower nickel steels required 4 hr, indicating that they were more severely sensitized by welding, but in all cases intergranular corrosion could be prevented by appropriate postweld heat treatment.

Effects of titanium.—The effect of titanium additions on the behavior of the 18% Cr-2% Mo alloys in the Strauss test was examined (Table VI). Titanium additions as small as 0.47% completely prevented intergranular corrosion in the Strauss test after all sensitizing treatments. This amount of titanium is about 14

times the weight per cent carbon or about six times the combined carbon and nitrogen content. The addition of up to 2% nickel along with the titanium had no pronounced effect on the behavior of these alloys.

It should be noted that the three alloys containing more than 1.2% titanium were brittle after the 1500°F annealing treatment, probably because titanium promoted the formation of sigma or some similar brittle second phase (11). This brittle phase could be avoided by solution treating at 1900°F and quenching in water.

Some of these alloys were also subjected to the boiling nitric acid test and quite different results were obtained after the higher-temperature heat treatments (Table VII). All the titanium-containing alloys suffered severe intergranular attack after heat treatment at 1900°F or welding. This was true whether or not nickel was also present in amounts up to 2%. Thus, titanium additions prevent intergranular corrosion in media with oxidizing potentials typified by the Cu-$CuSO_4$ couple (Strauss test) but not under the highly oxidizing conditions represented by boiling 65% nitric

acid. This is in accord with the observations of others (1, 12).

Effects of columbium.—Columbium, as well as titanium, is commonly used to stabilize austenitic stainless steels against intergranular corrosion. In austenitic steels, columbium is generally considered to be more effective than titanium under highly oxidizing conditions. The results obtained in the Strauss test on the series of alloys containing columbium additions are shown in Table VIII. Columbium additions of 0.61 and 0.93% were sufficient to prevent intergranular corrosion in the Strauss test even for the welded specimens. An addition of 0.32% columbium was sufficient to prevent sensitization at 1700°F but was borderline at 1900°F and ineffective at 2100°F. The alloy with 0.61% columbium has a Cb to C ratio of 17 or a Cb to (C+N) ratio of 8. Electrical resistance measurements on these specimens were less responsive to intergranular corrosion than was the bend test. This is similar to the observation of Streicher on austenitic steels (10).

Representative combinations of alloys and heat treatments were also tested in boiling nitric acid (Table IX). In marked contrast to the titanium-stabilized steels, the columbium-containing steels that passed the Strauss test also showed good resistance to intergranular corrosion in the Huey test. Even the as-welded samples containing 0.61% or more columbium were highly resistant to corrosion in this test. However, the as-welded 0.93% columbium specimen showed some preferential corrosion at the edges of the fusion zone.

Controlled potential experiments.—In addition to the standard tests for intergranular corrosion, controlled potential measurements were made on several alloys. Figure 3 shows typical results of potentiodynamic scans on a sensitized (1900°F anneal) and a nonsen-

sitized alloy (1500°F anneal). All alloys that had been sensitized to intergranular corrosion as indicated by the Strauss test results had higher currents throughout the passive region than did the corresponding alloys annealed at 1500°F. This was most pronounced at potentials of — 0.1 to 0.0V *vs.* SCE. In the active region and in the transpassive region, no difference could be detected in polarization behavior between sensitized and nonsensitized specimens.

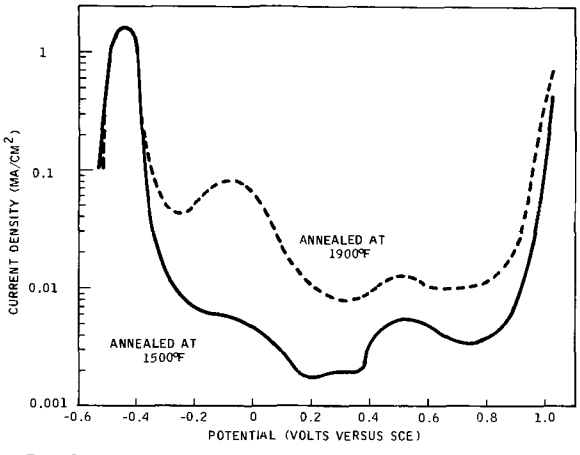

Fig. 3. Potentiodynamic polarization curves obtained at a scanning rate of 600 mV/hr in 5% sulfuric acid at 24°C on the 18% chromium-2% molybdenum alloy water quenched after a 1500° or 1900°F heat treatment.

The alloys that were stabilized by titanium additions showed identical polarization curves whether heat-treated at 1500° or 1900°F. Thus, for all alloys, the results of the Strauss test and of potentiodynamic polarization scans in 1*N* sulfuric acid were consistent. However, these polarization scans would not be used to predict the results of the boiling nitric acid test since all titanium-stabilized steels heat treated at 1900°F or higher were severely attacked by nitric acid, but showed polarization behavior identical to the unsensitized similar steels.

Some of these alloys, including Alloys 1a, 2a, 5, and 6, were subjected to potentiostatic polarization at 1.1V for 2 hr in 1*N* sulfuric acid at 24°C. These alloys were tested after annealing at 1500°F and after sensitizing at 1700° or 1900°F. In all tests, the current density was nearly the same with no correlation between heat treatment and current density. However, microscopic examination after these tests showed very clear intergranular attack on all the specimens that had been given a sensitizing heat treatment and no intergranular attack on any of the steels annealed at 1500°F and water quenched (Fig. 4). Thus, the appearance of electrodes held at 1.1V for 2 hr was in complete accord with the results of the Huey tests.

Discussion

These results show that ferritic stainless steels such as Type 430 become sensitized to intergranular corrosion when heated to 1700°F or higher. This behavior is in marked contrast to that of austenitic stainless steels, since they become sensitized only in a considerably lower temperature range. Nevertheless, there is considerable evidence that chromium depletion adjacent to chromium-rich precipitates is an important factor in causing intergranular corrosion in both classes of stainless steel (2, 13).

The differences in heat treatments leading to sensitization are a result of the differences in solubilities of carbides in ferrite and in austenite. Since the solubility of carbon in ferrite at temperatures as high as 1500°F is very low, no normal heat treatment can avoid the precipitation of carbides in ordinary ferritic stainless steels. Thus, at 1700°F, the solubility of carbides in the matrix is high enough to put a considerable amount of carbon into solution. On cooling from this temperature, the decrease in solubility results in precipitation of carbides containing a high proportion of chromium. If the cooling is moderately rapid, this causes the matrix adjacent to the carbides to be depleted of chromium and therefore susceptible to corrosion.

Most of the effects of alloying elements observed in this work are consistent with the chromium depletion mechanism. Thus, molybdenum is not a very strong carbide former and is a ferrite stabilizer, so it would not be expected to have much effect on the tendency

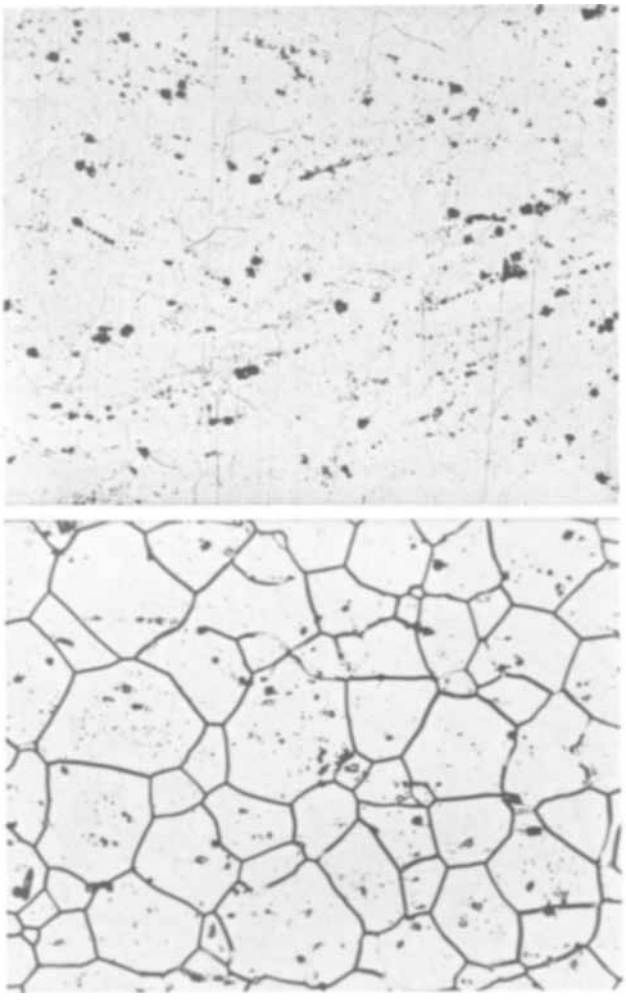

Fig. 4. Appearance of electrodes of 18% Cr-2% Mo-0.47% Ti alloy after heat treatment at 1500° or 1900°F for 2 hr and potentiostatic polarization in sulfuric acid at 1.1V *vs.* SCE: *top*—heated at 1500°F, *bottom*—heated at 1900°F. Original magnification 250X.

of a fully ferritic stainless steel to become sensitized to intergranular corrosion when heated above 1700°F.

The sensitivity to intergranular corrosion produced in molybdenum-containing steels on cooling slowly from temperatures of 1500°F or less is probably not caused by carbide precipitation. Rather, it is most probably a result of the same phenomenon as that which produces the so-called 885°F embrittlement. It has been shown that this embrittlement is the result of formation of a chromium-iron phase containing about 80% chromium (14), which either leads to local chromium depletion that causes susceptibility to preferential attack in nitric acid, or the chromium-rich phase itself is attacked by the highly oxidizing nitric acid. Evidently the function of molybdenum is to accelerate the precipitation reaction sufficiently so that it occurs when the ferritic alloys are cooled slowly through temperatures in the range of 900°F. As can be seen from Fig. 1, this form of sensitization can be eliminated by quenching from 1500°F.

The effects of nickel additions on intergranular corrosion are evidently a consequence of the tendency of nickel to promote the formation of austenite at the sensitizing temperature. This austenite will contain much of the carbon present, leaving the ferrite depleted. Consequently, a continuous chromium carbide precipitate is less likely to form at the grain boundaries. As a result, a continuous chromium-depleted region is not present for intergranular corrosion to follow. Since austenite does not form at the very high temperatures encountered in welding, the partitioning of carbon does not occur to an extent sufficient to prevent formation of continuous chromium-depleted zones. Baerlecken *et al.* (7) also found that austenite-forming alloy additions were ineffective in preventing intergranular corrosion after very high-temperature heat treatment.

On the other hand, titanium additions do prevent sensitization to intergranular corrosion even by welding, at least with respect to conditions represented by the Strauss test. Titanium carbides and possibly nitrides are formed in preference to chromium-rich precipitates so that no chromium-depleted zone is present. However, a grain boundary network of titanium carbides does form after heat treatment at 1900°F or welding. The network was severely attacked in the boiling 65% nitric acid test. The results of Bäumel (15) showed that bulk titanium carbide is attacked at oxidizing potentials corresponding to the oxidation potential of boiling nitric acid.[1] Evidently, the presence of up to 2% nickel or molybdenum has no effect on the tendency for formation of a grain boundary precipitate of titanium carbonitride that is attacked by boiling nitric acid.

The performance of columbium as a stabilizing addition was very similar to that of titanium with respect to the Strauss test results. Presumably, the mechanism leading to stabilization against intergranular attack is the same for titanium and columbium. However, columbium is also effective in reducing intergranular attack even in boiling nitric acid, which is also consistent with the work of Bäumel (15), who found that bulk columbium carbide was not attacked at oxidizing potentials up to and considerably beyond the oxidation potential of concentrated nitric acid.

Conclusion

Ferritic stainless steels containing molybdenum attain maximum resistance to intergranular corrosion in highly oxidizing media when cooled from 1500°F as rapidly as possible.

Titanium additions of about six times the combined carbon and nitrogen content, all in weight per cent, prevent intergranular corrosion as long as the corrodent medium is not strongly oxidizing.

Columbium additions of about eight times the combined carbon and nitrogen content minimize intergranular corrosion even under highly oxidizing conditions.

Nickel additions of up to 2% raised the temperature required to sensitize these steels, but provided as-welded steel with no protection against intergranular corrosion.

Minimizing Aluminum-to-Silicon Contact Resistance

G. McNeil

Fairchild Semiconductor, Research and Development Laboratory, Palo Alto, California

ABSTRACT

The effects of various alloy temperatures and times on aluminum-to-silicon contact resistance were determined using a special test vehicle that simulated integrated circuit processing. Contact resistance was measured to both p- and n-type doped silicon. The electrical data are summarized to show at what alloy conditions minimum contact resistance occurs.

Aluminum-to-silicon contacts have been used in integrated circuits for several years. Various alloy[1] conditions have been tried in processing, but until now no one has proved that a particular alloy cycle gives the lowest contact resistance.

In order to study the effects of various alloy conditions on contact resistance, a special test vehicle was designed. The test vehicle minimized the aluminum and silicon sheet resistances while maximizing the aluminum-to-silicon contact resistance. Figure 1 shows a cross section of the test vehicle. The test vehicle used polished silicon wafers that were subjected to typical integrated circuit diffusion and oxidation processes. An n^+-type layer simulating an emitter was diffused into p-type wafers, and a p-type diffusion representing a base was diffused into n-type wafers. After oxidation, the surface concentrations were 3 x 10^{20} cm^{-3} and 7 x 10^{18} cm^{-3}, respectively. Ten equal-sized contact holes were then etched in the oxide. The wafers received a 10-sec 10:1 HF dip before 1μ of aluminum was evaporated. The aluminum was etched so that alternate pairs of contact holes were connected by either 0.2-mil long metal or 0.6-mil long silicon, resulting in ten aluminum-silicon contacts in series. After alloying in nitrogen, the vehicle was tested with a 4-point probe (shown in Fig. 1) to avoid the problem of variable contact resistance between the probe and the wafer. A constant current of 10 mA was passed through the two outer probes and the voltage drop was measured between the two inner probes, with a Kintel high-impedance input microvoltmeter, model 202B. The shallow diffusions (0.9μ n^+ and 1.5μ p) kept the current near the surface and since, the silicon sheet resistance was much greater than that of the metal, most of the current would pass through the ten contacts.

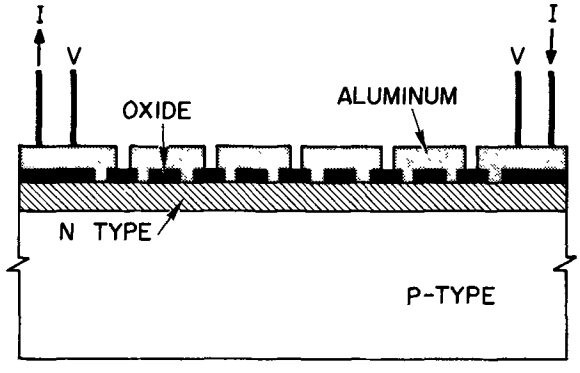

Fig. 1. Contact resistance test vehicle

Results

For each alloy condition at least 20 dice on each of three wafers were measured for each data point. The tests were repeated on a separate lot of wafers with similar results. Table I shows the effects of alloying at 500°, 550°, and 565°C on contact resistance. The numbers listed in the columns below the surface concentrations are measured resistances. The surface concentrations were measured with a 4-point probe. The measured resistance contains the silicon sheet resistance caused by the 0.6 mil between contacts, the small resistance from the aluminum, and the contact resistance of ten equal-size contacts. This is based on the assumption that all the current flows through the contacts. If this is not the case, then the actual contact resistance will be greater than indicated in this paper, but the condition of minimum contact resistance will not change. Each test pattern had three sets of contact holes. The hole size in each set was 0.2 x 0.2 mil, 0.2 x 0.8 mil, and 0.4 x 0.4 mil. Since the wafers were processed together, except for alloying, the only variable involved in the measured resistance was the contact resistance due to alloying. Therefore, any change in measured resistance corresponds to an equal change in contact resistance.

From Table I, it is obvious that two trends are present. For silicon with 7 x 10^{18} cm^{-3} p-type surface concentration, there is very little change in contact resistance when alloyed in the 500°-565°C range. However, for n^+ silicon, there is a great change in contact

[1] The term "alloy" is used in this paper as it is used in the semiconductor industry. Even though the temperature is below the silicon-aluminum eutectic, the heat treatment step to achieve a low aluminum-silicon contact resistance is referred to as an alloy.

Minimizing Aluminum-to-Silicon Contact Resistance

G. McNeil

Fairchild Semiconductor, Research and Development Laboratory, Palo Alto, California

ABSTRACT

The effects of various alloy temperatures and times on aluminum-to-silicon contact resistance were determined using a special test vehicle that simulated integrated circuit processing. Contact resistance was measured to both p- and n-type doped silicon. The electrical data are summarized to show at what alloy conditions minimum contact resistance occurs.

Aluminum-to-silicon contacts have been used in integrated circuits for several years. Various alloy[1] conditions have been tried in processing, but until now no one has proved that a particular alloy cycle gives the lowest contact resistance.

In order to study the effects of various alloy conditions on contact resistance, a special test vehicle was designed. The test vehicle minimized the aluminum and silicon sheet resistances while maximizing the aluminum-to-silicon contact resistance. Figure 1 shows a cross section of the test vehicle. The test vehicle used polished silicon wafers that were subjected to typical integrated circuit diffusion and oxidation processes. An n^+-type layer simulating an emitter was diffused into p-type wafers, and a p-type diffusion representing a base was diffused into n-type wafers. After oxidation, the surface concentrations were 3 x 10^{20} cm^{-3} and 7 x 10^{18} cm^{-3}, respectively. Ten equal-sized contact holes were then etched in the oxide. The wafers received a 10-sec 10:1 HF dip before 1μ of aluminum was evaporated. The aluminum was etched so that alternate pairs of contact holes were connected by either 0.2-mil long metal or 0.6-mil long silicon, resulting in ten aluminum-silicon contacts in series. After alloying in nitrogen, the vehicle was tested with a 4-point probe (shown in Fig. 1) to avoid the problem of variable contact resistance between the probe and the wafer. A constant current of 10 mA was passed through the two outer probes and the voltage drop was measured between the two inner probes, with a Kintel high-impedance input microvoltmeter, model 202B. The shallow diffusions (0.9μ n^+ and 1.5μ p) kept the current near the surface and since, the silicon sheet resistance was much greater than that of the metal, most of the current would pass through the ten contacts.

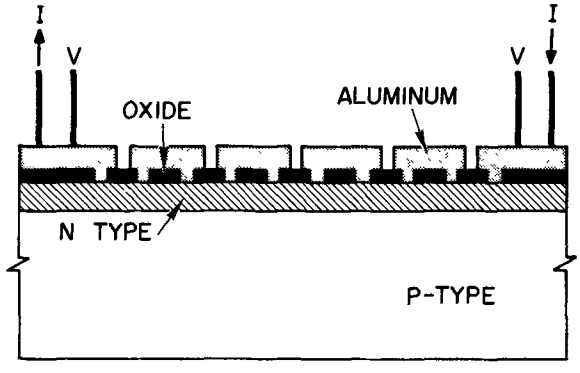

Fig. 1. Contact resistance test vehicle

Results

For each alloy condition at least 20 dice on each of three wafers were measured for each data point. The tests were repeated on a separate lot of wafers with similar results. Table I shows the effects of alloying at 500°, 550°, and 565°C on contact resistance. The numbers listed in the columns below the surface concentrations are measured resistances. The surface concentrations were measured with a 4-point probe. The measured resistance contains the silicon sheet resistance caused by the 0.6 mil between contacts, the small resistance from the aluminum, and the contact resistance of ten equal-size contacts. This is based on the assumption that all the current flows through the contacts. If this is not the case, then the actual contact resistance will be greater than indicated in this paper, but the condition of minimum contact resistance will not change. Each test pattern had three sets of contact holes. The hole size in each set was 0.2 x 0.2 mil, 0.2 x 0.8 mil, and 0.4 x 0.4 mil. Since the wafers were processed together, except for alloying, the only variable involved in the measured resistance was the contact resistance due to alloying. Therefore, any change in measured resistance corresponds to an equal change in contact resistance.

From Table I, it is obvious that two trends are present. For silicon with 7 x 10^{18} cm^{-3} p-type surface concentration, there is very little change in contact resistance when alloyed in the 500°-565°C range. However, for n^+ silicon, there is a great change in contact

[1] The term "alloy" is used in this paper as it is used in the semiconductor industry. Even though the temperature is below the silicon-aluminum eutectic, the heat treatment step to achieve a low aluminum-silicon contact resistance is referred to as an alloy.

		0.4 × 0.4	97	5.8

* Furnace recovery time ≈ 4 min as measured with a thermocouple in the wafer boat.

resistance when alloyed in this temperature range. It is evident that the more severe the alloy, the greater the contact resistance. The measured resistance increases by 5 ohms going from the least severe to the most severe alloy listed in Table I. This 5-ohm increase for ten contacts corresponds to a 0.5-ohm increase in contact resistance per contact.

This sharp increase in the measured resistance might be caused by the fact that the n^+ diffusion was relatively shallow and highly conductive. At the higher alloy temperatures, the silicon-aluminum interface moves rapidly down into the silicon. Since the n^+ diffused silicon increases quickly in sheet resistance as one goes deeper into the wafer, the increased measured resistance could be due to the increased silicon sheet resistance at the metal-silicon interface. Whatever the cause, this increase in resistance means more resistance within the circuit.

Since a 5-min, 500°C alloy gave the best results in Table I, alloy temperatures below 500°C were investigated as shown in Table II. Different trends were evident below 500°C. For the 7×10^{18} cm^{-3} p-type silicon, there was an increase in contact resistance when alloyed below 500°C. But the n^+ silicon, which had such a great change in contact resistance with alloy temperature above 500°C, showed very little change in contact resistance when alloyed in the 440°-500°C range. Wafers which had not been alloyed gave considerably higher and more erratic resistances than alloyed wafers. The typical spread across three alloyed wafers for a data point was ± 4%.

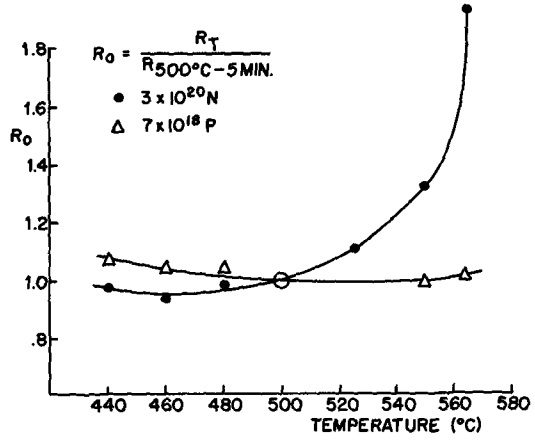

Fig. 2. Contact resistance vs. alloy temperature (10-min alloys)

Figure 2 is a plot of the data presented in Tables I and II. The basis of the normalized resistance, R_o, is the measured resistance after a 5-min, 500°C alloy, which was also the condition that gave the lowest contact resistance. The normalized resistance, R_o, equals the measured resistance after a given alloy divided by the measured resistance after a 5-min, 500°C alloy.

Conclusions

A 5-min, 500°C alloy gives the lowest contact resistance of aluminum to 7×10^{18} cm^{-3} p-type and 3×10^{20} cm^{-3} n-type silicon. Alloy conditions above 500°C greatly increase the contact resistance to n^+ diffused silicon. After punching through the film in the contact holes, overalloying will be quite damaging because it actually increases contact resistance.

Determination of Sodium in Furnace Atmospheres by Atomic Absorption Spectroscopy

T. E. Burgess and H. M. Donega

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The extremely low sodium vapor pressures which are present in hot quartz furnace tube atmospheres have been measured by atomic absorption spectroscopy. In the system described, sodium vapor pressures are measured between 10^{-6} and 10^{-9} Torr; however, this range can be extended by simple changes in optics and/or absorption cell length. The data show that the sodium vapor pressure in a new quartz tube changes slowly during heating until the rate of sodium in-diffusing from the hot ceramic liner is balanced by the rate of sodium out-diffusing to the cooler portions of the system. If the design of the furnace tube system is such that the source of the sodium, the furnace liner, is separated by an air space from the inner quartz tube, then the equilibrium sodium vapor pressure inside this tube may be decreased at least tenfold. Foreign gas composition has little effect on the sodium vapor pressure, providing no chemical reactions occur in the system. However, the reaction of hydrogen with the quartz surface results in a marked increase in the sodium vapor pressure. The system described may be easily adapted for determination of other contaminant vapors which could be present in hot quartz furnace tube atmospheres.

The detection of trace amounts of impurities in semiconductors which adversely affect their electrical characteristics continues to be a source of problems which tax the limits of most analytical methods. Analyses for these micro amounts of contaminants require more sophisticated approaches and specialized equipment than are usually used in routine problems.

The effect of sodium contamination on the electrical properties of silicon oxide and silicon nitride films has been the subject of many investigations (1-6). The distribution of this contaminant in these films and on cleaned silicon surfaces has been studied by flame emission, radiotracer, and neutron activation analytical methods (7-11). The main source of this impurity has been suggested to be the furnace tube and liner in which oxidation and diffusion reactions occur (4).

Analysis of furnace atmospheres for contaminants such as sodium ideally should be carried out under conditions which at least approach those used during actual operation when these contaminants become a problem. This report concerns the development of an atomic absorption method whereby the vapor pressure of sodium and that of many other trace elements can be measured at high temperatures over materials such as firebrick, mullite, quartz, and other ceramics or contaminated surfaces employed in furnace tube construction or subjected to high temperatures in production processes.

Theory

Atomic absorption spectroscopy is the study of absorption of resonance lines by free atoms in the vapor phase. In the process, radiant energy is absorbed by ground state atoms, and the outer valance electrons are excited. Measurement of the absorption of radiant energy and its relation to the number of absorbing atoms is the basis for this analytical procedure.

The relationship of the concentration of free atoms in the vapor phase to the absorption of radiant energy can be represented by equations and has been thoroughly discussed by several authors (12-17). These equations, which account for the various line-broadening phenomena occurring in the absorption process, are used to arrive at the results reported here.

If a parallel light beam of intensity, I_o, and frequency, ν, is allowed to pass through an absorbing media, x centimeters long, then the transmitted light I_ν, will be given by:

$$I_\nu = I_o e^{-K_\nu x} \qquad [1]$$

where K_ν is the absorption coefficient of the gas at frequency, ν.

This basic equation is modified to correct for certain line-broadening phenomena which tend to decrease absorption and reduce sensitivity. The most important of these are Doppler and Lorentz broadening. Doppler broadening is due to the random motion of the absorbing atoms and requires that the absorption coefficient, K, be modified to include the partial pressure of the absorbing atoms. Lorentz broadening is due to the presence of the foreign gas and introduces terms depending on its composition and partial pressure.

Equation [2] is derived from Eq. [1] by incorporating corrections for Doppler and Lorentz broadening, the sodium spectrum hyperfine structure and sodium oscillator strength.

$$\frac{I}{I_o} = \tfrac{3}{8} \exp\left(-A\frac{Px}{T^{3/2}}\right) + \tfrac{5}{8} \exp\left(-B\frac{Px}{T^{3/2}}\right) \qquad [2]$$

In Eq. [2], the experimentally measured quantity, I/I_o, is related to the partial pressure of the absorbing species. This equation in addition to P, the partial pressure of the sodium atoms, includes two constants, A and B, whose values depend on temperature, molecular weight, and pressure of the foreign gas. The reader is directed to the work of Vidali (16) for the complete review of this derivation.

Figure 1 shows a series of curves obtained by solving Eq. [2] with the aid of an IBM 1130 computer for selected values of I/I_o and certain experimental parameters. This particular set of curves shows the relationship between sodium vapor pressure and transmittance at three different partial pressures of argon. Between transmittance values of 0.1 and 0.9, this relationship is nearly linear and has a reasonably small slope. Beyond these values, the sensitivity of the method drops rapidly as the slopes approach infinity. By comparing the three curves, it can be seen that the effect of a foreign gas pressure of < 200 Torr on the relationship represented by the curves is small and, in fact, below 20 Torr the effect is insignificant. Foreign gas pressures used in these experiments were easily controlled to within a few Torr.

The influence of temperature on the relationship is somewhat less than that of foreign gas pressure. In the vicinity of 1300°K where most of these measurements were made, a 200° change in temperature has about the same effect as a 200-Torr change in pressure at the 100-Torr level.

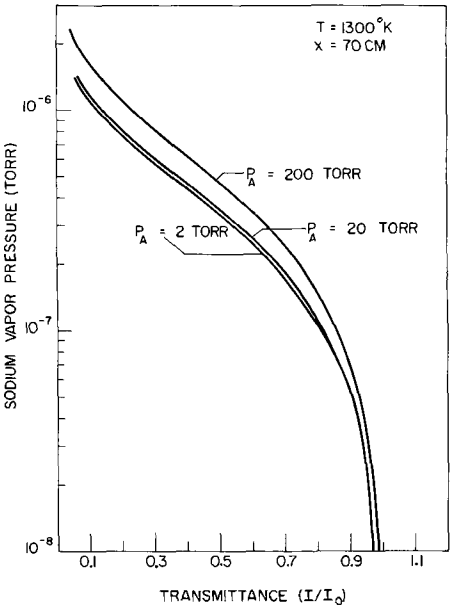

Fig. 1. Effect of foreign gas pressure on transmittance.

Since the transmittance, I/I_0, is a function of the product of the sodium vapor pressure, P, and the absorption path length, x, then any increase in this path length will increase the sensitivity of the method. For example, a change of path length from 10 to 70 cm increases the sensitivity 7 times. The curves shown in Fig. 1 were calculated for an absorption path length of 70 cm.

It is apparent from Eq. [2] that the substitution of appropriate values for the molecular weight of any foreign gas will produce curves very similar to those shown in Fig. 1. However, if the foreign gas has an influence on the ground state atom population of the absorbing element, then a corresponding influence will be observed in the transmittance. For example, oxygen would be expected to react with sodium at the temperatures used in this experiment and would reduce the ground state atom population by formation of the oxide. Although the amount of sodium in the atmosphere could remain unchanged, the sodium ground state atom population would be reduced and a corresponding decrease in absorption would be observed. Similar reactions could be expected such as reactions between foreign gases and quartz tube walls which would result in an increase in sodium vapor pressure.

If the conditions of temperature, foreign gas pressure, composition, and cell length described in Fig. 1 are met, then these curves may be used to determine the actual sodium vapor pressure existing in a tube furnace. These or similar curves calculated for the specific conditions of the experiment were used in this work.

Equipment

Measurements were made with an atomic absorption spectrophotometer which consisted of a hollow cathode light source and power supply, tube furnace, quartz furnace tube with quartz end windows, monochromator, strip chart recorder, lenses, chopper, and optical bar. A diagram of the optical system is shown in Fig. 2. Each element in the system was firmly mounted on a two-meter optical bar and a heat shield was placed between the furnace and the monochromator to reduce the effect of temperature changes on the monochromator optical system.

The light source was a Jarrell-Ash model #45-585 neon-filled hollow cathode sodium lamp which was operated from a Jarrell-Ash hollow cathode power supply. During operation, the lamp required about 30 min of warm-up before a stable source was obtained. The output from a Zeiss model M4Q III monochromator

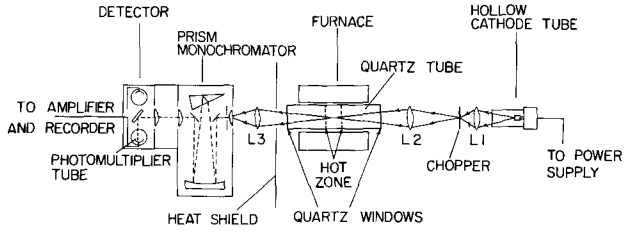

Fig. 2. Optical path diagram

and a model PMQ II indicator unit was monitored with a Sargent model SR strip chart recorder. The regular chopper in the Zeiss monochromator was disconnected for this application, and an external chopper of the same design, phase-locked to the photomultiplier a-c amplifier, was placed in the light beam between the lamp and the furnace. Only the modulated light from the hollow cathode lamp was amplified with this arrangement, and interference from stray radiation was avoided.

A 23-cm-long tube furnace with Kanthal windings on a 52-mm ID Norton Alundum-98 winding core was used as the means of producing the atomic vapor. This furnace was capable of reaching 1378°K and had a flat zone of about 5 cm at 1323° ± 5°K. The furnace temperature was controlled by a platinum-platinum 10% rhodium thermocouple connected to a Honeywell Regulator in the power supply. The temperature was regulated to within a few degrees of the setting at the upper end of the heating range. The furnace was mounted on a hinged platform which allowed it to be easily removed from the light path to permit calibration of the spectrophotometer during the heating cycle.

Two types of quartz furnace tubes fabricated from G.E. #204 quartz were used in this study. The tube shown in Fig. 2 which extended well beyond the hot zone had an outside diameter of 42 mm and an overall length of 70 cm. It was fitted with standard taper joints, fused quartz windows at each end, and an inlet for control of the foreign gas atmosphere within the furnace tube. The second tube which was designed to fit completely within the hot zone was only 5 cm long with an outside diameter of 38 mm. This tube was used to observe absorption where diffusion of the sodium vapor to cooler portions of the tube could not occur.

Results and Discussion

The system described in the preceding section allowed the sodium vapor level to be monitored in quartz furnace tubes under a variety of operating conditions.

Figure 3 shows the decrease in sodium vapor pressure in the furnace atmosphere which occurred upon extended heating of a new quartz 70 cm tube at 1323°K using a foreign gas mixture of 80% N_2 and 20% H_2 (forming gas) at 200 Torr. All the measurements were not made during one continuous heating period, but for various practical reasons three or four cooling and heating cycles were involved and actual measurements were made on three different days. Only the actual time at the selected temperature is plotted here.

The rapid decrease of the sodium vapor pressure from 16.5×10^{-8} to 7.0×10^{-8} Torr during the first 2 hr of heating is due to superficial cleaning of the quartz surface. The gradual decline in sodium vapor pressure after 2 hr of heating is caused by the approach of an equilibrium between the sodium in-diffusing from the furnace liner through the quartz tube at the hot zone and the sodium out-diffusing from the hottest area to the cooler parts of the tube. These results indicate that the preheating of new furnace tubes for several hours before their use for oxidation or other production procedures will result in a less contaminated operation.

Existence of this equilibrium is demonstrated by the fact that changes in the system, especially those

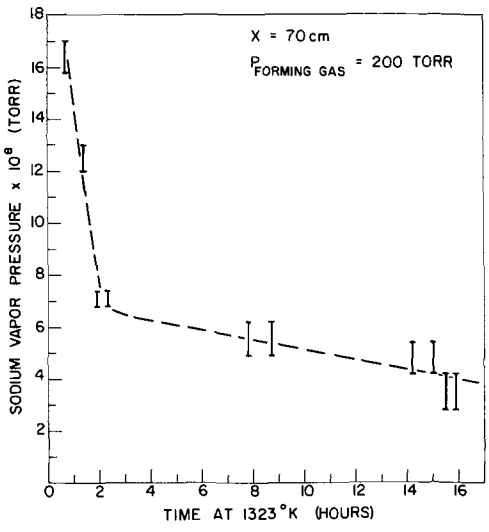

Fig. 3. Approach of equilibrium sodium vapor pressure in new quartz furnace tube.

which result in a shift of the "hot zone," are immediately reflected in the sodium vapor pressure level. For example, when the position of the quartz tube was shifted laterally 2.5 cm, the sodium vapor pressure reached after 16 hr of heating at 1323°K immediately increased from 3.5 x 10^{-8} to 5.0 x 10^{-8} Torr. Large instantaneous increases in the sodium vapor pressure occurred when rapid changes were made in the foreign gas pressure. Sodium vapor pressures as high as 10^{-6} Torr were observed at these times with a few minutes required for the sodium level to return to its equilibrium value of 10^{-8} Torr. These high sodium vapor pressures are caused by the disturbance of the equilibrium flow of sodium in the furnace atmosphere. Such temporarily high sodium levels in the furnace atmosphere could easily result in sodium contamination of products which are being treated in an otherwise "clean" system.

The influence of various furnace tube arrangements on the sodium vapor pressure within the tube is shown in Table I. These measurements were all made at 1323°K in a 200-Torr H_2 atmosphere. The equilibrium sodium vapor pressure in the 5-cm tube, fitting entirely within the hot zone with its walls touching the ceramic liner, was 7.2 x 10^{-7} Torr. The equilibrium sodium vapor pressure in this tube under the same conditions except with the quartz tube walls separated from the ceramic liner by an air space was below the detection limit of 5.2 x 10^{-8} Torr. In this case, sodium coming from the ceramic diffused from the hot portion of the furnace through the space between the ceramic and the quartz to the cooler parts of the system without penetrating the quartz walls.

The equilibrium sodium vapor pressure level in the 5-cm tube, 7.2 x 10^{-7} Torr, is much higher than that measured in the 70-cm tube, 6.4 x 10^{-8} Torr. This is contrary to what might be expected since the 70-cm tube with a larger diameter and a greater surface area in the hot zone should have favored the release of sodium into the furnace atmosphere. The results observed can be explained by the ease with which sodium inside the 70-cm tube can diffuse from the hot area to the cooler zones of the tube. In the case of the 5-cm tube, this can only occur by diffusion through the quartz end windows.

The effectiveness of a simple multiwalled tube system in lowering the sodium contamination level within the furnace was measured. The sodium vapor pressure in a 70-cm quartz furnace tube, previously contaminated with a small amount of sodium oxide, was lowered from 9.4 x 10^{-7} to 7.6 x 10^{-8} Torr by placing a second quartz tube inside the original tube, leaving a 1-mm space between the walls of the concentric tubes. This space allowed the sodium vapor to diffuse to the cooler portions of the system without penetrating into the inner furnace atmosphere.

Theoretically, for a given partial pressure of sodium, the I/I_0 observed will differ with the composition and pressure of the foreign gas. However, these effects are accounted for in Eq. [2]. If the proper values are used in its solution, the same partial pressure of sodium is obtained for each set of parameters.

Some experimentally measured equilibrium sodium vapor pressures obtained for the same 70-cm tube at 1357°K with different foreign gas compositions and pressures are shown in Table II. The same sodium vapor pressure within the precision of the measurement was observed for each of three inert gases at 2 and 200 Torr; however, in the presence of H_2, the sodium vapor pressures measured were considerably higher. These results reflect the reaction of H_2 at the quartz surface releasing sodium into the furnace atmosphere. The reaction of H_2 with a quartz surface has been previously proposed by Fewer and Gill (4).

Summary

Atomic absorption spectroscopy has been used to measure low sodium vapor concentrations present in hot quartz furnace tubes. Sodium vapor pressure measurements show that an equilibrium level is reached when the rate of sodium in-diffusing from the furnace liners through the quartz walls is equal to the rate of sodium deposition on the cooler portions of the system. In the case of a new quartz furnace tube, several hours of heating may be required before this equilibrium is established. Inert foreign gases present in the quartz tube have no effect, but chemical reactions of other gases with components in the system are possible which will change the measured sodium vapor concentration. The sodium contamination level of the furnace atmosphere may be decreased as much as tenfold by a simple multiwalled tube system.

Studies on Chlorate Cell Process

V. Theory and Practice of a Modified Technology for Electrolytic Chlorate Production

M. M. Jaksić,* A. R. Despić, I. M. Csonka,[1] and B. Z. Nikolić

Electrochemistry Department, Institute of Chemistry, Technology and Metallurgy, Beograd, Yugoslavia

ABSTRACT

A modified technology for electrolytic chlorate production has been developed. The cell is considered as a hypochlorite generator and the holding volume as a reactor for the conversion of available chlorine to chlorate. The holding volume is operated at an elevated temperature. The process as a whole then leads to higher current efficiencies. For such a closed-loop system, theoretical relationships were established between the current efficiency and other determining factors. These relationships were confirmed experimentally. Foerster's theory of electrolytic chlorate formation has also been confirmed by the present results.

Maximum current efficiency in chlorate production, according to Foerster (1, 2) is obtained when the conversion of hypochlorous acid and hypochlorite, *i.e.* the total available chlorine[2]

$$C_s = [HClO] + [ClO^-] \quad [1]$$

into chlorate occurs only by the chemical reaction

$$2HClO + ClO^- + 2H_2O \rightarrow ClO_3^- + 2Cl^- + 2H_3O^+ \quad [2]$$

However, almost unavoidably a simultaneous anodic oxidation of available chlorine to chlorate takes place, accompanied by oxygen evolution, *i.e.*

$$6ClO^- + 9H_2O \xrightarrow{6e} 2ClO_3^- + 6H_3O^+ + 4Cl^- + 3/2\,O_2 \quad [3]$$

and this represents an unnecessary loss of current.

The cathodic reduction of hypochlorite ions is also possible, but is usually eliminated by adding small amounts of dichromate to the electrolyte (3).

Let the anodic evolution of chlorine with successive hydrolysis and conversion into chlorate by reactions [2] and [3] be considered as the useful process, resulting in the current efficiency, t_1. In a closed-loop system in which the electrolyte is circulated between the cell and a holding volume (Fig. 1), the quasi steady state attained in respect to the available chlorine is characterized by the balance in the cell (*see* Appendix I):

$$V_c\left(\frac{dC_{sc}}{d\tau}\right) = \frac{(3t_1 - 2)\cdot I}{2F} - 3f_c^2 \cdot k_{r,c} \cdot V_c \cdot [HClO]_c^2 \cdot [ClO^-]_c - q(C_{sc} - C_{sh}) = 0 \quad [4]$$

where I represents the total current; f_c is the activity coefficient of hypochlorous acid; $k_{r,c}$ is the rate con-

[1] Present address: "Jugovinil," Kastel Sucurac, Split, Yugoslavia.
[2] The term "available chlorine" comprises the sum of concentrations of the hypochlorite ions, hypochlorous acid, and of the molecular chlorine in solution. Under operating conditions of chlorate cells and in all our experiments, the concentration of the molecular chlorine was negligible.

stant for reaction [2]; V_c is the volume of the electrolyte in the cell; and q is the flow rate. Subscripts h and c shall refer, throughout, to the quantities relating to the holding volume and the cell, respectively.

The first term of Eq. [4] takes care of the generation of available chlorine by the current, the second term represents the chemical conversion to chlorate in the cell, while the third term represents the difference in the amount of available chlorine leaving the cell and entering the cell from the holding volume. Equation [4] assumes that the cell works as a back-mix flow reactor.

One should note that losses due to evaporation of chlorine and hypochlorous acid in the stream of the evolving hydrogen, as well as that due to cathodic reduction of available chlorine and its catalytic decomposition, are neglected.

Hence, for the usual conditions of chlorate production, the current efficiency can be obtained from Eq. [4] as

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} [HClO]_c^2 \cdot [ClO^-]_c + \frac{2}{3}\mathbf{F}\left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) \quad [5]$$

The concentrations of hypochlorous acid and hypochlorite ions in Eq. [4] and [5] are difficult to assess analytically. However, they can be replaced by the concentration of available chlorine. Thus, the thermodynamic dissociation constant of hypochlorous acid is

$$K_a = \frac{a_{H3O+} \cdot f_{ClO-} \cdot [ClO^-]}{f \cdot [HClO] \cdot a_{H2O}} \quad [6]$$

or, rearranging (*cf.* [7])

$$K^* = \frac{a_{H3O+} \cdot [ClO^-]}{[HClO]} = K_a \cdot \frac{f \cdot a_{H2O}}{f_{ClO^-}} \quad [7]$$

Using Eq. [7] with [1], one can find the concentrations of hypochlorous acid and introduce them into Eq. [5]. One obtains

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot \frac{K_c^* \cdot (a_{H3O+})_c^2 \cdot C_{sc}^3}{[K_c^* + (a_{H3O+})_c]^3} + \frac{2}{3}\mathbf{F} \cdot \left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) \quad [8]$$

Separately, and if the holding volume is considered as a back-mix flow reactor, the material balance in it renders as follows

$$q(C_{cs} - C_{sh}) = 3 \cdot f_h^2 \cdot k_{r,h} \cdot V_h \cdot [HClO]_h^2 \cdot [ClO^-]_h \quad [9]$$

From Eq. [1], [7], and [9], it follows

$$q(C_{sc} - C_{sh}) = 3f_h^2 \cdot k_{r,h} \cdot V_h \cdot \frac{K_h^* \cdot (a_{H3O+})_h^2 \cdot C_{sh}^3}{[K_h^* + (a_{H3O+})_h]^3} \quad [10]$$

Replacing this into Eq. [8], one obtains

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot \frac{K_a^* (a_{H3O+})_c^2 \cdot C_{sc}^3}{[K_c^* + (a_{H3O+})_c]^3} + \frac{2f_h^2 \cdot k_{r,h} \cdot V_h \cdot \mathbf{F}}{I} \cdot \frac{K_h^* (a_{H3O+})_h^2 \cdot C_{sh}^3}{[K_h^* + (a_{H3O+})_h]^3} \quad [11]$$

Equation [11] shows that current efficiency can be treated as dependent on the operation of two parts of the chlorate production system, *i.e.* electrolytic cell and the holding volume. So far the two parts were considered isothermal, and the temperature in industrial electrolysis was limited by the graphite corrosion wear, which increases with the latter. This has placed limits to the value of the rate constant for the chemical conversion of hypochlorite to chlorate and hence to the increase of t_1. Actual t_1 values in usual production practice are known to be about 80% (16).

In the present treatment, it is seen that an increase in t_1 can be obtained if the holding volume, as a separate unit, is heated to higher temperatures than the cell, for the usual exponential dependence of the rate constant may make the third term in Eq. [11] significantly larger.

Since this possibility of increasing the current efficiency may be of considerable practical importance, the validity of Eq. [11] and its consequences are investigated in the present work.

Experimental

The apparatus used for the experiments is shown in Fig. 1. The cell was made of hard PVC (Fig. 2). A continuous flow of the electrolyte and a magnetic stirrer provided conditions of operation of a back-mix flow reactor. The overflow mantle allowed the separation of gas bubbles from the electrolyte prior to leaving the cell. Temperature in the cell was maintained constant by circulating the thermostat liquid through a cooling coil. The majority of experiments were carried out at a cell temperature of 25°C. The *p*H value of the outflow was controlled and maintained constant to ±0.1 *p*H unit by adding acid or base from an automatic titrator. Cell volume was 600 cm³.

The flow of electrolyte was provided by means of a membrane pump made of PVC, and was controlled by a differential manometer as a flow meter.

The flow rate could be varied from 1 to 4 liters/hr.

Two different holding volumes were used, 1.0 and 2.0 liters. A stirrer was used to provide the conditions of a back-mix flow reactor. The holding volume was thermostated to temperatures of 15.0°, 25.0°, 40.0°, 60.0°, and 80.0°C.

The electrolyte was 300 gpl of NaCl and 2.4 and 8 gpl of sodium dichromate. Electrolysis was carried out to 30 gpl of sodium chlorate, whereupon the electrolyte was renewed.

*p*H values in the cell were varied between 6.0 and 8.0 and currents of 2.0, 4.5, 9.0, and 12.0A, or current densities of 2.96-17.8 A/dm^{-2} were used.

Platinum gauze electrode used as the anode was of 67.5 cm² of active surface area.

Several quantities were measured simultaneously: the pH, the total available chlorine of inflowing and outflowing electrolyte (C_{sc}) and (C_{sh}), respectively, and the chlorine and oxygen content in the evolving gas. The total amount of the latter was measured with time using a soap bubble flow meter [17] and the amount of hydrogen was obtained by subtracting the amounts of oxygen and chlorine. The results of such a gas analysis were used to determine the current efficiency (*see* Appendix II).

Results and Discussion

A typical set of experimental data is given in Table I.

Under conditions where the chemical conversion inside the cell can be neglected (small cell volume and low temperature relative to those of the holding volume), Eq. [8] reduces to

$$t_1 - 2/3 = 2/3 \cdot \mathbf{F} \cdot (q/I) \cdot (C_{sc} - C_{sh}) \qquad [12]$$

The left-hand side gives a measure of the chemical conversion in the holding volume. If this is plotted as a function of $(q/I) \cdot (C_{sc} - C_{sh})$, a straight line should be obtained with a slope of 2/3 · **F**. Figure 3 represents the plot of the obtained experimental data.

The points are seen to follow fairly well the expected relation over the whole range of different q and I values, as well as over the range of holding volume temperatures whose effect is implicitly contained in $(C_{sc} - C_{sh})$.

This represents an experimental confirmation of the validity of the derived Eq. [12], and essentially also an additional confirmation of the validity of the Foerster equations (1, 2). Deviations should be due mostly to the fact that in some circumstances of relatively close temperatures in the two parts of the system the chemical conversion inside the cell was not negligible. The points near to the origin correspond to high pH values and low temperatures rendering relatively low current efficiencies (*see* Table I). Conversely, upper points reflect higher temperatures and lower pH values of the holding volume.

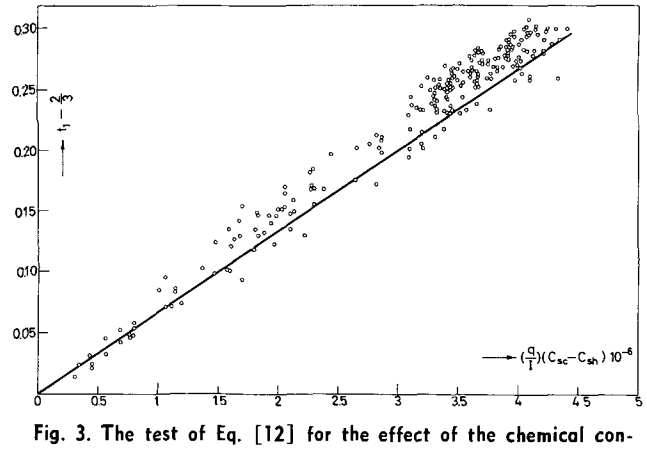

Fig. 3. The test of Eq. [12] for the effect of the chemical conversion in the holding volume. The solid line represents the theoretical slope.

The dependence of t_1 on holding volume temperature is not a straightforward one. One should have in mind that in addition to $k_{r,h}$, the effect of C_{sh} in Eq. [11] is also temperature dependent in a complex manner. This can be understood as follows. Equation [5], to which all others are related, merely reflects the Faradaic stoichiometry which determines that, the larger t_1, the higher should be the accumulation of available chlorine in the cell $(C_{sc} - C_{sh})$. However, there is an intrinsic reason, arising from the hydrodynamics of the problem (8), that the converse is true. An increasing C_{sc} decreases t_1, because of increased direct anodic oxidation of available chlorine. For this reason, although one should attempt to have $(C_{sc} - C_{sh})$ as large as possible, one should at the same time try to keep the C_{sc} as low as possible.

The C_{sc} can be lowered and yet $C_{sc} - C_{sh}$ increased if the removal of available chlorine from the cell is speeded up and at the same time the rate of conversion of available chlorine in the holding volume is increased by increasing the temperature. However, this possibility is obviously limited by two factors: (*a*) The increase in the rate of conversion with temperature must show an asymptotic tendency to some maximum value, in spite of the fact that the rate constant is increasing, because the concentration factor in the rate expression decreases with the third power; (*b*) the increase in the difference $C_{sc} - C_{sh}$ can be achieved only as long as C_{sh} is significant compared to C_{sc}.

The effect of temperature on t_1 at a constant pH in the holding volume is show in Fig. 4. It is seen to exhibit the expected asymptotic tendency toward a t_1 value determined by the hydrodynamic conditions in the cell at inflowing available chlorine concentration, C_{sh}, considerably smaller than the one generated by the cell process, C_{sc}. At large enough flow rates to make C_{sc} relatively as low as the one used in the given experiment, this value of t_1 is seen to approach unity.

When controlling the pH in the holding volume, it was found that the rates of conversion increased when pH was changed from the region of 7.0-7.5 [believed in literature to be optimal (4, 5, 6)] to the region of 6.0-6.5. This matter was discussed in detail elsewhere (7).

One should note also that our measurements show that, if a pH of 8.0 is maintained in the cell, the lowest efficiency of 66.7% is not obtained at temperatures of the holding volume other than 25°C or lower. At any higher temperatures the efficiencies are higher, since chemical conversion makes the expected contributions.

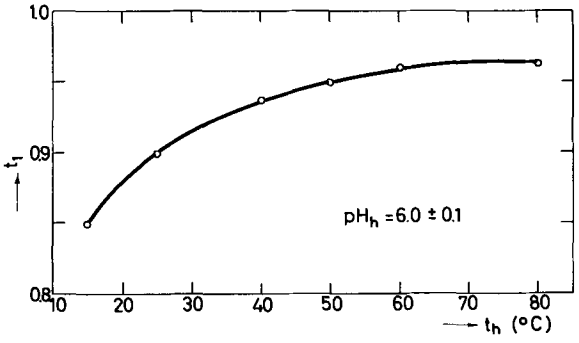

Fig. 4. The dependence of current efficiency on temperature of the holding volume at constant $pH_h = 6.0$, $I = 4.5A$, $q = 2.95$ liters/hr, $V_h = 2.2$ liters.

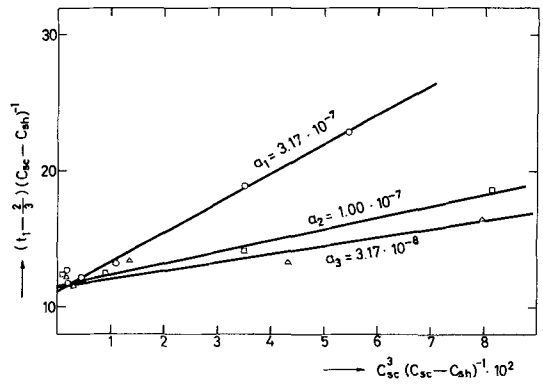

Fig. 5. y vs. x graph (Eq. [13] and [14]) for different pH of the cell electrolyte.

The effect of increasing flow rate, q, was also confirmed. This is not to be taken, however, as evidence of the effect of the linear velocity of flow past the electrodes [cf. Despić, Jaksić, and Nikolić (8)], but rather reflects a decreasing apparent current density per unit volume with increase in flow rate, and consequently smaller C_{sc} values.

Another way of testing Eq. [8] and its consequences was found in the following rearrangement

$$\frac{t_1 - \frac{2}{3}}{C_{sc} - C_{sh}} = \frac{2}{3} \cdot \frac{\mathbf{F} \cdot q}{I} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot \frac{K_c^* \cdot (a_{H_3O^+})_c^2}{[K_c^* + (a_{H_3O^+})_c]^3} \cdot \frac{C_{sc}^3}{C_{sc} - C_{sh}} \quad [13]$$

which is of the type

$$y = m + px \quad [14]$$

It is seen that if y is plotted *vs.* x for each constant pH value of the cell and constant q/I ratio, a straight line should be obtained. A set of results to be interpreted in this way is given in Table II. The resulting dependence [13] is seen in Fig. 5.

The slopes are seen to be functions of pH. By a digital computer analysis of pairs of slopes, the average value of the two unknown constants contained in them, $k_{r,c}$ and K_c^*, could be found since other parameters were known. The result was

$$k_{r,c} = 0.0304 \text{ liters}^2/\text{mole}^2 \cdot \text{sec}$$

$$K_c^* = 1.6 \cdot 10^{-7}$$

The rate constant, $k_{r,c}$, is in agreement with the value obtained by Foerster (1, 2). The dissociation constant is an order of magnitude higher (*cf.* [12]) than the known thermodynamic value in dilute solutions (*cf.* [9], [10]). This is in accordance with the fact discussed elsewhere (7), that the activity coefficient of hydrogen ions in the concentrated electrolyte is about 10.

The approach used seems to offer an interesting possibility for kinetic analysis of other similar systems consisting of back-mix flow reactors in a loop.

Figure 3 shows that, using appropriate conditions of electrolysis and chemical conversion in the described system, it is possible to obtain current efficiencies as high as 96% which are not reached in the usual practice of isothermal circulation in the chlorate cell process with graphite anodes.

Our measurements with graphite anodes in the same apparatus (Fig. 1) show that, other conditions being equal, graphite electrodes yield about the same current efficiency as platinum, although a systematic difference of about 2% seems to exist. Shliapnikov and Filippov (13, 14), however, showed that the maximum difference between the current efficiency obtained by electrolyte analysis and that calculated from gas analysis data is about 1%. Hence, the systematic difference in current efficiency on graphite and platinum is probably due to a direct chemical oxidation of graphite sludge during the process, by hypochlorous acid (15).

To implement the modification of the process based on the concept investigated above in chlorate production practice, two techniques are available:

1. Modern mercury cells in chlor-alkali electrolysis are operated at very high current densities (up to 10 kA/m^2) and there is a need to remove considerable quantities of heat (11). Since chlorate electrolyzers are usually built in the immediate vicinity of chlorine plants, it is possible to cool the mercury cell brine to a desired temperature in a heat exchanger by counterflowing the chlorate electrolyte. The latter can thus be heated up to 60°-80°C. The water used so far to cool the brine can be used to cool the chlorate electrolyte instead, in an additional heat exchanger.

2. It should also be possible to use the recuperation principle for the chlorate electrolyte itself, by flowing

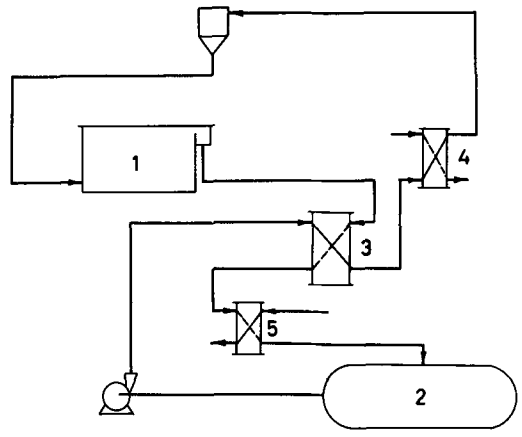

Fig. 6. Schematic representation of the industrial application of the modified process: 1—the cell; 2—holding volume; 3—heat exchanger; 4—additional cooler; 5—additional heater.

the inflow and outflow of the cell through a heat exchanger. Additional heat should be supplied in this case to compensate the losses (Fig. 6).

The first technique seems to be more favorable. It adds to the cost of the chlorate plant only the cost of a suitable titanium-plate type heat exchanger. Yet it should be able to increase the current efficiency by about 10%, reducing by that amount the cost of electrical energy. For a 10,000-tons/yr plant unit a total increase in capital cost should not be larger than U.S. $30,000. The modified technology should save about 6.0 x 10^6 kwhr of electrical energy per annum (about $42,000 at the price of 7 mills/kwhr).

Manuscript submitted Nov. 14, 1968; revised manuscript received April 25, 1969. This paper was presented in part as Paper 257 at the Boston Meeting, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

NOMENCLATURE

(Subscripts c and h refer to the quantities relating to the cell and the holding volume, respectively.)

C_s	the total available chlorine concentration (moles/liter) (C_{sc}, C_{sh})
[HClO], [ClO$^-$]	concentrations (moles/liter) of hypochlorous acid and hypochlorite ions, respectively ([HClO]$_c$, [HClO]$_h$, [ClO$^-$]$_c$, [ClO$^-$]$_h$)
t_1	the fraction of current (dimensionless unit) used for generation of chlorine by anodic oxidation of chloride ions with subsequent hydrolysis of elemental chlorine and chemical conversion or further anodic oxidation of available chlorine to chlorate.
I	cell load (amp)
A	active surface area of anode (cm^2)
$\mathbf{F}$	Faraday's constant ($\mathbf{F}$ = 96.500 coulombs/mole)
τ	time (sec)
k_r	rate constant (liters^2/mole^2 · sec) for reaction [2] ($k_{r,c}$; $k_{r,h}$)
V	volume of electrolyte (liters) in the cell (V_c) and in the holding volume (V_h)
q	electrolyte flow rate (liters/sec)
f, f_{ClO-}	activity coefficients of hypochlorous acid and hypochlorite ions, respectively (f_c, f_h)
a_{H3O+}, a_{H2O}	activities (moles/liter) of hydronium ions and water, respectively [$(a_{H3O+})_c$, $(a_{H3O+})_h$]
K_a, K^*	thermodynamic dissociation constant and rearranged dissociation constant of hypochlorous acid (K_c^*, K_h^*)
t_c, t_h	temperature of the cell and the holding volume respectively (°C)

The meaning of other symbols used is described in Appendix I and II.

APPENDIX I

One can arrive at Eq. [5] both in the given and an extended form, which takes into account all kinds of losses in the electrolytic production of chlorate for a closed-loop system, by considering the material balance of available chlorine with respect to the cell at quasi steady-state condition, which is defined by (*cf.* [4])

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right) = 0 \qquad [15]$$

The partial contributions of individual components of production, consumption, and loss of available chlorine during the process would be as follows:

(*a*) Anodic generation of available chlorine, which is converted to chlorate by two possible parallel paths (Eq. [2] and [3])

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G1} = \frac{t_1 \cdot I}{2\mathbf{F}} \qquad [16]$$

where t_1 is the fraction of current used for generation of chlorine by anodic oxidation of chloride

$$2\,Cl^- \rightarrow Cl_2 + 2e \qquad [17]$$

with subsequent hydrolysis

$$Cl_2 + 2H_2O \rightleftarrows HClO + H_3O^+ + Cl^- \qquad [18]$$

and conversion (Eq. [2]), or further *anodic oxidation* (Eq. [3]) to chlorate.

(*b*) Anodic generation of available chlorine, which is subsequently lost in the electrolytic production process by cathodic reduction

$$ClO^- + H_2O + 2e \rightarrow Cl^- + 2OH^- \qquad [19]$$

is described as

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G2} = \frac{t_2 \cdot I}{2\mathbf{F}} \qquad [20]$$

where t_2 is the fraction of the current used for generation of that part of available chlorine.

(c) Anodic generation of available chlorine, which is subsequently lost by evaporation in the hydrogen stream

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{G3} = \frac{t_3 \cdot I}{2F} \quad [21]$$

where t_3 is the fraction of the current used for unhydrolyzed chlorine.

(d) Further anodic oxidation of available chlorine to chlorate (Eq. [3]).

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{OX} = \frac{t_4 \cdot I}{2F} \quad [22]$$

where t_4 is the fraction of the current for the anodic chlorate formation.

(e) Available chlorine consumption by cathodic reduction

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{RED} = -\frac{t_2 \cdot I}{2F} \quad [23]$$

which corresponds to Eq. [20]

(f) Current losses by chlorine evaporation in the hydrogen stream

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{E} = -\frac{t_3 \cdot I}{2F} \quad [24]$$

(g) Conversion of available chlorine to chlorate (Eq. [2]) inside the cell (18, 19), which operates as back-mix flow reactor

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{CH} = -3f_c^2 \cdot k_{r,c} \cdot V_c \cdot [HClO]_c^2 \cdot [ClO^-]_c \quad [25]$$

(h) The difference in quantities of available chlorine leaving the cell and entering the cell from the holding volume in the considered time interval (which is equal to the conversion of available chlorine to chlorate inside the holding volume)

$$V_c \cdot \left(\frac{dC_{sc}}{d\tau} \right)_{H} = -q\,(C_{sc} - C_{sh}) \quad [26]$$

The material balance (Eq. [15]) thus is given by the following relation

$$\frac{t_1 \cdot I}{2F} + \frac{t_2 \cdot I}{2F} + \frac{t_3 \cdot I}{2F} - \frac{t_4 \cdot I}{F} - \frac{t_2 \cdot I}{2F} - \frac{t_3 \cdot I}{2F} - 3f_c^2 \cdot k_{r,c} \cdot V_c \cdot [HClO]_c^2 \cdot [ClO^-]_c - q\,(C_{sc} - C_{sh}) = 0 \quad [27]$$

Individual fractions of the anodic current are, in that case, connected by the relation

$$t_1 + t_2 + t_3 + t_4 = 1 \quad [28]$$

By combining Eq. [27] and [28], one obtains the explicit expression for the current efficiency on chlorate

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot F}{I} \cdot [HClO_c^2] \cdot [ClO^-]_c + \frac{2}{3}F\left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) - \frac{2}{3}(t_2 + t_3) \quad [29]$$

in which further transformations of the second and third terms are possible, as given in the main part of the paper. By dividing all terms of Eq. [27] by three, one can relate the generation and consumption of available chlorine with chlorate production, which means that t_1 also defines the current efficiency in the process of electrolytic chlorate production.

The current losses due to the catalytic decomposition of available chlorine and chlorate, or the anodic oxidation to perchlorate, are practically avoided under normal conditions of production, and thus need not be taken into consideration in the presented analysis.

The fraction of the current loss due to cathodic reduction is given as a ratio of the difference between the theoretical amount of hydrogen (V_o) and that actually produced amount (V_1), to the theoretically given amount (V_o) for a certain duration of electrolysis, namely

$$t_2 = \frac{V_o - V_1}{V_o} \quad [30]$$

The fraction of the current loss due to chlorine evaporation can also be determined by gas analysis as the ratio of percentage fractions of chlorine (Q) and hydrogen (H)

$$t_3 = \frac{Q}{H} \quad [31]$$

under the conditions of negligible cathodic reduction of available chlorine. If it is not negligible, this relation gives the ratio of evaporated chlorine to the theoretical amount of hydrogen developed for the same time interval.

In the presence of dichromate ions, with sufficiently high current densities and in a suitably defined pH region, both kinds of loss tend to zero, and Eq. [29] reduces to Eq. [5]

APPENDIX II

The equation for calculating the current efficiency from the gas analysis, which takes into account all kinds of losses, listed in Appendix I, can be derived using Faradaic stoichiometry, *i.e.* coulometric balance.

Consider the passage of N faradays through the cell during a definite time interval under quasi steady-state conditions of electrolytic chlorate production. This should be distributed as follows:

(a) Let x be the fraction of the charge, N, at the anode which is used to oxidize those chloride ions (Eq. [17]), which on discharge give molecular chlorine subsequently lost by evaporation (unhydrolyzed chlorine). Then $x \cdot F$ produce $x \cdot F/2$ moles of evaporated chlorine at the anode, and $x \cdot F/2$ moles of hydrogen at the cathode.

(b) Let y be the fraction used to oxidize chloride ions which produce available chlorine to replace that which is consumed by chemical conversion to chlorate (Eq. [2]). Then $y \cdot F$ produce $y \cdot F/2$ moles of available chlorine at the anode and $y \cdot F/2$ moles of hydrogen at the cathode.

(c) Let z be the fraction used to oxidize further the available chlorine into chlorate (Eq. [3]). Then $z \cdot F/4$ moles of oxygen are produced at the anode and $z \cdot F/2$ moles of hydrogen at the cathode.

(d) Let w be the fraction which produces hypochlorite ions to replace those reduced at the cathode (Eq. [19]). Then $w \cdot F$ produce $w \cdot F/2$ moles of available chlorine at the anode and reduce the same amount at the cathode.

All the fractions must sum up to give the total amount of charge as

$$x + y + z + w = N \quad [32]$$

The fraction of oxygen (S) in the gas mixture should then be

$$S = \frac{O_2}{H_2 + O_2 + Cl_2} = \frac{\frac{z \cdot F}{4}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{z}{y} + \frac{x}{2}\right) \cdot F} \quad [33]$$

while the content of unhydrolyzed (evaporated) chlorine (Q), obtained by gas analysis, is given by the equation

$$Q = \frac{Cl_2}{H_2 + O_2 + Cl_2} = \frac{\frac{x \cdot F}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{z}{y} + \frac{x}{2}\right) \cdot F} \quad [34]$$

The current fraction lost by cathodic hypochlorite reduction ($P = t_2$) is expressed by the following relation

$$P = \frac{\frac{w \cdot F}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{w}{2}\right) \cdot F} \quad [35]$$

The current efficiency of chlorate formation (t_1), which has to be equal to the theoretical amount of electricity required for the yield divided by the actual amount used, is then given, expressed as a fraction of unity, by

$$t_1 = \frac{\frac{y \cdot F}{2}}{\left(\frac{x}{2} + \frac{y}{2} + \frac{z}{2} + \frac{w}{2}\right) \cdot F} \qquad [36]$$

Equations [33-36] represent a system of four homogenous linear equations, which can be solved for t_1 by eliminating the unknown quantities x, y, z, and w

$$t_1 = \frac{(1 - 2Q - 3S)(1 - P)}{1 - Q - S} \qquad [37]$$

The partial fractions of oxygen (S) and chlorine (Q) are determined by the gas analysis, while the determination of the current fraction losses by hypochlorite reduction at the cathode ($P = t_2$) is discussed in Appendix I. Carbon dioxide is added to the oxygen content in the present calculations.

Technical Notes

A High-Voltage, Solid-State Battery System

I. Design Considerations

Charles C. Liang* and P. Bro*

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts

The solid electrolyte battery systems developed during the 1950's (1) had low voltages and high impedances which limited their usefulness drastically. The recent discovery (2-6) of high-conductivity ionic conductors of the $RbAg_4I_5$ type has stimulated the development of solid-state batteries with a high current carrying capability (7). Although these solid electrolytes have high conductivities, their composition limits their use to low-voltage systems with low energy densities.

We have investigated solid electrolytes compatible with high-voltage systems, and we report results below to demonstrate that thin-film, solid-state batteries can be made with energy densities approaching those of the best aqueous systems available.

Experimental Results

The Li/LiI/AgI system was chosen for investigation because of its high voltage and the low equivalent weight of lithium. The use of lithium restricted the choice of electrolyte to LiI which is a pure cationic conductor. Because of the high resistivity of LiI, 10^7 ohm-cm at 25°C (8), it was necessary to construct thin-film cells.

We found that thin films of the active materials and the electrolyte could be formed by carefully controlled vacuum evaporations, and cells were constructed by this means using purified analytical grade reagents. The thicknesses of the components of the cells were, typically: silver current collector, 13μ; AgI cathode, 30μ; LiI electrolyte, 15μ; and lithium anode, 5μ. The details of the experimental procedures and the cell structures will be given in subsequent publications.

The thin-film cell had an open-circuit voltage of 2.1V, and it exhibited the polarization curve shown in Fig. 1. The cell voltage decreased linearly with an increase in the current density and reached zero volts at about 120 $\mu A/cm^2$. This behavior demonstrated the ohmic nature of the cell impedance. A resistivity of 1.17×10^7 ohm-cm was calculated for LiI from the polarization curve, which agreed well with the published value. The resistivity of the AgI, 10^4 ohm cm (9), was neglected as being insignificant in comparison with that of LiI.

Discussion

The open-circuit voltage of the cells of 2.1V agreed well with the value of 2.09V calculated from the Gibbs free energy change (10) for the reaction:

$$Li + AgI = LiI + Ag$$

and it confirmed this to be the reaction of the cell.

The formation of LiI as a reaction product implied that the impedance of the cell would increase markedly during discharge. For example, the resistance of a single unit cell with a capacity of 100 mah/cm^2 would increase linearly from 12 kohms at the start of discharge to 1230 kohms at the end of discharge. Such a high impedance would render the cell useless for most practical applications, and it is evident that multilayer, parallel connected cell structures must be developed if practically interesting current carrying capabilities are to be achieved.

The impedances of hypothetical multilayer parallel plate cells were calculated to give the results shown in

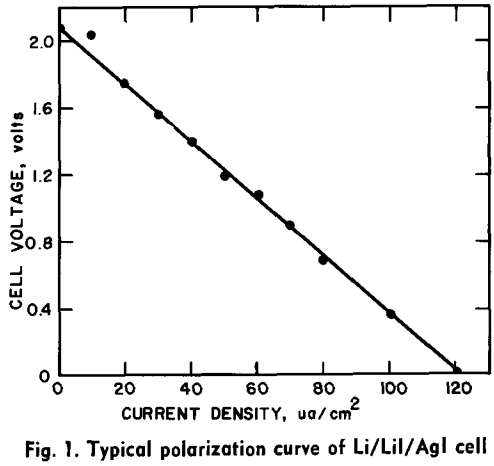

Fig. 1. Typical polarization curve of Li/LiI/AgI cell

* Electrochemical Society Active Member.

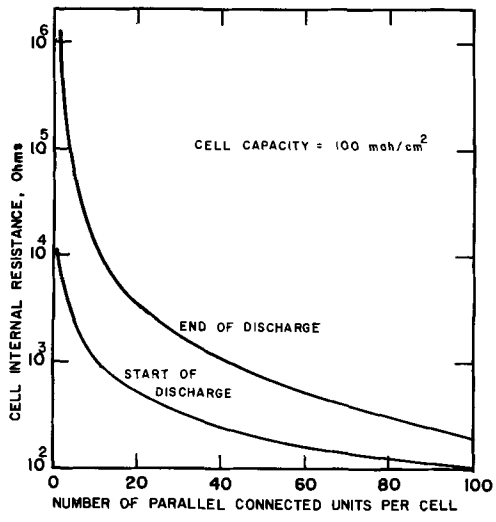

Fig. 2. The internal resistance of multilayer cell structures

Fig. 2. A capacity of 100 mah/cm² and a 100% depth of discharge were assumed. It may be seen that substantial improvements may be expected by the use of multilayer structures. The experimental unit cell had a stoichiometric anode limited capacity of 1 mah/cm² which indicated the technical feasibility of constructing from it a 100 mah/cm² consisting of 100 parallel connected units. Such a cell would have a short-circuit current density of 10 mA/cm² at the end of discharge. Practical cells have been made which delivered approximately 0.5 mah/cm² in a single unit cell to a 1V cutoff voltage at 20 μA/cm².

The stoichiometric energy densities of the multilayer cells would be less than that of single unit cells with the same capacity because of the added volume of the current collectors and substrates. Calculations showed that stoichiometric volumetric energy densities between 2 and 9 whr/in.³ may be realizable, depending on the number of units per cell, when the volumes of all the components except the outer cans were included in the calculations. The operating energy density of the single-layer, thin-film cell under a current drain of 10 μA/cm² was found to be 2.2 whr/in.³ (50% efficiency to a cutoff voltage of 1.0V at an average cell voltage of 1.7V).

It is concluded that the development of the high-voltage Li/LiI/AgI system is feasible and that multilayer, thin-film structures are required for cells capable of delivering currents in the low milliampere range. The volumetric energy densities of the cells may be expected to vary between 1 and 5 whr/in.³ for the various designs.

Some Electrochemical Studies on Ceramic Barium Titanate

Ashok K. Vijh*,[1]

Research & Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

In the present investigations, an attempt has been made to oxidize anodically semiconducting ceramic barium titanate (BT) disk electrodes. The object of this study was to obtain a thin insulating layer of oxidized BT, possibly with good dielectric properties, onto the body of the parent disk of reduced, semiconducting BT.

Experimental Procedures

Thermally reduced ceramic barium titanate, either pure or Nb-doped (*ca.* 0.1%) and of *ca.* 2-20 ohm-cm resistivity, was used in the form of pressed disks as the working electrode. The disks were masked either by a resin or were accommodated in a suitable glass-Teflon assembly. The nature of the electrolytic solutions, where relevant, will be mentioned in the section on Results and Discussion.

Ohmic contact to the ceramic was made by means of a Ga-In alloy.

Counterelectrodes were bright platinum wires.

Electronic circuits consisted of routine constant voltage and galvanostatic configurations similar to those described previously (1).

For metallographic studies, the anodized disks were angle lapped at the desired angle and subsequently polished to expose the enlarged (due to angle lapping, of course) anodized layer. This layer was then metallographically examined and photographic record was thus obtained of the thickness and appearance of the layer.

The final cleaning of the working electrodes was carried out in boiling trichloroethylene.

Results and Discussion

Anodization and cathodization.—Anodizations and reduction attempts were carried out in a variety of solutions in open beakers. The sole purpose of these studies was to obtain an insulating layer which might act as a good dielectric. Since kinetic-mechanistic aspects were *not* of interest in these particular runs, anodizations and cathodizations under crude experimental conditions of open beakers were regarded as quite satisfactory.

It was observed, rather empirically, that neutral (buffered phosphate) or mildly alkaline (0.1*N* Na_2CO_3 in water) solutions tend to give anodized layers which show better gross coherence than the ones obtained in highly acidic ($HClO_4$ or H_2SO_4) or highly alkaline (NaOH) or some other (NH_4NO_3) electrolyte compositions. Solutions only partially aqueous (*e.g.*, glycol-borate electrolyte + 20% H_2O) or nonaqueous

* Electrochemical Society Active Member.
[1] Present address: Institute of Research, Hydro-Quebec, 75 Blvd. Dorchester West, Montreal, P. Q., Canada.

(formate in formic acid) make it possible to anodize a BT disk to higher voltages than aqueous solutions. However, the anodized layers obtained in the partially or totally nonaqueous solutions are very uneven and show a spectrum of patches of anodically oxidized (white) and reduced (*i.e.*, the parent bluish-black disk) BT. In all cases of anodization in aqueous media, gas (presumably oxygen) evolution could be observed as a process parallel to the anodic "growth," from the very commencement of anodization. Attempts to reduce the anodic layer by cathodization were unsuccessful (*cf.*, cathodization of valve metal oxides).

Chemical composition of the layer.—The chemical characterization of the layer was carried out by electron probe microanalysis and by x-ray diffraction. The electron-probe microanalysis was carried out by employing a defocused beam of approximately 50μ diameter. It was observed that none of the films showed Ba:Ti ratio which would be expected for pure BT. For example, films formed in neutral phosphate solutions were rich in Ti, whereas those in carbonate solution were very low in Ti. The departures from stoichiometry in every case were very significant and varied randomly over a very wide range. Further, in the anodized layers formed in neutral phosphate solutions, presence of some phosphorus was also detected.

In the x-ray diffraction studies, several peaks *not* corresponding to pure BT were detected; this would indicate presence of compounds other than BT in the anodized layer. Only one of these extraneous compounds, however, could be identified and it was $BaCO_3$. It may be mentioned that the anodized layer that showed $BaCO_3$ was obtained by electrochemical oxidation of Nb-doped BT in 0.1*N* Na_2CO_3. Both electron probe microanalysis and x-ray diffraction studies thus indicate rather strongly that, during anodization, the components of the electrolyte solution get incorporated in the anodized layer. This observation is quite consistent with similar incorporation of the electrolyte components in the anodic films formed during oxidation of valve metals (2).

General appearance, porosity and mechanical strength of the anodic layer.—The layer was quite flaky and brittle. It was white and opaque as contrasted to the translucence of pure BT layer of perovskite structure. It did not, however, show any gross porosity as determined, *e.g.* by dye test at 30 psi.

Metallographic studies and the thickness of the layer.—Angle-lapping and subsequent metallographic examination of the anodized disks showed that a rather sharp boundary exists between the anodized layer and the parent reduced disk in the great majority of cases (Fig. 1). At least in one instance, it was observed that this boundary can sometimes be quite diffuse. The behavior represented in Fig. 1, however, is more representative of the general thickness and appearance of the anodized layer.

By controlling the voltage (in constant-voltage experiments) or current density (in galvanostatic experiments) and time of anodization, one can obtain anodized layers with the thickness range of 1-5 x 10^{-3} cm. The most suitable conditions for obtaining a layer of this thickness were a constant voltage (~50-70V) "pulse" lasting 5-10 sec in an aqueous (0.1*N* Na_2CO_3) solution. Longer times of anodization combined with higher anodization voltage (or current densities) gave much thicker deposits. These thicker deposits, however, were mechanically damaged since pieces of the "chipped" anodized layer could be seen falling into the solution. Again, applying a high-voltage pulse (~100V) in aqueous solutions at the very commencement of the anodization would result in the dielectric breakdown of the disk; the breakdown in some cases would be severe enough to blow the electrode to smithereens and cause sparking near the electrode surface. When the anodization voltage was increased gradually, *i.e.* in a manner which follows the anodic growth, much higher voltages (~300V) could be built across the disk.

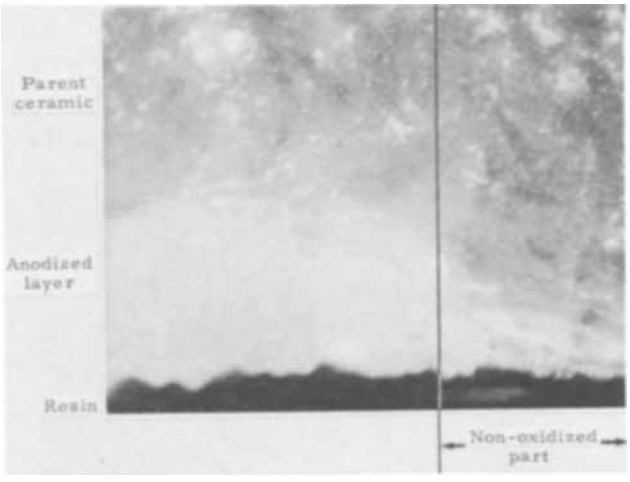

Fig. 1. A photographic record of the appearance of a typical angle-lapped anodized layer under metallographic examination. Boundary between the layer and the parent ceramic is reasonably sharp. The BT is Nb doped and was anodized in 0.1*N* Na_2CO_3 aqueous solution by a constant voltage (~60V) "pulse" (~2 sec); X1750 approximately; thickness ca. 2.1 μm.

Electrical resistivity of the film.—The d-c resistivity of the layer as "seen" by a low-signal, d-c voltage was in the range of 1 x 10^8-1 x 10^9 ohm-cm. This was measured both by the electrolyte contact to the anodized layer, as well as by electrodepositing a metallic copper electrode on this layer. This resistivity, it may be remarked, is appreciably lower than that of a thermally oxidized BT layer (~10^{12} ohm-cm) or a typical valve metal oxide, *e.g.* Ta_2O_5 (~10^{15} ohm-cm).

Dielectric properties.—Attempts were made to measure the a-c capacitance (C) and RC of a few assorted anodized disks. Non-zero values (in the range 0.01-1 μ**F** cm^{-2}, approximately) of C were obtained on some disks. However, the values of RC were usually in the range of 8-12 x 10^3 ohm-μ**F**/disk (area *ca.* 0.5 cm^2) thus showing high resistance in series. These values were *quite erratic*, and were strongly dependent on a-c frequency, d-c bias, time of subjection to d-c bias, and the area of the anodized disk on which the contact is made, thus showing that the layer is a very poor dielectric. Several types of "electrodes" were explored for dielectric measurements; none of these contacts, however, gave satisfactory values for C and RC.

Some theoretical considerations.—Here an attempt is made to speculate on some theoretical aspects of these studies, *e.g.* the comparison and contrast between thermal and anodic oxidation of semiconducting BT.

The only requirements in thermal oxidation are high melting point (so that the ceramic does not fuse during thermal oxidation) and high ionicity because otherwise the activation energy for the migration of oxygen vacancies would be too high. These two requirements are easily met for the case of perovskite oxides since the Madelung constants and lattice energies for these structures are very high (3); hence, probably the satisfactory dielectric layers obtained on *thermal* oxidation of semiconducting BT, *e.g.* in capacitor industry. During electrochemical oxidation, however, not only high lattice energies are required but the bond energies also need to be fairly high to sustain high fields (4). As pointed out elsewhere (4), high ionicity alone would give oxides on anodization, which have rather poor mechanical and electrical characteristics, *e.g.* oxides of alkaline earth metals. Since $BaTiO_3$ [1] contains both Ba-O and Ti-O bonds, weak

[1] In a complex structure (*i.e.*, perovskite) like that of BT, however, strength of Ba-O and Ti-O bonds would be expected to be somewhat different than that in BaO and TiO_2, respectively.

BaO bond energy (5) would, on electrochemical oxidation, give rise to a rather poor dielectric, as indeed is actually observed. Low bond energies and high ionicity would, further, result in a relatively easy dissolution, either "chemical" or anodic, of the growing oxide. This dissolution may very well be uneven, depending on the electrochemical factors (including surface heterogeneity, plane defects, *etc.*) that obtain in a given experiment; hence, perhaps, the departures from stoichiometry. The argument that relatively low Ba-O bond energy (5) would not result in a good anodized layer on reduced BT is also consistent with some other empirical evidence. It has been empirically observed that (2) for anodic oxides, high dielectric constant tends to be associated with low bond energies (4) and with *lower* ability of the oxide to sustain high fields for ionic growth. Since BT, even when not ferroelectric, has a fairly high dielectric constant, its ability to sustain fields would be quite low. It is indeed observed that "dielectric strength" [*i.e.*, ability to sustain field, without breakdown, during anodization, *e.g.* Ref. (2)] of the anodically grown BT in aqueous solutions is in the range *ca.* 1-3 x 10^5V cm^{-1}. This value is lower than that for any valve metal oxide (6).

Brief Communication

Ethylene Diamine-Catechol-Water Mixture Shows Preferential Etching of p-n Junction

J. C. Greenwood

Standard Telecommunication Laboratories, Harlow, Essex, England

We have found that the ethylene diamine-catechol-water etch described recently by Finne and Klein (1) will etch only n-type silicon in samples containing p-n junctions. The etching of the p-type part of the sample appeared to be completely inhibited, not just slowed down, until the n-type part of the sample had been removed.

This effect is demonstrated clearly in one particular experiment described here in more detail.

A slice of <100> n-type silicon was polished and diffused to give a p-type layer about 5 μm thick on the underside. The top side was chemically polished to give a thickness of about 200 μm and coated with silicon dioxide. Square windows were etched in the silicon dioxide. A diagrammatic cross section of the slice at this stage is shown in Fig. 1(a). The slice was etched in a mixture, described by Finne and Klein, of ethylene diamine, 17 ml; water, 8 ml; catechol, 3g, for a total of 6¾ hr at 110°C in a flask fitted with a reflux condenser. Nitrogen was bubbled through the mixture.

Square pits with sloping sides and flat bottoms were formed in the windows as shown diagrammatically in Fig. 1(b). At the bottoms of the pits, the etching stopped at the p-n junction, leaving a thin even layer

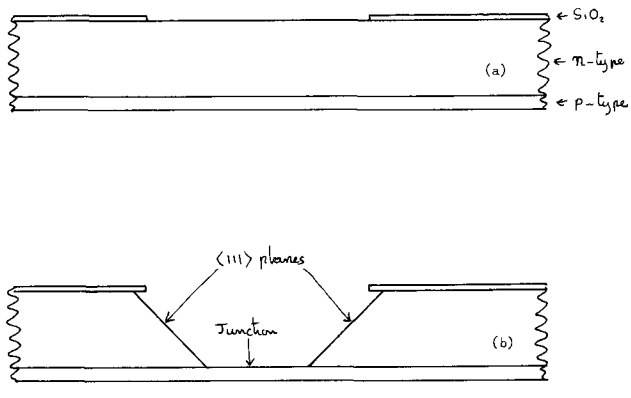

Fig. 1. Cross section of the slice: (a) before etching, (b) after etching.

of unattacked p-type silicon. The evenness of this layer is shown in Fig. 2 in which the slice is illuminated from underneath. The uniform thickness is main-

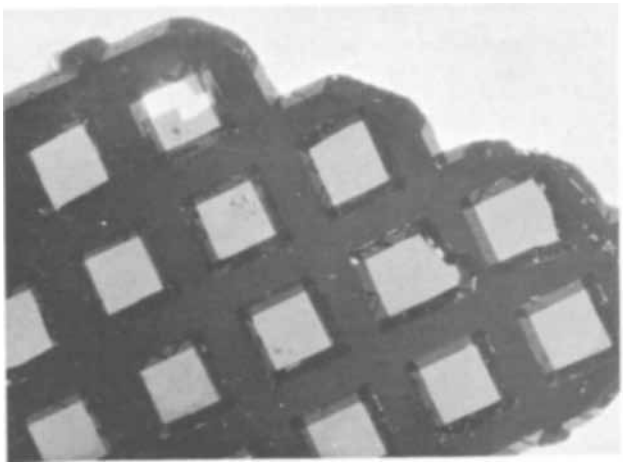

Fig. 2. Looking down on the slice after etching. It is illuminated from underneath to show light being transmitted through the silicon at the bottoms of the pits. The spacing of the squares is 0.050 in.

tained right to the edge of the slice where the junction was revealed early in the period of etching.

The sides of the pits corresponded to <111> planes; this is a result of the much slower rate of attack on <111> planes as is described by Finne and Klein.

The bottoms of the pits had a fabriclike texture, in contrast with the sloping sides which were smooth. It is believed that this is the actual shape of the junction and that the departure from flatness is due to irregularities in the crystal structure.

The inhibition effect described here could be useful in preparing thin samples of silicon, examining defects in junctions, and in making devices such as strain gauges in which the shape is critical.

A Theory for Porous Electrodes Undergoing Structural Change by Anodic Dissolution

Richard C. Alkire, Edward A. Grens II,* and Charles W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

A theoretical model is proposed for the description of flooded porous metal electrodes which undergo anodic dissolution by electrochemical reaction. Equations are developed to represent the pseudosteady state which prevails during dissolution after the concentration gradients have become fully established within the pores. The analysis leads to an understanding of how mass transfer, kinetic and geometric parameters of the system determine the electrode overpotential and its change during dissolution. The most uniform current distributions are predicted to occur not at vanishingly small currents but at finite anodic currents because of mass transfer limitations to the cathodic back reaction. Thus, for a range of anodic currents, an increase of applied current will result in a more uniform distribution of the electrochemical reaction throughout the porous electrode. Calculations illustrating the behavior are presented for the acid-copper system.

Electrodes which are porous have come into widespread use in electrochemical energy conversion devices because, in these, the electrochemical reaction takes place with a higher rate per unit volume and is accompanied by a lower polarization than would be possible with nonporous electrodes. Accordingly almost all batteries and fuel cells employ porous electrodes. In batteries the electrode pores are flooded with liquid electrolytic solution, and reactants and/or products are incorporated in the solid electrode matrix. Thus, during operation, the composition and configuration of the solid material changes, leading to departures from behavior that might be expected for electrodes with invariant matrices. The nature of such changes, which are dependent on the electrode system involved, can be very complicated indeed. In this work an analysis has been conducted of a simple class of electrodes experiencing structural change during operation: porous metal anodes undergoing electrochemical dissolution. The investigation of this type of electrode can illuminate some of the salient effects of structural changes in battery electrodes and can serve as a basis for extension of model studies of systems encountered in batteries.

The dissolving metal anode, of course, involves a relatively simple type of structural change. No changes in solid composition are involved. The behavior of most battery electrodes is far more complicated, but the state of description of such systems has not yet advanced sufficiently far to embrace these more complicated events. Theoretical analyses to date have proceeded by one of two routes. In the first, an idealized geometrical structure of the porous body is assumed and is taken into consideration when equations are derived for the current and potential distributions (1-3). This "microscopic" approach has been found to lead to severe mathematical difficulties and has been restricted to extremely simple geometries. The second method ignores the detailed structure of the porous electrode and, rather, treats the porous electrode as a pseudohomogeneous region in which there is transfer of current between electronic and ionic modes of conduction according to basic laws of transport phenomena and electrode kinetics. This "macroscopic" approach has been applied to electrode behavior in the initial state without concentration gradients (4-10), during the mass transfer transients (11), and in the steady state where concentration gradients are fully established (11-13). As more sophisticated models were examined, the solution of the equations was found to be more conveniently carried out by numerical methods implemented by high-speed digital computers (11).

To date, no theoretical analysis has been reported which takes into consideration the variation of electrode structure with extent of reaction. The macroscopic theory presented here examines the behavior of porous metal electrodes that are undergoing dissolution of anodic reaction and predicts the external electrode polarization and the electrode porosity distribution as a function of the extent of reaction.

The operation of battery systems involves other effects beyond those considered in the theoretical model used in this work. Typically, sparingly soluble salts take part in the reactions during cycling. These salts may be insulators or semiconductors and hence may greatly affect the potential distribution within the electrode. There may be composition gradients in the solid phase (for instance $Ag/Ag_2O/AgO$) and, furthermore, electronic transport in the solid phase may be important. Also, reactions may be locally nonuniform, and geometrical effects of crystal growth may be involved. Nevertheless, the theoretical model presented below represents an advance relative to existing treatments in the literature and should be useful in leading to some insight into more complex systems.

Model Formulation

The mathematical model for a dissolving porous anode is based on consideration of a porous metal plate whose accessible void spaces are completely filled with an aqueous electrolyte. On one side of the porous plate the pores are blocked (or a center of symmetry exists), and the other side (the face) is in contact with the electrolytic solution, which also fills the pores. There is no forced flow of solution through the pores. A second (counter) electrode is also in the solution but is of no concern in this model and serves only to complete the electrochemical circuit. With passage of anodic current through the porous electrode, the metal dissolves with formation of a soluble salt. The local rate of anodic dissolution varies from place to place within the porous electrode because the various positions are not equally accessible to the current and the reacting species transported in the electrolyte. The distribution of the reaction depends on the mass transfer, kinetic and geometric characteristics of the particular system.

When anodic current is switched on, two major changes begin to take place.[1] Because the removal of

* Electrochemical Society Active Member.

[1] During the first few milliseconds the electrical double layer becomes established. We shall not be concerned with the electrode behavior during this brief period of double layer charging.

dissolved product species from the pore is transport controlled, as is also the passage of current and movement of nonreacting ions in the electrolyte, the potential and concentrations of species in the solution within the pores change from the initially uniform values and become more or less unevenly distributed throughout the pores. Typically this mass transfer transient process is completed within a period of 10 sec to 1 hr, depending on the system (11). Second, and simultaneously, the geometry of the porous metal matrix changes owing to its dissolution by anodic reaction. As the nature of the electrode structure thus changes, the potential and concentration distributions also change, and these changes continue to take place as long as current is passed.

When anodic current thus passes through the porous metal electrode, the current in the metal is carried by electrons and the current in the solution is carried by the ions. The conversion from the electronically to the ionically conducting "phase" takes place throughout the porous electrode by virtue of the electrochemical reaction. If the local concentrations and potentials are known in both phases, the local reaction rate may be calculated, in principle, by a relation which suitably describes the kinetics of the electrode process. In turn, the local concentrations and potentials may be obtained by solving the equations of transport in each phase. Thus the local reaction rate may be determined throughout the electrode.

During the first moments of operation, the reaction distribution changes principally because of the production of ionic reaction products whose removal in the solution phase from the porous electrode is transport restricted. Along with this mass transfer transient process, the reaction distribution changes at some other rate owing mainly to the changes in structure caused by dissolution. The characteristic times of these two effects are usually different, the former being much faster. Consequently, after the mass transfer transient has been essentially completed, the reaction distribution continues to change, and it becomes a very good approximation to determine the rate of change solely from the effects of the structural dissolution. This is the pseudosteady state approximation that will be invoked in the present theory.

The equations describing electrode behavior arise from transport relations and electrode kinetic expressions. In definition of the model it is necessary to introduce a number of simplifying assumptions to facilitate the required calculations:

1. The one-dimensional macroscopic approach is applicable; pore dimensions are assumed to be small with respect to distances over which significant changes take place within the electrode.
2. The electrode operation under consideration takes place in the pseudosteady state. Behavior during the mass-transfer transient is ignored.
3. The electrical double layer can be disregarded. The pore dimensions are large compared to those of the double layer, and the time variations are slow compared to the rate of establishment of the double layer.
4. The motion of solute species in the electrolytic solution is adequately described by the equations of dilute solution theory. The transport parameters are constant, and hydrodynamic flow in the pores is due only to the net change of electrode and electrolyte volume with the extent of reaction. The density of the electrolytic solution is essentially constant throughout the pores, and the metallic electrode structure is isopotential.
5. The only electrochemical reaction is the anodic dissolution of the metal electrode to form ions having a single charge number, and the kinetic behavior of the reaction is adequately characterized by an expression of the Volmer form (14).
6. There are no insoluble substances within the pores.
7. The pores are circular cylinders which all have the same size at the onset of dissolution.
8. Mass transfer resistances external to the porous electrode can be disregarded.
9. The system is isothermal.

The analysis of electrochemical systems by the equations of transport as delineated, for instance, by Levich (15) and by Newman (16), has been applied to the formulation of a macroscopic porous electrode model by Grens and Tobias (11). It is here extended to account for the changes in matrix properties accompanying anodic dissolution of the matrix. Under the conditions described above, the conservation of solute species in the pseudosteady state is described by[2]

$$c_i \frac{\partial a}{\partial t} = -\frac{\partial}{\partial y}(N_i a) + S_i \qquad [1]$$

In this equation the left hand side represents the amount of species i associated with changes in pore volume while the terms on the right hand side are the divergence of the species flow (flux times local pore cross section) and the reaction source, respectively. For nonreacting species, the only net movement is that which must take place in order to fill the void volume created by the dissolving metallic phase. The time rate of change of the pore cross-sectional area may be related to the convective velocity by use of the relation for conservation of mass in the pores which, in the pseudosteady state, is

$$\rho_s \frac{\partial a}{\partial t} = -\frac{\partial}{\partial y}(\rho_s v a) + S_m \qquad [2]$$

The spatial coordinate, y, is taken to be zero at the back of the porous electrode and has the value of $+d$ at the mouth of the pores (face of the porous layer). The flux of solute species in the one dimensional electrolytic solution is given by the dilute solution expression

$$N_i = -D_i \frac{\partial c_i}{\partial y} - z_i D_i \frac{\mathbf{F}}{RT} c_i \frac{\partial \phi}{\partial y} + v c_i \qquad [3]$$

Here ϕ is the potential in the solution referred to the isopotential electrode matrix. For the electrode reaction which occurs in the pores, with the dissolved metal ion being designated species 1

$$\nu_0 M \rightarrow -\nu_1 M_1^{z_1} + ne^- \qquad [4]$$

the pseudohomogeneous species source term is

$$S_1 = -\frac{l\nu_1}{n\mathbf{F}} j \qquad [5]$$

where j is the local reaction (transfer) current density. Other source terms are absent. The transfer current density is in turn related to local concentrations and potential by the kinetic expression associated with the dissolution reaction, here the Volmer form

$$j = i_o \left[e^{-\frac{\alpha_a n\mathbf{F}}{RT}(\phi - \phi_e)} - \frac{c_1}{c_1^\infty} e^{\frac{\alpha_c n\mathbf{F}}{RT}(\phi - \phi_e)} \right] \qquad [6]$$

The pseudohomogeneous mass source term for the pore space is

$$S_m = \frac{m_1 l}{n\mathbf{F}} j \qquad [7]$$

Substitution of Eq. [2], [3], [5], [6], and [7] into Eq. [1] eliminates the time derivative term for pore area and incorporates the definitions of fluxes and sources in the species conservation equations. With neglect of the pseudohomogeneous mass source term, and with assumption of constant solution density, these equa-

[2] The meaning of symbols used in equations is given in the Notation section at the end of this article.

tions are

$$D_i \frac{d}{dy}\left(a\frac{dc_i}{dy}\right)+\frac{z_iD_i\mathbf{F}}{RT}\frac{d}{dy}\left(c_ia\frac{d\phi}{dy}\right)-\frac{d}{dy}(c_ivа)$$
$$=\frac{\nu_i l}{n\mathbf{F}}i_o\left[e^{-\frac{\alpha_a n\mathbf{F}}{RT}(\phi-\phi_e)}-\frac{c_1}{c_1{}^\infty}e^{\frac{\alpha_c n\mathbf{F}}{RT}(\phi-\phi_e)}\right]$$
$$-c_i\frac{d}{dy}(va) \qquad \nu_i=0 \text{ for } i\neq 1 \quad [8]$$

A conservation equation is written for each of the solute species i. These equations, along with the electroneutrality approximation

$$\sum_i z_ic_i=0 \qquad [9]$$

are sufficient in number for the calculation of the concentrations and the potential, provided that the pore area, pore perimeter, and convective velocity have been specified. For the system considered here, these are determined by the effect of local reaction on the solid matrix.

With the assumption that pores are circular cylinders, the radius will change at a rate proportional to the local reaction rate according to

$$\frac{d}{dt}(r^2)=\frac{2\bar{V}}{n\mathbf{F}}jr \qquad [10]$$

By integration of Eq. [10], the area and perimeter of the pores may be obtained at any one time during dissolution. The average local velocity past a point within the electrode is derived from a mass balance and is

$$v(y)=\frac{m_1}{n\mathbf{F}\rho_s a}\int_o^y l\left(1-\frac{\rho_s}{\rho_m}\right)j\,dy \qquad [11]$$

when the density of the electrolytic solution is constant. This equation indicates that the induced velocity arises from the difference between the densities of the solution and the metal, and that the velocity at position y depends on reaction in the portion of the electrode between that point and the back of the electrode.

The model is completely described when the appropriate boundary and initial conditions are specified. Prior to dissolution the pores are assumed to be of identical size and shape

$$a=a_o \text{ at } t=0 \qquad [12]$$

At the rear of the pores, the flux of each species is zero

$$N_i=0 \text{ at } y=0 \qquad [13]$$

At the entrance of the pores, the concentration of each solute species is equal to its value in the external electrolytic solution

$$c_i=c_i{}^\infty \text{ at } y=d,\ i\neq 1 \qquad [14]$$

The current density in the electrolyte at the mouth of the pores is defined as the sum of the individual ionic fluxes according to

$$i=\mathbf{F}\sum_i z_iN_i \qquad [15]$$

If the metal electrodes were not dissolving, then the current entering the pores could be solely attributed to the flux of the reacting ion. However, since the liquid volume within the pores is increasing by dissolution, that portion of the flux of the reacting ion passing into the electrode only to fill the void spaces is accompanied by equivalent counter ions and thus will not contribute to the current. The appropriate boundary condition in this case, derived by integration of the conservation equation over the entire electrode, is

$$i=-z_1\mathbf{F}D_1\frac{dc_1}{dy}-\frac{z_1{}^2\mathbf{F}D_1}{RT}c_1\frac{d\phi}{dy}+\frac{1}{a_f}\int_o^d va\,dc_1$$
$$\text{at } y=d \quad [16]$$

In many instances, the integral term will be negligibly small with respect to the sum of the other two terms and thus may be deleted from consideration. This was the case in the system for which numerical results were obtained for this paper.

The treatment of the equations is more convenient if the variables are made dimensionless. The following dimensionless variables are conveniently defined

$$Y=\frac{y}{d}, \qquad C_i=\frac{c_i}{c_{\text{ref}}}, \qquad \Phi=\frac{\mathbf{F}}{RT}(\phi-\phi_e),$$
$$V=\frac{vn\mathbf{F}}{i^*\bar{V}}, \qquad A=\frac{a}{a_o}, \qquad L=\frac{l}{l_o},$$
$$I=\frac{i}{i^*}, \qquad J=\frac{ld}{i^*a_f}j, \qquad \tau=\frac{\bar{V}i^*a_f}{n\mathbf{F}d}t$$

When these are introduced in Eq. [8] and [16], the following dimensionless groupings of the system parameters arise

$$\beta=\frac{i^*a_fd}{n\mathbf{F}c_{\text{ref}}D_{\text{ref}}a_o}, \qquad \xi=\frac{i_od^2l_o}{n\mathbf{F}c_{\text{ref}}D_{\text{ref}}a_o},$$
$$\zeta=\frac{i^*a_f\bar{V}d}{n\mathbf{F}D_{\text{ref}}a_o}, \qquad \gamma_i=\frac{c_i{}^\infty}{c_{\text{ref}}}, \qquad \pi_i=\frac{D_i}{D_{\text{ref}}}$$

With use of the notation prime (′) to denote differentiation with respect to the spatial variable Y, the dimensionless equations which describe the pseudo-steady state model become

$$(C_i'A)'+z_i(C_iA\Phi')'-\frac{\zeta}{\pi_iA_f}(C_i'AV)$$
$$=\frac{\nu_i\xi L}{\pi_i}\left[\exp(-\alpha_an\Phi)-\frac{C_1}{\gamma_1}\exp(\alpha_cn\Phi)\right] \qquad [17]$$

$$\sum_i z_iC_i=0 \qquad [18]$$

$$A=1+\int_o^\tau J\,d\tau \qquad [19]$$

$$V=\left(\frac{\rho_m}{\rho_s}-1\right)\frac{A_f}{A}\int_o^Y J\,dY \qquad [20]$$

Since the pores are circular cylinders, $L=\sqrt{A}$. The boundary conditions become

$$C_i'+z_iC_i\Phi'=0 \qquad \text{at } Y=0 \qquad [21]$$

and

$$\left.\begin{aligned} C_i&=\gamma_i\ (i\neq 1)\\ -\frac{n\beta}{z_1\pi_1A_f}&=C_1'+z_1C_1\Phi'\end{aligned}\right\}\ \text{at } Y=1 \qquad [22]$$

The calculations in this study were made with neglect of the integral term in Eq. [16], resulting in a boundary condition of the form of Eq. [22].

The mathematical model described above has extended previous treatments by accounting for two phenomena which take place during electrolytic dissolution: the change in specific surface area, and the convective motion arising from volumetric changes.

Solution of Equations

The solution of the set of equations and boundary conditions which describe the porous electrode model was carried out by a computer-implemented numerical technique. In principle, the calculation was accomplished in a stepwise manner, with use of finite difference methods for solution of the differential equations at each step. First, the conservation and electroneutrality equations, [17] and [18], were solved without the convection term and with constant porosity. The first approximation to the local convective velocity was then calculated by Eq. [20]. Conserva-

$\pi_1 = 0.7188$	$\pi_2 = 1.331$	$\pi_3 = 9.312$

tion and electroneutrality equations were again solved with use of the velocity distribution now at hand; these results corresponded to the conditions prevailing within the electrode at the end of the mass transfer transient but before appreciable dissolution had taken place. Then the calculations were made for specified time intervals during the pseudosteady state dissolution. With use of Eq. [19] and [20], the pore area (*i.e.*, porosity) distribution and the convective velocity distribution were calculated. With use of these new distributions, the conservation and electroneutrality equations were again solved, and the sequence repeated for as many time intervals as required.

The central problem of these calculations was the simultaneous solution of the species conservation expressions along with the electroneutrality condition. These coupled nonlinear ordinary differential equations were first linearized about an approximate solution and then put into finite difference form. The resulting set of tridiagonal matrices was solved by use of a computer-implemented technique described by Newman (17). The solution of the nonlinear problem was obtained by iteration with successive correction of the approximate solution.

Results and Discussion

The theoretical model developed above was used for generating predictions regarding the behavior of one porous electrode system. Ultimately it is intended that these model predictions be compared with the results of dissolution experiments that have been undertaken in a related project (18). Consequently the dissolution of porous copper anodes in acidified copper sulfate has been examined. For this system there are two alternate models for the electrolyte composition (and thus for electrolyte transport): the sulfate model (Cu^{+2}, H^+, SO_4^{-2}) and the bisulfate model (Cu^{+2}, H^+, HSO_4^-). For solutions having a larger concentration of sulfuric acid than copper sulfate the bisulfate model gives a more accurate prediction of the solution conductivity than does the sulfate model, and thus was chosen for these calculations. The system parameters are given in Table I.

For the moment, consider the state which exists after the mass transfer transient has decayed but before significant dissolution has taken place. Figure 1 shows the corresponding distribution of reaction rate

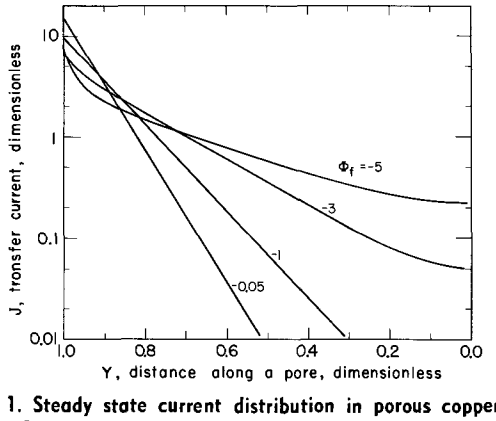

Fig. 1. Steady state current distribution in porous copper anode for $\xi = 25$ at several electrode overpotentials (Φ_f).

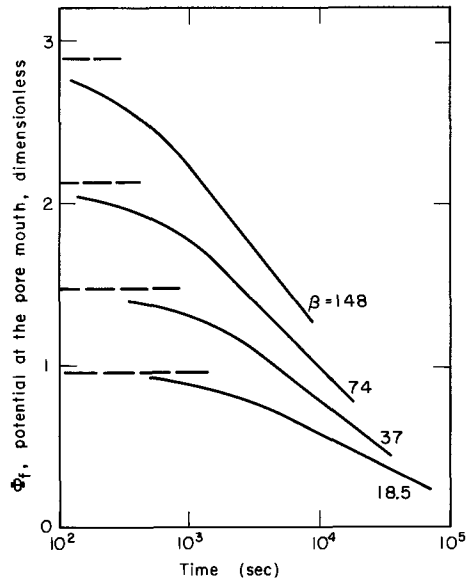

Fig. 2. Potential variation during dissolution of porous copper anode for $\xi = 400$ at several applied current densities (β).

throughout the porous electrode for various anodic values of applied potential, Φ_f. From this figure it may be seen that this initial steady state current distribution varies with applied potential, and that as the anodic potential is increased the reaction distribution generally becomes more uniform. For the case at hand, increasing $-\Phi_f$ above 3.0 renders the distribution still more uniform in the depth of the electrode while, nearer the pore entrance, the distribution begins to become more nonuniform.[3] This interesting situation may be understood by the following reasoning. Since the electrode consists of copper metal, the anodic reactant (the copper atom) is available in unlimited quantity whereas the cathodic reactant (the copper ion in solution) is not. Therefore the cathodic (back) reaction suffers from mass transfer limitations which do not hinder the anodic reaction. Consequently, at the same value of absolute potential, the cathodic reaction will be less uniformly distributed through the electrode. This tendency for the cathodic reaction to be less uniformly distributed carries over into the region of low anodic current where the cathodic back-reaction still occurs to an appreciable extent. Thus the most uniform reaction distribution is shifted into the anodic range of potentials. If both cathodic and anodic reactants had been available in unlimited quantity, the reaction distribution would have been most uniform at vanishingly small currents. This behavior is not predicted by simpler models which assume either constant concentration (thus neglecting concentration polarization of the back reaction) or a Tafel kinetic expression (neglecting the back reaction altogether).

The variation of electrode overpotential on dissolution is shown in Fig. 2. Results are shown for several values of the applied current density, β. The total overpotential of the electrode (the potential in the electrolytic solution at the pore entrance) increases with applied current density.[4] It can be seen that the polarization decreases below the "steady state" value (dashed lines in Fig. 2) and that the decrease in potential sets in earlier for the higher currents.

For the system at hand the theoretical model predicts that the uniformity of the reaction distribution near the pore entrance passes through a maximum at

[3] Hence for applied potentials more anodic than 3.0 it is not easy to designate which reaction distribution is most uniform, and arbitrary criteria must be used.

[4] Although the figure does not illustrate it, one may realize that for the same applied current density, the more rapid reactions, having higher values of ξ, suffer lesser polarization. For the slow reactions, charge transfer overpotential near the pore entrance forces the current deeper into the pore so that the reaction is more uniformly distributed at the expense of higher overpotential.

anodic potentials because of the mass transfer limitation of the back reaction as discussed above. Since the porosity distribution is equivalent to the time average current distribution, the "most uniform" final porosity distribution will correspond to a particular anodic current. Currents different from this particular one should lead to porosity distributions which are more nonuniform near the pore entrance. Final porosity distributions are given in Fig. 3 for several applied current densities. The total amount of charge passed is the same for all curves, and thus it may be seen that the model predicts the most nonuniform reaction distribution at the lowest applied current density ($\beta = 18.5$). As the applied current density is increased and the duration of electrolysis is decreased, the predicted final porosity distribution becomes more uniform. As the applied current density is increased still further, above $\beta = 148$, the porosity distribution near the entrance again begins to become nonuniform.

As dissolution proceeds, the current distribution becomes more uniform since the increased porosity facilitates penetration of current into the pores. Therefore the effect of porosity variation is to render the time average current distribution more uniform than the steady state distribution at uniform (initial) porosity. Also, for the system under study, the induced convection due to volumetric changes on dissolution tends to make the current distribution more uniform although, for this system, the current distribution is affected by less than 1% over the range of parameters presented here. It is possible that the pseudosteady state approximation would not be valid for cases where the induced convection was really significant. Although the current distribution thus changes as dissolution proceeds, if the change is only slight, the final porosity distribution may be estimated from the current distribution prevailing at the initial steady state conditions. When the final porosity distributions calculated by the pseudosteady state model (Fig. 3) were compared with similar results obtained with use of the initial steady state current distribution, the two methods gave results which agreed within 2% for the lower current densities. For β values of 148 and 296, the steady state model predicted porosities near the pore entrance which were up to 10% higher than the pseudosteady state model.

Conclusions

The performance of dissolving porous electrodes predicted in this work is, of course, subject to the limitations associated with the pseudosteady state macroscopic model used. The calculated results of the changing electrode structure are all entirely consistent in pattern with what should be expected on the basis of qualitative reasoning.

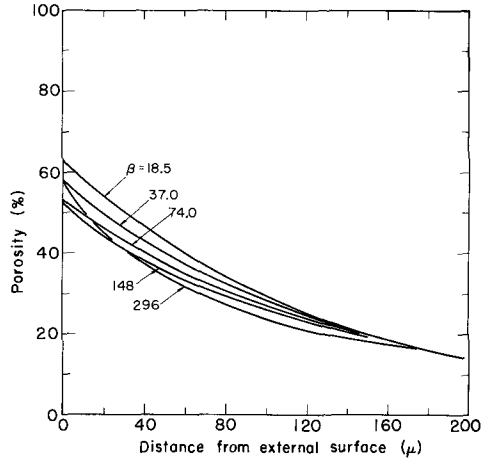

Fig. 3. Porosity distribution for porous copper anode after dissolution for 0.05 A-hr at several current densities ($\xi = 400$).

An interesting aspect of the behavior of anodically dissolving porous systems, although one not directly connected with matrix changes, is also evident in these results. That is the occurrence of the most uniform current distribution within the flooded porous electrode at a particular, nonvanishing applied current density as the result of mass transport limitations on the local cathodic (back) reaction.

In most practical flooded electrodes local variations in overpotential behavior due to inhomogeneities in the solid state, changes in microscopic configuration in the course of electrode reaction, and effects from reaction at the external electrode surface may cause significant deviations from the behavior patterns predicted by this theory. Also, in many systems, products, as well as reactants, appear in the solid state. However, consideration of these more complex cases will require better knowledge of mechanisms of electrode reactions and of the composition and distribution of solid materials in such electrodes before any meaningful quantitative analysis can be undertaken. In the meantime, useful insight into several performance characteristics for flooded porous electrodes can be gained from the present simplified theory. The pseudosteady state approach can be extended to more realistic cases as necessary information becomes available.

Cyclic Voltammetry of Mixed Metal Electrodes

Jaspal S. Mayell* and William A. Barber*

Central Research Division, American Cyanamid Company, Stamford, Connecticut

ABSTRACT

Repetitive potentiostatic triangular voltage sweeps cause a significant change in the surface structure and catalytic activity of mixed metal fuel cell electrodes. For the particular case of a platinum-rhodium black electrode, each successive cycle causes a decrease in the platinum oxidation and reduction peaks with a proportionate increase in the rhodium oxidation and reduction peaks. The complete elimination of the platinum peaks is related to the resistance of an electrode to CO poisoning. A possible mechanism of the above behavior along with data on other mixed metal electrodes is presented.

The electrochemical study of the surface characteristics of mixed metals can give new insight into their catalytic activity. Cyclic voltammetry of smooth platinum-gold alloys (1), has shown that the areas under the current-potential curves are proportional to the concentration of the metal present in the alloy. Using smooth platinum-chromium alloys, Breiter (2) attributed the change in the shape of the current-potential curves during the first 20 cycles to the gradual removal of impurities from the surface of the alloys. However, in our study repetitive triangular voltage sweeps caused a significant change in the surface structure and catalytic activity of mixed metals or alloy type electrodes. This behavior has not been reported previously.

The ultimate objective of this investigation is the development of fuel cell catalysts and electrodes which give enhanced performance on a hydrogen fuel containing up to 10% carbon monoxide. The most promising carbon monoxide resistant fuel cell electrodes reported are catalyzed by platinum-rhodium (3), platinum-ruthenium (4, 5), and platinum covered with sulfur (6-9). Repetitive cycling is shown in this study to improve the resistance of some mixed metal catalysts to carbon monoxide poisoning.

Experimental

The working and the auxiliary electrodes were accommodated in a conventional H-type Pyrex glass electrolysis cell. Each compartment had a sintered glass disk through which nitrogen was continuously bubbled. Both compartments were covered by polytetrafluoroethylene (PTFE) stoppers with holes for the electrode holders, reference probe, and other equipment. The cell was maintained at constant temperature by means of an oil bath. The auxiliary electrode was an 80-mesh platinum gauze. The use of a sintered glass disk as well as continuous bubbling of nitrogen prevented the gases evolved at the cathode from reaching the anode.

All porous test electrodes were made according to the procedure described previously (10). They were acid washed before use. They were made liquid impermeable by application of a 15 mil thick porous polyfluorocarbon backing material (Cyanamid L-3 backing). The backing was applied at 150°C, by pressing at 150 psi for 5 min. The electrodes were held in the anode halfcell by a PTFE screw cap (11). Electrical connection to the fluorocarbon-backed anode (test electrode) was made by a platinum wire spot-welded to the tantalum screen. The advantages of this electrode assembly include ease of changing the elec-

trodes and of keeping any desired gas atmosphere at the back of the electrode.

The hydrogen reference electrode was constructed from PTFE-bonded platinum black on platinum screen. Hydrogen was bubbled over the electrode in 85% phosphoric acid. The reference electrode assembly was separated from the main body of the solution by a porous Vycor bulb. Connection to the test cell was made through an electrolyte bridge and Luggin capillary. All potentials mentioned in this study are with respect to the above hydrogen reference electrode, kept at room temperature. However, since the work was performed at 100°C (where the phosphoric acid concentration is more nearly 95-97%), a correction of 30 mV[1] due to temperature and concentration gradients has been subtracted from the observed potentials. The electrolytes phosphoric acid and sulfuric acid were of reagent grade quality and no special precautions were taken to purify the electrolytes. Some experiments were performed with hydrogen peroxide treated phosphoric acid (excess H_2O_2 removed by heating) but the results were similar to those of untreated phosphoric acid.

Platinum black used alone or in physical mixtures was commercial material (Engelhard Industries) with a BET surface area of 25-30 m^2/g. Rhodium black used alone or in physical mixtures was prepared by diphenylsilane reduction of rhodium chloride in ethanol at 70°C. It had a BET surface area of 40 m^2/g. Codeposited mixed blacks were prepared by coreduction from mixed solutions of the corresponding noble metal halides using diphenylsilane under the conditions mentioned above. All ratios and percentages reported are by weight.

For cyclic voltammetry, a Hewlett-Packard Model 202A low frequency generator was used to drive the Wenking potentiostat, Model 61TRS. The potentiostat was connected to the appropriate electrodes and the resulting current-potential curves were followed on a Moseley Model 135 X-Y recorder. Cycling the electrodes at different scan rates, from 3 mV/sec to 100 mV/sec, made no difference in the over-all behavior. In this study most of the cycling was performed at 30 mV/sec. While cycling, a nitrogen atmosphere was maintained at the back of the porous electrodes.

Polarization curves were obtained by applying a constant potential between the working and the reference electrodes for 2-3 min (which time was enough to reach a steady state) and recording the currents at a set of predetermined potentials.

Results and Discussion

Cyclic voltammetry of porous electrodes.—Electrodes of physically mixed platinum black and rhodium black (at 15 mg noble metal/cm^2 and later at 5 mg/cm^2) were cycled by repetitive triangular voltage sweeps between 0.05V and 1.50V. During the first cycle of mixed electrodes the size of the peaks corresponding to each metal was roughly proportional to the concentration of platinum and rhodium, as would be expected. Each successive cycle caused an increase in the rhodium oxidation and reduction peaks with a proportionate decrease in the platinum oxidation and reduction peaks (Fig. 1). With continued cycling, complete disappearance of the platinum peaks was observed (curve 2, Fig. 2). Further cycling beyond the disappearance of the platinum peaks caused a further increase in rhodium oxidation and reduction peaks (to 700 cycles) as shown in curve 3 of Fig. 2. Finally, with prolonged cycling, a gradual decrease of the rhodium peaks occurred followed by reappearance of the platinum peaks, as shown by curve 4 of Fig. 2 (2500 cycles).

A similar over-all behavior was observed in 6*N* H_2SO_4 at room temperature. However, the platinum peaks reappeared much earlier in sulfuric acid, after

[1] The corrective value of 30 mV was observed when the reference hydrogen electrode was at room temperature and the electrolysis cell (with hydrogen atmosphere over the working electrode) was at 100°C.

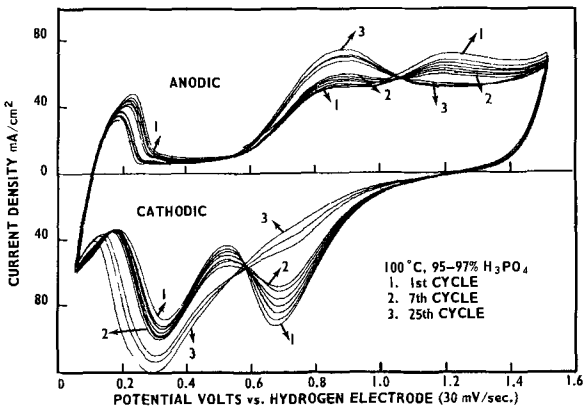

Fig. 1. Repetitive cycling of a porous mixed Pt-Rh electrode, 15 mg/cm^2 (2:1).

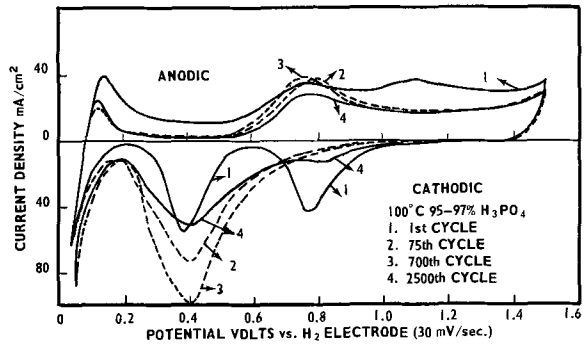

Fig. 2. Repetitive cycling of a porous mixed Pt-Rh electrode, 5 mg/cm^2 (1:1).

about 750 cycles, and they were approximately equal to the platinum peaks of the first cycle. The elimination and the reappearance of the platinum peaks with cycling is very characteristic, and its importance will be explained as the discussion proceeds. It should, however, be mentioned that the reproducibility of the peak heights (and consequently active electrochemical area) among different electrodes was not very good because of some apparently inherent nonuniformity in making the porous test electrodes.

Cyclic voltammetry of smooth electrodes.—To compare with high area electrodes, some work with smooth electrodes was performed. Cyclic voltammetric curves of smooth platinum, smooth rhodium and a smooth alloy of platinum-rhodium [50 w/o (weight per cent), 66 a/o (atom per cent) rhodium] are shown in Fig. 3. X-ray diffraction pattern of the platinum rhodium alloy (supplied by Engelhard Industries) showed the presence of a single phase. The first sweep of the alloy (curve 3) showed no platinum peaks. From the similarities of the curves 2 and 3, Fig. 3, the electrochemical surface characteristics of the alloy in the

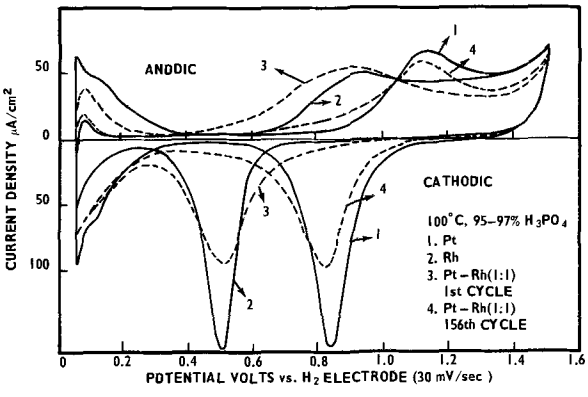

Fig. 3. Repetitive cycling of smooth electrodes

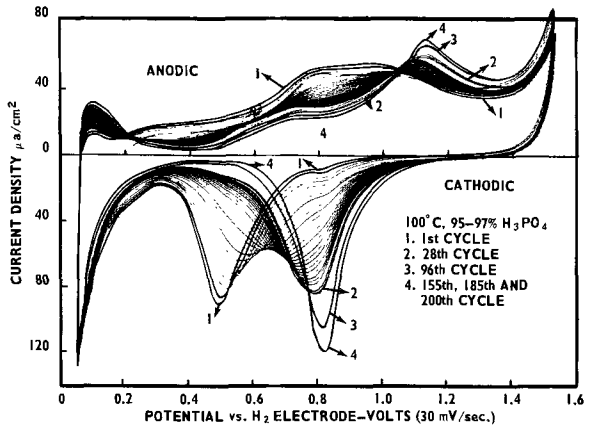

Fig. 4. Repetitive cycling of smooth Pt-Rh alloy (1:1)

beginning are similar to those of pure rhodium. However, a typical continuous cycling of the smooth alloy, Fig. 4, showed a gradual decrease in rhodium peaks and a proportionate increase in the platinum peaks with each successive cycle. Finally, only platinum peaks were visible as seen by curves 2 to 4, Fig. 4. Thus, cycling changed the surface characteristics of the smooth platinum-rhodium alloy from those of rhodium to those of platinum in about 150 cycles.

On first glance, the results obtained with a smooth alloy seem to contradict those reported earlier with porous mixed metals. However, we can reasonably well explain the above behavior if we assume that the rhodium oxides formed during the anodic cycle are at least partly soluble in the acid medium. In the case of smooth alloys, the rhodium oxides have a chance to diffuse away from the electrode surface and are not redeposited in the reduction half of the cycle, so that each succeeding cycle exposes more and more of the underlying immobile platinum sites and finally the surface behaves more like a pure platinum surface. In a porous electrode, however, the rhodium oxides are formed within the porous structure and do not have a chance to diffuse away completely but are redeposited during the cathodic half of the cycle covering some of the platinum in the process. Such a repetitive process of selective dissolution and random deposition would convert a physically mixed platinum-rhodium black surface to one with characteristics of rhodium alone. Not all of the rhodium oxides formed during each cycle were redeposited, as after very long cycling (2000 times or more) the rhodium peaks decreased and the platinum peaks reappeared. Qualitative analysis by atomic emission spectroscopy of the phosphoric acid electrolyte in which the porous platinum-rhodium electrode had been cycled showed the presence of rhodium and absence of platinum, indicating the validity of our assumption of the dissolution of rhodium oxides.

During cycling at 30 mV/sec two "iso-electronic" points, one at about 1.04V on the anodic sweep and the other at about 0.65V on the cathodic sweep, were observed both with porous as well as smooth platinum-rhodium electrodes. By analogy with "iso-sebestic" points of spectroscopy, it is likely that, during cycling, formation and reduction of oxides of rhodium and platinum occurred with the exclusion of other side reactions.

Polarization.—It is quite evident from the polarization curves of a series of electrodes (Fig. 5) made from physical mixtures of platinum black and rhodium black with from 0 to 100% rhodium, that the cycled electrodes (3 mV/sec) polarized less severely than the original uncycled electrodes. The over-all level of performance of the anode improved as the proportion of rhodium in the mixtures was increased both in the cycled as well as the original electrodes. Platinum black alone at 100°C performed very poorly while rhodium black showed the least polarization (Fig. 5).

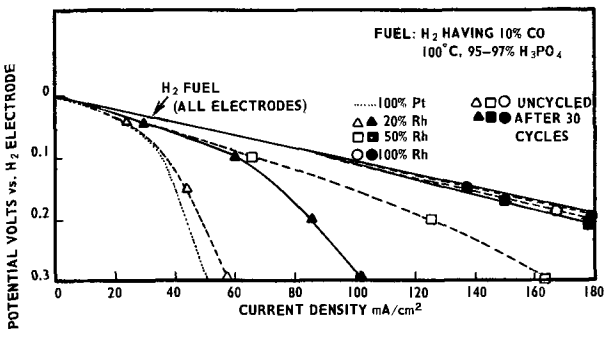

Fig. 5. Polarization curves of porous mixed Pt-Rh electrodes (15 mg/cm²).

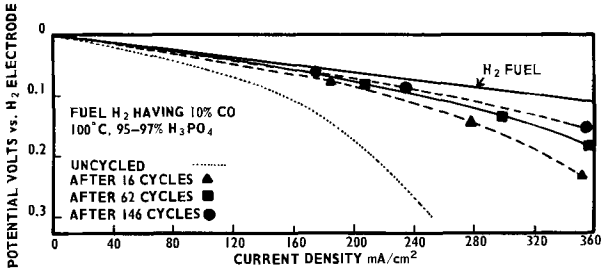

Fig. 6. Polarization curves of a porous mixed Pt-Rh electrode, 15 mg/cm² (1:1).

However, the cycled electrode having 50% or more of rhodium was almost as good as pure rhodium. Cycling (30 mV/sec) beyond the disappearance of the platinum peaks (about 30 cycles) caused a further decrease in polarization as seen in Fig. 6.

With the object of extending the performance improvements observed to lower catalyst levels, the concentration of the noble metals was decreased from 15 to 5 mg/cm². It was hoped that the catalyst could be spread to more advantageous sites by cyclic voltammetry. The polarization of such a physically mixed electrode decreased with cycling, as seen in Fig. 7 (during these cycles the rhodium peaks increased as at higher loadings but more gradually). However, after extremely long cycling (2350 times), the polarization increased considerably and was a little more than that of the original uncycled electrode (during these latter cycles, rhodium peaks decreased with reappearance of the platinum peaks). Attempts to increase the performance of 5 mg/cm² of a physically mixed platinum-rhodium with the addition of 5 mg/cm² of graphite as a conductive support were not successful. A new very small reduction peak at 0.85V was observed when the electrode containing graphite was oxidized to 1.50V. The identity of this peak was not established, but it may be due to reduction of oxides of carbon. In all cases of physically mixed platinum-rhodium black, a severe loss in performance was observed in going from 15 to 5 mg/cm².

No significant improvement in performance was observed when physically mixed platinum-rhodium

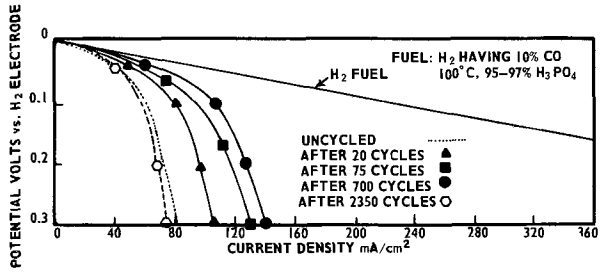

Fig. 7. Polarization curves of a porous mixed Pt-Rh electrode, 5 mg/cm² (1:1).

electrodes were cycled over the narrower region of 0.2-0.9V. Also, controlled potential oxidations at 0.9V (where rhodium oxide formation occurs) and at 1.5V (where both rhodium and platinum oxides are formed) caused no noticeable decrease in polarization. In one experiment the tantalum screen was replaced by a platinum screen to ascertain whether the disappearance of platinum peaks and the enhancement of rhodium peaks while cycling was in any way related to the presence of tantalum in the electrode. Cyclic voltammetric curves were similar with electrodes having either type of screen. However, the polarization obtained with a platinum screen electrode was less than that for a similar electrode using tantalum screen. This may be due to the better conductivity of the platinum screen.

Codeposit vs. physical mixture.—A codeposit of platinum and rhodium blacks was made by reduction of their chlorides with sodium borohydride and this catalyst was made into an electrode at 15 mg noble metal/cm^2. The results were then compared with a similar physically mixed electrode. On cycling, both electrodes showed improvement in resistance to carbon monoxide poisoning. However, the physically mixed electrode performed better at high current densities than the codeposited electrode. On the first cycle of a codeposited electrode, only one reduction peak (at 0.49V) was observed, and this shifted gradually to 0.45V after 150 cycles. This peak was between the platinum (0.77V) and rhodium (0.38V) reduction peaks of a physically mixed electrode. Prolonged cycling (1000 to 2000 times) of a codeposited electrode caused the appearance of a platinum reduction peak with a proportionate decrease in the initial peak. Qualitatively, this behavior was similar to a smooth alloy of platinum-rhodium, although only about 100 cycles were required to remove all the rhodium from the surface of the smooth alloy. The gradual appearance of the platinum peak with cycling on smooth alloy and codeposited platinum-rhodium electrodes is another indication of the dissolution of rhodium.

X-ray diffraction patterns using Cu-K radiation having a Ni filter (effective wavelength of 1.54050Å) of the physically mixed platinum and rhodium electrodes show two distinct phases, one platinum peak at 40° and the other rhodium peak at 41°, curve 1 of Fig. 8. After about 150 cycles, the two phases become better defined (curve 2, Fig. 8). The peaks were identified by comparing with the known samples of platinum and rhodium and also by checking with the literature data.

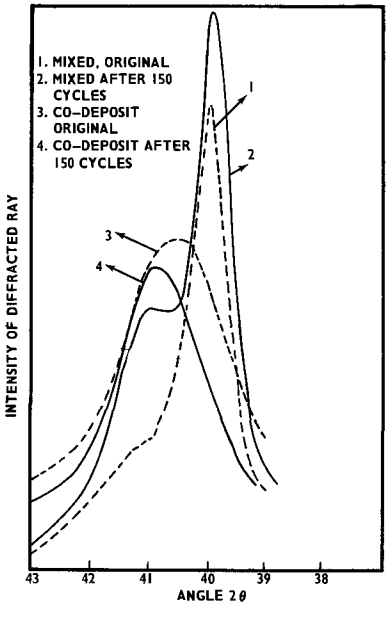

Fig. 8. X-ray diffraction patterns of mixed and codeposited Pt-Rh electrode, 15 mg/cm^2 (1:1).

The codeposited platinum-rhodium electrode on the other hand showed only a single (alloy) phase. After about 150 cycles, the peak shifted from about 40.5° to 40.8° (curves 3 and 4, Fig. 8) suggesting rhodium enrichment of the alloy phase near the electrode surface. This probably occurs by dissolution of the rhodium oxide during the anodic cycle and redeposition of rhodium on the platinum sites when the cycling is reversed. Cycling seems to result in crystallite size growth of the particles.

Electron microscopic data reveal that the metal phase in both codeposited and physically mixed platinum-rhodium electrodes is very fine and well-dispersed. Cycling caused an increase in the size of the particles and, in the case of the codeposited electrode, the formation of spheroidal metal particles (0.1 to 0.5μ).

It can be inferred from the results of cyclic voltammetry and x-ray diffraction data that a codeposited electrode is an "alloy," while the physically mixed electrode behaves as a simple mixture of platinum and rhodium even after cycling.

Palladium-rhodium electrode.—The results obtained with a physically mixed palladium black and rhodium black electrode were qualitatively similar to those obtained with the mixed platinum-rhodium electrode as discussed previously. As shown in Fig. 9, the initial twin peaks for palladium and rhodium were present, but with cycling the palladium reduction peak (at 0.63V) decreased leaving two small well-defined peaks (at 0.75 and 0.63V). The new peak at 0.75V may be due to platinum which is exposed at the surface because cycling caused dissolution of most of the palladium. Qualitative analysis by atomic emission spectroscopy of the electrode showed the presence of platinum (approximately 600 ppm) as an impurity. The performance of the uncycled electrode on H_2 having 10% CO at 100°C in phosphoric acid was good and improved with cycling (to 25 cycles). However, after longer cycling (to 214 times), the polarization increased while the rhodium peaks decreased. Also, during cycling a black precipitate, presumably due to the dissolution of palladium oxides, came out of the electrode. The black color became more intense during the anodic cycle at potentials > 1.20V. No significant change in polarization was observed when the mixed palladium-rhodium electrode was cycled between 0.2-0.9V instead of the usual 0.05-1.50V.

Platinum-ruthenium electrode.—Attempts to make electrodes of physically mixed platinum black and ruthenium black were not successful, since ruthenium dissolves in the acid wash given to all electrodes before use. A codeposit of platinum-ruthenium formed into an electrode was more stable and showed behavior qualitatively similar to a codeposited platinum-rhodium electrode. However, the ruthenium peaks disappeared almost completely in about 100 cycles, curve

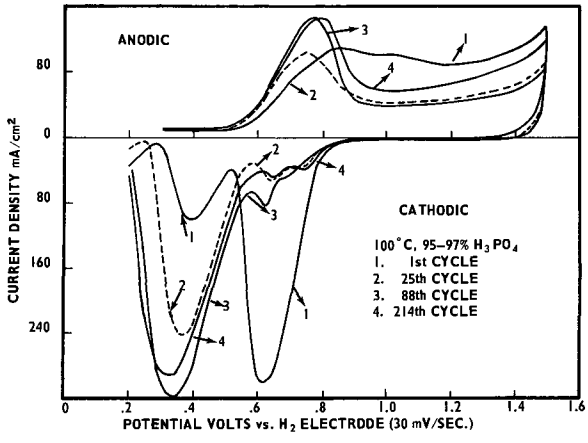

Fig. 9. Repetitive cycling of a porous mixed Pd-Rh electrode, 15 mg/cm^2 (1:1).

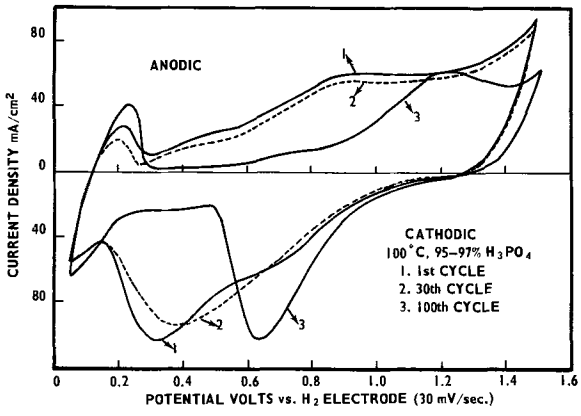

Fig. 10. Repetitive cycling of a porous codeposit of Pt-Ru, 10 mg/cm² (8:2).

3 of Fig. 10, and well-defined platinum peaks reappeared. This coincided with a sharp increase in polarization after 100 cycles. The disappearance of the ruthenium peaks and the formation of a brown precipitate during cycling suggests the dissolution or dispersion of ruthenium oxides into the acid electrolyte.

Gold-rhodium electrode.—Gold black (8 m²/g surface area) and rhodium black (30-40 m²/g surface area) were mixed in equal weight proportion to give an electrode with a total loading of 15 mg/cm². Cyclic voltammetry showed the oxidation and reduction peaks of rhodium (at 0.8 and 0.38V, respectively) and of gold (at 1.36 and 1.27V). Repetitive cycling decreased the gold peaks gradually. After about 20 cycles, no gold peaks were observed while a proportionate increase in rhodium peaks occurred. The original as well as the cycled electrode performed poorly on 10% CO in hydrogen.

RA (platinum-rhodium-WO_x) electrodes.—The RA catalyst is a special type found by empirical study to be unusually resistant to carbon monoxide poisoning. It is made (12) by codeposition of platinum-rhodium black in the presence of tungsten oxide (WO_x) with an oxidation state of the tungsten between 4 and 6. Cycling of this type of electrode showed only very large and well-defined rhodium peaks and no platinum peaks at all (curve 3, Fig. 11). Repetitive cycling decreased the rhodium peaks, evolved a yellow precipitate (more intense at potentials > 1.30V) presumably due to dissolution of higher oxides of tungsten, and caused an increase in polarization. Exceptionally good performance of such an electrode was obtained (Fig. 12) even at a total loading of noble metals of 5 mg/cm².

In another experiment platinum black and rhodium black were made separately in the presence of tungsten oxide. Although the two catalysts were made in a similar manner, on analysis it was found that the

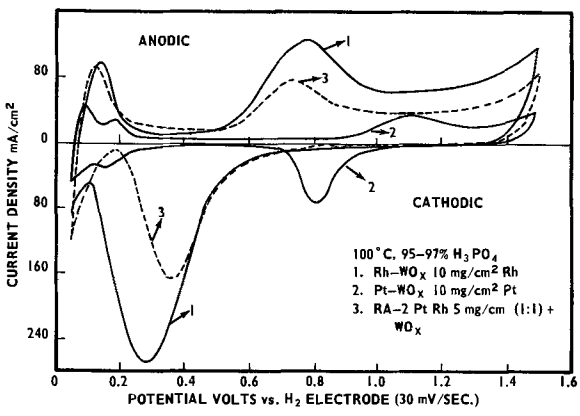

Fig. 11. Cyclic curves of various porous electrodes (first cycle)

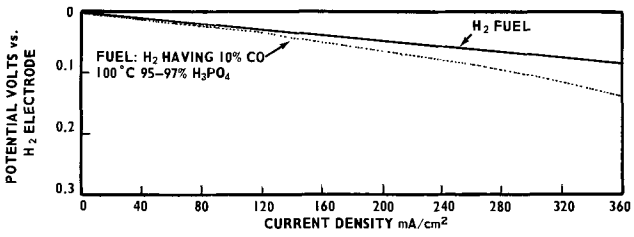

Fig. 12. Polarization curves of a porous RA2 electrode 5 mg/cm² Pt-Rh (1:1) 4 mg/cm² graphite + WO_x.

concentration of tungsten in the platinum black was about 3% while only about 0.3% in the rhodium black. Cyclic voltammetry of the rhodium-tungsten electrode shows a very large rhodium peak, curve 1 of Fig. 11, indicating that in the presence of tungsten oxide rhodium sites are readily exposed at the electrode surface. On the other hand, a platinum-tungsten electrode shows a very small platinum peak, curve 2 of Fig. 11, thereby indicating relatively few platinum electroactive sites.

Conclusions

Repetitive triangular voltage sweeps markedly changed the apparent surface structure of both porous mixed platinum-rhodium black electrodes and smooth alloy electrodes containing the same metals. In the case of mixed black electrodes, cycling changed the dual surface characteristics of platinum and rhodium to those of rhodium alone. However, very prolonged cycling caused the reemergence of platinum surface characteristics and diminution of rhodium characteristics. For a smooth platinum-rhodium alloy electrode, cycling changed the initial surface characteristics from those of rhodium alone to those typical of platinum.

The explanation of these observations appears to be the oxidation and selective partial dissolution of rhodium from the electrode surface. For the smooth alloy electrode it appears that rhodium oxide is selectively dissolved and diffuses into bulk solution before reduction can occur. For the mixed black electrode there appears to be selective solution and redeposition of rhodium on platinum within the porous electrode structure. Loss to bulk electrolyte is relatively slow, although when cycling is continued exhaustively, transfer to the bulk electrolyte becomes significant and platinum surface reappears with diminution of rhodium surface characteristics.

Studies of electrode polarization on hydrogen containing 10% CO indicate that maximum electrochemical performance (minimum polarization due to CO poisoning) occurs under conditions of maximum surface coverage of rhodium. Thus a cycled 1:1 platinum-rhodium black electrode which exhibited total replacement of platinum surface with rhodium was equivalent in performance to an electrode made of rhodium black alone.

In summary, the observed variations in electrocatalytic performance can be largely explained in terms of rhodium oxide dissolution and redistribution on cycling and the concept that maximum rhodium surface is required for minimum polarization due to CO poisoning.

The palladium-rhodium, platinum-ruthenium, and gold-rhodium systems all showed qualitative similarities to platinum-rhodium with respect to migration and redistribution of rhodium or ruthenium. The gold-rhodium system, however, was poor from an electrocatalytic standpoint, perhaps indicating that substrate composition can have an important influence on the activity of the rhodium surface. The general phenomena observed are thought to have broad application in the study of electrocatalysis.

The High Rate Oxidation of Silver Electrodes in Chloride Solutions

P. Bro* and N. Marincic*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Burlington, Massachusetts

ABSTRACT

The anodic oxidation of silver in zinc chloride solutions demonstrated the feasibility of operating rechargeable silver/silver chloride battery electrodes at charging rates up to 150C without any gas evolution. Specific capacities of about 2 mA-hr/cm^2 were obtained at current densities between 60 and 300 mA/cm^2. The greatest charge acceptance was obtained with thin silver electrodes and with zinc chloride solutions containing sodium perchlorate. The charging process was generally terminated by the boiling of the electrolyte in the diffusion layer at the electrode.

Conventional storage batteries have low intrinsic charging rate capabilities, and attempts to charge them quickly invariably lead to unwanted parasitic reactions. We have searched for a system with a high intrinsic charging rate capability, and we have reached the conclusion that the highest rates can be obtained, most probably, with electrodes formed by deposition from concentrated solutions of their salts. The rate capabilities have already been discussed of anodes which are formed by deposition from chloride solutions of the anode metals (1, 2), and the results indicated that very high charging rates could be employed. It would be expected, likewise, that cathodes might be charged rapidly when formed by the oxidation of suitable metals in concentrated solutions of salts containing the cathode anion.

We found that silver electrodes could be oxidized electrochemically at very high rates in chloride solutions without gassing, particularly in the case of thin silver electrodes, to give useful silver/silver chloride battery cathodes. The studies reported here were undertaken to obtain an understanding of the fast charging process and to establish the rate limiting factors. We also report the rate and charge acceptance capabilities of the silver/silver chloride cathode in an electrolyte suitable for the operation of rechargeable zinc/silver chloride cells.

Experimental Techniques

Flat silver electrodes were charged in zinc chloride solutions under constant current conditions in cells shown schematically in Fig. 1. Conventional chronopotentiometric circuitry was used. The constant current was derived from a 240V stack of lead acid storage batteries in series with a variable resistor or from a Harrison power supply, Model 6443B. The electrode potentials were measured with respect to a Ag/AgCl reference electrode in the same solution located about 0.5 cm in front of the working electrode. The chronopotentiograms were recorded with a Sargent recorder, Model DSRG. It is estimated that the currents remained constant within 2% during the charging process. The currents were measured with a Greibach ammeter, Model 560 or 700, with an accuracy of $\pm$ 0.5%.

The circular silver electrodes were made from 99.9% pure silver and had a diameter of 1.85 cm, almost equal to that of the inner diameter of the cylindrical cell, 1.90 cm, to provide a uniform current density on the electrode. Copper-constantan thermocouples made of 1 mil wires were cemented to the rear of the electrodes with silver amalgam, and the mounted thermocouples were calibrated in a constant temperature bath. The potential of the thermocouples was recorded directly on the Sargent DSRG duo-channel recorder concurrently with the potential of the working electrode. The response time of the electrode-thermocouple system was limited by that of the recorder, about 1 sec for full scale deflection. The finite thickness of the electrodes introduced a short but noticeable delay in the thermal response of the thermocouple to a change

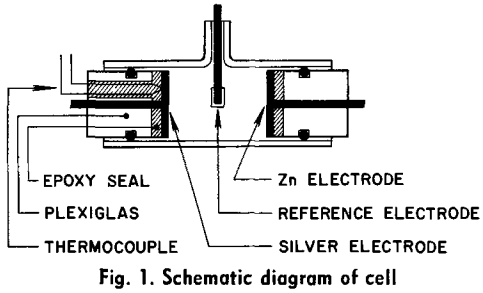

Fig. 1. Schematic diagram of cell

* Electrochemical Society Active Member.

in the temperature of the front surface of the electrodes.

The electrodes were reconditioned after each charge by the removal of the silver chloride and the repolishing of the electrode with a grade 500 emery cloth. The oxidation occurred uniformly over the silver surface, with occasional pitting, which allowed the change in the thickness of the electrodes to be calculated from the total charge per pulse. Measurements of the electrode thickness after several runs confirmed the validity of these calculations.

Zinc was used as a counterelectrode to avoid gas formation at the negative electrode during charging. All the solutions were prepared from reagent grade chemicals, and the zinc salt concentrations of the stock solutions were determined polarographically.

Experimental Results

A typical thermal response curve of a thin silver electrode is shown in Fig. 2. After an initial delay in the thermocouple response caused by the finite thickness of the electrode the temperature of the silver electrode rose rapidly with a positive curvature. Then, the rate of rise decreased, and strong thermal fluctuations developed. The voltage across the electrode followed a similar pattern. At the point where the thermal and potential fluctuations began, the silver chloride film began to deteriorate. Generally, microvolcanic eruptions occurred in the film accompanied by incipient boiling noises and an intense agitation of the electrolyte in the crater regions. Strong convective currents were generally observed within 5-20 sec of the start of the charging pulse, depending on the electrolyte composition and the current density. Occasionally, boiling occurred before film failure. The onset of film failure or boiling signalled the end of efficient charging and was used to define the charge acceptance of the electrode.

The charge acceptance of the electrodes did not vary much with the current density. The greatest change was observed in the 2.0M $ZnCl_2$, 0.5M $NaClO_4$ solution, Fig. 3, where it increased from about 1.5 mA-hr/cm^2 at current densities above 200 ma/cm^2 to values greater than 2.0 mA-hr/cm^2 at current densities below 60 ma/cm^2. Smaller changes were observed for the less concentrated supporting electrolytes. The smallest charge acceptance of about 0.8 mA-hr/cm^2 was found for electrodes charged in 2.0M $ZnCl_2$ containing no supporting electrolytes. At current densities below the values reported here the silver chloride films were either poorly attached to the electrode or the silver chloride was present as a loosely adhering powder. Although the low current densities gave high specific capacities on charge the poor quality of the silver chloride rendered the charge nonrecoverable.

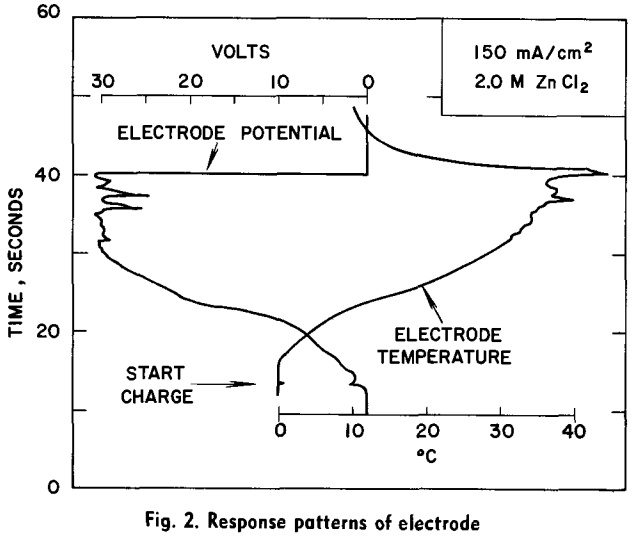

Fig. 2. Response patterns of electrode

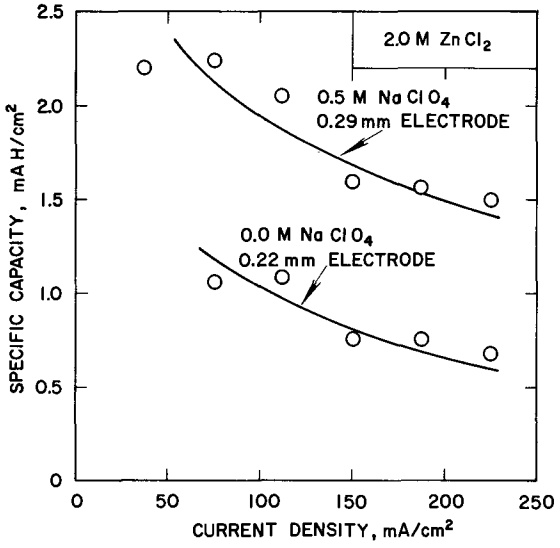

Fig. 3. Influence of the current density on the charge acceptance

The reported charge acceptance pertains to the charge rather than the discharge of the silver/silver chloride electrode. Separate experiments established that discharge efficiencies above 95% were obtained whenever visually sound films of silver chloride were formed. The discharges were performed at 0.4-4.4 mA/cm^2. Repeated cycling of Zn/AgCl cells under various conditions confirmed the high coulombic efficiency of the sytsem.

The zinc chloride concentration of the electrolyte exerted a strong influence on the behavior of the Ag/AgCl electrode. In saturated zinc chloride solutions the silver chloride films dissolved rapidly, 70 μA/cm^2, presumably due to the formation of soluble $AgCl_2^-$. The self-discharge rate was reduced to less than 1 μA/cm^2 at room temperature for zinc chloride concentrations below 2M. This was considered an acceptable self-discharge rate for the Zn/AgCl cells. Since it was desirable to use high zinc ion and high chloride ion concentrations to enhance the mass transfer rates at the electrodes, the 2.0M zinc chloride electrolyte represented a satisfactory compromise, and most of the studies were limited to this electrolyte.

The exploratory experiments had indicated that the high rate charging process gave higher capacities on thin electrodes than on thick ones. This led to the conjecture that a successful high rate charging depended on the heating of the silver chloride film. At elevated temperatures film defects would heal during the charging process and the film would also be more conductive. Because of its large heat capacity the temperatures of the silver chloride film on a thick silver electrode would remain low, the film would not heal, and the charge acceptance would be low. A series of experiments with a thick electrode containing 35g silver/cm^2 showed that it had only about one third the charge acceptance of the thin electrodes reported on here; the latter contained less than 0.7g silver/cm^2.

An examination of the charging curves indicated that the half-cell voltages at the film failure points varied little with the current density, which allowed the use of a mean failure voltage for each solution, Fig. 4. In the absence of a supporting electrolyte, the end of useful charging occurred at about 27V. It rose to about 31V in the 2.0M $ZnCl_2$, 0.5M $NaClO_4$ solution, and it decreased to about 21V in the 2.0M $ZnCl_2$, 1.0M $NaClO_4$ solution. The thickness of the electrodes did not influence the failure point voltages noticeably for the thin electrodes.

The initial thermal response of the electrodes would be expected to reflect the influence of the system variables more clearly than would their temperature at the failure points because of the strong convective disturbances in the electrolyte toward the end of the

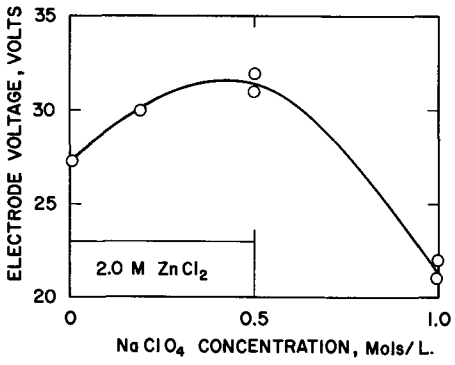

Fig. 4. End of charge voltage of the Ag/AgCl electrode

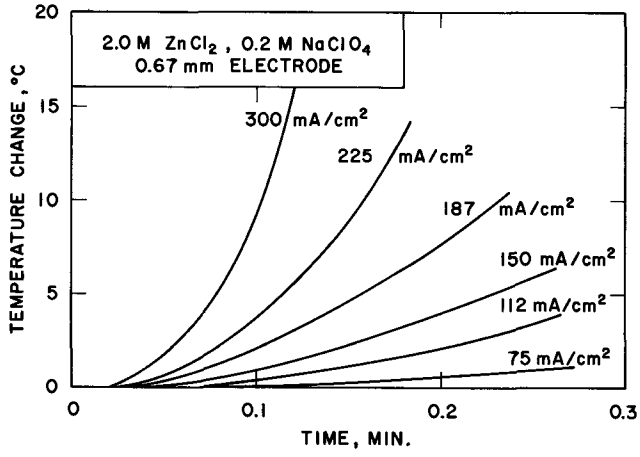

Fig. 5. Heating rate of the electrode

charging process. The rate of heating of the electrodes increased rapidly with the current density, Fig. 5. Rates were reached of 5°C/min at 75 mA/cm² and 250°C/min at 300 mA/cm² after 6 sec of charging in the 2.0M $ZnCl_2$, 0.2M $NaClO_4$ solution for a 0.067 cm thick electrode. The thickness of the thin silver substrates did not affect the rate of heating noticeably, Fig. 6. However, the composition of the electrolyte exerted a strong influence on the heating rate, Fig. 7. The lower the concentration of the supporting electrolyte, the greater the heating rate under otherwise identical conditions. In 2.0M $ZnCl_2$, 1.0M $NaClO_4$ it reached a value of 21°C/min after 12 sec at 150 mA/cm²; the corresponding value in 2.0M $ZnCl_2$ was 280°C/min.

The thermal histories beyond the initial charging period increased in variability, and the influence of the various parameters could not be discerned unambiguously.

Discussion

The experimental work demonstrated that flat silver electrodes could be charged efficiently at very high current densities, at rates as high as 150C in battery terminology, to give recoverable specific capacities of about 2 mA-hr/cm². The charging process was strongly dependent on the quality of the silver chloride film formed on oxidation. At current densities below about 40 mA/cm² inferior films were formed on the flat electrodes and they gave low discharge efficiencies. Above about 60 mA/cm² good films were formed which gave high coulombic efficiencies on discharge. These observations are in general agreement with the results reported in the literature. Jaenicke *et al.* (3) found that patchy films were obtained at low current densities which adhered poorly to the substrates. Above 30 mA/cm² silver chloride films were obtained which adhered well to their substrates.

Once a uniform silver chloride layer is present on a silver electrode no gas evolution would be expected at the AgCl/electrolyte interface since silver chloride is a purely ionic conductor. Exceptions were noted at the lower current densities where a transitory, thin, dark film appeared on the electrodes at the onset of charging. Very light gassing could then be seen which may be attributed to the electronic conductivity of the dark film which was, presumably, silver chloride with a high defect concentration. At the higher current densities the dark film persisted for a very short time only and no gas evolution could be seen.

In principle, it should be possible to oxidize a silver electrode at a very high rate since the process consists of the simple abstraction of electrons from the metal. Any rate limiting factors, if present, would be associated with the transport processes in the system. The evolution of chlorine at the silver/silver chloride interface might be a limiting process, but no observations indicated its occurrence. Two processes may be considered. Once a uniform silver chloride film is present on the electrode the rate of transport of silver ions through the film would be limited only by the voltage across the film. High potentials were used to operate the electrodes at the high rates and constant rates of transport could be maintained, but only by the use of a rapidly increasing voltage across the electrode to match the increasing resistance of the electrodes. Adequate rates of transport were maintained until the films failed. The failures appeared as localized fusion of the silver chloride film, and local boiling ensued which terminated the efficient charging process. It is probable that the failures began in the micropores thought to be present in silver chloride films (3). The other rate limiting process to be considered may be attributed to the removal of chloride ions by the precipitation of silver chloride and the attendant depletion of charge carriers in the electrolyte. The efficient deposition of silver chloride on the electrode indicated

that an adequate supply of chloride ions was available at the electrode. However, the heating and eventual boiling of the solution indicated that an appreciable carrier depletion had occurred which gave rise to an excessive resistive heating of the electrolyte adjacent to the electrode. The design of the cell and the experimental procedures did not allow a discrimination between the potential differences across the silver chloride film and across the diffusion layer. The discussion will be based, therefore, on inferences drawn from the effects of the electrolyte composition on the electrode performance.

The constant current charging process was accompanied by strong convective currents at the electrode which invalidated a conventional chronopotentiometric analysis of the charge acceptance. Nevertheless, it is instructive to consider this simple mass transfer limitation. Using the transition time data for concentrated zinc chloride solutions (1) it was estimated that specific capacities of 3 mA-hr/cm^2 should be obtained at 300 mA/cm^2 in the absence of a supporting electrolyte and about 1.5 mA-hr/cm^2 in the presence of a supporting electrolyte for 2.0M $ZnCl_2$ solutions. A contrary behavior was observed. The charge acceptance increased with an increase in the concentration of the supporting electrolyte. However, the charge acceptance increased with a decrease in the current density in conformity with the expectations based on the chronopotentiometric equations. These observations suggested that the charging process was transport limited in the supporting electrolyte. The observed and expected capacities were both 1.5 mA-hr/cm^2 at 300 mA/cm^2, and at 100 mA/cm^2 they were about 2 mA-hr/cm^2 and 4 mA-hr/cm^2, respectively. This is a reasonably good agreement, but not adequate for any quantitative deductions.

The smaller capacity in the absence of a supporting electrolyte suggested that a limiting process other than mass transport intervened, and, as noted earlier, the charging process was terminated by the excessive heating of the electrolyte. The thermal response of the electrodes showed that the heating rate of the system increased markedly with a decrease in the concentration of the supporting electrolyte. If the silver chloride film had been the principal source of ohmic heat, the rate of heating would have been the same at the same current density for the various solutions. Since they were markedly different, the principal voltage drop and heat generation must have occurred in the electrolyte; the more so the lower the concentration of the supporting electrolyte, and the electrode capacities would be less than those expected for a mass transport limited system, as observed.

The potential difference across the Ag/AgCl half-cell at the failure points reached a maximum value of about 32V for a 0.5M $NaClO_4$, 2.0M $ZnCl_2$ solution, and it decreased for both lower and higher concentrations of the supporting electrolyte. The smaller failure point voltages in the more concentrated supporting electrolytes may be attributed to the greater conductivity of the electrolytes. The smaller failure point voltages in the less concentrated supporting electrolytes may be explained with reference to the thickness of the silver chloride films. The charge acceptance data showed that the film thickness decreased for concentrations of the supporting electrolyte below about 0.5M $NaClO_4$; it remained essentially constant for more concentrated solutions. Therefore, for the given rate of energy deposition in the electrolyte needed to cause boiling, the total potential drop across the half-cell at the failure point would be less for the less concentrated solutions, as observed.

Conclusions

The search for a rechargeable battery cathode capable of accepting a high charging rate with a high efficiency showed that flat silver/silver chloride electrodes could be charged under constant current conditions at rates as high as 150C (300 mA/cm^2) to specific capacities of about 2 mA-hr/cm^2 in zinc chloride solutions. The high rate of charge was accompanied by a considerable evolution of heat at the electrode, and the charging process was generally terminated by the boiling of the electrolyte. The ohmic heating of the electrolyte in the diffusion layer was the principal cause of heat generation. Some heat was also generated by the ohmic heating of the silver chloride film. Low rates of charge in the same system, below 60 mA/cm^2, led to the formation of silver chloride films which could not be discharged efficiently.

The addition of sodium perchlorate as a supporting electrolyte in the zinc chloride solution decreased the rate of heat generation in the system and increased the charge acceptance by delaying the onset of boiling. When the termination of efficient charging was thus delayed the charge acceptance reached values close to those predicted from the chronopotentiometric equations for the depletion of chloride ions at the electrode.

The application of these results to a rechargeable cell will be considered in a subsequent report.

Erratum

In the paper "Study of the Lithium Oxide-Nickel Oxide System, I. Thermodynamics of Dilute Solid Solutions" by S. Pizzini, R. Morlotti, and V. Wagner which was published on pp. 915-920 of the July 1969 issue of the JOURNAL, Vol. 116, No. 7, there is a small error in Eq. [8] and [8a]. These should be written as follows:

$$\mathbf{F}E = -[\bar{G}_{LiNiO_2(x_1)} - \bar{G}_{LiNiO_2(x_2)}] \equiv RT \ln \frac{a^*_{2(LiNiO_2)}}{a^*_{1(LiNiO_2)}} \quad [8]$$

$$E = \frac{RT}{\mathbf{F}} \ln \frac{x_2}{x_1} \quad [8a]$$

The Effect of High Pressure on the Voltage and Current Output of Silver Oxide-Zinc and Mercury Oxide-Zinc Miniature Batteries

T. N. Andersen, B. A. Miner,[1] M. H. Ghandehari, R. J. Brodd,*[2] and H. Eyring

Departments of Chemistry and Metallurgy, University of Utah, Salt Lake City, Utah

ABSTRACT

The open circuit voltage (emf) and the voltage under load of alkaline silver oxide-zinc and mercuric oxide-zinc miniature batteries have been measured at pressures up to 20 kbars. The emf of these batteries varies with pressure in the manner expected based on the thermodynamics of the cell reactions. Pressure affects the voltage of the discharging silver oxide batteries only through its effect on the emf. The voltage of the discharging mercuric oxide battery is lowered with increasing pressure by approximately 5 mV/kbar. This decrease in voltage is due both to an increase in the overvoltage at the HgO electrode and also to the ohmic resistance. These pressure effects are discussed in terms of the postulated diffusion of hydroxyl ions through water channels in the reduced oxide and the influence of these channels on the number of oxide sites at which reduction may occur.

From thermodynamics it is possible to theoretically calculate the effect of pressure on the reversible emf, $E°$, of a voltaic cell or battery. The emf is related to the standard Gibbs free energy for the battery reaction according to the well-known relationship

$$\Delta G = n\mathbf{F}E° \qquad [1]$$

The standard free energy of the reaction is related to the standard change in entropy and volume for the battery reaction according to the expression

$$\Delta G = -\Delta S dT + \Delta V dP \qquad [2]$$

From Eq. [1] and [2] the pressure coefficient of the emf is given (at constant temperature) as follows

$$\left(\frac{dE°}{dP}\right)_T = \frac{\Delta V}{n\mathbf{F}} \qquad [3a]$$

or

$$\left(\frac{dE°}{dP}\right)_T \text{(in mV/kbar)}^3 = 1.036\,\frac{\Delta V}{n} \text{ (in cm}^3\text{/mole)} \qquad [3b]$$

Here n is the number of moles of electrons transferred during the consumption of one mole of reactants. For a particular reaction ΔV can be calculated by subtracting the molar volumes of the reactants from those of the products. At atmospheric pressure the molar volumes of the substances of concern to us here are readily found from density data (1). At high pressures one would need pressure *vs.* volume data in order to obtain ΔV and hence $(dE°/dP)_T$.

The circuit of a battery under load is shown schematically in Fig. 1. The voltage output, E_{AB}, of such a cell is given by

$$\left.\begin{aligned} E_{AB} &= iR_l = E_1 - E_2 - iR_{\text{int}} \\ &= E°_1 - E°_2 - |\eta_1| - |\eta_2| - iR_{\text{int}} \\ &= E° - |\eta_1| - |\eta_2| - iR_{\text{int}} \\ &= E° - |\eta_1| - |\eta_2| - (E_1 - E_2)\,\frac{R_{\text{int}}}{R_{\text{int}} + R_l} \end{aligned}\right\} \qquad [4]$$

Here R_{int} is the ohmic resistance of the electrolyte (including the matrix in which it is embedded, see Fig. 3) in the battery, E_1 and E_2 are the potentials of the electrodes 1 and 2 with respect to a fixed reference electrode, $E°_1$ and $E°_2$ are the open circuit potentials of electrodes 1 and 2 (such that $E°_1 - E°_2 = E°$, the emf of the battery), and η_1 and η_2 are the overvoltages of the electrodes at the given current output of the battery. The overvoltage terms both act to diminish the potential difference between the two electrodes and are due to free energy barriers to charge-transfer at the metal-metal oxide and metal oxide-electrolyte interphases as well as to concentration polarization of the reactants at these interphases due to the slow diffusion of ions or to slow crystallization. The effect of pressure on E_{AB} (Eq. [4]) cannot be predicted from thermodynamics alone, since only $E°$ is a thermodynamic quantity while η_1, η_2 and iR_{int} depend on the chemical kinetics and the transport properties of the system.

In this study we have measured the emf of Ag_2O-zinc and HgO-zinc batteries as a function of pressure. We have also compared the pressure effects on the voltage of these batteries while under load to the pressure effects on $E°$, relevant to studying the relative changes with P of the various terms in Eq. [4].

Experimental Setup

The batteries were squeezed in a piston-cylinder press as shown in Fig. 2. The pistons, of diameters 0.5 or 1.0 in., were driven by a hydraulic ram which was operated with a manual pump. Each battery under study was placed in a talc pressure medium within the cylinder such that the positive pole contacted the sintered tungsten carbide piston (*cf.* Fig. 2). A lead from the piston to the potentiometer thus contacted the latter with the battery. A wire lead was connected to the negative pole of the battery by means of a conductive-epoxy cement, and this lead was run out of the pressure cell between insulating sheets (as shown in Fig. 2) to the negative jack of the potentiometer. The flow properties of the talc under pressure made for a quite uniform pressure around the battery (semihydrostatic), and also prevented the battery

[3] In this work the pressure is expressed in kilobars (kbar) where 1 atm = 1.01325 bar.

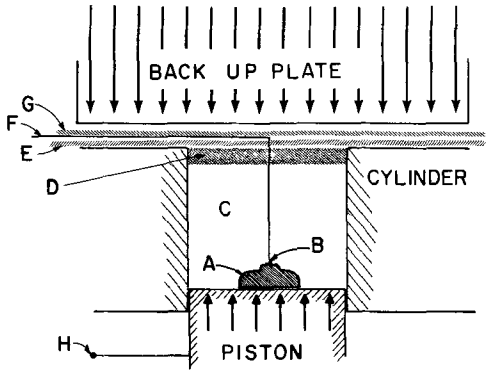

Fig. 2. Cross-sectional view of the essential components of the sample cell in the piston-cylinder press. A, battery; B, conductive epoxy connection between battery and wire lead; C, talc pressure medium; D, pyrophyllite disk; E, Teflon sheet; F, metal lead connecting negative battery terminal and potentiometer; G, mica sheet; H, wire lead to positive pole of potentiometer.

from deforming significantly during a run. Before measurements were made the pressure was increased to its maximum value in order to crush the talc around the battery, after which the pressure was decreased to 1 atm and then slowly increased to the desired pressure and the measurement made. From the above arrangement the pressure on the battery was considered to be equal to the average pressure on the face of the piston, which in turn was calculated from the oil pressure in the hydraulic line and the ratio of the areas of the faces of the ram and piston. Calibration studies (2) have shown the loss of pressure due to friction between the piston and cylinder wall to be small enough so as not to seriously alter these results. Emf measurements as a function of pressure were made by progressively and slowly increasing the pressure by small increments and then measuring the emf as the battery relaxed at the new pressure. When the voltage value did not change significantly with time, this value was recorded as the equilibrium value at the existent pressure. In practice 10 min was usually a sufficient relaxation time to allow between emf readings. Emf measurements were also made as the pressure was decreased, and typical results for such measurements are recorded in Fig. 4 and 9. Small differences in voltage between various batteries were found to be as great as the voltage changes produced by the pressure. Therefore, the effect of pressure on the dynamic battery voltages (under load or during recovery) was studied by taking continuous voltage readings of a battery as a function of time while simultaneously (slowly) varying the pressure as step functions of time. Through such a procedure, an effective voltage *vs.* time plot could be made at different pressures as is done in Fig. 5 and 7, and as could be done in Fig. 10 and 11.

The potential readings were made with a potentiometer to a precision of ±0.1 mV.

Experimental miniature batteries of Zn-Ag_2O and Zn-HgO varieties similar to types S-312 and E-312 (3) were studied. A schematic cutaway of these cells is shown in Fig. 3. The diameter of these batteries is approximately 0.31 in. and the thickness or height is approximately 0.14 in. The silver oxide battery consists of a depolarizing silver oxide cathode mixed with a small amount of graphite, a porous zinc anode of high surface area, and an electrolyte of potassium hydroxide solution absorbed into an inert material to produce a "solid" electrolyte. In addition, a cellophane type separator was used in the silver cell to prevent silver diffusion to the anode. The mercury battery has the depolarizing mercuric oxide cathode mixed with a small amount of graphite, a porous zinc anode, and an electrolyte of potassium hydroxide absorbed into an inert material.

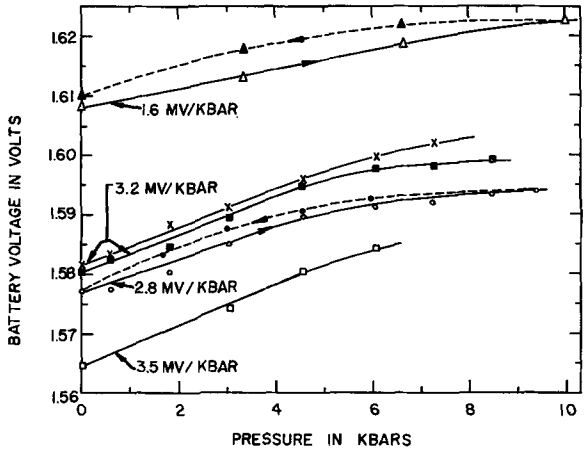

Fig. 4. Electromotive force vs. pressure for silver oxide batteries. Solid lines correspond to increasing pressure and dashed lines to decreasing pressure. $T = 25°C$.

Experimental Results

Silver oxide batteries.—The emf (open-circuit potential) as a function of pressure is shown in Fig. 4 for five different silver oxide batteries along with the measured value of $(dE°/dP)_T$ at atmospheric pressure. It is seen that the emf increases regularly with an increase in pressure, the slope $dE°/dP$ decreasing at higher pressures. The solid lines show $E°$ *vs.* P for increasing pressure while the dashed lines connect the points obtained while decreasing the pressure. The resulting hysteresis loop is due to friction at various places in the cylinder as well as within the sample as the materials relax to the newly applied pressures. Relaxation of the sample and pressure medium seemed to be more complete on the increasing branch (as evidenced by potential drift with time) and we accordingly have used the $dE°/dP$ values for increasing pressure in our discussion.

The effect of pressure on a battery under load can be seen from the voltage discharge curves at 1 atm and 6.1 kbars which are shown in Fig. 5. The voltage difference at the two pressures is seen to be independent of time and also is equal to the differences of emf at the two pressures (*cf.* Fig. 4). The manner in which this difference depends on the current through the battery is shown in Fig. 6. In this figure the i *vs.* E relationship is only shown for such low currents that the voltage is essentially a steady-state value 1 min after the current is allowed to flow.

The effect of pressure on the recovery of a silver oxide battery after current flow is stopped is shown in Fig. 7 and 8. In Fig. 7 the decay curves were constructed by measuring different segments of the decay curve at different pressures and by then joining the segments of equal pressures. In Fig. 8 the initial part of the decay curve was repetitively measured at different pressures in order to detect differences in the ini-

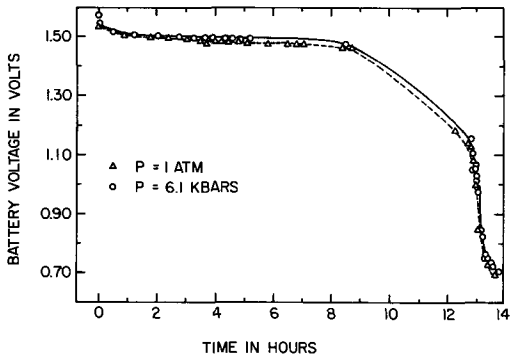

Fig. 5. Battery voltage *vs.* time at 1 atm and 6.1 kbars for silver oxide battery discharging through a load of 1065 ohms. The points at the two pressures were obtained with one battery by alternately increasing and decreasing the pressure.

tial rate of decay with changing pressure. Again only the difference in the emf at different pressures is noted in the charging and recovery curves.

Mercuric oxide batteries.—Open circuit voltage measurements (the emf) *vs.* pressure are shown for two mercuric oxide batteries in Fig. 9. Also listed are the experimental limiting slopes at atmospheric pressure.

The pressure effect on the voltage of the HgO battery under a load of 1065 ohms is shown in Fig. 10 and 11 in which cases the pressure on a given battery was successively raised or lowered while the current was passing. Two important differences are observed between the results of Fig. 10 and 11 for HgO batteries and those of Fig. 5 and 7 for Ag_2O batteries. (*i*) For working HgO batteries the differences between the voltages at different pressures are much greater (approximately 10 times) than the differences between

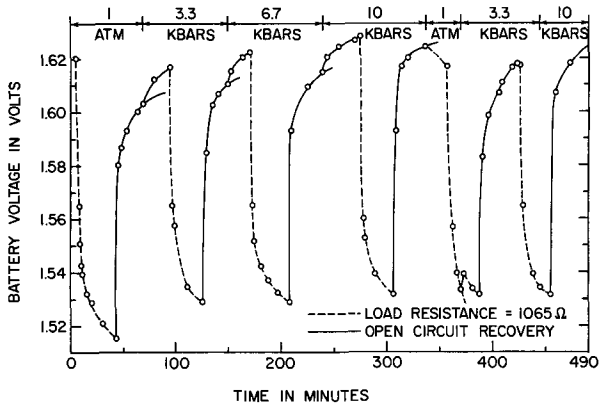

Fig. 8. Discharge and recovery curves for silver oxide battery at various pressures. The pressure or load was successively changed as indicated.

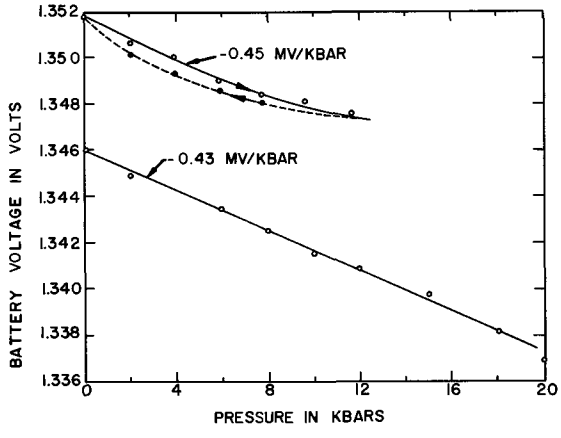

Fig. 9. Electromotive force *vs.* pressure for mercury oxide battery. Solid lines correspond to increasing pressure and dashed line to decreasing pressure. $T = 25°C$.

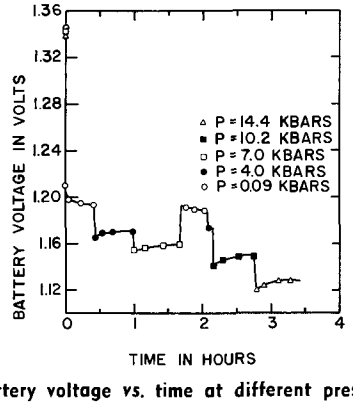

Fig. 10. Battery voltage *vs.* time at different pressures for mercury oxide battery discharging through a load of 1065 ohms. The voltage at zero time is equal to the emf. The pressure was intermittently changed without interrupting the flow of current. $T = 25°C$.

the emf's at these pressures. In the case of Ag_2O batteries these voltages differ by approximately the same amount whether or not current is passed. (*ii*) When the pressure is increased, the voltage of a working HgO battery does not immediately shift to a new value and "level out" but rather overshoots and then drifts back to the steady-state values. This overshooting of potential when the pressure is increased no doubt occurs at 20 kbars but is not observed in Fig. 11 due to the long waits between increasing the pressure and measuring the voltage. In Fig. 11 it is observed that the voltage at 20 kbars tends to decrease after the battery has operated for several hours, as if the battery were about to fail. Runs at 9.3 and 5.4 kbars with-

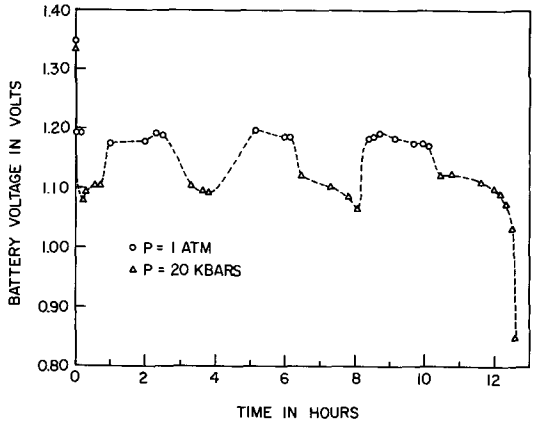

Fig. 11. Battery voltage *vs.* time for mercury oxide battery discharging through a load of 1065 ohms. The pressure was alternated between 1 atm and 20 kbars. $T = 25°C$.

out intermittently decreasing the pressure on the batteries, however, failed to show any decrease in voltage up to 8 hr.

After discharging an HgO battery through a load of 1065 ohms for several minutes at various pressures, the current was cut off and the voltage decay of the battery on open circuit was measured with an oscilloscope. This was done in order to determine what part of the polarization potential ($E - E°$) of the battery was due to ohmic resistance and how this resistance varied with pressure. Part of the polarization potential which is due to the ohmic resistance within the electrolyte and within the oxide (*i.e.*, those resistances which are in "series" with the potential-determining "capacitances") decays much more rapidly than the other overvoltage contributions, and may thus be readily separated out. From this determination we found that the fast potential decay corresponds to only a small fraction (~10%) of the total polarization [in agreement with the finding of others (4, 5)] and also that the change in this contribution with pressure was less than half the total change in polarization with pressure. Although part of the slow decay may be due to ohmic resistance (those resistances shunted by capacitances) as well as overvoltage, one may conclude that pressure must still cause a substantial increase in $\eta_1 + \eta_2$ in Eq. [4] as well as some increase in iR_{int}.

Discussion of Results

Silver-oxide batteries.—The probable reactions (6-8) which may occur at a silver-oxide-alkaline-zinc battery are listed in Eq. [5a], [5b], and [5c] along with the standard emf (8) and ΔV at 1 atm for each reaction. ΔV was calculated from the molecular weights and densities found in ref. (1).

$$\left.\begin{array}{l} Zn + Ag_2O + H_2O \rightarrow Zn(OH)_2 + 2Ag \\ E° = -1.587V\ (6);\ \Delta V = -6.5\ cm^3/mole \end{array}\right\} \quad [5a][4]$$

$$Zn + 2AgO + H_2O \rightarrow Zn(OH)_2 + Ag_2O$$
$$E° = -1.849V\ (6);\ \Delta V = +4.5\ cm^3/mole \quad [5b]$$

$$Zn + AgO + H_2O \rightarrow Zn(OH)_2 + Ag$$
$$E° = -1.718V;\ \Delta V = -0.99\ cm^3/mole \quad [5c]$$

$Zn(OH)_2$ rather than $HZnO_2^-$ ions is considered to be the product of the oxidation of zinc since the electrolyte is saturated with zincate ions. $Zn(OH)_2$ should thus be the thermodynamic product of the reaction even though some other species may kinetically form first.

From Eq. [3b] and the above ΔV values, the values for $(dE°/dP)_{1\ atm}$ calculated for reactions [5a] to [5c] are ($n = 2$) 3.37, −2.33, and +0.51 mV/kbar, respectively. In comparing the above values of $E°$ and $(dE°/dP)_{calc'd}$ with the $E°$ values and the $dE°/dP$ values of Fig. 4 it is apparent that the predominant reaction in the silver oxide batteries is that of reaction [5a]. One particular battery is seen to give $E°$ values several millivolts higher than those of the other batteries and also the value of $dE°/dP$ is significantly lower. Both of these tendencies indicate that reaction [5b] or [5c], as well as [5a], is important in establishing the behavior of the battery in question. Freshly prepared silver oxide electrodes yield potentials indicative of the AgO/Ag_2O couple (the corresponding battery equilibrium would be Eq. [5b]), but the spontaneous occurrence of the reaction

$$AgO + Ag \rightarrow Ag_2O \quad [6]$$

causes the decomposition of AgO (7, 5) such that electrodes which are not freshly prepared exhibit the potential of the Ag_2O/Ag couple (7).

From Fig. 5 it is observed that the battery voltage is increased approximately 15 mV by the application of 6.1 kbars of pressure. Since this voltage increase corresponds closely to the increase in emf with the same pressure increase (*cf.* Fig. 4), one may conclude that the change in emf is the dominant effect of pressure on the voltage at low overvoltages. Therefore the effect of pressure on the overvoltage (concentration polarization would appear to be the dominant overpotential contribution in this work based on the slow recovery shown in Fig. 7) is small compared to that on $E°$. Figure 6 shows that the effect of P on E is similar at all currents less than and equal to the value shown in Fig. 4. The precision of the points is not good in Fig. 6 because the voltage drifts somewhat at 1 min after the circuit is closed (see the steepness of the V *vs.* time curve in Fig. 7 and 8 at voltages from 1.54 to 1.60V). The insensitivity of the ionic diffusion to the pressure (compared to sensitivity of the emf to P) is also reflected in the recovery curves of the battery shown in Fig. 7 and 8.

Mercuric oxide batteries.—The over-all battery process is given by (6)

$$Zn + HgO + H_2O \rightarrow Zn(OH)_2 + Hg \quad [7]$$

for which $E° = 1.345V$ (6) and $\Delta V(1\ atm) = +0.747\ cm^3/mole$. Therefore the theoretical value for $(dE°/dP)_{1\ atm}$ is −0.39 mV/kbar which compares favorably with those obtained experimentally (see Fig. 9).

The contrasting effects of pressure on the discharge curves of the Ag_2O and HgO batteries help to distinguish the mechanism of reduction of these oxides, since the electrolyte and anode for both types of batteries are the same. We should first emphasize that the results of pressure in no way appear to be due to impairment or destruction of the batteries due to deformation, intermixing of phases, shorting, etc. Inspection of batteries which were bisected after pressing showed the same well-defined boundaries to be present between phases as were present before pressing (*cf.* Fig. 3). Pressing compacted the layers and hence diminished the size of the batteries by a few per cent, but the shape of a cell and the order within a cell were retained since the pressure medium (talc) distributed the pressure quite uniformly around the cell. Electrical measurements likewise indicated that the pressure did not destroy the boundaries between cell parts. Under pressure the HgO batteries as well as the silver oxide batteries readily recovered when the current was shut off. The emf and subsequent behavior of a battery after squeezing depended primarily on the total amount of discharge which a battery had undergone, in a way quite analogous to that of batteries discharged at atmospheric pressure.

In the case of the HgO electrode to which a small amount of graphite has been added, the mercury formed during reduction is found at the oxide-solution

[4] In order for the ΔV and $E°$ to correspond to the forward reactions as written in Eq. [5], the value of $E°$ must be taken as $E_{Zn} - E_{Ag}$ which is negative.

interface (9). Thus the electrons are conducted through the graphite from the metallic terminal to the oxide-solution surface where the Hg^{+2} ions are reduced and the $O^{=}$ ions react with the water. As the oxide surface is completely reduced the water must diffuse through pores and capillaries in the mercury and graphite matrix (the spent portion of the electrode) to the unreduced oxide in order for $O^{=}$ ions to be removed and thus for the cell process to continue. It is easy to envision the deleterious effect of pressure on this process. Since water is much more compressible than Hg (10), pressure would tend to diminish the size of these channels. In addition to the above effect one would expect the mercury formed to agglomerate into globules and shut off some of the channels. From these effects one would expect an increase in ohmic resistance as the migration and diffusion of OH^{-} ions in the capillaries is made more difficult. One would also expect an increase in overvoltage (*i*) due to concentration polarization of OH^{-} ions in the shrunken capillaries and (*ii*) due to the increased current density at the head (the HgO end) of the remaining channels as others are eliminated and thus as the effective HgO reaction area is diminished. Both an increase in ohmic resistance and in overvoltage with increased pressure are observed as discussed earlier. The above description is in accord with the studies of Mendzheritskii and Bagotskii (9) at atmospheric pressure. These investigators found that the concentration of KOH in the pores of the spent portion of the electrode is higher than that in the bulk of the solution, and also that a high porosity of the HgO leads to a more complete utilization of the HgO present in the electrode. Although studies were not made in this work of the effect of pressure on the output capacity of the HgO battery, Fig. 11 suggests that high pressures may cut short the life of the battery. When the size of and changes in the overvoltage with increasing pressure are considered (*cf.* Fig. 10 and the results of the resistance changes) one concludes that cause (*ii*) above for increasing overvoltage is more important than the concentration overvoltage [cause (*i*)] since the KOH is already concentrated enough that large increases in concentration (a 10 fold increase would be required for each 59 mV increase in η) cannot occur. The existence of and changes in the overvoltage due to the decrease in the number of reaction sites is directly seen from the voltage overshooting and then decaying back to the steady-state value on the application of pressure. Thus as OH^{-}-carrying channels are eliminated by the sudden increase in pressure which results in the current stoppage at some HgO sites, the overvoltage must increase until the discharge of Hg can occur at new sites in order to maintain constant current. After discharge has occurred at new sites at a higher overvoltage, nucleation of Hg occurs and the overvoltage decreases (corresponding to the positive decay in voltage) since the discharge of Hg against the metal occurs more easily than discharge without the presence of Hg. Micrographs of a partially reduced HgO surface (9) verify that Hg accumulates as droplets. An overshoot in voltage also occurs with a sudden decrease in pressure (*cf.* Fig. 10) due to first the expansion of some channels allowing new sites to be reactive (the decrease in η) followed by the plugging of some of these sites with Hg droplets (the increase in η as the battery voltage decays to its steady value). The plateaus in the voltage *vs.* time plot (see Fig. 10) are indicative of the effective number of HgO sites to which OH^{-}-carrying H_2O channels are available. Of course this number decreases with the discharge time. Other factors may influence the shape or "flatness" of the discharge curve also, such as the local *p*H and the formation of other solid substances during reduction [the effects of each of these factors have been determined for the Leclanché cell in ref. (4)].

Mercury freezes at approximately 12 kbars at 21.9°C (10) and water freezes at approximately 9 kbars at the same temperature (11). Thus freezing of the electrolyte and mercury would be expected to influence the operating characteristics of these batteries at high enough pressures. The present study did not deal with high enough pressures, for the most part, to directly see these freezing effects. However, one difference is noted between the discharge curve of the HgO battery at 20 kbars (see Fig. 11) and the discharge curves at pressures below the freezing point of the liquids. At 20 kbars the voltage of the discharging battery drifts to smaller values much more rapidly than at lower pressure. Figure 11 shows such a rapid loss of voltage whereas similar curves at 5 and 9 kbars showed no apparent decrease in voltage in an 8 hr run. This result indicates that ion movement is impeded progressively with time at 20 kbars as if the source of current-carrying ions was initially available but then depleted. Such a phenomena may arise from partial freezing of the liquid resulting in slush formation. The ion movement in the solid would be much slower than that in the liquid; then when the ions in the liquid are depleted the voltage is severely lowered.

Pressure does not influence the overvoltage or resistance of the Ag_2O cell to the same extent that it influences the HgO cell as is seen from the data. It has also been noted that the Ag formed during the reduction of an Ag_2O or AgO electrode forms at the cathode grid-oxide interface rather than at the oxide-solution interface (7). This implies that silver ions migrate from the oxide-solution interface to the metal grid or that the large $O^{=}$ ions migrate outward. If $O^{=}$ ions moved it would be difficult to explain the difference in the behavior of Ag_2O and HgO batteries, so we believe that Ag^{+} ions are the species which migrate. The resistivity of Ag_2O (5) is so high that the large current densities observed in battery operation would seem to require that the above ionic movement does not occur through the dry oxide but rather electrolytically through water-filled capillaries or channels. Since the divalent Hg^{+2} ion carries more primary hydration and hence has a larger effective size in diffusion or migration than Ag^{+}, it is not possible for Hg^{+2} ions to be transported to the metal grid at the cathode and hence Hg must be deposited from the solution side of the oxide (with additional needed overvoltage compared to that of the Ag_2O reduction, based on the differences in overvoltage we observe for HgO and Ag_2O batteries of equal size). That the overvoltage of the Ag_2O battery is not increased by pressure indicates that pressure is not effective in destroying the passageways through the irregular solid as it is with passageways in metallic mercury.

Conclusions

Studies dealing with pressure effects on the reduction of other oxides would be enlightening in terms of enlarging on the present model. Also this work suggests the need for, and perhaps the means of studying, the porosity of various materials and conduction through these pores.

On the practical side, this study shows that silver oxide batteries may be efficiently used as a power source under high pressures (such as at the bottom of the ocean or in other geophysical applications) whereas mercury oxide batteries suffer from diffusion and overvoltage effects in similar circumstances. Additionally, both types of batteries studied might be utilized as pressure sensors since the emf's are regular and predictable at elevated pressures. The small size of the miniature batteries studied would lend to the convenience of placing them in high pressure laboratory apparatus.

Since studies of smelting (12) and of corrosion indicate that the formation and the disappearance of metals is by electrolytic processes and since mercury, silver, copper, antimony, and bismuth as well as the

more noble metals occur in native form these studies of pressure effects on diffusion and reduction are relevant to an understanding of such ore bodies. Any conductor such as graphite or the metal itself can act as a floating electrode to collect electrons from reducing agents which in turn reduce the metal as in the developing of the latent image of photography.

A Study of the Formation and Dissolution of Porous Anodic Oxide Films on Aluminum: Behavior of the Porous Layer

J. W. Diggle,*[1] T. C. Downie,[2] and C. W. Goulding[3]

Physical Chemistry Laboratories, Rutherford College of Technology, Newcastle-upon-Tyne, England

ABSTRACT

The formation and dissolution of porous alumina films in sulfuric acid was studied by the incorporation of the radiotracer $^{35}SO_4^=$ into the film during preparation. The results have shown that (*a*) the formation site of the porous oxide is the barrier layer-porous layer interface, (*b*) the dissolution time for porous films is independent of thickness. Comparison with former work, on "duplex" barrier films, suggests a method of identifying barrier and porous type films. By the use of "duplex" films, dissolution studies have shown that a simple pore widening mechanism of dissolution is incompatible with the results. A pore widening-concurrent pore shortening dissolution mechanism based on a truncated pore model is proposed, and has been found to be experimentally valid.

In a previous paper (1), these authors reported the results of a study of the "open circuit" dissolution of the barrier layer underlying the porous layer in anodically produced alumina films. Since this study involved the use of a low signal frequency capacitance technique, no information as to the behavior of the porous layer during this dissolution was obtained.

Although much work (2-4) has suggested that some dissolution process occurs during porous film formation at the outer porous surface/electrolyte interface, only recently has any mechanism for such dissolution been proposed (5). It is the purpose of this study to investigate the behavior of the porous layer during "open circuit" dissolution in an attempt to add to the information previously published (5, 6).

It is well known (7-9) that anodic films produced in sulfuric acid contain some degree of incorporated electrolyte anions. Throughout this paper the incorporated sulfur will be assumed to be in the form of the anion [following Lan Tran *et al.* (10)]. Although it is realized that some doubt exists as to whether this is true (11, 12), the essential arguments presented here would be unaffected. If the distribution of this electrolyte anion was uniform throughout the porous layer, and if the anion was in a radioactive form of reasonable half-life, then the amount of radiation emitted after some dissolution time t could be used as an indicator as to the amount of porous layer remaining. Evidence that the distribution of incorporated anions is uniform has been reported by Wood, Marron, and Lambert (13) for an aluminum-magnesium alloy anodized in 15% sulfuric acid, and, therefore, considering that the nature of the porous film formed on an Al/Mg alloy is similar (13) to that formed on pure Al, the assumption on which the work is based is considered established.

Experimental

Preparation of the super-purity wire aluminum electrodes and their pretreatment and other preliminary work was identical to that reported in a previous paper (14).

The anodizing electrolytes used throughout this work were 15% w/w sulfuric acid with and without the addition of ^{35}S. When radioactive electrolyte was required, 2.5 mC $^{35}SO_4^=$ were added as neutral sulfate solution—this addition had a negligible effect on the

electrolyte pH. Anodizing conditions were constant throughout at 25° ± 0.1°C, 10V applied voltage with a current density of 7.1 mA cm^{-2}. As in previous work, the aluminum wire electrodes of 1.5 cm^2 area were allowed to attain the steady value of 10 μF cm^{-2} before anodizing was commenced.

Two types of experiments were done, (*i*) a study of the build-up of radioactivity during formation and (*ii*) the loss of radioactivity during dissolution. In both types of experiments, so-called "duplex" films were prepared by anodizing first in radioactive H_2SO_4, and then in nonradioactive H_2SO_4 and vice-versa; the thickness of each porous layer formed was controlled by varying anodizing times.

Following preparation in the appropriate electrolyte, the electrode was washed in running distilled water for 1 min (this time being chosen from the impedance work of Hoar and Wood (15) where it was shown that all adhering electrolyte was removed in this time), rinsed with acetone and air-blown dry, and a radioactivity count taken. The number of disintegrations was determined using a thin window Geiger-Muller tube with Dekatron Tube scaler. The electrode was rotated through four 90° turns, and an average of the four readings was taken.

In the dissolution experiments, the electrode was then immersed in the dissolution media 1.0*N* sulfuric acid at 25°C, previously deaerated with hydrogen. Purified hydrogen was continually passed over the solution to reduce oxygen diffusion inward. After a known dissolution time the electrode was withdrawn, the washing procedure outlined earlier was performed, and then the average activity was redetermined. The decrease in activity was then related to the progress of porous layer dissolution.

The average count rates were not corrected for natural decay since the half life of S^{35} is 87 days and the experimental times were such that the error incurred was < 0.1%. No subtraction of background level (15 c.p.m.) was performed, since the interest lies not in the amount of activity but in the change of activity with time during either formation or dissolution.

Results

Porous film formation.—Figure 1 shows the average radioactivity content of a "duplex" film prepared for 30 min in radioactive H_2SO_4 and then subjected to prolonged anodization in nonradioactive H_2SO_4. The c.p.m. is seen to decrease to near-background level after 2 hr anodizing in nonradioactive H_2SO_4.

Figure 2, curve i shows that the c.p.m. increases linearly for the reverse procedure, *i.e.*, 30 min film prepared in nonradioactive H_2SO_4 followed by anodization in radioactive H_2SO_4. Immediately following this experiment, curve ii in Fig. 2 was determined,

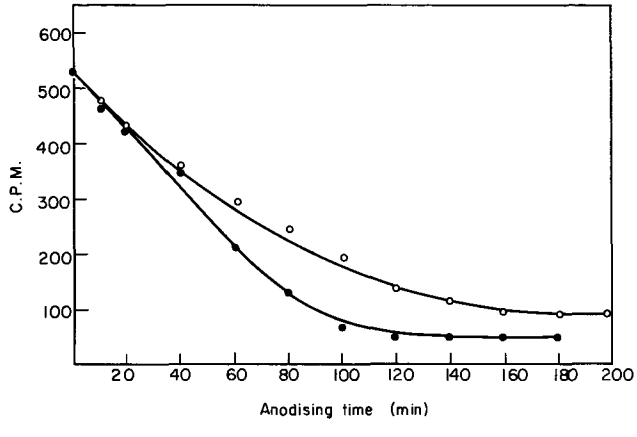

Fig. 1. ●, Experimental radioactivity (c.p.m.) as a function of anodizing for the second stage formation of a "duplex" film, R followed by NR; ○, theoretical curve based on NR being the outermost layer, and the c.p.m. decrease being due to absorption of weak β-radiation.

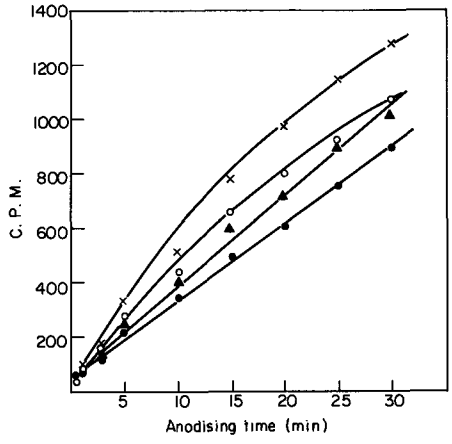

Fig. 2. ●, C.p.m. as a function of anodizing time for second stage formation of a "duplex" film NR followed by R (designated curve i); ○, similar curve for radioactive anodizing only (designated curve ii); x, c.p.m. for radioactive anodizing only corrected for a 20% thickness loss; ▲, theoretical curve resulting from absorption of β-radiation from a 30 min radioactive film by an outer film of NR material whose thickness is increasing with time.

which shows the increase in the c.p.m. against anodizing time for a film prepared only in radioactive H_2SO_4. It can be seen that, except during the initial stages, curve i, *i.e.*, the "duplex" film, is below curve ii.

Porous film dissolution.—Dissolution as a function of porous layer thickness.—Figure 3 shows how the radioactivity decreases as dissolution proceeds for three films, anodized for 30, 60, and 90 min, respectively. It is evident that the time required for the dissolution of the ^{35}S species is independent of the anodizing time in the active electrolyte. Since the pore separation is the only constant factor in these three films (16), this would suggest that the dissolution proceeds via a pore wall attack increasing the pore diameter to the oxide cell size (5, 6).

Dissolution of "duplex" films.—The results for a series of films prepared as previously outlined are shown in Fig. 4 and 5.

The dissolution time, which had been indicated to be independent of the porous film thickness, is seen to be appreciably constant (Fig. 4) for the preparation nonradioactive NR followed by radioactive R, while for the preparation R followed by NR, the dissolution time decreases as the ratio of the anodizing times NR to R increases (Fig. 5).

Discussion

Radioactive marker $^{35}SO_4^=$ mobility.—The essence of any investigation involving the use of radioactive markers (17-19) is that an assumption has to be made concerning its immobility. This assumption is often dubious, particularly when the marker is charged (17) and high electric fields are present under whose influence marker mobility can occur.

In the present experiments, the radioactive marker used exists in an area of the film where high field strengths are absent, *i.e.*, the porous layer. If mobility of $^{35}SO_4^=$ were to occur, the concentration at the inner sections of the porous layer, *i.e.*, nearest the metal, would be expected to possess higher sulfate concentrations than the outer sections of the film. The results in the literature (13) show that this is not so, but that sulfate distribution is uniform throughout the porous layer depth. The present authors propose that the results in this paper also suggest that the sulfate in alumina porous layers is immobile (Fig. 6).

For the anodizing sequence NR followed by R, the structure represented by Fig. 6(c) would be consistent with the results of Fig. 4. This structure can result from two causes, (*i*) that R forms below NR, (a) Fig. 6, or (*ii*) R forms above NR and that $^{35}SO_4^=$ migrates toward metal, (b) Fig. 6. For the reverse sequence, R followed by NR, Fig. 6(f) would be the structure suggested by Fig. 5, and this would result from either Fig. 6(d) or (e).

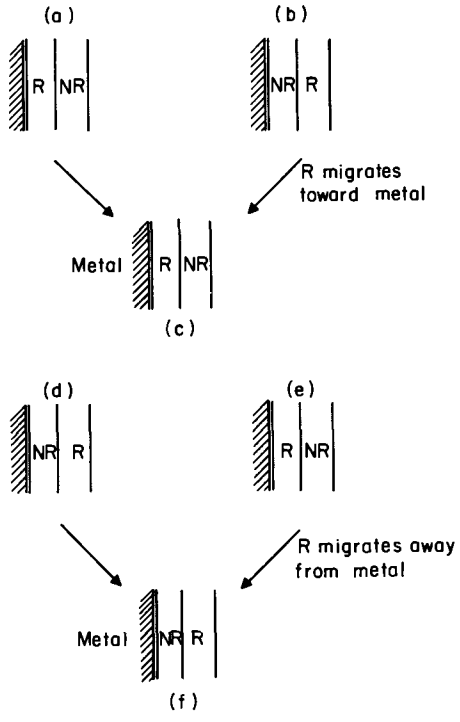

Fig. 6. Schematic representation of the formation of porous alumina "duplex" films. (a), (b), and (c) correspond to NR followed by R preparation, and (d), (e), and (f) correspond to R followed by NR preparation.

Since the migration of $^{35}SO_4^=$ away from an anode, Fig. 6(e), to produce Fig. 6(f) is clearly untenable, Fig. 6(d) then represents the porous film "duplex structure" for the R followed by NR preparation. However, to accept Fig. 6(d) requires that $^{35}SO_4^=$ be immobile, and, therefore, to be consistent, Fig. 6(b) is rejected as the model for the NR followed by R preparation.

The conclusion is that the $^{35}SO_4^=$ marker, in the present experiments, is immobile, and that the electrolyte used last characterizes the porous layer lying nearest the metal.

Porous film formation.—Figure 1 shows that the second stage anodizing in nonradioactive H_2SO_4 of a first formed radioactive film produces an essentially linear decrease in the count rate with increasing anodizing time. This may be accounted for in three possible ways: (*a*) exchange between $^{35}SO_4^=$ in the film and $SO_4^=$ in solution, (*b*) the growth of the second nonradioactive porous layer on top of the first radioactive porous layer with subsequent loss in radiation due to adsorption, and (c) by assuming the growth area of the porous layer to be at the barrier layer-porous layer interface, and postulating an outer surface dissolution process resulting in the loss of radioactivity to the solution.

Possibility (*b*) can be rejected on the grounds of (*i*) ionic transport, since for the growth area of the nonradioactive porous layer to be the oxide-solution interface, ionic transport of Al^{3+} ions through several microns of oxide would be necessary, a process which is clearly untenable, when one considers the electric field required for such a process, (*ii*) if a "duplex" film were produced in which the outermost section of the film were nonradioactive, then dissolution of such a film would not be expected to proceed according to Fig. 5, where the preparation mode was identical to that in Fig. 1, and (*iii*) the upper curve in Fig. 1, based on absorption of weak β-emission from the $^{35}SO_4^=$ decay due to a nonradioactive outer layer, is inconsistent with the experimental curve (lower curve, Fig. 1).

Possibility (c) in which the growth area is taken as the barrier layer-porous layer interface is much more probable, the oxygen-bearing species reaching the

reaction interface by mass transport down the previously formed pores in the radioactive film. The conclusion is that the electrolyte used first characterizes the outermost layer of a "duplex" porous film, a conclusion reached in some previously reported work (17). It is proposed here that the outer radioactive layer of porous oxide is dissolved by the nonradioactive H_2SO_4 during concurrent porous oxide formation near the metal-oxide interface.

From Sacchi's formula (20), the thickness of the radioactive porous layer prior to further anodizing is approximately 6 μm. After a further 2 hr anodizing, the total theoretical porous layer thickness should be 30 μm. If it is assumed that the outer 6 μm of radioactive layer has been completely dissolved, then the experimental thickness is 20% less than the theoretical thickness. Wood *et al.* (13) have shown that, for an Al/Mg alloy anodized in sulfuric acid, the films formed are of the theoretical thickness at 15°C, but are 33% less than theoretical at 30°C. Thus, the estimate of 20% less at 25°C is in good agreement with these results of Wood (13).

The possibility (*a*) of $SO_4^=$ ion exchange between the radioactive film and solution could perhaps give the result shown in Fig. 1. Since the thickness of the films formed in this work were not measured, the possibility of exchange cannot be overlooked, although the authors do consider the possibility of outer porous layer dissolution as more probable.

The reverse procedure for "duplex" film formation, *i.e.*, NR followed by R, is shown Fig. 2. If, as has been proposed, the formation of the innermost layer is characteristic of the second electrolyte, then the c.p.m. at any one dissolution time should be lower for NR followed by R (curve i) than for R alone (curve (ii) due to the absorption of the β-emission in the former case. Experimentally this is found to be the case. Calculations, represented in Fig. 2, demonstrate how, after correcting the radioactive film for a 20% thickness loss, the experimental curve (ii) produces a c.p.m.-anodizing curve in reasonable agreement with experimental curve (i) when it is assumed that the NR outer layer absorbs the weak β-emissions from $^{35}SO_4^=$ decay. Some deviation is observed as the anodizing time increases, this being due possibly to some electrolyte-dissolution penetration into the radioactive section as the film thickness increases.

Thus, the conclusion made earlier that the outermost section of a "duplex" porous film is characterized by the first electrolyte is confirmed. In this sense it produces "duplex" structures similar to those of barrier "duplex" layers formed by anion motion only. Comparison with the work of Lewis and Plumb (17), who reported that the outermost layer of "duplex" barrier films is that characteristic of the last electrolyte used, shows that, providing some cation motion is involved in barrier layer formation, the correlation of the outermost layer of any "twin duplex" film to either the first or second electrolyte can identify the film as either of a barrier or porous type.

Porous film dissolution.—Figure 3 shows that the time required for dissolution of the ^{35}S species in the porous layer is independent of the anodizing time in the active electrolyte, *i.e.*, the porous layer thickness, the dissolution time being seen as constant at approximately 120-140 min. It is of interest to note that this time is approximately equal to the time required for barrier layer dissolution of a film prepared at 10V(1).

For the "duplex" films NR followed by R, since the radioactive layer would be nearest to the metal the dissolution time would be expected to be constant, independent of the NR to R anodizing time ratio, and equal to the dissolution time of Fig. 3. From Fig. 4 this is seen to be the case.

Figure 5 shows that, for "duplex" films formed R followed by NR, the dissolution time decreases as the R to NR anodizing time ratio decreases from 2:1 to 1:6. This gives the first indication that the dissolution mechanism is not purely pore widening (5), for if it were, then the dissolution time should again be independent of R to NR ratio and equal to that in Fig. 3 and 4. A concurrent pore widening-pore shortening dissolution mechanism is proposed in which the pore diameter increases and approaches the oxide cell size, as the pore height decreases and approaches zero. Thus, the effect of the ratio R to NR should only be of importance in defining the dissolution time when the radioactive section of the "duplex" film is outermost (Fig. 5). Table I shows the experimental (taken as the time at which the c.p.m. became constant) and theoretical values (based on a pore shortening or a concurrent pore shortening-pore widening mechanism) for the dissolution time of the films in Fig. 5 (assuming that the time for complete dissolution is 140 min). Although some doubt exists as to where to define the experimental time, the agreement is seen to be reasonable.

Table I. Theoretical and experimental dissolution times required for the loss of porous alumina film activity for "duplex" films formed by radioactive followed by nonradioactive anodizing.

Minutes of radioactive anodizing	Minutes of nonradioactive anodizing	Theoretical dissolution time radioactive layer (min)	Experimental dissolution time (min)
60	30	93	90
30	30	70	60
30	60	47	50
15	90	23	20

Referring again to Fig. 4, it is clear that if a simple pore shortening mechanism for dissolution were operative, the count rate would be expected to increase during initial dissolution due to reduced absorption thickness of overlying nonradioactive oxide. Furthermore, if a simple pore widening mechanism were operative, the count rate would be expected to decrease initially and continue to decrease linearly (assuming dissolution to be uniform and constant). It is proposed that there are two possible ways in which the curves in Fig. 4 can be satisfactorily accounted for, both being based on the concurrent pore widening-pore shortening mechanism: (*a*) the time during which the count rate is appreciably constant can be considered to be due to a balance between the tendency for the count rate to increase due to pore shortening, and a tendency for the count rate to decrease due to pore widening—this model assumes uniform pore widening from pore mouth to pore base, (*b*) the time during which the count rate is appreciably constant is due to the reduced dissolution of the radioactive section in the lower reaches of the pore.[4] As dissolution proceeds, *i.e.*, the pore height decreases, the dissolution of the radioactive section increases due to a more free access of electrolyte to these areas—this second model is then based on nonuniform dissolution down the pore length, with the dissolution rate being greatest at the pore mouth.

Irrespective as to whether model (*a*) or (*b*) is correct, it can be seen that the rest period of the count rate should increase as the ratio of R to NR anodizing times decreases.

A paradox can be seen to exist in this data since Fig. 3 shows the dissolution time to be independent of radioactive porous film thickness, hence the pore widening concept, while Fig. 5 shows the dissolution time of the radioactive layer in a NR:R "duplex" film increasing with increasing radioactive layer thickness, hence the pore shortening concept. It is considered that this paradox can be resolved in terms of a pore shortening-pore widening mechanism based on the truncated pore model of Paolini, Masaero, Sacchi, and Paganelli (22).

[4] Some dissolution of the radioactive section of the pore must occur because in the complete absence of such dissolution the count rate must increase due to reduced absorption of β-radiation by the NR layer. Calculations show that after 50 min dissolution for the 60 min NR followed by 30 min R (Δ symbol, Fig. 4) the activity should have risen by 170 c.p.m.

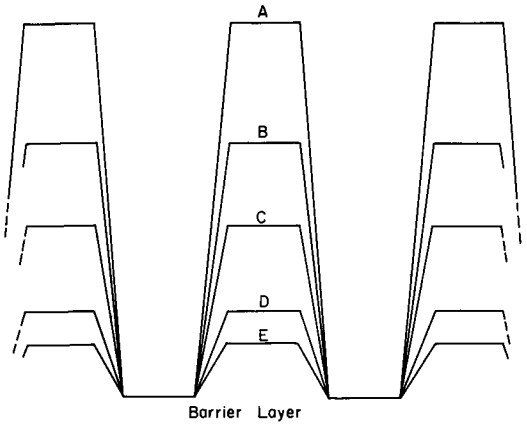

Fig. 7. Schematic representation of an idealized dissolution model based on a truncated pore and concurrent pore widening-pore shortening model. A is the original pore; B, C, D, and E are successive stages during dissolution.

Figure 7 shows how such a model, taken in conjunction with a greater dissolution rate at the pore mouth (due to the ease with which reaction products can diffuse away from the reaction site), leads naturally to a pore widening-pore shortening dissolution mechanism. It can be seen that a pore widening dissolution process, *i.e.*, dissolution of alumina from the pore walls, can, if the walls themselves are slanted, produce pore shortening. Thus, the major dissolution site in porous film dissolution is the internal surface of the pore; this is as expected since the internal surface presents the highest surface area for attack. Details of this dissolution model are to be published.

Acknowledgments

The work reported here was carried out in the Physical Chemistry Laboratories at the Rutherford College of Technology, Newcastle-upon-Tyne, England. The authors wish to acknowledge the facilities extended to them by the Principal of the College and the Head of the Chemistry Department. One of the authors (J. W. D.) wishes to acknowledge the award of a Research Studentship from the Newcastle-upon-Tyne Education Committee. Finally, the authors are indebted to the referees of this paper for their many helpful suggestions during the reviewing stage.

Electron-Optical Examination of Sealed Anodic Alumina Films: Surface and Interior Effects

G. C. Wood and J. P. O'Sullivan†

Corrosion Science Division, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

Sealing of porous anodic films, formed on aluminum in an oxalic acid electrolyte, has been studied by direct replica electron microscopy and electron diffraction. Pore plugging and changes in pore-wall material occur throughout the film but most rapidly at its exterior, while crystalline material forms on the outer film surfaces. Sealing appears to occur in three distinct but overlapping steps, the first being precipitation of material in the pores, especially near the outer film surface, the second formation of crystalline material at the surface which is a minor process, and finally further changes in the film depths involving aggregation of the oxide microcrystallites and a redistribution of porosity.

Many early theories for the sealing of porous anodic oxide films on aluminum involved a reaction which only occurred close to the outer film surface, producing there a pore "plug" of crystalline hydrated oxide from the initially denser amorphous oxide. More recently, Hoar and Wood (1, 2), Wood and Marron (3, 4), and Spooner and Forsyth (5) all postulated that long-term sealing occurs throughout the film depth but to a greater extent at the outer surface. The theories of Hoar and Wood (1, 2) and Wood and Marron (3, 4)

† Deceased.

were both suggested after impedance studies of film sealing. The former theory involved an initial outer boehmite plug with some inward movement of the pore walls, while the latter featured an initial gel-like precipitate which increased in depth and solid content during further sealing. Spooner and Forsyth (5) postulated a sealing mechanism involving pore wall dissolution in the depth of the film and its reprecipitation closer to the outer film surface. In contrast, Murphy proposed that the sole function of the sealing treatment is to plug the entrances to the intercrystallite surfaces, leaving only major pores unaltered (6).

Much of the previous work has suffered from the lack of direct visual evidence concerning the physical changes occurring during the sealing reaction. The objects of the present work were to clarify by electron microscopy the nature of these changes, particularly the extent of pore closure and other morphological changes, occurring throughout the depths of the anodic films, to correlate these changes with any crystallographic changes identifiable by electron diffraction and to consider the results together with detailed chemical and structural data obtained by infrared spectroscopy (7). The ability to observe the barrier layer and porous structure of high-voltage films directly (8) made this possible.

Experimental

Spade electrodes, 2 x 1 x 0.1 cm, of 99.99% aluminium (Cu 0.002%, Fe 0.004%, Si 0.003%) were individually electropolished in a perchloric acid/ethanol bath, washed, and dried. A porous anodic oxide film, about 40 μm thick, was then formed by anodizing each individual specimen for 1 hr at 25 mA/cm^2 in stirred 2% w/v oxalic acid (Analar grade) at 25°C. After the initial voltage fluctuations, a value of 50V was attained and this slowly rose to 100V by the end of the run. Each specimen was immediately removed from the electrolyte and washed in running distilled water to remove residual acid.

Electrodes which were not to be sealed were washed in ethanol and dried in a cold air stream. Specimens to be sealed were transferred immediately to the sealing solution without any prior drying, the sealing solution boiling under reflux. Sealing was carried out on individual specimens for varying times up to 24 hr, followed by removal, washing in running distilled water then ethanol, and finally drying in a cold air stream. The following sealants were used: (*a*) doubly-distilled water (pH 5.7, conductivity 10^{-5} to 10^{-6} ohm^{-1} cm^{-1} before boiling); (*b*) 6 g/l nickel acetate (as quadrahydrate) + 8 g/l boric acid, (pH 5.7); (*c*) 37 g/l potassium dichromate (0.25M Cr, pH 2.0); and (*d*) 79 g/l potassium chromate (0.25M Cr, pH 7.7).

The unsealed and sealed films were examined by both electron microscopy and electron diffraction. For the former technique a freshly anodized specimen was bent into a V-shape, thus producing cracks in the oxide parallel to the sides of the specimen which had not been bent. Excess debris was removed by an ultrasonic cleaner and by washing in distilled water. Direct carbon replicas of the film surfaces and sections were prepared by depositing a thin layer of carbon onto the film surfaces and exposed cleavage planes. These were then shadowed with a Pt/C mixture, deposited at an angle of incidence of 60°, but in the same vertical plane as the direction of the cracks in order to give maximum contrast to the replica of the porous structure. The replicas were stripped from the specimen surface by immersing the specimen in a 0.5% w/v HF solution, (made up with a 50:50 mixture of water and ethanol), which dissolved the oxide film, allowing the replicas to float free. The carbon was then transferred to a 10% w/v HCl solution to remove excess oxide before being given a final wash in distilled water. The replicas were removed, dried, and stored, prior to examination in an A.E.I. EM6 electron microscope (8, 9).

Several methods were attempted to obtain successful electron diffraction patterns from film surfaces and sections. These involved one-stage carbon and two-stage plastic/carbon extraction replicas, extraction replicas of the debris made by scratching metallographic sections of films with a microhardness tester (10) and diffraction through thin separated films. The only successful technique was that of reflection diffraction from film surfaces. In this technique, the specimen was grazed at a glancing angle in the diffraction stage of the electron microscope by the electron beam. Pure aluminum was used as a calibrating standard. The apparent *d* values of the crystalline materials produced on sealing were then compared with reference tables giving the known lattice parameters of likely products of the reaction between anodic alumina and boiling water (11).

Results

Electron microscopy.—Unsealed film.—The over-all morphology of unsealed anodic films formed in oxalic acid was similar to that of films formed in sulfuric and phosphoric acids (8, 9) (Fig. 1), corresponding generally to the model of Keller, Hunter, and Robinson (12). Some "texture" is visible in the micrographs but it is uncertain whether this is characteristic of the oxide itself or of its fracture. Both surface and section could be seen in situations similar to Fig. 1b because the replica relaxed into a planar configuration during stripping and washing. Since the cell voltage rose slowly during the anodization the oxide cell and pore sizes increased correspondingly, so that the last-formed film (Fig. 1c) contained larger cells and pores than that near to the outer film surface (Fig. 1b). Mean values of the cell diameter measured directly from electron micrographs of film sections were 1240Å close to the outer surface and 2300Å near the barrier layer. The pores showed a corresponding increase in diameter, the dependence being linear with voltage (9). The barrier layer thickness of 100V films was *ca.* 900Å, giving an Å/V ratio of 9.0. The barrier layer structure was again relatively uniform, whereas the pores visible on the outer surface (Fig. 1a) showed a range of diameters and were not always regular, in accordance with recent theory (9).

Water-sealed films.—Micrographs of outer surfaces of water-sealed films (Fig. 2) were not generally of a good quality due to a film of material covering them. Pores were still visible after 1 min sealing (Fig. 2a) and even after 10 min (Fig. 2b). After 30 min treatment (Fig. 2c), the porous structure was completely obliterated, to be replaced by a crystal-like arrangement. After 24 hr, a needle-like structure was observed above this (Fig. 2d).

Micrographs were taken from all regions across sections of films sealed for various times, but especially from locations close to the oxide/air and metal/oxide interfaces. After 1 min, little effect could be seen in any region of the film. After 5 min, some slight effect could be detected close to the outer interface (Fig. 3a), while close to the barrier layer, there was no significant change (Fig. 3b). Treatment for 10 min gave a more pronounced result, the porous structure being difficult to detect in the outer region of the film (Fig. 3c), although the pores were still visible on the corresponding outer surface (Fig. 2b).

Close to the barrier layer, however, (Fig. 3d), although the porous morphology was still clearly visible, the pores were now partly filled with apparently solid particles, *ca.* 100-400Å in size. Comparison of Fig. 3c and d indicates that the sealing reaction had affected both the pores and the cell walls near to the outer interface, while close to the barrier layer the cell walls remained apparently unaffected. Little further morphological change occurred in the film structure close to the outer interface on more prolonged sealing, except that the porous structure became virtually undetectable (Fig. 3e).

Nevertheless, changes were still occurring close to the metal; the regions corresponding to the pores in the unsealed film could still be detected there clearly for sealing times up to 30 min-1 hr (Fig. 3f), although

these were possibly more difficult to define after treatment for 24 hr (Fig. 3g). These "filled pores" had a rougher, more open structure than the apparently unreacted parts of the cell walls, which seemed to consist of a more compact oxide, even after treatment for 24 hr. The longer the sealing time, at least up to 30 min-1 hr, the more the fibrous regions extended laterally into the more compact cell walls, producing an effective increase in the "filled pore" diameter (Table I). This was quite clear despite the limitations of direct measurements of pore diameters from film sections (9, 13).

Any corresponding decrease in the thickness of the unreacted part of the barrier layer was not readily detected due to the tendency for the film to break away from the metal through the barrier layer rather than at the film/metal interface. However, such a reac-

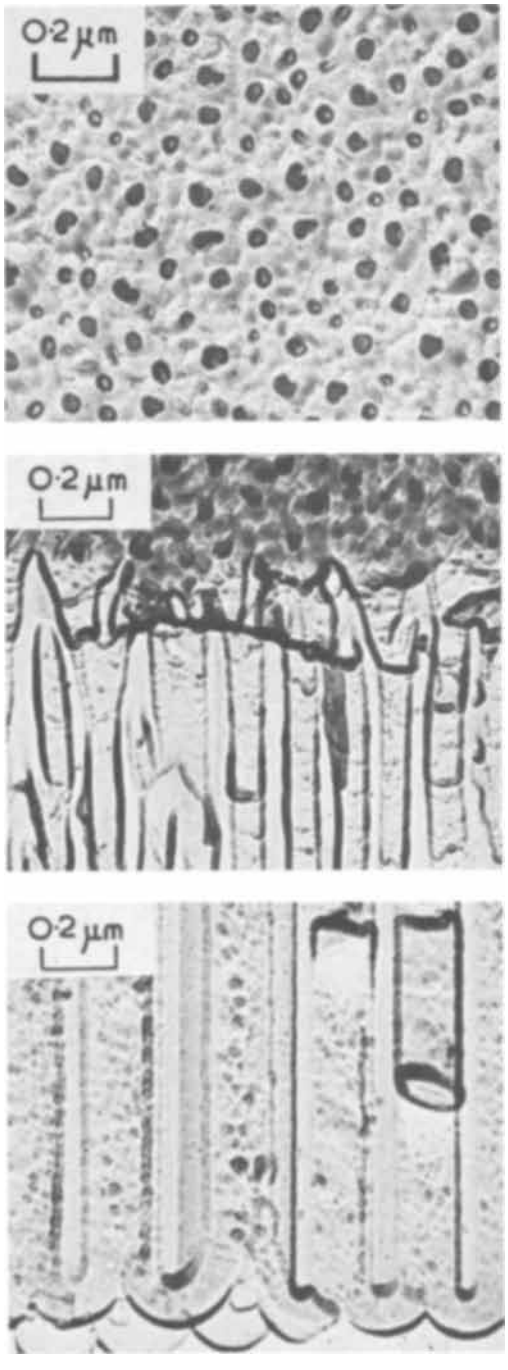

Fig. 1. Electron micrographs of films grown for 1 hr at 25 mA/cm^2 in 2% w/v oxalic acid at 25°C (voltage rising from 50 to 100V), (a, top) outer surface, (b, center) section near outer interface, (c, bottom) section near barrier layer.

0	760
10	900
30	1500
60	1600
1440	1400

tion would probably occur, and there is some evidence for it with the 24 hr specimen (Fig. 3g).

Examination of micrographs from entire sections showed the extent of sealing to decrease gradually as the metal was approached, rather than there being a distinct "plug" near the outer interface (Fig. 4). Figures 3c and d show the extreme interfaces of the film depicted in Fig. 4, but at a higher magnification. To some extent, the gradual change in the extent of sealing may have been due to the progressively smaller pore diameter toward the outer surface, this being the result of the steadily rising voltage during anodizing. However, it is unlikely that such large variations in film morphology with depth were due simply to a variation in pore diameter.

Salt-sealed films.—The salt type had a profound effect on the extent of film sealing. After 30 min in potassium dichromate at pH 2.0, the film surface was virtually unaltered (Fig. 5a) although some slight sealing was evident in section near the barrier layer (Fig. 5b). In nickel acetate/boric acid solution (pH 5.7) sealing was more obvious, the morphology having changed to a similar extent as after treatment in boiling water for the same time (Fig. 3e and f). However, in potassium chromate (pH 7.7) the porous structure was completely obliterated on the surface (Fig. 5c) and at the pore bases the extent of filled pore encroachment on the cells and probably the barrier layer was much greater than in the previous solutions (Fig. 5d).

Electron diffraction.—Only reflection diffraction from the outer film surfaces gave any evidence of crystallinity. The unsealed films revealed no diffraction patterns but charged up in the electron beam, probably due to their low conductivity. Films sealed for 5 min (Fig. 6a) and 24 hr (Fig. 6b) showed definite diffraction patterns, certain lines becoming more intense after the longer time. Comparison of the calculated d values with those of the known aluminas and their hydrates (11) gave no indication of any specific modification. The failure to identify the crystalline material may have been due to insufficient accuracy in the line measuring techniques and the unavailability of any data giving the intensities of individual lines in the electron diffraction patterns. Furthermore, more than one crystalline modification may have been formed during sealing, which would complicate any interpretation.

Thus, during sealing in water, crystalline material of an unknown composition was formed on the outer surfaces of the anodic oxide films and this corresponded with the crystallites seen in the micrographs.

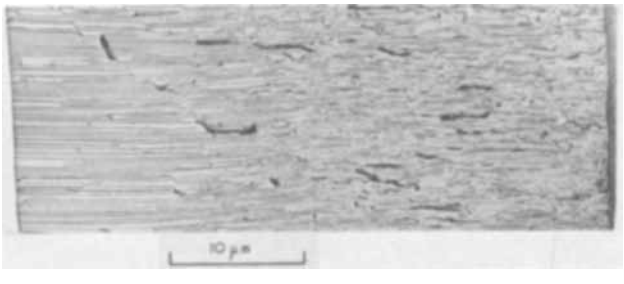

Fig. 4. Electron micrographs of section of film sealed for 10 min, showing the variation of film morphology with thickness. The outer film surface is on the right.

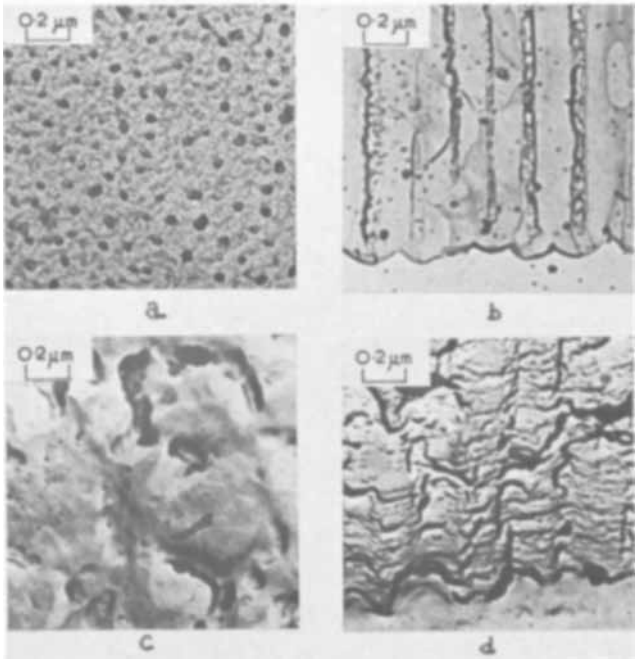

Fig. 5. Electron micrographs of films sealed for 30 min at 100°C (a) surface, and (b) section near barrier layer, for potassium dichromate (pH 2.0), (c) surface, and (d) section near barrier layer, for potassium chromate (pH 7.7).

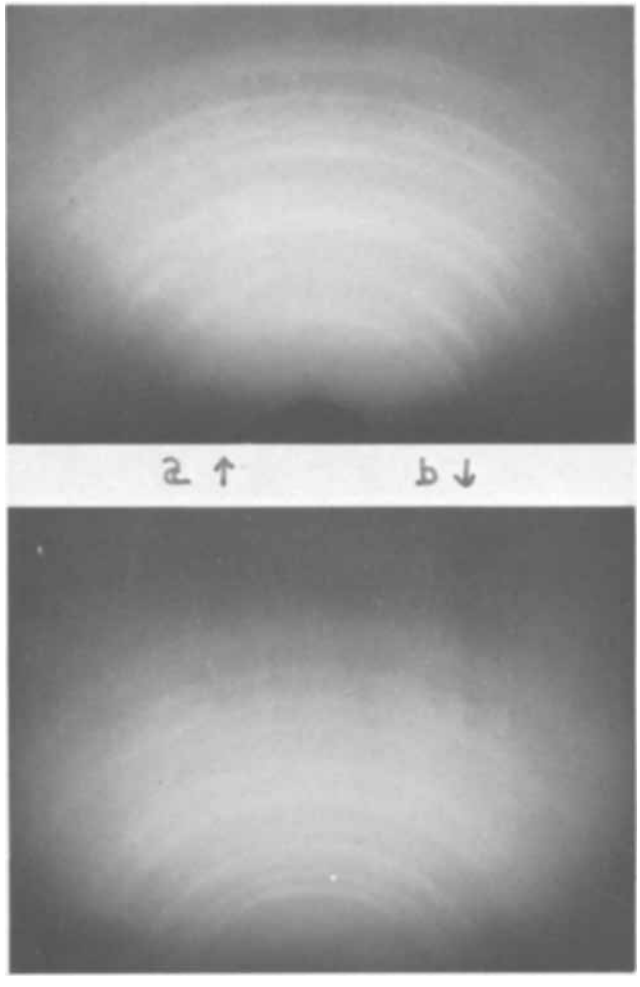

Fig. 6. Reflection electron diffraction patterns from film surfaces after sealing at 100°C for (a) 5 min, (b) 24 hr.

This material was not detected in the film depths and probably did not exist there.

Discussion

Preliminary considerations.—It is appropriate to mention briefly here other new data and theories on the mechanism of formation of unsealed and sealed films (7-9). Electron microscopy shows that the pore and cell geometry is broadly similar to Keller, Hunter, and Robinson's model but the detail and the mechanism of formation are different. The steady-state barrier layer thickness, the cell diameter and the pore diameter are all measured to be directly proportional to the anodizing voltage. Furthermore, the barrier layer thickness, decided largely by the equilibrium established between oxide formation in the barrier layer and field-assisted dissolution at the pore base, determines the cell and pore sizes by a simple geometrical mechanism. The dissolving power of the electrolyte in the presence of the field is far more important than the anion type in determining the pore structure. A natural consequence is that nonaggressive electrolytes produce thicker barrier layers, larger cells, and larger pores next to the barrier layer, although subsequent pore widening toward the outside of the film by simple chemical dissolution is more severe in aggressive electrolytes.

This model explains why the voltage, and therefore the barrier layer, cell, and pore dimensions next to the barrier layer, rise with time during anodizing at constant current density in oxalic acid. Depletion of the relatively weak solution in the depth of the pores, by anion incorporation into the film and pH changes, would lead to a reduction in the dissolving power of the electrolyte under the field. Such effects are not found in relatively concentrated solutions of the stronger sulfuric and phosphoric acids.

In contrast, the structure and composition of the interpore material profoundly influence the sealing reactions. Infrared spectroscopy (7), supported by electron diffraction data, suggests that the cells of unsealed films formed in sulfuric acid, are a relatively open array of amorphous, largely anhydrous crystallites, invisible to the electron microscope, permeated by molecular water, the surfaces of the crystallites carrying hydroxyl groups or ions, and the system being hydrogen bonded. Thus, the intercrystallite surfaces (14, 15) which carry the water and the acid anion are partially accessible to the anodizing solution and sealant. In more aggressive electrolytes too, the outer intercrystalline regions are opened up by acid action. Boiling water produces little change in the bulk oxide composition to specific alumina hydrates but causes major pore blockage, closure of the intercrystallite regions and possibly an increase in the hydroxyl and entrapped water content of the film, as judged by the evacuation and deuterium exchange properties (7). An agglomeration process causing rearrangement of the material to a form of lower surface area and energy was briefly proposed as a major contributor to the sealing process.

The sealing of films formed in oxalic acid are morphologically and structurally largely complete after 10-30 min near the surface, although more subtle changes occur near the barrier layer and on the film surface for 24 hr. At least three different, but to some extent concomitant processes appear necessary to explain the entire phenomenon: (*a*) an initial precipitation occurring in the pores, largely close to the outer surface except in high pH sealants; (*b*) crystalline material forms on the exterior film surface only, this being a minor process; and (c) the oxide, and any hydroxide, redistributes itself during prolonged sealing by the agglomeration process.

Precipitation reaction.—Pore closure is most efficient near the outer film surface, its efficiency gradually falling off as the metal is approached. The bulk solution pH of salt solutions also considerably affects the extent of sealing. Thus, the local conditions within the pores, such as pH and residual anion and Al^{3+} content, must influence the extent of sealing greatly. On introducing the film into the sealant, a gradient of these properties exists down the pore, with high pH sealing solution predominating at the top and residual acid concentration and Al^{3+} ion concentration near the bottom. A precipitation reaction, as proposed by Wood and Marron (3) and Spooner and Forsyth (5), occurs where the solubility product of hydroxide or hydrated oxide is exceeded. The precipitation is more extensive in the more open outer film regions affected by electrolyte and where the pH is highest, gradually declining toward the metal. Electron probe microanalysis (3) indicates that for most sealing solutions the precipitate plug is completed very quickly near the outer surface, severely limiting further entry of sealant into the pore and therefore further precipitation, although with dichromate solution, where the precipitation is slow, it may enter for long periods.

Initial precipitation is more extensive in higher pH sealants, the rapidity and depth of precipitation decreasing in the order potassium chromate (pH 7.7) > nickel acetate (pH 5.7) > potassium dichromate (pH 2.0), confirming the results of Wood and Marron (3) and Hoar and Wood (1, 2). Differences in pore closure rates for anodic films formed in various acids (the rates being sulphuric > oxalic > phosphoric) are partly due to pore size differences but are undoubtedly related to anion adsorption affecting the initial precipitation reaction.

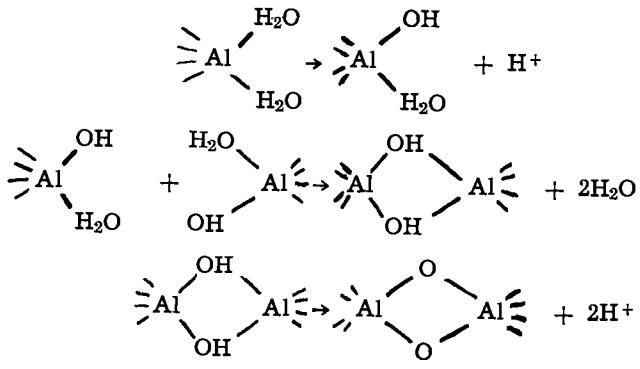
The material precipitated in the pores is insufficiently well crystallized to produce a sharp diffraction pattern. Furthermore, the sealing weight gains of Spooner and Forsyth (5) indicate that only a relatively small fraction of the pore volume can be blocked by precipitate, produced by uptake of liquid from outside the film. The same argument applies to the crystalline material on the outer surface now to be described.

Formation of the outer crystallites.—There is little or no evidence from the present or previous (5, 16) diffraction studies to suggest that this well-known outer crystalline material extends any significant depth into films sealed in water. The reaction cannot therefore be considered a major sealing process, with the proviso that it is this outer crust which contacts any corroding environment.

It is quite likely that the discrete crystals of alumina hydrate are formed by a process allied to the initial reaction within the pores, namely a dissolution and reprecipitation reaction. However, conditions on the surface are quite different from those in the pores, boiling sealant being rapidly replenished and any acid anions which might inhibit crystallization being rapidly dispersed or kept to a low level. Even on the surface, crystals visible in the electron microscope were only produced after 30 min although they were detectable by electron diffraction after 5 min.

Agglomeration process.—The above considerations require that the major, long-term, visible, pore-filling process in the film depths involves an extensive rearrangement of the oxide/hydroxide system, left after the first rapid precipitation reaction. A simple mass transfer reaction from the cell walls to the major pores must occur without physical collapse or deformation of the main film structure. Although possibly some increase of material volume occurs, the absence of extensive new phases such as crystalline hydrates (7, 9) suggests this is not predominant and that a redistribution of porosity is involved. The large initial regular pores are generally filled, the initial crystallites agglomerate into larger ones, and the intercrystallite regions, although occupying a lesser area, are in places larger in size. The outer crystallites, the precipitate, and the blocked pores prevent rapid entry of corrodants or dyestuffs; however, if the barrier layer is etched off, the underside of the film takes up some dye. This mechanism is supported by the fibrous appearance of the wide filled pore regions.

The cell wall structure after the initial precipitation is as described earlier except where the intercrystallite regions have been partly blocked by precipitate, especially near the outer surface. The incompletely filled pores contain some of the molecular water entrapped in the film (7). The most obvious mechanism for a mass transfer reaction in such a situation again involves slow dissolution of oxide from the cell microcrystallites and its reprecipitation some distance away in the pores. Thomas and Whitehead (17) have characterized the various steps in the formation of aluminum oxide from aqueous solutions, thus



Oxide production from a solvated aluminum ion basically requires replacement of water molecules by O^{2-} ions. The first two steps occur during the formation of an intermediate hydroxide precipitate, while the third step represents the final conversion of this hydroxide to oxide in a place other than where the original oxide molecule became hydrated. The precipitation probably occurs on the particles of oxide in the pores or on the cell walls. The initial step in the above scheme is favored by high *p*H, but clearly subsequent oxide formation results in a reduction in *p*H, slowing the precipitation reaction, and providing elsewhere dissolution and the consequent solvated Al^{3+} ions necessary for the continuation of the process. In places where the final conversion of hydroxide to oxide is incomplete, hydroxylic material is left attached to the growing crystallites, explaining the minor increase in OH^- ion content detected by infrared analysis (7).

Evidently such a reaction scheme, in which both the reactants and products are the same, *i.e.*, oxide, must have some driving force other than the change in chemical free energy between reactants and products. It is proposed that the over-all driving force is the decrease in the large surface area, and hence surface energies, of the relatively inaccessible microcrystallites, the net result being an increase in the average crystallite size. If the aggregation process occurred throughout the cell wall then a reduction in the bulk film thickness would be expected due to the compaction occurring in the film. Thickness measurements, however, gave no indication of any reduction in the bulk film thickness, which would seem to indicate that unreacted "pillars" of oxide remain between the pores, except perhaps at the very outer surface where the film was initially more open and aggregated quicker. These columns "support" the remainder of the unreacted film. Thus, there is no net reduction in film porosity after the initial precipitation reaction, but only a redistribution of the remaining porosity. After the sealing process there are less "intercrystallite" pores, but these are bigger than those in the unsealed film. Hence the filled pores spread laterally and eventually much of the film, other than the pillars, appears to consist of relatively larger but irregular oxide crystallites.

Kingery has suggested a mechanism for the aggregation of solid particles having only a limited solubility in a surrounding liquid phase (18, 19). This theory has been mainly applied to the phenomenon of liquid phase sintering, which occurs at much higher temperatures than used for sealing. Kingery considers the point of contact between two solid particles, where there is a sharply negative radius of curvature. In a gas/liquid system, the vapor pressure over such a localized surface is much reduced. In a solid/liquid system, such a pressure difference appears as a decrease in solubility. Thus, in a restricted region the oxide is less soluble than elsewhere, resulting in a deposition of solid material there by any possible mechanism, such as the proposed dissolution/reprecipitation reaction.

Other factors.—The current results and theories agree with earlier studies of the effects of sealing solution and type, and of film thickness, using impedance methods and electron probe microanalysis (1-3), although some modification of the theory has proved necessary, particularly with regard to the extent of boehmite formation and the final sealing stages. Aging effects could be due to long-term aggregation processes.

The variation in extent of sealing with different sealants may be due to the differing adsorbabilities of the various anions, as well as the *p*H effects. Thomas and Whitehead (17) found that aluminum hydroxide precipitates can be peptized by stabilization of the large ionic micelles, due to repulsion of the charges of strongly adsorbed anions, and thus precipitation could be prevented. Ginsberg and Wefers (20) have suggested a similar theory for the stabilization of internal surfaces in unsealed films. Murphy has proposed that such anions can greatly affect the sealing reaction, claiming that is consists largely of the replacement of such adsorbed anions, or even a proton space charge, by OH^- ions, thereby preventing the entry of further ions onto the cell walls (6). This theory, although it may be one factor, cannot explain the major deposition of material in the large pores, observed directly in the present work. Preferential adsorption of PO_4^{3-} ions must interfere with the initial precipitation reaction as well as with any subsequent aggregation process, presumably by preventing initial dissolution within the pores or deposition of precipitate. The induction period observed with dichromate sealing (1-3) must be related to the *p*H rise eventually achieved in the pores due to the adsorption of the anion on the film and its subsequent entry between the microcrystallites.

Acknowledgments

The authors are indebted to Professor T. K. Ross for the provision of facilities and to Mr. B. Vaszko for his collaboration with the electron microscopy.

Manuscript submitted April 7, 1969; revised manuscript received June 7, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

Electrochemical Reduction of 6-Thiopurine and Related Compounds: Polarography, Voltammetry and Macroscale Electrolysis

Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma

ABSTRACT

The electrochemical reduction of 6-thiopurine, purine-6-sulfinic acid, and purine-6-sulfonic acid has been investigated polarographically, coulometrically and by macroscale electrolysis. The reduction products have been investigated spectrophotometrically and chemically as well as by electrochemical methods. Between *p*H 1 and 3,6-thiopurine is reduced in two distinct steps; the first a 4*e* process to 1,6-dihydropurine; the second a 2*e* process to 1,2,3,6-tetrahydropurine which is subsequently hydrolyzed to a 4-aminoimidazole. At higher *p*H these two processes merge so that only a single 6*e* polarographic wave is observed. The *p*H dependence and slopes of the polarographic waves have been utilized to determine the rate controlling steps in these reductions. Purine-6-sulfinic acid is polarographically reduced in three separate processes; the first is the two electron reduction of the sulfinate monoanion to the 1,6-dihydro sulfinate which, between *p*H 2 and 6, decomposes to the purine-6-sulfenate which is immediately further reduced, in a 2*e* process, to 6-thiopurine. Between *p*H 7 and 9 the 1,6-dihydrosulfinate anion loses sulfoxylic acid to give purine. The second wave involves reduction of the purine-6-sulfinate dianion to the corresponding 1,6-dihydro derivative, which breaks down to yield purine and the sulfoxylate anion. The third wave involves, over-all, 4*e* and is due to further reduction of the 1,6-dihydrosulfinate to the corresponding 1,2,3,6-tetrahydro derivative which then loses sulfoxylic acid to give 2,3-dihydropurine; this is immediately further reduced to 1,2,3,6-tetrahydropurine which hydrolyzes to a 4-aminoimidazole. Purine-6-sulfonic acid is also polarographically reduced in three steps; the first wave involves a 2*e* reduction of the monoanionic species to the 1,6-dihydrosulfonate which decomposes to purine and, at low *p*H, purine-6-sulfinic acid; the latter is immediately reduced to 6-thiopurine. The second wave is the 2*e* reduction of the dianionic sulfonate to the 1,6-dihydro derivative which decomposes to purine. The third process is, over-all, a 4*e* reduction of the 1,6-dihydrosulfonate to a 4-aminoimidazole.

In some recent studies of the electrochemical oxidation of 6-thiopurine it became necessary to be able to both detect and quantitatively determine both the 6-thiopurine and two of its oxidation products, purine-6-sulfinic acid and purine-6-sulfonic acid (1). The analytical determinations of these and other electrooxidation products will be described elsewhere (2). This paper describes in detail the electrochemical reduction mechanisms for these reactions. 6-Thiopurine is used extensively as an antileukemia agent; it is also possible that both purine-6-sulfinic and purine-6-sulfonic acids or their salts may be minor, although important products of metabolism of 6-thiopurine in man and other species. Recent work (1, 3, 4) has suggested a possible parallelism between modes of electrochemical oxidation and biological oxidative transformations (*e.g.*, enzymatic oxidation). It is also important however, to fully understand the reduction behavior of biologically important molecules especially regarding those factors that influence the electron transfer processes, such as, for example *p*H.

There have been only a few reports of the electrochemical reduction of 6-thiopurine. Humlova has reported the oscillographic polarography of 6-thiopurine (5). Vacek (6) developed a method for the determination of 6-thiopurine by utilizing the height of the polarographic wave in McIlvaine buffer *p*H 7.1. There have been no reports of the polarographic behavior of purine-6-sulfonic or sulfinic acids. Consequently, it was decided to study systematically the polarography and voltammetry of 6-thiopurine, purine-6-sulfinic acid, and purine-6-sulfonic acid in order to define the nature and mechanisms of the electrochemical reduction.

Experimental

Chemicals.—6-Thiopurine was obtained from Calbiochem. Purine-6-sulfinic acid (sodium salt) and purine-6-sulfonic acid (potassium salt) were prepared accord-

ing to Doerr *et al.* (7). Hypoxanthine and purine were obtained from Nutritional Biochemicals.

Buffer solutions were prepared from analytical reagent grade chemicals.

Argon (Linde) used for deoxygenating purposes was equilibrated with water; no other purification was necessary.

Apparatus.—Polarograms and voltammograms were recorded on either a Sargent Model XV or Model XVI polarograph equipped with Sargent IR correctors. Water jacketed three compartment cells maintained at 25° ± 0.1°C and containing a saturated calomel electrode (SCE), and a platinum counterelectrode in saturated potassium chloride solution were employed. All potentials are referred to the SCE at 25°C.

The dropping mercury electrodes had normal m and t values. Triple distilled mercury was used for all coulometric and polarographic studies.

Cyclic voltammetry was performed with the apparatus described by Dryhurst *et al.* (8).

Controlled potential electrolyses were carried out using a Wenking Model 66TAl potentiostat. Potentials of interest were measured with a Sargent laboratory potentiometer. The pH was measured with a Beckman Zeromatic pH meter.

Current integration during coulometry utilized a titration coulometer described by Lingane (9).

Ultraviolet absorption spectra were obtained with a Beckman Model DB recording spectrophotometer, using 1.00 cm glass stoppered quartz cells.

The preparation of the PGE has been described earlier (4). A conventional two compartment macroscale electrolysis cell was employed using a mercury pool cathode and a platinum gauze counterelectrode. A Beckman pH type calomel reference electrode dipped directly into the working electrode compartment. The solution in the working electrode compartment was stirred with a magnetically rotated Teflon coated iron bar. A stream of argon gas was always bubbled through the test solution.

Polarographic procedure.—The test solution was prepared by diluting appropriate quantities of stock solutions with suitable background electrolyte; (on occasion when the compound was unstable at a particular pH, material was weighed directly into the deaerated buffer solution), the solutions were then deaerated for 10 min and then the polarogram run. The residual current was subtracted arithmetically from the total current; $E_{1/2}$ and i_l were determined graphically utilizing the average of the recorder trace.

Coulometric procedure.—One hundred and fifty milliliters of buffer solution was introduced into the electrolysis cell and deoxygenated for at least 20 min; the mercury was then introduced and the solution electrolyzed at the electrolysis potential until the titration coulometer showed a constant small titration rate. Then after turning off the potentiostat a weighed amount of the electroactive species was added. After dissolution, the desired potential was again applied; argon was bubbled continuously through these solutions.

At appropriate intervals 0.5 or 1.0 ml samples of the electrolysis solution were withdrawn and after dilution with water spectrophotometric measurements were taken.

Often polarographic or voltammetric runs were made directly in the test solution.

6-Thiopurine

Polarography.—Below pH 2.3 6-thiopurine exhibits two very close polarographic waves (waves I and II, respectively). The half-wave potential for both waves shifts linearly more negative with increasing pH; $E_{1/2} = -0.79\text{-}0.116$ pH for wave I, and $-1.00\text{-}0.0483$ pH for wave II. The two waves merge at about pH 3, the composite wave, up to pH 5, having the same pH dependence as that for wave I. Above pH 5 a further wave appears (wave III) whose $E_{1/2}$ also shifts linearly more negative with pH, $E_{1/2} = -1.29\text{-}0.027$ pH. Above pH 8 wave III disappears; one further wave is observed in ammonia buffer pH 9.1 (wave IV), which appears only at this pH, $E_{1/2} = -1.74$V.

At low pH the very large values of the diffusion current constant ($I = i_l/Cm^{2/3}t^{1/6}$) for both waves I and II are indicative of the involvement of catalytic hydrogen discharge (Table I). In 1*M* HOAc the I value indicates a 4*e* process as does the value for wave II; the involvement of catalytic hydrogen discharge however undoubtedly enhances these values, particularly that of wave II. Between pH 3 and 5.5 the sum of the diffusion current coefficients for wave I and wave II is indicative of six or more electrons. For wave III the diffusion coefficient decreases very rapidly with pH between pH 6 and 8; for wave IV the value is again indicative of at least a 6*e* process.

At pH 3.5 (acetate) the dependence of the limiting current on drop time supports the view that waves I and II are under over-all effective diffusion control (*i.e.*, linear dependence on $h^{1/2}$). However, at pH 8.1 (McIlvaine) the limiting current increased with h but less so than predicted by the square root relationship, hence it was concluded that wave III was partly under kinetic control at this pH (10). A concentration study at pH 3.5 showed a marked decrease in the i_l/C ratio with increasing concentration from 41.4 μA mM^{-1} at 0.028 m*M* to 30.9 μA mM^{-1} at 0.42 m*M*. The systematic decrease of the i_l/C ratio with increasing concentration is probably associated with the lowering of the hydrogen overpotential by 6-thiopurine. As the 6-thiopurine concentration increases hydrogen becomes more readily reduced so that there is a much poorer separation between the 6-thiopurine and hydrogen discharge waves.

At pH 3.5 the half wave potential becomes slightly more negative with increasing concentration. The temperature dependence of the wave at pH 3.5 was 1.0% per degree.

Electrolysis at wave I and wave II.—Attempts to determine a coulometric n value for wave I plus wave II between pH 3.5 and 5.5 gave extremely high values. Over the period of many hours electrolysis in these pH regions it was not possible to eliminate the 6-thiopurine polarographic wave; the electrolysis current remained at a high value throughout the course of the electrolysis and the solution pH increased. Such behavior indicates that a major part of the current controlling process under such conditions is the catalytic reduction of hydrogen ion. At the beginning of such electrolyses hydrogen sulfide was liberated. As the electrolysis proceeded a red color developed in the solution which intensified in the presence of air, and after a few days exposure to the atmosphere a fine black precipitate developed.

Electrolysis at wave III.—Macroscale electrolysis of 6-thiopurine on the crest of wave III (McIlvaine pH 7) also gave extremely high coulometric n values, H_2S was evolved, the pH increased and a red color devel-

Table I. Variation of 6-thiopurine diffusion current constant with pH

pH	Background[a]	Diffusion current constant Wave I	Wave II	Wave III	Wave IV
0.0	1*M* H_2SO_4	24.4	30.7		
1.0	Chloride	24.5	34.7		
2.3	1*M* HOAc	8.3	9.1		
3.4	Acetate	14.3			
4.4	Acetate	14.8			
5.7	Acetate	14.2			
6.0	McIlvaine			12.7	
7.0	McIlvaine			5.4	
8.0	McIlvaine			1.8	
9.1	Ammonia				14.8

[a] Except in the case of the 1*M* H_2SO_4 and 1*M* HOAc backgrounds, all buffers were 0.5*M* in ionic strength.

oped in the solution which behaved in an identical manner to the product obtained from waves I and II. However, after standing such a solution in air for only a few hours, a black precipitate formed.

Purine-6-Sulfinic Acid

Purine-6-sulfinic acid (P-6-Si) shows several polarographic waves over the normal *p*H range. In order that the origins of these waves could be completely understood it was necessary to ascertain the stability of P-6-Si in each of the backgrounds and to identify the breakdown products.

Stability studies.—Spectrophotometric and polarographic studies showed that between *p*H 1 and 5, P-6-Si decomposes to hypoxanthine (major product) along with sulfur dioxide and 6-thiopurine. The rate of decomposition decreased with increasing *p*H. At around *p*H 2 there were also indications, on occasion, that traces of purine were produced. Between *p*H 5 and 8.0, P-6-Si decomposed very slowly over the course of several days to P-6-So and hypoxanthine. P-6-Si was stable for several days in ammonia buffer *p*H 9.1.

Polarography.—Because of the number of electroactive decomposition products from P-6-Si the observed polarographic behavior of solutions of P-6-Si is extremely complex.

P-6-Si itself gives rise directly to three polarographic waves; all shift linearly more negative with increasing *p*H; $E_{1/2}$ = —0.37-0.094 *p*H for wave I, —0.79-0.075 *p*H for wave II and —0.99-0.080 *p*H for wave III.

The effect of *p*H on the diffusion current constant, I, reflects the instability of P-6-Si at low *p*H (Table II). Between about *p*H 3 and 7 the magnitude of I indicates that two 2*e* waves are involved (waves I and III). At *p*H 8 wave III disappears, wave I becomes much smaller and a new small wave (wave II) appears. At *p*H 9.1 again two 2*e* waves (waves I and III) appear. At higher *p*H only the single wave II appears having an I value intermediate between that expected for a one or two electron process.

At *p*H 9 (ammonia) the i_l/C ratios for waves I and III are 5.9 ± 0.1 and 6.4 ± 0.7 μA mM^{-1}, respectively; in carbonate buffer at the same *p*H the i_l/C ratio for wave II decreased slightly with increasing concentration from 6.7 μA mM^{-1} at 0.25 m*M* to 5.1 μA m*M* at 1.26 m*M*. At *p*H 4.4 (acetate) and 9.1 (ammonia) both waves I and III were entirely under diffusion control ($i_l/h^{1/2}$ constant). However, at *p*H 8 (McIlvaine) the droptime dependence of the limiting current for wave I was characteristic of a process partly under kinetic control although this effect was small.

Electrolysis of wave I.—Because of the instability of P-6-Si, coulometry and macroscale electrolyses were not performed below *p*H 3.

Table II. Variation of diffusion current constant with *p*H for polarographic waves of purine-6-sulfinic acid[a]

Background[b]	*p*H	Diffusion current constant[c] Wave I	Wave II	Wave III
1*M* HOAc	2.3	0.24		
Acetate	3.6	4.57		4.32
Acetate	5.4	4.23		4.45
McIlvaine	7.0	2.91		3.77
McIlvaine	8.0	1.62	1.35	
Ammonia	9.1	3.41		3.02
Carbonate	9.0		3.28	[d]
Hydroxide	11.6		2.79	
Hydroxide	12.3		2.32	

[a] Concentration 0.914 m*M*.
[b] With the exception of 1*M* HOAc all backgrounds had an ionic strength of 0.5*M*.
[c] $I = i_d/Cm^{2/3}t^{1/6}$.
[d] A wave was observed but was so indistinct that a meaningful I value could not be computed.

At *p*H 3.6 and 5.4, P-6-Si decomposes slowly primarily to hypoxanthine which is not electrochemically reducible, the observed *n* values of 2.4 and 3.6, respectively, were therefore expected to be low; the major electrolysis product was 6-thiopurine (along with some purine). At *p*H 7 and above 2*e* were transferred; the major product was purine; at *p*H 9.1 (ammonia) however purine is slowly further reduced in a 2*e* process to 1,6-dihydropurine. Product identification in these studies was based chiefly on polarography and ultraviolet spectra.

Electrolysis at wave II.—Attempts to obtain any meaningful coulometric data at the first wave in carbonate background *p*H 9 (wave II) were unsuccessful since a high current was observed throughout the electrolysis leading to extremely high *n* values. The solution turned pink as the electrolysis proceeded, particularly when air was allowed to come in contact with the solution.

Coulometry at wave II at *p*H 11.6 (λ_{max} for P-6-Si = 278 mμ) indicated that about 2*e* were transferred fairly rapidly with the formation of purine (λ_{max} = 271 mμ) followed by very slow transfer of a further 2*e* to form 1,6-dihydropurine (λ_{max} = 305 and 230 mμ).

Electrolysis at wave III.—After elimination of P-6-Si wave I in acetate *p*H 3.6 the potential was adjusted to coincide with the rising portion of the second wave (wave III). Immediately H_2S was evolved and the current increased to a large value; extremely high *n* values were obtained. After several hours electrolysis polarography showed no reducible products and the *p*H had increased by several units. As soon as the solution was exposed to the atmosphere it turned bright red-pink. Two u-v absorption peaks were observed (λ_{max} = 320 and 240 mμ corresponding to 6-thiopurine and the purine wave II electrolysis product.) Treatment of this solution with sodium nitrite then alkaline β-naphthol gave an orange pink dye (λ_{max} = 500 mμ). The wave III process at this *p*H thus involved reduction of 6-thiopurine in part to the wave II product of purine which is known to be a diazotizable primary amine (11). Because of the effect of 6-thiopurine and the purine wave II electrolysis product on the overpotential for hydrogen discharge the large *n* values were not unexpected.

Attempted coulometry directly on wave III at *p*H 6.9 (McIlvaine) gave very high *n* values, the *p*H increased, and the solution turned pink on exposure to air. The u-v spectrum showed a single broad absorption peak at $\lambda_{max} \cong$ 308 mμ, although the product solution did not give a good test with sodium nitrite-β-naphthol.

Purine-6-Sulfonic Acid

Polarography.—Purine-6-sulfonic acid (P-6-So) shows four polarographic waves over the normal *p*H range. At very low *p*H (*p*H 1.0 and below) P-6-So decomposes to hypoxanthine and sulfur dioxide although the decomposition is much slower than for P-6-Si.

Three of the waves shift linearly more negative with increasing *p*H. Wave I appears between *p*H 1 and 7, $E_{1/2}$ = —0.45-0.0782 *p*H. Between *p*H 3.6 and 12.5 wave II appears, $E_{1/2}$ = —0.675-0.0789 *p*H. Wave III appears between *p*H 1 and 9, $E_{1/2}$ = —0.98-0.0635 *p*H. A fourth wave, wave IV, is observed at *p*H 9.1, $E_{1/2}$ = —1.450V.

The temperature and droptime dependence of the current indicates that the waves are under diffusion control except at *p*H 6.9 (McIlvaine) when wave I was partly under kinetic control. The magnitude of the diffusion current constants (Table III) indicated that the polarographic *n* values for waves I and II reach a limiting value of 2; the magnitude of the constant for waves III and IV seems to indicate similar values, although at certain *p*H values (*e.g.*, wave III at *p*H 2 and 6.9) the involvement of more than 2*e* is suggested.

Table III. Variation of diffusion current constant with pH for polarographic waves of purine-6-sulfonic acid[a]

Background[b]	pH	Diffusion current constant[c] Wave I	Wave II	Wave III	Wave IV
Chloride	1.05	2.74		[d]	
Chloride	2.0	3.43		10.00	
1M HOAc	2.3	3.36		5.23	
Acetate	3.6	4.52	1.60	3.04	
Acetate	5.4	4.68	2.72	4.84	
McIlvaine	6.9	1.36	4.39	7.86	
McIlvaine	8.0		3.82	6.80	
Carbonate	8.9		5.3	3.82	
Ammonia	9.1		3.25	3.32	3.58
Hydroxide	11.6		2.86		
Hydroxide	12.3		3.38		

[a] Concentration of P-6-So, 0.81 mM.
[b] With the exception of 1M HOAc all backgrounds had an ionic strength of 0.5M.
[c] $I = i_d/Cm^{2/3}t^{1/6}$.
[d] A very large maxima appeared.

In ammonia and carbonate backgrounds pH 9 waves I, II, and III all give linear i_l-C plots.

Electrolysis at wave I.—The instability of P-6-So below pH 2 precluded coulometry in these regions. The data indicates that below pH 3 between 3 and 4e are consumed and electrolysis produces a mixture of 6-thiopurine and purine; above this pH purine is the sole product and 2e are consumed.

Electrolysis at wave II.—Coulometry on the plateau of wave II in acetate pH 3.6 and 5.4 after first eliminating wave I by electrolysis showed that 2e were involved in each case giving 1,6-dihydropurine as the product. The same product was obtained up to pH 8.0 by direct reduction of P-6-So at wave II although 4e were transferred. Above this pH the sole product was purine again with the involvement of 2e.

Confirmation of the nature of the product of wave II was obtained by cyclic voltammetry at the pyrolytic graphite electrode (PGE). If the initial sweep was toward negative potential (starting at 0.0V) no cathodic peaks were observed in the electrolysis solution; on sweeping toward positive potential a well-formed anodic peak was always observed. If the scan was run toward negative potential after having scanned this anodic peak a well-formed cathodic peak was observed. Purine, itself, on the initial scans showed only a cathodic peak, but having once scanned this peak a well-formed anodic peak was produced on sweeping toward positive potential. The potentials of these anodic and cathodic peaks observed for both purine and the P-6-So wave II product solutions always agreed exactly. Dryhurst and Elving (12) have discussed the mechanism of these processes.

Electrolysis at wave III.—Attempts to electrolyze at potentials corresponding to wave III and determine an n value were never successful. Very large n values were obtained and the pH increased several units after electrolysis; the solution turned red-pink especially when exposed to the atmosphere. The u-v absorption spectra of an electrolyzed solution was different to the wave II product, although no well-defined peaks were observed, rather plateaux at $\lambda_{max} \cong 330$, 300, and 270 mμ with end absorption occurring somewhat earlier than for background solution alone.

Electrochemical Reduction Mechanisms

6-Thiopurine.—Between about pH 2.3 and 5 the magnitude of the diffusion current constant for waves I and II suggests the involvement of six or more electrons. However, the evidence from concentration and coulometric studies and the more positive potentials for background discharge in the presence of 6-thiopurine suggests that catalytic hydrogen discharge enhances the magnitude of the constant. At low pH, wave I probably involves about 4e and wave II 2e, although catalytic hydrogen discharge obscures the values. The fact that H_2S is immediately evolved upon commencement of the electrolysis suggests that the initial point of attack is at 1,6-double bond to give purine. At low pH purine would be rapidly further reduced in a 2e process to 1,6-dihydropurine (11). The formation and reduction of purine in the over-all wave I process is evidenced by the magnitude of I at pH 2.3 indicating 4e and the fact that between pH 0 and 3 a second wave appears. Calculation from earlier data (11) indicates that the second purine reduction wave should occur at $E_{1/2} = -0.90$V at pH 0, −0.98V at pH 1.0, and −1.18V at pH 2.3; wave II for 6-thiopurine appears at −0.97V, −1.05V, and −1.12V, respectively, at the same pH. Because of the closeness of the two 6-thiopurine waves and hence the error involved in measurement of $E_{1/2}$ for wave II, these values are in good agreement. Beyond pH 3 the expected half-wave potentials for the second wave of purine occur at more positive potentials than those required for the initial reduction of 6-thiopurine and accordingly only a single 6e wave is observed. The red electrolysis product of 6-thiopurine produced between pH 3 and 5 which deepened in color on exposure to air and finally gave a black precipitate, agrees exactly with the behavior reported for the product of electrolysis at the second wave of purine, the black material being of a polymeric nature (11).

More detail regarding the electrode mechanism and rate controlling steps was obtained by computing αn_a values utilizing the wave slope $(E_{1/4} - E_{3/4})$ (13). Below pH 3, αn_a data was calculated for wave I, between pH 3 and 5 for wave I plus wave II and above pH 5 for wave III (Table IV). There appeared to be three distinct regions of constant αn_a values which correspond to these latter three pH regions. The rate of change of $E_{1/2}$ with pH along with αn_a data was used to calculate p, the number of hydrogen ions involved in the rate determining step (13).

For each of the pH regions examined there were only minor changes in droptime at the half-wave potentials so that $E_{1/2}$ was employed uncorrected (13). Values of p and αn_a are reported in Table IV. On the basis of α being *ca.* 0.5 the data suggests that wave I below pH 3 involves a two electron two proton rate controlling process; the diffusion current constant at pH 2.3 indicates a polarographic n value of 4. Accordingly, the mechanism can be represented as an initial rate determining attack at the 1,6-double bond to give the 1,6-dihydro derivative of 6-thiopurine (Fig. 1A, II) which rapidly loses H_2S to give purine which is further reduced in a two electron, two proton process to 1,6-dihydropurine (Fig. 1A, I → IV).

Wave II, which probably involves two electrons, is therefore identical to the second reduction wave of purine (11) namely reduction of IV, Fig. 1, to 1,2,3,6-tetrahydropurine (VI, Fig. 1) which is hydrolyzed by water to a 4-aminoimidazole (Fig. 1C).

Above pH 3 and below pH 5 the wave I and wave II processes occur simultaneously; the rate controlling step involves a one electron and one proton reduction

Table IV. Effect of pH and background composition on the rate determining step in polarographic reduction of 6-thiopurine

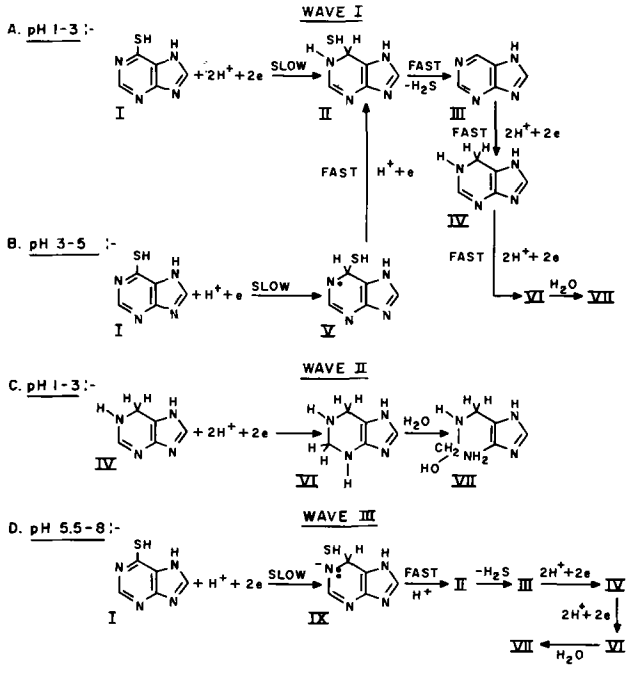

Fig. 1. Interpretation of electrochemical and chemical behavior observed for polarographic reduction of 6-thiopurine.

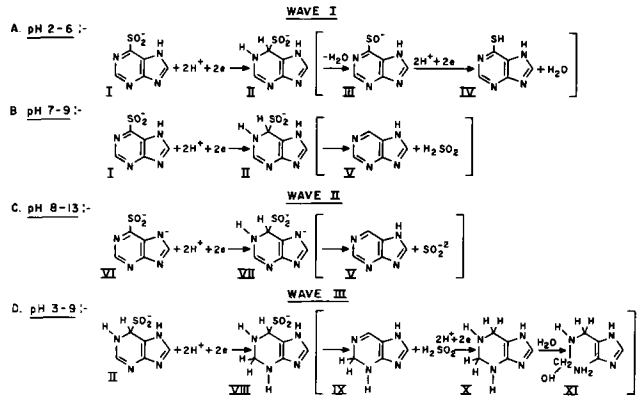

Fig. 2. Interpretation of electrochemical and chemical behavior for three polarographic waves observed for purine-6-sulfonic acid. Compounds and reactions enclosed in brackets are those which occur after the initial polarographic reactions (e.g., under coulometric conditions).

to give a free radical species (V, Fig. 1) which is rapidly further reduced to the 1,6-dihydro derivative of 6-thiopurine the further breakdown of which would be the same as for wave I and wave II so that the ultimate product is a 4-aminoimidazole, and a total of 6e are transferred (Fig. 1B).

Above pH 5.5 the rate controlling process again appears to involve two electrons and probably a single proton. Since the value of the diffusion current constant decreases with increasing pH and the wave is partly kinetically controlled, then the mechanism can be represented by an initial reduction to anionic species (IX, Fig. 1) which is rapidly protonated to give again the 1,6-dihydro derivative of 6-thiopurine which then undergoes the same reactions as outlined for waves I and II (Fig. 1D) so that again six electrons are finally consumed. Intermediate or mixed mechanisms apparently occur at pH 3 and 5.

Purine-6-sulfinic acid.—Due account being taken of the stability of P-6-Si particularly at low pH, the value of the diffusion current constant for wave I up to about pH 7 is in accord with a two electron reduction process. At pH 8 wave I appears to split into two waves (waves I and II) since the sum of the diffusion current coefficients are the same as for wave I alone at lower pH. At pH 9 and above, with the exception of ammonia background pH 9.1, wave I disappears and wave II becomes of about the same size as that for wave I at lower pH. Wave III has a diffusion current constant indicative of a 2e reduction except that it does not appear at pH 8 and it disappears behind background discharge above pH 9.

Between pH 3.6 and 5.7 coulometry indicates that more than two electrons are transferred at potentials corresponding to wave I and, bearing in mind the instability of P-6-Si at these pH regions, n probably approaches 4. Since the ultimate product is 6-thiopurine it is likely that the initial electrochemical reduction product decomposes, at low pH, to a species capable of further reduction with consumption of a further two electrons. That the ultimate product is 6-thiopurine at low pH indicates that electrochemical attack involves carbon atom 6; by analogy with earlier data for purine (11), the initial product is probably the 1,6-dihydroderivative of P-6-Si (II, Fig. 2) which subsequently loses water to give purine-6-sulfenic acid (III, Fig. 2) which is immediately reduced to 6-thiopurine (IV, Fig. 2). Purine-6-sulfenic acid has never been isolated; however, being an intermediate oxidation state between bis(6-purinyl)disulfide and P-6-Si it is probably reduced at some intermediate value between these two latter compounds. Bis(6-purinyl) disulfide is polarographically reduced at potentials close to 0.00V (1).

At pH 6.9 the pH dependence of wave I, and the diffusion current constant indicate that the polarographic reduction mechanism is unchanged (*i.e.*, steps I → II Fig. 2A). Coulometry, however, gives an n value of 2 and the main product is purine along with 6-thiopurine as the minor product. Accordingly, it is likely that the dehydration step (II → III, Fig. 2A) becomes less important and the chief breakdown route of the 1,6-dihydropurine-6-sulfinic acid involves liberation of sulfoxylic acid, H_2SO_2, and purine (V, Fig. 2B). Sulfoxylic acid has been shown to be the major product of reduction of sulfur dioxide at the DME (14).

At pH 8 (McIlvaine) wave I decreases in height and wave II appears, the sum of both waves being the same as wave I at lower pH. Wave I becomes partly kinetic controlled. Coulometry at wave I, however, involves two electrons and purine is the final product; wave II disappears and the product shows only the waves and spectra of purine. Doerr *et al.* (17) have calculated the pK_a for the imidazole dissociation of P-6-Si as 9.3. The evidence here seems to indicate a slightly lower pK_a such that at pH 8 the P-6-Si is predominantly in the dianionic form, the height of wave I, due to reduction of the monoanionic form, therefore being at least partially kinetically dependent on the rate of protonation of the former species. Wave II must, therefore, be due to reduction of the dianionic form of P-6-Si to the same product as for wave I. That this is so is indicated by the fact that coulometry of P-6-Si at wave II potentials at pH 11.6 gives an initial two electron reduction to purine, which at the potentials employed (—1.70V) is slowly further reduced to 1,6-dihydropurine (*i.e.*, this potential corresponds to one slightly more positive than $E_{1/2}$ for the first wave of purine at this pH) (12). Calculation shows that the potentials applied in carbonate buffer pH 9 (—1.60V) for electrolysis of P-6-Si wave II are sufficiently negative to completely electrolyze the expected product purine, hence giving rise to the large catalytic hydrogen discharge and hence very large n values. However, the evidence suggests that the product is identical to that obtained on complete electrochemical reduction of purine or 6-thiopurine.

The behavior of P-6-Si in ammonia buffer pH 9 is not readily explained. Since polarography in carbonate buffer pH 9 is quite different it must be assumed that ammonium ion (or ammonia) influences the ionization of the acid, since coulometry and polarography of the product solutions indicate that the over-all products are the same in ammonia buffer as in other compar-

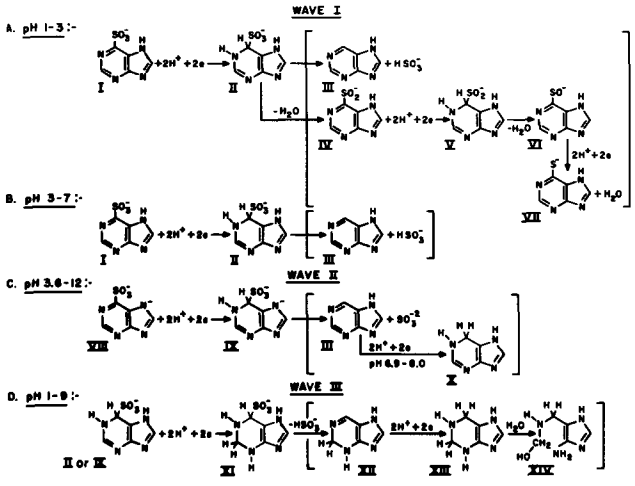

Fig. 3. Interpretation of electrochemical and chemical behavior observed for polarographic reduction of purine-6-sulfonic acid. Compounds and reactions enclosed in brackets are those which occur after the initial polarographic reactions (e.g., under coulometric conditions).

able backgrounds. The formation of amide or imide species may be important in interpreting the behavior in ammonia background.

Purine-6-sulfonic acid.—Between pH 1 and 5.5 the wave I diffusion current constant indicates that the polarographic reaction involves 2*e*. Coulometry at pH 2.3, however, indicates that more than 3*e* are involved and that the ultimate products are purine and 6-thiopurine. This immediately suggests that the initial attack is at C-6 but that the initial product is rather unstable at low pH. Accordingly, the probable initial product is 1,6-dihydropurine-6-sulfonate. The nonintegral number of electrons transferred and the fact that two products are produced suggests that this compound slowly decomposes by two routes; one by loss of sulfurous acid to purine, the other by loss of water to P-6-Si which is then further reduced by the mechanism developed earlier (Fig. 2A) to 6-thiopurine (Fig. 3A). Between pH 2.3 and 5.7 the only product is purine; the I value and coulometry indicate a two electron reduction.

At pH 3.6 wave II appears, and with increasing pH this wave grows until the diffusion current constant indicates a two electron process. At pH 6.9 wave I is very small and is under kinetic control. Doerr *et al.* (7), have calculated the pK_a for the second dissociation of P-6-So (imidazole dissociation) as 8.56. This would indicate that above pH 7 some dianionic species should be in solution. The kinetic nature of wave I at pH 6.9 suggests that this wave is due in part to the rate of protonation of the dianionic species to the monoanionic species. The fact that wave II is observed at pH values as low as 3.6 suggests that the literature pK_a value (7) is high. Accordingly, wave I is due to a two electron reduction of the monoanionic P-6-So to the 1,6-dihydro compound which a low pH, under coulometric conditions, decomposes to purine and purine-6-sulfinate, the latter undergoing further reduction. Between pH 3 and 6.9 the 1,6-dihydro derivative decomposes solely to purine (Fig. 3B).

Wave II is due to reduction of the dianionic form of P-6-So. The value of the diffusion current constant indicates that the polarographic process involves two electrons. Above pH 9 coulometry also indicates that two electrons are transferred and that the ultimate product is purine (Fig. 3C). However, coulometry at pH 6.9 and pH 8 indicated the transfer of 4*e* and that the product was identical to that obtained upon electrolysis of purine at its first wave. Calculations from earlier data (12) show that the potentials employed at pH 6.9 and 8.0 for electrolysis of P-6-So (—1.30V and —1.40V, respectively) were sufficiently negative to allow electrolysis of purine which is a breakdown product of the initial electrochemical product 1,6-dihydropurine-6-sulfonate (dianionic species) (Fig. 3C). For coulometry at pH 9.1 and 10.6 the applied potential (—1.30 and —1.58V, respectively) was not sufficiently negative to allow appreciable reduction of the ultimate product, purine.

The exact nature of the wave III process is difficult to assign. The I value indicates that at many pH values more than 2*e* are involved. Coulometry suggests that the product of wave III aids the catalytic reduction of hydrogen ion and the nature of the final product is very similar to that obtained on electrolysis of purine at its second wave (11, 12). The pH dependence of the wave III process is also very similar to that observed for the second wave of purine; hence, it is likely that wave III involves reduction of the wave I or wave II product (1,6-dihydro derivative) at the 2,3-position to give the 1,2,3,6-tetrahydro derivative. Presumably subsequent breakdown of this product to yield sulfurous acid followed by further reduction would be analogous to the mechanism developed for adenine (11) (Fig. 3D) resulting in the formation of a 4-aminoimidazole.

The exact nature of the electrode mechanisms in ammonia buffer pH 9.1 cannot at this time be explained, however, since the behavior in a carbonate buffer at the same pH agrees with the postulated mechanism suggests that the change in mechanism is associated specifically with ammonia.

Stirred H-Cell Measurements on Liquid Alloys of Cadmium with a Small Amount of Gold

Barton L. Houseman[1]

Department of Chemistry, Goucher College, Baltimore, Maryland

and Guy R. B. Elliott*

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

Stirred H-cell emf measurements on solvent concentration cells of the type

$$W\text{-}Cd, Au_{(liq\ soln)}/CdI_{2(l)}/Cd_{(l)}\text{-}W$$

were made with high precision using compositions from 0.001 to 0.021 mole fraction gold at 673°, 742°, and 773°K. Solubility and anodic current efficiency measurements are reported. Plotting techniques are discussed.

Olander (1) has shown that, for solid gold-cadmium alloys, electrochemical cells of the type

$$W\text{-}Cd_{(l)}/CdCl_2 \text{ in } K(Rb)Cl\text{-}LiCl_{(liq\ soln)}/Cd, Au_{(solid\ soln)}$$

can be used for measurements with a precision of about ± 0.1 mV. Other measurements by Elliott and Chipman (2) have shown that the precision can be pushed to about ± 0.02 mV using solvent concentration cells of the type $W\text{-}Cd,X_{(liq\ soln)}/CdCl_2$ in $LiCl\text{-}KCl_{(liq\ soln)}/Cd_{(l)}\text{-}W$. It is advisable to avoid lithium halide solutions if possible. however, because these halides are not easy to purify (3, 4).

The present measurements were obtained by an extension of the stirred H-cell technique (5-7) to the use of molten cadmium iodide as the electrolyte with cadmium and cadmium alloy electrodes.

Experimental Technique

The cells and furnace.—Stirred H-cells as in Fig. 1 were modified from an earlier design (5-7) and used for runs IV to VI. For runs I to III the cross arm was a simple horizontal section, constricted by each H-cell leg. Uniform temperatures were again established by regulating the temperature outside nesting copper cylinders (5, 6). Gold solute pieces could be added at will by tilting the cell and tapping the side arm.

Chemical purity.—Molten cadmium (99.999% pure by manufacturer's analysis) was freed of oxide and electrochemically important impurities by washing with boiling CdI_2 under vacuum.[2] Reagent CdI_2 was vaporized under vacuum (run I) or merely fused twice under vacuum (all other runs) then melted into the H-cell legs. Gold (99.98% pure by manufacturer's analysis) was cut up with clean cutters, washed with petroleum ether and acetone, and vacuum dried. Argon was purified by distillation. Tungsten was cleaned electrolytically using a-c current in concentrated NaOH with water wash.

EMF.—Temperatures were measured by the emf of Pt/Pt-10% Rh thermocouples read on a Leeds and Northrup K-2 potentiometer with an electronic null detector. This same potentiometer was used to measure the cell voltages and was checked against a calibrated potentiometer to assure that it was indicating proper emf values. No short-term fluctuations in the cell could be detected at the galvanometer, *i.e.*, these values were steady in the 0.0001 mV range. Except for one point (36B) which appears to be in error by 0.0057 mV, the similarities in the emf/T°K values indicate a long-term variation of < 0.001 mV in the emf for a particular alloy composition.

Cell operation.—Compared with the tin solutions (5-7), the cadmium solutions required considerably more stirring before equilibrium was reached. Presumably this was because the solubility of cadmium in its iodide (8-11) is greater than that of tin in its chloride (12, 13) near the halide melting points. (There is considerable contradiction in the literature regarding these values, but there is agreement that the iodide dissolves less cadmium than do the other cadmium halides.) For the gold additions, after about 1½ hr the equilibrium was achieved, and further stirring or long standing did not alter the emf except as discussed above.

Solubility measurements.—Cursory solubility measurements were undertaken to convince ourselves that the cadmium solubility in CdI_2 was not greater than the largest reported solubility (11) among the measurements mentioned above. First, the cadmium which had dissolved into the electrolyte in run I was deter-

mined by breaking open the cell, washing away the electrolyte, and establishing the weight loss from the cadmium reference electrode. Second, weighed cadmium and CdI_2 sealed in an evacuated quartz capsule were heated at ~ 765°K for a day, then the temperature was dropped to 756°K and held for a week. A handle on the capsule allowed the capsule to be spun in the furnace to stir it; this was done occasionally. The capsule was finally taken from the furnace, laid on its side to cool, then broken open. The washed cadmium button was weighed and the weight loss was assumed to measure the cadmium solubility.

Measurements of n in $\Delta G = -nF\epsilon$.—At the end of run VI the voltage was followed for two days to be sure it was not drifting. Current was then supplied from a lead-acid battery (of the stable voltage type used to operate potentiometers) to the cell and to a 10.01 ohms calibrated resistance in series. Current was monitored by occasionally measuring the voltage drop across the resistance. After passing current for four days, the cell was allowed to return to equilibrium by stirring and standing for four days; the cell voltage did not change during the last 2½ days. The process was then repeated twice, but using smaller current passage. Cadmium transfer was determined from the known emf-composition relationships as established from the solute addition experiments. (Again these were considered to be cursory measurements since the cell design was not right for highest accuracy for these particular measurements.)

Results

The voltages corresponding to different gold additions are presented in Table I. The activities are calcu-

[a] Assumed solubility from Topol and Landis (8): 773°K, $N_{Cd} = 0.067$; 743°K, $N_{Cd} = 0.053$; 673°K, $N_{Cd} = 0.028$. These values lead to almost the maximum solubility correction. If these solubility values are superseded by other data, a new correction can be calculated by multiplying the value in parentheses by the ratio of the new value over Topol's value. The correction is subject to uncertainty of ~5% of the value listed for the correction even if Topol's value is exact. This is because the electrolyte will not saturate itself by taking exactly half of its cadmium from each cell leg.

[b] Although the absolute compositions are not known this well, the extra figures are justified as relative values and to show the magnitude of the solubility correction for Cd into CdI_2.

[c] Corrections have been added to the observed emf to give the listed reading. These corrections were measured when no solute had been added to either cell leg. Values: run I, +0.0060 mV; run II, −0.0006 mV; run III, −0.0010 mV, run IV, +0.0020 mV; run v, −0.0155 mV; run VI, −0.0286 mV.

[d] Calculated as $\log a = 10082.11 \times \epsilon/T$ (10082.11 times emf in volts divided by temperature in degrees Kelvin). It is here assumed that $n = 2$ for the electrons involved per cadmium atom transferred.

[e] After 26 hr wait to test for cadmium diffusion through cadmium iodide electrolyte.

[f] After 18 hr wait.

[g] After 23 hr wait.

[h] After 48 hr wait.

lated using $n = 2$ in $\Delta G = -n\mathbf{F}\epsilon$, corresponding to a reaction in which Cd II species carry the current. The cadmium mole fractions are based on either zero solubility of cadmium in CdI_2 or on Topol and Landis' (8) large reported solubility to show the effect of this solubility uncertainty. The mole fractions plotted on Fig. 2 to 4 include the solubility corrections.

The value of n is given in Table II. It should be emphasized that the cell resistance during current passage from an external source (70.3 ohms) was not the same as the internal resistance (48.7 ohms) as evaluated by comparing the open circuit voltage with the voltage during drain through a 52 ohms shorting resistance. This difference suggests that the same reaction is not involved in both cases.

The solubility measurement results were: $N_{Cd\ in\ CdI_2} = 0.0148$ at 673°K and 0.0269 at 756°K. (Since two different methods of determination were used, these data should not be used to calculate a temperature coefficient of solubility.)

Discussion

Problems in establishing absolute activities.—The purpose of the present work was to determine the activity of cadmium in cadmium-gold solutions from precise emf and other corollary measurements. The determination of activity from emf is surprisingly difficult, both with the present system and with other types of electrolytes. Harned and Owen (14) have emphasized that the electrochemical cell reactions must always be treated as hypothetical until the corollary thermodynamic properties are checked by other techniques. In addition for active metals such as cadmium, the electrolyte solvent often is not sufficiently stable chemically (*e.g.*, for most metals, water is thermodynamically unstable and can only be safely used if it can be shown that the kinetics of attack are slow enough to let equilibrium be approximated by the electrochemical mechanism).

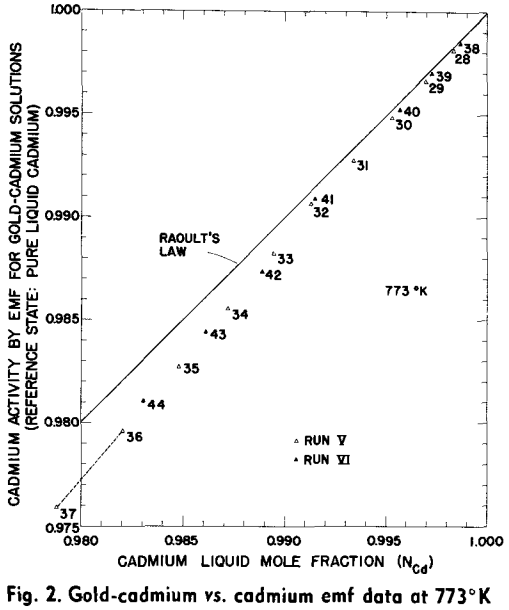

Fig. 2. Gold-cadmium *vs.* cadmium emf data at 773°K

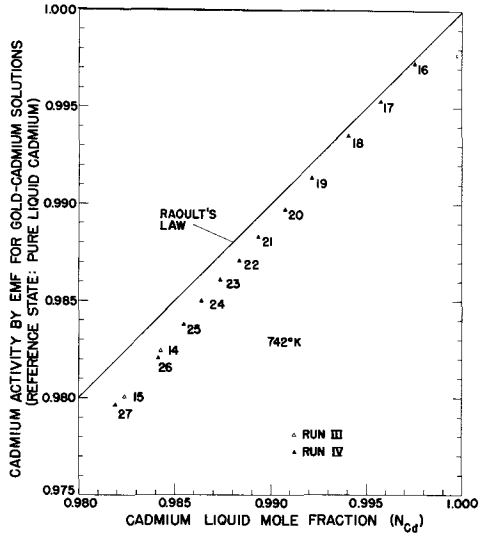

Fig. 3. Gold-cadmium *vs.* cadmium emf data at 742°K

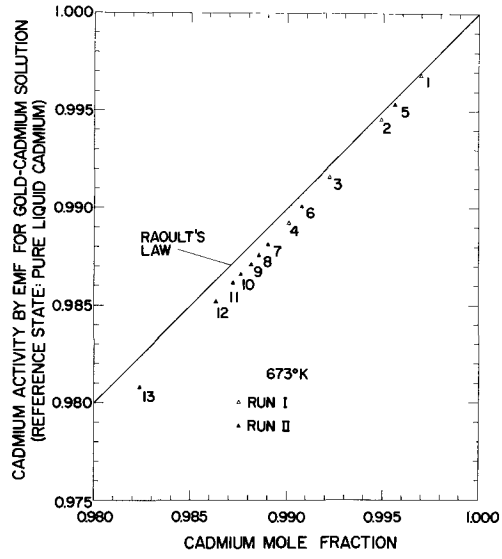

Fig. 4. Gold-cadmium *vs.* cadmium emf data at 673°K

With reference to molten salt electrolytes, one can often (*a*) fairly readily establish equilibrium concentrations, (*b*) effectively eliminate continuing side reactions, and (c) apparently achieve electrode reversibility. However, molten salts often dissolve significant quantities of metals, particularly their parent metals. The effects of the dissolved metals on the electrolyte activity and on n in $\Delta G = -n\mathbf{F}\epsilon$ are not easy to establish. If mixed molten electrolytes are used to reduce the metal solubility, the metal solubility problem is not eliminated, and the very difficult problem is created of achieving identical electrolyte compositions in both legs of the electrochemical cell.

In a corollary report [LA-4031, ref. (15)] there is given a rather extensive discussion of problems in evaluating the effects of these and other difficulties. Because the following discussion is less complete, we urge that the interested reader obtain this report either from us or from the Office of Technical Services, Washington, D. C. 20025.

The value of n.—Of all the uncertainties discussed in LA-4031, the most important for the present work is the effect of the cadmium dissolved in the electrolyte on the value of n in $\Delta G = -n\mathbf{F}\epsilon$. Table II in-

Table II. Electrons per atom from current-composition relationships following run VI

	Initial	After 1st current	After 2nd current	After 3rd current
Cadmium present:

amps		0.02635	0.02626	0.02649
hours		90.0	49.1	46.0
coulombs		8604	4643	4382
Apparent n for total change:		1.6 ± 0.1	1.5 ± 0.1	1.4 ± 0.1

[a] Topol and Landis (8) solubility assumed for Cd in CdI_2. Composition evaluated by interpolation from the data of run VI.
[b] Uncertainty evaluated from the scatter in the readings over two or three days. Ratio corresponds to cell open circuit voltage divided by the absolute temperature after composition changes.

dicates the results of an attempt to evaluate n directly from the cadmium transfer in the cell when current is passed through it.

The measured values for n range from about 1.6 to 1.4, *i.e.*, a third more ampere-seconds (coulombs) would have been required to move the material if n had equalled 2 as expected for pure CdI_2. Prior to interpreting these results, some aqueous results should be discussed.

An apparent efficiency of over 100% is not unusual in aqueous anodic corrosion measurements (16). Although in many cases the possibility of reaction with water has existed, this would seem to be absent in the copper(II) solutions studied by Royer *et al.* (17). Their value of n corresponds with over 100% efficiency, and this efficiency varied with temperature, current density, and concentration. Royer suggested that the primary reaction is the formation of copper(I) and that this species often gives up a second electron to form copper(II), thus leading to nonwhole-number values for n.

Regarding the present electrolyte, the conduction results may be interpreted as confirming the existence of a lower valence cadmium species which can carry current. The extra cadmium movement through the electrolyte far exceeds the proportion of cadmium dissolved in the electrolyte. The movement might result from kinetic processes under electrolysis which do not form the thermodynamically stable ratio of cadmium species, or it might be because the lower valence cadmium species simply have high mobility and high conductivity. These alternatives cannot be resolved from the present measurements. Certainly, however, the large apparent n value and the difference in the cell resistance under electrolysis or under drain both warn that the measured n is probably not applicable to the equilibrium situation. Therefore, in the absence of better information, we have assumed $n = 2$ for the activity calculations.

(It should be pointed out that approximate evaluations of n are made by checking emf results against other measurements such as phase diagrams. However, precise evaluations of n are seldom reported for molten salt equilibrium measurements.)

To pursue the implications if Cd_2^{++} forms when cadmium dissolves in CdI_2, as an approximation the value of n may be expected to drop about the same percentage as the percentage solubility of cadmium in the electrolyte. However, as discussed by Conant (18), the thermodynamically exact calculation is complex and requires an exact knowledge of the cadmium solubility, the species formed, and the species mobilities. This information is not available, and there are anomalies even when one tries to establish from published experiments whether the mobilities of Cd^{++} and the lower cadmium species are similar or are rather different.[3]

Reversibility and nonelectrochemical side reactions.—With these present emf measurements, after the solubility reactions are satisfied, the emf values are almost certainly close to equilibrium for the conditions reported. The long-term stability of emf is very good.

If there were a metallic conductivity character to the electrical conductivity of the CdI_2-Cd solutions, then this would lead to an internal drain of the cells and their emf would not be stable. Furthermore, runs III and IV used radically different shapes of H-cell cross arms which would change the resistance to internal drain and the measured emf values. Finally Aten's work (19) showed that the conductivity of $CdCl_2$ decreases smoothly as the amount of dissolved cadmium is increased: this is hardly in line with significant metallic conductivity in the salt.

As to the cell reversibility, the high precision of the data whether the equilibrium emf is approached from too high or too low a potentiometer emf, the smooth variations of emf with composition, and the stability of the cell all argue for reversibility. Actually an irreversible cell would tend to destroy part of the cell emf and would not cause deviations from Raoult's law in the direction shown on the plots to follow.

The zero voltage (bias) correction for unalloyed cadmium.—After the present measurements were carried out, Conant (18) studied the voltage bias when only cadmium was present in the legs of a stirred H-cell of this type. He established that the position of the cell in the furnace was the primary factor affecting the bias. If both legs touched the inner copper cylinder (see Experimental Technique), the bias was essentially zero (*i.e.*, ~0.0001 mV). If the H-cell was centered in the copper cylinder the bias rose as high as 0.05 mV.

The bias seems clearly to be a thermocell effect resulting from a slight difference in temperature between the two legs due to heat conduction up the H-cell tube legs and outside the furnace. However, the H-cell design essentially uncouples the two legs (or three legs, if that design is being used) as far as large heat transfer is concerned, and each leg achieves a very uniform temperature in the furnace. To avoid shifts in the bias due to slight movements of the cell during stirring, Conant concluded that the center position was to be preferred even if the starting bias was larger.

One may presume that the higher precision achieved by Conant as compared to the present work was primarily the result of his better H-cell positioning.

The temperature variations associated with these emf values have been discussed elsewhere (6, 7, 15, 18). To summarize: thermocell values of 0.3 to 0.8 mV per degree are customary. A bias of 0.0286 mV (this was the largest observed in the present group of measurements) would correspond with about 0.03° to 0.1°K temperature difference between the cell legs. However, the effects of stirring within a cell leg ($<$0.002 mV) indicate that temperature gradients within a leg and in the region of the metal-salt interface (where the reaction takes place) were not over 0.001°K.

Activity coefficient relationships.—Because activity coefficients are now so widely used to describe activity measurements, and because we normally prefer not to use them to present our data, this matter should be discussed.

Empirically excellent descriptions of the solvent activity derived from emf or vapor pressure measurements (5, 18, 20-24) have been developed using equations with the constant temperature forms

$$a_1 = c_1 - k_1 N_2 \quad [1]$$

or

$$a = c_1 - k_1 N_2 + b_1 N_2^2 \quad [2]$$

where c_1 is a reference activity applicable over a region of composition ($c_1 = 1$ in the case of very dilute solutions), k_1 adequately (Eq. [1]) or partially (Eq. [2]) describes the changes of solvent activity per mole fraction unit of solute added and b_1 describes the changes in solvent activity associated (perhaps) with solute-solute interactions. Again in the present case an empirically excellent description of the measurements at all three temperatures can be obtained by the use of two temperature dependent equations applying in different regions of composition: in the region 0.001 to 0.008 mole fraction of gold

$$a_{Cd} = 1 - 1.068\, N_{Au} - (T - 673)\,(0.00024) N_{Au} \quad [3]$$

and in the region 0.01 to 0.02 mole fraction of gold

$$a_{Cd} = 1.00020 + (T - 673)\,(0.00036) - 1.096\, N_{Au} - (T - 673)\,(0.00067) N_{Au} \quad [4]$$

[3] Conant cites an argument that the mobilities are similar. On the other hand Aten's work (19) which is discussed in the next section indicates a lower conductivity when cadmium dissolves in $CdCl_2$; this suggests a comparatively low mobility for Cd_2^{++}. One interpretation of the high transfer of cadmium discussed in the previous section would require a high mobility for the lower valence cadmium species.

The deviations are indicated in Table I, col. 9, with dashes to indicate the transition region points for which the relationships do not hold.

A mathematical analysis using a computer and fitting equations of the form

$$a_{Cd} = 1 - k_1 N_{Au} + b_1 N_{Au}^2 + d_1 N_{Au}^3 \quad [5]$$

by least squares rejects the Raoult's law based form, $k_1 = 1$, in favor of $k_1 \neq 1$. The mathematical analysis also favors the use of Eq. [3] and [4] at all temperatures instead of three independent equations, one for each temperature, of Eq. [5] form. This latter conclusion is less clear, however. This mathematical analysis is presented in LA-4031 (15).

A more customary presentation of the data would plot $(\log \gamma_{Cd})/N_{Au}^2$ *vs.* N_{Au} or N_{Cd}. This plot is closely related to Eq. [5] with $k_1 = 1$. Often in such a plot, one must try to extrapolate a curve to its supposedly finite interception with the axis at pure solvent. [For example, see the curvature in the mercury solvent region for the solutions in Fig. 10-22 of Darken and Gurry (25).] When a linear extrapolation is used, it is tacitly assumed that $(\log \gamma_1)/N_2^2 = \alpha + \beta N_2$ where α and β are constants in that region. If the assumption is valid, then it is a mathematical corollary that $(\log \gamma_1)/N_2 = \alpha N_2 + \beta N_2^2$, and $(\log \gamma_1)/N_2$ approaches zero at pure solvent.

A plot of this type is presented in Fig. 5 for the present data. As will be noted, there is little reason to be confident that these activity data as evaluated do approach a zero-zero intercept. Whether this deviation from apparent approach to Raoult's law would be removed by a more accurate calculation of the activity (*e.g.*, by using a more realistic value for n) is not clear. However, for the present, and consistent with our experience with the other precise vapor pressure and emf measurements (5, 20-24) we find an empirically better fit by assuming a nonzero intercept. This is equivalent to assuming that regular solution theory (as well as bN_2^2 deviations from Raoult's law) are not being followed by these activities, as calculated, within the region of measurement.

The plots in Fig. 5 magnify the absolute errors at low concentrations and are probably not as good as the mathematical analysis discussed three paragraphs back in choosing between the two-equation (Eq. [3] and [4]) or the three-equation (Eq. [5] with three sets of constants) fit to the data. The minimum deviation of the mean is achieved using the two-equation fit.

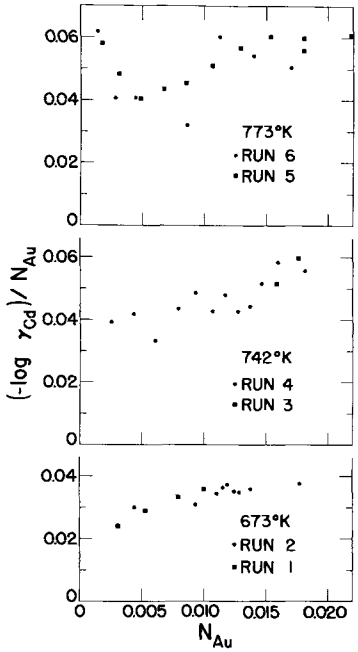

Fig. 5. Activity coefficient plots for these data. (Note that the abscissa is not of the usual form. See text.)

Conclusions

As evaluated by customary methods of calculation, the present emf data do not lead to activities in agreement with Raoult's law. We believe that these data are accurate, in the senses that the techniques used were proper and that anyone repeating these experiments would repeat these results.

Since we have not measured below 0.001 mole fraction of gold in cadmium, we cannot assert that we know what happens to the composition-activity measurements at lower concentrations. By making assumptions regarding the various species in solution and their mobilities, we could surmise values for the "effective" n for $\Delta G = -n\mathbf{F}\epsilon$ which would bring the cadmium activities for compositions below 0.008 mole fraction gold into good agreement with Raoult's law at the different temperatures. However, for both theoretical and experimental reasons, many of which have been discussed elsewhere (in order, 20, 26-28, 23, 29-31. 7, 32-34), we are not willing to accept the customary "thermodynamic" derivation of Raoult's law for dilute solutions.

Epilogue

One of our reviewers has proposed an equation to describe the 742°K data. The equation is equivalent (by our mathematical manipulations) to

$$\log a_{Cd} = \log N_{Cd} - 0.0001000 - 2.9\ (1 - N_{Cd})^2 \quad [6]$$

The equation is consistent with customary theory where our equation form is not generally accepted. Equation [6] can be reached by assuming 7 μV error in all 742°K measurements and then finding a curve to pass through the data and to the now different origin. Other postulated errors and other equation forms could also be proposed which would be appropriate for $n = 2$ and a Raoult's law-based equation.

Several questions are brought up. "Is a 7 μV error in all measurements a viable postulate?" Perhaps. Certainly any experimental data are subject to question. However, there were direct measurements of emf values between the cadmium samples in both legs of the cells before any gold was added. It was presumed that this should correct for any problems of this type such as thermocell effects. For the runs at 742°K these corrections were respectively -1.0 μV and $+2.0$ μV. That these direct measurements gave answers which actually were each in 7 μV error seems most unlikely to us.

"Can one properly assert that $n = 2$?" If n is not 2, then there is no theoretical basis to expect that activities calculated assuming $n = 2$ should approach Raoult's law. This n value question was not settled by our measurements, and we know of no experiments which have settled it for Cd-CdI_2 electrolytes or other electrolytes which dissolve their parent metal. Regarding this question there is another paper (35) which we found recently which gives an evaluation of n for mixed-valence working-electrolytes. There are important differences between that approach and the one used by Conant (18). The practical result of both approaches, and also of our own earlier approximation (15), is to reduce n from 2 to a value lower by the per cent solubility of cadmium in CdI_2. All the authors recognize that theirs is not a complete calculation when applied in this way, but a better approximation is not obviously available in the absence of more data no matter which method of calculation is used.

"Even if $n = 2$, can one really be sure that Raoult's law will be approached in this range of measurement?" The references in the Conclusions indicate why we question this.

Manuscript submitted Aug. 9, 1968; revised manuscript received May. 23, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

A Brief Review of the State of the Art and Some Recent Results on Electromigration in Integrated Circuit Aluminum Metallization

Stuart M. Spitzer and Seymour Schwartz*

National Aeronautics and Space Administration, Electronics Research Center, Cambridge, Massachusetts

ABSTRACT

This paper presents a report of the state of the art with respect to the electromigration phenomenon in integrated circuit (IC) metallization. Reported here are some of the latest research efforts, including the authors' research, on the effects of dielectric overcoatings on electromigration in aluminum interconnections. This research has shown that dielectric overcoating of the aluminum stripes yields interconnections with greater mean time between failures than found in many conventional integrated circuits.

Aluminum metallization is used almost exclusively in today's microelectronic circuitry. All industrial trends indicate that no other single-component metallization will replace aluminum, while the use of multicomponent metallization will be restricted to specialized applications for some time in the future (1).

In spite of the seemingly simple technology of a single-component metallization method, there are still many unanswered questions with regard to the characterization and utilization of aluminum in integrated circuits (IC's). For example, the interface involved in thermal-compression bonding (2) of gold wires to aluminum pads has produced intermetallic compounds leading to high resistivity and structural brittleness. The use of ultrasonic bonding (2) of aluminum to aluminum eliminates intermetallic compounds, but structural weakness results because lack of understanding of this process makes it difficult to establish controls in this system. Further problems arise with interactions at the Si-SiO_2-Al interface. When aluminum traverses oxide steps or oxide windows to contact the silicon, aluminum thickness varies, penetrating cracks and voids appear in the interconnection, and dissolution of silicon into aluminum occurs during thermal processing.

These problems become increasingly important in the light of the requirements for newer microelectronic devices. In large scale integrated circuits, multilevel integrated circuitry, and high speed switching devices, all dimensions must be reduced to accommodate the increased number of components, and to reduce inter-

* Electrochemical Society Active Member.

electrode interaction (capacitance, leakage, etc.). This reduction in dimensions causes increased current density at the original power level. For this reason, major emphasis has been concentrated on this new failure mode, the high current density problem.

The loss of aluminum from IC conductors at high current densities, once thought to be a result of evaporation due to internal heating, or of chemical reaction with other integrated circuit materials, is now known to be caused primarily by electromigration (3). Electromigration in the migration of atoms by momentum transferred from impinging electrons under d-c bias.[1] A result of this phenomenon is void formation near the electron source (cathode) and solute accumulation near the electron sink (anode). If, after the application of a d-c bias for sufficient time and temperature to produce electromigration and voids, the d-c bias potential is reversed, aluminum conductors will sometimes heal, and new voids will be formed at the other electrode. Blech and Sello (4) have qualitatively shown the dynamics of electromigration in a time lapse film.

It is important to note that in certain cases the problem of electromigration can be eliminated by proper device design and processing. In such instances, aluminum thickness is designed to maintain current densities below a predetermined threshold value. There are many times, however, where the need for small dimensions will not allow thicker conductors. For these cases research on the problem of electromigration in aluminum interconnections is needed and ways must be found to extend the operating limits of aluminum. The degrading effects of electromigration on integrated circuit interconnections are further aggravated by any metallization defects and these become increasingly significant as film thickness decreases.

Electromigration is a self-diffusion effect, and has an associated activation energy. Although the activation energy for bulk self-diffusion in aluminum is 1.48 eV, experimentally measured energies for electromigration in integrated circuit films range approximately from 0.5 to 1.2 eV. The lower observed energy may be or has been ascribed by investigators to structural imperfections in and on the surface of the aluminum film. It is to this problem that the following investigations have been addressed.

Review

Experimental relations predicting mean time between failure of aluminum interconnections with respect to electromigration have been determined. Black (5) has found

$$MTBF = \exp(\phi/kT) AJ^2 \qquad [1]$$

where $MTBF$ = mean time to failure in hours, ϕ = an effective activation energy of the film, k = Boltzmann constant, T = absolute temperature, A = constant for a given film and inversely proportional to the cross sectional area, and J = current density in A/cm^2.

Chhabra *et al.* (6) found $MTBF$ proportional to $1/J^3$ for constant temperature (between 100°-200°C) and for J 10^6 A/cm^2.

The importance of obtaining films of higher quality, *i.e.*, higher activation energy, can be seen by considering [1]. At a fixed current density, the ratio of the equations appropriate for two different films yields

$$\frac{MTBF_1}{MTBF_2} = \frac{A_2}{A_1} \exp(\phi - \phi_2)/kT \qquad [2]$$

At room temperature kT = 0.025 eV, and if $\phi_1 - \phi_2$ = 0.1 eV, then the exponential term gives a factor of 55.

We can further see, that at an elevated temperature, say 125°C, kT = 0.033 eV, and for the same increase in ϕ, the exponential of [2] gives a factor of only 20. Thus, at higher temperatures, increases in the activation energy ϕ, become less significant in increasing $MTBF$.

There are three basic factors contributing to the activation energy for the electromigration failure of the aluminum metallization; surface, grain boundary, and bulk diffusion components. It is clear that deposition and post-deposition heat treatment techniques can affect only the latter two components. Inasmuch as the activation energies for bulk diffusion, grain boundary diffusion, and surface diffusion decrease in that order, it would be expected that the relative advantage of well ordered metallization covered by a dielectric would be higher at low temperatures, and that at high temperatures the advantage of the higher effective activation energy would be relatively small in light of the exponential dependence on the activation energy.

Evaporation experimentation (5) has shown that for films less than 5000Å thick, deposition on a hot substrate is necessary to obtain large crystallite size. In this case, substrates heated to 200°C yield measured energies around 0.50 eV. For films thicker than 5000Å or for those deposited at high rates, the substrate heating becomes unimportant. Apparently these thicker films lose "memory" of the lower layers and grow with high crystalline order, attaining measured energies of 1.20 eV.

The two most common aluminum deposition techniques are filament evaporation and electron beam bombardment. Filament evaporation is more often used because of simplicity, however the electron beam method gives a higher degree of aluminum purity. High quality (1.20 eV), low resistivity aluminum films may be produced by evaporating from high purity tungsten or tantalum filaments at pressures in the 10^{-8} Torr range. The improvement obtained at high vacuum may be due to less oxide at grain boundaries, with less tendency for lattice vacancies to agglomerate, causing voids.

The surface is a discontinuity or defect in crystalline order, and diffusion along the surface will have a lower activation energy than in the bulk. The relative importance of the surface may be evaluated by finding the ratio of surface atoms to bulk atoms. For long thin conductors, this ratio is inversely proportional to thickness, t.

It should be noted here that aluminum atoms at the Al-SiO_2 interface are not equivalent to atoms at the exposed Al surfaces. Furthermore, the true surface to bulk ratio is one or more orders of magnitude greater than this apparent ratio due to surface irregularities or film porosity. The intent of this discussion is only to point out the $1/t$ dependence of the surface to bulk ratio. For films wherein bulk and grain boundary components of the activation energy have been maximized through good deposition and heat treatment techniques, the thickness of the film will determine the influence of the surface component.

By coating the surface of the test circuit with a dielectric, broken electron bond at the aluminum surface may be presumed to be filled, electromigration at the surface will be reduced (5, 7), and a higher activation energy should be realized. In light of the above discussion, such a surface treatment would be expected to have the greatest effects on thinner films.

Recent Results

At the Seventh Annual Reliability Physics Symposium, Washington D.C., December 1968, a complete session was devoted to electromigration (selected papers published in "Transactions on Electron Devices," April 1969). Summarized here are some of the results from I.B.M. (8, 9), Motorola (3), and NASA/ERC (10). It is important to note that many of the reported findings have resulted from examination by scanning electron microscopy [the uses of which were also reported at this symposium (11)].

Attardo *et al.* (8) have reported that the activation energy associated with electromigration corresponds

[1] Electromigration is observed under a-c stress, but much more slowly, because the oscillating electron motion tends to cancel any migration effects.

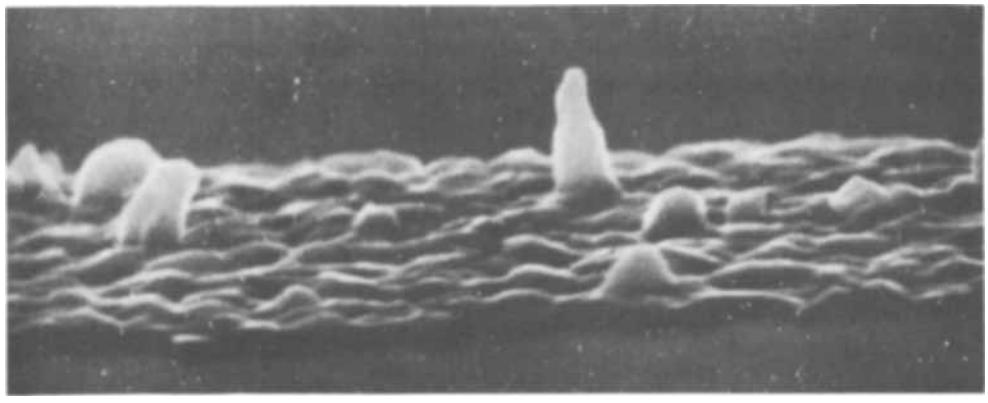

Fig. 1. Scanning electron micrograph of electromigration of aluminum perpendicular to the interconnection. (2145X and 80° from normal).

to the activation energy of grain boundary diffusion. An empirical relationship between *MTBF* and the critical parameters of electromigration in the same form as [1] has been found, but with a different interpretation of the effective activation energy. The activation energy is assumed independent of grain size (as long as grain size is smaller than the stripe width), whereas in Black's (3, 5) formulation the activation energy is a function of grain size. Thus the pre-exponential factors of Eq. [1] necessarily take on different values in Attardo's formulation. A further difference in measurements by Black and Attardo can be seen in the effects of stripe width. Where Black had determined *MTBF* to be directly proportional to cross section area, Attardo reports a greater than linear dependence on conductor width. These results have been interpreted as the grain boundary acting as a diffusion barrier in the narrow stripes and causing a divergence in the vacancy flux at that point. In the wider stripes this effect does not occur because grain size is less than stripe width.

Berenbaum and Rosenberg (9), and Black (3), have given some interesting examples of aluminum whisker growth perpendicular to the conductor stripe. The I.B.M. group reported on aluminum stripes deposited on thermally oxidized silicon, while Black at Motorola also examined the case where the aluminum was was coated with SiO_2.

Figure 1 (from Berenbaum and Rosenberg) illustrates a scanning electron micrograph of whisker growth at 2145X. In coated conductors, the whisker growth cracked the silicon dioxide in a "trap-door" type of effect. Both authors present extensive scanning electron micrographs in their papers, which give a good pictorial understanding of electromigration phenomena.

Research at NASA/ERC

Spitzer and Schwartz (10) of NASA/ERC, have made studies of electromigration in aluminum conductors passivated with dielectric overcoating. These studies suggest that improved *MTBF* is observed in dielectric coated conductors; a brief summary of this work follows.

In order to make comparisons between coated and uncoated conductors, test circuits were prepared using filament and electron beam aluminum evaporation. The aluminum thicknesses used were 1500 through 6000Å. The thinner stripes were used in accelerated tests to observe whether any trends would develop, and to emphasize the effects of the aluminum surface in the high surface to volume atom ratio. The thicker stripes were used to simulate more closely actual integrated circuit geometries.

The dielectric overcoat materials utilized were those found to be compatible in both integrated circuit and multilevel large scale integration (LSI) fabrication. These dielectrics are an amorphous mixture of SiO_2 and Al_2O_3, and an amorphous mixture of SiO_2 and P_2O_5.[2] To apply these coatings we used a relatively simple, chemically clean process wherein the dielectric is condensed from gases reacting on a heated silicon wafer. For example, wafers to be coated with SiO_2-P_2O_5 are heated on a hot plate to 375°C, then a mixture of oxygen, nitrogen, silane, and phosphine is introduced for approximately ½ min. The entire cycle takes 10 min. Control wafers, not to be coated, are placed on a hot plate and heated to the same temperature, in a dry nitrogen atmosphere, for the same time. By this means, the metallizations will be compatible for both coated and control wafers.

Tests were run to determine the mean time between failure of the aluminum interconnects as a function of current and temperature. We had special interest in the temperature range of 25°-200°C, and current density range of 10^5 to 2 x 10^6 A/cm^2, because this represents the area of maximum practical application. In order to learn the effect of dielectric overcoating (10), the *MTBF* was measured for coated and uncoated aluminum strips, which had undergone exactly the same thermal processing. The effective activation energy of the strips was found from [1], using the *MTBF*. In Fig. 2, we show the effect of dielectric overcoating (Al_2O_3-SiO_2). Significant improvements in the activation energy were observed for aluminum films less than 5000Å thick. Thus, the greatest contribution of surface passivation was made in cases where the surface to bulk atom ratio is appreciable.

Figure 3 shows the *MTBF* plotted against film thickness, with temperature as an independent parameter. Here we see that the effect of dielectric overcoating (or any treatment which helps to increase the effective activation energy) is minimized at elevated temperature.

In order to understand modes of failure and verify effects of electromigration, metallurgical analyses were made on most test devices.

Figure 4 shows a time sequence of electromigration failure. Figure 4A shows the unstressed device, while Fig. 4B and 4C show the development of voids. Figure 4D shows the final open circuit failure.

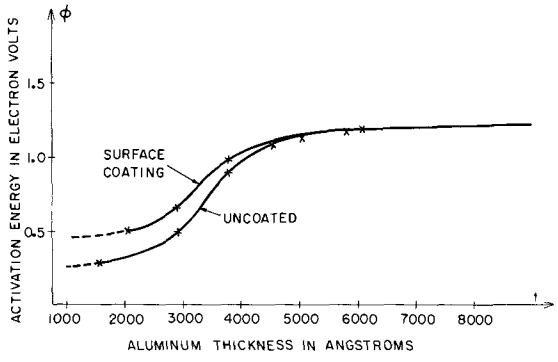

Fig. 2. Self diffusion activation energy as a function of aluminum thickness and surface passivation.

[2] It is interesting to note that glass passivation techniques have been used to protect the entire semiconductor chip. The intent in this earlier industrial application was to hermetically seal the silicon surface. Glass passivation has further application in multilevel isolation and metal protection.

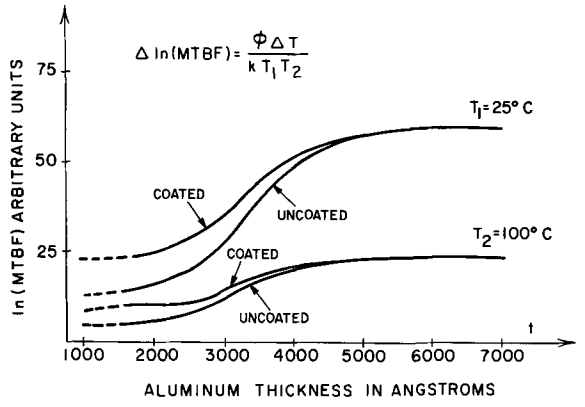

Fig. 3. Dependence of *MTBF* on temperature and surface passivation.

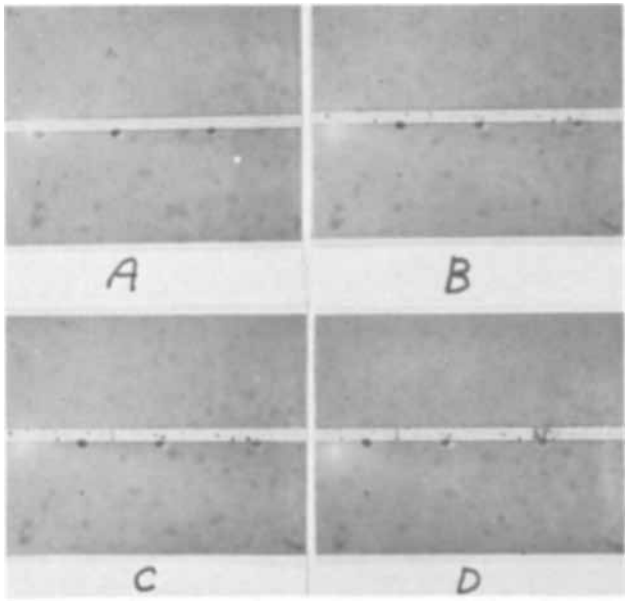

Fig. 4. Time sequence progression of electromigration. A. Unstressed 5000Å aluminum conductor. B. Same as A after 350 mA for 10 min and 500 mA for 5 min. Note development of spotted areas. C. Same device after 5 min more at 500 mA. The spots, electromigration areas, have grown. D. Same device which after 1 min more at 500 mA has open circuited.

It is important to point out that in many analyses of failed circuits electromigration is not easily identifiable as the failure mode (Fig. 5). When a conducting strip opens up due to electromigration, arcing masked the failure mode. Figure 6 is an electron microprobe x-y scan showing aluminum K-alpha counts of the device after electrical stress. We can clearly see the depletion of aluminum at the right (negative) side and the build up of aluminum just to the left of the void. Figure 7 shows the microprobe line scan used for thickness determination of the same device.

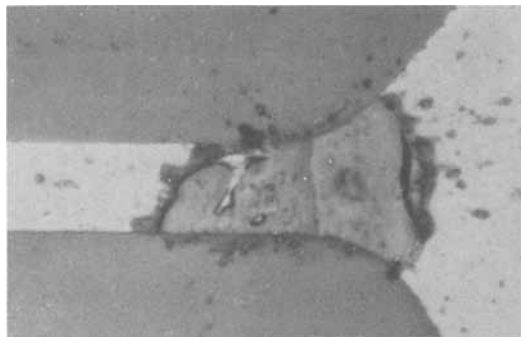

Fig. 5. Electromigration failure, 5000Å aluminum test strip (Al_2O_3-SiO_2 overcoat).

Figure 8, using the scanning electron microscope, shows by detection of secondary electrons, details of an area thinned by electromigration (2000X). The strip had not as yet failed, and is undamaged from electrical arcing.

Discussion

The ultimate goal of this electromigration study is to provide guidelines for reliable device design. The following areas of investigation are suggested for intensive activity.

First, confidence in the predicted *MTBF* is vague. Researchers (5, 6) have determined empirical relations, but variables such as crystallite size and aluminum impurities are not yet quantitatively included in these relations.

Next, the notion that electromigration can always be designed out of the circuit should be dispelled. Not only is this untrue in many cases, particularly in LSI, multilevel integrated circuitry, and high-speed switching circuits, but there is also the problem of processing errors which may increase current densities an order of magnitude above the designed circuit value.

Third, there is a need for better integrated circuit simulation in electromigration test devices. Most work has been done with aluminum on top of silicon dioxide, except at windows. In many cases aluminum is alloyed in, and the effects of this "dilute" metallization must be characterized.

Finally, electromigration life testing is generally carried out at currents exceeding normal maxima. For this reason, many circuits which fail due to electromigration under these accelerated conditions, would not do so under normal use. Tests should be devised which would provide an awareness of other possible failure mechanisms.

Bi-ionic Potentials with Sulfonic and Phosphonic Acid Cation-Exchange Membranes

D. K. Hale[1] and K. P. Govindan[2]

Ministry of Technology, National Physical Laboratory, Teddington, Middlesex, England

ABSTRACT

The use of bi-ionic potential measurements for the study of the selective behavior of synthetic sulfonic and phosphonic acid membranes toward sodium and potassium ions is described, and the effects of membrane thickness and solution flow rate on the results are discussed. A procedure for obtaining the thickness of the diffusion layer in the solution at the membrane surface from experiments on the interdiffusion of sodium and hydrogen ions is described. The bi-ionic potentials obtained with the Na^+-K^+ system and the sulfonic and phosphonic acid membranes (over the *p*H range 2.0-13.0) are correlated with the relative mobilities of the ions in the membranes and their selectivity coefficients and the significance of the results discussed.

If an ion-exchange membrane separates two electrolyte solutions which differ in concentration or composition, then, in general, an electrical potential difference will exist between the two solutions. This potential difference is termed the membrane potential. If the two solutions contain the same electrolyte at different concentrations, the membrane potential is known as a concentration potential. With an ideal ion-exchange membrane which is impermeable to co-ions and through which water transport is zero, an equilibrium will be set up in which there is a continuous interdiffusion of counter ions between the two solutions but no change in their concentrations. The membrane potential will be given by the Nernst equation

$$E_m = -\frac{RT}{z\mathbf{F}} \ln \frac{a''}{a'} \qquad [1]$$

where a' and a'' are the activities of the counter ion in the two solutions and z is its electrochemical valency (negative for anions).

When the membrane separates a solution of the electrolyte, AY, from one of the electrolyte, BY, at the same equivalent concentration, where A and B are membrane counter ions, then a rapid interdiffusion of counter ions will take place between the two solutions and, at equilibrium, the two solutions will have the same composition. If, however, the solutions of AY and BY flow continuously past the membrane surface or if the solution volumes are sufficiently large, then a stationary or quasi-stationary state can be set up in which the composition of the two solutions does not change appreciably with time and the effect of cross contamination is negligible. Under these conditions, with negligible co-ion transport and with the electrolytes AY and BY at the same equivalent concentration, the membrane potential is known as the bi-ionic potential (BIP). This term was introduced by Sollner (1, 2) who proposed the equation

$$E_{BIP} = \pm \frac{RT}{\mathbf{F}} \ln \frac{t_A^{\pm}}{t_B^{\pm}} \qquad [2]$$

in which $t_A^{\pm}$ and $t_B^{\pm}$ represent the transference numbers of the counter ions (either cations or anions) in the membrane.

If, for the case of a pair of uni-univalent electrolytes, the ratio of the transference numbers is replaced by the ratio of the products of the mobilities and concentrations, then the above equation may be written in the form

$$E_{BIP} = \pm \frac{RT}{\mathbf{F}} \ln \frac{\bar{u}_A}{\bar{u}_B} \frac{\bar{C}_A}{\bar{C}_B} \qquad [3]$$

where $\bar{u}_A$ and $\bar{u}_B$ are the mobilities of the ions in the membrane and $\bar{C}_A$ and $\bar{C}_B$ are the corresponding molar concentrations. The molar selectivity coefficient (K'^A_B) is given by

$$K'^A_B = \frac{\bar{C}_A}{\bar{C}_B} \frac{C_B}{C_A}$$

where C_A and C_B are the ion concentrations in solution so that when $C_A = C_B$

$$E_{BIP} = \pm \frac{RT}{\mathbf{F}} \ln \frac{\bar{u}_A}{\bar{u}_B} K'^A_B \qquad [4]$$

In this derivation of an equation for the BIP, the existence of concentration gradients in the membrane and Donnan potentials at the interfaces is, in effect, disregarded and it is implicitly assumed that the ion with the higher affinity is present to the greater extent in the membrane. Wyllie (3), extending an earlier treatment by Marshall (4), derived equations for the membrane potentials in bi-ionic and multi-ionic systems by using the Henderson equation to obtain the diffusion potential in the membrane, adding the Donnan potentials at the interfaces and making allowance for the effect of the preferential absorption which was assumed to take place in the membrane.

In his general treatment, using the Nernst-Planck flux equations, of transport processes in membranes, Teorell (5) discussed the bi-ionic potential as a special case. For simplicity, it was assumed that the distribution ratio was the same for all univalent ions at the solution-membrane interfaces. Teorell stated, however, that there was nothing to prevent the choice of other theoretical or empirical relations between the concentrations at the interfaces. Using this approach, Helfferich and Ocker (6) obtained an expression for the membrane potential in bi-ionic systems which, if the mobility ratio, the selectivity coefficient, and the total counter ion concentration in the membrane are constant, can be integrated (7) to give the equation

$$E_m = \frac{RT}{\mathbf{F}} \left[\frac{\bar{u}_B - \bar{u}_A}{\bar{u}_A z_A - \bar{u}_B z_B} \ln \frac{\bar{u}_B z_B}{\bar{u}_A z_A} + \frac{1}{z_A z_B} \ln K'_a{}^A_B + \frac{z_A - z_B}{z_A z_B} \ln \frac{\bar{C}}{C'} + \frac{1}{z_B} \ln \frac{C'}{C''} + \ln \frac{f'_A{}^{1/z_A}}{f''_B{}^{1/z_B}} \right] \qquad [5]$$

[1] Present address: Division of Inorganic and Metallic Structure, National Physical Laboratory, Teddington, Middlesex, England.
[2] Present address: Central Salt and Marine Chemicals Research Institute, Bhavnagar-2, India.

where $K'_{a}{}^{A}{}_{B}$ is the molar selectivity coefficient corrected for activity coefficients in solution, f'_A and f''_B are the molar activity coefficients for the ions A and B in the two solutions, C' and C'' are the total solution concentrations, and $\overline{C}$ is the total counter ion concentration in the membrane. For two univalent cations, this equation reduces to

$$E_m = \frac{RT}{\mathbf{F}} \ln \frac{\overline{u}_A}{\overline{u}_B} \frac{a'_A}{a''_B} \frac{\overline{f}_B}{\overline{f}_A} \quad [6]$$

$$= \frac{RT}{\mathbf{F}} \ln \frac{\overline{u}_A}{\overline{u}_B} \frac{a'_A}{a''_B} K'_{a}{}^{A}{}_{B} \quad [7]$$

It follows from Eq. [7] that the membrane potential in bi-ionic systems with univalent ions is given approximately by

$$E_m = \frac{RT}{\mathbf{F}} \ln \frac{\overline{u}_A}{\overline{u}_B} \frac{C'_A}{C''_B} K'^{A}{}_{B} \quad [8]$$

where C'_A and C''_B are the molar concentrations of the ions in the two solutions and $K'^{A}{}_{B}$ is the molar selectivity coefficient (assumed to be constant).

It is important to note that, in this derivation of the membrane potential equation, a selectivity factor is introduced as a consequence of the inclusion of the Donnan potentials. The selectivity has no effect on the concentration profiles; in fact, the slower ion tends to accumulate in the membrane (8). A more detailed treatment of systems with concentrated solutions, in which the effects of simultaneous co-ion and water transport are considered, has been given by Mackay and Meares (9).

In systems of the type under consideration, the rate of ionic interdiffusion between the two solutions will depend not only on the rate of diffusion of ions within the membrane but also on the rate of diffusion of ions up to and away from the membrane surfaces. However vigorously the solutions are agitated, it is often impossible, especially with dilute solutions, to maintain the solution composition uniform right up to the membrane surface, and concentration gradients develop in a layer of solution adjacent to the membrane. The theoretical treatment of the diffusion processes in the solutions can be greatly simplified by making use of the Nernst concept of a hypothetical "diffusion layer," the thickness of which depends on the degree of agitation in the solution. In effect, the bulk solution is assumed to be of uniform composition and to be separated from the membrane surface by a layer of completely unstirred solution. This approximation has been used successfully both in the theoretical treatment of the kinetics of ion exchange with particulate resins (10-12) and of transport processes in membranes (13, 14).

Two limiting conditions may be distinguished: (*a*) complete *membrane diffusion control*, in which case the composition of the solution is the same at the membrane surface as in the bulk solution, and (*b*) complete *film diffusion control* when there are no concentration gradients within the membrane.

In the interdiffusion of counter ions, the system is often subject to partial or almost complete film diffusion control especially when the solutions are dilute and the ionic mobilities and concentrations in the membrane are high. The equations previously given for the membrane potentials are applicable only to systems subject to membrane control. In other cases, corrections for the effect of unstirred diffusion layers have to be applied. In this paper, the term "bi-ionic potential" is taken to be the potential obtained with complete membrane control.

The effect of unstirred diffusion layers on the measurement of bi-ionic potentials has been discussed by Helfferich (7, 8) who used the Nernst-Planck equations for the calculation of the concentrations at the membrane-solution interfaces. Equations for the potentials in bi-ionic cells with unstirred diffusion layers have also been derived by Mackay and Meares (15). In their treatment, the effect of bulk flow, and of variations in the ionic mobilities and activity coefficients with membrane composition, were also considered. Good agreement was obtained in most cases between the experimental and calculated potential differences. For many purposes, however, where a high order of accuracy is not required, it would appear that the relatively simple relationships based on the Nernst-Planck treatment with films (but without solvent transfer and variations of mobilities and selectivity coefficient) are usually adequate. In previous work by Helfferich and Ocker (6), reasonably good agreement was obtained between experimental values for the membrane potential and theoretical values calculated using Eq. [5] not only with Na^+/K^+ and Na^+/H^+ systems but also with the Na^+/Sr^{++} system.

Since, for a given membrane and a given pair of counter ions of equal valency, the BIP is practically independent of concentrations and the nature of the co-ion (provided the activity ratio of the two counter ions is kept constant), it can be regarded as a measure of the ability of the membrane to discriminate in its permeability behavior between two counter ions, A and B. It should be noted, however, that if the counter ions are not of equal valency then it follows from Eq. [5] that the BIP will vary approximately linearly with the logarithm of the solution concentration (7). The relative mobilities of the two ions in the membrane can be calculated from the BIP if the ratio of the activity coefficients is known, or the latter may be calculated knowing the relative mobilities (16).

In the present work, the conditions for membrane control have been established and bi-ionic potentials have been measured for the sodium-potassium ion system with both sulfonic and phosphonic acid membranes. These have then been correlated with the relative affinity coefficients and mobility ratios. With the phosphonic acid membrane, the effect of *p*H on the BIP has been investigated and, with both membranes, the effect of film diffusion on the membrane potentials has been examined. The BIP of the phosphonic acid membrane is of special interest since, like the phosphonic acid ion-exchange resins (17-19), the membrane would be expected under neutral and alkaline conditions to have a higher affinity for sodium than potassium.

Previous work on the effect of membrane structure on bi-ionic potentials has been discussed by Malherbe and Mandersloot (20). It appears that little work has been published on the effect of the nature of the functional group on the BIP. Sollner and his co-workers (21) found significant differences in the behavior of different anion-permselective membranes toward, for example, chloride and acetate ions and in the behavior of polystyrene sulfonic acid and polyacrylic acid collodion matrix membranes toward potassium and lithium ions. Gregor and co-workers (22, 23) also found higher absolute values for the BIP with the Li^+/K^+ system and a carboxylic acid membrane than with a sulfonic acid membrane. Bergsma and Staverman (24) measured the BIP for four different pairs of ions and five different cation-exchange membranes, including a cellophane-type membrane with phosphonic acid groups. Rather surprisingly, they found that all the membranes behaved in more or less the same way toward Na^+ and K^+ ions and that there was no significant difference between the phosphonic and sulfonic acid membranes. They concluded that bi-ionic potentials had not been sufficiently investigated, either theoretically or experimentally, and that various phenomena could not be satisfactorily explained.

It appears that further work on the effect of the nature of the membrane on the BIP is desirable. The consequences of ion-exchange selectivity on transport processes in membranes are clearly of great biological interest and, in addition, may be of considerable importance in the utilization of membranes in separation processes.

Experimental

Preparation of sulfonic acid membranes.—The method used was essentially the same as that described by Hazenberg and Knoll (25). A weighed sheet of polyethylene film (10 cm × 10 cm) of thickness $\simeq 13 \times 10^{-3}$ cm was immersed for 5 min in a mixture of 90 parts of styrene and 10 parts of 50% divinylbenzene solution with 0.5 parts of benzoyl peroxide as catalyst, at 65°C. The impregnated film was blotted between filter papers and then heated in a bath of saturated sodium chloride solution at 65°C for 24 hr to effect the polymerization of the monomers. The film containing the cross-linked polystyrene was then washed with deionized water, wiped with filter paper, and dried in a vacuum desiccator over phosphorus pentoxide for 3 hr. From the weights of the film before and after impregnation, the percentage of the copolymer in the film was calculated. For the sulfonation, a glass tube containing the impregnated film and a mixture of 200 ml of 98% sulfuric acid with 50 ml of nitrobenzene was heated over a steam bath for 2 hr. The sulfonated film was washed with carbon tetrachloride and then with distilled water. After conditioning the membrane to the appropriate form, the characteristics were determined and are given in Table I.

Preparation of phosphonic acid membranes.—A cross-linked polystyrene matrix was incorporated in a polyethylene film (thickness: 25×10^{-3} cm) by the procedure described above. Phosphonic acid groups were introduced by a procedure similar to that described by Kressman and Tye (26) for the preparation of phosphonic acid resins. The film (10 cm × 10 cm) was refluxed with a mixture of ethylene dichloride (150 ml), phosphorous trichloride (65 ml), and anhydrous aluminum chloride (32.5g) in a glass tube over a steam bath for 6 hr. The film was removed, washed with ethylene dichloride, and then heated with a 10% solution of sodium hydroxide on a steam bath for 3 hr. The membrane characteristics are given in Table I. There was some variation in the total exchange capacity between different samples and the average value (2.5 mg equiv./g) was slightly less than that calculated from the phosphorus content (2.8 mg equiv./g).

Titration curve of phosphonic acid membrane.—Membrane strips were converted into the hydrogen form and, after washing with distilled water, their wet weights were determined. These strips were allowed to attain equilibrium with suitable mixtures of 0.1*N* solutions of hydrochloric acid, sodium chloride, and sodium hydroxide to cover the *p*H range from 1 to 13. After equilibration (about 1 week), the strips were removed from the solutions and rinsed quickly with distilled water after blotting them between filter paper. The strips were then leached with 5% hydrochloric acid and the sodium eluted was determined using a Unicam flame spectrophotometer. The equilibrium *p*H of the solutions was measured and the quantity of Na^+ ion exchanged, expressed as mg equiv./g dry membrane (H^+ form), was plotted against *p*H (Fig. 1).

Table I. Characteristics of sulfonic and phosphonic acid membranes

	Sulfonic acid membrane	Phosphonic acid membrane
Thickness (cm)	16×10^{-3}	28×10^{-3}
Total exchange capacity (mg equiv./g dry H^+ form membrane)	2.24	2.5

Determination of relative affinity coefficient (sulfonic and phosphonic acid membranes).—The relative affinity coefficients were determined by equilibrating the membranes with a solution consisting of a mixture of equal volumes of decinormal sodium chloride and potassium chloride, sodium hydroxide and potassium hydroxide, or sodium chloride and hydrochloric acid solutions. For the determination of K^{K}_{Na}, the sodium and potassium contents of the equilibrated membrane were obtained by elution with hydrochloric acid and analysis with the flame spectrophotometer. The values obtained for the two membranes are included in Table I. The relative affinity coefficient is given as the ratio of potassium to sodium or sodium to hydrogen in the membrane when the concentrations of the two ions in the external solution are equal.

Measurement of membrane resistance (sulfonic and phosphonic acid membranes).—The membrane was conditioned with a suitable electrolyte solution and mounted in a "Perspex" conductivity cell similar to that described by Lorimer, Boterenbrood, and Hermans (27). The solution flowed through the cell in such a way that the two faces of the membrane, each 1 cm in diameter, were flushed with a slow stream of the electrolyte solution at 25°C. The resistance was measured by means of a Wayne Kerr Universal Bridge B221. A low-impedance adaptor unit was employed when the resistance measured was below 10 ohms. The resistance of the cell without the membrane was also measured in the same way and, from the difference between the two values, the membrane resistance was obtained.

Cell for measurement of fluxes and potentials.—The cell consisted of two symmetrical halves provided with suitable inlets and outlets (Fig. 2a). The membrane was clamped between the two halves in such a way that the inflowing solutions, after passing through distributors, impinged directly on the membrane surfaces. The outflowing solutions passed through electrode cells fitted with thermometers (Fig. 3). The outflow from the electrode cells passed into two receivers from which the solutions were pumped into two upper reservoirs. From the upper reservoirs,

the solutions (2 liters) flowed down through two condensers and through the flowmeters into the cell. By circulating water at a controlled temperature through the condenser jackets, the temperature of the solutions was maintained at 25°C. For the investigation of the effect of membrane thickness, narrow membrane strips were mounted in "Perspex" clamps so that only the outer edges of the strips were exposed to the solution. In this way, the effective membrane thickness was determined by the thickness of the membrane clamp. These clamps consisted of two parallel-faced "Perspex" sheets which were held in position on either side of the membrane strip by metal clips (Fig. 2b).

Flux measurements.—Flux measurements were carried out using the sulfonic acid membrane with the system, sodium chloride-hydrochloric acid. Equinormal solutions (2 liters of sodium chloride and 2 liters of hydrochloric acid solution) were circulated at 1500 ml/min past the membrane surfaces at 25°C. The hydrogen ion which had diffused through the membrane was determined by titrating a small aliquot of the sodium chloride solution at known intervals. From the membrane area and the quantity of H^+ ion which had diffused through the membrane in a given time, the flux values (g equiv. cm^{-2} sec^{-1}) were calculated (Table II).

Table II. Effect of concentration of bulk solution on interdiffusion of Na^+ and H^+ ions, and solution concentrations at the membrane surface

Concentration of bulk solution	Flux (g ion cm^{-2} sec^{-1})	C^b	C^o	δ (cm)
1.00*N*	3.10×10^{-7}	0.98*N*	1.02*N*	1.8×10^{-3}
0.10*N*	2.15×10^{-7}	0.084*N*	0.116*N*	2.3×10^{-3}
0.01*N*	0.645×10^{-7}	0.0063*N*	0.0137*N*	1.8×10^{-3}

Potential measurements.—Potential measurements were carried out using a Pye Cambridge Universal Precision potentiometer with a high-impedance amplifier unit between the cell and the potentiometer. Silver-silver chloride electrodes were used except in the experiments with alkaline solutions where calomel electrodes with saturated potassium chloride bridges were employed. Concentration potential measurements with sulfonic and phosphonic acid membrane strips were carried out using sodium chloride solutions. All potential measurements were made with the solutions at a temperature of 25.0°C.

Effect of flow rate on membrane potentials.—Membrane potentials were determined with the sulfonic acid membrane ($\simeq 16 \times 10^{-3}$ cm and 132×10^{-3} cm thickness) and decinormal solutions of sodium chloride and potassium chloride (2 liters each) using flow rates ranging from 200 to 1500 ml/min.

Measurement of BIP.—Potentials were measured using flow rates of 1500 cc/min with a fixed concentration of sodium chloride and varying concentrations of potassium chloride and *vice versa*. A positive value for the potential indicates that the electrode in the sodium chloride solution was positive with respect to the other electrode. The potential values were plotted as a function of concentration of one solution when the concentration of the other was fixed and *vice versa*. The point of intersection of the two lines obtained was taken as the BIP value at that particular concentration.

Measurement of BIP of phosphonic acid membrane as a function of pH.—The BIP measurements were carried out using 0.1*N* solutions adjusted to different pH values. Calomel electrodes and KCl bridges were employed for potential measurements with alkaline solutions.

Results and Discussion

Although the importance of eliminating the effects of diffusion layers in measurements of bi-ionic potential has been recognized by several authors (2, 28-31), it would appear that these effects have frequently been overlooked probably because, in many of the systems investigated, the membrane potential observed with partial film diffusion control differs little from that with complete membrane control. With some systems, however, and especially with those containing two ions of different valency, the magnitude and even the sign of the potential under the two conditions may be completely different (32). Helfferich (8) has shown that, for the interdiffusion of two isotopes of the same counter ion, deviations from ideal membrane control are to be expected when

$$\frac{DCd}{\overline{D}\overline{C}\delta} < 50$$

where D and $\overline{D}$ are the diffusion coefficients of the counter ion in solution and in the membrane, C is the solution concentration, $\overline{C}$ is the total counter ion concentration in the membrane, d its thickness, and δ the thickness of each of the diffusion layers. Complete film control will be attained when $DCd/\overline{D}\overline{C}\delta < 0.1$. With

a typical ion-exchange membrane, $\bar{C} \approx 1N$, $D/\bar{D} \approx 5$ and $d \approx 0.1$ cm so that, with $0.1N$ solutions, a film thickness of less than 10^{-3} cm is necessary for the attainment of complete membrane control. With $0.001N$ solutions, the film thickness has to be reduced to 10^{-5} cm.

In the measurement of bi-ionic potentials, it is therefore clearly necessary to make sure that complete membrane diffusion control has been established. In previous work on the measurement of membrane potentials, the absence of any significant change in the potential on increasing the rate of stirring or the flow rate of the solutions has frequently been taken to indicate the establishment of membrane control. In the present work, however, in addition to investigating the effect of flow rate on the membrane potential, the thickness of the diffusion layers has been measured and the effect of varying the membrane thickness has been investigated.

Estimation of diffusion-layer thickness.—For the estimation of film thickness, the results obtained in the study of the rate of interdiffusion of sodium and hydrogen ions across the sulfonic acid membrane were used. Similar procedures have previously been employed by Mackay and Meares (13) and by Peterson and Gregor (33). Equations relating the cation flux in bi-ionic exchange systems to the thickness of the diffusion layers were derived by Mackay and Meares. These equations are, however, restricted in their application to systems in which the difference between the compositions of the two solutions, expressed as the equivalent fraction of either cation, is not too large. Peterson and Gregor, using the potassium-ammonium system, were able to assume that these two ions resembled one another sufficiently closely to serve as "tracers" for each other, and they could therefore obtain values for the film thickness by making use of the relatively simple relationships applicable to such systems. With the sodium-hydrogen system where the diffusion potential in the unstirred films is associated with an appreciable anion concentration gradient, we no longer have simple relationships for the interfacial boundary conditions. The interfacial concentrations and the film thickness can, however, be obtained by a graphical method. In this method, it has been assumed that the cation-exchange membrane separates solutions of the uni-univalent electrolytes AY and BY at the same equivalent concentration and that a steady state has been achieved in which there is negligible cross contamination of the two solutions. The boundaries of the membrane and the diffusion layers are represented by planes a, b, c, and d (*see* Fig. 4). It has also been assumed that the membrane is impermeable to anions, that water transport can be neglected, that the mobility ratios are independent of mole fraction, that equilibrium is attained at the membrane-solution interfaces, and that this equilibrium can be represented by the relationship

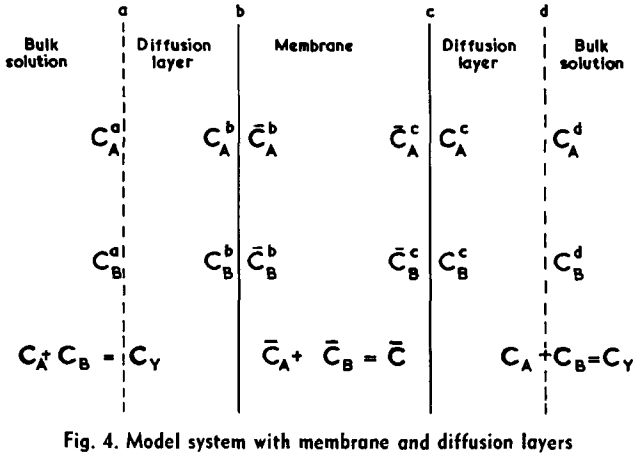

Fig. 4. Model system with membrane and diffusion layers

$$\frac{\bar{C}_A}{\bar{C}_B} = K'^{A}_{B}\frac{C_A}{C_B}$$

where C_A and C_B are the concentrations of the ions in solution and $\bar{C}_A$ and $\bar{C}_B$ are the concentrations in the membrane.

For the diffusion of the cations and anions in the unstirred films, we have the following flux equations

$$J_A = -u_A C_A\left(RT\frac{d\ln C_A}{dx} + \mathbf{F}\frac{d\phi}{dx}\right) \quad [9]$$

$$J_B = -u_B C_B\left(RT\frac{d\ln C_B}{dx} + \mathbf{F}\frac{d\phi}{dx}\right) \quad [10]$$

$$J_Y = -u_Y C_Y\left(RT\frac{d\ln C_Y}{dx} - \mathbf{F}\frac{d\phi}{dx}\right) \quad [11]$$

where J_A, J_B, and J_Y are the fluxes of the cations A and B and the anion Y; u_A, u_B, and u_Y, and C_A, C_B, and C_Y are the corresponding mobilities and concentrations; and ϕ is the potential at the plane x in the diffusion layer.

We also have the following relationships

$$J_A = -J_B = J \quad [12]$$

$$J_Y = 0 \quad [13]$$

$$C_Y = C_A + C_B \quad [14]$$

If $C_Y{}^a = C_Y{}^d = C$, it can be shown that

$$\frac{C_Y{}^b}{C} = 1 + \frac{a_A\delta}{2C}\left(\frac{u_B - u_A}{u_B}\right) \quad [15]$$

and

$$\frac{C_Y{}^c}{C} = 1 - \frac{a_A\delta}{2C}\left(\frac{u_B - u_A}{u_B}\right) \quad [16]$$

where

$$a_A = -\frac{J}{u_A RT}$$

and δ is the thickness of the diffusion layer. If $C_A{}^a = C_B{}^d = C$ and

$$\frac{\bar{C}_A{}^b C_B{}^b}{\bar{C}_B{}^b C_A{}^b} = \frac{\bar{C}_A{}^c C_B{}^c}{\bar{C}_B{}^c C_A{}^c} = K'^{A}_{B}$$

where barred symbols denote concentrations in the membrane, then it can also be shown that

$$\frac{\bar{C}_A{}^b}{\bar{C}} = \frac{1}{1+S} \quad [17]$$

and

$$\frac{\bar{C}_A{}^c}{\bar{C}} = \frac{1}{1+T} \quad [18]$$

where

$$S = \frac{-\frac{u_A}{u_B}\frac{a_A\delta}{2C}\left(\frac{C_Y{}^b}{C}+1\right)}{K'^{A}_{B}\left\{\left(\frac{C_Y{}^b}{C}\right)^2 + \frac{u_A}{u_B}\frac{a_A\delta}{2C}\left(\frac{C_Y{}^b}{C}+1\right)\right\}}$$

$$T = \frac{\left(\frac{C_Y{}^c}{C}\right)^2 + \frac{a_A\delta}{2C}\left(\frac{C_Y{}^c}{C}+1\right)}{-\frac{a_A\delta}{2C}\left(\frac{C_Y{}^c}{C}+1\right)K'^{A}_{B}}$$

and $\bar{C}$ is the total concentration of counter ions in the membrane.

By applying the Nernst-Planck flux equations to the diffusion processes in the membrane, it can be shown (*cf.* Eq. [3. 11b] in the paper by Helfferich (8)) that

$$bd = \ln \frac{\frac{\bar{C}_A{}^b}{\bar{C}} - \frac{\bar{u}_B}{\bar{u}_B - \bar{u}_A}}{\frac{\bar{C}_A{}^c}{\bar{C}} - \frac{\bar{u}_B}{\bar{u}_B - \bar{u}_A}} \quad [19]$$

where

$$b = -\frac{J}{RT\bar{C}}\left(\frac{\bar{u}_B - \bar{u}_A}{\bar{u}_A \bar{u}_B}\right)$$

$\bar{u}_A$ and $\bar{u}_B$ are the mobilities of the counter ions in the membrane and d is the membrane thickness.

If the value of $a_A\delta/C$ is known, then bd can be calculated using Eq. [15]-[19]. The relationship between bd and $a_{Na}\delta/C$ for the sodium-hydrogen ion system and the membrane used in these experiments is shown in Fig. 5. (In these calculations, the sodium ion was taken as ion B with a negative flux. Since J is then positive, Eq. [12], it follows that $-a_{Na}\delta/C$ is also positive). Values of bd were calculated from assumed values of $a_{Na}\delta/C$ by also assuming that $u_{Na}/u_H = 1.43$, $K'_H{}^{Na} = 1.40$, and $\bar{u}_{Na}/\bar{u}_H = 0.125$. Complete membrane control is attained when $a_{Na}\delta/C = 0$ and $bd = \ln \bar{u}_{Na}/\bar{u}_H$; and, under these conditions, the flux will be independent of the solution concentrations. Complete film control is attained when

$$bd = 0 \text{ and } -\frac{a_{Na}\delta}{C} = \frac{2}{\left(\sqrt{\frac{u_{Na}}{u_H}} + 1\right)^2} \quad [20]$$

and the flux will then be proportional to the solution concentration. [A more general solution for the case of complete film diffusion control has been given by Helfferich (15).]

It was found that, over a period of 4 hr, the rate of interdiffusion was approximately constant. With the 0.01N solutions, the amount of H^+ ion diffusing through the membrane in this time was approximately 2 mg equiv. Since the total volume of each solution is 2 liters, an interdiffusion flux of this magnitude could have led to appreciable cross contamination if the solutions had not been renewed at frequent intervals during the subsequent potential measurements.

The thickness of the diffusion layer was obtained from the results of the flux experiments by first calculating the value of bd corresponding to the interdiffusion flux at each of the three solution concentrations and then calculating the film thickness from the corresponding values of $a_{Na}\delta/C$ obtained from the curve shown in Fig. 5.

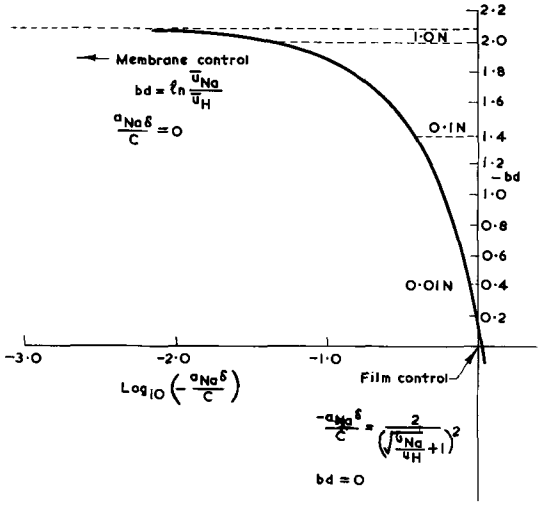

Fig. 5. Relationship between bd and

$$\log_{10}\left(-\frac{a_{Na}\delta}{C}\right) \text{ for } K_H{}^{Na} = 1.40$$

Calculated values for the film thickness and the solution concentrations at the membrane surface are given in Table II. It will be noted that with the 1.0N solutions there is little difference between the concentrations of the bulk solutions and the concentrations at the membrane surfaces. With the 0.1N and 0.01N solutions, however, the difference in the mobilities of the two cations leads to the development of marked concentration gradients in the diffusion layers. It will also be seen from Fig. 5 that complete membrane control is approached with the 1.0N solutions and that with the 0.01N solutions complete film control is approached but not achieved. With the 0.1N solutions, the system is in an intermediate condition. In these circumstances, the agreement between the values calculated for the film thickness is surprisingly good and may be partly due to the fortuitous cancellation of errors and approximations. The value of 2 x 10^{-3} cm for the film thickness is less than that of 4.5 x 10^{-3} cm obtained by Mackay and Meares (13) for a cell provided with mechanical stirring. Peterson and Gregor (33), who also used a cell fitted with stirrers, obtained values for the film thickness which ranged from 0.1 x 10^{-3} to 3.0 x 10^{-3} cm, depending on the rate of stirring. Cooke and van der Walt (34), using a cell in which NaCl solution flowed through a narrow compartment bounded on one face by the membrane, obtained values for the Nernst layer thickness ranging from approximately 3 to 7 x 10^{-3} cm, depending on the velocity of the solution. By using a spacer to promote eddy formation, the thickness was reduced to approximately 1 x 10^{-3} cm.

The effects of membrane and diffusion-layer thickness on membrane potentials.—If we consider the interdiffusion of two isotope counter-ions through the sulfonic acid membrane, we can calculate the value of $DCd/\bar{D}\bar{C}\delta$ assuming the film thickness is 2 x 10^{-3} cm. For this membrane, we may assume $D/\bar{D} \simeq 8$, $\bar{C} \simeq 1.4$ x 10^{-3}g ion cm^{-3}, and we obtain the following approximate values for $DCd/\bar{D}\bar{C}\delta$

Solution concentration	$DCd/\bar{D}\bar{C}\delta$		
	d = 0.016 cm	0.132 cm	0.320 cm
1.0N	45	400	900
0.1N	4.5	40	90
0.01N	0.45	4	9

With a membrane thickness of 16 x 10^{-3} cm, membrane control will therefore be closely approached with 1.0N solutions; complete film control will be approached but not attained with 0.01N solutions. Satisfactory measurements of bi-ionic potentials cannot therefore be made with 0.1N or 0.01N solutions, a membrane of this thickness, and a film thickness of 2 x 10^{-3} cm.

The effect of solution flow rate and membrane thickness on the potential with 0.1N solutions of KCl and NaCl is shown in Fig. 6 which clearly illustrates the difficulties which can arise in the measurement of bi-ionic potentials with ion-exchange resin membranes. With a membrane thickness of 16 x 10^{-3} cm, and above a flow rate of 500 cm^3/min, there is very little change in the potential with increase in flow rate. This clearly cannot be taken to indicate the absence of film control since, with a membrane thickness of 132 x 10^{-3} cm, the potential is considerably greater and, as shown above, complete membrane control would not be expected with a membrane thickness of 16 x 10^{-3} cm. The absence of a change in potential with change in flow rate cannot, in this case, be taken to indicate the establishment of membrane control; instead, it probably indicates the attainment of a limiting film thickness.

In these experiments, Ag, AgCl electrodes were used; and the emf of the cell therefore involves the

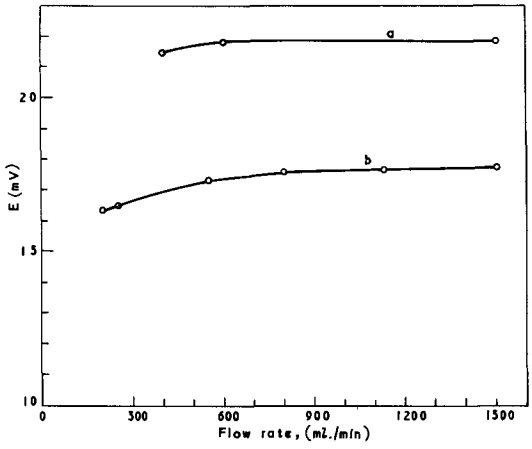

Fig. 6. Effect of flow rate on membrane potentials with a sulfonic acid membrane, 0.1*N* NaCl and 0.1*N* KCl solutions and Ag, AgCl electrodes: (a) membrane thickness, 132 x 10^{-3} cm; (b) membrane thickness, 16 x 10^{-3} cm.

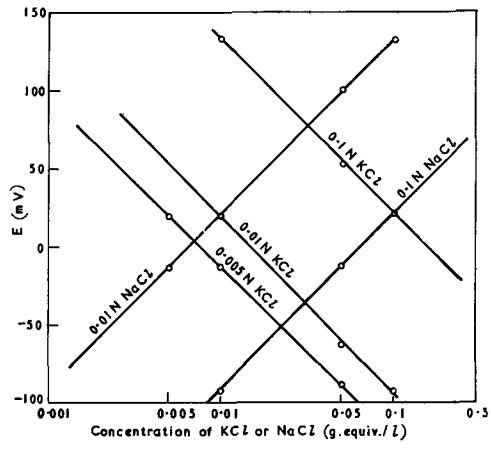

Fig. 7. Effect of solution concentration on potentials with a sulfonic acid membrane (thickness, 132 x 10^{-3} cm), NaCl and KCl solutions, and Ag, AgCl electrodes.

difference between the two electrode potentials as well as the membrane potential which is inaccessible to direct measurement. The emf of the cell is given by the equation

$$E = \frac{RT}{\mathbf{F}} \ln \frac{a_Y'}{a_Y''} + \frac{RT}{\mathbf{F}} \ln \frac{\bar{u}_A a_A'}{\bar{u}_B a_B''} K'_{a}{}^{A}{}_{B}$$

$$= \frac{RT}{\mathbf{F}} \ln \frac{\bar{u}_A}{\bar{u}_B} K'_{a}{}^{A}{}_{B} + \frac{2RT}{\mathbf{F}} \ln \frac{a_{\pm AY}}{a_{\pm BY}}$$

where $a_{\pm AY}$ and $a_{\pm BY}$ are the mean activities of the electrolytes AY and BY in the two solutions.

The potential corresponding to the system in which the mean activities $a_{\pm AY}$ and $a_{\pm BY}$ are equal can be found by the procedure described by Wyllie and Kanaan (16). If the mean activity of electrolyte BY is kept constant and the potential is measured with solutions of AY of differing mean activities, then, on plotting the potential against ln $a_{\pm AY}$, a straight line should be obtained with a gradient equal to $2RT/\mathbf{F}$. If the mean activity of AY is kept constant and the concentration of BY is varied, then, on plotting the results in a similar way, a straight line with slope $-2RT/\mathbf{F}$ is obtained. The intercept will correspond to the condition in which $a_{\pm AY} = a_{\pm BY}$. Since at these concentrations the mean activity coefficients for the two electrolytes differ by less than 1.1%, the emf obtained from the intercept will be very close to that obtained with solutions of equal concentration.

The effect of varying the concentration of one solution on the emf with a sulfonic acid membrane (thickness: 132 x 10^{-3} cm) is shown in Fig. 7. In all cases, linear relationships between the emf and the logarithm of the solution concentration were obtained. The gradients were slightly less than the theoretical but this was largely due to the use of concentrations instead of mean activities.

The effect of solution concentration and membrane thickness on the membrane potential when the solutions are equal in concentration is shown by the results given in Table III. With a membrane thickness of 16 x 10^{-3} cm, the membrane potential decreases slightly with decrease in solution concentration reaching a value of 16.4 mV at a solution concentration of 0.01*N*. With complete film control, there will be no concentration gradients in the membrane and the membrane potential should be the sum of the difference between the two Donnan potentials at the interfaces and the two diffusion potentials in the films. The total concentrations in solution at the interfaces can be obtained from Eq. [15], [16], and [20]. From the ratio of these concentrations, the difference between the two Donnan potentials is found to be $RT/\mathbf{F}$ ln $\sqrt{\bar{u}_A/\bar{u}_B}$. From the total concentrations in solution at the membrane surfaces and Eq. [9], [10], [11], and [13], it can be shown that the sum of the two diffusion potentials is also $RT/\mathbf{F}$ ln $\sqrt{\bar{u}_A/\bar{u}_B}$ so that the membrane potential is given by

$$E = \frac{RT}{\mathbf{F}} \ln \frac{u_A}{u_B} \quad [cf. \text{ Helfferich (8)}]$$

With KCl and NaCl solutions, the theoretical value for the membrane potential in 0.01*N* solutions is 10.2 mV (if the mobility ratio is estimated from transport number and conductivity data). This value is much lower than the experimental value quoted above and we may therefore conclude that complete film control has not been attained with the 0.01*N* solutions.

Comparison of results obtained with sulfonic and phosphonic acid membranes.—With the sulfonic acid membranes, the potentials obtained with membrane thicknesses of 132 x 10^{-3} cm and 320 x 10^{-3} cm are significantly higher than those obtained with a membrane thickness of 16 x 10^{-3} cm and, from the values of $DCd/\bar{D}\bar{C}\delta$ given above, complete membrane control would be expected to be closely approached with 0.1*N* solutions. The value of 21.5 mV obtained for the membrane potential with a membrane thickness of 132 x 10^{-3} cm can therefore be taken to be the bi-ionic potential. The results of measurements of concentration potentials showed that the slightly lower value obtained with 0.1*N* solutions and a membrane thickness of 320 x 10^{-3} cm was undoubtedly due to a slight leakage of chloride ion presumably between the membrane and the membrane clamp.

In the experiments with the phosphonic acid membranes, the membrane potential was measured over the *p*H range 2.0-13.0 using 0.1*N* solutions and membrane thicknesses 27 x 10^{-3} cm, 132 x 10^{-3} cm, and 320 x 10^{-3} cm. Silver-silver chloride electrodes were used for the experiments with solutions of *p*H < 9.6; calomel electrodes and KCl bridges were used when the *p*H was greater than 5. With the calomel electrodes, it was assumed that the emf of the cell was equal to the membrane potential and that the difference between the diffusion potentials at the KCl

(b) Calomel electrodes.

bridges could be neglected. It will be seen from Table IV that good agreement is obtained under conditions where both Ag, AgCl, and calomel electrodes could be used.

The results obtained with the two thicker membranes are in reasonably good agreement. In both cases, there is a slight decrease in the BIP with decrease in pH. Under all conditions, the value for the BIP with the thicker membranes is very much less than that obtained with a membrane thickness of 27 x 10^{-3} cm and considerably less than the value of 21.5 mV obtained for the BIP with the sulfonic acid membrane. This result is in contrast to that of Bergsma and Staverman (24) who found little difference in the behavior of membranes containing sulfonic and phosphonic acid groups toward sodium and potassium ions. It would, however, appear likely that, in these experiments, because of the low flow rate, the bi-ionic systems were subject to partial film control (35). This view is supported by the approximate agreement between the values obtained for the potentials with the thin sulfonic and phosphonic acid membranes.

The values obtained for the relative affinity coefficient K_{Na}^{K} with the two membranes are given in Table V. The value for the sulfonic acid membrane is approximately equal to that which would be expected for a sulfonated polystyrene resin with a 5% divinylbenzene content. With the phosphonic acid membrane, the value of K_{Na}^{K} in alkaline solution is less than unity and Na^+ is absorbed more strongly than K^+. At pH 5, there is a decrease in the affinity for sodium ion and the value of K_{Na}^{K} approaches unity. The affinity order Na > K, which obtains in alkaline solutions, is the same as that previously observed by Bregman and Murata (17, 18) with a phosphonic acid resin, and by Kennedy, Marriot, and Wheeler with a methylene phosphonic acid resin (19). It is, however, the reverse of that usually observed with sulfonic acid resins of normal capacity and cross linking. Bregman (18) suggested an explanation for this reversal of selectivity, which was based on the work of Teunissen and Bungenberg de Jong (36, 37) on the concentration of alkali chlorides necessary to bring about reversal of charge on organic colloids. This explanation assumed the following order of polarizability for the functional groups and for water: phosphonic acid group > water > sulfonic acid group. The greatest interaction through polarization would be expected with the Li^+ ion (with the highest field strength) and the phosphonic acid group, and with the phosphonic acid resins the affinity sequency would be expected to be $Li^+ > Na^+ > K^+$. With the sulfonic acid resins, the interaction between the cations and water would be of greater importance: the Li^+ ion would be the most strongly hydrated and this would lead to the affinity sequence $K^+ > Na^+ > Li^+$.

Table V. Correlation of bi-ionic potentials with relative affinity coefficients and mobility ratios

Membrane	pH	K^{K}_{Na}	$\frac{\bar{u}_K}{\bar{u}_{Na}}$	BIP calc. (mV)	BIP observed (mV)
Sulfonic acid	≃5	1.4	1.55	19.9	21.5
Phosphonic acid	≃5	0.88	1.62	9.1	5.0
	≃13	0.63	1.82	3.5	6.5

In Eisenman's approach to the problem of ion selectivity (38), the emphasis is placed on the "field strength" of the anionic group. He showed that a variation in the field strength of the anionic group could lead to the development of 11 different affinity sequences for alkali metal cations. If we assume that the pK_a values for the phosphonic acid groups in the membrane are 3 and 8, then from the relation between pK_a, r^-, and the affinity sequence given by Eisenman, we would expect the affinity order Na > K in alkaline solutions, and a sequence with K > Na in acid solutions.

Values for the relative mobilities of the Na and K ions in the membranes were obtained from the results of the conductance measurements and are given in Table V. No correction was applied for convection conductivity and the ratios can therefore be regarded only as approximate. The table also includes the observed bi-ionic potentials, and the bi-ionic potentials calculated from Eq. [15]. It will be seen that, taking into account the errors and approximations, fairly good agreement is obtained between observed and calculated values. The low value for the BIP obtained with a phosphonic acid membrane is clearly due mainly to the preferential absorption of sodium ion by this membrane, and it is noteworthy that at pH 5 there is relatively little difference in the relative mobilities of the sodium and potassium ions in the two membranes. In the experiments of Woermann described by Bonhoeffer (39), it was found that with a membrane prepared from a potassium selective ion-exchange resin the self-diffusion coefficient of K^+ was smaller than that of Na^+ and the activation energy for diffusion of K^+ was greater than that of Na^+. Similarly, with the phosphonic acid membrane, it appears that the higher relative affinity for the Na^+ ion under alkaline conditions is associated with a somewhat lower relative mobility in the membrane compared with that observed with a sulfonic acid membrane.

The above work was carried out as part of the research program of the former National Chemical Laboratory.

Effect of LiF and Li_3AlF_6 on the Electrical Conductivity of Cryolite-Alumina Melts

K. Matiasovsky, V. Danek, and M. Malinovsky

Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Czechoslovakia

ABSTRACT

Electrical conductivities of molten LiF, Li_3AlF_6, of two-component systems Na_3AlF_6-LiF, Na_3AlF_6-Li_3AlF_6 and of three-component systems Na_3AlF_6-Al_2O_3-LiF and Na_3AlF_6-Al_2O_3-Li_3AlF_6 were measured. It has been found that by the addition of both LiF and Li_3AlF_6, the electrical conductivity of cryolite-alumina melts is increased, the effect of LiF being much more pronounced. The effect of Li_3AlF_6 is relatively higher at high concentrations of lithium cryolite, which, on the other hand, is less attractive with regard to the technology of aluminum production.

Measurement of the electrical conductivity of molten fluorides and of their mixtures is interesting both from the theoretical as well as the practical point of view. In the field of fundamental research the investigation of electrical conductivity can, together with the investigation of other physicochemical properties, give us valuable information concerning the structure of fused salts. From the practical point of view the electrical conductivity is important especially with regard to the use of fluoride mixtures as electrolytes in electrometallurgy; namely, in the case of cryolite-alumina melts for aluminum production.

There is a close relationship between the electrical conductivity and the energy efficiency of Al electrolysis, which, at present, is approximately 30% (1-3). This relatively low energy efficiency is due mainly to the following factors: anodic overvoltage; anode effect; ohmic voltage drop in the electrolyte; and secondary reactions, *i.e.*, reactions which are not directly connected with the primary anodic or cathodic processes and hence do not influence the cell potential and which, nevertheless, lower the current efficiency (4, 5). These are especially the solution of deposited metallic aluminum in the electrolyte and reactions between the products of electrolysis.

It can be shown that the electrical conductivity of the electrolyte will influence not only the ohmic voltage drop in the cell but also, indirectly, the secondary reactions and thus the current efficiency of the electrolysis (6).

During the last years a series of papers was published dealing with the influence of different additions on certain, from the technical point of view interesting, physicochemical properties of aluminum electrolytes; the pertinent results were reported (1-7). As additives, fluorides and chlorides of alkali metals, of alkaline earth metals, and AlF_3 were used. As it follows from the above papers, from among different additives only LiF, Li_3AlF_6, and NaCl affect favorably most of the important physicochemical properties of electrolytes, including electrical conductivity. Influence of NaCl on the specific conductivity of cryolite-alumina melts was presented by Matiasovsky *et al.* (8, 9).

Measurement of the electrical conductivity of fused fluorides and of their mixtures is experimentally rather difficult owing to the reactive properties of these melts and with regard to the conditions of the experiment, especially the relatively high temperature at which the measurements must be performed. Experimental problems, together with some methodological aspects of measurement of the electrical conductivity of fused fluorides were discussed by Abramov *et al.* (1), Winterhager and Werner (10), and recently by Danek *et al.* (11).

With regard to the experimental difficulties of measurements it is not surprising that the values of electrical conductivity of individual fluorides and of their mixtures, as reported by different authors, vary considerably. Thus, *e.g.*, for specific conductivity of LiF at 950°C the values of 20.3 $ohm^{-1} \cdot cm^{-1}$ (12) and 8.8 $ohm^{-1} \cdot cm^{-1}$ (13) are reported. The reported values of specific conductivity of Li_3AlF_6 at 1000°C lie in the range of 3.93-4.71 $ohm^{-1} \cdot cm^{-1}$ (13-16). There are similar differences in case of the melts of the two-component systems Na_3AlF_6-Al_2O_3 (1, 9, 13, 17-20), Na_3AlF_6-LiF (2, 21) and Na_3AlF_6-Li_3AlF_6 (11, 15, 22). Concerning the three-component systems Na_3AlF_6-

Al_2O_3-LiF and Na_3AlF_6-Al_2O_3-Li_3AlF_6, the data reported by Belyaev (2) and by Mashovets and Petrov (15), respectively, are somewhat controversial regarding the electrical conductivity of pure cryolite and of the binary Na_3AlF_6-Al_2O_3 mixtures.

Experimental

A detailed description of the equipment used is reported by Danek *et al.* (11). A Pt crucible containing 15g of fused salt was used as conductivity cell. Disk electrodes of bright platinum, 5 mm in diameter, were used. Each electrode was provided with a current and a voltage connection (Pt30Ir, d = 0.5 mm). The interpolar distance was 12 mm. The electrodes were immersed 7 mm into the melt with the aid of a micrometric screw with an accuracy of ±0.01 mm. A Thompson double bridge was used for measuring the resistance of the melt (23).

Measurements were carried out with 10 mA current at a frequency of 18 kHz. At this frequency, only the ohmic resistance of the melt was measured (6, 11). The cell constant was determined by calibration with fused Na_3AlF_6. For the conductivity of cryolite at 1000°C the value of 2.80 $ohm^{-1} \cdot cm^{-1}$, determined by Edwards *et al.* (24) and later confirmed by Yim and Feinleib (13) and Bajcsy *et al.* (23) was accepted. (The above value is extrapolated, since the melting point of pure cryolite is 1010° ± 2°C). The reproducibility of the measurement was better than ±2%.

For preparation of samples the following substances were taken: Al_2O_3, reagent grade; LiF, reagent grade; AlF_3 prepared by sublimation of technical fluoride by procedure reported by Matiasovsky *et al.* (25); and Greenland hand-picked cryolite with melting point at 1006° ± 2°C, in which 54.7% of fluorine were determined by the pyrohydrolytic method (26), which corresponds to the composition of pure Na_3AlF_6.

Temperature was measured with Pt/Pt10Rh thermocouples. The hot junction of the thermocouple was placed in the melt between the electrodes. The alternating voltage induced from the furnace into the thermocouple was eliminated by the use of a frequency filter.

Results and Discussion

The influence of temperature on the electrical conductivity of LiF and Li_3AlF_6 was determined. Using the measured values the equations $\sigma = f(t)$ were calculated by the least squares method and the polytherms of electrical conductivity of LiF and Li_3AlF_6 were constructed. The dependence of conductivity on temperature can be expressed by quadratic equations

$$\sigma_{LiF} = -2.4871 + 17.2245 \cdot 10^{-3}t - 5.5475 \cdot 10^{-6}t^2 \quad [1]$$

$$\sigma_{Li_3AlF_6} = -0.7844 + 8.4400 \cdot 10^{-3}t - 3.4658 \cdot 10^{-6}t^2 \quad [2]$$

The values of conductivity of LiF calculated from Eq. [1] are in very good agreement with data reported by Yim and Feinleib (13). The value of specific conductivity of Li_3AlF_6 calculated from Eq. [2] is also in very good agreement with values reported in the aforementioned paper.

In Fig. 1 isotherms of conductivity of melts in the system Na_3AlF_6-LiF are presented. The effect of LiF on the increase of conductivity of cryolite, as it was found in the present work, is less pronounced than the effect at low concentrations of LiF reported by Belyaev (2) and Vakhobov and Belyaev (21). We may assume that this difference is caused by inaccurate calibration of the conductivity cell and by low frequency of the measuring current used by the above authors.

Isotherms of conductivity of melts in the system Na_3AlF_6-Li_3AlF_6 are shown in Fig. 2. The measured values of conductivity are somewhat higher than the values reported in papers (11, 14), but the general character of the dependence $\sigma = f$ (conc) is in all cases the same. The relatively lower values reported in the above works are evidently due to the low frequency of the measuring current. Basically different are the data reported by Mashovets and Petrov (15), both with as regard to the measured values and to the general character of the isotherm of conductivity of melts in the system Na_3AlF_6-Li_3AlF_6, which are probably due to deficiencies of their experimental technique.

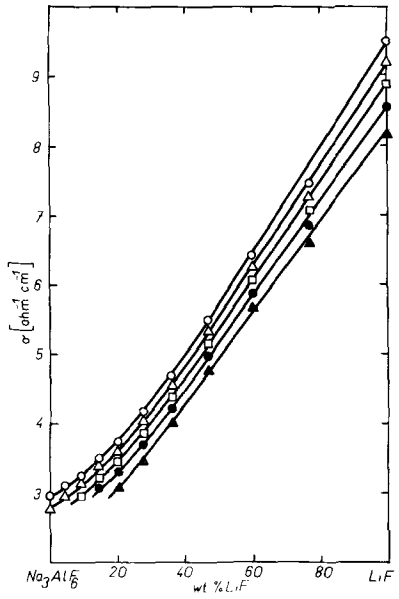

Fig. 1. Isotherms of the conductivity of molten Na_3AlF_6-LiF mixtures. ○, 1050°C; △, 1000°C; □, 950°C; ●, 900°C; ▲, 850°C.

the isotherm of conductivity of the ternary Na_3AlF_6-Al_2O_3-Li_3AlF_6 mixtures at 1000°C.

On comparison of the influence of additives on the electrical conductivity of cryolite-alumina melts it is evident that the gradient of conductivity increase caused by the addition of Li_3AlF_6 is relatively low, being but about 15% of the gradient for LiF and is even lower than the corresponding values for the addition of NaCl (8, 9). From the diagrams in Fig. 2 and 4 it may be seen that the gradient of electrical conductivity increase shows an increase in the area of higher concentration of Li_3AlF_6, which, however, is not suitable for technical application. It is very probable that the reason for this behavior lies somewhere in the structure of the melt similar to the negative deviation from the additive line of the melts in the systems Na_3AlF_6-LiF and Na_3AlF_6-Al_2O_3-LiF (Fig. 1, 3). In case of LiF we may assume that the negative deviation from the additivity is caused by the suppression of the dissociation of the complex ion AlF_6^{3-}, which, according to (27), dissociates partly in the fused cryolite according to the scheme $AlF_6^{3-} \rightleftarrows AlF_4^- + 2F^-$. By the admixture of LiF, the F^- ions are introduced into the melt and the dissociation equilibrium is shifted toward the left so that we may assume that the relative increase of the concentration of free F^- ions, which, apart from cations Li^+ and Na^+ contribute to the current transport, is smaller than the additive.

In spite of the fact that in the case of LiF the conductivity increase is also somewhat smaller than it should be according to the additivity line, the addition of LiF increases substantially the conductivity of the fundamental electrolyte. Thus, *e.g.*, at the concentration of 5% of LiF the conductivity of the electrolyte increases by 10%, which, as we pointed out in the introduction, is of great importance for the technical application. From the abovesaid it also follows that, with regard to the relatively poor effect of Li_3AlF_6 on the electrical conductivity of cryolite-alumina melts, it would be advisable to use the addition of LiF only in electrolytes that do not contain free AlF_3.

Manuscript submitted March 24, 1969; revised manuscript received May 26, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1970 JOURNAL.

High Rate Anodic Dissolution of Copper

Dieter Landolt,*[1] Rolf H. Muller,* and Charles W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

The anodic dissolution of copper at current densities of 10-150 A/cm^2 has been studied in neutral KNO_3 and K_2SO_4 solutions. An experimental flow system has been built which allows electrochemical measurements of the dissolution process to be performed under defined hydrodynamic conditions typical for the technical electrochemical machining operation. Design criteria for such a system have been analyzed. Copper dissolution proceeds in an active or a transpassive mode which differ in overvoltage by 10-20V. The onset of passivation seems to be due to the limiting mass transfer of dissolved metal from the electrode surface. The still higher dissolution rates in the passive state appear to be made possible by the removal of solid dissolution products. Etched, dull surfaces have resulted from active dissolution; pitted, bright surfaces from passive dissolution.

Electrochemical machining (ECM) has found widespread use in recent years for the shaping of metals. In this process, the workpiece is dissolved anodically at current densities in the order of 100 A/cm^2, characteristically with electrolyte flow rates of 0.5-70 m/sec and electrode spacings of 0.1-0.5 mm. As an electrochemical process, ECM is of particular interest because the current densities employed are about three orders of magnitude higher than those applied in conventional electrolysis. Most of the published literature on ECM deals with the correlation of practical process variables such as cathode feed rate, applied voltage, and electrolyte pressure, but little is known about the electrochemical factors involved.

A more detailed understanding of ECM may not only lead to further development and wider practical adoption of this highly interesting process, but it may also yield information relevant to the operation of other electrochemical processes at much higher rates than employed in current industrial practice. With this purpose in mind, the anodic dissolution of a metal with reasonably well understood electrochemical and metallurgical properties was subjected to study under conditions similar to those employed in ECM. The principal goal of the study was to develop an experimental method for estimating the anode potential values prevailing at high current density and for investigating the role of hydrodynamics in the anodic dissolution process. In addition, optical observations of the interelectrode gap were to be carried out in order to determine the influence of flow rate and current density on cathodic hydrogen evolution. The design of the experimental system and results obtained on the dissolution of copper in neutral KNO_3 and K_2SO_4 solutions in the current density range of 10-150 A/cm^2 are reported here.

Design Considerations

Cell voltage.—In order to keep the cell voltage in manageable limits electrodes have to be spaced closely. For example, assuming a current density of 100 A/cm^2, a specific electrolyte resistance of $\rho = 10$ ohm-cm, and an inter-electrode gap of 0.5 mm, the ohmic drop is as large as 50V. Geometrical arrangements like rotating disks or cylinders are not well suited since the cell resistance is dependent on the diameter which determines the surface area. The characteristic length (diameter) therefore can not be varied independent[2] of the resistance.

Temperature increase in solution.—The temperature rise is primarily due to ohmic heating which is determined by the power density. By neglecting heat losses, the rate of temperature rise can be expressed by

$$\frac{\Delta T}{\Delta t} \simeq \frac{i^2 \rho}{d\, c_p} \ (^\circ/\text{sec}) \qquad [1]$$

As an example, setting $i = 100$ A/cm^2, $\rho = 10$ ohm-cm, $d = 1$ g/cm^3, $c_p = 4.18$ joule/°g, one obtains

$$\frac{\Delta T}{\Delta t} \simeq 2.4 \times 10^4 \ (^\circ/\text{sec})$$

In order to limit the temperature rise, extremely short experimental times would be required, or the residence time of the solution has to be kept short by high flow rates.

In the latter case, the use of parallel plate electrodes is more suitable than, *e.g.*, rotating disk or cylinder electrodes, but high linear velocities of the electrolyte are to be employed, and the length of the electrode in flow direction is to be kept short. A rough estimate of the temperature increase in the flow direction is obtained from [1] by setting $\Delta t = L/u$ with L = electrode length and u = linear velocity. For example, using the current density and electrolyte properties given above, one obtains for $u = 1000$ cm/sec, and $L = 1$ cm, $\Delta T = 25°$.

Pressure drop.—The pressure drop in a flow system is proportional to the square of the flow velocity and proportional to the length of the system. In a flow channel cell, it is desirable to have a hydrodynamic entrance length of 70 to 100 hydraulic diameters[3] upstream of the electrodes. The entrance length serves to establish a fully developed velocity profile (2, 3), which is necessary in order to have well reproducible and analytically amenable mass transfer conditions. The requirement of a hydrodynamic entrance length increases the value of the inlet pressure necessary to maintain a given linear velocity at the electrode manifold. A decision therefore has to be made as to whether close control of mass transfer conditions justifies a substantial increase in pressure requirements. Data of a channel cell containing a hydrodynamic entrance length are given in the next section.

Mass transfer conditions.—Numerical estimations indictate that a rectangular flow channel cell under turbulent flow conditions is the most suitable experimental arrangement for realizing extremely high mass transfer rates. This arrangement has the drawback

* Electrochemical Society Active Member.

[1] Present address: University of California, Department of Engineering, Los Angeles, California 90024.

[2] Using the values above, one obtains for a rotating disk electrode of $R = 2$ mm radius [primary current distribution (1)] $U \simeq \pi/4\, i\rho R \simeq 160$V. For two concentric cylinder electrodes of 2 and 10 mm radius $U \simeq i\rho R_1 \ln(R_2/R_1) \simeq 320$V.

[3] The hydraulic diameter is defined as $D_h = \dfrac{4 \text{ cross section}}{\text{perimeter}}$.

that the thickness of the diffusion layer increases in the flow direction (4). However, under turbulent flow conditions, if the electrode is sufficiently long the variation of the diffusion layer thickness can be neglected (6), since a constant value is reached at a short distance from the leading edge of the electrode. Mass transfer rates for turbulent flow in pipes have been reported by Van Shaw, Reiss, and Hanratty (6). If the pipe diameter is replaced by the hydraulic diameter D_h, their results should be applicable to predict mass transfer in rectangular flow channels. In the mass transfer entry region, *i.e.*, at short distances from the leading edge of the electrode, experimental mass transfer rates under conditions corresponding to fully developed velocity profiles were described by Van Shaw, Reiss, and Hanratty (6) by the relation

$$Nu = 0.28\, Re^{0.58}\, Sc^{1/3} \left(\frac{D_h}{L}\right)^{1/3} \qquad [3]$$

where Nu represents the average Nusselt number defined by $Nu = \dfrac{i_l D_h}{z\mathbf{F}c_o D}$ with i_l = limiting current density, D_h = hydraulic diameter, z = number of electrons transferred per mole, $\mathbf{F}$ = Faraday constant, c_o = bulk concentration of reacting species, D = diffusion coefficient. The Reynolds number Re is defined by $Re = \dfrac{u\, D_h}{\nu}$ with u = linear flow velocity, ν = kinematic viscosity. Sc represents the Schmidt number defined by $Sc = \nu/D$. L is the distance from the leading edge of the electrode. Relation [3] applies if the condition

$$\frac{0.2\, L\, Re^{7/8}}{D_h} < 10^3 \qquad (4)$$

is satisfied.[4] Such was the case in the metal dissolution experiments described below.

In the region of laminar flow ($Re < 2000$) average mass transfer rates at fully developed velocity profile are given by (5)

$$Nu = 1.85 \left(Re\, Sc \frac{D_h}{L}\right)^{1/3} \qquad [7]$$

The hydrodynamic entrance length here is $S = 0.035\, D_h\, Re$ (3).

Current distribution.—Uniform current distribution can be realized with cylindrical or spherical electrodes. Nonuniform current distribution on the rotating disk electrode has been treated by Newman (1, 8). Wagner (9) gave an analytic solution of the Laplace equation for two parallel plate electrodes for linear current-voltage relationships. Uniform current distribution is approximated if the parameter $\dfrac{1}{\rho}\dfrac{d\epsilon}{di}$ (conductivity of solution times slope of current voltage curve) is large compared to a characteristic dimension, either the distance between two plane electrodes or the length of a small electrode, positioned far from the counterelectrode. In high-rate electrolysis studies, both a small length of the electrode and a small distance from the counterelectrode (see above) are desirable. This is in conflict with the requirement of uniform current distribution.[5]

Potential measurement.—Under the assumptions of the present study, potential gradients in the solution are in the order of 1000 V/cm. Consequently a separation of electrode surface and reference electrode junction (capillary tip) of only 0.1 mm leads to an error of 10V. If a backside capillary arrangement is used, high potential gradients parallel to the electrode surface near the electrode-insulator boundary still lead to errors. Furthermore, due to fast dissolution of the anode, the wall of the capillary may soon protrude from the surface. It has to be concluded that direct steady state potential measurements under high current density conditions are not possible. Certain electrode geometries such as cylindrical or spherical arrangements allow reasonable estimates of ohmic contributions, but, in view of their large value, such a procedure does not recommend itself at very high current densities, particularly since the conductance may vary considerably near the electrode. A similar comment applies to a procedure where several reference electrodes are placed at various distances from the working electrode and the ohmic part of the measured potential values is eliminated by extrapolation to zero distance (11). When using a fast transient method, the geometrical position of the reference tip is less critical, but due to the high rate of charging and discharging processes, subtraction of ohmic contributions from the measured potential value becomes difficult.

Anode positioning.—Due to rapid dissolution, the anode has to be readjusted continuously during a measurement or the amount of dissolved material has to be kept small. Continuous electrode adjustment is used in commercial ECM machines. In the present study only small amounts of material were dissolved, thereby maintaining the plane parallel electrode configuration. The use of this method is possible because at high flow rates steady state mass transfer conditions are reached in a short time, as shown theoretically by Siver (12). Assuming a stagnant diffusion layer the thickness of which is determined by convection, the author finds that for an applied constant current density smaller than the limiting current a steady state is approached when

$$\frac{Dt}{\delta^2} \geq 2 \qquad [8]$$

where D = diffusion coefficient, δ = diffusion layer thickness, t = time. Condition [8] corresponds well to results reported by Hale (13) who numerically solved the unsteady state mass transfer equation, including convection terms for a rotating disk electrode. The average value of the thickness δ of the diffusion layer is related to the average Nusselt number Nu by

$$Nu = \frac{D_h}{\delta} \qquad [9]$$

The value of δ to be used in Eq. [8] can therefore be estimated from known mass transfer relations, such as Eq. [6] and [7].

If the applied current density is larger than the theoretical limiting current density,[6] zero concentration of the reacting species at the electrode surface is reached after a transition time τ which is always smaller than the time t satisfying condition [8]. In the extreme case where the applied current density exceeds the limiting current density by at least a factor of 10, the transition time t may be predicted by the well known Sand equation (12).

The foregoing discussion demonstrates the impossibility of designing an experimental system satisfying all requirements. A compromise has to be made in each case, depending on the type of information desired. The use of fast transient measurements may be advisable in many instances, but not the same type

[4] For fully developed mass transfer profiles, *i.e.*, if

$$\frac{0.2\, L\, Re^{7/8}}{D_h} >> 10^3 \qquad [5]$$

mass transfer rates are described by the Deissler relation

$$Nu = 0.079 \sqrt{f^*}\, Re\, Sc^{1/4} \qquad [6]$$

where f^* represents the friction coefficient which is often given by the Blasius relation (7)

$$f^* = \frac{0.079}{Re^{1/4}}$$

[5] In this paragraph current distribution due to mass transfer is not considered. Near the limiting current, current distribution is no longer described by Laplace's equation alone, but local mass transfer values become determining (5).

[6] In a dissolution process a limiting maximum concentration of reaction products might be reached at the electrode surface. Passivation might then set in after a transition time τ.

of information is obtained as in steady state experiments. In the present study, an experimental arrangement was designed for steady state measurements in experiments of short duration.

Experimental Flow System

An apparatus has been built which allows electrochemical measurements to be performed under defined hydrodynamic conditions at linear flow rates along the electrodes of 1-25 m/sec. Figure 1 shows a diagram of the flow system. The electrolyte is pumped continuously through the electrochemical cell (C) by means of a regenerative turbine pump (T) made of "Hastelloy C."[7] The maximum pressure at the cell inlet is approximately 150 psi, which results in a volume flow of 1.65 gpm through the cell. The flow rate through the cell (C) is measured by means of a magnetic flow meter (F)[8] and regulated with two needle valves in connection with a bypass (Q). Stainless steel pipes are used throughout the system. An electrolyte reservoir (R) made of polyethylene typically contains 10-20 gal of solution. The electrochemical cell is made of epoxy resin. It is shown in Fig. 2 and 3. The electrolyte flows in a rectangular channel (d) of 0.5 x 8 mm cross section and 120 mm length. Two glass windows (e) serve as side wall and allow optical observation of the interelectrode gap. They are held in place by two stainless steel plates (f). The cell is sealed by O-rings (c) embedded in the cell body. The flow channel contains a hydrodynamic entrance length of 77 hydraulic diameters, which serves to establish a fully developed velocity profile at the electrodes (2). Capillaries (b) are drilled into the cell wall near the two electrodes. They provide for potential measurements against a reference electrode. Calomel reference electrodes[9] used in the present study were placed in a small glass container and connected to the capillaries by means of a short Tygon tubing. The electrochemical cell is connected to the stainless steel piping system by means of an O-ring sealed flange at the entrance and a short piece of tubing at the exit. The electrodes are of rectangular shape, 0.53 by 3.17 mm (area = 1.67 mm^2). They are cast into a cylindrical epoxy insert (a). The arrangement allows suppression of edge effects which might arise if there is a finite gap between metal and epoxy. The epoxy insert contains a flat shoulder, which allows the electrode surface to be easily positioned flush with the channel wall. The critical distance between shoulder and surface plane is obtained by mechanical grinding and polishing of the epoxy insert in a stainless steel holder of the desired dimensions. The electrode inserts are attached to the cell by means of three set screws, and sealed by

means of an O-ring (c). The described arrangement allows easy and reproducible exchange of electrodes between experiments. During the metal dissolution experiments described here, the short dimension of the electrodes was oriented parallel to the flow direction. This way, temperature differences along the electrodes and the influence of cathodically generated gas bubbles on the anode were kept to a minimum.

Mass transfer conditions corresponding to the described arrangement were estimated from the relations given in the previous paragraph. Estimated values of the average diffusion layer thickness (mass transfer entry region) ranged from 4 x 10^{-4} cm at a flow rate of 100 cm/sec to 8 x 10^{-5} cm at a flow rate of 2500 cm/sec.[10]

The electrical current was drawn from a constant current power supply[11] having a maximum output of 3A. At the start of an experiment the constant current was switched from a dummy circuit having negligible impedance to the cell circuit by means of a mercury wetted contact relay switch.[12] The relay was actuated by means of a pulse generator. It was switched back automatically after a presct time period by means of a flip flop circuit. The relay could be actuated manually if experimental times longer than 2 sec were desired. Experiments usually lasted between 160 msec and a few seconds, depending on current density. A charge of 25 coulomb/cm^2 was passed which corresponds to an average dissolution of copper in the order of 10μ. It was assumed that dissolution of such a small amount would not change the hydrodynamic conditions signi-

[10] It was assumed here that $D = 10^{-5}$ cm^2/sec, $\nu = 10^{-2}$ cm^2/sec.

ficantly. The experimental times were long enough, on the other hand, that a steady state could be reached during each run.

Anode and cathode potentials were measured against saturated calomel electrodes. The measured values which included large ohmic contributions were recorded simultaneously with over-all cell voltage and current by means of a light beam oscillograph.[13] The oscillograph had a frequency response of 1000 Hz. The input impedance of the preamplifiers was 100 k-ohms. This value is low for precise potential measurements against reference electrodes. It was sufficient, however, for the present study where gross effects were measured only. Each experimental run was started with a freshly prepared anode. Anode preparation consisted of grinding the surface on 0000 emery paper and then polishing it mechanically on 1μ diamond powder, using conventional metallographic equipment. Residual scratches in the copper surface after the polishing operation were less than 0.3μ deep as determined from interference micrographs and from electromicrographs of carbon replicas. The electrodes were cleaned with acetone and detergent. They were pre-electrolyzed cathodically at 100 mA/cm^2 for approximately 3 min in a solution of 1N NaOH. After an experimental run, the anode was removed from the cell immediately. It was rinsed with distilled water and dried with acetone. The surface texture was then examined microsopically.

Results

Current voltage relationships.—Typical voltage transients observed in constant current dissolution experiments are shown in Fig. 4 and 5. Under conditions corresponding to the experiment given in Fig. 4, constant values of all measured voltages were reached within the time resolution limit of the oscillograph (2-5 msec, depending on amplitude). The transient illustrated by Fig. 5 showed a step at the voltage value comparable to the steady state value of the experiment of Fig. 4, which was performed at the same current density of 50 A/cm^2 but at a higher flow rate. A second voltage rise occurred after a few milliseconds. After reaching a peak value both anode potential and cell voltage decayed slowly to a constant value lying in between the initial step value and the peak value. Irregular fluctuations were observed in this region. Experiments performed at different current densities and flow rates showed the decay time of the overshoot of the peak value to decrease with increasing flow rate and with increasing current density. Measured decay time in KNO_3 solutions varied from approximately 180 msec at a current density of 50 A/cm^2 and a flow rate of 100 cm/sec, to approximately 13 msec at 150 A/cm^2 and 2500 cm/sec. No systematic study of the phenomenon has been undertaken, however. After switching off the current, the measured voltage values decayed to zero within the time resolution of the oscillograph.

In all KNO_3 solutions studied, anode potential and cell voltage transients of the types shown in Fig. 4 and 5 were observed. Transients observed in sulfate solutions also showed the general behavior of Fig. 3 and 4, but the second voltage rise was about twice as high. In addition, they exhibited slow periodic fluctuations of many volts under certain conditions of current density and flow rate. Periodic fluctuations associated with passivation phenomena have been reported in the literature for experiments performed in stagnant solutions (10). No attempt has been made here to investigate the observed phenomena further.

The cathode potential trace in Fig. 5 shows a slight increase during the first few milliseconds, but a steady state is reached soon. Fast oscillations were observed at low flow rates and high currents. The relation of these oscillations to characteristics of the cathodic gas evolution is currently being studied by stop motion photography.

Measured values of anode and cathode potential under different flow conditions during copper dissolution in 2M KNO_3 are plotted *vs.* current density in Fig. 6. The given values represent steady state values in the case of transients of the type shown in Fig. 4, or peak values in the case of transients of the type of Fig. 5. Because the measurements contain large ohmic contributions, the absolute potential values of Fig. 6 have no significance. Figure 6 illustrates, however, the fact that the occurrence of the steep rise in the anode potential depends strongly on both current density and electrolyte flow rate. Variations in the cathode potential are less pronounced. Most of the observed deviation from linearity is probably due to partial coverage of the cathode with gas bubbles and to changes in over-all current distribution coincident with the drastic rise of the anode potential. It has been mentioned above that anode potential and cell voltage transients behave analogously. In Fig. 7 cell voltage measurements in different solutions are compared. All three solutions studied, namely 2M KNO_3, 0.4M KNO_3, and 0.2M K_2SO_4, exhibited a similar current-voltage behavior. The voltage jump was larger in the sulfate solution and for given flow conditions it occurred at lower current densities.

Surface textures.—Surface textures resulting from anodic dissolution were strongly dependent on the relative value of the applied current density, with respect to the current density corresponding to the

voltage jump discussed above. Etching was observed in connection with voltage transients of the type of Fig. 4, pitting and brightening in connection with transients of the type of Fig. 5. Photomicrographs of representative samples obtained in 2M KNO_3 solution at a current density of 50 A/cm² at flow rates of 2500 and 400 cm/sec are given in Fig. 9 and 10, respectively. At the high flow rate, the local dissolution rate seemed to depend on crystallographic parameters and the grain structure of the anode was clearly visible after dissolution.[14] The surface appeared dull, and steps and etch pits could be observed within each grain. Reduction of the electrolyte flow rate to 1000 cm/sec resulted in a similar surface structure with less microroughness. Figure 10 shows a surface obtained at 400 cm/sec (voltage transient of the type shown in Fig. 5). This surface appeared bright and contained round pits which were located preferentially, although not exclusively, along grain boundaries. Further decrease of flow rate to 100 cm/sec resulted in a strongly pitted surface of considerable microroughness between pits. Surfaces obtained under identical conditions in 0.4M KNO_3 solutions showed the same characteristics as those discussed. The appearance of the surfaces after dissolution in potassium sulfate solutions was less clear cut, although the same general pattern, *i.e.*, etching and pitting was observed. It may be added that in all cases the transition from the dull to the bright surface finish could be accomplished by changing current density or flow rate. The study of surface textures under different experimental conditions suggested that the best surface appearance was obtained in the immediate vicinity of the voltage jump.

Discussion of Results

Current cell voltage relationships.—The behavior of measured anode potentials illustrated by Fig. 4 and

[14] The large grains visible on Fig. 9 appear highly distorted. This is due to the fact that the electrodes (99999 copper) were made from extruded wire. Chemical etching confirmed the distorted structure.

5 suggests that passivation phenomena occurred under certain conditions. Visual evidence obtained both in experiments performed in stagnant solution and under forced convection conditions indicated that passivation coincided with the formation on the anode of a thick layer consisting of loosely attached powdery material. During dissolution in nitrate solution under forced convection, the anodic layer seemed to disappear in a few milliseconds after current was shut off. This was evidenced by studying potential transients by means of an oscilloscope, while two consecutive current pulses at various time intervals were applied to the cell. The anodes, after being taken out of the solution at the end of dissolution experiment in nitrate solution, appeared bright and no solids were adhering to the metal.[15] Electrodes examined after dissolution in sulfate solutions often were partly covered by anode films. No correlation between the pattern of film coverage and flow direction was observed. The composition of anodic films and the apparent valence of the dissolution process are being studied by Kinoshita (14). Distinct changes which coincide with the transition from active to transpassive dissolution have been observed.

It was mentioned above that exact values of the electrode potentials could not be measured with the present arrangement. There is evidence, however, born out by the results shown in Fig. 7, that the prevailing values of anode and cathode potentials were relatively low, compared to the voltage difference due to the ohmic resistance of the solution, as long as the experiment was performed at a current density smaller than the passivation current density, *i.e.*, for experiments performed in the active dissolution region.

Cell voltages corresponding to steady state values during active dissolution yielded straight lines when plotted against current density, up to current density

[15] Some solid material adhering to the epoxy downstream from the anode was found occasionally.

values of 50 to 150 A/cm^2 depending on the composition of the solution. Equivalent specific resistances ρ_i*[16] were calculated by dividing the least square fit slopes of the straight lines by the electrode separation. The ratios of the values obtained for different solutions were then compared to the ratios of the specific resistances of these solutions. A close correspondence between experimental and theoretical ratios has been observed: Experimental values obtained were ρ_1* = 4.37 ohm-cm, (2M KNO_3), ρ_2* = 17.7 ohm-cm (0.4M KNO_3), ρ_3* = 19.5 ohm-cm (0.2M K_2SO_4). Literature values for the specific resistance at 25°C are ρ_1 = 6.31 ohm-cm (2M KNO_3) (27), ρ_2 = 24.14 ohm-cm (0.4M KNO_3) (28), ρ_3 = 24.70 ohm-cm (0.2M K_2SO_4) (28). Corresponding ratios then become ρ_2*/ρ_1* = 4.05, ρ_2/ρ_1 = 3.83, ρ_3*/ρ_1* = 4.46, ρ_3/ρ_1 = 3.91.

Linear current-voltage relationships dominated entirely by the ohmic resistance of the solution have been reported in the literature for conditions corresponding to ECM (21, 22). Cole and Hopenfield (26) explained observed deviations from linear current voltage behavior by a model which considered the influence of cathodically generated gas bubbles on the ohmic resistance of the solution. Attempts aimed at measuring actual anode potentials during anodic dissolution under ECM conditions have been reported (21, 22), but no reliable results were obtained. A study aimed at separating ohmic contributions from measured potentials by using current interruptor techniques is in progress at this laboratory.[17]

The current-voltage curves given above demonstrate that passivation may lead to an increase in the anode potential of many volts. In this case, the ohmic resistance of the bulk solution can no longer be considered the only important resistance of the system. Local current distribution may, therefore, change significantly at the transition point between active and transpassive dissolution.

Passivation has been mentioned (25) as playing a role in improving dimensional accuracy during ECM, but the statement was based mainly on observations made at low current densities. The present investigations confirms that passivation phenomena play a decisive role in determining local metal dissolution rates under ECM conditions.
